

EDITORIAL: What's New for 1997

Bioconjugate Chemistry publishes high-quality research in all areas of conjugation chemistry. The Editors would like to expand the journal's coverage of topics relevant to combinatorial chemistry such as the reagents and methodology of attaching libraries to reporters, surfaces, or tags that add useful functionality. We will continue to offer authors of accepted **Review** articles the opportunity to submit an illustration for possible use on the cover of the issue where their article appears.

The 1997 Instructions to Authors for *Bioconjugate Chemistry*, which may be downloaded from the worldwide web address <http://pubs.acs.org/journals/bcches/index.html>, informs authors about practical aspects of electronic manuscript submission and the preparation of illustrations.

On an experimental basis, graphics files such as ChemDraw structures may be submitted on disk for highest-quality reproduction of some illustrations. Authors are requested to provide a copy of all illustrations reduced to single-column width (8.25 cm, 3.5 in.) to check legibility. Lettering and numbering should be no smaller than 2 mm in height upon reduction. Multiple-part figures should be combined on a single page.

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 1996 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the seventh volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The list of reviewers is on the following page.

Comb-Type Polycations Effectively Stabilize DNA Triplex

Atsushi Maruyama,* Maiko Katoh, Tsutomu Ishihara, and Toshihiro Akaike

Department of Biomolecular Engineering, Tokyo Institute of Technology, 4259 Nagatsuta, Midori, Yokohama 226, Japan. Received May 6, 1996[®]

DNA triplex formation has been studied as a potential strategy for regulation of gene expression. The triplex is, however, unstable under physiological conditions, so that an effective stabilizer for the triplex formation is needed. Here is shown a novel strategy to stabilize the triplex based on the molecular design of a comb-type polycation. Linear polycations, such as poly(L-lysine) and poly(L-arginine), thermally stabilize DNA duplexes (and triplexes). The complexes between DNA and the polycation are irreversible and are liable to precipitate out of aqueous media. The irreversibility and phase separating properties of the complex impede association of single-stranded (ss) DNAs in the complex to form duplexes and triplexes. A comb-type polycation consisting of a poly(L-lysine) backbone and grafted chains of hydrophilic polymers was prepared. The comb-type copolymers increased solubility of their complex with DNA and suppressed conformational changes of DNA. Thermal melting curve analyses revealed that the comb-type copolymer markedly stabilized DNA triplexes and did not disturb ssDNAs in forming duplexes and triplexes. Reversible and one-step melting/reassociation transitions of poly(dA)·2poly(dT) triplex were shown in the presence of the copolymers. The stabilizing effect of the copolymer was larger than that of spermine, a polyamine considered effective in stabilizing triplexes. These results indicated that molecular design of polycations with a comb-type structure is a novel strategy to create efficient triplex stabilizers. Such comb-type copolymer consisting of various types of polycation backbones and hydrophilic graft chains may have many applications in which specific and precise interactions of polynucleotides are involved.

Deactivation of a target gene with oligonucleotides which form triplexes with that gene has been proven to be a potential strategy for regulation of gene translation (1, 2). Triplex formation is, however, unstable in physiological conditions, which limits the utility of the triplex strategy. To extend the usefulness of the triplex strategy, several compounds that stabilize triplexes have been investigated (3–7).

Polyamines, such as spermine, spermidine, and putrescine, stabilized duplexes and triplexes (8–10). The stabilizing effect of polyamines was largely due to neutralization of electrostatic repulsion among phosphate anions in DNA molecules associating in the triplex and duplex. Their effect was, however, reduced considerably under physiological conditions, because interaction of polyamines with DNA was hampered by coexisting cations (9–11).

For neutralizing the electrostatic repulsion among DNA strands associated in triplexes or duplexes, macromolecular polycations, such as poly(L-lysine) (PLL) and poly(L-arginine), are more effective than oligomeric cations, leading to a considerable rise in the melting temperature (T_m) of the duplex (12, 13). Polycations, however, interact strongly with polyanions to form irreversible polyion complexes (or inter-polyelectrolyte complexes) (13, 14). Polycations severely compacted the DNA conformation (15, 16). Coacervation or precipitation

of the complex occurred (12, 14). Single-stranded (ss) DNAs rarely form duplexes and triplexes in the presence of polycations, resulting in irreversibility of duplex and triplex transitions (melting and reassociation).

The reversible transition of DNA might be, therefore, attainable by increasing the solubility of the complex and reducing the conformational changes of DNA. For this approach, the interactions of polycations with DNA have to be regulated. The interactions of polycations with DNA could be regulated by modifying polycations with DNA-immiscible chains such as electrostatically neutral polymer chains that interfere with these interactions. Modification of polycations with hydrophilic chains like polysaccharides may improve the solubility of a DNA/polycation complex, leading to prevention of phase separation of the complex from aqueous medium. On the basis of the hypothesis mentioned above, we prepared comb-type copolymers of poly(L-lysine) with polysaccharide side chains and evaluated their ability to stabilize DNA triplexes.

The comb-type copolymers, PLL-graft-dextran, were prepared by a reductive amination reaction of PLL·HBr (100 mg, $M_w = 4.5 \times 10^4$ from Peptide Institute, Inc., Osaka, Japan) with dextran (Dex, 600 mg, $M_n = 5900$, Dextran T-10 from Pharmacia Biotech, Uppsala, Sweden) using sodium cyanoborohydride (30 mg, from Wako Pure Chemical Industries, Ltd., Osaka, Japan) as a reductant in dimethyl sulfoxide. After the mixture was incubated for 48 h at 40 °C, the copolymers were isolated by dialysis against water for 7 days using Spectra/Por membrane (MWCO = 12 000–14 000, Spectrum, Los Angeles, CA). Isolation of the resulting copolymers from unreacted Dex

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1996.

Figure 1. Structural formula of PLL-*graft*-Dex comb-type copolymer. The copolymer with $m = 36.5$ (calculated from the number-average MW of Dextran T-10) and $n = 0.2$ (determined by $^1\text{H-NMR}$ spectrum) was used in this study.

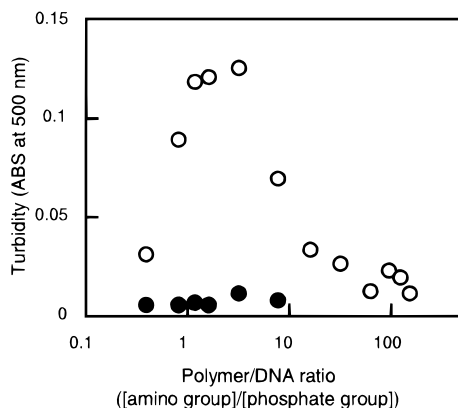

Figure 2. Turbidity of DNA solution to which the indicated amounts of PLL (○) or PLL-*graft*-Dex comb-type copolymer (●) were added. To 1 mL of 100 $\mu\text{g/mL}$ calf thymus DNA in Dulbecco's PBS was added the appropriate amount of polymers from 10 mg/mL stock solution at room temperature. The mixtures were diluted to 2.5 mL, followed by optical density measurement at 500 nm.

was confirmed by gel permeation chromatography on Waters Ultrahydrogel 250 and 500 columns connected with a multiangle light scattering detector and a differential refractive index detector. The molecular weight of the resulting copolymers was determined to be $M_n = 2.5 \times 10^5$ (as free salt). Composition of the copolymer was determined by $^1\text{H-NMR}$ spectrum in D_2O to be 90 wt % Dex and 10 wt % PLL, which meant that Dex chains were grafted onto an average of one of every five lysine units. Further, it was estimated that the coupling efficacy of Dex to PLL was $>90\%$. The structural formula of the copolymer is given in Figure 1.

The Dex-grafted chains on PLL increased the solubility of the complex with DNA. Figure 2 shows the turbidity change of calf thymus DNA in phosphate-buffered saline (PBS) by an addition of either PLL homopolymer or the comb-type graft copolymer. While significant turbidity appeared in PLL/DNA mixture, no turbidity was seen for corresponding comb-type copolymer mixtures. Thus, PLL-*graft*-Dex comb-type copolymer seems to form a soluble complex with DNA.

We then examined the comb-type copolymer for induced structural changes of DNA. Structural change of DNA is detectable by circular dichroism (CD). Figure 3 shows CD spectra of calf thymus DNA mixed with PLL homopolymer or the comb-type copolymer in 1/100 diluted PBS, where both mixtures are transparent. CD signals due to DNA base groups were considerably altered by the addition of PLL homopolymer. Complex formation between DNA and PLL is known to show cooperative association and irreversibility (13, 14). PLL condenses DNA into rod and toroid-like structures (15, 16), which accompanies a change in CD signals (14). In contrast to the PLL homopolymer, addition of the comb-type copolymers only shows a slight change. The CD signals did

Figure 3. CD of calf thymus DNA mixed with PLL or PLL-*graft*-Dex comb-type copolymer in 1/100 diluted PBS at room temperature (ca. 20 $^\circ\text{C}$). The samples were created using the same procedure described in Figure 2, except PBS concentration. The DNA/comb-type copolymer mixture in PBS showed almost the same CD signal as that in this figure, while CD of the DNA/PLL mixture was not obtained because of turbidity and precipitation of the mixture.

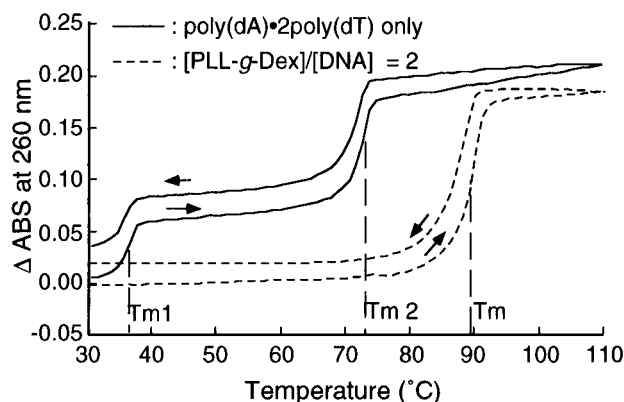

Figure 4. UV- T_m profile of poly(dA)•2poly(dT) triplex in the presence or absence of PLL-*graft*-Dex comb-type copolymer. Poly(dA) and poly(dT) were dissolved in 150 mM NaCl containing 10 mM sodium phosphate (pH 7.2) and 0.1 mM EDTA. Concentrations of the solutions were calculated using molar extinction coefficients of 8900 at 257 nm for poly(dA) and 9000 at 265 nm for poly(dT) (10). To a 1:2 mixture of poly(dA) and poly(dT) was added the comb-type copolymer at a polymer/DNA ([amino group]_{polymer}/[phosphate group]_{DNA}) ratio = 2. After dilution to a final DNA concentration of 14.5 (bp) $\mu\text{mol/L}$ with the same buffer, the mixtures were heated at 90 $^\circ\text{C}$ for 30 min, cooled to room temperature, and allowed to stand for 16 h. The UV- T_m curves were recorded at 0.2 K/min with a DU-640 spectrometer (Beckman) equipped with a micro- T_m apparatus.

not vary even when electrostatically excessive amounts of the copolymer were added (data not shown). Further, CD spectra of a comb-type copolymer/DNA mixture in PBS showed almost the same signals as that shown in Figure 3, while that of a PLL/DNA mixture was not obtained because of turbidity and precipitation of the mixture. Thus, the Dex graft was effective in preventing serious structural changes to DNA.

It was predictable from the results described above that the DNAs associated with the comb-type copolymer preserve an ability to form duplexes or triplexes. The stabilizing effect of the comb-type copolymers on DNA triplexes was then examined by recording thermal melting profiles with a UV spectrometer. Figure 4 shows UV- T_m curves of a poly(dA)•2poly(dT) triplex in PBS. At physiological ionic strength, the triplex showed two-step melting. The first transition at lower temperature (37

Figure 5. CDs of poly(dA)·poly(dT) duplex (dotted line), poly(dA)·2poly(dT) triplex (broken line), and the 2:1 mixture (solid line) of the comb-type copolymer and the triplex. The samples were prepared according to the same procedure as that described in Figure 4, except a 1:1 molar ratio of poly(dA)/poly(dT) was used for the duplex. CD measurements were done after T_m measurements. The spectra were recorded on a Jasco J-600 using a 0.5 cm length quartz cell at 20 nm/min as a scanning speed, 0.1 nm/point as a wavelength step, and 1 s/point as a time step. Each spectrum shown was the average of three scans and has been smoothed by a computer. The CD signal attributed to the comb-type copolymer was negligible under the condition.

°C) was the melting of the triplex to a duplex and a ssDNA, and the second transition at higher temperature (72 °C) was that of the duplex. In the presence of excess comb-type copolymers over DNAs, only one transition was observed at higher temperature (89 °C). As the magnitude in UV absorbance change (ΔABS) at T_m in the presence of the copolymer was equal to the sum of those at T_{m1} and T_{m2} in the absence of the copolymer, the transition is indicated to be a direct melting of the triplex to its constituting ssDNAs. The direct melting of the triplex was further indicated by ΔABS measurement with changing poly(dT)/poly(dA) molar ratio [while the concentration of poly(dA) was kept constant]. The ΔABS values reached a plateau at the changing poly(dT)/poly(dA) molar ratio over 2 (data not shown). It should be noted that the UV- T_m profile in the cooling process demonstrated reversibility of the transition even in the presence of the comb-type copolymer. It was indicated that the comb-type copolymer thermally stabilized the triplex but did not disturb triplex formation from its constituting ssDNAs. Formation of the poly(dA)·2poly(dT) triplex was further evaluated by CD measurements. As shown in Figure 5, whereas the CD spectrum of the poly(dA)·poly(dT) duplex has a strong positive band near 220 nm, the poly(dA)·2poly(dT) triplex has no positive band near this wavelength (17). The mixture of poly(dA)·2poly(dT) and the comb-type copolymers showed almost the same signals as the triplex alone even after T_m measurement. We conclude that the comb-type copolymers do not disturb inter-polynucleotide associations of ssDNAs to form the triplex.

The efficacy of the comb-type copolymer for stabilizing the triplex was then compared to that of spermine, a polyamine effective in triplex stabilization (10). Figure 6 shows the effects of comb-type copolymer and spermine on melting temperatures of the triplex at various stabilizer/DNA ratios. An electrostatically equivalent amount ($[\text{amino group}]_{\text{polymer}}/[\text{phosphate group}]_{\text{DNA}}$) of the comb-type copolymer increased the melting temperature of the

Figure 6. Stabilizing effect of spermine and the comb-type copolymer. All experiments were conducted under the conditions described in Figure 4. T_m was determined by generating the first derivative, dA/dT (where A and T are absorbance and temperature, respectively), of the UV- T_m curves.

triplex by 50 °C, while a large excess of spermine increased it by 20 °C. Moreover, one-step melting of the triplex was observed in the presence of the comb-type copolymer at a stabilizer/DNA ratio over 1, whereas two-step melting was still seen even in the presence of a large excess of spermine. Poly(dA)·2poly(dT) triplex stabilized with 7.5 μM spermine was reported to melt in a one-step manner in low ionic strength medium (10). The stabilizing effect was, however, significantly reduced in the presence of 0.15 M NaCl, resulting in the two-step melting of the triplex. Spermine is believed to be competitively displaced with Na cations. In contrast to spermine, the comb-type copolymer considerably stabilized the triplex of poly(dA)·2poly(dT). The one-step melting and considerable rise in T_m observed with an electrostatically equivalent amount of the comb-type copolymer implied its stable association with DNA.

The strong and stable stabilizing effect of the comb-type copolymer was considered to be directed by its high multivalency of cations. The copolymer, however, allows ssDNAs to form duplexes and triplexes. The Dex graft chains on the copolymer interfere with interaction between the PLL backbones and DNAs. Those graft chains might inhibit the close contact of DNAs to the PLL backbones and thereby dehydration and compaction, which are presumably involved in the irreversible complex formation between DNAs and homopolycations. Regardless of the weakened interaction, the comb-type copolymer could suppress the repulsive forces among DNA strands enough to stabilize the triplex.

In addition to the shielding effect upon the repulsive forces, Dex chains may play a role in stabilizing hydrogen bonding between base pairs. As the comb-type copolymer consists of 90 wt % Dex and 10 wt % PLL, the PLL backbone in the copolymer is likely surrounded by a phase concentrated with Dex segments. The DNAs that are attracted to the PLL backbone by electrostatic interactions are forced to merge with the Dex-enriched phases, which are low in dielectric constant. Such low dielectric environments might enhance hydrogen bonding between base pairs, leading to DNA triplex stabilization. It was reported that the triplex in a medium containing spermine was further stabilized by moderate concentrations of organic solvents (18). If the electrostatic repulsion was neutralized by polyamines or polycations,

medium with a low dielectric constant may further stabilize triplexes. Furthermore, specific interaction between Dex chains and DNA may affect the stabilization behavior (19).

These results indicate that the molecular design of polycations with a comb-type structure is a successful approach to create efficient triplex stabilizers. Comb-type copolymers consisting of various types of polycation backbones and hydrophilic graft chains may have many applications in which specific and precise interactions of polynucleotides are involved. Conjugation of triplex-forming oligonucleotides (TFOs) with the comb-type copolymer may allow specific and stable triplex formation at target genes. Modification of the comb-type copolymers with a cellular specific ligand and other functional groups will provide novel types of delivery systems for TFOs, which is not available with low molecular weight stabilizers.

Synthesis of a Novel [125 I]Neonicotinoid Photoaffinity Probe for the *Drosophila* Nicotinic Acetylcholine Receptor

Bachir Latli, Motohiro Tomizawa, and John E. Casida*

Environmental Chemistry and Toxicology Laboratory, Department of Environmental Science, Policy, and Management, University of California, Berkeley, California 94720-3112. Received August 12, 1996[®]

The insect nicotinic acetylcholine receptor (nAChR) is the target for the major insecticide imidacloprid (IMI) and for the first candidate photoaffinity probe described here. Addition to 1-[(6-chloro-3-pyridinyl)methyl]-4,5-dihydro-2-nitromethylene-1*H*-imidazolidine (the nitromethylene analog of the nitroimine IMI) of formaldehyde and any one of several primary amines is known to give hexahydro-8-nitroimidazo[1,2-*c*]pyrimidine derivatives. These imidazopyrimidines with a wide range of N-substituents were found to inhibit [3 H]IMI binding to the *Drosophila* or *Musca* nAChR by 50% (IC₅₀) at 0.7–38 nM. Esterification of the *N*-(2-hydroxyethyl) derivative with 2-azido-5-(trimethylstannyl)-benzoic acid and then iododestannylation using Na 125 I and chloramine-T provide the candidate photoaffinity probe 6-[2-(2-azido-5-[125 I]iodobenzoyl)ethyl]-1-[(6-chloro-3-pyridinyl)methyl]-1,2,3,5,6,7-hexahydro-8-nitroimidazo[1,2-*c*]pyrimidine. This compound (unlabeled) has an IC₅₀ of 8 nM for [3 H]-IMI binding in *Drosophila* head membranes, and the 125 I-labeled photoaffinity probe labels only a 66 kDa protein(s) at a specific site inhibited by (–)-nicotine, consistent with the insecticide-binding subunit of the nAChR.

INTRODUCTION

The nicotinic acetylcholine receptor (nAChR¹) is the target in insects for 1-[(6-chloro-3-pyridinyl)methyl]-4,5-dihydro-2-nitroimino-1*H*-imidazolidine (imidacloprid or IMI) and many analogs usually with (6-chloro-3-pyridinyl)methylamino and nitro substituents (1–3). This new class of insecticides is referred to as chloronicotinyls (4) or neonicotinoids (2). [3 H]IMI is the principal radioligand for characterizing and quantitating the insecticide binding site of the nAChR of *Drosophila melanogaster* (fruit fly) and *Musca domestica* (house fly) (5, 6) (Figure 1). The nitromethylene analog of IMI (CH-IMI) (2, 7–9) and an acyclic nitromethylene compound (nitenpyram) (6, 10, 11) (Figure 1) are of interest not only as potent insecticides but also as probes for exploring the structure of *Drosophila* and *Musca* nAChRs.

The insect nAChR is best understood for *Drosophila*, for which the structural features are deduced from molecular biology approaches (12) and the same three subunits of 69, 66, and 61 kDa have been isolated by chromatography on affinity columns based on α -bunga-

rotoxin (α -BGT) (a toxin from the elapidae snake *Bungarus multicinctus*, which is the classical competitive antagonist of the nAChR) and demethylnitenpyram (6). α -BGT cross-links with a protein(s) in *Drosophila* head membranes calculated to have a molecular mass of 42 kDa (13) and, as an azidosalicylate derivative, it photoaffinity labels a 66 kDa polypeptide in isolated *Drosophila* and *Musca* nAChRs (6). Although the neonicotinoids and α -BGT share the same binding site(s) in insects, on the basis of competition studies (1, 14), the site of insecticide binding is only partially defined with α -BGT since the molecular size is different, i.e. masses of 256 for IMI versus 8000 for α -BGT (3, 15). The photoaffinity probes used in characterizing the vertebrate (*Torpedo* electric organ) nAChR (16, 17) are not suitable for insects because of relatively low affinity or binding to a site not directly relevant for insecticidal activity (1, 11). The alternative is to specifically design a photoaffinity probe based on an IMI analog as in the case of our recent development of a nitenpyram analog as an affinity column for isolation of *Drosophila* and *Musca* nAChRs (6).

The design and development of the neonicotinoid photoaffinity probe involved the following steps: first, establish a site in the neonicotinoid for substitution allowing retention of moderate to high receptor potency in *Drosophila* brain membrane preparation; second, optimize the probe with candidate photoreactive substituents; and finally, prepare the radiolabeled photoaffinity ligand and test for light-dependent and protectable labeling of one or more nicotinic acetylcholine receptor subunits. The overall chemistry utilized is shown in Figure 1. Nitenpyram analogs were examined because of their successful use in preparing an affinity column (6). More extensive studies were made on nitromethylene imidazolidines such as CH-IMI since they are converted to insecticidal hexahydroimidazopyrimidines on ad-

[®] Abstract published in *Advance ACS Abstracts*, December 1, 1996.

¹ Abbreviations: α -BGT, α -bungarotoxin; CH-IMI, nitromethylene analog of IMI; DCC, 1,3-dicyclohexylcarbodiimide; DMAP, 4-(dimethylamino)pyridine; EI, electron impact; EtOAc, ethyl acetate; FAB-HRMS, fast atom bombardment high-resolution MS; FAB-LRMS, fast atom bombardment low-resolution MS; Hex, hexane; IC₅₀, concentration of test compound for 50% inhibition of specific radioligand binding; IMI, imidacloprid; nAChR, nicotinic acetylcholine receptor.

Figure 1. Structures of neonicotinoids including the radioligand ($[^3\text{H}]\text{IMI}$), analogs (CH-IMI and nitenpyram), derivatives, and the photoaffinity probe ($[^{125}\text{I}]\text{-14}$). Receptor potencies are indicated as concentrations for 50% inhibition (IC_{50}) of the displacement of $[^3\text{H}]\text{IMI}$ binding from *Drosophila* head membranes (data from this paper and ref 6).

dition of formaldehyde and a primary amine (18, 19). We find that fortunately the imidazopyrimidines derived from CH-IMI retain much of the affinity at the receptor of the parent compound and therefore allow the introduction of a variety of substituents in optimizing a candidate photoaffinity probe. Optimization studies ultimately led to synthesis of 6-[2-(2-azido-5- $[^{125}\text{I}]\text{-iodobenzoyl}$)ethyl]-1-[(6-chloro-3-pyridinyl)methyl]-1,2,3,5,6,7-hexahydro-8-nitroimidazo[1,2-c]pyrimidine ($[^{125}\text{I}]\text{-14}$) (Figure 1) as a candidate photoaffinity probe for the *Drosophila* nAChR.

EXPERIMENTAL PROCEDURES

Materials. Silica gel TLC for analysis was performed with precoated plastic sheets ($4 \times 8 \text{ cm}$, 0.25 mm gel layer) with fluorescent indicator (Polygram R SILG/UV254, Macherey-Nagel, Germany) and for preparative purposes with precoated silica gel GF plates ($20 \times 20 \text{ cm}$, Analtech). NMR spectra were recorded for CDCl_3 solutions with a Bruker AM-300 or AM-400 spectrometer. Chemical shifts (δ in parts per million) are reported for ^1H at 300 Hz or 400 MHz and for ^{13}C at 75 MHz relative to internal tetramethylsilane and CDCl_3 , respectively. Mass spectra were acquired by GC/MS with a Hewlett-Packard 5971A or 5985B instrument in the electron impact (EI) mode (70 eV, 200 °C). Fast atom bombardment (FAB)-MS (both low and high resolution) was conducted with the Fisons ZAB2-EQ spectrometer. UV absorbances were measured on a Hewlett-Packard 8452A diode array spectrophotometer. Photoreactivity of the candidate photoaffinity probe was determined for a solution in absolute ethanol in a 1 cm quartz cell positioned 3 cm from four 350 nm lamps in a Rayonet photochemical reactor (The Southern New England Ultraviolet Co., Hamden, CT). Melting points are uncorrected and were recorded on a Fisher-Johns melting point apparatus. All reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI) except EDTA, (–)-nicotine, ethylene glycol bis(β -aminoethyl ether)-*N,N,N,N*-tetraacetic acid, lithium dodecyl sulfate, and phenylmethanesulfonyl fluoride, which were obtained from Sigma Chemical Co. (St. Louis, MO). All solvents used were of reagent or HPLC grade. THF was distilled from sodium benzophenone under nitrogen in a recirculating still, with a deep blue color maintained in the distillation pot. Dioxane was dried by storage over molecular sieves.

Literature procedures were used to prepare 1-[(6-chloro-3-pyridinyl)methyl]-1-(ethylamino)-1-(methylthio)-2-nitroethene (6) and CH-IMI (7, 8). $[^3\text{H}]\text{IMI}$ at 25 Ci/mmol was prepared in this laboratory (5). L-[*N*-methyl- ^3H]-Nicotine ($[^3\text{H}]\text{nicotine}$) at 78 Ci/mmol and Na^{125}I at 584 MBq $^{125}\text{I}/\mu\text{g}$ of iodine ($\sim 2000 \text{ Ci/mmol}$) in dilute NaOH solution were purchased from DuPont NEN Research Products (Boston, MA) and Amersham Life Science Inc. (Arlington Heights, IL), respectively. Molecular mass markers were obtained from Bio-Rad (Richmond, CA). Liquid scintillation counting was performed with a Beckman LS 6000IC, using High Flash Point Cocktail, Safety-Solve, Research Products International Corp. (Mount Prospect, IL). Each intermediate and candidate probe was $>98\%$ pure on the basis of TLC and ^1H and ^{13}C NMR integrations. Compounds with photosensitive substituents were used in subdued light.

Synthesis of Azidohydroxybenzoyl (1–4), Azidoiodobenzoyl (5–7), and Azidotrimethylstannylbenzoyl (8, 9) Intermediates (Scheme 1). 4-Azido-2-hydroxybenzoic Acid (2). To a solution of 4-amino-2-hydroxybenzoic acid (1) (4.6 g, 30 mmol) in concentrated HCl (70 mL, 12 N) was added dropwise and with care at 0 °C a solution of sodium nitrite (6.21 g, 90 mmol) in cold water (30 mL). The mixture was stirred for 30 min before a solution of sodium azide (10 g, 155 mmol) in cold water (50 mL) was added slowly and dropwise. The resulting suspension was stirred at 0 °C for 3 h and then filtered, washed with cold water, and dried under vacuum to give 4.6 g of 2 as a brownish solid in 86% yield: mp = 165–167 °C; ^1H NMR (CDCl_3) δ 7.88 (d, $J = 8.03 \text{ Hz}$, 1H), 6.62 (d, $J = 8.03 \text{ Hz}$, 1H), 6.60 (s, 1H); ^{13}C NMR (CDCl_3) δ 172.82, 164.47, 148.47, 133.26, 111.17, 110.83, 107.74.

N-Hydroxysuccinimidyl-4-azido-2-hydroxybenzoate (3). To a stirred solution of 2 (2.33 g, 13 mmol) in dry THF (30 mL) was added *N*-hydroxysuccinimide (2.07 g, 18 mmol) at 0 °C followed by a solution of DCC (3.71 g, 18 mmol) in THF (2.0 mL), and the resulting mixture was stirred under nitrogen atmosphere for 6 h. It was then filtered and concentrated *in vacuo* to give 5.2 g of crude material. Purification by silica gel flash chromatography using CHCl_3 as eluent gave 3.6 g of product as a white solid in 100% yield: mp = 140–142 °C; $R_f = 0.73$ in MeOH/ CHCl_3 , 10:90; ^1H NMR (CDCl_3) δ 9.97 (d, $J = 8.64 \text{ Hz}$, 1H), 9.68 (s, 1H, OH), 6.68 (d, $J = 2.10 \text{ Hz}$, 1H), 6.62

Scheme 1. Preparation of Azidohydroxybenzoyl, Azidoiodobenzoyl, and Azidotrimethylstannylbenzoyl Intermediates^a

^a (a) HCl, NaNO₂, NaN₃, 86–90%; (b) NHS, DCC, THF, 100%; (c) H₂N(CH₂)₂NH₂, CH₃CN, THF, 91%; (d) MeOH, H₂SO₄, 100%; (e) Pd(PPh₃)₄, Me₃Sn–SnMe₃, dioxane, 67%; (f) LiOH, THF, 51%.

(dd, $J = 2.10, 8.64$ Hz, 1H), 2.93 (brs, 4H); ¹³C NMR (CDCl₃) δ 169.22, 163.83, 162.81, 149.32, 131.60, 111.11, 107.10, 104.62, 25.30.

N-(4-Azido-2-hydroxybenzoyl)ethylenediamine (4). A solution of **3** (1.1 g, 4.0 mmol) in dry THF (10 mL) was stirred at 0 °C under nitrogen atmosphere. Ethylenediamine (0.4 mL, 6.0 mmol) was added in acetonitrile (5.0 mL), and the resulting mixture was stirred overnight in the dark. The mixture was concentrated *in vacuo* and purified by preparative TLC (2.0 mm thickness plate) to give 0.8 g of **4** as a yellowish oil in 91% yield: $R_f = 0.1$ in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 7.73 (d, $J = 8.61$ Hz, 1H), 6.54 (d, $J = 2.25$ Hz, 1H), 6.48 (dd, $J = 2.25, 8.61$ Hz, 1H), 3.49 (t, $J = 5.88$ Hz, 2H), 2.91 (t, $J = 5.88$ Hz, 2H), 2.74 (brs, NH₂, NH); ¹³C NMR (CDCl₃) δ 169.53, 165.1, 144.51, 129.61, 113.63, 108.51, 107.48, 41.26, 39.20; FAB-LRMS MH⁺ (10%), M⁺ (75%), 192 (100%); FAB-HRMS C₉H₁₁N₅O₂H⁺, calcd 222.0991, found 222.0941.

2-Azido-5-iodobenzoic Acid (6). To a solution of 2-amino-5-iodobenzoic acid (**5**) (5.26 g, 20 mmol) in concentrated HCl (60 mL, 12 N), stirred at 0 °C, was added a solution of NaNO₂ (4.14 g, 60 mmol) in water (25 mL). The resulting mixture was stirred for 30 min before NaN₃ (6.5 g, 100 mmol) in cold water (30 mL) was added dropwise, and the mixture was stirred overnight. It was then poured into ice and the solid was filtered and dried *in vacuo* to give 5.2 g of **6** as a cream colored solid in 90% yield: mp = 118–120 °C; $R_f = 0.75$ in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 8.22 (d, $J = 2.21$ Hz, 1H), 7.75 (dd, $J = 2.21, 8.61$ Hz, 1H), 6.95 (d, $J = 8.61$ Hz, 1H); ¹³C NMR (CDCl₃) δ 169.31, 142.12, 141.12, 139.98, 123.72, 121.55, 87.50.

Methyl 2-Azido-5-iodobenzoate (7). To a solution of **6** (1.0 g, 3.46 mmol) in MeOH (50 mL) was added a few drops of concentrated H₂SO₄ (95–98%), and the mixture was stirred under reflux overnight. After the mixture cooled to room temperature, the solvent was evaporated and the residue was diluted in EtOAc. Aqueous workup with NaHCO₃ (5% solution), drying (MgSO₄), filtration, and concentration *in vacuo* followed by purification by silica gel flash chromatography using CHCl₃ as eluent gave 1.04 g (100% yield) of a solid as white needles: mp = 68–69 °C; $R_f = 0.68$ in EtOAc/Hex, 20:80; ¹H NMR (CDCl₃) δ 8.15 (d, $J = 2.12$ Hz, 1H), 7.80 (dd, $J = 2.12, 8.62$ Hz, 1H), 6.98 (d, $J = 8.62$ Hz, 1H), 3.90 (s, 3H); ¹³C NMR (CDCl₃) δ 163.83, 141.50, 140.08, 139.62, 123.86, 121.50, 87.15, 52.32.

Methyl 2-Azido-5-(trimethylstannyl)benzoate (8). A mixture of **7** (130 mg, 0.43 mmol) and tetrakis(triphenylphosphine)palladium(0) (10 mg, 8.65 μ mol) in anhydrous dioxane (5.0 mL) was made anaerobic by freezing, vacuum degassing, and introducing argon at-

mosphere three times at 0 °C. Then hexamethylditin (0.51 mL) was added, and the resulting mixture was stirred at 50 °C for 2 h. After the mixture cooled to room temperature, a saturated solution of NH₄Cl was added and the organic layer was extracted with EtOAc, dried (MgSO₄), filtered, and concentrated *in vacuo*. The pure product was isolated as a yellowish oil by silica gel flash chromatography using EtOAc in Hex (0–10%) as eluent to give 100 mg in 67% yield: $R_f = 0.78$ in EtOAc/Hex, 20:80; ¹H NMR (CDCl₃) δ 7.87 (d, $J = 1.16$ Hz, 1H), 7.58 (dd, $J = 1.16, 7.77$ Hz, 1H), 7.17 (d, $J = 7.77$ Hz, 1H), 3.87 (s, 3H), 0.27 (s, 9H); ¹³C NMR (CDCl₃) δ 166.30, 140.35, 139.84, 138.61, 138.50, 122.17, 120.40, 52.30, –9.23; EI-MS max mass for C₁₁H₁₅SnN₃O₂ as ¹²⁰Sn isotope, 341 (100%); EI-HRMS calcd 341.0276, found 341.0193 (M⁺ for tin and carbon isotopes pattern observed was similar to the one calculated).

2-Azido-5-(trimethylstannyl)benzoic Acid (9). To a solution of **8** (57 mg, 0.17 mmol) in THF (0.5 mL) was added a solution of LiOH (1 N solution, 0.34 mL). The mixture was stirred at 50 °C overnight and then cooled to room temperature and brought to pH ~7.0 by adding dropwise a potassium biphthalate buffer (0.05 M, pH 4). The aqueous fraction was extracted with CHCl₃, dried (MgSO₄), filtered, and concentrated *in vacuo*. Purification by silica gel flash chromatography using 3:1 Hex/EtOAc containing 2% acetic acid gave 28 mg of the desired acid as a yellowish solid: mp = 126–128 °C; $R_f = 0.16$ in EtOAc/Hex, 20:80; ¹H NMR (CDCl₃) δ 8.15 (d, $J = 2.1$ Hz, 1H), 7.72 (dd, $J = 2.1, 7.73$ Hz, 1H), 7.21 (d, $J = 7.73$ Hz, 1H), 0.32 (s, 9H); ¹³C NMR (CDCl₃) δ 169.21, 140.08, 139.95, 138.32, 132.98, 124.68, 119.03, –9.13.

Synthesis of Azidohydroxybenzoyl and Azidoiodobenzoyl Candidate Hexahydranitroimidazopyrimidine Photoaffinity Probes (10–14) (Scheme 2). **6-[2-(4-Azido-2-hydroxybenzamidy)ethyl]-1-[(6-chloro-3-pyridinyl)methyl]-1,2,3,5,6,7-hexahydro-8-nitroimidazo[1,2-c]pyrimidine (10).** To a solution of CH-IMI (127 mg, 0.50 mmol) and formaldehyde (85 μ L, 37% solution in water) in THF (5.0 mL) was added the diamine derivative (**4**) (110 mg, 0.50 mmol) in THF (5.0 mL), and the resulting mixture was stirred at room temperature overnight. Concentration *in vacuo* followed by purification by preparative TLC (2.0 mm thickness plate) gave 73 mg of the desired product as a yellowish solid in 29% yield: mp = 172–174 °C; $R_f = 0.63$ in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 8.33 (d, $J = 2.4$ Hz, 1H), 7.82 (dd, $J = 2.4, 8.2$ Hz, 1H), 7.74 (d, $J = 8.2$ Hz, 1H), 7.33 (d, $J = 8.61$ Hz, 1H), 6.54 (d, $J = 2.25$ Hz, 1H), 6.44 (dd, $J = 2.25, 8.61$ Hz, 1H), 4.80 (s, 2H), 4.13 (s, 2H), 3.85 (s, 2H), 3.40–3.74 (m, 6H), 2.75 (t, $J = 5.88$ Hz, 2H); ¹³C NMR (CDCl₃) δ 169.94, 163.71, 158.41, 151.23, 149.37, 145.00, 139.93,

Scheme 2. Preparation of Azidohydroxybenzoyl and Azidoiodobenzoyl Candidate Hexahydroimidazopyrimidine Photoaffinity Probes^a

^a Structures of intermediates are given in Scheme 1. (a) HCHO, THF, 29%; (b) HCHO, H₂N(CH₂)₂OH, THF, 96%; (c) DCC, DMAP, CH₂Cl₂, 60–94%; (d) Na¹²⁵I, chloramine-T, MeOH, 20%.

131.54, 130.68, 125.02, 109.68, 107.44, 107.22, 103.66, 65.89, 50.88, 47.62, 37.86, 52.54, 52.18, 51.90; FAB-LRMS MH⁺ (60%), 154 (100%); FAB-HRMS C₂₁H₂₂ClN₉O₄H⁺, calcd 500.1561, found 500.1551; UV λ_{270} ϵ = 20 290, λ_{348} ϵ = 19 380.

1-[6-(6-Chloro-3-pyridinyl)methyl]-1,2,3,5,6,7-hexahydro-6-(2-hydroxyethyl)-8-nitroimidazo[1,2-c]pyrimidine (11). To a solution of CH-IMI (254 mg, 1.0 mmol) in THF (20 mL) was added a solution of formaldehyde (0.153 mL, 37% solution in water) and ethanolamine (0.06 mL, 1.0 mmol). The resulting mixture was stirred overnight, concentrated *in vacuo*, and purified by preparative TLC (2.0 mm thickness plate) to give 312 mg of the desired product as a white solid in 96% yield: mp = 146–148 °C; R_f = 0.26 in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 8.34 (d, J = 2.45 Hz, 1H), 7.86 (dd, J = 2.45, 8.26 Hz, 1H), 7.34 (d, J = 8.26 Hz, 1H), 4.84 (s, 2H), 4.11 (s, 2H), 3.88 (s, 2H), 3.73 (t, J = 5.16 Hz, 2H), 3.62 (m, 4H), 2.73 (t, J = 5.16 Hz, 2H); ¹³C NMR (CDCl₃) δ 157.45, 151.01, 149.07, 139.18, 130.76, 124.41, 102.97, 65.92, 59.63, 55.04, 52.17, 51.03, 49.29, 46.69; FAB-LRMS MH⁺ (26%), MLi⁺ (346, 12%); FAB-HRMS C₁₄H₁₈ClN₅O₃H⁺, calcd 340.1176, found 340.1169.

6-[2-(4-Azido-2-hydroxybenzoyl)ethyl]-1-[6-(6-chloro-3-pyridinyl)methyl]-1,2,3,5,6,7-hexahydro-8-nitroimidazo[1,2-c]pyrimidine (12). To a solution of 11 (68 mg, 0.20 mmol) in dry CH₂Cl₂ (12 mL) was added acid 2 (44 mg, 0.25 mmol), DMAP (30 mg, 0.25 mmol), and then DCC (66 mg, 0.32 mmol) in CH₂Cl₂ (2.0 mL). The resulting mixture was stirred overnight, concentrated *in vacuo*, and purified using preparative TLC (2.0 mm thickness plate) to give 94 mg of the product in 94% yield as a yellowish solid: mp = 142–144 °C; R_f = 0.7 in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 8.34 (d, J = 2.40 Hz, 1H), 7.83 (m, 2H), 7.32 (d, J = 8.2 Hz, 1H), 6.62 (d, J = 2.10 Hz, 1H), 6.56 (dd, J = 2.10, 8.59 Hz, 1H), 4.83 (s, 2H), 4.49 (t, J = 5.55 Hz, 2H), 4.16 (s, 2H), 3.95 (s, 2H), 3.61 (m, 4H), 2.96 (t, J = 5.55 Hz, 2H); ¹³C NMR (CDCl₃) δ 169.21, 163.35, 157.28, 150.01, 149.06, 147.66, 139.24, 131.55, 130.58, 124.53, 110.66, 107.54, 107.24, 102.97, 65.97, 57.02, 52.21, 51.93, 50.83, 49.26, 46.51; FAB-LRMS MH⁺ (66%), 154 (100%); FAB-HRMS C₂₁H₂₁ClN₈O₅H⁺, calcd 501.1402, found 501.1393; UV λ_{272} ϵ = 24 020, λ_{352} ϵ = 13 790.

6-[2-(2-Azido-5-trimethylstannylbenzoyl)ethyl]-1-[6-(6-chloro-3-pyridinyl)methyl]-1,2,3,5,6,7-hexahydro-8-nitroim-

idazo[1,2-c]pyrimidine (13). Acid 9 (17 mg, 0.052 mmol), alcohol 11 (17 mg, 0.050 mmol), and DMAP (8 mg, 0.065 mmol) in dry CH₂Cl₂ (3.0 mL) were stirred at room temperature under nitrogen atmosphere. Then DCC (16 mg, 0.077 mmol) was added in CH₂Cl₂ (0.50 mL), the mixture was stirred overnight and concentrated *in vacuo*, and the residue was purified by preparative TLC (1.0 mm thickness plate) using MeOH/CHCl₃, 10:90, as eluent to give 10 mg of pure product as a yellowish solid in 31% yield: mp = decomposition at 130 °C; R_f = 0.73 in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 8.34 (d, J = 2.35 Hz, 1H), 7.91 (d, J = 1.25 Hz, 1H), 7.86 (dd, J = 2.46, 8.24 Hz, 1H), 7.64 (dd, J = 1.25, 7.86 Hz, 1H), 7.31 (d, J = 8.24 Hz, 1H), 7.23 (d, J = 7.86 Hz, 1H), 4.83 (s, 2H), 4.47 (t, J = 5.75 Hz, 2H), 4.12 (s, 2H), 3.96 (s, 2H), 3.62 (m, 4H), 2.97 (t, J = 5.75 Hz, 2H), 0.32 (s, 9H); ¹³C NMR (CDCl₃) δ 165.84, 159.28, 151.03, 149.13, 140.71, 139.84, 139.34, 138.85, 138.71, 130.67, 124.59, 121.47, 119.27, 103.18, 65.53, 63.10, 52.24, 52.05, 51.93, 49.22, 46.54, -9.34; FAB-LRMS C₂₄H₂₉ClN₈O₄SnH⁺ (649, 70%), 267 (100%); FAB-HRMS max MH⁺ peak for ¹²⁰Sn isotope calcd 649.1101, found 649.1104.

6-[2-(2-Azido-5-iodobenzoyl)ethyl]-1-[6-(6-chloro-3-pyridinyl)methyl]-1,2,3,5,6,7-hexahydro-8-nitroimidazo[1,2-c]pyrimidine (14) from 11. A solution of alcohol 11 (68 mg, 0.20 mmol) in dry CH₂Cl₂ (12 mL) was stirred at room temperature under nitrogen atmosphere. Then acid 6 (58 mg, 0.20 mmol) and DMAP (30 mg, 0.25 mmol) were added followed by DCC (66 mg, 0.32 mmol) in dry CH₂Cl₂ (2.0 mL). The resulting mixture was stirred overnight and then concentrated *in vacuo*. The solid residue was purified by preparative TLC to give 110 mg of a yellowish solid in 91% yield (decomposed at 160 °C): R_f = 0.57 in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 8.20 (d, J = 2.17 Hz, 1H), 8.14 (d, J = 2.11 Hz, 1H), 7.88 (dd, J = 2.11, 8.23 Hz, 1H), 7.82 (dd, J = 2.17, 8.49 Hz, 1H), 7.33 (d, J = 8.23 Hz, 1H), 7.00 (d, J = 8.49 Hz, 1H), 4.84 (s, 2H), 4.46 (t, J = 5.77 Hz, 2H), 4.09 (s, 2H), 3.96 (s, 2H), 3.61 (m, 4H), 2.94 (t, J = 5.77 Hz, 2H); ¹³C NMR (CDCl₃) δ 169.78, 163.68, 157.43, 151.22, 149.10, 142.03, 140.42, 140.32, 139.25, 130.65, 124.51, 121.76, 103.00, 87.40, 65.57, 63.24, 52.20, 51.74, 50.94, 49.21, 46.51; FAB-LRMS MH⁺ (58%), 225 (100%), 154 (30%); FAB-HRMS C₂₁H₂₀ClIN₈O₄H⁺, calcd 611.0419, found 611.0414; UV λ_{268} ϵ = 18 600; λ_{352} ϵ = 14 300.

Scheme 3. Preparation of Nitenpyram Analogs Including an Agarose Derivative as an Affinity Column^a

^a (a) EtOH, reflux, 29%; (b) H₂N(CH₂)₅OH, EtOH, reflux, 30%; (c) 2-hydroxybenzoic acid, DCC, DMAP, CH₂Cl₂, 44%.

Synthesis of **14 from **13**.** The method was validated by preparing unlabeled **14**. Thus, to a solution of **13** (1.3 mg, 2 μ mol of 1.0 mg/mL solution in MeOH) were added NaI (0.3 mg, 2 μ mol, 3 mg/mL solution in MeOH) and then chloramine-T (0.5 mg, 2 μ mol, 0.1 mL of a solution of 5 mg/mL in 200 mM phosphate buffer, pH 7.5). The resulting mixture was stirred for 10 min, the solvent evaporated under nitrogen, and the product taken up in CHCl₃. ¹H NMR data were identical to those of **14**, prepared via intermediates **11** and **6**, and comigrated with it on TLC.

Radiosynthesis of [¹²⁵I]-14** from **13**.** The above procedure was then used in the preparation of [¹²⁵I]-**14**. Thus, to a solution of Na¹²⁵I (5.6 mCi, 11 μ L) in dilute NaOH solution (pH 9.0) was injected the organotin precursor (**13**) (15 μ L, 0.1 mg/mL MeOH solution), followed by chloramine-T (6.0 μ L, 0.1 mg/mL 200 mM phosphate buffer solution, pH 7.5). The resulting mixture was shaken occasionally for 10 min before transfer to a vial for evaporation of the solvents under nitrogen. The residue was then dissolved in CHCl₃ and transferred to another vial, leaving insoluble materials behind. The ¹²⁵I-labeled product (1.0 mCi) cochromatographed with unlabeled **14** on TLC with the MeOH/CHCl₃ system above as observed by UV light and PhosphorImager (Molecular Dynamics, Sunnyvale, CA) detection.

Synthesis of Nitenpyram Analogs (15**–**19**) (Scheme 3).** 1-[(6-Chloro-3-pyridinyl)methyl]-1-(ethylamino)-1-[2-(2-hydroxybenzamidyl)ethyl]amino-2-nitroethene (**17**) via 1-[(6-Chloro-3-pyridinyl)methyl]-1-(ethylamino)-1-(methylthio)-2-nitroethene (**15**) and N-(2-Hydroxybenzoyl)ethylenediamine (**16**). A solution of **15** (100 mg, 0.35 mmol) and **16** (60 mg, 0.33 mmol, prepared similarly to intermediate **4** in Scheme 1) in EtOH (5.0 mL) was refluxed for 2 h and then concentrated *in vacuo* and purified by preparative TLC (1.0 mm layer thickness) to give 20 mg of product as a white solid (decomposed at 160 °C) in 29% yield: *R*_f = 0.5 in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 8.23 (d, *J* = 2.52 Hz, 1H), 7.72 (dd, *J* = 1.75, 7.92 Hz, 1H), 7.52 (dd, *J* = 2.52, 8.25 Hz, 1H), 7.35 (s, OH), 7.30 (dt, *J* = 1.75, 8.29 Hz, 1H), 7.23 (d, *J* = 8.25 Hz, 1H), 6.83 (d, *J* = 8.29 Hz, 1H), 6.72 (t, *J* = 7.92 Hz, 1H), 6.49 (s, 1H), 4.48 (s, 2H), 3.76 (brs, 4H), 3.61 (m, 4H), 3.27 (q, *J* = 7.13 Hz, 2H), 1.16 (t, *J* = 7.13 Hz, 3H); ¹³C NMR (CDCl₃) δ 170.75, 163.59, 160.39, 150.66, 148.02, 137.98, 133.37, 130.11, 128.34, 128.13, 124.51, 119.16, 116.34,

101.01, 49.87, 46.47, 44.86, 38.84, 12.0; FAB-LRMS MH⁺ (420, 20%), 164 (100%); FAB-HRMS C₁₉H₂₂ClN₅O₄H⁺, calcd 420.1439, found 420.1448.

1-[(6-Chloro-3-pyridinyl)methyl]-1-(ethylamino)-1-(5-hydroxypentyl)amino-2-nitroethene (**18**). The above methylthio derivative (**15**) (144 mg, 0.50 mmol) was refluxed in EtOH (5.0 mL) with 5-amino-1-pentanol (53 mg, 0.51 mmol) for 2 h and then concentrated *in vacuo*. Purification by preparative TLC (1.0 mm thickness plate) gave 51 mg of a white solid in 30% yield: *R*_f = 0.67 in MeOH/CHCl₃, 20:80; ¹H NMR (CDCl₃) δ 9.69 (s, 1H, NH), 8.30 (d, *J* = 2.40 Hz, 1H), 7.53 (dd, *J* = 2.40, 8.22 Hz, 1H), 7.36 (d, *J* = 8.22 Hz, 1H), 6.51 (s, 1H), 4.33 (s, 2H), 3.64 (t, *J* = 7.73 Hz, 2H), 3.37 (m, 2H), 3.13 (q, *J* = 7.04 Hz, 2H), 1.45–1.82 (m, 8H), 1.19 (t, *J* = 7.04 Hz, 3H); ¹³C NMR (CDCl₃) δ 150.23, 148.77, 143.32, 137.97, 130.25, 124.65, 104.28, 62.18, 50.00, 45.90, 44.88, 31.98, 29.91, 23.00, 12.18.

1-[(6-Chloro-3-pyridinyl)methyl]-1-(ethylamino)-1-[5-(2-hydroxybenzoyl)pentyl]amino-2-nitroethene (**19**). To the above alcohol (**18**) (17 mg, 0.050 mmol) in dry DMF (0.50 mL) was added 2-hydroxybenzoic acid (7 mg, 0.053 mmol), DMAP (6.1 mg, 0.050 mmol), and DCC (10.3 mg, 0.050 mmol) in DMF (0.50 mL). The mixture was stirred overnight and then concentrated *in vacuo* and purified by preparative TLC to give 13 mg of **19** as a white solid in 44% yield: mp = 190–192 °C; *R*_f = 0.67 in MeOH/CHCl₃, 10:90; ¹H NMR (CDCl₃) δ 9.68 (s, 1H), 8.28 (d, *J* = 2.32 Hz, 1H), 7.83 (d, *J* = 7.97 Hz, 1H), 7.46 (m, 2H), 7.34 (d, *J* = 8.15 Hz, 1H), 6.97 (d, *J* = 7.97 Hz, 1H), 6.90 (t, *J* = 8.15 Hz, 1H), 6.51 (s, 1H), 4.34 (t, *J* = 6.12 Hz, 2H), 4.32 (s, 2H), 3.34 (t, *J* = 6.12 Hz, 2H), 3.10 (q, *J* = 7.03 Hz, 2H), 1.42–1.82 (m, 8H), 1.17 (t, *J* = 7.03 Hz, 3H); ¹³C NMR (CDCl₃) δ 170.35, 162.32, 160.81, 156.38, 151.72, 148.52, 137.98, 135.61, 130.25, 129.73, 124.60, 119.10, 117.38, 103.82, 64.69, 49.11, 45.81, 44.71, 29.64, 28.05, 23.14, 12.13; FAB-LRMS MH⁺ (80%), 225 (100%); FAB-HRMS C₂₂H₂₇ClN₄O₅H⁺, calcd 463.1748, found 463.1752.

Receptor Assays. Binding studies with *Drosophila* and *Musca* head membranes (θ) involved ~300 μ g of protein incubated with 2.5 nM [³H]IMI (25 Ci/mmol) for 60 min at 25 °C in a total volume of 250 μ L of 10 mM sodium phosphate buffer, pH 7.4, containing 100 mM NaCl, 5 mM EDTA, 3 mM ethylene glycol bis(β -aminoethyl ether)-*N,N,N,N*-tetraacetic acid, 0.1 mM phenyl-

methanesulfonyl fluoride, and 0.02% NaN_3 . Alternatively, rat whole brain membranes (20) ($\sim 800 \mu\text{g}$ of protein) were incubated for 10 min at 25°C with 5 nM [^3H]nicotine (78 Ci/mmol) in 250 μL of 20 mM Tris buffer, pH 7.4, containing 118 mM NaCl, 4.8 mM KCl, 2.5 mM CaCl_2 , 1.2 mM MgSO_4 , and 1 mM EDTA. The incubated mixtures were rapidly filtered on Whatman GF/B filters presoaked in 0.1% polyethylenimine. The filter was rinsed twice (for rat) or three times (for insects) with 2.5 mL of ice-cold 0.9% NaCl. Radioactivity remaining on the filter was determined by liquid scintillation counting. Specific binding was defined as the difference in radioactivity in the absence or presence of 25 μM unlabeled IMI (for [^3H]IMI binding) or 10 μM unlabeled (–)-nicotine (for [^3H]nicotine binding). IC_{50} values were calculated by iterative nonlinear least-squares regression.

Photoaffinity Labeling. The procedure was similar to that we used before with the azidosalicylate derivative of [^{125}I]- α -BGT and irradiation at 350 nm (6). *Drosophila* head membranes photoaffinity labeled with ~ 4 nM [^{125}I]-**14** (~ 2000 Ci/mmol) in the absence or presence of 10 mM (–)-nicotine were separated by lithium dodecyl sulfate–polyacrylamide gel electrophoresis. The radioactive band(s) was detected by PhosphorImager analysis and compared with molecular mass markers on the same gel.

RESULTS

Synthesis of Hexahydronitroimidazopyrimidines (Figure 1; Schemes 1 and 2). Reaction of an enamine, possessing an NH substituent, with suitable biselectrophiles leads to heterocyclization by bond formations at both nucleophilic sites (21). The desired product in the present study is obtained by stirring CH-IMI with a primary amine and formaldehyde in THF. The benzoyl derivatives **10** and **12** were initially examined because of extensive background on their use in the preparation of [^{125}I]-labeled ligands (22, 23). Synthesis included the preparation, on a multigram scale, of *N*-hydroxysuccinimidyl-4-azidosalicylic acid (**3**) (available commercially from Pierce) (22). Compound **3** on treatment with ethylenediamine gave amino analog **4**, which upon coupling with CH-IMI in the presence of formaldehyde gave the penultimate intermediate (**10**). This step, however, was very sluggish; the yields were improved greatly by using the benzoyl rather than the benzamidyl series. Ethanolamine is preferred over ethylenediamine in coupling with CH-IMI because the diamine can react with formaldehyde and give many cyclic products (24). Thus, ethanolamine and formaldehyde were reacted directly with CH-IMI to give the alcohol (**11**) in 96% yield (19) and then coupled to 4-azidosalicylic acid (**2**) using DCC in 94% yield. Iodination of **12** failed to give a clean reaction, and HPLC would be needed to isolate the product from the monoiodo and diiodo compounds and the starting material to determine the specific activity (25).

Synthesis of [^{125}I]Azidobenzoyl Photoaffinity Probe (Schemes 1 and 2). Iodine-125 can be easily introduced by destannylation of compound **13** in the presence of chloramine-T in methanol (26). Thus, 2-azido-5-iodobenzoic acid (**5**) was prepared in 90% yield from the amino precursor (**6**) and then coupled to the alcohol derivative (**11**) with DCC in 91% yield to give **14**. This compound has suitable photoreactivity with a half-life of <10 min at 0.071 mM in absolute ethanol under UV (350 nm) light (Figure 2). To synthesize the organotin derivative (**13**), 2-azido-5-iodobenzoic acid (**6**) was esterified to the methyl ester (**7**), and then stannylation was carried out to give **8** in anaerobic conditions using tetrakis(triphenylphosphine)palladium(0) in anhydrous

Figure 2. UV absorbance and photodecomposition of compound **14** in EtOH. The times are given for exposure to 350 nm light.

dioxane. Direct stannylation of the acid (**6**) failed to produce the desired product (26–28). Hydrolysis with 2 equiv of 1 N LiOH in THF (27) gave the free acid (**9**) which was coupled with the alcohol (**11**) as before. To prepare the [^{125}I]-labeled analog, a solution of the organotin derivative in MeOH was added to a dilute NaOH solution of Na [^{125}I] followed by a solution of chloramine-T in pH 7.5 phosphate buffer. This reaction was carried out in a well-ventilated hood behind lead shielding. The product was easily purified from the tin precursor by flash chromatography using silica gel packed in a Pasteur pipet and 1% MeOH in CHCl_3 as eluent.

Synthesis of Substituted Demethylnitenpyram Derivatives (Scheme 3). Model compounds were designed in which 2-hydroxybenzoic acid is coupled via a spacer to form demethylnitenpyram derivatives. The synthesis of compounds **17** and **19** included the preparation of a hydroxybenzoyl ethylenediamine derivative **16** by reacting *N*-hydroxysuccinimidyl-2-hydroxybenzoate with ethylenediamine as described above. This derivative was refluxed with the methylthionitroethene (**15**) to give **17** in 29% overall yield. To prepare **19**, compound **15** was reacted with 5-amino-1-pentanol to give the alcohol **18** in 30% yield. Coupling with 2-hydroxybenzoic acid gave **19** in 44% yield.

Potency of Nitenpyram Analogs and Hexahydronitroimidazopyrimidines as Inhibitors of [^3H]IMI Binding in *Drosophila* or *Musca* Head Membranes and of [^3H]Nicotine Binding in Rat Brain Membranes. The successful use of a demethylnitenpyram–agarose affinity column in isolation of the nAChRs of *Drosophila* and *Musca* prompted the synthesis of analogs as photoaffinity candidates (Scheme 3). Thus, nitenpyram analogs with amino and methylamino substituents have IC_{50} values for the *Drosophila* site of 2.2 and 14 nM, respectively (6). However, 2-hydroxybenzoyl analogs proved to be disappointing, with IC_{50} values for the *Drosophila* receptor of $22\,800 \pm 1050$ nM for compound **17** and 1310 ± 87 nM for analog **19**.

Hexahydronitroimidazopyrimidines with a variety of 6-substituents (Figure 1) maintain high potency as inhibitors of [^3H]IMI binding (Table 1). This includes alkyl and aralkyl moieties and various esters and amides with azidohydroxybenzoate and azidoiodobenzoate substituents. Two compounds in the series are of particular interest: the benzophenone as a candidate photoaffinity probe (29) and the azidoiodobenzoate (**14**). The latter compound was selected for radiosynthesis because of suitable potency (IC_{50} 8 nM for *Drosophila* and 25 nM for *Musca* nAChRs; Figure 3; Table 1) and the high specific activity and ease of radiosynthesis with iodine-125. Two analogs were also tested with rat brain

^a R substituent at 6-position of hexahydronitroimidazopyrimidines (Figure 1). Numbers refer to candidate probes but not intermediates described in the text. Although not detailed here, other 6-substituents with similar potency at the *Musca* receptor are C₂H₅, *n*-C₃H₇, CH(CH₃)₂, *n*-C₄H₉, CH(CH₃)C₂H₅, CH₂CH(CH₃)₂, C(CH₃)₃, *n*-C₅H₁₁, C(CH₃)₂C₂H₅, C₂H₄CH(CH₃)₂, C(CH₃)₂C≡CH, cyclopropyl, cyclopentyl, cyclohexyl, pyridinyl-3-CH₂, CH(CH₃)C₆H₅, and adamantyl. ^b M = *Musca* and D = *Drosophila*, n = 3.

**Figure 3.** Displacement curves for compound **14** (unlabeled) on the [³H]IMI binding site in *Drosophila* and *Musca* head membranes and on the [³H]nicotine binding site in rat whole brain membranes.

membranes and [³H]nicotine binding revealing potencies of 71- and 93-fold less than with the *Drosophila* site (Table 1; Figure 3), indicating that with further optimization a photoaffinity probe might be achieved for the mammalian binding site.

Photoaffinity Labeling of 66 kDa Protein of *Drosophila* Head Membranes by [¹²⁵I]-14**.** A single protein band of 66 kDa is photoaffinity labeled by [¹²⁵I]-**14** and totally protected in the presence of 10 mM (–)-nicotine (Figure 4).

DISCUSSION

The discovery that optimized compounds with chloropyridinylmethylamino and nitromethylene substituents have outstanding insecticidal activity and very high affinity for a specific binding site in the insect nAChR provided the basis for preparing an affinity column reported recently (6) and candidate photoaffinity probes described here. The demethylnitenpyram series gave poorly active hydroxybenzoyl analogs as models for [¹²⁵I]-azido derivatives. Attention was then focused on the hexahydronitroimidazopyrimidine series, which is stable at neutral pH, by introducing a variety of substituents

**Figure 4.** Photoaffinity labeling of 66 kDa protein of *Drosophila* head membranes by [¹²⁵I]-**14**. Protein labeling was carried with or without nicotine, designated nicotine and none, respectively. Proteins are separated by lithium dodecyl sulfate–polyacrylamide gel electrophoresis and compared with protein standards (kDa and name): 14, lysozyme; 21, trypsin inhibitor; 31, carbonic anhydrase; 45, ovalbumin; 66, serum albumin; 97, phosphorylase *b*.

in the 6-position including alkyl, aralkyl, benzophenone, azidoxybenzamidyl (**10**), and azidoxybenzoyl derivatives (**12**). Clearly there is considerable structure latitude in groups' acceptability at this site. Iodination of the azidoxyaryls compounds was not complete even when using excess of iodinating reagents, giving a mixture of monoiodo and diiodo derivatives and unreacted starting material. Other analogs considered were the benzophenone or the acetate [as a model for the diazoacetate (**30**)], but introduction of iodine-125 in these candidates is not straightforward.

The preferred photoaffinity probe [¹²⁵I]-**14** is easily prepared from Na¹²⁵I by [¹²⁵I]iododestannylation with the highest specific activity obtainable, and the product is readily separated from starting material. The organotin derivative (**13**) is the precursor of choice for efficient introduction of iodine-125 into a ligand of this type. The precursor can be stored in MeOH solutions for prolonged time without significant decomposition. Compound **14** has suitable photoreactivity, and a preliminary study indicates that [¹²⁵I]-**14** covalently bound to *Drosophila* head membranes gives a derivatized protein at 66 kDa which appears to be associated with the ligand-binding subunit of the nAChR based on protection with (–)-nicotine.

In conclusion, this study describes the synthesis of a novel [¹²⁵I]neonicotinoid photoaffinity ligand by iododestannylation of a tin precursor with maximum ease of carrying out the labeling and separation of unreacted starting material. Further, the novel probe described appears to be suitable for photoaffinity labeling the insecticide-binding site of a putative nAChR subunit.

ACKNOWLEDGMENT

The study described was supported by Grant P01 ES00049 from the National Institute of Environmental Health Sciences, NIH. We received advice and assistance from our laboratory colleagues Gary B. Quistad and Pauline Yu. Donna Hackett and Gerald Rubin of the Department of Molecular and Cell Biology on this campus provided the *Drosophila*. Hélène Perrier (Merck Frosst Centre for Therapeutic Research, Quebec, Canada) made helpful suggestions on the synthesis of 2-azido-5-(trimethylstannyl)benzoic acid.

Conjugates of Oligonucleotides with Triplex-Specific Intercalating Agents. Stabilization of Triple-Helical DNA in the Promoter Region of the Gene for the α -Subunit of Interleukin 2 (IL-2R α)

Gail C. Silver,[†] Chi Hung Nguyen,[‡] Alexandre S. Boutorine,[†] Emile Bisagni,[‡] Thérèse Garestier,[†] and Claude Hélène^{*,†}

Laboratoire de Biophysique, Muséum National d'Histoire Naturelle, INSERM U201–CNRS URA 481, 43 rue Cuvier, 75231 Paris Cedex 05, France, and Laboratoire de Synthèse Organique, Institut Curie-Biologie, CNRS URA 1387, Bâtiment 110, 91405 Orsay, France. Received August 9, 1996[®]

The stabilization of triple-helical DNA under physiological conditions is an important goal for the control of gene expression using the antigene strategy, an approach whereby an oligonucleotide binds to the major groove of double-helical DNA to form a triple helix. To this end, triplex-specific intercalators, namely benzopyridoindole (BPI) and benzopyridoquinoxaline (BPQ) derivatives, have been conjugated to the 5' end or to an internucleotide position of a 15-mer oligonucleotide. These conjugates were then tested, using thermal denaturation experiments, for their ability to form and stabilize a triple-helical structure involving a 42-mer duplex target. All of the conjugates were found to do so. The B[h]PQ derivatives stabilized particularly well when attached to the 5' end with a ΔT_m of 15 °C and $-\Delta\Delta G_{37}^\circ$ of 3.4 kcal mol⁻¹ (pH 6.9, 140 mM KCl, 15 mM sodium cacodylate, 2 mM MgCl₂, 0.8 mM spermine). Though most of the derivatives when attached to the internucleotide position were not able to stabilize triple-helical DNA as well as when attached to the 5' end, one B[f]PQ derivative with an internucleotide attachment did so, with a ΔT_m of 13 °C and $-\Delta\Delta G_{37}^\circ$ of 2.8 kcal mol⁻¹. To a lesser degree, these conjugates were also able to stabilize duplex structures with single-stranded targets. Results were compared to the stabilization obtained with acridine conjugates as well as to a similar study performed with a different sequence.

INTRODUCTION

Oligonucleotides can recognize in a sequence-selective manner both single-stranded DNA (ssDNA¹) and double-stranded DNA (dsDNA). This feature has been exploited as a potential strategy for regulating gene expression with the purpose of treating genetic-based diseases (Hélène and Toulmé, 1990; Uhlmann and Peyman, 1990; Murray and Crockett, 1992; Crooke and Lebleu, 1993; Demesmaeker et al., 1995; Maher, 1996). By specifically recognizing and binding to m-RNA through Watson–Crick hydrogen bonds, an oligonucleotide may halt translation (antisense approach) (Stein and Cheng, 1993; Hélène, 1994; Pierga and Magdelenat, 1994). An oligonucleotide may also impede transcription by binding to the major groove of dsDNA (antigene approach) (Thuong and Hélène, 1993; Radhakrishnan and Patel, 1994a; Frank-Kamenetskii and Mirkin, 1995). In this latter approach, a (T,C)-containing third strand (pyrimidine motif) will bind parallel to the duplex purine strand with the formation of TA×T and CG×C⁺ base triplets using Hoogsteen bonds (Le Doan et al., 1987; Moser and Dervan, 1987; de los Santos et al., 1989; Rajagopal and Feigon, 1989). A (G,A)-containing third strand will run antiparallel and be bound through reverse Hoogsteen hydrogen bonds, forming CG×G and TA×A triplets (purine motif) (Beal and Dervan, 1991; Pilch et al., 1991). (G,T)-containing oligonucleotides can also form triple

helices (Durland et al., 1991) with an orientation that depends on sequence (Sun et al., 1991b; de Bizemont et al., 1996).

We have been interested in regulating gene expression via triple helix formation. One of the targets on which we have concentrated is a 15 bp oligopurine–oligopyrimidine sequence present in the promoter region of the gene coding for the α chain of the interleukin 2 receptor (IL-2R α), overlapping the binding sites for transcription factors NF κ B and SRF (Grigoriev et al., 1992) (Table 1). IL-2R α is a cellular receptor expressed in activated T-cells. The T-cell immune response is mediated by the binding of interleukin 2 to its high-affinity receptor (the α chain associated with the β and/or γ chains).

There are several limitations to the antigene strategy as a method for regulating gene expression. With a few exceptions (Svinarchuk et al., 1995), the stability of triple helices is limited under physiological conditions, due, in part, to the electrostatic repulsion between the third strand and the duplex, as well as the need for the cytosines on the third strand to be protonated in the pyrimidine motif. One strategy to improve triplex stability is to covalently attach DNA intercalators to the third strand (Hélène, 1989; Sun et al., 1989, 1991a; Giovannangeli et al., 1992; Thuong and Hélène, 1993). This approach has been used for the IL-2R α system using acridine-linked (Grigoriev et al., 1992, 1993a) and psoralen-linked (Grigoriev et al., 1993b) oligonucleotides. In both cases, specific inhibition of the transcription of reporter constructs containing the IL-2R α promoter in live cells was demonstrated.

In an attempt to look at more efficient chemical modifications of the third strand for the purpose of modulating *endogenous* gene expression, we have studied other intercalator–oligonucleotide conjugates. Benzopy-

ridoindoles (BPI) (Nguyen et al., 1990) and benzopyridoquinoxalines (BPQ) (Nguyen et al., 1995) are classes of tetracyclic aromatic compounds (Figure 1) having antineoplastic activity. They have been shown to stabilize pyrimidine motif DNA triple helices in solution (Mergny et al., 1992; Escudé et al., 1995; Marchand et al., 1996) and can intercalate into both duplexes and triplexes but bind preferentially to triplexes (Mergny et al., 1992; Pilch et al., 1993).

In this study, we have covalently linked several BPI and BPQ intercalators to the 5' end or at an internucleotide position of a 15-mer third strand probe with the IL-2Rα sequence (Table 1). We have examined the ability of this series of oligonucleotide conjugates to stabilize triple helices *in vitro* under physiological conditions. The stability of triplexes formed from unmodified and acridine-modified oligonucleotide counterparts was also investigated. The results are compared to a similar study performed with a different triplex sequence (Silver et al., 1997).

EXPERIMENTAL PROCEDURES

Oligonucleotides. Unmodified and acridine-modified (using 2-methoxy-6-chloro-9-aminoacridine) oligonucleotides were purchased from Eurogentec (Seraing, Belgium) or Genosys (Cambridge, England). The BPI- and BPQ-modified oligonucleotides were synthesized as described below. The linkage structures of the BPI, BPQ, and acridine-modified oligonucleotides are shown in Figure 2 for both the 5' and internal modifications. The

**Figure 1.** BPI (B[e]PI, B[g]PI), BPQ (B[f]PQ, B[h]PQ), and acridine derivatives. Oligonucleotides were attached to the terminal nitrogens on each of the side chains of the BPI and BPQ derivatives and to the nitrogen at position 9 of the acridine (indicated by boldface and underscoring).

Attachment through 5' end:

Attachment through internucleotide linkage:

**Figure 2.** Linkage structure of BPIs, BPQs, and acridine to oligonucleotides. Outlined characters indicate position of attachment to intercalator. Note that for BPI and BPQ derivatives, the NH group is that of the substituent R indicated in Figure 1, while for the acridine derivative the NH group is found in position 9 of the aromatic ring.

concentration of unmodified oligonucleotides was calculated using molar extinction coefficients at 260 nm derived using a nearest-neighbor model (Cantor et al., 1970; Rougée et al., 1992). The acridine-modified oligonucleotide concentration was calculated using $\epsilon_{424} = 8845 \text{ M}^{-1} \text{ cm}^{-1}$ (Asseline et al., 1984). The extinction coefficients for the BPI and BPQ conjugates were approximated by adding the experimentally derived extinction coefficient at 260 nm of the unconjugated BPI or BPQs in H₂O to the extinction coefficient for oligonucle-

otide 15IL2 ($\epsilon_{260} = 116\,000\text{ M}^{-1}\text{ cm}^{-1}$). All concentrations are given on a per strand basis.

Syntheses. To covalently link the BPQ and BPI derivatives to the 5' end of the oligomers (Godovikova et al., 1986; Mergny et al., 1994), the hexadecyl trimethyl ammonium salt of 150 μg of 5'-phosphorylated 15IL2 (5'-TTTTCCTCTCCCTCT-3') was incubated with 6.6 mg of dipyrindyl disulfide, 7.9 mg of triphenylphosphine, and 5 μL of *N*-methylimidazole in 100 μL of dry DMSO for 15 min at room temperature. Five microliters of triethylamine was added followed by a solution of the BPQ or BPI derivative (20 μL , 30 mM in DMSO). After 20 min, the oligonucleotide was precipitated with 3% LiClO₄ in acetone, reprecipitated from water with EtOH, and purified by reversed phase HPLC. Average yield = 21%. The oligonucleotide–intercalator conjugates were characterized by UV–visible spectroscopy.

To attach the BPQ and BPI derivatives to the interior of the oligonucleotide (Vasseur et al., 1991), 100 μg of oligo 15IL2+A (5'-TTATTCCTCTCCCTCT-3') or 15IL2+Nb (5'-TTNbTTCCTCTCCCTCT-3') was depurinated in a 100 μL solution of 30 mM HCl/1 mM EDTA for 22 h at 37 °C [Bailly and Verly, 1987; to form oligo 15IL2+Ap (5'-TTApTTCCTCTCCCTCT-3')]. Following EtOH precipitation, the oligonucleotide was reacted with the BPQ or BPI derivative (2.5 mM), NaOAc (pH 5.2, 200 mM), and NaBH₃CN (50 mM) in a total volume of 100 μL for 2 h. The oligonucleotide was recovered by reversed phase HPLC. Average yield = 53%. The oligonucleotide–intercalator conjugates were characterized by UV–visible spectroscopy.

Thermal Denaturation Studies. Experiments were carried out in 140 mM KCl, 15 mM sodium cacodylate, 1.5 mM MgCl₂, and 0.8 mM spermine, pH 6.9. Cacodylate buffer was chosen due to the limited dependence of pH on temperature. Absorbance versus temperature curves were obtained using a Uvikon 940 spectrophotometer interfaced to an IBM computer. The temperature of the two six-cell holders was regulated by a Haake P2 circulating H₂O/glycerol (4:1) bath. The temperature was varied at a rate of 6 °C/h by a Haake PG20 thermoprogrammer. To monitor triplex-to-duplex transitions, the temperature was varied from 62 °C (equilibrated for 70 min) to 0 °C (maintained for 70 min) and returned to 62 °C. To monitor duplex-to-single-strand transitions, the temperature was varied from 90 °C (equilibrated for 70 min) to 40 °C (maintained for 70 min) and returned to 90 °C. Oligonucleotide concentrations were 1 μM of duplex and 1.5 μM of third strand. When intercalator was added free in solution, it was added at 1.5 μM . When the target was single-stranded and not double-stranded, the probe strand was added at 1.0 μM (Table 3). The absorbance at 260 and at 600 nm was recorded every 8.3 min. Corrections for spectrophotometric instability were made by subtracting the absor-

bance at 600 nm from that at 260 nm. There is some hysteresis in the heating and cooling curves, due to slow kinetics of formation and dissociation of the triple-helical complexes (Rougée et al., 1992). The difference between the cooling and heating curves varied between 0.5 and 2 °C at the T_m value depending on the identity of the third strand. T_m values were approximated as the maxima in dA/dT vs T plots of the heating curves. The uncertainty in T_m values reported is estimated at ± 1 °C on the basis of repetition of experiments. Values reported are an average of three to six experiments.

Thermodynamic Calculations. As the hysteresis was minimal for many of the melting curves, we could estimate thermodynamic parameters from some of these curves. The heating and cooling curves were analyzed separately, and it was found that the differences between the two values were insignificant.

The transition to the triplex, T, from the duplex, D, and the monomeric oligonucleotide, M, is given by

Thermodynamic parameters were derived from the melting curves using a two-state model which assumes that the species with incomplete base pairing are not significantly populated (Cantor and Schimmel, 1980; Rougée et al., 1992). A linear absorbance vs temperature relationship was assumed for the calculation of A_D and A_T , the absorbances of the double- and triple-stranded species, respectively. Equilibrium constants at different temperatures were then calculated, and the plot of $\ln K_{eq}$ vs T^{-1} was used to determine ΔH° , ΔS° , and ΔG° (37 °C) as previously described (Breslauer et al., 1975; Albergo et al., 1981; Petersheim and Turner, 1983; Rougée et al., 1992; Wang and Kool, 1995). Errors are reported as the standard deviation.

RESULTS

To study the ability of BPI and BPQ conjugates to form stable triple helices, UV thermal melting studies were performed with each conjugate (15 nt) in the presence of a 42 bp target duplex (see top of Table 1). Hyperchromicity at 260 nm accompanies the dissociation of the third strand from the duplex. The midpoint of this transition (T_m) indicates the relative stability of the triple helix. Comparisons were made with the unmodified third strand (15IL2) and with the acridine conjugates. The results of these studies are shown in Table 1. Examples of the profiles of the fraction of triplex formed as a function of temperature are shown in Figure 3. These

Figure 3. Fraction of triplex formed calculated from the graphs of absorbance vs temperature [$\chi_T = (A - A_D)/(A_T - A_D)$]. One example each is shown of the triplex formed with the unmodified third strand (triangles) or with oligonucleotide **14** (circles) in the presence of duplex (42R/Y). The calculations were performed separately on the heating (solid circles/triangles) and cooling (open circles/triangles) curves. Conditions are those described under Experimental Procedures.

curves allowed the calculation of several thermodynamic parameters (ΔG_{37}° , ΔH° , and ΔS°), which are given in Table 2.

These results show that all of the triple helices formed with the oligonucleotide conjugates are more stable than those formed with the unmodified probe (15IL2), yet there are significant variations depending on the point of attachment to the oligonucleotide and the specific intercalator used. The most stable triplex is formed with conjugate **14**, where a B[h]PQ with a butyl linker arm is attached to the 5' end. The triplex formed melts at 31 °C compared with 16 °C for the triplex formed with the free oligonucleotide (**1**) and 29 °C for the 5' acridine conjugate (**17**). The B[f]PQ derivative, 1261, attached to the interior of the 15-mer (**21**) melts at 29 °C. In terms of standard free energy, this corresponds to a stabilization of the triplex by 3.4 kcal mol⁻¹ at 37 °C for B[h]PQ 1260 attached to the 5' end of the 15-mer (**14**) as compared to 2.7 kcal mol⁻¹ for the acridine derivative (Table 2). The B[f]PQ derivative, 1261, attached to the interior of the 15-mer (**21**) stabilizes the triplex by 2.8 kcal mol⁻¹.

For the 5' attachments, comparing the four intercalators, for the $-(CH_2)_3-$ linker arm B[h]PQ = B[g]PI \geq B[f]PQ > B[e]PI, for the $-(CH_2)_4-$ linker arm B[h]PQ > B[g]PI > B[e]PI \geq B[f]PQ, for the $-(CH_2)_5-$ linker arm B[h]PQ > B[e]PI = B[f]PQ, and for the $-(CH_2)_3$ NMe- $(CH_3)_2-$ linker arm B[h]PQ = B[e]PI \geq B[g]PI. In summary, B[h]PQ seems to be the best ligand for stabilizing the triple helix. Also, a chain length of four carbons is optimal for B[f]PQ, but a slightly higher stabilization is obtained with a chain of 5 carbons for B[e]PI and B[h]PQ. A linker arm of three carbons gave consistently less stabilization. Different linker lengths were not tested for the acridine complexes. However, the one tested [$-(CH_2)_5-$] stabilizes well in comparison to most of the BPI and BPQ derivatives, except for B[h]PQ derivatives 1260 and 1335.

Attached to the interior position, the most stabilizing is the B[f]PQ with a linker arm of $-(CH_2)_4-$ (**21**), which has a T_m of 29 °C. This particular intercalator shows a remarkable stabilization compared with all of the other intercalators tested including acridine at this position.

As is to be expected, the oligonucleotide precursors for these conjugates, namely 15IL2+Nb or 15IL2+A, and the oligonucleotide with an apurinic site (15IL2+Ap) (see Experimental Procedures) are much less stable than the unmodified third strand. As fewer conjugates were tested for the interior modifications, it is more difficult to generalize. However, it appears that the B[f]PQ derivatives are much more stable than any of the other intercalator conjugates, whereas in the 5' position it was one of the worst.

The results with the intercalator-oligonucleotide conjugates were compared to the stabilization gained by triplexes with the intercalators free in solution. The plain third strand, 15IL2 (1.5 μ M), was mixed with the duplex solution (1 μ M) in the same buffer as that used for the conjugate studies. Significant triplex stabilization has been seen for solutions where a 10-fold higher concentration of intercalator was used (vs the triplex concentration) at pH 6.2 (Escudé et al., 1995). In the current study, a 1.5-fold concentration (1.5 μ M) of the BPI or BPQ derivatives and a pH of 6.9 were used. All tested BPI and BPQ derivatives led to ΔT_m values of 2 °C except B[h]PQ 1256 and B[g]PI 1271, which gave ΔT_m values of 6 and 3 °C, respectively. This is likely due to the extra positive charge localized on the tertiary nitrogen found in the longer linker arms of these two derivatives providing greater affinity for the negatively charged nucleic acids. That the first of these derivatives stabilizes more than the second has been confirmed by previous studies (Escudé et al., 1995; C. Escudé, personal communication). The addition of acridine to a triplex solution under these conditions did not stabilize the triplex.

BPIs and BPQs are known to preferentially stabilize triple-helical DNA structures over double-helical DNA when in solution (Mergny et al., 1992; Escudé et al., 1995; Marchand et al., 1996). Nevertheless, they do intercalate into duplex structures (Mergny et al., 1992). Therefore, it was of interest to measure the stability of double-helical complexes formed upon binding of the 15-mer-intercalator conjugates to a single-stranded target. A single-stranded sequence complementary to the oligonucleotide-BPI/BPQ conjugates was mixed in equimolar quantity (1 μ M) with different conjugates and the T_m of the duplex-to-single-strand transition was determined. The results are shown in Table 3. The stabilization seen varies between 3 and 6 °C depending on the conjugate.

To attach the intercalators to the interior of the probe strand, we chose to *add* an extra nucleotide to the probe strand, which was then depurinated so that the intercalator could be attached at this position. The reason we chose to do so was based on molecular modeling studies which had indicated that adding, rather than replacing, an existing nucleotide would provide the most energetically favorable possibility (unpublished calculations). The duplex "spreads apart" upon binding of an intercalator (Wilson, 1992; Zhou et al., 1995). Thus, the alignment of the bases in the duplex with the third strand is thought to be better through the addition rather than the replacement of a base. To test this, we performed some melting studies with a target sequence in which an extra base pair was added opposite to the position of depurination on the probe strand. The results are given in Table 4. When the probe strand also contained an extra nucleotide complementary to the base pair added to the target, the T_m remained at 16 °C. However, the T_m values observed with the oligonucleotide conjugates (**20**, **21**, and **23**) dropped (2–8 °C), indicating that these conjugates could not form a more stable conformation with the 43-mer duplexes as compared to the 42-mer duplex. It is interesting to note that the T_m of the 15IL2 oligonucle-

otide also drops slightly with the 43-mer duplex (**Z**, **B** = T, A), even though it should also form a perfect triplex with the modified target. This phenomenon has previously been observed (J.-L. Mergny, personal communication). It is likely due to the distortion induced at the triplex–duplex junction which destabilizes the triple helix more for a py–py than for a pu–py step at the junction.

When the third strand hybridizes to the duplex, two sites are possible for intercalation of the BPI or BPQ derivatives: the duplex–triplex junction and within the triplex. To investigate the relative importance of intercalation at these two sites with the two types of conjugates synthesized, we performed melting temperature studies in the presence of a duplex where the overhanging 5' end (with respect to the purine strand) was removed (Table 5). As would be expected for intercalation within the triplex, the ΔT_m values for those conjugates where the intercalator is attached to the interior are almost the same as the ΔT_m values of these same conjugates with the standard (42R/Y) target. In the case where the intercalator was joined at the 5' end one sees a greater decrease in ΔT_m (i.e. 4–5 °C) when the overhanging duplex sequence is removed. Though not conclusive, these experiments suggest that when attached to the interior, the BPI/BPQ derivative intercalates within the triplex. However, when attached to the

5' end, a large part of the stabilization comes from intercalation into the junction. The T_m of the triplex formed with the unmodified third strand is somewhat higher with the blunt end target than with the target with the overhanging end (42R/Y). This is because the binding of a third strand induces a distortion of the triplex–duplex junction (Collier and Hélène, 1991), and the corresponding free energy has to be provided upon third strand binding leading to a destabilization of the complex.

A similar set of syntheses and melting experiments have previously been performed with a different sequence, called 14C3, shown in Table 6. These results are being reported elsewhere (Silver et al., 1996). However, a small selection of these 14C3 results is shown in Table 6 for the purpose of comparison. The 14C3 triplex is inherently more stable under the conditions used (the same as the present paper), as it contains only 21% cytosines vs 47% for the IL2Ra sequence. The pK_a of cytosines has been estimated at 4.7 in oligonucleotides (Manzini et al., 1990), and protonation is required for triplex formation. It is thus understandable that all of the T_m values obtained with the 14C3 sequence were higher than their 15IL2 counterparts.

However, it is interesting to note that the ΔT_m values for the 14C3 system were greater as well. The most significant Δ(ΔT_m) values [i.e. ΔT_m (14C3 system) – ΔT_m

(IL2 system)] were seen for 5' B[h]PQ attachments and for internally attached B[e]PIs. Thinking that the sequence around the site of the duplex–triplex junction could be influencing the amount of stability gained for the 5' attachments, we changed the duplex target sequence for the 14C3 system. In the IL2 system, at the junction the sequence is TATT in the pyrimidine strand, and for the 14C3 system it is AATT (see Table 6). So we changed the duplex target sequence for the 14C3 system to 3' GCTCTATTCTTCTTTTCTTAAC TCG 5' (outlined base indicates the one changed). The stability of the 14C3 triplexes formed with this target and a probe–intercalator conjugate was not lowered and in fact showed a 1–2 °C increase in T_m (data not shown), indicating that the conformation of the duplex–triplex junction is perhaps not responsible for the differences seen in ΔT_m values.

DISCUSSION

Certain DNA ligands have been shown to bind to DNA triple helices (Mergny et al., 1991; Scaria and Shafer, 1991; Durand et al., 1992; Park and Breslauer, 1992; Escudé et al., 1995). However, only a few compounds have been studied that *efficiently* and *selectively* bind to triple helices (Mergny et al., 1992; Lee et al., 1993; Wilson et al., 1993; Escudé et al., 1995; Fox et al., 1995; Latimer et al., 1995). Previous studies in our laboratory have concentrated on ligands of this latter type, namely benzopyridoindoles and benzopyridoquinoxalines. They stabilize the triple helix by intercalating between TA×T base triplets. Binding of these cationic derivatives to CG×C⁺ triplets is not favored due to the positive charge of this triplet. In this paper and another (Silver et al., 1996), we attached the BPI and BPQ derivatives to a run of thymines within the probe strand and examined the stability of triplexes formed with these conjugates.

The results of the current study indicate that all of the conjugates synthesized are able to stabilize the formation of DNA triple helices. However, certain conjugates did so to a greater extent. Differences were seen among the different derivatives and depended on which of the intercalators was attached, the length of the hydrocarbon linker chain, and the position of attachment to the probe strand. In general, better stabilization was seen with 5' attachments when arm lengths of at least four methyl- enes were used. The B[h]PQ derivatives worked par-

ticularly well here. That the B[f]PQ 1261 derivative (**21**) attached to the interior showed significant stabilization compared to both of the other intercalators attached at this position as well as to the same derivative attached to the 5' end suggests that this conjugate has a conformation allowing particularly favorable ligand–base stacking interactions within the triple-helical region. The mechanism by which these conjugates stabilize triple helices is likely the intercalation of the derivatives within the triplex (internal attachment) or at the duplex/triplex junction (5'-end attachment). When the BPI or BPQ is covalently attached to the oligonucleotide third strand, intramolecular interactions of the BPI or BPQ moiety with the bases of the third strand might also play a role in determining the thermodynamic parameters of the interactions of the conjugate with its target double helix.

It should be noted that the linker used to tether the BPI and BPQ derivatives to the oligonucleotide occupies a different position in the grooves of the triplex than when they are bound as *free* ligand. In the latter case, the linker is expected to be in the Watson–Crick groove for B[g]PI and B[h]PQ derivatives but has been shown to prefer the Watson–Hoogsteen groove for B[e]PI and B[f]PQ derivatives on the basis of molecular modeling (Escudé et al., 1995). [The nomenclature of the grooves has been previously described (Radhakrishnan and Patel, 1994b). The oligopyrimidine and oligopurine strand of the Watson–Crick duplex are *Watson* and *Crick*, respectively, and the third strand is *Hoogsteen*. Each groove of the triple helix is referred to by the names of the adjacent strands.] However, when attached to the third strand, the intercalating moiety is always introduced from the major groove side of the double helix. Therefore, B[g]PI and B[h]PQ should be in a less favorable position than B[e]PI and B[f]PQ. This seems to hold when the intercalator is attached to the interior of the third strand oligonucleotide but not when attached to the 5' end (Table 6). This might reflect the difference in the intercalation mode: within the triple-helical structure in the first case, at the duplex–triplex junction in the second case. On the other hand, the chemistry of dye attachment to the oligonucleotide is also different for an interior site and the 5' end (see Figure 2). A positive charge is still present on the linker when attachment occurs at an interior site as is the case for the free derivatives. This positive charge was taken into account for the modeling studies mentioned above. In contrast, the phosphoramidate linkage at the 5' end carries no positive charge, which may also explain the deviation from the results with the free ligands (Escudé et al., 1995).

It is informative to compare the current study with one performed with the 14C3 sequence (Table 6) (Silver et al., 1996). Both the T_m values and the ΔT_m values are significantly greater for the 14C3 system. The reason for the larger ΔT_m values is not obvious. Previous studies using the 14C3 sequence have suggested that the stretch of six TA×T base triplets is the major binding site for free BPI ligands (Mergny et al., 1992). When two thymines were replaced by two cytosines in the 14C3 sequence, leaving only four contiguous TA×T base triplets, a strong decrease in triple-helix stabilization was seen (Mergny et al., 1992). This probably occurs because the six contiguous TA×T base triplets provide a greater number of binding sites for the BPI ligands within the triplex. The IL2 sequence contains only a stretch of four TA×T base triplets, which might be one reason for the lower stabilization as compared to the 14C3 sequence. In addition, the four TA×T triplets of the IL2 sequence are located at the 5' end of the oligopurine target sequence, whereas the six TA×T triplets are located

toward the center of the 14C3 sequence. Finally, in the case of oligonucleotides with internal attachment of the ligands, the position of intercalation is only two base triplets away from the 5' end of the triplex structure in the case of the IL2 sequence. The last two thymines between the 5' end and the intercalator attachment site of the third-strand oligonucleotide might not be fully hydrogen-bonded to the two T·A base pairs of the target.

Despite the differences in sequence between the IL2 and 14C3, the same trends were seen with both systems in terms of which derivatives stabilized the most. To summarize, the B[h]PQs generally work particularly well and the B[f]PQs particularly poorly at stabilizing DNA triple helices when attached to the 5' end of the probe strand. As well, in both systems, for this site of attachment, the short linker arm, $-(CH_2)_3-$, does not work well. At the interior position, the results were somewhat more mixed, likely a result of several differences in the positioning of the intercalator. However, in both cases the B[f]PQ derivative 1261 shows great stabilization. For the 14C3 system the B[e]PIs also work well.

CONCLUSION

Benzopyridoindoles and benzopyridoquinoxalines have been shown to stabilize the formation of DNA triple helices when they are conjugated at both the 5' end and to an internucleotide position of the third-strand oligonucleotide. The particular derivative, the length of the linker arm, the point of attachment, and the sequence of base triplets around the ligand attachment site all play important roles in determining the stability of the triplexes formed. These results will be useful for studies using these conjugates to inhibit transcription in cellular systems as well as in the design of new oligonucleotide conjugates.

Poly(ethylene glycol) (PEG₅₀₀₀)-conjugated phosphatidylethanolamine was introduced onto the surface of hemoglobin vesicles (HbV); phospholipid vesicles encapsulating concentrated Hb ($d = 0.257 \pm 0.087 \mu\text{m}$; $P_{50} = 32 \text{ Torr}$). The obtained PEG-modified HbV (HbV-PEG) was studied for use as a red cell substitute from the viewpoint of rheology, surface properties, and hemodynamics. The viscosity of the unmodified HbV suspended in saline ($[\text{Hb}] = 10 \text{ g/dL}$) was 2.6 cP (shear rate = 358 s^{-1} , 37°C), less than that of human blood (4 cP). However, when suspended in a 5 g/dL albumin solution (HbV/albumin), it increased to 8 cP due to the molecular interaction between albumin and vesicles, and the viscosity increased with decreasing shear rate, *e.g.*, 37 cP at 0.58 s^{-1} . As for the HbV-PEG/albumin, on the other hand, the viscosity was 3.5 cP at 358 s^{-1} and was comparable with that of human blood. Optical microscopy showed formless flocculated aggregates of the unmodified HbV, while no aggregates were confirmed for the HbV-PEG. The steric hindrance of PEG chains seemed to be effective in preventing intervesicular access and the resulting aggregation. To estimate the flow profiles in the capillaries, the suspensions were allowed to penetrate through isopore membrane filters (pore size = $0.4\text{--}8 \mu\text{m}$, *cf.* capillary diameter = $4\text{--}10 \mu\text{m}$). The penetration rate of the HbV-PEG/albumin was higher than that of the unmodified HbV/albumin due to the suppression of aggregation, whereas both of them were significantly higher than that of human blood due to the smaller size of vesicles than RBC. Ninety percent exchange transfusion was performed with the HbV-PEG/albumin or HbV/albumin in anesthetized Wistar rats ($n = 6$). The blood flow in the abdominal aorta increased 1.5 times, and the total peripheral resistance decreased in the HbV-PEG/albumin-administered group in comparison with the HbV/albumin group. As for the blood gas parameters, the base excess and pH remained at higher levels in the HbV-PEG/albumin group, and the O_2 tension in mixed venous blood for the HbV-PEG/albumin group tended to be maintained at a higher level than that for the HbV/albumin group. Thus, the PEG modification of HbV reduced the viscosity by the suppression of aggregation and resulted in prompt blood circulation *in vivo*.

INTRODUCTION

To date, various efforts have been made to develop red cell substitutes, especially those utilizing Hb, to overcome the problems associated with blood transfusions such as the necessity for blood typing and cross-matching, blood-borne infections, and difficulties in storage (Chang, 1991; Winslow, 1995; Tsuchida, 1995). Hemoglobin vesicles (HbV)¹ or liposome-encapsulated hemoglobin (LEH) are candidates for red cell substitutes that have the cellular structure of phospholipid vesicles containing concentrated Hb (Djordjevic and Miller, 1980; Hunt *et al.*, 1985; Rudolph, 1995; Tsuchida and Takeoka, 1995). On the other hand, in the field of acellular Hb solutions such as chemically modified Hb and recombinant Hb, clinical trials are now underway (Winslow, 1995). However, vasoconstriction induced by acellular Hb solutions is reported. This is due to the trapping of endothelial-derived relaxation factor [EDRF; nitric oxide (NO)] by Hb with an intrinsic high affinity for NO (Vandegriff and Winslow, 1995; Tsai *et al.*, 1995). NO trapping also induces platelet activation (Olsen *et al.*, 1996). Com-

plexation of acellular Hb with endotoxin synergistically enhances the endotoxin biological activities, and it would be dangerous to use acellular Hb in septic shock (Kaca *et al.*, 1995). These problems seem to be related to the lack of physiological significance of the cellular structure of red blood cells (RBC), and it is expected that they will be solved by the encapsulation of Hb.

In previous papers, we have succeeded in preparing HbV with excellent physicochemical properties in terms of Hb encapsulation, Hb concentration, diameter control, oxygen affinity, *etc.* (Sakai *et al.*, 1996; Takeoka *et al.*, 1996). Moreover, in a 40% exchange transfusion with

the HbV suspended in saline, a high oxygen transporting capability of the HbV similar to that of the washed rat RBC was confirmed (Izumi *et al.*, 1996). Ninety percent exchange transfusion with the HbV was also successful in the presence of albumin as a plasma expander using rats (Izumi *et al.*, 1997).

Because the red cell substitutes are literally to be used as substitutes for a large amount of lost red blood cells, the rheological properties of HbV itself and the mixture with blood are important in relation to hemodynamics. Surface modification of phospholipid vesicles with some natural or synthetic glycolipids (Wu *et al.*, 1981; Allen *et al.*, 1987; Gabizon and Papahadjopoulos, 1988; Takeoka *et al.*, 1992) or poly(ethylene glycol) (PEG)-conjugated lipids (Kilbanov *et al.*, 1990; Woodle and Lasic, 1992; Woodle *et al.*, 1994; Harasym *et al.*, 1995; Zalipsky *et al.*, 1995) is known to improve the dispersion state of the vesicles and prolong the circulation time *in vivo* for drug delivery systems (DDS). For HbV, the surface was also modified to improve the dispersion state of the vesicles in the presence of water-soluble polymers or blood components (Yoshioka, 1991; Tsuchida and Takeoka, 1995). The PEG-modified HbV has been studied, and its oxygen transporting ability has been evaluated (Usuba *et al.*, 1993; Zheng *et al.*, 1993). PEG has thus been widely used for vesicular materials including DDS and HbV. However, little attention has been paid to the effect of the PEG modification on the low solution viscosity in the field of DDS because of the significantly low lipid concentration and small dosage. Also, these effects of PEG-modified HbV have not been clearly demonstrated in comparison with the unmodified HbV.

Using our HbV with high Hb encapsulation efficiency and high Hb concentration (Sakai *et al.*, 1996), we aimed to modify the surface with PEG chains by a simple method. The PEG-conjugated lipids with various molecular weights of PEG are currently commercially available, among which 2000 and 5000 seem to be most commonly used (Vertut-Do *et al.*, 1996). The effects of PEG, *e.g.*, longevity of circulation time and prevention of aggregation, increase with increasing chain length at the same molar composition. Our method enables PEG incorporation only on the outer surface of the vesicles; therefore, we thought that a smaller molar composition would be better not to disturb the lipid bilayer by the transbilayer asymmetry, and we selected a larger molecular weight of 5000. We tried to evaluate the HbV-PEG in comparison with the unmodified HbV, in terms of the dispersion state, rheological properties in a mixture with blood and the resulting oxygen transporting capabilities *in vivo* by observing the physiological responses to 90% exchange transfusion in anesthetized rats.

EXPERIMENTAL PROCEDURES

Preparation of HbV and Surface Modification with PEG-Phosphatidylethanolamine. HbV was prepared in the same manner as previously reported in the literature (Sakai *et al.*, 1993, 1995). The encapsulated carbonylhemoglobin (*ca.* 38 g/dL) contained pyridoxal 5'-phosphate (18 mM, Merck Co.) as an allosteric effector and DL-homocysteine (5 mM, Aldrich Chemical Co.) as a metHb reductant. The lipid bilayer was composed of Presome PPG-1 [a mixture of 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylcholine, (DPPC), cholesterol, and 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylglycerol (DPPG), Nippon Fine Chemicals Co.] and α -tocopherol (Merck Co.) at a molar composition of 5/5/1/0.1. After sizing by an extrusion method and removal of unencapsulated Hb using ultracentrifugation (50000g, 40 min), the surface modification of HbV with PEG was performed

by simply mixing the HbV suspension (lipid: 2.2 g/dL, 833 mL) with a saline solution of 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*[poly(ethylene glycol)] (PEG-DPPE, Avanti Co., 0.1 g/dL, 231 mL) at 37 °C under a CO atmosphere and stirring for 30 min. The resulting HbV-PEG was diluted with saline to an Hb concentration of 0.5 g/dL, and carbonylhemoglobin was converted to oxyhemoglobin by illumination with visible light under an O₂ atmosphere (Chung *et al.*, 1995). After the ultracentrifugation and redispersion of the HbV-PEG in 5 g/dL of albumin solution (albumin 5% cutter, Bayer Co.) were repeated, the suspension was filtered through sterilizable filters (Dismic, Toyo Roshi Co.; pore size = 0.45 μ m). The free PEG-DPPE, which was not incorporated into the HbV, was removed during the process of ultracentrifugation (50000g, 40 min) and redispersion. Finally, the Hb concentration was regulated to 10 g/dL using the albumin solution to obtain HbV-PEG/albumin. The unmodified HbV suspended in the albumin solution (HbV/albumin) was prepared in the same manner.

Quantitative Analyses of PEG-DPPE. The freeze-dried powder of HbV-PEG was dispersed in CDCl₃, and the filtrate (filter paper, Toyo Roshi, 5B) was analyzed using ¹H-NMR spectroscopy (JEOL, EX-270). The PEG content was estimated from the intensity ratio of the PEG methylene proton peak (δ 3.63) to that of the choline methyl protons in DPPC (δ 3.39) (Yoshioka, 1991; Hamada *et al.*, 1995).

Viscosity and Optical Microscopy of HbV-PEG/Albumin Mixed with Human Blood. Human venous blood was drawn into EDTA (1 mg/mL blood)-containing tubes. The hematocrit of the blood was 55%. The HbV-PEG or HbV in albumin was mixed with the human blood at volume compositions of 0, 15, 30, 60, 90, and 100%. The rheological properties and density at 37 °C were measured with a capillary viscosimeter [Oscillatory Capillary Rheometer and Density Meter (OCR-D, Anton Parr)], where the sample in the measuring capillary (0.9948 mm in diameter, 100.2 mm in length) was set into sinusoidal oscillations at a given frequency of 2 Hz to mimic the pulsatile flow *in vivo* (Schneiditz *et al.*, 1985). The shear rate ranged from 0.58 to 358 s⁻¹. The whole measurement was performed within 6 h after blood collection. The dispersion states of the vesicles and RBC were observed with optical microscopy (Olympus BH-2) at a magnification of 750.

Permeability through Isopore Membranes. To mimic the blood flow in narrow capillaries, the permeabilities of human blood and the HbV-PEG/albumin and the HbV/albumin through filters were observed. Each isopore membrane filter (Nuclepore, Coaster Co.; pore size = 0.4, 0.6, 1.0, 2.0, 3.0, 5.0, 8.0 μ m; diameter = 25 mm) was attached to a high-pressure resistant chamber (Extruder, Lipex Biomembrane, Inc., Canada). The filtration area was regulated to 1 cm². After the suspension was prefiltered through disposable filters (Dismic, Toyo Roshi Co.; pore size = 0.45 μ m), 5 mL of the suspension was injected and 5 min later the initial filtration rate of the outlet volume was measured at a pressure of 0.3, 0.4, or 4 kg/cm² at 37 °C.

Protein Adsorption onto the Vesicular Surface. The unmodified and PEG-modified vesicles, which did not encapsulate Hb, were prepared with the same lipid composition in the same manner except that phosphate-buffered saline (PBS, pH 7.4, 37 °C) was used in place of a concentrated Hb solution for lipid hydration. After regulation of the lipid concentration to 3.4 g/dL, the vesicles were suspended in a 5% albumin solution and incubated for 3 and 12 h at 37 °C. The vesicles were separated by gel permeation chromatography (Sephacrose

CL-4B, Pharmacia; column size: height = 12 cm, diameter = 3 cm) with PBS as an eluent. It took about 5 min to obtain the fractions of HbV and HbV-PEG. The concentrations of total lipids in the fractions were calculated from the cholesterol concentration measured with a cholesterol oxidase-*p*-chlorophenol method (Cholesterol test II Wako, Wako Pure Chemicals Co.). The amount of adsorbed albumin was measured by *o*-phthalaldehyde (OPA) fluorescence assay (Peterson, 1983), in which the fluorescence ($\lambda_{\text{ex}} = 340$ nm, $\lambda_{\text{em}} = 440$ –455 nm) induced by the reaction of thiol groups on albumin with OPA was measured with a fluorometer (Jasco FP-550).

Ninety Percent Exchange Transfusion Protocol. The procedure was almost the same as that previously reported (Izumi *et al.*, 1996). Twelve Wistar rats (weight 348 ± 11 g, mean \pm SD) were anesthetized with an intraperitoneal injection of sodium pentobarbital (50 mg/kg). Two catheters (PE-20 tubing, o.d. = 0.8 mm, i.d. = 0.5 mm), one of which was introduced into the right jugular vein for sample infusion and the other into the right common carotid artery, were used for blood withdrawal. The catheter in the common carotid artery was then connected to a pressure transducer (Polygraph System, Nihon Koden, Tokyo) for continuous monitoring of the mean arterial pressure (MAP) and the heart rate (HR). Next, a median abdominal incision was made and a miniaturized 20-MHz pulsed doppler probe (HDP 20 20R, 2 mm in diameter, Crystal Biotech, Holliston, MA) was implanted on the abdominal aorta to measure the blood flow. The probe was connected to a pulsed doppler flow module (Model PD-20, Crystal Biotech) (Gardiner *et al.*, 1990; Haywood *et al.*, 1981). Needle-type polarographic oxygen electrodes (Intermedical Co.) were placed in the cortex of the kidney and the cervical muscle for continuous renal cortical and skeletal muscle tissue oxygen tension measurements (Nelmarkka *et al.*, 1982). Approximately 10 min was allowed for the parameters to stabilize. From the MAP, blood flow (Q), and body weight, the total peripheral resistance index (TPRI), which indicates the resistance to blood flow, was calculated using the following equation:

$$\text{TPRI} = (\text{MAP}/Q)/(\text{body weight}) \quad (1)$$

Ninety percent of the estimated total blood volume of the rat (50 mL/kg) was exchanged with the HbV-PEG/albumin (HbV-PEG group, $n = 6$) or the HbV/albumin (HbV group, $n = 6$) at 2 mL of withdrawal (via the common carotid artery)/infusion (via the jugular vein) cycles at a rate of 1 mL/min. Blood samples for hematocrit measurements and arterial and venous blood gas analyses (Corning 170 pH/blood gas analyzer, Corning Medical, Medfield, MA) were taken with a heparinized 2 mL syringe on the first withdrawal as basal values at exchange rates of around 10, 40, 60, 70, 80, and 90%, and 30 min after the completion of the exchange transfusion. All animal studies were approved by the Animal Care and Use Committee of Keio University. The care and handling of the rats were in accordance with the National Institutes of Health guidelines.

Data Analysis. Data are expressed as the mean \pm SD for the indicated number of animals. Data were evaluated using analysis of variance (ANOVA) followed by Fisher's protected least significant difference (PLSD) test. The level of confidence was placed at 95% for all experiments.

RESULTS AND DISCUSSION

1. Characteristics of HbV-PEG/Albumin as a Red Cell Substitute.

The characteristics of the HbV-PEG/

Table 1. Characteristics of HbV-PEG/Albumin in Comparison with Human Blood (RBC)

parameter	HbV-PEG/albumin	human blood
diameter (μm)	0.25 ± 0.08	ca. 8

albumin are summarized in Table 1. The diameter was controlled to 0.25 ± 0.08 μm . By increasing the weight ratio of Hb to lipid to 1.74, the lipid concentration was reduced to 5.74 g/dL. This is the highest encapsulation efficiency ever reported, due to the control of intermolecular interactions during the assembling and sizing procedure of HbV (Takeoka *et al.*, 1996). The surface modifier, PEG-DPPE, was easily introduced onto the surface of HbV by the addition of the PEG-DPPE solution. Diameter changes were observed within experimental error. After the free PEG-DPPE was removed by repeating the centrifugation and redispersion, the content of PEG-DPPE was measured by ¹H NMR and the composition of the lipids was clarified to be DPPC/cholesterol/DPPG/ α -tocopherol/PEG-DPPE = 5/5/1/0.1/0.014 by molar ratio (PEG-DPPE = 0.13 mol %). More than 90% of the added PEG-DPPE was incorporated onto the outer surface of the HbV. The oxygen affinity, P_{50} (oxygen partial pressure required for the half-saturation of Hb with oxygen), was regulated to 32 Torr by coencapsulating PLP (18.6 mM). The amount of oxygen release was calculated to be 6.2 mL/100 mL, which was close to the 7.0 mL/100 mL of human blood due to the increased oxygen transporting efficiency (the difference in O₂ saturation between 40 and 110 Torr PO₂) of the HbV-PEG, 37%, compared to that of human red cells, 28%. No leakage of Hb was observed during and after the introduction of PEG-DPPE. The oxygen affinity of HbV-PEG was almost the same within experimental error, indicating that pH change in the inner aqueous phase and leakage of coencapsulated small molecules such as PLP, Na⁺, and Cl⁻, were negligibly small. The densities of the HbV-PEG/albumin and unmodified HbV/albumin suspensions were almost the same (1.0336 and 1.0335 g/cm³, respectively), and they were smaller than that of human blood (1.0525 g/cm³), mainly due to the fact that the concentration of albumin solution used is 5 g/dL, which is lower than the plasma protein concentration, ca. 7.5 g/dL. The concentration of albumin of the suspension is expressed as 3.2 g/dL due to 36% of the total volume being HbV particles.

2. Effect of PEG Conjugation on the Aggregation of HbV in Albumin Solution and Blood Mixture.

2.1. Optical Microscopic Observation of Dispersion States of HbV-PEG/Albumin. The dispersion states of the HbV-PEG/albumin and HbV/albumin when mixed with human blood were observed by optical microscopy (Figure 1). In the case of HbV-PEG/albumin, only RBCs were confirmed because of the small diameter of HbV-PEG (0.25 ± 0.08 μm), and no aggregate of HbV-PEG was confirmed in the photograph. In the case of HbV/albumin, on the other

Figure 1. Optical microscopic observation of (a) HbV-PEG/albumin (30%) + blood (70%) and (b) HbV/albumin (30%) + blood (70%). The bars indicate 40 μm . Only the RBCs can be seen in (a), while the aggregates of HbV are seen between RBCs in (b).

hand, flocculated aggregates of the HbV were actually confirmed among the RBCs. The RBCs were neither aggregated nor deformed, indicating that both HbV and HbV-PEG did not interact with RBCs. The aggregates of HbV were actually observed before mixing with blood. It is quite obvious that PEG chains suppress the HbV aggregation.

2.2. Viscosities of HbV-PEG/Albumin and Mixtures with Blood. When the unmodified HbV was dispersed in PBS, the viscosity of the vesicular suspension became 2.6 cP (shear rate = 230 s^{-1}), which is lower than that of blood (Sakai *et al.*, 1996). However, when dispersed in a 5 g/dL albumin solution to adjust the colloidal osmotic pressure, the HbV/albumin showed 8 cP viscosity (shear rate = 358 s^{-1}), which was substantially higher than that of blood (3.7 cP). In Figure 2, the HbV/albumin shows a non-Newtonian flow typical for particle suspensions and higher viscosities, especially at lower shear rates. In the case of the HbV-PEG/albumin, on the other hand, the viscosity was significantly reduced in comparison with that of the unmodified HbV/albumin and was almost the same as that of human blood at any shear rates (*e.g.*, 3.5 cP at 358 s^{-1}). These results indicate that the unmodified HbV aggregates due to the molecular interaction of albumin with the vesicular surface and increases the viscosity, while the surface modification of the HbV with PEG chains suppresses HbV aggregation and provides a low viscosity almost the same as that of human blood.

The effect of compositions of PEG-DPPE on viscosity was previously studied at 0.063, 0.13, and 0.25 mol %, for which the viscosities at 10.2 s^{-1} were 5.8, 5.2, and 7.2 cP, respectively. All of the compositions showed a

Figure 2. Shear rate dependence of the viscosity of (a) HbV-PEG/albumin and (b) HbV/albumin in the mixture with human blood measured with a capillary rheometer at 37 $^{\circ}\text{C}$. Blood volume (%): 0 (■), 10 (▲), 40 (●), 70 (□), 85 (△), 100 (○).

significant decrease in viscosity (*cf.* 22.5 cP without PEG-DPPE); however, the viscosity began to increase at 0.31 mol %. We therefore selected the composition at around 0.13 mol %.

When human blood was mixed with the HbV/albumin, the viscosity proportionally increased with increasing volume ratio of HbV/albumin. This indicates that the unmodified HbV already aggregates in the albumin solution, and there is no detectable additional interaction between the HbV/albumin and blood components from the rheological point of view. In the case of HbV-PEG/albumin, the viscosity was not changed at any shear rate and any mixing ratio, except at 30% HbV-PEG/albumin, at which there was a slight increase in viscosity; however, it is negligible in comparison with the high viscosity of the unmodified HbV/albumin.

Figure 3 shows the Casson plots for the mixtures of HbV/albumin or HbV-PEG/albumin with human blood, $\sqrt{\gamma}$ versus $\sqrt{\tau}$ (γ , shear rate; τ , shear stress). In the case of the HbV-PEG/albumin, all of the mixtures with blood coincided well with that of blood. A linear relationship indicates that the rheological property of the HbV-PEG agrees well with the Casson equation for a non-Newtonian fluid ($\sqrt{\tau} = k_0 + k_1\sqrt{\gamma}$) (Oka, 1984), with constants, $k_0 = 0.19 \pm 0.07$ (mean \pm SD) (dyn/cm^2) $^{1/2}$ and $k_1 = 0.18 \pm 0.002\text{ s}^{1/2}$. The stress yield (k_0^2), which indicates the change point from a solid to a fluid phase, seems to be similar to that of human blood. This linear relationship at all compositions indicates the absence of additional interaction with blood components. On the contrary, HbV/albumin showed a drastic increase in $\sqrt{\tau}$ at lower $\sqrt{\gamma}$ with increasing $\sqrt{\gamma}$ and then a linear relationship. The curves seem to fit the generalized Casson equation reported by Oka (1971). This equation is valid with the assumptions that the stress acts to break bonds between particles and that the shear rate acts independently in tending to prevent their reforming. Therefore, it can be easily surmised that the aggregates dissociate at the higher shear rates and that the sizes of HbV aggregates are different at each shear rate. The small stress yield for unmodified HbV/albumin may indicate that the aggregation is induced by the weak interaction between the albumin and vesicles.

Figure 3. Casson plots for the (a) HbV-PEG/albumin and (b) HbV/albumin of the mixture with human blood. Casson equation: $\sqrt{\tau} = k_0 + k_1\sqrt{\gamma}$ (τ , shear stress; γ , shear rate; k_0 , k_1 , constants. Blood volume (%): 0 (■), 10 (▲), 40 (●), 70 (□), 85 (△), 100 (○).

Figure 4. Comparison of the rates of penetration of the HbV/albumin (slashed bar), HbV-PEG/albumin (black bar), and human blood (white bar) through the Nuclepore isopore membrane filters at the applied pressure of 0.3 kg/cm² at 37 °C. For the membrane of 0.4 μ m pore size, the applied pressure was 0.5 kg/cm².

2.3. Permeability of HbV-PEG/Albumin through Isopores. In Figure 4, the permeabilities of the HbV-PEG/albumin, HbV/albumin, and human blood through isopore membranes are shown as a model of the blood flow through capillaries. This method is conventionally used for the RBC deformability measurement (Kukuchi and Koyama, 1984). The capillary and precapillary diameter is usually 3–15 μ m, and some narrow during circulatory failure such as hemorrhagic shock. A biconcave-shaped RBC with a diameter of 8 μ m deforms to a parachute-like configuration and permeates through the narrow capillaries. However, with decreasing pore size of the membranes from 5 to 2 μ m, the flow rate decreased for all suspensions, especially for human blood even though the applied pressure (0.3 kg/cm² \approx 220 Torr) is about twice that of normal blood pressure. When the pore diameter is 3 μ m, blood could hardly permeate, whereas both the unmodified HbV/albumin and HbV-PEG/albumin showed high permeability. The permeation through capillaries is very much influenced not only by viscosity but also by the capillary diameter. It was reported that the narrower the capillary is, the lower the viscosity of the blood is when the diameter of the artificial capillaries

decreased from 500 to 50 μ m with increased shear rate (Fahraeus and Lindqvist, 1931). However, when the diameter of the capillaries decreases to <4 μ m, the viscosity increases and finally there should be a limitation for the RBC penetration (Pries *et al.*, 1992). Due to the small size of HbV ($0.25 \pm 0.08 \mu$ m), both the HbV-PEG/albumin and HbV/albumin suspensions promptly permeate through the membrane filters with pores of sizes down to 0.4 μ m without changes in vesicular size or Hb leakage. Especially the HbV-PEG/albumin permeates more rapidly than the unmodified HbV/albumin because HbV-PEG did not aggregate. Even though the HbV/albumin showed aggregation in the optical microscopy, the aggregates dissociated at higher shear rates and permeated more promptly than expected. The difference in the permeation rate between the two suspensions becomes smaller, which should be related to the smaller difference in viscosity at higher shear rates in Figure 2. Both the HbV and HbV-PEG can penetrate through sterilizable filters of 0.45 μ m in pore size for preparation. No Hb leakage was confirmed, supporting the belief that the aggregation is reversible and that there is no deformation of the bilayer membrane. After the permeation, the suspension was ultracentrifuged, and the amount of PEG-DPPE in the supernatant was analyzed. However, no PEG-DPPE was detected. Therefore, PEG-DPPE was not removed during permeation through the pores of the membranes used in this experiment.

In spite of the fact that the viscometric properties of the HbV-PEG/albumin and blood are almost the same by viscometric analysis (Figures 2 and 3), the flow patterns in the capillaries *in vivo* would be influenced not only by the viscosity but also by the relationship between the diameters of the particles and capillaries.

3. Quantitative Analysis of Adsorbed Albumin onto the Vesicular Surface. The amounts of adsorbed albumin onto the vesicles after 3 and 12 h of incubation at 37 °C were quantitatively analyzed under the assumption that adsorbed albumin on the surface would induce vesicular aggregation. After 3 h, the amounts of albumin were 7 and 10 μ g/mg lipid for the unmodified and PEG-modified model vesicles, respectively. After 12 h, the amounts became 9 and 11 μ g/mg, respectively. At 11 μ g/mg, the surface of one vesicle (*ca.* 2.0×10^5 nm²) was calculated to be covered with *ca.* 100 albumin molecules (size: 3.8×15 nm); *ca.* 3% of the surface was covered with albumin. Some of the adsorbed albumin would be removed from the surface during gel permeation chromatography as Chonn *et al.* (1991) reported. However, the time required to obtain the HbV or HbV-PEG fraction was only 5 min and the desorption must be minimal. Contrary to the assumption, there was no significant difference between the modified and unmodified vesicles. PEG chains should prevent intervesicular access and aggregation rather than albumin adsorption. The repulsive interaction between PEG-modified surfaces has been clarified by the distance between the membranes using X-ray diffraction (Needham *et al.*, 1992) and the steric hindrance calculated using computer analysis (Torchilin *et al.*, 1994; Hristova and Needham, 1995). Because PEG chains do not completely cover the surface of the vesicles at the molar composition employed, albumin would penetrate through the PEG chain layers to the vesicular surface to be adsorbed. Even so, the repulsion between the PEG-modified vesicles, which are much larger than albumin, would be effective and the adsorbed albumin on the surface could not induce vesicular aggregation. This hypothesis is also supported by the results of Harasym *et al.* (1995), who found that the coupling of proteins onto PEG-modified phospholipid vesicles was not

Figure 5. Changes in hemodynamic parameters during the 90% exchange transfusion with HbV/albumin (○, $n = 6$) and HbV-PEG/albumin (●, $n = 6$) and 30 min post-transfusion, shown as percentages of the basal values: (a) MAP, mean arterial pressure; (b) blood flow in abdominal aorta, significant differences at 70% ($p < 0.05$) and 90% ($p < 0.05$); (c) HR, heart rate; (d) TPRI, total peripheral resistance index.

retarded but that the aggregation during the coupling was suppressed by PEG chains.

4. Ninety Percent Exchange Transfusion. During the exchange transfusion, the hematocrit of both the HbV and HbV-PEG groups decreased from about 50 to 5%, indicating that almost 90% exchange transfusion was theoretically and actually performed. In the glass capillaries for hematocrit measurements, the HbV precipitated on the RBC layer, while the HbV-PEG did not, and it was still dispersed in the supernatant after centrifugation (12000g), indicating that the HbV-PEG is well dispersed even in the presence of blood components.

Figure 5 summarizes the changes in hemodynamic parameters, which are shown as percentages of the basal values. The HR remained normal in both groups. The MAP showed a slight transient increase for both groups

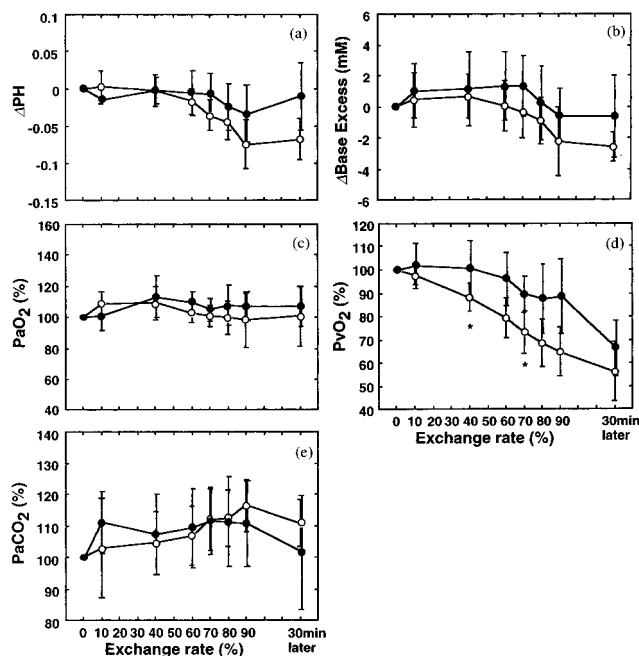

Figure 6. Changes in pH and blood gas parameters during the 90% exchange transfusion with HbV/albumin (○, $n = 6$) and HbV-PEG/albumin (●, $n = 6$) and 30 min post-transfusion: (a) pH, significant differences at 30 min post transfusion ($p < 0.05$); (b) base excess; (c) PaO₂, arterial blood partial oxygen tension; (d) PvO₂, mixed venous blood oxygen tension, significant differences at 40% ($p < 0.05$) and 70% ($p < 0.05$); (e) PaCO₂, arterial blood partial carbon dioxide tension. pH is shown as a difference from the basal value. Blood gas parameters are shown as percentages of the basal values.

and then decreased to 80–90% of the initial values. The transient increase at the first stage is maybe due to some form of immunological reaction accompanying the phospholipid vesicle injection as discussed later. The HbV-PEG group showed a significantly (*ca.* 50%) higher blood flow rate in the abdominal aorta with *ca.* 20% lower TPRI than the HbV group. This would be the result of the lower viscosity of the HbV-PEG/albumin, which promotes blood flow in the capillaries. The previous report of the 90% exchange transfusion with washed ratRBC/albumin (Hb = 10 g/dL) showed about a 30% increase in blood flow (Izumi *et al.*, 1997), less than that of HbV-PEG group, even though the HbV-PEG showed almost the same viscometric characteristics as mentioned above. This indicates that the rheological properties in narrow capillaries are not the same as those measured with the viscosimeter and that HbV-PEG would show prompt flow in the capillaries *in vivo* in just the same way as in the filter permeability measurements in Figure 4, because HbV-PEG is not aggregated and is smaller than RBC.

Parts a–d of Figure 6 show the differences in pH and the changes in blood gas parameters from the basal values. The pH began to decrease at an exchange ratio of around 60% for the HbV group. In spite of the fact that these levels of decreases are still small in comparison with the administration of albumin alone, as reported in the previous paper (Izumi *et al.*, 1997), the HbV-PEG group remained at a significantly higher level than the HbV group. The base excess values showed the same profiles. As for the arterial partial pressure of oxygen (PaO₂) and carbon dioxide (PaCO₂), both groups showed slight increases but remained in the normal range. The mixed venous partial oxygen pressure (PvO₂) of the HbV-PEG group was significantly higher than that of the HbV group. PvO₂ is a parameter for O₂ supply (Kobayashi *et al.*, 1995). Low PvO₂ indicates low oxygen saturation of

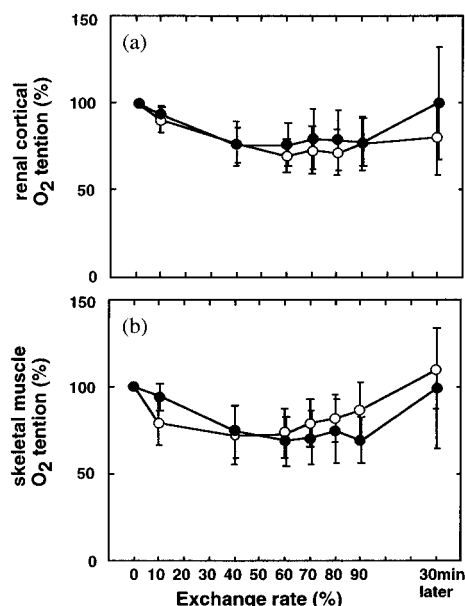

Figure 7. Changes in renal cortical (a) and skeletal muscle (b) tissue oxygen tensions measured by needle-type poplographic oxygen electrodes during the 90% exchange transfusion with HbV/albumin (○, $n = 6$) and HbV-PEG/albumin (●, $n = 6$) and 30 min post-transfusion. Both are shown as percentages of the basal values.

Hb, and a fall in PvO_2 implies decreased O_2 transport (Kandel and Aberman, 1983). The graph indicates that the HbV group is slightly hypoxic and the HbV-PEG shows better O_2 supply.

In spite of the fact that the PvO_2 was improved by the surface modification with PEG, the oxygen tensions at the renal cortex ($rPtO_2$) and skeletal muscle ($sPtO_2$) for both groups decreased to *ca.* 70% of the initial values at 90% exchange and were significantly low (Figure 7) in comparison with the RBC group ($rPtO_2 = 99\%$; $sPtO_2 = 99\%$ at 90% exchange; Izumi *et al.*, 1997), though they are significantly high in comparison with those who received only albumin ($rPtO_2 = 22\%$; $sPtO_2 = 35\%$ at 90% exchange; Izumi *et al.*, 1997). We presume that both the HbV and HbV-PEG somewhat influence the vasomotion, *e.g.*, indirect induction of vasoconstriction, which results in the decreased density of the capillaries and oxygen diffusion from capillaries to tissues. There is no difference in the high affinity of Hb for the endothelial-derived relaxation factor (nitric oxide) between HbV-PEG and HbV. One reason seems to be related to the shear stress in the capillaries. Some endothelial relaxation factor is reported to be generated in response to the shear stress in the capillaries (Malek and Izumo, 1995). The prompt flow of small HbV results in a shear stress decrease and vasoconstriction. The high fluidity in the vessels would adversely influence the vasomotion, and it would not always be convenient for blood flow (Tsai *et al.*, 1996). The other reason seems to be related to the immunological reaction accompanied by transient hypertension (Figure 5a) and thrombocytopenia, in which complements such as C3a would be generated and they would activate platelets and increase the thromboxane A_2 , which induces the vasoconstriction (Miyamoto *et al.*, 1988; Watanabe *et al.*, 1988; Loughley *et al.*, 1990; Rudolph, 1995). Anyway, both of the two groups recovered from the transient reaction and low tissue oxygen tensions at 30 min post exchange transfusion. All of the rats that received HbV/albumin or HbV-PEG/albumin survived for about 20 h, in spite of the fact that those which received only albumin died within 20 min post exchange transfusion.

In conclusion, the effects of the PEG modification of the HbV were observed as the suppression of inter-vesicular aggregation and prompt flow in vessels. This affects the hemodynamics, the increased blood flow, and the resulting stable blood gas parameters, indicating that HbV-PEG has the potential for efficient oxygen supply.

ACKNOWLEDGMENT

This work has been supported in part by Grants-in-Aid from the Ministry of Education, Science, and Culture, Japan (065159, 06771037, 07508005), the Ogasawara Foundation for the Promotion of Science and Engineering, and the Iwaki research fund. We are greatly indebted to Mr. Kenichi Hamada for skillful experimental works.

Nicole M. Jackson and Michael G. Hill*

Department of Chemistry, Occidental College, Los Angeles, California 90041. Received August 1, 1996*

Gold surfaces have been derivatized with 15-base-pair double-stranded DNA oligonucleotides containing a pendant 5' hexanethiol linker. The electrochemistry of intercalated methylene blue has been investigated at these modified electrodes. Chronocoulometry, cyclic voltammetry, ellipsometry, and quantitation via ^{32}P labeling are all consistent with a surface coverage of $\geq 75\%$ with the DNA helices stacked at an angle from the electrode surface. Cyclic voltammetry at low methylene blue/duplex stoichiometries yields well-behaved surface waves with $E^\circ = -0.25\text{ V}$ (vs SCE), a value 0.03 V negative of that in aqueous solution. A binding isotherm for methylene blue at an electrode derivatized with the double-stranded sequence 5' SH-(CH₂)₆-p-AGTACAGTCATCGCG 3' was obtained from coulometric titrations and gave an affinity constant equal to $3.8(5) \times 10^6\text{ M}^{-1}$ with a saturation value of 1.4(2) methylene blue intercalators per DNA duplex. Taken together, these experiments support a model for the surface morphology in which DNA duplexes are densely packed; methylene blue therefore reversibly binds to sites in the DNA that are close to the bulk solution. Electrochemistry at DNA-derivatized electrodes provides a valuable methodology to examine DNA-bound redox reactions and may offer new insight into DNA-mediated electron transfers.

The π -stack of aromatic heterocycles contained within the DNA helix presents a unique medium in which to explore electron-transfer reactions (1). As the hydrophobic interior of DNA differs substantially from aqueous solution, the redox properties of molecules intercalatively bound (and of the nucleic acid bases themselves) may vary significantly from those in solution. Redox reactions in the π -stack are particularly important for understanding charge delocalization in DNA and its effect on base damage (2–4). However, the irreversible electrochemistry of the nucleic acid bases has made it difficult to monitor directly the redox behavior of bases in either their monomeric or extended π -stacked forms where electronic interactions perturb the π -systems of adjoining base steps (5–6). Both organic molecules and transition-metal complexes have been employed as indirect probes of the electronic properties of DNA (1, 7–15).

Photophysical studies on DNA have shown that the π -stack mediates ultrafast electron transfer ($k_{\text{ET}} \sim 10^{10}\text{ s}^{-1}$) (1). Although various systems are being explored (9–12), fast photoinduced electron-transfer kinetics are only observed when both donor and acceptor are intercalated into DNA (13–15); under such conditions, efficient luminescence quenching has been observed over 40 Å (13). Moreover, recent photochemical studies suggest that the extended DNA π -stack facilitates long-range oxidative base damage (4). These results all point to the base stack of DNA as an effective pathway for electron transfer.

Electrochemical studies of small molecule/DNA complexes have focused primarily on solution-phase phenomena, in which DNA-induced changes in redox potentials and/or diffusion constants of organic and inorganic spe-

cies have been analyzed to yield association constants (16, 17). In addition, rates of guanine oxidation catalyzed by electrochemically oxidized transition-metal complexes have been used to evaluate the solvent accessibility of bases for the detection of mismatches (18). Electrochemical signals triggered by the association of small molecules with DNA have also been applied in the design of other novel biosensors. Toward this end, oligonucleotides have been immobilized on electrode surfaces by a variety of linkages [e.g., thiols on gold (19, 20), carbodiimide coupling of guanine residues on glassy carbon (21), and alkanebisphosphonate films on Al³⁺-treated gold (22)] for use in hybridization assays. Both direct changes in mass (measured at a quartz crystal microbalance) (20) and changes in current (19, 21) or electrogenerated chemiluminescence (22) due to duplex-binding molecules have been used as reporters for double-stranded DNA. Gold surfaces modified with thiolated polynucleotides have also been used for the detection of metal ions and DNA-binding drugs (23).

To investigate the redox chemistry of molecules within the DNA environment, we have employed gold surfaces modified with double-stranded, thiol-terminated DNA (24). The covalent attachment of DNA directly to an electrode surface provides a controlled environment in which kinetic and thermodynamic parameters of DNA-bound species can be evaluated. To probe DNA on these modified surfaces, we have examined the electrochemistry of methylene blue (MB) (25), an aromatic heterocycle that binds strongly to DNA via intercalation (26). Here we report the electrochemistry, binding affinity, and electron-transfer dynamics of intercalated MB at a gold electrode modified with 15-base-pair oligonucleotide duplexes, singly derivatized with a 5'-hexylthiol tether.

EXPERIMENTAL SECTION

Materials. Phosphoramidite reagents (including the C₆ S–S thiol modifier) were obtained from Glen Research. Methylene blue (Sigma Chemical Co.), ferrocene carboxaldehyde, and octadecyl mercaptan (Aldrich) were used as received. Potassium ferrocyanide (Fisher) was recrystallized from aqueous solution prior to use. [γ -³²P]dATP was obtained from NEN-DuPont.

Synthesis of Derivatized Duplexes. 5' Mercapto-hexyloligonucleotides and underivatized complements were synthesized according to automated solid-phase techniques (27), using a disulfide protected linker (C₆ S–S thiol modifier). Sequences were purified by reversed phase HPLC, deprotected using dithiothreitol, and re-purified before hybridization to unmodified complements. Single-stranded oligonucleotides were characterized by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry and HPLC retention times. Sequences prepared according to this method include 5' SH-(CH₂)₆-p-AGTGCGAA GCTGCGT 3', 5' SH-(CH₂)₆-p-AGTACAGTCATCGCG 3', and 5' SH-(CH₂)₆-p-AGTACAGTCATCAGT 3'. Duplexes were hybridized in deoxygenated 5 mM phosphate/50 mM NaCl (pH 7) by heating to 90 °C followed by slow cooling to room temperature. Unprotected duplexes were stored frozen under argon to prevent oxidation of the thiol.

Derivatization of Gold Electrodes. Bulk gold electrodes were polished successively with 0.3- and 0.05- μ m alumina (Buhler), sonicated for 30 min, and etched in 1.0 M sulfuric acid. Au(111) surfaces (28) were prepared by vapor deposition onto mica or glass. Electrodes were then modified by incubation in 0.1 mM solutions of derivatized DNA duplexes in 5 mM phosphate/50 mM NaCl (pH 7) for 12–48 h at ambient temperature. Modified electrodes were rinsed in buffer prior to use. For the investigation of DNA-modified electrodes at high MB loadings, deposition of the thiol-terminated DNA was performed in the presence of 0.6 mM MB; these electrodes were rinsed in 10 μ M MB/buffer solutions. CH₃(CH₂)₁₇-SH-modified electrodes were prepared by incubation in ethanol solutions for 48 h.

Electrochemistry. All electrochemical experiments were performed with a Bioanalytical Systems (BAS) Model CV-50W electrochemical analyzer. Cyclic voltammetry (CV) and chronocoulometry (CC) were carried out at 20 \pm 2 °C with a normal three-electrode configuration consisting of either a modified gold-disk or a hanging drop mercury working electrode and a saturated calomel reference electrode (SCE, Fisher Scientific). The working compartment of the electrochemical cell was separated from the reference compartment by a modified Luggin capillary. Potentials are reported versus SCE. Chronocoulometric measurements were corrected for double-layer charge as determined in buffer solutions. Heterogeneous electron-transfer rates were determined by cyclic voltammetry and analyzed as described previously (29). The electron-transfer kinetics of several previously reported systems (including benzo[*c*]cinnoline on gold and methylene blue on Hg) (30) were investigated using this method with our instrumentation, and in each case, excellent agreement with the literature values was observed.

Ellipsometry. Optical ellipsometry (λ = 632.8 nm) was carried out on dried samples at 25 °C using a Gaertner Model L116C ellipsometer.

³²P Labeling and Quantitation. A 15-base-pair oligonucleotide (5' CGCGATGACTGTACT 3') was 5' labeled with [γ -³²P]ATP and hybridized to a thiol-modified complement. Samples of Au(111) on mica (diameter

Figure 1. Cyclic voltammograms for 0.1 mM K₄[Fe(CN)₆] in 5 mM phosphate/50 mM NaCl (pH 7) at a DNA-modified (—) [5' SH-(CH₂)₆-p-AGTACAGTCATCGCG 3' + complement] and bare gold electrode (---). Scan rate = 100 mV/s; electrode area (*A*) = 0.02 cm².

= 0.41 cm) were treated with this duplex in the manner described above. After thorough rinsing in buffer solutions, dried samples were counted on a Beckman LS60001C scintillation counter, adjusted for attenuation by the presence of the mica, and compared to calibration standards that were prepared from known quantities of labeled oligonucleotide. The values obtained by scintillation counting and the surface areas of the modified mica were confirmed by analysis of the radioactivity of each sample by phosphorimager (Molecular Dynamics).

RESULTS

Surface Analysis. Modification of gold surfaces with 5'-thiol-terminated DNA duplexes was established by cyclic voltammetry, ellipsometry, and the direct quantitation of ³²P-labeled oligonucleotides on Au(111). The electrochemical window of 50 mM NaCl (pH 7) at DNA-modified gold extends from 0.70 to –0.70 V (versus SCE). The cyclic voltammograms of Fe(CN)₆^{4–} at bare and DNA-modified electrodes are shown in Figure 1. As ferrocyanide does not bind to the DNA polyanion, the lack of signal at the modified electrode implies essentially complete coverage by the thiol-terminated DNA. To ensure that Fe(CN)₆^{4–} was not merely electrostatically repelled from holes in the monolayer, a neutral probe, ferrocene carboxaldehyde, was investigated and gave a similar result.

Gold surface waves (generated by the formation and stripping of gold oxide) at bare and derivatized electrodes were also compared by cyclic voltammetry as a qualitative measure of the surface coverage (31, 32). These results suggest a very high loading (>85%). However, thiol–gold linkages are known to undergo oxidative desorption at high potentials (33), so an alternative method was used to quantitate the coverage.

DNA adsorbed on Au(111) was directly quantitated in a radioactive tagging (³²P) experiment. This assay yielded an average of 5.7(3) \times 10^{–12} mol of duplex DNA on a 0.14-cm² surface after 24 h of modification. From this value and the cross-sectional area of DNA (3.14 \times 10^{–12} cm²), the surface coverage was calculated as Γ = 4.1(2) \times 10^{–11} mol/cm², which corresponds to a close-packed fractional coverage of 0.75(3).

Ellipsometry of a 15-base-pair thiol-derivatized duplex on Au(111) was carried out and yielded an estimate for

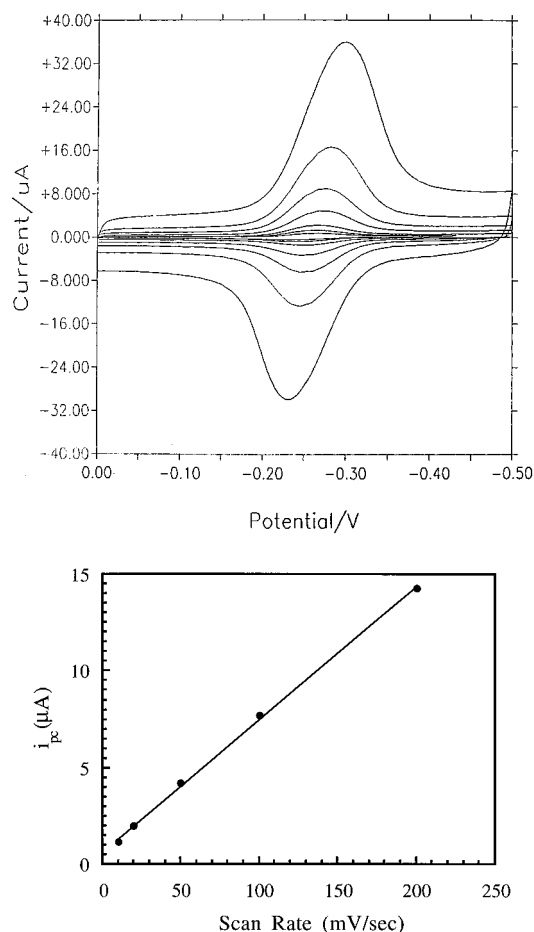

Figure 2. (A, top) Cyclic voltammetry of 1.0 μM methylene blue in 50 mM phosphate (pH 7) at a DNA-modified [5' SH-(CH₂)₆-p-AGTGCGAAGCTGCGT 3' + complement] electrode ($A = 0.7 \text{ cm}^2$; scan rate = 5, 10, 20, 50, 100, 200, and 500 mV/s). (B, bottom) Plot of i_{pc} vs scan rate.

the average monolayer thickness of 35 Å. As this measurement corresponds to an average thickness on the gold surface, it could reflect anywhere from 100% surface coverage with derivatized DNA duplexes stacked at an angle of 32° from the gold surface, to DNA helices oriented perpendicular to the surface with only 55% coverage, given a cylindrical DNA 15-mer duplex of 66-Å height (including the fully extended linker) and 20-Å diameter (34).

Cyclic Voltammetry of Methylene Blue. The cyclic voltammetry of 1.0 μM MB at a DNA-modified electrode is shown in Figure 2. The pronounced electrochemical response at such a low concentration is strong evidence that MB binds tightly and is electronically well coupled to the modified electrode surface. The reduction potential of MB at the DNA-modified electrode is -0.25 V (vs SCE), compared to -0.22 V at bare gold. A plot of cathodic peak current (i_{pc}) vs scan rate (ν) is linear (Figure 2B), establishing that MB is strongly adsorbed to the DNA-modified surface (35).

Qualitatively, ΔE_{p} increases as a function of scan rate (Figure 3), indicating slow electron-transfer kinetics on the CV time scale (29). For comparison, the peak separations are much less pronounced for MB adsorbed to a mercury surface, where the rate constant is reported as 1500 s^{-1} (25); at bare gold we observed essentially no peak splitting up to our fastest scan rates (50 V/s). Importantly, these measurements were all made at very low loadings of MB; thus, artifacts due to lateral charge migration or ohmic (iR) drop were minimized (at the largest currents used, iR was $<5 \text{ mV}$). These data

Figure 3. Plot of $E - E_{\text{pc}}$ vs $\log(\nu)$ for 0.1 μM methylene blue at a gold electrode derivatized with 5' SH-(CH₂)₆-p-AGTACAGT-CATCGCG 3' hybridized to its complement in 25 mM phosphate/75 mM NaCl (pH 7).

indicate that the electron-transfer rate is attenuated by the intercalation of MB into the DNA monolayer and that the rate is significantly faster at bare gold than at the derivatized surface. It is noteworthy that no appreciable differences in the CV responses were observed for the three oligonucleotide sequences examined.

Control experiments were also carried out to distinguish the binding characteristics of MB on different electrode surfaces. Coulometric experiments (36) on bare gold electrodes showed no evidence of adsorption of MB at sub-micromolar concentrations (Figure 4). In addition, electrodes treated with oligonucleotides lacking a thiol linker under the same conditions as those used for surface modification with the linker did not facilitate the subsequent adsorption of MB, and instead yielded irreproducible voltammetric responses that ranged from reversible to highly irreversible. Lastly, we contrast the behavior of MB at a DNA-modified electrode with that at a gold electrode modified with octadecanethiol (see Supporting Information). At the alkylthiol surface, cyclic voltammetry of MB reveals preferential binding to the surface in the reduced form, and a plot of i_{pc} vs $\nu^{1/2}$ is linear, consistent with diffusion of MB.

Determination of Methylene Blue Affinities. MB reversibly binds to DNA-modified electrodes, as established by transfer experiments in which the electrochemical response of a derivatized electrode was monitored during sequential and repetitive immersions in MB and MB-free solutions. The affinity of MB for the DNA-derivatized surface was determined using chronocoulometry (36). Figure 4 shows binding isotherms for MB at both DNA-modified [sequence = 5' SH-(CH₂)₆-p-AGTACAGT-CATCGCG 3'] and bare gold electrodes. The data obtained at the DNA-modified electrode were fit according to Langmuir's model (37), giving $K = 3.8(5) \times 10^6 \text{ M}^{-1}$ and $\Gamma_{\text{max}} = 1.2(1) \times 10^{-12} \text{ mol}$, where K is the association constant per site and Γ_{max} is the maximum number of MB binding sites (Figure 5). The good fit obtained with this model confirms independent, non-cooperative binding sites for MB on the 15-base-pair duplexes. Comparable values for K and Γ_{max} were obtained for the sequence 5' SH-(CH₂)₆-p-AGTACAGT-CATCAGT 3'. It is noteworthy that the affinity of MB to a bare gold electrode is significantly lower (Figure 4).

The value of Γ_{max} corresponds to a stoichiometry of 1.4(2) MB per 15-base-pair DNA duplex based upon 75% coverage of this surface. Yet maximum stoichiometries of MB bound to DNA in solution are expected to approach 7 MB per 15-base-pair oligonucleotide duplex (38). To test whether attachment of DNA to the electrode surface restricts access of MB, the electrochemistry of surfaces modified with duplexes presaturated with methylene blue

Figure 4. Adsorption isotherms for methylene blue (25 mM phosphate/75 mM NaCl, pH 7) at a gold electrode modified with 5' SH-(CH₂)₆-p-AGTACAGTCATCGCG 3' hybridized to its underivatized complement (A) and at a bare gold electrode (B). Surface concentrations were determined from the intercepts of Q vs $t^{1/2}$ curves obtained by chronocoulometry; $A = 0.02$ cm².

Figure 5. Plot of $[MB]/MB_{ads}$ vs $[MB]$ for the MB/DNA isotherm shown in Figure 4A. Data were analyzed as follows (37): $[MB]/MB_{ads} = (1/\Gamma_{max})[MB] + (1/K\Gamma_{max})$, where $[MB]$ is the bulk concentration of methylene blue, MB_{ads} is the number of moles of methylene blue adsorbed on the surface, and Γ_{max} is the number of methylene blue binding sites at saturation.

was investigated. Figure 6 shows the cyclic voltammogram of 10 μ M MB at an electrode derivatized with a 0.1 mM duplex solution that contained 0.6 mM MB (these conditions ensure that the DNA is almost entirely saturated, with a negligible concentration of MB free in solution). The very broad and cathodically shifted response is characteristic of interacting redox-active species (39). When this electrode was immersed in MB-free electrolyte, the response slowly decayed. Once the dissociation process was complete, the bulk concentration of MB was brought back to 10 μ M, but a much smaller response was observed. Importantly, the signal with 10 μ M MB was now identical to that observed for DNA-modified electrodes prepared in the absence of MB (i.e. not presaturated with MB). Integration of the currents shown in Figure 6 yields a 5:1 ratio, which is close to the ratio of saturation values expected for MB in solution versus that measured at the DNA-modified electrodes.

DISCUSSION

Gold Electrodes Derivatized with DNA. 5'-Thiol-terminated DNA duplexes covalently modify gold surfaces. Importantly, duplexes that lacked the thiol linker showed little and irreproducible adsorption to gold under identical conditions. Very high surface coverages of gold by thiol-terminated DNA were confirmed by evaluating the accessibility of the modified electrode to diffusing

Figure 6. Cyclic voltammograms of 10 μ M methylene blue in 50 mM phosphate (pH 7) at an electrode ($A \sim 0.07$ cm²) modified with a solution containing 0.1 mM DNA [5' SH-(CH₂)₆-p-AGTGGGAAGCTGCGT 3' + complement] and 0.6 mM MB (dotted line) and the same electrode after buffer equilibration and subsequent restoration of the bulk concentration to 10 μ M MB (solid line).

species in solution, integrating the gold surface waves, and quantitating the radioactivity of ³²P-labeled DNA electrodes.

Although packing of the DNA on the surface is high, the DNA helices do not appear to lie flat on the electrode surface. Since quantitation of the DNA duplexes on the surface shows at least 75% coverage, such high loading of covalently bound duplexes can only be accommodated with the majority of DNA duplexes at a substantial angle from the surface. Moreover, since the duplexes are relatively short (representing 1.5 helical turns), they can also be considered quite rigid across the duplex. Ellipsometric measurements (albeit on dried samples) combined with electrochemical data also suggest that the helices are stacked at an angle with respect to the surface. Hence, the morphology of the DNA-modified surface appears to involve a densely packed array of duplexes. However, it is important to note that no direct information regarding the degree of order of DNA duplexes on the electrode has been obtained.

Electrochemistry of Intercalated MB. Micromolar solutions of MB yield well-defined voltammetric responses at electrodes modified with thiol-derivatized DNA (Figure 2). The reduction potential for intercalated MB is cathodically shifted (~ 30 mV) from the value in aqueous solution. For comparison, the reduction potentials for MB in dimethylformamide, acetonitrile, and acetone are, respectively, -0.50 , -0.52 , and -0.48 V vs SCE (corrected for the junction potential, using ferrocene/ferrocene as an internal standard). Wider variations in reduction potentials are observed in aqueous solution as a function of pH since the reduction is coupled to proton transfer. At low concentrations of MB (<0.1 μ M), the cyclic voltammograms exhibit full-widths at half-heights of ~ 55 mV. This value is slightly larger than the predicted 45 mV for a 2e⁻ Nernstian system. Starting at low loadings of MB, the voltammograms broaden until saturation in binding of MB to DNA is reached; the broadest cyclic voltammograms are observed at electrodes presaturated with MB. In each case, the cathodic and anodic peak splitting approaches zero at slow scan rates. The broadening (which depends directly upon loading of MB) therefore indicates a distribution of binding environ-

ments with slightly different reduction potentials. A systematic examination of these parameters as a function of sequence for this and other DNA-binding molecules will be instructive.

Importantly, the binding affinity of MB for the DNA-modified electrode [5' SH-(CH₂)₆-p-AGTACAGTCATCGCG 3'; $K = 3.8 \times 10^6 \text{ M}^{-1}$] is comparable to that found for DNA in solution ($K = 10^6 \text{ M}^{-1}$ in 50 mM NaCl) (26). A preference for GC-rich DNA has been noted in some studies; we do not observe a significant change in binding affinity with an electrode modified with the sequence 5' SH-(CH₂)₆-p-AGTACAGTCATCAGT 3', which does not contain adjacent GC base pairs near its 3' terminus.

While the equilibrium binding constants of MB to our DNA-modified electrodes are similar to those found for DNA in solution, the saturation values are not. Our observed Γ_{max} corresponds to roughly 1 MB per 15-base-pair duplex. This stoichiometry is significantly less than that of the MB/base-pair stoichiometry found in solution (26), where MB may occupy many (>5) neighbor excluded (38) sites on a 15-mer duplex. Indeed, if the oligonucleotides are presaturated with MB before attachment to the electrode surface, loadings of MB closer to that predicted by neighbor exclusion are detected electrochemically. However, once this presaturating MB dissociates from the surface (after the electrode is immersed in pure buffer), subsequent binding of MB to the electrode is again restricted. These observations fully support the notion that the DNA helices on the gold surface are tightly packed, necessitating that MB binds at sites close to the DNA/solvent interface. Owing to dense DNA packing and to the high affinity of MB for DNA, diffusion down into the DNA monolayer may be severely inhibited.

Although available data suggest that MB binds to DNA that is densely packed at an angle from the electrode surface, we also considered the possibility that the DNA is lying flat on the electrode. If this were the case, we might expect the CV response to more closely resemble that of MB adsorbed directly onto gold; the significant difference in ΔE_p as a function of scan rate strongly argues against this possibility. Moreover, if a flat orientation were more favorable, we would expect to see similar behavior when the surfaces were modified with DNA lacking the linker. Instead, in experiments with DNA noncovalently associated with the electrode, we observe only very weak and irreproducible signals for MB.

One might also consider that the DNA merely facilitates delivery of MB to the gold surface. However, our adsorption isotherms clearly indicate that MB binds more strongly to DNA-modified electrodes than to bare gold. Therefore, appreciable dissociation of MB from DNA to the gold surface is highly unlikely. In this light, it is interesting that the ratio of the maximum surface coverages for MB and thiol-modified DNA on gold (18×10^{-11} and $6 \times 10^{-11} \text{ mol/cm}^2$, respectively) corresponds roughly to the ratio of cross-sectional surface areas for methylene blue (1 nm^2) (25) and double-stranded DNA (3 nm^2) (34). Additionally, the electrochemistry of MB at an electrode modified with octadecanethiol provides further evidence against a channeling mechanism. At the alkylthiol surface, MB exhibits diffusional behavior and appears to bind more strongly in the reduced form. This is in stark contrast to the electrochemical response of MB at a DNA-modified electrode. The strength of the interaction between DNA and methylene blue afforded by intercalation makes it much more energetically favorable for the intercalator to remain bound rather than to diffuse to the electrode.

Figure 7. Schematic illustration depicting MB (dark rectangles) bound to 15-base-pair oligonucleotides attached to a gold surface. The lengths of the DNA helices and alkylthiol chains are shown to relative scale. Helices are shown at an average angle of 40° from the normal with a surface coverage of 80%; surfaces are realistically more heterogeneous than depicted.

These data may therefore be taken together in developing a model that describes the binding of MB to the DNA-derivatized surface. In this model (Figure 7), closely packed DNA helices are tethered to the gold surface via thiol linkages. Solution-borne MB binds reversibly to accessible duplex sites on the derivatized electrode, with an affinity comparable to that for duplex DNA in solution. Since the duplexes are tightly packed on the surface, however, access appears to be restricted primarily to those sites near the bulk solution. MB is therefore separated from the electrode by both the σ -system of the aliphatic linker ($\sim 15 \text{ \AA}$) and the π -stacked base pairs ($\sim 50 \text{ \AA}$), which lead to the intercalation site. As a result, electrochemical reduction of MB at the derivatized surface occurs over long distance through the DNA duplexes.

If this model is correct, our results lead to the suggestion that electron transfer through the double helix is remarkably efficient. For example, applying a decay constant (β) characteristic of σ -only arrays (0.95 \AA^{-1}) (41), we would expect the electron-transfer rate to drop by more than 22 orders of magnitude through the π -stack alone. The almost reversible response observed at scan rates up to 500 mV/s for MB at DNA-modified gold rules out a rate constant of this small magnitude.

We stress, however, that if MB intercalates into sites evenly dispersed throughout the modified surface, the observed electrochemical response may not uniquely support long-range electron transfer through DNA. Specifically, if the decay rate of electron transfer through DNA were steep enough, in principle only MB bound at the first base steps from the aliphatic linker would give an electrochemical response. In this scenario, the observed rate of electron transfer would be attenuated essentially only by tunneling through the hexylthiol tether, as the rates of electron transfer to MBs intercalated further out would be too slow to measure. Although we cannot completely rule out this possibility, the electrochemical response of MB at presaturated DNA-modified electrodes (Figure 6) seems to indicate that intercalators bound throughout the double helix can contribute to the observed currents. Moreover, given a relatively large β , if the intercalators were distributed throughout binding sites along the entire helices, we would predict much less reversible voltammograms, as a wide range of rate constants would contribute to the overall currents.

Therefore, from the data now available, it appears that as long as the MB is intercalated into the DNA-modified electrodes (be it near the solvent-exposed terminus of the adsorbed DNA or dispersed throughout the double helix) electron transfer over long distance through the DNA is exceptionally efficient. Studies employing well-defined systems in which the location of the intercalator is

precisely determined will be required to assess quantitatively the electronic coupling mediated by the π -stack of DNA.

CONCLUSIONS

DNA-derivatized electrodes offer a valuable tool to examine the redox behavior of species within the DNA environment. Electrochemistry on DNA-modified surfaces provides a convenient method to determine equilibrium binding parameters of redox-active species and may represent an alternative means to investigate the dynamics of DNA-mediated electron-transfer processes.

ACKNOWLEDGMENT

We are grateful to the NIH (GM49216 to J.K.B.), the Research Corporation (M.G.H.), the Camille and Henry Dreyfus Foundation (M.G.H.), and the NSF (DUE-9551647 to M.G.H.) for their financial support. In addition, we thank Ashish Bansal for assistance with the ellipsometry experiments and Professor F. C. Anson for helpful discussions.

Influence of Endosome-Destabilizing Peptides on Efficacy of Anti-HIV Immunotoxins

Vladimir V. Tolstikov, Robert Cole, Hua Fang, and Seth H. Pincus*

Laboratory of Microbial Structure and Function, Rocky Mountain Laboratories, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Hamilton, Montana 59840. Received June 13, 1996[®]

The effects on immunotoxin efficacy of fusogenic peptides derived from influenza virus hemagglutinin have been studied. These peptides have an amphipathic nature and change conformation from random at pH 7 to helical at pH 5. Fusogenic peptides are reported to destabilize endosomal membranes, resulting in the release of contents into the cytoplasm. The use of two related fusogenic peptides to enhance the efficacy of anti-HIV immunotoxins is described. The direct toxicity of the peptides was tested on HIV-infected H9/NL4-3 cells. Peptide HA24 was considerably more toxic than HA23. The peptides were mixed with two different immunotoxins. Immunotoxin action was enhanced by both peptides, with HA24 providing greater enhancement than HA23. Immunotoxins were then constructed by coupling HA23 or HA24 to the targeting antibody with disulfide-containing linkers. Peptide HA23 enhanced the activity of the immunotoxin 4–5-fold. Surprisingly, HA24 significantly inhibited immunotoxin activity. Coupling the peptides to the immunotoxin had no effect on antigen binding characteristics or the activity of the toxic moiety. Bafilomycin A₁, an agent that inhibits vacuolar acidification, markedly potentiated the effects of all immunotoxins. These results demonstrate that amphipathic peptides can influence the efficacy of immunotoxins, but in sometimes unpredictable ways.

Immunotoxins are bifunctional molecules containing a targeting portion, usually either an antibody or a ligand of a cell-surface receptor, and a toxic moiety. Immunotoxins bind to target cells and are internalized, and the toxic moiety is translocated to its site of action. The toxic moiety of a number of immunotoxins are polypeptides displaying enzymatic activity. Ricin A chain (RAC¹) depurinates an adenine residue in 28 S rRNA. Diphtheria toxin and pseudomonas exotoxin A (PE) exhibit ADP-ribosylating activity. These enzymatic activities, requiring translocation to the cytoplasm, arrest protein synthesis and cause cell death. Although the toxins are extremely potent, cytotoxic activity is limited by lysosomal degradation of the vast majority of internalized molecules (1, 2). Potentiation of immunotoxin action can be achieved by coadministration of drugs that inhibit lysosomal function, including monensin, chloroquine, and ammonium chloride (1, 3).

The use of amphipathic peptides that interact with the membrane bilayer and are able to destabilize membranes under acidic conditions can enhance the efficiency of gene transfer (4, 5) and cytoplasmic delivery of antisense oligonucleotides (6). The peptides have a random configuration at neutral pH but assume an amphipathic helix at acid pH. Peptides containing the N-terminal amino acid sequence of influenza virus hemagglutinin

have been demonstrated to lyse liposomes and erythrocytes at pH 5, but not at pH 7 (5). Such peptides were used to prepare covalent (4, 6) and noncovalent (5) plasmid or oligonucleotide conjugates/complexes. It is believed that once in the endosome, the fusogenic peptides self-assemble and form a transmembrane channel, thereby disrupting the vacuolar membrane and preventing lysosomal degradation of the transferred nucleic acids.

In the present paper, we study the use of such peptides to enhance the action of immunotoxins. As a model system, we have used anti-HIV immunotoxins targeted to the HIV envelope protein gp120, expressed on the surface of persistently infected cells (7–10). Peptides were either mixed with or conjugated to the immunotoxin. The results indicate that this approach can enhance the cytotoxicity of immunotoxins, but some unexpected phenomenon were observed.

EXPERIMENTAL PROCEDURES

Immunotoxin Synthesis. HA23 peptide, corresponding to the NH₂-terminal 20 amino acids (AA) of hemagglutinin extended with a 3 AA COOH-terminal tail (GLFEAIAAGFIENGWEGMIDGGGC), and the acidic mutant HA24 peptide, corresponding to the NH₂-terminal 23 amino acids with A7 replaced with E and having a COOH-terminal C (GLFEAIEGFIENGWEGMIDGWYGC), were synthesized on an automated peptide synthesizer using standard methods (Applied Biosystems Inc., Foster City, CA; Model 431A). The peptides were cleaved from the resin with trifluoroacetic acid/water/phenol/thioanisole/ethanedithiol (10:0.5:0.5:0.66). Crude peptides were dissolved in 20 mM ammonium bicarbonate with 300 μ L of 25% ammonia/L, reduced with dithiothreitol (DTT) and *N*-methylmercaptoacetamide (Fluka Chemika-BioChemika, Buchs, Switzerland), and purified by high-performance liquid chromatography (HPLC, preparative Nova-Pak HR C₁₈, Waters/Millipore, Milford, MA) on a 40–95% methanol gradient. The purity of the peptides was determined by analytical

¹ Abbreviations: DTT, dithiothreitol; ELISA, enzyme-linked immunosorbent assay; HPLC, high-performance liquid chromatography; LC-SPDP, sulfosuccinimidyl 6-[3'-(2-pyridylthio)propionamido]hexanoate; PAGE, polyacrylamide gel electrophoresis; PDP, pyridyldithiopropionyl; PE, pseudomonas exotoxin A; RAC, ricin A chain; SEM, standard error of the mean; SPDP, succinimidyl 3-(2-pyridylthio)propionate.

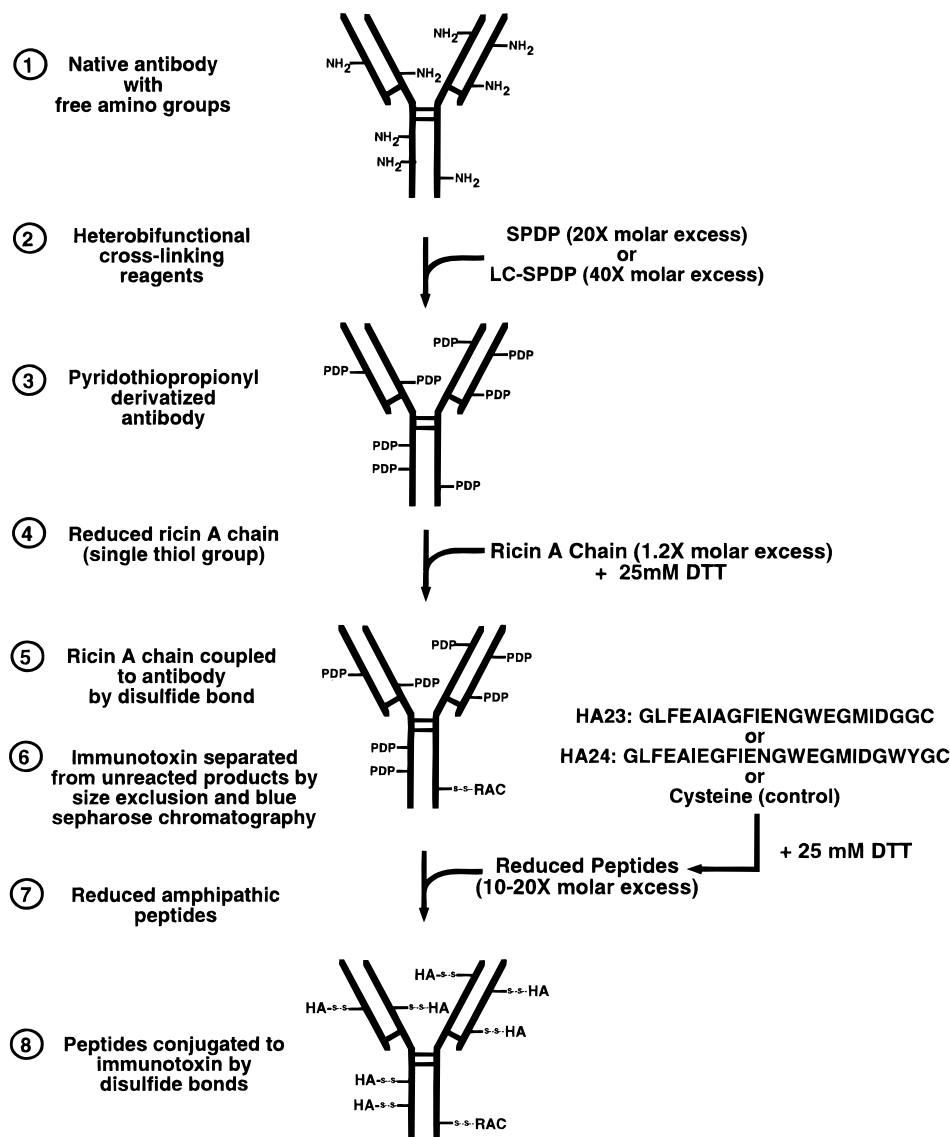

Figure 1. Construction of peptide-containing immunotoxins.

reversed phase HPLC. The amino acid sequence of both peptides was confirmed by sequence analysis (Applied Biosystems Inc., Model 470A protein sequencer equipped with a Model 120A PTH-amino acid analyzer).

A diagram of the conjugation scheme for the construction of the peptide-derivatized immunotoxins is shown in Figure 1. Monoclonal antibody 924 binds to the V3-loop of HIV gp120, strain IIIB (7). T7 is an irrelevant isotype matched antibody (11). Both were grown as hybridoma supernatants, purified on protein G-Sepharose (Pharmacia, Piscataway, NJ) and then by size exclusion HPLC (TSK-GEL G3000SW, TosoHaas, Japan). The antibody was treated with a 20-fold excess of sulfosuccinimidyl 6-[3'-(2-pyridylthio)propionamido]hexanoate (LC-SPDP; Pierce, Rockford, IL) or a 40-fold excess of succinimidyl 3-(2-pyridylthio)propionate (SPDP; Pierce) as previously described (12, 13). Modified antibodies were separated from an excess of reagent by size exclusion HPLC. The number of introduced pyridylthiopropionyl (PDP) groups was measured by reduction with 25 mM DTT and UV spectroscopy at 343 nm as described (14).

Deglycosylated ricin A chain (RAC; Inland Laboratories, DeSoto, TX) was reduced in the presence of 25 mM DTT and purified from DTT on Sephadex G-25M (Pharmacia) under nitrogen. A 1.2-fold molar excess of reduced

RAC was mixed with modified mAb, concentrated under nitrogen to 1 mg/mL of protein, and gently stirred for 48 h. Immunotoxins were separated from unreacted RAC by size exclusion HPLC. Unreacted mAb was separated by affinity chromatography on Blue Sepharose CL-6B (Pharmacia) as described (15). Purified immunotoxins were mixed with a 10–20-fold molar excess (relative to the amount of introduced PDP groups) of reduced HA23 or HA24 peptides or, as a control, cysteine, and gently stirred for 24 h. Modified immunotoxins were separated from unreacted peptides by size exclusion HPLC. The absence of the unreacted PDP groups was confirmed by measuring OD at 343 nm after reduction of purified immunoconjugates. There was no evidence of substitution of RAC by the peptides. The constitution of the immunotoxins was confirmed using SDS–polyacrylamide gel electrophoresis (PAGE) under both reducing and nonreducing conditions.

The immunotoxin CD4-PE40 is a chimeric fusion protein consisting of the two amino-terminal domains of CD4 coupled to the toxic domains of *Pseudomonas* exotoxin A (10, 16). It was the kind gift of Upjohn Laboratories (Kalamazoo, MI). Immunotoxins used in this study are summarized in the Table 1.

Immunoassay. Antigen binding and constitution of the immunotoxins were characterized by enzyme-linked

Table 1. Immunotoxins Used in This Study

immunotoxin	linker	specificity
T7-RAC	SPDP	synthetic polypeptide (Y,E)-A--K (irrelevant antigen)
CD4-PE40	fusion protein	CD4 binding site of HIV gp120
924-Ic-RAC	LC-SPDP	AA 309-318 (V3-loop) of gp120
924-Ic-RAC-HA23	LC-SPDP	AA 309-318 (V3-loop) of gp120
924-RAC	SPDP	AA 309-318 (V3-loop) of gp120
924-RAC-HA23	SPDP	AA 309-318 (V3-loop) of gp120
924-RAC-HA24	SPDP	AA 309-318 (V3-loop) of gp120

immunoassay (ELISA). Ninety-six-well U-bottom plates (Immulon-2, Dynatech, Chantilly, VA) were coated with a peptide corresponding to the V3-loop of gp120 (TRP-NNNTRKSIRIQRGPGRAFTVIGKIGNMRQAH) at 5 $\mu\text{g}/\text{mL}$ (17) and blocked with 3% BSA/0.1% Tween 20 in PBS. Plates were incubated with immunotoxins overnight at 4 °C. They were then washed and incubated with either guinea pig anti-RAC or rabbit anti-HA23 overnight at 4 °C. After washing, the plates were incubated with alkaline phosphatase-conjugated anti-guinea pig or rabbit Ig (Zymed Laboratories, South San Francisco, CA) for 2 h and washed again. As shown under Results, these anti-Ig do not cross-react with the mouse Ig component of the immunotoxin. Substrate (*p*-nitrophenyl phosphate; Sigma Chemical Co., St. Louis, MO) was added at 0.5 mg/mL, and OD₄₀₅ was determined 30–90 min later by using an automated ELISA reader (Bio-Rad Model 2550; Richmond, CA). Data are means and standard error of the mean (SEM) of triplicate samples.

Cell-Free Protein Synthesis. Untreated reticulocyte lysate *in vitro* translation kit was purchased from Ambion, Inc. (Austin, TX). Immunotoxin was added to a cell-free extract of rabbit reticulocyte lysate in the presence of [³⁵S]Met and incubated for 120 min at 37 °C. Protein was precipitated with trichloroacetic acid and the amount of label incorporated determined by liquid scintillation counting.

Assay of Immunotoxin Efficacy. The cytotoxic effect of the immunotoxins was tested on H9 cells persistently infected with the molecularly cloned strain of HIV-1 designated NL4-3 (7, 18, 19) by assaying [³⁵S]-Met incorporation into cellular proteins. Details of all techniques have previously been published (7). The results shown are means and SEM of triplicate samples.

RESULTS

Toxicity of Free Peptides on H9/NL4-3 Cells. Peptides HA23 and HA24 were tested for toxicity on persistently HIV-infected H9/NL4-3 cells at concentrations up to 1 mg/mL. HA23 peptide did not show any significant cytotoxicity, while a dose-dependent effect was obtained with HA24 peptide at concentrations as low as 125 $\mu\text{g}/\text{mL}$ (Figure 2). Thus, HA24 had greater direct toxicity upon HIV-infected cells. Similar results were obtained when both peptides were tested on uninfected H9 cells (data not shown). These results are consistent with previous studies showing greater membrane lysis by HA24 (5).

Effects of Mixing Peptides with Anti-HIV Immunotoxins. H9/NL4-3 cells were treated with suboptimal concentrations of immunotoxins (0.3 $\mu\text{g}/\text{mL}$) in the absence or presence of HA23 or HA24 (Figure 3). Peptides were tested at two concentrations within the nontoxic range for each peptide (the concentration of HA24 tested was lower than that of HA23). A small, dose-dependent enhancement of cytotoxicity was seen with each peptide. The effect was greater on CD4-PE40 than on 924-RAC. A marginal increase in toxicity of the irrelevant control immunotoxin was also observed.

Figure 2. Inhibitory effect of peptides on H9/NL4-3 cells. 4×10^4 HIV-infected H9/NL4-3 cells were incubated with various concentrations of the HA23 (\bullet) or HA24 (\circ) peptide for 48 h in 200 μL per well. Cells were pulsed with [³⁵S]Met (0.5 $\mu\text{Ci}/\text{well}$) and incubated for an additional 24 h; the cellular proteins were harvested onto filter paper and counted in a scintillation counter. Results are counts per minute, means of triplicate values.

Figure 3. Effect of HA23 and HA24 peptides on cytotoxicity of anti-HIV immunotoxins. H9/NL4-3 cells were incubated with the indicated immunotoxin and various concentrations of free HA23 or HA24 peptides. Because of the differences in the direct toxicities of the two peptides, they were tested at different concentrations so that the direct effect of the peptides was comparable. Immunotoxins were used at a suboptimal concentration (0.3 $\mu\text{g}/\text{mL}$). Protein synthesis was assayed as in Figure 2. Results are means and SEM of triplicate values.

Synthesis and Characterization of Immunotoxins Conjugated to HA-Peptides. Immunotoxins were constructed by conjugating antibody 924 with an excess of disulfide-containing linkers (either SPDP, 6.8 Å length, or LC-SPDP, 15.6 Å length). RAC was next coupled to the antibody at an approximate ratio of 1:1. The 924-RAC conjugates were divided into aliquots and then coupled to HA23, HA24, or cysteine. Table 1 summarizes the different constructions that were made, and Figure 4 shows the results of nonreduced gradient SDS-PAGE performed on the immunotoxin preparations. Immunotoxins incorporating peptides had an increased molecular weight compared to those modified with cysteine. Those modified with SPDP incorporate more peptide, consistent with the greater degree of PDP modification obtained with this linker. The presence of approximately equimolar concentrations of antibody and RAC was confirmed by SDS-PAGE under reducing conditions and western blots (data not shown).

Figure 4. PAGE of immunotoxin preparations. Immunotoxins were run on polyacrylamide gradient (5–10%) gels under nonreducing conditions. Gels were stained with Coomassie blue. (Lane 1) T7-RAC; (lane 2) 924-lc-RAC; (lane 3) 924-lc-RAC-HA23; (lane 4) 924-RAC; (lane 5) 924-RAC-HA23; (lane 6) 924-RAC-HA24. Lanes 1 and 2 demonstrate the presence of breakdown products. Lanes 3–6 contain higher order multimers. The band containing monomeric immunotoxin is the most intense band in each lane.

Figure 5. Identification of RAC in immunotoxins by ELISA. Microtiter wells were coated with a peptide representing the V3-loop of HIV gp120. Different immunotoxins over a range of concentrations were incubated in the wells, followed successively by guinea pig anti-ricin antibodies, alkaline phosphatase-conjugated anti-guinea pig Ig, and the addition of a chromogenic substrate. An important negative control is the use of unconjugated mab 924, which demonstrates that there is no cross-reaction between anti-guinea pig Ig and the mouse mab. Results are means of triplicate values.

The ability of immunotoxins to bind antigen was evaluated by ELISA. Using alkaline phosphatase-conjugated anti-mouse Ig, it was demonstrated that immunotoxins and unmodified antibody bound equivalently to antigen (not shown). The presence and amount of RAC in antigen-binding immunotoxins was measured using guinea pig anti-RAC antibody and an alkaline phosphatase-conjugated anti-guinea pig Ig to detect antigen-bound immunotoxin (Figure 5). The results show that all immunotoxin preparations contained equal amounts of RAC. The absence of binding to unconjugated antibody 924 demonstrates that the alkaline phosphatase-conjugated anti-guinea pig Ig did not cross-react with mouse Ig. We have defined the incorporation of peptides into immunotoxins in a similar fashion, using rabbit anti-HA23 antisera. Although this antiserum also reacted with HA24, reactivity was reduced by approximately half as measured by competitive ELISA (not shown). The presence of peptides in the appropriate immunotoxins is clearly shown in Figure 6, with 924-RAC-HA23 incorporating more peptide than 924-lc-RAC-HA23 as expected from the molecular weight of the conjugates (Figure 4).

Figure 6. Identification of HA23 and HA24 in immunotoxins by ELISA. ELISA was performed as in Figure 5 but using rabbit anti-HA23 antiserum and an alkaline phosphatase-conjugated anti-rabbit Ig.

Figure 7. RAC enzymatic activity in immunotoxins. Inhibition of cell-free protein synthesis by immunotoxins was measured using rabbit reticulocyte lysate. The lysate is an assay mixture containing [35 S]Met and was incubated at 37 °C for 120 min with immunotoxins. [35 S]Met incorporated into protein was measured as counts per minute. Data labeled lysate indicates protein synthesis in the absence of any immunotoxin. Results are means and SEM of triplicate values.

To determine whether the incorporation of peptides into immunotoxins hindered the enzymatic function of RAC, we measured the ability of the immunotoxins to inhibit cell-free protein synthesis from a rabbit reticulocyte lysate. Protein synthesis was measured as the incorporation of [35 S]Met. All immunotoxins inhibited cell-free translation to an equivalent degree (Figure 7).

Cytotoxicity of Immunotoxin–Peptide Conjugates. The cytotoxic efficacy of immunotoxin–peptide conjugates was determined by measuring cellular protein synthesis in H9/NL4-3 cells. Conjugation of immunotoxins to HA23 enhanced cell killing 2–4-fold compared to the equivalent cysteine-containing immunotoxin (Figures 8 and 9). This was seen with two completely different immunotoxin preparations, indicating that this is not a fortuitous result from an exceptionally efficient immunotoxin conjugation. Surprisingly, incorporation of the more toxic HA24 peptide resulted in a 10-fold diminution in immunotoxin activity (Figure 9). None of the immunotoxins had any effect on uninfected H9 cells (not shown).

Figure 8. Enhancement of immunotoxin efficacy by incorporation of HA23 peptide. The comparative efficacy of two immunotoxins, differing only in the attachment of HA23 (∇) or cysteine (▼), was tested in H9/NL4-3 cells. Protein synthesis in target cells was measured during a 3-day culture period. Results are means and SEM of triplicate values.

Figure 9. Contrasting effects of HA23 and HA24 on immunotoxin efficacy. Immunotoxins incorporating HA23 (●), HA24 (○), or cysteine (▲) were compared for cytotoxicity on H9/NL4-3 cells. Results are means and SEM of triplicate values.

Because vacuolar acidification is reportedly required for the action of the HA peptides (5), we have tested the effect of bafilomycin A₁, an inhibitor of the vacuolar H⁺ pump, on the immunotoxin-peptide constructs (Figure 10). Bafilomycin A₁ had an enhancing effect on all of the immunotoxins. However, even in the presence of bafilomycin A₁, the cytotoxic activity of 924-RAC-HA23 was greater and 924-RAC-HA24 was diminished in comparison to 924-RAC.

DISCUSSION

Inhibition of lysosomal function can potentiate the cytotoxic effects of immunotoxins because the majority of internalized immunotoxin molecules are degraded,

Figure 10. Effect of bafilomycin A₁ on immunotoxin action. Protein synthesis was assayed in H9/NL4-3 cells exposed to immunotoxin in the presence (□) or absence (■) of 3 nM bafilomycin A₁. Immunotoxins were used at 0.01 μg/mL. Results are means and SEM of triplicate values.

primarily in lysosomes, before they can reach their site of toxic action. In this paper we have explored the use of amphipathic peptides derived from the fusion region of the influenza hemagglutinin to enhance the activity of anti-HIV immunotoxins. Under appropriate conditions, the fusogenic peptides enhanced the activity of anti-HIV immunotoxins to the same degree as other inhibitors of lysosomal function, including monensin, chloroquine, and ammonium chloride (3).

The idea to use fusogenic peptides as enhancers of immunotoxin efficacy is based on the ability of these peptides to disrupt membranes at acidic pH (4, 5). The peptides have a random conformation at neutral pH but assume an amphipathic helix under acidic conditions. It is believed that once the endosome is acidified, the fusogenic peptides self-assemble and form a transmembrane channel, thereby disrupting the vacuolar membrane. This approach has been applied to the functional transfer of nucleic acids into target cells. Increased effects were seen with mixtures and with conjugates of nucleic acids with the fusogenic peptides (4, 5). A similar approach, using a genetic fusion of the N terminus of protein G of the vesicular stomatitis virus to ricin A chain, has demonstrated enhanced immunotoxin efficacy (20).

Peptides HA23 and HA24 were both tested in membrane lysis and gene transfer systems. Each was active in disrupting membranes and in increasing efficiency of gene transfer, with HA24 having greater activity than HA23 (5). Our studies of the toxicity of free peptides (Figure 2) and of the additive effect of peptides mixed with anti-HIV immunotoxins (Figure 3) confirm that HA24 is more toxic than HA23. Paradoxically, when the peptides were conjugated to the immunotoxin, HA23 enhanced cytotoxicity while HA24 markedly diminished the toxic effect of the immunotoxin.

The mechanism whereby the HA24 peptide inhibits, rather than enhances, the action of the immunotoxin conjugate is unclear. It does not prevent antigen binding or hinder the enzymatic activity of RAC. We do not believe that the differences are due to the amount of

peptide incorporated into the immunotoxin for the following reasons: 1. There is not simply a lack of enhancement but rather a marked inhibition of immunotoxin activity, suggesting that HA24 is actively interfering. 2. In preliminary studies (data not shown), immunotoxins conjugated with lower amounts of HA23 showed a lack of enhancement but no inhibition. One possibility to explain the inhibition of immunotoxin action by HA24 is that because it is so active in lysing membranes, the endocytic vacuole is lysed before reduction is complete and free RAC is not fully liberated from the immunotoxin complex.

We have demonstrated that the use of bafilomycin A₁ can markedly enhance the potency of immunotoxins. Bafilomycin A₁ is a specific poison of the vacuolar ATP-dependent proton pump. The most likely mechanism of potentiation of immunotoxin action is by inhibiting lysosomal degradation and allowing more RAC to reach the ribosomes, although other alterations of the intracellular routing of the immunotoxin cannot be ruled out. Bafilomycin A₁ has no effect on the processing or cell-surface display of the HIV envelope (data not shown).

Interestingly, the enhancing effect of HA23 and the inhibitory effect of HA24 were still active in the presence of bafilomycin A₁. This was unexpected because these peptides demonstrate greatest lytic activity under acid conditions. It is possible that the concentration of bafilomycin A₁ used did not fully prevent acidification of vacuoles, although we have also seen effects of these peptides in the presence of the lysosomal alkalinizing agent ammonium chloride (data not shown). Thus, these fusogenic peptides may also function under nonacidic conditions. While the ability of these peptides to lyse biological membranes is greatest at pH ≤ 5, some lytic activity has been reported at pH 7 (5).

The use of immunotoxins has been proposed for the treatment of cancer, autoimmune conditions, transplantation, and infectious diseases. Although significant problems are associated with the clinical use of immunotoxins, these therapies have shown some promise in early clinical trials. Methods that may potentiate the specific cytotoxic action of immunotoxins and not exacerbate the problems may prove useful. In this paper, we have demonstrated two novel approaches: the use of amphipathic peptides, either mixed with or conjugated to the immunotoxin, and bafilomycin A₁. Both most likely function through inhibition of lysosomal degradation of immunotoxins, and an additive effect of the two is seen (Figure 10). Although these effects were demonstrated using anti-HIV immunotoxins on HIV-infected cells, they should be generalizable to other targets of immunotoxin therapy.

Convenient methodology for preparation and conjugation of the protein-cutting iron chelate iron (S)-1-(*p*-bromoacetamidobenzyl)ethylenediaminetetraacetate (Fe-BABE) is given. This formulation of the reagent can be handled in a manner analogous to many other protein-labeling reagents, such as fluorescent probes or cross-linkers. By taking advantage of the recently discovered peptide hydrolysis reaction, the chelate may be tethered to a single site (e.g., a cysteine side chain) and used to map its proximity to individual peptide bonds by automated Edman sequencing of the protein fragments produced. The method is illustrated by conjugation of Fe-BABE to the carboxy terminal domain (amino acid residues 234–329) of the *Escherichia coli* RNA polymerase alpha subunit. The molecular mass of the protein conjugate was confirmed by electrospray ionization mass spectrometry.

Recently, we and others (1–3) have developed reagents based on small metal chelates that cleave polypeptide chains at sites determined by proximity to the chelate, apparently independent of the amino acid residues involved. By taking advantage of the recently discovered peptide hydrolysis reaction, the chelate may be tethered to a single site (e.g., a cysteine side chain) and used to map its proximity to individual peptide bonds (1). This methodology has rapidly developed to the point where it can be applied to complex biological systems such as membrane proteins (4).

Bifunctional chelating agents possess both a strong metal-binding moiety and a group that binds to a biological molecule (5). Since its original synthesis (6), the bifunctional chelating agent BABE¹ has been employed in a variety of ways to couple metal ions to biological molecules, including both radiopharmaceutical synthesis and targeted protein hydrolysis. Modified approaches to this and other related reagents have been developed in other laboratories (7, and references cited therein). Here we describe the preparation of a conve-

nient formulation of the protein cutting reagent Fe-BABE. This avoids the need to add iron after conjugation and can be handled in a manner analogous to many other protein-labeling reagents, such as fluorescent probes or cross-linkers.

To illustrate the conjugation method, the carboxy terminal domain (amino acid residues 234–329) of *Escherichia coli* RNA polymerase alpha subunit (alpha-CTD), which weighs 11 kDa and contains only one cysteine residue, was conjugated with Fe-BABE and the product isolated and characterized.

MATERIALS AND METHODS

One molar BH₃·THF, 10% palladium on carbon, bromoacetic acid, and bromoacetyl bromide were purchased from Aldrich Chemical Co. L-Phenylalanine was obtained from Sigma. The fluorescent dye CPM was purchased from Molecular Probes Inc. All other reagents were obtained from commercial sources and used without further purification. Pure water (18 MΩ cm⁻¹) was used throughout. All labware was either purchased as metal-free or acid-washed (8).

Thin Layer Chromatography. Plastic-backed silica gel TLC plates (Kieselgel 60 F₂₅₄, EM Science, Alltech) were developed in 95% EtOH/6.5 M NH₄OH (4:1 v/v). ⁵⁷Co metal binding assays and thiol plate TLC were performed according to the procedures of Moran *et al.* (9).

High-Performance Liquid Chromatography. HPLC was carried out on a Rainin three-pump HPXL system with titanium piston washing pump heads. UV absorbance was monitored at 254 nm. Analytical reversed-phase HPLC was performed at room temperature with a Dynamax 10 × 250 mm semipreparative C₁₈ column, flow rate 3 mL/min, to monitor the progress of reactions. Preparative reversed-phase HPLC, 12.5 mL/min, using a Dynamax 21.4 × 250 mm C₁₈ column was used for purification. The HPLC gradients used were as follows. (1) Solvent A, 0.1 M ammonium acetate, pH 6.0;

Microbore HPLC. Protein conjugates were prepared for mass spectrometry by passage through a C_8 reversed phase column (Applied Biosystems, Aquapore RP-300, 7 μm , 250 \times 1.0 mm) at 80 $\mu\text{L}/\text{min}$ at room temperature on an Applied Biosystems Model 172 system. UV absorbance was monitored at 214 nm. Protein solvent A, H_2O + 0.06% CF_3COOH ; solvent B, CH_3CN + 0.06% CF_3COOH : 5–35% B, 0–60 min; 35% B, 60–660 min; 35–75% B, 660–700 min; 75–100% B, 700–710 min; 100% B, 710–720 min; 100–50% B, 720–721 min; 50% B, 721–731 min; 50–5% B, 731–733 min; 5% B, 733–748 min. Fe-BABE microbore analysis was performed with UV absorbance set to 260 nm. The Fe-BABE solvent gradient used was as follows. Solvent A, 0.1 M Et_3NH^+ acetate, pH 6.5, 5% CH_3CN ; solvent B, 0.1 M Et_3NH^+ acetate, pH 6.5, 75% CH_3CN : 0–80% B, 0–60 min; 80–100% B, 60–65 min.

NMR Spectroscopy. ^1H NMR spectra were obtained at 300 MHz on a GE QE-300 spectrometer. Chemical shifts are reported relative to HDO (4.80 ppm).

Mass Spectrometry. FAB mass spectra of small molecules were obtained on a ZAB-HS-2F mass spectrometer. Mass spectra of the protein and its conjugate were obtained using a Quattro-BQ mass spectrometer (VG Biotech, Altrincham, U.K.). Samples were introduced by loop injection at a flow rate of 3 $\mu\text{L}/\text{min}$, and positive ion electrospray mass spectra were obtained using a capillary voltage of 3.5 kV, a counter electrode voltage of 500 V, and a cone voltage of 50 V. The mass spectrometer was scanned over the range of m/z 200–2000 at a rate of 20 s/scan, and the spectra were summed. Calibration of the mass scale was performed using horse heart myoglobin as calibration standard. Molecular weights of peptides were determined by mathematical transformation of the electrospray spectra to a true mass scale spectrum using the maximum entropy transformation algorithm MaxEnt.

(S)-1-(p-Bromoacetamidobenzyl)ethylenediaminetetraacetic Acid (7). As described in the Supporting Information, L-phenylalanine was converted into p-aminobenzyl-EDTA (6) according to the procedure shown in Scheme 1. The pH of 16 mL of a 37.5 mM

aqueous solution of **6** (0.60 mmol) was adjusted to 7–8 (according to pH strips) using DIEA. This solution was added dropwise to a stirring solution of 300 μ L of bromoacetyl bromide in 16 mL of CHCl_3 . The aqueous phase was adjusted to pH 7.0 with 100 mL additions of DIEA and stirred vigorously. After 5 min of stirring, a small aliquot was analyzed on HPLC to check for completion by the disappearance of the starting material peak (retention time 4.5 min) and the appearance of the product peak (retention time 10 min). The layers were separated, and the aqueous phase was extracted with CHCl_3 . The pH of the aqueous phase was adjusted to 7–8 with DIEA and extracted again with CHCl_3 . The pH of the aqueous phase was adjusted to 2 with 3 M HCl and extracted five times with equal volumes of Et_2O . The pH was readjusted to 2 with 3 M HCl and the aqueous phase extracted five times with Et_2O . This was continued until the pH remained constant. Residual ether was removed from the aqueous solution under house vacuum. The pH of the solution was adjusted to 5 with DIEA, and the solution was divided into aliquots, frozen in $\text{N}_2(\text{l})$, and stored at -70°C . The concentration of the solution was determined by cobalt metal binding assay: purified yield, 0.43 mmol (72%); microbore HPLC (using the Fe-BABE gradient above), product peak, 10 min; FAB-MS, m/z 516, 518 ($\text{M} - \text{H}^-$); high-resolution MS, m/z 516.0628 measured, m/z 516.0618 calculated for $\text{C}_{19}\text{H}_{23}\text{O}_9\text{N}_3^{79}\text{Br}$.

Fe(III) [(S)-1-(p-Bromoacetamidobenzyl)ethylene-diaminetetraacetic acid] (8**)**. In a 5 mL pear-shaped flask, 1 mL of 20.6 mM BABE (**7**) was combined with 1 mL of DMSO. To remove the water, the volume of the solution was reduced to 0.7 mL via gentle evaporation at room temperature. Occasionally, a fine white precipitate of NaCl forms in the orange solution. The salt is removed by passing the solution through a 0.2 mm nylon syringe filter (Rainin). The chelator concentration (28.6 mM) was determined by ^{57}Co metal binding assay, and the alkylating capacity (86%) was determined by a thiol TLC assay (*9*). Then 286 μ L of 50 mM $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ in DMSO was added to 500 μ L of BABE in DMSO. After vortex mixing, 20 μ L of DIEA (0.114 mmol) was added, and the yellow solution was mixed and allowed to stand at room temperature for 1 h. To measure the degree of saturation of the chelate with iron, a ^{57}Co competition experiment was performed by mixing the Fe(III)–BABE complex (**8**) with a 2-fold excess of ^{57}Co (*9*). Result: 97% saturation. The Fe(III)–BABE was divided into aliquots, frozen in liquid nitrogen, and stored at -70°C : yield, 0.012 mmol (83%); reversed-phase microbore HPLC (using Fe-BABE gradient above) product peak, 15 min.

Conjugation of **8 to Cys-269 in the C-Terminal Domain of *E. coli* RNA Polymerase α Subunit.** Alpha-CTD (*10*) in a TGE-50 mM NaCl buffer (10 mM Tris-HCl, pH 7.6, 5% glycerol, 0.1 mM EDTA, 50 mM NaCl) was exchanged into a conjugation buffer (10 mM MOPS, pH 8, 0.1 mM EDTA, 50 mM NaCl) by dialysis at 4°C . The 20 μ M protein was incubated with 400 μ M Fe-BABE at 37°C for 1 h. The reaction was quenched by the addition of an equal volume of 1 M Tris-HCl, pH 8, and dialyzed against a TGE-50 mM NaCl buffer at 4°C . The protein was purified by microbore HPLC as described above, completely dried under reduced pressure, and redissolved in water/acetonitrile (1:1) for mass spectrometry.

Assay of Free Sulfhydryl Groups. The concentration of free cysteine side chains was determined with the fluorescent reagent CPM on both unconjugated and conjugated proteins. The method of Parvari *et al.* (*11*) was slightly modified as follows: β -Mercaptoethanol standard solutions were prepared in MOPS buffer (10

mM MOPS, pH 7.9, 120 mM NaCl, 10 mM MgCl_2 , and 1.0 mM EDTA) at concentrations of 30, 20, 10, 5, 3, 1, 0.3, and 0.1 μ M. The protein sample in a TGE-50 mM NaCl buffer was exchanged into MOPS buffer by dialysis at 4°C , and the protein concentration was determined by micro-Bradford assay. A 15 μ L aliquot of 0.4 mM CPM in DMF was added to 15 μ L of each standard and each protein sample. After 1 h of incubation at room temperature, 3 mL of 1% Triton X-100 was added to each reaction. The intensity of fluorescence emission was measured on 2.9 mL samples, using a Perkin-Elmer LS 50B luminescence spectrometer. The excitation wavelength was 390 nm, and the emission wavelength was 473 nm.

RESULTS AND DISCUSSION

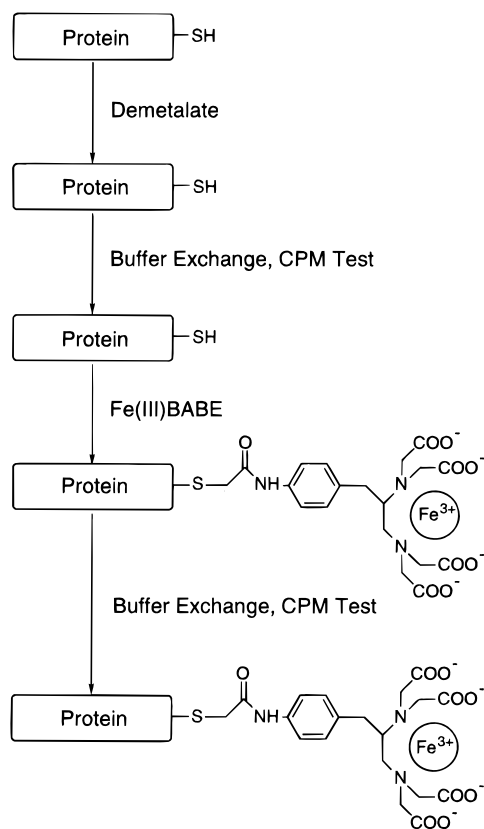

There are a number of different approaches to the use of metal complexes to map proteins. A recent example uses untethered chelates to map the overall surface and depends on changes in cutting sites to reveal binding interactions (*12, 13*). Another approach, employing a tethered reagent such as Fe-BABE, is similar in design to a cross-linking experiment (*3, 4*). Here it is essential that protein cutting is only due to the tethered reagent and not to unchelated metal coordinated directly to sites on the protein. In view of the results in ref *13*, we chose to prepare the iron chelate before conjugation to the protein, to avoid artifactual cutting by unchelated iron.

As reported by Moran *et al.* (*9*), the bromoacetylation reaction is quantitative as observed by HPLC. However, the reduced yield is due to sample loss during the necessarily extensive extraction workup of the product. The transfer of **7** into DMSO allows the reaction with ferric chloride to form **8** under mild nonhydrolyzing conditions. Furthermore, the difficulties associated with aqueous complexation of Fe(III), i.e. low pH, are avoided.

The preloaded bifunctional chelate (**8**) is used as a macromolecule modification reagent requiring only a single reaction to derivatize the target with Fe-EDTA. The general protocol for the derivatization is illustrated in Scheme 2. As shown, unless the macromolecule is stored in an EDTA buffer, the procedure begins by first demetalating the protein by incubation in a 0.1 M phosphate, pH 7.0, 20 mM EDTA buffer. Following the demetalation, the macromolecule is buffer exchanged (via size exclusion spin columns or dialysis) into a conjugation buffer composed of either 10–50 mM HEPES or MOPS, pH 8.0, and 0.1 mM EDTA. The presence of ≥ 0.1 mM EDTA is necessary to scavenge any unbound metal. Also, the conjugation buffer may contain simple salts (i.e. NaCl, KCl, MgCl_2 , NaOAc, etc.) and glycerol for macromolecular stability. The buffer must not contain free thiols.

Just prior to reaction, a sample of the macromolecule with the free cysteine is tested with CPM to quantify and confirm that it is available for conjugation. The amount of Fe-BABE added should be in 2–20-fold excess relative to the free thiol present. Since the reagent is in DMSO, to prevent possible denaturation the volume of chelate added should not exceed 5%. After the addition of Fe-BABE, the pH should be kept to $\text{pH } 8 \pm 0.5$ (adjust if necessary with DIEA). The conjugation reaction is performed at room temperature or 37°C for 0.5–1 h. The reaction is stopped by quenching with 1 M Tris buffer, pH 8, and/or buffer exchanging the macromolecule.

To demonstrate the conjugation procedure alpha-CTD was conjugated with Fe-BABE and analyzed by HPLC and mass spectrometry. The transformed ESI mass spectrum of unconjugated alpha-CTD shows only one

Scheme 2. Fe-BABE Conjugation to a Cysteine Side Chain

peak at mass 11 077, as expected for α residues 234–329 (Figure 1a). The mass spectrum of the Fe-BABE conjugated protein shows two peaks (Figure 1b); a peak at mass 11 076 for alpha-CTD and a peak at mass 11 566 corresponding to the conjugate of alpha-CTD with Fe-BABE (ΔMW 490, the mass of the iron chelate moiety). The conjugation yield determined by the CPM test was 40%, in good agreement with the yield determined from mass spectral peak ratios. Since mass spectrometry shows the fraction of protein conjugated and the species added, and the CPM test shows the loss of sulfhydryl groups, the combined results demonstrate that the Fe-BABE conjugation occurred at the cysteine side chain and not at other nucleophilic sites, such as histidine or lysine side chains.

As found by Ghaim *et al.* (4), cysteine residues on proteins fall into three categories. Some cysteines are unreactive toward alkylating reagents such as BABE or Fe-BABE (e.g., position 157 on subunit I of *E. coli* cytochrome *bd*); some are alkylated but produce no cleavage products upon treatment with ascorbate and peroxide (e.g., position 509 on subunit I of *E. coli* cytochrome *bd*); and some produce cleavage products (e.g., position 276 on subunit I of *E. coli* cytochrome *bd*). Cys-269 in the C-terminal domain of the *E. coli* RNA polymerase α subunit belongs to the second category; treatment with ascorbate and peroxide led to very little cleavage of the polypeptide backbone.

ACKNOWLEDGMENT

We thank Dr. Karin Hughes and Jeffrey Owens for helpful discussions and assistance with the CPM test. This work was supported by Research Grants GM25909 and CA16861 to C.F.M. from the National Institutes of Health and Grants NIEHS ES-04699 and ES-05707 for the purchase of the Quattro-BQ mass spectrometer.

Figure 1. (a) Transformed ESI mass spectrum of the alpha-CTD subunit (11077 Da) before Fe-BABE conjugation. (b) Transformed ESI mass spectrum of the alpha-CTD subunit after the conjugation reaction, showing two peaks corresponding to unconjugated alpha-CTD subunit and Fe-BABE-conjugated alpha-CTD subunit.

Site-Specific Photomodification of DNA by Porphyrin–Oligonucleotide Conjugates Synthesized via a Solid Phase H-Phosphonate Approach

Handong Li,[†] Olga S. Fedorova,^{†,‡} William R. Trumble,[§] T. Rick Fletcher,[†] and Leszek Czuchajowski*,[†]

Department of Chemistry and Department of Microbiology, Molecular Biology, and Biochemistry, University of Idaho, Moscow, Idaho 83844. Received July 31, 1996[®]

meso-Tris(4-pyridyl)[(ω-hydroxyhexamethylene)carbamoyl]phenyl]porphyrin was converted to its H-phosphonate derivative and conjugated using solid phase synthesis with the 5'-hydroxyl group of deoxyribonucleotides d(TCTTCCCA) and d(T)₁₂. These conjugates were transformed into their (*N*-methylpyridiniumyl)porphyrin analogs in the reaction with methyl iodide. A 532 nm laser beam was utilized to photoactivate both types of the conjugates in the presence of the target 22-mer and 16-mer oligonucleotides. Photoactivation of porphyrin–oligonucleotide conjugates resulted in site-specific DNA modification characterized by a main reaction site size of ~5 bases.

INTRODUCTION

Antisense oligonucleotides recognize a selected sequence on the target nucleic acid and can inhibit gene expression (1–3). Introduction of DNA-cleaving functional groups into an antisense oligonucleotide has been shown to generate site-directed damage on the target nucleic acids through chemical or photochemical reactions (4–6). A variety of chemical molecules have been covalently linked to oligonucleotides which were hybridized to cellular DNA to affect processes such as cellular uptake (2), nuclease resistance (3), and binding affinity (6).

Examples of those reactive molecules are alkylating agents such as aromatic (2-chloroethyl)amino derivatives (4–6), intercalating agents such as acridinium (3), ethidium, and phenazinium (6) derivatives, photoactivable cross-linkers such as psoralens (7–10), azides (11–13), or porphyrins (14–16), and artificial endonucleases such as EDTA–Fe(II) (17–19), Cu(I)–1,10-phenanthroline (20–21), bleomycin (22–23) or metalloporphyrins (24–32). The porphyrin–oligonucleotide conjugates and porphyrinyl–nucleoside derivatives (33–36) are of special interest to us due to their potential ability to modify nucleic acids either under dark conditions or under irradiation (37–39).

Sequence-specific modification of nucleic acids by porphyrin–oligonucleotide derivatives was reported using an excitation light wavelength around the porphyrin's Soret band (400–430 nm) (14–15) or in the case of porphyrin with an expanded structure such as lutetium(III) texatexaphyrin at an excitation wavelength of 732 nm (16). Porphyrins are used as anticancer agents in photodynamic therapy (PDT) (40). Their application as reactive groups of oligonucleotide derivatives in an antisense approach can result in selective inhibition of both oncogenes and proliferation of tumor cells (6).

Hitherto, only a few solution phase synthetic ap-

proaches have been reported for the preparation of the porphyrin–oligonucleotide conjugates. Amino derivatives of oligonucleotides were first made and then coupled with activated esters (15, 24–27, 29, 31, 32) or bromoalkyl derivatives (28) of porphyrin. Another method was based on the reaction between the activated 5'-phosphate group on an oligonucleotide and the amino group on a porphyrin (14, 28). Porphyrin with a hydroxyl group was also used as a monomer in triester solution phase synthesis of oligonucleotide derivatives (27).

Since porphyrin derivatives of oligonucleotides activated by light or active in dark conditions can be used as the selective anticancer drugs, simple and efficient synthetic methods for porphyrin–oligonucleotide conjugates are required to increase the availability. It appears that only the use of the porphyrin residue as the monomer in the synthesis of oligonucleotides leads to a high yield of conjugated product (27). Therefore, we developed a simple approach for producing porphyrin–oligonucleotide conjugates, based on the commercially available, fully protected resin-bound deoxyribooligonucleotides, synthesized by the phosphoramidite method. The porphyrin monomer was used in the form of the H-phosphonate derivative. The methodology of H-phosphonate coupling (41, 42) was modified to accomplish the porphyrin–oligonucleotide conjugation.

We chose two antisense oligonucleotides for application of this solid phase conjugation approach: a 12-mer of deoxyribothymidylate [d(T)₁₂], the complementary sequence to a riboadenylate track of single-stranded (+)-RNA in a wide variety of viruses such as potato virus Y and swine vesicular exanthema, and an 8-mer d(TCTTCCCA), the complementary fragment to the selected sequence of RNA of tick born encephalitis virus.

A green laser beam at 532 nm was applied to study the photoactivated modification of target nucleic acids in the presence of porphyrin–oligonucleotide conjugates. We found that photoactivation at porphyrin's Q band region (500–650 nm) was highly effective for modification of DNA. It is possible to suggest that porphyrin–oligonucleotide derivatives can be used as specific drugs in photodynamic therapy because the light source with this longer wavelength is more penetrating through tissue.

EXPERIMENTAL PROCEDURES

Materials. Fully protected resin-bound oligonucleotides synthesized by the phosphoramidite method were purchased from Bio-synthesis (Lewisville, TX). The target DNA sequences of d[(A₁₂)GTGT] (16-mer) and d(TGAATGGGAAGAGGGTCAGGT) (22-mer) were obtained from GIBCO BRL (Grand Island, NY). Oxidizers (I₂/pyridine/H₂O and H₂O/THF/Et₃N), adamantanecarbonyl chloride, pyridine, and acetonitrile were obtained from Glen Research Co. (Sterling, VA). All other chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI). ³²P labeling of the 16-mer and the 22-mer at their 5'-ends was accomplished using T4-polynucleotide kinase obtained from United States Biochemical (Cleveland, OH) and [γ -³²P]ATP purchased from New England Nuclear/Dupont (Boston, MA). Labeled oligomers were separated from the nonlabeled oligomers by electrophoresis in denaturing 20% polyacrylamide gels containing 7 M urea and subsequently electroeluted from the gel.

Synthesis of *meso*-Tris(4-*N*-pyridyl)[(methylcarboxy)phenyl]porphyrin 1. 4-Pyridaldehyde (16.1 g, 0.15 mol) and methyl 4-formylbenzoate (7.4 g, 0.05 mol) were dissolved in 600 mL of propionic acid and 10 mL of acetic anhydride in a 2000 mL flask. The solution was heated to 100 °C. Pyrrole (13.4 g, 0.2 mol) in 50 mL of propionic acid was added dropwise to the hot solution over 0.5 h. The solution became darker and was stirred and refluxed for an additional 1 h. At this point, about 600 mL of propionic acid was removed under vacuum. The residue was poured slowly into ice-cold 5% aqueous sodium bicarbonate with stirring. The black precipitate was washed with 5% aqueous sodium bicarbonate and then water until neutral and air-dried. The black solid was dissolved in chloroform, applied to a silica gel column, and eluted with chloroform and chloroform/methanol (50:1). The fifth fraction was collected and identified as compound **1**. The yield was 8%.

¹H NMR (CDCl₃, ppm): 9.03 (d, 6H, Py), 8.84 (m, 8H, β -pyrrole), 8.44 (d, 2H, phenyl), 8.27 (d, 2H, phenyl), 8.14 (d, 6H, Py), 4.10 (s, 3H, OCH₃), -2.93 (s, 2H, NH). MS (FAB): *m/z* 678 (M + 2). UV (CHCl₃, nm): 418 (Soret), 514, 548, 588, 644. MS (FAB): *m/z* 678 (M + 2), 647 (M + 2 - OCH₃).

Synthesis of *meso*-Tris(4-pyridyl)[[(ω -hydroxyhexamethylene)carbamoyl]phenyl]porphyrin 2. **1** (67.6 mg, 100 μ mol) and 6-aminoheptanol (2.0 g, excess) were introduced into a flask. The mixture was stirred at 65–70 °C under nitrogen for 48 h. The sublimated 6-aminoheptanol was melted down to the flask with a heating gun during the reaction. Aminoheptanol (1.5 g) was recovered by sublimation of the reaction mixture. The residue was introduced into ice/water and stirred for 10 min. The precipitate was collected and washed with ice/water until neutral and then air-dried. The dried purple solid was chromatographed on a silica gel (60–230 mesh) using 100:1 and 10:1 chloroform/methanol as eluent. Fraction 1 contained the starting material. Fraction 2 was identified as **2** with a yield of 80%.

¹H NMR (CDCl₃, ppm): 9.03 (d, 6H, Py), 8.82 (m, 8H, β -pyrrole), 8.30 (d, 2H, phenyl), 8.22 (d, 2H, phenyl), 8.15 (d, 6H, Py), 6.60 (t, 1H, NHCO), 3.76 (t, 2H, CH₂O), 3.68 (t, 2H, NCH₂), 1.81 (quint, 4H, CH₂CH₂), 1.74 (quint, 4H, CH₂CH₂), -2.91 (s, 2H, NH). MS (FAB): *m/z* 763 (M + 2), 663 [M + 3 - (CH₂)₆OH], 617 [M - CONH(CH₂)₆OH]. UV (CHCl₃, nm): 414 (Soret), 514, 548, 588, 644.

Synthesis of the H-Phosphonate Derivative of *meso*-Tris(4-pyridyl)[[(ω -hydroxyhexamethylene)carbamoyl]phenyl]porphyrin 3. **2** (15 mg, 20 μ mol) was dried under vacuum and dissolved in 10 mL of CH₂-

Cl₂. A catalytic amount of triethylamine and 12 mg (21 μ mol) of tris(1,1,1,3,3,3-hexafluoro-2-propyl) phosphite were added. The reaction was completed in 10 min. A mixture of 1 M triethylamine bicarbonate (TEAB) and triethylamine (50:1 v:v) was added to the reaction mixture. After 30 min, the product was extracted with chloroform, washed with 1 M TEAB, and dried over anhydrous sodium sulfate. The chloroform layer was evaporated, and the residue was chromatographed on silica gel using chloroform/methanol/triethylamine (from 100:2:0 to 100:10:2). The second fraction was collected and washed with 1 M TEAB and dried with sodium sulfate. The porphyrin H-phosphonate **3** was obtained after evaporation of the chloroform with a 82% yield.

MS (negative FAB): *m/z* 824 (M⁻). UV (CHCl₃/CH₃OH, 1:1, nm): 418 (Soret), 512, 548, 592, 638.

Synthesis of Conjugates of *meso*-Tris(4-pyridyl)-[(ω -hydroxyhexamethylene)carbamoyl]phenyl]porphyrin with Oligonucleotides d(TCTTCCCA) and d(T)₁₂ (6** and **7**, Respectively).** Fully protected resin-bound oligonucleotide (1 mmol) was packaged in a 1 mL syringe column which was connected to a vacuum line by a switch valve. All reaction agents and vessels were in a dry nitrogen glovebox. A procedure, closely approximating the reactions for automated DNA synthesis, was utilized as follows: (1) Detritylation was done with 2% Cl₂CHCOOH for 2 min. (2) Washing was done with CH₃CN and CH₃CN/pyridine for 2 min. (3) **3** (38 mg, 40 μ mol) dissolved in 1 mL of CH₃CN/pyridine and 20 mg (100 μ mol) of adamantanecarbonyl chloride was added immediately and applied to the column for 4 min. (4) Washing was done with CH₃CN/pyridine and CH₃CN for 2 min. (5) Oxidation was done with I₂/pyridine/H₂O and Et₃N/THF/H₂O for 5 min. (6) Washing was done with CH₃CN/pyridine and CH₃CN for 2 min. (7) Deprotection was done with concentrated NH₃·H₂O at room temperature for 12 h. The product was then lyophilized and redissolved in Tris-acetate/EDTA (TAE) buffer (pH 7.5) and purified on a Hewlett-Packard series 1050 HPLC apparatus with a variable wavelength UV detector set at 260 nm, using a Lichrospher 100 reverse phase C18 column (5 μ m). The solvent ramp followed a linear gradient from 9% CH₃CN and 91% 0.05 M TEAc (pH 7.5) at the beginning of each run to 81% CH₃CN and 19% 0.05 M TEAc (pH 7.5) at the end, 25 min later. The flow rate was 1.0 mL/min. HPLC profiles (shown in Figure 1) were recorded on a Hewlett-Packard 3396A integrator. The yields of **6** or **7** were about 60–70%. UV data are shown in Table 1.

Conjugates **6** and **7** were also analyzed by dynamic sieving capillary electrophoresis on a Biofocus 3000

Capillary Electrophoresis System (BioRad) using a coated column (length of 24 cm, diameter of 75 μm) in a buffer of 25 mM Tris-borate and 2 mM EDTA at pH 8.3. The absorption profiles (shown in Figure 2) were monitored at 260 nm for oligonucleotide moieties and at 416 nm for porphyrin units of the conjugates.

Concentrations of conjugates were estimated using absorption at 260 nm. The molar absorption coefficient at 260 nm was calculated as the sum of absorption for oligonucleotide and porphyrin moieties. The molar absorption coefficients of oligonucleotides at 260 nm were found using a procedure described in ref 43 to be $6.78 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ for d(TCTTCCCA) and $6.36 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ for d(T)₁₂. The molar absorption coefficient of porphyrin **2** was measured and is shown in Table 1.

Synthesis of *meso*-Tris(4-*N*-methylpyridiniumyl)-[(ω -hydroxyhexamethylene)carbamoyl]phenyl-porphyrin (2-Me**) and Its Conjugates with Oligonucleotides d(TCTTCCCA) and d(T)₁₂ (**8** and **9**, Respectively).** Compound **6**, **7**, or **2** was dissolved in DMF. Excess CH₃I was added, and the mixture was kept at room temperature for 3 h. *N*-Methylation of **2** was chosen as a model reaction for which completeness was monitored by TLC. The product **2-Me** was obtained by removing the excess CH₃I and DMF under vacuum with no need of further purification. The yield was 100%.

¹H NMR of **2-Me** (DMSO-*d*₆, ppm): 9.62 (d, 6H, 3, 5-Py), 9.18 (d, 6H, 2, 6-Py), 8.98 (m, 8H, β -pyrrole), 8.32 (m, 4H, phenyl), 4.72 (s, 9H, NCH₃), 3.48 (m, 4H, CH₂-CO and CH₂O), 1.67 (m, 4H, CH₂CH₂), 1.44 (m, 4H, CH₂-CH₂), -3.02 (s, 2H, porphyrin-NH).

UV [H₂O, λ_{max} (nm)]: 422, 520, 560, 592, 652. The molar absorption coefficient of porphyrin **2-Me** is presented in Table 1.

Compounds **8** and **9** were made in the same way as **2-Me**. Their UV-vis data are shown in Table 1. The red shifts of porphyrin Soret bands after conjugation with oligonucleotides are characteristic and consistent with our previous data (33).

Photomodification of Target DNA. Photomodification reactions were carried out in a 20 μL buffer solution containing 10 nM [³²P]16-mer (or 22-mer), 0.2 M NaCl, 10 mM Tris-HCl, 1 mM EDTA (pH 7.5), and porphyrinyl derivatives of the 12-mer (or 8-mer) at 25 °C in a polypropylene Eppendorff tube. Tubes were placed in a horizontal position with caps opened in the path of a laser beam and irradiated for 10 min. The laser was a Nd:YAG laser at 532 nm with 25 mJ/pulse and 10 pulses/s.

After irradiation, the oligomers were precipitated by the addition of 100 μL of 2% LiClO₄/acetone solution. The precipitate was washed three times with 100 μL of acetone and dried under vacuum. If required, the oligomer pellets were suspended in 10 μL of 10% piperidine at 95 °C for 30 min. The solutions were cooled and subjected to a second LiClO₄/acetone precipitation. The precipitates were dissolved in 4 μL of water and 3 μL of 95% formamide containing 0.025% bromophenol blue and 0.025% xylene cyanol and loaded onto a 20% denaturing polyacrylamide sequencing gel (19:1 cross-linked, 20 cm \times 20 cm \times 0.4 mm). The gels were run at 50 W/cm and exposed on Kodak X-ray film. The autoradiograms of the gels were quantitized using an UltrosanXL densitometer (LKB, Sweden). The autoradiograms are shown in Figures 3 and 4. The densitometry data were plotted as shown in Figures 5–7.

RESULTS AND DISCUSSION

Synthesis of Porphyrin–Oligonucleotide Conjugates. Porphyrin–oligonucleotide conjugates were syn-

Scheme 1. Synthesis of the Porphyrin H-Phosphonates

thesized by coupling of the H-phosphonate derivative of oligonucleotide with fully protected oligonucleotides. For this purpose, a porphyrin ester **1** was synthesized by the Rothmund–Longo method (44). An ω -hydroxyhexamethylene group was introduced through an ester–amide exchange reaction which gave a new porphyrin **2** with a hydroxyl group in a high yield (Scheme 1). A small amount of acetic anhydride was added to the solvent of propionic acid to prevent the hydrolysis of the ester group. An ester–amide exchange reaction was found to be very efficient for derivatizing the porphyrin ester into new porphyrins with different functional groups, such as hydroxyl and amine. This is an easy way to make pure porphyrin derivatives compared with reactions previously reported in the literature that employed activation of porphyrin carboxylic acid in DMSO or DMF and produced a low yield (28). The *meso*-trispyridylporphyrin H-phosphonate **3**, as the coupling active compound, was synthesized using an efficient fluorinated agent (45). Compound **3** has good solubility in pyridine/acetonitrile solution, which is necessary for the coupling reaction. The H-phosphonate derivative was activated by adamantane-carbonyl chloride and coupled with the 5'-hydroxyl group of deoxyribonucleotides d(TCTTCCCA) **4** or d(T)₁₂ **5** bound on the resin (Scheme 2). The H-phosphonate group was oxidized by I₂ to phosphate. Hydrolysis, removing the conjugates from the resin, and deprotection were carried out in one step at room temperature. Conjugates **6** and **7** were purified by HPLC and converted to cationic porphyrin–oligonucleotides **8** and **9** by methyl iodide.

The coupling was allowed to proceed for less than 3 min to avoid the hydrolysis of the previously formed

Scheme 2. Solid Phase H-Phosphonate Approach to the Synthesis of Porphyrinyl Oligonucleotides^a

^a CPG = controlled pore glass. Bp = (phenylacetyl)deoxyadenosine, deoxythymidine, and (phenoxyacetyl)deoxycytosine. B = T, A, or C. **6** and **8** have an oligonucleotide sequence of TCTCCCA. **7** and **9** have an oligonucleotide sequence of (T)₁₂.

Figure 1. HPLC profile of coupling reaction products from porphyrin **3** and 8-mer **4**.

H-phosphonate diester. Adamantanecarbonyl chloride was chosen instead of pivaloyl chloride to minimize the capping of the oligonucleotide. The aliphatic amide bond on the porphyrin is stable under both room-temperature hydrolysis conditions and deprotection conditions in concentrated ammonium hydroxide.

HPLC and Capillary Electrophoresis. As may be seen in the HPLC elution profiles of conjugates (Figure 1), the free oligonucleotide was eluted first, the conjugate second, and the free porphyrin last. The free porphyrin is neutral and least polar, compared to the free anionic oligonucleotide or the conjugate. The retention time and the polarity are very well correlated on the reverse phase column. Each fraction was confirmed by the UV-vis spectrum.

As compared with acrylamide gel electrophoresis, capillary electrophoresis should provide more precise information. It is very easy to identify the porphyrin-oligonucleotide conjugate by applying two different detector wavelengths: 260 nm for oligonucleotides and 416 nm for porphyrin units. Only free oligonucleotides and porphyrin-oligonucleotide can be detected at 260 nm, while only free porphyrin and porphyrin-oligonucleotide can be detected at 416 nm. The capillary electrophoresis profiles are shown in Figure 2.

UV-Vis Spectra. Soret bands of pyridylporphyrin-oligonucleotide and of pyridiniumylporphyrin-oligonucleotide exhibited a red shift up to 10 nm compared to the free pyridylporphyrin and N-methylated pyridiniumylporphyrin.

Selective Photomodification of Target DNA. Synthesized porphyrin-oligonucleotide conjugates were tested for their abilities to modify the complementary nucleic acid strands under irradiation by visible light in the spectral region of the porphyrin Q-bands at 532 nm. Photomodification reactions were carried out with 5'-³²P-labeled targets, d(TGAATGGGAAGAGGGTCAGGTT) (22-

mer) and d[(A)₁₂(GT)₂] (16-mer), at a concentration of $\sim 10^{-8}$ M. Concentrations of the porphyrin-oligonucleotide conjugates were equal to 4 μ M. In these equilibrium conditions, all targets must be in the form of a complex with the conjugate. The complementary complexes have the following structures:

where

Figure 4. Autoradiogram of a 20% denaturing polyacrylamide gel showing photomodification products produced by irradiation of the 16-mer for 10 min: controls without porphyrinyl conjugates (lanes 1 and 8), in the presence of 4×10^{-6} M conjugates **6** (lanes 4 and 11), **7** (lanes 2 and 9), **8** (lanes 5 and 12), **9** (lanes 3 and 10), A + G (lane 6), and G (lane 7). Samples in lanes 9–12 were treated with piperidine.

The products were separated by 20% polyacrylamide gel electrophoresis under denaturing conditions, in the presence of 7 M urea. Results of control experiments and sequence-specific photomodification of the 22-mer and 16-mer are shown in Figures 3 and 4, respectively. The

modification sites were identified after piperidine cleavage from comigrating Maxam–Gilbert sequencing ladders (46), namely A + G and G. No photomodification of the targets was seen in the absence of the porphyrin conjugates (lanes 1 and 8). Slow-migrating bands (corresponding to cross-linked products) appeared above the bands corresponding to the starting materials when the 22-mer was irradiated in the presence of **6** and **8** (Figure 3, lanes 2 and 3, respectively). When these targets were irradiated in the presence of conjugates **7** and **9** which are not complementary to the targets, the cross-linked products were absent (see Figure 3, lanes 4 and 5). In the case where the 16-mer was irradiated in the presence of **7** and **9**, the bands of cross-linked products were absent (Figure 4, lanes 2 and 3, respectively). The photomodification sites were assigned after piperidine treatment of the reaction mixture and were observed primarily at G11, G13, G14, and G15 for the 22-mer (Figure 3, lanes 9 and 10). For the case of the 16-mer, specific modification products were observed only after the treatment by piperidine at G13 and G15 (Figure 4, lanes 9 and 10). This suggests that alkaline-labile photomodification occurred.

Densitograms are presented in Figures 5 and 6 for the photomodification of the 22-mer by reagents **6** and **8**, respectively, and in Figure 7 for the modification of the 16-mer by **7** and **9**. Figures 5–7 also show the absolute cleavage yields for each site after piperidine treatment and illustrate the data for both complementary and noncomplementary oligonucleotide conjugates. No specific photomodifications of the target 22-mer and 16-mer were observed in the presence of conjugates which could not hybridize with the target DNA. Modification by conjugates containing an uncharged porphyrinyl group **6** and **7** or a positively charged porphyrinyl group **8** and **9** showed slightly different efficiency and site selectivity (Figures 5–7).

For the 22-mer, the total yield, of cleavage ($\sim 77\%$ for

Figure 5. Densitograms of the gel electrophoretic separation of the reaction mixture, containing 22-mer target modified by conjugate **6**; the data for noncomplementary conjugate **7** are presented as the control (line 1, without conjugates; lines 2 and 3, $4 \mu\text{M}$ **7**, with **6** absent; and lines 4 and 5, $4 \mu\text{M}$ **6** with **7** absent). Samples for lines 1, 3, and 5 were treated with piperidine.

Figure 6. Densitograms of the gel electrophoretic separation of the reaction mixture, containing 22-mer target modified by conjugate **8**; the data for noncomplementary conjugate **9** are presented as the control (line 1, without conjugates; lines 2 and 3, 4 μ M **9** and with **8** absent; and lines 4 and 5, 4 μ M **8** with **9** absent). Samples for lines 1, 3, and 5 were treated with piperidine.

Figure 7. Densitograms of the gel electrophoretic separation of the reaction mixture, containing 16-mer target modified by conjugate **7** or **9**; the data for noncomplementary conjugates **6** and **8** are presented as the control (line 1, without conjugates; line 2, 4 μ M **6**; line 3, 4 μ M **7**; line 4, 4 μ M **8**; and line 5, 4 μ M **9**). Samples for lines 1–5 were treated with piperidine.

6 and ~84% for **8**) are higher than the yields of cross-linked products (~20%). Therefore, the alkaline-labile

modification of the 22-mer occurred also as in the case of the 16-mer.

The most intensively utilized modification site consisted of about five nucleotides. Two factors may account for this result. First, the dimension of the photoactive center porphyrin molecule is 18 Å (47), equivalent to one-half of a DNA helix turn. Second, a singlet molecular oxygen (1O_2)-modifying agent is presumed to form after sensitization by the porphyrin. The lifetime of this species is equal to 1–20 μ s in solution (48). Therefore, this molecule can migrate a large distance along the polynucleotide chain.

The results of this study demonstrate that the porphyrinyl groups of oligonucleotide conjugates can be activated by a green laser beam with a wavelength in the spectral region of the porphyrin's Q-bands. The photomodification efficiency is high with a total yield around 80% for a specific modification site of five nucleotides. This efficient site-directed photomodification of DNA suggests that porphyrinyl agents may be developed as anticancer or antiviral drugs for use in photodynamic therapy.

Our procedure provide an efficient method for producing porphyrin-oligonucleotide conjugates in sufficient quantity and with sufficient purity to make these compounds readily available for medical and chemical applications.

Dioleoylmelittin as a Novel Serum-Insensitive Reagent for Efficient Transfection of Mammalian Cells

J. Y. Legendre,* A. Trzeciak, B. Bohrmann, U. Deuschle, E. Kitas, and A. Supersaxo

Preclinical Research and Development, F. Hoffmann-La Roche AG, CH-4070 Basel, Switzerland.

Received August 29, 1996[®]

Amphipathic peptides can be useful effectors to enhance gene delivery. However, peptide/DNA complexes usually require additional effectors, such as fusogenic lipids, to mediate efficient transfection. Due to weak and/or multiple interactions between the various components of the system, the transfecting complexes are often heterogeneous and unstable in biological fluids. Accordingly, a hybrid molecule resulting from the covalent coupling of an amphipathic, membrane-disturbing peptide to a lipid moiety might create a stable and efficient peptide-based gene transfer system. The present work describes such a novel hybrid molecule, dioleoylmelittin, resulting from the conjugation of dioleoylphosphatidylethanolamine-*N*-[3-(2-pyridyldithio)propionate] with [Cys¹]melittin. Dioleoylmelittin had a lower hemolytic and membrane-disturbing activity than melittin. Size and zeta potential measurements, DNA gel electrophoresis, and electron microscopy showed that dioleoylmelittin, unlike melittin, was able to complex plasmid DNA to form spherical particles with a net positive charge and a diameter between 50 and 250 nm. These particles, prepared at an optimal 10/1 dioleoylmelittin/DNA ratio (w/w), mediated efficient transient transfection of reporter genes in cultured mammalian cells including primary cells. The luciferase activity induced by the dioleoylmelittin/DNA complex was 5–500-fold higher than that induced by a cationic lipid/DNA complex, depending on the cationic lipid and the cell-line. Surprisingly, the presence of 10–50% fetal calf serum during dioleoylmelittin-mediated transfection enhanced 1.5–3-fold gene expression. Dioleoylmelittin represents a new class of efficient peptide-based transfection reagents, especially suited for serum-sensitive cells.

INTRODUCTION

Gene delivery is recognized as a key issue in the future development of gene therapy. Indeed, several recent gene therapy clinical trials in humans have shown the limitations of viruses to deliver genes (1). Nonviral gene delivery systems could therefore provide an easier and safer alternative to viruses (2). However, the transfection efficiency of synthetic carriers is still lower than that of viral vectors.

Cationic lipids are the most widely used nonviral transfection reagents both in cell culture and in animals (3, 4). These transfection competent molecules are composed of a cationic moiety, which binds DNA by charge interactions, and a lipophilic tail. Therefore, cationic lipids have the dual ability of condensing DNA and fusing or destabilizing cell membranes (3, 4). Another emerging gene transfer strategy is the use of amphipathic peptides (5–11). These peptides are either fusogenic or permeabilize cell membranes and, hence, improve gene transfer. For example, the cyclic peptide gramicidin S can facilitate DNA delivery into cells in culture (8–10). However, efficient transfection with this peptide requires the addition of co-lipids such as dioleoylphosphatidylethanolamine (DOPE) or short-chain phospholipids; both interact with the hydrophobic face of the gramicidin S (8, 9). This binding usually occurs via weak interactions, and as a result, the transfecting particles are rather heterogeneous and unstable in biological fluids. Accordingly, hybrid molecules resulting from the covalent binding of a lipid moiety onto an amphipathic peptide might provide single, stable transfection compe-

tent reagents. The present work describes the synthesis of such a novel hybrid molecule, dioleoylmelittin. Melittin, a 26 amino acid peptide, is a well-characterized membrane-disturbing molecule (12). When complexed with plasmid DNA, its lipophilic derivative, dioleoylmelittin, forms homogeneous and small particles that mediate highly efficient transfection of cells in culture, even in the presence of serum.

MATERIALS AND METHODS

Synthesis of the Dioleoylmelittin. Continuous-flow solid-phase peptide synthesis was performed on a Milligen 9050 synthesizer, starting from a Tentagel S resin (0.22 mmol/g, Rapp Polymere, Tübingen, Germany), as described (13). All chiral amino acids were of the L-configuration. The base-labile 9-fluorenylmethoxycarbonyl (Fmoc) group was used for α -amino protection. Side chains were protected with the following protecting groups: 2,2,5,7,8-pentamethylchroman-6-sulfonyl (Pmc) for arginine, triphenylmethane (Trt) for cysteine and glutamine, *tert*-butoxycarbonyl (Boc) for lysine and tryptophan, and *tert*-butyl (But) for serine and threonine. Fmoc-amino acids (2.5 equivalent) were activated with an equivalent amount of 1,1,3,3-tetramethyl-2-(2-oxo)-1(2*H*)-pyridyluronium tetrafluoroborate (14) and diisopropylethylamine. Fmoc deprotection was achieved with 20% (v/v) piperidine in dimethylformamide. The resin-bound peptide was treated with a mixture of 86% trifluoroacetic acid, 10% ethanedithiol, and 4% water for 3 h. The reaction mixture was concentrated and poured into diethyl ether, and the precipitate was collected by filtration and lyophilized from water. The crude peptide was purified by preparative HPLC. The fractions of the main peak were collected, concentrated under reduced pressure, and lyophilized, yielding 94.5 mg of compound **I** (CIGAVLKVLTTGLPALISWIKRKRQQ). The homogeneity of compound **I** was confirmed by analytical reversed

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1996.

Figure 1. Structure of dioleoylmelittin.

phase HPLC, and the molecular weight was determined by ionization spray positive mode mass spectrometry: $M = 2892.6$ ($M + H$)⁺ (calculated 2892.6 for $C_{132}H_{231}N_{39}O_{35}$). Ten micromoles of compound **I** was dissolved in a mixture of 1 mL of 100 mM phosphate buffer (pH 6.5) and 1 mL of acetonitrile (15). Eleven micromoles of 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[3-(2-pyridyldithio)propionate] (N-PDP-PE, Avanti Polar Lipids Inc., Birmingham, AL) in 2.8 mL of chloroform was then added. The mixture was left at room temperature for 1 h, and the organic solvent was removed by evaporation under nitrogen. The remaining solution was diluted with distilled water to a volume of 2.5 mL and passed through a Sephadex G-25 M column. The resulting lipopeptide, dioleoylmelittin (Figure 1), was eluted with distilled water and lyophilized, yielding 28.9 mg of a white solid. The molecular weight was determined by ionization spray positive mode mass spectrometry: $M = 3722$ (calculated 3722.7 for $C_{176}H_{311}N_{40}O_{40}PS_2$).

A control peptide resulting from the coupling of NPDP-PE with CKKKKK (dioleoyl- K_5) was prepared as above, yielding 60 mg of purified lyophilisate ($M = 1633.0$, calculated 1633.25 for $C_{79}H_{150}N_{13}O_{16}S_2$).

Hemolysis Test. Blood from beagle dogs was collected on lithium heparinate and centrifuged for 20 min at 1000*g*. Plasma and buffy coat were discarded, and red blood cells (RBC) were washed with isotonic saline and finally diluted to a concentration of about 6×10^8 cells/mL. Melittin (Sigma, St. Louis, MO; sequencing grade) or dioleoylmelittin, complexed or not with plasmid DNA at a 2/1 \pm charge ratio (assuming a charge of +5 for each peptide), was sequentially diluted with isotonic saline from 40 to 0.05 μ M in a 96-well plate. One hundred microliters of the RBC suspension was added per well, and the plate was incubated for 30 min at 37 °C. After centrifugation (15 min, 1000*g*), 80 μ L of each supernatant was transferred to a new 96-well plate and hemoglobin concentration was measured using a hemoglobin diagnostic kit (Roche diagnostic). Two hundred microliters of a 0.77 mM potassium cyanide solution was added per well, and after 10 min, absorbance was read at 560 nm using an ELISA plate reader. One hundred percent hemolysis was obtained by incubating the RBC with 1% Triton X-100. Background was measured after the RBC had been incubated in isotonic saline and was subtracted from each value.

Destabilization of Liposomes. Egg phosphatidylcholine liposomes (Lipoid, Ludwigshafen, Germany) were prepared by drying the lipids from a chloroform solution under vacuum and by rehydrating the lipid film with isotonic saline. Liposomes were then sonicated and extruded through polycarbonate filters with decreasing pore size (1, 0.4, 0.2 μ m) to generate liposomes with an apparent diameter of 203 ± 4 nm (16). Liposomes, at a final concentration of 1 mM in isotonic saline, were then incubated with increasing concentrations (from 5 to 140 μ M) of melittin or dioleoylmelittin. Five minutes after addition of the peptide to the liposomes, the modification

of the apparent diameter and the polydispersity of the liposomes was determined by dynamic light scattering (Zetasizer 4, Malvern Instruments, Southborough, MA).

Expression Vectors. The pGL3-CMV plasmid encoding for luciferase was constructed as follows: in a first step the *KpnI*–*BglII* TK promoter fragment from pT109luc (17) was introduced between the *KpnI* and *BglII* sites of pGL3basic (Promega, Madison, WI), respectively. From this construct the *XhoI*–*BglII* TK promoter was replaced by the CMV promoter excised as a 788 bp *XhoI*–*BamHI* fragment from pUHD10-1 (18), generating pGL3-CMV. The pCMV- β gal plasmid encoding for β -galactosidase was purchased from Clontech (Palo Alto, CA). Both plasmids were grown using standard methods and purified by column chromatography (Qiagen, Hilden, Germany).

Preparation of the Transfecting Complex. Dioleoylmelittin was dissolved in trifluoroethanol at a concentration of 1 mg/mL. One milliliter of the solution was dried under argon and then under high vacuum. The film was dissolved with 1 mL of 10 mM Tris maleate buffer (pH 6), and the solution was vortexed. Typical complex was prepared by diluting 10 μ g of plasmid DNA in a final volume of 200 μ L of sterile water in a polystyrene tube. Then, an appropriate amount (typically 100 μ L) of dioleoylmelittin was added dropwise and quickly mixed. The complex was allowed to stand at room temperature for 2–5 min before transfection. In some experiments, dioleoylmelittin was mixed with a 5-fold molar excess of DOPE (Avanti Polar Lipids) and subsequently added to plasmid DNA. The transfection efficiency of dioleoylmelittin was also compared to that of 1,2-bis(oleoyloxy)-3-(trimethylammonio)propane (DOTAP; Avanti Polar Lipids) and 1,3-dioleoyloxy-2-(6-carboxyspermyl)propylamide (DOSPER; Boehringer-Mannheim, Mannheim, Germany). DOTAP/DNA or DOSPER/DNA complexes were prepared according to the manufacturer's instructions and were used at a cationic liposome/DNA ratio of 5/1 (w/w). This corresponds to a 2/1 and 5/1 \pm cationic liposome/DNA charge ratio for DOTAP and DOSPER, respectively. The mean diameter of DOTAP/DNA and DOSPER/DNA complexes was 190 ± 10 nm, as determined by dynamic light scattering.

Transfection Experiments. CV-1 (monkey kidney fibroblasts) cells were plated at a density of about 2×10^4 cells per well in a 96-well plate (about 70–80% confluency) and grown for 24 h in 10% fetal calf serum (FCS, Gibco BRL, Grand Island, NY) containing medium. Transfection took place in 100 μ L of FCS-free Dulbecco's modified Eagle medium (DMEM), and 5 h later medium was removed and replaced by 10% FCS-containing medium. To each well was applied 0.2 μ g of plasmid DNA. In some experiments, transfection took place in 10% or 50% FCS-containing medium. Forty-eight hours later, β -galactosidase activity was measured. After medium removal, 50 μ L of 250 mM Tris Cl buffer (pH 8) containing 0.5% of Triton X-100 was added per well. Cells were frozen at -70 °C and then thawed at 37 °C, and 50 μ L of phosphate buffer saline (150 mM, pH 6, PBS) was added

per well. Finally, 150 μL of a 2 mg/mL solution of *o*-nitrophenyl galactopyranoside (Sigma) in 60 mM Na_2HPO_4 , 1 mM MgSO_4 , 10 mM KCl, and 50 mM β -mercaptoethanol was added per well. Optical density at 405 nm was measured after the plate was incubated for anywhere between 20 min and 1 h at 37 $^\circ\text{C}$, depending on the β -galactosidase activity. Values were computed from a β -galactosidase (Fluka) standard curve. Day-to-day β -galactosidase activity values usually varied by about 2-fold depending upon cell density and condition of the cells. Sensitivity of the assay was 50 μunits of β -galactosidase per well of CV-1 cells.

β -Galactosidase activity was also detected by cytochemical stain to evaluate the percentage of transfected cells (19). In this case, CV-1 cells and primary rabbit aorta smooth muscle cells (20) were grown in 60 mm dishes in 2 mL of appropriate medium. Two micrograms of pCMV β gal plasmid complexed with 20 μg of dioleoylmelittin was incubated with the cells during 5 h in 2 mL of serum-free medium. Forty-eight hours after transfection, cells were rinsed with PBS, fixed for 5 min with 4% formaldehyde in PBS, and then stained with X-Gal (5-bromo-4-chloro-3-indolyl- β -D-galactoside, Promega). The blue β -galactosidase-expressing cells were visualized under the microscope 2 h after staining and counted as the percentage of the total cell population.

The dioleoylmelittin transfection efficiency was also compared to that of cationic liposomes (DOTAP or DOSPER), and in this case a luciferase expression vector, pGL3-CMV, was used. Cell-lines CV-1, CHO-K1 (Chinese hamster ovary cells), and 293 (human kidney embryonic cells) were plated in six-well plates and grown for 24 h. Two micrograms of DNA complexed with either cationic liposomes or dioleoylmelittin was added per dish in 2 mL of 10% FCS-containing medium. Five hours later medium was removed and replaced by fresh 10% FCS-containing medium. Luciferase activity was measured 48 h later as previously described (21), and results were normalized to cell protein content (BCA protein assay reagent, Pierce, Rockford, IL).

Physicochemical Characterization. Size and zeta potential of the dioleoylmelittin/DNA complex were determined using a Zetasizer 4 (Malvern Instruments) after appropriate dilution in pure water. To estimate the interaction between plasmid DNA and dioleoylmelittin, plasmid DNA (0.5 μg) was mixed with increasing amounts of dioleoylmelittin (0–4 μg) and electrophoresed on a 0.8% agarose gel in the presence of ethidium bromide. Dioleoylmelittin/DNA complex was also imaged by electron microscopy (EM). For negative staining, a 5 μL aliquot of sample was adsorbed to a carbon-coated 200-mesh copper grid. Staining was done by adding directly 10 μL of 2% uranyl acetate to the adsorbed sample droplet, and the preparation was air-dried after removal of the excess of liquid with filter paper. Specimens were examined in a JEOL-1210 electron microscope operated at 100 kV. For cryoelectron microscopy of frozen-hydrated specimens, 5 μL of samples was applied to 700-mesh hexagonal copper grids. After the excess of solution was removed by blotting with filter paper, the grid was rapidly quench-frozen in a home-made guillotine-like device using liquid ethane as coolant. The frozen grids were mounted under liquid nitrogen in a side entry specimen holder (Model 626, Gatan, Pleasanton, CA) and examined at -172°C in a JEOL-1210 electron microscope equipped with an anticontaminator (Model TAC100, Oxford Instruments, Oxon, U.K.) and operated at 100 kV. Low-dose images were recorded 1.5–2.0 μ underfocus with an electron irradiation of approximately $10\text{ e}/\text{\AA}^2$ at a nominal magnification of 10 000–20 000. Digitized

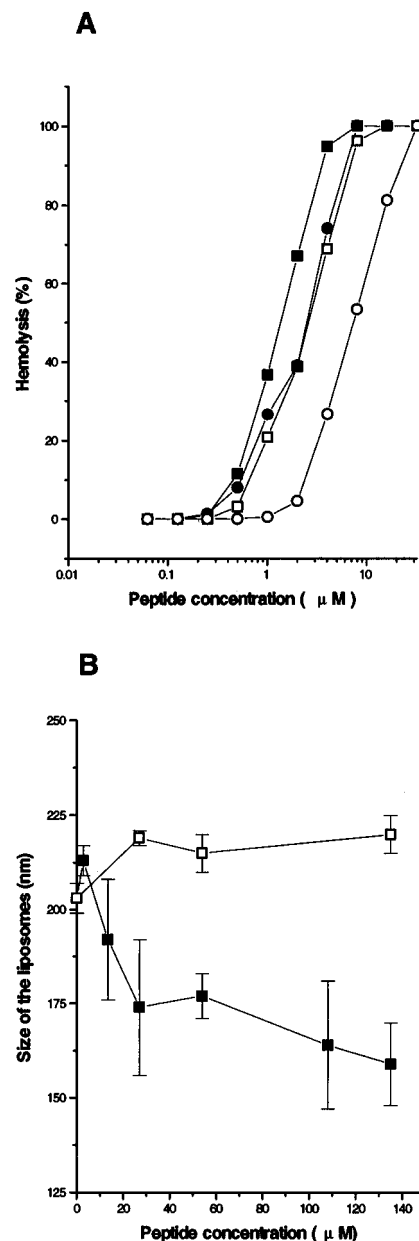

Figure 2. Hemolytic activity (A) and liposome-destabilizing activity (B) of melittin (■), melittin/DNA complex (●), dioleoylmelittin (□), and dioleoylmelittin/DNA complex (○). Complexes between peptides and DNA were prepared at a 2/1 (+/–) charge ratio, assuming 5 positive charges for each peptide.

micrographs were recorded with a slow scan CCD camera (Model 679, Gatan). Magnification calibration was done using negatively stained catalase crystals.

RESULTS

Membrane-Disturbing Activity of Melittin and Dioleoylmelittin Complexed or Not with Plasmid DNA. Two tests were used to evaluate the membrane-disturbing activity of dioleoylmelittin, as compared to melittin: the hemolytic activity and the solubilization of liposomes. When free melittin was incubated with erythrocytes at 37 $^\circ\text{C}$, 50% hemolysis could be detected at a peptide concentration of about 1.2 μM (Figure 2A). This concentration doubled when melittin was complexed with plasmid DNA. Dioleoylmelittin had a lower hemolytic activity than the original peptide, and 50% hemolysis was attained at a peptide concentration of 2.5 μM . After complexation with DNA, the dioleoylmelittin concentration that induced 50% hemolysis was 7 μM . At a

Figure 3. Effect of dioleoylmelittin/DNA ratio (w/w) on transfection efficiency of CV-1 cells in the presence (open bar) or absence (black bar) of DOPE in the complex. Results are the mean \pm SD of six wells in two separate experiments.

concentration of 5 μ M, melittin slightly increased the size of egg PC liposomes, but at concentrations above 10 μ M, it markedly decreased their size and increased their polydispersity (Figure 2B). This effect was attributed to the fusion of liposomes at low peptide/lipid ratios followed by the solubilization of the liposomes and the formation of discoidal structures at higher melittin concentrations (22). Conversely, dioleoylmelittin only slightly increased the size of the liposomes and did not modify their polydispersity in the range of concentration studied.

In Vitro Transfection with the Dioleoylmelittin/DNA Complex. The optimal dioleoylmelittin/DNA ratio for transfection of CV-1 cells was first determined (Figure 3). At a 1/1 or 2/1 dioleoylmelittin/DNA ratio (w/w), no transfection was detected. However, when the dioleoylmelittin/DNA ratio was at least 5/1 (w/w), β -galactosidase activity could be detected in CV-1 cells 48 h after transfection and the optimal dioleoylmelittin/DNA ratio was 10/1 (w/w). Above this ratio some toxicity appeared and transfection was reduced. When DOPE was added to the transfecting particles in a 5-fold molar excess to dioleoylmelittin, β -galactosidase activity was induced at dioleoylmelittin/DNA ratios at which DOPE-free formulations hardly mediated transfection. However, at the optimal ratio with DNA, the efficiency of the DOPE-containing formulations was reduced 5–10-fold as compared to the dioleoylmelittin alone. Furthermore, the control peptide dioleoyl-K₅ did not mediate any transfection of CV-1 cells at all lipopeptide/DNA ratios studied (data not shown).

Evaluation of the percentage of cells expressing β -galactosidase activity by cytochemical staining indicated that about 60–70% and 10–20% of the cells were transfected for CV-1 cells and primary rabbit aorta smooth muscle cells, respectively (data not shown).

The transfection efficiency of dioleoylmelittin was also compared to that of two commercially available cationic lipid transfection reagents, DOTAP and DOSPER, in various cell lines (Table 1). In the three cell lines studied, dioleoylmelittin mediated 3–40 and 25–500 times greater luciferase activity than DOSPER and DOTAP, respectively.

Effect of Serum and Lysomotropic Agents on Transfection Efficiency. Surprisingly, the presence of FCS in the medium had a favorable effect on the transfection efficiency of dioleoylmelittin in CV-1 cells (Figure 4). Ten percent FCS in the transfection medium slightly enhanced transfection, but 50% FCS enhanced β -galactosidase activity more than 2-fold. This effect was not cell line dependent since an improvement of transfection in the presence of serum was also observed for

Table 1. Transfection of Various Mammalian Cell Lines with Dioleoylmelittin Complex or Cationic Lipids

	luciferase activity		
	DOTAP	DOSPER	dioleoylmelittin
CHO-K1	2.69×10^6	2.50×10^7	5.19×10^8
CV-1	1.14×10^5	1.31×10^6	5.54×10^7
293	7.31×10^6	5.70×10^7	1.71×10^8

^a Results are expressed as light units per milligram of cell protein and are the mean of two experiments. Background (130 LU) was subtracted from each measurement.

Figure 4. Effect of various agents on dioleoylmelittin-mediated transfection. NT, no treatment. Results are the mean \pm SD of at least 10 wells in three separate experiments.

293 or COS-1 cells (data not shown). Furthermore, cell viability was at least 96% in the absence or the presence of serum, suggesting that FCS did not improve transfection by protecting the cells from a possible toxic effect of the dioleoylmelittin.

To gain some insight into the mechanism whereby dioleoylmelittin brings about transfection, cells were also treated with various agents during the transfection procedure (Figure 4). Addition of lysomotropic agents, monensin (10 μ M) and ammonium chloride (20 mM), at the beginning of the 5 h incubation time reduced 2–3 times the transfection level mediated by the dioleoylmelittin. These compounds have been shown to enhance cationic lipid-mediated transfection in CV-1 cells (23).

Characterization of the Dioleoylmelittin/DNA Complex. Rehydration of the dioleoylmelittin film resulted in a clear solution. Under negative-stain EM this solution appeared as aggregates or micellar-like structures with a size between 5 and 10 nm (Figure 5a).

Dynamic light scattering indicated that homogeneous particles with an apparent diameter of about 170 nm were formed when dioleoylmelittin was added to DNA at a weight ratio between 2 and 4 (Figure 6). When increasing amounts of dioleoylmelittin were added, the mean size of the complex slightly increased to 250 nm. Addition of DOPE to the dioleoylmelittin/DNA complex led to less homogeneous particles of a size larger than 400 nm (data not shown). Zeta potential measurements showed that when dioleoylmelittin was added to the DNA solution, particles became more and more positive. Charge neutralization (zeta potential between -1 and $+1$ mV) was obtained at a dioleoylmelittin/DNA ratio between 4/1 and 8/1 (w/w) (Figure 6). Similarly, gel electrophoresis showed that plasmid DNA was completely retained in the agarose gel when mixed at a dioleoylmelittin/DNA weight ratio above 4/1 (data not shown). This finding was in good agreement with zeta potential measurements.

Figure 5. Electron micrographs of negative-stained (a, b) or frozen-hydrated (c, d) samples: dioleoylmelittin (a), dioleoylmelittin/DNA 10/1 (w/w) complex (b, d), and dioleoylmelittin/DNA 2/1 (w/w) complex (c). Bars represent 200 nm and are the same for (a) and (b) and for (c) and (d).

The dioleoylmelittin/DNA complex was also imaged by negative-stain EM and cryo-EM (Figure 5). At a 2/1 dioleoylmelittin/DNA weight ratio, spherical, filled particles with diameters between 50 and 150 nm were visualized under cryo-EM (Figure 5c). No aggregates or large structures were seen in any sample. Similar structures were observed for the 10/1 dioleoylmelittin/DNA complex (w/w), although particles larger than 200 nm were sometimes visualized in the sample (Figure 5d). Negative-stain EM revealed similar structures as for cryo-EM, albeit aggregated particles were seen more frequently (Figure 5b). These results confirmed the data obtained by laser light scattering.

DISCUSSION

Conjugation of 1,2-dioleoylphosphatidylethanolamine-*N*-[3-(2-pyridyldithio)propionate] with [Cys¹]melittin resulted in a hybrid molecule, the dioleoylmelittin, with properties different from those of the native peptide melittin. Indeed, although melittin binds DNA by charge interactions, the melittin/DNA complex does not mediate transfection and, due to the fast partitioning of melittin into cell membranes, induces high toxicity (8). In contrast, dioleoylmelittin was able to complex plasmid DNA to form homogeneous and small particles. The resulting dioleoylmelittin/DNA complex mediated efficient transfection of various cell types *in vitro*, including primary cells.

Dioleoylmelittin in aqueous solution forms aggregates that resemble micellar structures rather than liposomes. This characteristic distinguishes dioleoylmelittin from cationic lipids which spontaneously form liposomes in aqueous solution (24, 25). Unlike dioleoylmelittin/DNA complexes, cationic lipid/DNA complexes often appear as heterogeneous structures in EM (25–27). Recently, it has been shown that complexation of DNA with cationic lipids in a micellar state followed by dialysis of the preparation to remove the surfactant allowed the formation of small and stable particles (28). Therefore, due to a higher molecular motion, cationic amphiphiles in a micellar-like state could interact more favorably with plasmid DNA than in a liposomal state (29).

Figure 6. Evolution of the mean size (□) and the mean zeta potential (●) of the particles as a function of the dioleoylmelittin/DNA ratio (w/w).

The highest transfection of CV-1 cells was obtained for a 10/1 dioleoylmelittin/DNA ratio (w/w), which corresponds to a theoretical 5/1 \pm charge ratio, assuming 5 positive charges for dioleoylmelittin. The particles formed at this ratio had a net positive charge (zeta potential of 1.2 mV) and, as indicated by DNA gel electrophoresis, plasmid DNA was totally complexed by dioleoylmelittin. The absence of other structure in negative-stain EM or cryo-EM indicates that these particles are likely to be responsible for transfection.

Unlike other amphipathic molecule-based transfection systems, dioleoylmelittin did not require DOPE to mediate transfection (3, 4, 8). In contrast, at the optimal dioleoylmelittin/DNA ratio, addition of DOPE increased particle size and transfection efficiency decreased. Another interesting feature of the dioleoylmelittin system is its ability to mediate high transfection in the presence of serum. This is also in contrast to other transfection reagents such as cationic liposomes or the gramicidin S/DNA/DOPE complex for which 50% FCS in the transfection medium dramatically reduces transfection efficiency (8). This property should make dioleoylmelittin an attractive transfection reagent for serum-sensitive cell lines. Nevertheless, the reason FCS increases transfection is still unknown. The formation of small, compacted structures is undoubtedly an important feature to mediate high transfection in the presence of serum, as shown for cationic lipid- or polylysine-based systems (28, 30). However, other factors such as complement activation may be involved in the enhancement of dioleoylmelittin transfection efficiency by serum (31). We are currently investigating this possibility.

The cationic nature of the melittin moiety was necessary but not sufficient to mediate high levels of transfection. Indeed, replacement of the melittin by an oligolysine of five residues completely abolished transfection. Although high molecular weight polylysine covalently coupled with phosphatidylethanolamine can mediate transfection of cells in culture, scraping of the cells or addition of a helper lipid is required for efficient gene transfer with this reagent (32, 33). This indicates that the entry of DNA into cells and/or lysosomal escape using lipopolylysine is poor, which is due to the fact that

polylysine has no or limited membrane-disturbing activity. In contrast, both melittin and dioleoylmelittin can destabilize membranes, as shown by their ability in lysing red blood cells. However, melittin and dioleoylmelittin have somewhat different behaviors regarding their action on membranes. Dioleoylmelittin did not solubilize liposomes at concentrations below 140 μM , and the concentration that induced hemolysis was about 2–3-fold higher than that of melittin. This could explain why dioleoylmelittin, in contrast to melittin, did not induce cell toxicity at the concentrations used for transfection ($\leq 5 \mu\text{M}$).

Treatment of the cells with lysomotrophic agents during the transfection procedure decreased 2–3-fold the level of β -galactosidase expression. This observation suggests that DNA delivery using dioleoylmelittin may involve an endosomal/lysosomal pathway (23). Cationic lipid/DNA complexes also enter the cell by endocytosis (23, 34). Xu and Szoka have recently proposed that after endocytosis of the cationic lipid/DNA complex, destabilization of the early endosome occurs followed by a flip-flop of the anionic phospholipids of the endosomal membrane (35). Then, these anionic lipids diffuse into the complex to form ion pairs with cationic lipids, leading to the displacement of plasmid DNA from the transfecting complex. In the case of dioleoylmelittin, such a mechanism may also be possible since melittin can induce a rapid and extensive lipid flip-flop in membranes (36). Furthermore, the affinity of melittin for membrane-containing anionic lipids is 100-fold greater than for zwitterionic lipids (12). However, in contrast to cationic lipids for which lysomotrophic agents usually increase gene transfer efficiency (23), dioleoylmelittin transfection efficiency was decreased when monensin or ammonium chloride were present during transfection. Nevertheless, the exact mechanism whereby dioleoylmelittin is mediating transfection is still unresolved. In particular, it is unclear whether dioleoylmelittin is the actual transfecting agent or if it acts as a prodrug that releases the more active melittin after reduction of the disulfide bridge.

The use of dioleoylmelittin for *in vivo* gene transfer, especially in humans, may be precluded by the immunogenic potential of the melittin (37). However, similar hybrid molecules based on membrane-disturbing, non-immunogenic peptides could perhaps be engineered to deliver genes *in vivo*. In conclusion, dioleoylmelittin represents a new class of efficient, *in vitro* transfecting reagent, especially suited for serum-sensitive cells.

ACKNOWLEDGMENT

We are grateful to Dr. J. Fingerle (F. Hoffmann-La Roche) for providing rabbit aorta smooth muscle cells. We greatly appreciate the expertise of Mrs. B. Hennequin in the dioleoylmelittin purification.

Optimization of Conditions for Formation and Analysis of Anti-CD19 FVS191 Single-Chain Fv Homodimer (scFv)₂

Duo Wang,[†] Erica Berven,[†] Quanzhi Li,[†] Fatih Uckun,[‡] and John H. Kersey^{*,†,§,||,⊥}

University of Minnesota Cancer Center, Biotherapy Institute, and Departments of Laboratory Medicine/Pathology and Pediatrics and Therapeutic Radiology, University of Minnesota, Minneapolis, Minnesota 55455. Received August 29, 1996[⊗]

In this report, we present the production of a dimeric form of anti-CD19 scFv, the FVS191cys (scFv)₂. Anti-CD19 scFv FVS191cys was constructed by engineering a cysteine residue at the C terminus of the V_L domain of scFv FVS191. FVS191cys (scFv)₂ was formed through a disulfide bond between two FVS191cys molecules. To optimize the yield of FVS191cys (scFv)₂, the effects of oxidation time, buffer pH, and temperature on the formation of dimeric scFv were analyzed. Our study indicates that the formation of FVS191cys (scFv)₂ is oxidation time- and buffer pH-dependent; a high pH buffer facilitates the formation of disulfide-linked (scFv)₂. The maximum yield of FVS191cys (scFv)₂ can be achieved when FVS191cys is air-oxidized at 4 °C, in buffer with a pH of 8.5–9. The biological activity of FVS191cys (scFv)₂ was analyzed by ELISA and an internalization assay. FVS191cys (scFv)₂ has a CD19 binding ability similar to that of its parental mAb B43 and is internalized by CD19 positive Nalm 6 cells. This study indicates that FVS191cys (scFv)₂ is a potential candidate for tumor diagnosis or therapy.

INTRODUCTION

Monoclonal antibodies (mAbs)¹ have been useful for antigen-specific targeting of tumor cells; however, the application of mAbs has demonstrated limited diffusion of mAbs from the vasculature into the tumor. The limited diffusion of intact antibodies is due to the large size of mAbs and the host effect elements of their Fc domains (1, 2). A recombinant single-chain Fv (scFv) composed of the minimal antigen binding domains, variable heavy chain (V_H) and variable light chain (V_L), is one-sixth of the size of a mAb (28 kDa). ScFvs have exhibited improved tumor penetration with higher tumor to normal tissue ratios than corresponding IgG or Fab and faster plasma clearance rates (3–5). However, scFvs have only one antigen binding arm which may decrease antigen binding affinity (4). Previous studies have demonstrated that homodimers of scFv [(scFv)₂], such as an anti-c-erb2 (scFv)₂, have exhibited divalent binding and increased retention in tumors as compared with the corresponding scFv monomers (6). Also, radiolabeled (scFv)₂ was found to have improved tumor imaging compared to Fab, monomeric scFv, and intact antibody (7). These studies suggest that dimers of scFvs may be useful candidates for tumor diagnoses and therapy.

Covalently linked (scFv)₂ have been generated by several different approaches: (i) forming a disulfide bond between carboxyl-terminal cysteine residues (6, 8), (ii) cross-linking with chemical linkers (6, 9), and (iii) forming covalent bundle helices or leucine zippers at the C terminus (10). The first method is carried out by introducing one cysteine at the 3' end of the scFv and forming a C-terminal disulfide bond through air oxidation. Chemical linking uses BMH or peptide-bridged MCA to link two scFvs (6). This method is complicated by the multiple steps involved in the chemical modification. Finally, engineering small peptides at the C terminus of scFv for formation of helix bundles or leucine zippers may be useful, but it may increase the immunogenicity of the molecules.

In this report, we studied the formation of dimeric forms of FVS191cys. FVS191 is an anti-CD19 scFv produced in our laboratory from the B43 hybridoma (11). FVS191cys was constructed by engineering a cysteine residue at the C terminus of FVS191. We focused on the production of a disulfide-linked (scFv)₂ because this species was relatively easy to generate and was stable in solution as chemically linked (scFv)₂ (6). It was observed that FVS191cys (scFv)₂ could be formed by air oxidation in basic buffers without any chemical modifications or manipulations. To optimize the conditions for formation of disulfide-linked (scFv)₂, we used FVS191cys as a model molecule to study the effects of oxidation time, buffer pH, and temperature on formation of FVS191cys (scFv)₂. In addition, the CD19 binding ability of FVS191cys (scFv)₂ was evaluated by ELISA. The internalization of FVS191cys (scFv)₂ by CD19 positive cells was also investigated.

MATERIALS AND METHODS

Construction of the Plasmid for the Expression of FVS191cys. The expression plasmid of FVS191cys was derived from pFVS191 (11). To insert an additional cysteine residue at the 3' end of the V_L gene, the pFVS191 plasmid was restricted with *Bgl*II and *Eco*RI and ligated with the annealed, complementary oligonucleotides of HLCys1 and HLCys2. The correct insertion of the oligonucleotides HLCys1/HLCys2 was verified by nu-

cleotide sequencing. The construction of pFVS191cys is shown in Figure 1.

Expression and Purification of FVS191cys. The pFVS191cys plasmid was transformed into *Escherichia coli* BL21(DE3) (Novagen, Madison, WI). The transformed bacterial cells were grown in 1 L of SOB medium (20 g of tryptone, 5 g of yeast extract, 0.5 g of NaCl, and 5 g of $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ per liter) at 37 °C. When the absorbance of A_{600} of the bacterial culture reached 0.65, recombinant protein production was induced with 1 mM isopropyl β -D-thiogalactopyranoside (IPTG) for 1.5 h at 37 °C.

The inclusion bodies of FVS191cys were isolated using the following procedures. The harvested cell pellets were mixed with 50 mL of inclusion body separation (IBS) buffer (0.1 M KCl, 0.02 M Tris-HCl, 5 mM EDTA, and 0.1% Nonidet P-40 at pH 8.0) and sonicated. Lysozyme was added to the sonicated cell mixture to a final concentration of 0.2 mg/mL. After incubation at room temperature for 1 h, the cell lysate was frozen at -80 °C. Cell lysates were then thawed at room temperature, sonicated, and centrifuged at 17000g for 30 min at 4 °C. The supernatant was discarded, and the pellet was suspended in 50 mL of IBS buffer. Sodium deoxycholate (10%, w/v) was added to the suspensions for a final concentration of 2%. The mixture was stirred at room temperature for 1 h and centrifuged at 17000g for 30 min at 4 °C. The inclusion body pellet was washed by suspending in IBS buffer and centrifuging at 17000g for 30 min. The wash was repeated once with water, and the inclusion bodies were stored at -80 °C.

Refolding of FVS191cys. FVS191cys was denatured and refolded according to Buchner's method (12) with some modifications. The inclusion bodies of FVS191cys were dissolved in a denaturing buffer [0.1 M Tris, 6 M guanidine hydrochloride, 0.3 M dithioerythritol (DTE), and 0.002 M EDTA at pH 8] at room temperature for 2 h. Insoluble materials were removed by centrifugation at 30000g for 30 min. The soluble protein concentration was determined using Coomassie Plus Protein Assay Reagent (Pierce) and bovine serum albumin (BSA) as standards. The final concentration of protein in denaturing solution was adjusted with denaturing buffer up to 20 mg/mL. Renaturation of FVS191cys was carried out by a rapid 100-fold dilution of the denatured protein into refolding buffer [100 mM Tris-HCl, 500 mM L-arginine, 8 mM oxidized glutathione (GSSG), and 2 mM EDTA at pH 8] at 10 °C and incubation for 48 h.

Purification of Refolded FVS191cys. After renaturation, the FVS191cys was concentrated and dialyzed against phosphate-buffered saline (PBS) buffer using an Amicon RA2000 concentrator with a YM10 cartridge (Amicon, Beverly, MA). FVS191cys proteins were purified by FPLC using a Superdex 75 (16 \times 60 mm) gel filtration column (Pharmacia). Purified FVS191cys monomers were concentrated by ultrafiltration through a YM10 membrane (Amicon).

Formation of the FVS191cys Dimer. FVS191cys (scFv)₂ was formed by air oxidation of FVS191cys at 4 °C. To study the oxidation time and pH effects on FVS191cys (scFv)₂ formation, 500 μ L of 400 μ g/mL purified FVS191cys was injected into Slide-A-Lyzer 10K Dialysis Cassettes (Pierce) and dialyzed against Tris/EDTA/NaCl (TEN) buffer (10 mM Tris-HCl, 2 mM EDTA, and 100 mM NaCl at pH 6.5–12). After dialysis, the proteins were transferred into FALCON 2059 tubes and air-oxidized for 1, 5, 12, 16, 20, and 29 days at 4 °C. To examine the formation of FVS191cys (scFv)₂, 50 μ L of the protein sample was run on a 12% nonreducing SDS-PAGE (Bio-Rad, Hercules, CA) and visualized with

Coomassie Brilliant Blue R-250. The relative amounts of monomers and dimers of FVS191cys were quantified using a GS-700 imaging densitometer with the program of Molecular Analyst (Bio-Rad). The proportion of dimeric FVS191cys (% d) was calculated as % d = dimer/(monomer + dimer) \times 100%. This quantification method was tested with BSA standards, and the result indicated that this method could be used to compare the amounts of proteins.

To study the effect of dithiothreitol (DTT) reduction on the formation of dimeric FVS191cys, FVS191cys was reduced with DTT before air oxidation. Purified FVS191cys in PBS buffer was added by $1/100$ volume of 200 mM DTT and incubated at room temperature for 1 h. After reduction, DTT was removed by a PD10 column (Pharmacia). Reduced FVS191cys was dialyzed against TEN buffers with the pH at 7, 7.5, 8, 8.5, 9, and 10. The formation of dimeric FVS191cys was examined by 12% nonreducing SDS-PAGE after air oxidation for 1, 5, 12, 16, 20, and 29 days. The visualization and quantification of monomers and dimers of FVS191cys were performed as described above.

The effect of temperature on the formation of dimeric FVS191cys was evaluated as follows. FVS191cys in TEN buffer at pH 8 was incubated at 4 °C, room temperature, and 37 °C. After air oxidation for 4 h or longer, the formation of FVS191cys (scFv)₂ was examined by SDS-PAGE.

Purification of FVS191cys (scFv)₂. FVS191cys (scFv)₂ was purified by FPLC using a Superdex 75 column (HiLoad 16/60) (Pharmacia). PBS buffer was used as an elution buffer; the column was run at a flow rate of 1 mL/min. The fractions containing FVS191cys (scFv)₂ were collected and concentrated by ultrafiltration using a YM10 membrane (Amicon).

¹²⁵I Labeling of FVS191cys. Purified FVS191cys (scFv)₂ was labeled with radioiodine using the IODO-BEADS method of Pierce (Pierce, Rockford, IL). FVS191cys (scFv)₂ (100 μ g) in 100 μ L of PBS was incubated with 100 μ L of ¹²⁵I solution containing 1 mCi sodium iodine (NEN, Boston, MA) in a 1 mL Reacti-Vial. The reaction proceeded for 10 min at room temperature. The free iodine was separated from the labeled dimers with a Sephadex G-25 gel filtration column (Pharmacia). The specific activity of labeled FVS191cys (scFv)₂ was approximately 2 μ Ci/ μ g.

CD19 Antigen Binding Assay. The specific CD19 binding ability of FVS191cys (scFv)₂ was assessed by ¹²⁵I-labeled proteins. CD19 positive (Nalm 6) and CD19 negative (Molt 13 and Peer) cell lines were grown in RPMI 1640 tissue culture medium supplemented with 10% fetal bovine serum (FBS). The log phase cells were harvested by low-speed centrifugation, washed once with fresh medium, and adjusted to a final concentration of 2×10^8 cells/mL. The ¹²⁵I-labeled FVS191cys (scFv)₂ was diluted in fresh tissue culture medium to a final concentration of 200 ng/mL. Pellets of 0.1 mL of cell suspension from each cell line in duplicate were incubated with 400 μ L of labeled antibody solution at 4 °C for 1 h. After incubation, the cells were washed three times with 1 mL of fresh tissue culture medium. The radioactivity associated with pellets of each cell line was determined in a γ counter (Beckman).

The CD19 binding ability of FVS191cys (scFv)₂ was further assessed by a competitive ELISA. The ELISA method was performed as follows. Purified B43 mAb was conjugated to alkaline phosphatase (B43-AP) using a commercial conjugation kit (Pierce). The conjugates were used directly without further purification. A series of experiments were carried out to determine the optimal

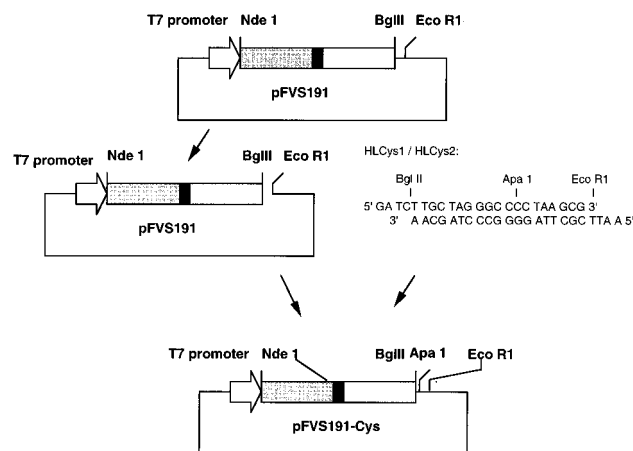

Figure 1. Cloning strategy used in the construction of FVS191cys. pFVS191 plasmid was restricted with enzyme *Bgl*III and *Eco*RI and inserted with annealed oligonucleotides HLCys1/HLCys2.

concentration of coating antigen and B43-AP for the ELISA. The CD19 antigens used in the ELISA were isolated from CD19 positive Daudi cells using the methods of Siegall et al. (13). ELISA plates (Immuron 4, Dynatech Laboratories Inc., Chantilly, VA) were coated with 50 μ L of isolated membrane proteins at a concentration of 80 μ g/mL. The plates were dried in a vacuum desiccator at 4 °C overnight and washed three times with PBS before use. Varying amounts of competing FVS191cys (scFv)₂ and a fixed amount of B43-AP (total volume of 100 μ L) were added to the wells and incubated at room temperature for 1 h. The final dilution of B43-AP was 1:2000. The plates were washed four times with PBS and incubated with 100 μ L of substrate solution at 4 °C overnight. The optical density of the wells was determined by an ELISA reader at 405 nm.

Internalization Assay. CD19 positive Nalm 6 cells were grown in RPMI 1640 medium supplemented with 10% FBS. The cells were harvested by centrifugation. ¹²⁵I-labeled FVS191cys (scFv)₂ (10 mg) was incubated with 1 \times 10⁸ cells in a volume of 5 mL and incubated on ice for 1 h. B43 mAb-blocked Nalm 6 cells were used as a control to assess nonspecific binding. After incubation, the cells were washed four times with cold RPMI 1640 without serum. Aliquots of 5 \times 10⁶ cells were transferred to 1 mL test tubes and incubated at 37 °C in a tissue culture incubator for various time intervals. Percentages of cell surface-bound, dissociated, internalized, and degraded FVS191cys (scFv)₂, based on the total cell-associated radioactivity at time 0, were determined according to the methods of Press et al. (14). Supernatants were separated from cell pellets by centrifugation. Precipitation of the supernatants by TCA further defined two portions of the labeled FVS191cys (scFv)₂: degraded FVS191cys (scFv)₂ (TCA nonperceptible) and dissociated FVS191cys (scFv)₂ (TCA perceptible). Cell pellets were treated with acid-papain; the radioactivity released by acid-papain treatment was regarded as cell surface-bound FVS191cys (scFv)₂, and the radioactivity associated with cell pellets after the treatment was seen as the internalized FVS191cys (scFv)₂.

RESULTS

FVS191cys Expression and Purification. A cysteine residue was introduced into the anti-CD19 scFv, FVS191, fragment by genetically engineering an additional codon at the 3' end of the gene encoding the V_L domain (Figure 1). The sulfhydryl group introduced to

The sizes of molecular mass markers are indicated at each side of the gel.

Figure 3. Formation and separation of FVS191cys (scFv)₂. Protein samples were analyzed by electrophoresis: lane 1, air-oxidized FVS191cys on a 12% nonreducing SDS-PAGE; lane 2, air-oxidized FVS191cys on a 12% reducing SDS-PAGE; lane 3, FVS191cys (scFv)₂ (peak II of FPLC) on a 12% nonreducing SDS-PAGE; and lane 4, FVS191cys monomers (peak III of FPLC) on a 12% nonreducing SDS-PAGE. The sizes of molecular mass markers are indicated on the left side of the gels.

the 3' end of FVS191 served as a specific site for the formation of disulfide-bonded dimeric FVS191cys. FVS191cys was produced as insoluble inclusion bodies by pFVS191cys-transformed BL21(DE3) *E. coli* cells. Figure 2 shows the expression and purification of FVS191cys on a SDS-PAGE. An average of 40 mg of FVS191cys inclusion bodies was isolated from 1 L of bacterial cell culture. The isolated FVS191cys was refolded in DTE-GSSG redox buffer. The final concentration of FVS191cys in refolding buffer influenced the refolding of FVS191cys. If the concentration of FVS191cys in refolding buffer were more than 20 mg/L, the amount of protein aggregates would increase. The refolded FVS191cys was purified by FPLC using a Superdex 75 column (Figure 2, lane 4).

Formation of the Disulfide-Bonded Dimer. FVS191cys scFv formed disulfide-linked homodimers through air oxidation. This was demonstrated by the formation of 56 kDa proteins when 28 kDa FVS191cys monomers were incubated at 4 °C (Figure 3, lane 1). The 56 kDa protein was reduced to a 28 kDa species in the presence of DTT (Figure 3, lane 2). After removal of DTT, the 28 kDa FVS191cys reformed the 56 kDa proteins (data not shown). This indicates that the 56 kDa protein is a disulfide-linked homodimer of FVS191cys.

FVS191cys (scFv)₂ was separated from monomers of FVS191cys by gel filtration chromatography. Figure 4 shows that FVS191cys (scFv)₂ was eluted from the Superdex 75 column in the second peak and FVS191cys monomers in the third peak. Fractions in the first peak contained high-molecular mass aggregates. The separated dimers and monomers of FVS191cys were examined by a nonreducing SDS-PAGE (Figure 3, lanes 3 and 4).

Time and pH Dependence of Dimer Formation. The formation of FVS191cys (scFv)₂ by air oxidation

Figure 4. FPLC separation of monomeric (peak III), dimeric (peak II), and aggregates of FVS191cys (peak I) using a Superdex 75 column. Conditions for separation are described in Materials and Methods.

Figure 5. Formation of FVS191cys (scFv)₂ with various pHs. After air oxidation for 12 days at 4 °C, 50 μ L of protein samples in TEN buffer (pH 6–12) were electrophoresed on a 12% nonreducing SDS–PAGE. Lanes 1–11 are proteins with pH 6, 6.5, 7, 7.5, 8, 8.5, 9, 9.5, 10, 11, and 12, respectively. The sizes of molecular mass markers are indicated on the left side of the gel.

depends on the length of air oxidation time and the pH of the buffer. The amount of FVS191cys (scFv)₂ increased with oxidation time and buffer pH. Figure 5 shows the formation of FVS191cys (scFv)₂ with varied pH after air oxidation for 12 days at 4 °C. From pH 6 to 9, increasing amounts of dimeric FVS191cys were found with the increments of pH (Figure 5, lanes 1–9). These data indicate that pH affects the formation of (scFv)₂ and basic buffer conditions favor dimer formation. When the pH was over 9, some of the FVS191cys degraded and some formed high-molecular mass aggregates. Therefore, the total amounts of dimers and monomers of FVS191cys with a pH of >9 were reduced (Figure 5, lanes 8–11).

The formation of FVS191cys (scFv)₂ was studied by using both DTT-nonreduced FVS191cys and DTT-reduced FVS191cys. Various reaction times and buffer pHs were investigated for the formation of FVS191cys (scFv)₂. The percentages of FVS191cys dimers under the above conditions were tabulated in Table 1.

Temperature Effect on Dimer Formation. FVS191cys (scFv)₂ can be formed at 4 °C, room temperature, and 37 °C as shown in Figure 6. At room temperature and 37 °C, high-molecular mass aggregates of FVS191cys were found (Figure 6, lanes 2 and 3). No aggregation of FVS191cys was visible at 4 °C (Figure 6, lane 1). A greater proportion of dimers was formed at room temperature than at 4 °C; however, at room temperature, FVS191cys formed aggregates that reduced the population of reactive FVS191cys. Therefore, 4 °C is the best condition for formation of (scFv)₂.

Specific CD19 Binding by FVS191cys (scFv)₂. A specific antigen binding assay was carried out with ¹²⁵I-labeled FVS191cys (scFv)₂. When the radioactivity associated with cell pellets of CD19 positive cells (Nalm 6) was arbitrarily expressed as 100%, the radioactivity associated with Molt 13 and Peer (CD19 negative cells) were determined to be only 6.2 and 7.9%, respectively. These results demonstrate that the FVS191cys (scFv)₂ is highly specific for CD19 antigen positive cells.

An ELISA assay was used to compare the CD19 binding ability of FVS191cys (scFv)₂ with that of mAb B43 or FVS191cys. Figure 7 indicates that the IC₅₀ of FVS191cys (scFv)₂ is 1.45×10^{-9} , the IC₅₀ of mAb B43 is 1.32×10^{-9} , and the IC₅₀ of monomeric FVS191cys is 1.05×10^{-9} . Therefore, the three different forms of B43-derived proteins have similar CD19 binding abilities.

Internalization by CD19⁺ Cells. FVS191cys (scFv)₂ was internalized by CD19⁺ Nalm 6 cells, as shown in Figure 8. The amount of internalized FVS191cys (scFv)₂ increased with time, and the amount of cell surface-bound FVS191cys (scFv)₂ decreased correspondingly. The amount of degraded and dissociated FVS191cys (scFv)₂ remained relatively constant.

DISCUSSION

In this report, we have described the production of FVS191cys, an anti-CD19 scFv engineered with a C-terminal cysteine, and demonstrated that FVS191cys forms a disulfide-linked homodimer.

In this study, the effects of air oxidation time, buffer pH, and temperature on the formation of dimeric FVS191cys were investigated for the purpose of defining the optimal conditions for dimer formation. Our results indicate that formation of disulfide-linked (scFv)₂ is dependent on oxidation time and pH. Specially, the yield of (scFv)₂ increases with time and pH.

The time dependence of (scFv)₂ formation is related to the size and tertiary structure of the scFv' protein. The solubility of thiols affects the reaction rate of the disulfide bond formation between two molecules; the longer the peptides, the harder it is for oxidation to occur (15). The scFv' has a mass of 28 kDa, which is large for a peptide, and is, therefore, slow to form (scFv)₂. If the C-terminal cysteine of scFv' is sterically hindered, it would be more difficult to form a disulfide bond.

The pH dependence of dimer formation is due to the oxidation process. There are two steps involved in the air oxidation of thiols: the formation of a thiolate anion and the formation of a thiyl radical by electron transfer between the thiolate anion and oxygen (15). Therefore, oxidation is promoted under basic conditions. In our case, the maximum yield of FVS191cys (scFv)₂ was achieved at pH 8.5 or 9. Above pH 9, although the ratio of dimer to monomer of FVS191cys was high, the dimer yield is low because the total amount of FVS191cys was decreased. The reduction of FVS191cys was due to the high pH in which FVS191cys was unstable and was degraded.

FVS191cys aggregates at temperatures above 4 °C. Different scFv's may have different intrinsic tendencies to form multimers or aggregates (16). Those tendencies may be related to the tertiary structures of the scFv' and the distribution of charged or uncharged amino acids on the surfaces of the scFv' molecules. At higher temperatures, the disulfide bond of scFv' was less stable; FVS191cys was more likely to form covalently linked multimers. Therefore, 4 °C was the best condition for formation of (scFv)₂.

FVS191cys (scFv)₂ can be formed from DTT-nonreduced FVS191cys; this indicates that DTT reduction is not necessary for dimer formation. However, McCartney et al. (16, 17) suggested that DTT reduction was a necessary step for forming (scFv)₂. Their different conclusion may have resulted from the different method that they used to refold scFv'. They used urea–glutathione redox buffer to refold 741F8 scFv'; the final concentration of oxidized glutathione in the refolding buffer was 100 mM. Their refolding method converted reduced thiol groups of scFv' to mixed disulfides with

^a The calculation of % d for dimers from DTT-nonreduced and DTT-reduced FVS191cys is described in Materials and Methods.

Figure 6. Formation of FVS191cys (scFv)₂ at 4 °C, room temperature, and 37 °C for 4 h. Proteins (50 μL) incubated at the above temperatures were electrophoresed on a 12% non-reducing SDS-PAGE: lane 1, proteins incubated at 4 °C; lane 2, proteins incubated at room temperature; and lane 3, proteins incubated at 37 °C. The sizes of molecular mass markers are indicated on the left side of the gel.

Figure 7. Affinity assay by competitive ELISA. Various amounts of FVS191cys (■), FVS191cys (scFv)₂ (●), and mAb B43 (○) were mixed up with a constant amount of B43-AP. The means of percentage inhibition of B43-AP binding were plotted against log molar concentrations of inhibition proteins. The bars represent a standard deviation.

glutathione; no thiol was available for forming a disulfide bond. Thus, DTT had to be used to eliminate the blocking group of C-terminal cysteines (16), and then the 741F8 (scFv)₂ was formed. In our study, however, we used DTE-GSSG redox buffer to refold FVS191cys; the final concentration of oxidized glutathione was 8 mM. Most FVS191cys compounds produced by our refolding method were not blocked by glutathione (data not shown). Therefore, DTT reduction was not necessary for formation of the FVS191cys (scFv)₂. DTT reduction is probably

Figure 8. Internalization of ¹²⁵I-labeled FVS191cys (scFv)₂ by Nalm 6 cells. The percentage of radioactivity calculated as the percentage of total CPM was plotted against each time point. At each time point, cell pellets were separated from supernatants by low-speed centrifugation: (Δ) acid-papain released, cell surface-bound FVS191cys (scFv)₂; (□) internalized FVS191cys (scFv)₂ which could not be released by acid-papain treatment; (○) dissociated FVS191cys (scFv)₂ which was precipitated by TCA from supernatant; and (▲) degraded FVS191cys (scFv)₂ which could not be precipitated by TCA from supernatants.

only necessary when the refolded scFv's are blocked by glutathione. Among the two dimer formation methods, our method has the advantages of fewer experimental steps and lower cost since GSSG is an expensive chemical.

It was also observed that the yields of FVS191cys (scFv)₂ from different preparations were variable. This phenomenon may be due to the differences in the protein concentration. The relationship between the concentration of scFv and the formation of (scFv)₂ was studied by Desplancq et al. (18). They reported that the proportion of associated dimer to monomer was a function of concentration, with an increased concentration of monomer leading to an increased proportion of dimers. Their study indicates that formation of (scFv)₂ can be improved by increasing the concentration of scFv. We found that there was an upper limit for the concentration of FVS191cys monomers. If the concentration of FVS191cys is over 1.5 mg/mL, it will aggregate. The optimal concentration of scFv' for dimer formation has to be studied individually since different scFv's have different tendencies to aggregate.

The CD19 binding assay with ¹²⁵I-labeled FVS191cys (scFv)₂ revealed the specific antigen binding ability of FVS191cys (scFv)₂. The ELISA assay indicated that the antigen binding ability of FVS191cys (scFv)₂ was similar to that of parental mAb B43 and monomeric FVS191cys.

Thus, dimers formed through C-terminal cysteines maintained the original antigen binding capability. This result is consistent with other reports (8, 9, 19). The ELISA assay with a (scFv)₂ derived from mAb215 showed that the binding constant was quite close to that of the parental mAb and 4-fold higher than those of the scFv' monomers (8). Dimeric ScAb, a bivalent single-chain antibody fragment against *Pseudomonas aeruginosa*, had an antigen binding profile similar to that of the parental antibody (19). These results indicate that dimeric scFv' has the same antigen binding characters as the intact antibody from which it was derived.

To our knowledge, FVS191cys (scFv)₂ is the first dimeric scFv' to be analyzed in an internalization assay. FVS191cys (scFv)₂ can be internalized by CD19⁺ cells in a manner similar to that of its parental mAb B43 (unpublished data). This result indicates that FVS191cys (scFv)₂ can potentially replace intact mAb as tumor targeting agents on the basis of their antigen binding and internalization ability.

ScFvs containing C-terminal cysteines have proved to be very useful molecules. So far, several homodimers of scFvs have been formed through the C-terminal cysteines (6, 8, 17). The other studies have shown that the free sulfhydryl groups of scFvcys can be used to form heterodimers (7) or immunoconjugates with other chemical agents (8). In our laboratory, FVS191cys has been used to form a single-chain immunotoxin containing ricin A chain (unpublished data). Utilization of engineered cysteine to form disulfide-bonded molecules has also been employed to generate bivalent (9, 20) and bispecific (21) recombinant antibodies.

An alternative method for producing bivalent scFv is expression of protein in an *E. coli* system in which the proteins are secreted periplasmically. In periplasmic space, the proteins are refolded and assembled into the dimeric form (22). This method is more attractive when the proteins of interest can be produced in a large amount. In our studies, scFv FVS191 was expressed in such a system, but the yield was low.

In conclusion, we have demonstrated a simple and efficient method for producing disulfide-linked dimeric scFv' through C-terminal cysteines. In this method, scFv' is refolded in DTE-GSSG buffer and dimeric scFv' is formed by air oxidation in high-pH buffer. The formation of FVS191cys (scFv)₂ through air oxidation is time- and buffer pH-dependent. We found the optimal conditions for forming dimeric FVS191cys by air oxidation to be 4 °C and a pH between 8.5 to 9. The FVS191cys (scFv)₂ has a CD19 binding ability similar to that of its parental mAb B43 and is internalized by CD19 positive cells. Therefore, FVS191cys (scFv)₂ may be a good candidate for immunotargeting while being one-sixth of the size of the intact mAb.

A series of chelating 4-(phenylethynyl)pyridines having various 1,3,5-triazin-2-ylamino groups at the *para* position of the phenyl ring was synthesized. Their europium chelates were coupled to antibodies and the properties of antibody conjugates analyzed by fluorometry and in time-resolved fluorometric immunoassay. The substituents in the triazine ring were observed to have various effects on the chelate luminescence, the labeling properties of the chelates, and the immunoreactivity of labeled antibodies. The series of substituted triazinyl derivatives serves as a model of bioreactive groups that can be applied when certain properties are searched for, such as improved chelate solubilities, minimized internal quenching, different effects on the ligand triplet state, and stipulated coupling reactivities.

INTRODUCTION

Due to their unique luminescence properties, such as high quantum yield, large Stokes shift, narrow-banded emission lines, and, in particular, the very long lifetime of the excited state, lanthanide chelates have found wide label applications in bioaffinity-based fluorometric assays (1, 2). The use of lanthanide chelates as probes in time-resolved fluorometry enables the reduction of background level and so markedly improves the assay sensitivities (3).

A dissociative fluorescence enhancement system, commercialized under the trade name of DELFIA by Wallac, is today the most widely used chelate label technology. It is based on binding reagents (e.g. antibodies) labeled with a stable but nonluminescent chelate and a dissociative fluorescence development performed after completion of immunoreactions and washings. The technology is widely applied in clinical diagnostics, *in vitro* DNA hybridizations, cytotoxicity assays, and receptor–ligand binding assays (2, 4–6). Another chelate label system applies a fluorogenic chelator as the label and after-assay cationic saturation (7, 8). The actual label in that system consists of a derivative of *o*-phenanthroline-2,9-dicarboxylic acid. The used tetradentate ligand does not, however, provide the stability and protection needed when the chelate is used as a directly luminescent label.

A large number of multidentate, highly luminescent, and stable lanthanide chelates have been synthesized to be used as labels in time-resolved fluorometry (9–13). Such a chelate omits the separate development step and opens up new time-resolved fluorometric applications, such as simplified assays, homogeneous assays, and microimaging (2, 8). In the majority of the chelates

reported so far, an aromatic isothiocyanato group is employed in coupling of the chelate to proteins. The isothiocyanato group offers a mild and efficient coupling well suited for antibody labelings (5, 9, 10). However, quite frequently there is a need for alternative coupling reagents, e.g. to find more reactive intermediates, more hydrophilic substituents (12), or substituents having less adverse effect on the ligand triplet state and causing less internal quenching (13–16). A cyanuric acid condensation product, the 4,6-dichloro-1,3,5-triazin-2-ylamino group (DTA), provides an alternative, more reactive, more hydrophilic, and less quenching reactive group (12–14, 16). Because of its reactivity, it can be used for labeling of other amino acid residues besides cysteine and lysine and even labeling of sugars. The high reactivity can also be a disadvantage. We have found that a number of monoclonal antibodies lose easily their affinity when conjugated with DTA-activated chelate (unpublished data).

The present study was conducted to evaluate various less reactive DTA derivatives and their effects on chelate luminescence and antibody functionality by replacing one of the chlorine atoms in the triazine ring with a suitable substituent. {[4-(4-Aminophenylethynyl)pyridine-2,6-diyl]bis(methylenenitrilo)}tetrakis(acetic acid) (13) was used as the fluorogenic ligand modified with different 6-substituted 2,4-dichloro-1,3,5-triazines and isothiocyanate and iodoacetyl groups for comparison (1–3; Figure 1) (13). We used a solid-phase immunometric assay of prostate-specific antigen (PSA) as a model.

EXPERIMENTAL PROCEDURES

Reagents. The anti-PSA antibody (clone H 50), anti-PSA (clone H 117) coated microtitration plates, PSA standards, assay buffer, wash solution, and DELFIA Enhancement solution were obtained from Wallac Oy, Turku, Finland. In immunoassays and in determinations of affinity constants for labeled antibodies, an alternative measurement solution, LANFIA, was used. LANFIA solution contains, per liter, 50 mmol of glycine, 1.75 mol of NaSCN, 2.0 mmol of Na₂CO₃, 5.0% glycerol, 0.0005% Tween 40, 4.5 μmol of DTPA, and 20% 1-propanol with

the final pH 10.0 (17). It dissociates immunocomplexes and creates optimized conditions for luminescence of that particular type of chelate. The assay buffers, other measuring buffers, and eluting buffers were based on TSA buffer consisting of 50 mM Tris-HCl, pH 7.75, 0.9% NaCl, and 0.05% NaN₃.

Equipment. Absorption spectra of the chelates were recorded with a Shimadzu UV-2100 spectrophotometer, emission spectra, luminescence yields, and decay times with a Perkin-Elmer LS5 luminescence spectrometer, and time-resolved fluorometric determinations of europium after the coupling reactions with a 1230 Arcus (Wallac Oy). Measurements of europium-labeled antibodies in immunoassays on microtitration plates were performed with a 1234 DELFIA Research fluorometer (Wallac Oy). A JEOL-JMN-GX400 spectrometer was used to record ¹H-NMR spectra at 400 MHz and a Perkin-Elmer 1600 FTIR spectrophotometer for IR spectra.

Synthesis of Activated Europium Chelates. General Synthesis of 6-Substituted 2,4-Dichloro-1,3,5-triazine (9–13, Scheme 1). A solution of alcohol (**4–6**) or thiol (**7, 8**) (12.0 mmol), acetone (5.0 mL), and 2,4,6-trimethylpyridine (1.45 g, 12.0 mmol) was slowly dropped into a cold solution of 2,4,6-trichloro-1,3,5-triazine (2.21 g, 12.0 mmol) in acetone (15.0 mL). The mixture was stirred for 0.5 h in an ice bath and for 3.0 h at room temperature and filtered. The filtrate was either evaporated to dryness or slowly poured into ice water, extracted with ethyl acetate, dried with Na₂SO₄, and evaporated to dryness. The product was purified by flash chromatography (FC).

2,4-Dichloro-6-(2-methoxyethoxy)-1,3,5-triazine (9): FC, silica gel, petroleum ether (40–60 °C)/ethyl acetate (5:2); yield, 80%; IR (film) 1544 ν(C=N), 1509 ν(C=N), 1347, 1303, 1254, 1055 cm⁻¹ ν(ether); UV (EtOH) 241 nm; ¹H NMR δ (CDCl₃) 3.42 (3 H, s), 3.75–3.77 (2 H, m), 4.64–4.66 (2 H, m).

2,4-Dichloro-6-(2-cyanoethoxy)-1,3,5-triazine (10): FC, silica gel, petroleum ether (40–60 °C)/ethyl acetate (5:1); yield, 43%; IR (film) 2257 ν(C≡N), 1544 ν(C=N), 1516 ν(C=N), 1360, 1307, 1257, 1058 cm⁻¹; UV (EtOH) 239 nm; ¹H NMR δ (CDCl₃) 2.91 (2 H, t, *J* = 6.5 Hz), 4.72 (2 H, t, *J* = 6.5 Hz).

Scheme 2. Synthesis of Europium(III) Chelates of 6-Substituted {2,2',2'',2'''}-[4-[4-[(4-Chloro-1,3,5-triazin-2-yl)amino]phenylethynyl]pyridine-2,6-diyl]-bis(methylenenitrilo)]tetrakis(acetic acid)} (15–19)

2,4-Dichloro-6-(2,2,2-trifluoroethoxy)-1,3,5-triazine (11): FC, silica gel, hexane/ethyl acetate (5:1); yield, 98%; IR (film) 1538 ν(C=N), 1303, 1259, 1172, 1085 cm⁻¹; UV (EtOH) 238 nm; ¹H NMR δ (CDCl₃) 4.90 (2 H, q, *J* = 7.9 Hz).

2,4-Dichloro-6-(thiophenoxy)-1,3,5-triazine (12): FC, silica gel, petroleum ether (40–60 °C)/ethyl acetate (10:1); yield, 28%; IR (film) 1505 ν(C=N), 1472 ν(C=N), 1260, 1244, 843 cm⁻¹; UV (EtOH) 263 nm; ¹H NMR δ (CDCl₃) 7.46–7.53 (3 H, m), 7.55–7.58 (2 H, m).

2,4-Dichloro-6-(ethoxycarbonylthiomethoxy)-1,3,5-triazine (13): FC, silica gel, petroleum ether (40–60 °C)/ethyl acetate (10:1); yield, 55%; IR (film) 1742 ν(C=O), 1515 ν(C=N), 1477 ν(C=N), 1304, 1266, 1244, 844 cm⁻¹; UV (EtOH) 260 nm; ¹H NMR δ (CDCl₃) 1.51 (3 H, t, *J* = 7.1 Hz), 4.17 (2 H, s), 4.47 (2 H, q, *J* = 7.1 Hz).

General Synthesis of Europium(III) Chelate of 6-Substituted {2,2',2'',2'''}-[4-[4-[(4-Chloro-1,3,5-triazin-2-yl)amino]phenylethynyl]pyridine-2,6-diyl]-bis(methylenenitrilo)]tetrakis(acetic acid)} (15–19, Scheme 2). A mixture of 6-substituted 2,4-dichloro-1,3,5-triazine (**9–13**) (0.10 mmol), acetone (1.0 mL), and water (1.0 mL) was added to a solution of compound **14** (**13**) (0.10 mmol) and 0.1 M NaOAc (1.5 mL, pH 4.9). After stirring for 30 min, the reaction mixture was treated with acetone, and the precipitate was centrifuged and washed with acetone. The purity of the chelates was tested with TLC plates. They were pure from any starting material. Before labeling, the chelates were dissolved in water and their europium concentrations were determined by using the DELFIA system.

Europium(III) Chelate of {2,2',2'',2'''}-[4-[4-[(4-Chloro-6-(2-methoxyethoxy)-1,3,5-triazin-2-yl)amino]phenylethynyl]pyridine-2,6-diyl]bis(methylenenitrilo)]tetrakis(acetic acid)} (15**):** IR (KBr) 2207 ν(C≡C), 1605, 1411 cm⁻¹ ν(C=O and C–O); UV (H₂O) 326, 298 (sh), 262 nm.

Europium(III) Chelate of {2,2',2'',2'''}-[4-[4-[(4-Chloro-6-(2-cyanoethoxy)-1,3,5-triazin-2-yl)amino]phenylethynyl]pyridine-2,6-diyl]bis(methylenenitrilo)]tetrakis(acetic acid)} (16**):** IR (KBr) 2207 ν(C≡C), 1605, 1411 cm⁻¹ ν(C=O and C–O); UV (H₂O) 326, 298 (sh), 262 nm.

Europium(III) Chelate of {2,2',2'',2'''-[4-[4-[4-Chloro-6-(ethoxycarbonylthiomethoxy)-1,3,5-triazin-2-yl]amino]phenylethynyl]pyridine-2,6-diyl]bis(methylenenitrilo)]tetrakis(acetic acid)} (19): IR (KBr) 2208 ν (C≡C), 1603, 1398 cm^{-1} ν (C=O and C–O); UV (H₂O) 330, 255 nm.

Labeling of Antibodies. The anti-PSA antibodies were labeled in 0.5 mg batches with different amounts of the chelates, either in carbonate buffer, pH 9.5, or borate buffer, pH 8.0. The conjugation was allowed to proceed at room temperature overnight. The effects of stoichiometric labeling ratio (Eu/IgG) and labeling pH (carbonate buffer at pH 10, 10.5, and 11) were further studied with the chelate 18. The labeling ratio was determined by measuring the europium concentrations of reagent solutions by the dissociative enhancement system (DELFA) (6). After the appropriate volume of stock solution was added, the labeling volume was adjusted to 1 mL. Labeled IgG fractions were purified by gel filtration on a column containing Sephadex G-50 (1.5 × 10 cm) and Sepharose 6B (1.5 × 30 cm) by eluting with TSA buffer. The labeling ratios were analyzed by recording UV absorbance at 280 and 330 nm (12) and by measuring the total europium concentrations (6).

Luminescence Properties of Chelate-Labeled Antibodies. Antibody-coupled chelates were characterized by absorption and by luminescence in various buffers. Europium (0.1 μM) in DELFIA Enhancement solution was used as a standard in spectrofluorimetry (luminescence yield, $\epsilon \times \Phi$, 26 300) (12). The measurement time was adjusted from 10 μs to 5 ms to integrate all emissions of each chelate regardless of decay time. The buffers were TSA buffer containing 0.5% bovine albumin and the LANFIA solution. The emission intensities of the most intense emission line ca. 613 nm are recorded.

Determination of Antibody Affinities, Specific Binding, and Nonspecific Binding. The affinities of the antibody conjugates were measured as previously described (18). Microtitration plate coated with anti-PSA antibody were first incubated with 1 ng of PSA in 25 μL of TSA buffer containing 7.5% bovine serum albumin. Thereafter, six different concentrations of labeled antibodies (from 6.25 to 200 ng in 100 μL of DELFIA assay buffer) were added and incubated at room temperature

for 2 h with slow shaking. After washings, the bound europium was measured with the DELFIA system (6). After the portion of nonspecific binding was subtracted from each value, the affinity was calculated according to the method of Scatchard (19). A sandwich assay of PSA was used to analyze the specific binding of labeled antibodies using 100 ng/mL PSA standard and nonspecific binding using zero calibrator.

RESULTS AND DISCUSSION

The reaction between 2,4,6-trichloro-1,3,5-triazine and suitable alcohols (4–6) or thiols (7, 8) in acetone and 2,4,6-trimethylpyridine gave only 6-substituted 2,4-dichloro-1,3,5-triazines (9–13, Scheme 1) without any formation of di- or trisubstituted byproducts. The syntheses of activated chelates (15–19) were performed by coupling triazines (9–13) to the europium(III) chelate having an aromatic amino group (14) (Scheme 2) (13).

The labeling properties of the chelates 1–3 and 15–19 were studied by labeling anti-PSA antibodies both in a borate buffer, pH 8.0 and in a carbonate buffer, pH 9.5. Chelate concentrations were adjusted (from 200- to 500-fold molar excess in pH 8.0 and from 20- to 50-fold in pH 9.5) to obtain similar degrees of labeling. The labeling efficiencies (given as percentage binding from the amount added), obtained ratios (Eu/IgG), aggregations (the percentage of protein aggregation), and affinities are given in Table 1. The DTA group (3) clearly had the highest labeling efficiency (4% at pH 8.0 and 26.5% at pH 9.5). Substitution of one chlorine atom in the triazine ring (15–19) decreased the reactivity to varying degrees. In all substituents, the labeling efficiency was greatly improved when pH was increased from 8 to 9.5, due to increased deprotonation of amino groups. In contrast to isothiocyanate coupling, which according to our experience tends to cause aggregations, losses of affinity, and increased nonspecific binding backgrounds when the labeling is done at high pH values (20), labeling with DTA and DTA derivatives resulted in higher affinities and less aggregations when done at pH 9.5 as compared to 8.0 (Table 1). The somewhat negative effect of DTA coupling to anti-PSA antibody was partly eliminated by chlorine substitutions (chelates 18 and 19).

The luminescence properties of the chelate-labeled antibodies are given in Table 2. In TSA buffer with albumin, the luminescence yields ($\epsilon \times \Phi$) are relatively analogous regardless of the activation method with the exception of isothiocyanate, which has clearly lower luminescence in TSA buffer. The decay times of these heptadentate chelates ($\approx 390 \mu\text{s}$) confirm that the remaining two coordination sites of the europium ion are occupied by two water molecules (20). In LANFIA solution the decay time is increased from 380–400 to over 800 μs (Table 2), as a result of either optimized environ-

**Figure 2.** Effect of labeling degree on the affinity of anti-PSA antibody. Labelings were done at pH 10.5 with increasing amounts of chelate **18**.

ment and decreased quenching or the replacement of the coordinated water molecules.

The effect of labeling pH was further evaluated with thiophenoxy derivative (**18**) by labeling anti-PSA antibodies in a series of increasing pH values (from 8.0 to 11.0). The analyzed affinities, specific signals, and backgrounds (normalized by dividing with labeling yield) are given in Table 3. The results confirm the data given in Table 1. The increase of pH up to pH 10.5 resulted in less decrease in affinity. On the other hand, there was a slight but clear increase in nonspecific binding beyond pH 9.5. These data are not, however, sufficient to accurately determine the optimum conjugation pH for that combination.

The effect of increasing labeling yields on the antibody affinity was studied by labeling anti-PSA antibody at pH 10.5 with increasing amounts of the thiophenoxy derivative (**18**). Increase in Eu/IgG steadily decreased the affinity from 16.4×10^8 with 1.8 Eu/IgG to 3.3×10^8 with 13.4 Eu/IgG (Figure 2). As shown earlier (13), the total luminescence of chelate-labeled antibody correlates directly with the labeling level, because the long Stokes shift eliminates inner filter quenching. In an immunoassay, the 5 time difference in affinity was compensated by a 7.4-fold increase in signal, and without extensive further studies, the data does not give definite answer to eventual optimal labeling level.

The performance of the labeled antibodies was briefly validated with the model assay of PSA. The correlation between the actual signal and antibody affinity, however, was poor. The signal correlated slightly better with relative luminescence intensities (data not shown). The poor correlation may relate to imprecisions in measured values or unknown factors related to immunoassays. Similarly, the nonspecific binding (highest with conjugates of chelate **18** and lowest of chelates **15** and **16**) did not exactly correlate with observed aggregation percentages (highest with **15**, **16**, and **18**).

As a conclusion, our study showed that the modifications of the reactive groups on the luminescent chelate both changed the luminescence properties of the chelate and had an impact on the immunoreactivity of labeled antibodies. The triazinyl derivatives provide a wide range of alternatives with various reactivities, hydrophilic properties, and various effects on antibody affinity and nonspecific binding properties. Despite the fact that the chosen model chelate did not clearly reveal the differences between the different substitutions (due to its high hydrophilicity and less critical triplet state energy), the DTA coupling and its modifications serve as valuable tools, particularly for larger, more hydrophobic chelates, in labelings where DTA may be too aggressive and with terbium chelates with ligands having a triplet state at a critical energy level.

Chromogenic Lactate–Leukocyte Esterase Substrates

Gary M. Johnson* and Robert Schaeper

Diagnostics Division, Bayer Corporation, Elkhart, Indiana 46515. Received June 24, 1996[®]

The first successful reported use of lactate-based chromogenic, colorimetric substrates for a serine protease-based enzyme is described. A series of hydroxy-protected 5-phenyl-3-hydroxypyrrolyl L-lactate substrates of the general formula RO-Lac-OPP were prepared and formulated into reagents for the determination of leukocytes in dry phase formats.

INTRODUCTION

The presence of leukocytes in urine is indicative of inflammation or infection. Human leukocyte elastase (HLE) is a serine protease contained within leukocytes, which is associated with physiological processes (1, 2) such as rheumatoid arthritis, adult respiratory distress syndrome, glomerulonephritis, pulmonary emphysema, and phagocytosis. Over the past 20 years, many types of substrates (3–9) have been developed to study the reactivity and specificity of HLE. One substrate (10) has been used to detect HLE in biological fluids as a diagnostic reagent strip in a urinary leukocyte assay (10, 11) known as LEUKOSTIX.

The assay operates by the general principle outlined in Scheme 1 using a test strip containing the reagents 3-[(*N*-tosylalaninyl)oxy]-5-phenylpyrrole (PPTA) and 4-sulfo-1,2-naphthoquinone 1-diazide (DNSA). When a urine sample containing HLE is applied to the strip, the enzyme catalyzes the hydrolysis of PPTA. This releases 3-hydroxy-5-phenylpyrrole (HOPP), which reacts with the diazide to produce a colored azo dye. The concentration of leukocytes in the sample is estimated by comparing the intensity of the final color to a standard color chart or by measuring the reflectance with a clinical reflectance meter such as CLINITEK-10.

We were interested in identifying new classes of HLE substrates that yield similar or greater sensitivity toward HLE. We report herein the synthesis and evaluation of a new class of chromogenic, colorimetric esterase substrates, hydroxy-protected 5-phenyl-3-hydroxypyrrolyl L-lactates (12) of the general formula RO-Lac-OPP. These substrates have reactivity and stability comparable to that of the corresponding isostere substrate 5-phenyl-3-hydroxypyrrolyl tosyl-L-alaninate (10), Ts-Ala-OPP.

CHEMISTRY

The synthesis of 3-(*O*-tosyl-L-lactoyl)-5-phenylpyrrole (TsO-Lac-OPP, **4a**) depicted in Scheme 2 is typical of the sequence used to prepare the lactic acid substrates (12) (RO-Lac-OPP, **4a–e**). Tosyl chloride is added to L-lactic acid ethyl ester in the presence of TEA to provide the intermediate *O*-tosyl ester (**1a**), in a 91% yield. This intermediate is then hydrolyzed with ethanolic NaOH at 0 °C, which after acidic workup provides the intermediate *O*-tosyl acid (**2a**) in a 76% yield. The acid (**2a**) is then quantitatively converted into the corresponding acid chloride (**3a**) with neat thionyl chloride. **3a** was then added to a chilled solution of 3-hydroxy-5-phenylpyrrole (HOPP) in the presence of pyridine at 0 °C to provide TsO-Lac-OPP (**4a**) in a 71% yield before purification.

Table 1 summarizes the synthesized chromogenic lactic acid substrates (**4a–e**), prepared similarly in like yields.

RESULTS AND DISCUSSION

It is well established (13) that hydrolysis of synthetic substrates by the serine protease HLE requires a small alkyl amino acid such as alanine or valine at the P₁ site as demonstrated by the substrate 5-phenyl-3-hydroxypyrrolyl tosyl-L-alaninate, Ts-Ala-OPP [the nomenclature of Schechter and Berger (14) is used to designate the individual amino acid residue (P₁, P₂, P_{1'}, or P_{2'}) of a peptide substrate]. Likewise, diagnostic test strips that detect the presence of HLE contain an alanine substrate along with a diazonium salt that acts as the color-generating system (Scheme 1).

The reactivity of these types of dry reagent strips toward an analyte is generally quantified by monitoring the intensity of reflected light at specific wavelengths (i.e. 557 nm for the LEUKOSTIX reagent) and applying the standard Kubelka–Munk equation (28): $K/S = (1 - R)^2 / (2R)$, where K = the absorption coefficient, S = the scattering coefficient, and R = the intensity of reflected light. Use of the equation permits color development to be proportional to analyte concentration. In addition, for the LEUKOSTIX reagent, linear kinetics are also observed over 2 min when the equation is applied.

In an average urine specimen, diagnostic reagent strips that contain an alanine substrate detect in 2 min at least 19 ng/mL HLE, which is the trace response with the LEUKOSTIX reagent strip. Lactic acid, is the non-amino acid, oxygen isostere of alanine, and it is well established that changes made to the substrate can dramatically affect the hydrolysis kinetics (15). Published work (15–22) on lactate derivatives with orientations at P₁ has previously shown that lactates act as inhibitors. Table 2 shows that the direct substitution of the phenylpyrrole ester of alanine with the phenylpyrrole ester of lactic acid produces a highly reactive substrate. As with its alanine parent, an assay incorporating this lactate derivative readily detects 19 ng/mL HLE. Similarly, Table 3 shows that substitutions made to the N terminus also produce reactive substrates. In each case, the assays using the lactate substrates readily detect 19 ng/mL HLE.

The substrates listed in Tables 2 and 3 contain an *N*-tosyl CH₃-phenyl-SO₂ terminal group, while conventional HLE substrates (13) generally contain amide linkages. Jackson et al. (23) recently confirmed that the N-terminal group dramatically influences reaction kinetics. Substituting a sulfonyl group for the amide group is shown to enhance the hydrolysis kinetics (23). Thus, Table 4 shows a dramatic decrease in hydrolysis when the sulfonyl group is changed to a C=O group. It is known (23, 24) for both the *N*-tosyl alaninate ester and

[®] Abstract published in *Advance ACS Abstracts*, January 1, 1997.

the *N*-carbobenzoxy alaninate ester substrates that the rate-limiting step is the deacylation of the enzyme–acyl intermediate. The dramatic change observed in the hydrolysis rates when the *N*-terminal C=O group is incorporated suggests that the acyl enzyme deacylates faster with sulfonyl groups.

The performance of lactate substrates with different types of *N*-sulfonyl groups shown in Table 3 is similar to

and at times superior to that of the natural alanine amino acid substrates. Thus, a wide variety of blocking groups can be used, ranging from simple alkyl through aromatic groups. Many functional groups can be envisioned, and this work would anticipate that such substrates would be highly reactive, providing that a sulfonyl group exists between the functional group and the O terminus of the lactate.

In this paper, we have demonstrated that lactate esters can act as substrates for HLE. Other groups (15–22) utilizing different enzymes and different substrates indicate that lactate esters either directly or indirectly affect enzymatic reactivity. Much of the previous work focused on designing inhibitors of HLE and other enzymes. In the chymotrypsin work of Ingles (25), he reported a 10-fold decrease in the enzymatic rate and a decrease in stereospecificity when phenyl lactate was substituted for phenylalanine. It was suggested that an important hydrogen-bonding interaction has been eliminated. An additional explanation for the apparent change in reactivity was found during the course of our experiments. We observed that, in the presence of 0.25 M NaCl, the reactivity of the lactate derivatives decreases by 33%. Consequently, experimental conditions such as ionic strength can influence the observed reactivity.

SUMMARY

In summary, it is well established that simple amino acid compounds can function as colorimetric, chromogenic HLE enzyme substrates. In this manuscript, we have demonstrated that lactate esters of varying length and functional composition act as highly reactive substrates for human leukocyte elastase.

MATERIALS AND METHODS

HLE was obtained from Athens Research Technology (Athens, GA). Buffer salts were analytical grade from

Fisher or Aldrich. DMSO and acetone were obtained from J. T. Baker, Inc. (Phillipsburg, NJ), and decanol was from Sigma Chemical Co. (St. Louis, MO). Polyvinylpyrrolidone (PVP) was obtained from Polysciences Inc. (Warrington, PA). Diazonium salts were prepared as previously described (26).

IR spectra were recorded on a Perkin-Elmer 710B spectrophotometer. NMR spectra were recorded on a GE 300NB-MHz spectrometer. Mass spectra were determined on a HP5985A instrument by fast atom bombardment (FAB) with direct introduction. Thin layer chromatography was carried out on Merck GF 254 silica plates. Optical rotations were determined on a PE141 polarimeter. C/H/N analyses were done by Galbraith Labs (Knoxville, TN).

HLE was dissolved in 50 mM sodium acetate (pH 4.5) buffer, and the concentration of HLE was determined spectrophotometrically according to the method of Baugh and Travis (29). Reagent papers were prepared by impregnating Whatman 3M filter paper with 0.8 M borate/NaOH (pH 8.8) buffer containing 1% PVP K60 and dried in an air foil dryer. The dried paper was subsequently immersed in a solution containing 1.1 mM substrate, 0.7 mM 6-nitro-1,2-naphthoquinone diazide, 1.5% decanol, and 3% DMSO and then dried as above. The reagent paper was made into reagent test strips that consisted of 0.2 in. squares of the final impregnated paper, which was adhered via double-stick adhesive to a polystyrene carrier. The reagent strip was quickly immersed in the testing solution [100 mM NaOAc (pH 5.6), 4 mM benzoic acid, 0.0025% yellow #7, and 0.00002% red #40] that contained 0 or 19 ng/mL HLE. After 2 min, the color intensity was measured with a clinical reflectance meter, the CLINITEK-10. The intensity of the reflected light was quantified by applying the standard Kubulka–Monk equation (28).

EXPERIMENTAL PROCEDURES

Step 1. To L-lactic acid ethyl ester (5.00 g, 4.81 mL, 42.3 mmol) in CH₂Cl₂ (50 mL) at 0 °C (ice bath), under argon, was added tosyl chloride (8.1 g, 42.3 mmol) in one portion with stirring. Triethylamine (5.57 g, 7.67 mL, 55 mmol) was added dropwise via syringe, and the reaction mixture was stirred for 7 h at 0 °C. The reaction mixture was then poured over a solution of 1 M aqueous HCl (75 mL) and ice (75 g). After separation, the organic layers were dried over MgSO₄, filtered, and concentrated *in vacuo* to give 10.5 g (91%) of crude product (1a).

Step 2. The crude L-tosyl lactate ethyl ester (10.5 g, 38.6 mmol, 1a) in absolute ethanol (12 mL) was added dropwise via addition funnel (1/4 h) to a chilled (0 °C, ice bath) solution of NaOH (1.8 g, 46 mmol) in distilled water (20 mL). After the mixture was stirred for 5 h under argon at 0 °C, the reaction was carefully quenched via dropwise addition of concentrated HCl to pH 2. Solid NaCl was added to saturation, and the aqueous layer was extracted with CH₂Cl₂ (4 × 50 mL). The organic phase was then dried over MgSO₄, filtered, and concentrated *in vacuo* to give 7.17 g (76%) of crude product (2a).

Step 3. The crude L-O-tosyllactic acid (1.50 g, 6.15 mmol, 2a) was placed in a 25 mL round bottom flask under argon equipped with a reflux condenser. Thionyl chloride (10.12 g, 6.2 mL, 85 mmol) was added in one portion and the reaction mixture placed into an oil bath, preheated to 50 °C, and stirred for 2 h. The reaction mixture was then cooled and placed in an ice bath, and ice cold hexane (25 mL) was added. When no solid product was observed, the solution was concentrated *in vacuo* to give 1.6 g (quantitative) of crude yellow oil (3a).

Step 4. To a chilled solution (0 °C, ice bath) of 5-phenyl-3-hydroxypyrrole (986 mg, 6.20 mmol) in CH₂-Cl₂ (30 mL) under argon was added pyridine (1.5 mL, 18.6 mmol) dropwise via syringe, followed immediately by rapid dropwise addition of a solution of L-*O*-tosyllactic acid chloride (1.60 g, 6.11 mmol, **3a**) in CH₂Cl₂ (5.0 mL). The residual contents were then added dropwise with an additional 5.0 mL of CH₂Cl₂. The reaction mixture was stirred for 1 h at 0 °C, allowed to come to room temperature over approximately 1 h further, and then stirred overnight at room temperature (16 h).

The reaction mixture was then extracted with aqueous 1 M HCl (2 × 25 mL), and the combined aqueous phases were back-extracted with CH₂Cl₂ (25 mL). The combined organic layers were then extracted with saturated aqueous bicarbonate (2 × 25 mL). After back-extraction of the basic aqueous phase, the combined organic layers were treated with norite carbon and MgSO₄, filtered, and concentrated *in vacuo*. The resulting oil was dissolved in hexane/EtOAc (1:1, 25 mL), treated with norite carbon once more, filtered, and concentrated *in vacuo* to give 1.7 g (71%) of solid crude product (**4a**).

This material was triturated with warm hexane (10 mL) followed by hexane/EtOAc (4:1, 2 × 8 mL), and decanted, and the resultant solid was dried under vacuum to provide 1.04 g of a pink solid. This material was dissolved in hexane/EtOAc (1:1), treated with norite carbon, filtered, and concentrated *in vacuo* at room temperature to give 932 mg (unoptimized yield) of creme product (**4a**).

Product 4a: ¹H NMR (300 MHz, CDCl₃, ppm) 1.65 (d, 3H), 2.42 (s, 3H), 5.12 (qu, 1H), 6.26 (dd, 1H), 6.84 (dd, 1H), 7.18–7.5 (m, 7H), 7.84 (d, 2H), 8.15 (brs, 1H); ¹³C NMR (75 MHz, CDCl₃, ppm) 18.51 (methyl), 21.66 (methyl), 73.96 (CH, lactate), 93.39 (CH, pyrrole), 107.89 (CH, pyrrole), 123.84 (CH, aromatic), 126.85 (CH, aromatic), 128.12 (CH, aromatic), 128.97 (CH, aromatic), 129.87 (CH, aromatic), 166.68 (C=O); EI/MS (18 EV, DIP) 385 (M⁺, 21.8), 227 (2.3), 199 (22.4), 158 (67.5), 155 (BASE), 91 (41.7); IR: (CDCl₃, cm⁻¹) 3450, 3022, 1770, 1600, 1570, 1550, 1514, 1450, 1370, 1260, 1240; optical rotation (λ = 578 nm) 10 mg sample, 1 mL of MeOH, room temperature, 1 cm cell, -64.8°. Anal. Calcd: C, 62.39; H, 4.97; N, 3.63; S, 8.33. Found: C, 62.44; H, 5.03; N, 3.57; S, 8.65.

Product 4b: ¹H NMR (300 MHz, CDCl₃, ppm) 1.10 (t, 3H), 1.75 (d, 3H), 2.20 (m, 2H), 3.30 (m, 2H), 5.35 (qu, 1H), 6.41 (dd, 1H), 6.95 (dd, 1H), 7.20–7.60 (m, 5H), 8.30 (brs, 1H); ¹³C NMR (75 MHz, CDCl₃, ppm) 12.87 (methyl), 17.23 (methylene), 18.59 (methyl), 53.64 (methylene), 73.49 (CH, lactate), 98.32 (CH, pyrrole), 107.94 (CH, pyrrole), 123.86 (CH, aromatic), 126.90 (CH, aromatic), 128.96 (CH, aromatic), 166.5 (C=O); FAB/MS 337.2 (M⁺, 55), 159 (BASE); IR: (CDCl₃, cm⁻¹) 3400, 3010, 2980, 1768, 1573, 1512, 1454, 1400, 1360, 1254, 1169; optical rotation (λ = 578 nm) 13 mg sample, 1 mL of MeOH, room temperature, 1 cm cell, -48.5°. Anal. Calcd: C, 56.97; H, 5.64; N, 4.15; S, 9.49. Found: C, 57.06; H, 5.75; N, 3.87; S, 9.91.

Product 4c: ¹H NMR (300 MHz, CDCl₃, ppm) 1.75 (d, 3H), 5.55 (qu, 1H), 6.40 (dd, 1H), 6.95 (dd, 1H), 7.15–7.7 (m, 8H), 8.1 (d, 2H), 8.2 (brs, 1H); ¹³C NMR (75 MHz, CDCl₃, ppm) 17.13 (methyl), 69.08 (CH, lactate), 98.57 (CH, pyrrole), 108.03 (CH, pyrrole), 123.82 (CH, aromatic), 126.68 (CH, aromatic), 128.41 (CH, aromatic), 128.89 (CH, aromatic), 129.91 (CH, aromatic), 133.33 (CH, aromatic), 165.98 (C=O), 166.48 (C=O); EI/MS (18 EV, DIP) 335 (M⁺, 3.1), 177 (42.8), 149 (22.2), 105 (BASE), 77 (0.7); IR: (CDCl₃, cm⁻¹) 3400, 3000, 1763, 1723, 1606, 1585, 1573, 1512, 1452, 1318, 1177; optical

rotation (λ = 578 nm) 12 mg sample, 1 mL of MeOH, room temperature, 1 cm cell, +13.3°. Anal. Calcd: C, 71.64; H, 5.07; N, 4.18. Found: C, 71.92; H, 5.22; N, 4.28.

Product 4d: ¹H NMR (300 MHz, CDCl₃, ppm) 1.78 (d, 3H), 1.98 (t, 2H), 2.62 (t, 2H), 2.75 (s, 3H), 5.37 (qu, 1H), 6.42 (brs, 1H), 6.98 (brs, 1H), 7.2–7.55 (m, 5H), 8.2 (brs, 1H); ¹³C NMR (75 MHz, CDCl₃, ppm) 18.52 (methyl), 28.42 (methylene), 47.29 (methylene), 52.4 (methyl), 74.14 (CH, lactate), 98.37 (CH, pyrrole), 107.93 (CH, pyrrole), 123.89 (CH, aromatic), 126.94 (CH, aromatic), 128.98 (CH, aromatic); FAB/MS 381 (M⁺, 63), 186 (8.5), 159 (BASE), 91 (12), 55 (24.5); IR: (CDCl₃, cm⁻¹) 3450, 3000, 1751, 1741, 1572, 1513, 1453, 1439, 1359, 1319, 1255; optical rotation (λ = 578 nm) 7 mg sample, 1 mL of MeOH, room temperature, 1 cm cell, -27.1°. Anal. Calcd: C, 53.54; H, 4.99; N, 3.67; S, 8.39. Found: C, 53.05; H, 5.07; N, 3.41; S, 7.75.

Product 4e: ¹H NMR (300 MHz, CDCl₃, ppm) 1.70 (d, 3H), 5.19 (qu, 1H), 6.32 (dd, 1H), 6.85 (dd, 1H), 7.12 (t, 1H), 7.20–7.50 (m, 5H), 7.70 (dd, 1H), 7.79 (dd, 1H), 8.19 (brs, 1H); ¹³C NMR (75 MHz, CDCl₃, ppm) 18.44 (methyl), 74.91 (CH, lactate), 98.34 (CH, pyrrole), 107.90 (CH, pyrrole), 123.85 (CH, aromatic), 126.85 (CH, aromatic), 127.54 (CH, thiophene), 128.95 (CH, aromatic), 134.09 (CH, thiophene), 134.71 (CH, thiophene); EI/MS (18 EV, DIP) 377 (M⁺, 63.1), 236 (4.4), 191 (13.8), 164 (4.9), 159 (BASE), 147 (66.1), 99 (8.2), 83 (1.1); IR (CDCl₃, cm⁻¹) 3450, 3050, 2940, 1760, 1573, 1509, 1453, 1404, 1378; optical rotation (λ = 578 nm) 12 mg sample, 1 mL of MeOH, room temperature, 1 cm cell, -34.3°. Anal. Calcd: C, 54.1; H, 3.98; N, 3.71; S, 16.98. Found: C, 53.4; H, 4.16; N, 3.69; S, 16.81.

Peptide-Mediated Gene Delivery: Influence of Peptide Structure on Gene Expression

Manpreet S. Wadhwa,[†] Wendy T. Collard, Roger C. Adami, Donald L. McKenzie, and Kevin G. Rice*

Divisions of Medicinal Chemistry and Pharmaceutics, College of Pharmacy, University of Michigan, 428 Church Street, Ann Arbor, Michigan 48109. Received September 13, 1996[®]

Cationic peptides possessing a single cysteine, tryptophan, and lysine repeat were synthesized to define the minimal peptide length needed to mediate transient gene expression in mammalian cells. The N-terminal cysteine in each peptide was either alkylated or oxidatively dimerized to produce peptides possessing lysine chains of 3, 6, 8, 13, 16, 18, 26, and 36 residues. Each synthetic peptide was studied for its ability to condense plasmid DNA and compared to polylysine₁₉ and cationic lipids to establish relative *in vitro* gene transfer efficiency in HepG2 and COS 7 cells. Peptides with lysine repeats of 13 or more bound DNA tightly and produced condensates that decreased in mean diameter from 231 to 53 nm as lysine chain length increased. In contrast, peptides possessing 8 or fewer lysine residues were similar to polylysine₁₉, which bound DNA weakly and produced large (0.7–3 μ m) DNA condensates. The luciferase expression was elevated 1000-fold after HepG2 cells were transfected with DNA condensates prepared with alkylated Cys-Trp-Lys₁₈ (AlkCWK₁₈) versus polylysine₁₉. The gene transfer efficiencies of AlkCWK₁₈ and cationic lipids were equivalent in HepG2 cells but different by 10-fold in COS 7 cells. A 40-fold reduction in particle size and a 1000-fold amplification in transfection efficiency for AlkCWK₁₈ DNA condensates relative to polylysine₁₉ DNA condensates suggest a contribution from tryptophan that leads to enhanced gene transfer properties for AlkCWK₁₈. Tryptophan-containing cationic peptides result in the formation of small DNA condensates that mediate efficient nonspecific gene transfer in mammalian cells. Due to their low toxicity, these peptides may find utility as carriers for nonspecific gene delivery or may be developed further as low molecular weight DNA condensing agents used in targeted gene delivery systems.

Nonviral gene delivery systems are being developed to transfect mammalian host cells with foreign genes (1–3). Plasmids encoding transgenes are complexed with carriers that facilitate the transfer of the DNA across the cell membrane for delivery to the nucleus. The efficiency of gene transfer into cells directly influences the resultant gene expression levels. Thereby, optimizing transfer efficiency is often necessary to achieve therapeutically relevant gene expression levels in a variety of host cells (4, 5).

Nonviral gene delivery systems rely on carrier molecules to bind and condense DNA into small particles that facilitate DNA entry into cells through endocytosis or pinocytosis (1). In addition, the carrier molecules act as scaffolding to which ligands may be attached to achieve site specific targeting of DNA (6–15).

The most commonly used DNA condensing agent for the development of nonviral gene delivery systems is polylysine in the size range of dp 90–450 (6–15). Its amino groups have been derivatized with asialoorosomucoid, transferrin, carbohydrates, folate, lectins, antibodies, or other proteins to provide specificity in cell recognition, without compromising its binding affinity for DNA (6–15). However, the high molecular weight and polydispersity of polylysine also contribute to a lack of chemical control in coupling macromolecular ligands, which leads to heterogeneity in polylysine-based carrier molecules. This can complicate the formulation of DNA

carrier complexes and limits the ability to systematically optimize carrier design to achieve maximal efficiency (16, 17).

To refine targeted gene delivery carriers aimed at transfecting hepatocytes via the asialoglycoprotein receptor, we previously developed a low molecular weight carrier (4500) by attaching a single complex carbohydrate ligand to low molecular weight polylysine (dp 19) (18). This glycopeptide bound to DNA and efficiently transfected HepG2 cells *in vitro* via the asialoglycoprotein receptor, establishing that low molecular weight glycopeptide carriers can function as efficiently as a macromolecular glycoconjugate carriers. However, despite the low molecular weight of this glycopeptide, the polydispersity of polylysine₁₉ and the lack of control of the carbohydrate coupling site both contributed to heterogeneity, limiting further opportunity for optimization.

In the present study we have taken the next step toward developing homogeneous glycopeptide carriers by attempting to define the minimal polylysine chain length that leads to DNA condensation. Earlier studies examined the influence of polylysine chain length for transferrin–polylysine-mediated gene delivery and found that the transfection efficiency decreased below dp 300 (12, 19). Another study examined the particle size of DNA condensates produced with polylysine varying in size from dp 30 to 1500 and found that low molecular weight polylysine condensed DNA into small particles (20–30 nm) and was also less toxic to cells in culture (20). Still others have quantitatively examined the binding of lysine-rich peptides (dp 3–10) to single- and double-stranded oligonucleotides and noted an enhancement in the binding affinity when increasing polylysine chain length up to dp 10 (21–23). Notably, the peptides utilized in these studies contained a tryptophan residue that allowed monitoring of DNA binding via fluorescence.

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1996.

A recent paper also highlighted the utility of a low molecular weight peptide (dp 13) possessing a lysine repeat of 8 as a DNA condensing for enhancing gene transfer (24). When coformulated with a fusogenic peptide and a plasmid encoding luciferase, this peptide mediated gene transfer in several cell lines, including hepatocytes, with efficiency comparable to that of cationic lipid mediated gene delivery.

The synthetic peptides used in the present study also possess a lysine repeat, which was varied from 3 to 36 residues and incorporated one or more tryptophan and cysteine residues. The results establish that a peptide of 13–18 lysine residues possessing a single tryptophan residue enhances gene transfer to cells in culture by up to 3 orders of magnitude relative to comparable polylysine peptides lacking a tryptophan. The mechanism of peptide-mediated gene transfer is related to the efficiency of condensing DNA into small particles. It is proposed that tryptophan plays a specific role in organizing the DNA binding of cationic peptides to produce small condensates that exhibit enhanced gene transfer efficiency. Therefore, tryptophan-containing peptides represent a new class of low molecular weight condensing agents that may be modified with ligands to produce low molecular weight carriers for site specific gene delivery.

MATERIALS AND METHODS

N-terminal Fmoc protected amino acids, and all other reagents for peptide synthesis, were obtained from Advanced ChemTech, Lexington, KY. Minimum essential media (MEM¹), Sephadex G-25, dithiothreitol, iodoacetamide, iodoacetic acid, and polylysine₁₉ (MW 1000–4000) were purchased from Sigma Chemical Co., St. Louis, MO. Ethanedithiol (EDT) was purchased from Aldrich Chemical Co., Milwaukee, WI. Trifluoroacetic acid (TFA) was purchased from Fisher Scientific, Pittsburgh, PA. LB media, LB agar, D-luciferin, and luciferase from *Photinus pyralis* (EC 1.13.12.7) were obtained from Boehringer Mannheim, Indianapolis, IN. HepG2 and COS 7 cells were from the American Type Culture Collection, Rockville, MD. Dulbecco's modified Eagle medium (DMEM), media supplements, and heat inactivated "qualified" fetal bovine serum (FBS) were from Gibco BRL, Grand Island, NY. Bradford reagent was purchased from Bio-Rad, Hercules, CA, and thiazole orange was a gift from Beckton Dickinson Immunocytometry Systems, San Jose, CA. The 5.6 kb plasmid pCMVL encoding the reporter gene luciferase under the control of the cytomegalovirus promoter was a gift from Dr. M. A. Hickman at the University of California, Davis. Peptide purification was performed using a semipreparative (10 μ m) C₁₈ RP-HPLC column from Vydac, Hesperia, CA. HPLC was performed using a computer-interfaced HPLC and fraction collector from ISCO, Lincoln, NE.

DNA Purification and Peptide Synthesis. Plasmid DNA was prepared by the alkaline lysis method and purified on cesium chloride gradient (25). Peptides were prepared by solid phase peptide synthesis on Fmoc-L-Boc-lysine-Wang resin (*p*-benzyloxybenzyl alcohol resin, 1% divinyl benzene cross-linked, 100–200 mesh) at a 136 μ mol scale (0.68 mmol/g resin). The synthesis was

accomplished using a computer-interfaced Model 90 synthesizer from Advanced Chemtech. Lysine and tryptophan side chains were Boc protected, and the sulfhydryl side chain of cysteine was protected with a trityl group. A 6 molar excess of N-terminal Fmoc-protected amino acid was activated *in situ* in the reaction vessel by adding equimolar diisopropylcarbodiimide and *N*-hydroxybenzotriazole in a total reaction volume of 18 mL. Coupling was carried out for 1 h and was followed with a capping cycle for 30 min with 10% acetic anhydride in 1% diisopropylethylamine. Fmoc deblocking was performed with 25% piperidine for 12 min. All reagents were dissolved in dimethylformamide.

At completion, the resin-conjugated peptide was washed with dichloromethane, dried, and weighed. Cleavage was performed in a solution of TFA/EDT/water (95:2.5:2.5 v/v) for 30 min at room temperature, which simultaneously deprotected the amino acid side chains. The peptide solution was extracted with diethyl ether, concentrated by rotary evaporation, and freeze-dried. Lyophilized crude peptides were dissolved in degassed and nitrogen-purged 0.1% TFA. Peptides (3 μ mol per injection) were purified on a semipreparative (2 \times 25 cm) C₁₈ RP-HPLC column eluted at 10 mL/min with 0.1% TFA and acetonitrile (5–20% over 40 min) while absorbance was monitored at 280 nm, 1.0 AUFS. Purified peptides were concentrated by rotary evaporation, lyophilized, and stored dry at –20 °C.

Lyophilized peptides (1 μ mol) were dissolved in 1 mL of nitrogen-purged 50 mM Tris HCl (pH 7.5) and reduced by the addition of 250 μ L of 100 mM dithiothreitol prepared in the same buffer by reacting at room temperature for 30 min. Alkylation was carried out by adding 25 mg of solid iodoacetamide or iodoacetic acid followed by reaction for 1 h at room temperature. The alkylated peptides were acidified to pH 2.0 with TFA and purified by RP-HPLC as described above. The yield of each purified peptide (approximately 25%) was determined from the absorbance of tryptophan ($\epsilon_{280\text{nm}} = 5600 \text{ M}^{-1} \text{ cm}^{-1}$). The TFA salt of polylysine₁₉ was prepared by chromatographing the hydrobromide salt on RP-HPLC eluted with 0.1% TFA and acetonitrile while detecting 214 nm as described above. The concentration of polylysine₁₉ was established by fluorescamine analysis (26) using a calibrated standard of AlkCWK₁₈ as a reference.

Dimeric peptides were prepared by dissolving 1 μ mol of each purified CWK_{*n*} (*n* = 3, 8, 13, or 18) peptide in Tris HCl (pH 7.5) followed by reaction at 37 °C for 24 h. Each dimeric peptide was purified using RP-HPLC as described above and quantified by Abs_{280nm} ($\epsilon = 11\,200 \text{ M}^{-1} \text{ cm}^{-1}$).

Peptides were characterized using MALDI-TOF-MS. The peptide (1 nmol) was reconstituted in 100 μ L of 0.1% acetic acid, and 1 μ L was applied to the target and analyzed using a Vestec-2000 Laser Tec Research laser desorption linear time of flight mass spectrometer using insulin as the internal standard. The instrument was operated with 23 kV ion accelerating voltage and 3 kV multiplier voltage using a 337 nm VSL-SS& ND nitrogen laser with a 3 ns pulse width.

Formulation of Peptide DNA Condensates. Peptide DNA condensates were prepared at a final DNA concentration of 20 μ g/mL and at a peptide/DNA stoichiometry varying from 0.1 to 1.5 nmol of peptide/ μ g of DNA. The condensates were formed by adding peptide (2–30 nmol) prepared in 500 μ L of isotonic Hepes-buffered mannitol (HBM, 0.27 M mannitol, 5 mM sodium Hepes, pH 7.5) to 20 μ g of DNA in 500 μ L of HBM while vortexing, followed by equilibration at room temperature for 30 min.

¹ Abbreviations: RP-HPLC, reversed phase high-performance liquid chromatography; CWK, cysteine–tryptophan–lysine; TFA, trifluoroacetic acid; EDT, ethanedithiol; MALDI-TOF-MS, matrix-assisted time of flight mass spectrometry; RLU, relative light units; DTT, dithiothreitol; FBS, fetal bovine serum; MEM, minimal essential media; DMEM, Dulbecco's modified Eagle media; HBM, Hepes-buffered mannitol; QELS, quasi-elastic light scattering.

Sedimentation of DNA condensates was evaluated by measuring the concentration of DNA in solution before and after centrifugation. After peptide DNA condensates were formed as described above, a 50 μ L aliquot (1 μ g of DNA) was diluted in 1 mL of water and the $Abs_{260\text{ nm}}$ was determined on a Beckman DU640 spectrophotometer. Following centrifugation at 13000*g* for 4 min at room temperature, an identical aliquot was diluted with 1 mL of water and the concentration of DNA remaining in solution was determined. The ratio of absorbances subtracted from unity and multiplied by 100 was defined as the percent sedimentation.

Peptide binding to DNA was monitored by a fluorescence titration assay (18). A 1 μ g aliquot of the peptide DNA condensate prepared as described above was diluted to 1 mL in HBM containing 0.1 μ M thiazole orange. The fluorescence of the intercalated dye was measured on an LS50B fluorometer (Perkin-Elmer, U.K.) in a microcuvette by exciting at 500 nm while monitoring emission at 530 nm, with the slits set at 15 and 20 nm and photomultiplier gain set to 700 V. DNA condensation was monitored by measuring total scattered light at 90° by setting both monochromators to 500 nm and decreasing slit widths to 2.5 nm. Fluorescence and scattered light intensity blanks were subtracted from all values before data analysis.

Transmission electron microscopy was performed by immobilizing condensed DNA on carbon-coated copper grids (3 mm diameter, 400 mesh; Electron Microscopy Sciences, Fort Washington, PA). Grids were glow discharged, and 3 μ L of peptide DNA condensate (20 μ g/mL), prepared as described above, was placed on the grid for 5 min. The grids were blotted dry and then stained by floating for 1.5 min on each of three 100 μ L drops of uranyl acetate (1%, in 95% ethanol) followed by rinsing with 0.4% detergent solution (PhotoFlo, Kodak) and drying. Electron microscopy was performed using a Philips EM-100 transmission electron microscope.

Particle size analysis was measured for peptide DNA condensates prepared at a DNA concentration of 20 μ g/mL in HBM and at a stoichiometry of 0.8 or 1.0 (DiCWK₃) nmol of peptide/ μ g of DNA. Samples were analyzed using a Nicomp 370 Autodilute submicrometer particle sizer in the solid particle mode, and acquisition was continued until the fit error was <10. The mean diameter and population distribution were computed from the diffusion coefficient using functions supplied by the instrument.

In Vitro Gene Transfection. HepG2 cells (2×10^6 cells) were plated on 6 \times 35 mm wells and grown to 40–70% confluency in MEM supplemented with 10% FBS, penicillin, and streptomycin (10 000 units/mL), sodium pyruvate (100 mM), and L-glutamine (200 mM). Transfections were performed in MEM (2 mL/35 mm well) with 2% FBS, with or without 80 μ M chloroquine. Peptide DNA condensates (10 μ g of DNA in 0.5 mL of HBM) were added dropwise to triplicate wells. After 5 h of incubation at 37 °C, the medium was replaced with MEM supplemented with 10% FBS.

Luciferase expression was determined at 24 h with some modification of a published method (27). Cells were washed twice with ice-cold phosphate-buffered saline (calcium and magnesium free) and then treated with 0.5 mL of ice-cold lysis buffer (25 mM Tris chloride, pH 7.8, 1 mM EDTA, 8 mM magnesium chloride, 1% Triton X-100, 1 mM DTT) for 10 min. The cell lysate mixture was scraped, transferred to 1.5 mL microcentrifuge tubes, and centrifuged for 7 min at 13000*g* at 4 °C to pellet debris.

Lysis buffer (300 μ L), sodium ATP (4 μ L of a 180 mM solution, pH 7, 4 °C), and cell lysate (100 μ L, 4 °C) were combined in a test tube, briefly mixed, and immediately placed in the luminometer. Luciferase relative light units (RLU) were recorded on a Lumat LB 9501 (Berthold Systems, Germany) with 10 s integration after automatic injection of 100 μ L of 0.5 mM D-luciferin (prepared fresh in lysis buffer without DTT). The RLU were converted into femtomoles using a standard curve generated each day using luciferase dissolved in Tris acetate, pH 7.5, and stored at –20 °C. The standard curve was constructed by adding a known amount of the enzyme (0.01–100 fmol with specific activity of 2.5 nanounits/fmol) to 35 mm wells containing 40–70% confluent HepG2 or COS 7 cells. The cells were processed as described above, resulting in a standard curve with an average slope of 130 000 RLU/fmol of enzyme.

Protein concentrations were measured by Bradford assay using bovine serum albumin as a standard (28). The amount of luciferase recovered in each sample was normalized to milligrams of protein, and the mean and standard deviation obtained from each triplicate are reported.

COS 7 cells were plated at 72 000 cells per well and grown to 50% confluency in DMEM (Gibco BRL) supplemented with penicillin (10 000 units/mL), L-glutamine (200 mM), and 10% FBS for 24 h. The cells were transfected as described for HepG2 cells.

Lipofectace (Gibco BRL, 1:2.5 w/w dimethyl dioctadecylammonium bromide and dioleoylphosphatidylethanolamine) was used to mediate nonspecific gene transfection according to the manufacturer's instructions. The ratio of DNA to Lipofectace was optimized for both COS 7 and HepG2 cells. An optimal DNA/Lipofectace ratio was achieved by dissolving 10 μ g of DNA in 100 μ L of serum free media (SFM) followed by adding 60 μ L of Lipofectace prepared in 140 μ L of SFM. The Lipofectace DNA complex was then diluted with 1.7 mL of SFM and used to transfect HepG2 or COS 7 cells for 5 h followed by replacement of the transfecting media with supplemented 10% FBS. The cells were incubated for a total of 24 h, then harvested, and analyzed for luciferase as described above.

Dose response curves were prepared by varying the dose from 1 to 50 μ g of DNA while keeping the peptide/DNA stoichiometry fixed at 0.6 nmol/ μ g of DNA and normalizing the volume to 0.5 mL. Alternatively, a dose response curve for Lipofectace was prepared by varying the DNA dose from 1 to 20 μ g while keeping the stoichiometry of Lipofectace to DNA constant and normalizing the total volume of each dose to 2 mL with SFM.

RESULTS

Design of Peptides for Gene Delivery. Cationic peptides were designed to probe the minimal size needed to mediate efficient gene transfer in mammalian cells. The synthetic strategy involved comparison of four peptides with various lysine chain lengths in the range of 3–18 residues. During peptide synthesis, truncated peptides were capped by N-acetylation and a tryptophan residue was placed near the N terminus to provide a chromophore for identification of full-length sequences during purification. This residue allows quantitation of peptide concentration and is also intended for use in monitoring fluorescence to evaluate peptide binding to DNA as previously described (21). In addition, each peptide possessed an N-terminal cysteine residue as a potential ligand attachment site.

The four peptides were alkylated with iodoacetamide to provide AlkCWK_{*n*} (where *n* = 3, 8, 13, or 18 residues)

Table 1. Peptides for Gene Delivery

name	sequence	mass (obsd/calcd ^a)
AlkCWK ₃	Alk-S-Cys-Trp-(Lys) ₃	750.2/750.0
AlkCWK ₈	Alk-S-Cys-Trp-(Lys) ₈	1391.1/1390.9
AlkCWK ₁₃	Alk-S-Cys-Trp-(Lys) ₁₃	2031.1/2031.8
AlkCWK ₁₈	Alk-S-Cys-Trp-(Lys) ₁₈	2672.7/2672.5
DiCWK ₃	(Lys) ₃ -Trp-Cys-S-S-Cys-Trp-(Lys) ₃	1382.5/1382.8
DiCWK ₈	(Lys) ₈ -Trp-Cys-S-S-Cys-Trp-(Lys) ₈	2664.5/2665.2
DiCWK ₁₃	(Lys) ₁₃ -Trp-Cys-S-S-Cys-Trp-(Lys) ₁₃	3946.2/3945.9
DiCWK ₁₈	(Lys) ₁₈ -Trp-Cys-S-S-Cys-Trp-(Lys) ₁₈	5227.8/5227.9
polylysine ₁₉	(Lys) ₁₉	nd ^b /2435.8

^a Masses are calculated as the average $M + 1$ of the free base.

^b The mass of polylysine₁₉ was not determined due to polydispersity.

(Table 1). A further extension of this peptide series was accomplished by allowing the cysteine of each monomeric peptide to oxidize, resulting in a panel of homodimeric peptides each possessing two tryptophans and a discontinuous lysine repeat of either 6, 16, 26, or 36 residues in length (Table 1). Each alkylated peptide and dimeric peptide was characterized using MALDI-TOF-MS, which produced a dominant ion corresponding to the anticipated molecular weight of each peptide (Table 1).

Purified AlkCWK₃, AlkCWK₈, AlkCWK₁₃, and AlkCWK₁₈ each demonstrated a minor (10%) peak eluting later than the major product on RP-HPLC. On storage in an acid solution, the minor peak increased proportionally to the loss of the major product. The new product was isolated and analyzed by MALDI-TOF-MS, which verified a loss of 17 amu. A byproduct of identical mass loss was formed for each of AlkCWK₃, AlkCWK₈, AlkCWK₁₃, and AlkCWK₁₈. We speculate that the new product represents a cyclization of N-terminal amine with the acetamido group attached to cysteine leading to the loss of ammonia. The proposed cyclic byproduct of AlkCWK₁₈ was isolated and found to be functionally equivalent to the parent structure in transfection assays. Substitution of iodoacetic acid for iodoacetamide in the alkylation step led to an AlkCWK₁₈ peptide that was acid stable and functionally equivalent in formulation and biological assays.

Peptide Binding to Plasmid DNA. Peptides were studied for DNA binding using a dye exclusion assay that has been described previously (18). Peptide binding to DNA leads to exclusion of thiazole orange intercalation and a decrease in fluorescence. Titration of AlkCWK₃, AlkCWK₈, AlkCWK₁₃, or AlkCWK₁₈ with DNA in the range of 0.1–1.5 nmol of peptide/ μ g of DNA led to a reduction in fluorescence except for the smallest peptide (AlkCWK₃), which failed to exclude the intercalator within the titration range (Figure 1A). An asymptote in the fluorescence decline was observed at a stoichiometry of 0.6, 0.4, or 0.2 nmol of peptide/ μ g of DNA for AlkCWK₈, AlkCWK₁₃, or AlkCWK₁₈, respectively (Figure 1A). The relative fluorescence intensity at peptide/DNA stoichiometries above the asymptote established that AlkCWK₁₃ and AlkCWK₁₈ were able to exclude thiazole orange intercalation more efficiently than AlkCWK₈.

Dimeric peptides (DiCWK_{*n*}, *n* = 8, 13, 18) also possessed high affinity for DNA as evidenced by the stoichiometry of the fluorescence asymptote and the reduction in residual fluorescence, both of which correlated with the number of lysine residues (Figure 1B). Of this series, DiCWK₃ possessed weak affinity for DNA and thereby produced an asymptote at a stoichiometry of 1 nmol of peptide/ μ g of DNA.

In contrast to these results, polylysine₁₉ demonstrated a markedly different fluorescence titration curve compared to the alkylated or dimeric peptides of comparable

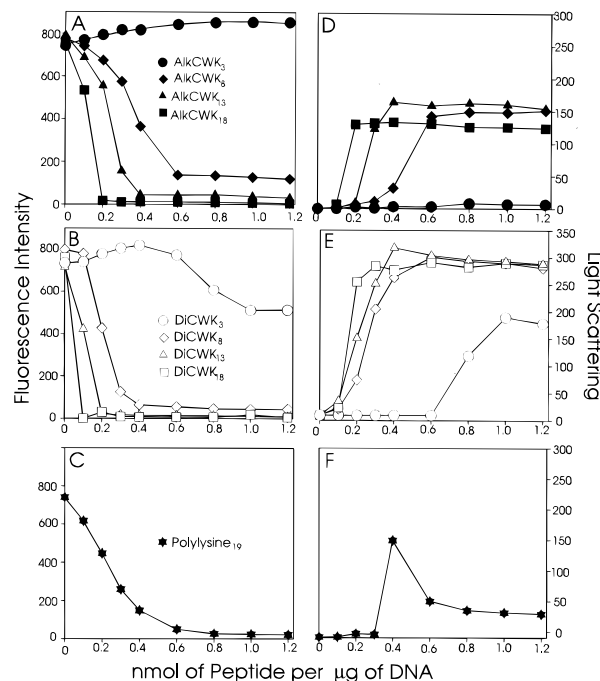

Figure 1. Fluorescence and light scattering titration of peptides with DNA. (A) Thiazole orange fluorescence was determined after titrating AlkCWK₃, AlkCWK₈, AlkCWK₁₃, or AlkCWK₁₈ with DNA as described under Materials and Methods. (D) Total light scattering measured simultaneously for each peptide DNA condensate. (B, E) Results of the fluorescence and light scattering titration using DiCWK₃, DiCWK₈, DiCWK₁₃, or DiCWK₁₈, respectively. (C, F) Fluorescence and light scattering titration of DNA with polylysine₁₉, respectively. Each titration represents the average of three determinations with average standard deviations of 7.4% for the fluorescence titration and 6.2% for the light scattering assay (error bars not shown).

length (Figure 1C). Even though polylysine₁₉ has a similar number of lysine residues as AlkCWK₁₈, its fluorescence asymptote occurs at a stoichiometry of approximately 0.6 nmol of peptide/ μ g of DNA. This result suggests that polylysine₁₉ binding to DNA is weak relative to AlkCWK₁₈.

Condensation of DNA with Peptides. Total light scattering at 90° was used to detect the peptide stoichiometry at which condensed DNA particles were formed (18, 29). Titration of AlkCWK₈, AlkCWK₁₃, or AlkCWK₁₈ with DNA produced a maximal total light scattering at stoichiometries that corresponded to the asymptote observed in the fluorescence exclusion assay (Figure 1D). A plateau in the light scattering profile observed at stoichiometries of 0.6, 0.4, and 0.2 for AlkCWK₈, AlkCWK₁₃, and AlkCWK₁₈, respectively, established the complete condensation of DNA at or above this peptide/DNA ratio. In contrast, titration of DNA with AlkCWK₃ failed to produce an increase in the light scattering, supporting earlier observations that indicate AlkCWK₃ fails to bind to DNA.

Titration of the dimeric peptides with DNA each produced condensates detected by light scattering (Figure 1E). Although the plateau light scattering levels for each dimeric peptide DNA condensate were nearly indistinguishable, the stoichiometry at which the plateau was achieved occurred at 0.6, 0.4, and 0.2 nmol of peptide/ μ g of DNA for DiCWK₈, DiCWK₁₃, and DiCWK₁₈, respectively. A weaker binding affinity for DiCWK₃ was evident from the plateau in light scattering which occurred at a stoichiometry of 1 nmol/ μ g of DNA (Figure 1E).

The light scattering profile for polylysine₁₉ was very distinct from that obtained for alkylated and dimeric

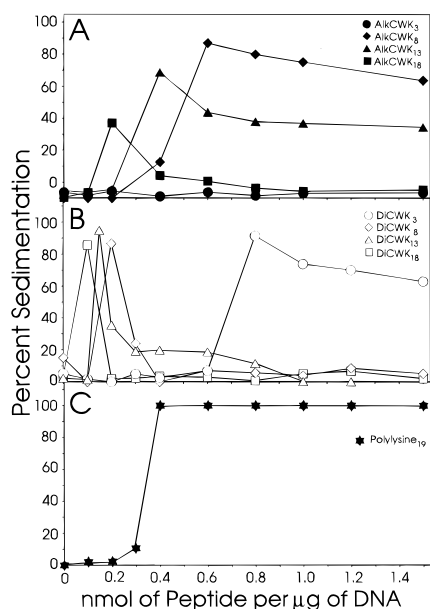

Figure 2. Sedimentation of peptide DNA condensates. The percent of DNA sedimented following centrifugation of peptide-induced DNA condensates is shown. The peptide/DNA stoichiometry was varied from 0.1 to 1.5 nmol of peptide/ μ g of DNA in HBM at a total DNA concentration of 20 μ g/mL. (A) Results for AlkCWK₃, AlkCWK₈, AlkCWK₁₃, and AlkCWK₁₈; (B) results for DiCWK₃, DiCWK₈, DiCWK₁₃, and DiCWK₁₈; (C) results for polylysine₁₉. The average standard deviation for the assay was 8.6% (error bars not shown).

peptides. A sharp increase occurred at a stoichiometry of 0.4 nmol/ μ g of DNA, which declined to approximately 50 light scattering units at higher peptide/DNA stoichiometries (Figure 1F). This light scattering titration profile distinguished the condensation properties of polylysine₁₉ from CWK_n peptides, suggesting differences in the particle size for polylysine₁₉ DNA condensates.

Sedimentation of DNA Condensates. To evaluate the relative particle size of DNA condensates prepared at stoichiometries ranging from 0.1 to 1.5 nmol of peptide/ μ g of DNA, a sedimentation assay was utilized to measure the DNA remaining in suspension following centrifugation at 13000*g* for 4 min (18) (Figure 2). Titration of DNA with AlkCWK₃ resulted in the complete recovery of the DNA following centrifugation, supporting earlier findings that indicate AlkCWK₃ fails to bind and condense DNA into particles. Alternatively, AlkCWK₈, AlkCWK₁₃, and AlkCWK₁₈ each produced maximal sedimentation at a stoichiometry that roughly correlates with the stoichiometry calculated for a charge neutral complex (Figure 2A). At stoichiometries greater than charge neutral, AlkCWK₈ condensates sedimented to a greater extent than AlkCWK₁₃ or AlkCWK₁₈ condensates, indicating their larger size.

A similar trend was observed when dimeric peptide DNA condensates were sedimented. The maximal sedimentation was observed at a stoichiometry of 0.8, 0.2, 0.15, and 0.1 nmol of peptide/ μ g of DNA for DiCWK₃, DiCWK₈, DiCWK₁₃, and DiCWK₁₈, respectively (Figure 2B). At stoichiometries above the calculated charge neutral point DiCWK₈, DiCWK₁₃, and DiCWK₁₈ DNA condensates failed to sediment, suggesting they are smaller in size (Figure 2B). It is also evident that DiCWK₃ DNA condensates were large due to the observed sedimentation (70–80%) at stoichiometries above the charge neutralization point (Figure 2B).

In contrast, polylysine₁₉ DNA condensates sedimented completely at 0.2 nmol of peptide/ μ g of DNA and failed to recover at higher stoichiometries. These data estab-

Table 2. QELS Particle Size Distribution

peptide DNA condensate ^a	particle size population	
	diameter ^b (nm)	σ^c (nm)
polylysine ₁₉	3102	297

DiCWK ₁₃	56	29
DiCWK ₁₈	64	27

^a Peptide DNA condensates were prepared at a concentration of 20 μ g/mL of DNA and at stoichiometry of 0.8 or 1.0 nmol (DiCWK₃) of peptide/ μ g of DNA in HBM. ^b Represents the mean diameter of particles. ^c Standard deviation of the population.

Figure 3. Electron microscopy of DNA condensates. The electron micrographs are shown for DNA condensates prepared at 0.5 nmol of peptide/ μ g of DNA for AlkCWK₁₈ (A) and at 0.8 nmol of peptide/ μ g of DNA for polylysine₁₉ (B). The calibration bar shown is 50 nm in length.

lished that once polylysine₁₉ DNA condensates are formed, they remained large throughout the titration range (Figure 2C).

Particle Size and Distribution. DNA condensates were prepared with alkylated peptides, dimeric peptides, and polylysine₁₉ at a stoichiometry of 0.8 nmol of peptide/ μ g of DNA, and particle sizes were compared using quasi-elastic light scattering (QELS). A population of particles with average diameters of 0.7–3.1 μ m was determined for polylysine₁₉, AlkCWK₈, and DiCWK₃ DNA condensates, whereas no particles were detected for AlkCWK₃ DNA condensates (Table 2), consistent with the results of sedimentation analysis.

Each alkylated or dimeric peptide possessing 13 lysine residues or more produced a population of particles with mean diameters of 53–231 nm (Table 2). It should be noted that particle populations were most often bimodal, possessing a major (>90%) smaller diameter population and a minor larger diameter population which contributed to the large standard deviation of the average particle size (Table 2).

Particle sizes determined by QELS were substantiated by analyzing DNA condensates using electron microscopy. Figure 3 compares the particle size and morphology for AlkCWK₁₈ and polylysine₁₉ DNA condensates. The images demonstrate that condensates produced with AlkCWK₁₈ are relatively uniform particles with diameters of approximately 50–100 nm, whereas polylysine₁₉-induced condensates were large flocculated particles, consistent with the result of particle size analysis by QELS (Figure 3).

In Vitro Gene Expression of Peptide DNA Condensates. Luciferase reporter gene expression was analyzed following transfection of HepG2 or COS 7 cells with peptide DNA condensates prepared at stoichiometries ranging from 0.1 to 1.5 nmol of peptide/ μ g of DNA.

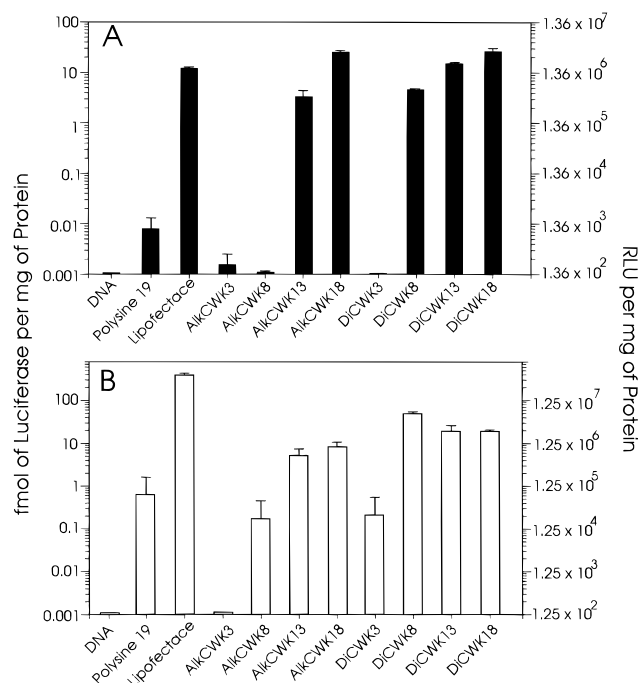

Figure 4. In vitro gene expression in HepG2 and COS 7 cells. Luciferase reporter gene expression is shown for DNA condensates prepared using alkylated peptides, dimeric peptides, polylysine₁₉, and Lipofectace. Chloroquine (80 μ M) was included in the transfecting media for peptides and polylysine₁₉. (A) Gene expression determined in HepG2 cells; (B) gene expression in COS 7 cells. Each bar represents the mean and standard deviation of three determinations.

A 10-fold enhancement in the gene expression level was achieved when chloroquine was included in the transfecting media. For each peptide-condensing agent, the maximal reporter gene expression occurred at a peptide/DNA stoichiometry that corresponds to the fully condensed DNA as determined by the asymptote in the light scattering assay (Figure 1D,E,F) (18). At stoichiometries greater than that required to achieve condensation, the gene expression remained constant. Thereby, the relative gene expression levels were compared for each peptide DNA condensate at a fixed stoichiometry of 0.8 or 1.0 nmol (DiCWK₃) of peptide/ μ g of DNA, which was sufficient for each peptide to fully condense DNA.

Transfection of HepG2 with 10 μ g of either uncomplexed plasmid DNA, AlkCWK₃ or AlkCWK₈, DiCWK₃, or polylysine₁₉ DNA condensates failed to produce significant reporter gene expression (Figure 4A). This result supported formulation experiments that predicted these peptides either fail to condense DNA (AlkCWK₃) or produce condensates that are large (0.7–3.1 μ m). Alternatively, AlkCWK₁₃, AlkCWK₁₈, DiCWK₈, DiCWK₁₃, and DiCWK₁₈ DNA condensates each demonstrated significant gene transfer efficiency that was 2–3 orders of magnitude greater than that of polylysine₁₉. Lipofectace-mediated gene expression levels were also found to be identical to peptide-mediated expression levels in HepG2 cells (Figure 4A).

To verify that peptide-mediated gene delivery was not dependent on the existence of cell type specific receptors, the reporter gene expression in HepG2 cells was compared to that in COS 7 cells (Figure 4B). Significant differences were observed for the transfection of COS 7 versus HepG2 cells such that only uncomplexed DNA and AlkCWK₃ DNA condensates failed to produce measurable gene expression levels. AlkCWK₈, DiCWK₃, and polylysine₁₉ DNA condensates each mediated a significant gene expression in COS 7 cells despite their inactivity

Figure 5. Dose response for peptide-mediated gene delivery. Luciferase gene expression levels in HepG2 are compared using an escalating dose of AlkCWK₁₈ DNA condensate prepared at a stoichiometry of 0.6 nmol/ μ g of DNA.

in transfecting HepG2 cells. However, the gene expression level mediated by these peptides was still 1–2 orders of magnitude below that afforded by AlkCWK₁₃, AlkCWK₁₈, DiCWK₈, DiCWK₁₃, and DiCWK₁₈ (Figure 4B). Also, Lipofectace-mediated gene expression in COS 7 cells was 1 order of magnitude greater than peptide-mediated gene delivery. These results suggest that the size restriction of peptide DNA condensates is less stringent in COS 7 cells compared to HepG2 cells.

To establish the effect of dose response using peptide DNA condensates, HepG2 cells were treated with escalating doses of AlkCWK₁₈ DNA condensates and Lipofectace DNA formulations. As demonstrated in Figure 5, a dose response curve for the AlkCWK₁₈ DNA condensate plateaus at 20 μ g of DNA and remains constant at higher doses, whereas the toxicity of Lipofectace above 10 μ g of DNA (data not shown) leads to reduced expression levels at higher doses.

DISCUSSION

The efficiency of carrier-mediated gene delivery depends on the reversible association of condensing molecules with plasmid DNA (1–3). The carriers that have been used most often are composed of polymers or lipids that bind to anionic sites on DNA. In the case of cationic peptides, this leads to condensation of plasmid DNA into small particles that gain entry into the target cell via nonspecific fluid phase pinocytosis (1). Attachment of ligands adds specificity to the delivery system and likewise alters the mode of DNA transfer across cell membranes such that DNA and ligand cotransfer via receptor-mediated endocytosis (5–15).

Previously we demonstrated that a low molecular weight glycopeptide mediated gene transfer to hepatocytes via the asialoglycoprotein receptor (18). Since this glycopeptide was prepared from low molecular weight polydisperse polylysine (dp 19), we sought to systematically optimize the peptide portion of the glycopeptide as a first step to improve its efficiency as a carrier for nonviral gene delivery.

The results establish that low molecular weight peptides possessing six or more lysine residues bind with sufficient affinity to condense DNA at stoichiometries above the charge neutral point (Figure 1). However, condensation of DNA is not sufficient to ensure significant transfection levels since AlkCWK₈, DiCWK₃, and polylysine₁₉ each produced DNA condensates but failed to mediate significant gene transfer in HepG2 cells (Figure 4A). The success or failure of individual peptide DNA condensates to mediate gene expression appears to be related to particle size such that larger condensates

are less efficiently pinocytosed (2). For HepG2 cells an apparent size restriction exists that excludes large DNA condensates. This is demonstrated by comparison of the transfection efficiency for AlkCWK₈ DNA condensates of 2.4 μm size relative to AlkCWK₁₃ DNA condensates, which possess an average diameter of 231 nm (Figure 4A). The addition of five lysine residues decreases particle size 10-fold, which leads to a 1000-fold amplification in gene transfer efficiency. Further reductions in the DNA particle diameters in the range of 231–53 nm only led to an additional 10-fold increase in transfection levels (Figure 4A). The size requirements described above for transfecting HepG2 cells are less stringent for COS 7 cells. Large (0.7–3.1 μm) peptide DNA condensates are moderately efficient at mediating transfection in COS 7 cells but are still 10–100-fold less efficient than smaller DNA condensates (Figure 4B).

The equivalent transfer efficiency of peptide DNA condensates into either HepG2 or COS 7 cells suggests a nonspecific mechanism related to the cationic nature of the condensates (1, 2). We have also transfected 293T cells with peptide DNA condensates (data not shown), which resulted in a similar high level of gene expression. Comparable gene expression levels were obtained using peptide or Lipofectace to mediate DNA transfer in HepG2 cells, whereas Lipofectace-mediated gene delivery was found to be more efficient than peptide-mediated gene delivery in COS 7 cells (Figure 4). These results reflect cell type specific differences that must be considered in the development of gene delivery systems (1, 2).

The discovery of a class of low molecular weight peptides that efficiently condense DNA into small particles is a major finding of this study. Apparently, some structural feature of AlkCWK_n peptides allows more efficient condensation of DNA relative to polylysine. This is demonstrated most clearly by AlkCWK₁₈, which condenses DNA into particles that are 40-fold smaller (78 nm) than those produced by polylysine₁₉ (3.1 μm). Given that the lysine chain lengths of these two peptides are nearly equivalent, the N-terminal cysteine or tryptophan is presumably responsible for the enhanced condensing activity. To investigate the structural requirements of an efficient DNA condensing peptide, we synthesized an isomer of AlkCWK₁₈ also possessing 18 lysine residues but in which cysteine is relocated to the C terminus and tryptophan is the N terminus (WK₁₈C). The alkylated and dimeric form of this peptide each mediated gene transfer as efficiently as AlkCWK₁₈ (data not shown), suggesting that the location of cysteine may not be key to the reported activity. On the basis of this and other observations discussed below, we hypothesize that tryptophan may be primarily responsible for the enhanced condensation activity of AlkCWK₁₈ compared to polylysine₁₉.

A tryptophan residue may increase the binding affinity between cationic peptides and DNA. Evidence supporting this hypothesis comes from the stoichiometry of AlkCWK₁₈ (0.2 nmol of peptide/ μg of DNA) needed to exclude intercalator binding to DNA versus that for polylysine₁₉ (0.6 nmol of peptide/ μg of DNA) (Figure 1A,C). Lohman and co-workers also identified a function for tryptophan in altering cationic peptide binding to DNA and RNA (22, 23). Curiously, they determined an enhancement in the entropy of peptide binding to DNA when substituting tryptophan for lysine (22, 23). However, this was offset by a decrease in the enthalpy of binding, leading to a net zero change in the association constant (22, 23). These studies also established that the location of tryptophan is not important and that multiple tryptophan residues do not influence the magnitude of

the association constant despite changes in the enthalpic and entropic contributions (22, 23). Recently, a low molecular weight cationic peptide possessing alanine, tyrosine, 10 lysines, and tryptophan has been co-complexed with a fusogenic peptide and DNA to achieve a 5 order of magnitude amplification in gene expression in HepG2 cells relative to uncomplexed DNA (24). The efficient DNA condensing activity of this low molecular weight peptide may also be linked the tryptophan residue, which flanks the polylysine sequence.

The precise mechanism of how tryptophan functions to increase binding affinity and decrease particle size is uncertain; however, it may relate to its ability to intercalate into DNA leading to an observed fluorescence quench (21–23). Tryptophan's hydrophobic interaction with DNA may organize the peptide binding on DNA, facilitating the formation of intermolecular ion pairs between multiple lysine residues and the DNA phosphate backbone.

Preparation of small DNA condensates has also recently been reported using polylysine dp 30 at a stoichiometric excess of 1.2 nmol/ μg of DNA (20). The present study establishes that simple amino acid substitutions allow polylysine peptides as small as dp 13 to acquire the necessary affinity to condense DNA into small particles at low stoichiometric excess.

The development of homogeneous peptides that actively condense DNA into small particles is an important advance toward the development of low molecular weight carriers for targeted gene delivery. Attachment of a receptor ligand such as a carbohydrate or peptide to a single cysteine residue should endow specificity to the gene delivery system and allow further systematic optimization of low molecular weight carriers for receptor-mediated gene delivery.

ACKNOWLEDGMENT

We acknowledge financial support for this work from NIH GM48049. The DNA used for these studies was prepared by Anna Calcagno. We also acknowledge technical assistance in performing mass spectroscopy by Bao-Jen Shyong at the Carbohydrate and Protein core facility, University of Michigan. Electron microscopy studies were performed with technical assistance from Bruce Donohoe and Chris Edwards in the Department of Cell Biology and Anatomy, University of Michigan. The QELS particle size analysis was performed with assistance from Ramachandran Chandrasekharan at the College of Pharmacy, University of Michigan.

TECHNICAL NOTES

Characterization of Oligodeoxyribonucleotide–Polyethylene Glycol Conjugates by Electrospray Mass Spectrometry

Theodore M. Tarasow,* David Tinnermeier, and Carina Zyzniewski

NeXstar Pharmaceuticals Inc., 2860 Wilderness Place, Boulder, Colorado 80301. Received September 26, 1996[®]

Electrospray mass spectrometry (ESMS) was used to characterize a number of differently functionalized polyethylene glycol–oligodeoxyribonucleotide conjugates. Sample preparation was found to be crucial to obtaining quality data. The resolution and precision of ESMS allowed for the identification of individual conjugates differing in MW by a single ethylene glycol unit with an accuracy of ≤ 1 (0.02% of the molecular weight). In addition, ESMS was shown to be valuable in identifying chromatographically unresolvable components of a derivatized polyethylene glycol–oligonucleotide conjugate mixture.

INTRODUCTION

Interest in oligonucleotides as research tools, diagnostic reagents, and therapeutics has increased dramatically. As scientific probes, oligonucleotides and oligonucleotide conjugates have been used in both macromolecular structural research and reaction mechanism investigations. From a commercial perspective, these molecules have shown promise as therapeutic and diagnostic agents (1). Potential oligonucleotide therapeutics include anti-sense molecules (2, 3), ribozymes (4), and oligonucleotides obtained from the systematic evolution of ligands by exponential enrichment (SELEX) (1, 5, 6). In particular, the SELEX-derived compounds are of intense pharmaceutical interest because of the high affinity and exquisite selectivity demonstrated for a broad range of targets. However, oligonucleotides as drugs suffer from two drawbacks, the first being their susceptibility to hydrolytic and enzymatic degradation and the second being their lack of bioavailability. A general strategy for overcoming these shortcomings has been chemical modification of oligonucleotides such that their inherent stability and bioavailability are increased (3, 7). In addition, oligonucleotides have been modified to facilitate their incorporation into stabilizers and delivery vehicles such as liposomes (8).

Oligonucleotide modifications have included conjugation of cholesterol (9, 10), fatty acids (12, 13), polycations (8, 11), proteins (14), and polymers (15, 16) to name a few. Characterization of these molecules is crucial to gaining knowledge about their mode of action and to qualify them as drug candidates. Unfortunately, the process of chemically modifying oligonucleotides often results in multiple reaction products, especially when polymers are involved, making characterization difficult. Most product characterizations have included some change in physical property such as a band shift in gel electrophoresis or a peak shift in high-performance liquid chromatography (HPLC). Although these techniques suggest a modification has taken place, they do not directly allude to the identity of the reaction product or

products. Furthermore, when multiple products are produced, these techniques are often unable to resolve the resulting mixture and identify the individual components. Analytical hurdles such as these were encountered early on in our efforts to produce 5' polyethylene glycol (PEG)-modified oligonucleotides using standard automated synthetic techniques. Somewhat similar conjugates had been prepared in the past (16); however, our oligonucleotide conjugate targets were designed with longer PEG units than previously described. As a result, new methods were required to prepare these compounds, and improved analytical analysis proved to be key in developing these procedures.

Mass spectrometry (MS) offers a characterization technique superior to those discussed above by providing a direct measurement of the molecular weight of the molecule or molecules of interest (17). In addition, one of the many valuable uses of MS has been mixture analysis, making the technique potentially useful for analyzing reaction product mixtures produced by the chemical modification of oligonucleotides. Indeed, two accounts revealed matrix-assisted laser desorption/ionization mass spectrometry (MALDI MS) to be a useful tool for the characterization of oligonucleotide–PEG conjugates (16, 18). However, the resolution and accuracy of MALDI are limited and decrease significantly with increasing molecular weight (MW). These limitations are especially evident in the MALDI analyses of the PEG–oligonucleotide conjugates where the polydispersity of the PEG polymer results in multiple species with similar molecular weights. These species became less resolved as the length of the oligonucleotide and/or the polymer was increased. Another MS technique which offers superior resolution and accuracy is electrospray mass spectrometry (ESMS). ESMS generates and detects multiple charge states of the sample, which upon reconstruction yields the molecular weights of the species present (19). Because of the mild ionization process and the increased measurable molecular weight range, ESMS has been particularly useful for characterizing large biomolecules (17), such as proteins (20), protein conjugates (21), protein–ligand complexes (22) and oligonucleotides (23, 24). Herein, we report the characterization of a variety of functionalized oligodeoxyribonucleotide–PEG conjugates by electrospray mass spec-

trometry. Further, we demonstrate the utility of ESMS in analyzing multiple reaction products as a result of the chemical modification of oligonucleotide-PEG conjugates. We also describe good yielding methods for the incorporation of PEG molecules with average molecular weights up to 2000 in oligonucleotide conjugates by automated synthesis using standard phosphoramidite chemistry.

EXPERIMENTAL PROCEDURES

General. Monoamino-PEG-2000 (average M_n of ≈ 2000) and monomethoxy-PEG-2000 were purchased from Shearwater Polymers Inc. (Huntsville, AL) and used as received. All other chemicals were purchased from Aldrich Chemical Co. and used as received unless otherwise specified. HPLC was performed on a Rainin Dynamax HPLC instrument equipped with a Rainin UV D-II dual-wavelength detector. Vydac C4 reverse phase HPLC columns were used with triethylammonium acetate (TEAA) at pH 7.0 and acetonitrile (MeCN) as eluents. NMR spectra were obtained on a Bruker AMX 300 instrument.

Functionalized PEG. The functionalized PEG molecules used to produce compounds **2–4** were prepared by acylation of monoamino-PEG-2000 with either the *N*-hydroxysuccinimide (NHS)-activated ester or the *p*-nitrophenyl-activated carbonate of the corresponding functional modification. The derivatized PEG compounds were purified by flash silica gel chromatography and precipitation from tetrahydrofuran (THF) with diethyl ether. The identities of the PEG molecules were confirmed by ^1H NMR.

The (*N*-acetylamino)cyclohexadienyl-PEG molecule used to synthesize compound **5** was prepared by addition of amino-PEG to the boron tetrafluoride salt of cyclohexadienylumiron(0) tricarbonyl with subsequent oxidative elimination of the iron tricarbonyl using ceric ammonium nitrate (T. Dewey, C. Zyzniewski, and B. Eaton, unpublished results). The derivatized PEG molecule was purified and characterized in a manner similar to that described above.

PEG Phosphoramidite Synthesis. All steps were carried out under an argon atmosphere using inert atmosphere techniques. THF was freshly distilled from potassium/benzophenone prior to use. The primary amine on the PEG used to prepare compound **1** was protected as the 9-fluorenylmethyl carbamate (fmoc) prior to phosphoramidite synthesis. The derivatized PEG (150 mg, 0.07 mmol) was dissolved in THF (1.5 mL) and added to a solution of 18.2 mg (0.077 mmol) of (2-cyanoethyl)-*N,N*-diisopropylchlorophosphoramidite and 14.7 mg (0.114 mmol) of diisopropylethylamine in THF (0.5 mL). The reagents were allowed to react at room temperature for 30 min, after which ^{31}P NMR indicated that the reaction was complete. Excess phosphoryl chloride as detected by ^{31}P NMR was quenched by the addition of methanol (20 μL). The mixture was then filtered through glass wool and the solvent removed under reduced pressure. The PEG phosphoramidite was used immediately in the automated oligonucleotide conjugation described below.

Oligonucleotide-PEG Conjugate Synthesis. All oligonucleotide-PEG conjugates were synthesized on an ABI 392 DNA synthesizer using standard cycles and conditions except for coupling of the PEG phosphoramidite. Reagents, including phosphoramidites, were obtained from Glen Research. All syntheses were performed at the 1 μmol scale using a Pharmacia polystyrene support. The PEG phosphoramidite was dissolved in anhydrous acetonitrile to a final concentration of 50 mM. Coupling of PEG phosphoramidite was achieved using a

modified ABI 1 μmol CE coupling cycle. The coupling time was increased to 45 min, and an additional coupling cycle was inserted prior to capping. Oligonucleotide cleavage from the polystyrene support and deprotection were carried out in concentrated NH_4OH at 55 $^\circ\text{C}$ for 12–16 h. The oligonucleotide-PEG conjugates were purified by HPLC using a 15 to 40% acetonitrile gradient over 20 min. Retention times of the oligonucleotide conjugates varied depending on what functionality was present at the end of the PEG. Due to the degree of polymerization and polydisperse nature of the PEG, conjugates typically eluted as an envelope of moderately resolved peaks. Oligonucleotide-PEG conjugates were collected, concentrated to dryness, dissolved in water, and quantitated by UV spectroscopy ($\epsilon_{260} \approx 91\,600$). Yields were typically 40–60%. These samples were used directly in the MS experiments described below.

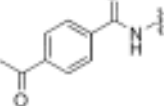

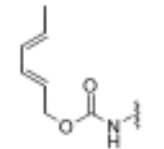

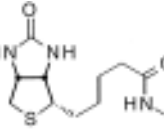

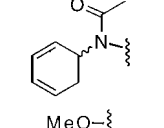

The alternative route to functionalized oligonucleotide-PEG conjugates **2** and **4** involved reaction of the amino-PEG-oligonucleotide (**1**) with the NHS ester of either 4-acetobenzoic acid or biotin, respectively. The resulting reaction mixture was HPLC purified as above and subjected to ESMS analysis. In both cases, HPLC was ineffective at separating the desired compounds, **2** and **4**, from undesired side products.

MS Analysis of Oligonucleotide-PEG Conjugates. Electrospray mass spectrometry was performed on a Fisons Quattro II (Beverly, MA) triple-quadrupole mass spectrometer using the negative ion mode. The first detector was used for mass detection. Nitrogen was used as the nebulizer gas at 20 L/h and the drying gas at 300 L/h. The cone voltage was -30 V , the capillary 2.65 kV, and the HV lens 0.33 kV. The source temperature was maintained at 80 $^\circ\text{C}$. Samples (10 μL) were injected via flow injection using a Rheodyne 7125 (Cotati, CA) manual injector with a 20 μL stainless steel loop. A Harvard apparatus model 22 (South Natick, MA) syringe pump was used to deliver 1:1 methanol/ H_2O (v/v) containing 0.1% triethylamine at 10 $\mu\text{L}/\text{min}$ to the mass spectrometer. All solvents used were HPLC grade and were obtained from Fisher Scientific (Fair Lawn, NJ). Data were acquired at 5 ms dwell, 0.1 step size between m/z 350 and 2000. The spectra were averaged across the entire sample plug, and background was subtracted. The instrument was calibrated using a 2 $\mu\text{g}/\mu\text{L}$ NaI solution. At least three charge states were used to determine the reported weights. The deviation reported is the error associated with the molecular weight calculation using several charge states. Transformation of the raw data was accomplished using MaxEnt, included in the MassLynx software from Fisons.

RESULTS AND DISCUSSION

Synthesis of Oligonucleotide Conjugates. A variety of oligonucleotide-PEG conjugates have been prepared in good yields using automated synthesis. The more efficient approach involved preparing the desired monohydroxy-PEG compound, converting it to the phosphoramidite, and coupling it to the oligonucleotide using a modified automated synthesis reaction cycle. This strategy resulted in good yields of HPLC-purified PEG-2000 (average M_n of ≈ 2000)-oligonucleotide conjugates as determined by UV quantitation. Crucial to obtaining reasonable yields were the support, coupling times, and repetitive coupling procedure. Yields were found to be lower with CPG supports than with polystyrene resins. In addition, CPG yields were highly dependent on pore size, with 2000 \AA supports giving the best yields. Increasing the coupling time to 45 min and including an

compound	R	n	calculated MW	measured MW
1	$\text{H}_2\text{N}-$	50	5323.4	5324.2 ± 0.3
2	$\text{H}_2\text{N}-$	50	5469.4	5468.3 ± 0.3
3		43	5139.2	5140.2 ± 0.9
4		43	5241.2	5240.5 ± 0.5
5		43	5135.2	5135.7 ± 0.2
6		42	4986.1	4986.4 ± 0.9

additional coupling step were also found to dramatically increase the yield of the conjugate.

An alternative, less efficient approach to differently functionalized PEG–oligonucleotide molecules was chemical modification of the PEG after conjugation to the 10-mer oligonucleotide. For example, the amino-PEG-2000–10-mer **1** was modified with various acylating reagents and the resulting functionalized oligonucleotide–PEG conjugate HPLC purified. Modification of the amino group generally resulted in a significant shift in the retention time, thus allowing for facile purification. However, some modifications resulted in unresolvable mixtures, in which case the MS proved invaluable to analysis of the product mixture (*vide infra*). In all cases, this approach resulted in significantly lower yields compared to yields obtained by modifying the PEG prior to automated oligonucleotide conjugation.

ESMS Analysis of Oligonucleotide Conjugates. Representative ESMS spectra for the conjugates listed in Table 1 are shown in Figure 1. The peaks fall into charge state envelopes in which each envelope consists of molecules of like charge and is spread over a range of m/z ratios due to the polydisperse nature of the PEG. The resolution of ESMS is demonstrated by the near baseline separation of peaks within an envelope, where the difference between two peaks represents one ethylene glycol unit. The smaller peaks observed within an envelope correspond to salt adducts of the parent molecule. Sample preparation is crucial to obtaining quality ESMS data. Conjugates should be purified using volatile buffers such as triethylammonium acetate or triethylammonium bicarbonate and should always be dissolved in deionized water. Contaminating cations, particularly sodium and potassium ions, can render a spectrum impossible to assign if present in high enough amounts. Undesired counterions can be exchanged using triethyl-

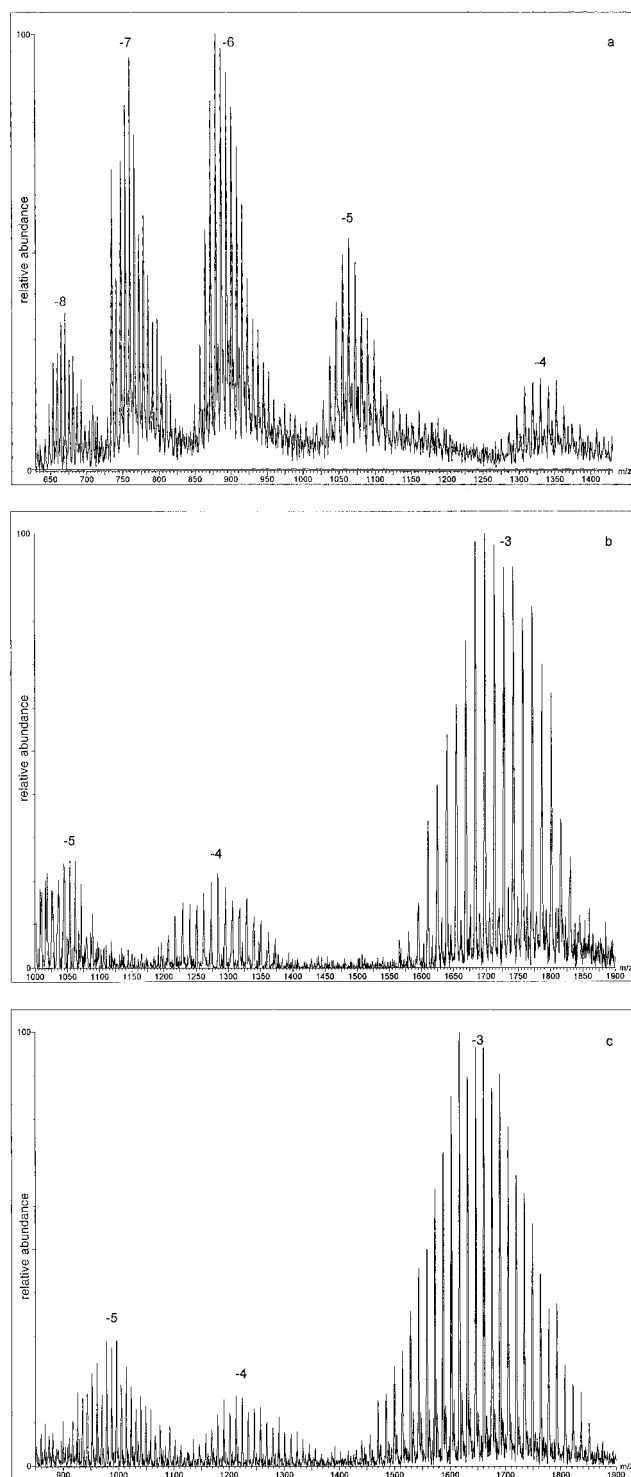

Figure 1. Representative ESMS spectra of selected oligoconjugates listed in Table 1. All data were obtained under conditions described in Experimental Procedures. Mass envelope charge states have been labeled: (a) compound **1**, (b) compound **3**, and (c) compound **5**.

ammonium buffers in either ion exchange HPLC, reverse phase HPLC, size exclusion chromatography, or dialysis.

Reconstruction of Figure 1a yielded the spectrum shown in Figure 2. Like the primary spectrum, the reconstructed spectrum shows the polydisperse nature of the PEG–oligonucleotide conjugate, but it also illustrates the accuracy of the ESMS technique. The molecular weight values listed in Table 1 agree well with the calculated molecular weights. Typically, a difference of less than 0.02% was obtained. Accuracy does not

Figure 2. Reconstructed spectrum of Figure 1a. The value of n is indicated for the maximum and minimum number of polyethylene glycol units, as well as for the most abundant species. The peak corresponding to the measured molecular weight reported in Table 1 is also labeled.

Figure 3. Reconstruction of mixture analysis data showing the mono (M) and bis (B) adduct mass envelopes. The two differently modified conjugates were the result of the derivatization of compound **1** with the NHS ester of 4-acetylbenzoic acid. The measured molecular weights for the $n = 48$, mono, and bis adducts have been labeled.

appear to be sequence dependent because ESMS analyses of oligonucleotide-PEG conjugates similar to those reported here, differing only in sequence, have generated equally accurate results (T. M. Tarasow, D. Tinnermeier, and C. Zyzanski, unpublished results). Furthermore, the resolution of ESMS provides data for the determination of oligonucleotide-PEG physical characteristics such as the range and distribution of PEG chain lengths. For example, using the reconstructed spectrum shown in Figure 2, the number of polyethylene glycol units ranges from 45 to 60 with a maximum around 49 units. These values can be easily determined for each batch of oligonucleotide conjugate to assure consistency in product and to help correlate physical differences between lots.

Figure 3 demonstrates the ability of ESMS to deconvolute chromatographically unresolvable mixtures. Modification of the amino-PEG-10-mer (**1**) with the NHS ester of 4-acetylbenzoic acid generated mono and bis addition products which were not resolvable by HPLC. Although the mass envelopes for the two products overlap, the ESMS-reconstructed spectrum was baseline resolved (Figure 3). The identity of the two components in the mixture could be assigned as the mono ($M_{r\text{-meas}} =$

5382.2 ± 0.4 , $M_{r\text{-calc}} = 5381.4$, $n = 48$) and bis ($M_{r\text{-meas}} = 5527.4 \pm 0.2$, $M_{r\text{-calc}} = 5527.4$, $n = 48$) acetophenone adducts. The synthetic modification of oligonucleotides quite often results in multiple products such as these, and while ESMS does not identify the regiochemistry of modification, it does provide data to more accurately characterize the reaction products.

Conjugation of PEG to oligonucleotides has been used to increase hydrolytic stability (16), to provide a flexible linker between oligonucleotides and other molecules (14, 25), and to purify oligonucleotides (26). While the utility of oligonucleotide-PEG conjugation is obvious, the characterization of the reaction products has been incomplete. The polymeric nature of PEG introduces additional analytical hurdles. Mass spectrometry techniques such as MALDI are less than ideal for the analysis of oligonucleotide-PEG conjugates with high degrees of polymerization ($n > 30$) due to poor resolution between MS peaks (16, 18). We have shown ES-quadrupole MS to be a valuable tool for the accurate and resolute analysis of a variety of highly polymerized, functionalized oligonucleotide-PEG conjugates. We anticipate that this technique will be widely applicable to the analysis of other polymer-modified oligonucleotides as well. In the future, the concept may even be extended to collision-induced dissociation ESMS/MS experiments (23) in which more detailed structural data of synthetically modified oligonucleotides may be obtained.

ACKNOWLEDGMENT

Determination of the Extent of Protein Biotinylation by Fluorescence Binding Assay

Srivatsa V. Rao,[†] Kimberly W. Anderson,^{*,†} and Leonidas G. Bachas^{*,‡}

Department of Chemical and Materials Engineering and Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506. Received June 30, 1996[⊗]

A method was developed to determine the total amount of biotin present in biotinylated protein conjugates. Conjugates of bovine serum albumin, alkaline phosphatase, and horseradish peroxidase were used in this case study. The extent of biotinylation was determined by complete acid hydrolysis or by enzymatic digestion using proteinase K to release biotin from the biotinylated proteins, followed by sensitive detection of biotin using a coupled HPLC–binding assay system. This detection system is based on the enhancement of the fluorescence of streptavidin-FITC by biotin. The extent of biotinylation determined by this method was compared with the values obtained by a conventional colorimetric method that is based on the displacement of the dye 4-hydroxyazobenzene-2-carboxylic acid (HABA) from the binding sites of avidin. It was found that, because the described method determines the amount of liberated biotin after hydrolysis, it does not suffer from steric hindrance problems associated with the ability of biotin on a protein surface to displace HABA from avidin. Therefore, this method can provide a more accurate determination of the extent of biotinylation. It was also determined that the acid hydrolysis of the biotinylated protein was more effective in releasing the conjugated biotin compared to enzymatic digestion by proteinase K.

INTRODUCTION

Biotin has an extraordinarily high affinity for (strept-)avidin with reported dissociation constants of $\sim 10^{-15}$ and $\sim 10^{-14}$ M for avidin and streptavidin, respectively (Green, 1990). Each (strept)avidin molecule has four binding sites that can bind biotin and biotinylated compounds. Further, a variety of biotinylating reagents are commercially available that can be used to attach biotin to proteins, nucleic acids, carbohydrates, and other biomolecules with relative ease (Wilchek and Bayer, 1990). This has led to an explosive growth in the use of biotin–(strept)avidin systems in various biotechnological, analytical, and therapeutical applications (Diamandis and Christopoulos, 1991; Wilchek and Bayer, 1988).

Biotinylation of proteins is generally achieved by an amidation reaction in which the free amino groups on lysine residues and the N terminus of proteins are reacted with an activated biotin derivative that is typically an *N*-hydroxysuccinimide (NHS) ester (Bayer and Wilchek, 1990). Sometimes, derivatives that introduce a spacer between the biotin and the protein surface are used to increase the accessibility of biotin toward (strept-)avidin (Barbarakis et al., 1993a). Knowledge of the degree of biotinylation is of importance in the characterization of biotinylated proteins for use in optimized binding assays, bioreactors, and biosensors.

Currently known methods for determining the extent of biotinylation of proteins can be broadly grouped into two categories: those that measure the accessible biotin on the protein, and those that measure the total biotinylation. 4-Hydroxyazobenzene-2-carboxylic acid (HABA) titration is one of the most commonly used methods to determine the extent of biotinylation (Bayer and Wilchek, 1990). In this case, HABA binds to avidin to give an absorption maximum at 500 nm. When biotin or biotin-

ylated proteins are added, biotin displaces HABA from avidin and the absorbance at 500 nm is reduced. The decrease in absorbance is then used to determine the extent of biotinylation. Because this method is based on an absorbance measurement, HABA titration suffers from low sensitivity. As a result, amounts typically in the order of several nanomoles of protein are required for the determination of the degree of biotinylation. More sensitive methods for biotin determination should reduce the amount of biotinylated protein sacrificed for this purpose.

Der-Bailian et al. (1990) developed a method to determine the degree of biotinylation that is based on quenching of the natural fluorescence of avidin by biotin moieties on the biotinylated protein. This method, though simple, sensitive, and reproducible, suffers from steric hindrance effects (i.e., not all biotin on a protein can simultaneously bind to avidin) and thus underestimates the extent of biotinylation. Shah et al. (1994) have developed a different method that is based on the competition between fluorescein-labeled biotin and the biotinylated protein toward an anti-biotin monoclonal antibody. The fluorescence polarization of the fluorescein-labeled biotin was measured and correlated to the extent of biotinylation. This method also suffers from steric hindrance effects that lead to underestimation of the extent of biotinylation. However, the two techniques mentioned above may be useful in determining the amount of functional (i.e., available for binding) biotins on proteins, although there still may be some questions raised about the proper calibration of the methods; that is, biotin cannot be used as a standard in these assays because it may induce a different fluorescence signal than the biotinylated protein (Mei et al., 1994). Smith et al. (1991) have reported a different method for the determination of the degree of protein biotinylation. This requires biotinylation with an ϵ -aminohexanoic acid derivative of biotin. After acid hydrolysis, amino acid analysis yields the number of aminohexanoic acids per protein, which is equal to the degree of biotinylation of the protein. This method has picomolar sensitivity, but can be used only if the bio-

tinylated residue has incorporated an ϵ -aminohexanoic acid spacer arm. Consequently, despite the extensive use of biotinylated proteins in a variety of applications, the literature on their characterization is sparse (Kurosky et al., 1993; Miles and Garcia, 1995; Miller et al., 1994; Yem et al., 1989), especially in terms of a general method that determines the total number of biotin moieties attached per protein molecule. Therefore, it is desirable to develop a new method that allows the accurate determination of the degree of biotinylation.

In this paper, we describe a method developed in our laboratory for the determination of the amount of biotin present in biotinylated proteins. This method is based on the complete acid hydrolysis of the biotinylated protein, followed by separation of the released biotin by HPLC, and determination of the amount of biotin present using a highly sensitive postcolumn reaction detection system that is based on a fluorescence binding assay. This method was also compared to an alternative hydrolysis approach that involved enzymatic digestion of the biotinylated protein using proteinase K.

EXPERIMENTAL PROCEDURES

Reagents. Biotin, horseradish peroxidase (HRP) type VIA, biotinylated bovine serum albumin (b-BSA), biotinamidocaproyl-labeled bovine serum albumin (bcap-BSA), biotinylated alkaline phosphatase (b-AP), avidin, *N*-hydroxysuccinimidobiotin (BNHS), sodium dodecyl sulfate (SDS), and proteinase K were all purchased from Sigma (St. Louis, MO). HABA and *N,N*-dimethylformamide (DMF) (ACS reagent grade), were obtained from Aldrich (Milwaukee, WI). Tris[hydroxymethyl]aminomethane (Tris) was from Research Organics (Cleveland, OH) and ethylenediaminetetraacetic acid (EDTA) from Mallinckrodt (St. Louis, MO). Streptavidin-FITC was purchased from Vector Laboratories (Burlingame, CA). Protein concentrations were determined according to the BCA protein assay (Pierce, Rockford, IL). Deionized water (Milli Q water purification system; Millipore, Bedford, MA) was used in the preparation of all solutions.

HPLC with Postcolumn Reaction Detection. The experimental setup used in this work consisted of a Rainin (Woburn, MA) HPLC system, which was interfaced with a Macintosh computer (Apple Computer, Cupertino, CA). The system included a Rainin Rabbit solvent-delivery system and a Rheodyne (Berkeley, CA) Model 7125 injector with a 20- μ L sample loop. The samples were separated using a reversed-phase 5 μ m Microsorb C₁₈ column (250 \times 4.6 mm i.d.) (Rainin). An 80:20 (v/v) mixture of phosphate buffer, pH 7.0, and methanol was used as the mobile phase at a flow rate of 0.4 mL/min.

The effluent stream from the HPLC column was mixed with the reagent stream containing 2 mg/L streptavidin labeled with fluorescein isothiocyanate (streptavidin-FITC) prepared by diluting a stock solution (purchased as 1 mg/mL solution) with 100 mM phosphate buffer, pH 8.4. The reagent solution was pumped by an ISCO (Lincoln, NE) Model LC-2600 syringe pump at a flow rate of 1 mL/min and was merged with the column effluent through a tee-connector followed by a 10.0-m knitted open-tubular (KOT) reactor made from PTFE tubing (0.5 mm i. d., 14-mm helix diameter) (Przyjazny et al., 1993). The binding of biotin to streptavidin-FITC resulted in an enhancement of fluorescence intensity (Hentz and Bachas, 1995). Detection of the change in fluorescence was carried out by using a Fluorolog-2 spectrofluorometer (SPEX Industries, Edison, NJ) with a μ -fluorescence flow cell (20- μ L cell volume; NSG Precision Cells, Farmingdale, NY). The excitation was set at 495 nm, and the

Figure 1. Calibration plot for biotin using the streptavidin-FITC-based postcolumn reaction detection system.

emission was monitored at 518 nm. The excitation and emission slit widths were each set at 2 nm. The SPEX spectrofluorometer was operated in the photon-counting mode. A calibration plot for biotin was prepared daily using biotin standards, and the corresponding peak areas were employed to estimate the amount of biotin present in each of the samples. A typical calibration plot is given in Figure 1.

Biotinylation of HRP. For the preparation of biotinylated HRP (b-HRP), HRP was dissolved in 100 mM sodium hydrogen carbonate solution, adjusted to pH 8, to obtain a 10 mg/mL solution. Sufficient volume of a BNHS solution (100 mM BNHS in DMF) was added to 100 μ L of an HRP solution to achieve an initial molar ratio of BNHS to HRP of 100. The biotinylation reaction was carried out in Reactivials (Pierce) for 3 h at room temperature. The reaction mixture was then dialyzed against phosphate buffer saline to remove unreacted BNHS.

Acid Hydrolysis of Biotinylated Proteins. The biotinylated proteins were hydrolyzed with 6 M HCl in an evacuated vacuole at 110 °C for 18–24 h and dried in a vacuum centrifuge (Savant Instruments, Hickville, NY). The samples were then dissolved in a known amount of deionized water and analyzed for the amount of biotin present.

Enzymatic Digestion of Biotinylated Proteins. The biotinylated proteins were digested with proteinase K and dissolved in 100 mM Tris-HCl buffer, pH 7.8, containing 5 mM EDTA and 0.5% (v/v) SDS. The molar ratio of proteinase K to biotinylated protein was 1:25 or 1:50. The digestion was carried out for 3 or 24 h at 37 °C. In all cases, the corresponding nonbiotinylated proteins were also processed under similar conditions and used as control samples. The digestion reaction was terminated by boiling the reaction mixture for 15 min. The samples were then used for biotin determination.

RESULTS AND DISCUSSION

The HABA titration method provides an estimate of the accessible biotin but not the true extent of biotinylation of a protein, because some of the biotin moieties on the protein may not be accessible for binding to avidin as shown in Figure 2. In scenario A, where both the biotins are accessible to avidin, the HABA titration gives an accurate value of the extent of biotinylation. However, erroneous results may be obtained with highly biotinylated proteins because of possible cross-linking between

Figure 2. Depending on the nature of biotinylated protein, the HABA titration may give erroneous results: (A) degree of biotinylation is 2 as determined by HABA titration; (B) degree of biotinylation is determined to be 6; (C) degree of biotinylation is determined to be 4 for the same conjugate as in (B). Av, B, P, and H represent avidin, biotin, protein, and HABA, respectively.

avidin and biotinylated protein molecules (as a result of the availability of four binding sites on avidin) and/or steric hindrance effects, all of which may prohibit some of the biotin moieties on the surface of the protein from binding to avidin. The effect of steric hindrance is illustrated in Figure 2 (parts B and C), where for the same conjugate the accessible biotin in scenario B is 6 and in C is 4. This is also true for other assays that are based on the interaction between the biotinylated protein and avidin, streptavidin, or anti-biotin antibodies (Der-Bailian et al., 1990; Shah et al., 1994). Therefore, the HABA titration and the other methods that use intact biotinylated protein typically underestimate the extent of biotinylation and may not even be accurate at calculating the functional biotins on the protein molecule because of steric/cross-linking effects. Further, as mentioned earlier, additional questions may be raised about the ability of some of these methods to determine the degree of functional biotin on proteins, because free biotin and biotinylated protein have a different effect on the intrinsic fluorescence of avidin (Mei et al., 1994).

Bayer and Wilchek (1990) have reported that one of the ways to circumvent the problems described above is to digest the biotinylated protein with proteinase K and determine the amount of free biotin released. This should give the true degree of biotinylation. As demonstrated in the present study (*vide infra*) and depending on the protein, the enzymatic digestion may lead to incomplete hydrolysis of the biotinylated protein and thus inaccurate results.

To determine the total number of biotin moieties attached per protein molecule, a highly sensitive method was developed in our laboratory, which is based on complete hydrolysis of the biotinylated protein followed by a fluorescence binding assay that monitors the enhancement of fluorescence of streptavidin-FITC by biotin. Complete hydrolysis of the protein is necessary because biotin and biotinylated peptides could induce different

Figure 3. Separation and detection of free biotin released by a 24-h proteinase K digestion from b-HRP (moles of b-HRP/mole of proteinase K = 25).

fluorescence enhancement to streptavidin-FITC (Barbarakis et al., 1993b), which may give erroneous results for the degree of biotinylation. By coupling a postcolumn reaction detection system based on this fluorescence binding assay to a HPLC separation, it is possible to verify the complete hydrolysis of the protein. It should be noted that the method has no interferences from amino acids that are not biotinylated, because these compounds do not induce a change in the fluorescence of streptavidin-FITC. The coupled HPLC-binding assay system also has good detection limits (4×10^{-13} mol of biotin), which reduces the amount of biotinylated protein needed for the assay.

Proteinase K digestion and acid hydrolysis were investigated as methods for the release of biotin from the biotinylated proteins. It was reported earlier that, in about 3 h, proteinase K digests protein completely (Bayer and Wilchek, 1990; Ebeling et al., 1974). It was found, however, that 3 h was not enough to completely digest b-HRP, and therefore longer digestion times were used for this purpose. The chromatogram of the digest after a 24-h hydrolysis with proteinase K is shown in Figure 3, where biotin elutes out at 15.2 min (the hold-up time is 10.8 min). These data, in conjunction with a calibration plot for biotin (see Experimental Procedures), were used to calculate the extent of biotinylation, which was found to be 1.8 biotins per HRP molecule. Given that biotinylation was performed with a 100-fold excess of BNHS, this value of the degree of biotinylation is consistent with previous observations reporting that only 2 of the 7 amino groups of HRP (6 lysines and the N terminus) are accessible for modification by NHS esters (Paek et al., 1993; Zaitsev et al., 1992). The small peak at ~19 min is most probably due to a biotinylated peptide and suggests incomplete hydrolysis of b-HRP even after a 24-h digestion with proteinase K. As anticipated, the chromatograms corresponding to the hydrolysis product of the nonbiotinylated proteins had no peaks, which indicates the selective nature of the postcolumn reaction detection system used toward the biotin moiety.

As shown in Figure 3, prolonged digestion of b-HRP with proteinase K does not always give complete hydrolysis. This is more pronounced in Figure 4, which shows the chromatogram obtained when b-BSA was digested for 3 h with proteinase K in amounts that were 25-fold less than b-BSA on a mole-to-mole basis. The additional peaks at retention times longer than that of biotin (biotin elutes at ~15 min) indicate that the hydrolysis of the protein was incomplete. It should be mentioned that the

Figure 4. Separation and detection of free biotin released by a 3-h proteinase K digestion from b-BSA (moles of b-BSA/mole of proteinase K = 25).

Figure 5. Separation and detection of acid-hydrolyzed b-BSA.

postcolumn reaction detection system used is highly selective and only detects biotin or biotinylated compounds. Thus, the additional peaks at 18.4 and 19.8 min are most probably due to biotinylated peptides. It was also found that the amount of proteinase K plays a role in the extent of hydrolysis and that an increase in the amount of proteinase K used causes an increase in the amount of biotin released. However, it was not possible to eliminate the additional chromatographic peaks by altering the amount of proteinase K used and/or the digestion time. The additional peaks were persistent even after 24 h of digestion with proteinase K. Therefore, proteinase K is not the ideal reagent to cause complete release of biotin, and this was verified as shown in Figure 4 by using the coupled HPLC–fluorescence system.

Hydrolysis of proteins with concentrated HCl is commonly used to achieve complete digestion of proteins prior to amino acid analysis. Given the shortcomings of the proteinase K digestion, acid hydrolysis in evacuated vacuoles was performed on b-BSA, b-HRP, and b-AP. When b-BSA, b-HRP, and b-AP were analyzed for biotin, the chromatograms showed a single peak due to biotin. Figure 5 depicts a typical chromatogram of an acid-hydrolyzed biotinylated protein. The values of the degree of biotinylation obtained by this method are higher than those determined by HABA titration (Table 1). The HABA titration gave degrees of biotinylation of 8.6 for b-BSA and 1.9 for b-HRP, while it was found by the method described above using acid hydrolysis combined with fluorescence binding assay that the ratios of (moles

Table 1. Comparison of Different Methods Used To Estimate the Extent of Biotinylation of b-HRP and b-BSA

method of determination	b-HRP	b-BSA
HABA titration	1.9	8.6
after enzymatic digestion with proteinase K, 3 h	0.8	10.1
after enzymatic digestion with proteinase K, 24 h	1.8	10.4
after acid hydrolysis	1.9	11.8

of biotin)/(mole of b-BSA) were 11.8 and 1.9, respectively. In the case of biotinylated alkaline phosphatase the chromatogram of the acid-hydrolyzed product also showed a single peak that corresponds to biotin. From these data the degree of biotinylation was estimated to be 6.2, while the enzymatically digested sample of the same conjugate gave a degree of biotinylation of 4.5.

Because it is based on the determination of the amount of free biotin released from a biotinylated conjugate, the proposed method does not suffer from the bane of steric hindrance. Biotin and biotinylated analogs when reacted with streptavidin-FITC enhance the fluorescence intensity by different amounts (Barbarakis et al., 1993b). Therefore, complete hydrolysis, as reflected in a single peak for free biotin when using the HPLC–fluorescence detection method, is important for the accurate determination of biotin present and, thus, the degree of biotinylation. In the case of enzymatic digestion, the digest contains a few biotinylated peptides along with the released free biotin (e.g., see Figure 4). Therefore, enzymatic digestion does not provide accurate results.

Biotinylating reagents that incorporate a spacer arm between biotin and the protein have also been used to reduce steric hindrance in the interaction with strept(avidin) (Barbarakis et al., 1992; Wilchek and Bayer, 1990). In that regard, a conjugate of BSA with a long-chain biotin derivative (bcap-BSA) was studied to compare the proposed method with the HABA titration. The HABA titration gave a degree of biotinylation of 10.9, while the acid hydrolysis followed by the HPLC–fluorescence detection gave a degree of biotinylation of 12.2. Thus, the HABA titration underestimates the degree of biotinylation of b-BSA (data discussed above) and bcap-BSA by 27% and 9.9%, respectively. The HABA titration has less relative error with bcap-BSA than with b-BSA, which is not surprising given the presence of the spacer arm between biotin and BSA. This allows for better accessibility of the attached biotin to avidin. However, even in bcap-BSA there are still on average 1.3 biotins per BSA molecule that are sterically hindered from binding to avidin. Complete acid hydrolysis of bcap-BSA, on the other hand, provides the total amount of biotin conjugated to the protein.

In conclusion, the method described in this paper is able to give an accurate estimation of the degree of biotinylation. The method has an excellent detection limit of 2×10^{-8} M for biotin. The acid hydrolysis to release biotin is superior to enzymatic digestion as it leads to complete hydrolysis of the protein. The enzymatic digestion is dependent on the amount of proteinase K used and the time of digestion. The currently described method should pose no problems when the degree of biotinylation of proteins prepared by using BNHS or longer chain esters of NHS is determined.

Synthesis of Oligonucleotides Containing 3'-Alkylcarboxylic Acids Using a Palladium Labile Oligonucleotide Solid Phase Synthesis Support

Tracy J. Matray, Dong Jin Yoo, Dustin L. McMin, and Marc M. Greenberg*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523. Received October 31, 1996[®]

Oligonucleotides containing a 3'-alkylcarboxylic acid are isolated using a Pd(0)-catalyzed cleavage reaction, in yields that are in most cases within experimental error of those isolated using standard oligonucleotide cleavage conditions (concentrated NH_4OH). In contrast to results obtained with photolabile solid phase synthesis supports, no reduction in isolated yields of the oligonucleotides is observed when their length is increased from 20 to 40 nucleotides. The oligonucleotides are characterized by anion exchange HPLC, electrospray mass spectrometry, and enzymatic digestion. When methyl phosphoramidites are employed in the synthesis of the biopolymers, **3** serves as an orthogonal solid phase oligonucleotide synthesis support.

Solid phase oligonucleotide synthesis has advanced to a very efficient state. Scientists working with nucleic acids now have a wide variety of methodologies available for preparing native oligonucleotides, as well as biopolymers containing modified backbones, nucleobases, and sugars (1). These recent advances in solid phase synthesis have led to strategies for the synthesis of oligonucleotide conjugates (2–5). Both naturally occurring and synthetic oligonucleotide conjugates show promise as therapeutic agents and diagnostic probes. For example, it has been shown that oligonucleotide bioconjugates can facilitate the transport of potential antisense agents through cell membranes (6–8). The methodology for synthesizing bioconjugates, particularly those in which the covalent linkage is at the 3'-terminus of the oligonucleotide, has lagged behind the aforementioned aspects of nucleic acid synthesis (9). One approach to bioconjugate formation involves utilizing fully depro-

tected oligonucleotides as substrates. The poor solubility of such substrates in many organic solvents limits the scope of reactions that can be utilized to effect conjugation. Another difficulty associated with this method of oligonucleotide conjugate formation is attributable to side reactions occurring with the exocyclic amines located throughout the biopolymer (10, 11).

To ameliorate these limitations, we, and others, have suggested utilizing protected oligonucleotides (retaining their nucleobase and phosphate protecting groups) that contain a single exposed functional group as substrates for nucleic acid conjugation reactions (12–16). Before such a bioconjugation strategy is pursued, it is necessary to develop methodology for cleaving protected oligonucleotides containing a single functional group at their 3'-termini from their solid phase supports. We have previously reported on several orthogonal solid phase supports that utilize the *o*-nitrobenzyl photoredox reaction (12–14). Oligonucleotides containing 3'-hydroxy- and 3'-alkylcarboxylic acids and 3'-alkylamines have been

^a Pd(0) cleavage reactions were carried out as described in footnote 2. ^b Determined as described in footnote 1.

obtained using these supports. These supports are compatible with commercially available reagents and automated oligonucleotide synthesis protocols. Isolated yields as high as 98% of oligonucleotides containing photodamage below detectable limits have been obtained using commonly available irradiation sources (12, 13).¹ A shortcoming of these photolabile synthesis supports was revealed during the synthesis of longer oligonucleotides. A decrease in yield was observed as the length of the biopolymer was increased from 20 to 40 nucleotides (12). This decrease in yield was attributed to greater competition for light by the protected biopolymer with the *o*-nitrobenzyl chromophore. While yields can be increased by extending the irradiation period, this also increases the amount of photodamage. This observation prompted us to investigate an alternative reaction for the cleavage of protected oligonucleotides from solid phase supports.

In designing a new generation of orthogonal oligonucleotide synthesis supports for which the cleavage reaction would not be dependent upon biopolymer length, we chose to utilize the proven Pd(0)-catalyzed allyl transfer reaction (17–21). This reaction has been used successfully for deprotecting the exocyclic amines of nucleobases and the phosphate diesters during oligonucleotide synthesis, as well as an orthogonal linker for peptide synthesis. Prior to commencing the synthesis of an appropriate solid support, we sought to ensure that the conditions employed to cleave the allyloxy linker were orthogonal with respect to the oligonucleotide protecting groups used in commercially available reagents. The stability of amide protecting groups for the exocyclic amines was not a concern. In addition, the 5'-*O*-dimethoxytrityl group of **1** was stable to Pd₂(dba)₃·CHCl₃

and PPh₃ in *n*-BuNH₂/HCO₂H (1.2 M) between 25 and 55 °C for up to 7 h. However, contrary to assumptions in a recent paper, the β -cyanoethyl group was cleaved completely within 1 h at 55 °C under these conditions

¹ Yields of oligonucleotides obtained from orthogonal solid phase supports are determined via comparison of the isolated yield of oligonucleotide obtained via Pd(0) cleavage and subsequent NH₄OH treatment versus that obtained via direct NH₄OH treatment of resin-bound oligonucleotide from the same oligonucleotide synthesis.

Scheme 1

(16). This problem was alleviated using monomer **2**. The *O*-methyl phosphate triester was shown to undergo only minor (\approx 10%) decomposition over the course of 7 h at 55 °C in the presence of these reagents.

Having established the suitability of the Pd(0)-catalyzed allyl transfer reaction as the basis for an orthogonal solid phase support, **3** was designed to function as a universal solid phase synthesis support for the preparation of oligonucleotides containing 3'-alkylcarboxylic acids (Scheme 1) (14). Support **3** was rapidly assembled in a convergent manner via the coupling of previously reported **4** and **5** (Scheme 2) (14, 22). The long-chain alkylamine controlled pore glass support (LCAA-CPG) was loaded (45 μ mol/g) using the trichlorophenyl ester of **7**. Oligonucleotides were synthesized on **3** using standard oligonucleotide synthesis cycles, in which (while not necessary) the 5'-*O*-dimethoxytrityl group was removed prior to cleavage of the oligonucleotide from the support. With the exception of the substitution of *t*-BuOOH in CH₂Cl₂ for I₂ in pyridine/H₂O (to guard against iodination of the double bond), all oligonucleotide synthesis reagents used were commercially available (17).

Conditions for the cleavage of oligonucleotides from **3** were optimized utilizing the isolation of an eicosameric polythymidylate (**8**). The yields were determined for fully deprotected, gel-purified oligonucleotides.¹ Consequently, cleavage reactions could be carried out on oligonucleotides prepared using β -cyanoethyl or methyl protected phosphoramidites. Initial Pd(0)-catalyzed cleavage reactions were carried out under the conditions prescribed for the removal of phosphate and nucleobase amine protecting groups (17). To obtain tractable material, it was necessary to remove the *n*-butylamine/formic acid buffer and phosphine reagent prior to treating the cleaved oligonucleotide with NH₄OH. However, removal of the large excess of PPh₃ via trituration of the residue with hexanes proved difficult. The amorphous organic material obtained was difficult to handle, resulting in erratic yields of isolated **8**. Utilization of bis(diphen-

Scheme 2

ylphosphino)ethane (DIPHOS) in place of PPh_3 enabled us to employ only 5 equiv of phosphine ligand relative to $\text{Pd}_2(\text{dba})_3 \cdot \text{CHCl}_3$.² Subsequent workup of the protected oligonucleotide yielded a more tractable material. Yields of eicosameric polythymidylate within experimental error of those obtained via direct ammonolysis were achieved from *O*- β -cyanoethyl phosphate protected oligonucleotides after 7 h at 55 °C (Table 1).¹ Eicosameric polythymidylates containing phosphate protecting groups (*O*-methyl) that are orthogonal with regard to the Pd(0)-mediated cleavage were also isolated in quantitative yields (Table 1). Further optimization of the reaction conditions proved that 5 h was sufficient to effect complete cleavage of the oligonucleotide from the solid support.

Electrospray mass spectrometry (ESMS) proved that the alkylcarboxy group remained intact during the various deprotection and purification procedures. Only a small amount of dealkylated material was formed. We believe that the dealkylated material results from formation of the dianion during NH_4OH deprotection, followed by intramolecular displacement of the phosphate-terminated oligonucleotide. ESMS could not distinguish between the polythymidylates cleaved directly from **3** with NH_4OH and those cleaved with Pd(0), as they differ by only 1 mass unit. However, the two products are separable on anion exchange HPLC, where **8** eluted more than 1 min later than the respective amide obtained from NH_4OH treatment of resin-bound oligonucleotide.

² Typical procedure for palladium(0)-mediated cleavage of CPG-bound oligonucleotides: In a typical procedure, $\text{Pd}_2(\text{dba})_3 \cdot \text{CHCl}_3$ (0.5 mg, 0.5 μmol) was added to a mixture of the appropriate oligonucleotide that was synthesized on **3** (1 mg, $\approx 0.05 \mu\text{mol}$) and 1,2-bis(diphenylphosphino)ethane (1 mg, 2.5 μmol) in THF (170 μL , sparged with N_2 for 30 min). After addition of *n*-butylamine (18 mg, 240 μmol , sparged with N_2 for 30 min) and formic acid (11 mg, 240 μmol , sparged with N_2 for 30 min), the mixture was vortexed well and heated at 55 °C. The reaction vessel was vortexed approximately every 15–30 min. After the appropriate reaction time, the solution was transferred to a vial and concentrated *in vacuo* to give a black residue. The residue was dissolved in a 1:1 mixture (by volume) of THF/ H_2O (1 mL) and evaporated to dryness. This process was repeated a second time. The residue was then triturated with hexanes (2 \times 2 mL), dissolved in CH_3CN (1 mL), and filtered through a nylon filter (0.45 μm). The filter was washed well with CH_3CN (3 mL) and then H_2O (3 mL). All of the washings were combined and evaporated to dryness *in vacuo*. The residue was suspended in concentrated NH_4OH and heated for 10 h at 55 °C. After the NH_4OH was removed *in vacuo*, the residue was suspended in formamide loading buffer (70 μL) containing sodium *N,N*-diethyldithiocarbamic acid (30 mM) and purified by denaturing polyacrylamide gel electrophoresis (20% polyacrylamide). The oligonucleotide was extracted from the gel slice with NaCl (0.2 M) and EDTA (1 mM) and desalted using a reversed phase purification cartridge.

Using the optimized conditions for cleaving methyl phosphate protected polythymidylates, we examined the suitability of the methodology for obtaining oligonucleotides containing all four native nucleotides. We determined that the yields of oligonucleotides prepared on **3** and cleaved via Pd(0) were not strongly dependent upon sequence or length (Table 1).¹ Furthermore, enzymatic digestion of heteropolymers prepared on **3** using β -cyanoethyl phosphoramidites that were cleaved with Pd(0) reveals that no extraneous nucleosides are formed, demonstrating that the Pd(0) cleavage process does not damage the biopolymer.

In summary, we have utilized Pd(0)-catalyzed cleavage of allyl groups to cleave oligonucleotides, conjugated to alkylcarboxylic acids at their 3'-termini, from their solid phase synthesis supports in very high yield.¹ The cleavage reaction is orthogonal to commercially available *O*-methyl phosphoramidite protecting groups. This methodology should prove to be highly useful for the preparation of more elaborate oligonucleotide conjugates.

Enclosed herein is additional primary data concerning the characterization of oligonucleotides obtained from the Pd(0) cleavage methodology presented. This data includes:

1. Enzymatic digests of eicosameric oligonucleotides of identical sequence obtained via direct ammonolysis (Labelled: A) of the biopolymer, and that isolated via ammonolysis following Pd(0) cleavage (Labelled: B) of the oligonucleotide. The oligonucleotide was synthesized using β -cyanoethyl phosphoramidites. The enzymatic digestion was carried out via standard procedures using snake venom phosphodiesterase, followed by dephosphorylation using calf intestine alkaline phosphatase. For an example of the description of such a procedure, see: Greenberg, M. M. and Gilmore, J. L. *J. Org. Chem.* **1994**, *59*, 746. The oligonucleotide digested is that shown below.

2. Electrospray mass spectrum of an eicosameric polythymidylate isolated via the Pd(0) cleavage procedure described in the manuscript. The observed ions are within one atomic mass unit of the calculated masses for **8** and the dealkylated product.

Received December 17, 1996[®]

Conjugates of biotin with the decamer of glutamic acid (glu₁₀) and the trimer of D,L-2-amino-5-phosphonovaleric acid (**I**) have been synthesized, and it has been shown that they mediate the binding of avidin to hydroxylapatite. In a similar way a conjugate of methotrexate with glu₁₀ mediates the binding of dihydrofolate reductase to the mineral. The presentation of ligands on the hydroxylapatite component of bone may find applications in clinical medicine.

Peptides containing several aspartic and glutamic acid residues, oligonucleotides, and other polyanions bind strongly but reversibly to hydroxylapatite; this is the basis of hydroxylapatite chromatography (1, 2). We have recently found that oligomers of glutamic acid as short as the hexamer bind quantitatively to hydroxylapatite and are not removed by washing with water or a 0.1 M NaCl solution (3). This suggests that negatively charged polypeptides might be used as linkers to bind ligands to the mineral component of bone with controllable affinity and retention time. In this paper we show that conjugates of biotin and methotrexate with negatively charged peptides may be used to mediate the binding of avidin and dihydrofolate reductase, respectively, to hydroxylapatite.

Glu₁₀ was synthesized by the Peptide Biology Laboratory at The Salk Institute. D,L-2-Amino-5-phosphonovaleric acid (**I**), methotrexate (MTX), chicken liver dihy-

drofolate reductase (DHFR), and *N*-hydroxysuccinimide (N-OH-succ) were obtained from Sigma; 1,1-carbonyldiimidazole (CDI) and dicyclohexylcarbodiimide (DCC) were from Aldrich. Succinimidyl-6-(biotinamido) hexanoate (NHS-LC-Biotin II) was obtained from Pierce, streptavidin from Boehringer, ¹²⁵I-labeled streptavidin from Amersham, and hydroxylapatite (HA) from Bio-Rad.

The biotin derivative of glu₁₀ was synthesized by reacting 25 nmol of the oligomer with 190 nmol of NHS-LC-Biotin II in 20 μ L of 0.1 M NaHCO₃ buffer at pH 8.4 for 45 min. The product was purified on a C₁₈ column using a 0.1% TFA/acetonitrile gradient and its identity confirmed by LDMS (calculated for C₆₆H₉₇N₁₃O₃₄S + Na⁺ 1670.6; found 1670.7).

The MTX derivative of glu₁₀ was synthesized via an *N*-hydroxysuccinimide intermediate (4). A solution (40 μ L) containing 0.05 M MTX, 0.05 M N-OH-succ, and 0.05 M DCC in DMF was allowed to stand at room temperature for 1 h and then at 2–4 °C overnight. Ten microliters of the resulting solution was added to 5–25 nmol of glu₁₀ in 30 μ L of 0.02 M NaHCO₃ at pH 8.2. The reaction mixture was shaken in the dark for 4 h and then diluted with 70 μ L of water. Unreacted MTX and salts were removed by shaking the reaction mixture with 10 mg of HA overnight, removing the supernatant, and washing the HA with water. Glu₁₀ and its MTX conjugate were eluted by shaking the HA with 2 \times 50 μ L of 0.02 M pyrophosphate for 30 min. The conjugate was purified by HPLC on a C₁₈ column. Its identity was confirmed by LDMS (calculated for C₇₀H₉₂N₁₈O₃₅ + H⁺ 1745.6; found 1745.0).

Oligomers of D,L-2-amino-5-phosphonovaleric acid (pvl) were synthesized from the monomer (**I**) using carbonyldiimidazole (CDI) as a condensing agent (5). A solution of the monomer at pH 8 (0.05–0.1 M) was added to a 3-fold excess of solid CDI, and the resulting solution was allowed to stand for 6 h (or overnight). Products ranging from the dimer to the pentamer were identified by paper chromatography (*n*-PrOH/NH₃/H₂O 7:1:2), and samples of the oligomers were eluted from the paper. HPLC of the reaction mixture on an RPC-5 column gave a series of peaks that were assigned to oligomers of known length by cochromatography with the material eluted from paper.

To determine the shortest oligomer that binds to HA, 2–3 μ g of the dimer, trimer, tetramer, or pentamer was separately shaken with 10 mg of HA, and any oligomer retained by the HA was eluted with K₄P₂O₇ as described above. HPLC analysis of the supernatant and K₄P₂O₇ eluate showed that trimers and longer oligomers of pvl were found only in the eluate and therefore had been bound by the HA. Dimers were not bound to HA and were found in the supernatant fraction.

To obtain the biotin derivative of (pvl)₃, 6 μ g of the tripeptide isolated from RPC-5 was first adsorbed to 10 mg of HA. The solid was separated by centrifugation and washed with H₂O to remove Tris and other components of the HPLC buffer. (Pvl)₃ was then eluted with pyrophosphate as described above. (Pvl)₃ (5–10 μ g) in 20 μ L of buffer containing 0.2 M pyrophosphate and 0.2 M NaHCO₃ (pH 8.4) was added to 0.1 mg of solid NHS-LC-Biotin II. The reaction mixture was then allowed to stand for 1 h at room temperature. The biotinyl derivative of the tripeptide was purified and isolated using an

Table 1. Biotin-Mediated Binding of Streptavidin to Hydroxylapatite

	% [125 I]streptavidin in supernatant	% [125 I]streptavidin on hydroxylapatite
glu ₁₀	97	3
pvl ₃	97	3
biotin-glu ₁₀	25	75
biotin-pvl ₃	32	68

RPC-5 column. Its identity was confirmed by ESMS (calculated for C₃₁H₅₇N₆O₁₆P₃S - H 893.2; found 893).

To recruit streptavidin to HA, 1 nmol of biotin-glu₁₀ or biotin-(pvl)₃ was first shaken with 1 mg of HA in 20 μ L of 0.01 M Tris-ClO₄ for 6 h (or overnight) at room temperature. The supernatant was removed by centrifugation, and the HA was washed with 100 μ L of water. A solution of 0.1 nmol of [125 I]-labeled streptavidin (25 000–50 000 cpm) in 100 μ L of buffer containing 1 M KCl and 0.01 M phosphate at pH 6.5 was added to the HA and shaken for 45 min. The supernatant was removed by centrifugation and the HA washed several times with 200 μ L of H₂O. The amounts of radioactivity found in the supernatant, wash, and HA fractions were then measured (see Table 1). In control experiments, biotin-glu₁₀ was replaced by glu₁₀ and biotin-(pvl)₃ was replaced by (pvl)₃. When a peptide bound to the HA was ligated to biotin about 70% of the streptavidin was recruited to the HA and 25–30% remained in the supernatant (Table 1). In the control experiments no more than 5% of the streptavidin was bound to the HA. Clearly the preadsorption of biotin conjugates of negatively charged polypeptides greatly enhances the adsorption of avidin to HA.

To recruit dihydrofolate reductase to HA, 1 nmol of MTX-glu₁₀ was adsorbed to HA as described above for biotin-glu₁₀. DHFR (0.52 nmol) in 200 μ L of buffer containing 0.1 M ammonium sulfate, 0.01 M potassium phosphate, at pH 6.4, and 5% glycerol was added to the HA and shaken for 45 min. The HA was separated from the supernatant, washed with 100 μ L of water, and then eluted twice with 20 μ L of 0.02 M K₄P₂O₇. In control experiments the MTX-glu₁₀ was replaced by glu₁₀. The supernatant, the washes, and the pyrophosphate eluate were analyzed on a 6% acrylamide SDS gel using Coomassie Blue to visualize DHFR. Figure 1 shows that in the control experiments with glu₁₀ more than 75% of the DHFR was found in the supernatant (Figure 1, lane 1) and only a small amount in the pyrophosphate eluate (Figure 1, lane 3). In experiments involving MTX-glu₁₀ more than 75% of the DHFR was found in the pyrophosphate eluate (Figure 1, lane 6) and very little in the supernatant (Figure 1, lane 4). Preadsorption of MTX-glu₁₀, therefore, greatly increases the amount of DHFR that binds to HA.

The above results show that conjugates of various ligands with anionic polypeptides adsorbed noncovalently on hydroxylapatite could be used as supports for affinity chromatography. More importantly, HA presents special opportunities in a related context, because it is the main mineral component of bone. The surface of bone is freely accessible to molecules in the extracellular fluid even if they are as large as proteins (6). The bisphosphonates, small molecules carrying four negative charges, have been used extensively to attach technetium to hydroxylapatite for bone scintigraphy (7). One example of the recruitment of an anticancer drug, methotrexate, to bone using a bisphosphonate has been reported (8). We believe that anionic polypeptides may prove particularly convenient as carriers of ligands to bone and may sometimes have advantages over the bisphosphonates.

Figure 1. Coomassie Blue stained SDS gel showing DHFR in the supernatant (lanes 1 and 4), the wash (lanes 2 and 5), or the pyrophosphate eluate (lanes 3 and 6) after shaking a solution of the enzyme with glu₁₀-bound hydroxylapatite (HA) (lanes 1–3) or with MTX-glu₁₀-bound HA (lanes 4–6). One nanomole of glu₁₀ or MTX-glu₁₀ was shaken with 1 mg of HA for 6 h. Excess peptide was removed by washing. The glu₁₀- or MTX-glu₁₀-bound HA was then shaken with 0.52 nmol of DHFR for 45 min. The supernatant was removed by centrifugation and the HA washed with 100 μ L of water. The glu₁₀ and MTX-glu₁₀ together with any bound DHFR were eluted from the HA by shaking with 2 \times 50 μ L of pyrophosphate solution for 30 min.

The mechanism of action of bisphosphonates on bone resorption is not fully understood, but it seems clear that it is not entirely a matter of adsorption to hydroxylapatite. The properties of osteoblasts are profoundly affected by submicromolar concentrations of bisphosphonates, suggesting that they attach to receptors, possibly pyrophosphate receptors, on the cell surface (9). The structures of polypeptides are completely unrelated to that of inorganic pyrophosphate, so by using them as carriers it should be possible to dissociate the direct effects of adsorption to HA from the indirect effects due to interaction with extracellular receptors on osteoblasts (or osteoclasts).

Polypeptides are uniquely convenient as carriers, because effective automated methods are already available for their synthesis, and the use of combinatorial peptide libraries is well-established. The strength of adsorption of the carriers could easily be controlled via their length, while more or less degradable carriers could be obtained by varying the ratio of D- to L-residues. In the special case of a peptide ligand, the ligand and the anionic carrier could be assembled in a single solid-phase peptide synthesis. Presentation of ligands on HA that interact directly with receptors on osteoblasts or osteoclasts, or which recruit proteins to bone, may find applications in medicine.

Mitogenic Activities of Water-Soluble and -Insoluble Insulin Conjugates

Guoping Chen, Yoshihiro Ito,* and Yukio Imanishi

Department of Material Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606-01, Japan. Received May 3, 1996[®]

Insulin was covalently bound to water-soluble polymers such as poly(oxyethylene) and poly(acrylic acid). The former and the latter product are water-soluble monovalent and multivalent conjugates, respectively. Insulin was also bound to a poly(acrylic acid)-grafted polystyrene film, to form a water-insoluble multivalent conjugate. The matrix polymer was prepared by graft polymerization of acrylic acid initiated by glow-discharged polystyrene film. Insulin coupled with poly(oxyethylene) reduced the mitogenic activity, but the poly(acrylic acid)–insulin conjugate stimulated cell growth more than native insulin. A concentration of immobilized insulin much lower than that of native insulin and the water-soluble insulin conjugates accelerated cell growth. The maximal mitogenic effect of the immobilized insulin was greater than that of native insulin or the water-soluble insulin conjugates. The findings suggest that the mitogenic effect of the water-insoluble, multivalent insulin conjugate lasts longer than that of the water-soluble conjugates, owing to the absence of internalization into the cell.

INTRODUCTION

Developments in molecular biology have revealed the importance of biosignaling polypeptides, including growth factors and cytokines. The covalent binding of biosignal molecules to a soluble or insoluble matrix has a wide range of applications, ranging from the elucidation of biosignaling mechanisms and receptor isolation to clinical therapeutics such as drug delivery and tissue regeneration systems (1–4). The binding of biosignal molecules to their specific receptors may lead to specific complexes which are assembled and internalized into the cytoplasm with a portion of the receptors returning to the cell surface (down-regulation). However, whether all of these processes are necessary has not been clarified. If the internalization of biosignal–receptor complexes is not indispensable for signal transduction, biosignal molecules covalently linked to water-insoluble matrix should be active.

We showed that insulin immobilized on various water-insoluble matrices enhances the growth of anchorage-dependent cells more than native insulin (5, 6). We considered that this effect was due to long-lasting signal transduction due to inhibited down-regulation (7). However, the growth-acceleration effect of immobilized insulin might involve effects arising from chemical modifications of the insulin and the generation of a multivalent ligand system. These effects of immobilized insulin have not been thoroughly investigated.

In the present study, to clarify the effect of chemical modification and the generation of a multivalent ligand system, we synthesized insulin–poly(oxyethylene) or insulin–poly(acrylic acid) conjugates and compared their effects with those of insulin immobilized to a poly(acrylic acid)-grafted polystyrene film.

MATERIALS AND METHODS

Materials. Insulin (Ins) (bovine origin, no. I-5500) and tresylated ω -methoxypoly(oxyethylene) (POE, MW = 5000) were purchased from Sigma Chemical Co. (St. Louis). [¹²⁵I]Insulin was purchased from Daiichi Chemical Ltd. (Tokyo). Poly(acrylic acid) (PAA, MW = 15 000), acrylic acid, and Clear-sol I were purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Polystyrene (PSt) was purchased from Wako Pure Chemical Ltd. (Osaka, Japan) and purified by precipitation in methanol before use.

Poly(oxyethylene) Conjugates. The synthetic scheme is shown in Figure 1a (8). A phosphate-buffered solution (pH 7.0, 0.5 mL) containing tresylated POE (100 μ g) and the same solution (0.5 mL) containing insulin (1 mg) with or without [¹²⁵I]insulin were mixed and stirred for 24 h at 4 °C. The product was purified by ultrafiltration (Millipore Molecut II, filtration off below 10 kDa) and referred to as Ins–POE. The formation of the insulin conjugate was confirmed by high-performance liquid chromatography (HPLC) using a column packed with Cosmosil 5Diol-120, purchased from Nacalai Tesque, Inc. [eluent, 0.02 M phosphate buffer (pH 7.0) and 0.2 M NaCl; elution rate, 1.0 mL/min at room temperature; detection, absorbance at 280 nm].

Poly(acrylic acid) Conjugates. The synthetic scheme is shown in Figure 1b. A phosphate-buffered solution (pH 7.0, 0.5 mL) containing PAA (100 μ g) was mixed with the same solution (0.5 mL) containing 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (water-soluble carbodiimide, WSC, 1 mg), and the mixture was stirred for 24 h at 4 °C. The solution containing activated PAA was quickly ultrafiltrated (Millipore Molecut II, filtration off below 10 kDa), mixed with a phosphate-buffered solution (pH 7.0, 1 mL) containing insulin (1 mg) with or without [¹²⁵I]insulin, and then stirred at 4 °C for 24 h. Thereafter, a phosphate-buffered solution containing glycine (10 mg, 1 mL) was added to the reaction mixture and left at 4 °C for a further 6 h to block any

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1996.

Figure 1. Synthetic schemes of insulin conjugates with (a) poly(oxyethylene) (POE), (b) poly(acrylic acid) (PAA), and (c) poly(acrylic acid)-grafted polystyrene (PSt) film. WSC is water-soluble carbodiimide.

activated carboxylic groups of PAA that remained unreacted. The product was purified by ultrafiltration and is referred to as Ins-PAA. The formation of Ins-PAA was confirmed by HPLC as described above for Ins-POE.

Immobilization of Insulin onto a Poly(acrylic acid)-Grafted Polystyrene Film. The synthetic scheme is shown in Figure 1c. A PSt film was cast from a toluene solution (15 wt %) on a circular glass plate (diameter, 15 mm). The film was glow-discharged (200 W) with a high-frequency wave generator (Nihon Koshuha Co., Yokohama, Japan) for 20 s under a pressure of 5.65 Pa. The film was exposed to air and incubated in a solution of acrylic acid (20 wt %) for 24 h at 60°C . The PAA-grafted PSt film was washed with distilled water until the absence of unreacted monomer and unbound PAA in the wash was confirmed by a pH monitor.

The PAA-grafted PSt film was immersed in a phosphate-buffered solution (pH 7.0) containing WSC (1 mg/mL) and ^{125}I insulin of various concentrations at 4°C for 48 h. After immobilization, the film was repeatedly washed with phosphate-buffered saline [PBS (pH 7.4), NaCl (8.0 g), KCl (0.2 g), KH_2PO_4 (0.2 g), NaH_2PO_4 (1.15 g), MgCl_2 (0.1 g), and CaCl_2 (0.1 g in 1 L of distilled water)] until the absence of ^{125}I insulin in the wash was confirmed. Non-radiolabeled insulin was immobilized under the same conditions. The immobilized insulin is

referred to as Ins-PSt. An insulin-adsorbed PSt film was prepared in a similar manner without using WSC. These films were disinfected with 70% ethanol and washed with sterilized PBS for biological experiments.

Measurement of Contact Angle, Electron Spectroscopy for Chemical Analysis (ESCA), Surface Concentration of Carboxylic Acid, and Composition of Conjugates. The contact angle of an air bubble placed on polystyrene film was measured to assess the surface wettability. Prior to the measurement, the PSt film was incubated at 37°C for 24 h. Surface modifications of polystyrene film were analyzed by ESCA using a Perkin-Elmer 5500 series multi-technique apparatus on freeze-dried samples. The surface amount of carboxylic acid was measured using rhodamine 6G as reported (5).

The composition of insulin in the conjugates was determined by measuring ^{125}I and fluorescence. The labeled conjugates were prepared by the same methods as the nonlabeled conjugates. The fluorescence was measured at 345 nm by excitation at 280 nm. The insulin contents were calculated by comparing the radioactivity and fluorescence intensity of insulin conjugates with that of insulin per unit weight.

Cell Culture and Growth Assay. Mouse fibroblast STO cells were subcultured in Dulbecco's modified Ea-

gle's minimum essential medium (DMEM) supplemented with 10% fetal bovine serum (FBS), purchased from Nissui Pharmaceutical Co. Ltd. (Tokyo).

The STO cells were harvested using PBS without magnesium or calcium ions [PBS(-)], containing 0.15% (w/v) trypsin (2000 units/g) and 0.02% (w/v) ethylenediaminetetraacetic acid (EDTA). The cells were washed once with DMEM containing FBS and once with DMEM, then suspended in DMEM (2×10^4 cells/well), and incubated in 24-well plates containing insulin conjugates in DMEM (1 mL/well) under a 5% CO₂ atmosphere at 37 °C. The cell growth was determined by measuring the uptake of [³H]thymidine (9). After cell culture for 45 h, the cells were incubated with [³H]thymidine for a further 3 h. Subsequently, the cells were washed once with PBS and three times with ice-cooled TCA (10 wt %) and then solubilized with 0.5 N NaOH. The lysate was neutralized with 5 N HCl and then mixed with Clear-sol I, and the radioactivity was measured.

Insulin Association with Cells. To determine the internalization into cells and specific or nonspecific complexation with the cell surface of the insulin conjugates (insulin association), STO cells were cultured in the presence of ¹²⁵I-labeled insulin conjugates for 3, 24, and 48 h. After three washes with PBS(-), the cells were detached from culture plates using PBS(-) containing 0.02 wt % EDTA until cells adhering to the plates became undetectable by optical microscopy. The cells were collected by centrifugation, and the radioactivity was measured in a γ counter.

RESULTS

Synthesis of Water-Soluble Insulin Conjugates.

Figure 2 shows the HPLC elution profile of the native insulin and the insulin conjugates with POE and PAA. Ins-POE eluted faster than the native insulin or POE. The Ins-PAA conjugate eluted faster than native insulin or PAA. Measuring the ¹²⁵I-labeled insulin showed that the insulin contents in Ins-POE and Ins-PAA were 0.95 ± 0.09 and 4.06 ± 0.22 mol/mol, respectively (\pm standard deviation, $n = 5$). Fluorescence measurements indicated that the contents in Ins-POE and Ins-PAA were 0.98 ± 0.11 and 3.90 ± 0.15 mol/mol, respectively (\pm standard deviation, $n = 3$). These results demonstrated that Ins-POE was composed of about one insulin molecule and one poly(oxyethylene) chain and that Ins-PAA contained about four insulin molecules in one poly(acrylic acid) chain.

Graft Copolymerization and Insulin Immobilization. The surface composition of polystyrene film after various manipulations was analyzed by ESCA, and the results are shown in Table 1. After glow discharge, the content of oxygen in the film surface increased, showing the formation of peroxides, alcohols, and other oxidation products. After graft polymerization of acrylic acid, the oxygen content increased, indicating the presence of PAA (O, 40%). The concentration of COOH groups on the PAA-grafted PSt film as determined with rhodamine 6G was $(4.3 \pm 0.2) \times 10^{-8}$ mol/cm². The content of oxygen decreased, and that of nitrogen became detectable by insulin immobilization (N, 15.4%; O, 18.4%). The surface wettability of the polystyrene film after various manipulations was estimated in terms of the contact angle of air bubbles in water, and the results are shown in Table 1. Glow discharge and graft polymerization of acrylic acid increased the wettability. Insulin immobilization slightly decreased the wettability of PAA-grafted PSt film.

PAA-grafted Pst film was immersed in an aqueous solution of insulin in the presence or absence of water-

soluble carbodiimide. The film was then repeatedly washed with PBS until insulin release from the film was undetectable. Complete removal of insulin, which was weakly adsorbed on the film, required over 20 washes. The amount of insulin immobilized or adsorbed on the PAA-grafted PSt film was measured using radiolabeled insulin, and the results are shown in Figure 3. With increasing feed concentrations, the amount of immobilized insulin increased. The maximal surface concentration of immobilized insulin corresponded to complete coverage of the film surface with insulin. A small amount of noncovalently (physically) adsorbed insulin was found on the film surface after repeated washing with PBS.

Table 2 shows that the covalently immobilized insulin was not released under any conditions investigated, while the adsorbed insulin was released into the culture medium or taken up by cells under some conditions.

The association of insulin conjugates with cells during culture is shown in Figure 4. Insulin internalization was slightly suppressed by binding to POE but enhanced by that to PAA. On the other hand, Ins-PSt was completely free from insulin internalization, while insulin nonco-

valently adsorbed on PAA-grafted PSt film was very slowly taken up by the cells.

Mitogenic Activities of Insulin Conjugates. Figure 5 shows the rate of DNA synthesis in mouse fibroblast STO cells cultured in the presence of various insulin conjugates. The mitogenic effect of Ins-POE was lower than that of native insulin. The effect of Ins-PAA was a little higher than that of the native insulin. Small amounts of Ins-PSt (0.1–0.05-fold the amount of native insulin) stimulated DNA synthesis in STO cells. The maximal mitogenic effect of Ins-PSt was much greater than that of the water-soluble insulin conjugates investigated.

DISCUSSION

Soluble Insulin Conjugates. Insulin has two chains, A and B, and three amino groups, A1-glycine, B1-phenylalanine, and B29-lysine. The reactivity is $A1 > B29 > B1$. The N terminus of the A chain is the most reactive and is considered to be in the neighborhood of the receptor binding site (10). Markussen et al. (11) coupled insulin selectively through the B1 amino group to divinyl sulfone-activated agarose using insulin that was protected in positions A1 and B29, to construct a high-capacity affinity chromatography system for insulin receptors. On the other hand, Schoelson et al. (12) incorporated benzoylphenylalanine, a photoactivable amino acid, into position 25 of the B chain by chemical synthesis and enzymatic semisynthesis to investigate the interaction between insulin and the receptor. They concluded that the efficiency of cross-linking was unusually high, ranging from 60 to 100%, and the cross-linking resulted in receptor and kinase activation. Weiland et al. (13) synthesized a covalently dimerized insulin derivative B29,B29'-suberoylinsulin and indicated that the derivative competitively inhibited insulin-stimulated DNA synthesis in 3T3-L1 fatty fibroblasts. However, it had no effect on mature rat adipocytes. These results demonstrate that it is difficult to estimate the activity of modified insulin.

In this study, the mitogenic effect of insulin was reduced by coupling to poly(oxyethylene). We considered the fact that the POE molecule hindered access of the

Figure 4. Time-dependent association with mouse fibroblast STO cells during culture in the presence of (Δ) native insulin, (▲) Ins-POE, (□) Ins-PAA, (●) Ins-PSt, and (○) insulin adsorbed on PAA-PSt. Bars represent the standard deviation. $n = 6$.

insulin to the receptor because insulin is linked to POE mainly through the chemically reactive and biologically active sites, A1 and B29. However, the Ins-PAA conjugate apparently possessed higher mitogenic activity than the Ins-POE conjugate, although we also considered the fact that insulin is linked to PAA through A1 and B29. This should be due to the multivalency of Ins-PAA. The Ins-PAA conjugate can be active by enhancing receptor dimerization, as well as the aggregation and internalization of insulin conjugate-receptor complex.

Insoluble Insulin Conjugates. Covalent immobilization by insulin onto the polymer matrix was first reported by Cuatrecasas in 1969, who found that the immobilized insulin stimulates isolated fat cells (14). However, Oka and Topper found that some material with insulin-like activity was released from insulin-Sepharose (15). This substance had greater activity than native insulin and was referred to as superactive insulin. Wilchek and co-workers (16) considered the fact that the biological effects attributed to the insulin-Sepharose conjugate may be best explained in terms of insulin/serum protein-substituted guanidine released from the Sepharose matrix during cell culture.

The present study showed that immobilized insulin, Ins-PSt, was more mitogenic than Ins-PAA. In addition to multivalency, some other mechanisms must be operating in the action of Ins-PSt. We reported that insulin immobilized on surface-hydrolyzed poly(methyl methacrylate) film activated insulin receptors longer than soluble insulin, due to inhibited down-regulation (7). Ins-PSt should also activate the cellular signal-transduction

system over a long period without internalization. Membrane-anchored growth factors or cytokines regulate cells as "juxtacrine stimulators" (17). Immobilized insulin is considered to be "an artificial juxtacrine stimulator". The high activity of the artificial system will extend the concept of juxtacrine stimulation.

Proteins physically adsorb onto solid materials, and it is impossible to completely remove them by washing (18, 19). Therefore, some noncovalently adsorbed insulin remained on poly(acrylic acid)-grafted polystyrene film even after repeated washing. However, the amount was very small; it was slowly released from the surface, and the mitogenic effect was negligible. In Ins-PSt, insulin was covalently bound and none was released during cell culture. There should be no space where insulin could physically adsorb on the activated PAA-grafted PSt film surface.

Another problem concerning the insulin-Sepharose gel conjugate is the porosity or the rough surface of the matrix, which hinders access of cells to immobilized insulin. Horwitz and co-workers (4) pointed out the importance of a smooth surface in the activity of immobilized biosignal proteins and reported that interleukin-2 immobilized to plasma-treated polystyrene film maintained the viability of an interleukin-2-dependent cell line.

In the present investigation, the effectiveness of insulin immobilization on insoluble matrix was demonstrated by comparing Ins-PSt with Ins-PAA or Ins-POE conjugates. The effectiveness probably arose from inhibited internalization. A comparison of two types of immobilization matrices, polystyrene film and Sepharose gel, indicated that the smooth film surface induced efficient interaction of immobilized insulin with adsorbed cells. We quantified the contribution of the lack of internalization to the activity of immobilized biosignal proteins for the first time, using smooth polystyrene film.

ACKNOWLEDGMENT

We acknowledge Prof. K. Saito of the Radioisotope Center of Kyoto University for his supervision on the radioisotope experiments. This work was partially supported by a grant-in-aid for scientific research from the Ministry of Education, Science, Culture, and Sports of Japan and partially supported by the Nissan Science Foundation.

Poly(ethylene glycol)-Grafted Liposomes with Oligopeptide or Oligosaccharide Ligands Appended to the Termini of the Polymer Chains

Samuel Zalipsky,^{*,†} Nasreen Mullah,[†] Jennifer A. Harding,[†] Joshua Gittelman,[†] Luke Guo,[†] and Shawn A. DeFrees[‡]

SEQUUS Pharmaceuticals, Inc., 960 Hamilton Court, Menlo Park, California 94025, and Cytel Corporation, 3525 John Hopkins Court, San Diego, California 92121. Received August 31, 1996[®]

Novel conjugates tailor-made for inclusion in liposomal formulations, containing distearoylphosphatidylethanolamine (DSPE) as a lipid anchor, heterobifunctional polyethylene glycol (PEG) with a molecular weight of 2000 as a linking moiety, and a biological cell adhesive ligand [YIGSR peptide or Sialyl Lewis^x oligosaccharide (SLX)], were synthesized. They were characterized by NMR, chromatography, and matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI–TOFMS). Inclusion of either of the ligand–PEG–lipid conjugates (2 mol %) in a lecithin/cholesterol/methoxy-PEG₂₀₀₀-DSPE (55:40:3 mole ratio) lipid mixture followed by preparation of unilamellar vesicles (100 nm) resulted in positioning of 55% of the YIGSR and 63% of the SLX ligands on the periphery of the outer surface-grafted polymeric “brush”, as determined by a combination of specific enzymatic alterations of each ligand and HPLC. Similar densities of ligand-bearing PEG chains were incorporated into liposomes by simply incubating (37 °C, 5 h) either one of the ligand–PEG–lipid conjugates with preformed lipid vesicles. This conjugate insertion process was aggregation free. Using enzymatic derivatization–HPLC, it was demonstrated that all the ligands incorporated into lipid membranes by this new approach were positioned exclusively on the outer leaflet of the liposomal bilayers. Since liposomes of this type are intended for *in vivo* use as long-circulating, ligand-presenting platforms, the insertion approach is preferable because of the more efficient utilization of ligand–PEG–lipid conjugates.

INTRODUCTION

Liposomes, spherical self-enclosed vesicles composed of amphiphilic lipids, constitute one of the most important and extensively studied classes of supramolecular constructs. They play an important role in a variety of subdisciplines ranging from studies of biological recognition to catalysis and chemical separations (1). Unilamellar liposomes of natural phospholipids loaded in their aqueous compartment with biologically active substances were long considered promising vehicles for improvement of *in vivo* properties of drugs. However, this promise was largely unfulfilled due to the tendency of liposomes to interact with plasma components, a process resulting in their rapid clearance from systemic circulation with concomitant accumulation by organs of the mononuclear phagocyte system (primarily liver and spleen). It has been discovered that grafting of flexible water soluble polymers on the surface of liposomes circumvents this problem to a large extent [see reviews (2–6)]. The optimal formulations of polymer-grafted liposomes (approximately 100 nm in diameter) have been obtained by including in the total lipid mixture 3–7 mol % of methoxypoly(ethylene glycol) with a molecular weight of 2000 in the form of distearoylphosphatidylethanolamine (mPEG-DSPE¹) conjugate, in addition to phosphatidylcholine (PC) and cholesterol. Although some other amphipatic polymers, most notably poly(2-methyl-2-oxazolines) (7, 8), were also able to convey comparable beneficial properties to liposomes, PEG remains the principal

polymer used for modification of liposomal surfaces. Such formulations possess extraordinarily long *in vivo* plasma circulation times (terminal $T_{1/2}$ = 45 h in humans, with most of the dose cleared under the longer half-life) (9). This property offers new opportunities for utilization of such polymer-grafted liposomes as long-circulating platforms presenting biologically relevant ligands. This type of system is useful for ligand-mediated targeting or as a means of increasing systemic exposure of small biologically active substance ligands, which, in their free form, are cleared from blood circulation very rapidly. Potentially useful ligands could be vitamins (10, 11), peptides (12), oligosaccharides (13), as well as macromolecules like immunoglobulins (14–17), other proteins (18), and polysaccharides (3). Since the surface of PEG liposome is covered by mobile, highly water-solvated polymer chains, it is logical to form covalent attachments with the biological ligands of interest through the end groups of these chains (19, 20). This allows for maximal exposure of the ligands on the periphery of the liposomes. The more conventional methods of binding ligands to polar head group residues of liposomal lipid components resulted in interference by the surface-grafted PEG chains in both the conjugation reactions and the interaction of the bound ligand with the intended target (15, 16). Several end group-functionalized PEG–lipid conjugates were recently introduced to facilitate the development of liposomes with ligands linked to the termini of the grafted PEG chains (17, 19–21). There are two principal approaches to preparation of such systems. One involves preparation of lipid vesicles containing the

appropriate amounts of X-PEG-lipid, where X is a reactive functionality, which is then used for covalent fixation of the appropriate ligands (12, 17, 18). An alternative methodology involves the initial preparation of a three-component conjugate of the general structure ligand-PEG-lipid, followed by formulation of the liposomes (10, 13). Since in the first approach the conjugation reaction is done after liposome formation, it unavoidably leaves some reactive functional groups on the inner leaflet of the lipid bilayer and often some on the outer leaflet as well. On the other hand, if the liposomes are formulated with the preformed three-component conjugates, some of the valuable ligands inevitably are facing the enclosed aqueous compartment and thus become unavailable for their intended interaction with their biological targets.

In this manuscript, we present the results of synthesis and formulation of two new PEG-phospholipid conjugates of biological-cell adhesive ligands (Figure 1): the peptide, Tyr-Ile-Gly-Ser-Arg (YIGSR), and the oligosaccharide, Sial α 2,3Gal β 1,4(Fuc α 1,3)GlcNAc (Sialyl LewisX, SLX), each representing a major group of potentially useful substances. The pentapeptide sequence is the shortest fragment of basement membrane glycoprotein, laminin, retaining the binding activity to laminin cell surface receptors. This binding was implicated in metastasis and angiogenesis processes (22, 23). SLX is recognized *in vivo* by E-, P-, and L-selectin, which play an important role in inflammation-related tissue injury (24). The conjugates were designed to fit in liposomal membranes of mPEG-grafted lecithin/cholesterol vesicles so that the biologically active ligands would be positioned on the periphery of the grafted polymer chains. Our results show that formulations obtained by mixing either of the conjugates with the appropriate lipid components and forming 100 nm unilamellar liposomes had approximately 60% of the ligands expressed on the exterior. After careful characterization of this type of lipid vesicle, we devised an improved method for formulation of ligand-bearing polymer-grafted liposomes which contain ligand-polymer components exclusively on the outer leaflet of the lipid bilayer. Thus, the new method overcomes the limitations of both of the above-mentioned approaches to ligand-bearing PEG liposomes. This is the first

description of this methodology, which holds great promise in development of long-circulating liposomes carrying biologically active ligands on their exterior.

RESULTS AND DISCUSSION

Synthesis of Conjugates. Our synthesis strategy, schematically depicted in Figure 1, relied on the nucleophilic displacement reaction between bromoacetylated oligosaccharide or oligopeptide ligands and thiol-terminated PEG-DSPE. The use of a DSPE-based lipid anchor was warranted to maximize the lipid bilayer affinity (25) and to minimize the ability of the produced conjugates to dissociate from liposomal bilayers (26). The bromoacetyl-thiol coupling reaction was previously used for preparation of various protein and peptide adducts (27–30). The thiol component was generated by a facile reduction of 3-(2-pyridyldithio)propionate residue of PDP-PEG-DSPE, derived from PEG₂₀₀₀ (17), with tributylphosphine (28). The peptide derivative, N^ε-(bromoacetyl)-YIGSR-NH₂, was prepared by standard solid-phase peptide synthesis (30). The reactive derivative of SLX containing bromoacetylated *p*-aminobenzoyl, appended onto the amino group of the glucosamine residue of the pentasaccharide, was assembled through a series of chemical and enzymatic steps as described elsewhere (13). The conjugation reaction between the thiol and bromoacetyl components proceeded only moderately under conventional conditions often employed in protein chemistry, e.g. aqueous buffer and close to neutral pH (30). After some optimization of reaction conditions, the best results were obtained by carrying out the coupling in DMF/aqueous bicarbonate (9:1, v/v) in the presence of potassium iodide. Under these conditions, we were able to obtain approximately 70% yields of reverse-phase silica-purified YIGSR or SLX conjugates of DSPE-PEG. Both conjugates were characterized by NMR, chromatography, and mass spectrometry. Figure 2 depicts the spectra obtained by MALDI-TOFMS analysis of the conjugates. Both produced a series of 44 Da-spaced lines centered around 3540 and 4056 Da for the pentapeptide and pentasaccharide conjugates, respectively, i.e. within 44 Da, the molecular mass of one ethylene oxide unit, of the theoretical values (3496 and 4012 Da). These results represent one of the first uses of MALDI-TOFMS for char-

Figure 2. MALDI-TOFMS spectra of SLX-PEG-DSPE (A) and DSPE-PEG-YIGSR-NH₂ (B).

acterization of conjugates of three different components assembled in a well-defined manner (31). Both of the three-component conjugates formed clear aqueous solutions thought to be micellar in analogy to previously described solutions of mPEG-DSPE (32, 33).

Liposome Formulation and Quantitation of External Ligands. Standard methodology of lipid film hydration followed by extrusion was utilized to form liposomes containing 2 mol % of one of the ligand-PEG-lipid conjugates. On the basis of our previous experience with optimal formulations of mPEG-grafted liposomes, the total content of PEG-lipid (sum of mPEG-DSPE and ligand-PEG-DSPE) was kept at 5 mole %, while the remainder of the components was PHPC and cholesterol (55:40 mole ratio) (2, 12, 13, 17). As demonstrated by cryoelectron microscopy (Figure 3), liposomes obtained by this methodology were predominantly unilamellar. The total content of each ligand-PEG-lipid was determined by HPLC. In the case of the YIGSR ligand, we also confirmed the content of the pentapeptide by amino acid analysis. Since potential applications of these systems involve interaction of the ligand residues with the corresponding target receptors, it is the outer leaflet-bound ligand that is of primary importance. In essence, the ligand moieties facing the interior aqueous compartment are going to be wasted. In order to determine the amounts of external surface-bound ligands, we devised a strategy involving an enzymatic alteration of each of the ligands followed by HPLC determination of the amounts of starting materials and products.

There are three primary reasons for choosing this strategy. (A) Enzymes are large proteins, and thus, they are not able to diffuse through lipid bilayers. (B) Enzymatic reactions take place under conditions mild enough that they do not cause liposomal bilayer mixing and reformation. (C) Finally, enzymatic reactions are clean; i.e. they produce only one product and will proceed until the supply of accessible substrate is completely

Figure 3. Cryoelectron micrographs of control (top, PHPC/cholesterol/mPEG-DSPE, 55:40:5 mole ratio, ≈ 100 nm diameter) and SLX-containing liposomes (bottom, PHPC/cholesterol/mPEG-DSPE/SLX-PEG-DSPE, 55:40:3:2 mole ratio, ≈ 100 nm diameter). Courtesy of Dr. Peter M. Frederik.

depleted. For this purpose, we chose two enzymatic cleavage reactions using readily available enzymes: sialidase and chymotrypsin. The sites of cleavage on each of the ligand residues are shown with arrows in Figure 1. Thus, enzymatic reactions performed on ligand-containing liposomes resulted in the appropriate alterations of enzyme-accessible ligand residues. Both enzymatic reactions (sialidase with SLX and chymotrypsin with YIGSR) were monitored by HPLC, which showed distinct peaks of the appropriate ligand-PEG-lipid conjugates and their enzymatically modified products. The micellar samples of both ligand-PEG-DSPE's subjected to such treatment proceeded cleanly to completion, yielding one-peak products on HPLC. Figure 4 illustrates the chromatogram of SLX-PEG-DSPE before, during, and after completion of the sialidase-mediated cleavage of the oligosaccharide. Similar chromatograms were observed in the course of DSPE-PEG-YIGSR-NH₂ digestion with chymotrypsin (data not shown). Integration of starting material and product peaks in the process of each of the enzymatic reactions provided information about the accessibility of each ligand. As can be seen from Figure 5, chymotryptic digestion of YIGSR-containing liposomes proceeded readily up to a point of approximately 55% conversion to the product, DSPE-PEG-Y. The product: starting material ratio did not change even after extended incubation with the enzyme. Since we established that all the accessible, micellar substrate is cleaved by the enzyme, this observation is consistent with 55% of the conjugate being anchored in the outer leaflet of the liposomal bilayer. Similar experiments performed with SLX liposomes showed that sialidase converted approximately 63% of liposomal SLX-PEG-DSPE into a single-peak product, LX-PEG-DSPE. Both enzymatic reactions were controlled for their activity in the presence of ligand-free liposomes.

These experiments established that slightly more than half of the total ligand-PEG-lipid conjugates (55 and

Figure 4. HPLC chromatograms of SLX-PEG-DSPE before (A) and after completion of sialidase-mediated cleavage of micellar or liposome-inserted conjugate (B). The bottom chromatogram (C), showing 63% LX-PEG-DSPE and 37% SLX-PEG-DSPE, was obtained after extensive sialidase-mediated cleavage of SLX liposomes made by premixing of all the lipid components. An identical peak profile was observed during partial cleavage of the micellar conjugate.

63%, respectively, for YIGSR and SLX liposomes) were accessible to enzymatic cleavage and thus were positioned on the external leaflets of the liposomal bilayers. These measurements of the external ligands are in accord with a simple picture of spherical unilamellar liposome geometry. Assuming a 100 nm diameter ($R = 50$ nm) and a 4 nm bilayer thickness (internal radius $r = 46$ nm), the percent of the ligand on the external leaflet should be $4\pi R^2 / (4\pi R^2 + 4\pi r^2)$, which equals 54%. Bulkier head groups of lipids, as well as deviations from the strictly spherical shape of vesicles (see Figure 3), should cause further preference for the outer surface (*1*). In comparison to YIGSR, SLX is a larger ligand. It is also a more rigid residue, and the attachment site was positioned on the second sugar moiety, further enhancing the requirements for steric accommodation. Thus, we think it is reasonable that, under otherwise identical formulation conditions, a somewhat larger percentage of SLX than YIGSR is positioned on the external surface of the liposomal bilayer.

Liposomes Bearing Ligands Exclusively on the Outer Surface. Since liposomes of this type are intended for *in vivo* applications as ligand-presenting long-circulating platforms, only the ligand residues on the external leaflet are potentially capable of interaction with their intended biological targets. Thus, it is apparent that maximal expression of the ligands on the external surface is desirable, and the inner leaflet-bound ligands are in essence wasted. Furthermore, preparation of three-component conjugates of the type described here, containing expensive biologically active ligands, is considered to be a formidable challenge. In light of these considerations, a formulation containing similar densities of ligand-PEG-lipid conjugates anchored exclusively on the external surface of the liposomal bilayer is preferable to more conventional preparations, which inevitably result in a substantial fraction of the valuable three-component conjugates being on the inner leaflet.

It has been known that incubation of some lipids with liposomes or biological cells can result in their incorporation into the lipid bilayer (*34*). Recently, Uster *et al.*

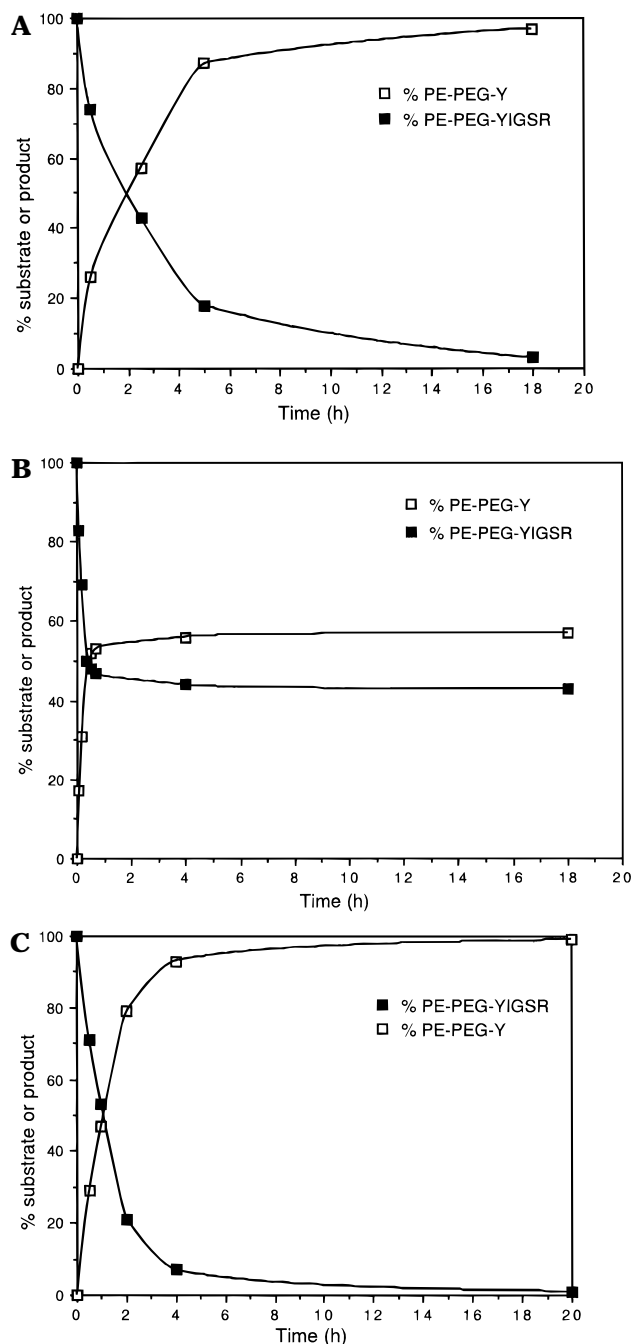

Figure 5. Results of HPLC followup of chymotryptic cleavage of DSPE-PEG-YIGSR-NH₂ (1–2 units per micromole of peptide) in a micellar form (A), liposomal formulation (PHPC/cholesterol/mPEG-DSPE/DSPE-PEG-YIGSR-NH₂, 55:40:3:2 mole ratio) obtained by the lipid film hydration–extrusion method (B), and liposomal formulation prepared by insertion of the three-component conjugate (1.2 mol %) into preformed liposomes (PHPC/cholesterol/mPEG-DSPE, 55:40:3 mole ratio) (C).

demonstrated that mPEG-DSPE can be inserted into lipid vesicles composed of lecithin/cholesterol, resulting in external surface PEG-grafted liposomes with physical and biological characteristics similar to those of liposomes obtained by hydration–extrusion of the mixture of all the lipids (*33*). Building on these precedents, we devised a method for preparation of ligand-bearing polymer-grafted liposomes containing ligand residues only on the external surface. In a few biological experiments, it was demonstrated that inclusion of 2 mol % of SLX-PEG-DSPE in mixed lipid film hydration–extrusion formulations resulted in good biological activity (*13, 35*). Therefore, our aim was to achieve the same external surface ligand

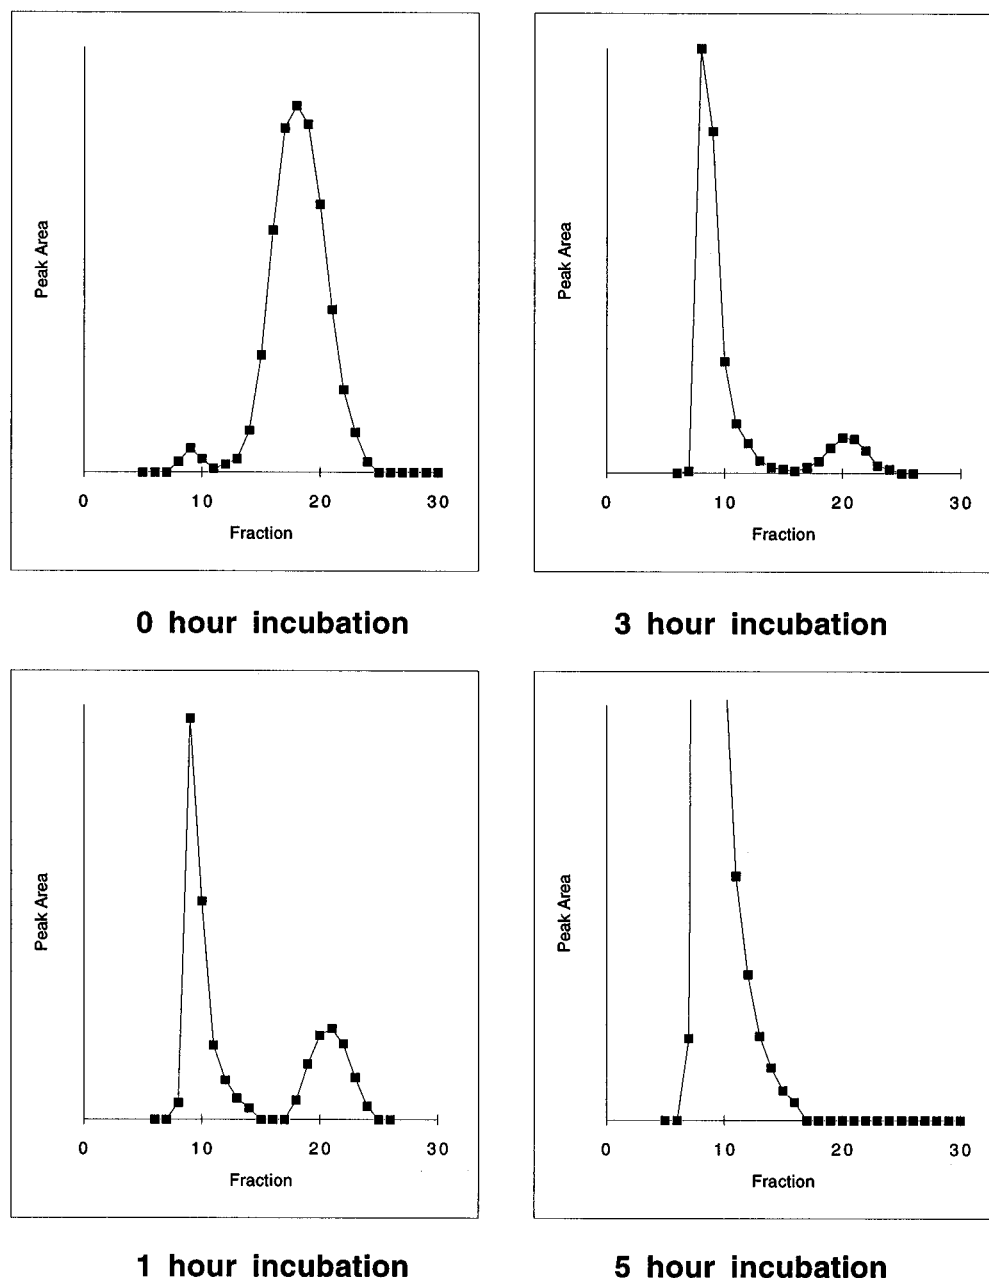

Figure 6. Separation of liposomes (peak centered around fraction 10) and micelles (peak centered around fraction 20) by size exclusion chromatography on a Biogel A50M column. Samples were taken at different time intervals after incubating SLX-PEG-DSPE (1.2 mol %) at 37 °C with preformed liposomes (PHPC/cholesterol/mPEG-DSPE, 55:40:3 mole ratio, ≈ 100 nm diameter).

density of ligand-PEG-lipid conjugates while keeping the amount of the mPEG component unchanged. According to the enzymatic cleavage experiments, approximately 60% of the ligand conjugates were on the external surface, which corresponds to 1.2 mol % of total lipid. Therefore, ligand-PEG-lipid conjugates corresponding to this amount were incubated with preformed PHPC/cholesterol liposomes containing 3 mol % of mPEG-DSPE. Thus, in contrast to previously published lipid insertion experiments (33), the starting liposomes contained mPEG-DSPE on both sides of the lipid bilayers. In exploratory experiments at various time intervals, aliquots of the liposomes incubated with SLX-PEG-DSPE at 37 °C were withdrawn and the liposomal peak was separated from the micellar conjugate by size exclusion chromatography (Figure 6). HPLC was used to determine the amounts of the ligand-containing conjugate in each of the fractions. As shown in Figure 7, insertion of the SLX-PEG-DSPE conjugate into the preformed liposomes proceeded readily at 37 °C and

noticeably more slowly at ambient temperature. Essentially, the same time course of the insertion process (data not shown) was observed upon incubation of DSPE-PEG-YIGSR-NH₂ with PHPC/cholesterol/mPEG-DSPE (55:40:3 mole ratio) liposomes. On the basis of these results, preparative batches of liposomes were obtained by 5 h of incubation at 37 °C of the appropriate amounts of either one of the three-component conjugates with the preformed liposomes. As summarized in Table 1, the average particle size determined by dynamic light scattering was only slightly increased during this process. The completeness of the incorporation of the ligand-PEG-DSPE conjugates was monitored by size exclusion chromatography. If all the inserted conjugate indeed becomes part of the external leaflet, then all the ligand in such a formulation should be available for the corresponding enzymatic cleavage. As shown in Figure 5C, and in contrast to results depicted in Figure 5B, all the liposome-inserted DSPE-PEG-YIGSR-NH₂ was completely consumed by chymotrypsin digestion. Incubation

Figure 7. Time course of SLX-PEG-DSPE (1.2 mol %) insertion into the preformed liposomes (same composition and size as in Figure 6).

Table 1. Summary of Particle Sizes of YIGSR and SLX Liposomes before and after Insertion of the Corresponding Three-Component Conjugates into the External Leaflet of Preformed Unilamellar Vesicles^a

liposomal sample type		particle size (nm)	
		90° angle	30° angle
YIGSR	before insertion	100	177
	after insertion	105	233
SLX	before insertion	98	126
	after insertion	99	137

^a Unilamellar vesicles (PHPC/cholesterol/mPEG-DSPE, 55:40:3 mole ratio) prepared by film hydration–extrusion as described in Experimental Procedures were incubated for 20 h at 37 °C with either DSPE-PEG–SLX or –YIGSR conjugates (1.2 mol %). This amount of the three-component conjugate ($2\% \times 0.6 = 1.2\%$) when completely inserted results in the same amount of external leaflet-bound ligands as formulations obtained by hydration–extrusion of PHPC/cholesterol/mPEG DSPE/ligand–PEG-DSPE in a molar ratio of 55:40:3:2. Note that larger particles scatter light much more intensely at the 30° angle than smaller particles, which biases the measurement taken at the 30° angle toward the larger particles. Thus, the apparent particle size taken at the 30° angle increases much more than those taken at the 90° angle.

of SLX-bearing liposomes prepared via the insertion process with sialidase also resulted in consumption of the entire three-component conjugate and its conversion into a single HPLC identifiable product, LX-PEG-DSPE (Figure 4B). These observations confirm that the inserted three-component conjugates are positioned exclusively on the external surface of the liposomes.

Summary and Conclusions. We demonstrated the synthesis of two conjugates composed of three components: DSPE, heterobifunctional PEG acting as a linking moiety, and an oligopeptide or an oligosaccharide cell adhesive ligand. The composition and purity of the three-part constructs, confirmed by NMR and chromatography, were further corroborated by MALDI–TOFMS. The conjugates were designed for incorporation into mPEG-grafted liposomes so that the biological ligand in such formulations would be positioned right at the periphery of the polymeric brush. Using a novel combination of enzymatic cleavage and HPLC analysis, we demonstrated that 100 nm liposomes containing such three-component conjugates prepared by the traditional lipid film hydration–extrusion process express only slightly more than half (55–63%) of the total ligands on their external surface, while the rest of the ligand moieties face the internal aqueous compartment and thus are unavailable for interactions with potential biological targets. To assure more efficient utilization of ligand–PEG–lipid

conjugates, we prepared liposomal formulations via a new approach utilizing bilayer insertion of the three-component conjugates. By this method, ligand-bearing PEG-grafted liposomes with the same ligand and mPEG external surface densities as in previously biologically tested traditional formulations were readily attainable.

EXPERIMENTAL PROCEDURES

Materials and Methods. mPEG-DSPE (21), PDP-PEG-DSPE (17), and the bromoacetylated derivative of Sialyl-Lewis^x (13) were prepared as described elsewhere. N^B-(Bromoacetyl)-YIGSR-NH₂ was purchased from AnaSpec, Inc. (San Jose, CA). The enzymes, sialidase from *Vibrio cholerae* and chymotrypsin, were purchased from Oxford GlycoSystems (Rosedale, NY) and Sigma (St. Louis, MO), respectively. Partially hydrogenated soybean phosphatidylcholine (PHPC, iodine value of 35) and cholesterol were obtained from Lipoid (Ludwigshafen, Germany) and Croda (Fullerton, CA), respectively. Thin layer chromatography (TLC) on silica gel GF plates (Analtech, Newark, DE) was visualized with iodine vapor, Dragendorff- (36) and phenol-sulfuric acid spray reagents, and UV light for detection of lipid, PEG, saccharide, and UV-absorbing ligands. NMR spectra was recorded on a 360 MHz Nicolet instrument at Acorn NMR (Fremont, Ca). Matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI–TOFMS) was carried out at M-Scan, Inc. (West Chester, PA) on a VG ToFSpec mass spectrometer utilizing a UV nitrogen laser at 337 nm and a VAX 4000 data station. Spectra of DSPE-PEG–oligopeptide or –oligosaccharide were acquired from 0.1 mg/mL solutions of the conjugates in 50 mM NaCl, containing *trans*-3-indoleacrylic acid (matrix material) and insulin (internal standard). The liposome particle size was determined by dynamic light scattering (Coulter N4MD, Hialeah, FL). Shimadzu and Rainin HPLC systems were used interchangeably. Amino acid analysis was performed on hydrolyzed aliquots of peptide liposomes at the Protein Structure Laboratory of the University of California, Davis.

Preparation of HS-PEG-DSPE. Tributylphosphine (80 μ L, 0.32 mmol) was added under N₂ to a clear solution of PDP-PEG-DSPE (200 mg, 0.064 mmol) in isopropanol/water (1:4, 6 mL) containing EDTA (10 mM). After 2 h, TLC (CHCl₃:CH₃OH:H₂O = 90:18:2) revealed that the reaction was complete. The starting material ($R_f = 0.56$) absorbed UV and was positive to Dragendorff spray. The product, HS-PEG-DSPE ($R_f = 0.58$), did not absorb UV but was positive to Dragendorff spray. The byproduct, 2-thiopyridone, was observed under UV light ($R_f = 0.65$). The reaction mixture was lyophilized. The yellowish solid residue was triturated with ether (3 \times 3 mL). The residual white solid (196 mg, 99% yield) was dried under a water aspirator pressure and then *in vacuo* over P₂O₅. It was used directly in the next step.

Preparation of SLX-PEG-DSPE. The bromoacetylated derivative of SLX (98 mg, 0.08 mmol) was added to a DMF (2.8 mL) solution of HS-PEG-DSPE (197 mg, 0.07 mmol) followed by potassium iodide (14.3 mg, 0.086 mmol). After \approx 5 min, a NaHCO₃ (0.4 M)/Na₂EDTA (10 mM) solution (pH 8.0, 328 μ L, 0.13 mmol of bicarbonate) was added. The reaction mixture was stirred at room temperature overnight. After 21 h, TLC (CHCl₃:CH₃OH:H₂O = 75:36:6) showed the SLX-PEG-DSPE product ($R_f = 0.37$, visualized by UV, Dragendorff and phenol/H₂SO₄ sprays) and weak spots of the starting materials: SLX derivative ($R_f = 0.0$) and HS-PEG-DSPE ($R_f = 0.85$). Water (12 mL) was added to the reaction mixture, and it was loaded onto a C8 silica column (8 g, 1 \times 40 cm, LC-8 Supelclean, Supelco). The column was eluted with

a stepwise gradient of methanol (0 to 70% v/v) in water (10% increments every 20 mL) and then 15:80:5 water/methanol/chloroform (60 mL). The product-containing fractions were pooled and evaporated at ambient temperature, producing colorless thick liquid. It was dissolved in *tert*-butanol (5 mL), lyophilized, and further dried *in vacuo* over P_2O_5 to yield a white fluffy solid (203 mg, 74%). 1H -NMR (CD_3OD): δ 0.88 (t, CH_3 -lipid, 6H), 1.15 (d, H-6 Fuc, 3H), 1.19 (t, OCH_2CH_3 , 3H), 1.29 (bs, $(CH_2)_n$, 56H), 1.61 (bm, $CH_2CH_2C=O$, 4H), 1.73 (t, H-3_{ax}-Sial, 1H), 2.01 (s, NHAc, 3H), 2.32 (2 \times t, CH_2CO , 4H), 2.58 (t, SCH_2CH_2CONH , 2H), 2.87 (dd, H-3_{eq}-Sial, 1H), 2.93 (t, SCH_2CH_2CONH , 2H), 3.35 (m, $NHCH_2$, 4H), 3.64 (s, PEG, \approx 180H), 3.7–4 (m, overlapping sugar peaks and $CH_2PO_4CH_2$, 8H), 4–4.31 (m, overlapping, 5H), 4.43 (dd, $CHCH_2CO$, 1H), 4.54 (d, H-1 Gal, 1H), 4.83 (m, H-5 Fuc, 1H), 4.90 (d, H-1 GlcN, 1H), 5.06 (d, H-1 Fuc, 1H), 5.2 (m, $POCH_2CHCH_2$, 1H), 7.70 and 7.84 (2 \times d, phenyl, 4H). MALDI-TOFMS (Figure 2A) produced a bell-shaped distribution of ions spaced at equal 44 ± 1 Da intervals and centered at 4056 Da (theory, 4012 Da).

Preparation of DSPE-PEG-YIGSR-NH₂. HS-PEG-DSPE (196 mg, 0.07 mmol) and *N*^ε-(bromoacetyl)-YIGSR-NH₂ (54.2 mg, 0.07 mmol, 1.2 equiv) were dissolved in DMF (2 mL) and treated with potassium iodide (14.1 mg, 0.09 mmol, 1.3 equiv), followed by a $NaHCO_3$ (0.4 M)/ Na_2EDTA (10 mmol) solution (pH 8.0, 326 μ L). After 21 h of stirring, TLC ($CHCl_3:CH_3OH:H_2O = 75:36:6$) confirmed the presence of expected product ($R_f = 0.55$) along with small amounts of the starting thiol and peptide derivatives. The reaction mixture was diluted with 5 mL of water and loaded onto a C8 silica column (8 g, 1 \times 40 cm, LC-8 Supelclean, Supelco), which was eluted with another 12 mL of water followed by a methanol gradient (0 to 70% v/v) in water (10% increments every 25 mL) and then 10:80:10 water/methanol/chloroform (60 mL). The product-containing fractions were pooled and evaporated at ambient temperature, producing colorless thick liquid. It was dissolved in *tert*-butanol (5 mL), lyophilized, and further dried *in vacuo* over P_2O_5 to yield a white fluffy solid (174 mg, 69% yield). 1H -NMR (CD_3OD): δ 0.9 (3 \times t, CH_3 of Ile and lipid, 12H), 1.2 (m, 1H), 1.26 (s, CH_2 , 56H), 1.58 (bm, $CH_2CH_2C=O$, 4H), 1.7 (m, 1H), 2.31 (2 \times t, $CH_2C=O$, 4H), 2.45 (t, SCH_2CH_2CONH), 2.7 (t, SCH_2CH_2CONH), 2.9 and 3.1 (dd, peptide, 2H), 3.2 (m, 2H), 3.35 (m, $NHCH_2$, 4H), 3.45 (t, 2H), 3.64 (s, PEG, \approx 180H), 3.7 (m, 4H), 3.9 (m, CH_2PO_4 , 4H), 4.0 (m, 3H), 4.15–4.2 (overlapping peaks, 4H), 4.3–4.45 (overlapping peaks, 3H), 4.6 (m, 2H), 5.2 (m, PO_4CH_2CH , 1H), 6.7 and 7.1 (2 \times d, phenyl of Tyr, 4H). MALDI-TOFMS (Figure 2B) produced a bell-shaped distribution of ions spaced at equal 44 ± 1 Da intervals and centered at 3540 Da (theory, 3496 Da).

Liposome Preparation. The ligand-containing liposomes were composed of PHPC, cholesterol, mPEG-DSPE, and ligand-PEG-lipid at a molar ratio of 55:40:3:2. All liposomes were prepared by mixing chloroform and/or methanol solutions of different lipids in a round bottom flask. The solvents were removed by rotary evaporation, and the dried lipid film produced was hydrated with either sodium phosphate buffer (10 mM, 140 mM NaCl, pH 7) or HEPES buffer (25 mM, 150 mM NaCl, pH 7) to produce large multilamellar vesicles. The resulting vesicles were passed repeatedly under pressure through 0.2, 0.1, and 0.05 μ m pore size polycarbonate membranes (37), until the average size distribution for the diameter (monitored by dynamic light scattering) was approximately 100 nm. The mean particle diameter measured from 12 different batches ranged from 92 to 111 nm with an average of 98 nm. The content of the

SLX-PEG-DSPE or DSPE-PEG-YIGSR-NH₂ in liposomes was determined by HPLC at 272 nm using reverse-phase HPLC. Quantitation of SLX-PEG-DSPE (Symmetry C8 column, 1 mL, Waters Associates, Milford, MA, mobile phase of 92% aqueous methanol containing 20 mM ammonium phosphate at pH 7.0) in the liposome preparations was greater than 97% of the amounts used in the corresponding formulations. A Prodigy C8 column (Phenomenex, Torrance, CA) with 92% aqueous methanol, containing 0.1% TFA, was used for detection and quantitation of DSPE-PEG-YIGSR-NH₂ and its digestion product. The amino acid composition of YIGSR liposomes determined by amino acids analysis was as follows: Tyr, 0.97; Ile, 1.00; Gly, 0.98; Ser, 0.96; and Arg, 1.08. The peptide content in 2 mol % formulations calculated from phosphate and amino acid analysis was in the range of 28–32 mmol per mole of phospholipid, which was in accord with the ligand contents determined by HPLC.

Cryoelectron microscopy photographs were obtained by previously published method of Dr. P. M. Frederik (38).

Quantitation of Outer Leaflet-Bound Ligands.

Liposomes containing SLX-PEG-DSPE (2 mol %, 12.5 μ mol/mL) were incubated for 16 h with sialidase (1 unit/mL) at 37 °C in the digestion buffer (50 mM histidine, 4 mM $CaCl_2$, and 150 mg/mL BSA at pH 6.5). Samples were diluted 10 fold with methanol and analyzed by HPLC. These experiments showed consistently that 62–64% of the initial oligosaccharide-containing conjugate was converted into the product, while 36–38% of the starting conjugate remained unchanged. Under the same conditions, micellar samples of SLX-PEG-DSPE (elution time of 1.5 min) were completely converted into a single-peak product (2.4 min), LX-PEG-DSPE. Liposomes containing DSPE-PEG-YIGSR-NH₂ (2 mol %) were digested with chymotrypsin (1–2 units per micromole of peptide) in HEPES buffer (25 mM, pH 7.2, 37 °C). At different time intervals, aliquots were taken, diluted with methanol, and analyzed by HPLC. The starting peptide conjugate eluted at 4.2 min, while the single-peak product, DSPE-PEG-Y, eluted at 7.6 min. Liposomal samples of peptide conjugates were cleaved with chymotrypsin to the extent of 52–59%. The remaining 41–48% of the starting conjugate, presumably localized in the inner leaflets of the liposomal bilayers, was not altered by the enzymatic reaction (Figure 5B).

Insertion of Ligand-PEG-DSPE Conjugates into Preformed Liposomes.

Liposomes were prepared as before with 3 mol % of mPEG-DSPE and no ligand conjugates. They were then incubated at ambient temperature or 37 °C for up to 48 h with amounts corresponding to 1.2 mol % of SLX-PEG-DSPE or DSPE-PEG-YIGSR-NH₂ (equal to 60% of 2 mol % in the original formulations). At various time points, free ligand conjugates (micelles) were separated from inserted ligands (liposomes) by size exclusion chromatography (SEC). For SLX liposomes, a Biogel A50M column equilibrated with 10 mM sodium phosphate, 140 mM sodium chloride, and 0.02% NaN_3 at pH 6.5 was used. For YIGSR-containing liposomes, a Sepharose 4B column was used with 10% sucrose and 10 mM HEPES at pH 7.0 as eluent. Fractions (1 mL) were collected, diluted 1:10 in methanol, and analyzed for ligand content by HPLC (see Figure 6).

ACKNOWLEDGMENT

We thank Dr. Paul Uster of SEQUUS Pharmaceuticals, Inc., for useful discussions about the lipid insertion phenomena and Dr. Peter M. Frederik of the University of Maastricht for preparation of cryoelectron micrographs of liposomes.

Oligonucleotides Tethering Hoechst 33258 Derivatives: Effect of the Conjugation Site on Duplex Stabilization and Fluorescence Properties

Kristin Wiederholt, Sharanabasava B. Rajur, and Larry W. McLaughlin*

Department of Chemistry, Merkert Chemistry Center, Boston College, Chestnut Hill, Massachusetts 02167.
Received September 26, 1996[®]

A series of DNA conjugates have been prepared in which two different derivatives of Hoechst 33258 have been tethered to a sequence containing a 5'-GAATTC-3' target site. The two derivatives differ only in the length of the tether between the DNA and the Hoechst fluorophore. By using a DNA backbone labeling protocol, one in which the Hoechst dye is tethered to an internucleotide phosphoramidate residue, it was possible to easily vary the site of attachment with respect to the A-T rich binding site. When tethered outside the GAATTC sequence, little if any helix stabilization results upon hybridization of the conjugate to its complementary sequence. As the site of conjugation is moved to one end of the target sequence and finally within the AATT sequence, more effective helix stabilization results. When tethered between the two A residues, or between the A and T residue, a ΔT_m of at least +20 °C is observed. Upon hybridization and formation of the B-form DNA, binding by the tethered Hoechst dye results, and the bound dye becomes brightly fluorescent. Upon a simple titration of the single-stranded conjugate with the complementary target sequence the quantum yield enhancement for hybridization only appears to be 5–7-fold at best. These fluorescence effects, generally less dramatic than those observed with other sequences, result from an increase in quantum yield for the single-stranded conjugate relative to the free Hoechst 33258. Heating the single-stranded conjugate reduces the inherent fluorescence of the single-stranded conjugate to a level comparable with that of the free Hoechst dye. In experiments monitoring absorbance vs temperature, a cooperative transition is observed for the single-stranded conjugate. Both the high quantum yield observed for the single-stranded conjugate and the observed thermally induced transition suggest that the single-stranded conjugate can dimerize (at the GAATTC site), mediated by the groove-binding fluorophore.

INTRODUCTION

The Hoechst dyes are a class of extended heterocycles based upon the bisbenzimidazole ring system that are capable of binding in the minor groove of B-form DNA at A-T-rich sequences. The flexible nature of this extended heterocyclic ring system permits the dye to adopt a conformation that is isohelical with the minor groove and thus optimize binding to double-stranded DNA (1). Crystallographic analyses (2–5) have confirmed the minor groove nature of these dye–DNA complexes and suggested that the preference for binding in A-T-rich sequences is the ability of the benzimidazole rings to penetrate deeply within the groove structure, where they can make hydrogen bonding contacts with specific thymine *O*-carbonyls and adenine *N*³-nitrogens (2–5). Electrostatic effects (6) and van der Waals contacts (7) also play an important role in complex formation. The presence of G residues in the DNA duplex results in one or more *N*²-amino groups protruding into the minor groove, and the presence of this functional group prevents penetration by the dye into the groove structure (8, 9). The sequence preferences for complex formation by Hoechst 33258 require a minimum of four contiguous A-T (T-A) base pairs (8, 10–14) with the double-stranded sequences AAAA·TTTT and AATT·AATT being the preferred binding sites. However, the exact nature of the binding may differ depending upon the target sequence; different sets of crystallographic analyses have indicated

that the position of the Hoechst 33258 fluorophore in the target sequence (GAATTC)₂ can be across the ATTC sequence (2) or across the AATT sequence (3, 5), and similar differences are observed for the target (CAAATTTG)₂ (15, 16).

In addition to their groove-binding characteristics, the Hoechst dyes have fluorescent properties with a relatively large Stokes shift (17). Although only moderately fluorescent in aqueous solution, upon binding to double-stranded DNA they exhibit a dramatically enhanced quantum yield (18). These effects appear to be related to the tight binding within the minor groove, where the excited state is protected from the aqueous solution and from processes involving nonradiative decay of the excited state (17). The fluorescence characteristics of bisbenzimidazoles have been used to automate DNA content assays (19–21), to determine cell numbers (22, 23), and to sort chromosomes (24). The quantum yield effects for these dyes are sensitive enough to permit the detection of one target cell per million in mixed cell populations using appropriate instrumentation (25).

The development of DNA conjugates that rely upon the well-characterized Watson–Crick hydrogen bonding interactions for sequence targeting, and also tether a ligand capable of reporting upon the hybridization event, should be important in the development of DNA-based diagnostics, such as *in situ* hybridization probes. In the current work, the ligand is a groove-binding agent that requires formation of the B-form DNA minor groove to initiate binding. In this respect, hybridization by the conjugate is required to trigger the binding event by the tethered ligand. The resultant fluorescent signal reports on the success of this event. We have previously described (26)

the synthesis of two Hoechst 33258 analogues used to prepare the DNA–Hoechst conjugates. In the present paper we examine a specific binding site (GAATTC)₂ containing four A-T (T-A) base pairs and determine how placement of the tethered Hoechst analogues affects both helix stability and the fluorescence properties of the conjugate/target hybridization complex.

EXPERIMENTAL PROCEDURES

Materials. Oligodeoxynucleotides were synthesized using 2'-deoxynucleoside phosphoramidites on an Applied Biosystems 381A DNA synthesizer. The four common 2'-deoxynucleoside phosphoramidites containing aryl- or isobutyrylamides were purchased from BioGenex (San Ramon, CA). H-phosphonate derivatives were obtained from Glen Research (Sterling, VA). The controlled pore glass support containing the 3'-terminal nucleoside was a product of CPG Inc. (Fairfield, NJ). Cystamine dihydrochloride, adamantanecarbonyl chloride, anhydrous solvents, and ammonium hydroxide were all obtained from the Aldrich Chemical Co. (Milwaukee, WI).

Nuclease P1 and snake venom phosphodiesterase were products of Boehringer Mannheim (Indianapolis, IN). Acrylamide and bis(acrylamide) were obtained from ICN Biomedicals (Cleveland, OH). Thin layer chromatography was performed on aluminum-backed precoated silica gel 60 F254 plates purchased from EM Science (Gibbstown, NJ). UV measurements for thermal denaturation studies employed an AVIV 14DS spectrophotometer equipped with digital temperature control. Fluorescence emission spectra were collected on a Shimadzu RF5000U fluorescence spectrophotometer containing a Shimadzu DR-15 microprocessor and graphics display terminal.

Methods. *Syntheses.* The synthesis of the two Hoechst derivatives **3** and **4** has been described elsewhere (26), and the DNA–Hoechst conjugates were prepared using a thiol-containing linker attached to the DNA backbone (27). The site of the cystamine-based linker was determined by the position at which the nucleoside H-phosphonate derivative was incorporated. For conjugation sites i and ii, the H-phosphonate of dG was employed, and for conjugation sites iii and iv the H-phosphonate derivative of dA was used.

Oligonucleotide Conjugation. To 1 A₂₆₀ unit of a single diastereomer of the desired dodecamer in 100 mM Tris·HCl, pH 8, was added DTT to a concentration of 10 mM, and the mixture was incubated at 50 °C for 1 h. HPLC analysis [50 mM triethylammonium acetate, pH 7.0, with a linear gradient of acetonitrile (7–28% over 30 min)] after this time period indicated the complete absence of the triphenylmethylacetyl-protected sequence (retention time ~ 28 min) and the presence of a new peak (retention time ~ 9 min). The bromoacetylated Hoechst derivative (**3** or **4**) in DMF was added to this reaction mixture to a concentration of 15 mM (40% DMF). The reaction mixture was shaken at ambient temperature for 48 h (a precipitate appeared during this period). An equal amount of formamide was added to the reaction mixtures; they were heated to 90 °C (to dissolve aggregates) and loaded directly onto the gel for isolation by electrophoresis.

The conjugated product was purified on a 20% denaturing (7 M urea) polyacrylamide gel. A fluorescent band (365 nm excitation) was present at a position that was retarded slightly from that of the oligomer containing the cystamine-based linker. This band was excised from the gel, crushed, and soaked in 0.3 M sodium acetate, pH 6. The gel was removed and the product desalted using a C₁₈ Sep-Pak column and a water/methanol gradient. The conjugated oligomer was eluted with

approximately 80% methanol in water. Yields varied, typically 0.3–0.5 A₂₆₀ units. The product exhibited a UV–vis spectrum having characteristics of both DNA (λ_{max} = 260 nm) and the Hoechst fluorophore (λ_{max} = 342 nm).

T_m Values. T_m values were obtained for complexes containing a 1:1 mixture of the conjugate and its complementary sequence in 21 mM HEPES, pH 7.5, containing 100 mM NaCl and 20 mM MgCl₂ at duplex concentrations in the low micromolar range (1–2 μ M). Solutions were heated to 90 °C and then cooled slowly to 0 °C prior to analysis. The samples were then heated in 0.5 or 1.0 °C steps, and absorbance readings were taken after a period of temperature stabilization. Absorbance and temperature readings were plotted using Igor software. T_m values were determined from first- and second-order derivatives, as well as graphically from the absorbance vs temperature plots.

Fluorescence Measurements. Fluorescence measurements were made in solutions typically containing ~1 μ M of the DNA–Hoechst conjugate in 21 mM HEPES, pH 7.5, containing 100 mM NaCl and 20 mM MgCl₂. All emission measurements were made with the following list of parameters: slit width, Ex/Em = 10 nm/10 nm, low sensitivity, medium speed. Samples were introduced into a 1.25 mL cell thermally isolated with a water jacket. Temperature was controlled with a recirculating water bath typically at 20 or 90 °C. Fluorescence emissions were measured at 470 nm with an excitation wavelength of 342 nm. The fluorescence enhancement (ΔF) values were ratios obtained at 450 nm. This emission wavelength represented the emission maximum for the duplex conjugates and was slightly off the emission maximum for the single-stranded conjugates.

RESULTS AND DISCUSSION

We have previously described the preparation of a series of DNA–Hoechst conjugates and characterized their thermal denaturation and fluorescence properties for a sequence target containing six contiguous A-T¹ base pairs (26). In the present work we examine complex formation between the conjugate and a target sequence containing only a four base-pair binding site for the Hoechst derivative and then determine how the site of conjugation impacts both helix stabilization and the fluorescence properties of the conjugated complexes. A four base-pair target site is required for binding by Hoechst 33258, and both AAAA·TTTT and (AATT)₂ have been shown to be the preferred four base-pair binding sites (8, 10–14). For this study we chose the binding site (GAATTC)₂ in which the palindromic four base-pair A-T-rich target site is flanked by two G-C base pairs. This target site has been used previously in crystal structure analyses (2, 3, 5) and identified by DNA footprinting studies using Hoechst 33258 (8, 10–14).

Synthesis of the Oligonucleotide Conjugates. The parent Hoechst 33258 cannot be covalently tethered to the oligonucleotides of interest without the introduction of appropriate functionality. We have described the synthesis of two Hoechst analogues (**3** and **4**, Scheme 1) (26) in which a bromoacetamide tether is incorporated into the terminal phenyl moiety of the parent fluorophore. The two analogues differ only in the nature of the tether. Hoechst derivative **4** contains an additional three atoms (–OCH₂CH₂–) to lengthen the tether slightly with respect to **3**. Both derivatives can be conjugated to an alkyl thiol in aqueous solutions at pH 8.

¹ All letter abbreviations refer to the 2'-deoxynucleosides.

Scheme 1

The two Hoechst analogues were conjugated to the DNA sequences using a postsynthetic approach. To vary the site of conjugation within the DNA sequence, we have employed a backbone labeling procedure (27, 28) in which the dye is tethered to a short thiol linker incorporated into the DNA sequence as a phosphoramidate internucleotide linkage. The internucleotide phosphoramidate is prepared by oxidation of an H-phosphonate linkage, immediately after its introduction to the DNA sequence, using pyridine/CCl₄ and the *N*-(triphenylmethylacetamyl)-cystamine (27). Oxidation of the H-phosphonate generates two isomeric phosphoramidate conjugates, the *Rp* and *Sp* diastereomers, tethering the *N*-triphenylacetamide derivative of cystamine (**1**, Scheme 1). Placement of the bulky triphenylacetamide on the linker attached to the stereochemical center of the phosphoramidates facilitated the separation of the *Rp* and *Sp* isomers during isolation by HPLC in most cases. A typical chromatogram is illustrated in Figure 1. After elution of the failed sequences, both those representing failed couplings and those representing failed oxidation of the

intermediate H-phosphonate, the two phosphoramidate diastereomers (a and b) tethering the triphenylacetamide-protected linker are eluted. The early eluting isomer "a" has been tentatively assigned as the *Rp* diastereomer (26), while the later eluting isomer "b" has been tentatively assigned as the *Sp* diastereomer. The yield of dodecamers tethering the cystamine-based linker is roughly half that expected for the native sequence. We believe this loss in yield results from hydrolysis of the putative phosphorochloridate (29, 30), the expected intermediate in the oxidation reaction. Owing to the reactivity of this intermediate with water, effective oxidation in the presence of the cystamine-based linker occurs only under strictly anhydrous conditions, and trace amounts of water will drastically reduce expected yields—and generally result in increased amounts of failed sequences (note the early eluting peaks in Figure 1). Equal amounts of both diastereomers were obtained in all cases, and only in one case were the diastereomeric sequences unresolvable. When the cystamine-based tether was placed at the internucleotide linkage between

Figure 1. HPLC isolation of the two phosphoramidate diastereomers (a and b) for the dodecameric sequence 5'-d[GpApGpGpAp(NHCH₂CH₂S-SCH₂CH₂NHCOPh₃)-ApTpTpCpGpApG]. HPLC conditions are described under Experimental Procedures.

^a Assignment of specific diastereomers is based upon arguments made elsewhere (26). The use of parentheses is to indicate that the assignments are tentative and are not yet corroborated by structural data. ^b T_m values are the average of at least two determinations and have an estimated error range of ±1 °C. ^c ΔF represents the ratio of the emission at 450 nm for the double-stranded conjugate relative to the single-stranded conjugate after titration by the complementary target. ^d ΔF* represents the ratio of the emission at 470 nm for the double-stranded conjugate relative to the single-stranded conjugate at 90 °C, after titration by the complementary target. ^e This value was obtained by comparing a solution of 1 μM Hoechst 33258 and 1 μM single-stranded GAATTC-containing sequence and then titrating this solution with the complementary target single-stranded DNA. The alternate experiment, comparing the fluorescence of 1 μM Hoechst 33258 and then titrating with excess DNA duplex, results in a ΔF = 26 (see text).

the G and A residues (site ii, Table 1), the diastereomeric sequences coeluted. For the conjugates **6** and **10** (Table 1), we could only prepare the requisite DNA sequence tethering the cystamine-based linker as a diastereomeric mixture.

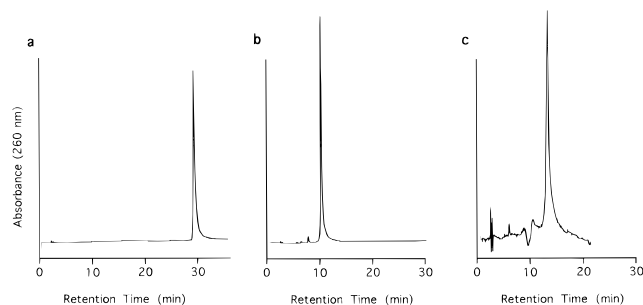

Figure 2. HPLC analyses of dodecameric sequences tethering (a) the triphenylacetamide derivative of cystamine (**1**), (b) the unmasked thiol (**2**), and (c) a Hoechst 33258 conjugate (**11**) (see Scheme 1). A peak with the same retention time as that in (c) was also present when the detector was set at 345 nm and a sample of **11** analyzed under the same HPLC conditions. HPLC conditions: 50 mM triethylammonium acetate, pH 7.0, with a linear gradient of acetonitrile (7–28% over 30 min). Retention times for the various dodecameric conjugates did not vary significantly with sequence or with the Hoechst derivative.

The conjugates were formed by cleavage of the disulfide bond to unmask the reactive thiol linker (**2**) and then treatment with either of the Hoechst analogues **3** or **4** (Scheme 1). After isolation by polyacrylamide gel electrophoresis, conjugates of the type **7** or **11** were obtained as both the *Rp* and the *Sp* diastereomers (as noted above, **6** and **10** were obtained as isomeric mixtures). We were unable to isolate the conjugated oligonucleotides by HPLC, largely due to the problems of aggregation of the excess fluorophore in the reaction mixture. The Hoechst derivatives are known to aggregate in aqueous solutions at concentrations above 30 μM, and the conjugations reactions, while performed in aqueous/DMF mixtures, required dye concentrations of roughly 15 mM. However, after completion of the reaction, the aggregates could be dissolved by the addition of excess DMF and then the product isolated by loading the entire reaction mixture onto a denaturing polyacrylamide gel. After electrophoresis, and excision and isolation of the fluorescent band from the gel, the conjugates (stored at concentrations of ~10 μM) could be analyzed by HPLC. HPLC analysis indicated that the initially prepared triphenylacetamide-protected sequence (Figure 2a), the unmasked thiol (Figure 2b), and the Hoechst conjugate (Figure 2c) could all be effectively resolved. Each conjugate exhibited a UV-vis absorbance spectrum characteristic of the absorption maximum for DNA (260 nm) as well as that for the Hoechst derivative (345 nm) (Figure 3).

T_m Characteristics of the Oligonucleotide Conjugates. The native dodecameric duplex exhibited a T_m value of 51 °C (Table 1). In the presence of 1 equiv of Hoechst 33258, the T_m was raised by 9 °C. We cannot determine from this assay whether a single complex is present since the fluorophore is known to bind to DNA by more than one mode. Nevertheless, the increased T_m suggests some minor groove binding, presumably at the A-T-rich site, with attendant helix stabilization. We then examined a series of conjugates prepared from the Hoechst derivative **3**. With the fluorophore tethered between the two G residues (**5**), but outside the (AATT)₂ binding site (conjugation site i), moderate helix stabilization was present for one isomer (ΔT_m = +9 °C), but the second diastereomer was less effective than the free fluorophore in stabilizing the dodecameric duplex. Contrary to previous observations, it is the *Sp* diastereomer that affords the more effective helix stabilizing characteristics. When tethered between the G and A residues at the end of the A-T binding site (conjugate ii), only the diastereomeric mixture was available, but this mixture

Figure 3. (a) Structure and UV-vis spectrum of the DNA-Hoechst conjugate (**9**) formed by the reaction of **4** with the dodecamer 5'-d(GpApGpGp(NHCH₂CH₂SH)ApApTpTpCpTpApG) tethering an unmasked thiol.

Figure 4. Absorbance vs temperature plots for the native dodecamer (left-side transition) and the conjugate **12** (*Rp* diastereomer) complexed to its complementary sequence (right-hand transition). The arrow indicates the approximate change in T_m value between the two samples (ΔT_m).

provided a 12 °C enhancement in T_m —likely an average value between the *Rp* and *Sp* diastereomers. In a previous study (26) the *Rp* diastereomers were always more effective than the *Sp* isomers in stabilizing the DNA duplex. This observation suggests that the purified *Rp*, if available, might exhibit a more significant T_m effect. In fact, this expectation was met with both conjugates **7** and **8**. In both of these latter examples, the *Rp* isomers resulted in T_m values that were 22–24 °C higher than that of the native duplex (Table 1). An example of two typical absorbance vs temperature transitions for a conjugate that effectively stabilizes the DNA duplex is illustrated in Figure 4. Both *Sp* diastereomers of **7** and **8** were also reasonably effective in stabilizing the DNA dodecamer (ΔT_m values of +10 and +5 °C, respectively). We have attributed the differences in helix stabilizing effects for the *Rp* and the *Sp* isomers to orientation effects related to the diastereomeric character of the linker. The *Rp* diastereomer orients the linker more toward the minor groove side of the DNA duplex, while the *Sp* diastereomer presents the linker more toward the major groove. The more effective helix stabilization by the *Rp* isomers of conjugates **7** and **8** is again consistent with

this relative orientation of the ligands tethered to the DNA backbone (26).

The *Rp* diastereomer **5** was not capable of providing very effective helix stabilization, but this result is more likely to reflect the position of the linker rather than any diastereomeric consequences. It remains unclear why the *Sp* diastereomer appeared more effective with this sequence, but even these effects are relatively moderate. With the tether placed outside the A-T-rich binding site, it is likely that the linker restricts access by the Hoechst derivative to the A-T-rich binding site. With the tether incorporated into the terminal phenyl ring of the Hoechst fluorophore, one might expect that positioning the linker near the end of the binding site would be most effective. With such a positioning, the Hoechst derivative would be directed along the binding site, ostensibly in its preferred binding mode. In this respect, conjugate **6** would appear to provide the optimal positioning for the linker. However, both sites that place the linker more toward the center of the binding target (iii and iv, Table 1) appear to provide nearly identical, and the most impressive, T_m effects. This result could reflect that there is sufficient linker flexibility to permit similar binding from either tethered position or that more than one binding mode within the (AATT)₂ minor groove is possible. Crystal structure analyses indicate that two modes of binding by Hoechst 33258 are possible within the (GAATTC)₂ binding site, differing in position by one base pair (2, 3, 5).

The DNA conjugates formed from the Hoechst derivative **4** differ from those described above in that the tether consists of an additional three atoms (–CH₂CH₂O–), which could provide additional flexibility in binding to the target A-T site. Tethering **4** outside the A-T-rich binding site between the two G residues (conjugation site i, Table 1) resulted in slightly more effective helix stabilization that correlated with the results for **3**. For the diastereomeric mixture of conjugate **10**, which tethered between the G and the A residues (conjugate ii, Table 1), only moderate stabilization was observed. However, for the remaining two conjugation sites (iii and iv, Table 1), both *Rp* diastereomers (**11** and **12**) provided in excess of a 20 °C enhancement in T_m values (see Figure 4). The corresponding *Sp* diastereomers were again not as effective but stabilized the helix somewhat more effectively than did the corresponding conjugates prepared from **3**.

Although it not clear why, conjugation at site ii with the derivative prepared from **3** resulted in a sequence that was more effective at helix stabilization than the corresponding derivative prepared from **4**. This suggests the role of the tether in some complexes is not fully elucidated, particularly with the minimum four base-pair binding site. Nevertheless, the most helix stabilizing conjugates were those that resulted from placing the linker within the targeted binding site. At both sites iii and iv the *Rp* diastereomers were most effective at helix stabilization, and this observation is also consistent with those regarding the conjugates prepared from **3**, as well as those prepared previously for a binding site composed of six contiguous A-T base pairs (26).

Fluorescence Properties. The four base-pair sequence (AATT)₂ should provide an effective binding site for the fluorophore, but the sequences outside the binding site may impact the nature of the groove, particularly its width, and result in less than optimal protection of the excited state from collisional decay processes involving water (17). At a concentration of 1 μM Hoechst 33258, in the presence of 1 μM single-stranded oligonucleotide, 5'-d(GpApGpGpApApTpTpCpGpApG), titra-

Figure 5. Fluorescence emission spectra ($\lambda_{\text{ex}} = 342$) for the single-stranded conjugate 5'-d(GpApGpGpAp(NHCH₂CH₂S-Hoechst)ApTpTpCpTpApG) (Rp **11**) (a) at 90 °C, (b) at 20 °C, and (c) in the presence of the complementary target at 20 °C after heating and cooling.

tion with the complementary sequence, 5'-d(CpTpCp-GpApApTpTpCpCpTpC) resulted in a moderate 2.5-fold enhancement in quantum yield. However, the alternate experiment, titration of free Hoechst 33258 by the *double-stranded* sequence, resulted in a 26-fold enhancement in quantum yield, very similar to what has been observed in other studies (18, 26). The solution containing free Hoechst 33258, and that containing the free fluorophore with one of the single strands of the GAATTC-containing sequence, differed in quantum yield by 10-fold. These differences in quantum yield enhancement suggest that the GAATTC-containing sequence, although not a complete palindrome, is capable of adopting a secondary structure in solution, perhaps mediated by the Hoechst 33258 groove binder, that results in significant enhancement in the emission quantum yield.

Tethering the minor groove-binding fluorophore to the oligonucleotide probe results in similar moderate increases in quantum yield upon hybridization. The process can be envisioned to occur in two steps, one a recognition event between the probe and the target sequence. Hybridization creates the minor groove-binding site and triggers the second step, that of ligand binding. Since each sequence tethers but a single ligand, the fluorescence properties of each complex should reflect the presence of a single ligand. For each sequence, the fluorescence of the single-stranded conjugate was measured, and then the sequence was titrated with the complementary target sequence. After the addition of each aliquot, the fluorescence spectrum was again measured, and the result obtained with 1 equiv of the complementary strand is illustrated in Figure 5c. The ratio of the emissions at 470 nm for the initial single-stranded conjugate and the final double-stranded conjugate was used to determine the fluorescence enhancement (ΔF) values (Table 1). The most significant fluorescence enhancement occurred with conjugate **12**, in which the dye is tethered essentially in the center of the target sequence. One diastereomer results in nearly a 7-fold increase in quantum yield, while the second diastereomer has a value nearly 5-fold larger than that measured for the single-stranded conjugate. These two complexes also exhibit some of the highest T_m values (72 and 67 °C, respectively) observed in this study; both properties suggest that the tethered ligand is most effectively bound to the DNA duplex, and the A-T-rich target site, when tethered in the center of the sequence.

Although the diastereomers of sequence **11** also exhibit relatively high T_m values, the fluorescence properties are more moderate. These observations suggest that the fluorescence characteristics of such complexes may be more sensitive to the nature of the binding event, and in some cases the ligand may not effectively penetrate the groove structure sufficiently well to avoid some relaxation effects by nonradiative (e.g., collisional) processes.

However, it is possible that the single-stranded conjugates can result in the formation of some secondary structure as noted above for the unconjugated sequences in the presence of Hoechst 33258. For example, they can undergo a self-complementary partial duplex assembly using the central palindromic (GAATTC)₂ sequence, with additional stabilization by one of the tethered groove-binding agents. Such a complex could also exhibit a significant enhanced fluorescence emission signal such as that observed for the free Hoechst dye in the presence of the unconjugated sequences. Dissociation of this palindromic partial duplex, followed by association with the complementary target sequence during the titration experiments, would result in only moderate apparent quantum yield enhancement effects—exactly what has been observed. Since we could not physically separate the tethered ligand and DNA sequence, instead we heated the single-stranded conjugates in an attempt to destabilize such structures and release the bound fluorophore. Under these conditions we observed a cooperative transition similar to that expected for a helix-to-coil transition. A decrease in the quantum yield of the emission spectrum for the single-stranded conjugate was also observed during heating over the temperature range 10–90 °C. The fluorescence observed for the single-stranded conjugate at 20 °C (Figure 5b) was reduced (Figure 5a) to a level comparable with that of free Hoechst 33258.

We then compared the fluorescence enhancement values for the complexes prepared by two procedures: (i) the single-stranded conjugate was titrated with the complementary target at 20 °C, and (ii) after formation of the 1:1 conjugated duplex, the complex was heated and cooled prior to fluorescence measurements. Regardless of the procedure used, the quantum yields observed in the fluorescence emission spectra were essentially the same, suggesting that simple titration by the complementary target sequence disrupts the putative GAATTC dimer and results in the formation of the conjugate–target duplex (in some cases the emission for the heated/cooled sample was very slightly reduced, reflecting perhaps minor amounts of degradation). With the presence of the dimerized single-stranded conjugate, and the inherent fluorescence enhancement from this complex, the ΔF values observed for the double-stranded conjugate–target complex seem, at best, only moderate (Table 1, compare parts b and c of Figure 5). We obtained a second set of fluorescence enhancement values (ΔF^* , Table 1) in which we compared the fluorescence emission spectra of the double-stranded conjugates (at 20 °C) with the single-stranded conjugates at 90 °C (compare parts a and c of Figure 5). Heating the single-stranded conjugate disrupts the putative dimer and permits a comparison of the fluorescence for the unbound (but tethered) ligand with that of the corresponding conjugated duplex containing the bound ligand. The quantum yield for the single-stranded conjugate typically decreases by roughly an order of magnitude with heating. At higher temperature, nonradiative collisional effects may be slightly increased, thus improving the apparent quantum yield enhancement. For example, when free Hoechst 33258 is titrated with the native, nominally single-stranded

GAATTC sequence, the quantum yield increases roughly 35-fold—consistent with expectations for the (GAATTC)₂ binding site. However, when this complex is heated at 90 °C, the quantum yield decreases an apparent 46-fold—presumably because of the enhanced collisional effects at higher temperatures. Thus, a comparison of the observed emission values for the single-stranded (90 °C) and double-stranded (at 20 °C) conjugates must be done cautiously. Nevertheless, the quantum yield enhancements were now found to be as high as 37-fold, similar to, or greater than, that observed for the free Hoechst 33258 (Table 1). In general, duplexes containing the Hoechst derivative **4** (with the longer linker) tethered near or at the center of the AATT sequence resulted in the highest enhancement values when compared with the heat denatured single-stranded conjugate (27–37-fold). These differences are likely to reflect the greater flexibility afforded the ligand by the longer linker, but even the shorter linker present in complexes prepared from **3** results in quantum yield enhancements from 9- to 16-fold.

Conclusions. We have shown that the tethered derivative of Hoechst 33258 can be used to target the four base-pair sequence (AATT)₂ and provide significant helix stabilization. The most effective position for the linker, employed to tether the fluorophore, is at the center of the targeted binding site. Both types of DNA conjugates, those prepared from either **3** or **4**, enhance the *T_m* values of the duplex by more than 20 °C when present as the tentatively assigned *Rp* diastereomer. The fluorescence properties after titration of the single-stranded conjugates with the target sequence are less defining and appear at best only moderate. However, fluorescence vs temperature, and absorbance vs temperature, plots indicate that the single-stranded conjugates adopt some secondary structure, most likely dimerization about the palindromic GAATTC core sequence. Heating the single-stranded conjugates reduced their fluorescence properties, consistent with a dimerized complex about the tethered Hoechst dye. Although titration by the complementary target sequence disrupts the secondary structure present in the single-stranded conjugate and permits complex formation, the results of this study suggest that probe sequences containing palindromic sequences rich in A-T base pairs may suffer from dimerization effects mediated by such groove-binding agents.

Amine-Reactive Forms of a Luminescent Diethylenetriaminepentaacetic Acid Chelate of Terbium and Europium: Attachment to DNA and Energy Transfer Measurements

Min Li[†] and Paul R. Selvin*

Department of Chemistry, University of California, Berkeley, California 94720, and Life Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California. Received July 24, 1996[®]

An isothiocyanate form of a lanthanide chelate which is highly luminescent when bound to terbium or europium has been synthesized. The chelate consists of diethylenetriaminepentaacetic acid (DTPA) covalently joined to a chromophore, 7-amino-4-methyl-2(1*H*)-quinolinone (cs124), and to *L*-*p*-aminophenylalanine, in which the aromatic amine was further converted to an isothiocyanate group. Ethylenediamine was also used in place of aminophenylalanine, but the isothiocyanate formed from the aliphatic amine was significantly less reactive. Site-specific attachments to triglycine and to the 5' ends of amine-modified DNA oligomers have been made. In addition, as an alternative method of coupling to macromolecules, DTPA anhydride–cs124 can be used to react specifically with a 5' amine group on base-deprotected synthetic DNA oligomers. Synthesis and purification is relatively straightforward in both cases, and luminescent properties are favorable for several applications, including as nonisotopic labels, as long-lifetime alternatives to fluorophores in imaging and diagnostics and particularly as donors in luminescence resonance energy transfer. Energy transfer measurements are consistent with previously reported measurements using different attachment mechanisms.

INTRODUCTION

Luminescent lanthanide chelates have highly unusual spectral characteristics that make them useful nonisotopic alternatives to radioactive probes (1–5), as alternatives to organic fluorophores, particularly where there are problems of background autofluorescence (6–9), and as donors in luminescence resonance energy transfer (10–16). These characteristics include millisecond lifetime, sharply spiked emission spectrum (<10 nm fwhm), large Stokes shifts (>150 nm), no self-quenching (17, 18), high quantum yield for lanthanide luminescence (~1), and excellent solubility.

A commonly used luminescent lanthanide chelate is diethylenetriaminepentaacetic acid (DTPA),¹ covalently attached to an organic chromophore, the latter acting as an antenna or sensitizer to absorb the excitation light and overcome the weak absorbance of the lanthanides (11, 19–22). We have previously shown that carbostyryl 124 bound to DTPA (11, 12) or to other polyamino-carboxylate chelates (23) can sensitize both europium and terbium, and the complex is an excellent donor in resonance energy transfer experiments.

Conjugation of DTPA–chromophore moieties is most often done through the dianhydride form of DTPA (24), where one anhydride reacts with an amine-containing chromophore and the other with amine-containing biomolecules (11, 17, 19, 21, 22). For conjugation, however,

the dianhydride has several disadvantages: (1) The anhydride is nonspecific in which nucleophilic acyl substitution reactions occur readily. When reacting with DNA, this concern led us to use base-protected DNA in our previous work (11, 12). However, base deprotection required strongly alkaline conditions, which we found cause significant cleavage of the DTPA–cs124 amide bond, particularly on longer DNAs, and more mild conditions led to questions of incomplete deprotection (12). (2) The anhydride is water-labile. (3) The dianhydride can lead to a number of products, including DTPA disubstituted with chromophore, DTPA attached to the macromolecule with no sensitizer, and macromolecules cross-linked by DTPA. (4) The length of the linker arm between DTPA and the macromolecule is fixed.

A number of groups have made isothiocyanate forms attached to the backbone of DTPA (without a sensitizer), in part to overcome these problems (25–28). The synthesis, however, involves many steps and is time-consuming, and its extension to DTPA-modified with a sensitizer is not necessarily straightforward. We have synthesized an isothiocyanate form of DTPA–cs124 by utilizing one of the carboxyl groups: caDTPA is reacted with cs124, followed by addition of diamino-compound, and one of the amines is then converted to an isothiocyanate group (29, 30). The synthesis is straightforward, and the isothiocyanate group formed from an aromatic amine is highly reactive and does not interfere with lanthanide luminescence. Furthermore, the amide-bond formed from one of the carboxyl groups is able to maintain coordination to the lanthanide (31) and the binding constant is sufficiently high for most practical purposes. We have also revisited the reaction of DTPA–cs124 anhydride with DNA (11, 12) and have found conditions in which base-deprotected DNA can be conjugated without side reactions.

EXPERIMENTAL METHODS

Chemicals. The following chemicals were purchased from Aldrich: diethylenetriaminepentaacetic acid dian-

[®] Abstract published in *Advance ACS Abstracts*, February 1, 1997.

¹ Abbreviations: DTPA, diethylenetriaminepentaacetic acid; caDTPA, dianhydride of DTPA; cs124 or carbostyryl 124, 7-amino-4-methyl-2(1*H*)-quinolinone; DMSO, dimethyl sulfoxide; DMF, dimethylformamide; EDA, ethylenediamine; HPLC, high-performance liquid chromatography.

Figure 1. Synthesis of isothiocyanate formed from DTPA-cs124 attached to ethylenediamine (**4**) or L-*p*-aminophenylalanine (**2**) and conjugation with amino-modified DNA. When using the anhydride-based conjugation (see text) with an amine-containing compound, the indicated "linker" is absent.

hydride; 7-amino-4-methyl-2(1*H*)-quinolinone; anhydrous *N,N*-dimethylformamide; anhydrous dimethyl sulfoxide; triethylamine; ethylenediamine; thiophosgene; europium chloride hexahydrate (99.99%); terbium chloride hexahydrate (99.999%). L-*p*-Aminophenylalanine was purchased from Sigma. Distilled and deionized water (18 MΩ cm⁻¹) was used throughout. All glassware was washed with a mixed acid solution and thoroughly rinsed with deionized, distilled water (32). All plastic (metal-free) labware was purchased from Bio-Rad. All chemicals were of the purest grade available.

Purification. High-performance liquid chromatography was performed at room temperature on either a Beckman Model 100 system or a Waters 600E with a Dynamax C₁₈ column (Rainin) for reversed-phase purification and a GenPak Fax (Waters) 4.6 × 100 mm column for anion exchange purification. The UV-absorbing fractions were detected at 328 nm for cs-124 compounds and at 260 nm for DNA oligos.

Synthesis (Figure 1). DTPA-cs124-L-*p*-Aminophenylalanine (**1**). To a solution of caDTPA (200 mg, 560 μmol) in 5 mL of DMF and 300 μL of triethylamine was added dropwise cs124 (115.5 mg, 1.2 × 560 μmol) in 2 mL of DMF. After 45 min, the reaction mixture was added dropwise to a solution of L-*p*-aminophenylalanine (121 mg, 1.2 × 560 μmol) in 5 mL of DMSO and 100 μL of triethylamine. After 3 h of stirring, the solvent was evaporated to dryness under reduced pressure and the residue was redissolved in 5 mL of 1 M triethylammonium acetate, pH 6.5. The product was purified by

reversed-phase HPLC using a 21.4 × 250 mm C₁₈ column (Dynamax 60 Å) with a flow rate of 12.5 mL/min. A 15-min linear gradient, from 10% to 15% solvent B (solvent A, 0.1 M triethylammonium acetate, pH 6.5; solvent B, CH₃CN), was used. The peak at retention time 14.5 min was collected and dried to give **1** as a light yellow solid: yield, 115 mg, 29%; ¹H NMR δ (D₂O, pD = 6.5) 2.16 (3H, s), 2.7–3.4 (16H, m), 3.50 (2H, s), 3.60 (2H, s), 4.23 (1H, m), 6.13 (1H, s), 6.88 (2H, d), 6.95 (2H, d), 7.08 (1H, d), 7.33 (1H, d), 7.35 (1H, s); FAB-MS, *m/e* 712 (M + H⁺).

DTPA-cs124-L-(*p*-Isothiocyanato)phenylalanine (**2**). Compound **1** (50 mg, 70 μmol) in 40 mL of 0.5 M HCl was added to 30 mL of CCl₄ (85% in CCl₄) at room temperature. The reaction was stirred vigorously for 1 h. The aqueous phase was washed with chloroform (5 × 5 mL) to remove excess CCl₄ and then purified by reversed-phase HPLC using a 21.4 × 250 mm C₁₈ column (Dynamax 60 Å) with a flow rate of 12.5 mL/min. A 25-min linear gradient, from 10% to 50% solvent B (solvent A, 0.1% CF₃COOH in H₂O; solvent B, CH₃CN), was used. The major peak at retention time 24 min was collected and dried to give **2** as a white solid: yield, 16 mg, 30%; ¹H NMR δ (CD₃OD) 2.42 (3H, s), 3.06 (2H, t), 3.15 (2H, t), 3.38 (8H, m), 3.51 (2H, s), 3.61 (2H, s), 3.92 (2H, s), 4.56 (1H, m), 6.35 (1H, s), 6.02 (2H, d), 7.09 (2H, d), 7.35 (1H, d), 7.65 (1H, d), 7.90 (1H, s); FAB-MS, *m/e* 754 (M + H⁺).

DTPA-cs124-EDA (**3**). To a solution of caDTPA (500 mg, 1.4 mmol) in 30 mL of DMF and 1 mL of triethylamine was added dropwise cs124 (240 mg, 1.4 mmol) in 4 mL of DMF and stirred. After 30 min, 5 mL (75 mmol) of ethylenediamine (EDA) was added, forming a white precipitate. The reaction was stirred for 2 h at room temperature and then stored in a refrigerator overnight, forming a brown precipitate. The precipitate turned white after several washes with 2-propanol and was finally washed with ether and dried overnight under vacuum. To remove excess EDA, the solid was redissolved in H₂O, loaded on a C₁₈ Sep-Pak (Waters), washed with 12 mL of 0.4 M NaOAc, pH 6, and 6 mL of H₂O, and eluted with 50% MeOH/H₂O. HPLC analysis [30-min linear gradient from 15% to 60% solvent B (solvent A, 0.1% CF₃COOH in H₂O; solvent B, CH₃CN), 3 mL/min with 10 × 250 mm C₁₈ Dynamax 60 Å column] showed two well-resolved peaks. The first peak at 16 min was confirmed to be DTPA-cs124-EDA: FAB-MS, *m/e* 592 (M + H⁺). The second peak at retention time 19 min was DTPA-(cs124)₂.

DTPA-cs124-EDA-Isothiocyanate (**4**). Approximately 10 mg of the precipitate containing **3** was dissolved in 3 mL of H₂O. Three milliliters of CCl₄/CCl₄ (85%) was added [precipitation of DTPA-(cs124)₂ was observed], followed by addition of solid CaCO₃. After 30 min of vigorous stirring, HPLC analysis of the supernatant showed that the DTPA-cs124-EDA peak at retention time 16 min (see **3**) was quantitatively converted to a peak with retention time 22 min, later shown to be **4**. The solution was extracted with CHCl₃, and the precipitate containing DTPA-(cs124)₂ was removed by centrifugation. The material in the water phase was purified by HPLC using a 15-min linear gradient, from 15% to 40% solvent B (solvent A, 0.1% CF₃COOH in H₂O; solvent B, CH₃CN) with a 21.4 × 250 mm C₁₈ Dynamax 60 Å column at a flow rate of 12.5 mL/min: FAB-MS, *m/e* 634 (M + H⁺).

Conjugation of **2 to DNA Oligo.** Thirty microliters of 0.1 M NaHCO₃, pH 7, was added to dried synthetic DNA oligo [10-mer with C6-amino linker at 5' end, 50 nmol; sequence: NH₂-CCT-AGA-GTG-G (12)]. The solution was mixed with compound **2** (20 × 50 nmol, dried by

SpeedVac prior to use). The pH of solution was adjusted to 9–10 using Et_3N aqueous solution. The mixture was incubated at 37 °C overnight and then passed through a P-6 column. The fraction was further purified on a reversed-phase HPLC using a $10 \times 250 \text{ C}_{18}$ column (Dynamax, 300 Å) with a flow rate of 3 mL/min. A 60-min linear gradient, from 10% to 25% solvent B (solvent A, 0.1 M triethylammonium acetate, pH 6.5; solvent B, CH_3CN) was used. Peak at 37 min was collected to give the conjugate. Unconjugated DNA eluted at 18 min. Yield: 40–80% based on HPLC profiles. Mass (by time-of-flight MALDI): 4006 (calcd 4008). A second peak, not fully resolved, eluted less than 1 min later and was found to contain an approximately equal mixture of product and a compound of 56 extra mass units. Further purification by anion exchange [120-min gradient from 20% to 55% B with a flow rate of 0.5 mL/min (solvent A, 25 mM Tris HCl, pH 8.0, in 10% CH_3CN ; solvent B, 25 mM Tris HCl, pH 8.0, and 1 M NaCl in 10% CH_3CN)] yielded two well-resolved peaks at 48 and 50 min, with the first peak containing twice the area and corresponding to the expected mass and the second peak corresponding to the species of 56 extra mass units. Conjugation with a 14-mer with C6-amino linker at 5' end, $\text{NH}_2\text{-CCT-AGC-AGC-AGT-GG}$, was over 90% on the basis of HPLC profiles. Conjugation of **2** with the same DNA lacking a 5' amine showed no reaction.

Conjugation of caDTPA–cs124 to DNA Oligo. To a solution of ca-DTPA (7.1 mg, 20 μmol) in 100 μL of DMSO and 11 μL Et_3N was added dropwise cs124 (5.1 mg, 1.5 $\times 20 \mu\text{mol}$) in 60 μL of DMSO at room temperature. After a 0.5 h, 43 μL of reaction solution was mixed with synthetic DNA oligos (e.g., 14-mer or 20-mer with C6-amino linker at 5' end, 10 nmol, reversed-phase HPLC purified) in 60 μL of DMSO and 26 μL of 0.1 M Et_3NOAc , pH 8. The mixture was incubated at room temperature overnight and then passed through a P-6 column. The fraction was further purified on a reversed-phase HPLC using a $10 \times 250 \text{ C}_{18}$ column (Dynamax, 300 Å) with a flow rate of 3 mL/min. A 60-min linear gradient, from 5% to 25% solvent B (solvent A, 0.1 M triethylammonium acetate, pH 6.5; solvent B, CH_3CN) was used. The peak at 44 min was collected and dried to give the conjugate: yield, 30–80% based on HPLC profiles; mass, 5011 (14-mer, calcd 5010), 6906 (20-mer, calcd 6906). Further anion exchange purification (see above) displayed a major single peak, with a second small (<10%) peak of 56 extra mass units. Conjugation of caDTPA–cs124 with the same DNA lacking a 5' amine showed no reaction.

Hybridization Conditions. DNA oligomers were hybridized to their complement in 10 mM Tris, pH 8.0, 10 mM MgCl_2 , and 150 mM NaCl by heating to 65–70 °C and cooling over a period of 15–60 min to either room temperature or 5 °C. The solvent was either H_2O or D_2O (99.9%; Aldrich). For energy transfer measurement, and an increasing amount of acceptor-labeled strand [tetramethylrhodamine (TMR) is the acceptor for terbium; Cy5 is the acceptor for europium] was added to lanthanide-labeled DNA at approximately 0.25 μM . Complementary DNA (labeled or unlabeled) was synthesized and purified as previously described (11, 12).

Spectroscopy. Absorption measurements were made on a Hewlett-Packard 8452A spectrometer. Time-resolved and gated luminescence measurements were made on a laboratory-built spectrometer used previously (11, 12, 23) utilizing 337-nm pulsed excitation (5 ns, 40 Hz) and photon-counting detection (GaAs PMT and multichannel scalar with 2- μs resolution). Terbium emission was monitored at 546 nm and europium emis-

sion at 617 nm. Data were curve-fit to one or two exponentials using TableCurve software (Jandel Scientific).

Metal Binding. All of the chelate-conjugated compounds were added in 1:1 molar ratio with a solution of TbCl_3 or EuCl_3 in triethylammonium acetate, pH 5. The solutions were incubated at room temperature for 30 min and diluted in the appropriate spectroscopy buffer.

RESULTS AND DISCUSSION

Proof of Structure. Figure 1 shows the synthesis pathways of two isothiocyanate forms of DTPA–cs124, **2** and **4**. Several lines of evidence confirm the synthesis and purity of the compounds. Single well-resolved HPLC peaks were found for the products, with starting materials running at different retention rates—conversion of the amine to an isothiocyanate resulted in significantly extended retention; mass spectroscopy confirmed the expected mass; NMR showed the expected peaks with no significant impurity components; both isothiocyanate forms reacted quantitatively with an excess of triglycine as determined by a shift in retention time in HPLC and by mass spectroscopy analysis; products were highly luminescent with terbium and europium, whereas starting materials mixed with lanthanides showed no significant lanthanide luminescence; absorption spectra showed characteristic spectra of carbostyryl as a 7-amide (maximum at 328 nm with secondary maximum at 342 nm (23)).

Reactivity Testing of –NCS Group. Compounds **2** and **4** were each mixed with ~50-fold excess of triglycine in a solution of 0.1 M triethylammonium acetate, pH 9, for 0.5 h at room temperature. HPLC analysis [30-min linear gradient 15–60% solvent B (solvent A, 0.1% CF_3COOH in H_2O ; solvent B, CH_3CN ; 3 mL/min with $10 \times 250 \text{ mm C}_{18}$ Dynamax 60 Å column] of the reaction mixtures showed a peak corresponding to **2** at retention time 23 min converted quantitatively to a peak at 13 min (FAB-MS, m/e 943 [$\text{M} + \text{H}^+$]) and a peak of **4** at retention time 16 min was quantitatively converted to a peak at 11 min, respectively. Under conditions appropriate for labeling amine-modified DNA (up to a 50-fold excess of **4** over DNA; see above), we found that **2** but not **4** was sufficiently reactive. This is in agreement with the results of Mujumdar et al., who found that an isothiocyanate of cyanine dyes formed from an aromatic—but not aliphatic—amine was sufficiently reactive with amine-containing biomolecules (33).

Proof of Conjugation to DNA. **2** and caDTPA–cs124 were each reacted with base-deprotected and HPLC-purified synthetic DNA oligomers containing a 5' amine. After both reversed-phase and anion exchange HPLC, well-resolved peaks of the expected product mass were isolated. Control reactions with DNA lacking a 5' amine showed no reaction of either **2** or caDTPA–cs124 with the amines of the (deprotected) DNA bases. For similar reaction conditions, no significant reaction of **4** with DNA was observed. With **2** there was a minor but significant second peak of 56 extra mass units which was not well resolved by reversed-phase HPLC alone but was resolved after additional anion exchange. The source of this extra mass is unknown, though it is possible that the chelate bound some trace heavy metals. The two peaks displayed identical luminescent properties after lanthanides were added, and both hybridized approximately equally well to complementary DNA. Nevertheless, we routinely purified the conjugated DNA by both reversed-phase and anion exchange HPLC to isolate the product of proper molecular weight and found that this gave the best hybridization results.

Figure 2. Lifetime of Tb^{3+} and Eu^{3+} bound to **2** attached to the 5' amine group of synthetic DNA. The Tb data are for DNA hybridized to an unlabeled complement. Solution conditions are the same as in Table 1. Data were acquired every 2 μs , digitally binned every 10 μs , and curve fit to a single exponential which showed no residual structure and $r^2 > 0.99$.

Table 1. Lanthanide Excited State Lifetime Attached to DNA^a

sample	H ₂ O; RT (ms)	D ₂ O; RT (ms)	D ₂ O; 5 °C (ms)
Tb-anhydride	1.5 (1.25)	2.38 (2.0)	2.98 (2.1–2.5)
Tb-ITC	1.43 (1.35)	2.50 (2.19)	3.06
Eu-anhydride	0.63 (0.63)	(2.38)	2.41 (2.46)
Eu-ITC	(0.60)	2.39	2.45

^a The table shows the excited state lifetime of terbium or europium attached to DNA either via **2** or via the anhydride reaction. The numbers in parentheses correspond to unhybridized DNA, those not in parentheses to lanthanide-labeled DNA hybridized to an unlabeled complement. Data were taken at 10 mM Tris, pH 8.0, 10 mM MgCl_2 , 150 mM NaCl. In some cases, particularly the single-stranded DNA, there was a minor component (<10%) with a highly quenched lifetime (a few hundred microseconds), likely caused by interaction of the chelate with the DNA bases. The relatively large spread in the data for the Tb-anhydride unhybridized data is due to variability in the temperature regulation of the cuvette.

Luminescence Measurements. *Triglycine Complexes.* Terbium and europium luminescence of both **2** and **4** conjugated to triglycine had lifetimes and intensities unchanged from the unmodified DTPA-cs124. This indicates that modification of the chelate complex with these isothiocyanate groups does not alter the luminescence properties of the bound lanthanide.

DNA Complexes. Figure 2 shows luminescence of **2** bound to Eu^{3+} or Tb^{3+} , conjugated to DNA, and hybridized to its DNA complement in a D_2O -based buffer. Table 1 summarizes the lifetime of both **2** and the anhydride DTPA-cs124 conjugated to DNA under a variety of solvent, temperature, and hybridization conditions. The Eu lifetime is relatively insensitive to environmental conditions, except for the well-known quenching effect of H_2O when ligated in the primary coordination sphere (34–36). The Eu lifetime of 2.48 ms shown in Figure 2 is very similar to that of the unconjugated, unmodified Eu-DTPA-cs124 [2.42 ms (23)] and to that of the Eu-DTPA-cs124 complexed to DNA via the anhydride reaction [2.48 ms, this work; 2.5 ms (11)]. As reported previously for the anhydride form (11), the Eu lifetime for both the isothiocyanate and the anhydride reactions changes <5% between single- and double-stranded DNA.

The terbium excited state lifetime when the chelate is bound to DNA is more sensitive to environmental conditions—temperature, salt, and hybridization conditions—than europium under similar conditions. The terbium lifetime in DTPA-cs124 not attached to a

macromolecule is insensitive to these conditions (23). It is likely that the origin of this greater sensitivity is due to strong interaction between the chelate and the DNA bases, and this interaction affects the excited state lifetime of Tb^{3+} more than Eu^{3+} (likely because of the greater energy of the terbium excited state). The 3.063 ms terbium lifetime in Figure 2 is somewhat longer than that of the unmodified Tb-DTPA-cs124 [2.63 ms (23)] and very similar to the lifetime of Tb-DTPA-cs124 complexed to DNA via the anhydride reaction and hybridized [2.98 ms, this work; 2.81 ms (12)]. (The small difference appears to be due to slightly lower temperature used in the current work, although both are reported as “5 °C”.) As we found previously for the anhydride reaction (12), the lifetime of the terbium when bound to DNA via the isothiocyanate increases upon hybridization (2.19 ms for single-stranded, 2.50 ms for double-stranded; both at room temperature and in D_2O buffer) and decreases with temperature (2.50 ms in D_2O at room temperature; 3.06 ms in D_2O buffer at 5 °C for the double-stranded, isothiocyanate-form) and increases slightly with salt. The emission intensity of the lanthanide complexes also decreases upon attachment to DNA (roughly 5–10-fold). In contrast, the terbium lifetime in the unreacted form is temperature and salt independent (23). These observations imply that the chelate interacts strongly with the DNA, and this interaction is modulated by hybridization, temperature, and salt. More specifically, hybridization increases the terbium lifetime, which is consistent with the symmetry in the crystal field surrounding the terbium increasing upon hybridization. In addition, particularly in the single-stranded form, the cs124 may be able to interact with bases, forming a new energy level which can lead to nonradiative deexcitation. We find, for example, that in the single-stranded case, terbium (but not europium) can have a small (typically $\leq 10\%$ amplitude) component of a few hundred microseconds, indicating a species which is quenched. The amplitude of this component generally decreases with increasing salt and with hybridization.

Energy Transfer Measurements: ITC-Based Reactions. We have performed energy transfer measurements by hybridizing the chelate-labeled DNA to a complementary DNA containing an acceptor dye attached to the 5' end, in analogy to our previous work (11–13). For Eu, we used Cy5 as the acceptor, and for Tb, we used tetramethylrhodamine (TMR) as the acceptor. Addition of 0.25 Cy5-labeled DNA per Eu-DTPA-cs124-ITC-14-mer-DNA yielded a biexponential donor lifetime at 617 nm of 22% $\exp(-t/786 \mu\text{s}) + 78\% \exp(-t/2405 \mu\text{s})$, indicating 67% energy transfer ($1-786 \mu\text{s}/2.41 \text{ ms}$) and a distance of 62.2 Å ($R_0 = 70 \text{ Å}$) for the hybridized species in D_2O buffer. As expected, addition of further amounts of Cy5 increased the amplitude of the short-time component, without changing its lifetime (see also below). For Eu bound via the anhydride, we found 70% energy transfer (60.8 Å) for the hybridized species (see below). These distances are in excellent agreement with the 61.2 Å found previously using the Tb-anhydride chelate attached to the same 14-mer (12).

Energy transfer from terbium bound to a 10-mer DNA via the isothiocyanate also yielded results consistent with previous (and current) anhydride-based reactions. In D_2O buffer, at room temperature, for example, an intermediate point in the titration with a TMR-labeled strand yielded a donor lifetime at 546 nm of 43% $\exp(-t/355 \mu\text{s}) + 67\% \exp(-t/2187 \mu\text{s})$. Previously, we found 329 and 2101 μs , respectively (12).

Energy Transfer Using Anhydride Reaction: Comparison to Previous Work. We repeated our previ-

ously published energy transfer measurements (11, 12) on the 10-mer DNA, which was based on a base-protected anhydride-coupling reaction, using our new anhydride-coupling procedure. The repeatability was excellent: In the current work, the terbium lifetime of terbium-labeled DNA hybridized to a TMR-labeled complement is 328–343 μ s, corresponding to 88% energy transfer (previous value 328 μ s, 88% energy transfer), and the terbium lifetime of the unhybridized donor strand is 2.19 ms (previous value 2.10 ms), although this latter value is fairly temperature-sensitive, increasing to as much as 2.50 ms if the temperature is not carefully controlled. The sensitized emission of the TMR is 333–356 μ s (326 μ s, previous value), in excellent agreement with the donor lifetime of the hybridized species.

Similar agreement is found with the Eu-anhydride–10-mer DNA hybridized to Cy5 complement (11). In this work, the unhybridized donor lifetime is 2.41 ms (previous value 2.40–2.52 ms) and the hybridized lifetime is 0.19 ms, corresponding to 92% energy transfer (previous values 0.22 ms, 91% energy transfer). The sensitized emission lifetime of Cy5 at 668 nm is 0.24 ms (previous value 0.25 ms).

Energy Transfer: Hybridization Conditions. Although no effort was made to achieve optimal hybridization conditions in this work, we generally found that our simple (but commonly used) hybridization procedure did not yield 100% hybridized donor strand, even with a 1.25-fold excess of acceptor strand and at 5 °C, which was well below the melting temperature of the DNAs. The amount of unhybridized donor strand varied from 10% to 50% (typically 10–20%). We generally found that DNA chelate purified by both reversed-phase and anion exchange yielded higher percentage of hybridization than those purified only by reversed phase, although this result is not rigorous and the reason for it is unclear. Since each strand was shown to be pure, we do not believe the unhybridized donor strand is due to some fraction of donor strand that cannot hybridize. Complete hybridization was achieved after gel purification to isolate the double-stranded complex under nondenaturing conditions (37): luminescence measurements on the DNA in gel fragments yielding a single exponential and quenched donor lifetime. Presumably kinetically trapped single-stranded DNA complexes were formed in solution in our simple hybridization procedures. We note that lanthanide-based energy transfer, with the capability to accurately measure multiexponential donor lifetimes, has the ability to detect even a relatively small percentage of unhybridized strands. Standard fluorescence resonance energy transfer does not have this ability. We believe, therefore, that caution should be exercised in assuming complete hybridization in FRET experiments and that gel purification of the double-stranded complex may be necessary, as others have found (37).

Conclusion. We have synthesized, purified, and spectrally characterized new isothiocyanate derivatives of DTPA–cs124 bound to small molecules and to DNA oligomers. We have also optimized conditions for the anhydride-based reaction of DTPA–cs124 with base-protected DNA and shown that specific reaction at a 5' amine can be achieved without side reaction at the DNA bases. Finally, we have used these new products in luminescence resonance energy transfer measurements and have shown that the results are consistent with previously published measurements. The facile attachment to biomolecules of luminescent lanthanide chelates should increase the utility of these compounds.

ACKNOWLEDGMENT

Immunoassay Reagents for Thyroid Testing. 2. Binding Properties and Energetic Parameters of a T₄ Monoclonal Antibody and Its Fab Fragment with a Library of Thyroxine Analog Biosensors Using Surface Plasmon Resonance

Maciej Adamczyk,* John C. Gebler, Angelo H. Gunasekera, Phillip G. Mattingly, and You Pan

Diagnostics Division, Division Organic Chemistry (9-NM), Abbott Laboratories, Building AP 20, 100 Abbott Park Road, Abbott Park, Illinois 60064. Received November 6, 1996[®]

A library of 16 thyroxine analog biosensors were prepared for use on the BIAcore surface plasmon resonance instrument. An anti-thyroxine monoclonal antibody and its Fab fragment were tested with each biosensor to generate the association and dissociation rate constants, equilibrium association constants, and Gibbs free energy values for characterizing the binding event.

INTRODUCTION

The literature has stressed the need for well-characterized immunoreagents used in immunoassays (1–9). While haptens, tracers, immunoconjugates, and antibodies are routinely characterized to determine their identity and purity, their kinetic and thermodynamic properties are seldom acquired. However, these parameters are useful at all stages of immunoassay development from selection of the antibody through determining the structural features important in the design of the tracer. Characterizing the avidity of the antibody for a particular ligand should be at least as critical as determining its subtype, molecular weight, or purity. Determination of these binding parameters can be a laborious endeavor (10). However, the use of the automated BIAcore (Pharmacia) technology greatly simplifies this task, thus creating a convenient reference method. The BIAcore instrument allows biomolecular interaction analysis (BIA) in real time based on the surface plasmon resonance (SPR) phenomenon (11). Briefly, one member of the hapten–antibody pair is conjugated to the hydrophilic dextran matrix supported on the gold layer of the SPR chip to form a biosensor. A solution of the other binding member is introduced at a constant rate to the surface of the biosensor. Binding causes a change in the refractive index measured at the surface, generating an instrument response which is directly related to the change in the mass concentration in the surface layer. The resulting response is transformed by the instrument software to a sensorgram that depicts response units (RU) versus time (*t*). Nonlinear or linear regression analysis of the sensorgram curves provides the value for the rates of association (k_a) and dissociation (k_d) and, thus, the equilibrium association constant (K_A) and the change of free energy (ΔG) for the binding event.

Our continuing interest in immunoreagents for thyroid testing led us to compare the binding interaction of a structurally diverse library of thyroxine analog biosensors with a previously described anti-thyroxine monoclonal antibody (5) and its Fab fragment using the BIAcore surface plasmon resonance instrument. Our aim was to characterize both of these binding proteins in terms of

their association and dissociation rate constants, equilibrium association constants, and Gibbs free energy values in their reaction with potential ligand structures and to further elucidate those structural features which are important for the binding interaction.

MATERIALS AND METHODS

Sodium D-thyroxine pentahydrate, sodium L-3,3',5-triiodothyronine, L-3,5-diiodothyronine, 3,3',5-triiodothyropropionic acid, 3,3',5,5'-tetraiodothyropropionic acid, and 3,3',5-triiodothyroacetic acid were obtained from Sigma Chemical Co. (St. Louis, MO). D-3,3',5-Triiodothyronine was obtained from ICN Biochemicals (Cleveland, OH). Sodium L-thyroxine pentahydrate and all other synthetic reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI) unless otherwise noted. Synthesized compounds were purified by HPLC [Waters (Millford, MA) system consisting of a model 590 pump, a Lambda-Max 481 UV detector, a model 745B data module, and a 40 × 100 mm μ Bondapak C18 column; flow rate, 45 mL/min]. Analytical HPLC was performed on a Beckman Gold system with UV detection using a Waters 8 × 100 mm μ Bondapak C18 column. ¹H NMR spectra were recorded at 300 MHz on a Varian Gemini spectrometer (Palo Alto, CA). Chemical shifts are reported in parts per million (δ) using tetramethylsilane (TMS) as the internal reference; coupling constants (*J*) are in hertz. Elemental analyses were performed by Robertson Microлит Laboratories, Inc. (Madison, NJ). Melting points were performed on an Electrothermal model 9100 digital melting point apparatus (Gillette, NJ) and are uncorrected. Electrospray ionization mass spectrometry (ESI/MS) was carried out on a Perkin-Elmer (Norwalk, CT) Sciex API 100 Benchtop system employing the Turbo IonSpray ion source. LC/ESI/MS was performed on the API 100 apparatus interfaced with a binary microbore HPLC system (Ultra Plus, Microtech Scientific, Sunnyvale, CA) equipped with a PLRP-S column (2.1 × 50 mm, Polymer Laboratories, Amherst, MA). Dialysis was carried out using SpectaPor 12–14 kDa molecular weight cutoff dialysis tubing (Scientific Products, McGaw, IL). SDS–PAGE was performed on a BioRad (Hercules, CA) Minigel system utilizing 12.5% polyacrylamide gels (7 cm × 10 cm × 1 mm), followed by staining with Coomassie Blue. Gel permeation chromatography was carried out on a Pharmacia P-50 system with UV detection at 280 nm. Surface plasmon resonance (SPR) measurements

[®] Abstract published in *Advance ACS Abstracts*, February 15, 1997.

were carried out on a Pharmacia BIAcore automated system using CM-5 four-channel sensor chips. Reagents for the BIAcore instrument consisted of HBS buffer [10 mM Hepes (pH 7.4), 150 mM NaCl, 3.4 mM EDTA, and 0.05% surfactant P-20], a coupling kit containing *N*-hydroxysuccinimide (NHS), *N*-ethyl-*N*-(3-(diethylamino)-propyl)carbodiimide (EDAC), and 1 M ethanolamine hydrochloride (pH 8.5), all from Pharmacia. Anti-thyroxine mAb (5) and anti-theophylline mAb were obtained from the Abbott cell culture facility (Abbott Laboratories, Abbott Park, IL).

3'-Bromo-3,5,5-triiodo-L-thyronine (4). To a solution of **5** (240 mg, 0.397 mmol) in NaHCO₃ (50 mg, 0.596 mmol)/H₂O (15 mL) with 50 μ L of methylamine (40% aqueous) was added I₂ (101 mg, 0.397 mmol), followed by stirring for 1 h. After removal of the solvent in vacuo, the residue was dissolved in DMF (6 mL) and purified by HPLC (40:60:0.05 CH₃CN/H₂O/TFA; retention time, 6.7 min) to give the product **4** (295 mg, 37%). ¹H NMR (CD₃OD): 7.84 (2 H, s), 7.12 (1 H, d, *J* = 3), 6.92 (1 H, d, *J* = 3), 4.15 (1 H, m), 3.19 (1 H, dd, *J* = 14, 5), 2.94 (1 H, dd, *J* = 14, 6). ESI/MS (negative ion mode) *m/z*: 729 (M - H)⁻. Mp: 214–216 °C dec (lit. 236–238 °C) (12).

3'-Bromo-3,5-diiodo-L-thyronine (5). Bromine (49 μ L, 0.95 mmol) was added to a solution of 3,5-diiodo-L-thyronine (**3**, L-T₂, 500 mg, 0.95 mmol) in AcOH (10 mL) containing 2 drops of concentrated HCl and stirred. After 40 min, the solvent was evaporated and the residue was dissolved in EtOH (6 mL). The solution was purified by HPLC (33:67:0.05 CH₃CN/H₂O/TFA; retention time, 5.6 min) to give the product **4** (415 mg, 69%). ¹H NMR (DMSO-*d*₆): 7.83 (2 H, s), 6.94 (1 H, d, *J* = 6.6), 6.81 (1 H, s), 6.65 (1 H, m), 4.06 (1 H, m), 3.14 (1 H, m), 2.99 (1 H, m). ESI/MS *m/z*: 604, 606 (M)⁺. Mp: 240–242 °C dec (lit. 246–248 °C) (12).

3',5'-Dibromo-3,5-triiodo-L-thyronine (6). Bromine (123 μ L, 2.38 mmol) was added to a solution of 3,5-diiodo-L-thyronine (**3**, L-T₂, 500 mg, 0.97 mmol) in AcOH (4 mL) containing 2 drops of concentrated HCl and stirred. After 2 h, another portion of Br₂ (50 μ L, 0.38 mmol) and AcOH (4 mL) were added. The resulting solution was stirred for 30 min. After evaporation of the solvent, the residue was dissolved in EtOH (6 mL) and purified by HPLC (37:63:0.05 CH₃CN/H₂O/TFA; retention time, 6.9 min) to give the product **6** (493 mg, 76%). ¹H NMR (DMSO-*d*₆): 7.83 (2 H, s), 6.95 (2 H, s), 3.61 (1 H, m), 3.18 (1 H, m), 2.86 (1 H, m). ESI/MS *m/z*: 682, 684, 686 (M)⁺. Mp: 259–261 °C dec (lit. 262–264 °C) (12).

L-Thyroxine Dimethylamide TFA Salt (7). (A) L-Thyroxine sodium salt pentahydrate (**1**, L-T₄, 7.75 g, 8.72 mmol) was dissolved in THF (50 mL) and water (50 mL, pH was adjusted to 10 with 1 N NaOH). Di-*tert*-butyl dicarbonate (1.75 g, 10 mmol) was added and the solution stirred. After 2 h, THF was evaporated in vacuo. The aqueous layer was diluted with water (30 mL) and acidified with HCl to pH 2. The white precipitate was collected and dried over P₂O₅ to give *N-tert*-Boc-L-thyroxine (7.6 g, 99%). ¹H NMR (DMSO-*d*₆): 7.78 (2 H, s), 7.19 (1 H, b), 7.03 (2 H, s), 4.14 (1 H, m), 3.05 (1 H, m), 2.73 (1 H, m), 1.30 (9 H, s). ESI/MS (negative ion mode) *m/z*: 876 (M - H)⁻. Mp: 206–208 °C (D isomer, lit. 211–213 °C) (13). Analytical HPLC (70:30:0.05 CH₃CN/H₂O/TFA; retention time, 4.76 min, 98% purity). (B) *N-tert*-Boc-L-thyroxine (424 mg, 0.48 mmol), EDAC (186 mg, 0.97 mmol), and NHS (111 mg, 0.97 mmol) in DMF (8 mL) were stirred for 1.5 h. Dimethylamine (40% aqueous, 2 mL, 18 mmol) was added to this solution and stirred. After 1 h, the solution was acidified with TFA. The reaction mixture was purified by HPLC (70:30:0.05 CH₃CN/H₂O/TFA; retention time, 5.94 min) to give *N-*

tert-Boc-L-thyroxine dimethylamide (312 mg, 71%). ¹H NMR (CD₃OD): 7.82 (2 H, s), 7.08 (2 H, s), 4.85 (1 H, m), 3.01 (3 H, s), 2.93–2.85 (3 H, s; 2 H, m), 1.42 (9 H, s). ESI/MS (negative ion mode) *m/z*: 903 (M - H)⁻. (C) *N-tert*-Boc-L-thyroxine dimethylamide (107 mg, 0.19 mmol) was stirred in TFA (2 mL) for 30 min and then evaporated in vacuo to give L-thyroxine dimethylamide TFA salt (**7**) which was used in subsequent reactions without further purification.

3,3',5-Triiodo-L-thyronine dimethylamide TFA salt (8) was prepared from 3,3',5-triiodo-L-thyronine sodium salt (**2**, L-T₃) following the procedure for **7**, above. (A) Compound **2** (2.58 g, 3.96 mmol) gave *N-tert*-Boc-3,3',5-triiodo-L-thyronine (2.85 g, 97%). ¹H NMR (DMSO-*d*₆): 10.01 (1 H, b), 7.80 (2 H, s), 7.19 (1 H, d, *J* = 9), 6.95 (1 H, s), 6.81 (1 H, d, *J* = 9), 6.54 (1 H, b), 4.14 (1 H, m), 3.06 (1 H, m), 2.74 (1 H, m), 1.32 (9 H, s). (B) *N-tert*-Boc-3,3',5'-triiodo-L-thyronine (416 mg, 0.554 mmol) gave *N-tert*-Boc-3,3',5'-triiodo-L-thyronine dimethylamide (314 mg, 73%). HPLC (63:37:0.05 CH₃CN/H₂O/TFA; retention time, 6.19 min). ¹H NMR (CD₃OD): 7.81 (2 H, s), 6.97 (1 H, d, *J* = 3), 6.75 (1 H, d, *J* = 9), 6.62 (1 H, dd, *J* = 3, 9), 4.73 (1 H, m), 3.02 (3 H, s), 2.93 (3 H, s), 2.85 (2 H, m), 1.42 (9 H, s). ESI/MS *m/z*: 779 (M + NH₄)⁺. (C) *N-tert*-Boc-3,3',5-triiodo-L-thyronine dimethylamide (106 mg, 0.14 mmol) gave compound **8** which was used as the crude salt in subsequent reactions without further purification.

O-Methyl-L-thyroxine TFA Salt (9) (14). (A) To a solution of *N-tert*-Boc-L-thyroxine (550 mg, 0.63 mmol) in DMF (7 mL) were added K₂CO₃ (433 mg, 3.14 mmol) and CH₃I (300 μ L, 4.82 mmol). After being stirred for 1 h, the reaction mixture was directly purified by column chromatography (SiO₂, 30% EtOAc in hexane) to give *O*-methyl-*N-tert*-Boc-L-thyroxine methyl ester (490 mg, 90%). ¹H NMR (CDCl₃): 7.73 (2 H, s), 7.26 (1 H, d, *J* = 3), 6.74 (2 H, m), 5.13 (1 H, b), 4.56 (1 H, m), 3.84 (3 H, s), 3.76 (3 H, s), 3.09 (1 H, m), 2.97 (1 H, m), 1.45 (9 H, s). ESI/MS *m/z*: 797 (M + NH₄)⁺. (B) A solution of *O*-methyl-*N-tert*-Boc-L-thyroxine methyl ester (432 mg, 0.48 mmol) and LiOH·H₂O (100 mg, 2.39 mmol) in THF (7 mL) and H₂O (7 mL) were stirred for 1 h. The reaction mixture was acidified with 1 N HCl to pH 2 and extracted with EtOAc (4 × 20 mL). The extract was dried over anhydrous sodium sulfate, filtered, and evaporated in vacuo to give *N-tert*-Boc-*O*-methyl-L-thyroxine (393 mg, 92%). ¹H NMR (CD₃OD): 7.80 (2 H, s), 7.15 (1 H, s), 6.84 (1 H, d, *J* = 9), 6.66 (1 H, d, *J* = 9), 4.34 (1 H, m), 3.79 (3 H, s), 3.14 (1 H, dd, *J* = 5, 9), 2.85 (1 H, dd, *J* = 9, 4), 1.41 (9 H, s). ESI/MS *m/z*: 783 (M + NH₄)⁺. (C) Treatment of *N-tert*-Boc-*O*-methyl-L-thyroxine (370 mg, 0.42 mmol) with TFA (4 mL) gave compound **9** in quantitative yield which was used in subsequent reactions without further purification.

O-Methyl-3,3',5-triiodo-L-thyronine TFA salt (10) (15) was prepared following the procedure given above for compound **9**. (A) *N-tert*-Boc-3,3',5'-triiodo-L-thyronine (487 mg, 0.65 mmol) gave *O*-methyl-*N-tert*-Boc-3,3',5'-triiodo-L-thyronine methyl ester (451 mg, 87%). ¹H NMR (CDCl₃): 7.64 (2 H, s), 7.15 (2 H, s), 5.15 (1 H, b), 4.56 (1 H, m), 3.83 (3 H, s), 3.76 (3 H, s), 3.07 (1 H, m), 2.96 (1 H, m), 1.45 (9 H, s). ESI/MS (negative ion mode) *m/z*: 904 (M - H)⁻. (B) *O*-Methyl-*N-tert*-Boc-3,3',5'-triiodo-L-thyronine methyl ester (410 mg, 0.53 mmol) gave *N-tert*-Boc-*O*-methyl-3,3',5'-triiodo-L-thyronine (386 mg, 96%). ¹H NMR (CD₃OD): 7.78 (2 H, s), 7.13 (2 H, s), 4.37 (1 H, m), 3.78 (3 H, s), 3.16 (1 H, m), 2.89 (1 H, m), 1.41 (9 H, s). ESI/MS (negative ion mode) *m/z*: 890 (M - H)⁻. (C) *N-tert*-Boc-*O*-methyl-3,3',5'-triiodo-L-thyronine (366 mg,

0.528 mmol) gave compound **10** in quantitative yield and was used in subsequent reactions without further purification.

General Procedure for Conjugation of Linker to Amino-Substituted Analogs. (A) A solution of *N*-tert-Boc-6-aminocaproic acid (9.4 g, 40.6 mmol), EDAC (19.4 g, 101 mmol), and *N*-hydroxysuccinimide (11.6 g, 101 mmol) in DMF (100 mL) was stirred for 20 h. The solvent was removed in vacuo. The residue was dissolved in ether (50 mL) and washed with buffer (200 mL, 50 mM phosphate, pH 6). The extract was dried over anhydrous sodium sulfate, filtered, and evaporated in vacuo to give *N*-tert-Boc-6-aminocaproic acid succinimidyl active ester (12.1 g, 91%). ¹H NMR (CDCl₃): 4.60 (1 H, b), 3.12 (2 H, m), 2.85 (4 H, s), 2.62 (2 H, m), 1.5–1.35 (13 H, m, s). ESI/MS *m/z*: 329 (M + H)⁺. (B) To a stirred solution of the amine (or TFA ammonium salt) (0.4 mmol) and *N*-tert-Boc-6-aminocaproic acid succinimidyl active ester (0.6 mmol) in DMF (6 mL) was added diisopropylethylamine (0.2 mL, 1.15 mmol). After analytical HPLC showed complete reaction (1 h), the reaction mixture was purified by preparative HPLC.

Compound 15L was obtained from compound **1L** (66%). HPLC (58:42:0.05 CH₃CN/H₂O/TFA; retention time, 7.6 min). ¹H NMR (CD₃OD): 7.80 (2 H, s), 7.07 (2 H, s), 4.67 (1 H, m), 3.29 (1 H, m), 3.00 (2 H, m), 2.93 (1 H, m), 2.20 (2 H, m), 1.56 (2 H, m), 1.42 (11 H, s, m), 1.28 (2 H, m). ESI/MS *m/z*: 991 (M + H)⁺. Anal. Calcd for C₂₆H₃₀I₄N₂O₇·CF₃CO₂H: C, 30.43; H, 2.80; N, 2.53. Found: C, 30.48; H, 2.69; N, 2.62.

Compound 15D was obtained from compound **1D** (83%). HPLC (60:40:0.05 CH₃CN/H₂O/TFA; retention time, 6.4 min). ¹H NMR (DMSO-*d*₆): 9.27 (1 H, b), 8.15 (1 H, d, *J* = 8.7), 7.78 (2 H, s), 7.03 (2 H, s), 6.70 (1 H, b), 4.43 (1 H, m), 3.04 (1 H, dd, *J* = 3, 8.6), 2.85 (2 H, m), 2.76 (1 H, m), 2.02 (2 H, m), 1.34 (13 H, s, m), 1.14 (2 H, m). ESI/MS *m/z*: 990 (M)⁺. Anal. Calcd for C₂₆H₃₀I₄N₂O₇·CF₃CO₂H: C, 30.43; H, 2.80; N, 2.53. Found: C, 30.49; H, 2.5; N, 2.64.

Compound 16L was obtained from compound **2L** (68%). HPLC (55:45:0.05 CH₃CN/H₂O/TFA; flow rate, 45 mL/min; retention time, 8.4 min). ¹H NMR (CD₃OD): 7.77 (2 H, s), 7.01 (1 H, s), 6.72 (1 H, d, *J* = 9), 6.57 (1 H, d, *J* = 9), 4.65 (1 H, m), 3.20 (1 H, dd, *J* = 4.6, 13.6), 3.00 (2 H, m), 2.89 (1 H, m), 2.19 (2 H, m), 1.55 (2 H, m), 1.34 (13 H, s, m), 1.27 (2 H, m). ESI/MS *m/z*: 865 (M + H)⁺. Anal. Calcd for C₂₆H₃₁I₃N₂O₇·CF₃CO₂H: C, 34.34; H, 3.27; N, 2.86. Found: C, 34.49; H, 3.22; N, 2.95.

Compound 16D was obtained from compound **2L** (85%). HPLC (55:45:0.05 CH₃CN/H₂O/TFA; retention time, 6.06 min). ¹H NMR (DMSO-*d*₆): 8.13 (1 H, d, *J* = 8.4), 7.76 (2 H, s), 6.93 (1 H, d, *J* = 3), 6.79 (1 H, d, *J* = 8.7), 6.69 (1 H, m), 6.55 (1 H, dd, *J* = 3, 8.6), 4.42 (1 H, m), 3.06 (1 H, dd, *J* = 4.6, 13.6), 2.85 (2 H, m), 2.83 (1 H, m), 2.05 (2 H, m), 1.34 (13 H, s, m), 1.13 (2 H, m). ESI/MS *m/z*: 865 (M + H)⁺. Anal. Calcd for C₂₆H₃₁I₃N₂O₇·CF₃CO₂H: C, 34.34; H, 3.27; N, 2.86. Found: C, 34.65; H, 3.26; N, 3.10.

Compound 17 was obtained from compound **3** (82%). HPLC (50:50:0.05 CH₃CN/H₂O/TFA; retention time, 6.4 min). ¹H NMR (DMSO-*d*₆): 8.15 (1 H, d, *J* = 8.1), 7.75 (2 H, s), 6.69 (1 H, m), 6.68 (2 H, d, *J* = 6.3), 6.48 (2 H, d, *J* = 6.2), 4.41 (1 H, m), 3.01 (1 H, dd, *J* = 3, 7.5), 2.88–2.72 (5 H, m), 2.05 (2 H, m), 1.34 (11 H, s, m), 1.29 (2 H, m). ESI/MS *m/z*: 739 (M + H)⁺. Anal. Calcd for C₂₆H₃₂I₂N₂O₇: C, 42.25; H, 4.33; I, 34.40; N, 3.79. Found: C, 41.92; H, 4.1; I, 34.11; N, 3.72.

Compound 18 was obtained from compound **4** (92%). HPLC (60:40:0.05 CH₃CN/H₂O/TFA; retention time, 6.05 min). ¹H NMR (DMSO-*d*₆): 7.80 (2 H, s), 7.06 (1 H, d, *J*

= 3), 6.85 (1 H, d, *J* = 3), 4.69 (1 H, dd, *J* = 10, 5), 3.22 (1 H, dd, *J* = 13, 4), 3.00 (2 H, t, *J* = 7), 2.89 (1 H, dd, *J* = 14, 10), 2.19 (2 H, t, *J* = 8), 1.55 (2 H, t, *J* = 7), 1.41 (11 H, s, m). ESI/MS (negative ion mode) *m/z*: 943 (M)[−]. Anal. Calcd for C₂₆H₃₀BrI₃N₂O₇: C, 33.08; H, 3.18; N, 2.97. Found: C, 32.78; H, 2.92; N, 2.90.

Compound 19 was obtained from compound **5** (83%). HPLC (58:42:0.05 CH₃CN/H₂O/TFA; retention time, 5.7 min). ¹H NMR (DMSO-*d*₆): 7.79 (2 H, s), 6.83 (1 H, d, *J* = 6.6), 6.80 (1 H, s), 6.53 (1 H, d, *J* = 6.6), 4.68 (1 H, m), 3.20 (1 H, m), 3.00 (2 H), 2.89 (1 H, m), 2.22 (2 H, m), 1.55 (2 H, m), 1.42 (11 H, s, m), 1.29 (2 H, m). ESI/MS *m/z*: 819 (M + H)⁺.

Compound 20 was obtained from compound **6** (93%). HPLC (60:40:0.05 CH₃CN/H₂O/TFA; retention time, 5.4 min). ¹H NMR (DMSO-*d*₆): 7.80 (2 H, s), 6.85 (2 H, d, s), 4.68 (1 H, m), 3.25 (1 H, m), 3.00 (2 H), 2.90 (1 H, m), 2.20 (2 H, m), 1.55 (2 H, m), 1.42 (11 H, s, m), 1.27 (2 H, m). ESI/MS *m/z*: 897 (M + H)⁺.

Compound 21 was obtained from compound **7** (68%). HPLC (65:35:0.05 CH₃CN/H₂O/TFA; retention time, 6.5 min). ¹H NMR (CD₃OD): 7.83 (2 H, s), 7.07 (2 H, s), 5.06 (1 H, m), 3.03–2.93 (3 H, s; 2 H, m), 2.93–2.83 (3 H, s; 2 H, m), 2.19 (2 H, m), 1.55 (2 H, m), 1.42 (10 H, s, m), 1.23 (3 H, m). ESI/MS *m/z*: 1018 (M + H)⁺.

Compound 22 was obtained from compound **8** (78%). HPLC (63:37:0.05 CH₃CN/H₂O/TFA; retention time, 5.5 min). ¹H NMR (CD₃OD): 7.81 (2 H, s), 6.95 (1 H, d, *J* = 3), 6.74 (1 H, d, *J* = 9), 6.62 (1 H, dd, *J* = 3, 9), 5.48 (1 H, m), 3.02–2.95 (3 H, s; 2 H, m), 2.93 (3 H, s), 2.85 (2 H, m), 2.19 (2 H, m), 1.55 (2 H, m), 1.42 (10 H, s, m), 1.23 (3 H, m). ESI/MS *m/z*: 892 (M + H)⁺.

Compound 23 was obtained from compound **9** (94%). SiO₂ column (10–20% MeOH in CHCl₃). ¹H NMR (DMSO-*d*₆): 7.75 (2 H, s), 7.15 (2 H, s), 4.27 (1 H, m), 3.73 (3 H, s), 3.18 (1 H, m), 2.98 (2 H, m), 2.80 (1 H, m), 2.02 (2 H, m), 1.37 (13 H, s, m), 1.14 (2 H, m). Anti-Thyroxine Monoclonal Antibody Preparation. The anti-thyroxine-mAb (**5**) derived from cell line ATCC HB1125 (American Type Culture Collection, Rockville, MD) which was raised against T₄ conjugate **59** (**3**) was purified using a Pharmacia FPLC system as follows. The tissue culture media containing anti-T₄ mAb (150 mL) was centrifuged at 3500*g* and filtered through a 0.2 μm filter to remove hybridoma cells. The super-

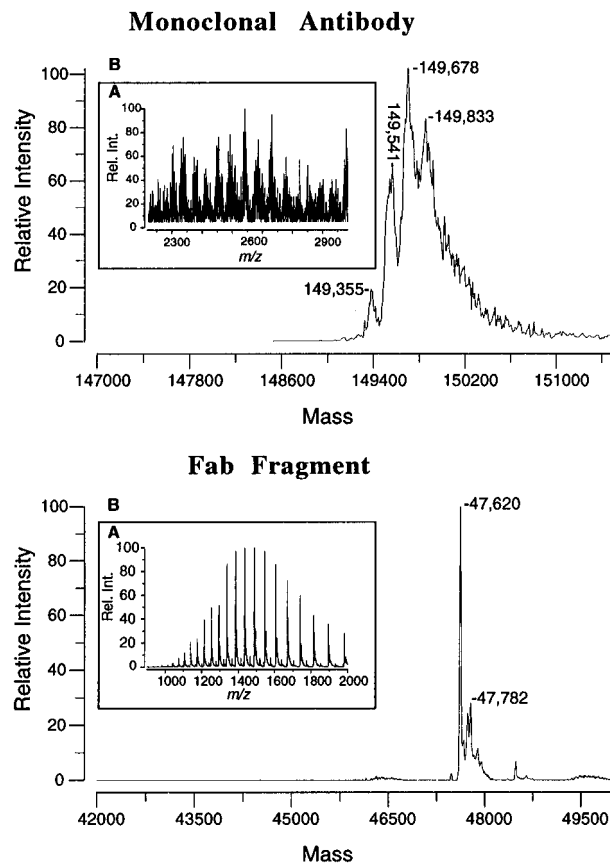

Figure 2. ESI/MS of anti-T₄ mAb and its Fab fragment. (A) Raw mass spectrum. (B) Deconvoluted mass spectrum.

natant was applied at a rate of 10 mL/min to a protein-A column (26 mm × 20 cm, 75 mL, Pharmacia) which had been equilibrated with IgG binding buffer (500 mL, Pierce). The protein-A column with bound monoclonal antibodies was further washed with IgG binding buffer (500 mL), and anti-T₄ mAb was eluted with IgG elution buffer (500 mL, Pierce), monitoring at 280 nm. Fractions (4 × 30 mL) containing the desired component were collected, combined, and dialyzed against PBS buffer (4 × 4 L, 2 days, 4 °C). The antibody concentration was 4.86 mg/mL as determined by UV spectroscopy at 280 nm using an absorption coefficient of 1.4 (16) and verified by the micro-BCA protein assay (17) reagent kit (Pierce) using mouse IgG as a standard protein. Purified anti-T₄ mAb was characterized for purity by SDS-PAGE (Figure 1), and its molecular weight was determined by LC/ESI mass spectrometry (Figure 2) according to the methods reported below. The total recovery of the purified anti-T₄ mAb was 194 mg.

Anti-Thyroxine Fab Preparation. The digestion of anti-T₄ mAb was carried out with the ImmunoPure Fab Preparation Kit (Pierce) according to the manufacturer's protocol. Thus, purified anti-T₄ mAb (40 mg) in digestion buffer (2 mL; 20 mM NaH₂PO₄, 10 mM EDTA, and 20 mM cysteine at pH 7.0) was incubated for 5 h in a 37 °C incubator-shaker with immobilized papain (2 mL). Papain-digested anti-T₄ mAb was passed through an immobilized protein-A column (2 mL) supplied with the kit to remove undigested mAb and the Fc fragments. The protein-A column was washed again with an additional ImmunoPure binding buffer (15 mL). Column flow-through and column washes were pooled and concentrated to 4 mL using a Centrprep-30 concentrator (Amicon, Beverly, MA). Concentrated anti-T₄ Fab was dialyzed against PBS (4 × 4 L, 2 days, 4 °C). The

Figure 3. Sensorgram for activation and conjugation to a sensor chip: (a) buffer baseline, (b) EDAC/NHS activation, (c) buffer wash, (d) thyroxine analog conjugation, (e) buffer wash, (f) ethanolamine quench, (g) buffer wash, (h) HCl wash, (i) buffer wash, and (---) reference line for ΔRU .

concentration of anti-T₄ Fab was 11.8 mg/mL as determined by the micro-BCA method using mouse IgG as a standard protein. Purified anti-T₄ Fab was characterized for purity by SDS-PAGE (Figure 1), and its molecular weight was determined by LC/ESI mass spectrometry (Figure 2) according to the methods reported below. The total recovery of the purified anti-T₄ FAB was 9 mg (~65% yield).

Analysis by Gel Electrophoresis. The antibody samples were dissolved in SDS-PAGE sample buffer (10 mM TRIS/HCl, 1 mM EDTA, 2.5% SDS, and 5.0% β -mercaptoethanol at pH 8.0) and heated to 100 °C for 5

min. Gels were loaded with 15 μ L of sample and run under denaturing conditions using the manufacturer's protocol. Upon completion, the gels were stained with Coomassie Blue using a standard developing routine from the manufacturer. The resulting gels were evaluated first by scanning (Apple OneScanner, Apple Computers, Cupertino, CA) and then analyzing the image with the gel plotting macros of NIH Image (version 1.58, public domain image processing and analysis program for the Apple Macintosh PowerPC from the NIH, Bethesda, MD, downloaded from zippy.nimh.nih.gov).

Mass Spectrometry Analysis. Monoclonal Antibody.

A solution of anti-T₄ mAb (1 mg/mL, 0.1% formic acid) was injected into the LC/ESI/MS apparatus and eluted with a linear gradient of 90:10 TFA (0.1% aqueous)/acetonitrile to 100% acetonitrile over 40 min at a flow rate of 75 μ L/min. The column output was directly interfaced to the mass spectrometer ion source. ESI/MS operating parameters were as follows: interface auxiliary air flow of 5 L/min at 400 °C and nebulizer air flow of 1.5 L/min, ion spray voltage (IS) of 4.8 kV, and orifice voltage (OR) of 80 V. The instrument scanned a mass range of 2200–3000 m/z in 0.1 amu steps for a total scan time of 8 s. The resulting spectra were reconstructed using the manufacturer's software (BioMultiview version 1.2) (Figure 2).

Fab Fragment. A solution of anti-T₄ Fab (1 mg/mL, 0.1% formic acid) was injected into the LC/ESI/MS apparatus and eluted with a linear gradient of 90:10 TFA (0.1% aqueous)/acetonitrile to 100% acetonitrile over 20 min at a flow rate of 100 μ L/min. The column output was directly interfaced to the mass spectrometer ion

source. ESI/MS operating parameters were as follows: interface auxiliary air flow of 4 L/min at 350 °C and nebulizer air flow of 1.5 L/min, ion spray voltage (IS) of 4.8 kV, and orifice voltage (OR) of 20 V. The instrument scanned a mass range of 700–2000 *m/z* in 0.25 amu steps for a total scan time of 5.2 s. The resulting spectra were reconstructed using the manufacturer's software (Bio-Multiview version 1.2) (Figure 2).

Conjugation of Thyroxine Analogs to Sensor Chips. (A) *Removing the tert-Boc Protecting Group.* A solution of the *tert*-Boc-protected analog (**15–28**) (5.2 mmol) in TFA (0.2 mL) was stirred for 30 min. After removal of the solvent in vacuo, the resulting TFA salt (**29–42**) was used for conjugation to the sensor chip without further purification.

(B) *Activation and Coupling to the Sensor Chip for Direct Kinetic Analysis* (18) (Figure 3). The CM-5 sensor chip was placed in the automated BIAcore instrument, and the HBS buffer flow was started (5 μ L/min), giving an instrument response as shown in region a. After about 4 min, the activation solution (5 μ L/min, 0.2 M EDAC and 0.05 M NHS) was injected (region b). After 6 min, HBS buffer was introduced (5 μ L/min, 90 s) (region c), before the thyroxine analog solution (**29–42**, 5 μ g/mL in 10% EtOH, 50 mM NaHCO₃, and 500 mM NaCl at pH 8.5) was added (region d). After 6 min, HBS buffer was again introduced (5 μ L/min, 2 min, region e), before the unreacted active ester groups remaining on the biosensor chip were blocked with ethanolamine (5 μ L/min, 1 M, 6 min, region f). Finally, the sensor surface was washed with HBS buffer (5 μ L/min, 2 min, region g), aqueous HCl (5 μ L/min, 100 mM, 2 min, region h), and HBS buffer (5 μ L/min, 4 min, region i) to remove any residual noncovalently attached thyroxine analog. All immobilization steps were performed automatically by

the BIAcore instrument to produce the biosensors **43–56** (Table 1).

Kinetic Analysis. Eight concentrations (0.5–100 nM in HBS buffer) of the binding protein (anti-T₄ mAb or anti-T₄ Fab) were each injected over the surface of each thyroxine analog biosensor (**43–56**) for 360 s at a rate of 5 μ L/min. Afterward, the binding protein solution was replaced with HBS buffer alone and the dissociation of the protein from the biosensor surface was monitored for 200 s. Any remaining bound proteins were dissociated by washing with formic acid (10 s, 1 M) in order to regenerate the biosensor. The association and dissociation rates were calculated by selecting regions from the binding and dissociation phases of the sensorgrams that corresponded to a 1:1 binding interaction (19) (Figure 4). Equilibrium affinity constants were derived from the ratio of association and dissociation constants. All experiments were performed at 25 °C. Data were collected at 2 Hz intervals and analyzed using least-squares statistics built into BIAevaluation 1.1.1 software (Pharmacia) on a NEC personal computer.

Analysis for Nonspecific Binding. (A) A control sensor chip lacking any ligand was prepared following the general procedure for conjugation presented above but substituting buffer for the ligand solution. Anti-T₄ mAb and anti-T₄ Fab were used in the direct kinetic analysis following the above procedure. The resulting sensorgrams are shown in panels A and B of Figure 5, respectively. (B) The binding of anti-theophylline mAb to each of the thyroxine analog biosensors (**43–56**) was evaluated under the same conditions as those used for anti-T₄ mAb and anti-T₄ Fab in the direct kinetic analysis, above. Six concentrations (0.5–100 nM) of anti-theophylline mAb were injected over the biosensor surfaces and the sensorgrams recorded (Figure 5C).

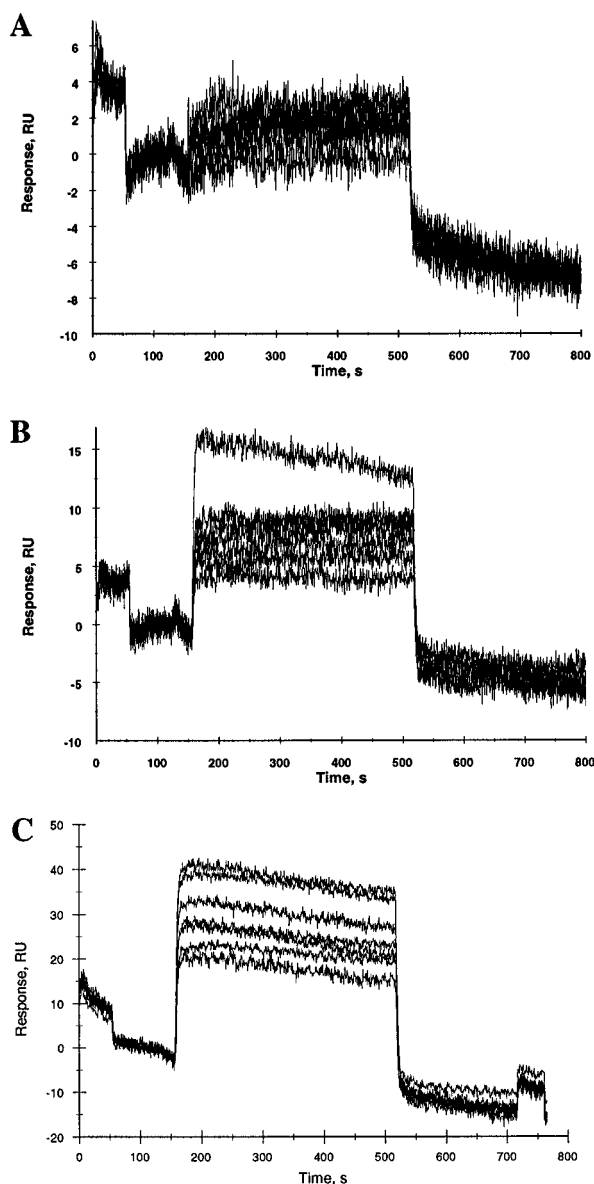

Figure 5. Sensorgrams showing the absence of nonspecific binding. (A) Sensorgrams generated with 2.5, 5, 10, 15, 20, 25, 50, and 100 nM mAb with no ligand on the sensor chip. (B) Sensorgrams generated with 2.5, 5, 10, 15, 20, 25, 50, and 100 nM Fab with no ligand on the sensor chip. (C) Sensorgrams generated with 2.5, 5, 10, 15, 20, 25, 50, and 100 nM theophylline mAb and sensor 43L.

RESULTS

Preparation of Thyroxine Biosensors. Derivatization of the carboxylated surface of the sensor chip first required the preparation of the chosen thyroxine analogs bearing aminoalkyl linkers. As detailed in Scheme 1, commercially available T_4 (**1**, L and D enantiomers), T_3 (**2**, L and D enantiomers), and T_2 (**3**) were employed directly in the reaction scheme without further modification. The bromo analogs **4–6** were prepared according to literature procedures (12, 20). Thus, **5** and **6** were obtained directly by bromination of T_2 (**3**), while **4** was prepared by the iodination of BrT_2 (**5**). Attempted bromination of T_3 (**2L**) led only to Br_2T_2 (**6**). Dimethylamide compounds **7** and **8** were prepared through the carbodiimide-mediated coupling of the corresponding *N*-*tert*-Boc-protected derivatives of T_4 (**1L**) and T_3 (**2L**) with excess aqueous dimethylamine and subsequent deprotection with TFA. The known *O*-methyl-substituted T_4 (**14**) and T_3 (**15**) compounds were likewise issued as

the TFA salts **9** and **10** in 83% overall yield, from the *N*-*tert*-Boc-protected derivatives after methylation with methyl iodide in the presence of potassium carbonate and deprotection with TFA. Analogs **1–10** were coupled with the NHS ester of *N*-*tert*-Boc-6-aminocaproic acid to give compounds **15–24** in 66–94% yield after preparative HPLC. Deprotection with TFA gave the aminoalkyl-substituted thyroxine analogs. Thyroalkanoic acids **11–13** (Scheme 2) were coupled to mono-*N*-*tert*-Boc-hexanediamine (**21**), giving compounds **25** and **26** (33–35% yield), and subsequently deprotected to give the requisite aminoalkyl derivatives **39–41**. The aminoalkyl-substituted 3,5-diiodothyrosine derivative **42** was prepared as shown in Scheme 3.

Conjugation of low-molecular weight ligands as typified by the L - T_4 analog **29** to the BIAcore sensor chips allowed the generation of the sensorgram illustrated in Figure 3. Buffer alone (region a) gave a baseline response of 9174 RU. Activation of the carboxylated surface of the chip with EDAC and NHS to give the NHS active esters produced a change of 6000 RU (region b). Washing returned the sensorgram to near baseline (9290 RU, region c). Introduction of the ligand-bearing reactive amino groups (region d) led to covalent attachment via newly formed amide bonds with a change of 12 000 RU. After washing, the instrument response fell to 9326 RU (region e). Final blocking of unreacted active esters on the solid surface with ethanolamine (region f) caused a rise in RU of 15 000. Washing with buffer, aqueous HCl, and buffer again gave the final biosensor chip. As expected for low-molecular weight ligands, the 36 Δ RU (region e – region i) after conjugation was too small to be a reliable indicator of ligand density. Successful conjugation was confirmed, however, on equilibration of the sensors with anti- T_4 mAb (Figure 4) where the Δ RU was dramatically larger. For our experiments, conjugation using the optimum concentration of the aminoalkyl thyroxine analogs (**29–42**) (5 μ g/mL) gave rise to a maximum Δ RU of about 1000 at saturation levels of anti- T_4 mAb for the resulting biosensors (**43–56**). These biosensors were suitable for use in the direct kinetic analysis, below.

To show that the interaction of anti- T_4 mAb was specific for the analyte on the biosensor and not to the dextran surface, three experiments were performed. First, a blank sensor was treated under the normal conjugation protocol except that buffer was substituted for the thyroxine analog ligand. Anti-thyroxine mAb and Fab were tested at eight concentrations with the sensor. The resulting sensorgrams are depicted in panels A and B of Figure 5, respectively. Finally, thyroxine sensor **43L** was equilibrated with anti-theophylline monoclonal antibody (Figure 5C). The sensorgram in all three experiments showed a very small Δ RU response within the noise level of the instrument. Additionally, the recorded response appeared to be random. It did not correspond to the incremental changes in the antibody concentration, thus indicating no binding.

Preparation of T_4 mAb and Fab. For this study, the desired monoclonal antibody to T_4 was obtained from tissue culture media after filtration, centrifugation, and protein-A column chromatography. After dialysis, the concentration of the antibody was found to be 4.86 mg/mL by UV spectroscopy. Assay by the micro-BCA method found the concentration to be 4.99 mg/mL, which was in close agreement with the UV value. Analysis by SDS-PAGE showed two bands (Figure 1). The upper band corresponded to the heavy chain of the antibody, with an apparent molecular weight of 55 kDa, while the light chain appeared as a sharp band at 27 kDa. LC/ESI/MS

Scheme 3

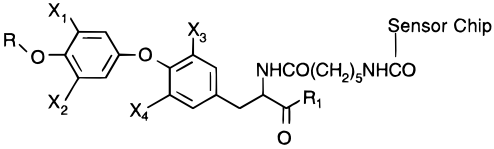

(Figure 2) of the antibody gave a series of multicharged ions centered at m/z 2600 (inset A). Deconvolution showed four species (inset B) with molecular weights of 149 355 (20%), 149 541 (65%), 149 678 (100%), and 149 833 Da (85%), consistent with the expected mass of an intact monoclonal antibody (22, 23).

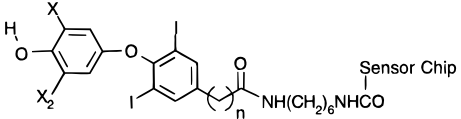

Digestion of the monoclonal antibody with papain produced a mixture containing the unreacted mAb, and the Fc and Fab fragments. Chromatography (protein-A) gave the Fab fragment in the void volume in 65% yield after dialysis. The final concentration of anti-T₄ Fab was 11.8 mg/mL (micro-BCA). SDS-PAGE (Figure 1) showed two bands (27 and 25 kDa) and no detectable mAb or Fc fragment. LC/ESI/MS (Figure 2) showed a series of multicharged species centered at m/z 1500 (inset A). On

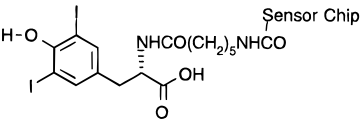

deconvolution (inset B), a single narrow peak was predominant at m/z 47 620 (100%), accompanied by a broad peak centered at m/z 47 782 (30%).

Direct Kinetic Analysis. Monoclonal Antibody to T₄. Each thyroxine analog biosensor (43–56) was tested with the purified anti-T₄ mAb at eight concentrations ranging from 0.5 to 100 nM on the BIAcore instrument to produce a series of sensorgrams. Typical results are illustrated in Figure 4A using biosensor 43L. The concentration-dependent binding kinetics of anti-T₄ mAb to biosensor 43L displayed in the sensorgrams were consistent with a two-component interaction model, i.e., $A + B \rightleftharpoons AB$, during the first 100 s of the association and dissociation phases. In panels B and C of Figure 4, the solid curves (with the left y-axis) represent the fitted data for these

^a All data are from nonlinear regression analysis of sensorgram curves. ^b — indicates that no binding was observed at the concentration tested.

regions of the association and dissociation phases, respectively. The coplotted residuals (right *y*-axis and the *x*-axis) show the difference between the fitted data and the experimental data for each point. The uniform distribution of points in the residual plots is typical for the proposed 1:1 binding model and indicates a good fit of the data (24). The plots were used to determine k_a and k_d (Table 1). Figure 4D shows the result of the linear regression analysis of the sensorgrams shown in Figure 4A, as a plot of k_s versus concentration, where k_s is the slope of dRU/dt versus RU_f . The slope of this plot is k_a , and the *y*-intercept is k_d . The resulting values were in close agreement with those in Table 1.

The T₂ analog (45), the *O*-methyl derivatives (51 and 52), the thyroacetic acids (53 and 54), and the tyrosine compound (56) showed no binding at the concentrations tested. Of the ligands that bound, all but 49 appeared to bind according to the proposed 1:1 binding model. The residual plots of the association and dissociation phases of the sensorgram for sensor 49 (not shown) were decidedly skewed, indicating a deviation from the model. Nonetheless, the association rate constant (k_a) values for all of the binding structures were similar, ranging from 1 to 7 × 10⁶ M⁻¹ s⁻¹. However, the recorded dissociation rate constants for the same structures exhibited a much wider range of values (1–592 × 10⁻⁵ s⁻¹). The equilibrium association constants, K_A , were derived from the equation

$$K_A = k_a/k_d$$

Of the analog biosensor surfaces that bound the T₄ mAb,

values of K_A ranged from 9 to 1140 × 10⁸ M⁻¹. The analogs fell into four groups. T₄ mAb had the highest affinity for the enantiomeric thyroxine analog sensors (43L,D) and the thyroxine dimethylamide sensor (49), all of which were linked through the α-amino group. The next group consisted of the mono- (46) and dibromo-substituted (48) analogs of thyroxine. T₃ derivatives (44L,D), like the thyroxine sensors, showed no preference for the stereochemistry of the α-amino group. The group with the lowest affinity included the monobromo T₃ analog (47), T₃ dimethylamide (50), and the T₃ derivative lacking the α-amino group (55). The values for the change in free energy on binding of the analog surfaces with T₄ mAb were obtained from the equation

$$\Delta G = -RT \ln(K_A)$$

and ranged from -12.2 to -15.0 kcal/mol. Using the ΔG value for sensor 43L as a point of reference, $\Delta\Delta G$ was determined from the equation

$$\Delta\Delta G = \Delta G_{\text{obs}} - \Delta G_{43L}$$

A difference of up to 2.8 kcal/mol was seen with the sensors that exhibited binding to the antibody.

Monoclonal Antibody Fab to T₄. Following the same evaluation and data reduction protocols used for the intact T₄ mAb, the binding kinetics of purified Fab to the biosensors (43–56) were recorded (Table 2). Those surfaces that bound T₄ mAb also bound the Fab fragment. All the binding events appeared to follow the proposed 1:1 interaction of the model based on the residual plots

and the low χ^2 values obtained from analysis of the sensorgrams. The association rate constants (k_a) were similar to those recorded for the whole antibody, $1\text{--}10 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, while the dissociation rates were from 1- to 11-fold higher. Equilibrium association constants ranged from 1 to $128 \times 10^8 \text{ M}^{-1}$. Again, the sensors could be separated into four groups with similar K_A values. The thyroxine sensor (**44L**) and the thyroxine dimethylamide (**49**) had the highest affinity constants, followed by the D enantiomer of the thyroxine sensor (**43D**). Unlike the intact antibody, the Fab fragment had a slight preference for the naturally occurring L stereochemistry. The mono- (**46**) and dibromothyroxine sensors (**48**) were next in the affinity ranking. T₃ (**44L,D**), T₃ dimethylamide (**50**), and thyropropionic acid (**55**) had the lowest affinity for the Fab fragment of those derivatives that bound. Values for ΔG spanned the range from -13.7 to -10.9 kcal/mol , giving $\Delta\Delta G$ values of $0\text{--}2.8 \text{ kcal/mol}$.

DISCUSSION

T₄ (3,5,3',5'-tetraiodothyronine or thyroxine) is a powerful hormone with far-reaching and diverse physiological effects. As the predominant hormone secreted from the thyroid gland, T₄ is essential for normal metabolic and neural activity. Only 0.05% of T₄ freely circulates in the blood, while the rest is bound to proteins such as thyroid binding globulin (TBG), thyroid binding pre-albumins, and albumins. The concentration of T₄ in serum is an important diagnostic indicator of thyroid function (25). The most common method of measuring serum levels of T₄ in the United States and Japan has been homogeneous fluorescence polarization immunoassay (FPIA) (26). An earlier report has dealt with the design and synthesis of T₄ FPIA immunoreagents (3). The increasing need for higher sample throughput, ease of automation, and economy in today's cost-conscious health care environment has brought about a renewed interest in heterogeneous immunoassays for T₄. The immunoreagents that have optimal performance in a homogeneous assay need not display similar performance in a heterogeneous format. Traditionally, the choice of reagents has been arrived at empirically by matching an antibody with a tracer in a particular assay format. This labor intensive approach has been successful but could have been greatly simplified if the basic kinetic and thermodynamic binding parameters of the immunoreagents had been known *a priori*. Such biospecific interactions are dynamic events which are reflected in the rates of association (k_a) and dissociation (k_d) of the binding molecules. From these values, equilibrium binding constants (K_A) can be determined. Additionally, the change of the K_A -derived Gibbs free energy (ΔG) during the binding event offers a convenient means of relating changes in hapten structure to changes in binding to protein. These critical immunocomponent properties can be determined by surface plasmon resonance on the automated BIAcore system.

In the approach presented here, one member of a binding pair is conjugated to the surface of a sensor chip while the other is injected in solution over the surface at a constant rate. The instrument response is directly related to the change in mass on the surface of the biosensor. When both the binding components are macromolecules, the choice of which component to conjugate to the sensor is largely arbitrary. Conjugation of either component to the sensor will generate a substantial initial rise in RU, and subsequent association with the other component will generate a large ΔRU . The kinetics of the interaction may not be the same for both approaches simply because the process of conjugation can

change the conformation and reactivity of the species involved (27).

Relatively few studies on the BIAcore system have been reported in which a low-molecular weight ligand (like T₄) interacts with a large binding protein (like an antibody). In this case, the choice of which component to conjugate to the sensor surface is critical due to instrument constraints. Conjugation of the antibody to the sensor surface induces a large shift in RU in accordance with the large mass of the protein, but the subsequent interaction with the ligand produces a small shift that cannot be measured reliably. Although, advances in the BIAcore instrument and the accompanying increase in the sensitivity of the detector have been reported to mitigate this limitation (28). As in the case of the bimacromolecular interaction cited above, it is difficult to assess what effect immobilization of the binding protein on the sensor chip has on its binding properties. Three approaches to conjugation of low-molecular weight ligands to the sensor chip have been reported. One approach has been to conjugate the ligand to a carrier protein, which can then be coupled to the sensor surface (29–34). A concern with this protocol is that the intermediate bioconjugate is a heterogeneous species requiring an additional conjugation step and characterization to produce reliable biosensors. Low-molecular mass ligands have also been attached to the sensor surface indirectly by use of the streptavidin–biotin interaction. A sensor covalently linked to streptavidin captures the biotinylated ligand which subsequently interacts with the binding protein to form a sandwich (35). Sensors of this type have a limited lifetime and tend to “leak”. Sensors made by the direct conjugation of the ligand to the biosensor surface are more rugged (35, 36) and well-defined. However, when the small ligand is bound to the surface, there is only a small shift in RU (Figure 3) so loading cannot be quantitated directly. Only on binding with the antibody can a large and easily quantitated ΔRU be obtained. This latter conjugation procedure was chosen for the present study. This method of evaluating the kinetic and thermodynamic properties of these immunocomponents mimics the characteristics of heterogeneous assays and avoids concerns about altering the binding site conformation of the antibody but requires the construction of a different biosensor for each ligand tested. Alternative methods (37) that would mimic homogeneous assay conditions are of interest but were not the subject of this study.

The T₄ mAb that is the principle subject of this investigation was obtained from immunization with the *N*-acetyl-T₄–bovine serum albumin (BSA) conjugate prepared as shown in Scheme 4. While the L enantiomer of *N*-acetyl-T₄ was used as the starting material, we expected from our own model studies (38) that the conjugated hapten would be racemized as a result of azalactone (39) formation during the activation. Racemization of *N*-acyl amino acids under carbodiimide coupling conditions is well-known (40). It was critical to probe whether the monoclonal antibody that resulted from this immunogen recognized the chiral center of the analyte. Thus, biosensors **43L**, **43D**, **44L**, and **44D** were prepared with care to avoid racemization of the chiral haptens. In particular, the dimethyl amides (**7** and **8**, Scheme 1) were prepared from L-T₄ and L-T₃ by activation of the *N*-tert-Boc amino acids under conditions that avoid racemization. Each of the other thyroxine analogs included in the library of biosensors was chosen to probe other structural requirements of the antibody. Sensors **43–48** were prepared to test how the degree and type of halogenation in the terminal aryl ring affected binding, while sensor

Scheme 4

56 tested whether that aryl group was necessary at all. Sensors **49** and **50** were prepared to address the necessity of the ionizable carboxyl group, while **51** and **52** reflected the absence of the ionizable phenol. Thyroalkanoic acid sensors **53–55** were employed to test the need for the α -amino group.

On the basis of the structure of the immunogen which was used to generate the monoclonal antibody, we expected that the diphenyl ether ring system would be a major antigenic determinant. Moreover, the molecular architecture of the hapten close to the site of conjugation to the carrier protein is known to render the resulting antibody relatively indifferent to changes surrounding the site of attachment (3). The data obtained from the surface plasmon resonance analysis on the BIAcore system (Table 1) supported our suppositions. The free energy of binding (ΔG) of the thyroxine analog sensors to the antibody became less favorable with the loss of each halogen from the terminal aryl ring (**43L** > **46** \approx **48** > **44L** > **47** \gg **45**). The initial iodo–bromo exchange on going from **43L** to **46** resulted in a 0.3 kcal/mol increase in ΔG . Removal of one iodo group (**43L** versus **44L**) resulted in a further increase in ΔG of 1.6 kcal/mol. The trend continued until the T_2 derivative (**45**) showed no binding at the concentrations studied. Likewise, the tyrosine derivative (**56**) which lacked the B-ring of the diphenyl ether entirely showed no binding. Eliminating the phenolic HO group by conversion to the corresponding methyl ether, as in sensors **51** and **52**, also prevented antibody binding. It seemed then that the binding of the mAb was indeed sensitive to changes in the diphenyl ether moiety.

Both the degree of halogenation and the presence of a free phenol were important determinants for binding. These observations may be directly related to the acidity of the phenolic HO group. It would be expected that changing a substituent from iodo to bromo would result in a decrease in pK_a of 0.1 [based on the literature (41) pK_a values for *o*-iodophenol and *o*-bromophenol of 8.5 and 8.4, respectively]. Replacing the iodo group with hydrogen would cause a much larger decrease of 1.5–2 pK_a units (based on the following pK_a data: 6.79, T_4 ; 8.86, T_3 ; and 10.28, T_2) (12). A change of 1 pK_a unit equals 1.32 kcal/mol. The $\Delta\Delta G$ of the antibody binding reaction between sensors **43L** and **44L** (ΔpK_a of 2.1) amounted to only 1.6 kcal/mol, about half of the expected value based on the change in pK_a of the analogs. A similar trend in antibody–thyroxine analog binding was seen by Rokos et al. (12). They reported cross reactivity data in an RIA format of several thyroxine analogs with an antibody directed toward an α -amino-linked L- T_4 ethyl ester immunogen. In their study, T_4 , Br T_3 , and Br T_2 (similar in structure to sensors **43L**, **46**, and **48**, respectively) displayed cross reactivity of 100, 85.6, and 47.6%,

respectively, while 3'-isopropyl- T_3 cross reacted only 8.9%. In their study, as well as ours, as the halogenation decreased, so did binding to the antibody. We conclude that, while the interaction of the phenolic HO group with this antibody is important, it need not be the only contributing factor. The higher polarizability of the iodo versus the bromo substituent may also contribute to the results noted here.

The SPR-derived binding data indicated that our mAb recognized both enantiomers of the thyroxine biosensors (**43L,D**) and the triiodothyronine biosensors (**44L,D**) to an equal degree, supporting the expectation that the antibody would not be sensitive to changes surrounding the chiral center. The dimethylamide-substituted sensors (**49** and **50**) showed affinity for the antibody nearly equivalent to that for the corresponding carboxy-substituted analogs (**43L** and **44L**). The triiodothyropropionic acid-derived sensor (**55**) which was linked via the carboxylic acid, thus lacking the chiral center, α -amino, and free carboxyl groups, had similar binding to the corresponding T_3 dimethylamide sensor (**50**). In light of the insensitivity of this mAb to changes in the structure surrounding the chiral center, α -amino, and carboxyl groups, it was surprising that neither the tetraiodo- nor the triiodothyroacetic acid analogs (**53** and **54**, respectively), which differed by a single methylene unit from sensor **55**, showed any binding to the antibody.

With only minor variations, the kinetic and thermodynamic values obtained from the SPR analysis of the Fab fragment with the same series of biosensors (Table 2) followed the same trend as seen with the whole antibody. In absolute terms, the values for ΔG for the Fab fragment were on average 0.8 kcal/mol less favorable than those seen with the mAb. The Fab fragment had very slight bias for the L enantiomer of thyroxine sensor (**43L**) and the triiodothyronine sensor (**44L**), unlike the intact antibody.

The kinetic binding data obtained for the Fab with the thyroxine analog sensors followed a true 1:1 binding event model which was represented by the dissociation and the association phases of the sensorgrams; i.e., dissociation rates were independent of the concentration of Fab (42). In contrast, this was true only for about the first 100 s of the dissociation phases in the mAb–thyroxine analog sensors binding sensorgrams. Thus, the rate constants obtained with the Fab fragment would appear to be absolute kinetic parameters, while in the case of the mAb, the numbers would represent apparent binding constants.

CONCLUSION

A library of ligand analogs were designed to probe the structural requirements for the binding interaction be-

tween hapten and antibody. The binding properties of the antibody were conveniently obtained using surface plasmon resonance on the automated BIAcore instrument. Conjugation of the ligand analogs to the SPR chip obviated concern about altering the conformation of the antibody while still mimicking a heterogeneous assay format but required the preparation of a separate biosensor for each ligand.

The data from the SPR analysis for the interaction of anti-T₄ mAb and its Fab fragment with a structurally diverse library of thyroxine analog biosensors pointed to the important contribution of the diphenyl ether ring system and the ionizable phenolic hydroxyl group to the interaction. Affinities recorded for the bivalent mAb and the monovalent Fab differed by a factor of 2–13. Additionally, the intact antibody was blind to the chirality of the hapten, whereas the monovalent Fab had a slight preference for the L enantiomers of the analogs of T₄ and T₃.

New and Versatile Ternary Ligand System for Technetium Radiopharmaceuticals: Water Soluble Phosphines and Tricine as Coligands in Labeling a Hydrazinonicotinamide-Modified Cyclic Glycoprotein IIb/IIIa Receptor Antagonist with ^{99m}Tc

D. Scott Edwards,* Shuang Liu,* John A. Barrett, Anthony R. Harris, Richard J. Looby, Marisa C. Ziegler, Stuart J. Heminway, and Timothy R. Carroll

The DuPont Merck Pharmaceutical Company, Radiopharmaceuticals Division, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received October 28, 1996*

A hydrazinonicotinamide-functionalized cyclic platelet glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonist [cyclo(D-Val-NMeArg-Gly-Asp-Mamb(5-(6-(6-hydrazinonicotinamido)hexanamido)) (HYNICTide)] was labeled with ^{99m}Tc using tricine and a water soluble phosphine (TPPTS, trisodium triphenylphosphine-3,3',3''-trisulfonate; TPPDS, disodium triphenylphosphine-3,3'-disulfonate; or TPPMS, sodium triphenylphosphine-3-monosulfonate) as coligands. The synthesis of technetium complexes, $^{99m}\text{Tc}(\text{HYNICTide})(\text{L})(\text{tricine})$ (**1**, **L** = TPPTS; **2**, **L** = TPPDS; **3**, **L** = TPPMS), can be performed in one or two steps in high yield and with high specific activity ($\geq 20\,000\text{ Ci/mmol}$). For example, the reaction of the HYNICTide, ^{99m}Tc pertechnetate, stannous chloride, and tricine at pH 4–5 and room temperature results in the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$, which reacts with TPPTS (50 °C for 30 min) to give complex **1** in $\geq 90\%$ yield as determined by radio-HPLC. Complexes **1–3** are formed as equal mixtures of two isomeric forms and are stable for $\geq 6\text{ h}$ in the reaction mixture and in dilute solution. Both isomeric forms of complex **1** were found by a platelet-binding assay to contain the ^{99m}Tc -labeled HYNICTide and possess biological activity. The composition of these complexes was determined to be 1:1:1:1 for Tc:HYNICTide:L:tricine through a series of mixed ligand experiments on the tracer (^{99m}Tc) level. Surprisingly, this composition is maintained over a wide range of relative ligand ratios. The relative bonding capability of the three phosphine coligands to the Tc was determined by spiking various amounts of TPPDS or TPPMS into TPPTS and falls in the order TPPMS > TPPDS > TPPTS. The lipophilicity of the ^{99m}Tc HYNICTide complexes can be systematically varied by the choice of the phosphine and aminocarboxylate coligands. Using the combination of tricine and a phosphine ligand, HYNIC-derivatized peptides or other small molecules can be labeled with ^{99m}Tc in high specific activity and with high stability for potential use as radiopharmaceuticals.

INTRODUCTION

We have been actively pursuing a research program to develop a thrombus imaging agent by labeling a platelet glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonist with ^{99m}Tc (1–6). Recently, we reported the ^{99m}Tc labeling of a hydrazinonicotinamide-conjugated GPIIb/IIIa antagonist (HYNICTide in Chart 1). We found that the HYNICTide can be labeled using tricine as the coligand and forms the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ with specific activity $\geq 20\,000\text{ Ci/mmol}$. However, $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ is not stable in solution and exists in many isomeric forms, which we attribute to coordination isomerism from the hydrazine moiety of the HYNICTide and the tricine coligand (5). Although the biological data from animal studies in a canine arteriovenous (AV) shunt and a deep venous thrombosis (DVT) model show that the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ is able to image both arterial and venous thrombus (3), it would still be difficult to develop for clinical use because of the solution instability and the presence of the many isomeric forms.

To prepare ^{99m}Tc HYNICTide complexes with higher solution stability and less isomerism, we used ethylene-

Chart 1. Cyclic HYNICTide

diamine-*N,N'*-diacetic acid (EDDA), which is more symmetrical and potentially tetradentate, as the coligand to label the HYNICTide. We found that EDDA forms the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})$, with much higher solution stability and less isomerism (5). However, the HPLC data showed that the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})$ exists in at least three isomeric forms. The use of *N*-substituted EDDA analogs produces ^{99m}Tc HYNICTide complexes with different lipophilicity but offers no improvement with respect to minimizing the number of coordination isomers. Thus, EDDA and its *N*-substituted

Chart 2. Structures of Three Water Soluble Phosphines

analogs are not ideal coligands for the ^{99m}Tc -labeling of the HYNICTide.

In this paper, we describe an alternative approach, in which a water soluble phosphine [Chart 2; trisodium triphenylphosphine-3,3',3''-trisulfonate (TPPTS); disodium triphenylphosphine-3,3'-disulfonate (TPPDS); sodium triphenylphosphine-3-monosulfonate (TPPMS)] is used as the second coligand to form a ternary ligand system. To our surprise, these monodentate water soluble phosphines react readily with $^{99m}\text{Tc}(\text{HYNICTide})\text{-(tricine)}_2$, replace one of its two tricine coligands, and form the technetium complexes $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{L})$ (**1**, **L** = TPPTS; **2**, TPPDS; **3**, TPPMS) in high yield and high specific activity ($\geq 20\,000\text{ Ci/mmol}$). Complexes **1–3** are very stable in both the kit matrix and dilute solutions. By two reversed phase HPLC methods, we found that these complexes are formed as equal mixtures of two species. Through a series of mixed ligand experiments, we determined the composition of these complexes to be 1:1:1:1 for Tc:HYNICTide:L:tricine (**L** = TPPTS, TPPDS, and TPPMS). This composition is maintained over a wide range of relative ligand ratios. We also evaluated these three complexes in the canine AV shunt and DVT models for their potential use as thrombus imaging agents. The results of the biological evaluation will be described in a companion report (7).

EXPERIMENTAL PROCEDURES

Materials. TPPTS and tetrabutylammonium dihydrogen phosphate (TBAP) were purchased from Aldrich Chemical Co. TPPTS was purified according to the literature method (8) before use for radiolabeling. TPPDS was prepared and purified according to the procedure described in the literature (9). TPPMS was purchased from TCI America, Portland, OR, and was used as received. *N*-(6-Hydrazinonicotinyl)-D-phenylalanine methyl ester hydrochloride was received as a gift from Michael J. Abrams and J. D. Higgins III, Johnson-Matthey Pharmaceutical, Wester Chester, PA. $\text{Na}^{99m}\text{TcO}_4$ was obtained from a Technelite $^{99}\text{Mo}/^{99m}\text{Tc}$ generator, DuPont Merck Pharmaceutical Co., North Billerica, MA. Deionized water was obtained from a Millipore MilliQ Water System and was of $>18\text{ M}\Omega$ quality. The synthesis and biological properties of the cyclic GPIIb/IIIa HYNICTide will be reported elsewhere (10, 11).

Instruments and Methods. The high-performance liquid chromatography (HPLC) methods used a Hewlett-Packard Model 1050 or Model 1090 instrument with radiometric detector. The instant thin layer chromatography (ITLC) method used Gelman Sciences silica gel strips and a 1:1 mixture of acetone and saline as eluant.

HPLC Method 1 used a Zorbax Rx C_{18} column (4.6 mm \times 250 mm, 80 Å pore size) at a flow rate of 1.0 mL/min with a gradient mobile phase from 100% A [95:5 (0.025 M, pH 3.7, phosphate buffer/0.005 M TBAP):acetonitrile] to 90% A and 10% B [20:80 (0.025 M, pH 3.7, phosphate

Table 1. Radio-HPLC Data for Complexes 1–3

L	complex	yield (%)	retention time ^a (min)
TPPTS	1	≥ 90	11.0/11.4
TPPDS	2	≥ 90	14.5/15.0
TPPMS	3	≥ 90	17.4/17.8

^a Using HPLC method 2.

buffer/0.005 M TBAP):acetonitrile] at 20 min, 40% B at 30 min, and 100% B at 33 min.

HPLC Method 2 used a Vydac C_{18} column (4.6 mm \times 250 mm, 300 Å pore size) at a flow rate of 1 mL/min with a gradient mobile phase starting from 100% A (10 mM phosphate buffer, pH 6) to 30% B (acetonitrile) at 15 min and 75% B at 25 min.

HPLC Method 3 used a heated (50 °C) Zorbax C_{18} column (4.6 mm \times 250 mm, 80 Å pore size) at a flow rate of 1 mL/min with a gradient mobile phase starting from 95% A (0.01 M phosphate buffer, pH 6) and 5% B (acetonitrile) to 13% B at 15 min and 75% B at 20 min.

HPLC Method 4 used a heated (50 °C) Zorbax C_{18} column (4.6 mm \times 250 mm, 80 Å pore size) at a flow rate of 1 mL/min. The mobile phase is isocratic from 0 to 12 min using 100% A [90:10 (0.025 M phosphate buffer, pH 8):acetonitrile] and from 13 to 45 min using 100% B [87:13 (0.025 M phosphate buffer, pH 8):acetonitrile].

Synthesis of Complexes 1–3. Two-Step Synthesis. To a 10 mL vial were added 0.2 mL of the HYNICTide solution (50 $\mu\text{g/mL}$ in H_2O), 0.2–0.4 mL of tricine solution (100 mg/mL in H_2O), 0.5 mL of $^{99m}\text{TcO}_4^-$ solution (100 mCi/mL in saline), and 25 μL of $\text{SnCl}_2\cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was allowed to stand at room temperature for 30 min. The HPLC showed radiochemical purity (RCP) of $\geq 95\%$ for the resulting complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$. To the solution was added 0.1 mL of phosphine solution (10 mg/mL in H_2O). The reaction mixture was heated at 50 °C for 30 min and analyzed by HPLC and ITLC.

One-Step Synthesis. To a 10 mL vial were added 0.2–0.4 mL of tricine solution (100 mg/mL in H_2O), 0.2 mL of HYNICTide solution (50 $\mu\text{g/mL}$ in H_2O), 0.1 mL of phosphine solution (10 mg/mL in H_2O), 0.5 mL of $^{99m}\text{TcO}_4^-$ solution (100 mCi/mL in saline), and 25 μL of $\text{SnCl}_2\cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The pH was adjusted to 4–5. The reaction mixture was heated at 50 °C for 30 min and analyzed by HPLC and ITLC. The ^{99m}Tc HYNICTide complexes prepared according to this approach were shown by HPLC to be identical to those prepared according to the two-step synthesis. The radiolabeling yields for complexes **1–3** along with their HPLC (method 2) data are summarized in Table 1.

Composition Studies on ^{99m}Tc -HYNICTide Complexes. Determination of the Number of HYNICTide Ligands. To a 10 mL vial was added 0.4 mL of tricine solution (100 mg/mL in H_2O), followed by 0.2 mL of HYNICTide solution (50 $\mu\text{g/mL}$ in H_2O), 0.2 mL of *N*-(6-hydrazinonicotinyl)-D-phenylalanine methyl ester hydrochloride solution (50 $\mu\text{g/mL}$ in H_2O), 0.5 mL of $^{99m}\text{TcO}_4^-$ solution (100 mCi/mL in saline), and 10 μL of $\text{SnCl}_2\cdot 2\text{H}_2\text{O}$ solution (10 mg/mL in 1.0 N HCl). The reaction mixture was heated at 50 °C for about 20 min. To the solution was added 0.1 mL of TPPTS solution (10 mg/mL in H_2O). The mixture was heated at 50 °C for another 30 min and was then analyzed by HPLC (method 3).

Determination of the Number of Phosphine Ligands. To a 10 mL vial were added 0.2 mL of HYNICTide solution (50 $\mu\text{g/mL}$ in H_2O), 0.4 mL of tricine (100 mg/mL in H_2O), 0.2 mL of TPPTS solution (20 mg/mL in

H₂O), 0.2 mL of TPPDS solution (10 mg/mL in H₂O), 0.5 mL of ^{99m}TcO₄⁻ solution (100 mCi/mL in saline), and 25 μ L of SnCl₂·2H₂O solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 50 °C for 30 min and was then analyzed by HPLC (method 4).

Determination of the Number of Tricine Ligands. To a 10 mL vial was added 0.1 mL of TPPTS solution (10 mg/mL in H₂O), followed by 0.2 mL of HYNICTide solution (50 μ g/mL in H₂O), 0.1 mL of tricine solution (200 mg/mL in H₂O), 0.5 mL of glycine solution (200 mg/mL in H₂O), 0.5 mL of ^{99m}TcO₄⁻ solution (100 mCi/mL in saline), and 25 μ L of SnCl₂·2H₂O solution (1 mg/mL in 0.1 N HCl). The mixture was heated at 50 °C for 30 min and then analyzed by HPLC (method 3).

Solution Stability Studies. *Solution Stability of Complex 1 in Kit Matrix.* Complex **1** in the kit matrix was analyzed by HPLC (method 3) without dilution. Aliquots of the reaction mixture were placed in eight autosampler vials and analyzed sequentially over 6 h.

Solution Stability of Complex 1 in Solution with 10-Fold Dilution. Aliquots (0.3 mL) of complex **1** were diluted with either 0.9% saline (2.7 mL) or 2 wt % tricine in saline (2.7 mL); the diluted solutions were analyzed by HPLC as described above.

Solution Stability of Complex 1 in Solution with 100-Fold Dilution. Aliquots (0.1 mL) of complex **1** were diluted with either saline (9.9 mL) or 2 wt % tricine in saline (9.9 mL); the diluted solutions were analyzed by HPLC as described above.

Solution Stability of Isolated Peaks. The two peaks of complex **1** were collected separately using HPLC method 3. The collected fractions were each divided into two separate 10 mL vials. The pH was adjusted to 4.0 in one vial and to 8.0 in the other. These solutions were monitored for ~24 h by HPLC.

TPPDS and TPPMS Spiking Studies. To each of four 10 mL vials was added 0.2 mL of HYNICTide solution (50 μ g/mL in H₂O), followed by 0.4 mL of tricine solution (100 mg/mL in H₂O), 0.1 mL of TPPTS solution (10 mg/mL in H₂O), 0.1 mL of H₂O containing various amounts of TPPDS (0, 50, 100, or 500 μ g) or TPPMS (0, 50, 100, or 200 μ g), 0.2 mL of ^{99m}TcO₄⁻ solution (200 mCi/mL in saline), and 25 μ L of SnCl₂·2H₂O solution (1.0 mg/mL in 0.1 N HCl). The pH was adjusted to 4–5. The reaction mixture was heated at 80 °C for 30 min and analyzed by HPLC (method 2).

Platelet-Binding Assay. The platelet-binding assay was performed according to the literature method (12) with some modification. Canine venous whole blood was collected into citrate-containing syringes (sodium citrate final concentration 0.38 wt %, Ricca Chemical Co., Arlington, TX). To form platelet-rich plasma, the whole blood was centrifuged at 900 rpm for 10 min (Sorvall Model RT6000B Rotor H1000B, DuPont Medical Products, Newtown, CT) and the supernatant retained. The platelets were rendered quiescent via the addition of aspirin (Sigma Chemical Co., St. Louis, MO) to obtain a final concentration of 50 μ M, prior to their incubation at 37 °C for 20 min. At the end of the 20 min incubation period, prostaglandin E₁ (final concentration 0.9 μ M, Sigma) was added and the pH was adjusted to 6.5–7 using 3.8 wt % sodium citrate (pH 5.5). The preparation was centrifuged at 2300 rpm for 10 min and the supernatant discarded. Approximately 3 mL of Tyrodes buffer was added, and the preparation was placed on a gel filtration column containing Sepharose CL-4B (Pharmacia Biotech, Uppsala, Sweden). The platelet fraction was collected and the platelets were counted on a cell analyzer (Simex K-1000, Baxter, Chicago, IL). The aliquot was

adjusted to achieve a final concentration of 1.8×10^7 platelets/well.

This assay was performed in a 96 well microtiter plate, and the reagents (expressed as final concentration) were added in the following order: Tyrodes buffer, calcium chloride (2 mM, BioData Corp., Horsham, PA), thrombin (0.1 unit/mL, Sigma), and platelets (1.8×10^7 platelets/well). After 2 min of incubation at room temperature, hirudin (0.5 unit/mL, Sigma) and the test agent (HPLC-purified complex **1** or one of its two isolated radiometric peaks) were added. The microtiter plate was incubated at room temperature for an additional 15 min, followed by centrifugation at 3000 rpm for 10 min. The pellet and supernatant were separated, and incorporation of complex **1** and its two isolated radiometric peaks was determined via gamma scintillation counting.

RESULTS AND DISCUSSION

Recently, Abrams and co-workers reported the use of HYNIC technology in labeling polyclonal IgG with ^{99m}Tc for imaging focal sites of infection (13–17). This technology has also been used for the ^{99m}Tc-labeling of chemotactic peptides (18–20) and antisense and DNA oligonucleotides (21–23). Since the HYNIC group can only occupy one or two sites in the technetium coordination sphere, a coligand such as glucoheptonate or tricine is required. It has been shown that the specific activity of the ^{99m}Tc-labeled polyclonal IgG using tricine as a coligand is much higher than that obtained using glucoheptonate (15–17).

We have labeled the HYNICTide (Chart 1) using tricine as the coligand to form the complex [^{99m}Tc(HYNICTide)(tricine)₂] (**5**). We found that the complex [^{99m}Tc(HYNICTide)(tricine)₂] is not stable in solution, particularly under dilute conditions, and exists in many isomeric forms, which we attribute to coordination isomerism from the hydrazine moiety of the HYNICTide and the two tricine coligands. To reduce the number of coordination isomers, we have used other more symmetrical polydentate aminocarboxylates (such as EDDA) as coligands for the radiolabeling. Although the complex [^{99m}Tc(HYNICTide)(EDDA)] has higher solution stability and less coordination isomerism, the radio-HPLC data show that it exists in at least three isomeric forms, which interconvert in solution (**5**). Therefore, EDDA and its N-substituted analogs are not ideal coligands for the ^{99m}Tc-labeling of the HYNICTide.

An alternative approach to reduce the coordination isomerism is to introduce an additional coligand (**L**), which may replace one of the two unsymmetrical, multidentate tricine coligands in [^{99m}Tc(HYNICTide)(tricine)₂] to form a complex [^{99m}Tc(HYNICTide)(tricine)(**L**)] with a ternary ligand system. The use of an appropriate additional coligand (**L**) may impart constraints on the possible coordination modes of the tricine and hydrazine ligands, thereby minimizing the number of possible coordination isomers. These constraints may arise from either a steric or electronic preference for the coordination of **L**. For this purpose, we have chosen three bulky monodentate water soluble phosphines (Chart 2) as the additional coligand for the ^{99m}Tc-labeling of the HYNICTide.

Triphenylphosphine itself is known to form complexes with Tc in various oxidation states (24). A number of Tc-hydrazido and Tc-diazenido complexes with monodentate and bidentate phosphine ligands have been reported (25–31), with well-defined coordination geometries, including complexes formed on the tracer level (^{99m}Tc) in aqueous solution (27). The sulfonate groups are expected to be deprotonated under physiological conditions, resulting in increased hydrophilicity and

Chart 3. Synthesis of Complexes 1–3

potentially improved target to background ratios for the technetium complexes (7).

Synthesis of Complexes 1–3. Synthesis (Chart 3) of complexes 1–3 can be achieved either in two steps, in which the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ is formed first and then reacts with TPPTS, TPPDS, and TPPMS, respectively, or in one step by direct reduction of ^{99m}Tc -pertechnetate with stannous chloride in the presence of the HYNICTide, tricine, and a phosphine coligand. The reaction is carried out by heating the reaction mixture at 50 °C for 30 min. The relative amounts of the three ligands can cover a wide range. The tricine concentration can be from 10 to 100 mg/mL. Using lower tricine concentration (<10 mg/mL) results in the formation of a significant amount of ^{99m}Tc colloid. The phosphine concentration can be from 1.0 to 5.0 mg/mL. Low phosphine coligand concentration results in either incomplete conversion of $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ to complexes 1, 2, or 3 in the two-step synthesis or the formation of $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ as a radioimpurity in the one-step synthesis.

The concentration of the HYNICTide can range from 1 to 100 $\mu\text{g/mL}$. The radiolabeling yields (Table 1) for complexes 1–3 are usually $\geq 90\%$ using 5 μg of HYNICTide (4.69×10^{-9} mol, FW = 1066 for HYNICTide-2TFA) and 100 mCi of ^{99m}Tc pertechnetate ($\sim 7 \times 10^{-10}$ mol of ^{99m}Tc and ^{99}Tc for 24 h generator). The HYNICTide/Tc ratio is about 7:1 under these conditions. Very high specific activity ($\sim 20\,000$ mCi/ μmol) can be achieved for complexes 1–3 without postlabeling purification. The radiolabeling efficiency of this new ternary ligand system is comparable to that obtained using tricine coligand only (5). Since the ^{99m}Tc HYNICTide complexes require no postlabeling purification, this procedure is amenable for clinical application.

HPLC Characterization. In our previous contribution (5), we found that the radio-HPLC (method 1) chromatogram of $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ (Figure 1) showed at least 10 partially resolved peaks with retention times ranging from 20 to 28 min. To our surprise, the reaction of $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ with TPPTS produces complex 1, which shows only one peak at 33.2 min (Figure 2) using the same method. However, by a gradient reversed phase method (method 2), we found two partially resolved peaks (Figure 3) for complex 1.

Figure 1. Radio-HPLC chromatogram for complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$.

Figure 2. Radio-HPLC chromatogram (method 1) for complex 1.

Figure 3. Radio-HPLC chromatogram (method 2) for complex 1.

Figure 4. Radio-HPLC chromatogram (method 3) for complex 1.

Using a different gradient HPLC method (method 3) or an isocratic reversed phase method (method 4), we were able to resolve the two peaks (Figures 3 and 4), with the area ratio being approximately 1:1. We also found that the complex prepared according to the two-step synthesis is exactly the same as that prepared according to the one-step synthesis. It is remarkable that the use of a simple monodentate phosphine ligand forms a new ternary ligand system and reduces the number of isomeric forms from >10 for $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$ to only 2 for complex 1.

Table 2. Results for Platelet-Binding Assay

Platelet-Binding Assay. A platelet-binding assay (12) was used to determine if the two peaks assigned as complex **1** do, in fact, represent species comprised of the ^{99m}Tc-labeled HYNICTide and are competent to bind to platelets. In this assay, there is marked excess of receptor to eliminate competition for the GPIIb/IIIa receptor sites. The assay was based on the following data. There are approximately 74 000 copies of the GPIIb/IIIa receptor per platelet; and $1 \times 10^7 - 2 \times 10^7$ platelets/well. In addition, we assumed that competition from fibrinogen released from platelet alpha granules does not effectively compete with our test agent. Thus, the receptor saturation should occur at approximately 12 nM of test agent.

We separated the two peaks using radio-HPLC method 3. The collected fractions were evaporated to dryness, redissolved in 0.9% saline, and diluted to the required concentration for the platelet-binding assay. As a control, we also collected both peaks as one fraction (combined peaks 1 and 2). The HPLC purified complex **1** (combined) and the two radiometric peaks were assessed at a fixed concentration of 10 pM. It was found that the HPLC-purified complex **1** (combined) and its two radiometric peaks bind to the gel-filtered canine platelets to the same extent (Table 2), demonstrating clearly that both isolated peaks contain the ^{99m}Tc-labeled HYNICTide and possess biological activity.

Composition Studies of [^{99m}Tc]HYNICTide Complexes. A mixed ligand experiment was performed to determine the number of HYNICTides bonded to the Tc. In this experiment, the HYNICTide and a model compound, *N*-(6-hydrazinonicotinyl)-D-phenylalanine methyl ester (HYNIC-D-Phe-OMe), were used in the same reaction mixture. After the radiolabeling, the reaction mixture was analyzed by radio-HPLC (method 3). If only one HYNICTide is bonded to the Tc, the chromatogram is expected to show two sets of peaks, one set from complex **1** and the other from the complex [^{99m}Tc(HYNIC-D-Phe-OMe)(tricine)(TPPTS)]. If there were two HYNIC-containing ligands in each complex, a third set of peaks from the mixed ligand complex, [^{99m}Tc(HYNICTide)-(HYNIC-D-Phe-OMe)(tricine)(TPPTS)], is expected. The presence of only two sets of peaks in the radio-HPLC chromatogram (Figure 5) demonstrates clearly that there is only one HYNICTide bonded to the Tc in complex **1**, and by inference to complexes **2** and **3**.

**Figure 6.** Radio-HPLC chromatogram (method 2) for complex **1** and [^{99m}Tc(HYNICTide)(TPPTS)(glycine)₂].**Figure 7.** Radio-HPLC chromatogram (method 3) for complexes **1** and **2**.

The number of tricine coligands in complex **1** was determined similarly using tricine and glycine as competing coligands. We used a 12:1 molar ratio of glycine to tricine since the bidentate glycine is not as strong a ligand as tricine. Figure 6 shows the radio-HPLC chromatogram (method 3) of the resulting reaction mixture. Two sets of peaks from complex **1** and [^{99m}Tc(HYNICTide)-(TPPTS)(Gly)₂] are seen at 12 and 14 min, respectively, suggesting that there is only one tricine coligand in complex **1**, and by inference in complexes **2** and **3**. The small peaks between these two sets of peaks are evident in the chromatogram obtained using glycine only.

The number of TPPTS coligands in complex **1** was determined similarly to that for the HYNICTide using TPPTS and TPPDS as competing coligands. The presence of two sets of distinctive peaks at 12 and 36 min in the radio-HPLC chromatogram (Figure 7) for complexes **1** and **2**, respectively, indicates clearly that there is only one phosphine coligand bonded to the Tc in these complexes.

On the basis of these data, we conclude that these technetium complexes contain one HYNICTide, one tricine, and one phosphine coligand (TPPTS, TPPDS, and TPPMS). It has been reported that on the carrier-added (⁹⁹Tc) level the reaction of [⁹⁹Tc]tricine complex with 2 equiv of HYNIC-D-Phe-OMe results in formation of two technetium complexes: [⁹⁹Tc(HYNIC-D-Phe-OMe)(tricine)]⁻ and [⁹⁹Tc(HYNIC-D-Phe-OMe)₂(tricine)₂]⁻ (16). On the tracer level (^{99m}Tc), however, the reaction of [^{99m}Tc]tricine complex with excess HYNICTide results in complex **1** as the only detectable product. No bis(HYNICTide) technetium complex was observed even at a HYNICTide concentration of ~100 μg/mL. We also carried out the synthesis of complex **1** changing the level of each component. Surprisingly, the 1:1:1 composition for Tc: HYNICTide:tricine:TPPTS was retained over a wide range of relative ligand ratios (HYNICTide, 1–100 μg; tricine, 10–100 mg; TPPTS, 1–5 mg).

Solution Stability Studies. Another advantage using this new ternary ligand system is the high solution stability of complexes **1–3**. We examined the solution

Figure 8. Plot of RCP vs time for complex **1** in the kit matrix.

stability of complex **1** both in the kit matrix and in solutions with 10- and 100-fold dilutions. For complex **1** in the kit matrix, the stability was assessed by radio-HPLC (method 3) by performing eight injections over ~6 h. For complex **1** in the dilute solutions, the reaction mixture was first diluted with either 2 wt % tricine solution or 0.9% saline, and the diluted solutions were monitored in a similar fashion. Figure 8 shows the plot of RCP (radiochemical purity) vs time for complex **1** in the kit matrix. Plots of RCP vs time for complex **1** in solutions with 10- and 100-fold dilutions are shown in Figures SI and SII, respectively. It is clear that complex **1** is stable for ≥ 6 h in solution and the peak ratio remains relatively constant.

We also examined the stability of the two isolated peaks of complex **1** in solutions at different pH values. The collected solution of each peak was divided into two fractions, and the pH was adjusted to 4 in one fraction and to 8 in the other. These fractions were monitored by radio-HPLC (method 3). It was found that both peaks are stable for at least 6 h in solution between pH 4 and 8 (Figures SIII and SIV). No interconversion was observed for the two isolated peaks under conditions used in this study.

Apparently, the use of this new ternary ligand system offers several major advantages. First, bonding of the phosphine coligand to the Tc dramatically reduces the number of isomeric forms of the [^{99m}Tc]HYNICTide complexes. Second, the solution stability of [^{99m}Tc]HYNICTide complexes is dramatically improved. Finally, the hydrophilicity of [^{99m}Tc]HYNICTide complexes with the new ternary ligand system can be tuned by either altering the number of sulfonate groups or using water soluble phosphines with other polar functionality. The tricine coligand can also be substituted by other potentially tetradentate aminocarboxylates, such as dicine [*N*-bis(hydroxymethyl)methylglycine] and bicine [*N,N*-bis(hydroxymethyl)glycine]. However, the specific activity of [^{99m}Tc]HYNICTide complexes using dicine and bicine as coligands is not as high as that of the corresponding tricine complexes. This is consistent with the literature results reported by Abrams and co-workers, who found that the [^{99m}Tc]tricine precursor complex has the highest reactivity with hydrazines (15).

In the past decade, the ligand design for technetium radiopharmaceuticals has been focused on preparing polydentate chelators [e.g., N_3S triamidethiols (32–34), N_2S_2 diamidedithiols (34–38), N_2S_2 diaminedithiols (39–50), N_2S_2 monoamide monoaminodithiols (51–54), *N*-4-oxopentan-2-ylidene-*N*-pyrrol-2-ylmethylethane-1,2-diamine ($\text{H}_3\text{MRP-20}$) (55, 56), and propylene amine oxime (PnAO) (57, 58)], which are able to form stable complexes with a 1:1 Tc:ligand ratio. Some of these chelators have

been successfully used to label proteins (37, 38), and peptides (34, 48) with ^{99m}Tc for the development of target specific radiopharmaceuticals. A binary ligand system containing a tetradentate N_2O_2 and two monodentate ether-substituted phosphine ligands was reported to form cationic Tc(III) complexes such as $^{99m}\text{Tc-Q3}$ (59, 60), which is used as a heart imaging agent. Very few binary ligand systems are used for the ^{99m}Tc -labeling of proteins and peptides.

Recently, tridentate ligands containing the SNS donor set were used in the synthesis of brain imaging agents (61, 62). The combination of a dianionic tridentate SNS ligand with a monodentate thiolate produces a binary ligand system that can bind to the Tc=O core and form neutral square-pyramidal technetium complexes. This “3 + 1” concept has been used for ^{99m}Tc -labeling of dopamine transporters (63, 64). The ternary ligand system described in this study contains three different ligands: a bifunctional coupling group (HYNIC), a monodentate phosphine, and the tetradentate tricine coligand. It is remarkable that these three different ligands react in one step with [^{99m}Tc]pertechnetate in the presence of stannous chloride and form a technetium complex with only two isomeric forms. This represents the first example of a ternary ligand system used for the ^{99m}Tc -labeling of peptides, proteins, or other biologically active molecules.

Traditionally, the development of a new class of ^{99m}Tc radiopharmaceuticals involves synthesis and characterization of new technetium complexes using macroscopic amounts of ^{99}Tc , followed by the translation of the macroscopic ^{99}Tc chemistry to the tracer level (^{99m}Tc) chemistry. The composition and structure of ^{99m}Tc complexes are determined by various spectroscopic (IR, NMR, and FAB-MS) and X-ray crystallographic studies on the corresponding ^{99}Tc analogs. In this study, we used a simple mixed ligand experiment to determine the composition of ^{99m}Tc complexes. The composition of complex **1** determined with this method is completely consistent with that of the corresponding ^{99}Tc analog, [^{99}Tc](HYNICTide)(TPPTS)(tricine), determined with ^1H NMR methods (65). This methodology also applies to the composition determination for ^{99m}Tc complexes with other binary or ternary ligand systems.

On the basis of the mixed ligand experiments, it is quite clear that complex **1** contains one HYNICTide, one tricine, and one TPPTS. However, the technetium oxidation state and the exact nature of bonding between these ligands (HYNIC, tricine, and phosphine) and the Tc metal center are not yet clear. It has been proposed that the technetium oxidation state in the [^{99m}Tc]tricine complex is +5 (15–17). However, the oxidation state might change when the HYNIC group and phosphine coligand are bonded to the Tc center. Furthermore, the technetium oxidation state largely depends on how the HYNIC group binds to the Tc and how one counts the charge on the HYNIC ligand.

When the HYNICTide binds to the Tc, it likely occupies one site of the Tc coordination sphere by forming either a Tc-hydrazido or Tc-diazenido bond. Complexes containing Tc-hydrazido and Tc-diazenido bonds have been previously reported and characterized by X-ray crystallography (25–31). If one assumes that the coordination geometry around the Tc is distorted octahedral, the tricine coligand is expected to be tetradentate. Several possible explanations can be envisaged for the existence of two isomeric forms of these complexes, including the resolution of diastereomers resulting from the chiral center on the coordinated tricine and different geometric orientations of the diazenido ligand due to restricted

Figure 9. Plot of RCP fraction versus molar fraction.

rotation around the Tc=N and N=N bonds. Efforts are continuing to better understand the complex coordination chemistry of this unique ternary ligand system.

The electron-withdrawing sulfonato groups have profound impact on the donating capability of the phosphine coligands. To study their relative donating capability, we performed mixed ligand experiments by spiking a range of amounts of either TPPDS or TPPMS, respectively, into the TPPTS solution. Plotting (Figure 9) the ratio of the yield of the ternary complex of the added phosphine to the total yield of the two ternary complexes $[RCP2/(RCP1 + RCP2)]$ versus the mole fraction TPPDS/(TPPDS + TPPTS) should give a measure of their relative bonding affinity. For TPPDS, a slope of 1.12 indicates that TPPDS is 1.12 times more powerful than TPPTS in coordinating to the Tc. For TPPMS, plotting RCP3/(RCP1 + RCP3) versus TPPMS/(TPPMS + TPPTS) also gives a straight line with slope of 1.35, suggesting that TPPMS is 1.35 times more powerful than TPPTS. It is clear that as the number of electron-withdrawing sulfonato groups on the benzene rings decreases, the electron density on the phosphine donor atom increases; therefore, the σ -donating capability increases. The relative donating capability for three water soluble phosphine coligands falls in the order TPPMS > TPPDS > TPPTS, as expected.

CONCLUSION

A hydrazinonicotinamide-functionalized cyclic GPIIb/IIIa receptor antagonist [HYNICTide: cyclo(D-Val-NMe-Arg-Gly-Asp-Mamb(5-(6-(6-hydrazinonicotinamido)hexanamide)))] was labeled with ^{99m}Tc using tricine and a water soluble phosphine (TPPTS, TPPDS, or TPPMS) as coligand. The combination of HYNICTide, tricine, and phosphine produces a new ternary ligand system which forms technetium complexes, $[^{99m}\text{Tc}(\text{HYNICTide})(\text{L})(\text{tricine})]$ (**1**, L = TPPTS; **2**, L = TPPDS; **3**, L = TPPMS), with high specific activity ($\geq 20\,000$ Ci/mmol) and high stability. Using two reversed phase radio-HPLC methods, we found that complexes **1–3** exist as equal mixtures of two isomeric forms, both of which contain the radio-labeled HYNICTide and have the capability to bind to platelets as demonstrated in a platelet-binding assay (for complex **1**). The composition of these complexes was determined to be 1:1:1:1 (Tc:HYNICTide:L:tricine) through a series of mixed ligand experiments and is maintained over a wide range of relative ligand ratios. Using the mixed ligand experiment, we also demonstrated that the

binding capability of the aryl phosphine ligand, L, to the Tc increases as the number of sulfonato groups decreases. The lipophilicity of these technetium complexes can be systematically varied by the choice of the phosphine coligand. The tricine coligand can also be replaced by other potentially tetradentate aminocarboxylates such as bicine, dicine (15), and EDDA. However, tricine remains the best with respect to the labeling efficiency. Using the combination of an aminocarboxylate and a phosphine as coligands, HYNIC-derivatized peptides or other biologically active small molecules can be labeled with ^{99m}Tc in high specific activity and high stability for potential use as radiopharmaceuticals.

ACKNOWLEDGMENT

Acknowledgement is made to Dr. J. L. Glajch and M. J. Poirier for the use of their radio-HPLC method (method 1), to Dr. M. J. Abrams and Dr. J. D. A hydrazinonicotinamide-functionalized cyclic glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonist [cyclo(D-Val-NMeArg-Gly-Asp-Mamb(5-(6-(6-hydrazinonicotinamido)hexanamide))) (HYNICTide)] was labeled with ^{99m}Tc using tricine and a water soluble phosphine [trisodium triphenylphosphine-3,3',3''-trisulfonate (TPPTS); disodium triphenylphosphine-3,3'-disulfonate (TPPDS); or sodium triphenylphosphine-3-monosulfonate (TPPMS)] as coligands. Three complexes, [^{99m}Tc (HYNICTide)(L)(tricine)] (**1**, **L** = TPPTS; **2**, **L** = TPPDS; **3**, **L** = TPPMS), were evaluated in the canine arteriovenous shunt (AV shunt) model and canine deep vein thrombosis imaging (DVT) model. All three agents were adequately incorporated into the arterial and venous portions of the growing thrombus (7.8–9.9 and 0.2–3.7% ID/g, respectively) in the canine AV shunt model. In the canine DVT model all three complexes had thrombus uptake that far exceeded the negative control, [^{99m}Tc]albumin. The findings indicate similar incorporation into a venous thrombus (% ID/g = 2.86 ± 0.4 , 3.4 ± 0.9 , and 3.38 ± 1.1 for complexes **1**, **2**, and **3**, respectively) and similar blood clearance with a $t_{1/2}$ of approximately 90 min. Gamma camera scintigraphy allowed visualization of deep vein thrombosis in as little as 15 min with the thrombus/muscle ratios being 3.8 ± 0.8 , 2.8 ± 0.4 , and 3.0 ± 0.8 for complexes **1**, **2**, and **3**, respectively. The visualization of the thrombus improved over time, and the thrombus/muscle ratios were 9.7 ± 1.9 , 13.8 ± 3.6 , and 9.4 ± 2 for complexes **1**, **2**, and **3**, respectively, at 120 min postinjection. The administration of complexes **1–3** did not alter platelet function, hemodynamics, or the coagulation cascade. Furthermore, complexes **1–3** did not significantly differ in their uptake into the growing thrombus, blood clearance, and target to background ratios. Therefore, all three complexes have the capability to detect rapidly growing venous and arterial thrombi.

INTRODUCTION

Our thrombus research program has focused on development of a thrombus imaging agent by labeling a platelet glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonist with ^{99m}Tc (*1–7*). In our previous paper (*1*), we described the ^{99m}Tc -labeling of a platelet GPIIb/IIIa receptor antagonist [[cyclo(D-Val-NMeArg-Gly-Asp-Mamb(5-(6-(6-hydrazinonicotinamido)hexanamide))) (HYNICTide)] using tricine and water soluble phosphines [trisodium triphenylphosphine-3,3',3''-trisulfonate (TPPTS); disodium triphenylphosphine-3,3'-disulfonate (TPPDS); sodium triphenylphosphine-3-monosulfonate (TPPMS)] as coligands. The combination of HYNICTide with tricine and phosphine produces a new and versatile ternary ligand system, which forms technetium complexes, [^{99m}Tc (HYNICTide)(L)(tricine)] (Figure 1, **1**, **L** = TPPTS; **2**, **L** = TPPDS; **3**, **L** = TPPMS), in high yield and high specific activity ($\geq 20\,000$ Ci/mmol). It was found that these complexes are formed as equal mixtures of two isomeric forms and are stable for ≥ 6 h in both the reaction mixture and dilute solutions. As a continuation of that study, we now present the biological evaluation of complexes **1–3** in the canine arteriovenous (AV) shunt and deep vein thrombosis (DVT) models.

Deep vein thrombus is the result of a hypercoagulable state coupled with a period of stasis occurring in a low-shear environment. The end result is the formation of a fibrin-rich thrombus which also contains some platelets and erythrocytes. In contrast, an arterial thrombus is the result of the rupture of an atherosclerotic plaque occurring under high-shear conditions, resulting in the formation of a platelet-rich thrombus (*8*). The GPIIb/IIIa complex is expressed on the membrane surface of activated platelets and plays an integral role in platelet aggregation and thrombus formation (*9*). Initial events in thrombus formation frequently entail the activation of platelets by thrombogenic conditions and their subsequent aggregation (*10*). Since the GPIIb/IIIa complex is expressed only on the membrane surface of activated platelets, the GPIIb/IIIa receptor makes an excellent target for the development of a thrombus imaging agent. Existing diagnostic modalities are inadequate to diagnose and determine the morphology of the evolving thrombus (*11*). Thus, the development of agents that will not only detect the location but, in addition, determine the age of the thrombi is a critical unmet need in nuclear diagnostic medicine.

EXPERIMENTAL PROCEDURES

Materials. TPPTS was purchased from Aldrich Chemical Co. TPPDS was prepared and purified according to the procedure described in the literature (*6*). TPPMS was purchased from TCI America, Portland, OR, and was used as received. $\text{Na}^{99m}\text{TcO}_4$ was obtained from a com-

Figure 1. HYNICTide complexes and three water soluble phosphine coligands.

mercial DuPont Merck $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator, N. Billerica, MA. $^{99\text{m}}\text{Tc}$ [albumin, canine ^{125}I]fibrinogen, and ^{111}In -oxine kits were purchased from Medi-Physics Inc., Arlington Heights, IL, and were used as directed. Deionized water was obtained from a Millipore MilliQ Water System and was of $>18\text{ M}\Omega$ quality.

Methods. The radio-HPLC method used a Hewlett-Packard Model 1050 instrument, a reversed phase Vydac C_{18} column ($4.6\text{ mm} \times 250\text{ mm}$, 300 \AA pore size) at a flow rate of 1 mL/min with the mobile phase starting from 100% A (0.01 M phosphate buffer, pH 6) to 30% B (acetonitrile) at 15 min and 75% B at 25 min . The ITLC method used Gelman Sciences silica gel strips and a $1:1$ mixture of acetone and saline as eluant.

The $^{99\text{m}}\text{Tc}$ labeling of the cyclic GPIIb/IIIa HYNICTide was achieved following the previously described procedure (1) with some modification. To a clean 10 mL vial were added 0.5 mL of tricine solution (80 mg/mL in H_2O , pH 5), the HYNICTide solution ($50\text{ }\mu\text{g/mL}$ in H_2O ; 0.1 mL for DVT model and 0.2 mL for AV shunt model), 0.2 mL of phosphine coligand solution (5 mg/mL in H_2O), 19 mCi of pertechnetate in 0.5 mL of saline, and $25\text{ }\mu\text{L}$ of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (1 mg/mL in 0.1 N HCl). The pH was adjusted to $4-5$. The reaction mixture was heated in a water bath at $80\text{ }^\circ\text{C}$ for 30 min and was then analyzed by radio-HPLC and ITLC. The radiochemical purity (RCP) for complexes **1-3** was $\geq 90\%$ with no detectable $^{99\text{m}}\text{Tc}$ colloid. Doses for biological evaluation were prepared by dilution with 2.0% tricine solution in saline to the required concentration: 0.3 mCi/mL for the AV shunt model and 1.5 mCi/mL for the DVT. The diluted solutions were reanalyzed by radio-HPLC before the animal study.

Canine Arteriovenous Shunt Methodology. Adult beagle dogs of either sex ($9-13\text{ kg}$) were anesthetized with pentobarbital sodium (35 mg/kg iv) and ventilated with room air via an endotracheal tube (12 strokes/min , 25 mL/kg). For arterial pressure determination, the left carotid artery was cannulated with a saline-filled polyethylene catheter (PE-240) and connected to a Statham pressure transducer (Model P23ID, Gould Co., Oxnard, CA). Mean arterial blood pressure was determined via damping the pulsatile pressure signal. Heart rate was monitored using a cardiometer (Grass Instrument Inc., Quincy, MA) triggered from a lead II electrocardiogram generated by limb leads. A jugular vein was cannulated (PE-240) for drug administration. Both femoral arteries and femoral veins were cannulated with silicon-treated (Sigmacote, Sigma Chemical Co., St. Louis, MO), saline-filled polyethylene tubing (PE-200) and connected with a 5 cm section of silicon-treated tubing (PE-240) to form extra corporeal arteriovenous (AV) shunts. Shunt patency was monitored using a Doppler flow system (Model VF-1, Crystal Biotech Inc., Hopkinton, MA) and flow probe ($2-3.5\text{ mm}$, Crystal Biotech) placed proximal to the locus of the shunt. All parameters were monitored continuously on a Model 7D polygraph recorder (Grass Instrument Inc., Quincy, MA) at a paper speed of 10 mm/min or 10 mm/s .

On completion of a 15 min postsurgical stabilization period, an occlusive thrombus was formed by the introduction of a thrombogenic surface ($4-0$ braided silk thread, 5 cm in length, Ethicon Inc., Somerville, NJ) into one shunt with the other serving as a control. A 1 h shunt period was employed with the test agent ($\sim 3.0\text{ mCi}$ in 10 mL) administered as an infusion over 5 min , beginning 5 min before insertion of the first thrombogenic surface. The thrombus formed was comprised of a platelet-rich component on the thrombogenic surface and a fibrin-rich tail. At the end of the 1 h shunt period, the silk was carefully removed, the portions separated and weighed. The percent incorporation was determined via well counting (LKB Model 1282, Wallac Inc., Gaithersburg, MD). Thrombus weight was calculated by subtracting the weight of the silk prior to placement from the total weight of the silk on removal from the shunt. Arterial blood was withdrawn prior to infusion and every 30 min thereafter for determination of blood clearance, whole blood collagen-induced platelet aggregation, prothrombin time (PT), activated partial thromboplastin time (APTT), and platelet count. Template bleeding time was also performed prior to infusion and every 30 min thereafter.

^{111}In Platelets Preparation. The isolation and ^{111}In -labeling of platelets were performed according to the literature method (12) with some modification. Canine arterial blood (40 mL) was withdrawn in 2.5% ACD solution (2.5 g of trisodium citrate, 1.4 g of citric acid, and 2.0 g of dextrose in 100 mL of H_2O , pH 4.5). An additional 20 mL of blood was drawn in 3.8% sodium citrate solution, which serves as control. The samples were centrifuged at 1400 rpm for 15 min to form platelet-rich plasma (PRP) and platelet-poor plasma (PPP). The ACD-PRP was pelleted (2800 rpm for 15 min) and washed twice with ACD. The platelet pellet was resuspended in ACD (2 mL), and $60-100\text{ }\mu\text{Ci}$ of ^{111}In -oxine was added. The suspension was incubated at $37\text{ }^\circ\text{C}$ for 5 min , followed by the addition of PPP (5 mL). The suspension was centrifuged at 2800 rpm for 10 min . The supernatant and platelet pellet were counted to assess labeling efficiency ($>80\%$ in all cases). The platelet pellet was resuspended in PPP (5 mL) and platelet viability determined by comparing collagen-induced platelet ag-

Figure 2. Thrombus uptakes for [¹²⁵I]fibrinogen, [¹¹¹In]platelets, [^{99m}Tc]albumin, and complexes 1–3 under both venous and arterial conditions in the canine AV shunt model. All values are expressed as the mean \pm SEM; $N = 10$ for [¹¹¹In]platelets and [¹²⁵I]fibrinogen (except for venous conditions, where $N = 5$), $N = 4$ for albumin, $N = 6$ for complex 1, $N = 3$ for complex 2, and $N = 2$ for complex 3.

gregation using nonlabeled and ¹¹¹In-labeled platelets. Only those [¹¹¹In]platelet preparations that were within 25% of control were injected into the animal.

Canine Deep Vein Thrombosis Methodology. This model incorporates the triad of events (hypercoagulable state, period of stasis, low-shear environment) essential for the formation of a venous fibrin-rich actively growing thrombus. Adult beagle dogs of either sex (9–13 kg) were anesthetized with pentobarbital sodium (35 mg/kg iv) and ventilated with room air via an endotracheal tube (12 strokes/min, 25 mL/kg). For arterial pressure determination, the right femoral artery was cannulated with a saline-filled polyethylene catheter connected to a pressure transducer (Model P231D, Gould Co.). Heart rate was monitored using a cardiometer (Grass Instrument Inc.) triggered from a lead II electrocardiogram generated by limb leads. The right femoral vein was cannulated for drug administration. For the induction of a venous thrombus, a 5 cm segment of both jugular veins was isolated and circumscribed with silk suture. A balloon catheter (3–4 F, Baxter Co., McGraw Park, IL) was advanced from the facial vein into the jugular vein. A microthermister probe (Physitemp Co., Clifton, NJ) was placed on the vessel, which serves as an indirect measure of venous flow. A period of stasis and hypercoagulability was induced by inflating the balloon and the local administration of 5 units of thrombin (American Diagnostica, Greenwich, CT) into the occluded segment. Fifteen minutes later, the balloon was deflated and flow reestablished as verified by the microthermister probe.

The test agent was administered over 5 min beginning at reflux. Serial images were acquired using a gamma camera (Digital Dyna Camera, Picker International, Cleveland, OH) every 5 min for 2 h and region of interest and target to background ratios calculated. Arterial blood was withdrawn prior to administration and every 30 min thereafter for determination of blood clearance, hematology, platelet function, and coagulation status. At the end of the protocol the animal was euthanized with an overdose of pentobarbital and the vessel excised. The thrombus was removed and weighed, and the amount of

incorporation was determined via a gamma well counter (LKB 1282, Wallac Inc., Gaithersburg, MD).

Hematologic Studies. Platelet, WBC, and RBC counts and hematocrit determinations were performed on whole blood collected in 2 mg/mL disodium EDTA using a Sysmex K1000 (TEA Medical Electronics Co., Los Alamitos, CA). Template bleeding time was assessed via an incision in the lower lip (Surgicutt, Baxter Co.) and the time to formation of a clot monitored. Whole blood platelet aggregation was measured using a lumiaggregometer (Chrono-Log Co., Havertown, PA) by recording the change in impedance (platelet aggregation). Blood samples were collected in 10 mM sodium citrate and diluted 50% with saline supplemented with 0.5 mM Ca. Aggregation was induced with collagen (5 μ g/mL, Chrono-Log Co.), and the changes in impedance were recorded over 6 min. APTT and PT were monitored using a microsample coagulation analyzer (MCA-210, BIO/DATA Co., Horsham, PA).

Data Analysis. All values are expressed as the mean \pm SEM. In the DVT studies the target (thrombus) uptake was calculated by drawing a 4 \times 4 pixel area in the region of interest and determining the average intensity. Background values were determined in a similar manner. Blood background was calculated using the jugular vein just distal to the locus of the thrombus. Statistical analysis consisted of a one-way analysis of variance and, when appropriate, Student's paired *t*-test, two-tailed probability for assessing differences within treatment and a Newman-Keuls test for assessing differences between means of treatment groups. Differences were considered significant at $P \leq 0.05$.

RESULTS AND DISCUSSION

In this study, we used a canine AV shunt model and a canine DVT imaging model to evaluate three platelet GPIIb/IIIa antagonists, [^{99m}Tc(HYNICtide)(L)(tricine)] (1, L = TPPTS; 2, L = TPPDS; 3, L = TPPMS), for their potential use in the detection of rapidly growing arterial and venous thrombi. The thrombus formed in the AV shunt model was comprised of a platelet-rich head

Figure 3. Blood clearance of $[^{125}\text{I}]$ fibrinogen, $[^{111}\text{In}]$ platelets, $[^{99\text{m}}\text{Tc}]$ albumin, and complexes 1–3, expressed as a percentage of the end of infusion value in the canine AV shunt model. All values are expressed as the mean \pm SEM; $N = 10$ for $[^{111}\text{In}]$ platelets and $[^{125}\text{I}]$ fibrinogen (except for venous conditions, where $N = 5$), $N = 4$ for $[^{99\text{m}}\text{Tc}]$ albumin, $N = 6$ for complex 1, $N = 3$ for complex 2, and $N = 2$ for complex 3.

(arterial conditions) and a fibrin-rich tail (venous conditions), which allowed the rapid assessment of an agent under both arterial and venous conditions. To validate this model, the amount of incorporation of $[^{111}\text{In}]$ platelets (58 μCi), $[^{125}\text{I}]$ fibrinogen (106 μCi), and $[^{99\text{m}}\text{Tc}]$ albumin (153 μCi) was assessed via well counting. $[^{111}\text{In}]$ platelets and $[^{125}\text{I}]$ fibrinogen were adequately incorporated into the growing thrombus with $[^{111}\text{In}]$ platelets favoring the platelet-rich head ($5.63 \pm 0.6\%$ ID/g) with lesser amounts of incorporation observed in the fibrin-rich tail ($0.17 \pm 0.02\%$ ID/g). Similar amounts of $[^{125}\text{I}]$ fibrinogen were incorporated under both the arterial and venous conditions (0.11 ± 0.02 vs $0.07 \pm 0.02\%$ ID/g, respectively), while little incorporation was observed with $[^{99\text{m}}\text{Tc}]$ albumin (arterial, $0.05 \pm 0.01\%$ ID/g; venous, $0.04 \pm 0.001\%$ ID/g) (Figure 2). The administration of $[^{111}\text{In}]$ platelets, $[^{125}\text{I}]$ fibrinogen, and $[^{99\text{m}}\text{Tc}]$ albumin did not alter any of the parameters studied (Table 1). Thus, the deposition on the thrombogenic surface mimics that of arterial conditions, i.e. high-shear, platelet-rich thrombus, and the platelet-poor tail mimics that of a venous thrombus, i.e. platelet-poor, low-shear environment.

Figure 4. Biodistribution of complexes 1–3. All values are expressed as the mean \pm SEM; $N = 6$ for complex 1, $N = 3$ for complex 2, and $N = 2$ for complex 3.

Complexes 1–3 were assessed in the canine AV shunt model, and all show incorporation into a growing thrombus in both the platelet-rich arterial portion and the venous platelet-poor tail (Figure 2). The greatest uptake of complexes 1–3 was observed under arterial conditions, which reflects the platelet-rich environment. Similar uptakes between complexes 1, 2, and 3 were seen under arterial conditions (arterial range, 7.78–9.93% ID/g), and all have significantly greater uptake than $[^{125}\text{I}]$ fibrinogen and $[^{99\text{m}}\text{Tc}]$ albumin. Complex 1 also exhibited significantly greater uptake under arterial conditions than $[^{111}\text{In}]$ platelets ($P \leq 0.05$). Venous conditions, as expected, demonstrated less uptake in the platelet-poor tail, with all three complexes having greater uptake than $[^{125}\text{I}]$ fibrinogen and $[^{99\text{m}}\text{Tc}]$ albumin ($P \leq 0.05$). Complex 3 appeared to have greater uptake; however, this apparent difference was not statistically significant due to interanimal variability. The uptake of complex 3 ranged from 1.2 to 6.2% ID/g. Complexes 1–3 share similar blood clearance with a half-life of about 90 min (Figure 3). The biodistribution data demonstrated that complexes 1 and 2 are preferentially renally excreted, while complex 3 was preferentially excreted via the hepatobiliary route (Figure 4). $[^{99\text{m}}\text{Tc}]$ albumin was renally cleared, while $[^{125}\text{I}]$ fibrinogen demonstrated a mixed hepatobil-

Table 1. Summary of the Hematological and Hemodynamic Effects of $[^{99\text{m}}\text{Tc}]$ Albumin and Complexes 1–3 at 1 mCi/kg iv in the Canine DVT Model and $[^{111}\text{In}]$ Platelets/ $[^{125}\text{I}]$ Fibrinogen at 150 $\mu\text{Ci/kg}$ iv in the Canine AV Shunt Model

^a All values are expressed as the mean \pm SEM; $N = 10$ for $[^{111}\text{In}]$ platelets and $[^{125}\text{I}]$ fibrinogen, $N = 4$ for $[^{99\text{m}}\text{Tc}]$ albumin and complex 1, $N = 3$ for complex 2, and $N = 2$ for complex 3.

Figure 5. Canine DVT thrombus uptake at 120 min (left) and thrombus/blood ratio (right) for [¹²⁵I]fibrinogen, [¹¹¹In]platelets, [^{99m}Tc]albumin, and complexes 1–3 under both venous and arterial conditions. The thrombus uptake and target/background ratios for all three complexes were significantly greater ($P < 0.05$) than for [^{99m}Tc]albumin. There were no significant differences between complexes 1, 2, and 3 ($P < 0.5$). Target to background ratios were calculated on the basis of an average 4×4 pixel area in the region of interest. All values are expressed as the mean \pm SEM; $N = 6$ for [^{99m}Tc]albumin, $N = 5$ for complex 1, $N = 4$ for complex 2, and $N = 4$ for complex 3.

Figure 6. Representative DVT images of complexes 1–3 at 15, 60, and 120 min postinfusion. The bar to the right of the images indicates the scale from 0 (white) to 506 (greatest/black). The images have not been filtered. Arrows indicate presence of thrombus in jugular veins.

lary/renal excretion pattern. In contrast, [¹¹¹In]platelets were sequestered in the spleen.

Complexes 1–3 and [^{99m}Tc]albumin have been evaluated in the canine deep vein thrombosis imaging model (DVT). The sample data from the LKB gamma well counter show no significant difference between the three complexes in respect to % ID/g, although all three are significantly greater than [^{99m}Tc]albumin ($P \leq 0.05$, Figure 5). All three complexes demonstrated similar rates of clearance from the circulating blood.

Representative unfiltered images of the three complexes in the DVT imaging model at 15, 60, and 120 min postinfusion are shown in Figure 6. The scale to the right of the images represents a fixed scale that increases to the hottest or most dense pixel represented by 506 (black). The region of interest (ROI) data acquired from the images are shown in Figure 6 as target to background ratios. Complexes 1, 2, and 3 were rapidly incorporated into the growing thrombus, which can be easily visualized by 15 min with the thrombus/muscle ratios of 3.8 ± 0.8 ,

2.8 ± 0.4 , and 3.0 ± 0.8 , respectively. Increased uptake over time was also observed with exceptional imaging at 60 min. All three complexes are significantly greater than [^{99m}Tc]albumin with respect to ROI data ($P \leq 0.05$). Hematologic and hemodynamic data were unaffected by the administration of the complexes and remained in normal range throughout the DVT study (Table 1). The present study is in agreement with the work of Oster et al. (14), who demonstrated that the 7E3 antibody, directed against the platelet GPIIb/IIIa receptor, was capable of detecting both arterial and venous thrombi. More recently, a series of disintegrins derived from snake venom demonstrated limited utility in detecting venous thrombi (15). In addition, a ^{99m}Tc -labeled peptide (P280) that targets the platelet GPIIb/IIIa site has been shown to detect growing venous thrombi in man (16). Thus, on the basis of these data the targeting of the platelet GPIIb/IIIa receptor is a viable approach for detecting thromboembolic events throughout the body.

In summary, complexes 1–3 show remarkably similar incorporation into a growing thrombus and blood clearance with a $t_{1/2}$ of 90 min. None of the compounds affected hemodynamics or hematological values, which was consistent with the subtherapeutic levels administered. In addition, complexes 1–3 exhibit similar abilities to detect a growing thrombus within 15 min postinjection. Further, complexes 1–3 did not significantly differ in their uptake into the growing thrombus, blood clearance, and target to background ratio. Therefore, it is concluded that all three agents are able to detect rapidly growing venous and arterial thrombi.

Synthesis of Cobalamin Dimers Using Isophthalate Cross-Linking of Corrin Ring Carboxylates and Evaluation of Their Binding to Transcobalamin II

Pradip M. Pathare,[†] D. Scott Wilbur,^{*,†} Donald K. Hamlin,[†] Shannon Heusser,[†] Edward V. Quadros,[‡] Patricia McLoughlin,[‡] and A. Charles Morgan^{†,§}

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195, VA Medical Center—SUNY Health Science Center, Brooklyn, New York 11209, and Receptagen Corporation, Edmonds, Washington 98020. Received August 21, 1996[®]

Several cobalamin (Cbl) dimers have been prepared for evaluation as potential antiproliferative agents in the treatment of AIDS-related lymphoma. The Cbl dimers were synthesized by cross-linking Cbl carboxylates, produced by acid hydrolysis of the *b*-, *d*-, and *e*-propionamide side chains of cyanocobalamin (CN-Cbl), through an isophthalate molecule. Linking molecules were used between the Cbl carboxylates and the isophthalate moiety. The linkers were incorporated to provide a distance between the two Cbl molecules such that the dimeric Cbls might bind two molecules of transcobalamin II (TCII), the Cbl transport protein in plasma. Initially, the linking moiety used was 1,12-diaminododecane, but the resulting dimers had low aqueous solubility. To improve the solubility of the dimers, 4,7,10-trioxa-1,13-tridecanediamine was employed as the linking moiety. This improved the water solubility of the dimers considerably, while retaining the distance between the Cbl molecules at 41–42 Å (fully extended). To introduce additional substitution on Cbl dimers, 5-aminoisophthalic acid was used as the cross-linking reagent. *p*-Iodobenzoyl and *p*-(tri-*n*-butylstannyl)benzoyl conjugates of 5-aminoisophthalate were synthesized and used to prepare Cbl dimers. The stannylbenzoyl-conjugated Cbl dimers were prepared as precursors to be used in radioiodination reactions, and the iodobenzoyl-conjugated Cbl dimers were prepared as HPLC standards for the radioiodinated product. Attempts to iodinate/radioiodinate the stannylbenzoyl Cbl dimers were unsuccessful. Although an explanation for this is not readily apparent, the failure to react may be due to the lipophilicity of the linker used and the steric environment of the two Cbl moieties. A biotinylated derivative of 5-aminoisophthalate was also synthesized and used to prepare biotinylated-Cbl dimers. In a competitive rhTCII binding assay with [⁵⁷Co]CN-Cbl, Cbl dimers containing the lipophilic diaminododecane linking moiety had decreased binding avidities compared to those of Cbl monomers substituted at the same corrin ring carboxylate. However, Cbl dimers containing the water-solubilizing trioxadecanamine linker appeared to have avidities similar to those of the Cbl monomers.

INTRODUCTION

Cobalamins (Cbls¹) are cofactors in enzymatic pathways associated with DNA and protein synthesis in cells (1, 2). Actively dividing cells, such as hematopoietic cells in bone marrow, avidly take up Cbls. Importantly, it has been noted that Cbls play a significant metabolic role in human leukemia cells (3, 4). These facts have led us to investigate the application of Cbl depletion to the therapy of rapidly dividing and proliferating cells found in

leukemias and lymphomas. Evidence for such an antiproliferative therapeutic approach is not without precedent as previous investigations have shown that therapeutic responses could be obtained in patients when they were isolated in an atmosphere containing the anesthetic agent nitrous oxide (N₂O) (5, 6). N₂O administration causes an oxidative inactivation of Cbl, depleting cells in the body of metabolically active forms of Cbl. The use of N₂O, while effective for inactivation of Cbl, presents several problems for its general application to the therapy of leukemias or lymphomas. One major problem is that patients are required to stay in an atmosphere of N₂O for extended periods of time, which results in extended hospitalization and the need for constant patient monitoring. Additionally, serious neurological side effects have been observed in some patients undergoing this treatment. Further, the nonspecific nature of the oxidation of Cbl with N₂O can have effects on many different biological systems and may lead to a number of toxicities. Thus, an alternative approach for depletion of cellular Cbl was conceived.

We have begun to investigate a novel approach to depletion of cellular Cbl which is directed at developing a pharmaceutical capable of blocking entry of endogenous Cbls into cells. Since the entry of Cbls into cells at physiological concentrations appears to be completely dependent on a receptor-mediated process (7), we are investigating synthetic Cbl derivatives designed to in-

[®] Abstract published in *Advance ACS Abstracts*, February 15, 1997.

¹ Abbreviations: Cbl(s), cobalamin(s); CN-Cbl, cyanocobalamin; DCC, dicyclohexylcarbodiimide; DMF, dimethylformamide; DMSO, dimethyl sulfoxide; EDC, 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide; 2HEDS, 2-hydroxyethyl sulfide; HSA, human serum albumin; LC, liquid chromatography; 3NBA, 3-nitrobenzyl alcohol; NCS, *N*-chlorosuccinimide; NHS, *N*-hydroxysuccinimide; PBS, phosphate-buffered saline; rt, room temperature; TCII, transcobalamin II; rhTCII, recombinant human transcobalamin II; TFP, tetrafluorophenyl; TFP-OH, tetrafluorophenol; TFP-OTFA, tetrafluorophenyl trifluoroacetate.

terfere with the receptor-mediated cellular uptake of endogenous Cbls. It is known that cellular uptake of Cbls is a complex and highly regulated process which involves (1) transport of Cbl in plasma via a high-affinity serum Cbl binding protein, transcobalamin II (TCII) (8); (2) cell surface binding of the Cbl/TCII complex with a glycoprotein receptor (9); (3) internalization of the Cbl/TCII/receptor complex; and (4) release of the Cbl to the cytoplasm. Importantly, it has been shown in leukemia cells (e.g. L1210 and K562 cell lines) that the Cbl/TCII cell surface receptor density, which is directly related to Cbl uptake, is up-regulated during proliferation and down-regulated during quiescence (10). Although the process of receptor-mediated uptake and delivery of Cbls to cytoplasm is not fully understood, it has been shown that the lysosomotropic agent chloroquine and the monocarboxylate proton ionophore monensin can drastically decrease the Cbl/TCII surface receptor concentration in K562 leukemia cells (10). The lack of information available on the effect of alterations in the Cbl molecule on receptor trafficking and release of Cbl to cytoplasm makes it impossible to have a rational design of Cbl derivatives. Therefore, our initial investigations have involved synthesizing a number of Cbl derivatives containing a variety of appended groups for evaluation in cellular proliferation assays. To focus our synthetic efforts somewhat, we reasoned that Cbl derivatives containing appended highly lipophilic groups (e.g. fatty acids), highly ionic groups (e.g. alkyl sulfonates), or lysosomotropic agents (e.g. polyamines) (11) might result in retention of the Cbl, and possibly the retention of TCII/cell surface receptor, in endosomes and/or lysosomes.

When considering possible Cbl derivatives for synthesis, we became intrigued by derivatives that contain two or more Cbl moieties on the same molecule. Of the many derivatives that might be prepared, it appeared that binding with more than one TCII molecule had a higher potential for altering the receptor recycling process. Following this logic, we became interested in dimeric Cbl derivatives as they presented less of a synthetic challenge than molecules with multiple Cbl moieties. Since our approach was to utilize the Cbl/TCII receptor-mediated cell internalization process, it was apparent that any synthetic Cbl derivative prepared must bind with the plasma protein TCII as effectively as endogenous Cbl. Previous studies by this group (12, 13) and several other groups (14–17) have shown that conjugation of chemical moieties on the corrin ring side chains provides a stable attachment to the Cbl moiety which, depending on the location of attachment, has a varying effect on the binding with TCII. That variability of binding has been found to range from 3 orders of magnitude decreased binding relative to cyanocobalamin (CN-Cbl), **1**, for conjugates at the *c*-acetamide side chain, to nearly equivalent binding to TCII for the *e*-propionamide side chain conjugates (12). Thus, cobalamin dimers that were linked through corrin ring attachments were targeted. As with other Cbl derivatives, we felt that the cobalamin dimers should be designed such that it was possible to append functional groups that could change the physical nature (e.g. lipophilicity and ionic nature), or add lysosomotropic properties, to the dimers, so a trifunctional cross-linking moiety was included in the design. Further, it seemed important to design the Cbl dimers in a manner that separated the Cbl moieties by a significant distance such that binding with two TCII molecules might be achieved.

Reported herein are the synthesis and preliminary binding studies of 14 Cbl dimers. The dimers prepared employ isophthalic acid or aminoisophthalic acid moi-

eties to cross-link corrin ring Cbl-carboxylates (*b*-, *d*-, or *e*-isomers). Cross-linking was accomplished by incorporating linker molecules, containing two terminal amino groups, between the Cbl carboxylates and the carboxylates of isophthalic acid. As part of the investigation, Cbl dimers containing arylstannanes were prepared such that radioiodine might be incorporated through an iododestannylation reaction (18, 19). Biotinylated Cbl dimers were also prepared in the investigation. Binding of 11 Cbl dimers with recombinant human TCII (rhTCII), relative to [⁵⁷Co]CN-Cbl, was measured in a competitive binding assay.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were of analytical grade or better and were used without further purification. Cyanocobalamin (CN-Cbl; vitamin B₁₂) was obtained from Sigma Chemical Co. (St. Louis, MO). *N*-Hydroxysuccinimide and isophthaloyl dichloride were purchased from Lancaster Synthesis Inc. (Windham, NH). All other reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Ion exchange chromatography was conducted with 200–400 mesh strongly basic anion, 2% cross-linked Dowex 1 chloride (Aldrich). Amberlite XAD-2 nonionic polymeric adsorbent and octadecyl functionalized silica gel for column chromatography were also obtained from Aldrich. Bio-Sil NH₂ (aminopropyl bonded silica) (40–63 μm) for column packing was purchased from Bio-Rad Laboratories (Hercules, CA). Phosphate-buffered saline (PBS) was prepared as a solution containing 8.1 mM Na₂PO₄, 1.2 mM KH₂PO₄, and 138 mM NaCl, pH 7.4. Human serum albumin (HSA) was obtained from Miles, Inc. (Elkhart, IN).

Molecular modeling of Cbl dimers was conducted to estimate the distance between the Cbl moieties. The modeling was conducted with ChemDraw Plus/Chem3D Pro software (CambridgeSoft Corp., Burlington, MA) on a Macintosh 8100/80 computer. Structures of the Cbl cross-linking reagents were drawn (fully extended) and minimized for structural error and energy, and interatomic distances were obtained directly from the computer program.

Spectroscopic Data. ¹H NMR spectra were obtained on either a Bruker AC-300 (300 MHz) or a Bruker AC-500 (500 MHz) instrument. The chemical shifts are expressed as parts per million using tetramethylsilane as an internal standard (δ = 0.0 ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. UV data were obtained on a Perkin-Elmer Lambda 2 UV–vis spectrophotometer or a Shimadzu UV 160U spectrophotometer. UV absorbances were obtained as previously described (12). Mass spectral data were obtained on a VG 70SEQ mass spectrometer with 11250J data system. Fast atom bombardment (FAB⁺) mass spectral data were obtained at 8 kV using a matrix of 3-nitrobenzyl alcohol (3NBA) or a matrix of 90% thioglycerol, 9% DMSO, and 1% TFA (DMIX). We were unable to find conditions for obtaining mass spectral data with the stannylbenzoyl-Cbl dimers **27–29**.

Identity of the Cbl derivatives was established by mass spectral and NMR data (see Supporting Information). Elemental analyses were not obtained for the Cbl dimers due to the difficulties encountered previously with monomeric Cbls (12, 13). Purity of the Cbl derivatives was established by HPLC analysis (see Supporting Information).

Analytical Chromatography. HPLC separations of compounds were obtained on a Hewlett-Packard quater-

nary 1050 gradient pumping system with a variable wavelength UV detector (360 nm). Analysis of the HPLC data was conducted on Hewlett-Packard HPLC Chemstation software. All reactions were monitored by HPLC.

Separations of the CN-Cbl, **1**, and Cbl derivatives **2–10** were conducted on an aminopropyl-silica column at a flow rate of 1 mL/min. The HPLC separations of the precursor compounds **1–7** were conducted on a 5 μ m, 4.6 mm \times 250 mm aminopropyl column (Rainin microsorb-MV amino column) eluting with 58 mM pyridine acetate, pH 4.4, in H₂O/THF (96:4) solution (9). Retention times for the Cbls evaluated with this system were as follows: **1** = 2.7 min; **2** = 3.8 min; **3** = 4.4 min; **4** = 5.1 min; **5** = 2.2 min; **6** = 2.2 min; **7** = 2.2 min; **8** = 2.3 min; and **10** = 2.3 min.

HPLC separations for benzoylaminoisophthalate **11–14** were conducted on a Hewlett-Packard LiChrospher 100 RP-18 (5 μ m; 4.6 mm \times 125 mm) C₁₈ column using a gradient solvent system. Solvent A in the gradient was MeOH. Solvent B was H₂O. Starting from 70% A, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% A over the next 10 min, and 100% A was held for 5 min. The gradient was decreased in percentage of A to 70% over the next 5 min. Retention times under these conditions were as follows: **11** = 3 min (solvent front); **12** = 6.6 min; **13** = 14.8 min; and **14** = 21.9 min.

HPLC separations for aminocaproate–biotin derivatives **15–20** and for dimers **21–31** were conducted on a C₁₈ reversed phase column employing a gradient. Solvent A in the gradient was methanol. Solvent B was aqueous 1% acetic acid. The gradient was begun at 40% A and was held at that composition for 2 min, and then the percentage of A was linearly increased to 100% over the next 10 min. The gradient was held at 100% A for 20 min. Retention times under these conditions for dimers were as follows: **15** = 6.1 min; **16** = 12.9 min; **17** = 7.2 min; **18** = 12.7 min; **19** = 8.4 min; **20** = 14.8 min; **21** = 12.6 min; **22** = 12.3 min; **23** = 13.0 min; **24** = 13.5 min; **25** = 13.8 min; **26** = 13.9 min; **27** = 8.6 min; **28** = 8.7 min; **29** = 9.0 min; **30** = 12.8 min; and **31** = 12.8 min.

For HPLC chromatography of dimers **32–34**, reversed phase chromatography was conducted at a flow rate of 1 mL/min. Solvent A in the gradient was methanol. Solvent B was H₂O. The gradient was held at the starting mixture of 70% A for 2 min, and then the percentage of A was linearly increased to 100% over the next 10 min. Retention times for the compounds examined under these conditions were as follows: **32** = 10.4 min; **33** = 10.8 min; and **34** = 10.8 min.

Preparative LC. A preparative LC system containing a Rainin Rabbit-plus peristaltic pump and a Dynamax Model FC-1 fraction collector was used to obtain pure samples of Cbl derivatives. Compounds were separated on either an aminopropyl silica column (1000 mm \times 25 mm; 40–63 μ m; Alltech) or a C₁₈ reversed phase column (25 mm \times 500 mm; octadecyl; Aldrich). Isolation of purified products was aided by evaluation of collected fractions from the preparative LC on an analytical HPLC column.

Preparation of Cyanocobalamin Monocarboxylic Acids **2, 3, or 4.** The *b*-, *d*-, and *e*-Cbl monocarboxylates (**2, 3, and 4**, respectively) were prepared as previously reported (12). Briefly, CN-Cbl was hydrolyzed in 0.1 N HCl over 10 days at room temperature. Following the hydrolysis reaction, the isomeric monocarboxylates were separated from starting CN-Cbl and from di- and triacids by ion exchange chromatography. Separation of the individual carboxylate isomers was accomplished by

preparative liquid chromatography on an aminopropyl-silica column (25 mm \times 1000 mm) at a flow rate of 0.15 mL/min.

General Procedure for Conjugation of **2, 3, or 4 with **1,12-Diaminododecane**; **Synthesis of **5, 6, and 7****.** The conjugation of the Cbl-monocarboxylates with diaminododecane was accomplished as previously described (12). Briefly, reaction of **2, 3, or 4** with diaminododecane, EDC, or NHS and in a 1:1 mixture of DMF and H₂O for 4 days yielded the desired compounds after purification by ion exchange chromatography.

Conjugation of Cyanocobalamin Monocarboxylic Acid with **4,7,10-Trioxa-1,13-Tridecanediamine; **Synthesis of **8 and 10****.** A 2.0 g (1.47 mmol) quantity of a CN-Cbl monocarboxylic acid, **2 or 4**, and 0.68 g (5.9 mmol) of NHS were dissolved in 100 mL of water. To that mixture was added 1.46 g (29 mmol) of NaCN, then 16 g (36 mmol) of 4,7,10-trioxa-1,13-tridecanediamine was added, and the pH was adjusted to 6 with 1 N HCl. To that solution was added 1.14 g (5.9 mmol) of EDC, and the pH of the solution was readjusted to 5.5. The reaction mixture was then stirred overnight in the dark at rt. In five intervals of 6–14 h, 0.68 g of NHS and 1.14 g of EDC were added to the solution, with the pH value readjusted to 5.5 each time. After a total reaction time of 4 days, the solution was evaporated to dryness. The residue was washed with 100 mL of acetone, and the solvent was decanted. The remaining solid was dissolved in 50 mL of H₂O and applied to an Amberlite XAD-2 (200 g; 4 cm \times 60 cm) column. The column was eluted with 1 L of water, and then the desired product was eluted with 500 mL of methanol. The methanol fractions were evaporated to dryness, and the residue was dissolved in 25 mL of water and was applied to a ion exchange column (100 g; 2.5 cm \times 60 cm; acetate form; 200–400 mesh). The final product was eluted using 250 mL of water, thereby leaving nonconverted Cbl-acid bound to the column, which was later eluted with 0.04 mol/L sodium acetate buffer, pH 4.7. The fractions containing the final product were evaporated to dryness and then washed with acetone and filtered. The solid obtained was recrystallized from aqueous acetone.

b-Isomer (**8**): yield, 2.0 g (87%); mp, 213–217 °C with decomposition; ¹H NMR (MeOH-*d*₄) δ 0.44 (s, 3H), 1.17 (d, 5H), 1.25 (d, 4H), 1.36 (d, 7H), 1.45 (s, 4H), 1.74 (m, 10H), 1.88 (s, 11H), 2.27 (d, 8H), 2.34 (m, 11H), 2.56 (m, 11H), 3.17 (t, 3H), 3.2 (m, 9H), 3.3 (m, 6H), 3.4 (m, 4H), 3.5 (s, 7H), 3.58 (s, 8H), 3.6 (m, 11H), 3.7 (m, 1H), 3.88 (m, 1H), 4.07 (m, 1H), 4.1 (m, 1H), 4.17 (m, 1H), 4.3 (m, 1H), 4.5 (m, 1H), 4.6 (m, 1H), 6.04 (d, 1H), 6.27 (s, 1H), 6.52 (s, 1H), 7.13 (d, 1H), 7.25 (s, 1H); MS (FAB⁺) mass calcd for C₇₃H₁₀₉N₁₅O₁₈CoP 1557, found 1558 (M + H)⁺; IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (H₂O) λ_{361} (ϵ = 17 500).

e-Isomer (**10**): yield, 1.5 g (65%); mp, 112–116 °C with decomposition; ¹H NMR (MeOH-*d*₄) δ 0.44 (s, 3H), 1.18 (s, 3H), 1.25 (d, 5H), 1.37 (d, 8H), 1.45 (s, 4H), 1.74 (m, 10H), 1.88 (s, 11H), 2.28 (d, 7H), 2.3 (m, 15H), 2.56 (d, 11H), 3.17 (t, 3H), 3.2 (t, 4H), 3.3 (m, 11H), 3.4 (m, 4H), 3.5 (s, 7H), 3.58 (d, 3H), 3.6 (m, 5H), 3.7 (m, 1H), 4.0 (m, 1H), 4.1 (d, 1H), 4.19 (m, 1H), 4.3 (m, 1H), 4.5 (d, 1H), 4.6 (m, 1H), 6.05 (d, 1H), 6.27 (s, 1H), 6.57 (s, 1H), 7.1 (d, 1H), 7.25 (s, 1H); MS (FAB⁺) mass calcd for C₇₃H₁₀₉N₁₅O₁₈CoP 1557, found 1558 (M + H)⁺; IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (H₂O) λ_{361} (ϵ = 12 800).

p-Iodobenzoyl-5-aminoisophthalic Acid, **12.** A 5.0 g (28 mmol) quantity of 5-amino-isophthalic acid, **11**, was dissolved in 30 mL of 1 N NaOH and placed in an ice/water bath. To the cold solution was added 7.5 g (28

mmol) of 4-iodobenzoyl chloride in 60 mL of acetonitrile, dropwise. The thick white precipitate was stirred for 10 min before the ice/water bath was removed, and the mixture was allowed to stir for an additional 10 min. The reaction mixture was adjusted to pH 4 with acetic acid and the resulting solid collected. This solid was dissolved in 30 mL of 1 N NaOH and washed with 2×50 mL of ether. The resulting aqueous solution was filtered and acidified to pH 4 with acetic acid. The white precipitate was collected and dried under high vacuum to yield 11.6 g (99+%) of **12**: mp >300 °C; ^1H NMR (DMSO- d_6) δ 7.84 (d, 2H, $J = 4.1$ Hz), 7.94 (d, 2H, $J = 4.2$ Hz), 8.27 (s, 1H), 8.51 (d, 2H, $J = 0.7$ Hz); IR (Nujol, cm^{-1}) 3570, 3300, 1645, 1580, 1525, 760; HRMS (FAB $^+$; DMIX) ($M + \text{H}$) $^+$ mass calcd for $\text{C}_{15}\text{H}_{11}\text{INO}_5$ 411.9682, found 411.9696.

p-Iodobenzoyl-5-aminoisophthalate DiTFP Ester, 13. A 5.0 g (12.2 mmol) quantity of **12** was suspended in 100 mL of anhydrous ethyl acetate. To this suspension was added 12.5 g (73 mmol) of 2,3,5,6-tetrafluorophenol (TFP-OH) followed by 5.0 g (24.2 mmol) of 1,3-dicyclohexylcarbodiimide (DCC). This suspension was stirred at rt for 3 days before filtering off the solid and washing with an additional 20 mL of ethyl acetate. The filtrate was evaporated to dryness. The resulting sticky white solid was suspended in 50 mL of acetonitrile, stirred for 30 min, and filtered to yield 3.75 g of **13** as a white solid (43%): mp 250–251 °C; ^1H NMR (DMSO- d_6) δ 7.81 (d, 2H, $J = 4.3$ Hz), 7.94 (d, 2H, $J = 4.2$ Hz), 8.04 (m, 2H), 8.57 (t, 1H, $J = 1.4$ Hz), 9.06 (d, 2H, $J = 0.7$ Hz); IR (Nujol, cm^{-1}) 3220, 3060, 1750, 1655, 1520, 1485, 1330, 1195, 1110, 1085, 955, 945; HRMS (FAB $^+$; 3NBA) ($M + \text{H}$) $^+$ mass calcd for $\text{C}_{27}\text{H}_{11}\text{F}_8\text{INO}_5$ 707.9554, found 707.9552.

p-(Tri-*n*-butylstannyl)benzoyl-5-aminoisophthalate DiTFP Ester, 14. A 2.0 g (2.8 mmol) quantity of **13** was dissolved in 20 mL of dry toluene under argon. To this solution was added 2.8 mL (5.5 mmol) of bis-(tributyltin), followed by 40 mg (0.04 mmol) of tetrakis-(triphenylphosphine)palladium(0). The mixture was stirred at rt for 15 min before heating to 80 °C for 2 h. After 2 h, an additional 40 mg of palladium catalyst was added. Within 1 h the mixture had turned black. After cooling to rt, the toluene was removed by rotary evaporation. The resulting black oil was taken into 20 mL of ethyl acetate and dried onto 10 g of silica gel while on a rotary evaporator. The oil-coated silica was added to the top of a 250 g (40×3.5 cm) silica gel column. The column was initially eluted with hexanes containing 5% acetic acid, but after eluting with 600 mL, the solvent was changed to 90:10 hexanes/ethyl acetate (containing 5% acetic acid). Fractions 14–16 were combined and dried to yield 1.5 g of **14** as a white solid (62%): mp 120–123 °C; ^1H NMR (CDCl_3) δ 0.89 (t, 9H, $J = 7.3$ Hz), 1.11 (m, 6H), 1.36 (m, 15H), 1.55 (m, 6H), 7.07 (m, 2H), 7.62 (d, 2H, $J = 4.1$ Hz), 7.84 (d, 2H, $J = 4.1$ Hz), 8.38 (s, 1H), 8.76 (t, 1H, $J = 1.6$ Hz), 8.87 (d, 2H, $J = 0.7$ Hz); IR (Nujol, cm^{-1}) 1750, 1645, 1520, 1480, 1185, 1100, 1085; MS (FAB $^+$) mass calcd (isotopic abundance) 868 (38%), 869 (37%), 870 (75%), 871 (53%), 872 (100%), 873 (41%), 874 (21%); mass found 868 (47%), 869 (42%), 870 (82%), 871 (55%), 872 (100%), 873 (42%), 874 (26%).

Biotin TFP Ester, 16. A 3.0 g (12.3 mmol) quantity of biotin, **15**, was dissolved in 60 mL of warm (70 °C) DMF under argon atmosphere. The solution was cooled to ambient temperature, and 2.79 g (13.5 mmol) of DCC was added, followed by 40.8 g (24.6 mmol) of TFP-OH. The reaction mixture was cooled to 0 °C and stirred at that temperature for 0.5 h. It was brought back to ambient temperature and stirred for another 4–5 h. The mixture was filtered and the filtrate evaporated to

dryness. The resultant solid was washed with 50 mL of acetonitrile and dried to yield 5.0 g (98%) of **16** as a white solid: mp 185–187 °C (20); ^1H NMR (DMSO- d_6) δ 1.4 (m, 2H), 1.7 (m, 2H), 2.5 (t, 2H), 2.8 (t, 2H), 3.1 (m, 1H), 4.1 (m, 1H), 4.3 (m, 1H), 6.4 (d, 2H), 7.9 (m, 1H); IR (KBr, cm^{-1}) 3250, 2915, 1790, 1710, 1520, 1480, 1090.

Biotin–Aminocaproate TFP Ester, 18. A 0.99 g quantity (7.5 mmol) of 6-aminocaproic acid was dissolved in 75 mL of H_2O . To this mixture was added 0.5 mL of triethylamine, followed by a solution of 1.96 g (5 mmol) of **16** in warm acetonitrile (300 mL). The reaction was stirred overnight at rt. It was filtered, washed with 50 mL of H_2O , and dried under high vacuum to yield 0.870 g (47%) of **17**. Additional material was obtained by evaporating the filtrate to dryness, dissolving the residue in 75 mL of CH_3CN , and allowing the CH_3CN solution to cool to rt. The resultant solid was filtered, washed with warm acetonitrile, and dried under high vacuum to give an additional 0.6 g. Total yield of **17** was 1.47 g (79%): mp 225–227 °C; ^1H NMR (DMSO- d_6) δ 1.2–1.6 (m, 8H), 2.0 (t, 2H), 2.2 (t, 2H), 2.5 (dd, 2H), 2.8 (dd, 2H), 3.1 (m, 3H), 4.1 (m, 1H), 4.3 (m, 1H), 6.4 (d, 2H), 7.7 (m, 1H); IR (KBr, cm^{-1}) 3280, 2915, 1710, 1630, 1540, 1260, 1030.

A 1.0 g quantity (2.68 mmol) of **17** was dissolved in 50 mL of DMSO. To that solution was added 0.4 mL of triethylamine, followed by 1.05 g (4.02 mmol) of TFP-OTFA (21). The reaction mixture was stirred at rt for 15–20 min and then evaporated to dryness. The residue was washed with ether and dichloromethane. The resulting solid was dried under vacuum to yield 1.24 g (89%) of **18**: mp 139–141 °C; ^1H NMR (DMSO- d_6) δ 1.2 (t, 2H), 1.3–1.7 (m, 5H), 2.1 (t, 2H), 2.6 (dd, 2H), 2.8 (m, 4H), 3.1 (m, 4H), 4.2 (m, 1H), 4.4 (m, 1H), 6.4 (d, 2H), 7.8 (t, 1H), 8.0 (m, 1H); IR (KBr, cm^{-1}) 3300, 2940, 1785, 1690, 1640, 1520, 950; HRMS (FAB $^+$, 3NBA) ($M + \text{H}$) $^+$ mass calcd for $\text{C}_{22}\text{H}_{28}\text{F}_4\text{N}_3\text{O}_4\text{S}$ 506.1737, found 506.1732.

Biotin–Aminocaproate 5-Aminoisophthalic Acid DiTFP Ester, 20. A 0.35 g (0.67 mmol) quantity of **18** was dissolved in 40 mL of DMF. To that solution was added 80 μL of triethylamine, followed by 0.182 g (1.01 mmol) of 5-aminoisophthalic acid. The reaction was stirred at rt for 8 days, with triethylamine (80 μL) added every 24 h. It was then evaporated to dryness, and the residue was applied to a silica column. The column was initially eluted with 450 mL of acetonitrile, followed by 40 mL of methanol, and then DMF, collecting 20 mL fractions. The fractions containing the final product (HPLC monitored) were evaporated to dryness to yield 230 mg (65%) of **19**: mp 193–195 °C; ^1H NMR (DMSO- d_6) δ 1.3–1.7 (m, 8H), 2.1 (t, 2H), 2.3 (t, 2H), 2.6 (m, 2H), 2.8 (m, 2H), 3.1 (m, 3H), 4.1 (m, 1H), 4.3 (m, 1H), 6.4 (d, 2H), 7.8 (t, 1H), 8.1 (m, 1H), 8.46 (s, 2H); IR (KBr, cm^{-1}) 3280, 2920, 1710, 1690, 1640, 1240, 1100, 900; HRMS (FAB $^+$, 3NBA) ($M + \text{H}$) $^+$ mass calcd for $\text{C}_{24}\text{H}_{33}\text{N}_4\text{O}_7\text{S}$ 521.2070, found 521.2070.

A 200 mg (0.376 mmol) quantity of **19** was dissolved in 30 mL of DMF under argon atmosphere. To this solution was added 241 mg (0.94 mmol) of TFP-OTFA by a transfer using a double-ended needle. That addition was followed by addition of 112 μL of triethylamine. The reaction mixture was stirred at rt for 24 h (HPLC monitored) and then evaporated to dryness. The light brown oil was triturated with ether, and the solution was filtered and washed with 50 mL of additional ether to yield 250 mg (86%) of **20**: mp 135–137 °C; ^1H NMR (DMSO- d_6) δ 1.3–1.7 (m, 8H), 2.1 (t, 2H), 2.3 (t, 2H), 2.6 (m, 2H), 2.8 (m, 2H), 3.1 (m, 3H), 4.2 (m, 1H), 4.4 (m, 1H), 6.4 (d, 2H), 7.8 (t, 1H), 8.1 (m, 2H), 8.57 (s, 1H), 8.9 (s, 2H); IR (KBr, cm^{-1}) 3280, 2920, 1260, 1200, 1690,

1520, 1185, 950; HRMS ($M + H$)⁺ mass calcd for $C_{36}H_{32}F_8N_4O_7S$ 817.1942, found 817.1920.

Conjugation of Cyanocobalamin Monocarboxylic Acid Diaminododecane with Isophthaloyl Dichloride; Synthesis of 21–23. To a solution of 0.300 g (0.192 mmol) of **5**, **6**, or **7** in 30 mL of DMF was added 18 μ L of triethylamine. To that solution was added 0.195 g (0.096 mmol) of isophthaloyl dichloride over a period of 10–15 min. The reaction mixture was stirred at 55–60 °C for 48 h. It was then evaporated to dryness. The solid residue was dissolved in 20 mL of methanol/H₂O (7:3) and eluted on a preparative reversed phase column (500 mm \times 25 mm) with the same solvent. The fractions containing the product were evaporated to dryness.

b-Acid Dimer (21): yield, 121 mg (38%); mp 220–222 °C with decomposition; ¹H NMR (D₂O) δ 0.43 (s, 6H, C-20 CH₃), 1.17 (s, 8H), 1.22 (d, 13H), 1.29 (s, 45H), 1.36 (d, 22H), 1.44 (s, 10H), 1.6 (m, 8H), 1.87 (s, 8H), 2.04 (m, 10H), 2.25 (s, 12H), 2.36 (m, 8H), 2.55 (d, 20H), 2.8 (m, 8H), 3.15 (m, 8H), 3.29 (s, 10H), 3.36 (m, 14H), 3.6 (m, 4H), 3.73 (m, 2H), 3.9 (d, 2H), 4.07 (m, 2H), 4.12 (m, 2H), 4.16 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.6 (s, 2H), 4.66 (m, 2H), 6.0 (s, 2H), 6.26 (d, 2H), 6.6 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.54 (t, 1H), 7.93 (d, 2H), 8.25 (s, 1H); MS (FAB⁺) mass calcd for $C_{158}H_{228}N_{30}O_{30}Co_2P_2$ 3208,² found 3208 (M)⁺; IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} (ϵ = 33 900).

d-Acid Dimer (22): yield, 96 mg (30%); mp 217–220 °C with decomposition; ¹H NMR (D₂O) δ 0.43 (s, 6H, C-20 CH₃), 1.18 (s, 8H), 1.3 (m, 36H), 1.37 (m, 12H), 1.46 (s, 10H), 1.6 (m, 8H), 1.9 (d, 12H), 2.05 (m, 10H), 2.2 (d, 16H), 2.35 (m, 8H), 2.6 (d, 18H), 2.8–3.0 (m, 16H), 3.15 (m, 6H), 3.3 (s, 8H), 3.37 (m, 14H), 3.6 (m, 4H), 3.76 (m, 2H), 3.9 (d, 2H), 4.07 (m, 2H), 4.12 (m, 2H), 4.18 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.6 (s, 2H), 4.68 (m, 2H), 6.0 (s, 2H), 6.26 (d, 2H), 6.6 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.54 (t, 1H), 7.95 (d, 2H), 8.25 (s, 1H); MS (FAB⁺) mass calcd for $C_{158}H_{228}N_{30}O_{30}Co_2P_2$ 3208, found 3208 (M)⁺; IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} (ϵ = 42 400).

e-Acid Dimer (23): yield, 96 mg (30%); mp 225–228 °C with decomposition; ¹H NMR (D₂O) δ 0.43 (s, 6H), 1.16 (s, 8H), 1.29 (m, 36H), 1.35 (d, 12H), 1.44 (s, 10H), 1.53 (m, 6H), 1.6 (m, 8H), 1.85 (s, 12H), 2.03 (m, 8H), 2.25 (d, 12H), 2.33 (m, 8H), 2.54 (d, 20H), 2.8 (m, 8H), 3.13 (m, 8H), 3.28 (s, 12H), 3.35 (m, 12H), 3.6 (m, 4H), 3.73 (m, 2H), 3.9 (d, 2H), 4.07 (m, 2H), 4.12 (m, 2H), 4.16 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.64 (m, 2H), 4.7 (s, 2H), 6.0 (s, 2H), 6.26 (d, 2H), 6.6 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.54 (t, 1H), 7.93 (d, 2H), 8.25 (s, 1H); MS (FAB⁺) mass calcd for $C_{158}H_{228}N_{30}O_{30}Co_2P_2$ 3208, found 3209 (M + H)⁺; IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} (ϵ = 31 700).

Conjugation of Cyanocobalamin Monocarboxylic Acid Diaminododecane with p-Iodobenzoyl Aminoisophthalate; Synthesis of 24–26. To a solution containing 0.30 g (0.192 mmol) of **5**, **6**, or **7** in 40 mL of a 3:1 mixture of DMF/H₂O was added 18 μ L of triethylamine. To that solution was added 68 mg (0.096 mmol) of **13** over a 5–10 min period. The reaction mixture was stirred at rt for 4–5 h and then evaporated to dryness. The solid residue was dissolved in 20 mL of a 4:1 MeOH/H₂O mixture and applied to a preparative reversed phase column (500 mm \times 25 mm), which was eluted with the

same solvent. The fractions containing the product were evaporated to dryness.

b-Acid Dimer (24): yield, 258 mg (70%); mp 285–290 °C with decomposition; ¹H NMR (D₂O) δ 0.43 (s, 6H), 1.17 (s, 8H), 1.22 (d, 13H), 1.29 (s, 45H), 1.36 (d, 22H), 1.44 (s, 10H), 1.6 (m, 8H), 1.86 (s, 12H), 2.04 (m, 10H), 2.25 (s, 12H), 2.36 (m, 8H), 2.55 (d, 20H), 2.83 (m, 8H), 3.15 (m, 8H), 3.29 (s, 10H), 3.36 (m, 8H), 3.58 (m, 2H), 3.65 (m, 2H), 3.75 (m, 2H), 3.9 (d, 2H), 4.06 (m, 2H), 4.12 (m, 2H), 4.16 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.57 (s, 2H), 4.65 (m, 2H), 6.0 (s, 2H), 6.26 (d, 2H), 6.5 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.7 (d, 2H), 7.89 (d, 2H), 7.98 (s, 1H), 8.26 (s, 2H); MS (FAB⁺) mass calcd for $C_{165}H_{232}O_{31}N_{31}Co_2P_2I$ 3453, found 3453 (M)⁺; IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} (ϵ = 41 500).

d-Acid Dimer (25): yield, 280 mg (76%); mp 230–233 °C with decomposition; ¹H NMR (D₂O) δ 0.43 (s, 6H), 1.19 (s, 8H), 1.3 (m, 36H), 1.37 (d, 12H), 1.46 (s, 10H), 1.63 (m, 8H), 1.87 (s, 12H), 2.05 (m, 10H), 2.27 (d, 16H), 2.35 (m, 8H), 2.6 (d, 18H), 2.8 (s, 8H), 3.0 (s, 10H), 3.15 (m, 8H), 3.3 (d, 8H), 3.37 (m, 14H), 3.6 (m, 2H), 3.68 (d, 2H), 3.76 (m, 2H), 3.9 (d, 2H), 4.07 (m, 2H), 4.12 (m, 2H), 4.18 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.64 (m, 4H), 6.0 (s, 2H), 6.26 (d, 2H), 6.6 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.7 (d, 2H), 7.9 (d, 2H), 7.99 (d, 1H), 8.28 (s, 2H); MS (FAB⁺) mass calcd for $C_{165}H_{232}O_{31}N_{31}Co_2P_2I$ 3453, found 3453 (M)⁺; IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} (ϵ = 48 900).

e-Acid Dimer (26): yield, 265 mg (72%); mp 253–255 °C with decomposition; ¹H NMR (D₂O) δ 0.43 (s, 6H), 1.16 (s, 8H), 1.22 (d, 12H), 1.33 (m, 36H), 1.43 (s, 10H), 1.53 (m, 6H), 1.6 (m, 8H), 1.86 (s, 12H), 2.03 (m, 8H), 2.25 (d, 12H), 2.33 (m, 8H), 2.54 (d, 20H), 2.8 (s, 4H), 3.0 (s, 4H), 3.28 (s, 10H), 3.35 (m, 8H), 3.58 (m, 2H), 3.65 (m, 2H), 3.73 (m, 2H), 3.88 (d, 2H), 4.05 (m, 2H), 4.1 (m, 2H), 4.17 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.57 (s, 2H), 4.63 (m, 2H), 6.0 (s, 2H), 6.26 (d, 2H), 6.5 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.7 (d, 2H), 7.89 (d, 2H), 7.98 (s, 1H), 8.26 (s, 2H); MS (FAB⁺) mass calcd for $C_{165}H_{232}O_{31}N_{31}Co_2P_2I$ 3453, found 3452 (M)²; IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} (ϵ = 48 200).

Conjugation of Cyanocobalamin Monocarboxylic Acid Diaminododecane with p-(Tri-n-butylstannyl)-benzoyl Aminoisophthalate; Synthesis of 27–29. To a solution containing 0.10 g (0.065 mmol) of **5**, **6**, or **7** in 40 mL of a 3:1 mixture of DMF/H₂O was added 6 μ L of triethylamine. To that solution was added 28 mg (0.033 mmol) of **14** over a 5–10 min period. The reaction mixture was stirred at rt for 12–14 h and then evaporated to dryness. The residue was washed with 100 mL of acetone, and the solvent was decanted.

b-Acid Dimer (27): yield, 93 mg (72%); mp >300 °C; ¹H NMR (D₂O) δ 0.43 (s, 6H, C-20 CH₃), 0.88 (t, 9H), 1.12 (t, 12H), 1.17 (d, 8H), 1.22 (d, 13H), 1.29 (s, 45H), 1.36 (d, 22H), 1.44 (s, 10H), 1.6 (m, 8H), 1.87 (d, 12H), 2.04 (m, 10H), 2.25 (s, 12H), 2.36 (m, 8H), 2.55 (d, 20H), 2.8 (m, 8H), 3.15 (m, 8H), 3.29 (s, 10H), 3.36 (m, 14H), 3.6 (m, 4H), 3.73 (m, 2H), 3.9 (d, 2H), 4.07 (m, 2H), 4.12 (m, 2H), 4.16 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.66 (m, 2H), 6.0 (s, 2H), 6.26 (d, 2H), 6.6 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.6 (d, 2H), 7.9 (d, 2H), 7.98 (br s, 1H), 8.28 (br s, 2H); IR (KBr, cm⁻¹) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} (ϵ = 59 300).

d-Acid Dimer (28): yield, 90 mg (70%); mp 208–212 °C with decomposition; ¹H NMR (D₂O) δ 0.43 (s, 6H), 0.88 (t, 9H), 1.15 (t, 12H), 1.19 (s, 8H), 1.3 (m, 36H), 1.37 (d, 12H), 1.46 (s, 10H), 1.6 (m, 8H), 1.9 (s, 12H), 2.05 (m, 10H), 2.28 (d, 16H), 2.35 (m, 8H), 2.6 (d, 18H), 2.8–2.9

² Obtaining exact mass values for molecules of >3000 amu is difficult. It is believed that the difference of 1 mass unit obtained is a reflection of the difficulty in assigning mass units to the spectrometer data, not an indication that the mass is different from that calculated for the desired compound.

(m, 16H), 3.15 (m, 8H), 3.3 (s, 8H), 3.37 (m, 14H), 3.6 (m, 4H), 3.76 (m, 2H), 3.9 (d, 2H), 4.07 (m, 2H), 4.12 (m, 2H), 4.18 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.68 (m, 2H), 6.0 (s, 2H), 6.26 (d, 2H), 6.6 (s, 2H), 7.1 (s, 2H), 7.25 (d, 2H), 7.6 (d, 2H), 7.9 (d, 2H), 7.99 (br s, 1H), 8.28 (br s, 2H); IR (KBr, cm^{-1}) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} ($\epsilon = 47\,700$).

e-Acid Dimer (29): yield, 100 mg (78%); mp 202–205 °C with decomposition; ^1H NMR (D_2O) δ 0.43 (s, 6H), 0.88 (t, 9H), 1.12 (t, 12H), 1.15 (s, 8H), 1.29 (m, 36H), 1.35 (d, 12H), 1.44 (s, 10H), 1.53 (m, 6H), 1.6 (m, 8H), 1.86 (d, 12H), 2.03 (m, 8H), 2.25 (d, 12H), 2.33 (m, 8H), 2.54 (d, 20H), 2.8 (m, 8H), 3.13 (m, 8H), 3.28 (s, 10H), 3.35 (m, 10H), 3.6 (m, 4H), 3.73 (m, 2H), 3.9 (d, 2H), 4.05 (m, 2H), 4.1 (m, 2H), 4.17 (m, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.6 (m, 2H), 6.0 (s, 2H), 6.26 (d, 2H), 6.6 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.6 (d, 2H), 7.9 (d, 2H), 7.98 (br s, 1H), 8.28 (br s, 2H); IR (KBr, cm^{-1}) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} ($\epsilon = 41\,900$).

Conjugation of Cyanocobalamin Monocarboxylic Acid Diaminododecane with Biotin–Aminocaproate Aminoisophthalate; Synthesis of 30 and 31. To a solution of containing 0.20 g (0.13 mmol) of **5**, **6**, or **7** in 40 mL of a 3:1 mixture of DMF/ H_2O was added 12 μL of triethylamine. To that solution was added 50 mg (0.065 mmol) of **20** over a 5–10 min period. The reaction mixture was stirred at rt for 3 h and then was evaporated to dryness. The residue was washed with 100 mL of acetone, and the solvent was decanted.

b-Acid Dimer (30): yield, 124 mg (62%); mp 195–198 °C with decomposition; ^1H NMR ($\text{MeOH}-d_4$) δ 0.43 (s, 6H), 1.17 (s, 8H), 1.3 (m, 20H), 1.35 (m, 22H), 1.46 (s, 10H), 1.6 (m, 8H), 1.8 (m, 6H), 1.87 (m, 10H), 2.0 (m, 4H), 2.17 (s, 10H), 2.25 (s, 12H), 2.57 (d, 16H), 3.16 (m, 9H), 3.29 (s, 8H), 3.37 (m, 6H), 3.6 (m, 4H), 3.76 (m, 2H), 3.9 (d, 2H), 4.07 (m, 4H), 4.16 (m, 2H), 4.28 (m, 4H), 4.5 (m, 4H), 4.7 (m, 2H), 6.04 (s, 2H), 6.26 (d, 2H), 6.5 (s, 2H), 7.1 (s, 2H), 7.2 (s, 2H), 7.9 (d, 1H), 8.1 (s, 2H); MS (FAB^+) mass calcd for $\text{C}_{174}\text{H}_{254}\text{N}_{34}\text{O}_{33}\text{Co}_2\text{P}_2\text{S}$ 3562, found 3561 (M^+); IR (KBr, cm^{-1}) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} ($\epsilon = 38\,700$).

e-Acid Dimer (31): yield, 100 mg (50%); mp > 300 °C; ^1H NMR ($\text{MeOH}-d_4$) δ 0.43 (s, 6H), 1.17 (s, 8H), 1.3 (m, 20H), 1.35 (m, 22H), 1.43 (s, 10H), 1.53 (m, 8H), 1.7 (m, 6H), 1.87 (m, 6H), 2.0 (m, 4H), 2.13 (s, 10H), 2.25 (d, 10H), 2.52 (d, 16H), 3.16 (m, 6H), 3.29 (s, 10H), 3.37 (m, 6H), 3.6 (m, 4H), 3.73 (m, 2H), 3.9 (d, 2H), 4.07 (m, 4H), 4.16 (m, 2H), 4.26 (m, 4H), 4.5 (m, 4H), 4.64 (m, 2H), 6.04 (s, 2H), 6.26 (d, 2H), 6.6 (s, 2H), 7.1 (s, 2H), 7.23 (s, 2H), 7.9 (d, 1H), 8.1 (s, 2H); MS (FAB^+) mass calcd for $\text{C}_{174}\text{H}_{254}\text{N}_{34}\text{O}_{33}\text{Co}_2\text{P}_2\text{S}$ 3562, found 3562 (M^+); IR (KBr, cm^{-1}) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (MeOH) λ_{360} ($\epsilon = 40\,000$).

Conjugation of Cyanocobalamin Monocarboxylic Acid–Trioxadiazine with Isophthaloyl Dichloride; Synthesis of 32. To a solution containing 300 mg (0.193 mmol) of **8** in 20 mL of DMF was added 30 μL of triethylamine. To that solution was added 19.5 mg (0.096 mmol) of isophthaloyl dichloride over a 10–15 min period. The reaction mixture was stirred at rt for 4–5 days, and 30 μL of triethylamine was added after each 24 h period. After evaporating to dryness, the solid was dissolved in 20 mL of a 1:1 methanol/ H_2O mixture and was applied to a preparative reversed phase column (25 mm \times 500 mm), which was eluted with the same solvent. The fractions containing the final product were evaporated to dryness.

b-Acid Dimer (32): yield, 100 mg (32%); mp 195–198 °C with decomposition; ^1H NMR ($\text{MeOH}-d_4$) δ 0.44 (s, 6H), 1.18 (s, 6H), 1.25 (d, 7H), 1.31 (t, 20H), 1.36 (s, 14H),

1.45 (s, 8H), 1.74 (m, 20H), 1.88 (d, 15H), 2.27 (s, 11H), 2.37 (m, 22H), 2.56 (d, 20H), 2.85 (s, 5H), 2.99 (s, 2H), 3.2 (m, 18H), 3.3 (m, 12H), 3.4 (m, 10H), 3.5 (s, 14H), 3.58 (s, 18H), 3.6 (s, 30H), 3.9 (d, 4H), 4.0 (d, 2H), 4.1 (d, 2H), 4.18 (d, 2H), 4.3 (m, 2H), 4.5 (m, 2H), 4.7 (m, 2H), 6.0 (s, 2H), 6.28 (s, 2H), 6.56 (s, 2H), 7.1 (s, 2H), 7.25 (s, 2H), 7.56 (m, 1H), 7.8 (d, 2H), 8.3 (s, 1H); MS (FAB^+) mass calcd for $\text{C}_{154}\text{H}_{220}\text{N}_{30}\text{O}_{36}\text{Co}_2\text{P}_2$ 3245, found 3245 (M^+); IR (KBr, cm^{-1}) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060; UV (H_2O) λ_{361} ($\epsilon = 33\,900$).

Conjugation of Cyanocobalamin Monocarboxylic Acid–Trioxadiazine with DiTFP Ester of Biotin–Aminocaproate Aminoisophthalate; Synthesis of 33 and 34. To a solution containing 300 mg (0.193 mmol) **8** or **10** in 15 mL of DMF was added 30 μL of triethylamine. To that solution was added 79 mg (97 mmol) of **20** over a 5–10 min period. The reaction mixture was stirred at rt for 3–4 days (HPLC monitored), adding 30 μL of triethylamine after each 24 h period. The reaction mixture was then evaporated to dryness. The solid residue was dissolved in 20 mL of a 1:1 methanol/ H_2O mixture and applied to a preparative reversed phase column (25 mm \times 500 mm), which was eluted with the same solvent. The fractions containing the product were evaporated to dryness.

Binding of Cobalamin Derivatives with rhTCII. Recombinant human transcobalamin II (rhTCII) was prepared as previously reported (22). Stock solutions of Cbl derivatives were prepared by dissolving 2 mg in 100–200 μL of DMSO, followed by dilution to 1.0 mL with H_2O . Quantification of the Cbl derivatives was accomplished by UV, based on the measured extinction coefficients at 360 nm (data provided with individual compounds). Thus, a 20 μL aliquot of the stock Cbl solution was diluted to 1 mL with H_2O , and the absorbance at 360 nm was measured. An aliquot of the original solution was diluted to obtain a 1 μM solution, which was further diluted to 0.1 μM for use in the assay.

rhTCII was partially purified on a cation exchange column as previously described (23). The rhTCII was diluted in PBS containing 0.025% HSA to bind approximately 10 pmol of CN-Cbl (**1**)/mL. Aliquots of 100 μL of the rhTCII solution were added to tubes containing 0.01 pmol of [^{57}Co]-**1** and 0.1–30 pmol of unmodified **1** or Cbl derivatives **2–18**. The solution volume in each tube was adjusted to 1.0 mL with PBS, and the samples

^a The binding inhibition quantity is that amount (pmol) of Cbl derivative required to inhibit by 50% the binding of 0.01 pmol of [⁵⁷Co]CN-Cbl and was obtained by dividing 100 by the 50% binding inhibition quantity.

were incubated at rt for 1 h. The protein-bound [⁵⁷Co]-**1** was then separated from free [⁵⁷Co]-**1** by adsorption to hemoglobin-coated charcoal (24). The amount of radioactivity in each fraction was determined in a gamma counter. The decrease in binding of [⁵⁷Co]-**1** in the presence of various amounts of a Cbl derivative was calculated and graphed (Figure 2). The quantities of each derivative required to inhibit the binding of [⁵⁷Co]CN-Cbl to rhTCII by 50% was determined, and the apparent affinities of the compounds relative to CN-Cbl were calculated (Table 1).

RESULTS AND DISCUSSION

There are only a few reported examples of the preparation of Cbl dimers. In one example, it is proposed that Co–S–S–Co Cbl dimers are prepared from reaction with hydrosulfide ion (25). More recently, cobalt oligomethylene bridged dimers [Co–(CH₂)_{*n*}–Co, where *n* = 4–6] have been prepared as potential “latent alkanediyl diradicals” (26). Since our ultimate goal is to obtain Cbl derivatives that could be used as therapeutic pharmaceuticals, the light sensitivity and instability of previously described cobalt-linked dimers made them unsuitable. Therefore, we directed our efforts to the synthesis of novel new Cbl dimers that are designed to be stable to degradation. The synthetic approach chosen for preparation of stable Cbl dimers was to employ a di- or trifunctional cross-linking reagent that could couple two Cbl corrin ring carboxylates through linking moieties, as depicted in Figure 1. While bioactive Cbl dimers may be obtained with a difunctional cross-linking reagent, the desire to incorporate other functionalities into the dimers led us to consider a trifunctional reagent. This cross-linking arrangement allows for attachment of other chemical moieties with specific biological properties without having to make a second attachment on the Cbl moiety. Since we were interested in the possibility of binding two TCII molecules to the same Cbl dimer, the distance between the two Cbl moieties was considered to be critical for formation of such a complex. The linker molecules employed have 14–15 atoms in the chain, and linking of two of these with the isophthalic acid cross-linking moiety provides a 41–42 Å (fully extended) distance between the Cbls. This distance was thought to be adequate to bind two TCII molecules.

Synthesis of Cobalamin Dimers and Precursor Molecules. Our approach to preparing the Cbl dimers was to synthesize the diamino-linker adduct of Cbl carboxylates first and then couple the two adducts with the cross-linking reagent. This approach was chosen

because the Cbl diamino-linker adducts had been previously prepared for related studies (12, 13). The initial dimeric Cbls synthesized (Chart 2) incorporated diaminododecane adducts **5–7** (Chart 1) with isophthalate cross-linking moieties. The alkylamino derivatives **5**, **6**, and **7** were prepared by conjugation of the Cbl-carboxylates **2**, **3**, or **4** with diaminododecane using the water soluble carbodiimide, EDC,³ in DMF. The carboxylates were prepared from mild acid hydrolysis of CN-Cbl, **1**, followed by careful separation of the isomers on a preparative LC system employing an aminopropyl-silica column (12). Synthesis of the isomeric Cbl dimers **21–23** was accomplished by reacting one of the diaminododecane adducts, **5**, **6**, or **7**, with isophthaloyl dichloride. All three isomeric derivatives (e.g. *b*, *d*, and *e*) were prepared to compare the TCII binding of dimeric molecules with their monomeric counterparts.

Radioiodination of Cbl dimers was initiated to evaluate the biological properties of these compounds. We have previously shown that, while direct radioiodination of Cbl does not yield the desired product, radioiodination of Cbls could be accomplished by conjugation with arylstannane moieties (13). In general, incorporation of high specific activity radioiodine into a benzoyl moiety is readily achieved from the corresponding trialkylstannyl benzoate intermediates (18). One approach to obtaining radioiodinated dimers was to prepare them from stannylbenzoyl adducts of aminoisophthalate cross-linked Cbls. Thus, *p*-(tri-*n*-butylstannyl)benzoyl-containing isophthaloyl dimers **27–29** were prepared to be used for incorporation of radioiodine into the dimers, and *p*-iodobenzoyl-containing isophthaloyl dimers **24–26** were prepared as HPLC standards for radioiodinated Cbl derivatives.

Prior to the synthesis of the Cbl dimers **24–29**, the requisite activated isophthaloyl derivatives had to be prepared. The synthesis of ditetrafluorophenyl (TFP) esters of the iodobenzoyl and stannylbenzoyl adducts of 5-aminoisophthalic acid, **13** and **14**, is shown in Scheme 1. Conjugation of *p*-iodobenzoyl chloride with 5-aminoisophthalic acid gave a nearly quantitative yield of the crude adduct, **12**. Preparation of the di-TFP ester **13** was accomplished in 43% yield by reacting **12** with DCC and TFP-OH in ethyl acetate. Conversion of the aryl iodide, **13**, into the aryl stannane, **14**, was accomplished in 62% yield using bis(tributyltin) and palladium catalyst.

Biotinylated Cbl dimers were of interest as reagents for analytical studies. Therefore, Cbl dimers **30** and **31** were prepared. Rather than preparing all three isomeric biotinylated derivatives, only the Cbls containing *b*- and *e*-propionic acid side chains (**2** and **4**) were employed for cross-linking reactions. Indeed, we were primarily interested in the *e*-isomer of the biotinylated dimer as it was expected to have the highest binding with TCII, but since the Cbl *e*-carboxylate was available in small quantities, initial development of cross-linking reaction conditions was conducted with the more abundant *b*-carboxylate, **2**. Prior to cross-linking the aminoalkyl-Cbls **5** or **7**, a carboxylate activated–biotinylated aminoisophthalic acid derivative, **20**, had to be prepared. Although *N*-hydroxysuccinimido ester of biotin–aminocaproate was commercially available,⁴ the high cost of this reagent led us to synthesize the corresponding TFP ester, **18** (Scheme 2). Reaction of **18** with 5-aminoisophthalic acid provided

³ EDC is also referred to as EDAC (Sigma Chemical Co., St. Louis, MO); 1-ethyl-3-(3-(dimethylamino)propyl)carbodiimide.

⁴ For example: sulfosuccinimido-6-(biotinamido)hexanoate is available from Pierce (Rockford, IL) as NHS-LC-Biotin, and biotinamidocaproate *N*-hydroxysuccinimido ester is available from Sigma Chemical Co. (St. Louis, MO).

Figure 1. General schematic representation of CN-Cbl dimers. The dimers contain two Cbl moieties, two linking moieties, a cross-linking moiety, and, where desired, an appended group. This example depicts corrin ring *e*-propionamide attachment.

19 in 65% yield, and further conversion to **20** using the transesterification reagent tetrafluorophenyl trifluoroacetate (TFP-OCOCF₃) (**21**) was accomplished in 86% yield.

It became apparent after the synthesis of Cbl dimers **21–31** that they had limited water solubility. Fortunately, very low concentrations of Cbls are required to obtain biological data with these compounds, permitting *in vitro* evaluations to be conducted. However, the increased lipophilicity of the compounds was considered to be a potential problem with nonspecific binding and

^a *i*-Cbl are isomers of Cbl carboxylates **2** (*b*), **3** (*d*), or **4** (*e*).

could ultimately make formulation of a pharmaceutical more difficult. Therefore, a method of water solubilization for the dimers was sought. The favored approach to solving this problem was to incorporate a more water soluble linking moiety. Thus, commercially available 4,7,10-trioxa-1,13-tridecanediamine was conjugated with two isomeric Cbl carboxylates, **2** and **4**, to yield Cbl adducts **8** and **10**. This linking arm is nearly the same length as the diaminododecane linker, resulting in distances between Cbl carboxylates of 41.6 Å for **23** (and related compounds) and 42.6 Å for **32** (and related compounds). The reason for preparing only the *b*- and *e*-isomers was based on availability of carboxylates as described previously. Conjugation of **8** with isophthaloyl dichloride provided Cbl dimer, **32**. Importantly, that compound was more soluble in water than its diaminododecane counterpart. Due to the anticipated increased water solubility of the simple isophthalate cross-linked molecules, the biotin dimers **33** and **34** were synthesized. The biotinylated Cbl dimers **33** and **34** were synthesized in 40–53% yield from the reaction of **8** or **10** with the

aminoisophthalate di-TFP ester **20**. Again, the resulting Cbl dimers were found to be more soluble in aqueous medium than their diaminododecane counterparts, **30** and **31**.

Iodination Reactions. Iodination and radioiodination of Cbl derivatives containing arylstannanes must be conducted under (near) neutral conditions or a side reaction for the formation of *c*-lactone can predominate (13). Attempts at iodination of HPLC purified stannyl derivatives **27–29** in MeOH using NaI and *N*-chlorosuccinimide (NCS)⁵ over a 30 min period resulted in no change in the starting material. Attempts at iodination using NaI/NCS in 5% HOAc/MeOH also did not alter the starting material. Because there was a concern that the iodide ion was somehow being inactivated toward oxidation with NCS (e.g. being bonded to the Co in the corrin ring), ICl was investigated as the iodination reagent. Attempts to iodinate **29** with ICl in MeOH over a 30 min period also failed to change the starting material; however, reaction of ICl in 5% HOAc/MeOH resulted in conversion to another compound. Unfortunately, the new compound was not the desired iodinated product as its HPLC retention time was not the same as that of **26**. Although the data obtained were insufficient to determine the nature of the new compound, it seems likely that it is the *c*-lactone derivative of **26**. An evaluation of the radioiodination of **29** also did not provide the desired compound.

The lack of conversion of the arylstannanes (**27–29**) to aryl iodides (**24–26**) was surprising. Under the reac-

tion conditions employed, no previous iodinations of arylstannyl-derivatized compounds have failed to affect rapid (generally <1 min) and nearly quantitative substitution of the stannyl group. This failure to react with electrophilic iodine could be due to unique nature of the Cbls synthesized. The mass spectral data and chemical shifts of butyl and aryl protons in the NMR spectra indicated that the arylstannane is present in the dimer. However, the HPLC retention time of the arylstannane derivatives **27–29** was not as expected. Generally on reversed phase HPLC, aryltri-*n*-butylstannyl derivatives are retained much longer than the corresponding aryl iodide derivatives. This was not the case with compounds **27–29**, as they had shorter retention times (8.6–9.0 min) than the corresponding aryl iodides **24–26** (14.1–14.2 min). Since the spectral data suggest that the compounds are as depicted in Table 2, it is very difficult to understand how this increased polarity is obtained in the arylstannyl Cbl dimers. We can only hypothesize that the lipophilic linker arms and the lipophilic arylstannane are somehow compressed between the more hydrophilic Cbl moieties, perhaps causing a shift in the benzimidazole rings or other portion of the molecule, making it more hydrophilic. It is anticipated that we will be able to obtain more information on the structures through a crystal structure determination of the aryl iodide derivative **26**. An attempt to obtain the crystal structure of **26** is underway.

Competitive Binding with TCII. Cbl dimers were evaluated for their binding to rhTCII in a competitive assay that measures the binding relative to CN-Cbl (**12**). The assay employed partially purified rhTCII as the binding protein, and high specific activity (e.g. 200 μCi/

⁵ These reagents were used because the conditions mimic the radioiodination reaction conditions where NCS oxidizes Na[*I] to an electrophilic species *in situ*.

μg) [⁵⁷Co]CN-Cbl as the tracer. The assay measures the decrease in the binding of [⁵⁷Co]CN-Cbl in the presence of increasing concentrations of a Cbl dimer. The competitive binding curves for Cbl dimers are shown in Figure 2. The binding curves for the four isophthalate cross-linked dimers, **21**–**23** and **32**, relative to CN-Cbl, **1**, are shown in Figure 2A. The data show that the *e*-isomer, **23**, binds more avidly than the *b*-isomer, **21**, or the *d*-isomer, **22**. It is interesting to note that the compounds of **21**–**23** appear to bind less avidly than the corresponding monomeric Cbls **5**–**7**, previously tested (12). The differences observed could be due to the decreased water solubility of the dimers compared to the monomers. Indeed, water solubility appears to affect Cbl binding as the more water soluble trioxadiazine-linked Cbl-*b*-dimer, **32**, bound more avidly than the diaminododecane Cbl-*b*-dimer, **21**.

Evaluation of iodobenzoyl-containing Cbl dimers, **24**–**26**, provided similar results to those observed for the other diaminododecane-containing dimers **21**–**23** (Figure 2B). Again, only the *e*-isomer, **26**, bound competitively with [⁵⁷Co]-**1**, and its binding appeared to be reduced from that of the monomeric counterpart **7**. Binding assays were not conducted on the stannylbenzoate-containing dimers **27**–**29** as these compounds were only to be used as intermediates to prepare (radio)iodinated derivatives **24**–**26**.

The results obtained for the biotinylated derivatives **30**, **31**, **33**, and **34** are shown in Figure 2C. Binding of the water-solubilized *b*- and *e*-isomers, **33** and **34**, to

rhTCII is similar to the isomeric monomers **5** and **7**. The *e*-isomer, **31**, which contains the less water soluble diaminododecane linking moiety, does not bind as competitively as the corresponding more water soluble *e*-isomer, **34**. Again, this difference may be due to the lower water solubility of **31**. Relative binding data for the Cbl dimers are provided in Table 1. From the data, the decrease in binding (from 100%) and the effect of various modifications in the Cbl dimers on binding can be readily assessed. It is interesting to note that substitution on the isophthalate moiety appears to have little effect on TCII binding, whereas there is a significant improvement in binding with the addition of the trioxadiazine linker.

One of the questions we attempted to address in this investigation was whether a Cbl dimer could bind two TCII protein molecules. On the basis of the data obtained from the competitive binding assay, it appears that under the assay conditions (e.g. excess Cbl), only one Cbl moiety in the dimers bound with rhTCII. However, unless large quantities (e.g. micrograms–milligrams) of a dimer were injected in patients, the amount of TCII should be in excess even when considering endogenous Cbls (8, 29). The results obtained in the competitive binding assay are not surprising as it seems likely that binding of a Cbl dimer with the one TCII molecule could occur at a rate similar to a monomer but that the second TCII molecule would have to combine with a Cbl that was highly sterically hindered from the side that had bound TCII. This would suggest that binding with a second TCII

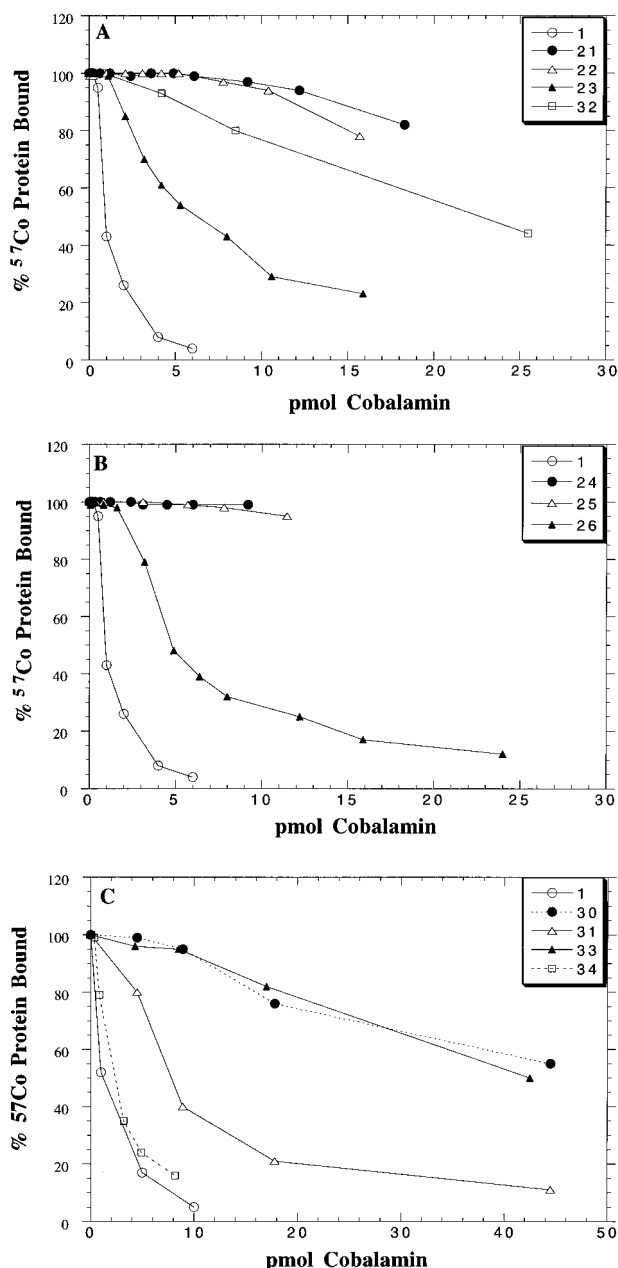

Figure 2. Competitive binding curves for $[^{57}\text{Co}]\text{CN-Cbl}$, **1**, and Cbl dimers **21–26** and **30–34** with rhTCII. To obtain the data, a quantity of rhTCII that would bind approximately 1 pmol of CN-Cbl was mixed with 0.01 pmol of $[^{57}\text{Co}]\text{-1}$ and 0.01–30 pmol of unmodified **1** or Cbl dimer. The mixture was diluted with PBS/HSA and incubated at rt for 1 h. Free Cbl was adsorbed onto hemoglobin-coated charcoal, and the protein-bound radioactivity in the supernatant fraction was measured. The amount of protein-bound ^{57}Co versus the amount of Cbl derivative present is plotted in panels A–C. Panel A (top) compares the competitive binding of the isophthalate cross-linked Cbl dimers that employed diaminododecane linker (**21**, **22**, **23**) and trioxadecanamine linker (**32**) with CN-Cbl (**1**). Panel B (middle) compares the competitive binding of *p*-iodobenzoyl-5-aminoisophthalate cross-linked Cbl dimers (**24**, **25**, **26**) with **1**. Panel C (bottom) compares the competitive binding of biotin containing Cbl dimers that employed the diaminododecane linker (**30**, **31**) and the trioxadecanamine linker (**33**, **34**) with **1**.

molecule might occur at a much slower rate. Determination of whether the dimers described herein bind with two rhTCII molecules when the TCII is in excess has proven to be difficult with *partially purified* rhTCII. Thus, future studies will be directed at obtaining radioiodinated Cbl dimers to improve sensitivity of detecting

Cbl/TCII complexes by electrophoresis and size exclusion HPLC.

SUMMARY

Fourteen isophthalate cross-linked Cbl dimers have been synthesized. To our knowledge, the reported compounds represent the first preparation of Cbl dimers that are coupled at a position other than at the Co atom. The Cbl dimers were prepared by cross-linking with carboxylate-activated derivatives of isophthalic acid or derivatized aminoisophthalic acid. To provide a distance between the Cbl moieties such that two TCII proteins might bind a Cbl dimer, linking molecules were incorporated between the Cbl moieties and the isophthalic acid moieties. The linker first evaluated, 1,12-diaminododecane, was found to decrease the water solubility of the Cbls considerably; therefore, a more water soluble linker, 4,7,10-trioxo-1,13-tridecanediamine, was also evaluated. The trioxatridecanediamine improved the water solubility significantly. In the investigation, Cbl dimers were evaluated for their binding with rhTCII. Analysis of the binding data shows that most of the Cbl dimers bound less avidly to rhTCII than CN-Cbl. As expected, the Cbl *ε*-carboxylate derived dimers bound most avidly of the three isomeric carboxylates studied. The more water soluble dimers bound rhTCII more avidly than their aliphatic counterparts, resulting in binding that was nearly equivalent to that of CN-Cbl for the *ε*-carboxylate isomer.

In this initial investigation, the Cbl dimers synthesized have provided basic information about their chemistry and binding to TCII. Studies are planned to prepare additional water soluble Cbl dimers and to obtain radioiodinated Cbl dimers. Once a radioiodinated Cbl dimer is obtained, the question of whether it can bind two TCII molecules will be assessed. It is anticipated that more highly derivatized Cbl dimers will be needed to be effective in Cbl/TCII cell surface receptor depletion, but all Cbl derivatives synthesized will be evaluated for potency as antiproliferative agents in *in vitro* assays. The data obtained from *in vitro* analyses will be reported elsewhere.

ACKNOWLEDGMENT

We thank Dr. Ross Lawrence (Medicinal Chemistry Department, University of Washington) for his efforts in obtaining mass spectral data on the Cbl derivatives. We are grateful for the financial support provided by Receptagen Corp. to conduct these studies.

Comments on Spectra and Chromatograms:

Note that the HPLC chromatograms of cobalamins were obtained from compounds purified by reversed-phase HPLC for analytical purposes. In most examples, the NMR spectra was obtained from purified material, but not necessarily as highly purified as the analytical HPLC samples. The stannylbenzoyl cobalamin derivatives **27**, **28**, **29** were not purified as they were not found to be useful in the iodination / radioiodination reactions. Thus, the HPLC and NMR data for these compounds reflect the crude reaction products. Compound **28** (*d*-isomer) was purified by HPLC to show that the iodination / radioiodination reactions were not affected by purity.

Radiation-Induced Formation of 3,4-Dihydroxyphenylalanine in Tyrosine-Containing Peptides and Proteins as a Function of X-Irradiation Dose

Rama Jain, Harold G. Freund, Edwin Budzinsky, and Minoti Sharma*

Department of Biophysics, Roswell Park Cancer Institute, Buffalo, New York 14263 . Received October 7, 1996[⊗]

Radiation-induced formation of 3,4-dihydroxyphenylalanine (DOPA) in Tyr and Tyr-containing peptides and proteins was investigated as a function of X-irradiation dose. Irradiated Tyr (0–30 Gy) and the acid hydrolysates of irradiated peptide and protein (0–240 Gy) were conjugated with dansyl chloride. The dansylated amino acids were analyzed by reversed-phase HPLC using fluorescence detection. Formation of DOPA, determined by integrated peak area, increased with dose. Analysis of the major product from irradiated tripeptide Tyr-Gly-Gly detected Gly and DOPA (2:1). Extension of the model study to irradiated BSA and RNase A showed correlation of DOPA formation with Tyr modification up to 120 Gy. Higher dose induced further transformation of DOPA. The fluorescence signal of dansylated DOPA was linear from 1.5 nmol to 0.5 pmol (correlation coefficient of 0.999, $n = 3$). The detection limit allows the detection of 1 molecule of DOPA/300 molecules of BSA in 5 μ g of dansylated hydrolysate. Most standard amino acid analysis techniques are limited to detect normal residues of protein. Protein-bound DOPA has been suggested to have a role in the replenishment of reduced transition metal ion involved free-radical-generating system *in vivo*. Sensitive analysis of protein-bound DOPA will be useful to study amplification of the radical-damaging event.

INTRODUCTION

There is increasing evidence that the oxidative modification of proteins may be physiologically important, serving as a "marking" step for initiation of protein degradation (1, 2). Oxygen radicals are formed ubiquitously in biological systems by both enzymatic and metal-ion-catalyzed oxidation (MCO) (3). Recent advances in the understanding of the chemistry of oxygen free radical and its role in modification of biological molecules have led to the recognition that oxygen free radicals are involved in physiological processes of aging as well as in the pathogenesis of age-related disease (4, 5). The findings that some amino acid residues are oxidized to carbonyl derivatives by active oxygen species produced during ionizing radiation, MCO, and ozone led to the development of sensitive assays for their detection and quantitation (6, 7). However, carbonyl compounds are highly reactive toward nucleophiles in biological systems. As a result, although useful as indicators of steady-state oxidation to proteins, carbonyl compounds may not be good candidate for assaying cumulative damage to long-lived proteins by oxidative reactions (8). The nucleic acids in crude tissue extracts and the unwashed free reagents used are two major problems often encountered in this assay (9). Besides, the introduction of carbonyl groups into amino acid residues does not indicate the involvement of a specific amino acid.

All aliphatic amino acids are potential targets of modification by radiolysis (10), but aromatic amino acid residues of proteins are particularly sensitive to oxidation by ozone, singlet-oxygen, radiolysis, and MCO. The formation of formylkynurenine from Trp, 3,4-dihydroxyphenylalanine (DOPA) from Tyr, and *o*-Tyr from Phe as major oxidation products was recognized several decades ago (11–14). Histidine residues are converted

to asparagine, aspartic acid, and 2-oxohistidine (5, 15, 16). Under anaerobic conditions, radiolytically generated radicals promote considerable protein–protein cross-linkage through \cdot OH-facilitated $-S-S$ and Tyr-Tyr (DT) bonding (17). Several oxidation products of Trp including *N*-formylkynurenine have been identified in the mature human lens (18, 19).

Fluorescence spectroscopy is used generally to measure the formation of DT and oxidation products of Trp. Upon irradiation at 325 nm, DT exhibits strong fluorescence at 410–420 nm. However, evidence based on spectrophotometric measurement of fluorescent emission at 410 nm for formation of DT has been cautioned due to the contribution of similar fluorescence at 400–450 nm by Trp oxidation and other protein modification when excited at 325 nm (7, 18). In a more specific procedure for DT and *o*-Tyr (20), deuterium-labeled DT and *o*-Tyr were added as internal standards to protein hydrolysates. Then, following enrichment, the amino acids were converted to their *N*-pentafluoropropyl *O*-isopropyl esters and analyzed by selected ion monitoring GC/MS. This technique requires the synthesis of deuterated amino acids for internal standards as well as derivatization of all the functional groups. For preparation of isopropyl esters the samples require heating at 110 $^{\circ}$ C. All modified amino acids may not survive such a drastic condition. Due to intrinsic sensitivity, 2-oxohistidine could be identified by HPLC analysis using electrochemical detection (21). A recent report on stabilization of this amino acid during derivatization has allowed the detection of 2-oxohistidine by fluorescence labeling (22).

The direct evidence that tyrosine residues in protein are converted to DOPA is rare (4). Protein-bound DOPA (PB-DOPA) may well be a more widespread component of protein and peptide than is generally accepted. The main reason for this suggestion is that DOPA derivatives are eclipsed by other amino acids in the standard analytical procedures. The same may be true with other chemical indicators of protein oxidation. The routine method for dealing with chromatographically ambiguous

[⊗] Abstract published in *Advance ACS Abstracts*, February 15, 1997.

PTH (phenylthiohydantoin) derivatives involved back hydrolysis of the PTH-amino acid in hydroiodic acid vapor (23). This procedure is frequently inconclusive due to the oxidative degradation of PTH-amino acids. Resolution of DOPA as its PTH derivative requires use of temperature jumps and solvent gradation (24).

The current high interest in oxidation-linked mechanism of disease (25) dictates that improved assay for oxidative stress be thoroughly explored. A systematic approach to develop a sensitive assay for routine analysis of oxidized amino acids discussed earlier is still lacking. Our laboratory is currently engaged in developing a technique to assay the chemical indicators of protein oxidation without relying on their intrinsic sensitivity. This report describes the analysis of induction of DOPA in peptides and proteins as a function of ionizing-radiation dose.

MATERIALS AND METHODS

Materials. Dns-Cl (5-dimethylaminonaphthalene-1-sulfonyl chloride), Dns-amino acids, L-DOPA, peptide TyrGlyGly, BSA (bovine serum albumin), and RNase A (ribonuclease A) were obtained from Sigma (St. Louis, MO). The standard amino acids and constant boiling 6 N HCl ampules were purchased from Pierce (Rockford, IL).

Eluents. HPLC grade solvents and analytical reagents (Baker analyzed) were used to prepare buffers for the various solvent systems used in the analysis (see figure legends). The working buffer (30 mM sodium phosphate, pH 6.5) was prepared daily from 0.3 M stock by dilution with double distilled, deionized water. All solvents were filtered through a Rainin nylon-66 filter (0.2 μ m) and degassed prior to use. A high-pressure inline filter (SSL, 0.5 μ m) was used as a further safeguard between the pump and the injector valve.

Apparatus. For most HPLC analysis, a microsorb C18 column (5 μ m, 4.6 mm i.d., 25 cm) and a HPXL pump from Rainin Instrument Co., Inc., to deliver the solvent (1 mL/min) were used with a Shimadzu fluorescence detector RF-530 to monitor the dansylated amino acids. For highly sensitive fluorescence detection, a fully programmable pump system from Rainin with a FL-750 B McPherson detector equipped with a high-sensitive accessory unit was used. In the McPherson detector the dansylated amino acids were irradiated at 365 nm with a xenon-mercury lamp. A typical spectrum of xenon-mercury shows 30% more output at 365 nm than at 340 nm, used commonly to excite dansylated derivatives. The dansylated amino acids, when scanned at stop flow mode, showed maximum emission at 520 nm. A Radial-Pak 8MBC18 cartridge (10 μ m, 8 mm i.d., 10 cm) from Waters and a variable-wavelength detector with an Altex spectrophotometer flow cell were used for isolation of a peak of interest from one 100 μ g sample per run.

A GE Maxitron 250 X-ray, operated at 240 KV, was used to irradiate the samples in distilled deionized water (0.33 mg/mL). Oxygen was bubbled through the solution for 20 min prior to and during the entire process of irradiation. When multidosages are needed from a sample to study the irradiation effect as a function of irradiation dose (1 Gy = 100 rad), aliquots were withdrawn during the irradiation so that the first withdrawn aliquot has zero dosage and the remaining aliquots have the sum of dosages up to the time each aliquot is withdrawn.

Hydrolysis of Peptide and Protein. Peptides and proteins were hydrolyzed with 6 N hydrochloric acid at 110° C in Millipore-Water's Pico Tag Work station following manufacturer's standard protocol. Typically

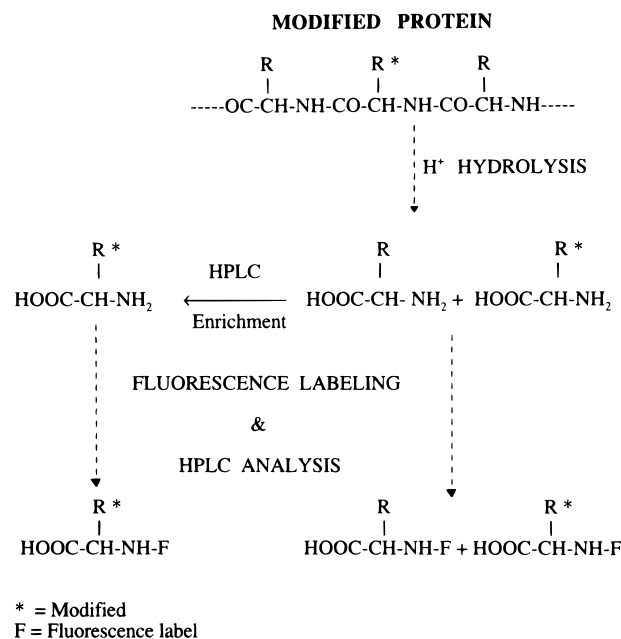

Figure 1. Schematic representation for assaying protein modification by fluorescence labeling.

5–10 μ g samples and 200 μ L of hydrochloric acid containing 1% (w/v) double distilled phenol were placed in the Pyrex sample vial (6 \times 50 mm, corning) and the reaction vial (pico tag), respectively. After 20 h the sample vials were placed in a clean reaction vial and left for 30 min under vacuum to dry the samples. We observed that the same procedure could be scaled up to 50 μ g per vial.

Dansylation of Amino Acids. The conditions for dansylation of amino acids were similar to those used by Tapuhi et al. (26) and Oray et al. (27). A Dns-Cl solution (4.5 mg/mL) was freshly prepared weekly with HPLC grade acetonitrile. The aqueous solutions of the amino acid mixture (1–10 nmol) and hydrolysates of peptides and proteins (0.1–1 nmol), after transferring from the hydrolysis vial to 1.5 mL Eppendorf tubes with 50 μ L of distilled deionized water, were lyophilized in a vacuum centrifuge. The residues were dissolved in 50 mM sodium borate buffer, pH 9.5. The ratio of Dns-Cl to buffer was 1:2, and the volume used varied according to the total concentration of Dns-susceptible amino groups present in the sample. The optimal conditions for the dansylation reaction were found to be at ratios of Dns-Cl to amino acids of 5:1 to 10:1 as reported (26). The reaction was carried at room temperature in the dark for 60 min. The reaction mixture was filtered on an ultrafree microcentrifuge unit (0.22 μ m) to remove any particulate material seen during dansylation. The filtrate was then subjected to HPLC analysis or stored at –22 °C until analyzed. The dansylated samples, as monitored by HPLC analysis, were found to be quite stable under these conditions.

RESULTS

Figure 1 outlines the scheme used for assaying DOPA in X-irradiated proteins. Briefly, modified protein is subjected to acid hydrolysis to release both normal and modified amino acids. The hydrolysate is labeled with Dns-Cl. Optimum elution conditions are devised to resolve the modified amino acid from the normal amino acids by HPLC using fluorescence detection. Alternately, the modified amino acid is enriched by HPLC, prior to dansylation, from the normal amino acids. The enriched

Figure 2. HPLC resolution of dansylated amino acids on a reversed phase C18 column (5 μ m, 4.6 mm i.d., 25 cm) using a 90 min linear gradient of 8–90% acetonitrile in 30 mM sodium phosphate, pH 6.5. Detection: excitation 340 nm, emission 520 nm. The peaks 1–20 correspond to Asp, Glu, Asn, Gln, Ser, Leu, Gly + Thr, Arg, Pro, Val, Met, Ile + Leu, Trp, Phe, Cys, Lys, Tyr, and DOPA, respectively.

amino acid is then labeled with Dns-Cl and analyzed by HPLC using fluorescence detection.

Figure 2 shows HPLC analysis of a mixture of dansylated amino acids. Except for Gly and Thr and Ile and Leu pairs, a 90 min linear gradient of 8–60% acetonitrile in 30 mM sodium phosphate buffer, pH 6.5, resolved all other amino acids including DOPA. Extension of the gradient from 90 to 120 min resolves the Gly and Thr pair (not shown). The reproducibility of the system was evaluated by injecting the mixture on different days. The average deviation of the retention times and areas were within 1% and 5%, respectively, $n = 5$.

Figure 3 shows the formation of DOPA from Tyr (top) and a modified peptide from the tripeptide Tyr-Gly-Gly (bottom) as a function of irradiation dose. The irradiated samples were labeled with Dns-Cl and analyzed by reversed-phase HPLC. A 50% solution of acetonitrile in 30 mM sodium phosphate, pH 6.5, under isocratic condition, and a 20 min linear gradient of 40–60% acetonitrile in the same buffer followed by a 20 min isocratic run with 60% acetonitrile were used to analyze the irradiation products formed from Tyr and Tyr-containing peptide, respectively. The percent modification of the peptide was calculated on the basis of the integrated peak area of the major modified peak shown in Figure 4 b. As described in the Materials and Methods, the samples (0.33 μ g/mL) were irradiated in aqueous solution in the presence of oxygen. The results shown in Figure 3 are an average of three separate runs from each dose used in the study.

Figure 4a shows the HPLC profile of the peptide (Gly-Gly-Tyr) prior to irradiation. The major modified peak shown in the profile from the irradiated peptide (see Figure 4b) was isolated by HPLC. Profiles c and d in Figure 4 show HPLC analysis of the precolumn derivatized acid hydrolysates from unmodified and modified peptides, respectively. The use of a 50 min linear gradient from 22 to 60% acetonitrile in phosphate buffer detected Gly, Tyr, and its modified amino acid in the

Figure 3. Formation of DOPA from Tyr (top) and a modified peptide from Tyr-Gly-Gly (bottom) as a function of irradiation dose (Gy).

dansylated hydrolysates. The identity of the peak at 36 min in the Figure 4d was confirmed as DOPA by cochromatography with authentic marker (results not shown). The amino acid composition of the peptides as Gly:Tyr (2:1) and Gly:DOPA (2:1) in profiles c and d showed that the major modified peptide in profile b resulted from conversion of the Tyr residue to DOPA during the irradiation. These results also support the stability of DOPA under the experimental conditions. The high level of recovery (>98%) of DOPA was also determined by adding a known amount of DOPA to the unmodified peptide prior to hydrolysis and HPLC analysis of the dansylated hydrolysate.

Figure 5 shows the HPLC profiles for assaying DOPA in (a) BSA as a control, (b) irradiated BSA, and (c) irradiated RNase A. The identities of peaks 1 and 2 in the profiles were confirmed as Tyr and DOPA by cochromatography of the postlabeled hydrolysate from irradiated RNase A with authentic Tyr and DOPA (see Figure 5d). The use of a 50% solution of acetonitrile in phosphate buffer as an eluent allowed the detection of Tyr and DOPA from the hydrolysate under isocratic conditions. Figure 6 shows analysis of Tyr modification to DOPA in RNase A (left) and BSA (right) as a function of irradiation dose. The percent formation of DOPA correlates with the percent modification of Tyr up to 120 Gy for both of the proteins. At higher doses (240 Gy), the yield of DOPA represents approximately 50% of Tyrosine modification. The recovery of most other amino

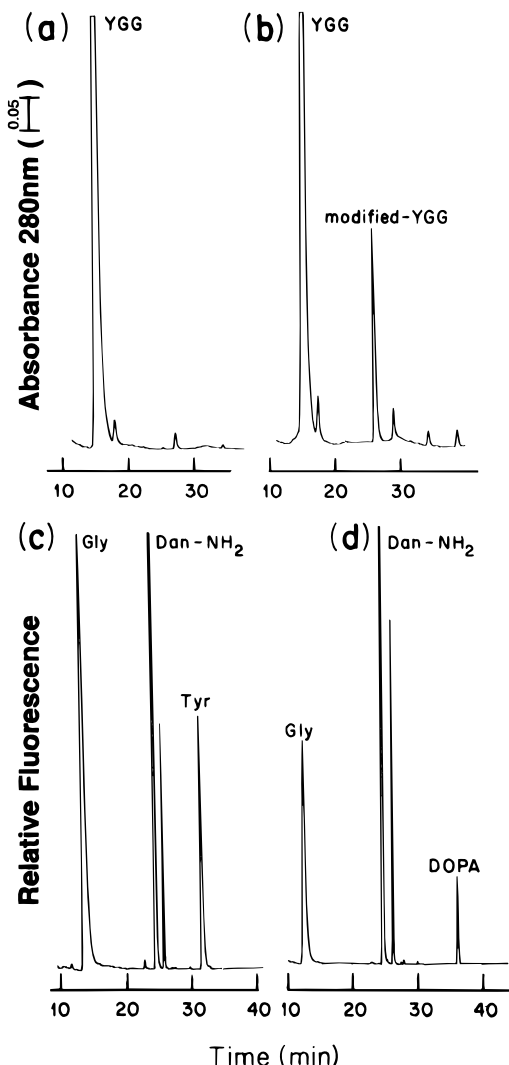

Figure 4. HPLC analysis of Tyr-Gly-Gly (a) and X-irradiated Tyr-Gly-Gly (b) on a Radial-Pak C18 cartridge using a 30 min linear gradient of 0–60% acetonitrile in 0.05% TFA; fluorescence labeling assay of Tyr-Gly-Gly (c) and modified-Tyr-Gly-Gly using a 50 min linear gradient of 22–60% acetonitrile in 30 mM phosphate buffer, pH 6.5.

acids also were affected 25–30% with respect to the control. For each dose, the same amount of dansylated hydrolysate (1.66 μ g) was analyzed under the conditions described in Figure 2. In agreement with the reported study (8) there was no change in valine content of the irradiated samples compared to the control. To correct for variation in protein content, tyrosine was normalized to valine content of an aliquot of original hydrolysate. The effect of each dose on Tyr content and subsequently on DOPA formation was determined from three separate experiments. The coefficient of variation was found to be 3% for DOPA and 5% for Tyr, respectively.

DISCUSSION

The scheme outlined in Figure 1 for protein modification assay involves the preparation and characterization of a modified amino acid of interest as an authentic marker. Determination of the effects of acid hydrolysis and labeling conditions on the stability of the marker and the quantitative labeling are some other considerations that require systematic investigation prior to application of the technique to study protein modification. In the present study, DOPA is available commercially and as discussed earlier was found to be quite stable to acid

Figure 5. Fluorescence labeling assay of (a) BSA, (b) X-irradiated BSA, (c) X-irradiated RNase A, and (d) cochromatography of c with authentic Tyr (peak 1) plus DOPA (peak 2) by reversed-phase HPLC using 50% acetonitrile solution in 30 mM phosphate buffer, pH 6.5.

hydrolysis conditions. Fluorescence labeling of DOPA with Dns-Cl was monitored by HPLC analysis of the labeling reaction mixture. Comparison of the integrated peak area with respect to a standard dansylated amino acid, showed quantitative labeling yield under the conditions used routinely for derivatization of standard amino acid. Successful application of the assay also depends on devising appropriate HPLC conditions to resolve the modified amino acids of interest from the standard amino acids. The chromatographic characteristic of the modified amino acid generated by subjecting a specific amino acid to a specific modification condition usually serves to identify the same lesion in protein exposed to the same condition. The identity of the peak of interest is confirmed further by cochromatography with authentic marker. Figure 2 shows the resolution of dansylated DOPA from the standard dansylated amino acids by reversed-phase HPLC. For those modified amino acids that do not resolve well from the standard amino acids, resolution could be improved by HPLC enrichment of the modified amino acids prior to labeling as outlined in the schematic representation of the assay (Figure 1). In this alternative procedure a fraction corresponding to the retention time of the authentic marker is collected during the HPLC analysis of the hydrolysate. The profile is monitored by UV absorption, usually at 280 nm. The collected fraction is lyophilized and labeled with Dns-Cl for sensitive detection of the peak of interest by fluorescence detector. Since most of the standard amino acids are eliminated during this procedure, HPLC analysis of the labeled amino acid can be carried out either isocratically or under a gradient system of short duration depending on the nature of modification of the amino acid. This approach will reduce background interference and improve detection limit substantially (28).

HPLC analysis of precolumn derivatized amino acids appears to be a valid alternative to classical ion-exchange chromatography with the subsequent postcolumn ninhydrin derivative (29). Precolumn derivatization of amino acid is performed using PTH, *o*-phthalaldehyde

(OPA), and Dns-Cl. The dansyl derivatives were selected for the present study because the quantitative preparation of the amino acid derivatives is easy and they are stable (26). The use of dansylated derivatives also avoids the loss of cysteine and proline which cannot be detected by the standard amino acid detection derivatives with OPA. Dansyl label has high quantum efficiency. Previously we reported sub-femtomole detection of dansylated nucleic acid by HPLC using laser-induced fluorescence detection (30). Separation of dansylated amino acid by HPLC has been reported earlier (27, 29, 31, 32). So far, all of the reported studies have dealt with the separation of standard amino acids. In a reported HPLC analysis using 30 mM phosphate buffer, pH 6.5, and acetonitrile, a complex three-step gradient was used for the separation of the standard dansylated amino acids (27). Using the same solvents Figure 2 shows resolution of 20 standard amino acids including one modified amino acid (DOPA) in a linear 90 min gradient. To our knowledge, this is the first report of analysis of a dansylated derivative of a modified amino acid.

Analysis of the major modified peak isolated from irradiated tripeptide Tyr-Gly-Gly validated the technique for DOPA analysis (Figure 4). The formation of DOPA could also be detected in the dansylated hydrolysate of the peptide before isolating the major modified peak from the hydrolysate. However, the peak was isolated to determine the amino acid composition which confirmed that the conversion of Tyr to DOPA was the major modification induced by ionizing radiation. The hydrophobicity and, as a result, the retention times of dansylated Gly differed considerably from those of dansylated Tyr and DOPA in reversed-phase HPLC analysis (see Figure 2). However, appropriate HPLC conditions were devised which allowed the determination of integrated peak ratios of Gly and Tyr in the unmodified and Gly and DOPA in the modified under the same conditions (Figure 4c,d).

Having validated the technique for assaying modified amino acid in the tripeptide, the model study was extended to detect the formation of DOPA in X-irradiated BSA and RNase A (Figure 5). BSA which contains several Tyr and two Trp residues is a representative protein model for oxidative modification (17). Ribonuclease A which lacks Trp has been subject of a number of radiobiological investigation due to its low molecular weight and known structure (33). The isocratic conditions chosen for the HPLC analysis shown in Figure 5 were convenient for rapid detection of tyrosine modification in the protein hydrolysates. However, for quantitative purposes, the samples were analyzed under the HPLC conditions described in Figure 2. The identities of peaks 1 and 2 in the profiles shown in Figure 5 were confirmed as Tyr and DOPA by cochromatography with authentic markers (Figure 5d). Figure 6 shows the formation of DOPA in RNase A (left) and BSA (right) as a function of irradiation dose. The results were obtained from analysis of 1.66 μ g of dansylated hydrolysates. The formula weight of RNase A is approximately five times less than that of BSA. In the same quantity of hydrolysate from each protein, the Tyr content was higher in RNase A than in BSA. In each case, as discussed earlier, the content of Tyr was normalized with respect to valine to determine the % modification.

Using a conventional fluorescence detector, we observed that the relationship of fluorescence signal and concentration of dansylated DOPA was linear from 1.5 nmol to 0.5 pmol with a correlation coefficient of 0.999, $n = 3$. This detection limit of fluorescence postlabeling assay of dansylated DOPA allows the detection of 1

Figure 6. Formation of DOPA in relation to Tyrosine content of X-irradiated RNase A (left) and BSA (right) as a function of irradiation dose (Gy).

molecule of DOPA/300 molecules of BSA in a 5 μ g protein sample. Dose-related appearance of protein-bound DOPA in BSA was reported by fluorometric detection (excitation, 280 nm; emission, 320 nm) using 10 times more sample and a dose range 230–920 Gy in the presence of oxygen (34). However, the present study shows that at doses higher than 120 Gy the percent of formation of DOPA does not correlate with the percent of modification of Tyr. When samples were irradiated with a dose range 200–600 Gy, a broad peak with a retention time longer than that of DOPA appeared, the intensity of which increased with dose at the expense of the DOPA peak (results not shown). Although the peak was not identified, such an observation combined with the generation of brownish yellow color seen in the irradiated samples suggests further transformation of DOPA with higher dose, leading perhaps to the formation of some polymeric material. Besides, the percent recoveries of most other amino acids in both the proteins were also affected 30% or more at 240 Gy.

Free DOPA and other reactive quinones have been implicated in a number of disease states (35). Protein-bound DOPA may have a role in the replenishment of reduced transition metal ion involved in a free-radical-generating system *in vivo* (36). This would result in amplification of the radical-damaging event that originally generated protein-bound DOPA. Since most standard amino acid analysis techniques are limited to detect normal residues of protein, sensitive assay of low-level oxidized amino acids implicated in protein oxidation will be useful for monitoring oxidative stress-related physiological and pathological processes.

Synthesis and Preliminary Biological Evaluation of (3-Iodobenzoyl)norbiotinamide and ((5-Iodo-3-pyridinyl)carbonyl)norbiotinamide: Two Radioiodinated Biotin Conjugates with Improved Stability

Catherine F. Foulon,* Kevin L. Alston, and Michael R. Zalutsky

Department of Radiology, Duke University Medical Center, Durham, North Carolina 27710. Received November 20, 1996[®]

A new class of radioiodinated biotin conjugates is described in which the amido bond between biotin and the labeled prosthetic group is reversed. One conjugate, (3-[¹²⁵I]iodobenzoyl)norbiotinamide (**4c**, [¹²⁵I]IBB) was labeled with Na¹²⁵I in one step from (3-(tributylstannyl)benzoyl)norbiotinamide (**4b**, TBB) via a demetalation reaction. However, the analogous reaction with ((5-(tributylstannyl)-3-pyridinyl)carbonyl)norbiotinamide (**6b**, TPB) failed to yield ((5-[¹³¹I]iodo-3-pyridinyl)carbonyl)norbiotinamide (**6c**, [¹³¹I]IPB), necessitating a two-step approach for synthesizing [¹³¹I]IPB. The binding of [¹²⁵I]IBB and [¹³¹I]IPB to streptavidin in vitro was identical to that of biotinyl-3-[¹²⁵I]iodoanilide, a conjugate with an amido bond with normal configuration. Both [¹²⁵I]IBB and [¹³¹I]IPB were stable in serum while the first-generation compound was rapidly degraded. The biodistribution patterns of [¹²⁵I]IBB and [¹³¹I]IPB in mice are consistent with limited degradation of these conjugates by biotinidase and deiodinases.

INTRODUCTION

The utilization of radiolabeled antibodies (MAbs)¹ for the localization and therapy of tumors has been impaired by the inability to achieve high tumor-to-normal tissue ratios in a time frame compatible with those of many radionuclides of potential clinical interest (1). Among the approaches being explored to circumvent this problem is pre-targeting, which involves separate administration of the MAb and the radionuclide. This strategy most frequently attempts to exploit the high affinity of biotin (1), a 244D vitamin found in low concentration in blood and tissues, for the 65 kD proteins avidin (2) or streptavidin (3). The feasibility of targeting radiolabeled biotin derivatives to (strept)avidin-conjugated MAbs previously localized on tumors was first demonstrated nearly a decade ago (4). The structural elements of biotin involved in binding to (strept)avidin are the urea moiety and the nonoxidized thioether (5), thus leaving the carboxylic group available for modification. For this reason, radio-labeled biotin derivatives generally have been prepared by direct functionalization of the carboxyl group of the vitamin, resulting in a CO–NH amido bond (Scheme 1).

This tactic, designated as First Generation, has been utilized to prepare biotin conjugates labeled with a wide variety of radionuclides including ^{123/125/131}I (6–9), ¹⁸F (10), ²¹¹At (11), ⁹⁰Y (12), ¹¹¹In (13, 14), ⁶⁷Ga (15), and ^{99m}Tc (16). Although most of these derivatives maintain a high

Scheme 2. Preparation of Third-Generation Biotin Derivatives^a

^a (i) *t*BuOH, TEA, diphenylphosphoryl azide. (ii) DMF, water, TEA. (iii) Na¹³¹I, NCS, CHCl₃, AcOH, 65 °C, 10 min. (iv) Na^{125/131}I, NCS, MeOH, Na₂S₂O₅, room temperature, 20 s.

affinity for (strept)avidin and have good stability in vitro, direct and indirect evidence suggests that these radiolabeled biotin conjugates are rapidly metabolized in vivo. The catabolic pathways involved include oxidation of the sulfur, cleavage of the valeryl chain, loss of the radiolabel, and cleavage of the radiolabeled prosthetic group by the action of biotinamide amino hydrolase (EC 3.5.1.12, biotinidase) (17). Avoiding biotinidase degradation has been attempted previously by introducing steric hindrance at the level of the amido bond, depicted in Scheme 1 as Second Generation (18, 19).

In this study, we have evaluated two radioiodinated biotin conjugates which have been designed to be resistant to degradation by both biotinidase and deiodinases. We attempted to impair recognition by biotinidase through the use of a reversed amido bond (i.e., NH–CO bond) between the valeryl chain of biotin and the prosthetic group, depicted in Scheme 1 as Third Generation. The templates used for radioiodination were selected on the basis of our previous experience with *N*-succinimidyl 3-iodobenzoate (**3a**, SIB) and *N*-succinimidyl 5-iodo-3-pyridinecarboxylate (**5c**, SIPC) as depicted on Scheme 2 (20–22). MAbs labeled via these reagents exhibited very low levels of deiodination in vivo and yielded labeled catabolites which were rapidly excreted via the urine, two properties of interest for improved radioiodinated biotin conjugates. (3-[¹²⁵I]Iodobenzoyl)norbiotinamide (**4c**, [¹²⁵I]-IBB) was prepared in one step from (3-(tributylstannyl)-benzoyl)norbiotinamide (**4b**, TBB) via a demetalation reaction. However, the analogous reaction of ((5-(tributylstannyl)-3-pyridinyl)carbonyl)norbiotinamide (**6b**, TPB) failed to yield ((5-[¹³¹I]iodo-3-pyridinyl)carbonyl)norbiotinamide (**6c**, [¹³¹I]IPB) necessitating a two-step approach for synthesizing [¹³¹I]IPB. We chose to radiolabel each of these compounds with a different isotope of iodine in order to evaluate their in vitro and in vivo biological properties simultaneously, by paired-label experiments. Both [¹²⁵I]IBB and [¹³¹I]IPB exhibited good stability and streptavidin binding, in vitro, and tissue distribution profiles in mice consistent with limited degradation by biotinidase and deiodinases.

EXPERIMENTAL PROCEDURES

Materials. Streptavidin was purchased from Sigma Chemical Co. St. Louis, MO, and all other chemicals were obtained from Aldrich, Milwaukee, WI. Norbiotinamine hydrochloride (**2**) was purchased from Molecular Probes, Eugene, OR, for preparing the radiohalogenated conjugates, whereas crude **2**, prepared as reported by Szalecki (23), was utilized for the synthesis of standards. *N*-Succinimidyl 3-iodobenzoate (SIB, **3a**), *N*-succinimidyl 3-(tributylstannyl)benzoate (**3b**), *N*-succinimidyl 5-bromo-3-pyridinecarboxylate (SBrPC, **5a**) and *N*-succinimidyl 5-(tributylstannyl)-3-pyridinecarboxylate (**5b**) were prepared as described in previous publications (21, 24). Biotinyl-3-[^{125/127}I]iodoanilide ([^{125/127}I]IBA) was prepared according to a previously reported procedure (25). Sodium [¹²⁵I]iodide and sodium [¹³¹I]iodide in 0.1 N NaOH were obtained from Dupont New England Nuclear, Billerica, MA. tC18 cartridges were purchased from Waters, Milford, MA.

HPLC purifications were conducted on a Beckman system (Model 126 pump, Model 168 UV detector, Model 170 radioactivity detector) connected to a Model 406 analog interface module. Chromatography was performed using either a reverse-phase column (Adsorbosphere C18, 10 μm, 250 × 4.6 mm, eluted with methanol: water, 55:45 at 1 mL/min) or a normal-phase column (Adsorbosphere Silica, 10 μm, 250 × 4.6 mm, eluted with hexane:ethyl acetate:acetic acid, 65:34.3:0.7 at 1 mL/min), both obtained from Alltech, Deerfield, IL. TLC was performed on silica gel IB2-F Baker-Flex sheets (J.T. Baker, Phillipsburg, NJ). Silica gel impregnated glass fiber ITLC plates were purchased from Gelman Science, Ann Arbor, MI, and cut in 1.5- × 8-cm strips. Radioactivity was quantified using a LKB 1282 Compugamma dual-channel, automated γ counter. Higher levels of activity were measured using a Capintec CRC-7R radioisotope calibrator. Elemental analyses were performed by Atlantic Microlab, Norcross, GA. ¹H NMR spectra were recorded on a General Electric Midfield 300 MHz spectrometer.

Norbiotinamine (2). This product was prepared as described by Szalecki (23). Briefly, to a flask (predried at 110 °C for 48 h) containing biotin (**1** (0.49 g, 2.01 mmol) dissolved in 20 mL of *tert*-butyl alcohol were added diphenylphosphoryl azide (475 μL, 2.21 mmol) and triethylamine (308 μL, 2.21 mmol). The reaction mixture was refluxed for 18 h under argon atmosphere, the solvent removed by rotative evaporation, and the oily residue dissolved in a 50% methanolic solution of 6 N HCl (20 mL) and stirred overnight. Solvents were removed using a vacuum pump, affording an oil (1.84 g) which was not purified further before reaction with the *N*-succinimidyl ester **3a**, **3b**, **5a**, or **5b**.

Preparation of IBB (4a), TBB (4b), BrPB (6a), and TPB (6b): General Procedure. The crude oil **2** was dissolved in DMF:water (4:1), and the pH was made basic using triethylamine. The *N*-succinimidyl ester derivative **3a**, **3b**, **5a**, or **5b** (1.2 equiv) in DMF was added to the above mixture and stirred at room temperature for at least 3 h. The reaction was monitored by TLC (chloroform:methanol, 6:1). The solvent was removed by rotative evaporation and the product subjected to column chromatography (silica gel, chloroform:methanol, 6:1). The desired fractions were pooled, evaporated to dryness, and recrystallized in DMF:H₂O (1:1). The white crystals thus obtained were filtered off and further dried under vacuum. The products were stored under argon at 4 °C.

(3-Iodobenzoyl)norbiotinamide (IBB, 4a). IBB was obtained as white crystals, in 18.3% yield. *R_f* (TLC)

M_p = 154–155 °C.

((5-Bromo-3-pyridinyl)carbonyl)norbiotinamide (BrPB, 6a). BrPB was afforded as white crystals, in 14.5% yield. R_f (TLC) = 0.39. Anal. Calcd for $C_{15}H_{19}N_4O_2SBr$: C, 45.12; H, 4.80; N, 14.03. Found: C, 45.19; H, 4.80; N, 13.95. 1H NMR (DMSO- d_6) δ (ppm): 8.85 (s, 1H, ArH2), 8.74 (d, 1H, ArH6), 8.61 (t, 1H, NHCO), 8.29 (s, 1H, ArH4), 6.36 (s, 1H, NHCO), 6.27 (s, 1H, NHCO), 4.20 (q, 1H, CHN), 4.05 (t, 1H, CHN), 3.15 (d, 2H, CH_2N), 3.00 (m, 1H, SCH), 2.71 (m, 2H, SCH_2), 1.42–1.28 (m, 6H, $(CH_2)_3$). M_p = 227–228 °C.

((5-(Tributylstannyl)-3-pyridinyl)carbonyl)norbiotinamide (TPB, 6b). TPB was obtained as white crystals, in 24% yield. R_f (TLC) = 0.55. Anal. Calcd for $C_{27}H_{46}N_4O_2SSn$: C, 53.21; H, 7.61; N, 9.19. Found: C, 53.11; H, 7.56; N, 9.10. 1H NMR (DMSO- d_6) δ (ppm): 8.83 (s, 1H, ArH2), 8.61 (s, 1H, ArH6), 8.56 (m, 1H, NHCO), 8.14 (s, 1H, ArH4), 6.39 (s, 1H, NHCO), 6.29 (s, 1H, NHCO), 4.24 (m, 1H, CHN), 4.07 (m, 1H, CHN), 3.15 (m, 2H, CH_2N), 3.05 (m, 1H, SCH), 2.78 (m, 2H, SCH_2), 1.46–0.80 (m, 33H, 3 nBu + $(CH_2)_3$). M_p = 134–138 °C.

***N*-Succinimidyl 5-[^{131}I]Iodo-3-pyridinecarboxylate ([^{131}I]SIPC, 5c).** To a vial containing $Na^{131}I$ (1 mCi) were added acetic acid:chloroform [5:95 (10 μ L)], *N*-chlorosuccinimide (10 μ L, 13.3 mg/mL of chloroform), and **5b** (10 μ L, 5 mg/100 μ L of chloroform). The vial was vortexed, and the reaction was allowed to proceed at 65 °C for 10 min. The product **5c** was isolated by HPLC (normal-phase column eluted with hexane:ethyl acetate:acetic acid, 65:34.3:0.7, at 1 mL/min). The product eluting at 14 min was concentrated under a stream of nitrogen and used directly for the next reaction.

Preparation of [^{131}I]IPB (6c). A solution of commercial **2**-HCl in pH 8.5 borate buffer (200 μ L, 2 mg/mL) was added to a vial containing 500 μ Ci of [^{131}I]SIPC **5c**. The reaction was performed at room temperature for 20 min, and the sample was purified on HPLC (C18 column, 55% methanol, 1 mL/min). The desired product was collected at 6.4 min and concentrated by elution through a tC18 cartridge; [^{131}I]IPB was isolated in 0.5 mL of methanol. The solvent was evaporated under a stream of nitrogen, and **6c** was reconstituted in water for use in the in vitro and in vivo studies. Radiolabeling yields ranged between 75 and 82%.

Preparation of [^{125}I]IBB (4c). $Na^{125}I$ (500 μ Ci) was added to a vial containing TBB (**4b**) (100 μ g in 100 μ L of methanol) along with *N*-chlorosuccinimide (20 μ L, 2 mg/mL of methanol). The vial was vortexed for a maximum of 20 s, and a saturated aqueous solution of sodium metabisulfite was added (2 \times 200 μ L). The product was purified on HPLC (C18 column, 1 mL/min, 55% MeOH), and **4c** was collected at 8.9 min. After evaporation, **4c**

was dissolved in 10 mL of water and concentrated on a tC18 cartridge; [^{125}I]IBB was collected in 0.5 mL of methanol, which was evaporated under a stream of nitrogen. The radiolabeling yields averaged 62%. The product was stored in methanol at 4 °C and was stable for up to 1 week.

In Vitro Binding to Streptavidin. The in vitro binding of the radioiodinated biotin derivatives to streptavidin was assessed. A constant activity (4 μ Ci in 100 μ L of distilled water) of [^{125}I]IBB, [^{131}I]IPB, or [^{125}I]IBA was mixed with increasing amounts of streptavidin (0–50 μ g, 100 μ L of distilled water) in a 1.5-mL polypropylene conical vial. The vials were placed on an orbital shaker and incubated at 37 °C for 5 h, and a 5- μ L aliquot was removed for analysis by silica gel ITLC. The plates were eluted with distilled water:ethanol (1:1). The radioiodinated biotin–streptavidin complex stayed at the origin whereas the free biotinylated compound moved with the solvent front. Each plate was cut horizontally, 1.5 cm above the origin, and the activity levels in the two parts were quantified. The percentage of radioiodine activity associated with the biotin–streptavidin complex was calculated as follows: the activity at the baseline multiplied by 100, divided the activity at the baseline and on the upper part of the plate.

In Vitro Stability in Serum, Cerebrospinal Fluid (CSF), and Distilled Water. A mixture of [^{125}I]IBB and [^{131}I]IPB (4 μ Ci each in a total volume of 20 μ L of distilled water) was incubated at 37 °C in 1.5-mL polypropylene centrifuge tubes with 200 μ L of either mouse serum, human serum, human CSF, or distilled water. An additional experiment was performed in single-label format to measure the stability of [^{125}I]IBA (4 μ Ci per tube). All measurements were performed in triplicate. The stability of [^{125}I]IBB and [^{131}I]IPB was monitored over 24 h by silica gel TLC eluted with chloroform:methanol (90:10). Plates were covered with tape to prevent the loss of volatile species. At each time point, an aliquot (4 μ L) from each tube was co-spotted on TLC with the appropriate cold standard; IBB, BrPB, and IBA had R_f values of 0.55, 0.48, and 0.51, respectively, under these conditions. The plates were cut into three sections: part A, below the spot of the cold standard, where the sulfoxide byproducts (R_f = 0.30) migrate, part B, with an R_f corresponding to the cold standard, and part C, with R_f greater than the cold standard, where iodide (R_f = 0.95), iodobenzoic acid, bromonicotinic acid (both R_f = 0.80), and 3-iodoaniline (R_f = 0.81) are found. The TLC sections were counted for radioactivity in the γ counter using a dual- or single-channel program as appropriate. The percentage of intact radioiodinated biotin conjugate was calculated from the following ratio: (activity in part B)/(activities in parts A + B + C) multiplied by 100.

Tissue Distribution. A paired-label experiment was performed to compare the tissue distribution of [^{125}I]IBB and [^{131}I]IPB. Normal BALB/c mice weighting 20–25 g were injected intravenously with [^{125}I]IBB (5 μ Ci, 100 μ L of saline) and [^{131}I]IPB (5 μ Ci, 100 μ L of saline). Groups of five animals were euthanized by halothane overdose at 5, 30, and 60 min as well as 6, 12, and 18 h. The organs were weighted and the ^{125}I and ^{131}I activity levels counted in the γ counter using a dual-channel program. The percentage of injected dose localized per organ was calculated; blood, muscle, and bone were assumed to account for 6%, 40%, and 10% of body weight, respectively. Statistical analysis of the differences between ^{125}I and ^{131}I tissue levels was performed using a paired *t*-test with P < 0.05 considered to be significant.

Figure 1. In vitro binding of [^{125}I]IBB, [^{131}I]IPB, and [^{125}I]IBA to streptavidin as a function of streptavidin concentration.

RESULTS

Radiochemical Synthesis. The preparation of [^{125}I]IBB was readily accomplished by destannylation of TBB using Na^{125}I and *N*-chlorosuccinimide as the oxidant. The total time required for synthesis and purification was 40 min with an average yield of 62%. The sulfoxide byproduct also was produced in 2–10% yield but was removed by HPLC. [^{125}I]IBB was identified by coelution with an authentic IBB standard at 8.9 min. No peak corresponding to IBB was observed by the UV detector during HPLC purification, consistent with the preparation of [^{125}I]IBB at the no-carrier-added level. Attempts to prepare [^{131}I]IPB in a one-step fashion from TPB using the same conditions were not successful. Modifying the reaction conditions through the use of other oxidants (iodogen, hydrogen peroxide), acid (acetic acid, hydrochloric acid), and elevated temperature (65 °C) were fruitless. Hence, a two-step procedure was utilized for the synthesis of [^{131}I]IPB. First, [^{131}I]SIPC was prepared from **5b** and isolated by HPLC in an average yield of 60%. This intermediate then was reacted in alkaline medium with commercial norbiotamine hydrochloride, and the reaction mixture was subjected to HPLC. The yield for this step was 80%. The identity of [^{131}I]IPB was established by coelution with a BrPB standard (6.4 min). With these reaction conditions, the sulfoxide byproduct was not produced. The lack of cold peak on the UV trace corresponding to IPB during HPLC purification is consistent with preparation of [^{131}I]IPB at the no-carrier-added level. Both [^{131}I]IPB and [^{125}I]IBB were stable for at least 1 week when stored in methanol at 4 °C.

Binding to Streptavidin In Vitro. The binding of [^{125}I]IBB and [^{131}I]IPB to streptavidin was evaluated in vitro in order to determine whether inversion of the amido bond impaired the affinity of these conjugates for streptavidin. Instant thin layer chromatography (ITLC) was used to separate bound and unbound radioligand, and [^{125}I]IBA was tested under identical conditions as a control. As shown in Figure 1, binding saturation curves for the three biotin derivatives were nearly identical. For example, in the presence of 50 μg of streptavidin, the percentage of radioligand bound was $88.5 \pm 1.0\%$ for [^{125}I]IBB, $84.7 \pm 0.1\%$ for [^{131}I]IPB, and $83.8 \pm 6.3\%$ for [^{125}I]IBA, indicating that inversion of the amido bond did not interfere with binding to streptavidin.

In Vitro Stability. The in vitro stability of the three radioiodinated biotin conjugates was compared following incubation with mouse serum, human serum, human CSF, and distilled water at 37 °C. Essentially all of the radioiodine activity remaining associated with intact [^{125}I]IBB, [^{131}I]IPB, and [^{125}I]IBA in distilled water (Figure 2A), CSF (Figure 2B) and human serum (Figure 2C). The stability of [^{125}I]IBB and [^{131}I]IPB was evaluated for 6 days, and in these three media, 90% or more of the radioactivity remained associated with the conjugate for 4 days. With time, an increasing fraction of radioiodine activity was found in the lower part of the TLC plate, consistent with the R_f of the sulfoxide byproducts. The activity at the top of the TLC plate reflects either the cleavage of the prosthetic group or deiodination. With the exception of the value measured for [^{125}I]IBB in human serum at 3 days ($3.4 \pm 2.6\%$), less than 2% of the activity eluted in the top part of the TLC plate. More striking differences were observed in murine serum (Figure 2D). The first-generation compound, [^{125}I]IBA, was degraded rapidly, with only $38.4 \pm 1.5\%$ and $14.2 \pm 1.6\%$ remaining after 30 min and 6 h, respectively. Most of the radioactivity ($61.1 \pm 1.4\%$, 30 min; $83.7 \pm 1.2\%$, 6 h) was found at the top of the TLC plate. In contrast, the percentage of radioiodine activity remaining as [^{125}I]IBB and [^{131}I]IPB in mouse serum at 6 h was $99.2 \pm 0.5\%$ and $97.9 \pm 0.4\%$, respectively. By 4 days, these values had decreased to $86.0 \pm 2.0\%$ and $88.2 \pm 2.5\%$. The percentage of activity moving to the top of the TLC plate was significantly higher from day 1 to 6 for [^{125}I]IBB (1.5 to 3.3%) than for [^{131}I]IPB (0.05 to 0.6%).

Tissue Distribution. The tissue distribution in normal mice of [^{125}I]IBB and [^{131}I]IPB was investigated in a paired-label experiment, and the results are presented in Table 1. Both compounds were cleared rapidly from the blood, with less than 1% of the injected dose remaining at 1 h. Although total recovery of urine was not performed, the level of activity in the urine sample obtained at necropsy was 22–26% at 1 h, suggesting rapid excretion of both tracers. Thyroid levels of ^{125}I and ^{131}I were less than 0.25% at all time points, consistent with a low degree of deiodination for both conjugates. Both [^{125}I]IBB and [^{131}I]IPB cleared rapidly from most normal tissues; however, retention of ^{131}I was significantly lower ($P < 0.05$, paired *t*-test) than that of ^{125}I in liver, spleen, lungs, heart, kidneys, and blood at most time points. High levels of both biotin conjugates were observed in the intestines during the first hour after injection; however, by 18 h, less than 1% of the injected dose remained in the intestines. The %ID in the intestines for [^{131}I]IPB was higher than that for [^{125}I]IBB with these differences being significant at all time points.

DISCUSSION

Antibody-mediated pre-targeting is an attractive strategy for the selective delivery of radionuclides to tumors because it attempts to exploit the specificity of the Mab without the disadvantages associated with its macromolecular size, namely slow blood clearance and poor diffusion. Multistep approaches have evolved which utilize the biotin–(strept)avidin system, with or without clearing agent, to improve target-to-normal tissue ratios. Encouraging results have been obtained in both diagnostic and therapeutic trials in patients (16, 26, 27) and animal models (1, 13). Efforts are underway to improve pre-targeting through the optimization of each component of this strategy, including the nature of the MAb–streptavidin conjugate, the clearing agent and the radiolabeled biotin derivative (12, 28).

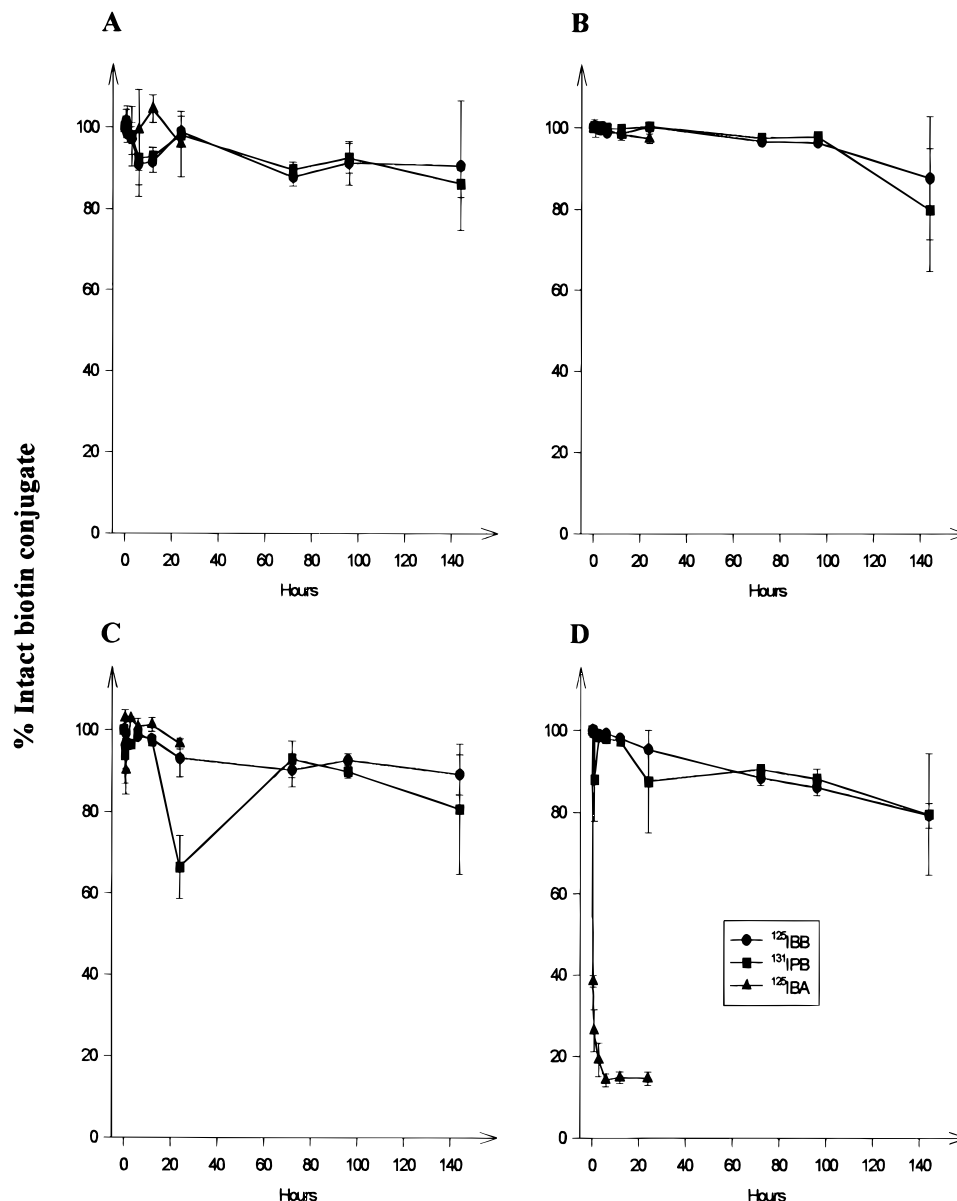

Figure 2. Profiles of metabolites of $[^{125}\text{I}]\text{IBB}$, $[^{131}\text{I}]\text{IPB}$, and $[^{125}\text{I}]\text{IBA}$ after incubation in distilled water (A), human CSF (B), human serum (C), and murine serum (D).

The goal of the current study was to develop a better radioiodinated biotin conjugate for use in pre-targeting. Two conjugates have been evaluated with regard to the following criteria: (a) ease of radiosynthesis, (b) retention of binding to streptavidin, (c) stability toward dehalogenation and degradation by biotinidase, and (d) clearance of activity from normal tissues.

The design of radiolabeled biotin conjugates is facilitated by the considerable amount of information available concerning the structural elements of biotin which are involved in binding to (strept)avidin as well as processing by biotinidase. Binding of the vitamin to (strept)avidin occurs via the interaction of its ureido moiety with five amino acids on these proteins (Asp 128, Asn 23, Ser 27, Tyr 43, and Ser 45) and its nonoxidized sulfur to Thr 90 (29) (Scheme 1). Thus, the carboxylic group is available to react with a wide variety of compounds, including radiolabeled prosthetic groups. However, since hydrogen bonds are established between the sp^2 oxygen and the hydroxyl group of biotin and Asn 49 and Ser 88, respectively (29), radiolabeled biotin conjugates in which these functionalities are modified can lose their potency for binding to (strept)avidin (10, 30).

A wide variety of first-generation radiolabeled biotin conjugates have been synthesized via an amino residue on the prosthetic group, resulting in the formation of a CO-NH amido bond (Scheme 1). Alkyl chain or aromatic group spacers have been used to bridge the vitamin and metal-labeled chelate conjugates (15, 16, 28, 30) or halogen-labeled prosthetic groups (6–11). Most of these biotin derivatives exhibit a good affinity for streptavidin; however, it does not appear that these conjugates remain intact after exposure to biological fluids in vitro or administration in vivo. For example, the biotinyl-3-halogenoanilides $[^{125}\text{I}]\text{IBA}$ and $[^{211}\text{At}]\text{AtBA}$ are rapidly converted to their corresponding haloanilines in murine serum in vitro (11), suggesting that cleavage of the CO-NH amido bond had occurred.

The rapid degradation of biotin conjugates such as $[^{125}\text{I}]\text{IBA}$ most likely reflects the actions of biotinamide amino hydrolase (EC 3.5.1.12, biotinidase). This enzyme specifically cleaves the CO-NH amido bond between the vitamin and the amino group of ϵ -lysyl residues of four classes of biotin-dependent carboxylases or nutritive proteins (31). Previous efforts to design more stable radiolabeled biotin derivatives by impairing the action

^a IV injection, mean ± standard deviation of five animals (sm. int., small intestine; lar. int., large intestine).

of biotinidase have focused on generating steric hindrance at the level of the amido bond (Scheme 1), either by substitution on the carbon in the vicinal position of the nitrogen (15, 19) or by methylation of the nitrogen itself (19).

Herein, we describe an alternate approach for the preparation of a more stable radiohalogenated biotin conjugate in which the amido bond between the vitamin and the prosthetic group is reversed (i.e., NH–CO bond, Scheme 1). To accomplish this, it was necessary to modify the vitamin such that a primary amino group be present. The extension of the alkyl chain via reaction with a diamino spacer was not suitable since this would lead to a first-generation compound. Therefore, we decided to transform the terminal carboxylic group of biotin into a primary amine. Although this compound, norbiotamine **2**, is now commercially available, we followed a recently published procedure (23) to prepare **2** from biotin. Isolation of the amino derivative from the starting material was problematic since both display the same polarity and lack UV absorbance. We proceeded directly to the coupling of **2** to the active esters (Scheme 2). Once the biotin moiety was coupled to the benzoyl or pyridyl group, the resulting product became UV absorbing, facilitating its purification using column chromatography. We were then able to prepare the two halogenated cold standards, IBB and BrPB, in adequate yield. The brominated analogue of SIPC, previously established as a valid substitute for the iodinated derivative (21), was used for convenience.

The sensitivity of biotin to oxidizing agents has been documented previously and has long prevented the direct radioiodination of biotin conjugates due to concerns about the production of non-avidin-binding sulfoxide byproducts (32). However, we have shown recently that the kinetics of iododestannylation occur faster than those of oxidation

and that the formation of the sulfoxide byproducts can be minimized by using a 20 s reaction time (25). Under these conditions, [¹²⁵I]IBB could be synthesized in about 60% yield in a single step from TBB along with 0–10% of the sulfoxide byproducts (which can be removed by HPLC). Synthesis of [¹³¹I]IPB from TPB in a single step could not be accomplished. This is not surprising since, unlike SIB, radioiododestannylation of SIPC requires elevated temperatures (21). Nonetheless, synthesis of [¹³¹I]IPB was readily achieved in two steps. An advantage of this procedure is that it avoids direct exposure of biotin to the oxidant *N*-chlorosuccinimide, and as a result, only negligible amounts of sulfoxide byproducts were produced. Disadvantages include the longer preparation time and the need for different columns and solvents for the two HPLC purification steps that are required.

The binding of [¹²⁵I]IBB and [¹³¹I]IPB to streptavidin was measured in vitro to determine whether inversion of the amido bond altered this interaction. This was a potential concern because the side chain of the biotin molecule is involved in streptavidin binding (29) and modifications of this side chain have been shown to influence the affinity of the biotin–avidin interaction (7). Our results indicate that [¹²⁵I]IBB and [¹³¹I]IPB binding to streptavidin was saturable and virtually identical with that of [¹²⁵I]IBA, a biotin analogue which we previously have shown to have the same affinity for streptavidin as biotin itself (25).

The in vitro stability of [¹²⁵I]IBB and [¹³¹I]IPB was compared to that of the first-generation biotin conjugate, [¹²⁵I]IBA, in the presence of distilled water, murine and human serum, and human CSF. Biotinidase levels in CSF are about 0.5% of those encountered in serum (33), and this medium was studied because of the potential for utilizing radiohalogenated biotin conjugates in the treatment of neoplastic meningitis (34). All three radio-

iodinated biotin conjugates were stable in distilled water and CSF with minor degradation seen in human serum. In murine serum, degradation of [^{125}I]IBA was rapid while both [^{125}I]IBB and [^{131}I]IPB remained intact. Even after 4 days incubation in murine serum at 37 °C, more than 85% of the radioiodine activity was still associated with [^{125}I]IBB and [^{131}I]IPB. Furthermore, nearly all of the remainder of the activity was present as the sulfoxide byproduct. These results suggest that inversion of the amido bond markedly increased the stability of [^{125}I]IBB and [^{131}I]IPB in murine serum, presumably by minimizing recognition of these conjugates by biotinidase.

The tissue distribution of radioiodine activity after injection of [^{125}I]IBB and [^{131}I]IPB was measured in normal mice. Thyroid uptake of both conjugates was low and at comparable levels to those observed previously with analogously labeled MAb conjugates (20–22, 35). The percentage of the injected dose of [^{125}I]IBB and [^{131}I]IPB found in the thyroid was about 5 times lower ($P = 0.0012$) than that reported for [^{125}I]IBA (11). Both [^{125}I]IBB and [^{131}I]IPB cleared rapidly from the blood pool and normal tissues as would be anticipated for these low-molecular-weight compounds. The retention of [^{131}I]IPB in normal tissues generally was lower than that of [^{125}I]IBB. This behavior is consistent with the lower lipophilicity and more rapid tissue clearance of 5-iodonicotinic acid compared with 3-iodobenzoic acid (21, 35).

In contrast to levels seen in other normal tissues, a high percentage of the injected dose of [^{125}I]IBB and [^{131}I]IPB was observed in the intestines at early time points. These levels were two to three times higher ($P = 0.0001$) than those seen previously with [^{125}I]IBA. Only limited information is available concerning the intestinal uptake of other radiolabeled biotin conjugates since published studies have not included data for intestines (10, 30). The accumulation of radioactivity in intestines with [^{125}I]IBB and [^{131}I]IPB could reflect the behavior of a labeled catabolite of these conjugates; however, neither 3-iodobenzoic acid nor 5-iodonicotinic acid (nor their MAB conjugates) exhibit significant accumulation in the intestines (20–22, 35). A more likely explanation is that this tissue distribution pattern reflects the behavior of radioiodinated biotin itself, since this new generation of derivatives is not subjected to cleavage by serum biotinidase. This possibility is consistent with the known biosynthetic pathways of vitamins, including biotin (36), and the demonstration of biotin uptake and biotinidase activity in the intestines (37, 38).

In conclusion, we have described the synthesis and biological characterization of a new class of biotin conjugates in which the labeled prosthetic group is linked to biotin via a reversed amido bond. The two radioiodinated conjugates [^{125}I]IBB and [^{131}I]IPB exhibited a high affinity for streptavidin and were found stable in vitro. The distribution of these compounds in normal mice was consistent with that anticipated for biotin conjugates which were resistant to both deiodination and the action of biotinidase. Taken together, these results suggest that this class of biotin conjugates may offer significant advantages for pre-targeting strategies.

ACKNOWLEDGMENT

The excellent technical assistance of Susan Slade is gratefully acknowledged. This work was supported by National Institutes of Health Grants CA42324, NS20023, and CA14236 and Grants 95ER62021 and 96ER62148 from the Department of Energy.

Chemoenzymatic Synthesis and Lectin Binding Properties of Dendritic *N*-Acetyllactosamine

Diana Zanini and René Roy*

Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5.

Received September 5, 1996[©]

Proof that multivalency amplifies individual carbohydrate–protein interactions is growing. *N*-Acetylglucosamine (GlcNAc)-based dendrimers with valencies of two (**9**), four (**10**), and eight (**11**) were prepared in fair to excellent yields (65–99%) on the basis of the rational scaffolding of L-lysine on solid phase using established Fmoc and HOBt chemistry. These GlcNAc dendrimers were then further transformed enzymatically (79–90% yields) into dendritic *N*-acetyllactosamine (LacNAc) derivatives [di- (**12**), tetra- (**13**), and octavalent (**14**)] using UDPglucose, UDP-glucose 4'-epimerase, and GlcNAc β -1,4-galactosyltransferase. GlcNAc and LacNAc dendrimers were used to inhibit lectin–porcine stomach mucin interactions. Wheat germ agglutinin and *Erythrina cristagalli* lectin were used for GlcNAc and LacNAc dendrimers, respectively. Di-, tetra-, and octavalent GlcNAc dendrimers exhibited IC₅₀s of 3100, 509, and 88 μ M (6200, 2040, and 703 μ M, with respect to monomeric GlcNAc content). IC₅₀s for the LacNAc series were 341, 143, and 86 μ M (682, 574, and 692 μ M, as compared with monomeric LacNAc content). These data represent more than 20-fold increases in inhibitory potential for dendritic GlcNAc as compared to that for monomeric GlcNAc. Studies with *E. cristagalli* do not reveal significant increased inhibitory potential with multivalency.

INTRODUCTION

Carbohydrates are involved in numerous biological functions, including cellular recognition, adhesion, cell growth regulation, cancer cell metastasis, and inflammation (*1*). However, it is known that individual carbohydrate–protein interactions are generally of low affinity (*2*). It is therefore important to investigate how such weak carbohydrate–protein interactions can be amplified in successful recognition processes. In fact, amplified interactions can be observed on the basis of the glycoside cluster effect (*3*). That is, the multivalent nature of cell surface carbohydrates may act cooperatively to increase the overall binding avidity of these interactions. Evidence for the requirement of multivalency for tight binding is growing. Glycopolymers (*4*) and, more recently, glycodendrimers (*5*) have been used to show that inhibitory potencies of glycosides are increased when carbohydrates are properly presented in multivalent form. This multivalency or cluster effect has been well characterized for asialoglycoprotein hepatic receptors (*6*) and for the inhibition of influenza virus attachment to host sialylated receptors (*4, 5*).

N-Acetyllactosamine [*O*-(β -D-galactopyranosyl)-(1–4)-2-acetamido-2-deoxy-D-glucopyranose; Gal β (1–4)GlcNAc, LacNAc] is well known as a biologically important disaccharide core structure of lactosaminoglycans, tumor-associated antigenic carbohydrates, and many carbohydrate receptors in glycoproteins and glycolipids (*7, 8*). Specifically, LacNAc-containing compounds have been implicated in mouse colon cancers (*9*), some thyroid disorders (*10*), the sexual transmission of the *H. ducreyi* pathogen (*11*), and corneal epithelial cell migration (*12*). To date, only a few hypervalent LacNAc clusters have been prepared for use in studies aimed at understanding these interactions. These LacNAc-based glycopeptides and glycopolymers have ill-defined chemical structures (*13*). They vary in size and carbohydrate density and,

as such, may not constitute ideal candidates for precise quantitative measurements.

Alternatively, dendrimers with covalently attached glycoside residues represent novel and chemically well-defined biopolymers with controlled densities (*14*). In addition, bidirectional dendrimers can be used advantageously as models for cell surface multiantennary glycoproteins as they share similar structural characteristics (*15*). It therefore seems natural to turn our attention to the synthesis of dendritic LacNAc conjugates as probes for the study of *N*-acetyllactosamine–protein interactions.

Purely chemical strategies for the synthesis of such compounds is not an easy task, and owing to the stereo- and regioselectivity in the formation of glycoside linkages, chemoenzymatic methodologies have been regarded as important tools for the preparation of structurally complex oligosaccharides (*16*).

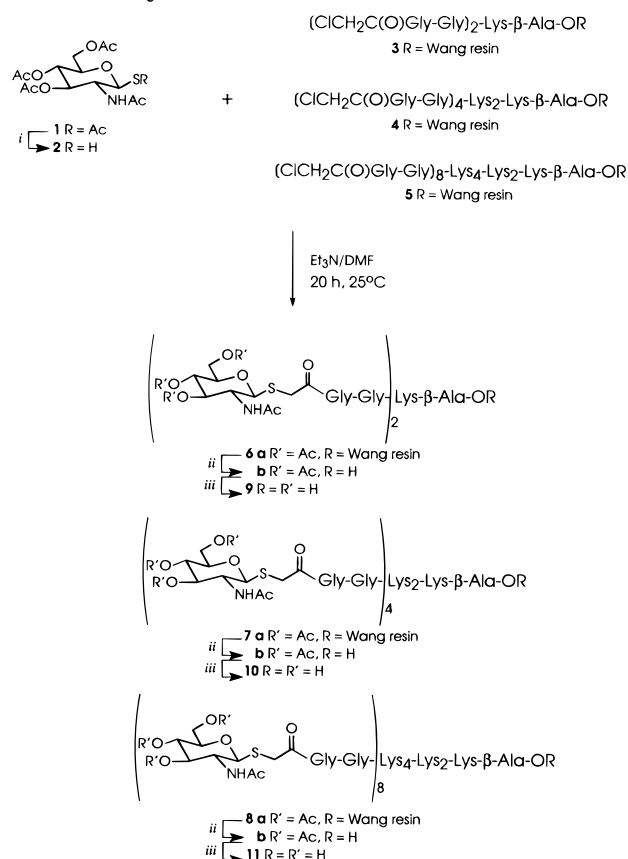

Herein, we present the efficient chemoenzymatic syntheses of *N*-acetyllactosamine dendrimers. Also, the specific binding properties of families of *N*-acetylglucosamine and LacNAc dendrimers with wheat germ agglutinin (WGA) and *Erythrina cristagalli* lectin (ECA) will be discussed.

MATERIALS AND METHODS

UDPglucose, bovine serum albumin, UDP-glucose 4'-epimerase (EC 5.1.3.2), calf intestinal alkaline phosphatase (EC 3.1.3.1), GlcNAc β -1,4-galactosyltransferase (EC 2.4.1.22), lectin from *Triticum vulgaris* (wheat germ agglutinin, WGA) peroxidase labeled, and porcine stomach mucin type III was purchased from Sigma. The lectin from *E. cristagalli* (ECA) peroxidase labeled was obtained from E-Y Laboratories (San Mateo, CA). Thiolated *N*-acetylglucosamine derivative **2** (2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-1-thio- β -D-glucopyranose, GlcNAc) (*17*) and *N*-chloroacetylated dendrimers were prepared as previously described (*5*).

The ¹H and ¹³C NMR spectra were recorded on a Bruker 500 MHz AMX NMR spectrometer. Proton

* Abstract published in *Advance ACS Abstracts*, February 15, 1997.

Scheme 1. Synthesis of GlcNAc Dendrimers 9–11^a

^a (i) H₂NNH₂·HOAc, DMF, N₂, 25 °C, 15 min; (ii) 95% aqueous TFA, 1.5 h; (iii) NaOMe/MeOH, 1.5 h, then H⁺ resin.

chemical shifts (δ) are given relative to internal dimethyl sulfoxide (2.49 ppm) for DMSO-*d*₆ solutions and to internal HOD (4.76 ppm) for D₂O solutions. Carbon chemical shifts are given relative to DMSO-*d*₆ (39.4 ppm). Assignments were based on COSY, HMQC, and/or DEPT experiments. Mass spectra were obtained on a Kratos Concept ITH spectrometer (FAB-MS, glycerol matrix). Gel permeation chromatography (GPC) was performed using Biogel P-2 and Sephadex G-50 columns using water as eluent. Optical densities (ODs) for the ELLA tests were measured on a Dynatech MR600 microplate reader.

Peracetylated Glucosamine Dendrimers (6a–8a). *N*-Chloroacetylated dendrimer backbones 3–5 (Scheme 1) were synthesized as previously described (5, 17). Coupling of 1-thio-*N*-acetylglucosamine derivative 2 (17) with dendrimers 3–5 was done on solid phase. Polymer-supported (Wang resin, 0.58 mmol/g substitution) dendrimers 3–5 were placed in a 1% Et₃N/DMF solution containing compound 2 (1.2 equiv per *N*-chloroacetyl functionality; 0.45, 0.34, and 0.24 mmol/g substitution for dendrimers 3–5, respectively). Agitation of the mixture was maintained for 16 h by bubbling nitrogen through the solution. Before the bulk of the dendrimers was released from the polymeric support, aliquots were withdrawn and hydrolyzed (95% aqueous TFA, 1.5 h). The completeness of the reaction was monitored by ¹H NMR spectra of the dendritic GlcNAc which showed characteristic signals for any residual *N*-chloroacetyl group at 4.12 ppm (DMSO-*d*₆). Where required, couplings were repeated.

Polymer-bound glycodendrimers 6a–8a were released from the polymeric support (95% TFA, 1.5 h) and obtained in 65–99% yields after dissolution in a minimum amount of neat TFA and precipitation in ether.

Compound 6b: ¹H NMR (DMSO-*d*₆) δ 1.16 (m, 2H, lysyl γ-CH₂), 1.33 (m, 2H, lysyl δ-CH₂), 1.46 and 1.61 (2m, 2H, lysyl β-CH₂, nonequivalent), 1.75 (s, 6H, NAc), 1.90, 1.95, 2.00 (3s, 18H, OAc), 2.36 (t, 2H, *J* = 7 Hz, β-alanyl α-CH₂), 3.00 (m, 2H, lysyl ε-CH₂), 3.20 (m, 2H, β-alanyl β-CH₂), 3.30 and 3.38 (2d, 2 × 2H, *J* = 14.1 Hz, SCH₂S), 3.66 (d, 2H, *J* = 5.8 Hz, glycylic CH₂), 3.73 (m, 6H, glycylic CH₂S), 3.81 (m, 2H, H-5), 3.89 (dd, 2H, *J*_{2,3} = 9.89 Hz), 4.00 (d, 2H, *J*_{5,6} = 10.3 Hz, H-6), 4.14 (m, 3H, lysyl α-CH, H-6'), 4.77 (d, 2H, *J*_{1,2} = 10.3 Hz, H-1), 4.86 (dd, 2H, *J*_{3,4} = 9.74 Hz, *J*_{4,5} = 9.74 Hz, H-4), 5.05 (dd, 2H, H-3), 7.73 (m, 1H, lysyl ε-NH), 7.90 (m, 2H, β-alanyl NH, lysyl α-NH), 7.98 (d, 2H, *J* = 9.26 Hz, NHAc), 8.12 and 8.20 (2m, 2 × 2H, glycylic NHs); ¹³C NMR δ 20.3, 20.4, 20.5 (OAc), 22.6 (NHAc), 22.7 (lysyl α-C), 28.7 (lysyl δ-C), 31.7 (lysyl β-C), 32.6 (SCH₂S), 33.7 (β-alanyl α-C), 34.8 (β-alanyl β-C), 38.4 (lysyl ε-C), 42.0 and 42.4 (glycylic Cs), 52.0 (C-2), 52.5 (lysyl α-C), 61.9 (C-6), 68.4 (C-4), 73.6 (C-3), 74.7 (C-5), 82.8 (C-1), 168.4 to 172.8 (C=Os); FAB-MS (positive) calcd for C₄₉H₇₃N₉O₂₅S₂ 1252.3, found 1253.2 (*M* + 1, 19.8%).

Compound 7b: ¹H NMR (DMSO-*d*₆) δ 2.35 (t, 2H, *J* = 6.8 Hz, β-alanyl α-CH₂), 3.00 (m, 6H, lysyl ε-CH₂), 4.77 (d, 4H, *J*_{1,2} = 10.3 Hz, H-1); ¹³C NMR δ 22.6 (NHAc), 32.6 (SCH₂S), 82.8 (C-1); FAB-MS (pos.) calcd for C₁₀₁H₁₅₁N₁₉O₄₉S₄ 2543.6, found 2544.3 (*M* + 1, 0.5%).

Compound 8b: ¹H NMR (DMSO-*d*₆) δ 2.35 (t, 2H, *J* = 6.7 Hz, β-alanyl α-CH₂), 3.00 (m, ¹⁴H, lysyl ε-CH₂), 4.77 (d, 8H, *J*_{1,2} = 10.4 Hz, H-1); ¹³C NMR δ 22.6 (NHAc), 32.5 (SCH₂S), 82.7 (C-1).

De-O-acetylated *N*-Acetylglucosamine Dendrimers (9–11). Each of the polymer free glycodendrimers (6b–8b) was de-O-acetylated with NaOMe/MeOH (25 °C, 1.5 h) followed by H⁺ resin treatment to give dendrimers 9–11 in quantitative yields.

Compound 9: ¹H NMR (D₂O) δ 1.40 (m, 2H, lysyl γ-CH₂), 1.57 (m, 2H, lysyl δ-CH₂), 1.77 and 1.83 (2m, 2H, lysyl β-CH₂, nonequivalent), 2.09 (s, 6H, NAc), 2.66 (t, 2H, *J* = 6.5 Hz, β-alanyl α-CH₂), 3.26 (t, 2H, *J* = 6.9 Hz, lysyl ε-CH₂), 3.46 to 3.97 (m, 26H, β-alanyl β-CH₂, glycylic CH₂S, SCH₂S, H-2, H-3, H-4, H-5, H-6, H-6'), 4.27 (m, 1H, lysyl α-CH), 4.74 (dd, 2H, H-1); ¹³C NMR δ 21.7 (NHAc), 21.8 (lysyl α-C), 27.3 (lysyl δ-C), 30.1 (lysyl β-C), 32.9 (SCH₂S), 33.0 (β-alanyl α-C), 34.7 (β-alanyl β-C), 38.5 (lysyl ε-C), 53.5 (lysyl α-C), 83.5 (C-1), 41.8, 42.0, 42.4, 54.0, 60.4, 69.2, 74.5, 79.4, and 81.3 (glycylic Cs, C-2, C-3, C-4, C-5, C-6), 170.6–175.6 (C=Os); FAB-MS (pos.) calcd for C₃₇H₆₁N₉O₁₉S₂ 999.4, found 1000.6 (*M* + 1, <1%).

Compound 10: ¹H NMR (D₂O) δ 2.09 (s, 12H, NAc), 2.66 (t, 2H, *J* = 6.5 Hz, β-alanyl α-CH₂), 3.26 (m, 6H, lysyl ε-CH₂), 4.74 (dd, 4H, H-1); ¹³C NMR δ 21.7 (NHAc), 83.5 (C-1).

Compound 11: ¹H NMR (D₂O) δ 2.11 (s, 24H, NAc), 2.68 (t, 2H, *J* = 6.1 Hz, β-alanyl α-CH₂), 3.28 (m, ¹⁴H, lysyl ε-CH₂), 4.75 (dd, 8H, H-1); ¹³C NMR δ 21.7 (NHAc), 83.5 (C-1).

***N*-Acetyllactosamine Dendrimers (12–14).** Enzymatic reactions were performed according to established procedures (18). Five milligram portions of GlcNAc dendrimers 9–11 were dissolved in 50 mM sodium cacodylate (pH 7.4, 565 μL) containing bovine serum albumin (0.5 mg), 1.1 μmol of MnCl₂, 3.4 μmol of NaN₃, 28.3 μmol of UDPglucose, 200 milliunits of GlcNAc β-1,4-galactosyltransferase (EC 2.4.1.22), 1 unit of UDP-glucose 4'-epimerase (EC 5.1.3.2), and 4 units of calf intestinal phosphatase (EC 3.1.3.1). The reaction mixture was incubated at 37 °C for 5 days while the pH was maintained at 7.4 by periodic addition of 0.1 M NaOH (Scheme 2).

Scheme 2. Chemoenzymatic Synthesis of LacNAc Dendrimers 12–14

LacNAc dendrimers were isolated by gel permeation chromatography on both a Biogel P-2 column (2.3 × 90 cm) and a Sephadex G-50 column (2.3 × 75 cm) using H₂O as eluent. Isolated yields were 79–90%. NMR data (D₂O, Figure 1) showed complete galactosyl incorporation as measured by the H-1 galactose signal at 4.55 ppm relative to the H-1 GlcNAc, the NAc GlcNAc, and β-alanyl α-CH₂ signals at 4.78, 2.11, and 2.57 ppm, respectively.

Compound 12: ¹H NMR (D₂O) δ 1.40 (m, 2H, lysyl γ-CH₂), 1.59 (m, 2H, lysyl δ-CH₂), 1.79 and 1.87 (2m, 2H, lysyl β-CH₂, nonequivalent), 2.11 (2s, 6H, NAc), 2.57 (t, 2H, *J* = 6.7 Hz, β-alanyl α-CH₂), 3.28 (t, 2H, *J* = 6.9 Hz, lysyl ε-CH₂), 3.42 to 4.11 (m, 38H, β-alanyl β-CH₂, glycylic CH₂s, SCH₂s, H-2, H-3, H-4, H-5, H-6, H-6' of GlcNAc and H-2, H-3, H-4, H-5, H-6, H-6' of Gal), 4.30 (dd, 1H, *J*_{lysylα,lysylβ} = 8.7 Hz, *J*_{lysylα,lysylβ'} = 3.2 Hz, lysyl α-CH), 4.55 (d, 2H, *J*_{1,2} = 7.8 Hz, H-1 Gal), 4.77 and 4.79 (dd, 2H, H-1 GlcNAc, nonequivalent); ¹³C NMR δ 21.7 (NHAc), 21.8 (lysyl α-C), 27.3 (lysyl δ-C), 30.1 (lysyl β-C), 32.9 (SCH₂s), 33.0 (β-alanyl α-C), 34.7 (β-alanyl β-C), 38.5 (lysyl ε-C), 83.5 (C-1 GlcNAc), 102.5 (C-1 Gal); FAB-MS (pos.) calcd for C₄₉H₈₁N₉O₂₉S₂ 1323.4, found 1324.3 (*M* + 1, 1.8%).

Compound 13: ¹H NMR (D₂O) δ 2.11 (s, 12H, NAc), 2.60 (m, 2H, β-alanyl α-CH₂), 3.28 (m, 6H, lysyl ε-CH₂), 4.55 (d, 4H, *J*_{1,2} = 8.1 Hz, H-1 Gal), 4.77 (dd, 4H, H-1 GlcNAc, nonequivalent); ¹³C NMR δ 21.7 (NHAc), 83.5 (C-1 GlcNAc), 102.5 (C-1 Gal).

Compound 14: ¹H NMR (D₂O) δ 2.11 (s, 24H, NAc), 2.47 (m, 2H, β-alanyl α-CH₂), 3.27 (m, 14H, lysyl ε-CH₂), 4.55 (d, 8H, *J*_{1,2} = 7.8 Hz, H-1 Gal), 4.77 and 4.79 (dd, 8H, H-1 GlcNAc, nonequivalent); ¹³C NMR δ 21.7 (NHAc), 83.5 (C-1 GlcNAc), 102.5 (C-1 Gal).

Enzyme-Linked Lectin Assays (ELLAs). Linbro (Titertek) microtitration plates were coated with porcine stomach mucin type III at 100 μL/well with a 5 μg/mL stock solution in 0.01 M phosphate buffer (pH 7.3). The wells were then washed three times with 300 μL/well with 0.01 M phosphate buffer (pH 7.3) containing 0.05% (v/v) Tween 20 (PBST). Washing with PBST was repeated after each incubation period. Wells were then blocked with 150 μL/well with 1% BSA/PBS for 1 h at 37 °C. After washing, wells were filled with 100 μL/well of inhibitor solutions and incubated again at 37 °C for 1 h. Inhibitors used include allyl 2-acetamido-2-deoxy-α-D-glucopyranoside (monomeric GlcNAc **15**) (**19**) and *O*-(β-D-galactopyranosyl)-(1-4)-2-acetamido-2-deoxy-β-D-glucopyranosyl azide (monomeric LacNAc **16**) (**20**) as reference monovalent compounds (Figure 4), di- (**9**), tetra- (**10**), and octavalent (**11**) GlcNAc dendrimers, and di- (**12**), tetra- (**13**), and octavalent (**14**) LacNAc dendrimers. Each inhibitor was added in serial 2-fold dilutions (60 μL/well) in PBS with the appropriate lectin–enzyme conjugate concentration (1000-fold dilution of a 1 mg/mL stock WGA solution in PBS for GlcNAc-based compounds and a 100-fold dilution of a 1 mg/mL stock solution of *E*.

Figure 1. ^1H NMR (D_2O , 500 MHz) spectrum of divalent *N*-acetylglucosamine dendrimer **12**.

crisagalli lectin in PBS for dendritic LacNAc) on Nunclon (Delta) microtiter plates and incubated at 37 °C for 1 h. These inhibitor solutions (100 μL) were transferred to the antigen-coated plates and incubated for a second hour. The plates were washed, and 50 μL /well 2,2'-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) (1 mg per 4 mL) in citrate phosphate buffer (0.2 M, pH 4.0 with 0.015% H_2O_2) was added. The reaction was stopped after 20 min by adding 50 μL /well of 1 M H_2SO_4 , and the optical density was measured at 410 nm relative to 570 nm. Percent inhibition was calculated as follows:

$$\% \text{ inhibition} = \frac{[A_{(\text{no inhibitor})} - A_{(\text{with inhibitor})}]/A_{(\text{no inhibitor})} \times 100}$$

IC_{50} s were reported as the concentration required for 50% inhibition of the coating antigen. All tests were performed in triplicate.

RESULTS AND DISCUSSION

GlcNAc-ending dendrimers with valencies of two (**9**), four (**10**), and eight (**11**) were synthesized in fair to excellent yields (65–99%) using chemical synthesis based on the rational scaffolding of L-lysine core structures on solid phase. The convergent strategy (Scheme 1) involved the solid-phase synthesis of *N*-chloroacetylated glycylglycine-capped multibranched L-lysine as previously described (5). Each *N*-chloroacetyl group was then substituted with the peracetylated 1-thio GlcNAc derivative **2**. Hydrolysis from the resin (95% TFA) and protecting group removal (NaOMe, MeOH) afforded **9–11**.

Figure 2. Inhibition curves for the binding of WGA to porcine stomach mucin type III: allyl 2-acetamido-2-deoxy- α -D-glucopyranoside (\blacksquare) and GlcNAc dendrimers **9** (\blacktriangle), **10** (\blacklozenge), and **11** (\bullet).

These GlcNAc-based dendrimers were then enzymatically transformed into di- (**12**), tetra- (**13**), and octavalent (**14**) LacNAc dendrimers (Scheme 2). Isolated yields were excellent (79–90%) and were indicative of the efficiency of this chemoenzymatic strategy. These results also indicate that even the shorter arms of the dendritic lysine core were sufficiently long and free of steric hindrance to be amenable to enzymatic transformations. While the enzymatic galactosylation of *N*-acetylglucosamine is known, this is the first reported achievement of the enzymatic conversion of GlcNAc to LacNAc on a synthetic dendrimer.

Porcine stomach mucin was used as a model coating antigen for carbohydrate–glycoprotein interactions as it is readily available and contains both *N*-acetylglucos-

amine and *N*-acetylglucosamine in high concentrations to allow for effective microtiter plate enzyme-linked inhibition assays (ELLAs) (21). WGA is a tetravalent lectin that binds GlcNAc moieties (22). Thus, it was used for inhibition testing using GlcNAc dendrimers **9–11**. To test *N*-acetylglucosamine dendrimers **12–14**, it was necessary to use a lectin specific to LacNAc and one that would not bind GlcNAc. For this reason, inhibition of carbohydrate–porcine stomach mucin interactions with dendrimers **12–14** was performed with *E. cristagalli* lectin (ECA). ECA is a divalent lectin, and binding studies have revealed that *N*-acetylglucosamine exhibits the highest affinity for ECA, where most of the binding energy is contributed by the nonreducing terminal galactose residue (23, 24). ECA–protein interactions are therefore not inhibited by GlcNAc residues. Thus, inhibition of binding of ECA to porcine stomach mucin by newly synthesized glycodendrimers **12–14** would unequivocally demonstrate galactose incorporation and inhibitory potency.

GlcNAc dendrimers having valencies of two (**9**), four (**10**), and eight (**11**) exhibited IC₅₀s of 3100, 509, and 88 μ M, respectively, in the inhibition of WGA–porcine stomach mucin type III binding. This represents IC₅₀ values of more than 6200, 2040, and 703 μ M, respectively, as compared to that of monomeric GlcNAc **15** (at concentrations of >15 mM, allyl 2-acetamido-2-deoxy- α -D-glucopyranoside exhibited 15% inhibition, Table 1). When IC₅₀s are plotted relative to monomer as a function of dendrimer valency, the curve generated for this set of data clearly indicates that multivalency enhances inhibitory potencies for the WGA–porcine stomach mucin type III interaction (Figure 5). The inhibitory potential of

Figure 4.

Figure 5. IC₅₀s as a function of dendrimer valency for GlcNAc dendrimers **9–11** (■).

Figure 6. IC₅₀s as a function of dendrimer valency for LacNAc dendrimers **12–14** (■).

dendrimer **11** represents more than a 20-fold increase over that of the analogous monomer **15**.

Thus, ELLA inhibition of binding of lectin to porcine stomach mucin by dendrimers **9–11** (Figures 2 and 3) showed a steady increase in the inhibitory potency as a function of GlcNAc content.

Di- (**12**), tetra- (**13**), and octavalent (**14**) LacNAc dendrimers, when used in the inhibition of binding of *E. cristagalli* lectin to porcine stomach mucin type III by ELLA, showed IC₅₀ values of 341, 143, and 86 μ M, respectively [682, 574, and 692 μ M, respectively, as compared to that of *O*-(β -D-galactopyranosyl)-(1-4)-2-acetamido-2-deoxy- β -D-glucopyranosyl azide (azido- β -LacNAc) **16**, Table 1]. As a control, octameric GlcNAc **11** did not inhibit the lectin–mucin interaction. When expressed on a per hapten basis, the average binding potency of **12–14** indicates that LacNAc residues in these dendrimers were not strong ligands toward ECA. In this case, no cluster effect was observed. One explanation may be that the presentation of the carbohydrate residues plays an important role in this particular carbohydrate–lectin interaction and perhaps the LacNAc residues in the form presented here are not properly scaffolded to confer steady increases as a function of multivalency. Indeed, this phenomenon has been previously observed for LacNAc clusters (24). These data do not negate the overall importance of the multivalency or glycosidic cluster effect in carbohydrate–protein interactions.

Rather, they stress the need for well-designed glycoforms. Of importance though is the fact that these results nicely confirm the enzymatic incorporation of galactose residues in the LacNAc dendrimers. No inhibition would have been observed without proper galactosylation of GlcNAc dendrimers since octavalent GlcNAc dendrimer **11** did not inhibit the binding at all.

The above results indicate that, indeed, multivalency can amplify carbohydrate–protein interactions. However, this effect is variable for each individual interaction, and to what extent multivalency plays a role in such interactions is still under active investigation.

ACKNOWLEDGMENT

We are grateful to the National Sciences and Engineering Research Council of Canada (NSERC) for financial assistance and a postgraduate scholarship to D.Z.

Versatile Linker Chemistry for Synthesis of 3'-Modified DNA

Matthew H. Lyttle,* Howard Adams, Derek Hudson, and Ronald M. Cook

Biosearch Technologies Inc., 40 Mark Drive, San Rafael, California 94903. Received November 14, 1996*

A general method is described for the solid phase supported synthesis of DNA containing 3'-terminal phosphodiester modified with linkers bearing either amino, thiol, or hydroxyl groups. These products are all made from a common intermediate, obtained by the reaction of trimellitic anhydride chloride with aminopropyl CPG. The anhydride-derivatized support was then reacted with three appropriate bifunctional spacers, giving DMT-protected hydroxyl solid supports bearing the masked functionality as an ester, amide, or thioester. DNA synthesis was then performed, followed by ammonia cleavage and deprotection, giving the hydroxyl-, amino-, or thiol-functionalized DNA 3'-phosphate diesters, respectively. Test mononucleotides synthesized with each of the new supports were identical with control mononucleotides made with 5'-immobilized nucleosides and alkylhydroxyl, alkylamino, and alkylthio phosphoramidites. The new supports were then used to prepare several 3'-modified oligonucleotides, which were characterized by gel electrophoresis, HPLC, and MALDI mass spectroscopy. The amino- and thiol-functionalized DNAs were conjugated with chromophores, and purification of these products was facilitated by use of reversed phase cartridges.

INTRODUCTION

The preparation of DNA containing unnatural 3'-terminal groups has become increasingly important in antisense applications (1) and for the attachment of reporter groups (2, 3). A variety of synthetic methods have been developed to meet these needs (4–8). We present a simple and yet general way to obtain such important materials.

Our work is based on an earlier contribution by Petrie et al. (9) in which a phthalimide-based linker, prepared and immobilized on controlled pore glass (CPG) in four steps, was used to prepare 3'-aminoalkyl phosphate functionalized oligonucleotides. A functionally analogous structure 4 may be prepared in two steps by treating aminopropyl CPG with trimellitic anhydride chloride 1, followed by reaction with 6-amino-1-hexanol (Figure 1). Automated DNA synthesis, followed by basic workup, gave the desired 3'-(6-amino)hexanol 1-phosphorylated oligonucleotides. Furthermore, the immobilized anhydride support 2 could be reacted with other nucleophiles. 1,3-Propanediol or 6-(4,4'-dimethoxytrityl)oxy-1-thiohexane gave the immobilized ester 3 and the thioester 5, respectively, which were then used in automated DNA synthesis to give 3'-hydroxyl or thioalkyl phosphate functionalized oligonucleotides.

MATERIALS AND METHODS

Aqueous ammonia, mercaptoethanol, Tris free base, and silver nitrate were of reagent grade from J. T. Baker; dichloromethane (DCM), pyridine, dimethylformamide (DMF), and acetonitrile were of Omnisolve grade from VWR. *N*-Methylimidazole, 6-amino-1-hexanol, 1,3-propanediol, triethylamine (TEA), dithiothreitol, Tris-HCl, and trimellitic anhydride chloride were from Aldrich. 4,4'-Dimethoxytrityl chloride was obtained from Chem Impex and fluorescein-5-maleimide from Pierce. Aminopropyl- and nucleoside-derivatized 1000 Å CPG and 5,6-carboxy-fluorescein succinimide ester were from Biosearch Technologies, Inc. MALDI mass spectroscopy was performed

by the University of Michigan Protein and Carbohydrate Structure Facility.

Synthesis of the Supports. 3-*N*-(1,3,4-Trimellityl-3,4-anhydride) Aminopropylsilane, 2. Aminopropyl CPG (5 g) was placed in a 125 mL Erlenmeyer flask with stopper. A solution of trimellitic anhydride chloride 1 (1 g) in a mixture of pyridine (10 mL) and methylene chloride (40 mL) was added, and the mixture was swirled every 10 min for 1 h. The CPG was poured into a sintered glass funnel and washed with methylene chloride (3 × 50 mL) and acetonitrile (3 × 50 mL). The support was dried *in vacuo* and tested for the presence of amino groups with a Kaiser test (10) and found to be negative.

1-DMT-*O*-dihydroxypropyl-3-*O*-(4' or 5'-trimellityl)-1'-*N*-trimellityl)aminopropylsilane, 3. Support 2 (2 g) was treated with a solution of 1,3-propanediol (1 mL) and *N*-methylimidazole (0.5 mL) in DMF (10 mL) for 3 h. The support was washed and dried as above and then slurried in dry pyridine (100 mL); DMT chloride (1 g) was then added. The mixture was shaken periodically, then allowed to sit overnight, and was washed and dried as previously (loading: 36 μmol/g by colorimetric DMT loading assay).

1-DMT-*O*-aminohydroxyhexan-6-*N*-(4' or 5'-trimellityl)-1'-*N*-trimellityl)aminopropylsilane, 4. Support 2 (2 g) was treated with a solution of 6-amino-1-hexanol (2 g) in DMF (10 mL) for 3 h. The support was washed and dried as previously. The material was reacted with DMT chloride as described above for 3, giving a loading of 76 μmol/g.

6-DMT-*O*-thiohydroxyhexan-1-*S*-(4' or 5'-trimellityl)-1'-*N*-trimellityl)aminopropylsilane, 5. Support 2 (2 g) was treated with a solution of 6-mercapto-1-*O*-DMT-hexane (1 g, ref 11) with 1 mL of TEA in DMF (10 mL) for 3 h. The support was washed as for 3 and dried to give a loading of 31 μmol/g.

Mononucleotide Synthesis. Automated DNA synthesis was performed on a Biosearch 8750 DNA synthesizer, with Beckman (Fullerton) amidites. A 0.4 M solution of 5-(ethylthio)-1*H*-tetrazole (AIC Corp, Strathmore) in acetonitrile was used as the amidite activator, with all other reagents the same as those previously described (12). 6-(4-Methoxytrityl)amino-1-*O*-(diisopropylaminocynoethyl)hexyl phosphoramidite was prepared according to the procedure of Sinha and Cook (13);

Figure 1. Synthesis of 3–5 from 2.

6-(trityl)thio-1-*O*-(diisopropylaminocyanoethyl)hexyl phosphoramidite was made according to the procedure of Connolly and Rider (14), and 3-*O*-(4,4'-dimethoxytrityl)-1-*O*-(diisopropylaminocyanoethyl)propyl phosphoramidite was synthesized with protocols described in Jaschke et al. (15). 5'-Succinoylnucleoside CPG (ILO CPG, inverse linkage CPG) was prepared as in Ortiago et al. (16). Control mononucleotide synthesis by conjugation of reporter group amidites onto ILO CPG was accomplished by semimanual methods as follows: The column containing the support was detritylated on the DNA synthesizer and thoroughly rinsed with dry CH_3CN . The liquid was removed from the column by an argon drying instrument step. The column was removed from the instrument. For a 200 nmol synthesis, the reporter group amidite solution (200 μL of a 100 mg/mL, dissolved under argon) was taken up in a 1 mL tuberculin syringe (luer slip-tip) and 200 μL of 0.31 M 5-(ethylthio)-1*H*-tetrazole in CH_3CN in a second syringe. One syringe was inserted into each end of the column, and the syringe containing the amidite was discharged into the column. Excess volume was allowed to enter the syringe containing the 5-(ethylthio)-1*H*-tetrazole solution. Next, the other syringe was discharged, while the first syringe was allowed to fill with the mixed fluid. The process was repeated (three times), and the column was allowed to stand for 2 min. The syringes were removed, the column was placed back on the instrument, and oxidation and washing steps were performed. For the DMT and MMT group containing products, deprotection was accomplished on the instrument with 3% dichloroacetic acid in DCM. The column was then rinsed with CH_3CN on the instrument, the support was removed from the column and then treated with concentrated ammonia in a sealed tube for 24 h at 55 $^\circ\text{C}$. The tube was cooled and the ammonia solution evaporated for further analysis. For the thiotrityl sample, 1 M AgNO_3 (500 μL) was pushed slowly through the

column over 10 min and then washed by water (3 mL). Next, 5% (v:v) aqueous mercaptoethanol (500 μL) was applied for a duration of 10 min, followed by washing with water (3 mL). The thiol mononucleotide was then ammonia cleaved as above. For the test mononucleotides, 200 nmol DNA synthesis columns packed with either 3, 4, or 5 were coupled with T amidite with standard automated DNA synthesis protocols and reagents as mentioned above. The DMT group was removed, and the CPG was treated with ammonia and heat for 18–24 h. For the thiohexyl test mononucleotide, DTT (2–3 mg) was added to the ammonia solution before the onset of heating. The samples were then dried under vacuum and redissolved in 20% acetonitrile in water for subsequent analysis.

3'-Modified Oligonucleotide Synthesis. DNA synthesis columns were packed with either 3, 4, or 5, and the DNA fragments (see Table 1) were synthesized with standard protocols and reagents. The 5'-DMT groups were left attached, and for the 3'-aminoethyl- or 3'-hydroxypropyl-derivatized fragments 18–24 h of 55 $^\circ\text{C}$ heating in concentrated aqueous ammonia (1 mL) was used to cleave the DNA from the support. For the 3'-thiohexyl DNA, 2–3 mg of DTT was added to the ammonia solution before the onset of heating. The samples were cooled, and the DNA was isolated with a reversed phase cartridge and protocols (17). The DNA was evaporated for analysis or conjugation.

Reversed Phase HPLC Conditions. The dried sample was dissolved in 20% acetonitrile in water, and 2–20 μL of this solution, depending on the concentration, was injected onto a C_{18} 3.3 cm cartridge (PE-ABI, 0258-0164) with detection at 260 nm, eluted at 1 mL/min with a gradient of 100% A (0.1 N ammonium acetate) for 2 min, 100% A to 90% A (B was 100% acetonitrile) over 10 min, then 90% A to 50% A over 10 min, and then back to 100% A over 1 min.

Table 1. Yields and Purity of 3'-Fluorescein Conjugates

sequence ^a	synthesis scale (nM)	yield ^b (ODs)	% conv ^c	ODs isolated ^d	HPLC purity ^e (%)

^a 14-mer sequence = 5'-dCCGAGTACTAATCA-3'; 16-mer = 5'-dATACTTATCATGAGCC-3'; 19-mer = T₁₉; 20-mer = 5'-dTCCAGTCATCGAGGTCATA-3'. ^b Yield of unconjugated DNA obtained after first Micropure Cartridge purification. ^c HPLC examination of size exclusion isolated material, after fluorescein conjugation. ^d Yield of fluorescein conjugate purified by Micropure Cartridge. ^e Purity of isolated probe, by HPLC. ^f Modified final purification: loaded onto the reversed phase cartridge in 3% aqueous ammonia, product eluted with 28% aqueous ammonia.

Anion Exchange HPLC. The dried sample was dissolved in 20% acetonitrile in water, and 2–20 μ L of this solution, depending on the concentration, was injected onto a 16 \times 40 mm Shodex DEAE 420-N 4 cM column (Phenomenex) eluted with a gradient to 100% B over 20 min. Buffer A was 0.025 M Tris-HCl, 0.01 M Tris; buffer B was A plus 1.0 M NaCl.

Fluorescein Conjugation Studies. For the 3'-amino-hexyl-modified DNA, 5,6-carboxyfluorescein succinimide ester (1 mg/10 ODs of DNA) was dissolved in DMSO (100 μ L) and added to a 2 mL screw cap polyethylene tube containing the purified DNA, followed by an aqueous solution 1 M in Na₂CO₃ and 1 M in NaHCO₃ (500 μ L). The tube was sealed and allowed to stand for 18–24 h at room temperature in the dark. The liquid was evaporated under vacuum, and the residue was dissolved in 2 mL of 0.05 M NH₄OAc in HPLC grade water. The solution was applied to a 1 \times 20 cm Sephadex G-25 column (Sigma catalog no. G-25-80) packed and eluted with 0.05 M NH₄OAc in HPLC grade water. The tagged DNA eluted rapidly as a green solution after 5–10 mL of liquid had eluted, and this fraction was collected and reduced to a solid under vacuum. The solid was dissolved in 15% aqueous ammonia (1 mL) and applied to a reversed phase cartridge (17), which had been pre-equilibrated with acetonitrile (4 mL) followed by 1 M triethylamine acetate (4 mL). The solution of the conjugate was reloaded twice and washed with 3% aqueous ammonia (4 mL) followed by water (4 mL). Some faint green color was sometimes observed to elute during the aqueous ammonia washes. Next, the column was washed with 20% acetonitrile in water (3 mL), and the strongly green liquid that emerged was collected and evaporated under vacuum to a solid for further analysis.

For the 3'-thiohexyl-modified DNA, 2 mg of fluorescein-5-maleimide (2 mg/10 ODs of DNA to be conjugated) was dissolved in DMF (100 μ L) and added to a 2 mL screw cap polyethylene tube containing the purified thiohexyl DNA isolated as above. Next, 50 mM sodium phosphate/150 mM sodium chloride, pH 7.2, buffer (500 μ L) was added. The tube was sealed, mixed, and allowed to stand for 18–24 h at room temperature in the dark. The liquid was evaporated under vacuum, and the residue was processed further as above.

RESULTS AND DISCUSSION

The three new supports (3–5) were synthesized from common intermediate **2**, obtained by the reaction of trimellitic anhydride chloride and aminopropyl CPG.

Figure 2. Synthesis of 3'-amino-hexyl phosphate functionalized T from two different solid supports.

Solutions of bifunctional linkers were added, and subsequent washing gave the hydroxyl-functionalized supports (Figure 1). In the case of the propanediol- and amino-hexanol-functionalized materials, the supports could be synthesized without protection of the additional hydroxyl group. A DMT group was added to these to gauge the loading during automated DNA synthesis. It was found necessary to protect the hydroxy groups of heterobifunctional spacers containing additional thiol functionality; otherwise, heterogeneous products were obtained after DNA synthesis. Insufficient differential reactivity between the OH and SH groups toward the immobilized anhydride most likely produces a mixture of both ester and thioester linked supports, the former giving rise to an undesired product.

To confirm the identity of the 3'-terminal functionality obtained from the use of 3–5, control mononucleotides were prepared by adding amidites containing amino-hexyl (13), thiohexyl (14), and hydroxypropyl (15) functional groups to a 3'-hydroxyl nucleoside immobilized through its 5'-hydroxyl group. These were then compared to the analogous structures prepared by coupling a single phosphoramidite nucleotide to 3–5. The experiment is shown schematically for the amino-hexyl case in Figure 2. After aqueous ammonia workup, the control mono-

Figure 3. Reversed phase HPLC analysis of products made in Figure 2. The peak at about 5 min is T nucleoside; the other minor peaks were not identified.

Figure 4. Anion exchange HPLC of 14-mers with 3' modification, after reversed phase cartridge purification: (A) 14-mer with 3'-hydroxypropyl phosphate; (B) 14-mer with 3'-thiohexyl phosphate; (C) 14-mer with 3'-aminoethyl phosphate and 24 h of ammoniolysis; (D) same as (C) with 8 days additional heating in concentrated ammonia.

nucleotides were found to be identical to those produced from **3–5**, according to coelution of the major products on reversed phase HPLC (Figure 3 shows the result with the aminoethyl example). DTT was added to the thiol-functionalized product to curtail oxidative dimerization.

Several longer DNA fragments were then synthesized on the new supports (Table 1). A 14-mer 5'-dCCGAG-TACTATTCA-3' was synthesized on **3**, **4**, and **5**, as well as with conventional dA-derivatized CPG. Overall coupling yields were similar in the four cases, and no evidence was observed for instability of the linkages during synthesis or problems arising from the pendant unblocked carboxyl groups. The DNA was cleaved from the CPG with aqueous ammonia and heating and purified on a reversed phase cartridge (17). Yields of purified DNA compared favorably with the amount normally obtained for cartridge purification at these two synthesis scales (see Table 1). MALDI mass spectroscopy (Table 2) showed the correct increase in mass for the 3'-modified 14-mers when compared to the spectrum of the unmodi-

Table 2. Observed MALDI Masses of Unmodified and 3'-Modified DNA^a

3' terminus	mass	calcd diff	found diff
unmodified	4217.2

aminoethyl	4400.0	179.2	182.8
thiohexyl	4524.9 ^b	195.3	193.7

^a Experimental error is ± 4.2 amu. ^b M/e-TFA.

fied 14-mer. Anion exchange HPLC of the three analogs (Figure 4) showed that good quality products were obtained in the case of the 3'-thiohexyl and 3'-propanol examples. For the 3'-aminoethyl-derivatized 14-mer, a substantial later eluting contaminant (20–30%) was present (Figure 4C). This could be somewhat diminished by prolonged heating with ammonia (Figure 4D shows the ammonia/DNA solution after 8 days of additional heating, after CPG removal), suggesting that this contaminant is unhydrolyzed amide with the mellitic acid linker. A recent paper (18) describes difficulty in removal

Figure 5. (A) Anion exchange HPLC of crude 3'-aminoethyl 14-mer conjugate with 5,6-carboxyfluorescein ONSu active ester. (B) purified compound isolated using reversed phase cartridge. A Gen-Pak Fax anion exchange HPLC column (Waters) was used instead of the Shodex column.

of phthaloyl groups from alkylamines by basic hydrolysis, in accord with this observation. However, the loss of material due to this side reaction was compensated by the yield of DNA obtained because of the high loading of the support. The later eluting contaminant did not interfere in subsequent reactions involving conjugation of the 3'-aminoethyl-functionalized material and was separated from the desired fluorescein conjugate with a reversed phase cartridge procedure (see below).

Our findings contrast with an earlier study implying that final products free of contaminants were obtained when a similar structure was used for DNA synthesis followed by hydrolysis with aqueous ammonia and heating (9). The later eluting impurity generated when 3'-amino-linked DNA was synthesized on **4** could be suppressed somewhat by using 1:1 methylamine/concentrated ammonia for 24 h at 60 °C as the basic workup step (data not shown). The use of methylamine as a component in the hydrolysis step necessitates the use of *N*⁴-acetyl dC phosphoramidite (in lieu of *N*⁴-benzoyl dC) during synthesis, because of a side reaction (19). Since the product still contains the unhydrolyzed impurity, this modification will not be worthwhile for most applications.

Another possibility is that the later eluting contaminant may result from reverse addition of the 6-amino-1-hexanol to the anhydride CPG **2**. DNA synthesized on this species would have a terminal hydroxyl instead of an amine and, hence, an additional net negative charge, eluting later in anion exchange HPLC. This was ruled out by the synthesis of **4** using 6-amino-1-*O*-DMT hexanol (20) and subsequent DNA synthesis followed by basic hydrolysis. The products obtained from **4** synthesized in this way had the same amount of the later eluting contaminant (data not shown).

The importance of hydroxylalkyl-functionalized DNA in antisense work is discussed in ref 15. The use of 3'-amino- and thiol-functionalized DNA in fluorescent dye conjugation was accomplished using variations on published protocols (21, 22). For the above 3'-amino-linked 14-mer DNA fragment made at a 200 nmol scale, about 75% conversion was obtained with 50 equiv of a mixture of fluorescein 5- and 6-carboxyhydroxysuccinimide active esters (see Figure 5A; Figure 4C shows the unreacted amino-functionalized oligonucleotide). This product could be purified to ca. 95% purity by a simple reversed phase cartridge method (see Figure 5B). Better amine conjugation efficiency (>90%) was obtained at larger synthesis

Figure 6. 20% PAGE of purified dye conjugated DNA and unconjugated fragments: (I) illumination with 254 nm UV and fluorescent backing; (II) illumination with 312 nm UV and black backing; X.C., xylene cyanol; (lane A) fluorescein-conjugated 3'-aminoethyl 20-mer; (lane B) fluorescein-conjugated 3'-thiohexyl 20-mer; (lane C) 3'-aminoethyl 20-mer; (lane D) fluorescein-conjugated 3'-aminoethyl 16-mer; (lane E) fluorescein-conjugated 3'-thiohexyl 16-mer; (lane F) 3'-aminoethyl 16-mer.

scales, perhaps because of concentration effects. Table 1 shows results with 16-mer and 20-mer examples at the 1 μ mol scale. The corresponding 3'-thiol-modified DNA gave lower efficiencies when conjugated with 100 equiv of fluorescein-5-maleimide (Table 1, 19–49% vs 75–>99%). Since very little dimerization of the thiol-containing DNA was observed during the reactions, the cause of these lower yields remains unclear. They may be due to solubility problems or the quality of the commercial fluorescein-5-maleimide used. Cartridge purification of the thiol-linked conjugates was also less effective, perhaps due to the lower polarity of the thiohexyl 3' moiety compared to the corresponding aminoethyl, leading to stronger binding of the starting material, the thiohexyl DNA, to the stationary phase and hence less effective purification. A 20% cross-linked PAGE gel of 3'-conjugated DNA fragments, made with both 3'-terminal modifications, showed strongly fluorescent products with about the same mobility on the gel as the underivatized DNA (Figure 6). The gel lanes of the thiol-linked conjugates contain some underivatized material, in accord with HPLC analysis.

CONCLUSION

An immobilized anhydride intermediate has been used in the synthesis of solid supports that provide 3'-modified DNA containing 3'-alkyl OH, SH, and NH₂ end groups. The structural integrity and utility of the 3'-modifications have been demonstrated. The thioester linkage of **5** has been shown to survive the conditions of automated DNA synthesis and may be useful in other systems where a terminal thiol group is desired after aqueous basic workup. Simple methods for isolating 3'-fluorescein conjugates with the SH- and NH₂-modified DNA have been developed.

In principle, the method is compatible with other homo- or heterobifunctional linkages, provided transient protection is used or the functional groups have sufficient differential reactivity. Also, only a single support is required for the generation of any single class of 3'-modified nucleotide. This new method is, therefore, more versatile and more easily implemented than many of the 3' derivatization methods previously presented. Our new linker methods may also be useful in other areas of solid

phase supported chemistry, such as peptide or combinatorial library synthesis.

Efficient Functionalization of 2',5'-Oligoadenyates with Sulfur

Krystyna Lesiak[†] and Paul F. Torrence*

Section on Biomedical Chemistry, Laboratory of Medicinal Chemistry,
National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health,
Bethesda, Maryland 20892. Received November 18, 1996[©]

To derivatize the 2'-terminus of 2',5'-oligoadenyates with a thiol group, the reaction of periodate-oxidized nucleotide and 2',5'-oligonucleotide with aminothiols was explored. Two separate synthetic approaches were employed, both of which relied upon the use of S-protected thiols. In one approach, 5'AMP was oxidized with sodium periodate to dialdehyde, which was reacted with cystamine hydrochloride. Sodium cyanoborohydride reduction of the unisolated intermediate ainal gave compound **4**. The second approach involved reaction of *S*-(2-tetrahydropyranyl)cysteamine with the dialdehyde obtained by periodate oxidation of 5'AMP to yield, after reduction with Na(CN)BH₃, the S-protected adduct **3**. Intermediate **3** could be oxidized with aqueous iodine to give disulfide **4**. Disulfide **4**, obtained by either of the above routes, was reduced with dithiothreitol (DTT) to the thiol **5**. This same reaction sequence was applied to 2–5A tetramer monophosphate, p5'A2'[p5'A2']₂p5'A (**6a**), to give via **6b** the 2'-terminal-modified derivative **6c**. Aqueous iodine oxidation of **6c** provided the disulfide **7**, which reacted with DTT to give quantitative conversion to product, the free thiol **8**. Both the disulfide **7** and the *S*-tetrahydropyranyl-protected derivative (**6c**) were bound effectively to the 2–5A-dependent RNase L of mouse L cells with IC₅₀ values of 1×10^{-9} M for **7** and 8×10^{-10} M for **6c**, not significantly different from the corresponding value for the parent unmodified 2–5A (**6a**) itself.

INTRODUCTION

Conjugates of 2',5'-oligoadenyates (2–5A's) (**1**, **2**) with small molecules and macromolecules, including carbohydrates, proteins, and nucleic acids, are of growing importance for affinity purification (**3**), affinity labeling (**4**), and targeted degradation of specific RNAs (**5–8**). Thiol-modified oligonucleotides present several conjugate construction advantages including sulfur's enhanced nucleophilicity, ease of disulfide-based conjugation, and the ready reversibility of the latter. Approaches that generally have been used for derivatizations with thiols have included direct synthesis from mononucleotidic precursors (**9–12**), including introduction of the modification into the starting nucleotide affixed to the solid support matrix (**13**). Since these latter procedures are not applicable to preformed nucleic acids, Chu and Orgel (**14**) exploited 5'-derivatization via 5'-phosphoramidate formation with cysteamine or cystamine. Such 5'-derivatization is not possible in the case of 2–5A since the 5'-terminus must bear a free phosphate or polyphosphate for maximum interaction with a key enzyme of the 2–5A system, the RNase L (**1**, **2**). Soukup and associates (**15**) employed phosphoramidite methodology to synthesize an oligonucleotide bearing a 3'-terminal primary amino group which was subsequently reacted with sulfosuccinimidyl-2-(biotinamidoethyl)-1,3-dithiopropionate. This conjugation product bore a disulfide bond in the linker moiety between the oligo and the biotin. Reduction provided a means of cleaving the biotin group from the oligonucleotide domain. Again, however, this approach would not be compatible with the need to derivatize a preformed oligonucleotide.

A valuable route to oligoribonucleotide 3'-modification involves periodate oxidization of the 3'-ribonucleotide to a dialdehyde, which is reacted with an amine or amino acid to yield a Schiff base, reduction of which by borohydride gives a product in which the 3'-terminal ribose is transformed to an N-substituted morpholine (**16–21**). We have explored this theme to functionalize 2',5'-oligoadenyate with a 2'-terminal thiol or a disulfide moiety.

EXPERIMENTAL PROCEDURES

Chemicals. Adenosine 5'-monophosphate, cysteamine (2-aminoethanethiol) hydrochloride, and cystamine [2,2'-dithiobis(ethylamine)] hydrochloride were from Aldrich (Milwaukee, WI). Fluka was the source for 3,4-dihydro-2H-pyran, while sodium periodate was from Sigma (St. Louis, MO), and 1,4-dithiothreitol was from Schwarz-Mann (Orangeburg, NY). 2',5'-Oligoadenyate trimer 5'-monophosphate was synthesized according to the procedure of Sawai (**22**) and purified by reversed-phase HPLC (Zorbax ODS).

HPLC. Analytical HPLC was carried out on a Zorbax ODS column (9.4 mm × 25 cm) using a linear gradient of 0–100% solvent B in buffer A, where A was 0.05 M ammonium phosphate of pH 7.0 and B was MeOH/H₂O (1:1) and the flow rate was 2 mL/min. Detection was by UV.

Physical Measurements. Proton NMR spectra were recorded on a Varian 220 MHz or 300 MHz spectrometer. ¹³C NMR spectra were recorded with the latter instrument operating at 75.5 MHz. Ultraviolet spectra were obtained on a Hewlett-Packard 8450 UV–vis spectrophotometer. Chemical ionization mass spectra were obtained on a Finnegan Extrel 1015 with NH₃ as carrier gas. Obtaining the mass spectrum of compound **3** required its conversion first to the free acid (with Dowex 50[H⁺]) and then (after lypophilization) silylation by reaction with bis(triethylsilyl)acetamide in DMF.

Enzymatic Procedures. Digestions with bacteria alkaline phosphatase (*Escherichia coli*) and snake venom

phosphodiesterase (*Crotalus adamanteus*, Worthington) were performed as described previously (23). The preparation of mouse L cell extracts and the procedures and reagents for the radiobinding assay to RNase L were also as described in the literature (4–6, 21).

Synthesis of *S*-(2-Tetrahydropyranyl)cysteamine Hydrochloride. Cysteamine hydrochloride (2.0 g, 17.6 mmol) was made anhydrous by addition and evaporation with ethanol/toluene (2:1, 3 × 50 mL). The resulting solid was suspended in 3,4-dihydropyran (50 mL), and this mixture was refluxed for 1 h. After evaporation of dihydropyran, the residue was recrystallized twice from EtOAc/EtOH (5:1) to give 1.86 g (9.54 mmol, 53.4%) of *S*-(2-tetrahydropyranyl)cysteamine hydrochloride, mp 142–145 °C; mass spectrum, m/z 162 [(M + H)⁺]; ¹H NMR (CD₃OD) δ 1.6 and 1.9 (br m, 6, C-3, C-4, and C-5 of THP), 2.8–3.1 (m, 2, cysteamine CH₂–N), 3.1–3.3 (m, 2H, cysteamine CH₂–S), 3.6 and 4.0 (br m, 1 each, THP C-6 H's), 5.9 (m, 1, C-2 H). Anal. Calcd for C₇H₁₆NOSCl: C, 42.52; H, 8.17; N, 7.08; Cl, 17.93; S, 16.22. Found: C, 42.34; H, 8.18; N, 7.14; Cl, 18.04; S, 16.52.

Preparation of 6'-Monophosphoryl-[3'-aza-3'-(β-*S*-tetrahydropyranylthioethylene)-1',2,3,4-tetradexopyranosyl]-adenine (3). Sodium periodate (0.5 mL of 0.1 M in H₂O, 0.05 mmol) was added in one portion to a pH 6.0 solution of 5'AMP (Na salt, 0.5 mL of 0.1 M in H₂O, 0.05 mmol), and the resulting mixture was kept in the dark at 0 °C for 30 min. To destroy unreacted periodate, ethylene glycol (200 mL of 1 M aqueous solution, 0.2 mmol) then was added, and the resultant solution maintained at 0 °C for an additional 10 min. *S*-(2-Tetrahydropyranyl)cysteamine hydrochloride (0.5 mL of 0.5 M solution in H₂O, 0.25 mmol) was added, and the pH of the reaction mixture was adjusted to 8.5–9.0 with 1 M NaOH. The resulting mixture was maintained at 0 °C for 30 min, and then sodium cyanoborohydride (total of 0.1 mmol, 0.5 mL of 0.5 M in water) was added. This reaction mixture was kept at 0 °C for 1 h, during which time the pH was maintained at 7.0 by the addition of 10% HOAc. The excess of cyanoborohydride was removed by treatment with acetone at pH 5 for 1 h. (All procedures using cyanoborohydride were conducted in a chemical fume hood.) Finally, the reaction mixture was diluted 10-fold with water, and the diluted solution was applied to a DEAE-Sephadex A-25 column (HCO₃[−] form, 1 × 15 cm). Elution was accomplished with a linear gradient of 0.05–0.5 M triethylammonium bicarbonate (TEAB) (pH 7.0, total of 500 mL). Fractions (4 mL) were collected. The desired product was found in fractions 42–52 (buffer concentration approximately 0.2 M). TEAB was removed by repeated additions and evaporations of water. Product 3 was isolated as a sodium salt by precipitation from a solution of 1% sodium iodide in acetone. Compound 3 had an HPLC retention time of 44.5 min in the above specified system. The final yield was 610 A₂₅₉ units (0.04 mmol, 80% yield): mass spectrum, m/z 691 [(M + H)⁺, trisilylated 3] and 763 [(M + H)⁺, tetrasilylated 3]; ¹H NMR (D₂O) δ 1.51, 1.72, and 1.82 (br m, 3, 4, and 5 methylenes of THP group), 2.35 (t, 1, ²J_{H4'–H4''} = ³J_{H4'–H5'} = 11.4 Hz, H4'), 2.80 (br m, 5H, H2' and exocyclic CH₂–N and CH₂–S), 2.87 (d, 1 H, ²J_{H4'–H4''} = 11.2 Hz, H4''), 3.21 (d, 1, ²J_{H2'–H2''} = 10.3 Hz, H2'), 3.52 (m, 1, CH₂–O of THP), 3.89 (m, 2, H6' and H6''), 3.96 (m, 1, CH₂–O of THP), 4.16 (m, 1, H5'), 4.84 (m, 1, S–CH–O), 5.85 (dd, 1, ³J_{H1'–H2'} = 10.4 Hz, ³J_{H1'–H2''} < 2 Hz), 8.11 (s, 1, purine 2H), 8.24 (s, 1, purine 8H); ¹³C NMR (D₂O) δ 21.69 (C4 of THP), 24.92 (C-5 of THP), 26.12 (CH₂–S), 31.28 (C3 of THP), 52.35 (C-4'), 54.41 (C2'), 57.40 (CH₂–N of cysteamine), 64.80 (C6'), 66.19 (C6 of THP), 75.37 (C5', ³J = 8.0 Hz), 79.41 (C1'), 82.85

(C2, THP), 118.46 (adenine C5), 140.2 (adenine C8), 148.32 (adenine C4), 152.86 (adenine C2), 155.61 (adenine C6).

Bis[6'-monophosphoryl-3'-aza-1'-(9-adenyl)-1',2,3,4-tetradexopyranosyl-3'-β-ethylene] Disulfide (4). Compound 4 was obtained in the same way as compound 3 from 0.2 mmol of AMP 2',3'-dialdehyde (prepared as above) and 1 mmol of cystamine hydrochloride (2 mL, 0.5 M, adjusted to pH 9.0 with NaOH). The product was purified by means of DEAE-Sephadex A-25 (HCO₃[−] form, 1.6 × 25 cm column) chromatography employing a linear gradient of 0.05–0.6 M TEAB, pH 7.5. Fractions of 4 mL were collected with the product being eluted in fractions 94–114 (buffer concentration approximately 0.5 M). TEAB was removed by repeated addition and evaporation of water, and the sodium salt of 4 was isolated by precipitation from 1% NaI in acetone. The final yield was 630 A₂₅₉ units (0.042 mmol, 23%). Compound 4 had an HPLC retention time of 39.0 min: ¹H NMR (D₂O) δ 2.33 (t, 1, ²J_{H4'–H4''} = ³J_{H4'–H5'} = 11.4 Hz, H4'), 2.74 (t, 1, ²J_{H2'–H2''} = ³J_{H2'–H1'} = 10.7 Hz, H2'), 2.94 (m, 4, S–CH₂–CH₂–N), 3.01 (d, 1, ²J_{H4'–H4''} = 11.7 Hz, H4'), 3.20 (d, 1, ²J_{H2'–H2''} = 10.7 Hz, H2''), 3.85 (m, 2, H6' and H6''), 4.13 (m, 1, H5'), 5.72 (dd, 1, ³J_{H1'–H2'} = 8.3, ³J_{H1'–H2''} < 2 Hz, H1'), 8.02 (s, 1, adenine H2), 8.18 (s, 1, adenine H8); ¹³C NMR (D₂O) δ 34.20 (CH₂–S), 52.57 (C4'), 54.36 (C2'), 56.50 (CH₂–N), 64.57 (C6'), 75.46 (d, ³J = 8.0 Hz, C5'), 79.44 (C1'), 118.28 (adenine C5), 140.02 (adenine C8), 148.03 (adenine C4), 152.71 (adenine C2), 155.40 (adenine C6).

Oxidation of Compound 3 with Aqueous Iodine. The sodium salt of compound 3 (950 A₂₅₉ units, 0.6 mmol) was dissolved in H₂O (750 mL), and iodine (0.05 M in 0.05 M NaI) was added in 10 mL portions at 0 °C. The addition of iodine solution was continued until a light brown color persisted for 1–2 min. At this point, TLC revealed that the reaction was completed as judged by the disappearance of starting material.

The excess iodine was removed by evaporation *in vacuo* at 10–20 °C (until the light brown color disappeared). The remaining solution was diluted 10-fold with water and applied to a DEAE-Sephadex A-25 (HCO₃[−]) column (1 × 15 cm), and the column was eluted with a linear gradient of 0.05–0.45 M, pH 7.5, TEAB. Fractions of 4 mL were collected, and the desired product was found in fractions 81–102 (approximately 0.4 M TEAB). The yield of oxidized product was 510 A₂₅₉ units (0.31 mmol, 52%). The product was identical by both TLC and HPLC with the product of the reaction of oxidized AMP (2) with cysteamine, i.e., compound 4.

Reaction of Compound 4 with Dithiothreitol. An aqueous solution of dithiothreitol (DTT, 1 mL of 1 M, 1 mmol) was added to a solution of compound 4 (500 A₂₅₉ units, 0.32 mmol) in H₂O. After 10 min at 0 °C, HPLC analysis revealed the presence of two major compounds with retention times of 31.6 min (82%) and 33.7 min (13%), respectively. This mixture was applied to a DEAE-Sephadex A-25 column (1 × 15 cm, HCO₃[−] form) which was eluted with a linear gradient of 0.05–0.3 M TEAB, pH 7.5. The total elution volume was 500 mL, and 4 mL fractions were collected. Fractions 40–62 contained two compounds, both of which were eluted at significantly lower salt concentration than was required to elute the starting material, compound 4. One compound had a retention time of 32.1 min (68%) and was identical with the major product in the original DTT reaction mixture. It was assigned the structure of 5. The second compound, which had a retention time of 39.3 min (26%), was identified as the starting disulfide 4. Free thiol 5 was very sensitive to air oxidation; for instance, when a

solution of **4** was reduced with β -mercaptoethanol, HPLC showed quantitative conversion to **5**. However, lyophilization of the solution resulted in complete conversion back to disulfide **4**.

Reaction of 5'-Monophosphoryladenyl(2'→5')adenyl(2'→5')adenyl(2'→5')adenosine with S-(2-Tetrahydropyranyl)cysteamine. **Preparation of 6c.** A procedure was employed that was similar to the synthesis of compound **3**. Specifically, the oligonucleotide p5'A2'p5'A2'p5'A2'p5'A (240 A_{259} units, 5 mmol) in 200 mL of H₂O was oxidized with NaIO₄ (60 mL of a 1 M aqueous solution, 6 mmol) at 0 °C. Excess periodate was destroyed with ethylene glycol (30 mL of 1 M aqueous solution), and then S-(2-tetrahydropyranyl)cysteamine (50 mL of 0.5 M, 25 mmol) was added in one portion. The pH of the reaction mixture was adjusted to 8.5–9.0. After 40 min of reaction at 0 °C, a solution of sodium cyanoborohydride (25 mmol in 50 mL of H₂O) was added, and the pH again adjusted, this time to approximately 7.0. The pH was maintained at about 7 by addition of 10% HOAc. After 1 h at 0 °C, the excess sodium cyanoborohydride was destroyed with acetone at pH 5. The resulting mixture was diluted 10-fold with H₂O and applied to a DEAE-Sephadex A-25 column (HCO₃⁻ form, 1 × 10 cm). The column was eluted with a linear gradient (0.05–0.6 M, total of 500 mL) of TEAB, pH 7.5. Fractions of 4 mL were collected. Product **6c** was eluted in fractions 63–71. After removal of TEAB by repeated addition and evaporation of H₂O, compound **6c** was converted to the sodium salt by treatment with NaI/acetone as before. The final yield was 133 A_{258} units (2.77 mmol, 55.4%). Compound **6c** had a retention time of 37.1 min. Bacterial alkaline phosphatase treatment of **6c** gave only one product which had a higher retention time of 41.39 min, as expected for the production of the less polar 5'-unphosphorylated core. Snake venom phosphodiesterase digestion of **6** resulted in the generation of 5'AMP and compound **3** in the required 3:1 ratio. However, in addition to the expected products, an additional product with a slightly greater retention time than 5'AMP (13.54 min compared to 13.03 for AMP) was formed in 13% yield.

Reaction of Compound 6c with Iodine. **Preparation of Compound 7.** Compound **6c** (70 A_{258} units, 1.46 mmol), in 300 mL of H₂O, was oxidized according to the identical procedure used for the oxidation of compound **3**. After completion of the reaction, the entire mixture was applied to a DEAE-Sephadex A-25 column (Cl⁻ form, 1 × 10 cm). Elution was accomplished with a linear gradient of 0.05–0.6 M LiCl (total of 500 mL). Fractions of 4 mL were collected. The product (**7**) was eluted in fractions 93–110 (LiCl concentration of approximately 0.55 M). These fractions were reduced to dryness *in vacuo*, and the residue was dried by two azeotropic evaporations with ethanol/benzene (1:2, 2 × 100 mL). Acetone (50 mL) was added to the residue. After the resultant mixture was stirred for 5–10 min, the insoluble component was centrifuged down, washed with acetone (2 × 5 mL), and then dried *in vacuo*. The final yield was 55 A_{258} units (1.15 mmol, 79%). Compound **7** had an HPLC retention time of 30.4 min.

RESULTS AND DISCUSSION

The reaction of periodate-oxidized ribonucleotides or oligoribonucleotides with amines or amino acids followed by reduction with borohydride gives products in which the ribose (or terminal ribose in the case of oligoribonucleotides) has been transformed to the corresponding morpholine derivatives (17, 18, 21). However, when we attempted to extend this reaction to conjugation of the simple aminothiols, 2-aminoethanethiol (cysteamine), we

Scheme 1

noted the formation of three major products and at least five minor products, none of which were identified (results not shown). We surmise that this result may be due to the reactivity of thiols with the aldehyde groups generated in the oxidation step (24, 25).

Guided by the above hypothesis, we explored protection of the reactive thiol functionality during the dialdehyde–amine conjugation reaction. Two separate but convergent approaches were employed.

The first approach (Scheme 1) used the natural disulfide of cysteamine, namely, cystamine. Thus, 5'AMP was oxidized with sodium periodate to the dialdehyde, which was reacted with cystamine hydrochloride followed by sodium cyanoborohydride reduction to give compound **4**.

The second synthetic approach used the tetrahydropyranyl group for S-protection. Thus, S-(2-tetrahydropyranyl)cysteamine was obtained in good yield by refluxing a suspension of cysteamine hydrochloride with 3,4-dihydropyran. This method was similar to that reported for protection of cysteine (26); however, in this case, no solvent was used. In turn, S-(2-tetrahydropyranyl)-cysteamine was reacted with periodate-oxidized 5'AMP to yield, after reduction with Na(CN)BH₃, the S-protected adduct **3**. It was particularly important to destroy all of the excess periodate before addition of protected thiol due to its high oxidation susceptibility (27, 28). Compound **3** could be deprotected with aqueous iodine (29) to give, after purification, a 52% yield of product identical in all respects to disulfide **4** above, obtained from the reaction of oxidized AMP with cystamine. Pilot reactions under various pH conditions demonstrated that the pH of the reaction mixture should not be higher than 6 to avoid overoxidation.

Disulfide **4**, obtained by either of the above routes, was reduced with DTT to the thiol **5** (Scheme 1). HPLC showed an 82% conversion to compound **5** during the DTT reaction. Although the thiol **5** was formed in high yield according to direct HPLC analysis of the reaction mixture, we were unable to isolate the pure free thiol (**5**) itself since it was contaminated by the disulfide **4**, apparently formed during workup by the facile air oxidation of compound **5**. Such ready oxidation of oligonucleotides bearing 3'-terminal thiols has been observed previously (13).

This successful reaction sequence was applied to 2-5A tetramer monophosphate, p5'A2'[p5'A2']₂p5'A. Synthetic conditions used to prepare **3** readily converted p5'A2'-[p5'A2']₂p5'A (**6a**) to the 2'-terminal-modified derivative **6c** in moderate yield. Characterization of compound **6c** was through snake venom phosphodiesterase digestion, which produced both 5'AMP and **3** in the requisite 3:1 ratio. A small amount of an additional compound was generated under these latter digestion conditions. We speculate that this arises from the partial decomposition of **3**, but this reaction product has not been characterized further.

Aqueous iodine oxidation of compound **6c** provided disulfide **7** in high yield. Characteristically, disulfide **7** could be 5'-dephosphorylated by bacterial alkaline phosphatase. Snake venom phosphodiesterase digestion gave, as expected, 5'AMP and the disulfide **4** in a 3:1 ratio. Limited digestion with a mixture of both bacterial alkaline phosphatase and snake venom phosphodiesterase further characterized the essential structural elements of the molecule by production of adenosine, 5'AMP, A2'p5'A, A2'p5'A2'p5'A, and compound **4**. The disulfide **7** reacted cleanly with DTT to give quantitative conversion to a product that was not isolated but was presumed to be the free thiol (**8**), in analogy to the reduction of **4** to **5**.

Both disulfide **7** and the *S*-tetrahydropyranyl-protected derivative were evaluated for their ability to bind to the 2-5A-dependent RNase L of mouse L cells. The concentrations (IC₅₀ values) of these derivatives required for replacement of 50% of the radiolabeled probe, p5'A2'p5'A2'p5'A2'p5'A3'[^32P]p5'C3'p, from the enzyme were 1 × 10⁻⁹ M for **7** and 8 × 10⁻¹⁰ M for **6c**, not significantly different from the corresponding value for 2-5A tetramer 5'-monophosphate itself. Assay conditions normally include an excess of β-mercaptoethanol, so that the disulfide would be reduced to the free thiol, and the IC₅₀ for **7** would be for the reduced oligonucleotide, not compound **7**.

CONCLUSIONS

The reaction of *S*-protected aminothiols with periodate-oxidized 3'-ribonucleotide-terminated oligonucleotides provides a viable synthetic approach to the introduction of thiols into preformed oligonucleotides. Specifically, we have demonstrated the key steps in this method using 5'AMP as a model and by applying it to the 2',5'-linked oligonucleotide, p5'A2'p5'A2'p5'A2'p5'A. However, in principle this chemistry should be applicable to any nucleic acid bearing a 3' (or 2')-terminal ribose, so long as no modified nucleotides are present which would be incompatible with the specific reactions involved in this derivatization.

As a practical matter, which preparative methodology would be preferable: (a) direct conjugation to cystamine or (b) reaction with *S*-(2-tetrahydropyranyl)cystamine and subsequent oxidation? A decision would depend upon the specific substrate under consideration. The faster approach would be cystamine conjugation, but this

would be limited by the relatively low yield of product and the increased difficulty of product purification. Thus, the latter method would be restricted to the simplest substrates, such as the mononucleotide AMP. For the more complex oligonucleotide substrates, the two-step sequence of conjugation with *S*-(2-tetrahydropyranyl)-cystamine followed by iodine oxidation would be preferable since the higher yields of the individual steps would allow more facile product purification.

Post-synthetically Ligated Ribozymes: An Alternative Approach to Iterative Solid-Phase Synthesis

Laurent Bellon,^{*,†} Christopher T. Workman,[†] Thale C. Jarvis,[‡] and Francine E. Wincott[†]

Departments of Oligonucleotide Chemistry and Cell Biology, Ribozyme Pharmaceuticals, Inc., 2950 Wilderness Place, Boulder, Colorado 80301. Received November 25, 1996[⊗]

To improve the overall yield of ribozyme synthesis, a convergent approach, based on the post-synthetic formation of an amino linker between two half-ribozymes was investigated. Borane-pyridine-mediated reductive amination of 3'-phosphoglycaldehyde-5'-half-ribozymes with 5'-aminoethyl-3'-half-ribozymes generated the corresponding amino-linked ribozymes in yields >77% on different scales. The investigation of a variety of reducing agents is discussed together with a kinetic analysis of the selected coupling reaction. These post-synthetically ligated ribozymes exhibited slightly reduced *in vitro* catalytic activity and cell efficacy.

INTRODUCTION

Ribozymes are RNA enzymes (Cech, 1993; Symons, 1994) that can be designed to cleave other RNA molecules. *trans*-Cleaving hammerhead ribozymes show great promise as therapeutic agents due to their inherent catalytic activity combined with highly specific binding to a chosen target RNA (Christoffersen and Marr, 1995). Improvements in the chemical synthesis of RNA (Wincott et al., 1995; Scaringe et al., 1990) have led to the site-specific introduction of various chemical modifications into hammerhead ribozymes providing nuclease resistance (Usman and Cedergren, 1992; Yang et al., 1992) and enhanced catalytic activity (Beigelman et al., 1995; Burgin et al., 1996). Because of the iterative nature of solid-phase oligoribonucleotide synthesis, only modest chemical yields of a 37-mer ribozyme can be achieved. Moreover, the necessary reversed-phase and anion-exchange purification steps further diminish this yield due to the inherent difficulty in separating the full-length ribozyme from the failures. As part of an ongoing effort to overcome these limitations, our group has designed an alternative approach (Bellon et al., 1996) in which two half-ribozymes are synthesized using known solid-phase methodologies. These halves contain complementary chemical functionalities that allow post-synthetic chemical ligation through a covalent linkage. Due to their lengths and the iterative synthesis process, the half-ribozymes are obtained in greater yield as compared to a full-length ribozyme. Therefore, this half-ribozyme approach has a theoretical advantage over the purely solid-phase procedure, with respect to yields, provided that the post-synthetic chemical ligation proceeds efficiently.

We describe herein the design, synthesis, and reductive amination coupling of half-ribozymes, on a pilot scale, together with a kinetic analysis of the conjugation reaction. The optimized conditions were then applied to a larger scale synthesis (50 μ mol), allowing a direct comparison between the half-ribozyme strategy and classical recurrent ribozyme synthesis. Catalytic activity and cell culture efficacy of the amino-linked ribozymes are also discussed.

MATERIALS AND METHODS

General Methods. Glyceryl-CPG and aminoethyl linker phosphoramidite were purchased from GlenResearch, Sterling, VA. Sodium cyanoborohydride, sodium borohydride, sodium triacetoxymethylborohydride, borane-pyridine, borane dimethylamine, and amberlyst A-26 borohydride were obtained from Aldrich Chemical Co., Milwaukee, WI. Sep-Pak Plus (C₁₈) purification cartridges were obtained from Waters Corp., Milford, MA.

Oxidative Cleavage of the 3'-Phosphoglyceryl-5'-half-ribozyme. A typical procedure is represented with half-ribozyme **4**. Half-ribozyme **4** (100 μ L, 50 nmol) was oxidized over 30 min with 10 equiv of aqueous NaIO₄ (1 μ L, 500 mM).

Small-Scale Desalting of the Ribozymes after Periodate Oxidation or Anion-Exchange HPLC. A typical procedure is represented with half-ribozyme **8**. The crude oxidized 3'-phosphoglycaldehyde-5'-half-ribozyme **8** was applied to a Waters Sep-Pak Plus (C₁₈) cartridge conditioned with CH₃CN/MeOH/H₂O (1:1:1, 10 mL) and SuperQ H₂O (20 mL). Following sample application, the cartridge was washed with SuperQ H₂O (10 mL) to remove formaldehyde and excess sodium periodate or excess sodium chloride in the case of anion-exchange-purified samples. Product was then eluted from the column with CH₃CN/MeOH/H₂O (1:1:1, 10 mL) and dried under reduced pressure.

Reductive Amination Ligation of 5'- and 3'-Half-Ribozymes. A typical procedure is represented by the synthesis of the amino-linked ribozyme **9**. 3'-Phosphoglycaldehyde-5'-half-ribozyme **8** (10 μ L, 500 μ M) and 5'-aminoethyl-3'-half-ribozyme **5** (10 μ L, 500 μ M) were mixed in a 1.5 mL Eppendorf tube. Sodium *N*₂-acetamido-2-iminodiacetate (ADA) (20 μ L of 200 mM, pH 6.2) was then added (125 μ M half-ribozyme final concentration). Reductive amination coupling was initiated with borane-pyridine in EtOH (1 μ L, 160 mM, 30 equiv). Reaction was sampled (0.5 μ L, 60 pmol) every few hours and diluted in water (200 μ L, 180 μ L injected) for HPLC analysis.

Analytical Anion-Exchange HPLC. All analyticals were run on a Hewlett-Packard 1090 HPLC using a Dionex NucleoPac PA-100 column, 4 \times 250 mm. Perchlorate buffers (buffer A = 10 mM NaClO₄/1 mM Tris-HCl; buffer B = 300 mM NaClO₄/1 mM Tris-HCl, both pH 9.3) and column heating to 50 $^{\circ}$ C were standard conditions. Analyticals were run with 30–60 pmol of ribozyme injected in a volume of 180 μ L. Half-ribozymes

[⊗] Abstract published in *Advance ACS Abstracts*, February 15, 1997.

were analyzed on a 30–60% B gradient over 12 min. Oxidized 3'-phosphoglycaldehyde-5'-half-ribozymes were run at 80 °C on a 45–75% B gradient over 12 min. Reductive amination reactions were analyzed on a 40–70% B gradient over 12 min.

Small-Scale Purification of the Amino-Linked Ribozymes. Crude samples (5 mL) were injected onto a Dionex NucleoPac PA-100, 22 × 250 mm (90 mL), column equilibrated with buffer A (buffer A = 20 mM NaCl/10% EtOH/1 mM Tris·HCl; buffer B = 1 M NaCl/10% EtOH/1 mM Tris·HCl, both pH 9.3). The linked ribozymes were purified at elevated temperatures since heat was necessary to melt the hybrid formed between the unreacted halves. A 55–70% B gradient was applied over 60 min. A 10 mL/min flow rate was used, and fractions were collected every minute. Fractions containing full-length product >80% by peak area were pooled and desalted using the method described for **8**.

Large-Scale Reversed-Phase HPLC Purification of the 5'-Half-Ribozyme **4 and Full-Length Control RPI.3718.** The crude material from a large-scale tritylation (50 μ mol) synthesis was applied to a Pharmacia Source 15RP 16/10 column equilibrated in 100% buffer A (buffer A = 1 M NaCl/5 mM Tris·HCl, pH 9.0; buffer B = 60% EtOH/5 mM Tris·HCl, pH 9.0) on a FPLC system (Pharmacia Biotech). A gradient from 0 to 40% B in 4 column volumes (CVs), from 40 to 42% B in 5 CVs, and then from 42 to 100% B in 3 CVs was applied at a flow rate of 10 mL/min (300 cm/h). Fractions containing over 60% full-length material by HPLC were pooled and subjected to manual detritylation with HCl. The solution was acidified to pH 2 (20–40 mM HCl) with 1 M HCl for 15 min. The pH of the solution was then adjusted to pH 7 with Tris base (1 M Tris base, pH 11–12). This material was analyzed by HPLC at >70% full-length by area.

Large-Scale Anion-Exchange HPLC Purification of the Half-Ribozymes **4 and **5**, Full-Length Control RPI.3718, and Amino-Linked Ribozyme **9**.** The reversed-phase purified, detritylated material was applied to a Pharmacia Source 15Q 26/10 (50 mL) anion-exchange column on a Pharmacia FPLC system. A NaCl gradient (buffer A = 20 mM NaCl/5 mM Tris·HCl, pH 9; buffer B = 1 M NaCl/5 mM Tris·HCl, pH 9) was applied at a flow rate of 10 mL/min. The half-ribozymes were purified using a 30–50% B gradient in 40 CVs. For the full-length control, RPI.3718, a gradient from 40 to 60% B in 40 CVs was used. The linked ribozyme **9** was purified at 55 °C with a gradient from 60 to 80% B in 20 CVs. The fractions containing over 80% full-length material were pooled. This material was analyzed by HPLC at >85% full-length by area.

Large-Scale Desalting of the 3'-Phosphoglycaldehyde-5'-half-ribozyme **8 and of the Anion-Exchange-Purified Ribozymes.** The ribozyme solutions were applied to a 1.6 × 10 cm (20 mL) bed of Bondapak C₁₈ 125 Å (37–55 μ M) packed in a Pharmacia HR 16/10 column pre-equilibrated in water. Application and desalting were run at a flow rate of 10 mL/min. Ribozyme was cleared from the column with a step gradient to 30% EtOH in water. All UV-absorbing fractions were pooled and dried under reduced pressure.

Electrospray Mass Spectrometry. Desalting was performed using a modified ammonium acetate precipitation procedure (Stults and Marsters, 1991). Ribozyme (10 nmol) was suspended in SuperQ water (30 μ L). NH₄-OAc (50 μ L, 5 M, pH 5.6) was added and the solution vortexed. After 10 min, absolute EtOH (600 μ L) was added and the ribozyme solution vortexed and placed in the –70 °C freezer overnight. Samples were centrifuged

(14 000 rpm, 30 min), and supernatant was carefully removed. The pellets were treated twice more with this procedure to ensure efficient ammonium exchange. ES-MS was performed on a Fison Instruments VG Quattro-SG quadrupole mass spectrometer. Desalted and ammonium-exchanged samples were suspended in deionized water (1 nmol/ μ L). The ribozyme solution (1 μ L) was added to an acetonitrile (ACN) solution [17 μ L, 80% ACN/2.5 mM 1,2 diaminocyclohexane-*N,N,N,N*-tetraacetic acid (CDTA)/0.1%TEA]. The ribozyme/ACN solution was injected through a fused silica loop (10 μ L) at 4 μ L/min. The instrument was run in ES(–) mode (cone voltage = 42 V) on a mass range of 400–1500.

Ribozyme Catalytic Activity Assay. RPI.3718, amino-linked ribozyme **9**, its inactive version, and 5'-³²P-end-labeled substrate **3** were heated separately in reaction buffer (50 mM Tris·HCl, pH 8.0; 40 mM MgCl₂) to 95 °C for 2 min, quenched on ice, and equilibrated to the final reaction temperature (37 °C) prior to the start of the reactions. Reactions were carried out in enzyme excess and were started by mixing ~1 nM substrate with 500 nM ribozyme in a final volume of 50 μ L. Aliquots of 5 μ L were removed at 0.5, 1, 2.5, 5, 10, 15, 20, 30, and 60 min, quenched in formamide loading buffer, and loaded onto 15% polyacrylamide/7 M urea gels. The fraction of substrate and product present at each time point was determined by quantitation of scanned images from a Molecular Dynamics PhosphorImager. Ribozyme cleavage rates were calculated from plots of the fraction of substrate remaining vs time using a double-exponential curve fit (Kaleidagraph, Synergy Software) (Burgin et al., 1996). For RPI.3718, the fast portion of the curve represented 54% of the total reaction; therefore, the observed cleavage rate (k_{obs}) was taken from fits of the first exponential. For amino-linked ribozyme **9**, the slow portion of the curve represented 93% of the total reaction; therefore, the observed cleavage rate (k_{obs}) was taken from fits of the second exponential.

Smooth Muscle Cell Proliferation Assay. Rat aortic smooth muscle cells (RASMC) were isolated and propagated as described (Jarvis et al., 1996a). Cell proliferation assays were performed according to a modification of the method of Jarvis et al. (1996a). Briefly, cells were set at a density of 5000 cells per well in a 24-well tissue culture plate and cultured in Dulbecco's Modified Eagle's Medium (DMEM) containing 10% FBS for 24 h at 37 °C in a 5% CO₂ atmosphere. Cells were then washed twice in Dulbecco's phosphate-buffered saline (DPBS) and serum starved in DMEM containing 0.5% fetal bovine serum (FBS) for 48 h to induce a quiescent state. Cells were then washed twice with DPBS and treated with 0.5 mL per well of 100 nM ribozyme complexed with 7.2 μ g/mL LipofectAMINE (GIBCO-BRL) for 1.5 h at 37 °C. Ribozyme/lipid complexes were then removed, and the cells were washed twice with DPBS and incubated in DMEM containing 0.25% FBS for an additional 6 h. Cells were then stimulated to proliferate by addition of 10% FBS. Cell proliferation was measured by incorporation of BrdU as described (Jarvis et al., 1996a).

RESULTS AND DISCUSSION

Synthetic Strategy. A realistic averaged stepwise chemical yield (ASWY) of 96.5% can be routinely obtained for ribozyme synthesis as determined by the ratio (μ mol of FLR/ μ mol scale)^{1/n} × 100, where μ mol of FLR is the amount of full-length ribozyme in the crude mixture, μ mol scale is the scale of synthesis and *n* is the number of synthesis cycles. This half-ribozyme approach has a theoretical advantage over the iterative procedure with

Figure 1. Theoretical chemical yield comparison between half-ribozyme approach and iterative ribozyme synthesis. Ligated ribozyme synthesis yields are calculated as follows: (49% \times ligation yield), where 49% is the 21-mer half-ribozyme synthesis yield as determined from a 96.5% ASWY; or (49% \times ligation yield) \times 80%, where 80% is the recovery yield of the additional purification step for the convergent route. The selected break-even point for the two strategies corresponds to 71%.

respect to yields. A 96.5% ASWY correlates in 28% theoretical yield for a 37-mer ribozyme, 49% theoretical yield for a 21-mer half-ribozyme, and 56% theoretical yield for a 17-mer half-ribozyme. A critical requirement is the chemical ligation yield of the two halves to form the full-length ribozyme (Figure 1). We have determined that a minimum coupling yield of 57% is theoretically sufficient to compete with iterative synthesis (49% \times 57% = 28%). However, the convergent route requires an additional purification step to separate the chemically ligated full-length ribozyme from the unreacted halves. Therefore, we have set the threshold that ensures the advantage of this segmented approach over iterative synthesis at 71% half-ribozyme coupling yield (Figure 1). It is clear from Figure 1 that any improvement in the ligation efficiency that raises it above 71% will provide a greater amount of full-length ribozyme. Ideally, quantitative ligation efficiency would lead to 39% FLR, to be compared with 28% for the iterative approach (Figure 1).

Design of Half-Ribozymes. An important requirement for this strategy to be successful is that the site of chemical ligation must not interfere with the ribozyme core to ensure that full catalytic activity is retained. It has been previously shown that the stem II or loop II of the hammerhead ribozyme is not essential for catalytic activity (Bellon et al., 1996; Tuschl et al., 1993; Benseler et al., 1993; Beigelman et al., 1994; Hendry et al., 1994). Similarly to our previous work (Bellon et al., 1996), the standard GAAA tetraloop II and the stem II region of the generic, nuclease stable ribozyme motif (Beigelman et al., 1995; Burgin et al., 1996), as represented by RPI.3718 (Jarvis et al., 1996a) **1** (Figure 2), were modified to accommodate post-synthetic chemical coupling (Figure 3). Chemical ligation or conjugation of oligonucleotides can be greatly enhanced by the presence of a template (Gryaznov and Letsinger, 1993; Herrlein et al., 1995). Therefore, we assumed that successful coupling reaction

Figure 2. Structures of RPI.3718 **1**, RPI.3718S **2**, and the RNA substrate **3**.

of the two half-ribozymes relied upon formation of the stem II bringing the two chemical moieties within close proximity to one another. Free energies predicting duplex stability of the suitable 5'-3' (**4.5** or **6.7**) and undesired 5'-5' (**4.4** or **6.6**) or 3'-3' (**5.5** or **7.7**) duplexes were calculated (Freier et al., 1986) with the standard self-complementarity ggcc stem II (as represented in **6** and **7**, Figure 3) or with a modified gcacc five base-pair stem II (as represented in **4** and **5**, Figure 3) (Table 1). The ΔG° values were clearly in favor of the 5 base pair stem II ensuring the formation of the correct duplex **4.5** by -3.3 kcal mol $^{-1}$ over the other possible duplexes **4.4** or **5.5**.

Furthermore, a uridyl residue was introduced between the 3'-phosphoglyceryl moiety and the stem II in the 5'-half-ribozyme **4** (Figure 3) to allow spatial bridging between the primary amine of **5** and the carbonyl

functionality of the oxidized **4**. Indeed, preliminary work on morpholino-linked ribozymes (Bellon et al., 1996) indicated that a single atom difference between an aminoethyl linker and an aminoethylene glycol linker had a tremendous influence on the extent of product formation (data not shown).

Reductive Amination Coupling of Half-Ribozymes.

We selected a linear amino linkage to covalently bridge the 5'- and 3'-half-ribozyme since reductive amination chemistry has been applied effectively to a wide range of oligonucleotide substrates under aqueous conditions (Goodchild, 1990; Morvan et al., 1996; Deschamp and Sonveaux, 1995; Harambilis et al., 1994; Lemaitre et al., 1987). The previously studied morpholino linkage (Bellon et al., 1996) was not chosen here because of long reaction time together with the formation of two linked products.

Half-ribozymes **4** and **5**, derived from RPI.3718, were synthesized on a 2.5 μ mol scale on glyceryl-controlled pore glass (Urata and Akagi, 1993) and on an inverted abasic polystyrene (Jarvis et al., 1996b), respectively, and then purified according to standard methods (Wincott et al., 1995). The 3'-phosphoglyceryl-5'-half-ribozyme **4** (125 μ M aqueous solution) was subjected to oxidative cleavage with 10 molar equiv of a 100 mM aqueous solution of sodium periodate (Figure 4A). Complete conversion of **4** to the 3'-phosphoglycaldehyde-5'-half-ribozyme **8** could be observed within 30 min (Figure 4B). Since the periodate-mediated oxidation of the 3'-phosphoglyceryl **4** generates 1 molar equiv of highly reactive formaldehyde, **8** was eluted from the reaction mixture on a Sep-Pak C₁₈ cartridge (Waters Corp.). Half-ribozymes **8** (125 μ M) and **5** (500 μ M) were then reacted with 30 molar equiv of aqueous NaBH₃CN (Borch et al., 1971) (500 mM) in ADA buffer (100 mM), pH 6.0 (Figure 5A). Unlike the morpholino ribozyme (Bellon et al., 1996), after 7 days of reaction, a substantial amount of unreacted 3'-phosphoglycaldehyde **8** could be observed (Figure 5B). After HPLC purification, **9** was identified as the desired amino-

Figure 5. (A) NaBH₃CN-mediated coupling of the amino-linked ribozymes **9** and **10**. (B) Anion-exchange HPLC analysis of the reductive amination of **8** with **5** after 0 and 150 h.

linked ribozyme on the basis of ES-MS analysis (calcd 11928.6, found 11929.0). Product **10** was assigned as a cyanoborane adduct in accordance with our previous data (Bellon et al., 1996). As a result of the incomplete reaction of the half-ribozymes, in addition to the undesired formation of the adduct **10**, the amino-linked ribozyme, **9**, was obtained in only 50.2% yield (Table 2). Since the necessary 71% coupling efficiency (Figure 1) was not obtained, we investigated other reducing agents to suppress the formation of the adduct as in **10** yet allow faster and higher yielding synthesis of **9**.

We assumed that the borane adduct formation could be prevented with the use of borane reducing reagents already complexed with an amine (Pelter et al., 1988). Such amine-borane complexes have reducing properties similar to those of hydroborates (Pelter et al., 1988), which are known to be rather selective for Schiff base reduction. We investigated the use of borane-pyridine (Pelter et al., 1984; Bomann et al., 1995; Moorman, 1993) and borane-dimethylamine (Billman and McDowell, 1961) complexes together with other types of hydroborates such as sodium borohydride (Abdel-Magid et al., 1994), sodium triacetoxyborohydride (Abdel-Magid et al., 1990; Hart

and Leroy, 1995), or borohydride exchange resins (Yoon et al., 1993; Gibson and Bailey, 1977). Half-ribozymes **8** (125 μ M) and **5** (500 μ M) were reacted in ADA buffer (100 mM), pH 6.0, in the presence of 30 molar equiv of the reducing agent for 48 h (Table 2). As seen from Table 2, borane-pyridine complex produced a very high yield of the amino-linked ribozyme **9** without the concomitant formation of a second ligated product. A small amount of unreacted 5'-half-ribozyme was still observed after 48 h of reaction (Figure 6). Following anion-exchange purification, this material was subjected to ES-MS to determine whether **8** could have been reduced (Andrews and Crawford, 1980) into the corresponding 3'-phosphoglycol, **11** (Urata and Akagi, 1993), thereby competing

with the reductive amination. The mass analysis (calcd 6652.2, found 6653.0) was in agreement with the molecular weight of alcohol **11**, although **8** (calcd 6650.2) and **11** (calcd 6652.2) only differ by 2 atomic mass units. The fact that **11** did not react with the 5'-aminoheptyl-3'-half-ribozyme **5** when subjected to the same reductive amination conditions (data not shown) provided supportive evidence regarding the 3'-phosphoglycol nature of **11**. Reducing the molar equivalent of borane-pyridine to 5 equiv lengthened considerably the reaction time (over 5 days) without preventing the formation of **11**. Adding the 30 molar equiv in two portions at a 12 h interval did not change the scope of the reaction (data not shown).

Kinetic Analysis of the Borane-Pyridine-Mediated Half-Ribozyme Coupling. To prepare for the large-scale (50 μ mol) comparison of the half-ribozyme approach vs recurrent synthesis, we felt it was important to fine-tune reaction conditions giving rise to the amino-linked ribozyme **9**. In particular, optimal reaction time and concentration of the halves were investigated. Coupling reactions were set in ADA buffer (100 mM), pH 6.0, in the presence of 30 molar equiv of BH₃·Pyr (800 mM in ethanol) with 1.25 mM, 125 μ M, or 12.5 μ M of the 3'-phosphoglycaldehyde-5'-half-ribozyme **8** and the 5'-aminoheptyl-3'-half-ribozyme **5** (1:1 stoichiometry). Anion-exchange HPLC monitoring of the coupling reaction allowed us to plot the formation of the amino-linked ribozyme, **9** (expressed in percent yield), vs time (Figure 7A). The 125 and 12.5 μ M reactions reached the same 72% coupling yield after 24 and 150 h, respectively, whereas a final 56% coupling efficiency could be obtained after only 5 h with the high 1.25 mM concentration (Figure 7A). Extending the reaction time up to 150 h for the three concentrations did not have any significant impact on the amount of product formed. One possible

Table 3. Initial Velocities of the Reductive Amination Cross-Coupling Reaction

	half-ribozyme 5 and 8 concentration		
	1.25 mM	125 μM	12.5 μM
k_{obs} (h^{-1})	0.611	0.290	0.086

explanation for this "plateau" effect is that the 3'-phosphoglycaldehyde-5'-half-ribozyme **8** was competitively reduced into the corresponding alcohol (Andrews and Crawford, 1980) during the reductive amination with **5**. To further validate this hypothesis, we designed a "rescue" experiment in which another equivalent of half-ribozyme **8** was added to the 125 μM reaction after 24 h. As predicted, this procedure increased the final coupling yield to 93.6% after 48 h (Figure 7B). Another "rescue" experiment in which a molar equivalent of **5** was added to the 125 μM reaction after 24 h did not have any effect on the formation of the product **9** (data not shown), corroborating the fact that **8** was consumed in a side reaction. Since these "rescue" experiments did not use the desired 1:1 stoichiometry, the single mixing of an equimolar amount of half-ribozymes (125 μM) together with a 24 h reaction time was selected for the 50 μmol large-scale comparison. The experimental time points (Figure 7A) were treated (Burgin et al., 1996) using a double-exponential curve algorithm (KaleidaGraph). Kinetic analyses of the initial velocities of the reactions revealed a direct relationship between half-ribozyme concentration and the initial rate constant (Table 3). The lower yield (72%) obtained in these kinetic experiments was attributed to the 1:1 stoichiometry since it is known that reductive amination works optimally in the presence of a 5-fold excess of the amine residue (Borch et al., 1971).

Catalytic Activity of the Amino-Linked Ribozyme **9 and Its "Inactive" Counterpart.** Once the amino-linked ribozyme **9** was synthesized and characterized, it was critical to ascertain the effect of this chemical linkage on the ribozyme activity. "Active" amino-linked ribozyme **9**, its "inactive" counterpart containing two mutations in the catalytic core that abolish cleavage activity (Beigelman et al., 1995; Jarvis et al., 1996) (see **4** and **5**, Figure 3), and the control RPI.3718 were assayed under single-turnover conditions for their cleavage rate on short substrate **3** (Figure 2). The amino-linked ribozyme **9** was approximately 10 times slower than RPI.3718 (Table 4), confirming that one can extensively modify the stem II/loop II region without dramatically affecting cleavage activity. As expected, the inactive amino-linked ribozyme completely lacked detectable catalytic activity.

Table 4. Cleavage Rate of the Substrate **3** by the "Active" Ribozyme **9**, Its "Inactive" Analog, and RPI.3718^a

^a Over 82%, 55%, and 0% of the substrate **3** was cleaved over 1 h with ribozymes RPI.3718, **9**, and inactive **9**, respectively. ^b [Rz] = 500 nM, [**3**] ~ 1 nM, 50 mM Tris-HCl, pH 8.0, 37 °C, 40 mM Mg^{2+} .

Cell Efficacy of Phosphorothioate-Containing Amino-Linked Ribozyme **14 and Its "Inactive" Counterpart **17**.** Equally important was to assess the cell culture efficacy (Jarvis et al., 1996a,b) of these amino-linked ribozymes as compared to the control RPI.3718 **2**. It has been shown that one to four phosphorothioates linkages are required at the 5'-end of the ribozyme to optimize cell efficacy of the ribozyme (Jarvis et al., 1996b). Therefore, the 3'-phosphoglyceryl-5'-half-ribozyme **12**, containing four phosphorothioate linkages at the 5'-end (Figure 3), was synthesized and periodate-oxidized under the same conditions as described for its all-phosphodiester analog **4**. Interestingly, a negative shift in the retention time was observed for the 3'-phosphoglycaldehyde **13** (Figure 8A), suggesting that in addition to the desired oxidative cleavage of the 3'-*cis*-diol, nonspecific oxidation of the phosphorothioate linkages to their phosphodiester analogs may have occurred. After Sep-Pak desalting, **13** (177 μM in ADA, 100 mM, pH 6.0) was reductively aminated with the aminohexyl-half-ribozyme **5** under the borane-pyridine conditions (Figure 8B). The expected partially thiolated amino-linked ribozyme **14** was formed and subsequently purified on anion-exchange HPLC. After ammonium acetate precipitation, this material was subjected to ES-MS analysis to assess its phosphorothioate content. As seen from the electrospray mass spectrum (Figure 9), two peaks corresponding to **14** with one remaining phosphorothioate linkage (calcd 11944.7, found 11944.0) or two remaining phosphorothioates (calcd 11960.7, found 11961.0) could be identified. This clearly confirmed that oxidation of at least two phosphorothioate linkages to their oxygenated homologs had occurred during the periodate-mediated oxidative cleavage. Surprisingly, no material corresponding to the all-phosphodiester amino-linked ribozyme **9** was observed, indicating that at least one of the thiolated positions seems to be particularly resistant toward oxidation. Desulfurization of phospho-

Figure 9. ES-MS for **14** (4.5 μ M) in 80% $\text{CH}_3\text{CN}/\text{H}_2\text{O}$, 0.1% TEA with CDTA, charge states 11– to 19–. The computer-deconvoluted masses are represented in the inset.

rothioate linkages using diverse oxidizing reagents is a commonly used method for base composition analysis of thiolated oligonucleotides (Connolly et al., 1984; Schuette et al., 1994; Wyrzykiewicz and Cole, 1994). To the best of our knowledge, a single study (Agrawal et al., 1990) describes the use of sodium periodate as the oxidizing agent. Base composition on phosphorothioate-containing ribozymes performed in our hands necessitated the use of 250 equiv of sodium periodate per phosphorothioate linkage at 37 $^\circ\text{C}$ over 2 h to complete full oxidation (D. Sweedler, unpublished data). Therefore, we were not expecting such an overwhelming side reaction under the relatively mild conditions used (a maximum of 2.5 equiv of NaIO_4 per phosphorothioate linkage, 30 min at room temperature). The exact position(s) of the(se) remaining phosphorothioate linkage(s) on the ribozyme is (are) under investigation using a modification of the iodethanol method developed by Gish and Eckstein (1988). The “inactive” version **17** of the amino-linked ribozyme **14** was synthesized similarly from half-ribozymes **15** and **16** (Figure 3). The same phosphorothioate/phosphodiester distribution could be observed as determined by ES-MS (**17** with one $\text{P}=\text{S}$, calcd 11896.6, found 11896.0; **17** with two $\text{P}=\text{S}$, calcd 11912.7, found 11912.0).

RPI.3718S **2** is a chemically stabilized 37-mer ribozyme targeted against site 575 of the proto-oncogene *c-myc* mRNA; it contains four phosphorothioate linkages at the 5'-end. RPI.3718S has been shown to inhibit vascular smooth muscle cell proliferation with an IC_{50} of approximately 75 nM (Jarvis et al., 1996a). “Active” and “inactive” amino-linked ribozymes **14** and **17**, respectively, together with the “active” control RPI.3718S and its inactive version RPI.3704 (Jarvis et al., 1996a) were delivered to quiescent RASCs using LipofectAMINE as a cationic lipid vehicle. The cells were stimulated with 10% fetal bovine serum, and cell proliferation was measured by a bromodeoxyuridine incorporation assay (Jarvis et al., 1996a). As seen in Figure 10, treatment of the cells with the catalytically active ribozymes **14** and RPI.3718S resulted in a significant inhibition of proliferation, whereas the “inactive” version (**17** or RPI.3704) failed to inhibit. It is apparent that a significant window of inhibition of cell proliferation exists between “active” and “inactive” ribozymes, confirming the mode of action of the ribozymes. Furthermore, the extent of this inhibition by the amino-linked ribozyme **14** is similar to that obtained with the control RPI.3718S. This clearly demonstrates that post-synthetically ligated ribozymes are as

Figure 10. RASCs were treated with ribozymes complexed with cationic lipid as described under Materials and Methods. Cell proliferation is displayed as the percentage of cells that undergo DNA replication in response to serum stimulation. The 0% and 10% FBS controls show the proliferative response of untreated cells in the absence of or presence of serum.

potent as their traditionally synthesized analogs in inhibiting *c-myc* mRNA-induced cell proliferation. In agreement with previous work (Jarvis et al., 1996a), the slightly diminished inhibition of cell proliferation can be attributed to the presence of only one and two thiolated linkages in the amino-linked ribozyme, **14**, whereas RPI.3718S contains four phosphorothioate linkages.

50 μ mol Large-Scale Comparison between Half-Ribozyme Approach and Iterative Synthesis. Cleavage activity and cell culture efficacy of these amino-linked ribozymes having been demonstrated, it was imperative to study the scale-up of this post-synthetic coupling to validate the theoretical advantage of the half-ribozyme approach in terms of yields (Figure 1). Therefore, the 5'-half-ribozyme-3'-phosphoglyceryl **4**, 3'-half-ribozyme-5'-aminoethyl **5**, and RPI.3718 (Figures 2 and 3) were synthesized on a 50 μ mol scale on a 390Z ABI synthesizer using known methodologies (Wincott et al., 1995). RPI.3718 and **4** were then purified using the routine two-step (trityl-on reversed-phase and trityl-off anion-exchange) purification, whereas **5** was submitted to a single anion-exchange procedure since it did not contain a trityl group at the 5'-end. As predicted from a 96.5% ASWY, RPI.3718 was obtained in 26.1% chemical yield at the crude reaction mixture stage. This yield was further diminished to 17.7% after purification (3102 $\text{AU}_{260\text{ nm}}$, 8.88 μ mol, Figure 11A) with a 96.3% HPLC spectrophotometric purity at 260 nm. The 5'-aminoethyl-3'-half-ribozyme, **5**, was obtained in 52.7% yield at the crude level, corrected to 34.9% after purification (2667 $\text{AU}_{260\text{ nm}}$, 18.45 μ mol, 97.9% HPLC purity, Figure 11A). More surprising was the much lower chemical yield obtained for the 3'-phosphoglyceryl-half-ribozyme, **4** (18.5%, 1750 $\text{AU}_{260\text{ nm}}$ before purification, Figure 11A), synthesized on glyceryl-CPG (63 μ mol g^{-1} , Glen Research). Analysis of the trityl release data indicated a sharp drop of the trityl cation-induced conductivity after the first coupling of the 2'-*O*-methyluridyl residue onto the glyceryl-CPG, while the conductivity remained constant thereafter. This suggested that the first coupling on the solid support was not optimal. Highly loaded ($>40\ \mu\text{mol g}^{-1}$) CPG solid supports are known (Wright et al., 1993) to lose the mechanical and fluidic properties suitable for large-scale

Figure 11. (A) Chemical yields of RPI.3718, half-ribozymes **4** and **5** after synthesis, reversed-phase and anion-exchange purification. (B) Chemical yield of the amino-linked ribozyme **9** after coupling and anion-exchange purification.

synthesis. Therefore, we functionalized highly cross-linked aminomethyl polystyrene solid support (McCollum and Andrus, 1991) with 1-*O*-dimethoxytritylglycerol according to a known procedure (Urata and Akagi, 1993). Under these conditions, glyceryl polystyrene solid support was obtained with a $11.6 \mu\text{mol g}^{-1}$ loading yield. Unfortunately, **4** synthesized from this resin was not obtained in any better yield as compared to CPG. This led us to believe that the electron-withdrawing acetoxy group (Urata and Akagi, 1993) adjacent to the dimethoxytrityl residue diminished the reactivity of the primary hydroxyl group generated after detritylation.

It was obvious that since **4** was obtained with a lower chemical yield ($6.88 \mu\text{mol}$) than the full-length control RPI.3718 ($8.88 \mu\text{mol}$, Figure 11), the coupling of the two halves could not generate more material than the iterative synthesis. However, the coupling study was completed to evaluate the scale-up of the pilot reactions (Figure 11B). 3'-Phosphoglyceryl-half-ribozyme **4** ($1305 \text{ AU}_{260 \text{ nm}}$, $6.88 \mu\text{mol}$) was oxidized as above into the 3'-phosphoglycaldehyde **8**, which was desalted on reversed-phase HPLC to remove excess NaIO_4 and formaldehyde. The aldehyde **8** was coupled in ADA buffer (100 mM, pH 6.0) with a stoichiometric amount of 5'-aminohexyl-half-ribozyme **5** ($994 \text{ AU}_{260 \text{ nm}}$, $6.88 \mu\text{mol}$, Figure 11B, final half-ribozymes concentration = $116 \mu\text{M}$) in the presence of 30 molar equiv of $\text{BH}_3 \cdot \text{Pyr}$ (80 mM in ethanol) for 24 h. As expected, the amino-linked ribozyme **9** was obtained cleanly in 77.6% coupling yield, well above the 71% threshold (Figure 1). After a final anion-exchange HPLC purification step to remove the unreacted 5'- and 3'-halves, $1344 \text{ AU}_{260 \text{ nm}}$ ($4.04 \mu\text{mol}$) of **9** exhibiting a 97.4% HPLC spectrophotometric purity at 260 nm was isolated (Figure 11B). This corresponds to a 58.7% coupling yield after purification. However, due to the low yield of its precursor **4**, the chemically ligated ribozyme **9** was only obtained with a 8.1% overall yield to be compared with the 17.7% overall yield for RPI.3718 (Figure 11).

CONCLUSION

Post-synthetically amino-linked ribozymes have been shown to possess the necessary cleavage activity and cell efficacy required to be considered as alternatives to solid-phase synthesized ribozymes. Furthermore, it has been demonstrated, on both small- and large-scale, that the post-synthetic assembling of half-ribozymes through a reductive amination coupling reaction meets the theoretical yield requirement to be competitive with iterative synthesis. However, this yield advantage is counterbal-

anced by the necessity of using a 3'-phosphoglyceryl-5'-half-ribozyme that cannot be synthesized in satisfactory yields.

ACKNOWLEDGMENT

We thank Susan Grimm, Victor Mokler, and Lara Maloney for the synthesis and purification of the different oligoribonucleotides, James McSwiggen for free energy calculations, Carolyn Gonzalez for catalytic activity assay, Alex Burgin for fruitful kinetic discussions, and Nassim Usman for continuous support.

Received October 24, 1996[⊗]

To explore whether endosomal release presents a major barrier to lipospermine-mediated gene delivery, acidic membrane-active peptides derived from influenza virus or artificial sequences were incorporated into DNA/dioctadecylamidoglycylspermine (=Transfectam) complexes. Depending on the cell line used, gene expression levels are approximately 3–30-fold higher than those obtained by applying DNA complexed to optimal amounts of Transfectam alone. In addition, gene transfer efficiency of DNA complexes with lower amounts of Transfectam (1.5–2 charge equiv) is increased by a factor of up to 1000 by peptides INF6 (influenza virus derived sequence) and INF10 (artificial sequence). The helper lipids 1,2-dioleoylphosphatidylethanolamine, egg phosphatidylethanolamine, and 1,2-dioleoyl-*rac*-glycerol also can enhance the gene transfer. Thus, endosomal escape seems to be only a moderate barrier for optimized, positively charged DNA/Transfectam complexes, but a substantial bottleneck for less positively charged complexes.

INTRODUCTION

Gene therapy relies on strategies that allow efficient and safe introduction of genetic information into human cells. Although most gene therapy protocols use recombinant viral vectors, the limitations of those biological vectors have prompted the design of a great variety of new synthetic systems, among which mono- and polycationic amphipathic molecules, able to complex DNA, have proven to be very attractive (Felgner et al., 1987, 1994; Behr et al., 1989; Leventis and Silviu, 1990; Gao and Huang, 1991; Rose et al., 1991; Hawley-Nelson et al., 1993; Solodin et al., 1995). This class of vectors has been shown to be applicable for *in vivo* administration in experimental animals (Brigham et al., 1989; Alton et al., 1993; Zhu et al., 1993; Canonico et al., 1994; Liu et al., 1995; Schwartz et al., 1995; Thierry et al., 1995) and in clinical trials (Nabel et al., 1993; Caplen et al., 1995). Despite the advances, the efficiency of these vectors, based on number of administered genes, remains orders of magnitude behind that of viral vectors. Efforts to further improve lipid-based gene transfer have been primarily focused on the direct modification of the cationic lipid (acyl chains, spacer arm, hydrophilic part; Felgner et al., 1994; Remy et al., 1994); the mechanism and the limiting steps of gene delivery remain unclear. Packaging of DNA into compact particles, uptake into the cell, release from internal vesicles, release of the DNA from the cationic lipid, and transfer into the nucleus are considered important steps of DNA delivery. Complexation of cationic lipids and DNA results in the formation of nucleolipidic particles (Behr, 1994; Sternberg et al.,

1994; Gao and Huang, 1996), which bind to the cell membrane surface by charge interaction, and endocytosis seems to be an efficient and the major delivery pathway (Legendre and Szoka, 1992; Behr, 1993; Zhou and Huang, 1994; Wrobel and Collins, 1995; Zabner et al., 1995) in many cell types. However, subsequent steps, i.e. the transport of DNA from the endosome to the cytoplasm and thence to the nucleus (Zabner et al., 1995) and the release of DNA from the cationic lipid (Zabner et al., 1995; Xu and Szoka, 1996), are considered to represent bottlenecks in successful gene transfer. Release of DNA from endosomes is suggested to proceed by destabilization of the endosomal membrane triggered by mixing the cationic lipids with the cellular anionic lipids (Leventis and Silviu, 1990; Xu and Szoka, 1996); it is, however, unclear how efficiently this mechanism proceeds.

The goal of this work was to evaluate whether gene expression mediated by the lipospermine Transfectam (dioctadecylamidoglycylspermine, DOGS¹) (Behr et al., 1989) can be further enhanced by adding compounds that should facilitate the transfer across the endosomal membrane. As membrane-destabilizing agents we used amphipathic peptides (Plank et al., 1994; Mechtler and Wagner, 1997) as well as helper lipids (Duzgunes et al., 1989; Leventis and Silviu, 1990; Felgner et al., 1994; Zhou and Huang, 1994; Remy et al., 1995) added to Transfectam/DNA. Amphipathic peptides were previously found to strongly (up to ≥ 1000 -fold) enhance polycation-based gene transfer (Plank et al., 1994; Gottschalk, 1996; Mechtler and Wagner, 1997; Zauner, 1995). As reported in this paper, we found that incorporation of peptides into Transfectam/DNA complexes results in (only) 3–30-fold higher gene expression as

compared to optimized, positively charged Transfectam/DNA complexes. This suggests that for Transfectam/DNA complexes the escape of DNA from endocytic vesicles is an existing, but minor, bottleneck. However, transfection of more electroneutral formulations is strongly increased by peptides and helper lipids by up to 1000-fold, indicating that for these particles endosomal escape is a limiting step.

MATERIALS AND METHODS

Materials. The plasmid pCMVL, coding for the *Photinus pyralis* luciferase gene under control of the cytomegalovirus enhancer/promoter, has been described (Plank et al., 1992). Endotoxin content was measured by the *Limulus amoebocyte* lysate assay (BioWhittaker, Walkersville, MD). Lipopolysaccharide content of pCMVL used in transfection experiments was 0.2 endotoxin unit/ μ g of DNA. Transfectam was synthesized as described (Behr et al., 1989) and is available from Promega (Madison, WI). Chloroquine, bafilomycin A₁, DOPE, MOG, DOG, EPE, EPC, cholesterol, and melittin (from bee venom) were obtained from Sigma (St. Louis, MO).

Peptide Synthesis. Peptides described in Table 1 were assembled on an Applied Biosystems 433 synthesizer with feedback monitoring by using fluorenylmethoxycarbonyl (Fmoc)-protected amino acids. Amino acids were coupled by the HBTU activation method (Fastmoc^U; 0.25 mmol scale; Knorr et al., 1989). The following side chain protecting groups were used: (Boc)Lys, (t-Bu)Glu, (t-Bu)Asp, and (Trt)Asn.

The synthesis and purification of the INF5 and INF6 peptides are described in Plank et al. (1994). The peptides INFA, INF10, and ECLA-I were synthesized according to the method of Mechtler and Wagner (1997). In brief, for ECLA-I, an HMP-resin (TentaGel R PHB; 0.22 mmol/g, Rapp Polymere) was chosen, using a mixture of 70% *N*-methylpyrrolidone/30% dimethylformamide (DMF) as solvent. Peptides INFA and INF10 were synthesized on a Cys(Trt) preloaded aminomethylated polystyrene resin with a *p*-carboxytrityl chloride linker (0.52 mmol/g; PepChem, Tübingen, Germany) using DMF as solvent.

The peptides were cleaved from the resin, and side chain protecting groups were removed with a mixture of trifluoroacetic acid/water/phenol/thioanisole/ethanedithiol (10:0.5:0.75:0.5:0.25) for 1.5 h at room temperature. Crude peptides were precipitated by dropwise addition of diethyl ether and were collected by centrifugation. Peptides were washed three times with ether and subsequently dried under a stream of argon followed by high vacuum. Crude peptides, dissolved in 1 M triethylammonium bicarbonate (pH 9), were subjected to gel filtration (Sephadex G-10; 20 mM triethylammonium acetate, pH 7.3). The purified peptide fractions were freeze-dried in a Speedvac (Savant) and stored as a powder at -80 °C.

The purity of the peptides was determined by analytical reversed phase HPLC, and peptide identities were confirmed by time-of-flight mass spectroscopy performed with a Finnigan MAT Lasermat instrument. Purified peptides were stored at -80 °C as lyophilized powder or in a 75:25 (v/v) HBS/glycerol mixture. Peptide INF6 lost its biological activity when stored in solution, most likely by structural changes involving aggregation (changes in HPLC profile). The membrane disruption activity of the peptides was tested in liposome and erythrocyte lysis assays (Plank et al., 1994; Mechtler and Wagner, 1997).

Liposome Leakage Assay. The ability of peptides INF6 and INF10, in free form or associated with Transfectam, to disrupt liposomes was assayed by the release of calcein from liposomes loaded with a self-quenching concentration of calcein. Liposomes (lipid compositions in molar ratio: EPC/EPE/cholesterol/SM, 10:3:5:2) were prepared as described (Mechtler and Wagner, 1997) by reversed phase evaporation with an aqueous phase of 100 mM calcein (dissolved by addition of 3.75 equiv of sodium hydroxide) and 50 mM NaCl and extruded through a 100 nm polycarbonate filter to obtain a uniform size distribution. The liposomes were separated from unincorporated material by gel filtration on Sepharose 4B with an iso-osmotic buffer (200 mM NaCl, 25 mM HEPES, pH 7.3). For the leakage assay in 96 well microtiter plates, the liposome stock solution was diluted (10 μ L/mL) in assay buffer (200 mM sodium chloride containing 20 mM citrate, pH 5.5, or 20 mM HEPES, pH 7.3). Fivefold serial dilutions of the test samples (stock solutions in 100 μ L of buffer: 5 μ g of peptide INF6 or 7.5 μ g of INF10, either in free form or associated with 7.5 μ g of Transfectam) were prepared in a 96 well microtiter plate (rows B–G). Row H was left as blank. Eighty microliters of the serial dilution of the test samples was added to 100 μ L of the liposome solution in another 96 well microtiter plate (final lipid concentration: 15 μ M) and, after 20 min of incubation at room temperature, assayed for calcein fluorescence at 515 nm (excitation 495 nm) on a microtiter plate fluorescence photometer (Perkin-Elmer). The value for 100% leakage was obtained by addition of 1 μ L of a 10% Triton X-100 solution to row A; row H (liposomes without peptide) was defined as 0% leakage.

Preparation of the Cationic Lipid/DNA Complexes with/without Membrane-Active Peptides or Helper Lipids. Complexes of DNA and Transfectam were prepared as described (Barthel et al., 1993). Briefly, plasmid DNA (3 μ g) and the desired amount of Transfectam were each diluted into 75 μ L of 150 mM NaCl and gently mixed. After 10–20 min, the two solutions were mixed. After an additional 10 min, the mixture was diluted with serum-free medium to a final volume of 2 mL; 1 mL of the transfection mixture was put on each well of the duplicate.

We use the term "charge equivalent" to indicate the amount of lipid used for a transfection; 1 charge equiv corresponds to the amount required to neutralize all of

the negative charges carried by the phosphate groups of the plasmid. For example, 3 μg of DNA corresponds to 9 nmol of negative charges; the charge ratio is calculated by taking into account the fact that 1 mol of Transfectam carries three positive charges, as three ammonium groups are protonated at physiological pH; according to this calculation, 3 μg of nucleic acid is neutralized by 3 nmol (3.8 μg) of Transfectam.

Membrane-active peptides (0.5 or 1 mg/mL solutions in HBS/glycerol, 3:1) were added to the preformed Transfectam/DNA complexes; after a 10–20 min period, the transfection volume was adjusted to 2 mL with culture medium, and 1 mL of this transfection mixture per well was pipetted onto the cells.

Helper lipids (DOPE, DOG, EPC, EPE, MOG) and cholesterol were diluted in ethanol containing a trace of methylene chloride (10 μL in 1 mL ethanol). The Transfectam/DNA/helper lipid complexes were formed by mixing the desired amounts of Transfectam/helper lipid (the amounts of helper lipids used are given in equivalents (mole/mole) to Transfectam) prior to dilution with the DNA solution.

Chromatography of Peptide/Transfectam/DNA Complexes. To demonstrate that the negatively charged peptides (at physiological pH) are bound via electrostatic interactions to the Transfectam 2 equiv/DNA complex, we subjected purified INF5 (90 μg) or Transfectam 2 equiv/60 μg of DNA with/without 90 μg of INF5 to gel filtration (Superose 12 HR10-30, Pharmacia, 10 \times 300 mm, HBS, flow rate 0.5 mL/min). Free peptide was detected by spectrophotometry measuring at 280 and 230 nm.

Cell Culture. Media, horse serum, and fetal calf serum (FCS) were from Gibco-BRL (Gaithersburg, MD). Culture media were supplemented with 2 mM L-glutamine and antibiotics. Human melanoma cells (H225) were kindly provided by S. Schreiber and G. Stingl (University of Vienna, Austria). BNL CL.2 (mouse embryonic liver cells), A549 (human lung carcinoma cells), and M-3 (Cloudman S91 melanoma cells; clone M-3) were obtained from ATCC (Rockville, MD). H225 cells were cultured in Roswell Park Memorial Institute (RPMI) medium 1640/10% FCS/1 mM sodium pyruvate, A549 cells in Dulbecco's Modified Eagle Medium (DMEM)/10% FCS, BNL CL.2 cells in high-glucose DMEM/10% FCS, and M-3 cells in Ham's-F10 medium/15% horse serum/5% FCS.

Transfection of Cells. Fifty thousand to seventy-five thousand cells per well for 24 well plates (Nunc, Roskilde, Denmark) and 150 000 cells per well for 6 well plates were plated the day before transfection. For all experiments, the final transfection volume was 1 mL per well. After 3–4 h, transfection medium was replaced with fresh medium containing 10% FCS. Luciferase activity was assayed 24 h after transfection. Each experiment was carried out several times; within a series, experiments were done in duplicate.

Luciferase Activity. Cells were harvested after 24 h in 150–200 μL of 250 mM Tris (pH 7.3)/0.5% Triton X-100. The cell lysate was then transferred to 1.5 mL Eppendorf tubes and centrifuged for 5 min at 10000g to pellet debris. Luciferase light units were recorded (using a Clinilumat LB9502 instrument from Berthold, Bad Wildbad, Germany) from an aliquot of the supernatant (20 μL) with 10 s integration after automatic injection of freshly prepared luciferin solution (Cotten et al., 1991). Luciferase background (150–250 light units) was subtracted from each value, and the transfection efficiencies were expressed as total light units per well and are the

Figure 1. Transfection efficiency of Transfectam/DNA/INF6 complexes. Complexes of 1 (\diamond), 1.5 (\circ), 2 (\square), and 4 (\triangle) charge equivalents of Transfectam/3 μg of pCMV in the presence of increasing amounts of the membrane-active peptide INF6 were used. DNA complexes were mixed with RPMI 1640 culture medium and added to the human melanoma cells H225 (75 000 cells per well in 24 well plates). After 4 h, the transfection medium was replaced by fresh RPMI containing 10% FCS. The cells were harvested 24 h after transfection and assayed for luciferase activity. Total luciferase activity of the cells is shown and is the mean of duplicates (\pm SD). (Insert) Representation of the luciferase activity versus the calculated charge ratio (Transfectam/DNA + INF6; \pm) of the different complexes. As the negatively charged peptide INF6 (four negative charges per molecule at neutral pH) associates with the positively charged lipospermine/DNA complex, the charge ratio \pm is modified.

means of duplicates. The Bradford dye-binding assay (Bio-Rad, Hercules, CA) was used to quantify the protein content.

Flow Cytometry. Plasmid DNA was incubated with the fluorescent intercalator dye YOYO-1 (Molecular Probes, Eugene, OR; ca. 1 dye molecule/300 bp), after which complexes were mixed as described above. The complexes were added to 300 000 H225 cells per well (6 well plates) at either 4 $^{\circ}\text{C}$ (cell surface association) or 37 $^{\circ}\text{C}$ (cell surface association and cellular uptake) for 4 h. The cells were washed twice with cold PBS and harvested with 1 mM EDTA in PBS. Cells were then analyzed on a FACScan (Becton Dickinson, San Jose, CA).

RESULTS

Increased Efficiency of Lipospermine/DNA Complexes through Membrane-Active Peptides. Complexes of plasmid pCMV (encoding a luciferase reporter gene) and 1, 1.5, 2, or 4 charge equiv of Transfectam in combination with various amounts of the membrane-active peptide INF6 (see Table 1) were prepared. As the influenza-derived peptide INF6 has four negative charges at pH 7, it will associate, via electrostatic interactions, with the cationic lipid/DNA particles. Almost all of the peptide was found to bind to the transfecting particles (as determined by chromatography, see Materials and Methods). Transfection efficiencies were determined by using human H225 melanoma cells (Figure 1) and several other cell lines (Figure 2). As shown in Figure 1, a 100–1000-fold increase could be observed upon addition of INF6 when 2 and 1.5 equiv, respectively, of lipid were used. In optimal conditions (4 equiv) only a slight enhancement (up to 5-fold) could be obtained in H225 cells. No enhancement was observed when neutral particles (1 charge equiv) were used, presumably because only few peptides can bind to these complexes. In fact, interactions with the cell membrane might be reduced

Figure 2. Peptide effect can be observed on several cell lines. The efficiency of Transfectam 2 equiv/pCMVL/5 µg of INF6 complexes was tested on H225, BNL CL.2, and A549 cells (100 000–150 000 cells plated per well in 6 well plates) and on M-3 cells (60 000 cells per well plated in a 24 well plate coated with 0.1% gelatin). Total luciferase activity of the cells is shown and is the mean of duplicates (\pm SD).

because residual positive charges on the complex required for cell interaction have been masked by the peptide association. The insert of Figure 1 presents the transfection efficiency of Transfectam/DNA/INF6 complexes versus the theoretical charge ratio (\pm) of the complexes. High luciferase expression can be achieved with almost electroneutral lipid-based vectors.

We tested several other cell lines to determine whether the effects of the membrane-active peptide on lipospermine-mediated gene transfer is specific for H225 melanoma cells or not (see Figure 2). The results obtained on mouse embryonic liver cells (BNL CL.2), human lung carcinoma cells (A549), and murine melanoma cells (M-3) demonstrate that the enhancement of transfection efficiency through addition of INF6 to DNA/2 equiv of Transfectam is a more general phenomenon. The extent of increase in gene expression mediated by the peptide is cell type dependent; while in H225 cells with DNA/2equiv of Transfectam/INF6 similar results were obtained as with DNA/4equiv of Transfectam (see also Figure 1), in the other tested cell lines approximately 10–50-fold higher expression levels were obtained.

To determine whether the peptide might influence the association of the DNA complexes with the cell, flow cytometry studies of various transfection complexes were performed on H225 cells. For this purpose the plasmid DNA was labeled with the intercalator YOYO-1 (Rye et al., 1992; Hirons et al., 1994) before formation of the lipid/DNA complex. As shown in Figure 3, the association of the Transfectam/DNA complexes with the cell surface varies with the charge ratio: with 2 equiv, a heterogeneous cell population is found, while at 4 equiv a classical Gauss curve is obtained. Addition of membrane-active peptides to 2 equiv (or 4 equiv, not shown) of Transfectam does not significantly modify the association with the cell (compare parts B and C of Figure 3), at either 37 or 4 °C (not shown). These experiments suggest that the peptide acts as expected; that is, it improves the release of the complexes from the endosomes.

Enhancement Is Peptide Sequence Dependent. Previous work with ligand/polylysine DNA complexes in association with membrane-destabilizing peptides showed that peptides with specificity for low pH were the most useful (Plank et al., 1994; Mechtler and Wagner, 1997). Our preliminary results (described above) led us to test a series of membrane-active peptides (Table 1) in association with 2 charge equiv of Transfectam.

The peptides INF6, INF4, and melittin, which possess a good membrane disruption activity but no specificity

for low pH (Plank et al., 1994; Mechtler and Wagner, 1997), displayed different behaviors: INF4 and INF6 (negatively charged) increased the transfection efficiency of 2 charge equiv of Transfectam 10- and ~200-fold respectively, while melittin (positively charged) only slightly increased the luciferase expression (Figure 4). Moreover, melittin was highly toxic at 2.5 µg/mL. The peptides INF5 and INF10, which can efficiently disrupt membranes at pH 5.0 (Plank et al., 1994; Mechtler and Wagner, 1997), gave better results than the INF4 peptide but were less efficient than the INF6 derivative. The artificial pH-specific peptide EGLA-I, in which one of the alanine residues in the repeat of GALA (Parente et al., 1988a,b) has been replaced by glycine (Mechtler and Wagner, 1997), gave results comparable to those of the INF5 peptide but had less activity than INF6.

Thus, the most efficient peptide in combination with Transfectam appeared to be peptide INF6 whose membrane-destabilizing activity is pH independent. To confirm that the peptides are still active when ionically bound to the cationic lipid/DNA complex, we measured leakage activity of the two most efficient peptides, INF10 (Figure 5A) and INF6 (Figure 5B), either in free form or associated with Transfectam, using calcein-loaded liposomes of natural lipid composition (EPC/EPE/cholesterol/SM) at neutral or acidic pH. As can be seen, the peptides efficiently release calcein also in combination with Transfectam, although the activity is diminished in quantity. In quality, the characteristics of the peptides are retained: INF10 shows specificity for acidic pH, whereas INF6 is effective at both pH levels.

To check whether the peptides may act at the level of acidic endocytic vesicles, we measured the level of reporter gene expression obtained with Transfectam 2 equiv/DNA + peptide in the presence or absence of the specific inhibitor of the vacuolar proton pump bafilomycin A₁ (Bowman et al., 1988; Yoshimori et al., 1991). As expected, the INF10 formulation (with specificity for low pH) was more sensitive to bafilomycin (5-fold decreased gene expression) than the INF6 formulation (see Figure 6). Note that transferrin-polylysine/acidic-peptide mediated gene transfer was shown to be also inhibited approximately 5-fold by bafilomycin (Plank et al., 1994; Zauner et al., 1995). Bafilomycin did not decrease the efficiency of 4 charge equiv of Transfectam. This latter observation is consistent with the buffering properties of the spermine headgroup (Behr, 1994).

Combination with Neutral Lipids (Helper Lipids) Affects the Transfection Efficiency. The efficiency of Transfectam/DNA complexes near electroneutrality is strongly increased when 1.5–2 equiv of the helper lipid DOPE (moles per mole to Transfectam) is added (Remy et al., 1995). We tried to find other lipids able to increase the efficiency of Transfectam when such suboptimal amounts were used. The combination of 2 charge equiv of Transfectam with 1–3 equiv (mol/mol) of DOPE, EPE, or DOG resulted in 10–20-fold higher gene expression levels (Figure 7). MOG enhanced expression approximately 4-fold, whereas EPC and cholesterol could not improve the transfection efficiency on H225 cells. An additional increase—up to 7-fold—of the Transfectam/DOPE formulation could be obtained by mixing DOG (1 mol % to DOPE) with these two lipids (data not shown). The effect of DOPE and DOG relies presumably on their ability to induce fusion and to stabilize H_{II} phases (Duzgunes et al., 1989; Siegel et al., 1989). The addition of DOPE to 2 charge equiv of Transfectam completely changes the FACScan profile (compare parts B and D of Figure 3): the cell population is more homogeneous and

Figure 3. FACS analysis. Three hundred thousand H225 cells were incubated in the presence of transfection complexes containing 1.5 μ g of YOYO-1-labeled pCMVL and either Transfectam 4 (A) or 2 equiv (B), Transfectam 2 equiv/1.5 μ g of INF5 (C), or Transfectam 2 equiv/1.5 equiv of DOPE (D). After 4 h, the cells were washed twice with PBS, harvested with 1 mM EDTA/PBS, and analyzed by FACS (thick lines). Cells incubated with YOYO-1-labeled DNA alone were indistinguishable from unstained control cells and are shown as negative control (thin lines).

Figure 4. Several peptides are able to increase the efficiency of Transfectam 2 equiv. Increasing amounts of peptide were added to Transfectam 2 equiv/3 μ g of DNA complexes (as described under Materials and Methods and Figure 1). The best formulation for each peptide is compared to Transfectam 4 and 2 charge equivalents. Total luciferase activity of the cells is shown and is the mean of duplicates (\pm SD).

the cell association and uptake are higher with than without helper lipid.

DISCUSSION

The efficiency of DNA transfer mediated by cationic lipids or polycations is dependent on many factors, including size and structure of complexes, immunogenicity, stability in serum and against intracellular enzymes, binding and uptake into the cell, release into the

cytoplasm and transfer into the nucleus, or the release of the DNA from the cationic carrier.

Transfection based on receptor-mediated endocytosis of polylysine conjugate/DNA particles is thought to be particularly limited in efficiency by the accumulation of DNA complexes in intracellular vesicles. Methods to destabilize the endosomal membrane, such as addition of replication-defective adenoviruses (Curiel et al., 1991), membrane-active peptides derived from influenza virus (Wagner et al., 1992; Plank et al., 1994) or from rhinovirus (Zauner et al., 1995), and—in some cell types—the use of lysosomotropic agents (Wagner et al., 1994) or glycerol (Zauner et al., 1996), have been shown to strongly enhance the level of gene expression.

There is mounting evidence that DNA delivery seems to take place by endocytosis also in cationic lipid-based gene transfer (Felgner et al., 1987, 1994; Behr et al., 1989; Leventis and Silvius, 1990; Gao and Huang, 1991; Rose et al., 1991; Hawley-Nelson et al., 1993; Solodin et al., 1995; Legendre and Szoka, 1992; Behr, 1993; Zhou and Huang, 1994; Wrobel and Collins, 1995; Zabner et al., 1995). Cationic lipid-based gene transfer has been found to be efficient in a great variety of cells; in contrast to polylysine-based gene transfer, it has been less clear whether the release of the DNA from endosomal compartments is limiting this method of gene transfer (Leventis and Silvius, 1990; Zabner et al., 1995; Xu and Szoka, 1996). This also may depend on the nature of the particular applied cationic lipid or lipid mixture.

Using the lipospermine Transfectam, it was found in previous studies that transfection efficiency was optimal

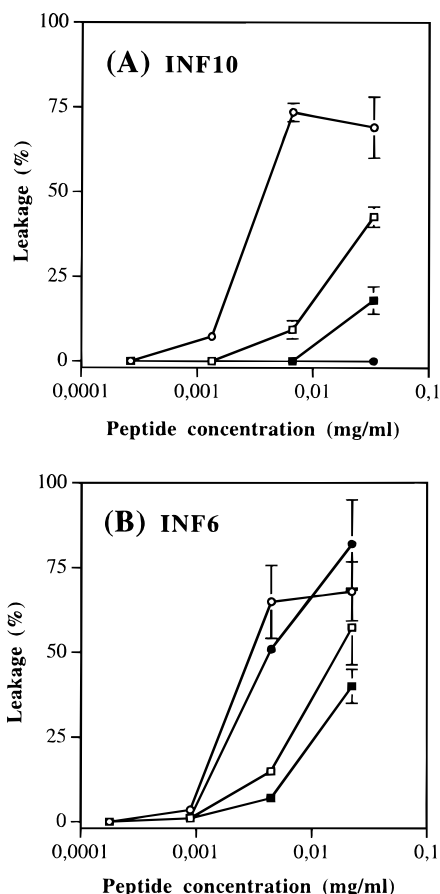

Figure 5. Liposome leakage assay. The leakage activity of peptides INF10 (A) and INF6 (B), in free form (circles) or associated with Transfectam (squares), was determined at pH 7.3 (solid symbols) and 5.5 (open symbols) on EPC/EPE/cholesterol/SM (10:3:5:2) liposomes loaded with 100 mM calcein.

Figure 6. Effects of bafilomycin A₁ on the transfection efficiencies of Transfectam/DNA/peptide or DOPE complexes. Transfection of H225 cells was performed in the absence (light bars) or presence (dark bars) of bafilomycin A₁ (final concentration 200 nM). After 4 h of incubation, the medium was replaced by a fresh one containing 10% FCS. Total luciferase activity of the cells is shown and is the mean of duplicates (±SD).

when the charge ratio of cationic lipid to DNA was highly positive (i.e. about 3–6; Barthel et al., 1993). The positive charges promote binding and uptake of the complex into cells. In addition, Transfectam has endosome buffering capacity (pK_a of the least basic secondary amine ca. 5.4), thus protecting DNA from enzymatic

Figure 7. Helper lipids are able to increase the efficiency of 2 charge equiv of Transfectam. Transfection complexes were prepared as described under Materials and Methods. Total luciferase activity of the cells is shown and is the mean of duplicates (±SD).

degradation and potentially causing also some osmotic destabilization of buffered endosomes (Behr, 1994).

We were interested whether the efficiency of Transfectam-mediated plasmid delivery can be enhanced by incorporating influenza-derived peptides. This series of peptides has been previously shown to be able to disrupt liposomes, erythrocytes, or endosomes of cultured cells, enhancing receptor-mediated gene transfer up to approximately 1000-fold (Plank et al., 1994; Mechtler and Wagner, 1997). When optimal amounts of Transfectam are used in association with membrane-destabilizing peptides, a significant, but only moderate (3–30-fold), enhancement of the gene expression was obtained (Figures 1 and 2). Thus, in this context, escape from endocytotic vesicles seems not to be a major bottleneck of gene transfer. Related findings were reported by Kamata et al. (1994), who showed that two influenza-derived peptides can increase the level of gene expression of the commercially available formulation Lipofectin by up to a factor of 5.

However, when we used less positively charged complexes, the addition of membrane-active peptides resulted in up to a 1000-fold increase in expression (1.5 charge equiv of Transfectam in the presence of 2 μg of INF6), reaching or surpassing the level obtained with the optimized amounts of cationic lipid (Figures 1 and 2). The peptide did not change binding of DNA to the cell (Figure 3). Consistent with the working hypothesis that the peptides act on an endosomal level, the effect mediated by the pH-specific peptide INF10 was sensitive to endosomal neutralization by bafilomycin A₁ (Figure 6). Among the peptides tested, only the acidic (negatively charged) ones gave good results in combination with Transfectam. This is in agreement with the hypothesis that for improved endosomal escape of DNA the peptides have to be in the same endocytotic vesicles as the lipid/DNA complexes, which is the case when (negatively charged) peptides are ionically bound to the positively charged Transfectam/DNA particles. The order of efficiency of peptides, when associated with 2 charge equiv of Transfectam, was found to be as follows: INF6 > INF10 > EGLA-I, INF5 > INFA > melittin (Figure 4). These results are different from those obtained with the ligand/polylysine-based system. While INF5 was found to be the best peptide in association with transferrin/polylysine, and approximately 50-fold more effective than INF6 (Plank et al., 1994; Mechtler and Wagner, 1997), in Transfectam-based gene transfer INF5 is 10 times less efficient than INF6. Peptide INF5 has membrane disruption activity only at acidic pH, whereas INF6 is also

active at neutral pH. In lipid-free polylysine-based gene transfer such an activity at neutral pH results in toxic side effects, which were not observed in cells transfected with peptide INF6 in the liposomal system. An additional possible explanation for the higher efficiency of peptide INF6 (compared to INF5 or INF10) is a reduced acidification of endosomes resulting from the buffer capacity of Transfectam (Behr, 1994).

It has recently been shown that highly efficient DNA complexes with low charge (2 equiv of Transfectam) can also be generated by the inclusion of the helper lipid DOPE (Remy et al., 1995). We compared this type of complex with the peptide-containing complexes. The enhancement by DOPE is thought to rely on its capacity for transition from the bilayer ($L\alpha$) phase to the inverted hexagonal (H_{II}) phase. The endosomal protonation promotes this transition, resulting in membrane-active activity (Allen et al., 1990; Litzinger and Huang, 1992; Farhood et al., 1995). Our FACS data suggest an additional, potentially important effect of the helper lipid: the cell association of the transfection complexes is far more pronounced when 1.5 equiv of DOPE is added to 2 charge equiv of Transfectam (Figure 3D) than when the lipospermine is used alone. This suggests that DOPE not only improves the escape of DNA from the endosomes but also increases cell association (and uptake) of the complexes. The existence of this second effect of DOPE is also supported by the fact that the Transfectam/DOPE efficiency is only partially abolished by the presence of the vacuolar proton pump inhibitor bafilomycin A_1 (Figure 6).

Besides DOPE, we used several other lipids in combination with Transfectam to compare their helper capacity with the activity of the membrane-active peptides. EPE and DOG, but not EPC or cholesterol, could enhance the gene expression in H225 cells (Figure 7) to an extent similar to that shown by peptides INF6 and INF10. The lipids that enhance are diacylglycerols, i.e. lipids which do not form stable lamellar structure due to a small headgroup surface. This reinforces the conclusion that the helper lipid has to possess a membrane destabilization activity.

These results show that the modes of action of Transfectam and polylysine after endocytosis of DNA complexes are different. In contrast to polylysine-mediated gene transfer, gene transfer mediated by optimized positively charged Transfectam/DNA complexes cannot be greatly enhanced by the addition of membrane-active peptides, DOPE, glycerol (Zauner et al., 1996), or replication defective adenoviruses [when added to Transfectam/DNA at up to 30 000 particles per cell, data not shown; see also Zabner et al. (1995)]. This finding is not unexpected and is in agreement with the hypothesis that a surplus of positively charged lipids in the DNA complex can directly destabilize the endosomal membrane by lipid mixing (Leventis and Silvius, 1990; Xu and Szoka, 1996) and/or osmotic stress resulting from endosomal protonation of the surplus of Transfectam. In keeping with these hypotheses, the transfection efficiency of DNA complexed with lower, suboptimum amounts of lipids (i.e. 1.5–2 charge equiv) can be increased up to 1000-fold by a membrane-active peptide (without influencing cell association). This confirms that for these particles endosomal escape is a limiting step, similar to what has been observed for polylysine-based gene delivery.

Efficient lipid/DNA transfection complexes that possess a charge ratio near neutrality may be useful for *in vivo* gene transfer. They might be prerequisite for selective, targeted liposomal gene transfer by specific receptor ligands (Remy et al., 1995; Compagnon et al., 1996). This

is also supported by recently published findings of Lee and Huang (1996), who demonstrated that folate-targeted liposome/DNA complexes carrying a net positive charge lose their specificity. In addition, as has also been shown for the polylysine-based system (Plank et al., 1996), positively charged lipid/DNA complexes interact with serum complement; only electroneutral particles do not activate the complement system. This correlates well with the *in vivo* results obtained by Schwartz et al. (1995): they observed highest reporter gene expression when low positively charged Transfectam/DNA complexes (i.e. 0.8 or 1.8 equiv) were used in combination with the lipid DOPE. Thus, for *in vivo* applications, the charge ratio between the carrier and nucleic acids seems to be a key parameter, meaning that Transfectam/DNA/membrane-active peptides might be an alternative to other cationic lipid formulations.

ACKNOWLEDGMENT

We thank Helen Kirlappos for excellent technical support. We are grateful to Ciaran Morrison and Wolfgang Zauner for helpful discussions and to Matt Cotten and Tim Skern for critical review of the manuscript. This work was done with the financial support of the Austrian Science Foundation (FWF).

Nuclease Activity and Binding Characteristics of a Cationic “Manganese Porphyrin–Bis(benzimidazole) Dye (Hoechst 33258)” Conjugate

Silvana Frau, Jean Bernadou,* and Bernard Meunier*

Laboratoire de Chimie de Coordination du CNRS, 205, route de Narbonne, 31077 Toulouse cedex, France.
Received July 22, 1996*

To increase the binding affinity and/or the sequence selectivity of the chemical nuclease manganese(III) tetrakis(4-*N*-methylpyridiniumyl)porphyrin, we synthesized a conjugate molecule by associating a tris(4-*N*-methylpyridiniumyl)metalloporphyrin motif to Hoechst 33258 (H33258), a DNA minor groove binding dye known for its selective affinity for A·T tracts. Selected double-stranded (ds) 35-mer oligodeoxyribonucleotides have been used to probe DNA chain breakages induced by the manganese derivative of the conjugate after activation by potassium monopersulfate. Gel electrophoresis analyses show that DNA cuts were generated by the metalloporphyrin moiety of the hybrid molecule, with the H33258 entity interacting in two different possible orientations, upstream or downstream, with its preferred affinity site inside the minor groove. Also studied was the cleavage of a ds 29-mer oligodeoxyribonucleotide containing two stretches of A·T basepair (bp) which clearly showed that the hybrid can occupy the binding region at least in four preferred ways. These cleavage experiments support the strong and selective interaction of the metalloporphyrin–dye hybrid with DNA and allow the estimate of 10 bp as an average size for the affinity site of an isolated conjugate molecule. Further studies by UV–visible spectroscopy, DNA melting temperature determinations, and DNase I footprinting showed, for higher concentrations of H33258 conjugate, a preferential interaction of only the H33258 moiety with DNA (estimated binding site size 6–7 bp) with the porphyrin entity pushed out of the groove and, for the highest concentrations, self-aggregation of the H33258 conjugate all along the DNA strand in a nonselective mode.

INTRODUCTION

Inhibition of gene expression by creating specific irreversible damage on DNA might be a potentially useful strategy. Such achievement is based on the preparation of molecules able to damage selected sequences on the targeted DNA. Based on bleomycin, an antitumor antibiotic agent combining both DNA binding properties and ability to cleave DNA (1, 2), a variety of DNA binders linked to cleaving reagents have been prepared: distamycin–EDTA iron (3), bis(1,10-phenanthroline)–copper (I) (4), and Hoechst 33258–1,10-phenanthroline–copper (I) (5).

The metalloporphyrin [*meso*-tetrakis(4-*N*-methylpyridiniumyl)porphyrinato]manganese(III) activated with an oxygen atom donor such as KHSO₅ is able to cleave double-stranded (ds) DNA at nanomolar concentration (6). The active form generated in situ with KHSO₅ is a Mn^V–oxo complex reminiscent of the activated form of cytochrome P-450 (7). The mechanism of DNA cleavage

involves the oxidative activation of C₁–H or C₅–H bonds of deoxyriboses in a ratio depending on the presence of triplets of adenine–thymine basepairs (bp's) (8, 9). To increase the binding affinity and/or to modulate the cleavage specificity of this chemical nuclease (which is itself sequence specific, cutting at three adjacent A·T residues), a [tris(4-*N*-methylpyridiniumyl)porphyrinato]manganese(III) moiety has been previously coupled with intercalating agents (10–12), oligonucleotides (13–15), and peptide nucleic acids (16). DNA minor groove binders have also been extensively studied for their capacity to bind to defined sequences of DNA. Netropsin, one of them, has been recently covalently attached to a cationic porphyrin (17). Here, we focused our interest on another minor groove binder, the bis(benzimidazole) dye Hoechst 33258 (H33258 for short, 2'-(4-hydroxyphenyl)-5-(4-methyl-1-piperazinyl)-2,5'-bis(1*H*-benzimidazole)) that was attached to a cationic manganese porphyrin. Interactions between H33258 and nucleic acids have been studied in detail by X-ray diffraction (18–22), NMR spectroscopy (23–26), fluorescence spectroscopy (27–29), electric linear dichroism (30), and a range of other biophysical methods (31–33). From all of these data, it appears that the high-affinity site of H33258 is a quadruplet of adenine–thymine bp's. Concerning this quadruplet, the exact nature of the sequence as also the nature of the flanking bases may modulate the interaction of H33258 (32).

So, association of a cationic metalloporphyrin and H33258 could lead to an efficient nuclease with an improved affinity for DNA and an increased selectivity for A·T rich regions (H33258 should enhance the affinity and direct the specificity of the hybrid). Here, we remind that binding of the general transcription factor TATA box binding protein (TBP, i.e. a protein with high affinity for

Figure 1. Structures of the conjugate molecules **1** ($M = \text{Mn}$) and **2** ($M = \text{Ni}$), H33258 **3** and its methylated analogue **4**, and the porphyrin precursor **5** ($M = \text{Mn}$).

A·T rich sequences) to a promotor located upstream from the transcription start site is essential for the accurate and efficient initiation of transcription (34). Causing damage on DNA on such regions could inhibit transcription. On the other hand, it has been recently demonstrated that some minor groove binders (like H33258) are effective inhibitors of the formation of a DNA/TBP complex (35) or topoisomerases (36, 37). Adding a reactive entity such as a metalloporphyrin endowed with oxidative properties should improve the efficiency of this class of inhibitors.

We report here, in a first part, cleavage experiments performed with the conjugate molecule "manganese porphyrin–H33258" **1** (Figure 1) on a series of synthetic oligonucleotides. These ODNs were built to contain or not (i) one well-characterized affinity site of H33258 [5'-CAAATTTG-3'] (32) and (ii) one or two affinity sites of MnTMPyP [(A·T)₃] (8).

The other part of this article concerns additional physicochemical data to discuss the behavior in solution and the mode of interaction of conjugate **1** with DNA models. On the basis of melting temperature determinations, DNase I footprinting experiments in the presence of the conjugate, and UV–vis spectroscopy studies in the presence of varying concentrations of poly(dA)·(dT), poly[d(A·T)·d(A·T)], and poly(dG)·(dC), we can propose a model of the interaction of conjugate **1** with DNA.

EXPERIMENTAL PROCEDURES

Spectrometry. UV–visible spectral measurements were carried out on a diode array HP8452 spectrometer using a 1 cm quartz cuvette. NMR spectra were recorded on a Bruker AM250. FAB mass spectroscopy was performed on a Nermag R1010.

Preparation of Compounds 1, 2, and 5 (Figure 1). The porphyrin precursor **5** and the hybrid molecules **1** and **2** were synthesized according to previously reported methods (13 (5); 38, 39 (1 and 2)).

Preparation of the H33258 Analogue 4 (Figure 1). The hydrochloride salt (94 mg, 0.15 mmol) of H33258 (3HCl, 5H₂O, from Aldrich) was dissolved in 30 mL of water. The free base **3** was precipitated by addition of 30 mL of aqueous 5% NaHCO₃, extracted with a large excess of ethyl acetate, and crystallized in this solvent (59 mg, 95% yield). NMR data were in agreement with the literature (40). Methylation of **3** to give **4** was obtained as follows: 11 mg (0.026 mmol) of **3** and 15 μL (0.26 mmol) of CH₃I were mixed in 2.3 mL of DMF for 1.5 h at room temperature. The evolution of the reaction was followed by TLC (R_f values on silica gel were 0.32 for **3** and 0.0 for **4** with CH₂Cl₂/MeOH (50/50) as the eluent). The crude product was precipitated with a

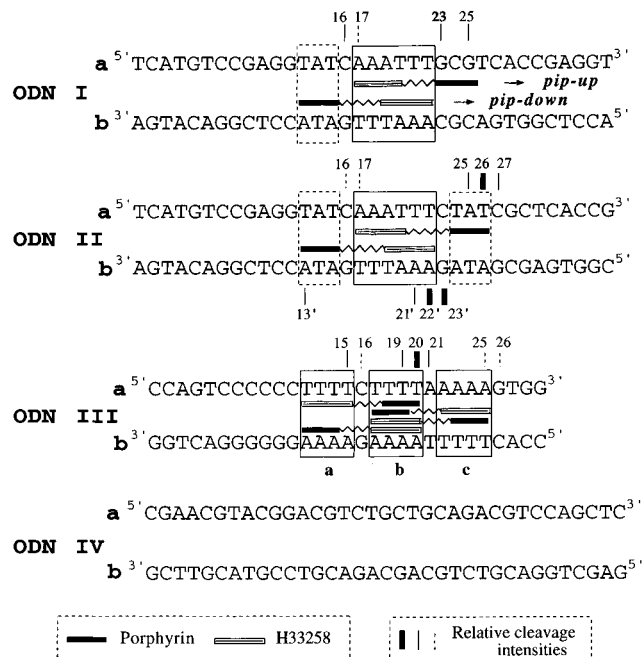

Figure 2. Bases sequences of ODNs and schematic representation of conjugate **1** in its site. Solid boxes show the possible ways the conjugate **1** (and more precisely the H33258 moiety) can occupy the binding region. Dashed boxes (ODNs I and II) indicate the position of the metalloporphyrin in its preferred (A·T)₃ site. Bars indicate the cleavage positions induced by **1** in the presence of KHSO₅.

mixture of MeOH and Et₂O (14 mg, 0.025 mmol, 95% yield). MS (FAB in DMF): m/z 439.5 (M^+). ¹H NMR (CD₃COOD), δ ppm: 8.34 (1H, s, H₇), 8.12 (1H, d, $J = 9$ Hz, H₈), 7.97 (2H, d, $J = 9$ Hz, H₁₀), 7.87 (1H, d, $J = 9$ Hz, H₉), 7.65 (1H, d, $J = 9$ Hz, H₆), 7.29 (1H, d, $J = 9$ Hz, H₅), 7.17 (1H, s, H₄), 6.98 (2H, d, $J = 9$ Hz, H₁₁), 3.71 (8H, m, H₂, H₃), 3.40 (6H, s, H₁). UV–vis (6 μM in MeOH), λ nm ($\epsilon_M \times 10^{-3}$, M⁻¹ cm⁻¹): 262 (20), 340 (40).

Oligonucleotides: Syntheses and Labeling. The eight oligonucleotides used in this study (ODN Ia,b, ODN IIa,b, ODN IIIa,b, and ODN IVa,b; Figure 2) were synthesized by a standard solid-phase (β -cyanoethyl)-phosphoramidite chemistry on a Cyclone Plus DNA synthesizer from Milligen Biosearch. Concentrations of single-stranded oligonucleotides were determined by UV titration at 260 nm: $\epsilon_M \times 10^{-3}$, M⁻¹ cm⁻¹ = 337 (ODN Ia), 342 (Ib), 329 (ODN IIa), 355 (IIb), 263 (ODN IIIa), 285 (IIIb), 326 (ODN IVa), 322 (IVb). They were labeled at the 5'-end by reaction with γ -[³²P]ATP and T4 polynucleotide kinase using a standard procedure.

Cleavage and Footprinting Experiments. Double-stranded ODNs I–IV were formed as follows: to a

solution (8 μ L) containing 100 nM (final concentration) 5'-labeled single strand in 100 mM NaCl and 40 mM Tris buffer (pH 8) was added a solution of the complementary strand in the same solvent (4 μ L, final concentration 100 nM). After 5 min of heating at 90 °C, the hybridization of the duplex was achieved by slowly cooling the solution to 25 °C. Conjugate **1** (4 μ L, final concentration varying from 20 nM to 10 μ M) was preincubated with the duplex for 1.5 h at 37 °C. For cleavage experiments, 4 μ L of 5 mM KHSO₅ solution (final concentration 1 mM) was added and the reaction was allowed to proceed for 1 h at 37 °C. The reaction was stopped by addition of 1 μ L of 1 M Hepes buffer (pH 8). For alkaline treatment (in order to reveal lesions on G bases of the target duplex), the reaction solution was heated at 90 °C for 30 min in the presence of a 1 M piperidine solution. In DNase I footprinting experiments, the enzyme (from Gibco BRL, 4 μ L, 1 unit) was added to 16 μ L of a solution containing the duplex (5'-³²P-labeled on one strand) preincubated with **1** and was allowed to react for 5 min at 4 °C. In both cases (footprinting and cleavage experiments), the samples were diluted after reaction with 1 μ L of yeast tRNA (10 mg/mL) and 100 μ L of 0.3 M sodium acetate (pH 5.2) and then precipitated with 300 μ L of cold ethanol. The pellet was finally rinsed with 70% aqueous ethanol and lyophilized. Fragments of DNA were analyzed by denaturing (7 M urea) 20% polyacrylamide gel (4 h at 2000 V). Establishment of sequences involved guanine and guanine-adenine specific cleavage of DNA (Maxam and Gilbert protocols) and for ODN **I**, reference to the cleavage pattern of the 5'- and 3'-labeled polymer in the presence of DNase I.

DNA Models. Poly(dA)·(dT), poly[d(A-T)·d(A-T)], poly(dG)·(dC), and poly[d(G-C)·d(G-C)] (purchased from Sigma) were used without purification. Concentrations (always calculated in base pairs) were determined by UV titration using the following molar extinction coefficients. ϵ_{M} , M⁻¹ cm⁻¹ bp⁻¹: poly(dA)·(dT), 12 000 (260 nm); poly(dG)·(dC), 14 800 (253 nm); poly[d(G-C)·d(G-C)], 16 800 (254 nm) (41); poly[d(A-T)·d(A-T)], 13 200 (262 nm) (42).

Influence of H33258 and Related Compounds on the Melting Temperature of Poly[d(A-T)·d(A-T)]. Duplex dissociation was followed by UV spectroscopy at 260 nm. Melting curves were obtained with a diode array HP 8452 spectrophotometer equipped with a Peltier temperature controller; heating increments were of 2 °C from 36 to 58 °C (with 3 min of stabilization after each increment) and then of 1 °C (with 3 min stabilization) to go to 90 °C. One centimeter path length cuvettes were used for data collection. The duplex absorbance was measured by using a solution containing 75 μ M bp target duplex poly(dA)·(dT) dissolved in 1.2 mL of 40 mM Tris (pH 8) and 100 mM NaCl. For T_m experiments the concentration ratio of DNA bp over ligand was P/D = 5. The melting temperatures of the DNA target–minor groove binder (**1**, **4**, or **5**) complexes were determined after subtraction of solvent absorbance.

UV–Vis Absorption Studies for Mixtures of Conjugate **1 and Poly[d(A-T)·d(A-T)], Poly(dA)·(dT), Poly(dG)·(dC), and Poly[d(G-C)·d(G-C)].** UV–vis absorption spectra were recorded for mixtures of **1** and various DNA polymers in 40 mM Tris (pH 8) and 100 mM NaCl, at room temperature. The molarity of **1** was 2, 5, or 10 μ M, and the molarity of the DNA polymers varies in the range 0–200 μ M bp. The complex was allowed to equilibrate for 1.5 h at 37 °C before measurements. Variations of absorbance maxima for H33258 chromophore and at the Soret band (intense absorption band of porphyrins in the visible spectrum) were followed

according to increasing concentrations of DNA polymers in the range P/D = 0–20 (Figure 5).

RESULTS

Cleavage Experiments on ODNs I–IV with the Conjugate **1/KHSO₅ System.** For all of the following experiments performed on synthetic ODNs, the concentration of ds target duplex was 100 nM. Nuclease activity of conjugate **1** (see Figure 1 for structures of the manganese derivative **1**; conjugate **2** is the nickel analogue which was used as a control with no nuclease activity) was studied on two ODNs containing both sites of high affinity for H33258 and manganese porphyrin (ODN I and ODN II), on one ODN with two A·T tracts (ODN III), and on another one (ODN IV) containing no more than two consecutive A·T bp (see Figure 2 for sequences). In conjugate **1**, due to the constraints of the synthesis, the H33258 moiety was methylated on the nitrogen of the methylpiperazine to give an additional cationic center. Incidence of this point will be discussed further.

Footprinting and Cleavage Experiments on ODN Ia. The affinity of **1** for DNA is, in part, due to the four positive charges present in its structure (three *N*-methylpyridiniumyl groups on Mn porphyrin and one ammonium on H33258 moiety). To make sure that neither the supplementary methyl group on H33258 nor the presence of the metalloporphyrin moiety changed the intrinsic affinity of H33258 for DNA, we performed a DNase I footprinting study on ODN **I** in the presence of compounds **1**, **3**, and **4**. They all reacted in the same way: the three ligands protected the (A·T)₆ site at low concentration and complete protection was reached for concentrations up to 100–200 nM (Figure 3). This is clearly shown in lanes 8 (**1**), 19 (**3**), and 24 (**4**) where the bands corresponding to the hydrolysis of the phosphodiester bonds A19–A20 (very weak band), T20–T21 (weak), T21–T22, and G23–C24 completely disappeared. Even if the steric hindrance of the piperazine ring is more important in **4** compared to **3**, it did not seem to have any influence on the recognition of the affinity site. The same conclusions are also valid concerning the presence of the metalloporphyrin substituent attached to the H33258 part in **1**. Footprinting with **1** exhibited selective protection of the (A·T)₆ site at low concentration (half-protection with 20 nM, lane 6; complete protection with 100 nM, lane 8; Figure 3). Additionally, for concentrations higher than 2 or 3 μ M (lanes 10–14), the bound drug was found to prevent DNase I from cleaving all along the ODN strand. Controls with the porphyrin precursor **5** or with the parent dye H33258 **3** or its methylated derivative **4** did not show any particular protection of the duplex at such high concentrations (see lanes 17, 22, and 27 for experiments performed in the presence of 10 μ M of **5**, **3**, and **4**, respectively). This point will be discussed at the same time as the spectroscopic behavior of conjugate **1** in the presence of varying amounts of DNA polymers.

We can also notice that footprinting experiments with the porphyrin precursor **5** did not exhibit any particular protection except at high concentration (10 μ M, lane 17) where some decrease in intensity of the enzymatic digestion bands T15–C16 and C16–A17 was observed and might correspond to a lower affinity of the metalloporphyrin motif (compared to H33258) for its own preferred binding site, the TAT triplet located at T13A14T15.

Figure 4 shows the results of cleavage experiments performed on ODN **I** with compound **1** activated by potassium monopersulfate. Degradation of labeled ODN **Ia** occurred on both sides of the sequence (A·T)₆: on the

Figure 3. Footprinting on ODN **I** (**Ia** was 5'-³²P-labeled). Target was 100 nM in Tris-HCl (40 mM, pH 8) and NaCl (100 mM). Digestion by DNase I was performed for 5 min at 4 °C. Duplex alone: lane 1. Duplex in the presence of **1**, **3**, and **4**: lanes 2–4. DNase I cleavage in the absence of ligand: lane 5. DNase I cleavage in the presence of various concentrations of **1** (0.02, 0.05, 0.1, 1, 2, 3.5, 5, 7.5, and 10 μ M): lanes 6–14. DNase I cleavage in the presence of the porphyrin precursor **5** (0.1, 1 and 10 μ M): lanes 15–17. DNase I cleavage in the presence of H33258 **3** (0.02, 0.2, 2, 5, and 10 μ M): lanes 18–22. DNase I cleavage in the presence of the H33258 analogue **4** (0.02, 0.2, 2, 5, and 10 μ M): lanes 23–27. Lanes 28 and 29 are sequencing Maxam and Gilbert, G and GA. On the left is indicated the sequence established for DNase I cleavage.

5'-side, where one (A·T)₃ triplet was present, two main individual bands appeared at C16 and A17 (lanes 2–4); on the 3'-side, where no (A·T)₃ triplet was present, the pattern of cleavage consisted of a smear stretching from approximately C24 to A28 (lanes 2–4). After heating at 90 °C during 1 h in the presence of 1 M piperidine, the two discrete bands at C16 and A17 observed by direct cleavage resisted piperidine treatment when the smear from C24 to A28 was transformed to discrete cleavage bands corresponding mainly to G23 and G25 (lanes 5–7). This pattern with cleavage bands of rather similar intensities on both sides of the H33258 affinity site suggests that conjugate **1** can adopt two different possible orientations in this site. In a control experiment we checked that the redox inactive nickel derivative **2** was not able to induce any damage on this DNA target (not shown).

Cleavage pattern with MnTMPyP showed the main cleavage sites at T15/C16/A17, on the 3'-side of the TAT triplet, and also at T20/T21/T22, on the 3'-side of the three overlapping triplets located from positions A17 to T21, which confirmed A·T triplets as preferred sites of DNA interaction of the "free" metalloporphyrin (positions of cleavage are indicated by arrows on the left of Figure 4) (8, 43, 44). A secondary site of cleavage was also observed at A28 when relatively drastic cleavage occurred; 43).

Cleavage on ODN II. To confirm the two possible orientations of conjugate **1** within the minor groove, we used ODN **II** which possesses two (A·T)₃ triplets on both sides of the high-affinity site of H33258. If the Mn porphyrin moiety can point toward the 3'-end as well as 5'-end of strand **a** or **b** of the duplex, then two distinct

oxidation sites must be observed. Effectively, the pattern of cleavage products supported the existence of two cleaving sites presenting well-defined breaks at C16, A17 and A25, T26, C27 on strand **a** and C12', A13' and A21', A22', G23' on strand **b** (lanes 8–13; Figure 4). The position of the cleavage bands on strand **b** corresponded to a shift of three or four bases toward the 3'-end as compared with breaks on strand **a**, meaning that the Mn porphyrin moiety was located and reacted inside the minor groove of the target duplex. Cleavage intensity increased when the concentration of conjugate **1** was increased (lanes 8–10), but for P/D = 3.5 (10 equiv of conjugate per duplex molecule, lane 11), the intensity slightly decreased. These facts will be correlated in the Discussion with UV–vis spectroscopy results supporting nonspecific interactions of the conjugate all along the double-stranded DNA when the duplex is overloaded with conjugate molecules. We must also note the more intense cleavage on the 3'-side of the (A·T)₃ triplet at positions 24–26 compared to that one at positions 13–15.

When we compared the nuclease activity of MnTMPyP and conjugate **1** on this target, we saw that positions of cleaving sites observed with conjugate **1** were clearly different than with MnTMPyP (see arrows on the sequence of ODN **IIa** for MnTMPyP cleavage sites, Figure 4).

Cleavage on ODN III. The main sites of cleavage were observed at T15, T19, T20 (the most intense), and A21 and to a minor extent at A25 and G26, while MnTMPyP induced cleavage on the 3'-side of all (A·T)₃ triplets of the duplex: T15 and C16, T20, A21, A22, A23, A24, A25, and G26. Conjugate **1** seemed to be able to select a particular high-affinity site in the A·T track of this

Figure 4. Cleavage on ODN I (**Ia** 5'-³²P-labeled), ODN II (either ODN **IIa** or ODN **IIb** was 5'-³²P-labeled), and ODN III (**IIIa** was 5'-³²P-labeled). Target was 100 nM in Tris-HCl (40 mM, pH 8) and NaCl (100 mM). ODN I: cleavage was performed in the presence of 1 mM KHSO₅ for varying concentration of conjugate **1** (0.1, 0.5, and 1 μ M) without (lanes 2–4) or with alkali treatment (lanes 5–7). Alkali treatment control on the duplex alone: lane 1. ODN II cleavage was performed in the presence of 1 mM KHSO₅ for varying concentration of conjugate **1**: 0.05, 0.1, 0.5, and 1 μ M (lanes 8–11) for study of ODN **IIa** and 0.5 and 1 μ M (lanes 12 and 13) for study of ODN **IIb**. ODN III: cleavage was performed in the presence of KHSO₅ (500 μ M, lanes 14 and 15; 1 mM, lanes 16 and 17) for two concentrations of conjugate **1** (0.5 μ M, lanes 14 and 16; 1 μ M, lanes 15 and 17). Arrows indicate the cleavage positions induced by MnTMPyP in the presence of KHSO₅.

duplex, with for the lower concentrations a selective cleavage at T20 (see lane 14 in Figure 4).

Cleavage on ODN IV (Data Not Shown). Duplex ODN IV was designed as a control. In the absence of A·T triplets, MnTMPyP was unable to find a strong high-affinity site but can cause some weak (unspecific) oxidations on C5, G6, C9, G10, G18, G21, and G27 on strand **a**, or G14, G23, and G35 on strand **b**. At similar concentrations, conjugate **1** did not seem to interact at all with this duplex: no cleavage bands were observed.

Cleavage with the Ni Derivative 2. The same cleavage experiments as described above were performed on ODNs **I**, **II**, **III**, and **IV** with the Ni conjugate **2** as a control. In all cases, no nuclease activity was detected.

Interaction of Conjugate 1 with DNA Models. *Stabilization of Duplex Structure Due to the Presence of MnTMPyP, 1, or Related Precursor 4.* Thermal melting experiments were carried out with poly[d(A-T)·d(A-T)] and the ligands MnTMPyP, **1**, or **4** in a ratio P/D = 5. In these conditions we could observe that the methylated H33258 derivative **4** and MnTMPyP as well as the conjugate **1** gave a noticeable increase of the overall stability of the duplex (T_m values were increased of about

30 °C) similar to that described for H33258 itself ($\Delta T_m > 25$ °C, 45). With poly(dG)·(dC), no significant change in T_m values ($\Delta T_m \leq 4$ °C) was observed.

Absorption Behavior of 1 in the Presence of Synthetic DNA Polymers. The absorption spectrum of **1** (final concentration 2 μ M, Figure 5) in buffer pH 8 showed two main maxima at 470 nm (0.064 OD unit, Soret band of manganese porphyrin) and 340 nm (0.048 OD unit, H33258 chromophore). The progressive addition of poly-(dA)·(dT) or poly[d(A-T)·d(A-T)] produced at low [DNA bp]/[dye] mole ratios (P/D = 0.5) a decrease in absorbance of the Soret band (lower value = 0.040 OD unit) and a decrease (lower value = 0.029 OD unit) and a bathochromic shift of the maximum of H33258 chromophore (Figure 5). Then, there was a progressive increase in absorbance when increasing P/D and the maximal hyperchromicity was observed at P/D = 10 (DNA concentration about 20 μ M) with maxima values raising 0.113 OD unit (Soret band) and 0.064 OD unit (with a shift to 350 nm of the H33258 chromophore). When the starting concentration of **1** was increased to 5 or 10 μ M, the minimal DNA concentration sufficient to induce maximal hyperchromicity increased to 40–50 μ M bp or 100 μ M

Figure 5. UV-visible absorption spectra for poly[d(A-T)·d(A-T)]/conjugate **1** mixtures in varying ratios in buffer (pH 8). Molarity of **1** was 2 μ M. Inset: dependence of absorbance maxima at 338–350 nm (H33258 chromophore) and 470 nm (Soret band) for increasing concentrations of poly[d(A-T)·d(A-T)] ($P/D = 0$ –20).

Table 1. Determination, at Two Wavelengths, of DNA bp Concentrations (μ M) Which Gave Half-Hyperchromic Effects When the Conjugate **1** Interacted with Poly[d(A-T)·d(A-T)] in Varying Concentrations^a

	2 μ M 1	5 μ M 1	10 μ M 1
at 470 nm	8.5	26	42.5
at 340–350 nm	7.5	28.5	52.5

^a Linear correlations between $y = [\text{bp}]$ and $x = [\text{1}]$: at 470 nm, $y = 2.13 + 4.15x$, $R = 0.97$; at 340–350 nm, $y = -1.90 + 5.54x$, $R = 0.99$.

bp, respectively. Implications of this dependence on conjugate **1** concentration will be discussed later. Using poly(dG)·(dC) or poly[d(G-C)·d(G-C)], no significant change in absorption characteristics could be observed.

Half hyperchromic effects estimated between the lowest absorption value observed after initial addition of A·T polymers ($P/D = 0.5$ –2) and the highest value of absorption reached for high DNA concentration ($P/D \geq 10$) were observed for DNA concentrations depending on the concentration of conjugate **1** as indicated with data collected at both 470 (Soret band) and 340–350 nm (H33258 chromophore) in Table 1 and Figure 5. The linear correlations presented in caption of Table 1 allowed us to exclude the association/dissociation equilibrium for formation of the conjugate **1**:DNA complex as the explanation of this phenomenon (see Discussion).

DISCUSSION

Cationic metalloporphyrins are well-established efficient chemical nucleases (9, 46). We coupled such a reactive entity to H33258, a B-DNA minor groove binder, to take advantage of its capacity to bind to (A·T)₄ sequences of DNA. Interaction of this conjugate with ds DNA was investigated through studies on nuclease activity, footprinting experiments, and UV-vis behavior in the presence of DNA models (hypochromic/hyperchromic effects and increase in stabilization of the duplex).

We used in this study synthetic DNA polymers and also four synthetic ds oligonucleotides (Figure 2): ODN **I** and ODN **II** possessed high-affinity sites for both H33258 and porphyrin moieties ([A·T]₄ and [A·T]₃, respectively); ODN **III** contained two tracts of A·T bp's. The last oligonucleotide (ODN **IV**), devoid of any A·T triplets, was a control for which **1** should have a very weak affinity.

During the multistep synthesis of conjugate **1**, the H33258 moiety was methylated on the piperazine ring (38) in the same time as the tripyridylporphyrin was converted into the tris(methylpyridinium)porphyrin. A first question was, does this additional methyl group on piperazine as well as the presence of the bulky Mn

Scheme 1. Ways of Binding of Conjugate **1** in the Minor Groove of DNA Models Depending on the DNA bp/Dye Ratio (P/D)^a

^a Conjugate **1** molecules may exist (A) free in solution as self stacked entities, (B) aggregated outside (or possibly inside) the minor groove of DNA, (C) either aggregated or unstacked in the minor groove (in the situation around half-hyperchromicity conditions), or (D) interacting with the DNA sites without any stacking with other conjugate molecules (the porphyrin moiety is probably located in the DNA minor groove for the highest values of P/D).

porphyrin attached to the H33258 modify the dye affinity for A·T rich sequences of DNA? The pattern of the enzymatic digestion with DNase I in footprinting experiments (Figure 3) gave a negative answer to this question. These studies were performed on ODN **I** interacting with conjugate **1**, H33258 **3**, or its methylated derivative **4** and showed that these three compounds protected the same sequence at similar concentrations and with the same efficiency. These data allowed us to conclude that neither the methylation of piperazine ring on H33258 moiety nor the presence of linked Mn porphyrin in conjugate **1** did affect the selectivity and the strength of interaction of the dye moiety with its usual recognition site. However, at high concentrations of ligand (above 1 μ M, $P/D \leq 3.5$, less than 3.5 bp for one ligand molecule), we could observe that the behavior of conjugate **1** differed from those of compounds **3** and **4**. In these conditions, only the first one gave a nonspecific protection all along the duplex (complete protection was observed at concentrations above 3.5 μ M, $P/D \leq 1$). This fact may be interpreted as self-aggregation of conjugate **1** along the minor groove as indicated in Scheme 1 (form B; more than two stacked molecules is a likely situation for the lowest values of P/D): the first conjugate molecule interacts with its specific site in the minor groove, then the second and the following ones aggregate, probably outside of the groove in a nonspecific way reminiscent of the nonspecific (charge- or dye-mediated) binding previously observed for H33258 by Loontjens et al. (28). Additional support for this schematic representation is given by the UV-vis study discussed further.

We have also compared T_m values of poly(dA·dT) and poly(dG·dC) in the absence and in the presence of MnTMPyP, **1**, or **4**. The observed increase of the T_m value for interaction of **1** with poly(dA·dT) conformed with literature data for H33258 (27, 45). The fact that ΔT_m was almost the same for conjugate **1** and precursor molecules allowed us to suggest that a strong interaction in the minor groove correspond to a high stabilization of the duplex form of DNA. Conjugate **1** did not interact strongly with poly(dG·dC).

The nuclease activity of conjugate **1** was then studied in order to have a best knowledge of the nature of its

interaction (sequence specificity, orientation of the ligand) with synthetic oligonucleotides.

ODN **I** and ODN **II** were built to contain a sextuplet AAATTT, which is a favorite site for H33258 (22), and also, in its close vicinity, one or two (A·T)₃ triplets which are high-affinity sites for the cationic Mn^{III} porphyrin, MnTMPyP (8). Two distinct cleavage sites were pointed out on each strand, indicating that conjugate **1** can interact with its affinity site with two different orientations, as it is shown in Figure 2 and in agreement with the so-called "piperazine-up" (pip-up) and "piperazine-down" (pip-down) orientation; for example, "pip-up" means that the piperazine end of H33258 is oriented toward the 5'-end of the upper strand in the usual representation of ODNs (21).

Another noteworthy fact was the dissymmetry on the intensity of cleavage at the two sites for ODNs **IIa,b**. The pip-up orientation was predominant and gave the most efficient cleavages. Although the H33258 site is a self-complementary one, the two possible polarities for conjugate **1** in its site were not equivalent underlining the role of the flanking bases (C or G on the 5'-side of the H33258 site AAAT for ODN **IIa** or **IIb**, respectively; T on the 3'-side in both cases) in directing the nature of the interaction. For ODN **I** where the flanking bases were identical whatever was the orientation of the conjugate in its site (C on the 5'-side and T on the 3'-side of the H33258 site AAAT), the cleavage extent was rather similar on the two strands. In addition, this result indicates that the presence of a porphyrin affinity site on one side did not help to discriminate between the two orientations.

These results obtained in solution confirmed the crystallographic data on H33258/dodecanucleotide (CG-CAAATTTGCG)₂, which gives the 5'-AAAT sequence as the main site of interaction. However, neither from these cleavage results (Figure 4) nor from footprinting studies (Figure 3) can it be completely excluded that **1** interacts with the central quadruplet AATT which has been recently shown to be a high-affinity site for H33258 (32). When an (A·T)₃ sequence was adjacent to the AAATTT site, on one side (ODN **I**) or on both sides (ODN **II**), well-defined cleavage was directly observed on the 3'-side of the A·T triplet. When such a sequence was absent, as it is the case on one side of the AAATTT site of ODN **I**, then the site of cleavage appeared like a "smear" which gave, after alkaline treatment, well-defined bands located at G positions. This particular behavior was recently attributed to oxidative damage on G bases present at or near the cleavage site (47), indicating a cutting pattern strongly dependent on the oxidizability of the bases present at this site.

When cleavage experiments were carried out with the ODN **II** duplex which contains one (A·T)₃ sequence on each side of the H33258 high-affinity site, two breaks illustrating the two polarities were detected on each strand and showed a shift (of four bp) of the cleavage position in the 3' direction, on one strand compared to the complementary one. This was typical for an interaction of the cleaving reagent in the minor groove (48). Additionally, the four-bp shift and the fact that fragments comigrated like Maxam–Gilbert cleavage products strongly support at this site an oxidative C5' chemistry as initial damage on the deoxyribose (8, 9). An oxidative C1' chemistry, the other mode of DNA cleavage previously described for cationic metalloporphyrins (9), might be discarded since we never observed on electrophoresis gels ODN fragments carrying the characteristic α,β -unsaturated lactone at their 3' end which are known to

migrate ahead of the corresponding 3'-phosphate-ending fragments (9, 49, 50).

Experiments performed with ODN **III** showed three distinct cleavage sites with different relative intensities. On the basis of cleavage data obtained with ODN **I** and ODN **II** and the two possible orientations of conjugate **1** within the different (A·T)₄ sequences on ODN **III**, we can propose four potential ways of interaction which depend on the preference of the H33258 moiety for some particular sequences of bases in the (A·T)₄ site, boxes **a** (pip-up), **b** (pip-up and pip-down), and **c** (pip-down), to explain the observed cleavage patterns (Figure 2). The combination of these four possibilities gave distinct cleavage intensities on the different sites, e.g. T20 was the most intense cleavage band and may result from the conjunction of two positions of conjugate **1**, in box **a** (pip-up) and in box **c** (pip-down).

For all ODNs (**I**, **II**, or **III**), the observed pattern of binding/damage supports the preference of the conjugate for A·T tetranucleotide site and underlines the role of base sequence in this site as also the nature of flanking bases, probably in relation with variation of DNA conformations (31, 51). The cleavage patterns with conjugate **1** appeared substantially different from those observed for MnTMPyP, in which classical cuts are located on the nucleotide adjacent on the 3'-side of each (A·T)₃ triplet, i.e. for ODN **II**, for example, on C16, T20, T21, T22, C23 (weak), and C27 (ODN **IIa**) and C12', G16', T17', T18', T19', G23', and A24' (ODN **IIb**). The presence of the H33258 vector attached to the Mn porphyrin precursor clearly changed and directed the metalloporphyrin selectivity toward targets close to the H33258 binding site. This probably results of the 100-fold higher DNA affinity of H33258 compared to that of MnTMPyP ($K_{\text{aff}} = 10^8 \text{ M}^{-1}$ (28) and $K_{\text{aff}} = 10^6 \text{ M}^{-1}$ (12), respectively).

When no quadruplet of A·T bp was present, like in ODN **IV**, and only at high concentrations of the conjugate ($>2 \mu\text{M}$), a nonspecific and very weak cleavage activity was detected and appeared as a "smear". This nonspecific interaction, also observed in footprinting experiments for ODN **I** at similar concentrations, might correspond to charge- or dye-mediated nonspecific binding of conjugate **1**. It might explain the low efficiency of cleavage because the aggregation of conjugate **1** molecules should favor self-bleaching of the Mn porphyrin entities rather than oxidative cleavage on DNA. Such a phenomenon could also explain the low intensity of cleavage observed for high conjugate **1** concentrations in ODN **II** cleavage experiments (Figure 4, lane 11).

Indeed, this proposal was confirmed with results obtained by UV–vis spectroscopy in concentration conditions far beyond the DNA concentrations giving an association/dissociation equilibrium. If we looked at variation of absorption of **1** in the presence of various concentrations of DNA (Figure 5), the first hypochromicity step (for P/D < 2.5) should result from complete aggregation of **1**, initiated by a tightly bound conjugate molecule in the minor groove of the DNA polymer, which led to polymeric stacking interactions outside (or inside) the minor groove (Scheme 1, form B; for a discussion on the different possible polymeric associations, see ref 28). Around the half-hyperchromic concentration conditions (P/D = 2.5–6), both aggregated and unstacked molecules can exist (form C). On the other hand, when DNA concentration was sufficient (P/D > 6 , form D; for the upper values of P/D, the most likely mode of interaction involves both porphyrin and H33258 moieties lying in the minor groove), then conjugate molecules interacted with the minor groove without self-stacking and, thus,

the absorption of both Mn porphyrin and H33258 chromophores was exalted (relatively to forms A or B) and reached a maximum for $P/D > 6$. The same behavior was observed whatever was the initial concentration of conjugate molecule (2, 5, or 10 μM). A ratio $P/D \geq 6$ was always necessary to dissociate aggregated molecules present along the DNA strand and to give complete interaction of isolated molecules with DNA sites. In the absence of DNA, the self-stacked structure A (Scheme 1) is the most likely for **1**, since this conjugate strictly obeyed the Beer–Lambert's law in neutral solution in the range 0–10 μM (data not shown), when the parent dye H33258 in similar conditions (28) presents a concentration-dependent decrease of ϵ values at 338 nm indicating formation of dye aggregates.

The variation of spectroscopic data has been already described for H33258 in the presence of CT-DNA (52) as also the formation of DNA-stacked H33258 complexes (28). Thus, if we suppose that interaction of conjugate **1** with DNA is similar to that of H33258, it is logical that this aggregation occurred when an excess of conjugate vs DNA bp was present. Moreover, we must note the crucial role of the porphyrin moiety which greatly enhanced the propensity of H33258 dye to aggregate: indeed, in footprinting experiments, the conjugate **1** completely protected the DNA duplex against hydrolytic cleavage by DNase I in conditions (2–10 μM) where H33258 itself was inefficient (lanes 10–14 to be compared with lanes 20–22, Figure 3). Extension of the overall number of aromatic rings involved in the stacking process (form B, Scheme 1) could explain this increase of stability.

In addition, we observed that the bp concentration necessary to reach half of the hyperchromic effect (see Results and Table 1) was linearly correlated with concentration of conjugate **1** (see footnote of Table 1). This fact excludes the possibility of an association/dissociation equilibrium (in this case, the DNA bp concentration needed to give half-bound ligand should be independent of the initial concentration of ligand) and supports the hypothesis of a redistribution between the nonspecific interaction of stacked conjugate molecules and a specific interaction with isolated conjugate molecules bound to their preferred affinity site inside the minor groove (Scheme 1, redistribution from B to C and D). In these conditions, about five bp per conjugate **1** molecule (deduced from the linear correlations presented in caption of Table 1 ($y/x \approx 4.2\text{--}5.5$) was the mean value necessary to observe the half-hyperchromic effect. If we consider dimers/monomers in similar proportion as the most likely distribution at this point, then the average size of the interaction site for **1** should be $4 \times 5/3 \approx 6.5$ bp (number of conjugate molecules \times size of binding site/number of occupied binding sites). This last value, probably slightly overestimated due to arrangements which were not strictly from end to end and which included also upstream and downstream orientations of the conjugate, is in agreement with the previously reported size of the affinity site of H33258 and indicates that, in this range of DNA bp/conjugate concentrations, only the H33258 part interacts with the minor groove, the porphyrin moiety being pushed outside of DNA (Scheme 1, form C).

All of these observations were only available for poly(dA)·(dT) and poly[d(A-T)·d(A-T)]. With poly(dG)·(dC) or poly[d(G-C)·d(G-C)], variations of characteristic absorption bands of **1** were not significant supporting a very low affinity of **1** for G-C rich polymers. These spectroscopic results are in agreement with the low level of DNA cleavage observed on ODN **IV** with conjugate **1**.

Chart 1. Schematic Representation of the Two Possible Orientations of Conjugate **1 in Its Site of Interaction with ODN **II****

CONCLUSION

In conclusion, we synthesized a conjugate molecule Mn porphyrin–H33258 by associating an efficient chemical nuclease to a highly selective (A·T)₄ binding agent. We could check that chemical modifications introduced on the H33258 entity, especially the covalent linkage of the bulky metalloporphyrin, did not modify its intrinsic binding properties: the H33258 entity was still directing the sequence specificity of the conjugate, not the metalloporphyrin moiety.

Analyses of DNA breaks induced after chemical activation of conjugate **1** at low concentration allowed us to localize its site of interaction and to estimate its size at about 10 bp's. At this site, the conjugate may interact with the piperazine residue oriented either in the 5'- or 3'-direction, giving two possibilities of breaks on each strand. These breaks, when an A·T triplet was adjacent to the H33258 site, resulted from the usual 5'-deoxyribose oxidative chemistry; in the absence of such a triplet, damage probably affected the guanine base(s) present at or near the site of cleavage. At high concentrations of conjugate (with respect to the concentration of DNA target), nonspecific interactions of stacked conjugate molecules all along the DNA double strand were observed.

One example of the two possible interactions of conjugate **1** with its target is presented in Chart 1.

Without question, as it was shown on several ds oligonucleotides, the attachment of the cleaver motif [tris-(4-*N*-methylpyridiniumyl)porphyrinato]manganese(III) to the minor groove binder H33258 as a vector allowed specific recognition and cleavage of the DNA target. These data provided additional support for further investigations on such DNA damaging drugs in the field of molecular biology or pharmacology.

Time-Resolved Fluorescence Detection of Oligonucleotide Hybridization on a Single Microparticle: Covalent Immobilization of Oligonucleotides and Quantitation of a Model System

Harri Hakala and Harri Lönnberg*

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received October 15, 1996®

Several alternative methods have been described for the immobilization of oligodeoxyribonucleotides to uniformly sized glycidyl methacrylate/ethylene dimethacrylate particles. Hybridization of complementary oligodeoxyribonucleotides labeled with photoluminescent europium(III) chelates to these particle-bound oligonucleotide probes was followed by subjecting a single microparticle to a time-resolved fluorescence measurement. The hybridization was further quantified by releasing the europium ion to a fluorescence enhancement solution and determining its concentration against europium(III) chloride standards. Both the efficiency and kinetics of the hybridization were observed to depend markedly on the linker employed to tether the oligonucleotide probes to the particles. These effects and those of the experimental conditions, such as oligonucleotide concentration in solution, oligonucleotide density on particles, and number of particles in a given volume of assay solution, are discussed.

INTRODUCTION

Detection of gene mutations by assays based on oligonucleotide hybridization has gained increasing popularity in clinical diagnostics since the introduction of efficient amplification techniques, such as polymerase chain reaction (PCR) (1). Since a reliable diagnosis of a given genetic disease often requires detection of multiple DNA mutations, simultaneous analysis of several potentially mutated sequences from a single biological sample appears highly desirable. Covalent immobilization of arrays of allele-specific oligonucleotides to a glass plate has recently been shown to offer a feasible basis for the development of such multiparameter analysis (2–4). The fluorescent labeled PCR products are hybridized to a support-bound oligonucleotide array, and the identity of the hybridized sequences is then determined by the location of fluorescent spots on the support. Alternatively, microscopic particles, each bearing a given allele-specific oligonucleotide and a reporter group defining the particle category, may be used for the same purpose (5). A mixture of particles is used as the solid support in the hybridization assay, and subsequently each particle is separately subjected to measurement to identify the particle category and to quantitate the possible hybridization with a complementary fluorescent labeled oligonucleotide in the PCR sample. We have previously (6) demonstrated that a highly sensitive miniaturized assay format may be developed by using uniformly sized (50 μm) glycidyl methacrylate/ethylene dimethacrylate particles (7) for covalent immobilization of the oligonucleotide probes and a photoluminescent europium(III) chelate (8) for oligonucleotide labeling instead of conventional organic fluorophores. Accordingly, time-resolved fluorescence detection may be used, enabling efficient elimination of background fluorescence. We now report on covalent immobilization of the oligonucleotide probes to microparticles and quantitation of the hybridization by

time-resolved fluorescence. The factors affecting the kinetics and efficiency of hybridization are discussed.

EXPERIMENTAL PROCEDURES

Materials. Uniformly sized (50 μm) porous glycidyl methacrylate/ethylene dimethacrylate particles (1) prepared by SINTEF Applied Chemistry (Norway) (7) were used for immobilization of the oligonucleotide probes. The particles were obtained by copolymerization of glycidyl methacrylate (40%) with ethylene dimethylacrylate (60%) (37% matrix) and derivatized with bis(3-aminopropyl)-amine reacted with the particle-bound epoxy functions. The density of the primary amino functions was of the order of 1 mmol g^{-1} , the surface area 137 $\text{m}^2 \text{g}^{-1}$, and the total pore volume 0.822 mL g^{-1} . The pore size ranged from <5 to 500 nm, the average size being of the order of 30 nm.

Preparation of SH-Derivatized Particles 3 and 5. Particles bearing *N*-(mercaptoacetyl) functional groups (3) were prepared as follows. The amino functions of particles 1 were partly acylated with the pyridinium salt of dithiodiglycolic acid, as described previously (9) for long-chain alkylamine controlled pore glass support. Accordingly, the particles (0.1 g) were treated with a mixture of dithiodiglycolic acid (0.01 mmol), *N,N*-diisopropylcarbodiimide (0.02 mmol) and *N*-hydroxysuccinimide (0.01 mmol) in pyridine (4 mL). After 0.5 h, the particles were washed with pyridine, and the unreacted amino functions were acetylated by treating the particles four times for 15 min with a mixture of acetic anhydride, pyridine, and 1-methylimidazole (1:5:1 v/v; 7 mL). The capped particles 2 were washed with pyridine and ether and then dried for 30 min under reduced pressure. The particle-bound disulfide bonds were finally cleaved with methanolic 1,4-dithio-D,L-threitol (1 mL of 0.5 M solution) in the presence of triethylamine (3 μM) to give the SH-derivatized particles 3. The loading of the mercapto functions of these particles, determined by the 2-thiopyridone response (10), was 80 $\mu\text{mol g}^{-1}$.

Particles bearing *N*-(ω -mercaptoundecanoyl) functional groups (5) were prepared via acylation of particles 1 with 10-undecenoic acid to 4, followed by radical addition of thioacetic acid to the terminal double bond of the *N*-(10-

® Abstract published in *Advance ACS Abstracts*, February 15, 1997.

undecenoyl) group and ammonolysis of the resulting thioester. The experimental details have been published elsewhere (11). According to the 2-thiopyridone response, the loading of the mercapto groups was $22 \mu\text{mol g}^{-1}$.

Preparation of NH_2 -Derivatized Particles 7. The amino functions of particles 1 were partly acylated with *N*-Fmoc-protected β -alanine. For this purpose, the particles (0.1 g) were treated with a mixture of *N*-Fmoc- β -alanine (0.1 mmol), *N,N*-diisopropylcarbodiimide (0.2 mmol) and *N*-hydroxysuccinimide (0.1 mmol) in pyridine (4 mL). After 1 h, the particles were washed with pyridine, and the unreacted amino functions were repeatedly acetylated as described above for particles 2. The Fmoc loading of the capped particles (6) was determined by detecting fluorometrically the amount of dibenzofulvene released upon treatment of part of the particles with a 1:4 mixture of 40% aqueous methylamine and pyridine. The loading was observed to be $20 \mu\text{mol g}^{-1}$. Finally, the Fmoc protection was removed with morpholine in pyridine (20%; 0.5 h), and the particles (7) were washed with pyridine and ether and dried under reduced pressure.

Immobilization of Oligonucleotides to the SH-Derivatized Particles 3 and 5. A 3'-[*N*-(6-amino-3,4-dithiahexyl)carboxamidomethyl] phosphate conjugate 8 of the 16-meric oligodeoxyribonucleotide 5'-d(CCTATGATGAATATAG)-3' was prepared by phosphoramidite chemistry as described previously (12) and converted to the *S*-(2-pyridyl) disulfide conjugate 9 via reduction with 1,4-dithio-D,L-threitol (25 mM; 4 h) in aqueous solution and subsequent reoxidation of the chromatographically isolated oligomer with bis(2-pyridyl) disulfide (3 mM; 17 h) in ethanol. The activated oligonucleotide conjugate 9 was finally purified by RP HPLC (Nucleosil 300 C₁₈, 4×250 mm, 5 μm ; buffer A, 0.05 M aqueous NH_4OAc ; buffer B, 0.05 M NH_4OAc in 65% aqueous MeCN; flow rate 1 mL min⁻¹; linear gradient from 0 to 30% B in A in 30 min) and desalted. When the SH-derivatized particles 3 (1.4 mg) or 5 (1.7 mg) were treated with the desired amount of 9 (from 0.25 to 3 OD) in aqueous solution (500 μL) for 24 h, the oligonucleotide was quantitatively attached to the particles giving 10 and 11, respectively, as indicated by complete disappearance of the nucleobase absorption at 260 nm and concomitant appearance of the 2-thiopyridone absorption at 343 nm. In this manner oligonucleotide loadings ranging from 1 to 8 $\mu\text{mol g}^{-1}$ were obtained. Finally, the unreacted mercapto functions were capped with maleimide in a 1:1 mixture of pyridine and ethanol (1 mL of 0.5 M solution). The particles were washed with pyridine and ether and dried under reduced pressure.

Alternatively, a 3'-[*N*-(2-aminoethyl)carboxamidomethyl] phosphate conjugate 12 of the same 16-meric oligodeoxyribonucleotide probe (0.25 OD, 1.5 nmol) was prepared, as described previously (12). The primary amino function of 12 was allowed to react with 30-fold excess of 2,4,6-trichlorotriazine in aqueous solution (96 μL) in the presence of *N,N*-diisopropylethylamine (135 nmol). After 5 min, the SH-derivatized particles 3 (2.0 mg) were added, and the reaction was allowed to proceed for 20 h. According to time-dependent UV absorption spectra of the solution, the oligonucleotide was quantitatively attached to the particles, giving an oligonucleotide loading of $0.7 \mu\text{mol g}^{-1}$. The particles were washed with water, and the unreacted mercapto functions were capped with maleimide, as described above for 10 and 11. The capped particles 13 were finally washed with pyridine and ether and dried under reduced pressure.

Immobilization of Oligonucleotides to the NH_2 -Derivatized Particles 7. The 3'-[*N*-(2-aminoethyl)carboxamidomethyl] phosphate conjugate 12 (0.30 OD,

1.8 nmol) was activated with 15-fold excess of 2,4,6-trichlorotriazine. After 5 min, particles 7 (2.3 mg) were added, and the reaction was allowed to proceed for 20 h. Quantitative attachment of 12 to the particles resulted in an oligonucleotide loading $0.8 \mu\text{mol g}^{-1}$. The particles obtained (14) were washed with pyridine and ether and dried under reduced pressure.

Fluorescent Oligonucleotide Conjugates. The fluorescent oligonucleotide conjugates used in hybridization assays were obtained by assembling sequences 5'-d(CTATATTCATCATAGGAAACACCAAAGATGATA-TTX₅C)-3' [X = *N*⁴-aminohexyl-2'-deoxycytidine; 15], as described previously (13), and labeling (14) them with a photoluminescent Eu(III) chelate, {2,2',2'',2'''-[4'-{4'''-[(4,6-dichloro-1,3,5-triazin-2-yl)aminophenyl]-2,2':6,2''-terpyridine-6,6''-diyl}bis(methylenenitrilo)}tetrakis-(acetato)}europium(III) (8). The extent of labeling was determined by releasing Eu(III) ion in solution with a fluorescence enhancement solution and measuring the fluorescence intensity on a time-resolved fluorometer against a europium(III) chloride standard solution (15). 15 was observed to be fully labeled, bearing thus 5 Eu(III) chelates. A similarly labeled 32-mer, 5'-d(X₂₀-ATCATCTTTGGT)-3' (16), was prepared to determine the unspecific binding of oligonucleotides to particles 10, 11, 13, and 14. The extent of labeling was determined to be 17 chelates per oligomer.

Hybridization Assays. The hybridization assays were carried out in a Tris buffer (50 mM, pH 7.5, 0.01% Tween 20, 0.5 M NaCl). Usually 50 particles were incubated in 10 μL of the buffer containing a known amount of the fluorescently labeled oligonucleotide (15 or 16). However, for examining the kinetics of hybridization, the total volume was 100 μL and aliquots of 10 μL were withdrawn. Hybridization reactions were typically allowed to proceed for 24 h. The particles were usually washed twice with 200 μL of glycine buffer (50 mM, pH 10), containing 20% propanol, and then transferred into a quartz capillary tube for measurement. However, when the kinetics of hybridization was followed, only one wash with 300 μL of buffer was carried out. The fluorescence emission of each particle was determined separately on a time-resolved microfluorometer based on a Nikon TDM inverted microscope, as previously described in detail (6). Typically 10 individual particles were measured, the standard deviation ranging from 2 to 8%. To convert the intensity of the fluorescence signal to number of europium(III) ions, and hence to number of oligonucleotides hybridized, the europium(III) ion was in some cases released in solution with a fluorescence enhancement solution, and the fluorescence emission was measured on a time-resolved fluorometer against a europium(III) chloride standard solution (15).

RESULTS AND DISCUSSION

Covalent Immobilization of Oligonucleotides to Microparticles. Uniformly sized (50 μm) porous microparticles (1) prepared by copolymerization of glycidyl methacrylate (40%) with ethylene dimethylacrylate (60%) and functionalized with primary amino groups (7) were used for the immobilization of a 16-mer oligodeoxyribonucleotide, 5'-d(CCTATGATGAATATAG)-3'. For this purpose, the particles were further derivatized in one of the three alternative manners depicted in Scheme 1. Accordingly, a desired proportion of the amino functions of particles 1 was first acylated with either dithiodiglycolic acid to give 2, 10-undecenoic acid to give 4, or *N*-Fmoc- β -alanine to give 6, and the rest of the amino groups were acetylated. Reductive cleavage of the disulfide bond of particles 2 with 1,4-dithio-D,L-threitol gave

N-mercaptoacetylated particles **3**, radical addition of thioacetic acid to the terminal double bond of particles **4** and subsequent ammonolysis gave *N*-(ω-mercapto-undecanoyl) functionalized particles **5** (11), and removal of the *N*-Fmoc protection from particles **6** gave particles **7**. A 3'-[*N*-(6-amino-3,4-dithiahexyl)carboxamidomethyl] phosphate conjugate **8** of the 16-meric oligodeoxynucleotide was then prepared (12), converted to the *S*-(2-pyridyl) disulfide conjugate **9**, and reacted with SH-derivatized particles **3** and **5** to result in covalent immobilization via a disulfide linkage (**10** and **11** in Scheme 2). Immobilization to particles **3** was also achieved by activating the 3'-[*N*-(2-aminoethyl)carboxamidomethyl] phosphate oligonucleotide **12** (12) with 2,4,6-trichlorotriazine (**13** in Scheme 3). In the same manner, the oligonucleotide conjugate **12** was attached to the NH₂-derivatized particles **7** (**14** in Scheme 3). The oligonucleotide loading of the particles ranged from 0.7 to 8 μmol g⁻¹.

Kinetics of Hybridization to Particle-Bound Oligonucleotides. The hybridization of the fluorescent oligonucleotide conjugate **15** to the particle-bound oligonucleotides was followed by shaking 500 microparticles (**10**, **11**, **13**, **14**) in 100 μL of Tris buffer (50 mM, pH 7.5, containing 0.5 M NaCl and 0.01% Tween) containing **15** at nanomolar concentrations. Aliquots of 10 μL (50 particles) were withdrawn at appropriate intervals. The particles were washed with 300 μL of glycine buffer, and the fluorescence emission of a single particle was measured by time-resolved fluorometry. The results obtained at 25 °C are presented in Figure 1. With each particle, unspecific binding of the noncomplementary oligonucleotide **16** was negligible; <1% of **16** was bound to the particles. Even with particles exhibiting the poorest hybridization properties, the sequence specific signal represented >10% of the total amount of the labeled oligomer. Accordingly, the background signal referring to unspecific binding of **16** remained always <10% of the

Scheme 3

Figure 1. Kinetics of hybridization of fluorescent labeled oligonucleotide **15** with a complementary sequence covalently immobilized via various linkers to glycidyl methacrylate/ethylene dimethacrylate particles: (\blacktriangle) **10**, (\blacksquare) **11**, (\triangle) **13**, (\square) **14**.

specific one resulting from binding of **15**, usually only a couple of percent. The low level of unspecific binding was further verified by replacing the base triplet T7C8A9 of **15** with a triplet G7T8G9. This three-base mismatch was sufficient to result in complete disappearance of sequence specific signal of **15**.

As seen, the kinetics of hybridization depend considerably on the structure of the linker employed to tether the oligonucleotide to the particle. The half-saturation took place in 1.2, 4, 4, and 3 h with **10**, **11**, **13**, and **14**, respectively. All of these half-lives were practically independent of the initial concentration of **15**, as long as the amount of **15** was small compared to that of the covalently immobilized oligonucleotides. Under these conditions, i.e. when the immobilized sequences are present in large excess, the hybridization obeys rather well the kinetics of two reversible first-order reactions, the rates of the opposite reactions being proportional to the amount of **15** in solution and hybridized to the particle, respectively. The curves indicated in Figure 1 represent the best least-squares fit obtained on the basis of this simple model. As seen, no systematic deviation from the assumed kinetics occurs.

Somewhat unexpectedly, the density of immobilized oligonucleotides on the particle had practically no effect on the hybridization kinetics. For example, particles **11** having oligonucleotide loadings of 1 and 6 $\mu\text{mol g}^{-1}$ both underwent half-saturation in 4 h (data not shown). Increasing the number of particles in a given volume of the hybridization mixture, in turn, markedly reduced the time needed to reach the equilibrium. In fact, the half-life of hybridization was observed to be approximately inversely proportional to the number of particles. In

summary, when the amount of particle-bound oligonucleotide probes is much higher than that of the complementary oligonucleotide (**15**) in solution, the hybridization can be accelerated by increasing the area of the solid support in contact with the solution, but not by increasing the oligonucleotide density, keeping the surface area constant.

Calibration of the Fluorescence Measurement from a Single Microparticle. The efficiency of hybridization, i.e. the proportion of the fluorescent oligonucleotide conjugate **15** hybridized to particles **10**, **11**, **13**, and **14**, was quantified as follows. Two sets of hybridization assays on particles **10** were carried out, changing the initial concentration of **15** from 1.7 pM to 1.7 μM , i.e. from 10^9 to 10^{12} molecules of **15** per reaction (50 particles in 10 μL). After the hybridization equilibrium had settled, one set of particles was subjected to microfluorometry measurements by the single-particle techniques used above. From the other set of washed particles, europium(III) ion was released to solution and determined according to the DELFIA protocol (15). Similarly, the amount of **15** in the solution phase before and after the hybridization assay was determined by releasing the europium(III) ion from **15** and determining its amount by DELFIA. The sum of the amount of europium(III) ion released from the solution and solid phase after hybridization was always equal to the amount of europium(III) ion released from the solution phase before hybridization. Plotting of the microfluorometry signals determined from single particles against the amount of europium(III) ion released from the particles and quantified by DELFIA gave the calibration line depicted in Figure 2. Approximately 50 particles were used in each europium release assay. The possible contribution of unspecific binding was always estimated with the aid of the labeled noncomplementary oligonucleotide, **16**. In all cases this contribution was negligible. As seen from Figure 2, the microfluorometry signal is linearly related to the number of europium(III) ions on particle over a range of 3 orders of magnitude, in striking contrast to the behavior of conventional fluorophores. This calibration line was exploited to convert the microfluorometry signals to the amount of europium(III) ion on the particle and further to the amount of **15** hybridized to the particle. Comparison of the total amount of **15** on all particles to the total amount of **15** initially added to the system then enabled estimation of the hybridization efficiency.

Efficiency of Hybridization. All of the particles studied (**10**, **11**, **13**, **14**) exhibited selective hybridization with the complementary oligonucleotide (**15**) in solution. Binding of a noncomplementary oligonucleotide conjugate

Figure 2. Intensity of the microfluorometer signal of a single particle plotted against the number of europium(III) ions on the particle.

Figure 3. Intensity of the microfluorometer signal of a single particle plotted against the number of labeled oligonucleotide molecules used in the hybridization assay.

(16) was always negligible. As mentioned above, the structure of the linker used to tether the oligonucleotide probe to the particle markedly affects the kinetics of hybridization. Unfortunately, the kinetics and efficiency of hybridization do not correlate; as seen from Figure 1, faster hybridization does not necessarily mean more efficient hybridization. Application of the calibration curve in Figure 2 to the data in Figure 1 (and several similar measurements) gave average hybridization efficiencies of 25, 80, 20, and 10% for particles **10**, **11**, **13**, and **14**, respectively. Accordingly, tethering of oligonucleotide probes to particles via a long hydrocarbon chain, as with particles **11**, appears preferable, in spite of the fact that the kinetics of hybridization is slower than with some other alternatives studied.

With all of the particles studied, the efficiency of hybridization was observed to be, analogously to the kinetics of hybridization, independent of the concentration of the complementary oligonucleotide (**15**) over a wide range. As an example, the data obtained with particles **10** are given in Figure 3. Experiments with the same particles (**10**) also showed that the density of the covalently immobilized oligonucleotide probes exerts only

a minor effect on the efficiency of hybridization, as long as the particle-bound oligonucleotide probes are present in large excess. Increasing the oligonucleotide loading from 1 to 8 $\mu\text{mol g}^{-1}$ increased the hybridization efficiency from 25 to 40%. Interestingly, tethering 4 $\mu\text{mol g}^{-1}$ of a pentameric T₅ sequence to these particles, keeping the loading of the recognizing oligonucleotide probe at 1 $\mu\text{mol g}^{-1}$, also increased the hybridization efficiency of **15** from 25 to 40%, while the unspecific oligonucleotide binding remained at low level. The physicochemical basis of the enhanced binding is obscure, but the observation suggests that truncated oligonucleotide sequences on the particles are not necessarily detrimental to the binding properties. Possibly, the desired oligonucleotide probes could be assembled directly on the microparticles without a marked loss of efficiency and selectivity of hybridization.

From the point of view of potential applications, the relatively slow kinetics of hybridization form the major hurdle to overcome. As discussed in the foregoing, increasing the number of particles, i.e. increasing the surface area and keeping the density of immobilized probes constant, reduces the time needed to reach equilibrium. At the same time the efficiency of hybridization appeared to remain almost unaltered. Accordingly, high particle density would enable short assay times. Unfortunately, the fluorescence intensity when determined from a single particle is inversely proportional to the number of particles, and hence what one wins in time is lost in sensitivity. The attempts to accelerate the hybridization by increasing the temperature led to a similar result. Increasing the temperature from 25 to 40 °C reduced the apparent half-life of hybridization to approximately half of the original value, but simultaneously the hybridization efficiency was decreased by almost 50%.

ACKNOWLEDGMENT

We thank Dr. Ruth Schmid, SINTEF (Norway), for the generous gift of the particles employed and Prof. Timo Lövgren, Dr. Antti Iitiä, and Ms. Pia Heinonen for helpful discussions. We gratefully acknowledge financial support from the Academy of Finland, the Research Council for Natural Sciences and Technology.

Epoch Pharmaceuticals Inc., 1725 220th Street S.E. No. 104, Bothell, Washington 98021, Department of Nuclear Medicine, Clinical Center, National Institutes of Health, Bethesda, Maryland 20892, and Department of Radiation Oncology, University of Washington, Seattle, Washington 98195. Received October 16, 1996[®]

A rapid and efficient method for the synthesis of ^{125}I -labeled oligodeoxynucleotides (^{125}I ODNs) is described. The key intermediates are tributylstannylbenzamide-modified ODNs (Sn-ODNs). Reaction conditions are described for the preparation of 5'-modified Sn-ODNs. Treatment with NaI and chloramine T gave conversion to the desired I-ODN, which was easily isolated by reversed phase chromatography. Thermal denaturation (T_m) studies showed that hybridization properties were not disturbed by the 4-iodobenzamide modification. An ^{125}I ODN was prepared and characterized by hybridization to ^{32}P -labeled DNA targets. Sequence specific cleavage of the target DNA strand by ^{125}I was measured.

INTRODUCTION

^{125}I -labeled oligodeoxynucleotides (^{125}I ODNs)¹ have been used for years as probes to detect complementary nucleic acids. Appropriately labeled ^{125}I ODNs can also act as efficient, sequence specific, DNA cleavage agents (1). The nuclear decay process of ^{125}I (electron capture and internal conversion) generates ~ 22 low-energy electrons that dissipate their energy within a few nanometers of the decay site (2). If this decay process (Auger emission) occurs in close proximity to duplex DNA, double-strand breaks can occur with $\sim 100\%$ efficiency/decay event. The short DNA cleavage range of the Auger emitting isotopes makes them promising agents for sequence specific targeting by oligonucleotides. For example, when ^{125}I -labeled deoxycytidine (^{125}I dC) was enzymatically incorporated into a single position in an ODN and hybridized to a complementary ssDNA target, more than 70% of the cleavage products were found within 15–20 Å of the site of ^{125}I decay (1). Recently it has been shown that an ^{125}I -dC labeled triplex forming ODN can specifically cleave a homopurine sequence in a plasmid DNA target containing the *nef* gene of HIV. Each ^{125}I decay gave approximately 0.8 dsDNA breaks (3).

As a result of its efficient DNA cleavage properties, ^{125}I is extremely cytotoxic when incorporated into the DNA of dividing cells as ^{125}I dU (4). Therapeutic (anticancer) implications of Auger emitting radionuclides have been reviewed (5). Although ^{125}I is an efficient DNA cleavage agent, its 60 day half-life is an obvious disadvantage for *in vivo* applications. The shorter half-life, Auger emitting isotope ^{123}I (13.2 h half-life) has also been shown to be cytotoxic when incorporated into DNA using ^{123}I dU (6)

or targeted to DNA using ^{123}I -labeled estrogens (7). The DNA cleavage efficiency of ^{123}I dU incorporated into cellular DNA has been determined (8). Each decay of ^{123}I gave 0.45–0.74 dsDNA breaks if DNA repair is accounted for. Radiolabeling of ODNs with ^{123}I has not been reported.

This paper describes a rapid and convenient radiolabeling method for making I-ODNs from tributylstannylbenzamide-modified ODN intermediates (Sn-ODNs). Aryl tin intermediates have been valuable for radiolabeling small molecular weight compounds via halodestannylation reactions (9). A 15-mer ODN bearing a 5'-terminal hexylamine linker was used to develop the conjugation chemistry. The effect of the 4-iodobenzamide linker system on hybridization properties of nontadioactive (^{127}I) labeled ODNs was studied spectrophotometrically. The terminally modified ^{125}I ODN was then prepared and hybridized to a ^{32}P -labeled ssDNA target. Analysis of the ^{32}P fragments after 15 days showed sequence specific DNA cleavage at the site of the attached ^{125}I . Our ultimate goal is to prepare ^{123}I -labeled ODNs and to determine how the position of attachment of ^{125}I and ^{123}I affects DNA cleavage efficiency of I-ODNs.

EXPERIMENTAL PROCEDURES

General Chemical Procedures. Reversed phase HPLC analysis of nonradioactive compounds used a Rainin pump system. Pump control and data processing used a Rainin Dynamax chromatographic software package (Macintosh). Aqueous solutions were dried at <1 Torr on a Speed Vac centrifugal evaporator (Savant Instruments, Farmingdale, NY). T_m studies were performed on a Perkin-Elmer Lambda 2S UV-vis spectrophotometer equipped with a PTP6 thermal programmer. Radio-HPLC was done on a Beckman pump system with an in-line γ detector (Beckman Model 170). Alternatively, radio-HPLC was done on a Hewlett-Packard pump system with an IN/US γ -RAM detector. To account for variations in HPLC systems, retention times of the ^{125}I ODNs were always verified by injection of nonradioactive standards. Isolated radiochemical yields were determined using a Capintec dose calibrator.

Synthesis of Oligodeoxynucleotides. ODNs were prepared on an Applied Biosystems Model 384 synthesizer using the 1 μmol protocols supplied by the manufacturer. Protected β -cyanoethyl phosphoramidites, CPG

[®] Abstract published in *Advance ACS Abstracts*, March 1, 1997.

¹ Abbreviations: ODN, oligodeoxynucleotide; I-ODN, iodinated ODN; Sn-ODN, tributyltin-modified ODN; ssDNA, single-stranded DNA; dsDNA, double-stranded DNA; ChT, chloramine T (sodium salt of *N*-chloro-*p*-toluenesulfonamide); TEAA, triethylammonium acetate; PAGE, polyacrylamide gel electrophoresis; PBS, phosphate-buffered saline.

supports, deblocking solutions, cap reagents, oxidizing solutions, and tetrazole solutions were purchased from Glen Research (Sterling, VA). The structure and sequence of the amine-modified ODN (**1**) used in this study are shown in Figure 1. The sequence of the 42-mer target (ODN **4**) is shown below. The underlined region is complementary to modified ODN **1**.

5'-CCAGCAGCCTCCCGCGACGATGCCCTCAACGTTAGCTTCAC

The 3'-hexanol modification was introduced into ODN **1** through use of a hexanol-modified CPG support (10). The 5'-aminoethyl modification was introduced into **1** using an N-MMT-hexanolamine phosphoramidite linker (Glen Research). HPLC purification, detritylation, and butanol precipitation of the synthetic ODNs were carried out as previously described (11).

Characterization of Modified ODNs. The concentrations of all ODNs were determined from the UV absorbance at 260 nm in PBS (pH 7.2). An extinction coefficient for each ODN was determined using a nearest-neighbor model (12), correcting for the molecular weight (but not ϵ) of appended modifications. The value for ϵ was used to calculate a theoretical ratio of A_{260} to concentration in micrograms per milliliter as listed in Table 1. All modified ODNs were analyzed by HPLC using the method described in Figure 2. Retention times are listed in Table 1. ODN purity was further confirmed by polyacrylamide gel electrophoresis. PAGE was carried out under denaturing conditions (7 M urea) using cross-linked 20% gels [bis(acrylamide)/acrylamide, 1:19; $0.4 \times 170 \times 390$ mm] at 45 W for 40 min. TBE (pH 8.3; 100 mM Tris base, 100 mM boric acid, 1 mM EDTA) was used as a running buffer. Bromophenol blue was used as a marker. The nucleotidic bands were visualized by silver staining. Unless otherwise noted, all modified ODNs were >95% pure by HPLC and one major band by PAGE.

5'-Modified Sn-ODN (2). To 0.13 mL of a 0.77 mM solution of ODN **1** ($0.10 \mu\text{mol}$) were added 0.1 mL of 1 M sodium borate buffer (pH 8.3) and 0.3 mL of 0.1 M sodium borate buffer (pH 8.3) in a 1.7 mL Eppendorf tube. A solution of 5 mg ($10 \mu\text{mol}$) of *N*-hydroxysuccinimidyl 4-*tri*-(*n*-butyl)stannylbenzoate (13) in 0.5 mL of THF was added, and the milky emulsion was shaken for 16 h. The mixture was concentrated to a volume of ~ 0.1 mL on a Speed Vac to remove THF. The cloudy solution was dissolved in 0.4 mL of 0.1 M TEAA (pH 7.5) and filtered through a $0.45 \mu\text{m}$ syringe filter. The filter was rinsed with an additional 0.2 mL of buffer, and the combined filtrate was purified by HPLC using the conditions described in Figure 2. The desired product (31 min peak) was collected, and 0.1 mL of 1 M borate buffer (pH 8.3) was added before taking to dryness on a Speed Vac. The white solid product was reconstituted with 0.5 mL of water, and the concentration was determined by A_{260} measurement. Recovery of **2** was 0.23 mg (42% yield).

5'-Modified [¹²⁵I]ODN (3). *Method A.* To 12 μL of an 83 μM solution of Sn-ODN **2** (1 nmol) were added 7.5 μL (5 nmol) of a 0.1 mg/mL solution of sodium iodide and 6.9 μL of 0.1 M borate buffer (pH 8.3). Reaction was initiated by adding 4.56 μL (20 nmol) of a 1 mg/mL solution of chloramine T hydrate (ChT) in water. After 5 min, the reaction was quenched with 5 μL of a 10 mg/mL solution of sodium bisulfite. The reaction was analyzed by HPLC and showed complete conversion of **2** (31 min) to the desired product **3** (16 min) as shown in Figure 2.

Method B. To 0.127 mL of a 0.79 mM solution of ODN **1** ($0.10 \mu\text{mol}$) were added 0.1 mL of 1 M sodium borate buffer (pH 8.3) and 0.3 mL of 0.1 M sodium borate buffer

(pH 8.3) in a 1.7 mL Eppendorf tube. A solution of 4-iodobenzoyl chloride (2.5 mg, $9.4 \mu\text{mol}$) in 0.5 mL of THF was added, and the solution was kept at room temperature for 16 h. HPLC showed complete reaction of **1** (8.7 min). The reaction mixture was diluted to 2 mL and purified by centrifugal ultrafiltration through a 1000 MW cutoff concentrator (Filtron). This process removed excess hydrolyzed acid chloride and gave the desired product **3** in 97% purity as evidenced by HPLC. The retentate was diluted to 0.5 mL with water, and concentration was determined by A_{260} measurement. Recovery of **3** was 0.41 mg (77% yield). This product coeluted with **3** prepared according to method A and was used for thermal denaturation experiments.

Thermal Denaturation Studies. The hybridization properties of all modified ODNs were examined by forming duplexes with complementary ODN **4** and determining the melting temperatures (T_m). Each ODN was present at 2 μM in pH 7.2 PBS (9.2 mM disodium phosphate, 0.8 mM monosodium phosphate, 0.131 M sodium chloride). UV absorbance was measured as the samples were heated from 10 to 90 °C with a temperature increase of 0.5 °C/min. Thermal dissociation curves were obtained from A_{260} vs temperature. The T_m was determined from the derivative maximum. Data from one representative run are given in Table 1.

Radiolabeling Procedures. The volatile nature of ¹²⁵I dictates certain handling precautions. Radiohalogenation of ODNs was carried out in a Plexiglas "iodination box", which had its own exhaust fan and charcoal filter (Radiation Physics, Beltsville, MD) and which was placed within a fume hood. ¹²⁵I was handled using standard syringe techniques. Labeling reactions were conducted in a reaction vessel that was vented to the inside of the iodination box through a 10 mL syringe filled with charcoal. Double gloves were routinely used to prevent the volatile halogens from penetrating the first glove layer. Commercially available "sleeve protectors" were used to decrease contamination of lab coats. Monitoring with a Geiger counter was conducted continually throughout an experiment. Between 24 and 72 h postlabeling, investigators should have a thyroid bioassay conducted.

Conversion of 2 to [¹²⁵I]ODN (3). To a solution of 11 μg (2 nmol) of Sn-ODN **2** in 22 μL of 0.1 M borate buffer (pH 8.3) were added 1.41 mCi (~ 0.64 nmol, 2200 Ci/mmol) of Na¹²⁵I in 3 μL of 0.1 M NaOH (New England Nuclear) and 20 μg (88 nmol) of ChT in 20 μL of water. After 15 min, the reaction was quenched with 10 μL of sodium bisulfite (10 mg/mL). A 5 μL aliquot of the crude reaction mixture was analyzed by radio-HPLC. The γ -detector indicated 69% conversion of ¹²⁵I to the desired I-ODN **3** (22 min peak) as shown in Figure 3. The remaining [¹²⁵I]ODN reaction mixture was loaded on a Poly-Pak reversed phase syringe cartridge (Glen Research) and eluted first with 2 mL of TEAA and then with 2 mL of 20% acetonitrile in TEAA. Fractions of ~ 0.5 mL were collected, and each was measured in the dose calibrator. The most concentrated fraction (no. 5) contained 0.384 mCi (27% radiochemical yield) of [¹²⁵I]ODN **3**. Radio-HPLC analysis of this sample showed 96% purity. Earlier radioactive fractions were not analyzed for purity.

Alternatively, the [¹²⁵I]ODN product was isolated from the reaction mixture by reversed phase HPLC. In a separate labeling run, 50 pmol of **2** in 20 μL of 50 mM borate buffer (pH 8.5) was treated with 350 μCi (~ 160 pmol) of Na¹²⁵I and 20 μg of ChT. After 10 min, the reaction was quenched with 10 μL of sodium bisulfite (10 mg/mL). The mixture was passed through a Sephadex G-50 microspin column (Pharmacia). The product (**3**) was

Method A (^{125}I , ^{127}I):**Method B** (^{127}I):

Figure 1. Synthesis of I-ODN conjugates. Reagents: (a) 4-(tributylstannyl)-benzoate, NHS ester; (b) Na⁺I⁻, chloramine T; (c) 4-iodobenzoyl chloride.

recovered in 50 μL of TES buffer buffer (50 mM Tris, pH 8, 50 mM NaCl, 1 mM EDTA) and contained 25 μCi of ^{125}I while 320 μCi was retained by the column. HPLC purification used a 150 \times 4.6 mm C₁₈ column (Supelcosil LC-18-T) and the gradient specified in Figure 2. The radioactive peak corresponding to product (11–16 min) was collected in 0.5 mL fractions. Fractions 3–5 (3.8 μCi , 1.73 pmol) were combined and taken to dryness on the Speed Vac. The residue was dissolved in 10 μL of TES buffer. [^{125}I]ODN **3** appeared as a single band by both denaturing and nondenaturing PAGE.

Duplex Preparation with [^{125}I]ODN (3). The 42-mer target (ODN **4**) complementary to ODN **3** was purified by gel electrophoresis prior to 5'- ^{32}P labeling with [^{32}P]- γ -ATP using T4 polynucleotide kinase. The product was purified on a Pharmacia Microspin G50 gel filtration column according to the manufacturer's protocol, and its final concentration was estimated to be 0.25 pmol/ μL on the basis of quantitative recovery of ODN. HPLC-purified [^{125}I]ODN **3a** (0.4 pmol, 2.5 μL) and ODN **4** (0.25 pmol, 1 μL) were annealed at 40 $^{\circ}\text{C}$ for 10 min in 1 \times TES buffer. Two different duplex solutions were prepared with final volumes of either 25 μL (sample D1) or 10 μL (sample D2). The products of annealing were analyzed in 20% native PAGE as shown in Figure 4. Extent of duplex formation was quantitated using a FUJI BioImager BAS1500 and MacBAS software.

DNA Strand Break Analysis. After 15 days at -70°C , the duplex samples D1 and D2 described above were analyzed for fragmentation of the ssDNA target by 10% denaturing PAGE as shown in Figure 5 (panel A). The bands corresponding to fragmentation of each duplex were quantitated on the FUJI BioImager, and the distribution of breaks in [^{32}P]ODN **4** for sample D2 are presented in Figure 5 (panel B). A control sample containing [^{32}P]ODN **4** but no [^{125}I]ODN **3a** showed trace bands that were subtracted as background.

RESULTS

The conjugation and iodination chemistry were developed using the nonradioactive isotope of iodine (^{127}I). As shown in Figure 1, two methods were used to prepare iodinated ODNs, but only method A was used to prepare ^{125}I -labeled ODNs. An amine-modified ODN (**1**) was treated with *N*-hydroxysuccinimidyl *p*-tributylstannyl-

Figure 2. HPLC chromatograms describing synthesis of I-ODN **3** from Sn-ODN **2**, as shown in Figure 1 (method A). The HPLC system used a 250 \times 4.6 mm C₁₈ column (Rainin Dynamax 300 Å) and a gradient of 5–85% solvent B over 40 min (flow rate = 1 mL/min), where solvent A = 0.1 M triethylammonium acetate (pH 7.5), solvent B = acetonitrile; detection was by UV absorbance at 260 nm. Chromatogram for ODN **3** shows the reaction mixture 5 min after treatment of ODN **2** with NaI and chloramine T.

benzoate to give the key Sn-ODN precursor (**2**). Conversion to the desired I-ODN (**3**) was accomplished by treatment with excess NaI and ChT. To confirm the structure of the I-ODN prepared from Sn-ODN intermediate, I-ODN (**3**) was also prepared directly from **1** by reaction with 4-iodobenzoyl chloride (method B).

The structure and sequence of the starting amine-modified ODN (**1**) are shown in Figure 1. The ODN sequence is a 15-mer that is complementary to the initiation codon region of the *c-myc* oncogene. The 3'-hexanol modification was introduced into the ODN to improve serum stability (10). The 5'-hexylamine linker group was readily introduced into **1** on the DNA synthesizer using a commercially available phosphoramidite.

Preparation of the Sn-ODN was complicated by poor water solubility of the lipophilic tributyltin NHS ester. Suitable reaction conditions for synthesis of **2** used an excess of the NHS ester in an emulsion of THF and borate buffer (pH 8.3). Reversed phase HPLC analysis showed complete conversion of **1** to **2** after several hours. As shown in Figure 2, the lipophilic Sn-ODN (31 min retention time) was isolated by HPLC in high purity. Only 42% yield was obtained, presumably due to losses in the prior filtration step. The organometallic product destannylates under acidic conditions, so the Sn-ODN solutions were stored at pH 8 or above. These solutions had good stability (<5% degradation after 6 months at 0–5 $^{\circ}\text{C}$).

Treatment of **2** with 20 equiv of NaI and ChT gave complete conversion of the Sn-ODN to the I-ODN (**3**). After 5 min, HPLC analysis showed no remaining **2** and a new peak at 16 min. To prove that this peak was indeed the desired product, the same I-ODN product (**3**) was prepared using method B. Treatment of **1** with 4-iodobenzoyl chloride in borate buffer/THF gave 77% yield of a product (**3**) that coeluted with the I-ODN product from method A. Method B was more convenient for the larger scale preparations of I-ODN needed for T_m studies.

HPLC retention times and other physical properties of the modified 15-mer ODNs are listed in Table 1. Hybridization properties were determined by measuring the melting temperature (T_m) of DNA duplexes formed with a complementary 42-mer ODN target (**4**). The T_m data show that the 4-iodobenzamide modification has little effect on the ability of **3** to form stable duplexes. In

Figure 3. Radio-HPLC analysis of crude and purified [¹²⁵I]ODN **3**. The HPLC system is described in Figure 2. Upper trace is reaction mixture 10 min after addition of ChT. Lower trace is [¹²⁵I]ODN **3** after reversed phase (syringe column) purification.

Table 1. Properties of Modified ODNs^a

ODN	MW	A ₂₆₀ = 1 ^b (μg/mL)	HPLC ^c (min)	T _m ^d (°C)
1	5016	33.1	8.7	58.8
2	5409	35.7	31	57.4
3	5246	34.6	16	59.6

^a Sequences and structures of modified ODNs are shown in Figure 1. ^b Calculated concentration of ODN that gives 1.00 absorbance unit at 260 nm. ^c Elution time; C₁₈ HPLC conditions described in Figure 2. ^d Determined for 2 μM solutions of modified ODN and complementary 42-mer ODN **4** as described under Experimental Procedures.

fact, a slight increase in *T_m* (0.8 °C) was observed. The bulky tributylstannylbenzamide group in **2** gave a slight drop in *T_m* (1.4 °C), but even this ODN formed stable duplex structures as evidenced by the normally shaped melting curve.

After the hybridization properties were evaluated with the nonradioactive [¹²⁷I]ODN, the [¹²⁵I]-labeled ODN was prepared from the Sn-ODN intermediate. Radioiodination of Sn-ODN **2** with 1.41 mCi of [¹²⁵I] gave facile conversion to [¹²⁵I]ODN **3**. The reaction conditions were similar to that described for [¹²⁷I], except that 3.6-fold excess of the Sn-ODN was used to drive incorporation of the more valuable radionuclide. After 5 min, the reaction mix was quenched with sodium bisulfite (to reduce volatile iodine byproducts) and analyzed by reversed phase HPLC. As shown in Figure 3, the Na¹²⁵I (4–6 min retention time) was efficiently converted to a product with the same retention time (22 min) as the [¹²⁷I]ODN standard (**3**). Although the product peak was off scale on the chart recorder, the γ-detector indicated 69% conversion of [¹²⁵I] to the desired I-ODN **3**. A late eluting side product (35 min) was also present in the labeling mixture. The UV trace (not shown) was noisy due to the small injection volume but showed unreacted Sn-ODN (34 min).

[¹²⁵I]ODN **3** was purified by passing the reaction mixture through a disposable reversed phase syringe cartridge. These columns are routinely used for "tritylon" purification of synthetic ODNs. We used the protocol supplied by the manufacturer to isolate the desired product (0.38 mCi) in ~0.5 mL of 20% acetonitrile/TEAA. HPLC analysis of this material showed 96% purity by γ detection, and no detectable Sn-ODN by UV. The radioactive forerun was not analyzed for purity but presumably contained the remaining [¹²⁵I]ODN **3** and unreacted radioiodine. The excess of unreacted Sn-ODN was easily separated from the I-ODN product.

In a separate radiolabeling reaction, 3.2 equiv of [¹²⁵I] was used in relation to Sn-ODN **2**. After removal of unreacted [¹²⁵I] by gel filtration chromatography, analytical HPLC showed no unreacted Sn-ODN and some residual [¹²⁵I]. Further purification was accomplished by HPLC. Although the in-line radiometric detector gave

Figure 4. Nondenaturing PAGE showing duplexes formed from [¹²⁵I]ODN **3** and ³²P-labeled ODN **4**. Molecular weight (MW) markers: mixture of ³²P-labeled pBR322 Msp 1 digest and 8–32 oligo dT. Lanes: (1) [³²P]ODN **4**; (2) duplex D1; (3) duplex D2; (4) [¹²⁵I]ODN **3**.

better control over the purification process, radiochemical yield was low (3.5%) due to nonspecific adsorption to the C₁₈ packing. The fraction containing [¹²⁵I]ODN **3** was dried *in vacuo* and reconstituted in the desired buffer for the DNA cleavage assay. Nondenaturing PAGE analysis of this fraction showed one radioactive band (Figure 4, lane 4).

To study hybridization properties of [¹²⁵I]ODN **3**, a 5'-³²P-labeled 42-mer (ODN **4**) was prepared. A solution of 0.4 pmol (1.6 equiv) of I-ODN was annealed with an estimated 0.25 pmol of **4**. We assumed complete recovery of ³²P-labeled **4** from a gel filtration spin column on the basis of the manufacturer's claims of >90% recovery and our prior experience with these columns. Two different duplex solutions were prepared with different ODN **3** concentrations. These preparations were assayed for duplex formation by nondenaturing PAGE as shown in Figure 4. The less concentrated sample (D1) showed 65% of the slower moving duplex band, whereas sample D2 showed 89% duplex formation. As expected, both samples showed unhybridized I-ODN. The samples were frozen in liquid nitrogen and kept at -70 °C for strand break analysis of ODN **4**.

After 15 days of storage, the [¹²⁵I]ODN **3a**/[³²P]ODN **4** duplexes were analyzed for fragmentation by denaturing PAGE as shown in Figure 5A. The length of the 5'-³²P-labeled fragments in lanes 1 and 2 provides evidence for sequence specific cleavage by [¹²⁵I] decay. The position of the breaks relative to the sequence of ODN **4** was determined by counting the bands from the top of the gel. Breaks at a given position are due to complete removal of the corresponding base and result in a fragment *n* - 1 nucleotides long, where *n* is the position

Figure 5. (A, top) 10% denaturing PAGE showing fragmentation of ODN **4** after 15 days of decay. Lanes: (1) duplex D1; (2) duplex D2; (3) [^{32}P]ODN **4**; (4) [^{125}I]ODN **3**. (B, bottom) Bar graph showing distribution and relative intensity of breaks at individual bases of ODN **4** for duplex D2. X indicates position of attachment of iodobenzamide conjugate group. Total yield of strand breaks was 4.6% for D1 and 6.6% for D2.

of the nucleotide from the 5'-end. For example, a break at T34 (maximum in Figure 5B) corresponds to the 33 nucleotide long fragment in the gel. The bar graph in Figure 5B shows the relative intensity of these cleavage bands for the more concentrated duplex sample (D2) and how their position corresponds to the sequence of ODN **4**. The pattern of breaks for sample D1 was identical, but the intensity of each band was slightly lower. The value of each bar represents percent intensity of the band compared to the sum of the intensities of all bands including the top band (unbroken ODN **4**). The total yields of the strand breaks were calculated to be 4.6% for sample D1 and 6.6% for sample D2.

DISCUSSION

Before the advent of automated ODN synthesis, ^{125}I -labeled DNA probes were obtained by direct treatment with thallium chloride and sodium iodide at elevated temperature (14). The oxidized form of ^{125}I (I^+) reacts with random cytosine bases in the DNA to give 5,6-saturated pyrimidine residues. The harsh reaction conditions degraded the DNA and gave mixtures of iodinated products. Direct iodination of the cytosine residues is undesirable since the modified bases compromise hybridization properties of shorter probes.

Automated synthesis of 3'-labeled [^{125}I]ODNs from a [^{125}I]dU-modified solid support has been reported (15). The I-ODN products were used as PCR primers for preparation of internally modified [^{125}I]ODNs. This method is unsuitable for labeling with shorter half-life radiohalogens. More direct methods for radioiodination

of ODNs use conjugate groups that can be selectively iodinated. For example, 5'-hexylamine-modified ODNs have been chemically conjugated to 4-hydroxyphenyl (16) or 4-methoxyphenyl groups (17). Recently, a phosphoramidite reagent has been developed that allows direct incorporation of 4-hydroxyphenyl groups into 5-methyl dC nucleotides using a DNA synthesizer (18). To ensure that no cytosine residues react (and to speed the reaction), the modified ODN is generally present in large excess with respect to the small quantities of radioiodine that are used. Unreacted (carrier) ODN must be separated from the I-ODN since it competes for complementary nucleic acid target sites. This separation is difficult for the conjugates studied to date.

The radioiodination method reported here uses a tributylstannylbenzamide precursor (Sn-ODN **2**). The major advantage of this new radiolabeling procedure is that unreacted Sn-ODN and free iodine are easily separated from the desired I-ODN product. The lipophilic organometallic precursor was soluble and stable in aqueous buffer (pH 8.3). The hexylamine linker arm in ODN **1** reacted cleanly with tributylstannylbenzoic acid NHS ester to give **2**. This active ester has been used for labeling monoclonal antibodies with a number of radiohalogens (19). The strong UV absorbance of ODNs allowed the iodination chemistry to be developed using ^{127}I and reversed phase HPLC methods. Conversion of the Sn-ODN to I-ODN **3** proceeded quantitatively when excess NaI was used. The identity of **3** was confirmed by preparation via a more direct route (Figure 1, method B). T_m studies showed that the addition of the 4-iodobenzamide conjugate group did not adversely affect hybridization.

Radioiodination of ODN **2** with ^{125}I gave 69% conversion to [^{125}I]ODN **3**. The large shift in retention time allowed easy isolation and identification of the I-ODN product. Reversed phase chromatography using a disposable syringe cartridge gave 27% isolated yield of no carrier added [^{125}I]ODN **3** in 96% purity. A large excess of Sn-ODN was not required to drive the reaction, but a slight excess ensured complete reaction of the relatively expensive radioisotope. Although a C_{18} stationary phase was useful for analytical HPLC, recovery was poor in a preparative mode. We are experimenting with other reversed phase packings and HPLC methods to improve radiochemical yields.

The hybridization and DNA cleavage properties of [^{125}I]ODN **3** were studied using gel electrophoresis assays. We were especially interested in the effect of the relatively long 5'-linker in **3** on DNA cleavage efficiency. The reported 15–20 Å cleavage range (1) of [^{125}I]dC or [^{125}I]dU-modified ODNs hybridized to ssDNA targets may be an ideal situation. Substitution of ^{125}I at the 5-position of the pyrimidine ring essentially "locks" it into the major groove, approximately 5 Å from the axis of the B-form DNA helix. We suspected that the hexylaminebenzamide linker arm used to attach ^{125}I to the 5'-terminus might be too long (~16 Å) and flexible to allow efficient DNA cleavage.

Nondenaturing PAGE analysis of the duplex formed between [^{125}I]ODN **3** and 42-mer ODN **4** showed that extent of duplex formation was concentration dependent. Duplex sample D1 (10 nM in **4**) showed 65% dsDNA, whereas sample D2 (25 nM in **4**) showed 89% dsDNA. After 15 days (16% ^{125}I decay), the duplex samples were assayed for strand breaks using denaturing PAGE (Figure 5). Samples showed a Gaussian distribution of DNA fragments typical for strand breaks caused by ^{125}I . Taking into account that only 65% and 89% of ODN **4** formed duplexes, we recalculated the effective yield of

breaks as 7.1% and 7.4% for D1 and D2, correspondingly. Therefore, the yields in terms of breaks per decay were 0.44 and 0.46.

It is interesting that the DNA fragment of maximum intensity corresponds to the position of attachment of the 5'-terminal [¹²⁵I]benzamide containing linker. If this linker were stretched out in either the 5'- or 3'-direction, then the pattern of bands would be expected to shift (up to five nucleotides). The high cleavage efficiency (0.45 break per decay) indicates that the ¹²⁵I atom is constrained close to the sugar-phosphate backbone of the target DNA strand, much like the geometry obtained from labeling at the 5-position of the pyrimidine ring. It is not clear how the DNA cleavage efficiency of these different linker systems compares since no values have been reported for cleavage of ssDNA targets with ¹²⁵I-labeled dC or dU. Results showed 0.8 ds break per decay from ¹²⁵I-dC-labeled triplex forming ODNs that lie in the major groove of target dsDNA (3). Further investigations are planned to explore the effect of different linker systems on the DNA cleavage properties of ¹²⁵I. For example, 5-(aminoalkyl)uridine linkers can be used to prepare internally modified ODNs that constrain the iodobenzamide group in the major groove of duplex DNA. The rapid radioiodination method reported here should also allow the DNA cleavage properties of ¹²³I to be explored.

TECHNICAL NOTES

Effect of Cast Solvent on the Electron Transfer Reaction for Poly(ethylene oxide)-Modified Myoglobin on the Electrode in Poly(ethylene oxide) Oligomers

Natsue Y. Kawahara, Waki Ohkubo, and Hiroyuki Ohno*

Department of Biotechnology, Tokyo University of Agriculture & Technology, Koganei, Tokyo 184, Japan.
Received July 14, 1996[®]

Myoglobin from horse skeletal muscle was modified with poly(ethylene oxide) (PEO) with an average molecular weight of 2000 or 5000. Myoglobin was soluble after this modification in several organic solvents and PEO oligomers. The electron transfer reactions of PEO-modified myoglobin cast on the indium tin oxide (ITO) glass electrode were investigated by cyclic voltammetry. The PEO-modified myoglobin, cast on the electrode from water or a methanol solution, showed quasi-reversible redox reactions in PEO (average MW of 400). On the other hand, no redox response was seen in PEO-modified myoglobin cast on it using chloroform or benzene as a casting solvent. A clear redox response of the PEO-modified myoglobin was observed after methanol treatment of these layers cast from chloroform or a benzene solution. This suggests that the conformational change of the adsorbed PEO-modified myoglobin layer on the ITO electrode cast from chloroform or a benzene solution was not irreversible. The cast condition of PEO-modified myoglobin on the ITO glass electrode was revealed to affect the electron transfer reaction for protein considerably in PEO oligomers.

INTRODUCTION

Poly(ethylene oxide) (PEO)–protein hybrid was the most popular material in bioconjugate chemistry (1, 2). There are many papers on the enzymatic activity (3–6) and structure (7, 8) of PEO-modified proteins. Further, various methods for PEO modification of proteins were also reported (9–12). PEO modification of proteins is known to provide a nonimmunogenic response, and it also supports the improved solubility of these proteins in nonaqueous media keeping their functions. PEO is not only a polymer for protein modification but also a typical base material for preparing an ion conductive polymer matrix (13–15). Since PEO has a unit structure ($\text{CH}_2\text{-OCH}_2$) quite similar to that of water, we are studying the electrochemistry of a variety of water-soluble molecules in PEO (16–18).

On the other hand, there are extensive studies on the electrochemical characteristics of heme proteins such as cytochrome *c* (19–24), myoglobin (25–28), and so on in buffer solution. These redox reactions of heme proteins have been analyzed in only aqueous solutions. We mentioned PEO as a nonaqueous medium for electrochemical reaction of PEO-modified heme proteins. By using PEO as a solvent for electrochemistry of PEO-modified heme proteins, a novel electrochemical redox response is expected. Myoglobin is one of the water-soluble proteins, and it showed a direct electron transfer reaction at the electrode in a buffer solution without any mediator (25–28). PEO-modified myoglobin was then expected to be soluble in PEO oligomers, and it shows redox behavior similar to that in an aqueous medium.

As expected, PEO-modified myoglobin was also soluble in PEO oligomers and showed quasi-reversible electron transfer reactions at an indium tin oxide (ITO) glass electrode without any mediator in PEO oligomers (29–31). The electron transfer reaction of that was quite slow in PEO oligomers. PEO-modified myoglobin was cast on the electrode to eliminate the effect of the diffusion of proteins (30). However, there was no detailed knowledge on the redox response of PEO-modified myoglobin cast on the ITO electrode. The study of the relationship between the electrode response and the casting state of proteins on the electrode was an important subject in the field of electrochemistry for PEO-modified heme proteins in nonaqueous media.

Here we wish to show the effect of casting solvents on the direct electron transfer reaction of PEO-modified myoglobin on the electrode in salt-containing PEO oligomers.

EXPERIMENTAL SECTION

Materials. Myoglobin from horse skeletal muscle (Mb) (Sigma M-0630) was used without further purification. PEO₄₀₀ (average MW of 400) containing no additive such as an antioxidant was purchased from NOF Co. Ltd. PEO₄₀₀ containing 0.20 mol dm⁻³ KCl was used as a solvent after drying *in vacuo* at 60 °C for 3 days. PEO monomethyl ethers with molecular weights of 750, 2000, and 5000 were purchased from Aldrich Co. Ltd. All other reagents, not noted here, were purchased as analytical grade from Kanto Chemical Co. Ltd.

An indium tin oxide (ITO) glass electrode (ITO layer thickness of 1300 Å, surface resistance of 30.9 Ω/square) was purchased from Oji Tobi Co. Ltd. These were used as working and counter electrodes for cyclic voltammetry measurements after washing with acetone and then with chloroform. Silver wire (ϕ of 0.5 mm) was purchased as an electrode from Tokuriki Honten Co. Ltd.

^a +, soluble; ±, sparingly soluble; and —, insoluble. ^b Average molecular weight of modified PEO on protein. ^c Number of PEO chains per Mb. ^d Methyl alcohol. ^e Ethyl alcohol. ^f Carbon tetrachloride. ^g Ethyl acetate.

Synthesis of PEO-Modified Mb. The activated PEO (A-PEO) was synthesized according to the conventional method (29). First, PEO succinate was prepared by reacting PEO monomethyl ether and succinic anhydride. Then, A-PEO was prepared by reacting PEO succinate and *N*-hydroxysuccinimide. Mb was stirred with A-PEO for 1 h at 30 °C in a 0.05 mol dm⁻³ borate buffer solution at pH 9.0. A-PEO is known to react with amino groups of Mb in an aqueous medium. Mb was modified with A-PEO with average molecular weights of 750, 2000, or 5000. The unbound A-PEO was removed by ultrafiltration (Millipore, PTGC10K) using distilled water. PEO-modified Mb (PEO-Mb) in the dry state was prepared by the lyophilization (Tokyo Rika, FDU-540) of this solution.

Determination of the Degree of PEO Modification. The average number of PEO chains on one Mb was estimated from the titration results of amino groups of Mb by 2,4,6-trinitrobenzenesulfonic acid (32–34). The average number of PEO molecules with an average MW of 750, 2000, and 5000 attached onto one molecule of Mb was estimated to be 15 ± 1, 18 ± 1, and 18 ± 1, respectively.

UV-Vis Spectroscopy. Mb, having 18 PEO₅₀₀₀ chains, was dissolved in several organic solvents to a final concentration of 1.0 × 10⁻⁵ mol dm⁻³. The PEO-Mb solution was introduced into a quartz cuvette with a light path length of 10.0 mm. The UV-vis absorption spectrum was recorded with a Shimadzu UV-2200A spectrophotometer at room temperature.

Cyclic Voltammetry Measurement. Mb, modified with 18 chains of PEO₂₀₀₀ on average, was individually dissolved in casting solvents (water, methanol, chloroform, or benzene) to a concentration of 7.0 × 10⁻⁵ mol dm⁻³. Distilled casting solvent was used for all experiments. The PEO-Mb solution was cast onto the ITO glass electrode with a casting density of 10 μL cm⁻². After drying, the ITO glass electrode as a working electrode was faced with another ITO glass electrode as a counter one. They were fixed as a thin layer cell with silicone resin and dried *in vacuo* for 1 h. The thickness of the thin layer cell was 100 μm. Then polished silver wire (0.5 mm φ) was further introduced as a reference electrode. After complete drying, the cell system was soaked with PEO₄₀₀ (average MW of 400) containing 0.20 mol dm⁻³ KCl, and the solution was then raised in the cell by the capillary action. The electron transfer reaction of PEO-Mb cast on the ITO electrode in PEO₄₀₀ was investigated with cyclic voltammetry (Fuso Seisakusho HECS 972, 321B) at room temperature under a nitrogen atmosphere.

RESULTS AND DISCUSSION

Property of PEO-Mb in Organic Solvents. The solubility of synthesized poly(ethylene oxide)-modified myoglobin (PEO-Mb) in organic solvents is shown in Table 1. Since Mb, modified with PEO₇₅₀ (average MW of 750), was not soluble in those organic solvents, this hybrid was not used for further experiments. Longer PEO chains (≥2000) onto the proteins were preferable for making Mb soluble in organic solvents. Newly

Figure 1. UV-vis spectra of PEO-Mb in various solvents at room temperature. PEO₅₀₀₀-Mb was dissolved in phosphate buffer at pH 7.4 (A), methanol (B), chloroform (C), and benzene (D).

prepared PEO-Mb, having 18 chains of PEO₂₀₀₀, was soluble in water, methanol, chloroform, and benzene. When Mb was modified with PEO₅₀₀₀, PEO₅₀₀₀-Mb became more soluble in various organic solvents. This suggested that PEO₂₀₀₀ and PEO₅₀₀₀ were preferred material for the modification of myoglobin to dissolve it in organic solvents. This result is in agreement with that reported by Inada et al. (3–7).

The conformation of newly prepared PEO-Mb was analyzed in several organic solvents. UV-vis spectrophotometry revealed that PEO-Mb showed spectra in organic solvents and an aqueous solution as shown in Figure 1. The difference of both the absorbance and wavelength at the absorption maximum was observed in the different solvents. The UV-vis spectrum of PEO-Mb was affected by the solvent species, suggesting a small conformational change. The PEO-Mb in buffer solution (Figure 1A) exhibited an absorption maximum at the Soret band that is the same as that of unmodified Mb (oxidized form) in an aqueous solution (29). The absorption maximum at the Soret band, arising from π - π^* transitions of the heme active site, was not influenced by the PEO modification. Little shifts of Soret bands (400.0–414.7 nm) for PEO-Mb (Fe³⁺) were found in different solvents which means a little structural change around heme in PEO-Mb. Even after PEO modification, the solvent species was revealed to affect the chemical environment of heme in PEO-Mb. Furthermore, a strong conformational change of PEO-Mb in organic solvents was not found by absorption at 200–250 nm with CD spectrometry (data not shown).

Electrochemistry of PEO-Mb Cast on the ITO Electrode in a PEO Oligomer. Figure 2 shows cyclic voltammograms of PEO-Mb in PEO₄₀₀, where the PEO-Mb was cast onto the ITO electrode with various casting solvents. The PEO-Mb, cast from aqueous and methanol solutions, showed clear redox peaks in PEO₄₀₀. On the other hand, no response was seen for those cast from chloroform and benzene solutions. The conformation of PEO-Mb was suggested not to be strongly changed even in chloroform and benzene by UV-vis and CD spectrometry as mentioned above; however, the nature of the PEO-Mb film on the ITO glass electrode after casting seemed to be changed by casting solvent species. The dimensional characteristics of adsorbed PEO-Mb at the

Figure 2. Cyclic voltammograms of PEO-Mb on the ITO electrode cast from water (A), methanol (B), chloroform (C), and benzene (D). The voltammograms were taken in PEO₄₀₀ containing 0.5 mol dm⁻³ KCl, recorded with a sweep rate of 33 mV s⁻¹ at room temperature.

molecular level on the electrode should not be suitable for electron transfer when it was cast from a chloroform or benzene solution. A distinct difference in solubility of PEO-Mb in organic solvents, such as methanol, chloroform, or benzene, was not observed as seen in Table 1. However, spread-out forms of PEO chains onto Mb may be affected by solvent species. Macroscopically, the PEO-Mb cast ITO glass electrodes, prepared from water or a methanol solution, was transparent. Against these, those films cast from chloroform or benzene were obscure opaque. The PEO-Mb cast from chloroform or benzene might be assembled as massive particles on the electrode during the drying process. This flocculation might inhibit the electron transfer with the ITO glass electrode. It was also observed that the different morphology of PEO cast on the glass plate was formed by the casting solvent. It was quite similar to that for PEO-Mb cast on ITO glass electrode. The nature of PEO-Mb cast on the electrode from organic solvents should depend on the conformation and/or aggregated state of the modified PEO chains. When chloroform or benzene was used as a casting solvent, modified PEO chains of PEO-Mb were adsorbed on the electrode and inhibited the electron transfer between the protein and the ITO electrode. A very small conformational change affected by the redox processes has been detected by FTIR spectroscopy (35). This result supported the fact that the conformation of PEO-Mb adsorbed on the ITO electrode was an important factor in keeping the electrochemical activity of proteins.

Since PEO-Mb showed no response when it was cast from chloroform and benzene, a small amount of methanol was added dropwise onto these modified electrodes, and the redox response was analyzed in PEO₄₀₀ as shown in Figure 3. As a result, a clear redox response of the PEO-Mb was found after methanol treatment. This clearly supports the fact that both chloroform- and benzene-cast PEO-Mb films, i.e., redox inactive ones, were shifted to be redox active. The conformational change of the adsorbed PEO-Mb layer on the electrode cast from chloroform or benzene was not irreversible. Niki and his co-workers reported that three conformations of adsorbed cytochrome *c*₃ on the surface of mercury. These conformational changes are reported to be irreversible and depend on the applied potential (36). In our study, the electrochemical activity of adsorbed proteins on the electrode was changed and it depended on

Figure 3. Cyclic voltammograms of PEO-Mb on the ITO electrode with methanol post-treatment after casting from chloroform (A) or benzene (B) in PEO₄₀₀ containing KCl. The sweep rate was 33 mV s⁻¹ at room temperature.

Figure 4. Cyclic voltammograms of PEO-Mb on the ITO electrode with methanol post-treatment after casting from benzene solution in PEO₄₀₀ containing KCl. The sweep rates were 10, 33, 50, and 100 mV s⁻¹ at room temperature.

the casting solvent. The property of the adsorbate was influenced by the species of electrode, protein, solvent, and method. This is also consistent with the reported result, which described the nature of the electrode surface as a decisive factor for the electron transfer between protein and electrode. On the other hand, the important role of hydration for the indium oxide electrode surface in the electrode transfer reaction of proteins has already been reported by several researchers (19, 27). The electroactivity for PEO-Mb cast on the ITO electrode from the organic solvent may be influenced by the surface hydrophilicity of the electrode.

The PEO-Mb was post-treated with methanol after casting on the ITO glass electrode from benzene solution, and its cyclic voltammograms were recorded at various sweep rates in PEO₄₀₀ (Figure 4). The electrochemical response for PEO-Mb on the ITO glass electrode was stable with continuous cycling for at least 24 h. The formal potential of PEO-Mb, estimated from the anodic and cathodic peak potentials, is -57 mV vs Ag, and the ratio of the anodic to cathodic peak currents is 0.89 ± 0.05 in the sweep rate range from 5 to 100 mV s⁻¹. The formal redox potential of cast PEO-Mb on the electrode in PEO₄₀₀, obtained in our study, shifted to a positive side

Figure 5. Sweep rate dependence of the cathodic peak current for PEO-Mb on the ITO electrode with methanol post-treatment after casting from benzene solution in PEO₄₀₀ containing KCl at room temperature.

Figure 6. Effect of the sweep rate (ν) on the quantity of electricity (Q) for the reduction of cast PEO-Mb on the ITO electrode in PEO₄₀₀ containing KCl. The casting solvents were as follows: water (●), methanol (◆), chloroform and then methanol (post-treatment) (▽), and benzene and then methanol (post-treatment) (△).

compared with that of purified myoglobin in buffer solution (26). However, it is in fairly good agreement with that of PEO-Mb dissolved in PEO₂₀₀ (−55 mV vs Ag). A shift of the formal redox potential of PEO-Mb in PEO₄₀₀ is considered to be due to the PEO being a solvent. The peak separation of PEO-Mb cast onto the ITO glass electrode slightly increased with increasing sweep rates. Both the anodic and cathodic peak currents of the PEO-Mb cast on the ITO glass electrode depended on the sweep rate in PEO₄₀₀ as shown in Figure 5. It increased linearly in the sweep rate range up to 50 mV s^{−1}, suggesting that an electron transfer process should be the rate-determining step.

There is a small sweep rate dependence on the quantity of electricity (Q) in a wide sweep rate range from 1.0 to 100 mV s^{−1} as shown in Figure 6. Since the Q value was affected by the casting solvent species, the casting solvent was strongly suggested to affect the molecular packing of PEO-Mb on the ITO glass electrode. For example, it was 4.0×10^{-6} C for those cast from methanol and 2.3×10^{-6} C from water regardless of the sweep rate between 5.0 and 100 mV s^{−1}. Sweep rate-independent Q values were consistent with the result of the direct electron transfer between the ITO glass electrode and PEO-Mb at the interface of the electrode. This Q value was reasonable when the molecular cross section of PEO-Mb was estimated to be about 2000 Å²/molecule and taking surface roughness of the ITO electrode into

consideration. The calculated Q value was 4.0×10^{-6} C when the mean surface area of the ITO electrode was estimated to be 5 times larger than the apparent one. This is in good agreement with that obtained in this experiment as mentioned above. It is apparent that a rapid electron transfer occurred between the ITO glass electrode and only PEO-Mbs which were in direct contact with the electrode. A larger Q value was detected by decreasing the sweep rate to less than 1.0 mV s^{−1} only when organic solvent was used as a casting solvent. This increased Q value was constant during repeated scanning with the sweep rate of 1.0 mV s^{−1}. This suggests the possibility of intermolecular electron transfer perpendicular to the electrode between adjacent PEO-Mbs in the cast layer.

CONCLUSIONS

PEO-modified myoglobin, having 18 chains of PEO with an average molecular weight of 2000 or 5000, was soluble in organic solvents such as methanol, chloroform, and benzene. Water and methanol provided excellent casting conditions for such PEO-Mbs, and quasi-reversible electron transfer reaction was observed between PEO-Mb and the ITO glass electrode. Against this, the PEO-Mb, cast from a chloroform or benzene solution, showed no redox response in PEO oligomers. This electroinactive PEO-Hb layer was not irreversible and became electroactive after treatment with methanol. For the cast system, the casting condition of protein on the electrode was a very important factor for an electron transfer reaction of PEO-Mb in PEO oligomers.

Synthesis of an Amino Acid Analogue To Incorporate *p*-Aminobenzyl-EDTA in Peptides

Anne In. Song[†] and Tariq M. Rana*

Department of Pharmacology, Robert Wood Johnson Medical School, University of Medicine and Dentistry of New Jersey, 675 Hoes Lane, Piscataway, New Jersey 08854. Received July 24, 1996[®]

A convenient and straightforward synthesis of an amino acid analog, [*p*-(*N*- α -Fmoc-L-aspartic acid- β -amido)benzyl]-EDTA tetra-*tert*-butyl ester, compatible with Fmoc solid phase peptide synthesis strategy is described. This reagent was used to incorporate *p*-aminobenzyl-EDTA at an internal sequence position in an HIV-1 Tat protein fragment. After cleavage from the resin and standard deprotection, the peptide was purified by high-performance liquid chromatography and characterized by mass spectrometry. Through this methodology, flexible linkers of different lengths and containing various structures can be placed between the α -carbon backbone of peptides and metal chelates. These peptides will provide a new class of affinity cleaving reagents that can be directed against protein and nucleic acid targets.

Interaction of transition metal complexes with nucleic acids and proteins makes them a useful tool in molecular biology. Metal complexes can be synthesized for specific recognition and cleavage of nucleic acids, or they can be used as nonspecific nucleases (for an excellent review, see ref 1). Shape-selective metal complexes have been designed to target specific DNA and RNA structures (2–4). An iron–EDTA complex cleaves DNA nonspecifically and can be applied to determine the helical periodicity of DNA and structural details of bent DNA (5, 6). Cleavage of DNA and RNA by metal chelates is an important new approach to characterize specific structural features of nucleic acids and their complexes in solutions (7–11). The metal chelate attachment converts sequence-specific DNA-binding protein or oligonucleotide to sequence-specific DNA-cleaving molecules that function under physiological pH, temperature, and salt conditions (9, 10, 12–16).

As with nucleic acids, methods for specific and non-specific cleavage of proteins have been developed. Site-specific cleavage of proteins is achieved by introducing a metal-binding site at one position in a polypeptide chain or attaching it to protein binding ligands (17–26). Recently, an Fe-EDTA-catalyzed protein cleavage method has been applied to complex biological systems such as membrane proteins (27). Nonspecific protein cleavage by an untethered Fe-EDTA has been recently applied to map protein domains involved in macromolecular interactions such as the surface of a DNA-binding protein (28) and interactions between subunits of the multisubunit RNA polymerase (29). Artificial proteolytic reagents would be extremely useful to characterize important structural features of proteins and their complexes under physiological conditions.

To accurately probe structure–function relationships in nucleic acids, proteins, and nucleic acid–protein complexes by affinity cleaving methods, the development of both general and specific methods for single-site

modification of the peptide sidechain is required. Reagents potentially useful for such experiments are the “bifunctional chelating agents,” so called because they incorporate a strong metal-chelating group and a chemically reactive functional group. Bifunctional chelating agents have been synthesized and used to provide biological molecules with the nuclear, physical, and chemical properties of chelated metal ions (30–32).

To prepare peptides labeled with metal chelates, protected derivatives of EDTA analogs compatible with Merrifield solid phase protein synthesis using *N*-*tert*-butyloxycarbonyl (Boc)-protected amino acids were developed (13, 33–35). There are two major concerns about this synthetic strategy: (a) repetitive TFA acidolysis in Boc-group deprotection could lead to acid-catalyzed side reactions and (b) cleavage and deprotection of peptides requires HF and specific laboratory setup which is not available to many researchers. Due to these concerns 9-fluorenylmethyl carbamate (Fmoc) solid phase peptide synthesis was developed which employs *N*- α -Fmoc amino acids (36). In this strategy, the Fmoc group is deprotected with piperidine and TFA is required only for the final cleavage and deprotection step. In this paper, we have synthesized an amino acid analog, [*p*-(*N*- α -Fmoc-L-aspartic acid- β -amido)benzyl]-EDTA tetra-*tert*-butyl ester (**9**). We report here a new selective protection scheme for the preparation of amino acid analog **9** which is designed to be compatible with the Fmoc solid phase peptide synthesis strategy. The synthetic route for this synthesis is outlined in Scheme 1. EDTA analog **3** was synthesized with modifications of the method published by Studer and Meares (37).

To test the use of reagent **9** to incorporate *p*-aminobenzyl-EDTA in internal sequence of a peptide, we synthesized a fragment of HIV-1 Tat protein (amino acids 56–72) on an automated peptide synthesizer. We used standard HOBt/DCC peptide synthesis protocols to incorporate reagent **9** in the peptide sequence. The amino acid sequence of the Tat peptide contained Arg-X-Pro-Pro-Gln-Gly-Ser-Gln-Thr-His-Gln-Val-Ser-Leu-Ser-Lys-Gln, where X was the modified amino acid **9**. After standard TFA deprotection, the peptide was purified and characterized by mass spectrometry, which confirmed the incorporation of EDTA in the peptide sequence. Tat protein is a potent transactivator of transcription from the viral long terminal repeat and acts by binding to a stem-loop RNA

structure called TAR RNA (38). Tat peptides modified with metal chelates at various sequence positions would provide a class of affinity cleaving reagents that can be directed against TAR RNA, and these studies are in progress.

EXPERIMENTAL SECTION

Anhydrous DMF, *N,N*-diisopropylethylamine, fluorene-methanol, TFA, piperidine, DMAP, and 10% Pd on charcoal were purchased from Aldrich. DCC and HOBT were obtained from Sigma. *N*- α -Fmoc- β -*tert*-butyl ester L-aspartic acid was purchased from Bachem. All chemicals were of reagent grade unless otherwise specified. NMR spectra were recorded at 200 MHz on a Gemini 200 spectrometer (Varian). The FAB MS spectrum was recorded using *m*-nitrobenzoic acid/NaI as matrix. IR spectra were obtained on a Perkin-Elmer FT 1600 as thin film. TLC was performed with precoated 0.2 mm silica gel 60 F-254 TLC plates (EM Reagents, Darmstadt, Germany).

(*p*-Nitrobenzyl)-EDTA Tetra-*tert*-butyl Ester (2). To a 100 mL round-bottom flask were added 0.92 g (3.4 mmol) of (*p*-nitrobenzyl)ethylenediamine dihydrochloride and 50 mL of dry acetonitrile. The flask was flushed with nitrogen for 10 min, and to the stirring mixture were added 2.46 g (17.7 mmol) of K_2CO_3 and 0.64 g (3.8 mmol) of KI. Finally, *tert*-butyl bromoacetate (2.9 mL, 17.9 mmol) was added to the mixture slowly. The mixture was refluxed at 105 °C for 120 h in the dark and then cooled to room temperature. Evaporation of solvent gave brown oil containing powdery deposit. The crude mixture was dissolved in methylene chloride and filtered through a glass frit, and the solid was washed with more methylene chloride until the powder on top of the frit turned white. The filtrate was collected and evaporated to give a yellow oil, which was silica gel column purified with 10% ethyl acetate in methylene chloride. The ^1H NMR showed several kinds of para-disubstituted phenyl groups, seemingly a mixture of mono-, di-, tri-, and tetraprotected EDTA moieties. Another silica gel column with 5% ethyl acetate in CH_2Cl_2 gave the final product (1.53 g, 2.4 mmol, 70.6% yield): IR 1731 cm^{-1} ($\text{C}=\text{O}$, br s); ^1H NMR (CDCl_3) δ 8.03 (2H, d, 8.76 Hz), 7.42 (2H, d, 8.42 Hz),

3.37 (4H, s), 3.34 (4H, s), 3.30 (2H, m), 2.95 (2H, m), 2.34 (1H, m), 1.36 (36H, s); ^{13}C NMR δ 171.42, 171.09, 149.41, 146.66, 130.69, 123.64, 63.52, 56.89, 56.08, 53.81, 37.54, 28.54, 28.49.

(*p*-Aminobenzyl)-EDTA Tetra-*tert*-butyl Ester (3). To dried compound 2 (1.5 g, 2.3 mmol) in 100 mL of THF were added 415 mg (3.0 mmol) of K_2CO_3 and 400 mg of 10% Pd/C under nitrogen flow at room temperature. After addition, hydrogen inlet was used instead of nitrogen, and with vigorous stirring and strong hydrogen flow, the mixture was allowed to react overnight at room temperature under H_2 atmosphere. The reaction mixture was filtered through a glass frit, and the solid was washed with more THF. The collected solution was evaporated to give a yellow oil. Silica gel column separation with ethyl acetate and another column with methylene chloride gave yellow oil, which was identified as pure product by ^1H and ^{13}C NMR spectra (0.78 mg, 1.3 mmol, 56.5% yield): IR 1731 cm^{-1} ($\text{C}=\text{O}$, br s); ^1H NMR in CDCl_3 δ 6.98 (2H, d, 8.18 Hz), 6.57 (2H, d, 8.22 Hz), 5.29 (2H, s), 3.48 (4H, s), 3.43 (4H, s), 3.03 (1H, m), 2.81 (2H, m), 2.55 (2H, m), 1.43 (18H, s), 1.40 (18H, s); ^{13}C NMR δ 172.05, 171.58, 145.11, 130.23, 115.62, 63.54, 56.69, 55.35, 53.92, 35.69, 20.50.

***N*- α -Fmoc- β -*tert*-butyl Ester L-Aspartic Acid 9-Fluorenylmethyl Ester (5).** To a 25 mL round-bottom flask was added compound 4 (0.411 g, 1 mmol) dissolved in 5 mL of methylene chloride. At 0 °C, 206 mg (1 mmol) of DCC and 2 mg of DMAP were added to the mixture and stirred for 1 h at the same temperature. Prepared solution of 9-fluorenylmethanol (216 mg, 1.1 mmol) in 2 mL of CH_2Cl_2 was added, and the mixture was stirred overnight at room temperature. Filtration to remove white salt (DCU) and evaporation of the filtrate gave a light yellowish oil. Silica gel column with 30% ethyl acetate in petroleum ether gave 0.5 g of colorless oil and 0.1 g of white solid. NMR confirmed the oily compound as the product (0.5 g, 0.85 mmol, 85% yield): ^1H NMR (CDCl_3) δ 7.50 (16H, m), 6.00 (1H, d, 8.5 Hz, NH), 4.76 (1H, dt), 4.48 (4H, 2d), 4.29 (2H, 2t), 2.94 (2H, dd, 4.48 Hz, 15.10 Hz), 1.48 (9H, s); ^{13}C NMR δ 171.49, 170.54, 156.55, 144.41, 144.27, 144.03, 141.81, 128.42, 128.27, 127.74, 127.62, 125.59, 125.56, 120.60, 120.54, 68.33, 67.84, 51.24, 47.66, 47.23, 38.27, 28.57.

***N*- α -Fmoc- α -9-fluorenylmethyl Ester L-Aspartic Acid (6).** At 0 °C, 1.5 mL of trifluoroacetic acid was added to 0.309 g (0.52 mmol) of 5 in 4 mL of methylene chloride. The mixture was stirred for 2 h at 0 °C, and the solvent was evaporated under vacuum. Complete dryness gave 0.25 g (0.47 mmol, 90.4% yield) of white powder, which was confirmed to be 6 by mass spectrum: ^1H NMR (CD_3OD) δ 7.80–7.27 (16H, m), 4.70–4.20 (7H, m), 2.80 (2H, m).

[*p*-(*N*- α -Fmoc L-aspartic acid 9-fluorenylmethyl ester β -amido)benzyl]-EDTA Tetra-*tert*-butyl Ester (7). To a 25 mL round-bottom flask containing 126 mg of 6 (0.24 mmol) was added 50 mg (0.37 mmol) of HOBT in 5 mL of 1:1 mixture of THF and DMF. DCC (100 mg, 0.48 mmol) in 3 mL of methylene chloride and 0.5 mL of IPEA were added to keep the pH about 8. The reaction mixture was stirred for 30 min at 0 °C and for 2 h at room temperature. Without filtration, compound 3 (0.14 g, 0.225 mmol) in 3 mL of THF was added to the mixture and left for stirring overnight. TLC in 15% petroleum ether/ethyl acetate showed two spots, one corresponding to the mixture of Fmoc derivatives and another to the coupled product. Spin chromatotron separation with 80% petroleum ether in ethyl acetate gave 150 mg of pure product (0.13 mmol) as yellow oil, which was identified by NMR and high-resolution mass spectra to be com-

pound **7** (MS = 1137.581, theor = 1137.580; 58% yield): IR 1731 cm^{-1} (C=O, br s); ^1H NMR (CDCl_3) δ 7.50 (20H, m), 6.25 (1H, d), 4.50 (7H, m), 3.49 (4H, s), 3.44 (4H, s), 2.85 (8H, m), 1.44 (18H, s), 1.41 (18H, s); ^{13}C NMR δ 171.83, 171.41, 168.40, 156.80, 144.30, 144.16, 144.09, 144.00, 141.74, 137.31, 135.78, 130.29, 128.28, 128.20, 127.69, 127.60, 125.65, 125.51, 120.47, 120.28, 68.18, 67.88, 63.81, 60.92, 56.81, 55.94, 54.06, 51.31, 47.55, 47.15, 39.03, 36.83, 28.63, 21.58, 14.70.

[p-(L-Aspartic acid β -amido)benzyl]-EDTA Tetra-*tert*-butyl Ester (8**).** To 150 mg of **7** (0.13 mmol) was added 5 mL of 20% piperidine in methylene chloride, and the mixture was stirred for 2.5 h. The solvent was evaporated completely. The obtained yellow solid was washed with a minimal amount of ether and filtered through a micropipet with cotton. White solid, which was not ether soluble, was washed again with 2 mL of ether. The filtrate, which contains the product and Fmoc derivatives, was concentrated. The resulting yellow oil was fractionally crystallized in petroleum ether (72.4% yield; M + Na = 759.3065, theor = 759.3061): IR 1731 cm^{-1} (C=O, br s); ^1H NMR (CDCl_3) δ 7.55 (2H, d), 7.10 (2H, d), 3.42 (8H, 2br s), 3.20–2.50 (8H, m), 1.42 (18H, s), 1.40 (18H, s).

[p-(N- α -Fmoc-L-aspartic acid β -amido)benzyl]-EDTA Tetra-*tert*-butyl Ester (9**).** To a round-bottom flask was transferred compound **8** (405 mg, 0.55 mmol), and 10 mL of 10% Na_2CO_3 was added. A solution of 270 mg of Fmoc-OSu (0.8 mmol) in 20 mL of DME was also added to the mixture. The reaction mixture was stirred for 5 h at room temperature. After the solvent was evaporated, 10 mL of H_2O was added to the crude mixture and the pH was adjusted to 7 with 1 N HCl. The mixture was extracted with ethyl acetate and washed with H_2O and brine. Spin chromatotron purification with 50% ethyl acetate in methanol gave 200 mg (0.21 mmol) of yellow oil as the product (38% yield; M + Na = 959.503, theor = 959.502): IR 1731 cm^{-1} (C=O, br s); ^1H NMR (CDCl_3) δ 7.7–7.0 (12H, m), 3.32 (8H, m), 3.20–2.20 (14H, m), 1.53 (18H, s), 1.47 (18H, s).

PEPTIDE SYNTHESIS

All Fmoc-amino acids, piperidine, 4-(dimethylamino)-pyridine, dichloromethane, *N,N*-dimethylformamide, 1-hydroxybenzotriazole (HOBt), 2-(1*H*-benzotriazo-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), diisopropylethylamine, and HMP-linked polystyrene resin were obtained from Applied Biosystems Division, Perkin-Elmer. Trifluoroacetic acid, 1,2-ethanedithiol, phenol, and thioanisole were from Sigma. Tat-derived peptide (from amino acids 56–72) was synthesized on an Applied Biosystems 431A peptide synthesizer using standard FastMoc protocols. Reagent **9** was incorporated in the peptide sequence by HOBt/DCC peptide coupling procedures. Cleavage and deprotection of the peptide was carried out in 2 mL of reagent K for 6 h at room temperature. Reagent K contained 1.75 mL of TFA, 100 μL of thioanisole, 100 μL of water, and 50 μL of ethanedithiol (**39**). After cleavage from the resin, peptide was purified by HPLC on a Zorbax 300 SB-C₈ column. The mass of fully deprotected and purified peptides was confirmed by FAB mass spectrometry: calculated mass for Tat (56–72 containing Asp-aminobenzyl-EDTA at position 57) = 2494.6, found 2495.6 (M + H).

ACKNOWLEDGMENT

We thank Xilu Wang for critical reading of the manuscript. This research was supported by Research Grant AI 34785-01 from the National Institutes of Health.

Preparation of Succinimidyl and Pentafluorophenyl Active Esters of 5- and 6- Carboxyfluorescein

Maciej Adamczyk,* Jeffrey R. Fishpauqh, and Kevin J. Heuser

Diagnostic Division, Division Organic Chemistry (D-9NM), Building AP-20, Abbott Laboratories, 100 Abbott Park Road, Abbott Park, IL 60064-3500. Received November 8, 1996[®]

A mixture of 5- and 6-carboxyfluorescein was activated with 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride in the presence of either *N*-hydroxysuccinimide or pentafluorophenol to give the corresponding succinimidyl and pentafluorophenyl esters. The regioisomeric mixtures were separated to give the 5- and 6- succinimidyl and pentafluorophenyl active esters in >98% purity.

INTRODUCTION

Fluorescein derivatives have been widely used as fluorescent markers in bioanalytical chemistry (1–5) and have found exceptional utility as the fluorophores of choice in fluorescent polarization immunoassays (FPIA) used for monitoring the level of drugs and hormones in human fluids (6, 7). Active esters of 5- and 6-carboxyfluorescein¹ are used for production of labels and conjugates (1, 4, 8–10). The 5- and 6-carboxyfluorescein mixture (61:39 isomer ratio) is commercially available (11). The pure isomers are also available, but at a high cost, while the pure succinimidyl active esters can be purchased at a cost of \$7600/g (12). From the literature (13, 14) only limited information is available for the preparation, purification, and analysis of the fluorescein succinimidyl active esters, while the corresponding pentafluorophenyl active esters, which usually possess higher hydrolytic stability (15), have not been previously reported. Thus, there is a need for an efficient and cost effective method for the preparation of these active esters. We now report a method for the preparation of 5- and 6-carboxyfluorescein succinimidyl (**2a** and **2b**, respectively) and new pentafluorophenyl (**2c** and **2d**) active esters from the inexpensive, commercially available mixture of 5(6)-carboxyfluorescein (**1**) as shown in Scheme 1.

MATERIALS AND METHODS

All reagents were purchased from Aldrich Chemical Co. (Milwaukee, WI) except for 5(6)-carboxyfluorescein (**1**), which was purchased from Kodak (Rochester, NY), and these chemicals were used without further purification. Solvents were of HPLC grade and used without further purification. Silica gel 60 (230–400 mesh) was purchased from EM Science (Gibbstown, NJ). Biotage FLASH 75 purification system and KP-SIL silica cartridges (32–63 μ m, 60A, 7.5 \times 30 cm) were purchased from Biotage, Inc. (Charlottesville, VA). ¹H NMR spectra were recorded at 300 MHz, on a Varian Gemini 300 spectrometer. Electrospray ionization mass spectra were recorded on a Perkin-Elmer Sciex API 100 instrument. Elemental analyses were performed by Robertson-Microlit Laboratories, Inc. (Madison, NJ). Analytical HPLC

was performed using a Waters (Milford, MA) 8 \times 100 mm μ Bondapak radial compression C₁₈ column with a flow rate of 2 mL/min and UV detection at 225 nm. Preparative HPLC was performed using a Waters 40 \times 100 mm μ Bondapak radial compression C₁₈ column with a flow rate of 45 mL/min and UV detection at 225 nm.

5- and 6- Carboxyfluorescein Succinimidyl Active Esters (2a, 2b). To a solution of 5(6)-carboxyfluorescein (5.0 g, 13.3 mmol) in anhydrous *N,N*-dimethylformamide (DMF; 50 mL) was added 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDAC; 3.1 g, 16.0 mmol) followed by *N*-hydroxysuccinimide (HOSu; 1.9 g, 16.0 mmol). The reaction was covered with foil, stirred under nitrogen, and monitored by analytical HPLC (22% CH₃CN/22% MeOH/56% aqueous 0.1% formic acid). After 4.5 h, additional EDAC (510 mg, 0.2 equiv) was added, and the reaction was stirred for an additional 18.5 h. The reaction mixture was rinsed into a separatory funnel with DMF (10 mL) and diluted with acetone (200 mL). Buffer (0.05 M, pH 6 phosphate buffer, 250 mL) was added, and the mixture was extracted with diethyl ether (Et₂O)/ethyl acetate (EtOAc) (2:1, 300 mL). The organic layer was separated, and the aqueous layer was extracted two times with Et₂O/EtOAc (2:1, 250 mL). The combined organic extracts were washed with water (3 \times 200 mL) and brine (1 \times 250 mL), dried over Na₂SO₄, and filtered, and the solvents were removed *in vacuo* to afford 4.7 g of crude 5(6)-carboxyfluorescein succinimidyl active esters. Separation of the isomers on the Biotage system was performed as follows: (a) the Biotage column was equilibrated with 2 L of eluent (15% acetone/85% toluene containing 0.05% acetic acid); (b) crude active ester mixture, adsorbed onto silica gel (50 g), was loaded into the SIM (16); and (c) the isomers were eluted at a main system pressure of 100 psi and solvent pressure of 55–60 psi, to afford 1.7 g of **2a** (<2% of **2b** present) and 1.2 g of **2b** (<3% of **2a** present). For further purification, each lot was adsorbed onto silica gel (10–15 g), loaded into the SIM, and purified using the previous conditions to afford 795 mg of **2a** (21% yield, >99% pure with <0.1% of **2b** present) and 780 mg of **2b** (32% yield, >99% pure with <0.1% of **2a** present). Complete spectral and analytical data are shown in Tables 1 and 2.

Flash Chromatography. The crude reaction mixture (4.7 g) adsorbed onto silica (50 g) was loaded onto an equilibrated flash column (14 \times 30 cm bed of silica) and separated (17) to afford 1.2 g of **2a** (<0.1% of **2b** present) and 1.5 g of **2b** (24% of **2a** present).

Preparative HPLC. A crude mixture (50 mg) was separated by reversed phase preparative HPLC (25% CH₃CN/75% aqueous 0.1% formic acid) to afford **2a** (27

mg, 5% hydrolysis observed) and **2b** (18 mg, 12% hydrolysis observed).

5- and 6-Carboxyfluorescein Pentafluorophenyl Active Esters (2c, 2d). To a solution of 5(6)-carboxyfluorescein (5.0 g, 13.3 mmol) in anhydrous DMF (40 mL) was added EDAC (3.1 g, 16.0 mmol) followed by a solution of pentafluorophenol (3.0 g, 16.0 mmol) in DMF (10 mL). The reaction flask was covered with foil, and the reaction was monitored by analytical HPLC (35% CH₃CN/35% MeOH/30% aqueous 0.1% formic acid). After stirring under nitrogen for 22 h, the reaction was worked up as described above to afford 6.3 g of crude 5(6)-carboxyfluorescein pentafluorophenyl active esters. Partial separation on the Biotage system using the method and eluents described above for **2a** and **2b** gave 3.2 g of the active ester mixture **2c** and **2d** with no observed separation between the 5 and 6 regioisomers. Separation by flash chromatography was achieved by adsorbing the mixture onto silica (25 g), loading it onto an equilibrated flash column (70% ethyl acetate/30% toluene, 7.5 × 23 cm bed of silica), and eluting (18) to afford 1.1 g of **2c** (25% yield, >99% with <0.5% of **2d** present), 814 mg of a mixture, and 555 mg of **2d** (>91% with 6% of **2c** present). Partially separated **2d** was adsorbed onto silica (5 g), loaded onto an equilibrated flash column (20% acetone/80% toluene containing 0.1% acetic acid, 3 × 20 cm bed of silica), and further purified using the above solvent system to afford 350 mg of **2d** (13% yield, >98% with <1.8% of **2c** present). Complete spectral and analytical data are shown in Tables 1 and 2.

Preparative HPLC. A crude mixture (65 mg) was separated by reversed phase preparative HPLC (55% CH₃CN/45% aqueous 0.1% formic acid) to afford **2c** (21

mg) and **2d** (17 mg); however, only small amounts of material could be loaded onto the 40 × 100 column per run (30 min, ~95 runs needed to separate the total 6.3 g of mixture).

RESULTS AND DISCUSSION

The mixture of **1** was reacted with EDAC and HOSu in anhydrous DMF to convert each acid to its respective succinimidyl active ester (**2a** and **2b**). Workup conditions consisted of pouring the crude reaction mixture into a separatory funnel, adding pH 6 buffer solution, and extracting with a mixture of ether/ethyl acetate (2:1). The selection of solvent combination was necessary to fully maximize extraction of the desired active esters and minimize the presence of HOSu, while the choice of pH 6 phosphate buffer prevented undesired hydrolysis. This workup gave active esters **2a** and **2b** with <0.5% of the starting acids. Separation of the active esters was attempted according to three different methods: flash chromatography, preparative reversed phase HPLC with a 40 × 100 mm radial compression column, and the Biotage FLASH 75 system.

Separation by flash chromatography was inefficient since it did not afford good resolution between the two fluorescein succinimidyl ester regioisomers. Preparative reversed phase HPLC separation was attempted using a 50 mg mixture of **2a** and **2b** and resulted in complete separation of the two isomers, but with partial hydrolysis (5–12%) of the active esters. A third method was sought that would combine the ease of use of flash chromatography with the separation capabilities of HPLC. The Biotage FLASH 75 system, introduced in 1994, was attractive because it is designed for milligram to kilogram

scale separations and provides solutions to critical operational problems typically found with glass columns: speed, safety, and performance (19). For gram scale separations, Biotage cartridges operate at higher pressures (85–120 psi) with higher flow rates (100–300 mL/min) than flash chromatography, which results in shorter run times (19). This self-contained system reduces the concern of using glass columns under pressure, while its radial compression technology eliminates voids and channels that often occur in conventional flash chromatography (19).

Separation of the crude mixture of fluorescein succinimidyl esters using the Biotage FLASH 75 system afforded good separation of **2a** from **2b** (both >97% by analytical HPLC). Further purification afforded **2a** and **2b** with purity >99%, see Table 1. A disadvantage for any silica gel based chromatographic separation of active esters is hydrolysis of the active ester while on the column, which frequently leads to diminished product yields. Mass recoveries using the Biotage system were in general <80%. This method of separation was found to be the most effective for the production of fluorescein succinimidyl active esters **2a** and **2b**.

Pentafluorophenyl active esters were prepared in a similar manner as the succinimidyl esters using EDAC/pentafluorophenol (C₆F₅OH), and separation was also attempted according to the three methods described for **2a** and **2b**. Preparative reversed phase HPLC separated **2c** and **2d** (<0.5% hydrolysis); however, this is a time-consuming process by which only a relatively small amount of material (65 mg) could be separated in a 30 min run using a 40 × 100 mm radial compression cartridge. The Biotage system was ineffective in separating **2c** and **2d**; however, rapid separation of the active esters from other components present after aqueous workup was achieved. Further purification of the active ester mixture by flash chromatography afforded **2c** and **2d** in low to moderate yields and high purity (>98%, see Table 1). In this case, the combination of Biotage and flash chromatography was found to be the most effective for obtaining the desired pentafluorophenyl active esters **2c** and **2d**.

In summary, our method transforms the inexpensive, commercially available 5(6)-carboxyfluorescein (**1**) to the highly useful 5- and 6-carboxyfluorescein succinimidyl active esters (**2a** and **2b**) and pentafluorophenyl active esters (**2c** and **2d**). Separation on the Biotage system gave very pure (>99%) succinimidyl active esters, and the combination of Biotage and flash chromatography afforded very pure (>98%) pentafluorophenyl active esters. These procedures allow for the rapid and cost effective production of these carboxyfluorescein active

esters, and the Biotage FLASH 75 system offers the advantages of safety, reproducibility, and speed over other techniques for the separation of larger amounts of material.

Syntheses of Haptens Containing Dioxaphosphorinan Methoxyacetic Acid Linker Arms for the Production of Antibodies to Organophosphate Pesticides

Wolter ten Hoeve,[†] Hans Wynberg,[†] William T. Jones,^{*,‡} Dawn Harvey,[‡] Gordon B. Ryan,[‡] and Paul H. S. Reynolds[‡]

Syncom, University of Groningen, Groningen, The Netherlands, and Plant Improvement Division, The Horticulture and Food Research Institute of New Zealand, Private Bag 11 030, Palmerston North, New Zealand. Received October 16, 1996[®]

Four generic heterobifunctional reagents, namely 2-(2-chloro-5-methyl-1,3,2-dioxaphosphorinan-5-yl)methoxyacetic acid methyl ester, *p*-sulfide, 2-(2-chloro-5-methyl-1,3,2-dioxaphosphorinan-5-yl)-methoxyacetic acid methyl ester, *p*-oxide, 2-(2-mercapto-5-methyl-1,3,2-dioxaphosphorinan-5-yl)-methoxyacetic acid bispotassium salt, *p*-sulfide-, and (2-methoxy-5-methyl-1,3,2-dioxaphosphorinan-5-yl)methoxyacetic acid, methyl ester, have been synthesized and used to prepare organophosphate, thiophosphate, and dithiophosphate haptens containing a functional carboxyl group which can be used to conjugate the haptens to proteins. These hapten-protein conjugates have been used as antigens for preparing polyclonal sera against all classes of organophosphate pesticides. The eight examples used protein-hapten conjugates of chlorpyrifos, parathion, diazinon, paraoxon, azinphos, dimethoate, demeton, and dichlorvos. These were all immunogenic and resulted in sera containing antibodies that recognized the corresponding parent pesticide with high specificity.

INTRODUCTION

Residues of pesticides used for protection of horticultural crops against insect infestations need to be monitored from a human health as well as an economic perspective. Legal maximum residue limits are stipulated by both national and international regulatory agencies for many of these compounds in most food crops

and products. Increasingly, levels of such residues are being monitored by the international and domestic agencies.

Accordingly, there is a need for internationally acceptable, rapid, reliable, sensitive, and cost-effective assay systems for determining the presence of these compounds. Suitably designed immunoassay-based tests can fulfill all these requirements. Modern immunoassays are based on two important phenomena: (i) the extraordinary discriminatory power of antibodies and (ii) detection systems that allow the reaction of the antibody with its hapten to be quantified at low concentrations of the reactants (antibody and hapten).

The use of enzyme immunoassays (EIAs) and solid phase technology has brought about widespread use of these techniques. An excellent review of enzyme immu-

Figure 1. Synthetic scheme for the production of generic intermediates for synthesis of organophosphate, organothiophosphates, and organodithiophosphate haptens.

noassay is provided by Tijssen (1990). A large number of assays have been developed for aflatoxins (Chu *et al.*, 1991) and herbicides and insecticides (Aston *et al.*, 1992).

Residues are small molecules ($M_r < 1000$) and are usually unable to invoke an immune response when injected into animals. These molecules therefore have to be conjugated to larger immunogenic carrier molecules to produce the desired response. The organophosphate group of pesticides, being small molecules, are not immunogenic, nor can the majority of them be readily conjugated to a suitable carrier protein to render them antigenic. Until recently, antibodies have been raised only to those organophosphates that could easily be modified to allow coupling of the modified pesticide to the carrier protein (parathion, Ercegovich *et al.*, 1981; paraoxon, Brimfield *et al.*, 1985; Heldman *et al.*, 1985).

Heldman *et al.* (1985) produced antibodies to paraoxon by conjugation via a β -alanine linker attached through the phosphate atom. McAdam *et al.* (1992) described the production of haptens for preparing antibodies to fenitrothion. This entailed coupling the hapten through the phosphate group to the carrier protein and produced haptens resembling those of Heldman *et al.* (1985). This method of coupling through the phosphate group produced the best antibodies (Hill *et al.*, 1992). McAdam and Skerritt (1993) described the use of *tert*-butyl-3-[[chloro(methoxy)phosphorothioyl]amino]propanoate as a generic intermediate in preparing haptens of the organothiophosphate pesticides and successfully raised antibodies to fenitrothion, chlorpyrifos-methyl, and pyrimphos-methyl.

This work describes the synthesis of new generic heterobifunctional intermediates containing a dioxaphosphorinane ring which can be used to synthesize organophosphate, thiophosphate, and dithiophosphate haptens containing a functional carboxyl group to conjugate to proteins. These hapten-protein conjugates can be used as antigens for preparing antibodies for use in the development of specific immunoassays for the detection of specific pesticides.

RESULTS

Synthesis of Haptens and Conjugates. Access to haptens of some common organophosphate pesticides was investigated in the first instance through replacement of the methoxy or ethoxy group in these pesticides by another alkoxy group which would contain an amino or carboxylic acid function. The difficulties encountered in attaining such unsymmetrical compounds in a pure state

led to the investigation of an approach in which both methoxy and ethoxy groups were replaced by a group that would lead to a more symmetrical compound. Such a compound would presumably be easier to purify. On this basis, a 1,3-propanediol was chosen which contained a group at position 2 with a protected carboxylic acid function. 2-(Hydroxymethyl)-1,3-propanediol is commercially available and can be converted easily to 5-(hydroxymethyl)-2-methyl-1,3-dioxane (Gash, 1972). We reasoned that functionalization of the free hydroxy group leading to a group containing a carboxylic ester function, followed by coupling of the deprotected diol part to the phosphorus atom of pesticides, and finally selective hydrolysis of the carboxylic ester should lead to the desired haptens.

In practice, this approach (shown in Figure 1) appeared to be useful for the preparation of a series of haptens. Treatment of 5-(hydroxymethyl)-2-methyl-1,3-dioxane **1** with 2 equiv of sodium hydride in DMF followed by the addition of bromoacetic acid gave the sodium salt of the coupled product. This was directly reacted with dimethyl sulfate to furnish the methyl ester **2**. In order to gain access to the desired haptens, it was necessary to transform the acetal moiety into a diol, while maintaining the ester moiety intact. Common acidic cleavage methods led to the loss of the ester group, but under mild conditions, using pyridinium *p*-toluenesulfonate, the acetal was preferentially cleaved. The resulting crude diol **3** was used in the following transformations to prepare a set of generic intermediates useful for syntheses of organophosphate, organothiophosphate, and organodithiophosphate haptens.

(1) Treatment with thiophosphoryl dichloride and triethylamine in toluene gave a mixture of two isomeric (chlorine atom *cis* or *trans*, respectively) thionodioxaphosphorinanes **4**, the major isomer of which could be isolated as a crystalline compound. (2) Treatment with phosphoryl chloride and triethylamine in toluene gave a mixture of two isomeric dioxaphosphorinanes **5** which, in our hands, were inseparable. (3) Heating with phosphorus pentasulfide in toluene followed by treatment with potassium hydroxide resulted in the precipitation of the bispotassium salt **6**. (4) Stirring with trimethylphosphite and trimethylamine (Edmundson *et al.*, 1985) gave the distillable cyclic phosphite **7**.

The precursors **4–7** were then used for the preparation of the following haptens (Figure 2).

(a) *Chlorpyrifos*. The sodium salt of trichloropyridinol (obtained from the pyridinol with sodium hydride in DMF) was reacted with the crystalline isomer of chloride **4** in DMF at room temperature (RT). The resulting crystalline ester **8** could be hydrolyzed, under very mild basic conditions, viz., potassium carbonate in water, methanol, and THF, to the hapten, crystalline acid **9**.

(b) *Parathion*. 4-Nitrophenol was coupled to chloride **4** as described for chlorpyrifos to yield crystalline ester **10**. The ester was hydrolyzed with lithium hydroxide, resulting in crystalline acid **11**.

(c) *Diazinon*. The sodium salt of isopropylmethylpyrimidinol was reacted with chloride **4** to furnish crystalline ester **12**. Hydrolysis with potassium carbonate gave crystalline acid **13**.

(d) *Paraoxon*. 4-Nitrophenol was reacted with the mixture of isomeric chlorides **5**, resulting in two isomeric esters **14**, which could be separated by recrystallization. The paraoxon hapten **15** was prepared by potassium carbonate hydrolysis of the methyl ester. The use of lithium hydroxide, as for parathion, led to hydrolysis of the phosphate ester.

(e) *Azinphos*. The bispotassium salt **6** was treated with 1 equiv of hydrochloric acid to protonate the weaker carboxylic acid function and reacted with 3-(chloromethyl)-1,2,3-benzotriazin-4(3*H*)-one in acetone to give hapten **16** which was purified through acid-base separation and by crystallization.

(f) *Dimethoate*. This was prepared as for azinphos. *N*-Methylchloroacetamide was reacted with bispotassium salt **6** to give crystalline acid **17**.

(g) *Demeton*. Access to hapten **19** was possible by making use of the known O-S rearrangement (Sasse, 1964). Ethylthioethanol was reacted with butyllithium followed by addition of chloride **4**. The resulting ester **18** slowly underwent O-S rearrangement. However, the product could not be hydrolyzed to acid **19** without completely destroying the molecule. Therefore, ester **18** was hydrolyzed before rearrangement took place. The resulting crude acid slowly underwent O-S rearrangement, and hapten **19** was obtained in low yield as a crystalline solid.

(h) *Dichlorvos*. Phosphite **7** was reacted with anhydrous chloral by the Perkow reaction (Gallenkamp, 1982) to yield crude ester **20** which was hydrolyzed with potassium carbonate to the crystalline acid **21** together with an unknown acid. The desired hapten **21** was purified from the unknown acid by washing with ether and recrystallization from water/methanol.

None of the haptens inhibited cholinesterase activity at 200 ppm when tested with a commercial kit (Enzytec Inc.). This contrasts with the parent pesticides which gave 100% cholinesterase inhibition at concentrations ranging from 0.3 to 2.0 ppm. No deterioration has been observed when haptens were stored dry at 4 °C for 2 years.

Production of Antibodies to Haptens. The carboxyl function on haptens **9**, **11**, **13**, **15–17**, **19**, and **21** was activated to a succinimidyl ester (Langone and Vanakis, 1975) and coupled to free amines on ovalbumin (OVA) or mouse serum albumin (MSA) to produce antigens with which to immunize mice or to use as plating antigens for enzyme-linked immunoassays (ELISAs), respectively.

Using this procedure, conjugates were prepared with the degree of coupling between being 8 and 20 mol of hapten per mole of OVA and 12–30 mol of hapten per mole of MSA. OVA immunoconjugates of haptens were injected into mice, and the resulting antisera were assessed in an ELISA format as described in Materials

and Methods. In all cases, immunization resulted in the production of antisera recognizing haptens conjugated to MSA. No reaction was observed when preimmune sera were reacted with MSA-haptens or when sera from immunized mice were tested against MSA. Thus, a specific reaction to the hapten was apparent.

Optimal plating concentrations of MSA-hapten and sera dilution of individual mice to give an absorbance at 492 nm of 0.8–1.2 were established for each antigen by checkerboard titration. Competition, defined as the inhibition of binding of antibody to microwell plates as a result of incubation with organophosphate pesticide or hapten, was observed in all experiments for the pesticide resembling the hapten (i.e., chlorpyrifos for the chlorpyrifos hapten) used to immunize mice. Within a particular assay, variation was observed between mice in the I_{50} and in the useful range (I_{20} – I_{80}) for measuring of organophosphate, with specific results as follows.

(a) *Chlorpyrifos Immunoconjugate*. The optimal dilutions of MSA-hapten were 25, 90, 50, and 25 ng/mL and of sera 1/32000, 1/64000, 1/32000, and 1/32000 for mouse **1–4**, respectively. I_{50} , I_{20} , and I_{80} for chlorpyrifos using mouse **1** and **2** sera were 300 ng/mL, 60 ng/mL, and 1.5 μ g/mL and mouse **3** and **4** sera 150, 25, and 860 ng/mL, respectively. Competition was not measurable at concentrations of paraoxon, parathion, and azinphos-methyl up to 200 μ g/mL. The chlorpyrifos hapten had an I_{50} of 20 ng/mL; I_{20} = 1 ng/mL and I_{80} = 100 ng/mL for all mice.

(b) *Parathion Immunoconjugate*. The optimal dilutions of MSA-hapten were 25, 25, 50, and 50 ng/mL and of sera 1/32000, 1/64000, 1/32000, and 1/64000 for mouse **1–4**, respectively. I_{50} , I_{20} , and I_{80} for parathion using mouse **1** serum were 1.2 μ g/mL, 80 ng/mL, and 16 μ g/mL, using mouse **2** serum were 800 ng/mL, 60 ng/mL, and 11 μ g/mL, using mouse **3** serum were 4 μ g/mL, 300 ng/mL, and 31 μ g/mL, and using mouse **4** serum were 2.1 μ g/mL, 350 ng/mL, and 33 μ g/mL, respectively. For all mouse sera, no competition was observed with chlorpyrifos and azinphos. Paraoxon showed cross reactivities of 0.6 and 0.4% for mouse **1** and **2**, respectively, and no cross reaction for mouse **3** and **4** sera. Competition with parathion hapten gave an I_{50} of 20–25 ng/mL, an I_{20} of 1–2 ng/mL, and an I_{80} of 80–100 ng/mL.

(c) *Paraoxon Immunoconjugate*. The optimal dilutions of MSA-hapten were 200, 150, 25, and 25 ng/mL and of sera 1/16000, 1/32000, 1/8000, and 1/16000 for mouse **1–4**, respectively. I_{50} , I_{20} , and I_{80} for paraoxon using mouse **1** serum were 8.1, 1.2, and 46 μ g/mL, using mouse **2** serum were 2.2 μ g/mL, 710 ng/mL, and 105 μ g/mL, using mouse **3** serum were 8, 1.2, and 43 μ g/mL, and using mouse **4** serum were 2 μ g/mL, 200 ng/mL, and 23 μ g/mL, respectively. No cross reaction was observed for any sera from mice injected with paraoxon-hapten immunoconjugates, with parathion, chlorpyrifos, or azinphos-methyl or -ethyl. The paraoxon hapten gave an I_{50} of 20 ng/mL, an I_{20} of 2 ng/mL and an I_{80} of 100 ng/mL.

(d) *Azinphos Immunoconjugate*. The optimal dilutions of MSA-hapten were 25, 12.5, 25, and 25 ng/mL and of sera 1/64000 for mouse **1–4**, respectively. I_{50} , I_{20} , and I_{80} for azinphos-methyl using mouse **1** and **3** sera were 4 μ g/mL, 400 ng/mL, and 30 μ g/mL, using mouse **2** serum were 20 μ g/mL, 800 ng/mL, and 120 μ g/mL, and using mouse **4** serum were 800 ng/mL, 20 ng/mL, and 34 μ g/mL. Chlorpyrifos and paraoxon showed no cross reaction. Parathion showed cross reaction at 1–2% azinphos-methyl. Azinphos-ethyl was slightly more competitive than azinphos-methyl. For the azinphos hapten, I_{50} ranged from 6 to 10 ng/mL, I_{20} from 1 to 2 ng/mL, and I_{80} from 60 to 100 ng/mL.

(e) *Demeton Immunoconjugate*. The optimal dilutions

Figure 2. Overall synthetic scheme for organophosphate haptens.

of MSA-hapten were 25, 200, 50, and 50 ng/mL and of sera dilution of 1/32000, 1/64000, 1/128000, and 1/32000 for mouse 1–4, respectively. I_{50} , I_{20} , and I_{80} for demeton using mouse 1 and mouse 4 sera were 20 μ g/mL, 800 ng/mL, and 120 μ g/mL, using mouse 3 serum were 66, 7, and >200 μ g/mL, and using mouse 2 serum were 20.0, 1.8, and 80.0 μ g/mL, respectively. For the demeton hapten, I_{50} ranged from 10 to 20 ng/mL, I_{20} from 2 to 6 ng/mL, and I_{80} from 80 to 150 ng/mL.

(f) *Dimethoate Immunoconjugate.* The optimal dilutions of MSA-hapten were 500, 250, 500, and 500 ng/mL and of sera dilution 1/32000, 1/10000, 1/64000, and 1/64000 for mouse 1–4, respectively. I_{50} , I_{20} , and I_{80} for dimethoate using mouse 1–3 sera were 45, 6, and 180 μ g/mL and using mouse 4 serum were 66, 7, and >200 μ g/mL, respectively. For the dimethoate hapten, I_{50} ranged from 20 to 30 ng/mL, I_{20} from 4 to 10 ng/mL, and I_{80} from 90 to 150 ng/mL.

(g) *Dichlorvos Immunoconjugate*. The optimal dilutions of MSA-hapten were 90, 250, 500, and 500 ng/mL and of sera 1/32000 for mouse 1–4, respectively. I_{50} , I_{20} , and I_{80} for dichlorvos using mouse 1, 2, and 4 sera were 80, 12, and >200 μ g/mL and using mouse 3 serum were 200, 35, and >200 μ g/mL, respectively. For the dichlorvos hapten, I_{50} ranged from 20 to 40 ng/mL, I_{20} from 5 to 15 ng/mL, and I_{80} from 90 to 180 ng/mL.

(h) *Diazinon Immunoconjugate*. The optimal dilutions of MSA-hapten were 250, 500, 250, and 250 ng/mL and of sera 1/25000, 1/12800, 1/25000, and 1/25000 for mouse 1–4, respectively. I_{50} , I_{20} , and I_{80} for diazinon using mouse 1 serum were 2.1 μ g/mL, 250 ng/mL, and 15 μ g/mL, using mouse 2 serum were 1.4 μ g/mL, <45 ng/mL, and 10.2 μ g/mL, using mouse 3 serum were 750 ng/mL, 70 ng/mL, and 9 μ g/mL, and using mouse 4 serum were 750 ng/mL, 130 ng/mL, and 8 μ g/mL, respectively.

DISCUSSION

Development of an immunoassay for a small hapten requires covalent attachment of the hapten to an immunogenic carrier protein to generate reagent antibodies. The small molecule may already have a functional group that can be conjugated to the carrier, but frequently, a derivative of the hapten must be synthesized for conjugation to occur (Van Emon *et al.*, 1985). The nature of the linker arm and its position on the organophosphate hapten molecule will affect the specificity of the antibody and the ability of the free hapten to react with the antibody, although invariably, the hapten–protein immunoconjugate does react with the antibody.

Antibodies generated to hapten–protein immunoconjugates must therefore be tested to show that they react with the free hapten, with the parent organophosphate, as well as with the immunoconjugate. Antibodies must also be tested for their specificity; i.e., do they cross react with other small molecules having some of the common structural features found in the hapten used for immunization. Generally, the specificity of the antibody is highest for that part of the molecule most distal to the site of conjugation (Nugent, 1992).

We have described the syntheses of four novel generic intermediates that can be used to prepare organophosphate haptens of the phosphate, phosphorothioate, and phosphorodithioate groups. The generic intermediates are based on the dioxaphosphorinane ring and contain a protected carboxylic function which, after synthesis of the protected hapten, can be deprotected under mild conditions to yield stable haptens. Since the carboxyl group, which is used to couple the hapten to the carrier protein, is located distal to the unique functions of the hapten, we have synthesized hapten conjugates that should favor the production of antibodies that possess a high degree of specificity for individual organophosphate pesticides.

Mice immunized with the OVA-hapten conjugates elicited a strong immune response, resulting in antibodies of high titer to the corresponding MSA-hapten immunoconjugates. Furthermore, results indicated that a proportion of the antibody mixture recognized the parent organophosphate pesticide as well as the conjugated and unconjugated haptens. In all cases, under the conditions used, the unconjugated hapten was more effective in competing than was the parent pesticide, indicating that the dioxane ring of the linker arm plays a role in the structure of the epitope recognized by the major species of antibody present in polyclonal sera. It was further noticeable that haptens containing aromatic or heterocyclic structures produced polyclonal sera that were inhibited by lower concentrations of the corresponding pesticide than sera prepared from haptens containing

smaller aliphatic chains. Presumably, in these cases, the dioxane ring may play a more important role in filling the paratope of the major species of immunoglobulin present in the polyclonal sera.

The aim of the research reported in this paper was to show the applicability of our synthetic schemes, based on “generic” intermediates, in preparing haptens suitable for preparing antibodies to all classes of organophosphate pesticides. We have therefore given eight examples from the diverse groups of phosphates, thiophosphates, and dithiophosphates containing aliphatic, aromatic, and heterocyclic esters and shown that in each case the hapten conjugates are immunogenic and mice produce sera containing antibodies that recognize the parent pesticide. Although the concentrations of pesticide required to inhibit 50% binding of sera to MSA-hapten conjugates were in the nanogram to microgram per milliliter range and possibly of too low a sensitivity to be of use for developing polyclonal sera-based immunoassays for detection of organophosphates, we have recently been able to prepare hybridoma cell lines from the mice described in this paper, which secrete monoclonal antibodies (MAbs) to chlorpyrifos, parathion, diazinon (W. T. Jones and G. B. Ryan, unpublished results), and azinphos (Jones *et al.*, 1995) that can be used to develop sensitive assays. In our experience, 10–20% of hybridomas secreting antibodies to the hapten conjugate also recognize the parent pesticide in a competitive ELISA and it has been possible to select high-affinity antibodies with minimal cross reactivity to other organophosphates. For example, we recently described (Jones *et al.*, 1995) the production of monoclonals to azinphos, which only showed cross reactivity between azinphos-methyl and -ethyl and were able to develop an ELISA with a limit of detection of 80 pg/mL. We have also prepared monoclonal antibodies to the parathion hapten and easily been able to select high-affinity antibodies, some of which recognize also paraoxon while others show no cross reactivity to paraoxon, to chlorpyrifos which showed 0.4% cross reactivity to fenitrothion but no detectable cross reactivities to other pesticides and to diazinon, which gave 0.1 and 0.25% cross reactivity with etrimfos- and pyrimifos-methyl, respectively, but no detectable reactions to other pesticides (W. T. Jones and G. B. Ryan, unpublished results). Thus, in all cases, we have been able to select MAbs that when used in ELISAs resulted in greater sensitivity (limit of detection in the picogram per milliliter range) and higher specificity for the organophosphate pesticide than the corresponding polyclonal sera.

We have therefore described the synthesis of four generic heterobifunctional intermediates that can be used to prepare suitable haptens for preparing antibodies for the development of sensitive and highly specific immunoassays for individual organophosphates of phosphate, monothioate, and dithioate classes. Furthermore, the stability and undetectable level of cholinesterase inhibition are important features of the hapten and the protein conjugates in considering their usage in the development of immunoassay kits (Nugent, 1992).

MATERIALS AND METHODS

Bovine serum albumin (BSA), ovalbumin (OVA), Tween-20, horseradish peroxidase (HRP), peroxidase-labeled sheep anti-mouse IgG (γ chain specific), α -phenylenediamine (OPD), and succinimidylpyridyldithiopropionic acid (SPDP) were obtained from Sigma Chemical Co. (St. Louis, MO). *N*-Hydroxysuccinimide (NHS) and *N*-ethyl-*N*-[3'-(dimethylamino)propyl]carbodiimide hydrochloride (EDC) were from Pierce Ltd. (Rockford, IL). MicroELISA flat bottom F16 modules (Maxisorb) were obtained from

Nunc (Roskilde, Denmark). Pesticides were purchased from Chem Services (West Chester, PA). All other reagents and solvents used in the synthesis of haptens were reagent grade, and all other solvents used in other procedures were of analytical grade or better. NMR spectra were recorded on a 60 or 200 MHz spectrophotometer.

Synthesis of Haptens. *5-(Hydroxymethyl)-2,2,5-trimethyl-1,3-dioxane.* A mixture of 2-(hydroxymethyl)-2-methyl-1,3-propanediol (240 g, 2 mol), acetone (120 g, 2 mol), a few crystals of *p*-toluenesulfonic acid, and benzene (800 mL) was heated under reflux for 24 h with azeotropic removal of water. The reaction mixture was concentrated by rotary evaporation, and the residue purified by bulb-to-bulb distillation, to yield 288.8 g (1.805 mol, 90%) of the desired alcohol **1**, with a bp of 80 °C (0.2 mmHg). ¹H-NMR (CDCl₃): δ 0.8 (s, 3H), 1.35 (s, 3H), 1.40 (s, 3H), 3.5–3.7 (m, 6H).

2-(2,2,5-Trimethyl-1,3-dioxan-5-yl)methoxyacetic Acid, Methyl Ester. Alcohol (**2**, 285 g, 1.78 mol) dissolved in 200 mL of DMF was added to sodium hydride (157 g, 55–65% in mineral oil, washed twice with 300 mL of hexane) in 800 mL of DMF. The reaction mix was cooled in ice/water to maintain the temperature of 10–25 °C and stirred for 3 h at RT. Bromoacetic acid (249 g, 1.79 mol) in DMF (500 mL) was added over a 2 h period with ice cooling and mechanical stirring to maintain the temperature at 16–22 °C. The reaction mixture solidified, and DMF (1 L) was added and the suspension stirred overnight at RT.

The mixture was warmed to 30 °C and stirred for a further 2 h at 37 °C. Dimethyl sulfate (210 mL, 2.22 mol) was added and the mixture maintained at 30–35 °C for 2 h, cooling where necessary, in ice. The suspension was stirred for 5 h at RT and rotary evaporated to remove most of the DMF.

Water (1 L) and toluene (1 L) were added to the residue; the mixture was shaken, and the layers were allowed to separate. The aqueous layer was extracted with 750 mL of toluene, and the combined toluene layers were washed with 2 × 1 L of water. The toluene layer was dried and evaporated. The residue was purified by bulb-to-bulb distillation to yield 240.2 g (1.035 mol, 58%) of the desired product **2**. ¹H-NMR (CDCl₃): δ 0.85 (s, 3H), 1.35 (s, 3H), 1.40 (s, 3H), 3.5–3.7 (AB, *J* = 12 Hz, 4H), 3.5 (s, 2H), 3.7 (s, 3H), 4.1 (s, 2H). ¹³C-NMR (CDCl₃): δ 17.9, 20.7, 26.6, 34.3, 51.6, 66.2, 68.7, 74.5, 97.8, 170.9.

2-[3-Hydroxy-2-(hydroxymethyl)-2-methylpropoxy]acetic Acid, Methyl Ester. Pyridinium *p*-toluenesulfonate (6.9 g, 27.5 mmol) was added to a solution of the acetal ester **2** obtained above (96.0 g, 0.414 mol) in 450 mL of methanol, followed by 120 mL of water. The solution was stirred for 4 h, during which time a total of 400 mL water was added in 100 mL portions. The resulting solution was rotary evaporated, and 100 mL of toluene was added to the residue. This solution was rotary evaporated, and a further 100 mL of toluene was added. Rotary evaporation of this solution yielded 90 g of the desired product **3**. ¹H-NMR (CDCl₃): δ 0.8 (s, 3H), 3.4 (s, 2H), 3.5 (s, 4H), 3.6 (s, 2H), 3.7 (s, 3H), 4.1 (s, 2H).

*2-(2-Chloro-5-methyl-1,3,2-dioxaphosphorinan-5-yl)methoxyacetic Acid, Methyl Ester, *p*-Sulfide.* The crude diol **3** obtained above (27.3 g, containing 3.1 g of pyridinium *p*-toluenesulfonate) was dissolved in 100 mL of toluene, and to this was added pyridine (25 mL, 0.316 mol). The mixture was cooled to 10–15 °C, and thiophosphoryl chloride (distilled, 26 g, 0.153 mol) was then added over a 3 min period (the temperature of the mixture was allowed to rise to 25–30 °C). The suspen-

sion was stirred overnight at RT. Water (250 mL) and toluene (100 mL) were then added; the resultant mixture was shaken, and the layers were separated. The organic layer was then washed with 250 mL of water, and the aqueous layers were extracted with 100 mL of toluene. The combined toluene layers were then dried over sodium sulfate and rotary evaporated. The resultant residue was dissolved in a small amount of toluene and filtered over a column of aluminum oxide (5 × 3 cm), and the product eluted from this column with toluene. The filtrate was evaporated and the residue stirred overnight with a mixture of 30 mL of ether and 30 mL of ligroin (bp of 40–60 °C). After cooling to –10 °C for 2 h, the suspension was filtered with suction and the solid phase then washed with a 2/3 mixture of ether and ligroin. This procedure yielded 12.95 g of the product **4** which, by NMR, appeared to be principally comprised of one isomer. The crystallization filtrate was then evaporated, leaving a residue of 12.72 g which, by NMR, appeared to be a 1/2 mixture of the crystalline and liquid isomers **4**. The total yield was 25.67 g (88.0 mmol, 71% yield based on acetal ester **2**). The crystalline isomer had singlets at δ 0.9, 3.7, and 4.1 ppm. Both isomers had multiplets in the δ 3.8–4.8 ppm region.

*2-(2-Chloro-5-methyl-1,3,2-dioxaphosphorinan-5-yl)methoxyacetic Acid, Methyl Ester, *p*-Oxide.* The oxygen analogue **5** was prepared in a manner identical to the preparation of **4**, using phosphoryl chloride in place of thiophosphoryl chloride. After filtration of the crude product over aluminum oxide, and evaporation of the toluene eluate, the product (21.8 g, 80 mmol, 63% yield based on the acetal ester **2**) was obtained as an oily mixture of two isomers **5**. Attempted purification through vacuum distillation resulted in almost complete decomposition. ¹H-NMR (CDCl₃): δ 1.0 (s), 1.3 (s) (ratio of about 2/1), 3.3–4.7 (m) with singlets at 3.4, 3.7, and 4.1.

*2-(2-Mercapto-5-methyl-1,3,2-dioxaphosphorinan-5-yl)methoxyacetic Acid, Bispotassium Salt, *p*-Sulfide.* Diol **3** (35.4 g, 0.184 mol) (see above) was dissolved in 300 mL of toluene. Phosphorus pentasulfide (35.4 g, 0.144 mol) was then added and the suspension stirred first for 1 h at 60–70 °C, then overnight at RT, and finally at 80–90 °C for 3 h (most of the phosphorus pentasulfide dissolved during the heating process). The mixture was then vacuum filtered, and the solids were washed with toluene. The filtrate was evaporated, and 200 mL of methanol was added to the residue, followed by the addition of 30 g of potassium hydroxide in 100 mL of methanol over a 15 min period (with cooling, the temperature was allowed to rise to approximately 35 °C). The resultant suspension was filtered under vacuum and the solid phase washed with methanol. The yield was 31.9 g (91.7 mmol, 56% based on the acetal ester **2**) of the colorless bispotassium salt **6**. This product was then recrystallized from a mixture of ethanol and water. ¹H-NMR (D₂O): δ 1.0 (s, 3H), 3.5 (s, 2H), 3.9, 4.0 (s, 4H), 4.25 (s, 2H).

(2-Methoxy-5-methyl-1,3,2-dioxaphosphorinan-5-yl)methoxyacetic Acid, Methyl Ester. The acetal ester **2** (42 g, 0.181 mol) was converted to diol **3** in the usual way using 200 mL of methanol, 2.1 g of pyridinium *p*-toluenesulfonate, and 240 mL of water. The resultant diol was stirred with 400 mL of toluene, 33 g of trimethyl phosphite (0.266 mol), and 16 drops of triethylamine for 3 days [see Edmundson *et al.* (1985) for a similar procedure]. After rotary evaporation at 300 mmHg and 40 °C, the residue was washed with 2 × 100 mL of water, dried, and evaporated. The residue was then purified by bulb-to-bulb distillation at 0.1 mmHg to give 28.21 g of the pure product **7** (0.112 mol, 62%). ¹H-NMR (CCl₄):

δ 0.75 s and 1.2 s (ratio of 2/1), 3.1–4.7 (m) with singlets at 3.3, 3.5, 3.6, and 4.0.

2-[5-Methyl-2-(3,5,6-trichloropyridin-2-oxy)-1,3,2-dioxaphosphorinan-5-yl]methoxyacetic Acid, *p*-Sulfide (*Chlorpyrifos Hapten*). DMF (50 mL) was first added to sodium hydride in mineral oil (50–55%, 1.94 g, 44.4 mmol, washed twice with 40 mL of ligroin), after which trichloropyridinol (9.2 g, 46.3 mmol) was added in portions over 10 min. After the mixture was stirred for 30 min, the crystalline isomer **4**, obtained above, was added (10.15 g, 35.18 mmol), followed by an additional 10 mL of DMF. After being stirred for 3 days at RT, the mixture was poured into 500 mL of water (containing 10 g of sodium bicarbonate). The product was then extracted with 500 mL and then 250 mL of chloroform, and the combined organic layers were first washed with 500 mL of water, dried, and evaporated. The residue, which solidified on standing, could be purified by stirring with a 1/1 mixture of ether and ligroin to yield a single isomeric product. ¹H-NMR (CDCl₃): δ 1.0 (s, 3H), 3.8 (s, 5H), 4.2 (s, 2H), 4.2–4.4 (m, 4H), 7.9 (s, 1H). ¹³C-NMR (CDCl₃): δ 16.1, 36.2, 51.7, 68.5, 71.8, 74.0, 121.0, 127.4, 141.1, 144.2, 150.2, 170.4. Similarly, from the oily mixture of chlorides **4**, a mixture of esters **8** was obtained. The more soluble isomer had singlets at δ 1.3, 3.3, 3.7, 3.9, and 7.9 ppm and a multiplet at δ 3.7–4.8 ppm.

THF (75 mL), followed by 75 mL of methanol, was added to the methyl ester **8** (15.0 g) obtained above. A solution of potassium carbonate (5.28 g, 38.3 mmol in 35 mL of water) was added over a period of 10 min, followed by the addition of 50 mL of water over a 15 min period. After the mixture was stirred for 2 h, 500 mL of water was added and the mixture then extracted first with 400 mL of a 3/1 mixture of toluene and ethanol and then with 300 mL of toluene, to remove the unreacted ester **8**. The combined aqueous layers were acidified by the addition of 10 mL of concentrated hydrochloric acid and then extracted with 4 \times 250 mL of toluene. The combined toluene layers were then dried and rotary evaporated to yield a residue which was dissolved in 100 mL of warm methanol. Water (about 60 mL) was added, followed by some seed crystals. After the mixture was stirred at RT for some time, the precipitate was collected by vacuum filtration. The precipitate **9** so obtained weighed 6.50 g and, on the basis of NMR, appeared to consist of a single isomer. Using the same procedure, a further 1.78 g of **9** was obtained from the filtrate. NMR revealed this product to consist of a 3/2 mixture of the more soluble and less soluble isomers. The total yield was 8.28 g (18.97 mmol, 54% yield based on chloride **4**). Similarly, from the oily mixture of chlorides **4** obtained above, the acid **9** was obtained (after the methanol/water purification) as a 5/2 mixture of the more soluble and less soluble isomers. ¹H-NMR (CDCl₃) for the less soluble isomer: singlets at δ 1.0 (3H), 3.7 (2H), 4.8 (2H), 7.8 (1H), 8.9 (1H, broad), multiplet at δ 3.8–4.9. ¹H-NMR (CDCl₃) for the more soluble isomer: singlets at δ 1.3, 3.4 (broad), 7.8, multiplet at δ 3.7–4.9.

2-[5-Methyl-2-(4-nitrophenoxy)-1,3,2-dioxaphosphorinan-5-yl]methoxyacetic Acid, *p*-Sulfide (*Parathion Hapten*). 4-Nitrophenol (3.00 g, 20 mmol) was added in 0.5 g portions to a mixture of sodium hydride (1.10 g, 50–55%, 22.9 mmol, washed twice with 30 mL of ligroin) and DMF (30 mL). After the mixture was stirred for 1 h, 5.15 g (20 mmol) of crystalline chloride **4** was added and the mixture stirred for 3 days at RT. The reaction mixture was then poured into 250 mL of a 4% sodium bicarbonate solution and the product extracted with 250 mL of toluene. Washing with 2 \times 250 mL of water followed by drying and evaporation gave the crude product as a 3/2

mixture of isomers (by NMR). Addition of 50 mL of ether yielded a solid which, after filtration and washing with ether, gave 2.07 g of methyl ester **10** (one isomer by NMR, major isomer in the crude product). Similarly, from 5.15 g of the oily mixture of chlorides **4** was obtained 1.59 g of a single isomer. The ether filtrates of both products were combined, evaporated, treated with 50 mL of ether and a small amount of ligroin, and then stored at –15 °C to give 3.45 g of product **10** (3/2 mixture of the more soluble and less soluble isomers). The total yield was 7.31 g (18.7 mmol, 47% yield). ¹H-NMR (CDCl₃) of the less soluble isomer: δ 1.0 (s, 3H), 3.7 (s, 5H), 4.1 (s, 4H), 4.1–4.35 (AB, *J* = 12 Hz, 2H), 7.1–8.2 (AB, *J* = 9 Hz, 4H). The more soluble isomer had a singlet at 1.3 ppm, and a complicated pattern in the 3.4–4.9 ppm range with singlets at 3.4, 3.7, and 4.0 ppm.

Sufficient THF (about 20 mL) was added to 3.66 g (9.36 mmol) of the single isomer ester **10** in methanol (70 mL) to completely solubilize the mixture. Lithium hydroxide (232 mg, 9.65 mmol) in 20 mL of 1/3 water/methanol was added with stirring over 30 min. This mixture was further stirred for 1 h and then poured into 500 mL of water. This solution was extracted with 250 mL of toluene, which was washed with 50 mL of water. The combined aqueous layers were acidified by the addition of 1.5 mL of concentrated hydrochloric acid and then extracted with 2 \times 250 mL of toluene. The combined toluene layers were dried and evaporated to give a solid residue, which was then stirred with ether. Subsequent filtration and washing with ether yielded 1.26 g of the free acid of the less soluble isomer **11**.

Similarly, 1.01 g of the more soluble isomer (isomer ratio of 2/1) was obtained from 3.45 g of the mixture of esters **10** (see above) after this mixture had been treated with ether. From the combined filtrates of both reactions, a further 0.79 g of an almost 1/1 mixture of isomers was obtained following treatment with ether. The total yield was 3.06 g (8.12 mmol, 43%). ¹H-NMR (CDCl₃) of the less soluble isomer: δ 1.0 (s, 3H), 3.6–4.6 (m), 3.8 (s), 4.2 (s, 8H), 7.5–8.6 (AB, *J* = 9 Hz, 4H). The more soluble isomer had singlets at δ 1.3, 3.45, and 4.1 ppm.

2-[5-Methyl-2-(2-isopropyl-6-methylpyrimidin-4-oxy)-1,3,2-dioxaphosphorinan-5-yl]methoxyacetic Acid, *p*-Sulfide (*Diazinon Hapten*). DMF (30 mL), followed by 2-isopropyl-6-methyl-4-pyrimidinol (4.7 g, 30.9 mmol) added in portions over 5 min, was added to sodium hydride in mineral oil (50–55%, 1.13 g, 25.9 mmol, washed twice with pentane). After the mixture was stirred for 4 h, crystalline isomer **4** (6.8 g, 23.6 mmol) was added and the mixture stirred for a further 2 days at RT. The resultant mixture was then added to 300 mL of sodium carbonate and 500 mL of toluene and the solution mixed. The layers were separated, and the toluene phase was back washed with 300 mL of water, dried, and evaporated. The oily residue, ester **12**, was dissolved in 150 mL of 1/1 THF/MeOH.

Aqueous sodium carbonate (5.5 g in 50 mL of water) was added with stirring for 30 min. Water (50 mL) was added and the mixture stirred for a further 4 h followed by the addition of another 300 mL of water. The mixture was extracted with 2 \times 300 mL of toluene, and the toluene layer was back washed with 250 mL of water. The combined aqueous layers were acidified by the addition of concentrated hydrochloric acid (10 mL) and then extracted with 3 \times 250 mL of toluene. The toluene was dried and evaporated and the residue stirred overnight with ether (50 mL). The residue was then filtered and washed with ether to yield the desired product **13** (4.31 mmol, 18% yield based on chloride **4**). ¹H-NMR (CDCl₃): δ 1.0 (s, 3H), 1.35 (s, 3H), 1.4 (s, 3H), 2.6 (s,

3H), 3.2 (m, 1H), 3.8 (s, 2H), 4.2–4.5 (m, 6H), 4.25 (s, 6H), 6.9 (s, 1H).

2-[5-Methyl-2-(4-nitrophenoxy)-1,3,2-dioxaphosphorinan-5-yl]methoxyacetic Acid, p-Oxide (Paraoxon Hapten). 4-Nitrophenol (10.2 g, 73.4 mmol) was added over a 10 min period to a mixture of sodium hydride (3.14 g, 50–55%, 72 mmol, washed twice with 40 mL of ligroin) and 75 mL of DMF. After the mixture was stirred for an additional 30 min, chloride **5** (16.9 g, 62.0 mmol) in 20 mL of DMF was added. This mixture was stirred for 3 days at RT and then poured into 500 mL of 2% sodium bicarbonate solution. The product was extracted with 500 mL of toluene and the toluene layer washed with 2 × 500 mL of water, dried, and evaporated. Ether (100 mL) was then added to the residue (which consisted of two methyl ester isomers in a 3/2 ratio) and the mixture stirred for 2 h. The solid was then filtered off and washed with ether to give 12.6 g of material principally comprised of the less soluble major isomer **14**. Evaporation of the filtrate left 7.94 g of material, the major constituent of which was the other isomer. The total yield was 20.54 g of methyl ester **14** (54.8 mmol, 88%). ¹H-NMR (CDCl₃) of the less soluble isomer: δ 1.0 (s, 3H), 3.7 (s, 5H), 3.9–4.8 (m, 6H), 4.15 (s, 6H), 7.2–8.3 (AB, *J* = 9 Hz, 4H). ¹H-NMR (CDCl₃) of the more soluble isomer: δ 1.3 (s, 3H), 3.4 (s, 2H), 3.7 (s, 3H), 3.9–4.9 (m, 6H), 4.0 (s, 6H), 7.2–8.3 (AB, *J* = 9 Hz, 4H).

Methanol (100 mL) was added to a solution of ester **14** (10.1 g, 26.9 mmol, less soluble isomer) in 160 mL of THF. This was followed by the dropwise addition of a solution of potassium carbonate (4.20 g, 30.4 mmol) in 50 mL of water over a 15 min period. A further 100 mL of water was subsequently added over a 5 min period. After being stirred at RT for 90 min, the reaction mixture was poured into 750 mL of water. Extraction with 2 × 300 mL of toluene, followed by washing of the combined toluene layers with 150 mL of water, removed unreacted ester **14**. The combined aqueous layers were acidified by the addition of about 6 mL of concentrated hydrochloric acid and then extracted with 3 × 300 mL of toluene. Drying and rotary evaporation of these toluene layers yielded a solid residue which was then stirred with a small amount of ether. Subsequent filtration and washing with ether gave 4.70 g of the acid **15** (13.0 mmol, 48% yield). ¹H-NMR (CDCl₃/DMSO-*d*₆): δ 0.95 (s, 3H), 3.7 (s, 2H), 3.9–4.6 (m, 6H), 4.05 (s, 6H), 7.2–8.2 (AB, *J* = 9 Hz, 4H).

2-[5-Methyl-2-[[4-oxo-1,2,3-benzotriazin-3(4H)-yl]thio]-1,3,2-dioxaphosphorinan-5-yl]methoxyacetic Acid, p-Sulfide (Azinphos Hapten). Concentrated hydrochloric acid (3.3 g, 1.172 mmol) was added to a suspension of the bispotassium salt **6** (11.0 g, 31.6 mmol) in 100 mL of methanol followed by 30 mL of water. The resulting clear solution was evaporated completely, and the residue was dissolved in absolute ethanol (100 mL) by warming the stirred suspension. Toluene (100 mL) was added and the mixture evaporated to dryness. Toluene (100 mL) was added to the residue and the mixture rotary evaporated again. The solid residue was dissolved in acetone (100 mL), and 3-(chloromethyl)-1,2,3-benzotriazin-4(3*H*)-one [6.13 g, 31.36 mmol, prepared according to Lorenz (1957)] was added. The mixture was stirred for 64 h at RT and evaporated. The residue was stirred with a mixture of potassium carbonate (6.0 g, 43.5 mmol), water (150 mL), and toluene (150 mL). The aqueous layer was extracted with toluene (250 mL), and the toluene layers were extracted with water (150 mL). The combined aqueous layers were acidified with concentrated hydrochloric acid (10 mL) and extracted with toluene (2 × 250 mL), washed with water (150 mL), dried, and evaporated to a viscous

oil which solidified on standing. The solid was stirred in ether, filtered, and washed with ether to give 6.08 g of the desired product **16** (45% yield based on **6**) as a 1/1 mixture of isomers. These isomers are probably the result of attack on either the axial sulfur or the equatorial sulfur atom in the dipotassium salt **6**. ¹H-NMR (CDCl₃) of **16** (a 1/1 mixture of isomers): δ 0.9 (s, 3H), 1.25 (s, 3H), 3.5 (s, 2H), 3.7 (s, 2H), 3.8–4.6 (m, 6H), 5.7 (s, 2H), 6.0 (s, 2H), 7.5–8.5 (m, 4H).

2-[5-Methyl-2-[[2-(methylamino)-2-oxoethyl]thio]-1,3,2-dioxaphosphorinan-5-yl]methoxyacetic Acid, p-Sulfide (Dimethoate Hapten). Hydrochloric acid (4.21 g, 40.5 mmol), followed by 30 mL water, was added to a suspension of the bispotassium salt **6** (14.67 g, 42.16 mmol). The resultant solution was evaporated to dryness, the residue resuspended in absolute ethanol (100 mL), and the suspension warmed and then re-evaporated to dryness. Toluene (100 mL) was added to the residue, and the suspension was again evaporated. This procedure was repeated one more time. Acetone (100 mL), followed by *N*-methylchloroacetamide (5.05 g, 46.98 mmol), was then added to the residue; the mixture was stirred for 3 days at RT and then evaporated. Potassium carbonate (8.80 g) in water (250 mL), followed by 250 mL of toluene, was added to the residue. After the mixture was stirred for 15 min, the layers were separated, the aqueous layer was extracted with 250 mL of toluene, and the combined organic layers were washed with 100 mL of water. To the combined aqueous layers was added 17 mL of concentrated hydrochloric acid, and the resulting mixture was extracted with 3 × 200 mL of chloroform. The chloroform layers were dried and evaporated to leave 8.2 g of residue. Concentrated ammonia (5 mL) was added to the residue and the solution evaporated to dryness. Acetone was added to the residue; the mixture was stirred, and the resulting solid (the ammonium salt of **17**) was filtered off and washed with acetone. This gave 2.77 g of product (single isomer by NMR, apparently only one of the two possible isomers is formed or one of the two possible isomers is much less soluble than the other isomer), which was then dissolved in 100 mL of water. Concentrated hydrochloric acid (2 mL) was added and the mixture extracted with 3 × 100 mL of chloroform. Drying and evaporation left a residue from which, on stirring with ether, the pure acid **17** was precipitated. Subsequent filtration and washing yielded 1.765 g (5.15 mmol, 12% based on **6**). ¹H-NMR (CDCl₃): δ 1.0 (s, 3H), 2.8 (s, 3H), 2.9 (s, 3H), 3.4 (s, 2H), 3.7 (s, 2H), 3.6 (s, 2H), 3.8–4.6 (m, 6H), 4.1 (s, 6H), 6.5 (broad s, 1H), 9.3 (s, 1H).

2-[2-[[2-(Ethylthio)ethyl]thio]-5-methyl-1,3,2-dioxaphosphorinan-5-yl]methoxyacetic Acid 17, p-Oxide (Demeton Hapten). *n*-Butyllithium (18 mL, ca. 2.25 M in hexanes, 40.5 mmol) was added over 5 min to an ice-cooled solution of ethylthioethanol (4.26 g, 40 mmol) in 50 mL of THF. The suspension was stirred for 1 h at RT and cooled with ice, and the acid chloride **4** (mixture of isomers, 11.60 g, 40.2 mmol), dissolved in 15 mL of THF, was then added over 10 min. This mixture was stirred overnight at RT and poured into 250 mL of water, and the product was extracted with 2 × 200 mL of toluene. The combined toluene layers were washed with 3 × 100 mL of water, dried, and evaporated. The residue, **18**, was then dissolved in a mixture of 100 mL of methanol and 100 mL of THF. A solution of 5.50 g of potassium carbonate (39.9 mmol) in 50 mL of water was added over 10 min, followed by the addition of 100 mL of water over 30 min. This solution was then stirred for 3 h at RT, poured into 500 mL of water, and extracted with 2 × 250 mL of chloroform (some sodium chloride being added). The combined chloroform layers were washed with 2 × 100 mL of water

(some ethanol being added). The combined aqueous layers were acidified by the addition of 10 mL of concentrated hydrochloric acid and then extracted with 3 × 250 mL of chloroform. After drying and evaporation, a residue was obtained which was then stirred in 50 mL of toluene at RT for 10 days (this allowed slow isomerization from the sulfide to the oxide). The solution was evaporated and the residue stirred for a further 2 days at RT with ether to precipitate the desired **19** (one isomer precipitates). Filtration and washing with ether afforded a final yield of 350 mg of **19** (1.02 mmol, 2.5% based on acid chloride **4**). ¹H-NMR (CDCl₃): δ 1.0 (s, 3H), 1.3 (t, *J* = 7 Hz, 3H), 2.3–3.4 (m, 6H), 3.7 (s, 2H), 3.9–4.6 (m, 6H), 4.0 and 4.1 (s, 6H), 9.6 (1H).

2-[2-[(2,2-Dichloroethenyl)oxy]-5-methyl-1,3,2-dioxaphosphorinan-5-yl]methoxyacetic Acid, p-Oxide (Dichlorvos Hapten). The phosphite **7** obtained above was dissolved in 150 mL of toluene and 20.0 g of chloral (0.136 mol) in 25 mL of toluene added over a 15 min period with ice cooling. The solution was first stirred for 1 h at 0–10 °C and then for 3 h at RT, after which time it was evaporated to dryness, leaving as a residue the crude methyl ester **20**. ¹H-NMR (CCl₄): δ 1.0 and 1.3 (s, 3H, ratio of 1/2), 3.2–4.7 (m) and singlets at 3.3, 3.7, 4.0, and 4.1 (11H), 7.0 (d, *J* = 6 Hz, 1H). The crude ester was dissolved in a mixture of 100 mL of THF and 150 mL of methanol, and a solution of 15.0 g of potassium carbonate (0.109 mol) in 100 mL of water was then added in 10 min. A further 100 mL of water was added over 15 min and the mixture then stirred at RT for 3 h. Water (500 mL) was added and the mixture extracted with 2 × 250 mL of chloroform. The organic layers were washed with 250 mL of water. The chloroform layers contained impurities and starting ester. Chloroform (250 mL) was added to the combined aqueous layers, followed (with stirring) by 25 mL of concentrated hydrochloric acid. The layers were separated, and the aqueous layer was extracted with 2 × 250 mL of chloroform. Drying and evaporation yielded 11.6 g of crude product which was then stirred with 100 mL of ether to give a colorless solid. Filtration and washing with ether afforded 5.17 g of a mixture of **21** and an unknown acid which did not contain (NMR) a vinyl proton. Evaporation of the filtrate yielded crude **21** which was dissolved in 25 mL of methanol. Water (40 mL) was added dropwise with stirring, upon which pure **21** crystallized (the unknown acid proved to be much more soluble in water/methanol than **21**). Filtration and washing with water/methanol (3/1) yielded 2.10 g (6.27 mmol, 6% based on the phosphite **7**, mainly one isomer) of pure **21**. Repetition of the latter procedure gave one isomer of **21**. ¹H-NMR (CDCl₃): δ 1.3 (s, 3H), 3.4 (s, 2H), 3.8–4.8 (m, 8H), 4.0 (s, 8H), 7.0 (d, *J* = 5 Hz, 1H), 9.5 (broad s, 1H).

Synthesis of Hapten–Protein Conjugates. The haptens were conjugated to carrier proteins MSA and OVA using the active ester procedure (Langone and Van Vunakis, 1975). Briefly, the hapten (0.2 mM) was dissolved in 1 mL of dimethylformamide (DMF), and to this were added 30 mg of NHS and 40 mg of EDC; the mixture was stirred for 2 h at RT to convert the carboxyl group into the succinimidyl ester function. MSA (60 mg) or OVA (40 mg) was dissolved in 1.8 mL of distilled water, cooled in ice and DMF (1.2 mL) slowly added to the dissolved protein in stirred reactivials (Pierce Chemicals). The hapten–NHS esters (50 μL) were added to the protein solutions and incubated overnight at 4 °C. The reaction mixture was dialyzed exhaustively against distilled water and stored at –70 °C in aliquots. The number of moles of hapten per mole of protein was determined using protein estimation (Bradford, 1976)

and phosphorus (atomic absorption spectroscopy) to determine the moles of conjugated hapten.

Anti-Cholinesterase Activity of Haptens and Organophosphate Pesticides. Organophosphate pesticides and their haptens were tested for their ability to inhibit cholinesterase activity using a pesticide biosensor detector kit (Enzytec Inc., Kansas City, MO). The lowest concentration to inhibit a positive reaction was determined for each test molecule using the manufacturer's protocol.

Immunization of Mice. Female mice (Balb/c PN X DBA, four mice) 6–8 weeks old were immunized at intraperitoneal (IP) and subcutaneous (SC) sites with 100 μg of OVA–hapten conjugates in complete Freund's adjuvant (CFA).

The mice received a further three immunizations at 28 day intervals of 50 μg of conjugate in incomplete Freund's adjuvant (IFA). Blood was taken from each mouse, prior to the first immunization (preimmune) and 10 days following the fourth immunization, and tested for antibodies against the hapten–MSA conjugates and the parent pesticide.

Micro-ELISA Procedures. Microtiter wells were coated with hapten–MSA conjugates for 3 h at 37 °C in phosphate-buffered saline (100 μL per well). BSA (2%) in phosphate-buffered saline (PBS) was used to block the remaining protein-binding sites on the microwell surface.

Stock solutions of pesticides and synthetic intermediates were prepared by dissolving the appropriate compound in methanol (10 mg/mL). Standard solutions (20 × working concentration) were prepared by dilution of the stock solution into methanol. Working standards (2 × final concentration; 3 ng/mL to 200 μg/mL) were prepared by diluting 1 mL of the standard solutions with 9 mL of dilution buffer [PBST (PBS and 0.1% Tween-20) containing 2% BSA].

Optimal conditions for ELISA (Jones *et al.*, 1992) were determined by varying the incubation time and reagent concentrations. Between additions of reagents, the plates were washed six times with PBST. Substrate (OPD, 40 mg of 100 mL citrate/phosphate buffer at pH 5.0 containing 40 μL of 30% H₂O₂; 200 μL/well) was added, and the plates were incubated at RT for 30 min. The peroxidase reaction was stopped by addition of 4 M sulfuric acid (50 μL/well), and the absorbance was measured at 492 nm (*A*₄₉₂) in a Dynatech MR 5000 plate reader with Biolinx 1.0 software (Dynatech Laboratories, Inc., Chantilly, VA).

Serum in dilution buffer (100 μL/well) was added to wells for 2 h at 37 °C. Antibodies to hapten conjugates were detected after incubation with peroxidase-labeled anti-mouse IgG (1/2000 in dilution buffer, 1 h, 37 °C) and addition of peroxidase substrate. Sera reacting with conjugate were further tested using a competitive ELISA for reactivity with pesticides. Plates were coated with hapten conjugates at minimal dilution to achieve an *A*₄₉₂ of <0.050 when incubated with peroxidase-labeled anti-mouse IgG (1/2000). Sera were diluted to determine the concentration which gives an absorbance of approximately 1.0 (*C*_{1.0}) when detected as described above.

Equal volumes of sera diluted to 2*C*_{1.0} and serial dilutions of pesticide, prepared as described above, were mixed and incubated at 37 °C for 1 h. These solutions (100 μL) were added to the microwells, coated with hapten conjugate, and incubated for 3 h at 37 °C. The wells were washed and incubated with peroxidase-labeled anti-mouse IgG (Sigma Chemicals Fc specific antibody at 1/2000 dilution, 100 μL/well) for 1 h at 37 °C. Wells were washed and developed with substrate as described above. Standard curves were generated, and the concentrations of pesticide inhibiting binding of sera to

microwell plate by 20% (I_{20}), 50% (I_{50}), and 80% (I_{80}) were determined. The percent cross reactivity was determined as the ratio of I_{50} for the parent pesticide divided by I_{50} for test compound $\times 100$.

DNA Binding and Cleavage by a Cationic Manganese Porphyrin–Peptide Nucleic Acid Conjugate

Pascal Bigey,[†] Søren Holst Sønnichsen,[‡] Bernard Meunier,[†] and Peter E. Nielsen^{*,‡}

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, F-31077 Toulouse Cedex, France, and Center for Biomolecular Recognition, Department of Biochemistry B, The Panum Institute, Blegdamsvej 3c, DK-2200 N Copenhagen, Denmark. Received November 11, 1996[⊗]

A cationic manganese porphyrin–peptide nucleic acid (PNA) conjugate has been prepared and used to cleave a double-stranded DNA target. Cleavage experiments were performed with a 247-base pair restriction DNA fragment containing a 10-base pair homopurine binding target for the PNA. Oxidative activation by this Mn porphyrin–PNA conjugate leads to sequence specific, 3'-staggered cleavage of both DNA strands near the strand displacement junction. Furthermore, the Mn porphyrin–PNA porphyrin conjugates bind over 100-fold better to double-stranded DNA compared to the native PNA.

INTRODUCTION

The sequence specific recognition of double-stranded DNA is an essential biological process performed by DNA-binding proteins and involved in the regulation of transcription, replication, recombination, and DNA repair. The design of synthetic molecules that bind sequence specifically to unique sites on human DNA, thereby to some extent mimicking the action of the natural proteins, may have major implications for the treatment of genetic, oncogenic, and viral diseases. Oligonucleotide (via triple-helix binding), oligopeptide, or protein fragments have been used during the past decade (1–3). More recently, homopyrimidine peptide nucleic acids (PNAs) were shown to form stable triplexes with single-stranded DNA and to invade double-stranded DNA, thereby providing a novel approach to sequence specific DNA recognition (4–6).

Encouraged by the work on oxidative DNA cleavage by tetrakis(4-*N*-methylpyridiniumyl)porphyrinatomanganese(III) activated by potassium monopersulfate (KH₂SO₅) (7–9) and the attachment of trimethylpyridiniumylporphyrinatomanganese(III) motif (Mn-TrisMPyP-COOH) to oligonucleotides (10–12), we found it of interest to prepare a metalloporphyrin–PNA conjugate using the same porphyrin precursor to utilize the DNA targeting properties of the PNA. Here we report the preparation of such a "cationic manganese porphyrin–PNA" molecule (see Figure 1 for structure) and its ability to cleave a double-stranded DNA target.

EXPERIMENTAL PROCEDURES

Preparation of Mn-TrisMPyP–PNA Conjugate 1 (See Chart 1 and Figure 1 for Structure). The metallated cationic porphyrin precursor MnTrisMPyP-COOH was prepared according to the procedure given in ref 13 and activated by 1,1'-carbonyldiimidazole (CDI) and 1-hydroxybenzotriazole (HOBt) according to the procedure given in ref 10. MnTrisMPyP-COOH (1 mg, 62.5 nmol) was dissolved in 110 μ L of dry dimethylformamide (DMF), and CDI (1.5 mg, 9.2 μ mol) was added. The mixture was allowed to react for 1 h at room temperature before addition of a solution of HOBt (1.7 mg, 12 mmol in 40 μ L of dry DMF). After an extra 1 h

at room temperature, the excess of CDI was eliminated by addition of 30 μ L of 20 mM sodium 4-morpholinopropanesulfonate (MOPS) buffer, pH 7.5, and 5 μ L of pyridine was added. The activated ester solution was added to 9 OD units of PNA-1 (57 nmol) dissolved in 30 μ L of 20 mM MOPS buffer, pH 7.5. The reaction was allowed to proceed for 45 min at room temperature. One

⊗ Abstract published in *Advance ACS Abstracts*, April 1, 1997.

milliliter of cold ethanol was then added, and the mixture was allowed to precipitate overnight at -20°C . After centrifugation, the supernatant was discarded. The precipitate was dissolved in water, and conjugate **1** was purified on a C₁₈ Sep-Pak cartridge from Millipore. The yield of the conjugate was 80–90% (based on starting PNA) after purification. Conjugate **1** (and **2** and **3**) was characterized by laser desorption mass spectrometry (MALDI-TOF) on a Kratos MALDI-II instrument. The main peak was detected at 6671 (and 6809 and 6962) and corresponds to the molecular weight of conjugate **1** (and **2** and **3**). [Calcd $M = 6670$ (6815 and 6960) without axial ligand on the metal and with all of the counterions of the 4-*N*-methylpyridiniumyl residues of the metalloporphyrin moiety being removed. This should give a trication, the metalloporphyrin having three 4-*N*-methylpyridiniumyl residues. As only a monocation was observed, this probably implies the loss of two protons.]

The PNA was synthesized according to the procedures given in refs 14, 15, and 16. Concentrations of PNA were determined at 260 nm (assuming that base extinction coefficients are identical in oligonucleotides and PNAs).

DNA Cleavage Experiments. The ³²P-labeled *Eco*RI–*Pvu*II restriction fragment of plasmid pA8G2 (see ref 6 for details) was mixed with conjugate **1** (for concentrations, see caption of Figure 3) in a 20 μL volume of TE buffer (10 mM Tris-HCl, pH 7.4, 1 mM EDTA). The mixture was incubated for 2 h at 37°C , and then 0.6 μL of a 2 M NaCl solution or 2 μL of salmon DNA was added as desired. The resulting mixture was allowed to equilibrate at room temperature for 1 h.

For cleaving experiments, 2 μL of a 5 mM KHSO₅ solution was added at room temperature to the hybridization mixture and the reaction was allowed to proceed for 15 min. The reaction was stopped by the addition of 1 μL of 100 mM Hepes buffer (pH 8). Samples were then diluted with 1 μL of yeast tRNA (10 mg/mL) and 100 μL of 0.3 M sodium acetate (pH 5.2), precipitated with 350 μL of absolute ethanol, and finally rinsed with 70% aqueous ethanol and lyophilized. The DNA was analyzed on a 10% denaturing polyacrylamide gel, and radioactive fragments were visualized by autoradiography. Autoradiograms were scanned using a Molecular Dynamics laser densitometry scanner.

RESULTS AND DISCUSSION

The manganese porphyrin moiety was linked to the amino end of the PNA molecule, and the hybrid molecule was characterized by mass spectrometry. The DNA target and PNA shown in Chart 1 were used in the present study.

We used a bis-PNA that is able to invade double-stranded DNA by strand displacement (4–6, 16, 17) in a bimolecular process. To optimize triplex formation (16), we used cytosines in the antiparallel (Watson–Crick recognizing) strand, while pseudoisocytosines (termed J; see Figure 1 for structure)—that allow Hoogsteen hydrogen bond formation independent of pH (16)—were used in the parallel (Hoogsteen recognizing) strand.

Binding of conjugates **1**, **2**, and **3** to a 247-base pair duplex DNA restriction fragment containing a 10-base binding site for the PNA (Chart 1) was studied using electrophoretic mobility shift assay (Figure 2), and the pseudo affinity constant K_d^{ps} for all three conjugates was 25 nM. This pseudo affinity constant, which more accurately reflects the binding rate constant (18), was over 100-fold higher for the manganese porphyrin–PNA conjugates than for the free PNAs ($K_d^{\text{ps}} \approx 10$ mM). We ascribe this dramatically improved binding efficiency of the conjugate to the high affinity of the metalloporphyrin

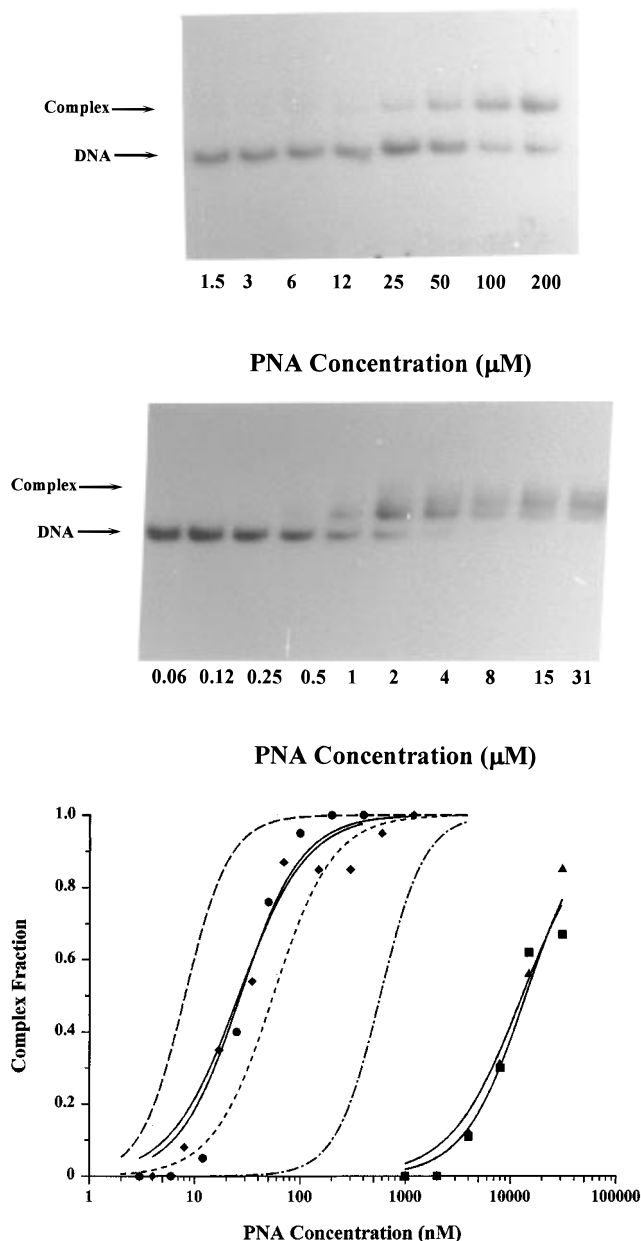

Figure 2. (a, b) Gel shift analysis of the DNA binding of PNA **1** (a) and metalloporphyrin–PNA conjugate **1** (b). (At present we do not know if the appearance of multiple bands at higher concentrations (>4 mM) is due to complexes of different conformation or structure, but it is unlikely that they represent different binding sites since no other obvious targets are present in the DNA fragment.) (c) Binding isotherms of the DNA binding of PNA **1** (■) and **2** (▲) and metalloporphyrin–PNA conjugates **1** (●) and **2** (◆). For comparison, the binding isotherms of three other bis-PNAs with total charges of +2 (in the form of one lysine and the terminal amino group) (– · –), +4 (3 lysines) (– – –), or +5 (4 lysines) (– – –) are also shown.

moiety for the minor groove of double-stranded DNA, which will effectively increase the local concentration of the PNA moiety close to the DNA helix and thus increase the probability of duplex invasion. Additional charges *per se* have been shown to increase binding efficiency [Nielsen and Demidov (in preparation), 19, 20], but the manganese porphyrin–PNA conjugates that have three positive charges bind even better than an analogous PNA with four positive charges but without the manganese porphyrin moiety (Figure 2).

Oxidation activation of the targeted manganese porphyrin with potassium monopersulfate (see ref 9 for the formation and the reactivity of manganese–oxo porphy-

Figure 3. Sequence selective oxidative cleavage of a double-stranded DNA target by the metalloporphyrin-PNA conjugate **1**. (Lane 1) A/G sequence reaction; (lane 2) control with KHSO_5 and free PNA **1**; (lane 3) control with metalloporphyrin precursor ($1 \mu\text{M}$) and KHSO_5 and free PNA **1**; (lanes 4–6) cleavage with porphyrin-PNA conjugate **1** (0.1 , 0.3 , and $1 \mu\text{M}$, respectively) and KHSO_5 ; (lane 7) as lane 3 except for the presence of 50 mM NaCl ; (lane 8) as lane 7 except for the presence of $1 \mu\text{M}$ control PNA (without conjugated porphyrin); (lanes 9–11) as lanes 4–6 except for the presence of 50 mM NaCl ; (lanes 12 and 13) as lanes 5 and 6 except for the presence of salmon sperm DNA ($1 \mu\text{g/mL}$).

rin complexes in water solutions) led to sequence specific cleavage of this long DNA fragment proximal to the PNA target. The main cleavage occurred at the duplex-to-triplex junction as a discrete band (Figure 3, lanes 4, 9, and 12; Figure 4a), whereas control experiments with the free metalloporphyrin in the presence of free PNA-**1** led to very little cleavage at the PNA target (Figure 3, lane 3; Figure 4). Cleavage with conjugate **1** on the purine-rich strand under the same conditions occurred primarily at the triplex-to-duplex junction (Figure 4c,d), whereas hardly any cleavage was observed inside the binding site. Some cleavage also took place at the 5'-end of the purine target (Figure 4a,d). This cleavage could be due to the formation of a kinetically trapped complex in which the PNA binds eight bases in the opposite direction (Figure 4f). (Conjugates **1–3** gave virtually identical cleavage results.) It is noteworthy that the cleavage occurs at a 3'-staggered fashion across the two DNA target strands, thereby indicating that the cleavage takes place from the minor groove in full accordance with the expected binding mode of the porphyrin, although it should be considered that the DNA helix is most probably significantly distorted proximal to the strand displacement loop. It is also interesting that conjugates **2** and **3**, in which the linker between the PNA and the porphyrin is increased, cleave the DNA at virtually the same positions as conjugate **1**. These results indicate that the precise site of cleavage to a significant extent is determined by the altered/distorted DNA structure proximal to the PNA binding loop. Finally, we notice that increased concen-

Figure 4. Densitometric scanning and schematic representations of the cleavage results: (a) cleavage of the pyrimidine strand by the metalloporphyrin-PNA conjugate **1** (corresponding to lane 4 of the autoradiogram presented in Figure 3); (b) control (corresponding to lane 3); (c) cleavage positions on the double-stranded DNA target; (d) cleavage of the purine strand by the metalloporphyrin-PNA conjugate **1** (analogous to the experiment of lane 4 in Figure 3, but performed on a DNA fragment with the ^{32}P -label at the 5'-end of the *Eco*RI site; X denotes a background band also present in the control samples); (e) schematic structure of the PNA DNA strand displacement complex showing the position of the metalloporphyrin group (por); (f) alternative complex (minor) that may account for the slight cleavage at the 5'-end of the pyrimidine strand of the target.

trations of the porphyrin-PNA conjugate decrease the site specific cleavage (Figure 3, lanes 5 and 6) and that addition of carrier DNA both restores this cleavage and suppresses unspecific cleavage at other sites of the DNA fragment (Figure 3, lanes 12 and 13), as would be expected since lower affinity sites are titrated out by the carrier DNA without affecting the high-affinity target.

No efforts to optimize the cleavage reaction with the metalloporphyrin-PNA conjugates have been undertaken. Thus, it is likely that the relatively low yields (estimated as 5–10%) observed in the experiments presented here can be improved once the mechanism of the cleavage reaction and the DNA binding of these metalloporphyrin-PNA conjugates are better understood. Furthermore, the properties and efficiencies of the present DNA cleavers should be directly compared with

other analogous PNA conjugates based on Fe (20) or Ni (21) redox chemistry.

In conclusion, conjugation to the cationic porphyrin dramatically enhances the duplex invasion potency of the PNA. Furthermore, the oxidative activation of a manganese porphyrin–PNA hybrid molecule allows the cationic metalloporphyrin to efficiently create irreversible damages on the double-stranded DNA target at the expected sites. Thus, further studies of such metalloporphyrin–PNA hybrid molecules are of interest in the development of sequence specific gene targeting and cleaving reagents.

Heptadecadeoxynucleotides containing 5-(*N*-aminoethyl- or *N*-aminohexyl)carbamoyl-2'-deoxyuridines (**E** or **H**) were synthesized using a newly developed postsynthetic modification method. As a convertible nucleoside unit, 5-methoxycarbonyl-2'-deoxyuridine (**1**) was initially incorporated into oligodeoxynucleotides (ODNs) according to the phosphoramidite method at various positions using a DNA synthesizer. Fully protected ODNs attached to a solid support were treated with alkyldiamines such as ethylenediamine and 1,6-hexanediamine to give the above modified ODNs. The thermal stability, resistance toward nuclease digestion, and stability in fetal calf serum of the modified ODNs were studied. An increase in the number of 5-(*N*-aminoethyl)carbamoyl-2'-deoxyuridines (**E**) in the ODNs was found to effectively stabilize duplex formation with both the corresponding complementary DNA and RNA and protect against nucleolytic hydrolysis by snake venom phosphodiesterase. In particular, the half-life of ODN **19**, which contained four **E** residues, was about 162 h in the presence of the nuclease. Furthermore, **19** was also stable in medium containing 10% fetal calf serum with a $t_{1/2}$ of about 48 h, while $t_{1/2}$ for the corresponding unmodified ODN was 13 min.

INTRODUCTION

Various oligodeoxyribonucleotide (ODN¹) analogues containing modified backbones or linker groups have been synthesized and used for biological and biophysical studies, such as antisense studies (1–7). For antisense studies, phosphorothioate and methylphosphonate analogues have been extensively used due to their nuclease-resistance properties, since a natural phosphodiester linkage in DNA is a good substrate for ubiquitous nucleases (7). However, these backbone-modified analogues have several drawbacks for use in antisense studies: (1) Phosphorothioate ODNs have lower binding affinity for their complementary strands than phosphodiester ODNs, possibly due to their diastereomer formation (8–11). (2) Although the role of RNase H cleavage in the antisense strategy is not clearly understood, it has been reported that the RNA is not a substrate for the enzyme when the methylphosphonate ODN is the complementary strand (12, 13). (3) Nonspecific binding of phosphorothioate ODNs to certain proteins was more frequent than that of the corresponding phosphodiester

ODNs, perhaps due to an inherited characteristic of the P=S bond (14, 15). Several attempts have been made to overcome these problems. One of the most promising methods is to use natural phosphodiester ODNs if they are resistant to nucleolytic digestion.

Recently, we reported the synthesis of ODNs with normal phosphodiester linkages containing a 2'-deoxyuridine analogue that carries an aminoalkyl tether at the 1'-position. We found that these were more resistant to nuclease P1 and venom phosphodiesterase than unmodified ODNs (16, 17). We also synthesized ODNs containing a novel 2'-deoxyuridine analogue with *syn*-norspermidine at the 5-position, which not only stabilized both duplex and triplex formation but also protected against hydrolysis by nuclease P1 and snake venom phosphodiesterase (18). Increased stability of *N*²-imidazolylpropylguanine- and *N*²-imidazolyl-2-aminoadenine-modified ODNs toward nucleases and thermal denaturation has also been reported (19). It is also well-known that bacteriophage ϕ W-14 DNA contains up to 50% α -putrescinyllthymine in place of thymine and is more resistant to nucleolytic enzymes such as DNase I and venom phosphodiesterase than unmodified DNAs (20–24). In addition, this modification results in a higher melting temperature (T_m) than that expected for unmodified DNA on the basis of the GC content (23, 24). However, short synthetic ODNs containing α -putrescinyllthymine were found to reduce thermal stability compared with their parent ODNs in our laboratory (25). On the basis of the result of this study, we thought that the length of the amino linkers and the distal position of the amino group would be important factors in protecting against nuclease degradation and stabilizing duplex and triplex formation.

A classical method for the synthesis of ODNs with such amino linkers is to first prepare such nucleoside phosphoramidite units separately and then to incorporate

them into ODNs by an automated DNA synthesizer (26). However, this method sometimes involves tedious protection-deprotection processes and solubility problems in the synthesis of the mononucleotide units. In particular, when the optimum length of the linker group for a desired function is not known, several nucleoside phosphoramidite units with linkers of various lengths have to be constructed separately, and these mononucleotide units have to be incorporated independently. To avoid such time-consuming processes, postsynthetic modifications have been developed (27–32). In these methods, a nucleoside unit with a leaving group within a molecule (a convertible nucleoside unit), which should be stable under the conditions of DNA synthetic cycles, is initially introduced into an ODN (a convertible ODN unit) and then appropriately modified linkers and/or further functionalized linkers are introduced into the ODNs. Thus, postsynthetic modification would be suitable for identifying the proper length of the linkers.

We previously developed a new convertible nucleoside, 5-methoxycarbonyl-2'-deoxyuridine (**1**), which reacts smoothly with alkyldiamines in MeOH under mild conditions, and developed a new postsynthetic modification method using **1** as a convertible nucleoside unit as shown in Figure 1 (33). In this paper, we describe the synthesis of ODNs containing 5-(*N*-aminoethyl- or *N*-aminohexyl)-carbamoyl-2'-deoxyuridines (**E** or **H**) using this new postsynthetic modification, their thermal stabilization properties, their protective effects against nucleolytic enzymes, and their stability in FCS.

RESULTS AND DISCUSSION

Synthesis. As a convertible nucleoside unit, 5-(methoxycarbonyl)-2'-deoxyuridine (**1**) was synthesized via pal-

^a (a) DMTrCl, pyridine, room temperature; (b) (1) $\text{NH}_2(\text{CH}_2)_n\text{NH}_2$ ($n = 2$ or 6), MeOH, room temperature, (2) aqueous 80% AcOH, room temperature; (c) (1) Ac_2O , DMAP, pyridine, room temperature, (2) NH_3/MeOH , room temperature; (d) (1) b, (2) anthraquinone-2-carboxylic acid, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride, pyridine and DMF, room temperature; (e) aqueous 80% AcOH, room temperature; (f) 2-cyanoethyl *N,N*-diisopropylphosphoramidochloride, *N,N*-diisopropylethylamine, CH_2Cl_2 , room temperature; (g) succinic anhydride, pyridine, 70 °C; (h) pentachlorophenol, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride, DMF.

ladium-catalyzed carbonylation of a commercially available 5-iodo-2'-deoxyuridine with carbon monoxide in MeOH (33). Compound **1** was converted to 5'-*O*-dimethoxytrityl (DMTr) derivative **3** and then phosphoramidite unit **4** according to a standard protocol without modifications. To incorporate **1** into the 3'-end of the ODNs, **3** was further derivatized to its 3'-*O*-succinate **5**, which was then coupled with pentachlorophenol to give **6**. Reaction of **6** with a controlled pore glass (CPG) gave a solid support containing **1** (21.9 $\mu\text{mol/g}$) (Scheme 1).

For the synthesis of reference nucleosides, **3** was treated with ethylenediamine or 1,6-hexanediamine in MeOH at room temperature to give the corresponding 5-(*N*-aminoalkyl)carbamoyl-2'-deoxyuridines (**2**; **E** and **H**) after detritylation. *N*-Acetamidoethyl- (**AcE**), *N*-acetamidoethyl- (**AcH**), *N*-(2-anthraquinonylcarbonyl)aminoethyl- (**AntE**), and *N*-(2-anthraquinonylcarbonyl)amino-

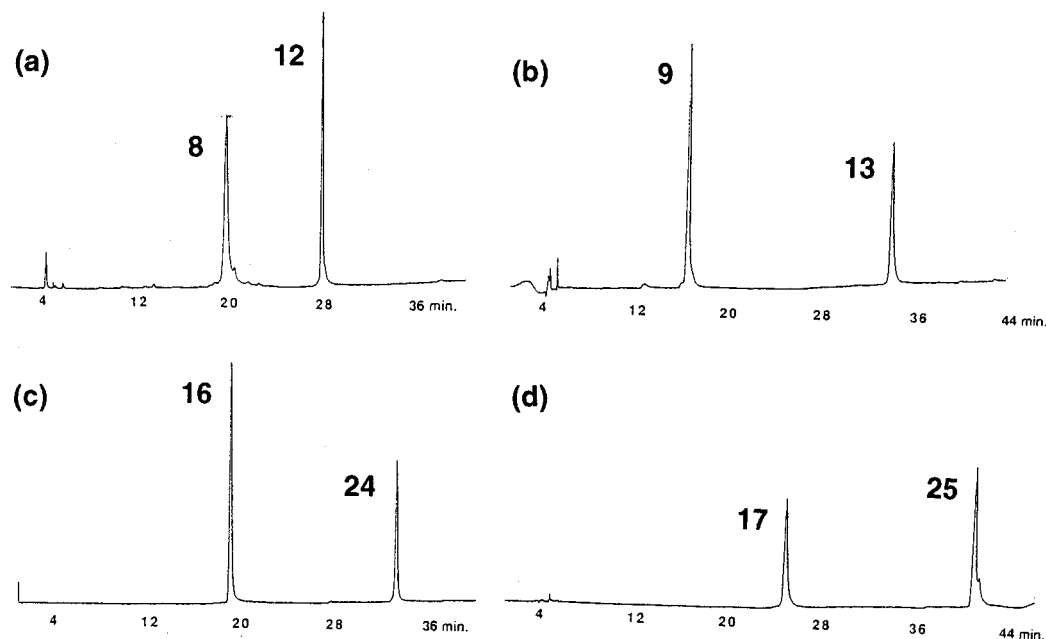

Figure 2. Examples of HPLC profiles of the ODNs with a C₁₈ column: (a) co-injection of **8** and **12**; (b) co-injection of **9** and **13**; (c) co-injection of **16** and **24**; (d) co-injection of **17** and **25**. We used a linear gradient of CH₃CN from 10 to 15% (20 min) and then from 15 to 30% (20 min) in 0.1 M TEAA buffer (pH 6.8).

hexyl- (AntH) carbamoyl derivatives were also synthesized from **3** or the corresponding amino derivatives.

Heptadecamers containing various numbers of **1** at various positions were synthesized on a DNA synthesizer using **4** and/or the solid support bearing **1**. The average coupling yield of **4** was 97% using a 0.1–0.12 M solution of **4** in CH₃CN and a coupling time of 360 s. Each fully protected ODN linked to the solid support was treated with a large excess of ethylenediamine or 1,6-hexanediamine in MeOH at room temperature or at 45 °C for 12–14 h. This treatment produced simultaneous conversion of the methoxycarbonyl group into the (*N*-aminoalkyl)-carbamoyl group, deprotection, and detachment from the solid support. Subsequent purification by C₁₈ column chromatography and following detritylation gave the corresponding heptadecamers **8–11** and **16–19** (Table

1), which were further purified by ion-exchange column chromatography followed by C₁₈ HPLC. It was necessary to remove excess 1,6-hexanediamine using Sephadex G-25 column chromatography prior to further purification. Starting from 1 μmol of nucleoside residues attached to the CPG, 8.5–23 OD units (at 254 nm) of ODNs were obtained. Reactions of these ODNs with Ac₂O or *N*-[(anthraquinone-2-carbonyl)oxyl]succinimide (**17**) at room temperature gave the desired functionalized ODNs **12–15** and **20–27** (Table 1) in good yields, which showed single peaks by HPLC analyses with C₁₈ HPLC (some examples are shown in Figure 2).

To confirm the presence of modified nucleosides in the heptadecamers, each ODN was completely hydrolyzed to the corresponding nucleosides by a mixture of snake venom phosphodiesterase and alkaline phosphatase, and

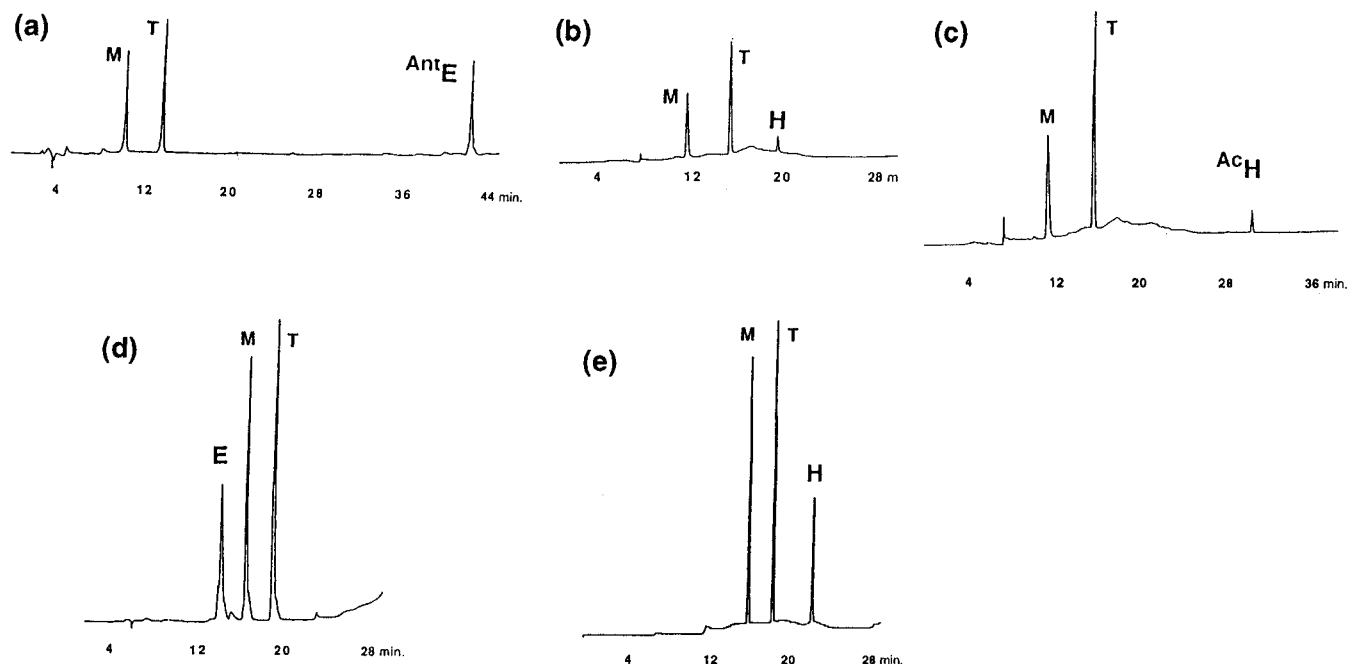

Figure 3. Examples of a profiles of HPLC analysis of a nucleoside mixture obtained by complete hydrolysis of ODNs by an enzyme mixture with a C₁₈ column: (a) **13**; (b) **17**; (c) **25**; (d) **10**; (e) **18**. For the nucleoside mixture containing **E** or **H**, HPLC was performed with a linear gradient of CH₃CN from 0 to 25% (20 min) and then from 25 to 60% (5 min) in 0.1 M TEAA buffer (pH 6.8). For the nucleoside mixture containing **AntE** or **AcH**, HPLC was performed with a linear gradient of CH₃CN from 0 to 25% (20 min) and then from 25 to 80% (25 min) in 0.1 M TEAA buffer (pH 6.8).

the nucleoside composition was analyzed by HPLC (several examples are shown in Figure 3). Peaks corresponding to the modified nucleosides, confirmed by coelution with authentic samples, were observed, and the composition of the nucleosides calculated from the areas of the peaks was close to the theoretical value. Thus, this postsynthetic modification, in which we reacted ethylenediamine and 1,6-hexanediamine with a solid support containing the convertible nucleoside **1**, worked well without problems.

Duplex and Triplex Formation by Heptadecamers. Duplex formation of the heptadecamers **8–27** with the complementary ODN, 5'-d[TG(GA)₉GGT]-3' (**28**), was studied by thermal denaturation in 0.01 M NaCl. One transition was observed in the melting profile of each duplex. *T_m* values are shown in Table 1. All of the ODNs bearing the terminal amino groups and the intercalator stabilized the duplex formation. The thermal stabilities of the duplexes formed by **28** and ODNs **9** or **17**, which bore one molecule of **E** or **H** at the 5'-end, were almost the same, and therefore, at the 5'-end, the effect did not depend on the length of the linker, although the *T_m* values are higher than that of the control (5 and 6 °C, respectively). The ODNs **13** and **21**, which bore the anthraquinone group at the terminal amino group (**AntE** and **AntH**), showed even higher *T_m* values (7 and 9 °C, respectively), while the acetamidohexyl derivative **25** had a decreased *T_m*, which was still higher than that of the control duplex. Incorporation of one modified nucleoside at the center of ODNs such as **8**, **12**, **16**, **20**, and **24** had less of a stabilizing effect on duplex formation. However, with an increase in the number of **E** or **H** in heptadecamers such as **10**, **11**, **18**, and **19**, duplex stability increased somewhat proportionally and the increase in the *T_m* values was greater for ODNs containing **H** (**18** and **19**) than for those containing **E** (**10** and **11**). Since a stabilizing effect was not observed for ODNs containing **AcH** (**26** and **27**), the enhanced thermal stability of the duplexes is likely due to the effect of the terminal ammonium ion, which may be close to the phosphate

anion of the complementary strand or the self-strand. Introduction of the anthraquinone group to the terminal amino group, although it counteracts the stabilizing effect of the ammonium ion, gave higher *T_m* values than the control duplex, while an increase in the number of **AntE** or **AntH** did not produce a cumulative effect on the *T_m* values.

The importance of the ammonium ion in stabilizing duplexes was further examined in two ways. First, *T_m* values were compared under conditions of a higher (0.1 M NaCl) ionic strength (Table 1). $\Delta T_m [T_m (0.1 \text{ M NaCl}) - T_m (0.01 \text{ M NaCl})]$ for the control duplex (14 °C) was greater than those of duplexes **28** and **8** (11 °C), **10** (11 °C), **11** (10 °C), **18** (9 °C), and **19** (9 °C), whereas ΔT_m values (14 and 12 °C, respectively) for duplexes with ODNs containing **AcH** (**26** and **27**) were similar to or slightly lower than that of the control duplex. Thus, the effect of salt concentration on duplex stability indicates that the terminal ammonium ion stabilized duplex formation by neutralizing phosphate anions, which is consistent with a recent paper by Hashimoto *et al.* (34). For duplexes containing the intercalator group, the effects of intercalation on the stabilization of duplex formation should also be taken into account. Second, the polyacrylamide gel electrophoretic mobility (PAGE mobility) of **7** was compared with those of ODNs containing **H** and **AcH** using 5'-³²P-labeled ODNs. Relative PAGE mobility is calculated in Table 1. An increase in the number of **H** clearly decreased the relative mobility from 96 to 82%, although with an increase in size, changes with **AcH** were less than those with **H**. Therefore, it is clear that the ammonium ion at the terminal position of the linker can contribute to the stabilization of duplex formation.

Stable duplex formation with mRNA is one of the most important factors in antisense research. Therefore, duplex formation by heptadecamers with the complementary RNA strand, 5'-r[(AG)₈A]-3' (**30**), was next studied by thermal denaturation in a buffer of 0.01 M sodium cacodylate (pH 7) containing 0.1 M NaCl. As

Figure 4. PAGE of 5'-³²P-labeled ODNs hydrolyzed by snake venom phosphodiesterase: (a) **7**; (b) **8**; (c) **16**; (d) **12**; (e) **20**. ODNs were incubated with venom phosphodiesterase for 0 min (lane 1), 10 min (lane 2), 20 min (lane 3), 30 min (lane 4), 1 h (lane 5), and 2 h (lane 6). Experimental conditions are described under Experimental Procedures.

shown in Table 1, T_m values gradually increased when the number of modified nucleosides **E** or **H** increased in the ODNs. The increase in T_m values in ODNs containing **H** was greater than in ODNs containing **E** and a 6 °C increase was observed in **19**, which contains four **H**s in the ODN. On the other hand, attachment of the intercalator to the amino terminus did not produce a cumulative increase in T_m values. This tendency was different from that in duplexes with **28**. The data indicated structural differences between the DNA–DNA duplexes and the DNA–RNA duplexes, and the bulky intercalator may not be well-accommodated in the narrow major groove formed by the DNA–RNA duplexes.

Triplex formation by heptadecamers with the target duplex, d[AG(TC)₉C(T)₅AG(GA)₉CT]-3' (**29**), was also studied by thermal denaturation in a buffer containing 0.5 M NaCl (pH 7.0). Two transitions were observed in a melting profile of each triplex. Transitions at higher T_m values due to the melting of the target duplex **29** (88 °C) and transitions at lower T_m values due to dissociation of the third strands from the triplexes were observed (Table 1). While heptadecamers containing one molecule of **E** at both the 5'-end and at the center, as well as those with **H** at the 5'-end, did not stabilize triplex formation, the ODN containing one molecule of **H** at the center showed slight stabilization. When the terminal amino group was modified by the anthraquinone group, T_m values increased to 3 °C for **13** and to 5 °C for **21**, compared with that of the control triplex (36 °C), while ODNs **12** and **20** destabilized triplex formation. However, when the number of **E** or **H** together with **A^cH** per molecule increased, the T_m values tended to decrease. Therefore, further experiments are needed to identify the proper length for stabilizing triplex formation.

A postsynthetic modification method is a convenient approach to constructing ODNs with functional groups. Our newly developed method would be superior to the previously reported nucleobase-modified methods (27–

32) with regard to the thermal stability of both DNA–DNA and DNA–RNA duplexes. Substitutions of *O*⁴-(2,4,6-trimethylphenyl)uracil (**27**) and *O*⁶-phenylpurine (**28**) in ODNs by various amino nucleophiles to give ODNs with *N*⁴-aminoalkylcytosines and *N*⁶-aminoalkyladenines, respectively, have been reported. However, the introduction of linkers at the exocyclic amino groups reduced the T_m values of duplexes with unmodified complementary ODNs, due to a decrease in the acidity of exocyclic NH groups, which would be unfavorable for hydrogen bonding to the complementary nucleobases. The replacements of thymine by α-putrescinythymine (**25**) and 5-ω-amino-hexyluracil (**34**) also reduced the thermal stability of the duplexes. The pK_a value of the N3-H in **E** was measured by titration to be 8.1 (33), which is 1.7 units lower than that of thymidine and 1.2 units lower than that of 2'-deoxyuridine (35). Since incorporation of 5-propynyl-uracil (**36**, **37**) and 5-heteroaryluracils (**38**) into ODNs gives increased T_m values compared with unmodified duplexes, the introduction of such electron-withdrawing groups at the 5-position of uracil is important to obtain the thermal stability of duplexes.

In addition, a variety of amino nucleophiles can be conveniently incorporated into ODNs using our method, and the most suitable length of linkers for desired functions can be easily identified. Thus, the 1,6-diaminohexane linker was found to stabilize duplex formation with either DNA or RNA as a complementary strand, but not triplex formation. The importance of the ammonium ion was estimated by the effect of the salt concentration on T_m and by changes in mobility on PAGE. This is also supported by the fact that an increase in the number of ammonium ions in an ODN results in greater duplex stability. The terminal ammonium ion in **H** may effectively neutralize the phosphate negative charge, although whether its distal position is close to the phosphate anion in the complementary strand or that in the self-strand remains to be clarified. Moreover, an in-

Figure 5. PAGE of 5'- ^{32}P -labeled ODNs hydrolyzed by snake venom phosphodiesterase: (a) **7**; (b) **11**; (c) **19**; (d) **15**; (e) **23**. ODNs were incubated with venom phosphodiesterase for 0 h (lane 1), 3 h (lane 2), 6 h (lane 3), 12 h (lane 4), 24 h (lane 5), and 48 h (lane 6). Experimental conditions are described under Experimental Procedures.

tramolecular hydrogen bond between the O^4 atom and one of the carbamoyl protons was observed in the crystal structure of 5-carbamoyl-2'-deoxyuridine (**33**). Although it is not clear whether this conformational fixation contributes to stabilization of the duplexes, the enhanced hydrogen-donor ability at N3-H and the neutralizing effect of the terminal ammonium ion should work in cooperation to give duplex stabilization. Therefore, ODNs containing **H** can be useful for antisense studies if they have nuclease-resistance properties.

Nuclease Resistance of Modified ODNs. Resistance of the heptadecamers to nucleolytic digestion was examined next. The heptadecamers **8**, **12**, **16**, and **20**, which carried modified nucleosides in their centers, were labeled at the 5'-end with ^{32}P and incubated with snake venom phosphodiesterase, a 3'-exonuclease. The reactions were then analyzed by 20% PAGE under denaturing conditions (Figure 4). Due to a difference in the rate of hydrolysis between 5'-TpM-3' linkages and 5'-MpT-3' linkages, spots for the newly generated ODNs containing an M residue at the 3'-end were faint, while spots for ODNs containing a T residue at the 3'-end were bold. Although the control **7** was hydrolyzed randomly within 2 h, all of the modified ODNs were hydrolyzed only at the 3'-side of the modified nucleosides. The phosphodiester linkages at the 5'-side of the modified nucleosides were completely resistant to the nuclease for 2 h.

On the other hand, the ^{32}P -labeled ODNs **11**, **15**, **19**, and **23**, which contained four modified nucleoside residues, were completely resistant to the nuclease for 2 h under the same conditions (data not shown). After 3 h, they began to be gradually hydrolyzed, and the half-lives of these ODNs were about 105, 126, 162, and 48 h, respectively (Figure 5). The control ODN **7** was completely hydrolyzed randomly within 3 h under the same conditions. Thus, ODNs containing 5-(*N*-aminoalkyl)-carbamoyluracils and with an anthraquinone group at the terminal amino group were fairly stable against the nuclease, although other nucleases with different substrate specificity remain to be elucidated.

Figure 6. PAGE of 5'- ^{32}P -labeled ODNs incubated in the medium containing 10% FCS: (a) **7**; (b) **19**. ODNs were incubated for 0 min (lane 1), 15 min (lane 2), 30 min (lane 3), 1 h (lane 4), 3 h (lane 5), 5 h (lane 6), 10 h (lane 7), 24 h (lane 8), and 48 h (lane 9). Experimental conditions are described under Experimental Procedures.

Next, we compared the stabilities of **7** and **19** in a medium containing 10% FCS. A mixture of ^{32}P -labeled **7** or **19** (at the 5'-ends) with their unlabeled ODN (25 μM) was incubated separately in FCS, which was partially heat-denatured for 30 min at 56 $^{\circ}\text{C}$ prior to use, and analyzed by 20% PAGE under denaturing conditions (Figure 6). The half-lives of these ODNs were 13 min

and 48 h, respectively. This experiment clearly shows that **19** is fairly stable in the presence of 10% fetal calf serum (FCS). Thus, due to both the thermal stabilization and nuclease resistance conferred by the 5-(*N*-amino-hexyl)carbamoyl substituent, ODNs containing **H** should be suitable for use as antisense ODNs.

CONCLUSION

A new postsynthetic modification method was developed using 5-(methoxycarbonyl)-2'-deoxyuridine (**1**) as a convertible nucleoside unit. After incorporation of **1** into ODNs attached to a solid support, treatment of the resin with alkyldiamines proceeded concomitantly with several processes, such as incorporation of the alkyldiamines into the ODN, deprotection, and detachment from the solid support to give the desired modified ODNs in which modified uracils were incorporated in appropriate numbers and positions. Furthermore, the modified heptadecamers were fairly stable to nuclease degradation using a 3'-exonuclease and to FCS. These properties make the ODNs potentially useful as antisense ODNs. Related studies are currently underway in our laboratory.

EXPERIMENTAL PROCEDURES

General Experimental Data. TLC was done on Merck Kieselgel F254 precoated plates (Merck). The silica gel, the neutralized silica gel, or the silanized silica gel used for column chromatography was YMC gel 60A (70–230 mesh) (YMC Co., Ltd.), ICN silica 60A (ICN Biochemicals), or preparative C₁₈ (Waters, 125Å). Melting points were measured on a Yanagimoto MP-3 micro melting point apparatus (Yanagimoto) and are uncorrected. Fast atom bombardment mass spectrometry (FAB-MS) was measured on a JEOL JMS-HX110 (JEOL) at an ionizing voltage of 70 eV. The ¹H NMR spectra were recorded on a JEOL JNM-GX 270 (270 MHz) or JEOL EX 400 (400 MHz) spectrometer (JEOL) with tetramethylsilane as an internal standard. Chemical shifts are reported in parts per million (δ), and signals are expressed as s (singlet), d (doublet), t (triplet), m (multiplet), or br (broad). All exchangeable protons were detected by disappearance on the addition of D₂O. UV absorption spectra were recorded with a Shimadzu UV-240 spectrophotometer (Shimadzu Co.).

5-(Methoxycarbonyl)-5'-*O*-(dimethoxytrityl)-2'-deoxyuridine (3**).** Dimethoxytrityl chloride (12.4 g, 36.7 mmol) was added to a solution of **1** (33) (10.0 g, 34.9 mmol) in anhydrous pyridine (100 mL), and the mixture was stirred overnight at room temperature. EtOH (10 mL) was added to the mixture, and the whole was stirred for 10 min. The mixture was concentrated *in vacuo* and was taken in CHCl₃, which was washed with saturated aqueous NaHCO₃ (two times) and brine. The separated organic phase was dried (Na₂SO₄) and concentrated to dryness. The residue was purified on a silica gel column (6 × 35 cm) with 0–8% MeOH in CHCl₃ containing 0.2% pyridine to give **3** (18.3 g, 87%, as a white foam): FAB-MS, *m/z* 590 (M⁺ + 1); NMR (CDCl₃) δ 8.69 (1 H, s, H-6), 8.23 (1 H, br s, 3-NH), 6.81–7.45 (13 H, m, Ph), 6.26 (1 H, t, H-1', *J*_{1',2'} = 6.7 Hz), 4.40–4.47 (1 H, m, H-3'), 4.03–4.09 (1 H, m, H-4'), 3.80 (6 H, s, OMe), 3.54 (1 H, dd, H-5'a, *J*_{5'a,4'} = 4.0, *J*_{gem} = 10.5 Hz), 3.33 (1 H, dd, H-5'b, *J*_{5'b,4'} = 3.4, *J*_{gem} = 10.5 Hz), 3.30 (3 H, s, CO₂Me), 2.52 (1 H, ddd, H-2'a, *J*_{2'a,1'} = 6.7, *J*_{2'a,3'} = 4.0, *J*_{gem} = 12.3 Hz), 2.29 (1 H, dd, H-2'b, *J*_{2'b,1'} = 6.7, *J*_{gem} = 12.3 Hz), 2.01–1.92 (1 H, m, 3'-OH).

5-[(*N*-Aminoethyl)carbamoyl]-2'-deoxyuridine (E**).** Ethylenediamine (2.0 mL, 23 mmol) was added to a solution of **3** (400 mg, 0.68 mmol) in MeOH (4 mL), and

the mixture was stirred for 2 days at room temperature. The volatiles were removed *in vacuo*, and the residue was taken in CHCl₃, which was washed with saturated aqueous KH₂PO₄ (two times) and brine. The separated organic phase was dried (Na₂SO₄) and concentrated. The residue was dissolved in aqueous 80% AcOH (10 mL), and the mixture was stirred for 5.5 h at room temperature. The solvent was removed *in vacuo*, and the residue was coevaporated several times with H₂O. The residue was partitioned between H₂O and Et₂O (two times). The H₂O phase was concentrated, and the residue was crystallized from Et₂O with saturated H₂O to give **E** (157 mg, 73%): mp 218 °C (dec); FAB-MS, *m/z* 315 (M⁺ + 1); UV λ_{max} (H₂O) 277 nm (ε 15 100), λ_{max} (0.1 N HCl) 276 nm (ε 17 000), λ_{max} (0.1 N NaOH) 276 nm (ε 14 000); NMR (D₂O) δ 8.63 (1 H, s, H-6), 6.29 (1 H, t, H-1', *J*_{1',2'} = 6.5 Hz), 4.41–4.51 (1 H, m, H-3'), 4.05–4.12 (1 H, m, H-4'), 3.85 (1 H, dd, H-5'a, *J*_{5'a,4'} = 4.2, *J*_{gem} = 11.0 Hz), 3.77 (1 H, dd, H-5'b, *J*_{5'b,4'} = 3.5, *J*_{gem} = 11.0 Hz), 3.65 (2 H, t, CONDCHa₂CHb₂, *J*_{a,b} = 5.5 Hz), 3.16 (2 H, t, CONDCHa₂CHb₂, *J*_{b,a} = 5.5 Hz), 2.18–2.43 (2 H, m, H-2'a,b). Anal. (C₁₂H₁₈N₄O₆·1/2H₂O): C, 44.58; H, 5.92; N, 17.33. Found: C, 44.52; H, 5.76; N, 17.36.

5-[(*N*-Acetamidoethyl)carbamoyl]-2'-deoxyuridine (^{Ac}E**).** Acetic anhydride (0.13 mL, 1.44 mmol) was added to a solution of **E** (100 mg, 0.32 mmol) in pyridine (4 mL) containing DMAP (10 mg), and the reaction mixture was stirred for 2 days at room temperature. H₂O (1 mL) was added to the mixture, and the whole was further stirred for 10 min. The solvent was removed *in vacuo*, and the residue was coevaporated several times with H₂O. The residue was treated with NH₃/MeOH (saturated at 0 °C, 4 mL) overnight at room temperature, and the solvent was removed *in vacuo*. The residue was purified on a silica gel column (1.9 × 5 cm) with 0–20% MeOH in CHCl₃ to give **^{Ac}E** (37 mg, 31% as a white crystal): mp 203–205 °C; FAB-MS, *m/z* 357 (M⁺ + 1); UV λ_{max} (H₂O) 277 nm (ε 12 900), λ_{max} (0.1 N HCl) 276 nm (ε 14 300), λ_{max} (0.1 N NaOH) 277 nm (ε 13 800); NMR (DMSO-*d*₆) δ 11.86 (1 H, br s, 3-NH), 8.75 (1 H, t, 5-CONH, *J* = 5.5 Hz), 8.69 (1 H, s, H-6), 7.92–7.94 (1 H, m, AcNH), 6.12 (1 H, dd, H-1', *J*_{1',2'a} = 7.1, *J*_{1',2'b} = 6.1 Hz), 5.26 (1 H, d, 3'-OH, *J* = 3.9 Hz), 4.98–5.01 (1 H, m, 5'-OH), 4.21–4.24 (1 H, m, H-3'), 3.83–3.87 (1 H, m, H-4'), 3.55–3.57 (2 H, m, H-5'a,b), 3.25–3.38 (2 H, m, 5-CONHCHa₂CHb₂), 3.15 (2 H, dt, 5-CONHCHa₂CHb₂, *J*_{b,a} = 6.0, *J*_{b,NH} = 5.5 Hz), 2.12–2.18 (2 H, m, H-2'a,b), 1.78 (3 H, s, Ac). Anal. Calcd for C₁₄H₂₀N₄O₇: C, 47.19; H, 5.66; N, 15.72. Found: C, 47.06; H, 5.78; N, 15.51.

5-[[*N*-(2-Anthraquinonylcarbonyl)amino]ethyl]-carbamoyl]-2'-deoxyuridine (^{Ant}E**).** Ethylenediamine (0.50 mL, 5.75 mmol) was added to a solution of **3** (59 mg, 0.10 mmol) in MeOH (2 mL), and the mixture was stirred for 2 days at room temperature. The solvent was removed *in vacuo* and the residue was taken in CHCl₃, which was washed with saturated aqueous KH₂PO₄ (two times) and brine. The separated organic phase was dried (Na₂SO₄) and concentrated. Anthraquinone-2-carboxylic acid (76 mg, 0.30 mmol) and 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (57 mg, 0.30 mmol) were added to a solution of the residue in a mixture of pyridine and DMF (1:1, 2 mL). The reaction mixture was stirred overnight at room temperature and was diluted with CHCl₃. The solution was washed successively with H₂O (two times), saturated aqueous NaHCO₃ (two times), and brine. The separated organic phase was dried (Na₂SO₄) and was concentrated to dryness. The residue was treated with NH₃/MeOH (saturated at 0 °C, 5 mL) overnight at room temperature, and the solvent was removed. The residue was further treated with aqueous

80% AcOH (5 mL) for 2 h at room temperature. The solvent was removed, and the residue was coevaporated with H₂O. The residue was purified on a silica gel column (1.1 × 14 cm) with 0–8% MeOH in CHCl₃ to give **AntE** (18 mg, 31% as an oil). A part of the sample was crystallized from EtOH: mp 187–189 °C; FAB-MS, *m/z* 549 (*M*⁺ + 1); NMR (DMSO-*d*₆) δ 11.86 (1 H, br s, 3-NH), 9.06–9.08 (1 H, m, anthraquinone-CONH), 8.87–8.89 (1 H, m, 5-CONH), 8.71 (1 H, s, H-6), 7.95–8.65 (7 H, m, anthraquinone), 6.12 (1 H, t, H-1', *J*_{1',2'} = 6.6 Hz), 5.28 (1 H, d, 3'-OH), 5.01 (1 H, t, 5'-OH), 4.21–4.24 (1 H, m, H-3'), 3.84–3.85 (1 H, m, H-4'), 3.53–3.57 (2 H, m, H-5'a,b), 3.43–3.50 (4 H, m, NCH₂CH₂N), 2.13–2.20 (2 H, m, H-2'a,b). Anal. Calcd for C₂₇H₂₄N₄O₉: C, 59.12; H, 4.41; N, 10.21. Found: C, 58.93; H, 4.60; N, 10.08.

5-[(N-Aminohexyl)carbamoyl]-2'-deoxyuridine (H). To a solution of **3** (2.0 g, 3.39 mmol) in MeOH (30 mL) was added 1,6-diaminohexane (11.8 g, 101 mmol), and the mixture was stirred overnight at room temperature. Workup and the detritiation were done as described for the synthesis of **E** to give **H** (704 mg, 56%, crystallized from MeOH): mp 213 °C; FAB-MS, *m/z* 371 (*M*⁺ + 1); UV λ_{max} (H₂O) 276 nm (ε 12 300), λ_{max} (0.1 N HCl) 277 nm (ε 14 200), λ_{max} (0.1 N NaOH) 276 nm (ε 12 100); NMR (DMSO-*d*₆ + D₂O) δ 8.67 (1 H, s, H-6), 6.12 (1 H, t, H-1', *J*_{1',2'} = 6.5 Hz), 4.24–4.22 (1 H, m, H-3'), 3.88–3.84 (1 H, m, H-4'), 3.57–3.55 (2 H, m, H-5'a,b), 3.32–3.24 (4 H, m, 5-CONHCH₂CH₂), 2.21–2.12 (2 H, m, H-2'a,b), 1.54–1.24 [8 H, m, -(CH₂)₄]. Anal. Calcd for C₁₆H₂₆N₄O₆·1/2 H₂O: C, 50.65; H, 7.17; N, 14.77. Found: C, 50.73; H, 7.08; N, 14.52.

5-[(N-Acetamidohexyl)carbamoyl]-2'-deoxyuridine (AcH). To a solution of **3** (200 mg, 0.34 mmol) in MeOH (4 mL) was added 1,6-diaminohexane (788 mg, 6.80 mmol). The mixture was stirred for 3 days at room temperature. The volatile was removed *in vacuo*, and pyridine (6 mL) was added to the residue. The resulting precipitates were removed by filtration, and Ac₂O (0.60 mL, 15.3 mmol) and DMAP (41 mg, 0.34 mmol) were added to the filtrate. The mixture was stirred overnight at room temperature. H₂O (1 mL) was added to the mixture, the solvent was concentrated, and the residue was coevaporated several times with H₂O. The residue was taken in CHCl₃, which was washed with saturated aqueous NaHCO₃ (two times) and brine. The separated organic phase was dried (Na₂SO₄) and concentrated. The residue was treated with aqueous 80% AcOH (10 mL) overnight at room temperature. The solvent was removed *in vacuo* and coevaporated several times with H₂O. The residue was kept in NH₃/MeOH (saturated at 0 °C, 4 mL) overnight at room temperature, and the solvent was concentrated *in vacuo*. The residue was purified on a silica gel column (2.5 × 13 cm) with 0–15% MeOH in CHCl₃ to give **AcH** (98 mg, 70%, as a white solid): mp 162–163 °C; FAB-MS, *m/z* 413 (*M*⁺ + 1); UV λ_{max} (H₂O) 277 nm (ε 13 700), λ_{max} (0.1 N HCl) 276 nm (ε 14 700), λ_{max} (0.1 N NaOH) 276 nm (ε 14 300); NMR (DMSO-*d*₆) δ 11.86 (1 H, br s, 3-NH), 8.70 (1 H, t, 5-CONH, *J* = 6.3 Hz), 8.67 (1 H, s, H-6), 7.76 (1 H, br s, AcNH), 6.12 (1 H, t, H-1', *J*_{1',2'} = 6.5 Hz), 5.28 (1 H, d, 3'-OH, *J* = 3.9 Hz), 4.98–5.00 (1 H, m, 5'-OH), 4.23–4.24 (1 H, m, H-3'), 3.85–3.86 (1 H, m, H-4'), 3.54–3.56 (2 H, m, H-5'a,b), 3.24 (2 H, q, 5-CONHCH₂CH₂, *J*_{a,b} = *J*_{a,NH} = 6.6 Hz), 2.99 (2 H, q, CONHCH₂CH₂, *J*_{b,a} = *J*_{b,NH} = 6.3 Hz), 2.12–2.20 (2 H, m, H-2'a,b), 1.77 (3 H, s, Ac), 1.24–1.48 [8 H, m, -(CH₂)₄]. Anal. Calcd for C₁₈H₂₈N₄O₇·1/2 H₂O: C, 51.30; H, 6.94; N, 13.29. Found: C, 51.46; H, 6.87; N, 13.26.

5-[(N-Anthraquinonylcarbamoyl)amino]hexyl]-carbamoyl]-2'-deoxyuridine (AntH). A mixture of **3**

(400 mg, 0.609 mmol) and 1,6-diaminohexane (2.12 g, 18.3 mmol) in MeOH (10 mL) was heated for 2 days at 50 °C. Workup and condensation with anthraquinone-2-carboxylic acid (231 mg, 0.914 mmol) and 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (174 mg, 0.914 mmol) were done as described for the synthesis of **AntE** to give **AntH** (42 mg, 11% as a yellow solid): mp 200–201 °C; FAB-MS, *m/z* 605 (*M*⁺); UV λ_{max} (MeOH) 257 nm (ε 30 900), 309 nm (ε 3 000), 319 nm (ε 3 200), 323 nm (ε 3 300), λ_{max} (0.1 N HCl) 258 nm (ε 35 000), 271 nm (ε 18 800), 278 nm (ε 19 100), 327 nm (ε 3 900), λ_{max} (0.1 N NaOH) 258 nm (ε 35 700), 278 nm (ε 20 000), 328 nm (ε 4 900); NMR (DMSO-*d*₆) δ 11.86 (1 H, br s, 3-NH), 8.94 (1 H, t, 5-CONH, *J* = 5.5 Hz), 8.73 (1 H, t, CH₂-NHCO), 8.69 (1 H, s, H-6), 8.66 (1 H, s, ant-H), 8.33 (2 H, d, ant-H, *J* = 6.3 Hz), 8.27 (1 H, d, ant-H, *J* = 4.8 Hz), 8.24 (2 H, d, ant-H, *J* = 4.8 Hz), 7.99–7.96 (2 H, m, ant-H), 6.13 (1 H, t, H-1', *J*_{1',2'} = 6.5 Hz), 5.28 (1 H, d, 3'-OH, *J* = 4.2 Hz), 5.00 (1 H, m, 5'-OH, *J* = 4.8 Hz), 4.26–4.23 (1 H, m, H-3'), 3.86 (1 H, dt, H-4', *J*_{4',5'a} = *J*_{4',3'} = 3.5 Hz), 3.58–3.55 (2 H, m, H-5'a,b), 3.27 (2 H, q, 5-CONHCH₂CH₂, *J*_{a,b} = *J*_{a,NH} = 6.5 Hz), 2.21–2.14 (2 H, q, CONHCH₂CH₂, *J*_{b,a} = 6.5 Hz), 2.21–2.14 (2 H, m, H-2'a,b), 1.59–1.36 [8 H, m, -(CH₂)₄]. Anal. Calcd for C₃₁H₃₂N₄O₉·MeOH: C, 60.37; H, 5.70; N, 8.80. Found: C, 60.09; H, 5.66; N, 8.59.

β-Cyanoethyl [5-(Methoxycarbonyl)-5'-O-(dimethoxytrityl)-2'-deoxyuridin-3'-O-yl]-N,N-diisopropylphosphoramidite (4). After successive coevaporation with pyridine, **3** (0.50 g, 0.85 mmol) was dissolved in anhydrous CH₂Cl₂ (10 mL) containing *N,N*-diisopropylethylamine (0.29 mL, 1.7 mmol). 2-Cyanoethyl *N,N*-diisopropylphosphoramidochloride (0.22 mL, 1.28 mmol) was added to the solution, and the reaction mixture was stirred for 50 min at room temperature. The mixture was diluted with CHCl₃ and washed with saturated aqueous NaHCO₃ (two times) and brine. The separated organic phase was dried (Na₂SO₄) and concentrated. The residue was purified on a neutral silica gel column (2.2 × 10 cm) with EtOAc to give **4** (0.57 g, 85% as white foam): FAB-MS, *m/z* 789 (*M*⁺); ³¹P NMR (CDCl₃) 144.59 and 144.08.

5-(Methoxycarbonyl)-5'-O-(dimethoxytrityl)-3'-O-[(pentachlorophenyl)succinyl]-2'-deoxyuridine (6). Succinic anhydride (51 mg, 0.51 mmol) was added to a solution of **3** (200 mg, 0.34 mmol) in anhydrous pyridine (3 mL). The mixture was stirred at 70 °C overnight. H₂O (10 mL) was added to the mixture, and the whole was further stirred for 10 min. The solvent was removed *in vacuo*, and the residue was purified over a silica gel column (1.9 × 15 cm) with 0–10% MeOH in CHCl₃ to give **5** (198 mg, 85% as a pale brown foam): FAB-MS, *m/z* 688 (*M*⁺ + 1). Pentachlorophenol (88 mg, 0.34 mmol) and 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (81 mg, 0.42 mmol) were added to a solution of **5** (198 mg, 0.29 mmol) in DMF (2 mL). The mixture was stirred for 4 h at room temperature and then diluted with EtOAc. The solution was washed successively with H₂O (two times), saturated aqueous NaHCO₃ (two times), and brine. The separated organic phase was dried (Na₂SO₄) and concentrated. The residue was purified over a neutral silica gel column (2.2 × 21 cm) with EtOAc/hexane (1:1) to give **6** (121 mg, 46% as a white foam): FAB-MS, *m/z* 936 (*M*⁺); NMR (CDCl₃) δ 8.71 (1 H, s, H-6), 8.03 (1 H, br s, 3-NH), 6.81–7.42 (13 H, m, Ph), 6.26 (1 H, dd, H-1', *J*_{1',2'a} = 5.2, *J*_{1',2'b} = 8.8 Hz), 5.31–5.34 (1 H, m, H-3'), 4.15–4.18 (1 H, m, H-4'), 3.79 (6 H, s, OMe), 3.56 (1 H, dd, H-5'a, *J*_{5'a,4'} = 3.3, *J*_{gem} = 10.7 Hz), 3.33 (1 H, dd, H-5'b, *J*_{5'b,4'} = 2.8, *J*_{gem} = 10.7 Hz), 3.24 (3 H, s, CO₂Me), 3.02 (2 H, t, 3'-OCOCH₂CH₂, *J*_{3',2'} = 6.6 Hz).

$J_{a,b} = 6.5$ Hz), 2.77 (2 H, t, 3'-OCOCH₂CHb₂, $J_{b,a} = 6.5$ Hz), 2.05–2.58 (2 H, m, H-2'a,b).

Synthesis of the CPG Support Containing 5-(Methoxycarbonyl)-5'-*O*-(dimethoxytrityl)-2'-deoxyuridine. Aminopropyl CPG (376 mg, 32.3 μ mol, 85.7 μ mol/g, CPG Inc., NJ) was added to a solution of **6** (121 mg, 129 mmol) in anhydrous DMF (1 mL), and the mixture was kept for 22 h at room temperature. After the resin was washed with anhydrous pyridine, 1 mL of a capping solution (0.1 M DMAP in pyridine/Ac₂O = 9:1) was added, and the whole was kept for 2 h at room temperature. The resin was washed with EtOH and acetone and was dried under vacuum. The amount of loaded nucleoside to the solid support is 21.9 μ mol/g from the calculation of released dimethoxytrityl cation by 0.1 M *p*-toluene-sulfonic acid in CH₃CN.

Synthesis of ODNs. ODNs were synthesized on a DNA synthesizer (Applied Biosystem Model 381A, CA) according to the phosphoramidite method using 1 μ mol of nucleoside residue attached to the resin (39). For the incorporation of 5-methylcytidine, β -cyanoethyl [*N*-(dimethylamino)methylene]-5'-*O*-(dimethoxytrityl)-2'-deoxy-5-methylcytidin-3'-*O*-yl]-*N,N*-diisopropylphosphoramidite was used (0.1 M in CH₃CN solution). Then, fully protected ODNs bearing the solid support were treated with ethylenediamine (1 mL) or 1,6-hexanediamine (400 mg) in MeOH (1 mL) at room temperature or at 45 °C for 12–14 h. After filtration of the resin, which was washed well with MeOH, the filtrate was concentrated *in vacuo*. The residue obtained from the reaction with ethylenediamine was purified by C₁₈ silica gel column chromatography (1.0 \times 7 cm) with a linear gradient of CH₃CN from 0 to 30% in 0.1 M TEAA buffer (pH 7.2). The residue obtained from the reaction with 1,6-hexanediamine was chromatographed on Sephadex G-25 (1.7 \times 27 cm) with 0.1 M TEAA buffer (pH 7.2) before purification on the C₁₈ column. Fractions were concentrated, and the residue was treated with 80% AcOH at room temperature for 20 min; then the solution was concentrated, and the residue was coevaporated with water. The residue was dissolved in water, and the solution was washed with Et₂O; then the H₂O layer was concentrated to give a deprotected ODN. The sample was purified on a DEAE cellulose column (1 \times 9 cm) with a linear gradient from 0.1 to 1.0 M TEAB buffer (pH 8) and then further purified by HPLC with a C₁₈ silica gel column (Inertsil ODS-2, GL Science Inc.) using a gradient of solution A (5% CH₃CN in 0.1 N TEAA buffer, pH 7.0) and solution B (50% CH₃CN in 0.1 N TEAA buffer) to give **8** (23.0), **9** (12.6), **10** (8.5), **11** (11.7), **16** (20.4), **17** (12.4), **18** (16.6), and **19** (14.5). The yields are indicated in parentheses as OD units at 260 nm starting from 1 μ mol scale.

Acetylation of ODNs. A solution containing each ODN (1.0 OD unit at 254 nm) and acetic anhydride (2 μ L) in 0.2 M HEPES buffer (200 μ L, pH 7.2) was kept for 1 h at room temperature. Concentrated NH₄OH (400 μ L) was added to the mixture, and the whole was kept overnight at 4 °C. The solvent was removed *in vacuo*, and the residue was purified by HPLC with the C₁₈ column. Average yields for **24**–**27** were >70%.

Reaction of ODNs with *N*-(Anthraquinone-2-carbonyl)oxy)succinimide. A solution containing each ODN (0.5–3.0 OD units at 254 nm) and *N*-(anthraquinone-2-carbonyl)oxy)succinimide (**17**) (50 μ L, 20 mg/mL in DMF) in 0.05 M NaHCO₃/Na₂CO₃ (50 μ L, pH 10.3) was kept overnight at room temperature. The solvent was removed *in vacuo*, and the residue was taken in H₂O (300 μ L). The solution was acidified by adding 1 N HCl (10–20 μ L) to pH 3–4 and was washed with EtOAc (eight

times). The aqueous phase was neutralized by adding saturated aqueous NaHCO₃, and each ODN was purified by HPLC with the C₁₈ column. Average yields for **12**–**15** and **20**–**23** were more than 70%.

Complete Hydrolysis of ODNs. A solution containing alkaline phosphatase (0.4 unit, Takara Shuzo Co., Ltd.) in 0.1 M Tris-HCl (pH 7.7) and 2 mM MgCl₂ (total 130 μ L) was heated on boiling water for 10 min to inactivate adenosine deaminase activity contaminated in the enzyme solution. The solution and snake venom phosphodiesterase (10 μ g, Boehringer Mannheim) were added to each ODN (0.2 OD unit), and the whole was incubated at 37 °C for 24 h. After heating on boiling water for 5 min, cold EtOH (320 μ L) was added to the reaction mixture, and the whole was kept at –20 °C for 1 h. The cold solution was centrifuged for 20 min (12 000 rpm), and then a supernatant was separated and concentrated. The residue was analyzed by HPLC with the C₁₈ column.

Thermal Denaturation. Each solution contains each ODN (3 μ M) and the complementary strand **28** (3 μ M) and **30** (3 μ M) or the target duplex **29** (3 μ M) in an appropriate buffer. The solution containing each ODN was heated 70 °C for 20 min, then cooled gradually to an appropriate temperature, and used for the thermal denaturation studies. Thermally induced transition of each mixture was monitored at 260 nm on a Gilford Response II. Sample temperature was increased 1 °C/min. Each T_m is given as an average of three measurements.

Partial Hydrolysis of ODN with Venom Phosphodiesterase. Each ODN labeled with ³²P at the 5' end (0.01 OD unit) (**40**) was incubated with venom phosphodiesterase (0.4 mg) in the presence of Torula RNA (0.3 OD unit at 260 nm) in a buffer containing 37.5 mM Tris-HCl (pH 8.0) and 7.5 mM MgCl₂ (total 20 μ L) at 37 °C. Aliquots of the reaction mixture were separated and added to a solution of EDTA (5 mM, 10 μ L) at appropriate periods, and then the mixtures were heated at 100 °C for 3 min. The solutions were analyzed by electrophoresis on 20% polyacrylamide gel containing 8 M urea (**40**). Densities of radioactivity of the gel were visualized by a Bio-imaging Analyzer (Bas 2000, Fuji, Co. Ltd.).

Stability of **19 in the Medium Containing FCS.** The ODN **7** or **19** labeled with ³²P at the 5' end (10 pmol) was mixed with the corresponding unlabeled ODN (each 1 nmol). The mixture was incubated in RPMI 1640 medium (40 μ L) containing 10% FCS (heat-denatured at 56 °C for 30 min prior to use) at 37 °C. Aliquots (4 μ L) of the reaction mixture were separated and added to a solution of EDTA (5 mM, 10 μ L) at appropriate periods, and then the mixtures were heated at 100 °C for 5 min. The solutions were analyzed by electrophoresis on 20% polyacrylamide gel containing 8 M urea. The gels were analyzed as described above.

ACKNOWLEDGMENT

Synthesis of Conjugates for a Barbiturate Screening Assay

Maciej Adamczyk,* Jonathan Grote, Jeanine Douglas, Robert Dubler, and Charles Harrington

Department of Chemistry (D9NM), Abbott Diagnostics Division, Abbott Laboratories, 100 Abbott Park Road, Abbott Park, Illinois 60064-3500. Received November 29, 1996*

Novel derivatives of barbiturates functionalized with free carboxylic acids were designed and synthesized. Coupling of 5-cyclopentyl-5-carboxycrotylbarbituric acid via its active ester to an aminofluorescein derivative produced a fluorescent tracer. Conjugation of the 5-cyclopentenyl-5-carboxyethylbarbituric acid via its mixed anhydride to thyroglobulin allowed for subsequent development of a polyclonal antibody which was evaluated for binding in a fluorescence polarization immunoassay format with various barbiturates. The binding studies showed good cross-reactivity of a variety of barbiturates containing both aromatic and aliphatic 5-substituents with the tested antisera. The relationship between the immunogen architecture, the chemical structure of the binding analytes, and the characteristics of the antisera is also presented.

INTRODUCTION

Barbiturates are central nervous system depressants that are frequently administered on a therapeutic basis as sedatives, hypnotics, and anticonvulsants. These drugs have been known for several decades, having been introduced into therapeutic use by Fisher and von Mering in the early 1900s (1). A large number of different barbiturates have since been synthesized, several of which are still in use (2).

Disubstitution at the 5-position is required for pharmacological activity, as unsubstituted or 5-monosubstituted barbituric acids demonstrate no CNS activity. Small structural variations in these 5-substituents cause substantial changes in the drug's physiological effects and duration (2). Because of the rapid onset of their CNS activity, the most frequently abused barbiturates (including secobarbital, pentobarbital, and amobarbital) have alone or in combination with other drugs been frequently used to commit suicide (3, 4). Therefore, rapid determination of the presence or absence of barbiturates in a comatose patient prior to emergency medical treatment can be the difference between life and death (4).

Structurally, barbiturates can be divided into two classes: those containing aliphatic 5-substituents (such as secobarbital, Figure 1) and those containing an aromatic 5-substituent (such as phenobarbital, Figure 1).

The ideal screening assay for barbiturates would allow for rapid determination of the presence or absence of a variety of structures with subtle structural differences. Competitive binding immunoassay techniques are advantageous over chromatographic techniques such as high-performance liquid chromatography (HPLC) and gas chromatography (GC) for this purpose, since chromatographic techniques need initial sample extraction and have lengthy assay time requirements (5). However, immunoassay techniques such as enzyme immunoassay (EIA) and substrate-linked fluorescence immunoassay (SLFIA) both contain enzymes that are sensitive to enzyme inhibitors or other reactive enzymes contained in the sample (6), while radioimmunoassay (RIA) has other severe shortcomings, including short shelf life

Figure 1. Structures of secobarbital and phenobarbital.

Scheme 1. Synthesis of the Barbiturate Immunogen

reagents and the hazards of working with, storage of, and disposal of radioactive materials (7). Alternatively, fluorescence polarization immunoassay (FPIA) is ideally suited for automation and employs fluorescent tracers and antibodies, thus avoiding the disadvantages associated with enzyme sensitivity and the hazards of radio-labeled tracers (8).

The quality of a screening immunoassay greatly depends on the availability of antibodies that are specific for the target class of analytes. In this work, we present the design and synthesis of a hapten that shows the structural properties of both the aliphatic and aromatic classes of barbiturates (Scheme 1). This hapten was conjugated to prepare an immunogen useful for eliciting antibodies in sheep. A complementary fluorescent tracer was also synthesized (Scheme 2). The binding characteristics of the obtained antibodies were assessed with various barbiturates in competition with the fluorescent tracer.

Scheme 2. Synthesis of the Barbiturate Tracer**MATERIALS AND METHODS**

All reagents were purchased from Aldrich Chemical Co., Inc., Milwaukee, WI, and were used without further purification, except where noted. Solvents (HPLC grade) and silica gel were obtained from E. Merck Science, Darmstadt, Germany, and were used without further purification. ^1H NMR and ^{13}C NMR were recorded at 300 and 75 MHz, respectively, on a Varian Gemini 300 spectrometer with tetramethylsilane (TMS) as internal standard. Electrospray mass spectrometry (ESMS) was performed on a Perkin-Elmer Siex API III. HPLC was performed on a Waters RCM C_{18} (8 \times 100 mm) reversed phase μ Bondapak column at 2 mL/min (detection at 220 nm) with the solvent indicated.

Preparation of the Barbiturate Immunogen (5). Dicyclopentadiene (50 mL) was depolymerized (9), providing 31.22 g of cyclopentadiene. To the cyclopentadiene cooled to -78°C was added gaseous HCl (9) in portions until the weight had increased to 46.4 g. The resulting crude 3-chlorocyclopentene was added in portions to a preformed solution of sodium diethylmalonate, prepared by adding diethyl malonate (73 mL, 0.48 mol) to a solution of sodium (11.0 g, 0.48 mol) in ethanol (200 mL). Each addition of the 3-chlorocyclopentene produced a noticeably exothermic reaction. After the addition was complete, the resulting yellow suspension was refluxed for 14 h. Most of the ethanol was removed by rotary evaporation from the cooled solution, and the residue was diluted with 300 mL of water. The solution was extracted with ether (3 \times 100 mL), and the combined ether extracts were washed with water (2 \times 50 mL), dried over MgSO_4 , and concentrated to a red oil. Distillation provided 45.194 g (42%) of diethyl cyclopentenylmalonate (**1**) as a colorless oil: bp $99\text{--}103^\circ\text{C}$ (0.8 mm); ^1H NMR (CDCl_3) δ 5.81 (ddd, olef H, 1H, $J = 5.7, 4.5$, and 2.3 Hz), 5.66 (ddd, olef H, 1H, $J = 5.7, 4.3$, and 2.1 Hz), 4.18 (q, ethyl CH_2 , 4H, $J = 7.1$ Hz), 3.34 (m, allyl CH, 1H), 3.22 (d, 1H, malonate CH, $J = 9.6$ Hz), 2.34 (m, allyl CH_2 , 2H), 2.13 (m, aliph CH, 1H), 1.60 (m, aliph CH, 1H), 1.25 (t, ethyl CH_3 , 6H, $J = 7.2$ Hz); ^{13}C NMR (CDCl_3) δ 168.9, 168.8, 132.9, 131.6, 61.1, 57.0, 45.2, 31.6, 27.7, 14.0; ESMS, m/z 227 ($\text{M} + \text{H}$) $^+$, 244 ($\text{M} + \text{NH}_4$) $^+$.

To a solution of sodium (3.51 g, 153 mmol) in ethanol (50 mL) was added urea (3.05 g, 51 mmol) and diethyl cyclopentenylmalonate (**1**, 10.00 g, 44.2 mmol). After 14 h of refluxing, the white suspension was dissolved in water and acidified to pH ~ 2 . The off-white solid collected by filtration was crystallized from ~ 200 mL of 30% ethanol/water, to provide 5.656 g (66%) of cyclopentenylbarbituric acid (**2**) as tan plates, mp $192\text{--}193^\circ\text{C}$. An additional 1.314 g of light brown powdery crystals (17%) with mp $186\text{--}188^\circ\text{C}$ was obtained by concentration to 80 mL and crystallization over 14 h. Both materials showed the following: ^1H NMR ($\text{DMSO}-d_6$) δ 11.17 (s, barb. NH, 1H), 11.13 (s, barb. NH, 1H), 5.80 (m, olef CH, 1H), 5.59 (m, olef CH, 1H), 3.30 (br s, allyl CH + barb. CH, 2H), 2.22–2.08 (m, allyl CH_2 , 2H), 2.01–1.78 (m, aliph. CH_2 , 2H); ^{13}C NMR ($\text{DMSO}-d_6$) δ 170.4, 170.2, 151.3, 133.2, 130.4, 52.2, 48.5, 31.7, 26.2; ESMS, m/z 195 ($\text{M} - \text{H}$) $^-$.

Sodium hydride (95%, 135 mg, 5.36 mmol) was suspended in 2 mL of tetrahydrofuran (THF), and a solution of 5-cyclopentenylbarbituric acid (**2**, 1.00 g, 5.10 mmol) in 18 mL of dimethylformamide (DMF) was added. After 4 h of stirring, ethyl 3-bromopropionate (0.72 mL, 5.61 mmol) and potassium iodide (169 mg, 1.02 mmol) were added, and the reaction was refluxed for 24 h. The reaction mixture was poured into 100 mL of water and extracted with ethyl acetate (3 \times 50 mL). The combined extracts were washed with water (2 \times 50 mL), dried over MgSO_4 , and concentrated. Chromatography on a 2 \times 18 cm column of silica gel, eluting with 100 mL each of 30, 40, and 50% EtOAc/hexanes, provided 1.159 g (77%) of the disubstituted barbituric acid ester (**3**) as a white solid: mp $93\text{--}94^\circ\text{C}$; ^1H NMR (CDCl_3) δ 8.77 (s, barb. NH, 1H), 8.67 (s, barb. NH, 1H), 5.93 (m, olef CH, 1H), 5.64 (m, olef CH, 1H), 4.08 (q, ethyl CH_2 , 2H, $J = 7.5$ Hz), 3.29 (m, allyl CH, 1H), 2.42–2.25 (m, allyl CH_2 + propionate CH_2CH_2 , 6H), 2.05–1.97 (m, aliph cyclopentenyl CH_2 , 2H), 1.21 (t, ethyl CH_3 , 3H, $J = 7.2$ Hz); ^{13}C NMR (CDCl_3) δ 172.6, 171.3, 170.9, 149.2, 136.0, 60.8, 57.9, 56.6, 31.9, 29.7, 27.5, 24.5, 14.0; ESMS, m/z 293 ($\text{M} - \text{H}$) $^-$.

The barbiturate ester (**3**, 200 mg, 0.68 mmol) was suspended in a solution of 1.0 mL of 10% HCl in 1.0 mL of dioxane and stirred for 24 days at ambient temperature. HPLC showed that $>90\%$ of a single product had been formed. The resulting solution was purified by preparative reversed phase HPLC on a C_{18} μ Bondapak 40 mm \times 100 mm PrepPak column, eluting at 40 mL/min with 35% acetonitrile/65% 0.05% CF_3COOH in water, to produce 167 mg (92%) of the acid **4** as a white solid: ^1H NMR ($\text{DMSO}-d_6$) δ 12.10 (br s, COOH, 1H), 11.43 (s, barb. NH, 1H), 11.37 (s, barb. NH, 1H), 5.88 (m, olef CH, 1H), 5.54 (m, olef CH, 1H), 3.11 (s, allyl CH, 1H), 2.19–2.12 (allyl CH_2 , 2H), 2.05–1.80 (m, aliph CH_2 s, 6H); ^{13}C NMR (CDCl_3) δ 173.7, 172.0, 171.8, 150.3, 134.6, 56.7, 55.5, 31.6, 29.5, 27.2, 24.1; ESMS, m/z 265 ($\text{M} - \text{H}$) $^-$.

To a solution of the acid (**4**, 20.7 mg, 77 μmol) in *p*-dioxane (1.6 mL) were added isobutyl chloroformate (17 μL , 134 μmol) and triethylamine (17 μL , 125 μmol). After 2 h of stirring at ambient temperature, the dioxane mixture solution was added to a rapidly stirred solution of 318 mg of bovine thyroglobulin in 17 mL of 0.05 M, pH 9.5, borate buffer. After 2 h of stirring at ambient temperature, the solution was dialyzed against 0.05 M, pH 7.5, phosphate (five changes, at least 8 h between changes), to produce the immunogen **5**. TNBS titration (**10**) indicated that 70% of the available amino groups had been modified.

Preparation of the Barbiturate Tracer (10). Sodium (9.2 g, 0.40 mol) was carefully dissolved in ethanol (150 mL), and diethyl malonate (60 mL, 0.40 mol) was added. After a brief period of stirring, cyclopentyl bromide (44 mL, 0.40 mol) was added, and the reaction mixture was refluxed for 14 h. The suspension was poured into 100 mL of water and extracted with ethyl acetate (3×100 mL). The combined extracts were dried over MgSO_4 and concentrated. Distillation afforded 66.535 g (73%) of diethyl cyclopentylmalonate (**6**) as a clear colorless oil: bp $104\text{--}106^\circ\text{C}$ (3 mm Hg); ^1H NMR (CDCl_3) δ 4.16 (q, ethyl CH_2 , 4H, $J = 7.1$ Hz), 3.15 (d, malonate CH, 1H, $J = 10.3$ Hz), 2.45 (m, cyclopent CH, 1H), 1.85–1.51 (m, cyclopent CH_2 , 8H), 1.24 (t, ethyl CH_3 , 6H, $J = 7.2$ Hz); ^{13}C NMR (CDCl_3) δ 169.2, 61.0, 57.3, 39.4, 30.6, 24.8, 13.9; ESMS, m/z 229 ($\text{M} + \text{H}$) $^+$, 246 ($\text{M} + \text{NH}_4$) $^+$.

Sodium (11.3 g, 490 mmol) was carefully dissolved in 150 mL of ethanol, and urea (9.80 g, 163 mmol) was added, followed by diethyl cyclopentylmalonate (32.409 g, 142 mmol). After 14 h of refluxing, the suspension was poured into water, and the mixture was acidified to pH ~ 2 . The white crystals collected by filtration were recrystallized from ~ 200 mL of 30% ethanol/water, to provided 21.243 g (80%) of cyclopentylbarbituric acid (**7**) as white plates: mp $222\text{--}223^\circ\text{C}$; ^1H NMR ($\text{DMSO}-d_6$) δ 9.56 (br s, barb. NH, 2H) 3.37 (d, 1H, barb. CH, $J = 10.8$ Hz), 2.42 (m, cyclopent CH, 1H), 1.71–1.44 (m, cyclopent CH_2 , 8H); ^{13}C NMR ($\text{DMSO}-d_6$) δ 170.8, 151.4, 51.7, 42.4, 29.0, 24.3; ESMS, m/z 195 ($\text{M} - \text{H}$) $^-$.

Sodium hydride (95%, 271 mg, 10.7 mmol) was suspended in DMF, and a solution of 5-cyclopentylbarbituric acid (2.00 g, 10.2 mmol) in 40 mL of 85% DMF/THF was added. After 3 h of stirring, ethyl 4-bromocrotonate (1.54 mL, 11.2 mmol) and potassium iodide (423 mg, 2.55 mmol) were added, and the reaction was refluxed for 14 h. The reaction was poured into 100 mL of water and extracted with ethyl acetate (2×100 mL). The combined extracts were washed with water (3×50 mL), dried over MgSO_4 , and concentrated. Chromatography on a 3×30 cm column of silica gel, eluting with 100 mL each of 20, 30, 40, 50, and 70% EtOAc/hexanes, provided 1.917 g of a clear pale yellow oil. Crystallization of this material from EtOAc/hexanes provided 1.602 g (51%) of disubstituted barbiturate ester (**8**) as a white solid: mp $141\text{--}142^\circ\text{C}$; ^1H NMR (CDCl_3) δ 7.98 (br s, barb. NH, 2H), 6.65 (dt, 1H, β -olef CH, $J = 14.3$ and 7.5 Hz), 5.90 (d, α -olef CH, 1H, $J = 14.3$ Hz), 4.15 (q, ethyl CH_2 , 2H, $J = 7.2$ Hz), 2.92 (dd, allyl CH_2 , 2H, $J = 7.7$ and 1.1 Hz), 2.43 (m, cyclopent CH, 1H), 1.78–1.49 (m, cyclopent CH_2 , 8H), 1.26 (t, ethyl CH_3 , 3H, $J = 7.1$ Hz); ^{13}C NMR (CDCl_3) δ 171.0, 166.2, 149.3, 126.3, 60.6, 57.7, 50.0, 36.2, 27.1, 24.1, 21.1, 14.0; ESMS, m/z 307 ($\text{M} - \text{H}$) $^-$.

The barbiturate ester (**8**, 200 mg, 0.65 mmol) was suspended in 12 mL of concentrated HCl and refluxed for 45 min. Concentration furnished a white solid, which was crystallized from water to yield 173 mg (95%) of the disubstituted barbiturate acid (**9**) as white needles: mp $217\text{--}218^\circ\text{C}$; ^1H NMR ($\text{DMSO}-d_6$) δ 11.55 (br s, NH and COOH, 3H), 6.48 (dt, β -olef CH, 1H, $J = 15.5$ and 7.7 Hz), 5.72 (d, α -olef CH, 1H, $J = 15.5$ Hz), 2.76 (d, allyl CH_2 , 1H, $J = 7.0$), 2.26 (m, cyclopent CH, 1H), 1.72–1.34 (m, cyclopent CH_2 , 8H); ^{13}C NMR (CDCl_3) δ 181.8, 176.7, 160.0, 152.1, 135.7, 66.3, 58.8, 45.5, 36.8, 34.0; ESMS, m/z 279 ($\text{M} - \text{H}$) $^-$.

To a solution of the acid **9** (20 mg, 71 μmol) in DMF (100 μL) were added *N*-hydroxysuccinimide (11 mg, 93 μmol) and dicyclohexylcarbodiimide (16 mg, 78 μmol). After 8 h of stirring, 4'-aminomethylfluorescein hydrochloride (28 mg, 71 μmol) and triethylamine (10 μL , 71

μmol) were added, and the suspension was stirred for 96 h. Concentration furnished an orange solid, which was dissolved in methanol and purified by preparative reversed phase HPLC on a C_{18} $\mu\text{Bondapak}$ 40 mm \times 100 mm PrepPak column, eluting at 40 mL/min with 38% $\text{CH}_3\text{CN}/62\%$ 0.05% CF_3COOH in water (220 nm), to produce 26 mg (59%) of the fluorescent tracer **10** as a bright yellow solid: $R_T = 5.68$ min (45% $\text{CH}_3\text{CN}/55\%$ 0.05% CF_3COOH in water); ESMS, m/z 622 ($\text{M} - \text{H}$) $^-$.

Immunization of Animals and Preparation of Antisera. Eight sheep were initially immunized with 1 mg of immunogen in 1.0 mL of complete Freund's adjuvant. The sheep were subsequently bled 7–10 days after immunization and then boosted monthly with 0.5 mg of the immunogen in 0.5 mL of incomplete Freund's adjuvant until the response was mature, after which time the animals were boosted with 0.5 mg of the immunogen monthly. From the blood obtained from each animal every 2 weeks, the serum was separated and stored at -20°C . Antisera titers rose slowly and demonstrated consistent titer after about 6 months. Production bleeds (~ 200 mL) collected for 16 weeks were combined to give the antisera pool, which is characterized below.

Evaluation of the Pooled Antisera. The antisera pool was evaluated by fluorescence polarization immunoassay on an Abbott TDx analyzer equipped with Revision 15 software and operated as described in the TDx system operation manual (8) and Popelka et al. (11) using TDx dilution buffer (0.1 M phosphate buffer, pH 7.4, with 0.1% bovine γ -globulin and 0.1% sodium azide). Except where noted, antisera and tracer were added to the internal 3-POT serum vial (S) and tracer vial (T) containers, respectively. Analyte was added to the sample well of the disposable sample cartridge. Polarization measurements were recorded in millipolarization units (mP).

To measure antisera activity, serial dilutions of antibody were added directly to the cuvette, and polarization measurements were made with and without analyte. In these experiments, the serum vial was filled with TDx dilution buffer. Displacement (ΔmP) was calculated by taking the difference between the polarizations of tracer binding without analyte minus tracer binding with analyte. The working titer was selected from the dilution having the maximum displacement. The antisera were further evaluated by comparing the zero calibrator and the A–F span. Once consistent pool-to-pool titer and performance were obtained, the antisera pools were evaluated on the AxSYM analyzer.

Standards were prepared by the addition of analytically pure secobarbital to normal human urine diluent (confirmed to be negative for barbiturates) at concentrations of 0, 200, 400, 700, 1200, and 2000 ng/mL. Using a four-parameter weighted curve fit (duplicate determinations), a calibration curve was constructed (Figure 2). Mean responses to these standards were established using multiple instruments and stored in barcode form for each antisera pool. The two-point Master Calibration Curve thus derived is specific for each pool and refits the standard six-point calibration curve based on the response of an individual instrument to the two-point curve.

Sensitivity of the assay was determined by identifying the lowest measurable concentration of drug in human urine that could be distinguished from a sample known to contain 0 ng/mL of the drug with a 95% confidence limit ($n = 20$). Replicates of a human urine sample known to be negative for barbiturates and the 0 ng/mL standard were both analyzed. The standard deviation of the replicates was then calculated, and twice this

Figure 2. Standard curve with secobarbital as calibrator.

number was subtracted from the average of the replicates in each case.

The antisera was tested for binding with several different barbiturates. Percent cross-reactivity was calculated as $100 \times$ the measured concentration of drug divided by the concentration of analyte added.

RESULTS

Immunogen and Tracer Synthesis. The first step toward development of an immunoassay is to prepare a carefully designed immunogen. This was accomplished by selective conjugation of the unsaturated acid (**4**, Scheme 1) linked at its 5-position to bovine thyroglobulin. This acid was derived from ester (**3**) via hydrolysis at ambient temperature. Attempted hydrolysis at higher temperatures resulted in lower yields of difficultly purified products. Formation of cyclopentenylbarbituric acid (**2**) was derived ultimately from dicyclopentadiene, via cracking to cyclopentadiene (**9**), low-temperature addition of HCl gas (**9**), and addition of the resulting allylic chloride to a preformed solution of sodium diethylmalonate. Formation of the monosubstituted barbituric acid was performed prior to propionate alkylation instead of attempting to form the barbituric acid ring with a bisalkylated malonate, since the presence of the third propionate ester could result in side reactions and lower yields in the formation of the barbiturate ring.

The isobutyl mixed anhydride was formed by reaction with isobutyl chloroformate and triethylamine in *p*-dioxane, and reaction with bovine thyroglobulin produced the desired immunogen (**5**). Analysis by TNBS (**10**) showed that 70% of the available amino groups of the thyroglobulin had been modified.

The multistep synthesis of the tracer proceeded along a similar path (Scheme 2). Cyclopentylmalonate (**6**) was synthesized by alkylation with commercially available cyclopentyl bromide. The second alkylation was again performed after barbiturate formation for the same reasons noted above. Thus, the crotonate side chain was introduced by alkylation of barbituric acid **7** with sodium hydride in the presence of potassium iodide. Carboxylic acid **9** produced via acid hydrolysis of ester **8** was activated as described above and reacted with 4'-aminomethylfluorescein to produce the fluorescent tracer **10**.

Antisera Characterization. All animals responded by producing consistently titered antiserum after about 6 months. The maximum displacement identified for the mature pool of antisera was obtained at 1/76000 dilution, which gave a dynamic range of 107 mP (Figure 2) when tested against secobarbital. Using a two-point calibration curve, negative urine yielded a sensitivity of 34 ng/mL, and the 0 ng/mL standard a sensitivity of 37 ng/mL. With a standard six-point calibration curve, values of 24 and

27 ng/mL were obtained. These values are statistically indistinguishable. The assay was thus able to detect concentrations of secobarbital at <40 ng/mL.

Good cross-reactivity was obtained in the screening assay with a number of different barbiturates, including those containing both aliphatic and aromatic 5-substituents, at clinically observed concentrations. Of the 18 barbiturates tested, 13 demonstrated cross-reactivities of >22% (Table 1, upper two groups). Other barbiturates showed lower cross-reactivity: veronal, thiopental, and 5-ethyl-5-(4-hydroxyphenyl)barbituric acid (4-hydroxyphenobarbital, a phenobarbital metabolite) showed limited (3–7%) cross-reactivity at 2000 ng/mL, while hexobarbital, metharbital, and methohexital showed (<1%) cross-reactivity that was observable only at extremely high concentrations.

Additionally, cross-reactivity was evaluated with structurally similar compounds (Table 2). These compounds generally showed low (<1%) cross-reactivities observable only at extremely high concentrations. Glutethimide showed limited cross-reactivity (4.5%) at 10000 ng/mL.

DISCUSSION

An ideal screening assay for barbiturates would allow for rapid, automated determination of the presence of frequently abused barbiturates with equivalent recognition at similar concentrations. In the design of an immunogen, taking structural information into account can be critical in generating a response that will lead to the desired reactivity profiles. Our previous work has stressed the important relationship between the architecture of the immunoconjugate used for the inoculation of the animals and the characteristics of the antibodies obtained (12–15).

Figure 3. Larger 5-substituent structure of several barbiturates.

Figure 4. Overlay of the energy-minimized structures of hapten **4** (yellow), secobarbital (green), amobarbital (blue), and phenobarbital (red).

For a screening assay, one needs antibodies with a broad recognition of the class of molecules of interest. For barbiturates, three structural elements are important to closely mimic: the pyrimidinetrione ring, the larger 5-substituent, and the smaller 5-substituent. The imide hydrogens on the pyrimidinetrione ring are particularly important, as they take an active role in hydrogen bonding within the active site, a key interactive force in antibody binding (16).

While the smaller 5-substituent shows little variability (generally ethyl or allyl), considerable variation is observed in the larger 5-substituent (Figures 3 and 5). Thus, linking the barbiturate hapten via the smaller unbranched 5-substituent would appear to be the best strategy, in order to leave the remaining more important determinants fully exposed for optimal antibody recognition. An aliphatic carboxyethyl linker was thus chosen.

Further consideration of the structures of most of the aliphatic barbiturates leads one to observe that the larger of the two 5-substituents, while not always cyclic, can be considered as a fragment of a cyclopentyl ring structure (Figure 3). While conformational studies have shown that unsubstituted noncyclic aliphatic structures are not planar (unsubstituted cyclohexyl rings, for example, exist in the well-known chairlike conformation), phenyl rings are flat, due to the densities of shared π electron structure above and below the plane of the six-membered carbon ring. Electron densities are important

antigenic determinants, since the mechanism of antibody binding relies on the three-dimensional orientation of electron densities rather than on the recognition of chemical structure as such (16). Alternatively, the static conformation of a cyclopentyl ring is much like an envelope, with four atoms in a single plane and the remaining atom above the plane (like the flap of the envelope). In the time-averaged picture, rapid transformation occurs, resulting in each atom temporarily assuming the flap position. The choice of a cyclopentenyl ring as our larger 5-substituent thus offered both the three-dimensional and the π electron character we required for developing an antibody that would detect both aliphatic and aromatic types of 5-substituents of barbiturates. Therefore, hapten **4** became our target.

Tracer design also requires careful consideration of structural information. While a good starting point is frequently the same hapten used in the assay, some discreet modifications in structure are frequently needed to make the tracer bind less strongly, so that in a competitive format it can be effectively displaced by analytes whose structures may not be as well recognized by the antibody. Since several barbiturates contain an allyl group as a 5-substituent, a natural, but slightly different, choice for the linking arm of the tracer was a crotyl substituent. Cyclopentyl was chosen as the another 5-substituent slightly different from the cyclopentenyl group of the hapten, and the crotyl-functionalized cyclopentyl barbiturate **9** became the desired precursor for the tracer.

To better illustrate the previously described structural requirements of barbiturates, molecular modeling was performed (17). Shown in Figure 4 is an overlay of the energy-minimized structures of secobarbital (green) and amobarbital (blue), two frequently abused barbiturates, phenobarbital (cyan), the most frequently prescribed barbiturate containing an aromatic 5-substituent, and the cyclopentenyl barbiturate haptan 4 (yellow). Clearly observable is the structural homology between the barbituric acid ring and the smaller of the two 5-substituents. Even though the larger of the 5-substituents does not display the same spacial homology, rotational changes are possible about the 5-position bonds, as are conformational changes with all of the 5-substituents except the phenyl ring. Such changes would be expected during a normal multistep binding event with an antibody binding site capable of considerable flexibility (16).

As indicated by the cross-reactivity listed in Table 1, desirable recognition was obtained with a variety of different barbiturates at clinically observed concentrations. In all, 13 barbiturates were effectively recognized in the assay at clinically observed concentrations. Secobarbital was selected as the calibrator for the assay and thus shows 100% cross-reactivity. Cyclopentobarbital showed the highest recognition, since it has the greatest structural homology with the hapten. The relatively higher recognition demonstrated by secobarbital and alphenal, which contain a 5-allyl group, as compared to pentobarbital and phenobarbital, which are structurally identical except for their 5-ethyl group (Figure 5), indicates that barbiturates containing a 5-allyl group demonstrate better competitive binding against the fluorescent tracer, which contains an olefinic linker. Talbutal contains a branched 5-isobutyl group, which is structurally more similar to hapten **4** than the smaller 5-isopropyl group of aprobarbital, the 5-bromoallyl group of brallobarbital, or the unbranched 5-allyl group of allobarbital, and thus displays better recognition. Size and branching of the larger 5-substituent are thus observed to be important factors in recognition. Even butalbital, which

Figure 5. Structural comparisons of barbiturates.

Figure 6. Structures of barbiturates with extremely low recognition.

contains an isobutyl group that would appear to be a poor fit with antisera raised to a hapten containing a cyclic 5-substituent, shows excellent recognition. Barbiturates containing a 5-ethyl substituent generally showed lower recognition. Butabarbital, which contains a branched 5-substituent, would be expected to show higher cross-reactivity than its structural isomer butobarbital, which contains an unbranched 5-butyl group, due to a greater homology with the cyclic group of the hapten. Amobarbital shows lower recognition as compared to other 5-ethyl barbiturates, since its isopentyl group contains a methyl group, which is a poor fit with this antisera (see also Figures 3 and 4, blue structure).

Metharbitol, methohexital, and hexobarbital all showed very low recognition (observable only at extremely high concentrations). This is not surprising, in view of the fact that these barbiturates each have an *N*-methyl group present on the barbiturate ring in place of one of the pyrimidinetrione hydrogens, as shown in Figure 6. For example, veronal is structurally identical to metharbitol, except it lacks the *N*-methyl substituent and, as indicated in Table 1, shows significantly better recognition than metharbitol. The considerably larger size of the *N*-

Figure 7. Overlay of the energy-minimized structures of hapten 4 (yellow), metharbitol (blue), and methohexital (red).

methyl group (in place of hydrogen), as well as substitution with a group which can no longer serve as a hydrogen bond donor, demonstrates that influencing both

Figure 8. Structures of barbiturates with limited recognition.

Figure 9. Overlay of the energy-minimized structures of hapten 4 (yellow) and 4-hydroxyphenobarbital (blue).

the van der Waals (hydrophobic) and electrostatic components of binding forces can have a profound effect on antibody recognition. Methohexital also has a pentynyl group which orients four carbons in a sterically inflexible linear arrangement. An overlay of the energy-minimized structures of hapten 4 with metharbital and methohexital (Figure 7) further illustrates the difference the pyrimidinetrione methyl substituent introduces. These molecular features render these barbiturates significantly less susceptible to recognition by the antibody developed here, and thus, these compounds demonstrated measurable cross-reactivity only when tested at very high concentrations.

The specificity of the antibody was further illustrated by the limited recognition observed for 4-hydroxyphenobarbital, thiopental, and veronal at 2000 ng/mL. As seen in Figure 8, thiopental is structurally identical to secobarbital, except that thiopental has a sulfur atom in place of the 3-position pyrimidinetrione oxygen. This contrast between secobarbital and thiopental is analogous to Kollman's study of the recognition of biotin and thiobiotin by streptavidin (18, 19). Kollman expresses binding free energy as a function of the interactions of the analyte with both the solvent and binding protein. Thiobiotin binds much more weakly to streptavidin than biotin, because binding free energy is reduced much more by the O \rightarrow S substitution than the solvent interactions, since three hydrogen bonds of the uriedo oxygen to

Figure 10. Structurally similar compounds.

Figure 11. Overlay of the energy-minimized structures of hapten 4 (yellow) and glutethimide (blue).

protein are affected. Presumably, similar effects, resulting in lower recognition, are operating in this case.

On the other hand, 4-hydroxyphenobarbital has a phenolic hydroxy group on the larger of the 5-substituents. The hydroxyl group is sterically larger than the corresponding hydrogen atom in phenobarbital and, due to the polarity of the group, would not be well accommodated by an antibody designed to accommodate hydrophobic 5-substituents. An overlay of hapten 4 with 4-hydroxyphenobarbital (blue structure, Figure 9) further illustrates this point. The attenuated recognition thus observed in comparison to phenobarbital (Table 1) would be expected. Veronal contains two 5-ethyl groups, which would offer poorer van der Waals interactions with the antibody than the saturated butyl groups of analogous 5-ethyl barbiturates butabarbital or butobarbital. Veronal thus displays a lower cross-reactivity in this assay.

Additionally, cross-reactivity was tested with structurally similar compounds that are not barbiturates and was found to be extremely low. Glutethimide (Figure 10), an addictive, rarely prescribed sedative-hypnotic, had to be tested at 10 000 ng/mL to detect any cross-reactivity. While glutethimide is structurally similar to phenobarbital, it possesses two methylene groups in place of the 3- and 4-position imide functionality and thus lacks the hydrogen bonding potential of phenobarbital at these positions. The two methylenes also render its hetero-

cyclic ring less planar than a barbiturate ring and thus affect the antibody van der Waals interactions as well. Figure 11 further illustrates these differences. Primidone also resembles phenobarbital, but has a methylene in place of the 2-position carbonyl. In addition to the differences in heterocyclic structure, both aminoglutethimide and 5-(4-hydroxyphenyl)-5-phenylhydantoin also have polar or charged groups on the phenyl ring which are larger than the analogous hydrogen and would not be well recognized by an antibody designed to accommodate hydrophobic 5-substituents. All of these structures are thus poorly recognized in this assay.

In conclusion, we have provided methods for the development of antisera suitable for a barbiturate screen assay by rational design of immunocomponents. We have demonstrated that a carefully designed immunogen is responsible for the characteristics of the antisera generated. In fact, the antisera generated here demonstrate the desired recognition of a series of clinically important barbiturates. The reactivities observed are attributable to the relationship between the architecture of the immunogen, the characteristics of the resulting antisera, the structure of the fluorescent tracer, and the structures of the barbiturates being tested.

Radiolabeling of Epidermal Growth Factor with ^{99m}Tc and *in Vivo* Localization following Intracerebral Injection into Normal and Glioma-Bearing Rats

Jacek Capala,^{*,†} Rolf F. Barth,[†] Michael Q. Bailey,^{‡,§} Robert A. Fenstermaker,^{||} Michael J. Marek,[⊥] and Buck A. Rhodes[⊥]

High grade gliomas may have amplified expression of the epidermal growth factor receptor (EGFR) gene *c-erb-B*, which often is associated with increased expression of transmembrane EGFR. The purpose of the present study was to develop a method for labeling EGF with ^{99m}Tc and to determine whether the resulting radioligand would localize, following intracerebral injection, in rats bearing EGFR-positive gliomas. EGF has a relatively low molecular mass (~6 kDa) compared to monoclonal antibodies, and this has allowed smaller bioconjugates, which should diffuse more rapidly within the brain and more effectively target disseminated glioma cells, to be constructed. In the present study, EGF has been labeled with either ^{131}I or ^{99m}Tc , and *in vitro* uptake of the resulting radioligand has been investigated using C6_{EGFR} rat glioma cells, which had been transfected with the EGFR gene. Cellular uptake of ^{131}I radioactivity peaked after ~30 min of incubation with [^{131}I]EGF, following which time it declined, while ^{99m}Tc radioactivity continued to increase over a 6 h incubation with [^{99m}Tc]EGF. To determine if radiolabeled EGF had *in vivo* tumor-localizing properties, C6_{EGFR} glioma cells were implanted stereotactically into the brains of Fischer rats. Four weeks later, either ^{99m}Tc - or ^{131}I -labeled EGF was injected intracerebrally into normal or glioma-bearing animals using the same stereotactic coordinates. External gamma scintigraphy revealed that ^{131}I radioactivity disappeared rapidly from the brain regions of tumor-bearing animals compared to ^{99m}Tc , ~50% of which remained in the tumor for up to 12 h. In contrast, only ~20% remained in the brains of non-tumor-bearing animals after 6 h. These studies are the first to describe a method for radiolabeling EGF with ^{99m}Tc and to detect it by external scintigraphy in the brains of tumor-bearing animals.

INTRODUCTION

Epidermal growth factor (EGF)¹ is a ~6 kDa, single-chain, 53 amino acid containing polypeptide (Carpenter and Cohen, 1979), which usually is promptly internalized and transferred to lysosomes, where both EGF and its receptor (EGFR) are degraded (Carpenter, 1987; Todderund and Carpenter, 1989). The relatively low molecular mass of EGF has permitted construction of relatively small bioconjugates, which have high affinity for EGFR on tumor cells (Capala et al., 1993, 1996) and possibly could be used to target receptor-positive tumors, especially those in the brain, for either diagnosis or therapy (Harris, 1990; Carlsson et al., 1994).

The majority of high grade gliomas have amplified expression of the EGFR gene, *c-erb-B*, which often is associated with an increase in cell surface receptor expression (Torp et al., 1991; Mondjtahedi and Dean, 1994). As reported by Bigner et al. (1990), 45% of 33 human glioma biopsies showed amplification of the EGFR gene. Subsequently, this was confirmed by Ekstrand et al. (1991) and Tuzi et al. (1991). Gene amplification often results in significantly increased expression of EGFR on the surface membrane of tumor cells (Bigner et al., 1990; Torp et al., 1991). Due to the cellular heterogeneity of high grade gliomas, the distribution of EGFR in each individual tumor is not uniform, but, in 25 of 42 human gliomas studied by Torp et al., more than 50% of the tumor cells bound biotinylated EGF. Because the number of EGFR on tumor cells may be 100 times greater than that on normal, untransformed cells, EGFR has been considered as a potential target for the specific delivery of tumoricidal agents using mAbs against the EGFR or their fragments (Mendelsohn, 1988; Sato and Sato 1989; Modjtahedi and Dean, 1991; Lofts and Gullick, 1994). Preliminary clinical trials have been carried out using anti-EGFR mAbs as a delivery agents of ^{131}I for radioimmunotherapy of brain tumors (Epenetos et al., 1985; Kalofonos et al., 1989; Brady et al., 1991; Snelling et al., 1995), and although no definitive conclusion can yet be made about therapeutic efficacy, no significant toxicity was observed and there was some evidence of a clinical response. One major problem, however, is that only a very small amount of systemically administered anti-EGFR monoclonal antibody (mAb) localizes within the brain tumor. In a recently reported phase I clinical

study (Faillot et al., 1996) on the possible use of anti-EGFR mAb for the treatment of malignant gliomas, the fraction of antibody recovered per gram of tumor 48 h following continuous intravenous (iv) infusion was in the range of 0.00001–0.0001% of the injected dose per gram. Targeting the EGFR by means of EGF is another approach for delivering potentially tumoricidal agents to malignant gliomas expressing increased amounts of EGFR. The preparation of ^{131}I -labeled EGF for targeted radiotherapy (Capala et al., 1990, 1991; Andersson et al., 1992; Carlsson et al., 1994) and of ^{10}B -labeled EGF as a potential delivery agent for boron neutron capture therapy (BNCT; Capala et al., 1996) previously has been reported.

The purpose of the present study was to extend our previous work to develop a method for radiolabeling EGF with $^{99\text{m}}\text{Tc}$, a gamma-emitting radionuclide whose short half-life (6.8 h) and favorable energy spectrum allow optimal imaging with minimal biological damage. Such a radioligand may be used to identify those tumors with increased amounts of EGFR for better, receptor specific, therapeutic targeting. In this paper we describe a simple method for radiolabeling EGF with $^{99\text{m}}\text{Tc}$ and compare the *in vitro* and *in vivo* properties of [$^{99\text{m}}\text{Tc}$]EGF with those of [^{131}I]EGF.

EXPERIMENTAL PROCEDURES

EGF. Human recombinant EGF, which previously has been shown to bind with high affinity to the EGFR on human glioma U-343MG (Capala et al., 1993) and rat C6_{EGFR} glioma cells (Fenstermaker et al., 1995), was purchased from Upstate Biotechnology, Inc., Lake Placid, NY.

Cells. All cell lines were grown in Dulbecco's Modified Eagle's Medium (DMEM; Gibco, Grand Island, NY) supplemented with 10% fetal bovine serum (Sigma, St. Louis, MO), L-glutamine (2 mM), solution I (1 mM oxaloacetic acid, 0.2 IU/mL crystalline insulin, 0.5 mM sodium pyruvate), streptomycin (100 mg/mL), and penicillin (100 IU/mL) in a humidified atmosphere at 37 °C. The parental C6 rat glioma cells (American Type Culture Collection, Rockville, MD) were transfected with the gene encoding EGFR (Fenstermaker et al., 1995) to yield stable transfectants, designated C6_{EGFR}. As determined by a radioligand binding assay and Scatchard analysis, parental C6 cells did not express EGFR, while transfected cells expressed 3×10^6 receptor sites/cell (Fenstermaker et al., 1995).

Intracerebral Rat Tumor Model. Male CD Fischer rats, weighing 236 ± 16 g (mean \pm SD), were purchased from Harlan Sprague Dawley, Indianapolis, IN, and were maintained on standard rat chow and water *ad libitum*. Intracerebral implantation of C6_{EGFR} tumor cells was carried out according to the method of Clendenon et al. (1990). Animals were anesthetized by intraperitoneal (ip) injection of a 1.6/1.0 mixture of ketamine (100 mg/mL)/xylazine (20 mg/mL) at a dose of 1.3 mL/kg and placed in a stereotactic frame (David Kopf Instruments, Tujunga, CA). The surface of the skull was exposed by a midline incision, and a small burr hole was drilled at a location 7 mm anterior to the interaural line and 3.5 mm to the right of the midline. Then, a precision-milled plastic screw equipped with an injection port was screwed into the hole. Tumor cells (10^5), mixed with serum-free DMEM (10 mL) containing 1.25% low melting point agarose (gelling temperature < 30 °C), were injected into the right caudate nucleus over 10 s. At the end of the procedure the viability of the remaining cells was determined by means of the trypan blue exclusion method. To allow for the implanted glioma cells to produce a tumor of adequate size, *in vivo* studies were carried out 4 weeks

Figure 1. Chemical scheme for radiolabeling EGF with $^{99\text{m}}\text{Tc}$ pertechnetate as modified from the original postulated by Rhodes (1991).

following tumor cells implantation. On the basis of previous studies with this tumor model (San-Galli et al., 1989), as well as our own with the C6 (Fenstermaker et al., 1995) and F98 gliomas (Clendenon et al., 1990; Barth et al., 1997), animals injected intracerebrally die as a result of the expanding brain tumor, which at the time of death is ~ 5 –6 mm in diameter.

Radiolabeling of EGF with ^{131}I . As previously described (Capala et al., 1990), EGF was radioiodinated by means of the chloramine-T method. Briefly, 10 μg of lyophilized EGF was dissolved in 100 μL of 0.25 M potassium phosphate buffer, pH 7.5, and incubated for 1 min with 1 mCi of sodium [^{131}I]iodide and 20 μL of freshly prepared chloramine-T solution (2 mg/mL in 0.5 M phosphate buffer, pH 7.5). The reaction was quenched by adding 50 μL of freshly prepared sodium metabisulfite solution (2 mg/mL in 0.5 M phosphate buffer, pH 7.5). Unbound ^{131}I was separated from [^{131}I]EGF using a desalting, Sephadex G-25 column (PD-10, Pharmacia Biotech, Piscataway, NJ) and eluted with phosphate-buffered saline (PBS), pH 7.2.

Radiolabeling of EGF with $^{99\text{m}}\text{Tc}$. The chemical procedure employed to radiolabel EGF with $^{99\text{m}}\text{Tc}$ pertechnetate is shown in Figure 1. To introduce a thiol group into the terminal amino group of EGF, 400 mg of EGF first was reacted at ambient temperature with 2-iminothiolane (Pierce, Rockford, IL; $50\times$ molar excess) in 600 mL of 7 mM potassium phosphate, 0.1 M NaCl, 1 mM EDTA, and 60 mM triethanolamine under a nitrogen atmosphere for 1 h. Excess, unreacted 2-iminothiolane was separated from EGF using a PD-10 column (Pharmacia Biotech) eluted with protein elution buffer (0.15 M NaCl, 40 mM potassium monohydrate phthalate, 10 mM potassium sodium tartrate, 4 mg/mL inositol, 4 mg/mL glycine, pH 5.6). One milliliter fractions were collected, and protein concentrations were determined spectrophotometrically by measuring absorbance at 280 nm using a Beckman DU-6 spectrophotometer (Beckman Instruments Inc., Irvine, CA). Aliquots of each fraction were mixed with Ellman's reagent [5,5-dithiobis(2-nitrobenzoic acid)] in 0.1 M sodium phosphate buffer, and absorbance at 412 nm was measured spectrophotometrically to determine the presence of sulfhydryl groups. Fractions containing EGF-SH were concentrated by means of Centricon 3 microconcentrators (Amicon, Danvers, MA), and then, the direct labeling method of Rhodes (1991) was used to attach $^{99\text{m}}\text{Tc}$ to thiolated EGF. Modified EGF-SH in protein elution buffer was mixed 1:1 with a nitrogen-purged reducing solution (20 mM potassium monohydrophthalate, 10 mM potassium–sodium tartrate, 1.5 mM stannous tartrate, pH 5.6) and reacted with $^{99\text{m}}\text{Tc}$ sodium pertechnetate (10 mCi) at

ambient temperature for 1–10 min. The reaction mixture was applied to a PD-10 column, eluted with PBS, pH 7.2, and the overall recovery of ^{99m}Tc was determined by collecting the total column effluent and comparing the radioactivity present in it with the radioactivity added to the column. To determine the labeling efficiency, the yield was multiplied by the percentage of ^{99m}Tc associated with the peptide peak. The amount of free pertechnetate and unbound ^{99m}Tc was estimated by thin layer chromatography (TLC) on TLC-SG strips (Gelman Sciences, Ann Arbor, MI) using 85% ethanol as a mobile phase, which separated the soluble, unbound, migrating with the solvent, free ^{99m}Tc pertechnetate from the nonmigrating [^{99m}Tc]EGF. The ratio of bound ^{99m}Tc was expressed as radioactivity detected in the first (origin) half of the strip divided by the total radioactivity, with all measurements corrected for background. Radiocolloid was determined using serum albumin-coated silica gel strips. In this case the ethanol–ammonia–water (2:1:5) mixture was the mobile phase and colloid-bound ^{99m}Tc remained at the origin, while free ^{99m}Tc pertechnetate and radiolabeled EGF migrated with the solvent. The stability of [^{99m}Tc]EGF was determined at various times up to 24 h following labeling.

In Vitro Cellular Uptake and Retention of EGF-Delivered ^{99m}Tc and ^{131}I Radioactivity. Cellular uptake of ^{99m}Tc was determined as follows. C6_{EGFR} glioma cells ($\sim 2 \times 10^5$ per well), grown in 24-well plates (Corning, Corning, NY), were incubated at 4 °C for 90 min in cell culture medium containing various concentrations of [^{99m}Tc]EGF in the range 0.00165–165 nM. At the end of each experiment, the cells were washed with cold PBS and the cell-associated radioactivity was determined by gamma scintillation counting (Tm Analytic, Model 1185, Elk Grove Village, IL). Wild type C6 cells, which did not express EGF receptors, were used as controls to assess background, nonspecific binding, and this was subtracted from the total counts obtained for each sample. Repeated attempts to determine the affinity constant (K_A) of [^{99m}Tc]EGF by a direct binding assay were unsuccessful due to high levels of nonspecific binding (data not shown). Cellular retention of the EGF-delivered radioactivity was determined in the next series of experiments. C6_{EGFR} cells, grown in 24-well plates ($\sim 10^5$ cells/well), were incubated at 37 °C with medium containing 165 nM [^{99m}Tc]– or [^{131}I]EGF for periods of time ranging from 5 min to 6 or 3 h, respectively. In another experiment, the cells were exposed to 165 nM radiolabeled EGF at 37 °C for 30 min, and then the cells were washed and incubated in supplemented DMEM for periods of time ranging from 5 min to 2.5 or 5.5 h. Cell-associated radioactivity and that in the medium were measured by gamma scintillation counting. Again, wild type C6 cells were used as controls and background counts due to nonspecific binding were subtracted from the total counts obtained for each test sample.

Scintigraphic Studies. Four weeks after intracerebral implantation of tumor cells, non-tumor- and tumor-bearing rats were injected either intracerebrally or intratumorally with 1.7–2.3 μg (34–43 μCi) of [^{99m}Tc]EGF or with 1–5 μg (60–200 μCi) of [^{131}I]EGF. The distribution of radioactivity was monitored by means of external scintigraphy using a Sigma 410 gamma camera with a low-energy collimator optimized for ^{99m}Tc detection. The gamma camera was interfaced with a Technicare 560 computer (Ohio-Nuclear, Inc., Solon, OH) for the imaging data collection and processing. Three to five animals were used in each study. The quantity of ^{131}I or ^{99m}Tc radioactivity retained in the brains of non-tumor- and tumor-bearing animals was determined as a function

Figure 2. Cell-associated ^{99m}Tc radioactivity following incubation of C6_{EGFR} cells with [^{99m}Tc]EGF. The cells ($\sim 2 \times 10^5$ cells/well) were incubated with increasing concentrations (0.00165–165 nM) of [^{99m}Tc]EGF at 4 °C for 90 min and then washed, and cell-associated radioactivity was determined by gamma scintillation counting. Background values resulting from non-specific binding, obtained from control parental C6 cells, which do not express EGFR, were subtracted at each [^{99m}Tc]EGF concentration. The mean value and the maximum variation of results from two or three samples are shown for each point.

of time, using intrinsic features of the computers' software, which permitted calculation of the average number of counts per pixel in each outlined region of interest.

RESULTS

Radiolabeling of EGF with ^{99m}Tc . The labeling efficiency of EGF-SH with ^{99m}Tc sodium pertechnetate increased from 77% after a reaction time of 1 min to 87% after 10 min, and the estimated specific activities of radiolabeled EGF ranged from 18 to 21 mCi/mg. Since the differences in the efficiency were insignificant, a 1 min reaction time was used to minimize possible damage to the EGF molecule as a result of the reducing conditions of the reaction. As determined by TLC on silica gel strips using 85% ethanol as the solvent phase, and on serum albumin-coated silica gel strips using ethanol–ammonia–water mixture as the solvent phase, $\sim 97\%$ of the ^{99m}Tc radioactivity in the protein peak remained bound to EGF at ambient temperature for up to 24 h.

In Vitro Cellular Uptake and Retention of EGF-Delivered ^{99m}Tc and ^{131}I Radioactivity. [^{99m}Tc]EGF binding as a function of its concentration and ^{99m}Tc uptake as a function of time of incubation with [^{99m}Tc]EGF were studied *in vitro* using C6_{EGFR} cells. Direct binding of [^{99m}Tc]EGF to C6_{EGFR} cells was assessed by measuring cell-associated radioactivity following incubation with increasing concentrations (0.00165–165 nM) of [^{99m}Tc]EGF. As shown in Figure 2, there was a stepwise rather than linear increase of the cell-bound radioactivity with increasing concentrations of the bioconjugate. Similar experiments carried out with wild type C6 cells, which do not express EGFR, showed an order of magnitude lower binding at each concentration, and background due to this nonspecific binding has been subtracted. Cell-bound radioactivity as a function of time following incubation with [^{131}I]EGF or [^{99m}Tc]EGF is shown in Figure 3. Continuous incubation with [^{99m}Tc]EGF resulted in an increase of cell-associated radioactivity proportional to the time of incubation, while incubation with [^{131}I]EGF produced a peak value of cell associated radioactivity at ~ 30 min followed by a 30% decrease over the next 2 h due to release of ^{131}I from the cells after EGF

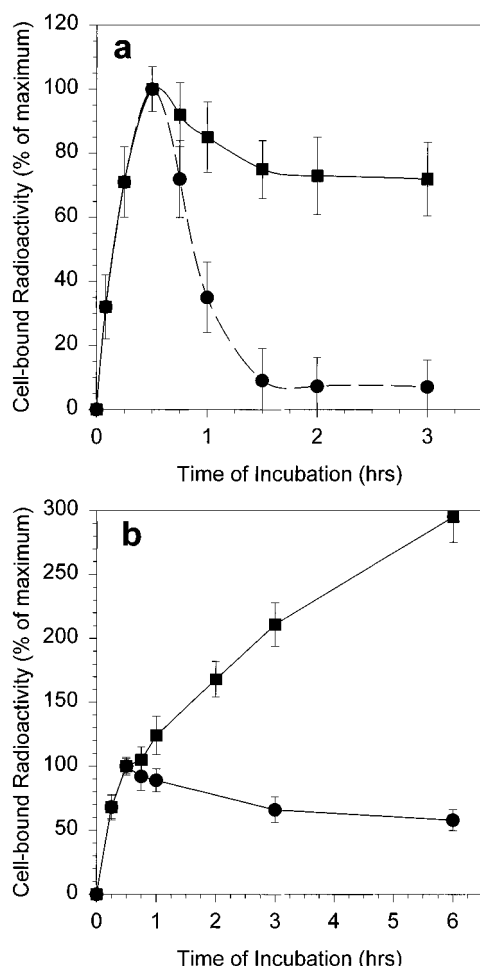

Figure 3. Cell-bound radioactivity as a function of time following incubation with 165 nM $[^{131}\text{I}]\text{EGF}$ (a) or $[^{99\text{m}}\text{Tc}]\text{EGF}$ (b): (■) continuous incubation with radiolabeled EGF; (●) incubation in medium devoid of radiolabeled EGF. The cells were seeded into 24 well plates (~ 105 cells/well) and then, following 30 min of incubation with radiolabeled EGF, incubated further with or without 165 nM radiolabeled EGF. Background values resulting from nonspecific binding, obtained from control parental C6 cells, which do not express EGFR, were subtracted at each EGF concentration. The mean values and standard deviations obtained from triplicate samples are shown.

had been catabolized. When a 30 min incubation of cells with $[^{131}\text{I}]\text{-}$ or $[^{99\text{m}}\text{Tc}]\text{EGF}$ was followed by incubation in medium devoid of radiolabeled EGF, ^{131}I radioactivity was released from the cells after EGF had been catabolized, while approximately 60% of the $^{99\text{m}}\text{Tc}$ radioactivity was retained within the cells for at least 6 h. At this time, the reason for the continued cellular retention of either $^{99\text{m}}\text{Tc}$ -labeled EGF or free $^{99\text{m}}\text{Tc}$ is unknown, but it is possible either that radiolabeling may have altered the catabolism of EGF or that $^{99\text{m}}\text{Tc}$ was retained within cells after EGF had been degraded.

Scintigraphic Studies. Scans were carried out after injection of radiolabeled EGF into 4-week-old tumors or into the corresponding sites of non-tumor-bearing animals. Figures 4 and 5 show images obtained 6 h following injection of $[^{131}\text{I}]\text{-}$ or $[^{99\text{m}}\text{Tc}]\text{EGF}$, respectively. ^{131}I radioactivity disappeared more rapidly from the brain regions of tumor-bearing animals compared to non-tumor-bearing animals. This probably was due to the release of iodine following rapid internalization and degradation of $[^{131}\text{I}]\text{EGF}$ by brain tumor cells. The scans of animals injected with $^{99\text{m}}\text{Tc}$ -labeled EGF, on the other hand, showed that radioactivity persisted in the brain regions of the tumor-bearing animals, but was dispersed

Figure 4. Scans of ^{131}I distribution following ic injection of ~ 5 μg of $[^{131}\text{I}]\text{EGF}$ (200 μCi) in normal rats (left panel) or intratumoral injection of ~ 1 μg of $[^{131}\text{I}]\text{EGF}$ (60 μCi) in tumor-bearing rats (right panel). The tumors were grown for 4 weeks to reach an estimated size of 5 mm in diameter.

Figure 5. Scans of $^{99\text{m}}\text{Tc}$ distribution following ic injection of ~ 2.3 μg of $[^{99\text{m}}\text{Tc}]\text{EGF}$ (43 μCi) in non-tumor-bearing control rats (left panel) or intratumoral injection of ~ 1.7 μg of $[^{99\text{m}}\text{Tc}]\text{EGF}$ (34 μCi) in glioma-bearing rats (right panel). The tumors were grown for 4 weeks to reach an estimated size of 5 mm in diameter.

in non-tumor-bearing animals (Figure 5). Relative quantitative changes of radioactivity retained in the brain regions of tumor-bearing versus normal rats following injection of ^{131}I - or $^{99\text{m}}\text{Tc}$ -labeled EGF were determined by comparing counts per pixel recorded by the gamma camera. The changes of ^{131}I radioactivity detected in the brain regions were faster in tumor-bearing and slower in non-tumor-bearing control rats (Figure 6a). A different localization pattern was observed for $^{99\text{m}}\text{Tc}$, where $\sim 50\%$ of the radioactivity persisted in the brain regions of tumor-bearing animals for up to 12 h, while only $\sim 20\%$ remained in the brain region of non-tumor-bearing rats after 6 h (Figure 6b). Because it was impossible to precisely define the regions of interest corresponding to other organs on each image, changes of radioactivity in organs such as liver, kidneys, and thyroid could be assessed only qualitatively rather than quantitatively. Comparison of the images obtained with $[^{131}\text{I}]\text{EGF}$ indicated that less activity was present in the liver and it accumulated more quickly in the thyroid of tumor-bearing animals compared to non-tumor-bearing controls.

DISCUSSION

In the present study, we have described a method for radiolabeling EGF with $^{99\text{m}}\text{Tc}$ pertechnetate using a

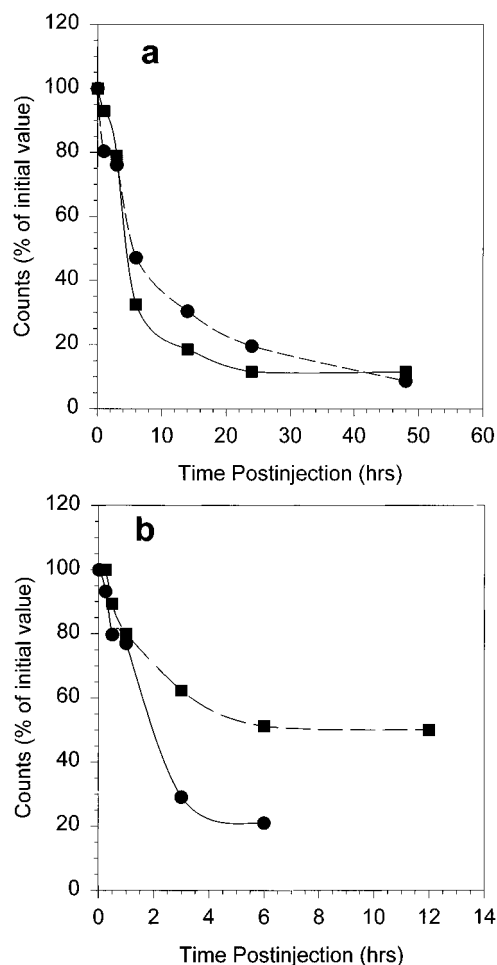

Figure 6. Quantitative evaluation of ^{131}I (a) or ^{99m}Tc (b) radioactivity retained in the brain of control (●) or tumor-bearing animals (■) following ic injection of radiolabeled EGF.

procedure originally described by Rhodes et al. (1991) for the direct labeling of proteins. However, before radiolabeling of EGF could be carried out, it was necessary to introduce a thiol group into the amino-terminal end of the EGF molecule. Although the heterobifunctional reagent *N*-succinimidyl 3-(2-pyridyldithio)propionate could have been used to derivatize EGF, this probably would have broken internal cysteine bonds, thereby changing the tertiary structure of the molecule. To minimize these changes and to preserve EGF's ability to bind to its receptors, thiolation was carried out under mild conditions with 2-iminothiolane.

Using rats bearing intracerebral implants of C6_{EGFR} glioma that express EGFR, we studied the *in vivo* localization of radiolabeled EGF following intratumoral or intracerebral injection. As determined by external scintigraphy, ^{131}I radioactivity disappeared more rapidly from the brain regions of tumor-bearing compared to control animals. This may have been due to the release of iodine following rapid internalization and degradation of [^{131}I]EGF in tumor cells, which would correlate with our *in vitro* observation that cell-associated ^{131}I activity rapidly disappeared after [^{131}I]EGF-containing medium had been replaced with EGF-free medium. This phenomenon also has been observed in human fibroblasts (Carpenter and Cohen, 1976) and in human glioblastoma cells (Capala et al., 1993). As determined by gel filtration of the incubation medium, in both cases the radioactivity released from the cells was in a low molecular mass form. Following intratumoral injection, EGF most likely was catabolized by tumor cells, as suggested by the rapid loss

of ^{131}I radioactivity from the brain, lower levels of radioactivity in the liver, and faster accumulation of iodine in the thyroid. On the other hand, following injection of ^{99m}Tc -labeled EGF into tumor-bearing rats, ~50% of ^{99m}Tc remained in the brain regions for up to 12 h, compared to only ~20% remaining after 6 h in non-tumor-bearing animals. These findings also correlated with our *in vitro* data, which showed that 60% of ^{99m}Tc remained cell-associated for at least 6 h following 30 min of incubation with [^{99m}Tc]EGF. It is possible that the covalent sulfur–technetium bond, which is produced during the labeling procedure described above, was stronger than the carbon–iodine bond produced by the chloramine-T iodination method. Furthermore, there are specific dehalogenating enzymes that could cause the release of iodine from proteins (Wilbur, 1992; Carrasquillo, 1993) and, thereby, decrease stability of the iodinated EGF. On the other hand, since technetium is not a naturally occurring element, there are no specific enzymes that degrade Tc-labeled proteins, which could explain the differences in *in vitro* and *in vivo* pharmacokinetics of ^{131}I - and ^{99m}Tc -labeled EGF. Increased stability of ^{99m}Tc -, ^{186}Re -, and ^{188}Re -labeled mAbs and peptide-based ligands has been reported previously (Zamora et al., 1993, 1996; Rhodes et al., 1995). However, tumor retention and biodistribution profiles of the ^{131}I -labeled somastatin analogue, RC-160, were similar to those of [^{188}Re]RC-160 (Zamora et al., 1996). At this time we do not know whether the ^{99m}Tc pertechnetate inhibited the degradation of EGF or whether the radionuclide was retained following intracellular degradation of EGF.

Zamora et al. (1996) have successfully used [^{188}Re]RC-160, a directly radiolabeled somastatin analogue, to treat xenografts of a somastatin-receptor-positive human prostate adenocarcinoma grown in nude mice. Since the chemistry of ^{186}Re or ^{188}Re perrhenate is similar to that of ^{99m}Tc pertechnetate, EGF might be useful as a tumor-targeting agent for these radionuclides (Griffiths et al., 1994). Rémy et al. (1995) have produced a human EGF-(1–51) construct that included a branched peptide with four metal-chelating sites, which could be radiolabeled with ^{111}In . The resulting bioconjugate retained the receptor-binding properties of the native EGF *in vitro*. Scott Robson et al. (1991) have described a method for radiolabeling EGF with positron-emitting ^{76}Br and have compared [^{76}Br]EGF to [^{125}I]EGF *in vitro* and *in vivo*. [^{125}I]EGF and [^{76}Br]EGF bound equally well to EGF-positive glioma cells *in vitro*. The *in vivo* studies showed that the biodistributions of both radioconjugates were similar following intravenous injection into normal rats, although the biological half-life of ^{76}Br was greater than that of ^{125}I in some organs.

As recently reviewed by Carlsson et al. (1994), EGF also might be used as a targeting agent for boron neutron capture therapy, the success of which depends upon the delivery of a large number of boron atoms to tumor cells (Barth et al., 1996). Carlsson et al. have produced an EGF–dextran containing ~1000 boron atoms per conjugate unit and have shown that the ^{131}I radioactivity delivered to the tumor cells by EGF–dextran–tyrosine- ^{131}I remained cell-associated for at least 20–24 h. Recently, we have described a method for boronating EGF by linking EGF to a boron-containing starburst dendrimer (Capala et al., 1996). The resulting bioconjugates contained ~960 boron atoms per molecule of EGF, specifically bound to the EGFR on tumor cells, and were internalized and localized in lysosomes, where they persisted for up to 3 h.

The blood–brain barrier (BBB), which effectively limits the diffusion of both low and high molecular mass

substances from the vascular compartment to both normal brain and tumor within it (Brightman, 1989), is an obstacle to the delivery of EGF radioconjugates to brain tumor following systemic injection. Nevertheless, there are a number of strategies that could be used to circumvent this problem. Radiolabeled EGF could be injected either into the tumor, as we did in the present study, or into the site from which the tumor had been surgically resected (Liebert et al., 1990; Riva et al., 1994). Alternatively, radiolabeled EGF might be delivered directly into the brain, using polymers (Brem et al., 1991) or implantable pumps (Kroin and Penn, 1989; Madrit et al., 1991) that would release it over a longer period of time. The intracarotid infusion of a hyperosmotic solution (1.373 mOsmol/mL) of mannitol can disrupt the BBB (Neuwelt et al., 1986), and this approach significantly increased the tumor uptake of both intact mAbs (Neuwelt et al., 1994) and their F(ab) and F(ab')₂ fragments in brain-tumor-bearing rodents (Neuwelt et al., 1988), as well as low molecular mass boron compounds in glioma-bearing rats (Barth et al., 1997; Yang et al., 1996, 1997a,b). Studies currently are in progress in our laboratory to further evaluate intratumoral versus intracarotid injection, with or without BBB disruption, of ^{99m}Tc-labeled and boronated EGF. These studies should provide relevant information concerning the optimal route for the administration of EGF to brain-tumor-bearing rodents, and if these are sufficiently promising, then studies in larger animals such as canines would be warranted to assess the feasibility of using EGF as a targeting agent for either diagnosis or therapy of human brain tumors. EGF-based bioconjugates also might be used to target other kinds of tumors, such as sarcomas and squamous carcinomas, whose cells have been shown to express increased amounts of EGF (Carpenter, 1987; Helseth et al., 1990). [^{99m}Tc]EGF radioconjugates might be useful for evaluating *in vivo* EGFR expression, as well as optimizing the route of delivery of other EGF bioconjugates such as [⁷⁶Br]EGF for positron emission tomography, boronated EGF for BNCT, or [¹⁸⁶Re]- or [¹⁸⁸Re]EGF for targeted radiotherapy of EGFR positive tumors. Further studies will determine whether any of these approaches are successful.

Synthesis of a New Photoreactive Derivative of Dipyridamole and Its Use in the Manufacture of Artificial Surfaces with Low Thrombogenicity

Yvette B. J. Aldenhoff,[†] A. Paul Pijpers,[‡] and Leo H. Koole^{*,†}

Centre for Biomaterials Research, Maastricht University, P.O. Box 616, 6200 MD Maastricht, The Netherlands, and DSM Research, Geleen, The Netherlands. Received November 15, 1996[®]

Photoimmobilization of dipyridamole (Persantin) was accomplished through the use of a new synthetic conjugate molecule, **1**. Persantin is a powerful inhibitor of platelet activation and aggregation and is widely used as a vasodilator. Conjugate **1** consists of triply protected dipyridamole [three of the four hydroxyl groups carry a *tert*-butyldimethylsilyl (TBDMS) protective group] and the photoreactive 4-azidobenzoyl group. A short hydrophilic spacer chain, derived from triethylene glycol, separates the protected dipyridamole system and the photoreactive group. Compound **1** was immobilized on polyurethane sheets (Pellethane D-55) through irradiation with ultraviolet (UV) light, and the protective groups were removed afterward. The resulting modified polyurethane surfaces were characterized by different physicochemical techniques: UV extinction, contact angle measurements (captive bubble technique), and X-ray photoelectron spectroscopy (XPS). The UV extinction measurements showed the presence of 13 ± 1 nmol of immobilized dipyridamole/cm². The contact angle measurements revealed that the modified surface was markedly more hydrophilic than the control (i.e. unmodified polyurethane). XPS measurements clearly established the presence of immobilized dipyridamole in the outermost layers of the modified surface. This was especially clear from the XPS spectra recorded at a low take-off angle ($\sim 6^\circ$). Furthermore, the XPS spectra showed that the TBDMS protective groups had been quantitatively removed during the deprotection/washing treatment. The *in vitro* blood compatibility of the modified surface was studied with the thrombin generation assay as developed in our group, as well as with scanning electron microscopy. The thrombin generation test produced a lag time of 1275 s for the modified surface, as opposed to 569 s for the control. Scanning electron microscopy showed that far fewer platelets adhere to the modified surface (approximately $7 \times 10^3/\text{mm}^2$) as compared to the control (approximately $6 \times 10^2/\text{mm}^2$). Taken together, the experimental data reveal that the modified surface has excellent blood compatibility *in vitro*. It is discussed that the use of conjugate **1** leads to simultaneous exposure of dipyridamole at the modified surface and to a marked increase of the surface hydrophilicity, which is likely to hamper adsorption of plasma proteins. The combination of these effects is uniquely related to the molecular buildup of **1**. Conjugate **1** will be used in future work that is aimed at preparing small-caliber polyurethane vascular grafts with a blood compatible luminal surface.

INTRODUCTION

Dipyridamole is a nontoxic drug that acts as an inhibitor of the activation and aggregation of blood platelets (1, 2). The drug is also a powerful vasodilator, i.e. a substance which induces widening of the blood vessels after its systemic injection (1, 2). Dipyridamole,

which is marketed as Persantin, is commonly administered to patients before and after percutaneous transluminal coronary angioplasty ("Dottering"), mostly in com-

bination with aspirin. We became interested in dipyridamole in the course of our work, which is aimed at the manufacture of new materials with improved blood compatibility. We concentrate both on the preparation and on the testing (*in vitro* and *in vivo*) of such materials (3–7). Blood clotting as a result of the contact between blood and an artificial surface remains perhaps the most important problem in the development of improved cardiovascular devices. We know, particularly from the pioneering work of Vroman et al. (8–10), that contact between blood and an artificial surface immediately leads to adsorption of plasma proteins. Adsorbed proteins may be displaced by others, and these processes probably occur within several minutes. Proteins in the adsorbed state adopt a different molecular conformation as compared to the circulating state, and platelets and leukocytes may adhere via receptor sites that match structural patterns of an adsorbate. It has become clear that immunoglobulins, fibronectin, and fibrinogen have specific significance as adsorbates (11). When a platelet is activated through this mechanism, it may in turn trigger other platelets and induce generation of thrombin, leading to deposition of fibrin. These events will result in the formation of a thrombus. Recent work by Bamford

Scheme 1. Preparation of Conjugate Molecule 1

et al. implied that dipyridamole could play a role in the development of new blood-compatible materials (12, 13). Bamford et al. chemically coupled dipyridamole to a series of water-soluble macromolecules and subsequently showed that the drug retained its platelet-inhibitory activity. In some cases, the drug was even slightly potentiated. As the macromolecular vehicles containing dipyridamole cannot cross the platelet's membrane, these experiments revealed—although in an indirect manner—that dipyridamole can exert its function via a putative receptor site on the exterior of the platelet.

Later, we could also show that coupling of dipyridamole onto water-insoluble polymers (e.g., the polyurethane Pellethane D-55) markedly contributes to the blood compatibility of the surface, at least *in vitro* (3). Evidence in support of an inhibitory action of immobilized dipyridamole on contacting platelets has accumulated. Our data, taken together, suggest that the platelet inhibition by immobilized dipyridamole counteracts or overrules platelet activation by adsorbed plasma proteins (e.g., fibronectin or fibrinogen).

Immobilization of dipyridamole onto the surface of water-insoluble polymers was accomplished through a novel photoimmobilization technique (3–5, 14). To this end, we synthesized a series of novel molecules, which consist of a triply *tert*-butyldimethylsilyl (TBDMS)-protected (15) dipyridamole connected to a 4-azidobenzoyl group. It could be demonstrated that such conjugate molecules can be covalently coupled to a polyurethane surface via irradiation with ultraviolet (UV) light (14). The 4-azidobenzoyl group loses molecular nitrogen (N_2) upon UV irradiation, and this photoreaction generates a highly reactive (electrophilic) didehydroazepine structure (16–18). Then, reaction with a nucleophilic site at the polymer surface (e.g., a urethane NH group) generates a new covalent bond between the conjugate and the polymer surface.

We report here a comprehensive study on a new conjugate molecule, **1**, which has the characteristic

feature that the (protected) dipyridamole unit is linked to 4-azidobenzoyl via a *short hydrophilic* spacer chain.

We decided to prepare and test such a system since we anticipated that a hydrophilic spacer chain could facilitate exposure of the deprotected dipyridamole in the aqueous boundary layer at the polymer's surface. We report consecutively (i) synthesis of **1**, (ii) photoimmobilization of **1** on polyurethane sheets, (iii) deprotection and purification, (iv) physicochemical characterization of the modified surfaces (contact angles, XPS), and (v) *in vitro* tests of the blood compatibility of modified and unmodified surfaces. Moreover, it is described how compound **1** can be immobilized on the luminal surface of a short polyurethane vascular graft, which will be used in followup *in vivo* investigations.

MATERIALS AND METHODS

Preparation of Conjugate 1. The synthesis route to **1** is outlined in Scheme 1. The preparation started out with tris[*tert*-butyldimethylsilyl]dipyridamole (**2**), which was prepared from dipyridamole as described earlier (14). Compound **2** was reacted with 1-(2'-*O*-tritylethoxy)-2-(2'-bromoethoxy)ethane (**3**) in the presence of sodium hydride (19). This reaction afforded compound **4**, which was subsequently treated with zinc bromide to cleave the trityl group (20). The resulting alcohol, **5**, was esterified through reaction with 4-azidobenzoyl chloride. This reaction afforded the desired conjugate structure **1**, in 18% overall yield based on **2**. Purity and identity of conjugate **1** and all synthetic intermediates were estab-

lished unequivocally. Different analytical techniques, including chromatography (thin layer), high-field nuclear magnetic resonance (NMR, 400 MHz for ^1H), and fast atom bombardment mass spectrometry, were used.

All solvents and starting materials were of the highest available purity or were purified as specified. Pyridine and dichloromethane were distilled from calcium hydride and stored over Linde 3Å molecular sieves. Triethylamine was distilled from calcium hydride and stored over potassium hydroxide pellets. Tetrahydrofuran was passed through an alumina column, distilled from calcium hydride, and stored over Linde 3Å molecular sieves. Methanol was predried with iodine and magnesium turnings, distilled, and stored over Linde 3Å molecular sieves. Thin layer chromatography was performed on glass plates (3 × 10 cm) with a fluorescent indicator. Silica gel 60 (particle size 0.063–0.200 mm) was used for column chromatography. Mass spectra were run on a Kratos MS 80 RF instrument. ^1H NMR and ^{13}C NMR were recorded at 399.9 and 100.6 MHz, respectively, on a Varian Unity-Plus spectrometer, using deuterated chloroform or deuterated methyl sulfoxide as the solvent. Tetramethylsilane was used as the internal reference (δ = 0.00 ppm).

Preparation of 1-(2'-*O*-Triphenylmethylethoxy)-2-(2'-bromoethoxy)ethane (3). To a stirred solution of triethylene glycol (75.09 g, 500.00 mmol) and 4-(dimethylamino)pyridine (0.38 g, 3.13 mmol) in 125 mL of anhydrous pyridine was added triphenylmethyl chloride (17.42 g, 63.50 mmol) in 10 portions during 3 h. The solution was stirred for 16 h under exclusion of moisture. Then, pyridine was removed (last traces were removed by coevaporation with toluene). The residue was taken up in dichloromethane and washed with saturated aqueous bicarbonate (three times) and water (three times). The organic layer was dried on magnesium sulfate, filtered, and concentrated to dryness under reduced pressure. The crude product was applied to a silica gel column. Elution with 1:1 petroleum ether/ethyl acetate afforded pure 1-(2'-*O*-triphenylmethylethoxy)-2-(2'-hydroxyethoxy)ethane (i.e. monotritylated triethylene glycol) as a viscous oil: R_f (petroleum ether/ethyl acetate 1:1) = 0.38; yield, 20.56 g (84%); ^1H NMR (CDCl_3) δ 7.50–7.15 (15H, m, CPh_3), 3.66 (8H, m, $\text{OCH}_2\text{CH}_2\text{O}$), 3.59 (2H, t, CH_2OH), 3.24 (2H, t, CH_2OCPh_3), 2.95 (1H, br s, OH); ^{13}C NMR (CDCl_3) δ 144.09, 128.70, 127.80, 126.98, 86.59, 72.60, 70.68, 63.29, 61.69.

A solution of bromine (12.27 g, 76.81 mmol) in anhydrous dichloromethane (60 mL) was added dropwise to a solution of triphenylphosphine (18.60 g, 70.90 mmol) in anhydrous dichloromethane (125 mL). The addition was stopped as the yellow-brown color of free bromine persisted. Subsequently, anhydrous triethylamine (10.76 g, 106.35 mmol) and a solution of 1-(2'-*O*-triphenylmethylethoxy)-2-(2'-hydroxyethoxy)ethane (20.19 g, 59.08 mmol) in 75 mL of anhydrous dichloromethane were added dropwise. The resulting mixture was stirred for 1 h under exclusion of moisture. Then, all volatiles were removed under reduced pressure. The residue was taken up in diethyl ether and washed with water. The organic layer was dried on magnesium sulfate, filtered, and concentrated to dryness under reduced pressure. The crude product was applied to a silica gel column. Elution with dichloromethane afforded **3** as a white solid: R_f (dichloromethane) = 0.43; yield, 23.85 g (89%); ^1H NMR (CDCl_3) δ 7.50–7.18 (15H, m, CPh_3), 3.85 (2H, t, $\text{CH}_2\text{-Br}$), 3.70 (6H, m, $\text{OCH}_2\text{CH}_2\text{O}$), 3.44 (2H, t, CH_2O), 3.21 (2H, t, CH_2CPh_3); ^{13}C NMR (CDCl_3) δ 144.08, 128.69, 127.74, 126.91, 86.6, 71.28, 70.79, 70.75, 70.66, 63.31, 30.34; mp, 57.8 °C.

Preparation of Compound 5. Sodium hydride (60%, 0.906 g, 22.65 mmol) was added to a solution of **2** (3.84 g, 4.53 mmol) (**19**) in 50 mL of anhydrous tetrahydrofuran. The mixture was sonicated under argon for 15 min. Then, compound **3** (2.27 g, 4.98 mmol) was added and the reaction mixture was magnetically stirred for 16 h. The reaction mixture was poured into saturated aqueous ammonium chloride (150 mL), which was extracted with ethyl acetate. The combined organic layers were dried on magnesium sulfate, filtered, and concentrated to dryness under reduced pressure. The residue (crude **4**) was taken up in 10 mL of anhydrous dichloromethane and treated with 2 mL of anhydrous methanol and anhydrous zinc bromide (10.00 g, 45.00 mmol). This reaction mixture was magnetically stirred for 2 h. The solvents were evaporated under reduced pressure, and the residue was taken up in ethyl acetate and washed consecutively with a 0.1 M citric acid, saturated bicarbonate, and brine. The organic layer was dried on magnesium sulfate, filtered, and concentrated to dryness under reduced pressure. Crude **5** was applied to a silica gel column. Elution with 1:1 petroleum ether/ethyl acetate afforded pure **5** as a yellow viscous oil: yield, 1.10 g (25%); ^1H NMR (CDCl_3) δ 4.70–3.80 (34H, m, $\text{CH}_2\text{-N}$ and $\text{CH}_2\text{-O}$), 1.68–1.62 (12H, br s, CH_2 of piperidine rings), 0.84 (27H, s, *t*-Bu), 0.02 (18H, s, $\text{CH}_3\text{-Si}$).

Preparation of 4-Azidobenzoyl Chloride. A solution of 4-azidobenzoic acid (7.50 g, 45.98 mmol) (**21**) and thionyl chloride (16.29 g, 138.04 mmol) in 250 mL of anhydrous tetrahydrofuran was refluxed for 30 min. All volatiles were removed under reduced pressure (in the hood, stench). The solid residue was recrystallized from hexane to give pure 4-azidobenzoyl chloride as a yellowish solid: yield, 6.76 g (81%); ^1H NMR (CDCl_3) δ 8.05 (2H, d, aromatic H), 7.05 (2H, d, aromatic H); ^{13}C NMR ($\text{DMSO}-d_6$) δ 166.39, 143.87, 131.15, 127.20, 119.34, 119.05.

Preparation of Compound 1. Compound **5** (1.35 g, 1.39 mmol) and 4-azidobenzoyl chloride (0.28 g, 1.52 mmol) were dissolved in 50 mL of anhydrous pyridine, and the solution was magnetically stirred for 3 h. Then, pyridine was evaporated (last traces were removed by coevaporation with toluene). The residue was taken up in ethyl acetate and washed with 0.1 M citric acid, saturated bicarbonate, and brine. The organic layer was dried on magnesium sulfate, filtered, and concentrated to dryness under reduced pressure. The crude product was applied to a silica gel column. Elution with 4:1 petroleum ether/ethyl acetate afforded pure **1** as a yellow-brown oil: R_f (petroleum ether/ethyl acetate 1:1) = 0.68; yield, 1.12 g (72%); ^1H NMR (CDCl_3) δ 8.02 (2H, d, aromatic H), 7.02 (2H, d, aromatic H), 4.43 [2H, t, $\text{CH}_2\text{-C(O)}$], 4.05–3.48 (32H, m, $\text{CH}_2\text{-N}$ and $\text{CH}_2\text{-O}$), 1.65 (12H, br s, CH_2 of piperidine rings), 0.95 (27H, s, *t*-Bu), 0.02 (18H, s, $\text{CH}_3\text{-Si}$); ^{13}C NMR (CDCl_3) δ 160.34, 160.28, 153.69, 132.54, 131.51, 118.76, 70.36, 70.49, 69.76, 69.21, 64.18, 61.48, 51.50, 51.28, 48.82, 48.63, 26.24, 25.94, 25.12, 18.29, -5.32; FABMS, calcd for $\text{C}_{55}\text{H}_{97}\text{N}_{11}\text{O}_8\text{Si}_3$ m/z = 1224, obsd m/z = 1225 ($\text{M} + \text{H}$) $^+$.

Preparation of Modified Polyurethane Surfaces. Throughout our experiments, we used a medical grade polyurethane foil (Pellethane D-55). The foil had a smooth surface (as could be verified with scanning electron microscopy) and was transparent; its thickness was 0.4 mm. Compound **1** was dissolved in 2-propanol (concentration 1 mM), and this solution was sprayed onto several specimens of the polyurethane foil (dimensions 50 × 50 mm). A compressed-air sprayer was used (tube-type, Aldrich Z12,629-2). During spraying, the polymer surface was placed horizontally and consecutively wetted,

dried (air föhn), and turned by 90°. The procedure of wetting, drying, and turning was repeated 20 times. Then, each foil was irradiated for 15 min with a Philips HPA 1000 high-power UV lamp (Philips Lighting, Eindhoven, The Netherlands). The distance between the lamp and the foil surface was 30 cm. Technical details on the lamp are as follows: nominal power, 930 W; radiation output (mW/cm², measured at 1.00 m distance), UV-A 2500, UV-B 900, UV-C 230. After irradiation, each foil was thoroughly washed with 2-propanol and immersed for 24 h in a stirred solution of tetrabutylammonium fluoride in nitromethane (22). This reagent is known to effectively cleave the TBDMS groups. Each foil was then thoroughly washed with 2-propanol and water and stored in dry form.

Physicochemical Characterization of the Modified Surfaces. The UV extinction of dipyrindamole provided a convenient means to obtain an estimate of the surface concentration. The UV absorption spectrum of dipyrindamole shows a maximum at $\lambda = 408$ nm. The molar extinction coefficient at this wavelength is 4397 L mol⁻¹ cm⁻¹. A piece of the unmodified polyurethane (138.79 mm²) was dissolved in tetrahydrofuran (4.50 mL). The UV extinction spectrum was measured and stored in the digital memory of the spectrometer. Then, a similar piece of the modified polyurethane (139.67 mm²) was dissolved in 4.53 mL of tetrahydrofuran (same concentration as the blank). The UV extinction was measured at 408 nm, and the density of immobilized dipyrindamole coupled to the polyurethane was calculated (3).

Contact angle measurements were performed according to the captive bubble method (23). The contact angle apparatus consists of a traveling microscope with a 40× eyepiece with fine right-angle crosshairs and a long-distance objective, a variable intensity light source, and a micrometer-adjustable X-Y stage vertically mounted on an optical bench. The stage contains a plexiglass box. The polyurethane sheets were held on the underside of a polycarbonate plate with the modified surface exposed. The box was then filled with doubly distilled water, and the plate containing the polyurethane sheet was lowered in the box until the polyurethane sheet was completely immersed. A bubble of air with a volume of ~0.1 mL was positioned under the surface and the contact angle was measured.

For the X-ray photoelectron spectroscopy (XPS) experiments, polyurethane sheets were mounted on a standard sample holder and inserted via a separately pumped load lock into a Leybold MAX200 XPS instrument. Sample areas of 4 × 7 mm² were analyzed. Mg K α (1253.6 eV) radiation of a Mg/Al double-anode X-ray tube (13 kV, 20 mA) was used. The spectrometer was calibrated using Ag, Cu, and Au (24). At the used pass energy of 48 eV, the full width at half-maximum for Ag 3d_{5/2} was 0.95 eV. The base pressure in the analysis chamber was well below 1 × 10⁻⁹ mbar. The instrument was controlled by a HP A400 computer, and a Leybold DS100 data system was used for data acquisition and analysis. For the quantitative analysis the spectra were corrected for the analyzer transmission function, and a linear background was subtracted (25). Sensitivity factors were calculated, using the approach of Nöller et al. (26) and the Scofield cross sections (27). For energy referencing a C 1s binding energy of 285.0 eV for aliphatic carbon was used (28). The samples were measured with different take-off angles. Besides the usual angle (90°), the sample holder was rotated in such a way that a take-off angle of ~6° was obtained. Derivatization of the hydroxyls of the dipyrindamole by trifluoroacetic anhydride was achieved

Figure 1. 400 MHz ¹H NMR spectrum of **1**, dissolved in CDCl₃. Spectral parameters: spectral width, 6000 Hz; number of transients, 8; time domain, 32K; size, 64K; Fourier transformation without application of a spectral window. by exposing the polyurethane surface to trifluoroacetic anhydride vapor for 5 min in a sealed vessel (29). The polyurethane surface was then removed and dried.

Biochemical Characterization. The unmodified and modified surfaces were subjected to the *in vitro* thrombin generation assay developed by Lindhout et al. (30) and described extensively in our previous work (3, 7, 31). Two reference materials were included in the assay: polyethylene (PE), which has a high surface thrombogenicity, and poly(vinyl chloride) (PVC), which is a relatively passive material. Note that the blood was taken from a healthy donor; the blood plasma was anticoagulated with citrate prior to the assay, and the addition of calcium chloride marks the actual start of the experiment.

Following incubation with platelet-rich plasma, the unmodified and modified surfaces were subjected to scanning electron microscopy (SEM) to study the morphology of adhered platelets. The platelets attached to the polyurethane surfaces were fixed with glutaraldehyde. The specimens were then dehydrated with ethanol, subjected to critical point drying, and sputter-coated with gold.

RESULTS

Physicochemical Characterization. The chemical synthesis of conjugate compound **1** proceeded smoothly. Figure 1 shows the 400 MHz proton NMR spectrum of **1**, dissolved in deuterated chloroform. The spectrum clearly reveals the identity and purity of the product. Fast atom bombardment mass spectrometry provided further evidence for the identity of **1** (*vide supra*).

Measurements of the surface density of immobilized dipyrindamole were performed through UV spectrophotometry. The modified surfaces (dimensions approximately 50 × 50 mm) showed uniform density of immobilized dipyrindamole. This was concluded after comparison of different pieces (dimensions 10 × 15 mm), cut out of the foil. All physicochemical and biochemical experi-

Table 1. Contact Angles Measured with the Captive Bubble Method for the Unmodified and Modified Surfaces

unmodified surface		modified surface	
49.5	51.2	19.1	22.3

47.3		20.8	

ments reported here correspond with a surface density of 13 ± 1 nmol/cm² of immobilized dipyridamole.

Table 1 compiles the results of the water contact angle measurements on both the unmodified and modified surfaces. The contact angles were measured with the captive-bubble method. Under each surface, five air bubbles (~ 0.1 mL) were placed, and height (h) and diameter (d) of the bubbles were measured. The contact angle α was then calculated from the formula (23)

$$\alpha = \cos^{-1}[-1 + 2h/d]$$

The data in Table 1 clearly show that the modified surface is more hydrophilic than the unmodified surface.

Furthermore, both surfaces were studied with XPS. As expected, oxygen, nitrogen, and carbon were detected. No contaminations were found on either surface. The observed binding energies for the oxygen, nitrogen, and carbon species are in good agreement with those of Beamson and Briggs (28). The spectra were analyzed by applying curve deconvolution, using a Gaussian line shape. The N 1s narrow-scan subspectrum was used to get more detailed information on the nature of the surface. The increase of the N 1s signal was not significant, and this inspired us to measure the modified surface also under another take-off angle. This enables one to look more at the outermost layer of the modified surface. The sample holder was rotated in such a way that a take-off angle of $\sim 6^\circ$ was obtained. This experiment clearly showed a change in surface chemistry, which could be derived from changes in the peak shape of the narrow-scan spectra. Figure 2 shows the expansion of the N 1s narrow-scan spectrum measured at a take-off angle of 90° . Figure 3 shows the expansion of the N 1s narrow-scan spectrum measured at a take-off angle of $\sim 6^\circ$. The N 1s line is less intense, but broadened, consistent with the presence of another nitrogen functionality in the outermost surface layer (aromatic nitrogen from the dipyridamole). Table 2 gives the atomic percent C, N, and O and the elemental ratios C/O and C/N for the unmodified and modified surfaces. Another important conclusion that can be drawn from the XPS spectra of the modified surface is that the Si protective groups were completely removed in the deprotection/washing steps following the irradiation with ultraviolet light. The XPS spectra do not show the very characteristic Si signals at approximately 102 (Si 2p) and 153 (Si 2s) eV. For this reason, we expected the presence of free hydroxyl groups (three OH groups for each immobilized dipyridamole) for the modified surface. This expectation could be verified by exposure of the modified surface to a vapor of tetrafluoroacetic anhydride in a sealed vessel. The anhydride then reacts with free hydroxyl groups to form the trifluoroacetic ester. This vapor-phase labeling of hydroxyl groups has been shown to be very successful (29). The CF₃ tag is easily detected since two extra peaks appear in the XPS spectrum: (i) the F 1s line at approximately 690 eV and (ii) the F Auger line at approximately 600 eV (Mg K α radiation; see ref 28, p 236, and ref 29). Figure 4 shows the overall XPS scan of the modified surface (take-off angle of $\sim 6^\circ$). Figure 5 shows the XPS scan of the modified surface after

Figure 2. N 1s narrow-scan XPS spectrum of the modified surface measured at a take-off angle of 90° . The experimental spectrum can be simulated by adding the simulated spectra i and ii. Note that (iii), which equals (i) + (ii), fits the experimental spectrum; (i) corresponds with the aromatic N of the dipyridamole ring system, and (ii) corresponds with the N atoms of the polymer urethane groups, and the nonaromatic Ns of dipyridamole.

Figure 3. N 1s narrow-scan XPS spectrum of the modified surface measured at a take-off angle of $\sim 6^\circ$. Spectral simulation was accomplished as described in the legend to Figure 2.

Table 3. Results of the Thrombin Generation Test

material	lag time (s)	[thrombin] _{max} (nM)
PE	395	169
PVC	859	79
polyurethane	569	85
modified polyurethane	1267; 1282	68; 75

Biochemical Characterization. The unmodified and modified surfaces were subjected to the *in vitro* thrombogenicity test developed by Lindhout et al. (30). PE, a highly thrombogenic material, PVC, a relatively passive material, and unmodified polyurethane were used as reference materials. The assay produces a thrombin generation curve for each surface tested. The experiments on the modified surface were performed in duplicate. Figure 6 shows the thrombin generation curves for both the unmodified and modified surfaces, exposed to human platelet-rich blood plasma. Each thrombin generation curve yields two parameters, which are directly related to the thrombogenicity of the material. The first parameter is the lag time, i.e. the time elapsing between the moment of recalcification and the moment at which the free thrombin concentration starts to increase. The second parameter is the maximal concentration of free thrombin reached during the experiment. The results of these experiments with all surfaces are compiled in Table 3. It should be noted that the maximum thrombin concentrations were obtained after correction of the experimental thrombin generation curves for the residual amidolytic activity of the thrombin- α_2 -macroglobulin complex according to the method of Hemker et al. (32). The thrombogenicity of the different surfaces decreases in the following order: PE > polyurethane > PVC > modified polyurethane. The

Figure 7. Overview scanning electron micrograph of the unmodified surface after incubation with platelet-rich plasma.

Figure 8. Overview scanning electron micrograph of the modified surface after incubation with platelet-rich plasma.

surface immobilization of compound **1** leads to a decrease of the thrombogenicity of the polyurethane; the lag time increases from 569 s for the unmodified polyurethane to 1267 and 1282 s (duplicate) for the modified surface. The maximum free thrombin concentration decreases from 85 nM for the unmodified polyurethane to 68 and 75 nM (duplicate) for the modified surface.

The unmodified and modified surfaces were further studied with SEM to look at the adherence and activation of platelets on the surfaces. The unmodified surface was covered to a large extent by activated/spreaded platelets, as is shown in Figure 7. From the scanning electron micrographs, a surface density of approximately 7×10^3 platelets/mm² could be estimated. The modified surface showed far less adhered platelets (Figure 8); the scanning electron micrograph indicated a surface density of approximately 6×10^2 platelets/mm². This implies that the surface modification results in a decrease of platelet adhesion by, roughly, 1 order of magnitude. This finding is in good agreement with our previous work (3, 5). Figure 9 shows a detail scanning electron micrograph of an individual platelet, adhered to the modified surface. While this particular platelet merely shows the formation of small pseudopodia, and no spreading, it should be noted that spread platelets could also be found on the modified surface.

DISCUSSION AND CONCLUDING REMARKS

The present results clearly demonstrate that dipyrindamole can be immobilized onto polyurethane surfaces through use of conjugate **1**. A combination of different physical analytical techniques reveals the presence of fully deprotected dipyrindamole in the outermost layer of

Figure 9. Detailed scanning electron micrograph showing the morphology of a platelet adhered to the modified surface. Formation of small pseudopodia is noted.

the modified surface. Furthermore, the modified surface features a markedly increased hydrophilicity, as compared to the control (i.e. unmodified polyurethane). This can be attributed to the short polyethylene glycol spacer chain that bridges dipyridamole to the polymer surface.

To the best of our knowledge, the present results show for the first time that it is possible to couple a pharmacologically active drug to a polymer surface via a chain of covalent bonds and to simultaneously achieve a substantial increase of the surface hydrophilicity. We believe that this combination of effects holds promise with respect to passivation of artificial surfaces. From the classic work of Vroman and others (*vide supra*), it is known that contact between blood and an artificial surface first leads to adsorption of plasma proteins and then to activation of platelets or leukocytes, which recognize one or more specific structural patterns of the proteinaceous adsorbates. A modified surface as studied in our present work interferes with this mechanism at two different stages: (i) the hydrophilic nature of the surface leads to substantial hydration and hence to a diminished affinity for proteins; (ii) the exposure of a platelet inhibitory agent (dipyridamole in our case) suppresses activation of contacting blood platelets.

We did not perform a quantitative comparison of the modified surfaces based on **1** and those to which dipyridamole was coupled either directly or via a short hydrophobic spacer chain. Nevertheless, our thrombin generation assay suggests that photoimmobilization of **1** leads to the best results (15). This idea is reinforced by a comparison of the scanning electron micrographs. Figure 8 (this work) shows that the modified polyurethane surface, prepared with conjugate **1**, adsorbs far fewer platelets after exposure to human platelet-rich plasma (approximately $7 \times 10^3/\text{mm}^2$) as compared to the control (approximately $6 \times 10^2/\text{mm}^2$). Upon use of a short hydrophobic spacer chain $[-\text{C}(\text{O})\text{CH}_2\text{CH}_2\text{CH}_2\text{O}-]$, we previously found that platelet adhesion was also markedly suppressed (in comparison with the control) (3). However, the platelets present on the latter surface showed substantial spreading and formation of pseudopodia.

On the basis of our experience with photoimmobilization of dipyridamole to polyurethane surfaces, we are currently working on photoimmobilization of conjugate **1** on the luminal surface of a polyurethane vascular graft. This graft has an inner diameter of 5 mm and a flexible, compliant, and porous wall structure. Our results with this new vascular graft (*in vitro* and *in vivo*) will be published later.

Received September 20, 1996[⊗]

σ -Receptors have recently been shown to be expressed in a variety of human tumor cells. In an attempt to prepare ^{99m}Tc chelates that would bind to σ -receptors and be useful for imaging σ -receptor-positive tumors, we have synthesized and characterized a bisaminothiol (BAT) chelate appended with a σ -receptor pharmacophore. The synthesis of target ligand **VII** was accomplished in three steps starting from bicyclic imidazolidino[1,2-*d*]dithiazapine. The labeling of the BAT ligand with ^{99m}Tc was carried out in high yields (>80%) using stannous tartarate as a reducing agent, resulting in the target σ -receptor-binding chelate [^{99m}Tc]BAT-EN6, **III**. Similarly, ^{99g}Tc chelate with ligand **VII** was prepared from ammonium pertechnetate by reduction with stannous tartarate. ^{99m}Tc -radiolabeled chelate was purified by reversed phase HPLC, and cell binding with human breast ductal carcinoma (T47D) was performed. A high degree of specific binding (90–97%) was obtained when σ -receptor ligands such as halogenated phenylethylenediamines were used to determine nonspecific binding. A modest affinity dose-dependent inhibition of binding was found with BD1008, **I**, and 4-IPEMP, **II** ($\text{IC}_{50} = 47 \pm 2$ and 59 ± 5 nM, respectively), known σ -ligands. No specific binding was found with [^{99m}Tc]BAT, **VIII** [without appended σ -pharmacophore (*N*-alkyl-substituted ethylenediamine)], showing that biological activity resulted from the pendent pharmacophore. ^{99g}Tc complex was found to be a potent inhibitor ($K_i = 42.7 \pm 8.5$ nM) of [^3H]DTG binding in guinea pig brain membranes. Scatchard analysis of [^{99m}Tc]BAT-EN6 (spiked with [^{99g}Tc]BAT-EN6) binding in T47D breast cancer cells showed a saturable binding, with a K_d of 43.5 ± 14.7 nM and a B_{max} of 3121 ± 130 fmol/(mg of protein). A biodistribution study of [^{99m}Tc]BAT-EN6 chelates in Sprague Dawley rats showed hepatic clearance, as expected. A blocking study at 4 h postinjection using 2 μmol of BD1008 with [^{99m}Tc]BAT-EN6 showed a significant decrease of radiopharmaceutical in liver (15.32 vs 22.31% ID/organ) and kidney (1.01 vs 2.21% ID/organ), organs known to possess high concentrations of σ -receptors. These results imply that [^{99m}Tc]BAT-EN6 binds with high affinity to σ -receptors expressed in human breast tumor cells, and it may be useful for imaging breast cancer.

INTRODUCTION

Recently, we have been interested in the development of molecular probes for imaging σ -receptor sites on tumors. σ -Receptors exist in at least two distinct subtypes termed σ -1 and σ -2 (*1*). Tritiated σ -ligand probes such as (+)-pentazocine (a σ -1 selective ligand) (*2*) and tritiated 1,3- σ -ditolylguanidine (DTG, a σ non-subtype selective ligand) (*3*) were recently used to characterize the expression of σ -receptors on various human tumor cell lines and to establish the pharmacological profiles for various drugs. A very high density of both σ -1 and σ -2 receptor subtypes was expressed on many human and rodent tumor cell lines [$B_{\text{max}} = 1000$ – 4000 fmol/(mg of protein)] (*4*). High levels of σ -receptors have also been reported in the membrane preparations from surgically removed solid human tumor tissue using [^3H]DTG (*5*). Furthermore, σ -receptors expressed in human melanoma cells (*6*), breast cancer cells (*7*, *8*), non-

small cell lung carcinoma (*9*), and human prostate tumor (*10*) cells have been characterized using different radioiodinated σ -ligands. Scatchard analysis of [^{125}I]-4-(*N*-benzylpiperidin-4-yl)-4-iodobenzamide binding in human breast adenocarcinoma (MCF-7) cells revealed that breast cancer cells possess approximately 1 million receptors per cell (*4*). σ -Receptors are therefore very attractive targets for the development of diagnostic probes. Hence, we embarked on a study of ^{99m}Tc -radiolabeled chelates that would bind to the σ sites because of the excellent physical characteristics of this radionuclide.

^{99m}Tc is one of the most widely used radionuclides in clinical nuclear medicine due to its instant availability from the $^{99}\text{Mo}/^{99m}\text{Tc}$ generator, ideal physical properties ($t_{1/2} = 6.02$ h; γ -energy = 140 keV), an absence of β -emissions, a low radiation burden to patients, and its low cost. One of the major challenges in the development of receptor-based ^{99m}Tc radiopharmaceuticals for diagnostic imaging is the design and synthesis of high-affinity ^{99m}Tc chelates for specific receptor sites. In order to provide in vivo stability to the radiolabel, ^{99m}Tc has to be complexed to a chelate. Thus, a molecule suitable for imaging a particular receptor site would possess a chelating moiety and a pharmacological entity appended to the chelate. This generally results in an increase in steric bulk of the molecule, and the affinity for the receptors is often compromised. In recent years, some progress has been made for imaging steroid receptors (*11*), muscarinic

receptors (12), and vesamicol receptors (13) using bisaminothiol-based ^{99m}Tc chelates.

Halogen-substituted arylenediamines have been studied extensively for their σ -affinities (14, 15). BD1008 [*N*-2-[(3,4-dichlorophenyl)ethyl]-*N*-methyl-2-pyrrolidinylethylamine], **I**, is one of the most potent halogenated arylenediamine derivatives. One congener of this series, *N*-[2-(4-iodophenyl)ethyl]-*N*-methyl-2-(1-piperidinylethylamine) (4-IPEMP, **II**), has recently been well-studied (Figure 1) (16). Compound **II** showed very high specific binding to human breast and melanoma tumor cells. The inhibition binding isotherms for 4-[^{125}I]PEMP in guinea pig brain also were consistent with σ -receptor pharmacology. On the basis of the structure-activity relationship of de Costa et al. (14), we reasoned that the substituted ethylenediamine portion of **II** is the molecular recognition fragment that imparts high affinity for σ -receptor, with the halogen-substituted aromatic ring occupying the lipophilic pocket of the receptor. Therefore, we decided to append the *N*-methyl-2-piperidinylethylamine pharmacophore into a basic bisaminoethanethiol ligand **VIII** (Figure 2) (that is known to form highly stable, neutral, and lipophilic complexes with ^{99m}Tc) to test the hypothesis that this molecular recognition fragment would impart specificity for the σ -receptors to the resulting ^{99m}Tc -labeled complex. In this article, we report preliminary results of the synthesis of our target ligand **VII**, its complexation with ^{99m}Tc and ^{99}Tc , and the preliminary pharmacological characterization and in vivo distribution of the resulting complexes.

EXPERIMENTAL PROCEDURES

General. All chemicals and reagents not otherwise noted were purchased from Aldrich Chemical Co. Melting points were determined with a Fisher-Johns apparatus and are reported uncorrected. ^1H NMR spectra were recorded on a Bruker 300 AM spectrometer. The thin-layer chromatography (TLC) system consisted of Analtech uniplat silica gel GF plates (250 μm , 10 \times 20

cm). Mass spectra (chemical ionization or electron impact) were recorded on a Finnigan 1015 mass spectrometer. For ^{99}Tc complex, electrospray ionization (ESI) mass spectra was obtained using the Finnigan TSQ700 triple-quadrupole mass spectrometer. $\text{Na}^{99m}\text{TcO}_4$ was eluted with the $^{99}\text{Mo}/^{99m}\text{Tc}$ generator obtained from DuPont Merck (Billerica, MA). Elemental analysis was performed by Quantitative Technologies, Inc. (Whitehouse, NJ). Imidazolidino[1,2-*d*]dithiazepine (**IV**) was prepared according to a published method (17).

Chemical Synthesis. *Reaction of Imidazolidino[1,2-*d*]dithiazepine (IV) with Chloroacetyl Chloride.* To a solution of imidazolidino[1,2-*d*]dithiazepine (8.6 g, 37 mmol) in CHCl_3 (50 mL) was added 10% NaOH (50 mL), and the mixture was cooled with an ice/water bath. To this was added chloroacetyl chloride (4.2 mL, 53.3 mmol), and the mixture was stirred for 1 h. The bath was removed, and the mixture was stirred for an additional 0.5 h. The organic layer was separated, dried over anhydrous sodium sulfate, and evaporated to a thick oil. This oil was dissolved in ethyl acetate/hexanes (1:5) to give white solid **V** (5.2 g, 45%): ^1H NMR (CDCl_3) δ 1.23 (s, 3H), 1.24 (s, 3H), 1.27 (s, 3H), 1.34 (s, 3H), 2.58 (d, J = 15 Hz, 1H), 2.83–2.87 (m, 1H), 3.24 (m, 1H), 3.32 (d, J = 15 Hz, 1H), 3.45–3.55 (m, 1H), 3.70–3.76 (m, 1H), 4.04 (s, 2H), 4.71 (s, 1H). Anal. Calcd for $\text{C}_{12}\text{H}_{21}\text{N}_2\text{OS}_2\text{Cl}$: C, 46.66; H, 6.85; N, 9.07. Found: C, 46.75; H, 6.68; N, 9.03.

Reaction of V with N-Methyl-2-(1-piperidinyl)ethylamine. To a solution of **V** (6.0 g, 20 mmol) in dry DMF (50 mL) was added powdered potassium carbonate (3.3 g, 23.9 mmol). To this was added *N*-methyl-2-(1-piperidinyl)ethylamine (4.26 g, 29.9 mmol), and the mixture was stirred overnight at room temperature. This was evaporated to dryness under vacuum and washed with water (2 \times 50 mL). This was redissolved in chloroform, washed with water, and dried over anhydrous sodium sulfate. The organic layer was evaporated to dryness. This oil was converted to hydrochloride salt and recrystallized from 20% ethanol in acetonitrile to give quantitative yields of **VI**: ^1H NMR (CDCl_3) δ 1.17–1.26 (m, 12H), 1.33–1.49 (m, 6H), 2.21 (s, 3H), 2.3–2.5 (m, 9H), 2.5–2.7 (m, 1H), 2.9–3.1 (m, 2H), 3.2–3.3 (m, 3H), 3.9–4.0 (m, 1H), 4.65 (s, 1H). Anal. Calcd for $\text{C}_{20}\text{H}_{38}\text{N}_4\text{OS}_2$: C, 57.93; H, 9.24; N, 13.51. Found: C, 58.05; H, 9.12; N, 13.39.

Reduction of VI with LAH. To the suspension of LAH (2.2 g) in THF (100 mL) was added a solution of amide (4.0 g), and the mixture was heated at reflux for 19 h. The reaction was quenched with saturated aqueous NH_4Cl , and ether (50 mL) was added and filtered through a pad of Celite. The solid was washed with ether (3 \times 50 mL), and to the combined ether layer was added ethanol saturated with HCl to give a sticky white solid **VII**. To this more was added ethanol to give a powdery white solid (2.0 g, 38%): MS (m/e) 403 [M + 1] $^+$.

Radiochemical Synthesis. *Preparation of [^{99m}Tc]BAT-EN6 Complex.* An aqueous solution of ligand **VII** (1.0 mg/mL) was prepared. To a 0.2 mL solution of the ligand was added 2.0 mCi of $\text{Na}^{99m}\text{TcO}_4$. A freshly prepared solution from a saturated aqueous stannous tartarate (0.2 mL) was added to the mixture and the mixture incubated at room temperature for 10 min. A saturated solution of sodium bicarbonate (0.2 mL) was added to the mixture, and [^{99m}Tc]EN6 was vortexed and extracted in 1.0 mL of chloroform. The organic layer was separated from the aqueous layer, evaporated under a stream of air, dissolved in methanol, and purified by HPLC. The desired fractions were collected and solvents

removed in vacuo and dissolved in normal saline for cell binding studies.

Preparation of [^{99g}Tc]BAT-EN6 Complex. To a 20 mL scintillation vial were added ammonium pertechnetate (104 mg, 0.57 mmol), hydrochloride salt of ligand **VII** (273 mg, 0.59 mmol), and 50% aqueous ethanol (10 mL). The mixture was stirred at room temperature, and solid stannous tartarate (154 mg) was added. The contents were stirred at room temperature overnight, whereby the color of the solvent turned light brown. The complex was extracted from the solvent by addition of (2×1 mL) chloroform. The organic layers were combined and evaporated overnight in a hood, and [^{99g}Tc]BAT-EN6 complex was purified by passing through a silica gel column eluting with 90:10 $\text{CHCl}_3/\text{MeOH}$: MS (m/z) 517 (MH^+).

BIOLOGICAL PROCEDURES

Cell Culture. Human ductal breast carcinoma cells (T47D) were purchased from ATCC, (Rockville, MD) and cultured in serum-supplemented 1640 RPMI containing 10% heat-inactivated fetal bovine serum (GIBCO) at 37 °C. The cells were adherent and split weekly in a 1:20 ratio using trypsin/EDTA (GIBCO).

In Vitro σ -Receptor Binding Assays. The binding assays were carried out essentially as previously described using guinea pig brain membranes with some modifications (8a,b). Guinea pig brain membranes (500 μg of proteins) were incubated with 5 nM [^3H]DTG (39.4 Ci/mmol) and various concentrations of competing ligand in 0.5 mL of Tris-HCl (pH 8.0) for 120 min at 25 °C. Nonspecific binding was determined in the presence of 10 μM haloperidol. [^{99g}Tc]BAT-EN6 was used in 12 concentrations ranging from 0.05 to 10 000 nM. Assays were determined by dilution with 5 mL of ice-cold 10 mM Tris-HCl (pH 8.0) and filtration through glass fiber filters using a Brandel cell harvester (Brandel, Gaithersburg, MD). Filters were then washed twice with ice-cold buffer. Filters were soaked in 0.5% poly(ethyleneimine) for at least 30 min at 25 °C prior to use. The filters were then counted in CytoScint (ICN, Costa Mesa, CA) after an overnight extraction of counts. In order to control for possible interference with tritium β counting from ^{99g}Tc β emission, parallel curves were run under exactly the same conditions using membranes and 0.05–10 000 nM [^{99g}Tc]BAT-EN6, except with the omission of [^3H]DTG. No radioactivity above background could be detected in the tritium channel at [^{99g}Tc]BAT-EN6 concentrations up to 1000 nM; thus, no correction was necessary. IC_{50} values were determined using the computerized iterative curve-fitting program GraphPAD Inplot4 (GraphPAD Software, San Diego, CA).

Competition Binding Studies in T47D Cells. The cells were scraped using a cell scraper from T75 culture flasks and centrifuged in a Sorvall 6000B centrifuge at a speed of 4000 rpm. The growth medium was removed, and the cell pellet was resuspended in RPMI 1600 serum free media. The affinity of compounds for sites labeled by [^{99m}Tc]BAT-EN6 in human breast cancer cells was determined by heterologous in vitro competitive binding assays in whole cells. The following method was used. A small aliquot of the cell suspension (100 μL) was incubated with [^{99m}Tc]BAT-EN6 and varying concentrations (10^{-4} – 10^{-12} M) of aryethylenediamines, keeping a total volume of 1.0 mL constant. The cells were incubated at 37 °C for 1 h and subsequently filtered through a Brandel cell harvester (Brandel) and washed with deionized cold water. The radioactivity associated with the cells on filters was counted on a Beckman (DP 5500) γ counter. The optimum pH for the binding was found

to be between 7 and 8. Each data point represents an average of three values. The K_i values are average of two experiments. The data were analyzed with the iterative nonlinear least-squares curve-fitting program GraphPAD Inplot (GraphPAD Software). The Cheng–Prusoff equation was then used to convert IC_{50} values to apparent K_i values.

Saturation Binding and Scatchard Analysis. Saturation binding and Scatchard analysis of [^{99m}Tc]BAT-EN6 were carried out in membranes from T47D human ductal breast cells, which were prepared as described previously (4). A methanol/sodium phosphate buffer (pH 8.0) solution of carrier free [^{99m}Tc]BAT-EN6 in trace concentration was mixed in equal proportion with a 10 μM solution of [^{99g}Tc]BAT-EN6 to approximately 0.35 Ci/mmol. This solution was diluted into glass or polypropylene assay tubes to final concentrations ranging from 1 to 1000 nM. Incubations were carried out in a final volume of 0.25 mL of 50 mM Tris-HCl containing 250 μg of membrane protein for 120 min at 37 °C. Nonspecific binding was determined at each radioligand concentration in the presence of 10 μM BD1008, a ligand with high affinity for both σ -1 and σ -2 receptors. Assays were terminated by addition of 0.5 mL of ice-cold 10 mM Tris-HCl (pH 8.0) and filtration through glass fiber filters. Filters were then washed twice with 0.5 mL of ice-cold buffer and counted in a γ counter. Filters were soaked in 0.5% poly(ethyleneimine) for at least 30 min prior to use in order to reduce nonspecific binding of radioligand to filters. Each experiment was carried out in duplicate. Data were analyzed using the iterative curve-fitting program BDATA (Baltimore, MD).

Animal Biodistribution and Blocking Studies in Rats. Sprague–Dawley rats (200–250 g) were anesthetized with ketamine/xylazine and injected intravenously with [^{99m}Tc]BAT-EN6 (10–20 μCi) in 0.2 mL of saline containing up to 20% ethanol solution. At 0.5, 1, and 4 h postinjection, blood samples were drawn by cardiac puncture, and the rats were sacrificed thereafter by cardiectomy while under ketamine/xylazine anesthesia. The organs of interest were then excised, blotted with tissue paper, and weighed, and the radioactivity was counted. The percent injected dose/organ was determined by comparison of the tissue radioactivity with suitably diluted, known quantity aliquots of the injected dose. For in vivo blocking studies, 2.16 μmol of BD1008 was premixed with [^{99m}Tc]BAT-EN6 and then injected through the tail vein. The animals were sacrificed at 4 h postinjection, and the organs of interest were removed and handled as above.

RESULTS AND DISCUSSION

The synthesis of the tetradentate N_2S_2 ligand was achieved (Scheme 1) through the sodium borohydride-initiated transannular cyclization of 1,2-dithia-5,8-diazacyclodeca-4,8-dienes (17). The resulting bicyclic imidazolidino[1,2-*d*]dithiazapine **IV** was acylated with chloroacetyl chloride in a mixture of chloroform and 10% aqueous sodium hydroxide. The acylated imidazolidino[1,2-*d*]dithiazapine **V** was then alkylated with *N*-(methylethyl)piperidine to produce amide **VI**. Reduction of this amide using lithium aluminum hydride in THF gave the desired ligand **VII** possessing free bisaminothiol groups for chelating ^{99m}Tc along with the pendent recognition elements for σ -receptor affinity. The labeling of **VII** with ^{99m}Tc was carried out in high yields (80–95%) by incubating an aqueous solution of ligand with generator-eluted sodium [^{99m}Tc]pertechnetate (carrier free) in the presence of freshly prepared stannous tartarate which was the reducing agent. The lipid soluble ^{99m}Tc complex

Figure 3. Inhibition binding isotherms of [^{99m}Tc]BAT-EN6 with substituted haloarylethylenediamines in human ductal carcinoma (T47D) cells. Diamonds represent BD1008, and circles represent IPEMP.

Scheme 1. Synthesis of [^{99m}Tc]N₂S₂-Conjugated Substituted Ethylenediamine^a

III [^{99m}Tc]BAT-EN6 was extracted from the aqueous solution using chloroform and purified by using C-18 reversed phase HPLC column [retention time = 15 min, 90:10 methanol/trishydrochloride (10 mM, pH 4.5) buffer]. It is well-known for BAT ligands that they form a square pyramidal technetium(V)-oxo core with the oxo group occupying the apical position. The complexation of *N*-monoalkylated BAT ligands with technetium results in the formation of syn and anti diastereomeric isomers each as a pair of enantiomers. The stereochemistry reflects the orientation of the *N*-alkyl group, syn or anti, with respect to apical oxygen (18). An HPLC trace of ^{99m}Tc complex indicated two peaks related to syn and anti isomers in an approximate ratio of 55:45. A ground state (^{99g}Tc) complex of the ligand was prepared by reaction with ammonium pertechnetate using stannous tartarate as a reducing agent. As expected, a neutral, lipophilic, Tc^{VO} complex was obtained that was characterized by electrospray ionization mass spectroscopy ($\text{MH}^+ = 517$). The mass spectral fragmentation [a loss of $[\text{SC}(\text{CH}_3)_2-$

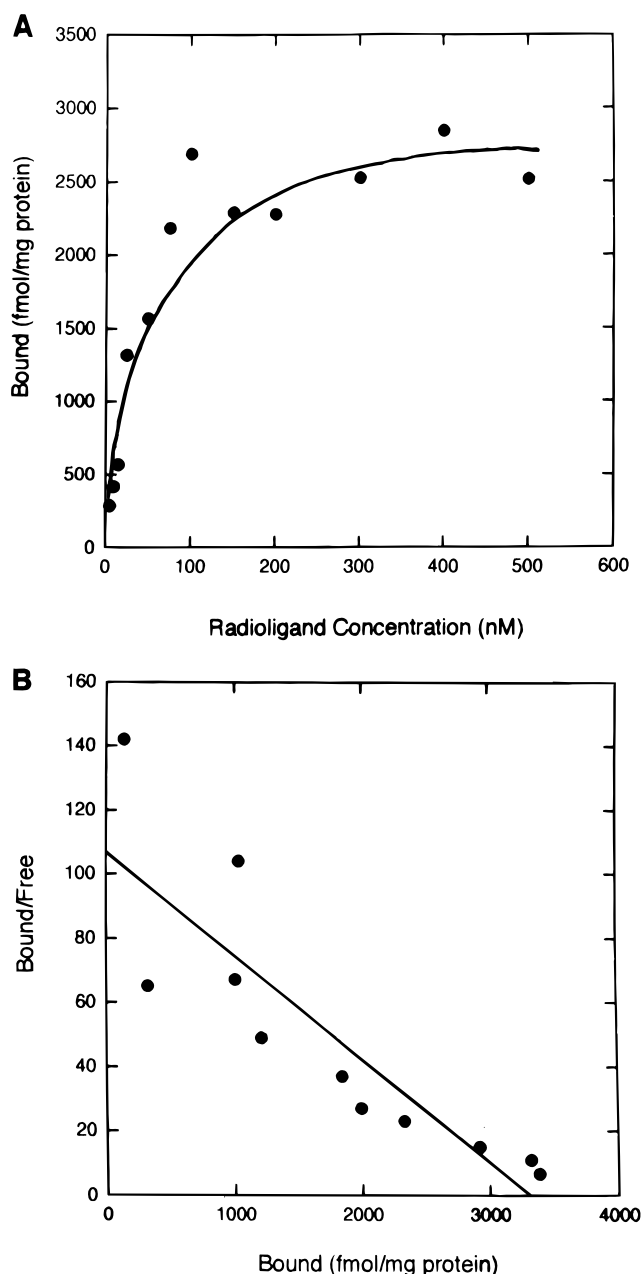

Figure 4. Saturation analysis of [^{99m}Tc]BAT-EN6 binding in T47D breast cancer cell membranes. Panel A shows the saturation plot, and panel B shows the Scatchard plot.

$\text{CH}_2]$ ($m/z = 429$) was also consistent with the chemical structure. The HPLC retention times for both ^{99m}Tc and ^{99g}Tc were identical under identical conditions, indicating the formation of the same species with carrier free and the ground state radionuclide.

The receptor binding specificity of ^{99m}Tc complex **III** was determined by its binding to human ductal breast cancer (T47D) cells. We have shown previously that T47D cells possess a high density of both σ -1 and σ -2 sites (4). A high degree of specific binding (90–97%) of ^{99m}Tc complex **III** was obtained when σ -receptor ligands such as halogenated phenylethylenediamines (BD1008 and IPEMP) were used to determine nonspecific binding. In order to determine that this binding was related to σ -receptors in T47D cells, two high-affinity σ -ligands BD1008 and IPEMP [$K_i = 2.1 \pm 0.8$ and 0.82 ± 0.13 nM, respectively, for σ -1 sites in guinea pig brain against [^3H](+)-pentazocine and $K_i = 8.1 \pm 2.2$ and 15.2 ± 2.35 nM, respectively, for σ -2 sites in rat liver membrane preparation against [^3H]DTG in the presence of dextrallorphan]

Table 1. Tissue Distribution of [^{99m}Tc]BAT-EN6 in Sprague-Dawley Rats^a

tissue	0.5 h	1.0 h	4.0 h	4.0 h with 2.10 μmol of BD1008
blood	5.13 \pm 1.03	4.45 \pm 0.74	2.33 \pm 0.18	0.82 \pm 0.02
heart	0.27 \pm 0.01	0.20 \pm 0.03	0.14 \pm 0.01	0.06 \pm 0.01
liver	14.42 \pm 2.01	16.85 \pm 2.05	22.31 \pm 2.37	15.32 \pm 1.21
lung	2.21 \pm 0.33	2.07 \pm 0.95	1.32 \pm 0.20	0.62 \pm 0.10
kidney	3.48 \pm 0.30	3.02 \pm 0.45	2.21 \pm 0.19	1.01 \pm 0.10
spleen	0.77 \pm 0.08	0.66 \pm 0.06	0.50 \pm 0.05	0.23 \pm 0.07
stomach	3.32 \pm 0.85	1.38 \pm 0.19	1.13 \pm 0.60	1.36 \pm 0.55
small intestine	5.29 \pm 2.70	11.63 \pm 3.97	14.52 \pm 2.86	13.65 \pm 2.90

were used in competition experiments. A dose-dependent inhibition of binding of ^{99m}Tc complex **III** was observed using BD1008 and IPEMP ligands ($\text{IC}_{50} = 47 \pm 2$ and 59 ± 5 nM, respectively), indicating that it is labeling σ -receptors (Figure 3). In order to determine the binding affinity of the ^{99m}Tc chelate, the binding studies of ^{99g}Tc complex were studied in guinea pig brain membranes against [^3H]DTG (a known σ -ligand). A high-affinity dose-dependent inhibition of binding of [^3H]DTG was found in the presence of ^{99g}Tc complex, indicating the binding at σ sites. The K_i value for ^{99g}Tc complex was found to be 42.7 ± 8.57 nM. This represents a combined binding affinity for σ -1 and σ -2 subtypes as [^3H]DTG is a σ nonsubtype selective ligand. An exact affinity of ^{99g}Tc chelate at the individual σ subtypes is currently being investigated. The affinity of the two isomers (syn and anti) for the receptor sites also remains to be studied. It should be noted, however, that there was no specific binding of the parent ^{99m}Tc complex **VIII** (Figure 2) without the pendent pharmacophore, confirming that binding activity resulted from the pendent ethylenediamine moiety and indicating that the binding was to σ sites.

The saturation binding of [^{99m}Tc]BAT-EN6 in membrane preparations of T47D cells was studied using Scatchard analysis. The incubation of an increasing concentration of HPLC-purified [^{99m}Tc]BAT-EN6 chelate [spiked with a known concentration of [^{99g}Tc]BAT-EN6] showed a saturable binding, with a K_d of 43.5 ± 14.7 nM and a B_{max} of 3121 ± 130 fmol/(mg of protein). The data from a representative experiment are shown in Figure 4 (panel A shows the saturation plot and panel B shows the Scatchard plot). The binding saturates with increasing concentration of the tracer, and a high B_{max} was found. This result is consistent with our earlier findings, where we had shown that a high density of σ -receptors [$3000\text{--}3500$ fmol/(mg of protein)] was expressed in T47D cells on the basis of [^3H]DTG binding in T47D cell membranes. The biodistribution of [^{99m}Tc]BAT-EN6 in Sprague-Dawley rats (Table 1) showed a hepatobiliary excretion, as expected. The tracer cleared quickly from the blood pool and was extracted in high amounts by liver (14.42% ID/organ at 30 min and 22.31% ID/organ at 4 h postinjection). A good uptake of the tracer was also found in lungs and kidneys. The evidence for in vivo receptor binding was established by in vivo blocking of specific binding with BD1008. The uptake of the radiopharmaceutical at 4 h post-iv injection was 2.21% ID/organ in the kidney, whereas uptake in the presence of 2 μmol of BD1008 was 1.01% ID/organ (Table 1). Thus, a co-injection of ^{99m}Tc complex along with 2 μmol of BD1008 in male Sprague-Dawley rats resulted in an inhibition of binding of about 55% at 4 h post-iv injection in the kidneys, an organ that is known to possess high densities of both σ -1 and σ -2 receptors (19). Similarly, a significant

reduction of radioactivity was also found in liver (32%) and lungs (50%) at 4 h postinjection.

CONCLUSION

In summary, the results presented here indicated that the bisaminothiol ligand system possessing the pendent σ -receptor pharmacophore complexed with ^{99m}Tc in very high yields. This complex displayed a very high specific binding in T47D breast cancer cells and a dose-dependent inhibition of binding with known σ -ligands. No specific binding was found with ^{99m}Tc chelate without substituted ethylenediamine pharmacophore. Furthermore, the in vivo blocking study revealed a significant reduction of the uptake of the ^{99m}Tc complex in kidneys. This is the first ^{99m}Tc chelate shown to bind σ -receptor sites in human breast cancer cells. Derivatives of this chelating ligand system or another chelating ligand (to alter in vivo distribution) possessing the σ -pharmacophore may be useful for diagnostic receptor scintigraphy of σ -receptor-positive tumors.

ACKNOWLEDGMENT

We acknowledge Dr. C. E. Costello (Boston University School of Medicine) and Mr. Noel Whittaker (NIDDK, NIH) for mass spectroscopic studies. Financial support of this work by the Department of Radiology, George Washington University Medical Center, is gratefully acknowledged. We are grateful to Prof. John Katzenellenbogen for helpful suggestions and comments on the manuscript.

Critical Parameters for Adduct Formation of the Carcinogen (+)-*anti*-Benzo[*a*]pyrene-7,8-dihydrodiol 9,10-Epoxy with Oligonucleotides

Mario Funk,[†] Ingrid Pontén,[†] Albrecht Seidel,[‡] and Bengt Jernström^{*,†}

Institute of Environmental Medicine, Division of Biochemical Toxicology, Karolinska Institutet, S-17177 Stockholm, Sweden, and Department of Toxicology, University of Mainz, D-55131 Mainz, Germany. Received May 15, 1996[®]

Various parameters relevant for the formation of dG adducts produced in the reaction of individual benzo[*a*]pyrene diol epoxide (BPDE) stereoisomers with oligonucleotides have been studied. Reaction time, temperature, pH, molar ratio of diol epoxide and oligonucleotide, base sequence, and buffer system were shown to affect the amount of (+)-*anti*-BPDE dG adducts formed. Optimum experimental conditions for dG adduct formation were different depending on the base sequence context of the oligonucleotide employed [5'-d(CCTATAGATATCC) or 5'-d(CCTATTGCTATCC)]. In general, low temperature to allow a longer reaction time, slightly alkaline Tris-HCl (pH 7.5–8.0) or alkaline phosphate buffer (pH 11), low concentration of organic solvent, and a molar excess of (+)-*anti*-BPDE promote dG adduct formation with an oligonucleotide. Low incubation temperature and Tris-HCl buffer also favor dG adduct formation of (–)-*anti*-BPDE and both enantiomers of *syn*-BPDE to both 5'-d(CCTATAGATATCC) and 5'-d(CCTATTGCTATCC).

INTRODUCTION

Since its detection as one of the principal carcinogens in coal tar (Cook *et al.*, 1933), benzo[*a*]pyrene has served as an important model substrate for investigating the mutagenic and carcinogenic properties of polycyclic aromatic hydrocarbons (PAH¹). Benzo[*a*]pyrene is not biologically active *per se*, but requires metabolic activation to elicit its hazardous properties. The most widely accepted metabolic activation pathway involves (i) arene oxide formation at the 7,8-position by action of CYP 1A1, (ii) epoxide hydrolase catalyzed ring opening of the intermediate arene oxide to produce the *trans*-7,8-dihydrodiol, and (iii) a second attack by CYP 1A1 in the bay region at the 9,10-position of the dihydrodiol. The latter reaction preferentially results in the formation of the 7(*R*),8(*S*)-dihydroxy-9(*S*),10(*R*)-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene [(+)-*anti*-BPDE; Figure 1] and, to a lesser extent, of the 7(*R*),8(*S*)-dihydroxy-9(*R*),10(*S*)-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene [(–)-*syn*-BPDE] (Thakker *et al.*, 1977; Yang *et al.*, 1977a; Jerina *et al.*, 1985).

Among the four possible stereoisomeric bay-region diol epoxides the (+)-*anti*-BPDE reveals the highest mutagenic and carcinogenic activity in most mammalian test systems (Thakker *et al.*, 1977; Stevens *et al.*, 1985; Wislocki and Lu, 1988). This biological activity appears to be causally linked to covalent binding of (+)-*anti*-BPDE to DNA, which occurs almost exclusively at the exocyclic

Figure 1. Absolute structures of (+)-*anti*-BPDE (left) and its *trans*-(+)-*anti*-BPDE-*N*²-dG adduct (right) predominantly formed on reaction with DNA.

amino group of deoxyguanosine (dG) (Jeffrey *et al.*, 1976). Stereochemically favored is the *trans* opening of the oxirane ring by nucleophilic attack of the amino group at the benzylic C-10 position (Cheng *et al.*, 1989); the structure of the adduct emerged from this reaction is shown in Figure 1. In contrast, the reaction of (–)-*anti*-BPDE and the two enantiomers of *syn*-BPDE with DNA is much less selective regarding dG *vs* dA binding and the stereochemical course of the oxirane ring opening. Thus, binding to dG *vs* dA residues depends on the absolute stereochemistry of the diol epoxide and results in different ratios of adducts with *cis* and *trans* stereochemistry (Cheng *et al.*, 1989; Sayer *et al.*, 1991).

To get insights into the underlying mechanisms of mutagenesis and carcinogenesis, it is of pivotal interest to investigate the structural and physicochemical properties of defined DNA adducts in specific oligonucleotide sequences by spectroscopic methods as well as to perform studies with adducted sequences in biological systems (Cosman *et al.*, 1990; Geacintov *et al.*, 1991; Margulis *et al.*, 1993; Jernström and Gräslund, 1994). However, experimental access to the required amounts of material for structure investigations by spectroscopic methods, in particular by 2D NMR, provides a strong limitation in this field of research.

The chemical synthesis of defined adducted oligonucleotides with the control about the *cis* and *trans* stereochemistry has been demonstrated (Lee *et al.*, 1990, 1995; Zajc *et al.*, 1992; Kim *et al.*, 1992; Lakshman *et al.*, 1992;

¹ PAH, polycyclic aromatic hydrocarbons; BPDE, benzo[*a*]pyrene diol epoxide; (+)-*anti*-BPDE, 7(*R*),8(*S*)-dihydroxy-9(*S*),10(*R*)-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene; (–)-*anti*-BPDE, 7(*S*),8(*R*)-dihydroxy-9(*R*),10(*S*)-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene; (+)-*syn*-BPDE, 7(*S*),8(*R*)-dihydroxy-9(*S*),10(*R*)-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene; (–)-*syn*-BPDE, 7(*R*),8(*S*)-dihydroxy-9(*R*),10(*S*)-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene; DMSO, dimethyl sulfoxide; THF, tetrahydrofuran; DMF, dimethylformamide; TEA, triethylamine.

Steinbrecher *et al.*, 1993), but it includes quite material-intensive and laborious working steps to obtain larger quantities, and the methodology seems to be more successful for the preparation of oligonucleotides with dA adducts of diol epoxides. A much faster approach is provided by the direct synthesis, which includes incubation of the diol epoxide with the oligonucleotide and subsequent separation of the sequences bearing individual adducts. However, it is necessary to perform this reaction repeatedly to produce required amounts since the yields in specific modified oligonucleotides obtained by this method are usually relatively low. Therefore, upscaling of the direct synthesis of dG-specific modified oligonucleotides by incubation of diol epoxides with oligonucleotides has been considered to be an attractive goal. The direct method for the synthesis of modified oligonucleotides containing defined diol epoxide adducts of BPDE by reaction of racemates or individual configurational isomers of BPDE with a single-stranded oligonucleotide of short length followed by HPLC separation of the resulting modified sequences and adduct characterization was initially developed by Geacintov and co-workers (Cosman *et al.*, 1990). The availability of oligonucleotides containing a single or more structurally defined adducts derived from BPDE binding at the exocyclic amino group of dG has proven to be of great importance in elucidating structural features of this type of adduct and their relationship to effects in biological and biochemical systems. For instance, the conformation of structurally defined BPDE–dG adducts site-specifically positioned in double-stranded oligonucleotide has been successfully elucidated by high-resolution NMR [Cosman *et al.*, 1992, 1993; de los Santos *et al.*, 1992; Fountain and Krugh, 1995 (reviewed in Geacintov *et al.* (1997))], the effect of individual BPDE–dG adducts on DNA replication, transcription, or transcription-associated activities and repair have been studied in *in vitro* systems (Hruszkewycz *et al.*, 1991; Shibutani *et al.*, 1993; Zou *et al.*, 1995; Persson *et al.*, 1996), and attempts to elucidate the mechanisms underlying BPDE–dG adduct-induced mutations have been carried out in bacterial systems (Jelinsky *et al.*, 1995).

To elucidate and to rationalize the experimental conditions being most important in promoting the formation of dG adducts by reacting the individual (+)-*anti*-BPDE stereoisomer directly with an oligonucleotide, the influence of temperature, pH, solvent polarity, the molar ratio of diol epoxide/oligonucleotide, reaction time, buffer system, and the oligonucleotide sequence context was investigated. Adduct yields using different sequence context in the oligonucleotide have been compared for all four BPDE stereoisomers under standard reaction conditions.

EXPERIMENTAL SECTION

Caution: Benzo[a]pyrene diol epoxides are carcinogens, and thus experimental handling must be carried out under special safety conditions, e.g. those outlined in the NCI guidelines.

Materials. The optically active stereoisomers of BPDE were synthesized as described previously (Pontén *et al.*, 1996 and references cited therein). Oligonucleotides were obtained from Kebo, Stockholm, Sweden. Their purity was checked by HPLC (see below). Other chemicals and solvents used were purchased from different commercial sources and were of analytical or HPLC grade.

Reaction of BPDE with Oligonucleotides. As a standard system the reaction of the oligonucleotide 5'-(CCTATAGATATCC) with (+)-*anti*-BPDE was selected. In the system used here the oligonucleotide was dissolved

in 50 mM Tris-HCl/0.5 mM EDTA at pH 7.5 (measured at 20 °C) to a final concentration of 50–70 μ M together with a 5-fold molar excess of BPDE, added as a single portion dissolved in dimethyl sulfoxide (DMSO; final concentration of DMSO was 8.5%). The addition of sodium chloride has been avoided since high concentrations of chloride ions have been shown to favor *cis* adduct formation (Wolfe *et al.*, 1994). The mixture was kept at 0 °C in the dark for 5 h followed by storage at 4 °C for at least overnight to allow the reaction to be completed before HPLC analysis. The rates of (+)-*anti*-BPDE hydrolysis leading to tetraols and of the adduct formation were determined after the excess of BPDE was trapped with alkaline 2-mercaptoethanol [*cf.* Michaud *et al.* (1983) and Dock *et al.* (1987)] at different time points and subsequent HPLC analysis of the products.

The effect of temperature on the adduct formation was studied using the standard conditions (see above) and with the reaction temperature varied between 0 and 40 °C. It should be noted that increased temperature is associated with a reduction in pH; the pH of the standard buffer at 20 °C (7.5) changes to 7.9 at 0 °C and to 7.2 at 40 °C. To see if the increased adduct formation observed for (+)-*anti*-BPDE at lower temperature can be considered as a more general phenomenon, the corresponding (–)-*anti*-BPDE as well as both enantiomers of *syn*-BPDE were reacted with 5'-d(CCTATAGATATCC) or 5'-d(CCTATTGCTATCC) at 0 and 20 °C. In another set of experiments with (+)-*anti*-BPDE, the standard Tris-HCl buffer, pH 7.5, was adjusted at 20 °C to a pH varying between 6.0 and 9.5.

The influence of selected organic solvents on the reaction yield was studied by addition of various amounts of DMSO, tetrahydrofuran (THF), and dimethylformamide (DMF). The final volume concentrations of these solvents were 2%, 10%, and 25%, respectively. All other reaction parameters were used according to the standard procedure.

To study the effect of base sequence context on adduct formation, the extent of binding of (+)-*anti*-BPDE to dG in the oligonucleotides 5'-d(CCTATAGATATCC) and 5'-d(CCTATTGCTATCC) was compared under standard conditions as described above and at 20 °C.

The influence of different buffer systems, near-neutral Tris-HCl buffer or phosphate buffer supplemented with 1.5% triethylamine (TEA) (Margulis *et al.*, 1993), and incubation time on the adduct yield was also investigated.

HPLC Analysis. The analysis of diol epoxide oligonucleotide adducts was in principal performed as described earlier (Pontén *et al.*, 1994, 1996). In brief, a Dynamax (Rainin Instrument Co., Woburn, MA) reversed phase column (C₁₈, 5 μ m, 300 Å, 4.6 \times 250 mm) equipped with a precolumn and thermostated at 37 °C was used as stationary phase. The mobile phase consisted of 0.1 M triethylammonium acetate, pH 7.0 (solvent A), and a 1:1 mixture of this solution with acetonitrile (solvent B) at a flow rate of 1.5 mL/min. The samples were eluted with a gradient from 10% to 25% solvent B in solvent A over 10 min, isocratically for 10 min with 25% solvent B in solvent A followed by a 10 min gradient from 25% to 30% solvent B in solvent A, and finally 30% to 60% solvent B in solvent A over 10 min.

Analysis of diol epoxide–mercaptoethanol conjugates was performed essentially as previously described (Dock *et al.*, 1987). Briefly, a Nova-Pak reversed phase column (C₁₈, 4 μ m, 3.9 \times 150 mm, Waters, Milford, MA) and a solvent system composed of 25 mM ammonium acetate, pH 4.0 (solvent A) and acetonitrile (solvent B) delivered at 1 mL/min were employed. The samples were eluted

Figure 2. HPLC elution profiles of the reaction products of the (+)-*anti*-BPDE-modified oligonucleotide 5'-d(CCTATAGATATCC) monitored by light absorbance at 260 nm (A) and by fluorescence emission at 400 nm ($\lambda_{\text{excitation}} = 350$ nm) (B).

with a gradient ranging from 20% to 40% solvent B in solvent A during 20 min.

Adduct Identification. Studying single-stranded oligonucleotides containing a single dG in a number of different sequence contexts, Margulis *et al.* (1993) demonstrated that dG in 5'-AGA exhibited the lowest reactivity and dG in 5'-TGC the highest reactivity with (+)-*anti*-BPDE. In this study we have used the two oligonucleotides 5'-d(CCTATAGATATCC) and 5'-d(CCTATTGCTATCC), each containing one of the target sequences and, therefore, representing an experimental system with a broad range of reactivity. The overall yield of dG adducts and the individual adduct distribution (adducts with *cis* or *trans* stereochemistry) resulting from the reaction of the oligonucleotides with all four possible stereoisomers of BPDE have been estimated from HPLC analysis (Figure 2). The amount of N^2 -dG adducts was calculated from the sum of unmodified and dG-modified oligonucleotide peak areas. Identification and characterization of the dG adducts formed by the reaction of (+)-*anti*-BPDE within the triplet 5'-TGC or 5'-AGA have been described by Margulis *et al.* (1993), of *anti*- or *syn*-BPDE within 5'-AGA by Pontén *et al.* (1994 and 1996, respectively), and of (-)-*syn*-BPDE within 5'-TGC by Pontén *et al.* (1997). The stereochemistry of the major dG adduct formed from (-)-*anti*-BPDE (*trans* adduct) and (+)-*syn*-BPDE (*cis* adduct) within the sequence context 5'-TGC was determined by circular dichroism measurements (Pradhan *et al.*, 1997).

RESULTS AND DISCUSSION

Effect of Time, Temperature, and Buffer System on the Binding of BPDE to 5'-d(CCTATAGATATCC) and 5'-d(CCTATTGCTATCC). Figure 3 shows the extent of adduct formation of (+)-*anti*-BPDE (defined as the proportion of oligonucleotides reacted with BPDE) as a function of time and under different experimental conditions. In general, the 50 μ M oligonucleotide was incubated with 250 μ M diol epoxide. This concentration by far exceeds the solubility of BPDE in aqueous solutions, and thus the compound is expected to be partly present in aggregates or microcrystals. Parts A and B of Figure 3 demonstrate that both temperature and buffer

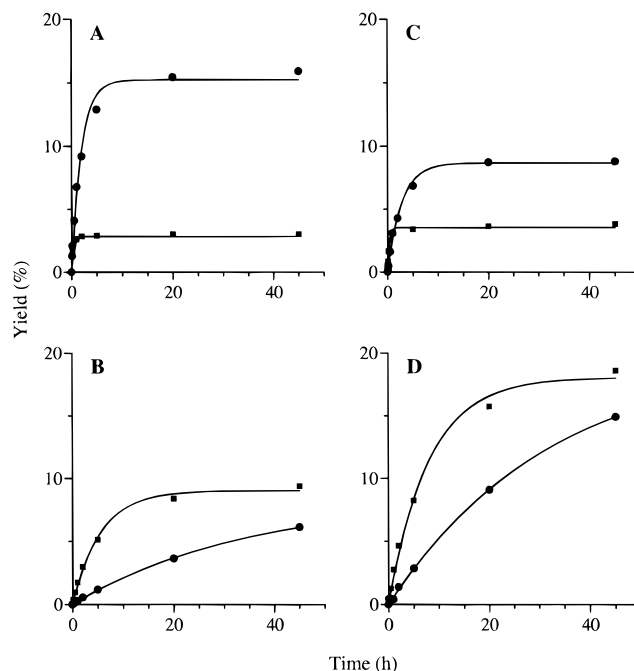

Figure 3. Time-dependent formation of the *trans* adducts of (+)-*anti*-BPDE with the oligonucleotide 5'-d(CCTATAGATATCC) at 0 and 20 °C in Tris-HCl (pH 7.5) (A) and at 0 and 20 °C in phosphate/TEA buffer (B) and of (+)-*anti*-BPDE with 5'-d(CCTATTGCTATCC) at 0 and 20 °C in Tris-HCl (pH 7.5) (C) and at 0 and 20 °C in phosphate/TEA buffer (D): incubation at 0 °C (●) and 20 °C (■). For further experimental details, see Experimental Section.

system greatly influence the rate of adduct formation. In Tris buffer the maximum binding of (+)-*anti*-BPDE to 5'-d(CCTATAGATATCC) was attained after approximately 1 h at 20 °C or after 5 h at 0 °C. The large influence of low temperature on adduct formation is remarkable (Figure 3A). Replacing the Tris buffer with phosphate supplemented with 1.5% TEA results in a markedly reduced rate of adduct formation. In this system the reaction at 20 °C with 5'-d(CCTATAGATATCC) seemed to approach completion after about 20 h of incubation. At 0 °C the reaction is far from complete even after 45 h of incubation. Parts C and D of Figure 3 show the extent of adduct formation to 5'-d(CCTATTGCTATCC) in Tris or alkaline phosphate buffer. It is obvious that the change in sequence context from 5'-AGA to 5'-TGC in conjunction with the buffer system used greatly influences adduct formation. In Tris buffer the initial rate of adduct formation and adduct yield are substantially lower with 5'-d(CCTATTGCTATCC) and the effect of temperature is less pronounced (Figure 3C). In contrast, in alkaline phosphate buffer a higher yield of adducts was obtained with 5'-d(CCTATTGCTATCC) at both 0 and 20 °C. The results in Figure 3D indicate that prolonged incubation ($\gg 45$ h) most probably results in a similar adduct yield. This is also clear from the data compiled in Table 1 obtained from a number of experiments in which the reaction of (+)-*anti*-BPDE with 5'-d(CCTATAGATATCC) or 5'-d(CCTATTGCTATCC) has been allowed to continue to completion or near completion. In fact, in the presence of phosphate buffer no statistically significant difference in adduct yields at 0 or 20 °C was observed. The preference of (+)-*anti*-BPDE to react with dG in 5'-TGC rather than with dG in 5'-AGA in alkaline phosphate buffer observed here is in full agreement with the results of Margulis *et al.* (1993). The influence of the base sequence context on adduct formation will be further discussed below.

Table 1. Yields of Trans Adducts Formed between (+)-*anti*-BPDE and 5'-d(CCTATAGATATCC) or 5'-d(CCTATTGCTATCC): Effect of Different Buffer Systems and Temperature Dependence

system	temp (°C)	5'-AGA	5'-TGC
Tris-HCl buffer, pH 7.9 ^a	0	16.7 ± 2.7 (16) ^b	7.5 ± 1.2 (7)
	20 ^c	3.4 ± 1.6 (5)	2.9 ± 0.8 (5)

	20	7.7 ± 3.3 (8)	18.1 ± 8.4 (9)

^a Incubation time in Tris buffer, ≥20 h. ^b Number of experiments (*n*) is given in parentheses. ^c The pH at 20 °C in Tris buffer is 7.5. ^d Incubation time in phosphate buffer, ≥45 h.

**Figure 4.** Yield of trans adducts formed between (+)-*anti*-BPDE and 5'-d(CCTATAGATATCC) as a function of temperature.

The buffer- and temperature-dependent shift of preferred sequence context shown here has certain implications for the universal applicability of previous studies.

The difference in adduct yields in the presence of Tris or phosphate buffer cannot be due to a different pH values of the reaction medium, since higher pH results in lower binding efficiencies in Tris buffer (*vide infra*). Furthermore, addition of 1.5% TEA to the Tris-buffered system did not improve adduct yields (data not shown).

The experiments described above demonstrate that the temperature is an important factor when (+)-*anti*-BPDE is reacted with oligonucleotides in Tris buffer. To study this in more detail, the diol epoxide was incubated with 5'-d(CCTATAGATATCC) at temperatures ranging from 0 to 40 °C. As shown in Figure 4 an exponential decline of the reaction yield from about 20% at 0 °C to about 5% at 40 °C was observed (*cf.* Table 1). It should be noted that the increased temperature is associated with a reduced pH in Tris buffer (7.9 at 0 °C and 7.2 at 20 °C). However, it is unlikely that differences in pH had any significant effect on adduct formation (*vide infra*).

The most obvious explanation for the increased adduct formation at low temperature is the increased average lifetime of the diol epoxide molecules allowing an increased formation of hydrophobic BPDE-oligonucleotide complexes, a process that possibly precedes adduct formation. This interpretation is in agreement with previous observations (Geacintov *et al.*, 1988) as well as recent findings of Geacintov *et al.* (personal communication). The major chemical reaction pathways of BPDE in the experimental systems described here are hydrolysis to tetraols and adduct formation. The results demonstrate that the contribution of tetraol formation to the overall reaction, as exemplified by the experiments with (+)-*anti*-BPDE, is considerably smaller at low temperature (Figure 3).

To see if the increased adduct formation observed for (+)-*anti*-BPDE at lower temperature can be considered

as a more general phenomenon, the corresponding (–)-*anti*-enantiomer as well as the (+)- and (–)-*syn*-BPDE enantiomers were reacted with 5'-d(CCTATAGATATCC) or 5'-d(CCTATTGCTATCC) at 0 and 20 °C. The results are compiled in Table 2, including those obtained with (+)-*anti*-BPDE (*cf.* Table 1) for comparison. As can be seen, increasing the temperature from 0 to 20 °C reduced the relative yields of oligonucleotide adducts with all four BPDE stereoisomers. Interestingly, the temperature effect seems to be dependent on the flanking bases since the reduction in adduct formation with the 5'-AGA sequence is significantly more pronounced than with the 5'-TGC sequence. The absolute oligonucleotide modifications obtained within the 5'-AGA sequence at 0 °C were approximately 17%, 6%, 2.5%, and 3.5% for (+)-*anti*-BPDE, (–)-*anti*-BPDE, (+)-*syn*-BPDE, and (–)-*syn*-BPDE, respectively. With the exception of (+)-*anti*-BPDE (*cf.* Table 1), changing the sequence context from 5'-AGA to 5'-TGC had little or no effect on the amount of adducts formed from BPDE isomers at 0 °C with the oligonucleotides (Table 2, *cf.* Table 1). Despite the fact that the total yield was reduced, an increase in the reaction temperature significantly influenced the *cis* vs *trans* stereochemistry of the adducts formed, and the formation of adducts with *cis* stereochemistry was favored for each BPDE stereoisomer investigated (Table 2).

Effect of pH on the Adduct Formation. As evident from the results shown in Figure 5, the optimum pH for adduct formation in Tris buffer at 0 °C is between 7.5 and 8.0. Under these conditions about 20% modified oligonucleotide was obtained.

Effect of Solvent Polarity on the Adduct Formation. Addition of DMSO or THF up to 10% had no significant effect on adduct formation in Tris buffer at 0 °C. However, a further increase to 25% of DMSO or THF substantially reduced the extent of adduct formation (data not shown). The inhibitory effect of relatively high THF concentrations on adduct formation has also been observed by Geacintov *et al.* (personal communication). The presence of DMF strongly inhibited the reaction at all concentrations tested and almost abolished diol epoxide binding at 25% (data not shown). Differences in the ease of formation of intercalation complexes depending on the defined sequence context have recently been discussed to explain the nearest-neighbor effects on the ratio of *cis* vs *trans* adduct formation of diol epoxides with double-stranded oligonucleotides (Cheh *et al.*, 1994). The effects of organic solvents on adduct formation observed here suggest that the diol epoxide also in the single-stranded oligonucleotide has to be oriented in a well-defined manner relative to the exocyclic amino group of dG for efficient reaction. The marked decrease in reaction yields observed with the strong polar organic solvent DMF is probably due to a conformational change of the single-stranded oligonucleotide accompanied by a destruction of the catalytic environment. Lack of a specific oligonucleotide conformation results in very poor reaction yields, as has also been observed for direct reactions of BPDE and single nucleotides and/or nucleosides (M. Funk and B. Jernström, unpublished observations).

Effect of Molar Excess of BPDE and of Tetraols on Adduct Formation. As shown in Figure 6, increasing the molar ratios of (+)-*anti*-BPDE and the oligonucleotide (varied from 1:1 to 20:1) resulted in ratios of up to 5:1 in a nearly linear improvement of the reaction yield [*cf.* Margulis *et al.* (1993)]. At higher ratios the improvement in adduct yield was reduced, which might be due to an overproportional hydrolysis to tetraols favored at higher diol epoxide/oligonucleotide ratios. However, at

**Figure 5.** Yield of trans adducts formed between (+)-*anti*-BPDE and 5'-d(CCTATAGATATCC) as a function of pH. The pH values given represent those at the incubation temperature of 0 °C.**Figure 6.** Yield of trans adducts formed between (+)-*anti*-BPDE and 5'-d(CCTATAGATATCC) as a function of increasing diol epoxide/oligonucleotide molar ratio.

ratios exceeding 20:1 an adduct yield of >30% can be accomplished. In terms of efficient use of BPDE in Tris buffer, a 5–10-fold molar excess of (+)-*anti*-BPDE seems to be optimal.

Incubations under standard conditions using (+)-*anti*-BPDE in the presence of the tetraol, which is formed by trans hydrolysis of *anti*-BPDE, at a concentration equimolar to that of (+)-*anti*-BPDE lead to a diminished reaction yield (about 12%; data not shown). This effect is most probably caused by the competition between the tetraol and the diol epoxide for potential noncovalent binding sites preceding adduct formation. The noncovalent interaction of tetraols to duplexed DNA (Ibanez *et al.*, 1980) and single-stranded oligonucleotides (Geacintov *et al.*, personal communication) has been demonstrated. The inhibitory effect of tetraols has to be taken into account when one is performing the reaction by stepwise addition of BPDE aliquots to the oligonucleotide-containing solution (Cosman *et al.*, 1990; Fountain and Krugh, 1995). Stepwise addition of (+)-*anti*-BPDE aliquots rather than

a single addition of the total amount had no effect on reaction yields in the Tris-buffered system (data not shown). This may be due to the presence of tetraols and, consequently, to a reduced ease of adduct formation [*cf.* Liu *et al.* (1996)].

Oligonucleotide-Catalyzed Hydrolysis of (+)-*anti*-BPDE. DNA catalyzes the hydrolysis of BPDE (Geacintov *et al.*, 1980, 1982; MacLeod and Selkirk, 1982; MacLeod and Zachary, 1985a). The increased rate of hydrolysis can probably be attributed to a general-acid catalysis due to protonation of the phosphate diester groups (Michaud *et al.*, 1983) and/or the nucleophilic properties of these groups resulting in the formation of unstable phosphotriesters (Gamper *et al.*, 1977; Di Raddo and Chan, 1983). Also, the exocyclic amino group of dG has been suggested to play a role in the catalysis (MacLeod and Zachary, 1985b). Considering that hydrolysis of BPDE constitutes the major competing reaction of adduct formation, it was of interest to study the catalytic properties of the parts of the oligonucleotide sequence flanking the dG position, which are not directly involved in adduct formation. The oligonucleotide 5'-d(CCTATAIATATCC), in which dG was replaced by deoxyinosine (dI), was incubated with (+)-*anti*-BPDE, and differences of the oligonucleotide in single- or double-stranded form to catalyze hydrolysis to tetraols were studied. A partial duplex was obtained by hybridization with 5'-d(ATATCTATA). For comparison, the diol epoxide was also allowed to undergo hydrolysis in standard buffer. The plot of the remaining diol epoxide (determined as the 2-mercaptoethanol conjugate) vs reaction time revealed an exponential decline of the diol epoxide concentration both in the absence and in the presence of DNA [Figure 7; *cf.* Michaud *et al.* (1983)]. The diol epoxide half-life ($t_{1/2}$) values were obtained from plots of the logarithm of residual (+)-*anti*-BPDE vs time (Michaud *et al.*, 1983; Dock *et al.*, 1987). The $t_{1/2}$ of (+)-*anti*-BPDE in Tris buffer at 0 °C was estimated to be 2.8 h. The presence of single-stranded oligonucleotide increased the rate of hydrolysis ($t_{1/2}$ = 1.6 h). A further increase in the rate of hydrolysis was observed in the presence of the partial oligonucleotide duplex ($t_{1/2}$ = 1.1 h; see Figure 7). We conclude from these experiments that the hydrolytic properties of double-stranded DNA compared to the single-stranded form do not seem to be of qualitative difference; the double-stranded oligonucleotide behaves in our system approximately as a double molar equivalent of the single-stranded form. Thus, a DNA duplex is *per se* not more efficient in catalyzing hydrolysis than a corresponding amount of single-stranded DNA. Furthermore, the base sequence seems to be of little importance in catalyzing hydrolysis since no difference in rates was observed in the presence of 5'-d(CCTATAGATATCC) or 5'-d(CCTATTGCTATCC).

Effect of Base Sequence Context on Adduct Formation. The oligonucleotides 5'-d(CCTATAGATATCC) and 5'-d(CCTATTGCTATCC) were employed,

Figure 7. Hydrolysis of (+)-anti-BPDE ($c = 300 \mu\text{M}$) at 0°C in 50 mM Tris-HCl buffer (pH 7.9): (●) in the absence of oligonucleotide; (■) in the presence of $50 \mu\text{M}$ of the oligonucleotide 5'-d(CCTATAIATATCC); (▲) in the presence of $50 \mu\text{M}$ of the oligonucleotide 5'-d(CCTATAIATATCC) and $50 \mu\text{M}$ of the oligonucleotide 5'-d(ATATCTATA).

both with a central dG as the binding site but having different bases at the adjacent 5' and 3' sides, as well as buffer systems based on Tris-HCl or sodium phosphate. The extents of binding of (+)-anti-BPDE to dG in the two oligonucleotides were compared. As shown previously (Figure 3 and Table 1), the overall amount of dG adducts formed with the oligonucleotide containing 5'-AGA was about 2-fold higher relative to the one containing 5'-TGC under standard conditions (Tris buffer, pH 7.5 at 0°C). This was unexpected since previous results with (+)-anti-BPDE and the oligonucleotides 5'-d(CTATAGATATC) and 5'-d(CTATTGCTATC) demonstrated the opposite reactivity (Margulis *et al.*, 1993). In their study the diol epoxide was incubated with the oligomers overnight at room temperature in sodium phosphate supplemented with TEA and sodium chloride. The results showed that dG surrounded by pyrimidines in general yields higher amounts of adducts than dG surrounded by purines. It was suggested that purines flanking dG lower the reactivity by steric effects due to their bulkiness and/or noncovalent interactions with the diol epoxide. Either mechanism is expected to decrease the optimum conditions for the formation of bimolecular transition state complexes. Taken together, the results indicate that flanking purines seem to promote the formation of a bimolecular dG/BPDE transition state in Tris buffer but have the opposite effect in phosphate buffer. The reason for this discrepancy is presently not completely understood.

Earlier studies have been performed with both native DNA and oligomers in single- or double-stranded form to establish the influence of flanking bases on adduct formation of BPDE stereoisomers with dG (Reardon *et al.*, 1989; Kootstra *et al.*, 1989; Osborne, 1990; Schwartz *et al.*, 1994). Osborne (1990) studied the effect of sequence context on the binding of (+)-anti-BPDE to dG in a series of self-complementary oligonucleotides. The diol epoxide and oligonucleotide duplex were incubated at 0°C in slightly acidic sodium cacodylate buffer overnight, and the results showed lowest yields of adduct formation with dG flanked by dA and dT and highest yields with dG in mixed d(GC) sequences [*cf.* Kootstra *et al.* (1989)]. In a more recent study (Schwartz *et al.*, 1994), the base sequence selectivity in binding of (+)-anti-BPDE to self-complementary oligonucleotides was investigated. In this case the diol epoxide was incubated with the oligonucleotide duplex at 0°C in neutral Hepes/sodium chloride buffer overnight. Consistent with previ-

ous results (Osborne, 1990) the study showed that dG surrounded by dC reacted to the greatest extent, whereas dG surrounded by dA and dT gave the lowest yield of adducts. A preference of (+)-anti-BPDE for dG flanked by another dG on either the 5'- or 3'-side was also noted. These latter results are in contrast to those obtained by Margulis *et al.* (1993) and Mao *et al.* (1995) on single-stranded oligomers.

The strong influence of the buffer system on the preferred sequence context for (+)-anti-BPDE binding was most unexpected in the present study. The factors underlying the shift in the binding preference from pur-dG-pur in Tris buffer to pyr-dG-pyr in phosphate buffer (Table 1) seem to warrant further investigation. As mentioned before, the buffer- and temperature-dependent shift of preferred sequence context shown here has certain implications for the universal applicability of previous studies.

CONCLUSIONS

From the experiments reacting (+)-anti-BPDE with two different oligonucleotide sequences in Tris buffer we conclude that (i) low incubation temperature, slightly alkaline pH, and high diol epoxide/oligonucleotide ratios promote adduct formation; (ii) elevated temperature promotes the formation of adducts with *cis* stereochemistry; (iii) the reaction time required to complete the reaction is <10 h; (iv) the addition of tetraols, being hydrolysis products of BPDE, or high amounts of an organic solvent inhibits the reaction; and (v) a substantially higher yield of adducts with *trans* stereochemistry (17%) is obtained with flanking purines (5'-AGA) than with flanking pyrimidines (5'-TGC). The same set of experiments performed with (+)-anti-BPDE in the phosphate/TEA-buffered system revealed that (i) temperature is in general of less importance for adduct formation (see below), provided that the reaction is allowed to go to completion (incubation time >20 h depending on the temperature); and (ii) a similar high yield of *trans* adducts (18%) is obtained upon reaction with 5'-d(CTATTGCTATCC), whereas the yield with the 13-mer containing 5'-AGA was substantially lower.

Taking the results of the present study together, incubation time and temperature along with the varying lifetime of a given PAH diol epoxide in different buffer systems and, as a consequence, greatly varying rates of adduct formation may also be factors that have to be taken into account when one is interpreting the results from studies on the sequence selectivity of diol epoxide binding.

A 15-Base Acridine-Conjugated Oligodeoxynucleotide Forms Triplex DNA with Its IL-2R α Promoter Target with Greatly Improved Avidity

Jan Klysik,^{*,†,‡,§} Berma M. Kinsey,^{†,‡} Pascal Hua,^{†,||} G. Alexander Glass,[†] and Frank M. Orson^{†,‡,§}

Veterans Affairs Medical Center Research Center on AIDS and HIV Infections and Department of Internal Medicine, Department of Microbiology and Immunology, and Department of Otolaryngology, Baylor College of Medicine, Building 109, Room 226, VAMC, 2002 Holcombe Boulevard, Houston, Texas 77030. Received August 12, 1996[®]

Attachment of 6,9-diamino-2-methoxyacridine to the 5' end of a purine-rich oligodeoxynucleotide targeting a 15 bp oligopurine-oligopyrimidine stretch in the promoter region of the interleukin-2 receptor alpha chain (IL-2R α) gene results in an approximately 500-fold increase in its triplex forming avidity as determined by both band shift assay and DMS footprinting (K_d lowered from 2.5 μ M to 5 nM). This oligonucleotide participates in Mg²⁺-dependent three-stranded DNA formation in which it is oriented antiparallel relative to the purine strand of the target duplex as determined by acridine moiety sensitized photoreactivity with the target duplex DNA. The oligonucleotides used in these studies were synthesized with a 3-amino-2-hydroxypropyl group at the 3' end to protect against exonucleolytic degradation for future *in vivo* applications. The 3'-amino group underwent partial removal, probably during the NaOH deprotection step. Both the 3'-amino and the 3'-free forms of the oligo have the same binding avidity and specificity. The interaction of the third strand with its target is sequence specific and can be essentially abolished by a point G \rightarrow T transversion 4 bases away from the 3' end of the target oligopurine block or severely reduced by other mutations within the target duplex. Thus, the attachment of the acridine moiety to the 5' end of the oligonucleotide does not seem to substantially compromise the sequence specificity of binding. Additionally, the oligonucleotide composed of G and A nucleotides was found to be superior to the oligonucleotide containing G and T residues since the difference in avidity of binding to the same target site was 17-fold.

INTRODUCTION

Stretches of oligopurine-oligopyrimidine duplex DNA have the unique property of being able to associate with an internally (Hanvey et al., 1988; Htun and Dahlberg, 1988; Klysik, 1995; Klysik et al., 1991; Lyamichev et al., 1986) or externally (Cheng and Pettitt, 1992; Hélène, 1991; Hélène and Toulme, 1990) provided third strand to form triple-stranded helical DNA structures via Hoogsteen or reverse Hoogsteen hydrogen bond interactions. Triplexes are of considerable interest as they could be useful in the regulation of gene expression (Dervan, 1989; Hélène and Toulmé, 1989), the delivery of a desired mutagen to its specific nuclear target (Giovannangeli et al., 1992; Praseuth et al., 1988; Wang et al., 1996), the specific fragmentation of the genome at designated sites (Moser and Dervan, 1987; Orson et al., 1996b), or DNA purification by triplex affinity capture (Ito et al., 1992). Many potential oligopurine/oligopyrimidine genomic target sites do not exceed 15 base pairs in length. One way to enhance the binding of such short oligonucleotides is to attach an intercalating agent to one end of the chain (Grigoriev et al., 1992; Orson et al., 1994; Sun et al., 1989; Zhou et al., 1995). In the present studies we have chosen as an intercalating agent 6,9-diamino-2-methoxyacri-

dine (DAMA), which is similar to the well-known vital nuclear stain rivanol. It has a bright greenish-yellow fluorescence that can be detected by UV illumination.

In prior studies of DAMA-conjugated oligonucleotides, we established that the structure of the link between the acridine and the oligo has a great influence on triplex stability (Orson et al., 1994). For example, the best linker–DAMA combination was capable of reducing the effective K_d of T₁₀ to its ideal target sequence from >250 μ M to 1 μ M. In this paper we extend these studies to oligonucleotides targeting a 15 bp oligopurine sequence in the promoter region of the interleukin-2 receptor alpha (IL-2R α) gene (Leonard et al., 1985). IL-2 receptors are of substantial importance in the normal functioning of the immune system (Diamantstein and Osawa, 1986; Strom et al., 1992; Williams et al., 1988). An abnormal expression of IL-2R α is associated with many lymphoid malignancies including adult T-cell leukemia, hairy cell leukemia, acute and chronic granulocytic leukemia, cutaneous T-cell lymphoma, and Hodgkin's disease. An increased expression of the IL-2 receptor has been documented to take place in a long list of autoimmune diseases including rheumatoid arthritis, systemic lupus erythematosus, insulin-dependent diabetes mellitus, and many others. Also, elevated expression of the IL-2R α chain on the surface of T cells occurs in allograft rejection. Since the IL-2R α subunit is required for high-affinity IL-2 binding, selective regulation of IL-2 interaction with its cognate receptor may be achieved by regulation of IL-2R α gene expression. The promoter of the IL-2R α receptor gene offers a 15 bp long oligopurine stretch that can be targeted by an appropriate oligonucleotide (Grig-

[®] Abstract published in *Advance ACS Abstracts*, April 1, 1997.

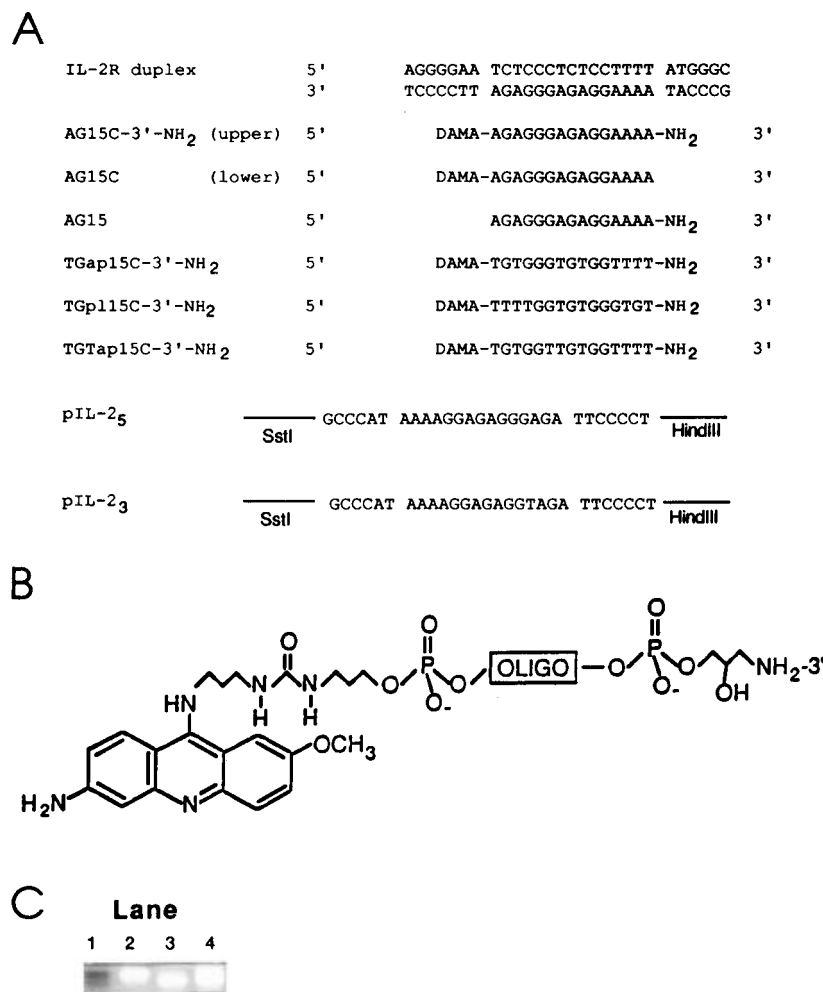

Figure 1. DNAs used in these studies. (A) List of synthetic oligonucleotides and plasmid inserts. AG15C-3'-NH₂ is the derivative as shown in panel B and migrates as the slower (upper) band when separated on an acrylamide gel (cf. panel C). AG15C refers to the 3'-unmodified derivative, which migrates more rapidly (lower band) in an acrylamide gel (cf. panel C). The identities of both AG15C-3'-NH₂ and AG15C were confirmed by MALDI-TOF mass spectrometry. AG15 (5'-DAMA-unconjugated) appears to be a mixture of 3'-modified and 3'-unmodified molecules. TGap15C-3'-NH₂ is a 3'-modified and 5'-acridine-conjugated oligonucleotide composed of G and T nucleotides and designed to bind the target duplex in an antiparallel orientation. TGap15C-3'-NH₂ is an oligonucleotide similar to TGap15C-3'-NH₂ except that it is designed to bind in the parallel orientation. TGTap15C-3'-NH₂ is an oligonucleotide identical to TGap15C-3'-NH₂ except for a single G → T transversion within the sequence. (B) Structural formula for the conjugated oligos containing a 3-amino-2-hydroxypropyl group at the 3' end. (C) Relative migration of individual species on an acrylamide gel: (lane 1) AG15; (lane 2) purified AG15C-3'-NH₂; (lane 3) purified AG15C (no 3-amino-2-hydroxypropyl phosphate); (lane 4) mixture obtained after synthesis and HPLC purification (referred to as AG15C mix elsewhere in the text). Note that the acridine derivatives produce bright fluorescent bands, whereas AG15-3'-NH₂ gives a dark band upon UV shadowing. One hundred picomoles of DNA is present in each lane.

oriev et al., 1992; Orson et al., 1991). In this paper we have characterized oligonucleotides conjugated to an acridine (DAMA) derivative by DMS footprinting. We found that acridine conjugation enhances binding of an oligonucleotide composed of G and A residues about 500-fold while maintaining a high degree of binding specificity. An acridine-conjugated oligonucleotide composed of G and T nucleotides, on the other hand, bound to the target sequence less efficiently.

EXPERIMENTAL PROCEDURES

Synthesis and Purification of Oligonucleotides.

Oligonucleotides listed in Figure 1 were synthesized and HPLC purified as described previously (Orson et al., 1996a). We further separated AG15C-3'-NH₂ (upper band migrating more slowly) from the more rapidly migrating AG15C (no 3-amino-2-hydroxypropyl phosphate) (Figure 1C) in a preparative denaturing acrylamide gel. Denaturing acrylamide gel separation was also used to purify TGap15C-3'-NH₂, TGpl15C-3'-NH₂, and TGTap15C-3'-NH₂. Target duplexes were made by

annealing equimolar amounts of complementary strands under conditions described before (Orson et al., 1996a). The duplexes were further purified by hydroxyapatite chromatography to separate any residual single-stranded oligonucleotide.

Mass Spectrometry. The matrix-assisted laser desorption/ionization time of flight mass spectrometry of the upper (AG15C-3'-NH₂) and lower (AG15C) bands were performed at The Midland Certified Reagent Co.

Plasmids. pIL-2₅ was obtained by cloning the IL duplex (Figure 1A) into a *Hinc*II site of the pUC19 vector. pIL-2₃ was the same as pIL-2₅ except for point transversion within the oligopurine tract (Figure 1A). Plasmids were purified by CsCl/ethidium bromide banding. The inserts were verified by Maxam and Gilbert sequencing (Maxam and Gilbert, 1980) and used for footprinting experiments.

Conditions for Triple-Helix Formation. Unless indicated otherwise, the specified amounts of third-strand and duplex DNA were mixed together in a volume of 10 mL containing 10 mM MgCl₂ and either 10 mM Tris

buffer, pH 7.4. or 80 mM Tris-borate buffer, pH 8.2. The third-strand bindings were equivalent in either buffer.

Band Shift Assay. Separation of triplex from duplex DNA and unbound oligonucleotide was performed on 12–16% acrylamide gels run in 100 mM TES/50 mM Tris buffer, pH 7.4, containing 10 mM MgCl₂ as described previously (Orson et al., 1994). K_d values were determined under conditions in which 50% of the oligonucleotide was bound to its target according to the equation $K_d = (OD)/T$, where O is the concentration of the oligo, D is the concentration of the duplex, and T is the concentration of the triplex.

DMS Footprinting. The *HindIII*–*SstI* restriction fragment from pIL-2₅ or pIL-2₃ containing the target sequence was labeled using [³²P]dATPαP and Klenow polymerase and then mixed with the third strand (concentration as indicated) in triplex binding buffer (80 mM Tris-borate, pH 8.2, 10 mM MgCl₂). Unless stated otherwise, samples were equilibrated overnight at room temperature and DMS was added to a final concentration of 0.5%. The reaction was stopped after 3.5 min at room temperature by adding 1 μL of 5 M 2-mercaptoethanol. The DNA was precipitated with 4 volumes of ethanol, treated with 1 M piperidine at 90 °C for 30 min, vacuum dried, dissolved in formamide, and loaded on the sequencing gel.

Photocleavage Reaction. The ³²P-labeled *HindIII*–*SstI* restriction fragment from pIL-2₅ (0.1 nM) containing the IL target sequence (Figure 1A) was mixed with AG15-3'-NH₂ (100 nM) or AG15C (100 nM) in triplex binding buffer and preincubated overnight at room temperature. Samples (10 μL) contained in 0.5 mL Eppendorf tubes were exposed to sunlight for the indicated period of time. The illuminated samples were either precipitated with ethanol, cleaved with hot piperidine, vacuum dried, dissolved in formamide, and loaded on a sequencing gel or denatured for 5 min at 90 °C, treated with 0.5% DMS for 3.5 min at room temperature, cleaved with piperidine, and subjected to sequencing gel electrophoresis.

Quantitation of the Gels. Autoradiograms were traced and quantitated using video densitometry [IMAGE for Macintosh (Wayne Rasband, NCI Bethesda, MD)]. In calculations of the K_d values derived from footprinting experiments, the individual lanes were standardized by dividing the intensities of the protected bands within the oligopurine tract over the intensities of three unprotected bands and plotted as a function of the concentration of the third strand.

RESULTS

Figure 1A lists the oligonucleotides and cloned fragments employed in these studies. AG15C-3'-NH₂ and AG15C are synthetic oligonucleotides designed to bind antiparallel relative to the purine strand of the IL-2Rα target duplex by forming G:G·A and A:A·T triads (Klysik et al., 1991; Kohwi and Kohwi-Shigematsu, 1988). AG15C-3'-NH₂ has a 3-amino-2-hydroxypropyl group attached at the 3'-phosphate terminus as a protection against cellular nucleases for future *in vivo* applications. The full formula is shown in Figure 1B. In the course of the NaOH deprotection of AG15C-3'-NH₂, some of the 3'-amino groups are eliminated (Vu et al., 1995), leading to the appearance of two electrophoretically distinct products (Figure 1C, lane 4). As determined by mass spectrometry, the upper band (referred to as AG15C-3'-NH₂, Figure 1A) is the expected 3'-amino derivative, whereas the lower band lacks the 3-amino-2-hydroxypropyl phosphate group. Since this 3'-amino-modifier product (Glen Research, Sterling, VA) is frequently used as a protecting group against cellular degradation of oligos

(McShan et al., 1992; Orson et al., 1991; Zendegeui et al., 1992), it was of interest to assess the binding properties of both forms of the oligonucleotide to the target IL-2Rα sequence relative to that of the unconjugated AG15-3'-NH₂ counterpart.

The Binding of AG15C-3'-NH₂ Oligonucleotide Is Enhanced 500-fold When the Acridine (DAMA) Is Attached to Its 5' End. Our prior band shift determinations performed using a nonseparated mixture of AG15C and AG15C-3'-NH₂ (AG15C-mix) resulted in a K_d of 5 nM (Orson et al., 1996a). Band shift analysis is an inexpensive, fast, and simple way to characterize the triplex binding properties of synthetic oligonucleotides, and for this reason it has been used routinely in such determinations. However, since the individual components of the mixture separate during gel electrophoresis, the results of this assay may not reflect the equilibrium state of the system. We therefore performed footprinting analyses using dimethyl sulfate (DMS) (Hanvey et al., 1988; Klysik, 1992, 1995). DMS, which alkylates the N-7 of G residues in B DNA, is a chemical widely used for assessing DNA structure. It is especially suitable for assaying triplex DNA because when the N-7 atom is involved in Hoogsteen hydrogen bond formation, the G of the duplex is relatively protected against this chemical.

Figure 2A shows the results of the footprinting analysis performed at 37 °C with AG15C-3'-NH₂ and with AG15-3'-NH₂, which does not carry the DAMA function at the 5' end. Almost 70% diminution in the intensities of the bands corresponding to the G residues of the target oligopurine segment can be detected at 10 nM concentration of AG15C-3'-NH₂. The protection of the oligopurine segment of the duplex increases further as the oligonucleotide concentration increases. Quantitation of the data presented in Figure 2A revealed that 50% protection of the oligopurine tract (K_d) occurs at a 5 nM concentration of AG15C-3'-NH₂ under the conditions applied in this experiment. However, for acridine-free AG15-3'-NH₂ oligonucleotide (Figure 2A) the K_d was found to be 500-fold higher (2.5 μM). Figure 2B compares the binding properties of AG15C-3'-NH₂ and AG15C as determined by footprinting analysis performed at 37 °C. No difference was found between the two forms of these DAMA-conjugated oligos.

In summary, the footprinting analysis presented above indicates that the attachment of the DAMA acridine to the 5' end of the AG15-3'-NH₂ (to produce AG15C-3'-NH₂) significantly enhances its binding to the target sequence by reducing its K_d value from 2.5 μM to 5 nM.

Acridine (DAMA) Attached to the 5' End of the Oligonucleotide Does Not Substantially Compromise Specificity of Binding. Intercalation of an acridine between the planar bases of the double helix is not sequence specific. Thus, it was of interest to determine whether attachment of DAMA to the 5' end of a triplex forming oligonucleotide would compromise the specificity of triplex formation. For the purpose of these investigations we synthesized and cloned an oligopurine target identical to that found in IL-2Rα promoter except that it contained a single point G → T transversion (see pIL-2₃ in Figure 1A). The *HindIII*–*SstI* restriction fragment containing this mutated sequence was used in footprinting experiments with AG15C-3'-NH₂ serving as a third strand. Figure 3B shows the effect of increasing concentrations of AG15C-3'-NH₂ on the DMS reactivity of G residues in the mutated target duplex. No protection could be detected even at the highest concentration of AG15C-3'-NH₂ employed (10 μM). Thus, a single transversion in the target duplex is capable of affecting substantially the specific binding of the third strand.

Figure 2. DMS footprinting. (A) DMS footprinting of the IL-2R α target duplex sequence cloned within the pIL-2₅ plasmid as a function of third strand concentration. The *Hind*III–*Sst*I restriction fragment from pIL-2₅ was labeled at the 3' end of the purine strand and used as a duplex target (<0.1 nM) to preform the triplex in a buffer containing 10 mM MgCl₂. Samples were equilibrated at 37 °C for 4 days. Treatment with DMS (see Experimental Procedures) was also done at 37 °C. The bar indicates the oligopurine target sequence. Concentration of the oligonucleotide is shown above each lane. Quantitation of the autoradiograms was as described under Experimental Procedures. (B) Footprinting of AG15C-3'-NH₂ and AG15C with DMS. Other details are as in panel A.

Some mutations in the target duplex seem to be more effective in preventing triplex formation than others. Using the band shift assay technique, we have determined K_d values for the mixture of AG15C-3'-NH₂ and AG15C and numerous duplexes carrying mutations in the targeted sequence (Table 1). The mutated duplexes fall into two categories: (i) those with mutations in the block of three G's located closer to the 3' end of the oligopurine strand of the duplex and 4–6 bp away from the intercalation site of the acridine attached to the third strand and (ii) those with mutations in the block of two G's located closer to the 5' end of the oligopurine strand and distal to the intercalation site of the acridine. In general, mutations within the block of three G residues were more effective in preventing triplex DNA formation. As expected, double mutations destabilized triplex DNA more profoundly than single-point mutations. Greater than 500-fold decreases in binding avidity have been observed in all cases except for the G \rightarrow T transversion (50-fold decrease) and G \rightarrow A transition (100-fold decrease) within the block of two G's (see Table 1, duplexes 2 and 4).

Taken all together, these results strongly indicate that the sequence-dependent recognition of the target sequence is not significantly compromised by the attachment of DAMA to the 5' end of the third-strand oligonucleotide.

Potassium Ions Have an Effect on the Binding of AG15C-3'-NH₂. Figure 3A shows the DMS footprinting experiment performed with AG15C-3'-NH₂ as a function of increasing concentration of KCl present in the stan-

dard triplex binding reaction. At a concentration of 10 mM and lower, KCl does not seem to have any significant effect on the binding properties of the DAMA-conjugated oligonucleotide. However, 55% inhibition of protection of the target duplex against DMS was observed at 100 mM KCl (Figure 3A, cf. lanes 1, 2, and 7). As the concentration of KCl increased to 200 mM, only 16% of the target duplex protection remained, compared to the sample containing no KCl (cf. lanes 1, 2, and 8). Thus, similar to unconjugated oligos composed of G and A residues, DAMA-conjugated oligonucleotide AG15C-3'-NH₂ is sensitive to physiological concentrations of potassium cations. However, the potassium-mediated inhibition seems to be less pronounced compared with similar studies in which nonconjugated oligonucleotides were used (Cheng and Van Dyke, 1993; Olivas and Maher, 1995).

DAMA-Sensitized Photooxidation Reaction Demonstrates Antiparallel Orientation of AG15C-3'-NH₂ Relative to the Oligopurine Strand of the Target Duplex. Upon light illumination, DNA can undergo a process of photooxidation in the presence of a sensitizing dye (Pooler and Valenzano, 1981). In general, double-substituted purines (i.e. G residues) are more sensitive than other bases, but any base can be dye-sensitized and photooxidized (Rahn and Patrick, 1976). DAMA attached to the 5' end of AG15-3'-NH₂ can be regarded as a sensitizing dye which may promote photoreactivity of the bases at the site of intercalation. Thus, when triplex DNA is preformed using AG15C-3'-NH₂ and exposed to

Figure 3. Effect of KCl concentration and of point mutation of the target duplex on binding of AG15C-3'-NH₂. (A) Labeled *Hind*III-*Sst*I restriction fragment (<0.1 nM) was mixed with AG15C-3'-NH₂ (100 nM) and equilibrated overnight in the triplex binding buffer (containing 10 mM Mg²⁺) supplemented with increasing concentration of KCl as indicated above each lane. DMS footprinting was performed as described under Experimental Procedures. (B) The *Hind*III-*Sst*I restriction fragment from pIL-2₃ was labeled at the 3' end of the purine strand and used for preforming the triplex DNA with AG15C-3'-NH₂ (concentrations as indicated). Conditions of the experiment and DMS treatment were as described in the legend to Figure 2.

light, specific degradation of the target duplex could be expected 3' to the oligopurine block of the oligopurine duplex strand, if the orientation of the third strand is antiparallel relative to the oligopurine strand of the target duplex.

Figure 4. Acridine-sensitized triplex-mediated cleavage of the target duplex. The labeled *Hind*III-*Sst*I insert of pIL-2₅ (concentration < 0.1 nM) was mixed with 100 nM AG15C-3'-NH₂ (lanes 1-3) or 100 nM AG15C-3'-NH₂ (lanes 4-6) in triplex binding buffer. After overnight equilibration at room temperature, samples were exposed for the indicated period of time to sunlight in 0.5 mL Eppendorf tubes. The DNA was precipitated, treated with 1 M hot piperidine for 30 min, vacuum dried, dissolved in formamide, and resolved on a sequencing gel. G refers to the Maxam and Gilbert sequencing reaction (Maxam and Gilbert, 1980). An arrow indicates the DAMA-sensitized photocleavage band.

Figure 4 presents the results of such an analysis. When the mixture of AG15C-3'-NH₂ (no acridine) and the labeled restriction fragment containing the target oligopurine block was illuminated with sunlight for 0, 1, and 3 h (Figure 4A, lanes 1-3, respectively), followed by treatment with hot piperidine and resolution of the

Figure 5. Acridine-sensitized triplex-mediated cleavage of the target duplex. The experiment was performed as described in the legend to Figure 4 except that the samples after illumination with the sunlight (45 min) were heated for 5 min at 90 °C, modified with 0.5% DMS for 3.5 min, and then subjected to piperidine cleavage. The sample shown in lane 1 contained no AG15C-3'-NH₂. The sample in lane 2 contained 100 nM AG15C-3'-NH₂, whereas the sample in lane 3 contained 100 nM unconjugated DAMA acridine.

products on the sequencing gel, a background degradation pattern developed. For the triplex preformed with AG15C-3'-NH₂ (lanes 4–6) a similar illumination-induced background degradation could be observed. However, a strongly enhanced band can be seen after 1 or 3 h of illumination (lanes 5 and 6) that is not present in the background pattern of the nonilluminated sample (lane 4) or in the samples containing AG15-3'-NH₂ (lanes 1–3).

An even more pronounced site specific DAMA-sensitized photocleavage effect was obtained when the illuminated DNA was denatured and treated with DMS prior to the piperidine cleavage step (Figure 5). The sample with AG15C-3'-NH₂ omitted (lane 1) resulted in the expected pattern of bands indicating degradation of the sequence at G residues. When the third strand was present (lane 2), a strong band corresponding to a T residue at the 3' flank of the oligopurine block becomes visible in addition to the regular pattern resulting from cleavages at methylated G residues. This band is triplex

specific since no selectively enhanced degradation can be obtained with intercalator alone (lane 3).

The appearance of this band (see arrows in Figures 4 and 5) indicates an acridine-induced and triplex-mediated site specific photoreactivity. The most reactive base is a T residue adjacent to the 3' end of the oligopurine sequence. Since the DAMA group is attached to the 5' end of the oligo, the AG15C-3'-NH₂ must be oriented antiparallel relative to the purine strand of the target duplex.

An Acridine-Conjugated Oligonucleotide Containing Exclusively T and G Nucleotides Binds 17 Times Less Efficiently than a Conjugated Oligonucleotide Composed of G and A Residues. When designing an oligonucleotide for binding to the specific oligopurine duplex target at neutral pH, it is widely accepted that a G residue in the third strand binds well to the GC Watson–Crick base pair of the target duplex, forming a G:GC triad (Dervan, 1989; Hélène, 1991; Kohwi and Kohwi-Shigematsu, 1988). However, for the AT base pair of the duplex, a stable triad can form by an interaction with either a T residue (T:AT) or an A residue (A:AT) (Beal and Dervan, 1991; Klysik et al., 1991; Orson et al., 1996a; Zendegui et al., 1992). Since third-strand oligonucleotides can be composed exclusively of G's and A's or G's and T's (Beal and Dervan, 1991; Jayasena and Johnston, 1992; Orson et al., 1996a; Young et al., 1991), it was of interest to compare the binding avidity of acridine-conjugated oligonucleotides based on these two motifs. We have synthesized and purified an oligonucleotide TGap15C-3'-NH₂ that is identical to AG15C-3'-NH₂ except that all A residues were replaced with T residues (see Figure 1). It should bind antiparallel to the purine strand of the Watson–Crick IL-2R α target duplex. Figure 6, lanes 1–7, shows an example of DMS footprinting performed as a function of increasing concentration of TGap15C-3'-NH₂ using the *Hind*III–*Sst*I restriction fragment of pIL-2₅. As the concentration of TGap15C-3'-NH₂ increased, the oligopurine block became increasingly protected against DMS modification. Quantitation of the data revealed that 50% inhibition of the DMS reactivity of G residues in the oligopurine block of the duplex (K_d) took place at 88 nM TGap15C-3'-NH₂ (an average of three independent experiments). Thus, the dissociation constant of TGap15C-3'-NH₂ was 17 times higher than that of the AG15C-3'-NH₂ (K_d = 5 nM).

Figure 6, lanes 8–14, shows the footprinting analysis of the TGap15C-3'-NH₂ composed of G and T nucleotides and designed to bind parallel to the IL-2R α target duplex. No binding could be detected within the concentration range tested. We also assessed the binding properties of TGTap15C-3'-NH₂, the sequence of which is identical to that of TGap15C-3'-NH₂ except for having one G \rightarrow T transversion (see Figure 1). The T:GC mismatch severely affected binding, and the DMS methylation reaction was not inhibited even at a concentration of 10 μ M (data not shown).

DISCUSSION

In this paper we have assessed the effect of acridine conjugation on the binding avidity and specificity of the 15 base oligonucleotide targeting the IL-2R α binding site. We found that attachment of DAMA to the 5' end of AG15-3'-NH₂ profoundly lowers the K_d . This has been determined by band shift assay (Orson et al., 1996a) and footprinting analysis, with the two methods providing comparable results. A 500-fold decrease in the K_d value is of particular significance since the targeted site is short, and concentrations in the low nanomolar range may be required for effective future applications *in vivo*.

Figure 6. Example of DMS footprinting of the IL-2R α target duplex sequence cloned within the pIL-2 β plasmid as a function of TGap15C-3'-NH $_2$ or TGpl15C-3'-NH $_2$ concentration. The concentration of the oligonucleotide is shown above each lane. Quantitation of the autoradiograms was as described under Experimental Procedures. For other details see legend to Figure 2A.

An enhancement of binding achieved by the attachment of a different acridine to the 5' end of an oligo has been reported before (Grigoriev et al., 1992, 1993; Sun et al., 1989). However, our data provide a quantitative description of the equilibrium binding enhancement induced by acridine attachment to a third strand composed exclusively of purine bases. It is important to remember that the 500-fold lower K_d seen in the course of this work could be achieved only after prior optimization of the linker structure used to attach the DAMA portion to the synthetic oligonucleotide (Orson et al., 1994).

The 3'-amino group was included in the DAMA-conjugated oligonucleotides to protect them from exonucleolytic degradation in future *in vivo* experiments (McShan et al., 1992; Orson et al., 1991). However, preparation of the oligo resulted in a mixture of the 3'-amino protected and unprotected forms (Vu et al., 1995). The two species were separated on a gel (Figure 1C) and their identities confirmed by mass spectral analysis. They were then characterized with respect to their triplex forming capacity. We found that both AG15C-3'-NH $_2$ and AG15C had the same affinity toward the target duplex sequence (Figure 2B). Furthermore, the acridine-conjugated oligonucleotides composed of G's and A's (AG15C-3'-NH $_2$ and AG15C) appeared to have superior binding avidity compared to an oligonucleotide composed of G's and T's (TGap15C-3'-NH $_2$).

As expected, binding of the third strand was affected by mutations in the target duplex. The degree to which the triplex became destabilized depended on the nature of the mutation (Greenberg and Dervan, 1995) as well as on the location of the mutation (Cheng and van Dyke, 1994) within the targeted sequence (Table 1). The smallest effects were observed for the G \rightarrow T transversion and G \rightarrow A transition located in the block of two G's. This is consistent with prior work demonstrating a relatively lower triplex destabilization effect for G \cdot TA and G \cdot AT triads (Fossella et al., 1993; Yoon et al., 1992). Mutations in the block of three G residues affected binding capacity of the duplex more than the mutations in the block of two G's. Although the reason for this is not entirely clear, it is most likely related to (i) the local nucleotide composition surrounding the mutated site, (ii) the distance of the mutation from the acridine intercalation site, or (iii) a combination of these two factors.

It was unexpected to find that the DAMA-sensitized photoreactivity is primarily limited to the single base immediately adjacent to the oligopurine tract. This may reflect a precise and unique intercalation point stereochemically compatible with the triplex state and the linker structure. Alternatively, the structure of the triplex/B-DNA junction located immediately adjacent to the oligopurine block may offer a greatly preferred site for intercalation of this acridine as suggested by others (Collier et al., 1991).

The interaction of AG15C-3'-NH $_2$ or AG15C with the duplex target remained similar with respect to all of the basic properties characteristic of unfunctionalized oligos composed of purine bases: (i) Mg $^{2+}$ ions were required in the binding buffer (McShan et al., 1992) at a concentration of ≥ 5 mM; (ii) binding was affected, but not abolished, by KCl at concentrations of 100–200 mM; however, the KCl-mediated triplex inhibition was less pronounced than the inhibition reported for similar but nonconjugated oligonucleotides (Cheng and Van Dyke, 1993; Olivas and Maher, 1995); (iii) the specificity of binding of the acridine-derivatized oligo to the target sequence remained very high, such that specific mutations in the 15 bp long target sequence either essentially abolished binding (Figure 3B) or significantly reduced it (Table 1) depending on the position and nature of the mutation; (iv) the orientation of the acridine-conjugated oligo remained antiparallel relative to the oligopurine strand of the target duplex as determined by an acridine-sensitized photodynamic oxidation reaction (Birg et al., 1990) (Figure 4), even though in theory the sequence could allow parallel binding via the first 9 bases adjacent to the acridine (the methodology used herein may be of general applicability in cases of other dye-conjugated oligonucleotides); (v) the kinetics of triplex formation was slow (Maher et al., 1990), so that no binding of AG15C-3'-NH $_2$ to the oligopurine target could be detected after 1 h of preforming the triplex at 22 $^{\circ}$ C, but the reaction was virtually complete by 24 h (data not shown).

Potential applications of synthetic oligonucleotides in the regulation of gene expression are widely recognized (Dervan, 1990; Hélène and Toulme, 1990), and such oligos may be utilized both for basic science and for medicine. There are several examples where the regulation of gene expression achieved by oligonucleotide treatment of cells in culture is well established (McShan et al., 1992; Roy, 1993). The work presented herein encourages and justifies further studies of AG15C-3'-NH $_2$ type molecules as potential regulators of IL-2R α expression. In more general terms, conjugation of DAMA to synthetic oligonucleotides may be particularly advantageous in the case of many other genes where the target oligopurine

sequence is relatively short and binding enhancement needs to be introduced via oligonucleotide modification.

New Coupling Reagents for the Preparation of Disulfide Cross-Linked Conjugates with Increased Stability

Silvia Arpicco, Franco Dosio, Paola Brusa, Paola Crosasso, and Luigi Cattel*

Dipartimento di Scienza e Tecnologia del Farmaco, V. P. Giuria 9,
10125 Torino, Italy. Received September 30, 1996[®]

To improve the *in vivo* stability of disulfide-linked immunotoxins (ITs), a series of sterically hindered cross-linking reagents were designed and synthesized. These ligands are characterized by a thioimide group linked to an *S*-acetyl thiol or a substituted arylthio group. To select the reagent of choice, several arylthiothioimides, substituted with a methyl or a phenyl group adjacent to the disulfide, were analyzed in thiol–disulfide exchange reactions. Also analyzed were the following: (i) the stability and solubility of the linkers in aqueous solution, (ii) the rate of protein derivatization, and (iii) the steric hindrance due to methyl or phenyl group substituents toward cleavage of the disulfide bond by glutathione. Ethyl *S*-acetyl 3-mercaptopropionthioimide (M-AMPT) was chosen as reagent to prepare two types of stable disulfide-containing AR-3–gelonin conjugates (IT2 and IT3). IT2 was prepared by a 3-(4-carboxamidophenylthio)propionthioimide (CDPT)-derivatized antibody coupled to the M-AMPT-derivatized gelonin to afford a conjugate characterized by the presence of a methyl group adjacent to the sulfide bond. In the IT3 conjugate, an M-AMPT-derivatized toxin was coupled to the antibody thiolated with M-AMPT and then activated with Ellman's reagent (DNTB). The *in vitro* and *in vivo* stabilities of the three immunoconjugates were assayed, respectively, (i) by adding an excess of glutathione and monitoring protein release and (ii) by studying their pharmacokinetic behaviors. The specificity and cytotoxicity of all ITs were analyzed on target and unrelated cell lines, and no significant differences in activity were observed. IT3, consisting of a symmetrical dimethyl-substituted disulfide bond, was substantially more stable *in vivo* ($t_{1/2\beta} = 88.3$ h) than the corresponding IT2, characterized by a disulfide-protected monomethyl substituent bond ($t_{1/2\beta} = 60.2$ h) compared to the unhindered conjugate IT1 ($t_{1/2\beta} = 27.9$ h). This family of cross-linking reagents therefore offers advantages, such as minimal perturbation of the protein structure and controlled reactivity due to the thioimide moiety, as well as the capacity to yield immunotoxins possessing substantial stability *in vivo*.

INTRODUCTION

Immunotoxins (ITs¹) are a class of therapeutic agents composed of antibodies linked to a proteic toxin, constructed as both chemical conjugates and fusion proteins (1–3).

Chemical conjugation of the antibody and the toxin is generally accomplished by means of cross-linking agents such as *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) or 2-iminothiolane (2-IT) to introduce a disulfide bond between the proteins (4–7). The presence of a reducible disulfide bond is a prerequisite for cytotoxicity of ITs constituted by RIP-1 (ribosome inactivating protein) linked to a monoclonal antibody (mAb) directed to

a tumor-associated antigen (1, 8, 9). In particular, the A-chain type ITs containing a nonreducible thioether bond are much less cytotoxic than those containing a labile disulfide bond. On the other hand, such conjugates are unstable *in vivo*, because cleavage of the disulfide bond regenerates free antibody and toxin (10–12). Premature cleavage reduces the amount of conjugate that can bind to target cells; in addition, released antibody remains in circulation longer than the conjugate and can compete with intact conjugate for target cell binding. Thus, in multiple-dose therapeutic treatment, IT potency may decrease because tumor antigens are masked by the previously released antibody. Ideally, an immunotoxin should be labile enough to facilitate intracellular cytotoxicity but sufficiently stable to survive administration and delivery *in vivo*. Attempts to minimize this problem have focused on the synthesis of hindered cross-linking reagents in which bulky side chains proximal to the disulfide bond afford protection from nucleophilic attack (13–17). These “second generation” ITs are stable and long-lived and are highly toxic to target cells. One of these, consisting of mAb covalently bound to the deglycosylated ricin A chain by hindered disulfide linkers, has been successfully used in clinical trials for the treatment of non-Hodgkin's (B-cell) lymphoma (18).

In preceding papers, we have reported the preparation of two new acyclic thioimide cross-linking reagents, 3-(4-carboxamidophenylthio)propionthioimide (CDPT) and ethyl *S*-acetylpropionthioimide (AMPT) (19, 20). We used these reagents to prepare immunotoxins made from the RIP-1 gelonin (21) and the AR-3 mAb that recognizes the CAR-3 antigen widely expressed among

¹ Abbreviations: ITs, immunotoxins; M-AMPT, ethyl *S*-acetyl-3-mercaptopropionthioimide; CDPT, 3-(4-carboxamidophenylthio)propionthioimide; DNTB, Ellman's reagent; SPDP, *N*-succinimidyl 3-(2-pyridyldithio)propionate; 2-IT, 2-iminothiolane; RIP-1, ribosome inactivating protein; mAb, monoclonal antibody; AMPT, ethyl *S*-acetylpropionthioimide; THF, tetrahydrofuran; Ph-AMPT, ethyl *S*-acetyl-3-mercaptopropionthioimide; M-CDPT, ethyl 3-(4-carboxamidophenylthio)butyrylthioimide; Ph-CDPT, carboxymethyl 3-phenyl-3-(4-carboxamidophenylthio)propionthioimide; PBS, phosphate-buffered saline; DMF, dimethylformamide; TNB, 5-mercapto-2-nitrobenzoic acid; DTT, dithiothreitol; GSH, reduced glutathione; SDS–PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; SMPT, 4-[(succinimidyl)oxy]carbonyl- α -methyl- α -(2-pyridyldithio)toluene.

human adenocarcinomas of the stomach, colon, pancreas, ovary, and uterus (22). These ITs were found to be more effective than the corresponding conjugates made by *N*-succinimidyl ester linkers, taking advantage of the ability to amidinate proteins, thus preserving a positive charge on the molecule. These reagents also offer an additional advantage over 2-IT to introduce thiol groups into proteins because during the coupling procedure the sulfhydryl group remains protected from air oxidation, and the acetyl group can be subsequently cleaved in mild conditions by hydroxylamine to give the thiol group.

In this study, in an effort to improve the *in vivo* stability of our thioimide cross-linking reagents, we synthesized a series of thioimide-based sterically hindered reagents provided either with a thioacetyl or with a substituted arylthio group. These reagents were then used to prepare immunotoxins that have improved *in vitro* and *in vivo* stability. The conjugates made by these new cross-linkers have *in vitro* cytotoxic activity similar to that of the corresponding unhindered derivatives.

EXPERIMENTAL PROCEDURES

Materials. Thiolacetic acid and cinnamionitrile were obtained from Merck (Milan, Italy). Crotononitrile, ethanethiol, mercaptoacetic acid, dichloromethane anhydrous, and Ellman's reagent (DTNB) were from Aldrich (Milwaukee, WI).

Diethyl ether was distilled from lithium aluminum hydride, and dry tetrahydrofuran (THF) was obtained by distillation from sodium.

General Procedures. Melting points were determined with a Reichert Kofler apparatus and are uncorrected.

¹H NMR spectra were recorded on a JEOL PMX-60 spectrometer, operating at 60 MHz, with tetramethylsilane as internal standard. IR spectra were obtained as KBr disks on a Shimadzu FT-IR 8101 M spectrophotometer; wavelengths are given in inverse centimeters. Mass spectra were obtained with a Finnigan-MAT TSQ-700 or with a VG Analytical 70-70 EQ-HF spectrometer. Ultraviolet spectra were recorded on a Beckman DU-70 spectrophotometer.

The reactions were checked on F₂₅₄ silica gel precoated sheets (Merck). Purification was done by column flash chromatography on silica gel 60 (Merck, 230–400 mesh) or by distillation under reduced pressure with Kugelrohr apparatus.

3-(Acetylthio)butyronitrile (1). Thiolacetic acid (20.7 mL, 0.29 mol) was added dropwise to crotononitrile (18.81 mL, 0.232 mol) under an argon atmosphere, and the reaction mixture was stirred for 24 h at room temperature and then refluxed for 1 h. The unreacted products were eliminated under reduced pressure (15 mmHg, 50 °C); distillation of the product (3 mmHg, 100 °C) then gave a yellow oil, which slowly crystallized at room temperature (16.6 g, 50%): ¹H NMR (CDCl₃) δ 3.8 (m, 1H, CH), 3.0 (d, 2H, CH₂), 2.4 (s, 3H, SAc), 1.5 (d, 3H, CH₃).

3-(Acetylthio)-3-phenylpropionitrile (2). Thiolacetic acid (12 mL, 0.169 mol) was added slowly to cinnamionitrile (20 mL, 0.159 mol) under an argon atmosphere, and the reaction mixture was refluxed for 3 h to give a pale yellow precipitate that was washed several times with ethanol to remove unreacted products (26 g, 80%): ¹H NMR (CDCl₃) δ 7.6 (m, 5H, Ar-H), 5.1 (t, 1H, CH), 3.2 (d, 2H, CH₂), 2.3 (s, 3H, SAc).

5-(3-Cyano-2-propyldithio)-2-nitrobenzoic Acid (4). To 3-(acetylthio)butyronitrile (22.9 g, 0.16 mol) was added an excess of 12% aqueous sodium hydroxide, and the mixture was stirred at 25 °C for 12 h. After extraction

with diethyl ether under Ar, the aqueous layer was acidified with 6 N H₂SO₄ and reextracted with ether. Evaporation of the dried ether extracts of this aqueous layer yielded 3-mercaptoputyronitrile (**3**) as a dark yellow oil, which was purified by distillation under reduced pressure (70 °C, 3 mmHg) (6 g, 38%): ¹H NMR (CDCl₃) δ 3.3 (m, 1H, CH), 2.7 (d, 2H, CH₂), 1.9 (d, 1H, SH), 1.5 (d, 3H, CH₃). 3-Mercaptoputyronitrile (0.5 g, 0.005 mol) in methanol was added to a solution of DTNB (3.96 g, 0.01 mol) in 250 mL of sodium phosphate buffer, pH 7.4, deaerated and saturated with Ar. After stirring for 4 h at 25 °C, the solution was acidified with 1 N HCl and extracted with ethyl acetate; the organic layers were pooled, dried, and concentrated *in vacuo* to give a crude product, which was purified by flash chromatography with elution in dichloromethane/methanol/acetic acid (99/0.5/0.5, v/v). The pure product **4** was obtained as a pale yellow oil (0.82 g, 55%): ¹H NMR (CDCl₃) δ 9.2 (s, 1H, COOH), 8.2 (m, 3H, Ar-H), 3.3 (t, 1H, CH), 2.8 (d, 2H, CH₂), 1.7 (d, 3H, CH₃).

5-(2-Cyano-1-phenylethylthio)-2-nitrobenzoic Acid (6). 3-(Acetylthio)-3-phenylpropionitrile (24.2 g, 0.118 mol) was hydrolyzed for 12 h at room temperature with an excess of aqueous sodium hydroxide; the mixture was then extracted with ether, as described below, and evaporated to give a yellow oil, which was purified by flash chromatography with elution in petroleum ether/dichloromethane (90/10, v/v) to give 7.7 g of 3-mercaptop-3-phenylpropionitrile (**5**) (40%): ¹H NMR (CDCl₃) δ 7.5 (m, 5H, Ar-H), 4.4 (q, 1H, CH), 3.1 (d, 2H, CH₂), 2.2 (s, 1H, SH). Compound **6** was prepared in a manner analogous to that of **4** and was purified by flash chromatography (dichloromethane/methanol/acetic acid 97.5/2/0.5) to give an orange oil (0.467 g, 54%): ¹H NMR (CDCl₃) δ 9.8 (s, 1H, COOH), 7.5 (m, 3H, Ar-H), 7.1 (m, 5H, Ar-H) 4.25 (m, 1H, CH), 3.1 (d, 2H, CH₂).

4-(3-Cyano-2-propyldithio)benzamide (7). To 4-carbamoylbenzenesulfenyl chloride (3.62 g, 0.0193 mol) dissolved in 100 mL of hot glacial acetic acid was added 3-mercaptoputyronitrile (1.95 g, 0.0193 mol) in 1.5 mL of glacial acetic acid. The reaction mixture was stirred at 90 °C for 45 min and, after the mixture had cooled to room temperature, 300 mL of water was added and the mixture was left for 12 h at 4 °C. The resulting precipitate was filtrated and the solution was extracted with ethyl acetate; the organic extracts were dried and evaporated under reduced pressure. The residue and the precipitate previously obtained were pooled and purified by flash chromatography using diethyl ether as eluent to give **7** as white crystals (2.43 g, 50%): mp 140 °C; ¹H NMR (CD₃COCD₃) δ 8.2 (d, 2H, Ar-H), 7.8 (d, 2H, Ar-H), 3.5 (m, 1H, CH), 2.9 (d, 2H, CH₂), 1.5 (d, 3H, CH₃).

4-[(2-Cyano-1-phenylethyl)dithio]benzamide (8). The procedure used to prepare **7** was followed. The crude product was purified by flash chromatography (diethyl ether/ethyl acetate, 99.5/0.5) to give a yellow solid (3.1 g, 50%): mp 115–117 °C; ¹H NMR (CDCl₃) δ 7.8 (q, 4H, Ar-H), 7.5 (m, 5H, Ar-H), 6.5 (s, 2H, NH₂), 4.3 (m, 1H, CH), 3.1 (d, 2H, CH₂).

General Procedure for Preparation of Thioimide Ester Hydrochlorides (9–15). Hydrogen chloride gas, dried by passing through concentrated sulfuric acid in two washing bottles, was bubbled through ice-cold ethanethiol (3.25 mL, 0.0435 mol) or mercaptoacetic acid (3.5 mL, 0.0435 mol) for the derivative **14**, for 1 h. The purified nitriles (0.00435 mol) diluted in anhydrous diethyl ether (**1** and **4**), dry THF (**2** and **7**), and anhydrous dichloromethane (**6** and **8**) were quickly added to the cold solution under stirring, and the reaction was left overnight at 0 °C. Anhydrous cold diethyl ether was then

added to the reaction mixture, which was left at -20°C until a crystalline solid was formed. The supernatant was decanted, and the precipitate was washed with anhydrous diethyl ether under argon and dried under reduced pressure at room temperature.

Ethyl S-Acetyl-3-mercaptopropionthioimide Ester Hydrochloride (M-AMPT, 9): yield 0.79 g (75%); mp 112°C ; ^1H NMR (CDCl_3) δ 3.4–3.2 (m, 5H, $-\text{SCH}_2\text{CH}_3$, CH and CH_2), 2.43 (s, 3H, SAc), 1.6 (d, 3H, CH_3), 1.43 (t, 3H, $-\text{SCH}_2\text{CH}_3$); IR (KBr) cm^{-1} 3300–2400 (NH), 1690 (C=O), 1620 (C=N), 1360 (SAc); MS-EI, m/z (relative intensity) 206 (M^+ , 7), 162 (100), 145 (53), 130 (20), 102 (65), 89 (20), 75 (33), 61 (52), 43 (100).

Ethyl S-Acetyl-3-mercaptopropionthioimide ester hydrochloride (Ph-AMPT, 10): yield 1.1 g (84%); mp 85°C ; ^1H NMR (CDCl_3) δ 7.6 (m, 5H, Ar-H), 4.9 (t, 1H, CH), 3.9–3.3 (m, 4H, $-\text{SCH}_2\text{CH}_3$, and CH_2), 2.5 (s, 3H, SAc), 1.6 (t, 3H, $-\text{SCH}_2\text{CH}_3$); IR (KBr) cm^{-1} 3300–2400 (NH), 1730 (C=O), 1610 (C=N), 1360 (SAc); MS-EI, m/z (relative intensity) 268 (M^+ , 8), 130 (100), 103 (40), 77 (35), 43 (38).

Ethyl 3-[(3-Carboxy-4-nitrophenyl)dithio]butyrythioimide Ester Hydrochloride (11): yield 1.3 g (78%); mp 112°C ; ^1H NMR (CD_3OD) δ 8.2 (m, 3H, Ar-H), 3.8–3.2 (m, 5H, $-\text{SCH}_2\text{CH}_3$, CH and CH_2), 1.5 (q, 3H, CH_3), 1.25 (t, 3H, $-\text{SCH}_2\text{CH}_3$); IR (KBr) cm^{-1} 3300–2500 (NH and OH), 1610 (C=N), 1570, 1530 (NO_2), 1370 (NO_2).

Ethyl 3-Phenyl-[(3-carboxy-4-nitrophenyl)dithio]propionthioimide Ester Hydrochloride (12): yield 1.6 g (80%); mp 120°C ; ^1H NMR (CD_3OD) δ 7.4 (m, 3H, Ar-H), 7 (m, 5H, Ar-H), 3.8–3.2 (m, 5H, $-\text{SCH}_2\text{CH}_3$, CH and CH_2), 1.25 (t, 3H, $-\text{SCH}_2\text{CH}_3$); IR (KBr) cm^{-1} 3300–2500 (NH and OH), 1610 (C=N), 1570, 1530 (NO_2), 1370 (NO_2).

Ethyl 3-[(4-Carboxamidophenyl)dithio]butyrythioimide Ester Hydrochloride (M-CDPT, 13): yield 1.17 g (77%); mp 118°C ; ^1H NMR ($\text{DMSO}-d_6$) δ 8.2 (d, 2H, Ar-H), 7.8 (d, 2H, Ar-H), 4.1 (m, 1H, CH), 3.4–3.2 (m, 4H, $-\text{SCH}_2\text{CH}_3$ and CH_2), 1.5 (d, 3H, CH_3), 1.25 (t, 3H, $-\text{SCH}_2\text{CH}_3$); IR (KBr) cm^{-1} 3300–2200 (NH_2 and NH_2^+), 1650 (C=O), 1620 (C=N); MS-EI, m/z (relative intensity) 315 (M^+ , 38), 254 (8), 226 (18), 212 (100), 195 (20), 163 (100), 153 (18), 89 (18), 44 (10).

Carboxymethyl 3-Phenyl-3-[(4-carboxamidophenyl)dithio]propionthioimide Ester Hydrochloride (Ph-CDCT, 14): yield 1.5 g (78%); mp 115°C ; ^1H NMR ($\text{DMSO}-d_6$) δ 7.8 (q, 4H, Ar-H), 7.4 (m, 5H, Ar-H), 4.5 (t, 1H, CH), 3.6 (s, 2H, $-\text{SCH}_2\text{COOH}$), 2.85 (d, 2H, CH_2); IR (KBr) cm^{-1} 3300–2200 (NH_2 and NH_2^+), 1650 (C=O), 1620 (C=N); MS (FAB^+) 407 (M^+ + 1).

Ethyl 3-Phenyl-3-[(4-carboxamidophenyl)dithio]propionthioimide Ester Hydrochloride (Ph-CDPT, 15): yield 1.36 g (78%); mp 120°C ; ^1H NMR ($\text{DMSO}-d_6$) δ 7.8 (q, 4H, Ar-H), 7.3 (m, 5H, Ar-H), 4.2 (t, 1H, CH), 3.4–3.2 (m, 4H, $-\text{SCH}_2\text{CH}_3$ and CH_2), 1.3 (t, 3H, $-\text{SCH}_2\text{CH}_3$); IR (KBr) cm^{-1} 3300–2200 (NH_2 and NH_2^+), 1650 (C=O), 1620 (C=N); MS (FAB^+) 377 (M^+ + 1).

Determination of Aryldithio Group Reactivity. Stock solutions (0.25 mM) of disulfides **4**, **6**, **7**, and **8** were prepared in ethanol (95%) and diluted to 0.028 mM with sodium phosphate buffer (0.0056 M Na_2HPO_4 , 0.014 M $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$, 0.2 M NaCl, 0.003 M EDTA disodium salt, pH 6.5), deaerated and flushed with Ar. To 900 μL of each disulfide solution in a photometer cell was quickly added 100 μL of different concentrations of freshly prepared solutions of cysteine hydrochloride monohydrate (0.5 and 1 mM) in the same buffer. The thiol–disulfide exchange reaction was then monitored by recording the absorbance–time curve relative to the displacement of the substituted thiophenol (which is

balanced with its ionized form) in the presence of double and quadruple molar excesses of cysteine.

The kinetic constants were calculated (19) using the second-order equation

$$dx/dt = k(a - x)(b - x); \quad k = \frac{1}{t(a - b)} \ln \frac{(b - x)a}{(a - x)b}$$

where a is initial aryldithio derivative molar concentration, b is initial cysteine molar concentration, and x is thiophenol molar concentration at time t (s). The value of x is calculated by the equation

$$dx/dt = k(A - A_0/A_{\text{inf}} - A_0)a$$

where A is the absorbance at time t (s), A_0 is the initial absorbance of the aryl disulfide, and A_{inf} is the final absorbance at 100% of reaction with cysteine.

For each couple A/t relative to the registered kinetic curves, the value of x and the kinetic constant k ($\text{L} \cdot \text{mol}^{-1} \cdot \text{s}^{-1}$) were calculated.

Reaction of Thioimide with AR-3 mAb and Determination of Degree of Derivatization. The mouse IgG1 monoclonal antibody AR-3 was purified from ascitic fluid with affinity chromatography on Sepharose Cl–protein A. A solution of AR-3 (60 μM , 1 mL) in PBS–EDTA (100 mM sodium phosphate, 100 mM NaCl, 1 mM EDTA, pH 7.4), deaerated and flushed with Ar, was mixed at 25°C with different molar excesses (10-, 20-, 30-fold) of the linkers **9**, **10**, **13**, and **14** previously dissolved in absolute ethanol (**9**, **10**) or anhydrous dimethylformamide (DMF) (**13** and **14**) (40 μL). The degree of derivatization was evaluated at different time intervals after purification from the excess of ligands by gel filtration on a 15×55 mm Bio-Gel P6-DG column (Bio-Rad, Hercules, CA) pre-equilibrated in PBS–EDTA at 20°C .

The number of thioacetylated groups linked to the protein was calculated spectrophotometrically by reaction of the sample with the deacetylating reagent hydroxylamine hydrochloride (0.5 M, 12.5 mM EDTA, pH 7.4) followed by thiol–disulfide exchange with DTNB as described by Duncan (23). Determination of the aryldithio groups linked to AR-3 was evaluated following the release of thiolated anion at 313 nm, after incubation of the protein sample (1 mL) in the presence of 2-mercaptoethanol in PBS–EDTA (11 mM sodium phosphate, 50 μL) and NaOH (1 M, 40 μL) to a final pH of 8.8–9.4. The molar absorptivity value for the 4-carboxamidophenylthiolate anion under these conditions at 313 nm was $15\,200 \pm 300$.

Disulfide Bond Stability in Modified AR-3. The protein (33.3 μM , 1 mL) was reacted with the ligands M-AMPT, Ph-AMPT, M-CDPT, and Ph-CDCT and with the analogous unhindered thioimides AMPT and CDPT, previously prepared in our laboratory (19), so as to incorporate an average of 1–1.2 mol of linkers/mol of protein.

Before purification in the derivatization mixture, the thioacetylated groups were replaced with TNB by deacetylation with hydroxylamine solution and successive exchange with DTNB 800 μM for 1 h at 25°C .

The samples were purified by gel centrifugation as described below.

The linker/protein ratio was spectrophotometrically determined by quantifying the release of TNB at 412 nm after the addition of a solution of dithiothreitol (DTT, 50 mM); the release of 4-carboxamidophenylthiolate anion was followed at 313 nm as described below.

To test the stability of the disulfide bond introduced into proteins, the samples were incubated with reduced glutathione (GSH) (2 and 4 molar excess with respect to thiol groups linked), and the release of thiophenol was spectrophotometrically followed at 412 or 313 nm.

Preparation and Purification of Immunoconjugates. Gelonin solution (Inland Laboratories, Inc., Austin, TX) (187 μ M, 1 mL) was stirred with ethanolic solutions of AMPT (64.2 mM, 30 μ L) or M-AMPT (51 mM, 30 μ L) for 30 min at 25 °C so as to incorporate an average of 1–1.1 linkers/mol of gelonin. The mixture was purified by gel centrifugation. The purified antibody dissolved in PBS–EDTA was separately reacted with two different cross-linkers, CDPT and M-AMPT.

The method used to derivatize AR-3 with CDPT is described in ref 20; briefly, the cross-linker (16 μ M, 43 μ L) in dry DMF was reacted for 30 min at 25 °C with AR-3 (47 μ M, 890 μ L) to obtain a molar ratio of 1:1.2 (AR-3/CDPT).

The reaction of AR-3 with M-AMPT proceeded as follows: M-AMPT in absolute ethanol (11 mM, 40 μ L) was added to the solution of the mAb (44.6 μ M, 1 mL), and the mixture was stirred for 30 min at 25 °C; then solutions of hydroxylamine (0.5 M, 100 μ L) and DTNB (40 mM, 30 μ L) were added and the reaction was stirred for 1 h. The AR-3/M-AMPT molar ratio was 1:1.1. In both cases the mixture was purified by gel centrifugation.

The derivatized mAb and RIP were mixed in the presence of a solution of hydroxylamine (1:10, v/v). The conjugation reactions proceeded for 5 h at 25 °C followed by 18 h at 4 °C; at the end of the reaction a solution of *N*-ethylmaleimide (20 mM, 20 μ L) was added to block free thiol groups.

Immunoconjugates were purified as follows: the reaction mixtures were centrifuged and the supernatants applied to an HPLC gel filtration column (TSK G 3000 SW, 7.5 \times 600 mm) in several steps and eluted in sodium phosphate buffer, pH 6.8 (50 mM phosphate, 0.15 M NaCl). The fractions containing unreacted mAb and conjugate were pooled, concentrated, dialyzed against 50 mM phosphate buffer/10 mM NaCl, pH 7.4, and loaded onto an Affi-Gel Blue column (7 \times 50 mm) preequilibrated in the same buffer. Unconjugated AR-3 did not bind to the solid phase under these conditions of ionic strength and was eluted. The conjugates were then eluted with the same buffer containing 1 M NaCl. The fractions containing immunoconjugates were dialyzed and concentrated.

Purity of the immunotoxins was monitored by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) using 4–15% precast gels (Bio-Rad) under non-reducing conditions and Coomassie blue staining.

In Vitro Study of Disulfide Bond Stability. The *in vitro* stability of the bond in the various conjugates was evaluated in two different ways. In the first method the samples (1 mg/mL, 3 μ L) were incubated for 1 h at 37 °C with solutions of GSH (3 μ L) in increasing excess (from 3- to 10000-fold), and the reaction was stopped by addition of excess of iodoacetamide. The samples were then tested by densitometric analysis of SDS–PAGE 4–15% precast gels stained by Coomassie blue to calculate the amount of mAb released (2202 ULTROSCAN Laser Densitometer, LKB, Bromma, Sweden). The other experiment was similar to the procedure of Carroll (16): immunotoxins (5.5 μ M, 10 μ L) were incubated for 1 h at 37 °C with different concentrations of GSH (from 30- to 3000-fold), and iodoacetamide was then added; the samples were dialyzed by a microdialyzer System 500 (Pierce, Rockford, IL) to remove the low molecular weight products and then chromatographed on a Zorbax Bio

Series GF 250 column (DuPont, Newtown, CT) equilibrated in 0.2 M Na₂HPO₄, pH 7.5. The elution was monitored at 280 nm, and the amount of gelonin released was quantified by area integration (CBS-10A Communications Bus Module, Shimadzu, Duisburg, Germany).

Cytotoxicity Assay. The cell lines used were HT-29, a human colon adenocarcinoma expressing the CAR-3 antigen, as target cell line, and the MeWo human melanoma as control. These cell lines were tested in the presence of serial dilutions of three immunotoxins, according to the method of Cattel et al. (24). The results were expressed as percentage of [³H]leucine incorporation with respect to control (background values subtracted).

Pharmacokinetic Evaluation. The immunoconjugates were labeled with ¹²⁵I according to the iodogen method (25) to specific activity of approximately of 7 mCi/mg. Pharmacokinetic studies were performed as previously described (26) using female Balb/c mice (1 month old, 18–20 g; Charles River Italia, Milan, Italy); care and handling of animals were in accordance with the provisions of the European Economic Community Council Directive 86/209 recognized and adopted by the Italian Government (approval decree no. 230/95 B). The mice drank water plus 0.2% (v/v) Lugol solution 3 days before and during the experiment to block thyroid iodine uptake. The animals were treated with 4.5 μ Ci (135–180 μ g/kg) of conjugate. The samples were diluted in a carrier solution of PBS, pH 7.4, containing 0.1% bovine serum albumin to a volume of 100 μ L. The solutions were injected intravenously (iv) into the tail vein (groups of three animals each). Blood samples were taken from the retroorbital plexus at various times (0, 0.5, 1, 2, 4, 6, 24, 48, 72, and 144 h); both the Pasteur capillary and the Eppendorf vials used for the sample collections were washed in a heparin solution 1 day before use. Because blood was taken from each animal no more than four times, the different groups were overlapped to cover the chosen time range. The experiments were repeated three or four times.

The treatment of blood samples was quite similar to that described by Scott (27): samples were diluted to the same volume of 54 mM aqueous iodoacetamide to prevent oxidation of free thiol groups possibly formed; proteins were rapidly precipitated with 1 mL of cold trichloroacetic acid (12.5%, w/v). The samples were directly counted in a gamma counter (L'ACN, Milan, Italy) and then centrifuged; the resultant pellets were counted separately from the supernatants and used to determine the pharmacokinetic parameter.

The plasma samples from each time point were also analyzed by 7.5% SDS–PAGE gels using volumes containing 350–3000 cpm. Autoradiographs of the dried gels were obtained and analyzed with a Phosphor Imaging GS-250 (Bio-Rad); then the immunotoxin and antibody areas were calculated with Molecular Analyst software version 1.2 (Bio-Rad).

Pharmacokinetic parameters were determined from a two-compartment analysis using the program PCNONLIN (Statistical Consultants, Inc., Lexington, KY).

RESULTS

Chemistry. The S-acetylated thioimide ester hydrochlorides M-AMPT **9** and Ph-AMPT **10** were prepared as shown in Scheme 1. The precursor nitriles **1** and **2** were prepared by the addition of thiolacetic acid to the unsaturated nitriles according to the method of Holmberg and Schjamberg (28). Transformation to the corresponding thioimide followed the Pinner synthesis (29) by the

Scheme 1. Synthesis of S-Acetylated and 3-Carboxy-(4-nitrophenyldithio)thioimide Reagents**Scheme 2. Synthesis of (4-Carboxamidophenylthio)thioimides**

addition of the nitrile to a solution of ethanethiol previously saturated with dry hydrogen chloride.

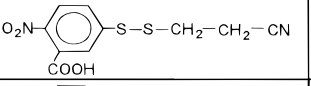

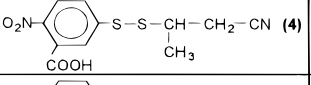

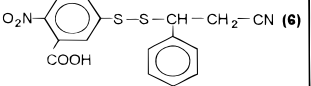

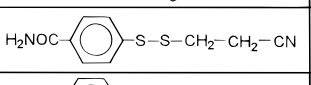

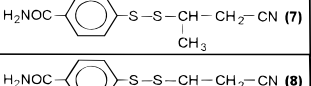

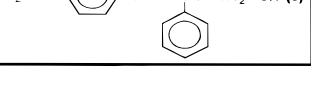

The (3-carboxy-4-nitrophenyldithio)thioimides **11** and **12** were synthesized from the corresponding nitriles **4** and **6** (Scheme 1) prepared by a reaction of thiol-disulfide exchange between DTNB and 3-mercaptoputyrionitrile (**3**) or 3-mercapto-3-phenylpropionitrile (**5**) previously obtained by hydrolysis of respective thioacetylated derivatives (**1** and **2**).

The carboxamidoaryldithio derivatives M-CDPT **13**, Ph-CDCT **14**, and Ph-CDPT **15** were prepared from the corresponding nitriles **7** and **8** (Scheme 2) obtained by the reaction of 4-carbamoylbenzenesulfenyl chloride (**30**) with the mercaptans **3** and **5**. For preparation of the ligand **14**, the classical Pinner reaction was modified using mercaptoacetic acid instead of ethanethiol. In this way it was possible to increase the hydrophilicity of the poorly water soluble phenyl-substituted linker by replacing the *S*-ethyl function by an *S*-carboxymethyl group.

The compounds were characterized by 1H NMR, IR, and MS.

The thioimides required storage under very anhydrous conditions and were kept in tightly stoppered flasks at $-20^\circ C$ under Ar.

Kinetic Studies. To verify the relationship between steric hindrance and stability of the disulfide bond in the (aryldithio)thioimide linker series, we studied the reactivity toward thiol-disulfide exchange in the precursor nitrile derivatives **4**, **6**, **7**, and **8** using cysteine as thiol reagent (**19**).

The progress of disulfide reductive scission was followed at 412 or 313 nm (for TNB or carboxamidophenylthiolate anion, respectively), and the relative rate constants k (L·mol⁻¹·s⁻¹) were calculated. The rate constants obtained using 2-fold molar excess of cysteine are shown in Table 1 and compared to the value obtained for the unhindered derivatives 5-[(2-cyanoethyl)dithio]-2-nitrobenzoic acid and 4-[(2-cyanoethyl)dithio]benzamide. As shown in Table 1, the lower value of the rate constant in the hindered compounds **4**, **6**, **7**, and **8** relative to that found for the unhindered derivatives indicates a reduction in the reactivity of cysteine toward thiol-disulfide exchange, and the comparable k values suggest that the methyl and phenyl groups conferred similar stability to the disulfide bond.

Among the compounds tested, the 3-carboxy-4-nitrophenyldithio series showed higher reactivity than the carboxamidophenyldithio derivatives. Derivatives **4** and **6** were in turn transformed by synthesis to the corresponding thioimide derivatives **11** and **12**, which did not show sufficient stability in aqueous media to allow their use as cross-linkage reagents, while compound **15** was excluded from further experiments because of its very low water solubility. Instead, the thioimide derivatives **13** and **14**, obtained from the less reactive nitrile precursors **7** and **8**, were much more stable in aqueous solution. Consequently, we chose the hindered derivatives M-CDPT **13** and Ph-CDCT **14** as linkers for further testing of protein derivatization.

Reaction of Thioimide with Protein. The reactivity of linkers **9**, **10**, **13**, and **14** toward the lysyl ϵ -amino groups of AR-3 was evaluated. Degrees of derivatization versus time using a fixed molar excess of linker (pH 7.4, 20 $^\circ C$) are shown in Figure 1.

For these reagents, prolonging the reaction time increased the degree of substitution on the protein in proportion to the molar excess of ligand; after 2 h of reaction, no increase appeared. As shown in Figure 1, the hindered derivatives, being more lipophilic and hence less soluble in the aqueous buffer, were generally less

Figure 1. AR-3 derivatization degree with various thioimide esters. The mAb (60 μ M) was reacted with a fixed molar excess of ligand ($\times 10$); the derivatization efficacy was evaluated at different time intervals after purification from the excess of ligand as described under Experimental Procedures. The points represent the arithmetic means of three determinations. SDs (not reported) were $<10\%$ of the means.

reactive toward protein, the exception being M-AMPT, which showed roughly the same reactivity as the parent AMPT.

Stability of Model Disulfides in Derivatized AR-3. The relative stability of the disulfide bond introduced into AR-3 by derivatization with ligands M-AMPT **9**, Ph-AMPT **10**, M-CDPT **13**, and Ph-CDCT **14** was analyzed by comparison with the parent unhindered linkers AMPT and CDPT (**19**) using GSH as reducing agent.

To study the stability of the S-acetylated thioimide linkers (AMPT, M-AMPT, and Ph-AMPT) after derivatization with the protein, the thioacetylated groups were replaced by TNB by deacetylation with hydroxylamine followed by exchange with DTNB. In this way it was possible to measure the strength of the disulfide bond introduced in the protein by following spectrophotometrically the release of TNB at 412 nm after the addition of GSH (Figure 2A).

Instead, to analyze the stability of the dithio group introduced in the AR-3 protein after derivatization with the series of the (carboxamidophenylthio)thioimide linkers (CDPT, M-CDPT, and Ph-CDCT), it was sufficient to measure spectrophotometrically the release of the carboxamidophenylthiolate anion at 313 nm after addition of GSH (Figure 2B). Figure 2 indicates that there is an increase in stability of the disulfide bond after introduction of a methyl or phenyl group in an adjacent position. As it was found for the kinetic constant values of the nitrile precursors (Table 1), M-CDPT is the most stable compound among the carboxamido derivatives, while among the TNB derivatives, the most stable toward thiol–disulfide exchange was that derived by the Ph-AMPT linker.

Parts A and B of Figure 2 also show a different value for the release of thiophenol due to higher thiol–disulfide exchange reactivity in TNB-modified derivatives.

Preparation of Immunotoxins. Gelonin, a 30 kDa cytotoxic single-chain glycoprotein obtained from the seeds of *Gelonium multiflorum* (**31**, **32**), was selected as toxin to generate ITs after chemical conjugation with the monoclonal antibody AR-3. According to the preceding results, three different coupling procedures were followed to compare the relative stability of the immunotoxins.

IT1 (Scheme 3). The CDPT ligand was first reacted with the mAb to introduce 1.2 arylthio groups/protein

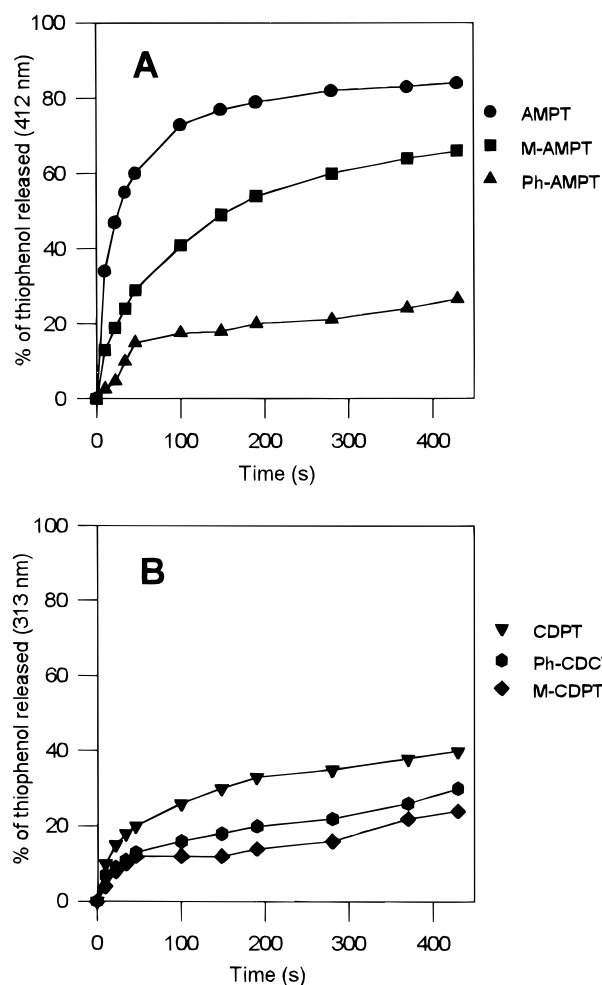

Figure 2. Stability of disulfide bond introduced into AR-3 by derivatization with different linkers so as to incorporate an average of 1–1.2 mol of linkers/mol of antibody. The release of thiophenol was monitored spectrophotometrically after the addition of GSH. In (A) the release was followed at 412 nm after the substitution of S-acetylthio group with TNB, while in (B) the release was followed at 313 nm. Results were normalized by dividing the absorbance at any time point by that obtained with an excess of DTT and multiplying the product by 100. The points represent the arithmetic means of three determinations. SDs (not reported) were $<8\%$ of the means.

molecule, whereas 1–1.1 acetylthio residues were introduced into gelonin with AMPT; the derivatized proteins were coupled in the presence of hydroxylamine to deprotect the acetylthio groups to obtain the corresponding IT.

IT2 (Scheme 3). The CDPT-modified AR-3 was reacted with the gelonin previously thioacetylated with the hindered linker M-AMPT (0.9–1.1 groups).

IT3 (Scheme 4). Both proteins were derivatized with M-AMPT by introducing 0.9–1.1 acetylthio groups; the modified mAb was then deacetylated with hydroxylamine and reacted with DTNB and further directly coupled to the S-acetyl-containing gelonin in the presence of hydroxylamine by a thiol–disulfide exchange reaction. In this way the disulfide group was protected by the introduction of two symmetric methyl groups in the protein–protein linkage.

All of the coupling reactions proceeded for 5 h at 25 $^{\circ}$ C and for 18 h at 4 $^{\circ}$ C, and then aliquots were analyzed by SDS–PAGE (Figure 3). The ITs (IT1 and IT2) prepared using CDPT as ligand gave pure conjugate with a molar ratio 1:1 mAb/gelonin at 85%; in fact, the carboxamidophenylthiolate leaving group, being less

Scheme 3. Preparation of IT1 and IT2**Scheme 4. Preparation of IT3**

reactive, produced the monoconjugate species in higher yield compared with the TNB leaving group.

The results showed an inverse correlation between disulfide bond stability and efficiency of conjugation in

this order: $\text{IT1} \geq \text{IT2} > \text{IT3}$; conjugation yields were approximately 10% for IT1 and IT2 and 3–4% for IT3.

The disulfide-linked immunotoxins were purified by HPLC gel filtration to remove the aggregates and the

Figure 4. Release of mAb from the immunoconjugates. The conjugates were incubated with different concentrations of GSH for 1 h at 37 °C. The amounts released were measured by densitometric analysis of SDS-PAGE. Results are the average of three independent experiments (SDs were <10%).

unreacted toxin; then to completely remove the free mAb from the conjugate, the mixtures were subjected to Affi-Gel Blue affinity chromatography.

Disulfide Bond Stability of Conjugates *in Vitro*. To test the *in vitro* stability of the immunotoxins, two types of experiments were done using GSH as reagent. First, the samples, after incubation with different excesses of GSH, were tested by densitometric analysis of SDS-PAGE; the results showed less release of mAb from conjugates IT2 and IT3 containing a steric hindrance (Figure 4). In the second experiment the release of toxin after reaction with GSH was monitored by HPLC and quantified by area integration (data not shown).

The results obtained with the two methods were comparable. However, using an excess of GSH >7000, the cleavage of the mAb disulfide bond was measurable only by the SDS procedure.

Evaluation of the Specific Cytotoxicity of Immunoconjugates. The cytotoxicity of each immunoconjugate was evaluated on target (HT-29) and control (MeWo) cell lines. The three conjugates showed the same activity in inhibition of protein synthesis since the IC_{50} values were around 0.2–0.3 nM. All of the immunotoxins were less effective on the nontarget MeWo cells (Figure 5).

Pharmacokinetics. To check the *in vivo* stability of

the hindered and unhindered disulfide bond, pharmacokinetic behavior after iv bolus administration in Balb/c mice was evaluated. Each immunotoxin was radio-labeled with ^{125}I and injected iv in groups of mice. Blood samples were collected at interval times, and radioactivity was determined. The plasma samples were analyzed by SDS-PAGE autoradiography and densitometry (Figure 6). The rate at which the unhindered conjugate IT1 broke down to release the free antibody *in vivo* was faster than that of IT2 and IT3. For these, the plasma samples contained approximately equal amounts of intact immunotoxin and released mAb 42–48 h after injection. As was found *in vitro*, IT1 appeared to uncouple more quickly *in vivo*; in fact, the conjugate band decreased to 50% after about 6–8 h.

Plasma concentrations of immunotoxin at each time point were used to construct pharmacokinetic curves for each conjugate (Figure 7). Computerized analysis of the

Figure 7. Blood clearance. Mice were given iv injections of radioiodinated immunotoxins, and blood samples were removed at various time intervals later. The percentage of the injected dose that corresponded to intact immunotoxin was determined with plasma samples both by γ counting and by scanning autoradiographs of SDS gels. The points represent the arithmetic means of three determinations. SDs (not reported) were <9% of the means.

clearance data using an open two-compartment pharmacokinetic model gave the parameters shown in Table 2.

The elimination curves were biphasic, having an initial rapid α phase followed by a slower β phase. The immunoconjugates most stable *in vitro* (IT2 and IT3) were eliminated more slowly, while IT1 was cleared rapidly, as shown by progressive increase of the respective β -phase half-lives (from 27.9 h for the unhindered IT1 to 60.2 and 88.3 h for the hindered IT2 and IT3, respectively). In contrast, the enhanced stability of the linker did not effect the α phase half-life, which mainly influences the distribution.

DISCUSSION

In an attempt to evaluate factors affecting immunoconjugate preparation and potency, we developed a series of heterobifunctional cross-linking reagents (19). In this study we synthesized linkers that should be useful to prepare immunotoxins containing disulfide bonds with improved stability *in vivo*. Two different types of bifunctional linkers were synthesized: (1) a set of differently substituted (aryldithio)thioimide derivatives based on an amine-reactive thioimide function and a dithiophenyl group able to perform thiol–disulfide exchange reactions; (2) a series of thioimide derivatives containing a protected *S*-acetyl thiol group. These types of linker share in common reactivity toward lysyl ϵ -amino groups, generating an amidinated linkage and thereby preserving the positive charge of the protein. Some authors have reported that modification of gelonin with reagents that forms positively charged amidines preserves its activity, while it is inactivated by derivatization with *N*-hydroxy-succinimide esters (33). These linkers were designed to generate a protected disulfide linkage after protein–protein conjugation in which a methyl or phenyl group is bound to the carbon atom adjacent to the dithio bond.

To assess the ability of the cross-linking reagents to produce immunoconjugates highly stable *in vivo* but reducible intracellularly, we developed different test procedures.

In the aryldithio series we first tested the reactivity of the precursor nitrile derivatives (hindered versus unhindered) in a thiol–disulfide exchange type using cysteine as thiolating reagent. By considering the kinetic constant values of the thiol–disulfide exchange reaction of the two parent unhindered compounds, 4-[(2-cyanoethyl)dithio]benzamide and 5-[(2-cyanoethyl)dithio]-2-nitrobenzoic acid, we found the major factor in determining the reactivity toward cysteine to be the presence of strong electron-withdrawing groups in the aromatic ring (19). In both cases stability of the linker was strongly enhanced when a methyl or a phenyl group was bound to the carbon near the disulfide bond. For practical purposes we selected the carboxamidothioimide derivatives **13** and **14** to further test the reactivity of this set of linkers toward the protein, since the more reactive **11** and **12** were not sufficiently stable in aqueous buffer.

The next step was to evaluate the ability of the linkers to derivatize the AR-3 mAb and to check the stability of the disulfide group introduced. Reactivity toward the protein strongly decreased when a phenyl group was bound to the carbon atom adjacent to the disulfide bond. In contrast, with a different series of 5-substituted 2-iminothiolanes, reactivity with protein amino groups was unaffected by ring substituents (34). Probably in our series some factors limited the overall reaction kinetics as the aqueous solubility became predominant.

To choose the best hindered cross-linking for preparation of stable disulfide-linked immunotoxins, different features were evaluated, such as (a) stability and solubility of the linker in aqueous solution, (b) reactivity of the linker toward the model protein, and (c) the protective effect of the methyl or phenyl groups toward disulfide bond cleavage. Taking these factors together, M-AMPT appeared to be the best balanced coupling reagent. We therefore applied two coupling procedures taking M-AMPT as reference linker in constructing stable dithio bond-containing immunotoxins: (1) a CDPT-derivatized antibody coupled to M-AMPT-thiolated gelonin to introduce one methyl group adjacent to the disulfide bond (IT2); (2) an M-AMPT-derivatized gelonin coupled to the antibody first derivatized with M-AMPT followed by activation of the thiol group by DTNB (IT3). In this case we introduced symmetrical methyl groups at each end of the dithio linkage. As reference we synthesized an unhindered IT by using CDPT and AMPT to derivatize the antibody and the gelonin respectively (IT1).

Conjugates IT1, IT2, and IT3 showed almost the same cytotoxic activity toward the target HT-29 cell line, whereas they were nearly ineffective on the nontarget MeWo cell line.

In vivo the stability of the hindered versus the unhindered immunotoxins was verified by studying the pharmacokinetic behavior after iv bolus administration in Balb/c mice.

All three ITs had similar α phase half-lives, suggesting

that reducibility of the linkage is not a limiting factor during the α phase.

Instead, in the β phase the sterically hindered conjugate IT2 had a significantly longer half-life (60.2 h) compared with that of the unmodified disulfide IT1 (27.9 h), while the symmetrical dimethyl disulfide-linked IT3 (88.3 h) had the longest β phase half-life. To our knowledge, this is the longest β phase half-life so far reported for an immunotoxin in rodents. Potentially increased *in vivo* therapeutical efficacy of the hindered immunoconjugates was also suggested by the increases in the AUC and MRT values.

Thorpe, both in preclinical and clinical studies (14, 17, 18), showed that IT with a methyl-hindered linker had greater antitumor activity, when given in equimolar dose, than IT with unhindered linkers. Excellent *in vivo* stability as well as favorable pharmacokinetics were also shown in a colorectal tumor-directed immunotoxin (35). Other authors disagreed; studying the *in vivo* therapeutic efficacy of two anti CD7-saporin ITs constructed with either hindered (SMPT) or unhindered (SPDP) linkers, they were unable to show any significant difference (36). It is possible that in some cases the tertiary structure of the coupled protein surrounding the linkage may inhibit the ability of GSH to cleave the disulfide bond in the IT (37). Indeed, it was shown that Abrin A chain IT was less susceptible to cleavage *in vitro* and *in vivo* than other ITs made with ricin A chain, gelonin, or momordin (38).

In conclusion, all of our data are in agreement with previous findings that the introduction of a hindered disulfide linkage into ITs has little or no effect on pharmacological potency (14–16), suggesting that disulfide cleavage is not the rate-limiting step in intoxication of cell by AR-3–gelonin conjugates. Moreover, resistance to cleavage of dithio bond *in vitro* or *in vivo* is directly related to the degree of steric hindrance afforded by the group adjacent to the disulfide bond.

We noted that ITs such as IT3 made with a symmetrical dimethyl-substituted disulfide bond showed a substantially greater *in vivo* stability than the monomethyl-substituted IT2. When two geminal methyl groups are linked to the α -carbon adjacent to the dithio bond, comparable stability and plasma elimination profiles have been observed in comparison to the monomethyl-substituted IT (16).

It will be possible to extend the approach described to design protein–protein or drug–protein conjugates in which controlled time-dependent release of the drug, following systemic delivery, is desirable.

ACKNOWLEDGMENT

We appreciate the excellent technical assistance of Mr. D. Zonari. We thank V. Rossi for the gift of AR-3 monoclonal antibody and Dr. A. Pecorale for the protein radiolabeling, both from Sorin Biomedica, Saluggia, and Prof. G. Bussolati, Dipartimento di Scienze Biomediche ed Oncologia Umana of Turin, for using the Phosphor Imaging. This work was supported by MURST (40–60%), by Associazione Italiana per la Ricerca sul Cancro, by Azienda Ospedaliera San Giovanni Battista, and by CNR grants.

Single-Chain Fv/Folate Conjugates Mediate Efficient Lysis of Folate-Receptor-Positive Tumor Cells

Bryan K. Cho,[†] Edward J. Roy,^{‡§} Todd A. Patrick,[§] and David M. Kranz^{*,†}

Department of Biochemistry, Department of Psychology, and Neuroscience Program, University of Illinois, 600 South Matthews Avenue, Urbana, Illinois 61801-3792. Received October 11, 1996[®]

Bispecific antibodies that bind to a tumor antigen and the T cell receptor (TCR) redirect cytotoxic T lymphocytes (CTL) to lyse tumor cells which have escaped normal immune recognition mechanisms. One well-characterized tumor antigen, the folate receptor (FR), is expressed on most ovarian carcinomas and some types of brain cancer. Recently, it was shown that conjugates of folate and anti-TCR antibodies are extremely potent bispecific agents that target tumor cells expressing the high-affinity folate receptor, but not normal cells expressing only the reduced folate carrier protein. In this paper, it is shown that the size of these conjugates can be reduced to the smallest bispecific agent yet described (30 kDa) by attaching folate to a single-chain antibody, scFv, of the anti-TCR antibody KJ16. The scFv/folate conjugates are as effective as IgG/folate conjugates in mediating lysis of FR⁺ tumor cells by CTL. The optimal folate density was in the range of 5–15 folate molecules per scFv or IgG molecule, which yielded half-maximal lysis values (EC₅₀) of approximately 40 pM (1.2 ng/mL for scFv). Finally, the scFv/folate conjugates could efficiently target tumor cells even in the presence of free folic acid at concentrations that are normally found in serum. Compared to conventional bispecific antibodies, the small size of scFv/folate conjugates may prove advantageous in the ability to penetrate tumors and in reduced immunogenicity.

INTRODUCTION

It has been known for over 50 years that the immune system is capable of attacking and eliminating very large tumor burdens but sometimes fails to do so (1). Although the basis of this "escape" is incompletely understood (2), one mechanism involves the failure of tumor cells to express antigens in a context that is essential for recognition by the immune system [reviewed by Pardoll (3)]. Another mechanism might be the loss of costimulatory ligands and adhesion molecules that aid in the recognition and activation of T cells (4).

One potential way to direct T cells or other immune effector cells against tumor cells is with bispecific antibodies [reviewed by Fanger (5)]. Bispecific antibodies can be constructed to recognize two separate antigens, one on the tumor surface and the other on the surface of a cytotoxic T cell (e.g. TCR¹). Many tumor cells have potential target antigens that are tumor-specific or quantitatively more abundant on tumor cells than normal

cells (tumor-associated). By bringing together the tumor cell and an activated T cell, bispecific antibodies can redirect the cytotoxicity of T cells against tumors. Previous work has demonstrated the effectiveness of bispecific antibodies against tumors *in vitro* and *in vivo* and some clinical trials have been initiated (e.g. see refs 6–12). It has generally been agreed that optimizing the properties of bispecific antibodies should improve their clinical effectiveness.

Among the tumor antigens targeted with bispecific antibodies has been the high-affinity folate receptor (FR), also called the folate binding protein. The FR is now known to be expressed at elevated levels on many human tumors, including ovarian carcinomas [e.g. one study showed that 98% of ovarian tumors express the FR (13)], choroid plexus carcinomas, and ependymomas (14, 15). These cancers affect a significant segment of the population: ovarian cancer is the fourth leading cause of cancer death among women (16) and at least 30% of early childhood tumors are diagnosed as ependymoma or choroid plexus tumors (17, 18).

The presence of high levels of FR on human tumor cells has made it an attractive candidate for tumor-specific therapeutics. Monoclonal antibodies to the human FR have been generated and shown to be effective at targeting FR⁺ tumors *in vitro* (19–21). Clinical trials with radiolabeled antibodies and anti-FR/anti-CD3 bispecific antibodies have recently been initiated (9, 10, 12). Another approach has been to use the endocytic properties of the FR to deliver toxins or antisense nucleotides to the interior of malignant cells (22, 23). Although relatively low levels of FR mRNA have been detected in most normal human tissues (14), several studies have shown that normal choroid plexus, kidney, thyroid, colon, and placenta may have elevated levels [14, 24, 25; reviewed by Antony (26)]. Despite the presence of FR on normal human tissue, clinical trials using the anti-FR/anti-CD3 bispecific antibody have not demonstrated any toxicity associated with cytolysis of normal FR expressing tissue (9, 10).

[®] Abstract published in *Advance ACS Abstracts*, April 1, 1997.

¹ Abbreviations: CTL, cytotoxic T lymphocyte; FR, folate receptor; TCR, T cell receptor; scFv, single-chain antibody binding domain; MHC, major histocompatibility complex; K_D, dissociation constant; SV40, simian virus 40; EC₅₀, concentration of antibody/folate conjugate required for half-maximal CTL mediated cytotoxicity; fol, folate; EDC, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride; FITC, 5-aminofluorescein isothiocyanate; Ga, gallium; Fab, antigen binding fragment derived from papain digestion of Ig molecule; V regions, variable regions of IgG heavy and light chains; ϵ , extinction coefficient; SDS, sodium dodecyl sulfate; PAGE, polyacrylamide gel electrophoresis; PBS, 10 mM phosphate buffer, 150 mM NaCl, pH 7.3; PBS-BSA, PBS containing 0.1% bovine serum albumin; MTX, methotrexate.

The high intrinsic affinity of folate for FR ($K_d \sim 1$ nM) suggested to us that attachment of folate directly to an anti-TCR antibody might efficiently target FR⁺ tumor cells for lysis by T cells. We recently reported that such conjugates have very potent targeting activity without adversely affecting normal cells that express only the reduced folate carrier protein [$K_d \sim 1.5 \times 10^{-6}$ (27)], which is responsible for normal dietary uptake of folate and the transport of folate-based dihydrofolate reductase inhibitors such as methotrexate. It is reasonable to predict that the most effective agents for targeting solid tumors will have reduced sizes that allow greater tumor penetration. For instance, comparative biodistribution studies with ¹²⁵I-labeled IgG, F(ab)₂, Fab fragments, and scFv in human colon carcinoma xenografts in athymic mice demonstrated that scFv molecules penetrated tumor more rapidly, to a greater depth, and more uniformly than other forms of the antibody (28).

In this paper, a 29-kDa scFv of the anti-V β 8 antibody KJ16 (29) was conjugated with folate and its targeting potential was evaluated *in vitro*. Cytotoxicity assays with these preparations showed that lysis of mouse FR⁺ tumor cells was highly specific and correlated directly with FR density ($r = 0.93$). Comparison between folate-labeled-IgG and scFv demonstrated that both conjugates have nearly identical targeting efficiencies ($EC_{50} = 40$ pM), and lysis with scFv/folate could be detected at concentrations as low as 1 pM. Direct competition experiments with free folate demonstrated that the scFv/folate conjugate could effectively target FR⁺ tumor cells even at folate concentrations above normal serum levels. The reduced size of the scFv/folate compared to other bispecific reagents as well as its high potency suggests that it has potential for *in vivo* therapy. In addition, the conjugate may serve as a model for the development of future novel bispecific agents that contain small ligands specific for tumor cell surface antigens.

EXPERIMENTAL PROCEDURES

Cell Lines and Antibodies. The following DBA/2-derived tumor cell lines were maintained in RPMI 1640 containing 5 mM HEPES, 10% fetal calf serum, 1.3 mM L-glutamine, 100 units of penicillin/mL, 100 μ g/mL streptomycin, and 50 μ M 2-mercaptoethanol: Mel, murine erythroleukemia cell (30); La, a subline of Mel selected on low folate (31); L1210, a murine leukemia cell line (32); and F2-MTX^rA, a MTX-resistant subline of L1210 selected for increased expression of FR- β by growth on low folic acid (33). La expresses primarily the α isoform of folate receptor (FR), F2-MTX^rA expresses only the FR- β isoform, and L1210 expresses both α and β isoforms. CTL clone 2C, a V β 8⁺ alloreactive cell line specific for L^d (34), was maintained in the same RPMI medium supplemented with 10% (v/v) supernatant from concanavalin A-stimulated rat spleen cells, 5% methyl α -mannoside, and mitomycin C treated BALB/c mouse spleen cells as stimulators. KJ16 is a rat IgG antibody specific for the V β 8.1–2 domains of the TCR (35) and was provided by Drs. Kappler and Marrack. KJ16 monoclonal antibody was prepared from tissue culture supernatant generated in a Vita-Fiber miniflow path bioreactor (Amicon) and concentrated by precipitating twice in 50% ammonium sulfate. KJ16 Fab fragments, FITC-labeled Fab fragments, and KJ16 scFv were generated and purified as described previously (29). Briefly, scFv was refolded from inclusion bodies, and monomeric scFv was purified by G-200 HPLC purification. Monoclonal antibody 30.5.7 is specific for the major histocompatibility complex (MHC) class I product L^d (36) and was prepared as ascites

fluid and used without further purification in some cytotoxicity assays.

Preparation of Antibody/Folate Conjugates. Folate was coupled through its carboxyl groups to antibody amine groups using a carbodiimide procedure described previously (27, 37). Unless indicated, a 5-fold molar excess of 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC, Pierce Chemical Co.) was added to folate (Sigma) dissolved in dimethyl sulfoxide. After 30 min at room temperature in the dark, a 20–700-fold molar excess of the EDC-activated folate was added to 0.1–0.5 mg of antibody in 0.1 M MOPS, pH 7.5. After 1 h at room temperature, the sample was either applied to a Sephadex G-25 column pre-equilibrated in 0.1 M MOPS or immediately dialyzed into phosphate-buffered saline (PBS; 10 mM sodium phosphate, 150 mM sodium chloride, pH 7.3). If passed over a G-25 column, the excluded-peak fractions were pooled and dialyzed against PBS. After dialysis, protein concentrations were determined using the bicinchoninic assay (Pierce) using a protein A purified intact mouse antibody as the standard. Antibody conjugates were also analyzed spectrophotometrically at 363 nm, and the density of the folate per antibody was calculated by dividing the molar concentration of folate on the conjugate (A_{363}/ϵ_M ; $\epsilon_M = 6197$ M⁻¹) by the antibody concentration. Folate densities obtained ranged from ~ 1 to ~ 120 folates/antibody. Conjugates were stored at 4 °C in the dark.

Mass Spectrometry. Mass spectra were obtained on a ToFSpec using electrospray ionization. Samples were dialyzed against 1 mM potassium phosphate buffer, pH 8.0, and concentrated to 10–25 pmol/mL. Analysis was performed by the Mass Spectrometry Laboratory, School of Chemical Science, University of Illinois.

Folate Binding Assays. Binding assays were conducted by using ¹²⁵I-labeled folate (NEN; specific activity = 2200 Ci/mmol; 1 Ci = 37 GBq). Cells were washed with PBS containing 0.1% bovine serum albumin, pH 7.3 (PBS-BSA), to remove excess free folate present in the cell culture medium. Cells, labeled folate, and competitors were incubated in triplicate in 50 μ L of PBS-BSA for 1 h at 37 °C. Incubation at 37 °C has previously been shown to produce levels of binding similar to that obtained with acid pretreatment (27). Samples were loaded into tubes containing 300 μ L of oil [80% (v/v) dibutyl phthalate/20% (v/v) olive oil], and bound and free ligand were separated by a 3 s centrifugation at 12000g. Tubes were frozen and cut to allow the radioactivity in the cell pellet and supernatants to be quantitated separately.

T Cell Receptor Binding Assays. The relative affinity of the scFv/folate conjugates for the TCR was determined by a competition assay with 5-aminofluorescein isothiocyanate (FITC)-labeled KJ16 Fab fragments as previously described (29). In brief, various concentrations of antibody were added to triplicate sets of 6×10^5 2C cells in the presence of a constant amount of FITC-labeled Fab fragments. After a 30 min incubation on ice, the entire mixture (antibody + FITC-labeled Fab fragments + 2C cells) was passed through a flow cytometer without washing. Inhibition by various KJ16 preparations was measured by quantitating the decrease in bound fluorescence by flow cytometry (performed with a Coulter Electronics EPICS 752 at the University of Illinois Biotechnology Center). The concentrations of unlabeled antibody giving 50% inhibition (IC_{50}) were determined relative to the maximum fluorescence (in the absence of inhibitor) and the background fluorescence (in the presence of a large excess of intact antibody).

Cytotoxicity Assays. Tumor cells were labeled with

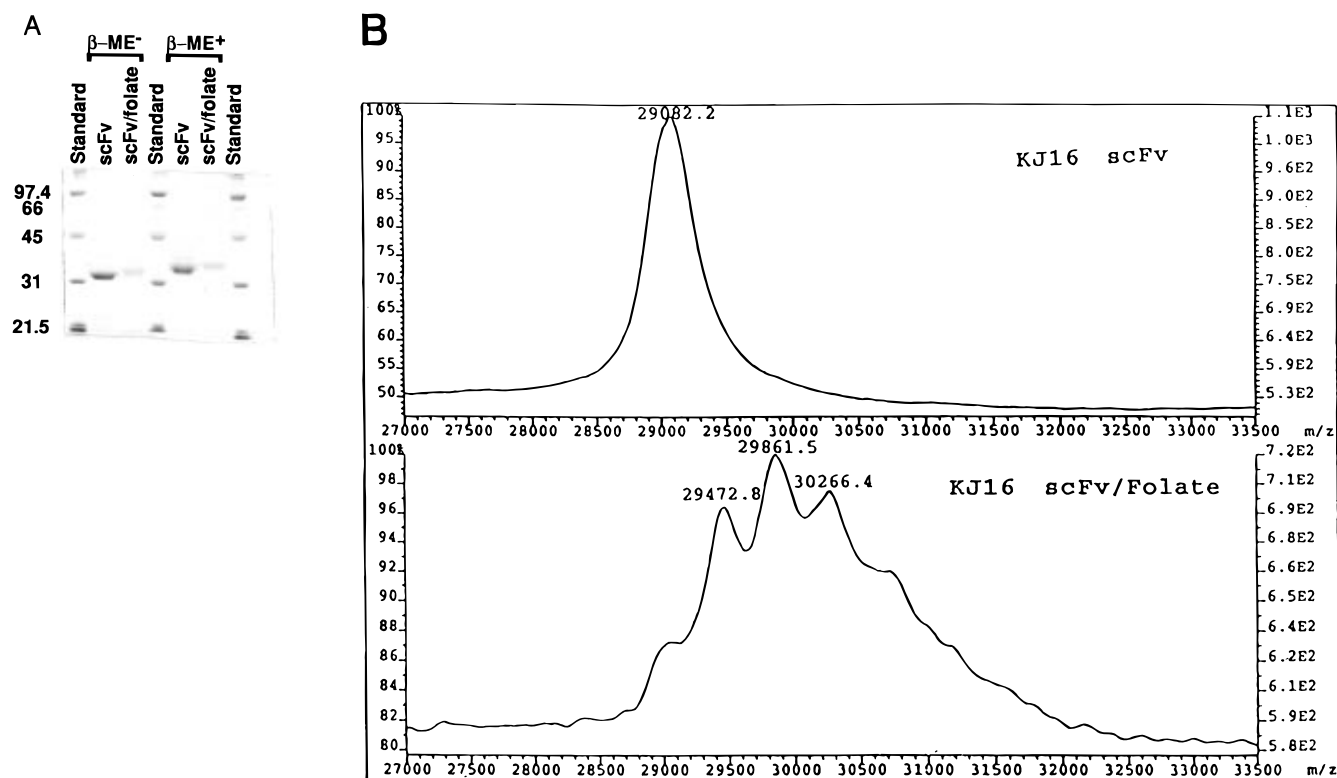

Figure 1. SDS-PAGE analysis and mass spectra of purified preparations of scFv KJ16 and scFv/folate conjugate: (A) samples were electrophoresed through a 10% polyacrylamide gel under reducing and nonreducing conditions, and proteins were visualized by staining with Coomassie Blue; (B) samples were concentrated, dialyzed against 1 mM potassium phosphate buffer, pH 8.0, and mass spectra were obtained on a ToFSpec using electrospray ionization. Purified scFv existed as a single species with a molecular mass of 29 082 Da. In contrast, folate-labeled scFv existed as a collection of antibody populations, each differing by the molecular mass of a folate molecule (~400 Da), detectable up to 7 folates per antibody.

50–100 μ L of ^{51}Cr (2.5 mCi/mL) for 60 min at 37 $^{\circ}\text{C}$, washed twice with folate-free RPMI 1640 medium containing 5% (v/v) fetal calf serum (folate-free media), and used in 96-well plate cytotoxicity assays at 10^4 cells per well. Because each of these cell lines also expressed the alloantigen L^d, which is recognized by CTL 2C, assays were performed in the presence of anti-L^d antibody to minimize non-FR-mediated lysis. Ascites of anti-L^d antibody 30.5.7 was diluted 1:100 into folate-free media containing effector cells (2C). Effector cells were added to target cells at an effector-to-target cell ratio of 5:1. Antibodies and folate/antibody conjugates were diluted in folate-free media and added to triplicate wells at various concentrations. Plates were incubated at 37 $^{\circ}\text{C}$ for 4 h in 5% CO_2 , and supernatants were removed for γ counting. For the inhibition of scFv/folate by free folate, a nonsaturating concentration of scFv/folate (3 nM) that would generate maximal cytotoxicity was used together with various concentrations of free folate. Unless indicated otherwise, the specific release mediated by the folate conjugates was determined by subtracting the release in the absence of the conjugates [e.g. % specific release = (experimental counts – spontaneous counts)/(maximal counts – spontaneous counts) \times 100].

EC_{50} values (i.e. the concentration of antibody/folate conjugate required for half-maximal specific lysis) were determined by linear regression. Among independent experiments, EC_{50} values and maximum cytotoxicity could vary for the same conjugate preparation primarily due to differences in CTL activity. For example, noticeable reductions in CTL 2C activity can be observed after multiple passages *in vitro* (unpublished data, D.M.K.). Therefore, for comparison of EC_{50} values from different experiments (i.e. Figure 5B), assay results were normalized by dividing each calculated EC_{50} by the EC_{50} of the

most potent conjugate in a given experiment [e.g. $\text{EC}_{50}^{\text{normalized}} = (\text{EC}_{50}/\text{EC}_{50}^{\text{low}})$]. The inverse of this normalized value, $[(\text{EC}_{50}^{\text{normalized}})^{-1}]$, which we have called the targeting index] was plotted as a function of folate density on the antibody, where a targeting index = 1 specifies the most potent conjugate.

RESULTS

Characterization of scFv/Folate Conjugates. The scFv of KJ16, an anti-V β 8 antibody, was purified from *Escherichia coli* inclusion bodies after guanidine denaturation, refolding, and HPLC gel filtration. Purified scFv migrated as an apparent 35-kDa protein on SDS-PAGE gels (Figure 1A). Folate was coupled to the scFv using the carbodiimide (EDC) reaction, which links carboxyl groups of folate to primary amine groups on the protein. In the engineering of the scFv, the V_L and V_H domains were joined by the 26 residue linker, 205s, that contains 8 lysine residues (29, 38). We reasoned that the presence of multiple lysine residues in a highly accessible, solvent-exposed region may result in higher folate densities in the linker region as opposed to the antibody V regions. In initial studies, folate was coupled to the scFv at a 100:1 folate to antibody molar ratio. Under these conditions, scFv/folate preparations contained an average of 3–8 folates per antibody ($N = 3$), on the basis of spectrophotometric analysis. Consistent with this finding, migration of the scFv/folate conjugate on SDS-PAGE gels was slightly slower than that of scFv and the band was more diffuse (Figure 1A).

The folate density determined by photometry does not provide information about the heterogeneity of the conjugates. To determine the range of epitope densities within a single preparation, scFv/folate conjugates were

Figure 2. Binding of KJ16 scFv/folate to cell surface T cell receptor. The binding of FITC-labeled KJ16 Fab fragments to the V β 8-positive T cell clone 2C was inhibited by purified scFv/folate, scFv, or Fab fragments. A total of 6×10^5 2C cells was incubated for 30 min at 4 °C with FITC-labeled KJ16 Fab fragments ($\sim 7.0 \times 10^{-8}$ M) and various concentrations of folate-labeled scFv KJ16 (7.8 fol/scFv, \blacktriangle), unlabeled scFv (\blacksquare), and unlabeled Fab fragments (\circ). A relative affinity of the scFv/folate was determined by comparing the concentrations required to inhibit 50% of the FITC-labeled Fab fragments from binding the 2C TCR.

examined by electrospray ionization mass spectrometry (Figure 1B). Unlabeled scFv demonstrated a single peak with a molecular mass of 29 082 Da. In contrast, folate-labeled scFv existed as a collection of antibody populations, each differing by the molecular mass of a folate molecule (~ 400 Da), detectable up to 7 folates per antibody. Integration of mass spectra showed that $>85\%$ of the scFv molecules were labeled with one or more folate molecules. Folate densities estimated from mass spectra were generally 1.5–2-fold lower than densities estimated by spectrophotometry. This could in part be due to lower solubility of high-density conjugates under conditions required for mass spectrometry or to the dissociation of some folate molecules during ionization.

Binding of scFv/Folate Conjugates to the T Cell Receptor. To examine if folate conjugation affected the binding of scFv antibodies to the TCR, a scFv/folate conjugate was compared with unlabeled scFv. In a competitive flow cytometric assay, fluorescein-labeled KJ16 Fab fragments were inhibited from binding the V β 8-positive CTL clone 2C by unlabeled Fab fragments, scFv, or scFv/folate (Figure 2). As shown previously, scFv antibodies have an approximate 3-fold higher apparent affinity than Fab fragments, possibly because of the presence of noncovalently associated scFv dimers (29). Comparison of folate-labeled and unlabeled scFv showed that the folate conjugate had an apparent affinity ~ 3 -fold lower than scFv (i.e. approximately equal to KJ16 Fab fragments). This decreased binding, compared to unlabeled scFv, could be due either to chemical modification of active site residues with folate or to the interference of dimer formation by folate. The fact that folate conjugates bound the TCR as well as KJ16 Fab fragments, which have a K_D of ~ 130 nM (29, 39), indicated that the conjugates have potential to mediate lysis of target cells by CTLs.

Binding of scFv/Folate Conjugates to Folate Receptors on Tumor Cells. The ability of scFv/folate conjugates to bind folate receptors (FR) on the surface of tumor cells was examined by a competition binding assay using 125 I-labeled folate as the labeled ligand (Figure 3). The competition assay used the F2-MTX^A cell line that expresses the β isoform of the FR. Competitors included various concentrations of free folate, unlabeled scFv, and three different scFv/folate preparations. Examination of

Figure 3. Binding of KJ16 scFv/folate to folate receptors. 125 I-labeled folate ($\sim 1.8 \times 10^{-10}$ M, 2000 Ci/mM) was incubated with F2-MTX^A cells in the presence or absence of competitors for 1 h at 37 °C. Concentrations refer to folate rather than antibody concentrations. Competitors included free folate (\square) and KJ16 scFv/folate conjugates with different folate densities: 2.8 fol/scFv (\circ), 9.2 fol/scFv (\blacksquare), and 20.4 fol/scFv (\blacktriangle). Inhibition was not observed in the absence of competitor (Δ) or in the presence of unconjugated scFv (\bullet) (error shown is \pm average SEM).

Figure 4. Cytotoxicity assay of various tumor cell lines with the scFv/folate conjugate and CTL clone 2C. Various concentrations of the scFv/folate conjugate were incubated with 51 Cr-labeled tumor cells and CTL 2C for 4 h at an effector-to-target ratio of 5:1. Experiments were performed in the presence of anti-L^d antibody to minimize lysis due to recognition of L^d, the nominal ligand for CTL 2C. Lysis correlated directly with the level of FR expressed by the cell line: F2-MTX^A (200 000 sites/cell, \blacktriangle); La (60 000 sites/cell, \blacksquare); L1210 (8 000 sites/cell, \bullet); Mel (not detectable FR, \circ). Assays with free folate at a final concentration of $1.5 \mu\text{M}$ were performed with the scFv/folate conjugate at a concentration of 0.09 nM (+ folate).

the binding curves showed that folate-conjugated antibody, but not unlabeled scFv, binds to the FR⁺ tumor cell line. However, on the basis of molar folate concentration, the folate conjugates had a relative affinity that was approximately 10–30-fold less than that of free folate. This decrease in apparent affinity was consistent with previous observations (27) and could be partly attributed to the carbodiimide labeling procedure. This procedure links folate through either the α or γ carboxyl group, but only linkage through the γ carboxyl retains binding (40). It is also possible that receptor-mediated internalization or decreased accessibility of the FR may also explain the lower apparent affinity of the folate conjugate. Included in the latter is the possibility that neighboring folates or amino acids sterically hinder interaction with the FR.

CTL-Mediated Lysis of FR⁺ Tumor Cells by scFv/Folate Conjugates. The specificity and efficiency of tumor targeting with scFv/folate conjugates were examined in a 51 Cr release assay with CTL clone 2C (Figure 4). Four different tumor cell lines that have a range of cell surface FR densities were used as target cells: F2-

MTX^rA (200 000 sites/cell); La (60 000 sites/cell); L1210 (8 000 sites/cell); Mel (no detectable FR). Each of the FR⁺ cell lines was lysed in the presence of the scFv/folate conjugate, and the extent of lysis was directly correlated with the expression level of the FR ($r = 0.93$). Lysis was completely inhibited by free folate, indicating that targeting of the tumor cells was specifically mediated by the folate receptor and not some other cell surface molecule. The lysis mediated by these conjugates was highly specific (e.g. the FR⁻ cell line Mel was not lysed by the conjugate even at concentrations over 10^5 times that required for detectable killing of the FR⁺ cell line F2-MTX^rA) and extremely potent (e.g. lysis was detectable at concentrations as low as 1 pM of scFv/folate). The slight reduction in observed lysis at the highest concentrations of conjugate occurs because excess bispecific antibody yields monospecific binding without cell-to-cell cross-linking (41). The presence of reduced folate carrier protein (as present in Mel and in all other normal cells) does not result in cell destruction. It is important to point out that the FR density reportedly on ovarian tumors is even higher (~1 million/cell) than those on these tumor cell lines (21).

Effects of Folate Density on Targeting. To examine the effects of folate density and labeling on the targeting efficiency of scFv/folate conjugates, the antibody was labeled with folate under various carbodiimide-mediated coupling conditions. The carbodiimide EDC couples folate through the free carboxyl groups, but when used in the presence of protein, it may also lead to protein modification and subsequent precipitation or inactivation. To evaluate the optimal levels of EDC for folate coupling, several different concentrations of EDC at a constant folate concentration were used during coupling. EDC used at either 13 or 65 mM generated conjugates with approximately equal targeting efficiency. EDC used at 260 mM yielded conjugates with reduced efficiency and frequently led to protein precipitation (data not shown).

To directly examine the effect of folate density, activated folate was prepared at a constant EDC/folate ratio (5:1) and conjugates were produced by adding different ratios of activated folate to the scFv protein. After dialysis to remove unreacted folate and excess EDC, conjugates were evaluated by spectrophotometry to determine folate densities and cytotoxicity assays to evaluate targeting efficiency. Folate densities ranged from approximately 1 to 20 folates per scFv. As shown in Figure 5A, each of the conjugates was capable of mediating lysis of the FR⁺ tumor cell line by CTL clone 2C. However, conjugates with either the lowest density (1.3 folates/scFv) or highest density (20.4 folates/scFv) were 5–10-fold less effective than conjugates with intermediate folate densities.

To better evaluate the effects of folate density, the above experiment was performed with several additional folate conjugate preparations. To directly compare the results of these assays, the EC₅₀ of each conjugate was determined by linear regression and divided by the EC₅₀ of the conjugate that yielded the highest targeting efficiency (i.e. the lowest EC₅₀; see Experimental Procedures). A plot of the normalized targeting values as a function of the folate density (Figure 5B) demonstrates that optimal folate density appears to be in the range of 5–15 folates/scFv. At higher folate densities, the targeting efficiency of the conjugates is generally lower and more variable than those of conjugates with an intermediate amount of folate. The reduction in targeting efficiency at higher folate densities is not due to the inability of these conjugates to bind to FR⁺ cells (Figure 3), but is likely a consequence of chemical modification

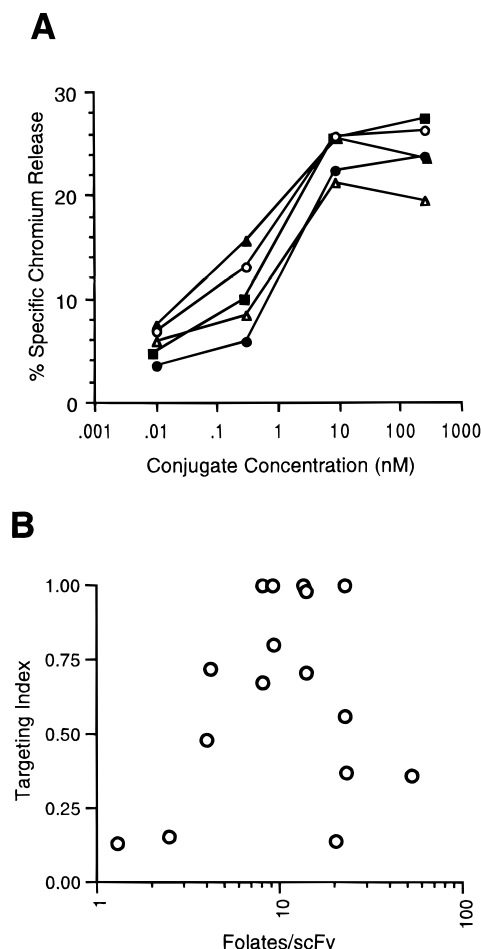

Figure 5. Effect of folate density on targeting with scFv/folate conjugates: (A) scFv/folate conjugates with different folate densities were prepared by labeling scFv protein with various amounts activated folate, using an EDC/folate ratio of 5:1 (EDC = 65 mM). Folate densities were 1.3 fol/scFv, ●; 4.0 fol/scFv, ■; 9.2 fol/scFv, ▲; 9.3 fol/scFv, ○; and 20.4 fol/scFv, △. Conjugates were tested in cytotoxicity assays using F2-MTX^rA and CTL 2C. (B) Relative targeting efficiency of various scFv/folate conjugates as a function of increasing folate density. Targeting index values were determined by normalizing EC₅₀ values of the various conjugates with the most effective conjugate (value = 1) (see Experimental Procedures for details). Each open circle (○) represents a single scFv/folate conjugate prepared using an EDC/folate ratio of 5:1 (EDC 33–65 mM) and tested in cytotoxicity assays using F2-MTX^rA and CTL 2C.

of amino acid residues important in TCR binding by the scFv or in scFv stability.

Comparison of Intact Antibody and scFv. To determine the relative effectiveness of intact KJ16 IgG versus scFv-KJ16, both forms were labeled with folate at a 100:1 molar ratio of activated folate to antibody and under identical EDC reaction conditions (33 mM EDC, 6.7 mM folate). These conditions yielded folate densities of 7 and 5 for the scFv and intact antibody, respectively. Cytotoxicity assays with these preparations showed nearly identical targeting efficiencies for the intact and scFv forms of KJ16 (Figure 6). The concentration required to obtain 50% of the maximal specific release (EC₅₀) was approximately 40 pM (1.2 ng/mL for scFv). Comparison of intact and scFv conjugates in an ¹²⁵I-labeled folate binding assay indicated no significant difference in their ability to bind FR (data not shown).

Intact KJ16 antibody was also labeled at various folate densities to determine if targeting efficiency could be optimized further. Conjugates were again evaluated by spectrophotometry to determine folate densities and cytotoxicity assays to evaluate targeting efficiency (Fig-

Figure 6. Comparison of scFv/folate and IgG/folate in CTL-mediated lysis of tumor cells. Folate was conjugated to KJ16 scFv and intact antibody under identical conditions (3.3 mM EDC, 100:1 molar ratio of folate/antibody), yielding conjugates with 7 fol/scFv (●) and 5 fol/IgG (■). Cytotoxicity assays were performed with these conjugates using ^{51}Cr -labeled F2-MTX^rA cells and CTL clone 2C.

Figure 7. Effect of folate density on targeting with IgG/folate conjugates. Intact antibody was labeled at several folate concentrations to determine if, like scFv, a specific range of folate density would yield the optimal targeting effectiveness. Conjugates with the following densities were assayed with ^{51}Cr -labeled F2-MTX^rA cells and CTL clone 2C: 4.5 fol/IgG, □; 7.0 fol/IgG, ●; 13.6 fol/IgG, ▲; 56.7 fol/IgG, ■; and 126.2 fol/IgG, ○.

ure 7). Folate densities ranged from approximately 4–126 folates/antibody molecule. As shown with scFv preparations, high and low folate density resulted in decreased targeting effectiveness for the intact antibody. As with scFv preparations, the optimal densities appear to be in the range of 5–15 folates/antibody, as determined by spectrophotometry.

Inhibition of scFv/Folate Conjugate-Mediated Lysis by Free Folate. Normal serum folate may reduce the effectiveness of the scFv/folate conjugate by competing for the folate receptor *in vivo*. A ^{51}Cr release assay was used to evaluate the effectiveness of the scFv/folate conjugate-mediated lysis at biologically relevant concentrations of free folate (Figure 8). Free folate was diluted in folate-free media, and various concentrations were added to triplicate wells containing ^{51}Cr -labeled F2-MTX^rA cells, 2C effector cells, and a fixed, nonsaturating concentration of scFv/folate conjugate (3 nM) that would generate maximal specific release. The resulting titration curve demonstrated that at normal human serum folate levels [9–36 nM (42, 43)] the scFv/folate conjugate retained most of its activity. For instance, at 20 nM folate, the scFv/folate conjugate exhibited over 80% of its CTL-mediated targeting potential. Although murine serum folate levels are significantly higher than normal human serum values (124–700 nM) due to folate-rich chow (44, 45), even at these elevated folate concentra-

Figure 8. Inhibition of scFv/folate-mediated lysis by free folate. Various concentrations of free folate were added to triplicate wells containing ^{51}Cr -labeled F2-MTX^rA cells, 2C effector cells, and a fixed, nonsaturating concentration of scFv/folate conjugate (~8 fol/scFv) that would yield maximal specific release (3 nM). Inhibition was calculated as a function of the specific release in the absence of folate competitor. Normal human serum folate concentrations range from 9 to 36 nM (42, 43).

tions, the scFv/folate conjugate exhibited 30–60% of its targeting potential.

DISCUSSION

The most effective agents for targeting solid tumors will likely have reduced sizes that allow greater tumor penetration. This paper characterizes the smallest bispecific agent yet described for redirecting the activity of immune effector cells against tumors. Initial bispecific antibody studies to target ovarian tumors that express high-affinity FR have used intact heterobifunctional antibodies (~150 kDa) that bind to CD3 and the FR. These agents showed efficacy in animal models, and they have recently entered testing in clinical trials (9, 10, 12). Although not yet reported for anti-FR antibodies, several laboratories have shown that it is possible to engineer smaller bispecific antibodies of ~60 kDa by linking two scFv regions (41, 46, 47). Here we show that the size of a bispecific targeting agent can be reduced even further to ~30 kDa for the scFv/folate conjugates. Furthermore, the targeting efficiency of the engineered scFv/folate conjugate is comparable to that of the native intact antibody/folate conjugates.

For coupling of folate to the anti-V β 8 scFv KJ16, a carbodiimide reaction that links the carboxyl groups of folate to the amino groups of the antibody was used. KJ16 scFv binds to the cell surface TCR with an affinity that is similar to that of the intact KJ16 antibody (29). The V_L and V_H regions of the scFv are linked by a 26 amino acid region that contains 8 lysine residues. We reasoned that this charged linker would be accessible to folate, would be located distal to the binding site, and would contain multiple attachment sites for folate through the EDC reaction. Under coupling conditions where folate concentrations are nonsaturating, the scFv and intact antibody have comparable densities of folate attached per molecule (~5–15 folates/molecule), despite the 5-fold greater size of the intact antibody. Cytolytic assays demonstrated that these conjugates have very similar targeting efficiencies (Figure 6).

Although folate is probably attached to lysines present in the linker, the scFv/folate conjugates are actually heterogeneous populations as evidenced by mass spectra (Figure 1B). Within a scFv/folate preparation there are most likely conjugates with enhanced targeting properties and conjugates with diminished targeting properties. The former could include not only those with folate at an accessible location but perhaps those with multiple

folates that allow for multivalent interactions with FRs on tumor cells. Conjugates which have diminished bispecific properties would include those that have folate attached through amine groups in the scFv active site or in regions which destabilize the V_L – V_H interaction. These are analogous to those preparations derived with very high folate densities, where the targeting efficiency is significantly reduced (Figures 5 and 7).

Several considerations suggest that further optimization of the scFv/folate conjugates could yield even more potent agents. The anti-TCR antibody KJ16 has a relatively modest K_D of ~ 100 nM (29). Our laboratory is currently engineering higher affinity anti-TCR antibodies by antibody display methods; antibodies with $K_D \leq 1$ nM have been routinely generated using similar approaches (48). In addition, the affinity of the scFv/folate conjugate for the FR⁺ tumor cells was up to 30-fold less than the affinity of free folate for the FR (Figure 3). Coupling of folate through the γ carboxyl, plus homogeneous linkage perhaps through cysteine or multiple cysteines, should improve the affinity for the FR. Alternatively, other folate analogs with higher affinity than folate could be employed (49). The use of these strategies should allow the development of scFv conjugates that have EC_{50} values considerably less than those described in this paper.

It is of significant note that the scFv agent described here not only is the smallest agent but is at least as potent *in vitro* as bispecific antibodies described in the literature. For example, the EC_{50} of other bispecific agents range from 1 to 100 ng/mL (21, 50–52). Various other antibody or folate-based targeting agents have EC_{50} values that range from 0.1 to 200 ng/mL (e.g. refs 37, 40, 53–56). *In vitro* assays for these other agents typically involved 24 h incubation periods, while the cytotoxicity assays for CTL-mediated lysis, described here and elsewhere, are 4 h incubations. Thus, there is reason to believe that the scFv/folate conjugate has considerable promise *in vivo*. It has an EC_{50} of approximately 1 ng/mL, is smaller than the other agents, and remains effective at folate levels found in normal human serum. The scFv/folate targeting effect was inhibitable by free folate, but only at concentrations that were considerably higher (>1000-fold) than the folate conjugate concentration (Figure 8). Schodin *et al.* (57) have previously shown that <1% of the total number of TCRs per CTL need to be triggered for CTL-mediated cytotoxicity to occur. Thus, it is possible that >90% of the folate/antibody conjugates were inhibited from binding the target cell but sufficient conjugate remained bound to trigger maximal lysis.

The fact that the scFv/folate conjugate is in direct competition with serum folate also brings about the intriguing possibility of modulating the effectiveness of scFv/folate conjugate treatment by altering the levels of serum folate. For instance, recent studies with mice have shown that serum folate can be intentionally decreased up to 100-fold with special low-folate diets (44, 45). The decreased folate concentration greatly enhanced the ability of a ^{67}Ga -labeled deferoxamine/folate conjugate to image FR⁺ tumors *in vivo* (44). We envision that similar low-folate diets will likewise enhance the therapeutic effectiveness of the scFv/folate conjugate. Conversely, serum folate could be increased in situations where nonspecific T cell interactions lead to adverse side effects. Thus, the use of folate as the small molecule ligand specific for a tumor antigen may allow for additional levels of regulation normally not available with other immunotargeting agents.

In vivo tests to compare scFv and intact folate conjugates are currently underway in SV40 transgenic mice

that develop choroid plexus tumors exhibiting elevated levels of the high affinity folate receptor (58). Preliminary results indicate that T cells specifically infiltrate the tumor after treatment with the scFv/folate conjugate (B.K.C., T.A.P., D.M.K., and E.J.R., unpublished data). At this time, it is unclear whether conjugate-bound T cells extravasate into the tumor or if T cells first extravasate into the tumor and subsequently recognize the conjugate bound to cell surface FR. The latter mechanism would favor the enhanced tumor penetration characteristics of the smaller scFv molecule and would likely lead to increased therapeutic effectiveness.

ACKNOWLEDGMENT

We thank Drs. John Kappler and Philippa Marrack for providing the KJ16 hybridoma line, Carol Schlueter for providing the anti-L^d ascites fluid, and Drs. Brigle, Spinella, and Goldman for the DBA/2 tumor cell lines. This work was supported by grants from the University of Illinois Research Board (E.J.R.), the National Institutes of Health (AI35990, E.J.R. and D.M.K.), the Department of the Army (DAMD17-94-J-4347, D.M.K.), and the National Institutes of Mental Health (MH11189-01, T.A.P.). The ToFSpec mass spectrometer was purchased in part with Grant RR07141 from the Division of Research Resources, National Institutes of Health. Mass spectrometry was performed by Nelson Huang.

Received September 30, 1996[®]

Receptor binding peptides labeled with medically important radionuclides such as technetium and rhenium are an important tool for the imaging and treatment of many forms of cancer. This paper describes a method of labeling peptides with rhenium using a natural amino acid chelating moiety. The structural characteristics of this chelate moiety, *N*-acetyl-cysteine-glycine-cysteine-glycine (NAC-CGCG) complexed with nonradioactive rhenium, have been investigated. The stability of this peptide–metal complex has been evaluated on the tracer level using radioactive rhenium-186. The rhenium-bound peptide has been appended to the N termini of receptor binding α -melanocyte stimulating hormone (α -MSH, NAc-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-NH₂) fragments via solid phase peptide synthesis. Bioassays and receptor binding studies of the resulting complexes demonstrate that the fragments retained biological activity and exhibited receptor binding constants ranging from 0.3 to 1.1 nM. This method could provide a general means of labeling bioactive peptide fragments that would simplify product purification and characterization.

INTRODUCTION

Biologically active molecules that selectively interact with specific cell types are attractive vehicles for radioisotope delivery. Peptides, which possess specific affinities for receptors upregulated in certain malignancies (1), are receiving increasing attention due to their *in vivo* targeting and pharmacokinetic properties. Small peptides such as somatostatin (1–3), vasoactive intestinal peptide (4, 5), chemotactic peptides (6–10), and the α -melanocyte stimulating hormone (α -MSH)¹ (11–14) have all shown promise as radioisotope delivery agents.

The group VIIA transition metals technetium (Tc) and rhenium (Re) are among the most commonly used radioisotopes in medicine due to the favorable emission energies and decay properties of the radioactive isotopes Tc-99m, Re-186, and Re-188 (15). As a result, increasing attention has been focused on developing methods of attaching these radionuclides to bioactive peptide sequences. Currently, the most common approaches to labeling peptide hormones have involved attachment of either In-111 or I-123 (2–4, 11–14). For the coordination of Tc and Re, many studies have shown that ligand

systems containing two nitrogen atoms and two thiol sulfur atoms (N₂S₂ systems) are effective (16–25). Often, these chelating systems are built via organic syntheses of varying complexity. In some cases, researchers have taken advantage of solid phase peptide synthesis to design peptide chelators that either lack sulfur or contain sulfur in the context of non-natural groups such as the mercaptoacetyl group (23, 24, 26, 27). More recent studies have demonstrated that amino acid sequences such as Cys-Gly-Cys, Cys-Thr-Cys, and Gly-Gly-Cys can be used to coordinate Tc-99m in peptides (1, 7–10, 28) and proteins (29).

In this paper, we have used conventional ¹H and ¹³C NMR methods to characterize the solution conformation of the peptide *N*-Acetyl-Cys-Gly-Cys-Gly (NAC-CGCG) complexed to a nonradioactive rhenium(V)–oxo core. The remarkable stability of this peptide–metal complex allowed us to synthesize, purify, and then append this complex to the N termini of α -melanocyte stimulating hormone (α -MSH, NAc-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-NH₂) receptor binding fragments. The attachment of the metal-complexed peptide was carried out as the last step of a conventional solid phase peptide synthesis (SPPS). Attachment of the peptide–metal complex to the N termini of the α -MSH fragments resulted in readily purifiable products which were labeled with rhenium and retained receptor binding affinity. This coupling was also carried out on the tracer level with Re-186-labeled NAC-CGCG and resulted in a readily purifiable radiolabeled peptide product. These experiments show that SPPS can be used to attach preformed peptide–metal chelates to bioactive peptides. This method of labeling peptides could have general use as a means of obtaining high specific activity rhenium-labeled bioactive peptides.

EXPERIMENTAL PROCEDURES

Sodium [¹⁸⁶Re]perrhenate (530 Ci/mmol) was obtained from the Missouri University Research Reactor (MURR). [¹²⁵I]-labeled [Nle⁴,D-Phe⁷]- α -MSH (1700 Ci/mmol) was obtained from Advanced Chemtech in Louisville, KY. Fmoc amino acids and automated peptide synthesis reagents were obtained from Applied Biosystems (Foster City, CA). Dithiothreitol (DTT), methanol (MeOH), di-

ethyl ether, *N*-methylpyrrolidinone (NMP), and dichloromethane (DCM) were obtained from Fisher Scientific (St. Louis, MO). Thioanisole, ethanedithiol, and dicyclohexylcarbodiimide (DCC) were obtained from Aldrich Chemical Co. (St. Louis, MO). Trifluoroacetic acid (TFA) was obtained from Sigma Chemical Co. (St. Louis, MO).

Preparation of NAc-CGCG. The peptide was synthesized by conventional SPPS techniques, using Fmoc/HBTU chemistry (30). The synthesis was carried out on a Synergy desktop peptide synthesizer from Applied Biosystems. The peptide was N-terminally acetylated by activation of excess glacial acetic acid after deprotection of the N-terminal Cys residue. Cleavage and deprotection were carried out by incubation in a 36:2:1:1 mix of TFA/thioanisole/ethanedithiol/water for 2 h. This solution was then filtered and the product precipitated with diethyl ether. The resulting precipitate was dried, dissolved in 1 mM DTT, and lyophilized.

Preparation of Nonradioactive ReO-NAc-CGCG. Labeling of compounds followed roughly the procedure of Hansen et al. (31). Fifteen milligrams of NAc-CGCG was dissolved in 1 mL of 62% MeOH, and the pH was adjusted to about 8 with 1 M NaOH. $\text{ReOCl}_3(\text{Me}_2\text{S})\text{-(OPPh}_3\text{)}$ (26 mg) (32, 33) was added as a solid, giving a green suspension. Heating at 60–70 °C for 60 min resulted in an orange-brown solution. The reaction mixture was filtered to remove an H_2O -insoluble gray precipitate and purified by RP-HPLC. Purification was carried out on a C_{18} semipreparative HPLC column (Vydac), utilizing a 30 min gradient of 3–12% acetonitrile/0.1% TFA in H_2O /0.1% TFA. Product elution was monitored by UV detection at 400 nm using an Isco V⁴ absorbance detector. The product peak (retention time = 24 min) was collected and lyophilized.

Preparation of $^{186}\text{ReO-NAc-CGCG}$. The radiolabeled peptide complex was prepared by substitution onto ^{186}Re -labeled citrate. Briefly, 0.235 mCi of $\text{Na}^{186}\text{ReO}_4$ was added to 0.8 mL of degassed, 1 M sodium citrate, pH 8.8, containing 250 mg of stannous tartrate. After 10 min at room temperature, 0.1 mg of reduced NAc-CGCG was added, and the solution was allowed to stir for 1 h at 65–70 °C. Isolation of the resulting complex proceeded as for the nonradioactive complex, with the exception that radioactivity was monitored using a Radiomatic Series A-200 radiochromotography detector.

Evaluation of Labeled Peptide Stability. The *in vitro* stability of the nonradioactive rhenium complex was evaluated by incubation at room temperature with the cleavage/deblocking mixture. Samples were taken at various times and analyzed by RP-HPLC. The stability of the radioactive complex was assessed by diluting the reaction mixture 1:2 into fresh solutions of 20 and 2 mM L-cysteine. Again, RP-HPLC was used to quantitate complex stability over time.

Structural Determination Using ^1H and ^{13}C NMR. A sample of 5–10 mg of purified complex was solubilized in 80% H_2O /20% D_2O . ^1H spectra were referenced to the H_2O peak at 4.75 ppm. ^{13}C spectra were externally referenced to dioxane at 67.4 ppm. All spectra were collected at 298 K on a Bruker AMX500 spectrometer. Scalar connectivities were obtained from COSY experiments; sequential assignments were made on the basis of NOESY experiments. The NOESY mixing time was 200 ms. All spectra were recorded using the time-proportional phase incrementation (TPPI) method. In most cases the spectral width was 6000 Hz. Typically, the data set size was $2048(t_2) \times 256(t_1)$ blocks with 16 scans/fid. H_2O suppression was carried out by presaturation (1.5 s) at the water frequency during the relaxation delay between scans (as well as during the mixing time

in NOESY expts). NMR spectra were processed with the NMR software within the SYBYL program (Tripos, Inc.) on an SGI Indigo R4000 workstation. Data sets were multiplied by a 0–90° shifted sinebell squared transformation function and zero-filled to 1024 K in t_1 prior to Fourier transformation. The assignment of indices 1 and 2 to methylene protons follows the convention that the lower index denotes the most downfield shifted resonance of the pair.

Attachment of the Nonradioactive Complex to Bioactive α -MSH Sequences. The peptides $[\text{D-Phe}^7]\text{-}\alpha\text{-MSH}_{5-10}\text{-NH}_2$ and $\text{NAC-}[\text{Nle}^4, \text{D-Phe}^7]\text{-}\alpha\text{-MSH}$ were synthesized by conventional SPPS techniques, as previously described (30). As a final step, the Fmoc group was removed from the N-terminal residue by piperidine deprotection, and ReO-NAc-CGCG was coupled to the growing chains via its free Gly_4 carboxylate. In each case, the final coupling step was repeated twice to ensure maximal incorporation of the rhenium-labeled fragment, since the molar amount of ReO-NAc-CGCG used was less than the theoretical 0.25 μmol needed for maximum yield. The rhenium-labeled α -MSH peptide analogs were cleaved from the resin and deprotected in a 36:2:1:1 mix of TFA/thioanisole/ethanedithiol/water. This solution was then filtered and the product precipitated in diethyl ether; the precipitate was dried, dissolved in H_2O , and lyophilized. The identity of rhenium-containing peptides was confirmed by fast-atom bombardment–mass spectroscopy (FAB-MS). For $\text{ReO-NAc-CGCG-}[\text{D-Phe}^7]\text{-}\alpha\text{-MSH}_{5-10}\text{-NH}_2$, the $(\text{M} + \text{H})^+$ peak was observed at m/z 1392.2 (calculated 1391.6). For $\text{ReO-NAc-CGCG-}[\text{Nle}^4, \text{D-Phe}^7]\text{-}\alpha\text{-MSH}$, the $(\text{M} + \text{H})^+$ peak was observed at m/z 2166.5 (calculated 2166.5).

Attachment of $^{186}\text{Re-NAc-CGCG}$ to a Bioactive α -MSH Sequence. Purified, lyophilized $^{186}\text{Re-NAc-CGCG}$ (1.4×10^{-11} mol) was solubilized in NMP and added to 8 mg of blocked peptide resin containing 1.6×10^{-6} mol of $[\text{D-Phe}^7]\text{-}\alpha\text{-MSH}_{5-10}\text{-NH}_2$. A mixture of 1.6×10^{-4} mol of HOBT/DIEA in NMP was added, followed by the addition of 1.6×10^{-4} mol of DCC on ice. The solution was allowed to stir on ice for 1 h and for an additional 3.5 h at room temperature. At that time the resin was thoroughly rinsed with NMP, 1:1 MeOH/DCM, and DCM and allowed to dry. After drying, the resin was deprotected by incubation in a 36:2:1:1 mix of TFA/thioanisole/ethanedithiol/water. After 2 h, the cleavage/deprotection mix was centrifuged, and the supernatant was applied directly to a C_{18} RP-HPLC column (Vydac).

Measurement of Melanin Production by B16 F1 Murine Melanoma Cells. Peptide bioactivity was determined by measuring melanin production in an *in vitro* assay using B16 F1 murine melanoma cells acquired from the American Type Tissue Culture collection. The assay followed the method developed by Siegrist and Eberle (34). Briefly, cells were seeded in 96 well tissue culture plates and allowed to attach to the plates overnight. At that time, cells were exposed to various concentrations of peptides to be tested. After 12–24 h, the peptide solutions were removed and fresh medium was added to each well. After an additional 3–5 days, the absorbance of each cell-containing well was measured at 405 nm in a Vmax kinetic microplate reader from Molecular Devices. Absorbance values were compared to a standard curve obtained using synthetic melanin from Sigma. The standard curve was linear over the experimental range of absorbance values.

Quantitation of Peptide Binding to B16 F1 Cells. Quantitative receptor binding assays were carried out following a method described previously (35, 36). Cells were seeded at a density of 5×10^5 cells per well in 24

Table 1. ^1H NMR Resonance Assignments for NAc-CGCG and ReO-NAc-CGCG^a

resonance	NAc-CGCG δ	ReO-NAc-CGCG δ	$\Delta\delta^b$

well tissue culture plates and allowed to attach overnight. Cells were then exposed to various concentrations of peptides to be tested in 0.5 mL of binding media. The binding medium consisted of 25 mM HEPES/NaOH (pH 7.4), 0.2% BSA, and 0.3 mM 1,10-phenanthroline and contained approximately 100 000 cpm of [¹²⁵I]-[Nle⁴,D-Phe⁷]- α -MSH (37) per 0.5 mL. Cells were incubated in this mixture at 4 °C for 8 h, then rinsed with PBS, lysed with 1 M NaOH, and counted in a 1275 minigamma gamma counter from LKB Wallac.

RESULTS

Synthesis of Rhenium–Peptide Complexes. The nonradioactive ReO-NAc-CGCG complex was synthesized utilizing the ReOCl₃(Me₂S)(OPPH₃) exchange ligand (32, 33). The radioactive ¹⁸⁶ReO-NAc-CGCG complex was synthesized via a direct labeling reaction with citrate as the exchange ligand. Both metal complexes were found to coelute under the RP-HPLC conditions used to purify them, indicating the complexes differ only in isotopic composition. The purified nonradioactive complex was characterized by NMR.

Assignment of ^1H Resonances. Sequence specific ^1H resonance assignments of NAc-CGCG and ReO-NAc-CGCG were made using COSY and NOESY spectra (38). Assignments for both compounds are given in Table 1. Deprotonation of two amide nitrogens occurred during the metal complexation reaction. The assignment of the deprotonated amide nitrogens was determined by an intrasidue NOE between the *N*-acetyl methyl group and the Cys¹ amide proton. A Cys³ α H-Gly⁴NH sequential NOE is also present, showing that the amide nitrogens of Gly² and Cys³ are deprotonated and presumably involved in metal coordination. A minor species (<10%), assumed to be an isomer, was also present in the sample. After a period of 1 week, no increase in the intensity of these signals was observed, indicating that the minor species is not a degradation product. 1D spectra of NAc-CGCG and ReO-NAc-CGCG are shown in Figure 1.

Chemical Shift Changes upon Metal Coordination. ^1H chemical shift changes between metal-free and metal-bound forms of the peptide are given in Table 1. The α -protons of both Cys residues are found to shift downfield in the rhenium compound, as is to be expected upon thiol coordination of an electropositive transition metal (25). It is generally thought that metal coordination should have the effect of deshielding nearby protons in a ^1H spectrum due either to the electron withdrawing effect of the metal or to the magnetic anisotropy of the metal–oxo bond. It might be expected therefore that the

β proton resonances should be further shifted downfield. While this is the case for the Cys³ β protons, Cys¹ β H₁ is seen to resonate upfield in the metal-bound form, while Cys¹ β H₂ is slightly less deshielded than Cys¹ α H.

¹³C chemical shift assignments for ReO-NAc-CGCG are shown in Table 2. These assignments were made via an HMBC (39) spectrum of the complex acquired at 298 K. The ¹³C chemical shifts of the complex were compared to average ¹³C chemical shifts for nonterminal Cys and Gly residues in model peptides (40). The results of this comparison are also given in Table 2. Downfield shifts of the Cys¹ and Gly² carbonyl ¹³C resonances were expected due to metal coordination by the proximal amide nitrogens. The Cys³ and Gly⁴ carbonyl carbons, which both lie outside the torsionally constrained metal coordinating rings, are found to be only slightly deshielded. The α carbons of both Cys¹ and Cys³ are deshielded in the metal-bound peptide. However, Cys³ α resonates 11.4 ppm further downfield than Cys¹ α . Also, Cys¹ β is actually shielded relative to average Cys β carbons in non-terminal cysteines of metal-free peptides, while Cys³ β is deshielded 8.7 ppm.

Torsional Angles Derived from 3J -Coupling Data. The structure of ReO-NAc-CGCG derived from NMR data consists of three fused heterocycles (Figure 2). J -coupling information derived from resolution-enhanced 1D spectra and 2D ^1H –¹³C HMBC spectra suggests specific ranges for the torsional angles about Cys¹ ϕ , Gly³ ϕ , Cys¹ χ , and Cys³ χ (Table 3). Since the ring structures are essentially locked by coordination to the metal, the measured 3J values probably reflect a single preferred χ angle, rather than an interconverting rotamer population. Dihedrals external to the three-ring system, however, such as the ϕ angles of Cys¹ and Cys³, are more properly viewed as free to rotate in solution.

Measured $^3J_{\alpha\text{H}\beta\text{H}}$ values for Cys¹ β H₁ and Cys¹ β H₂ indicate that these protons are trans and gauche, respectively, with respect to Cys¹ α H. The $^3J_{\alpha\text{H}\beta\text{H}}$ coupling constants of Cys³ suggest that Cys³ β H₁ and Cys³ β H₂ are intermediate between gauche and trans positions with respect to Cys³ α H. The χ angle of Cys³ derived from the experimental J -coupling values results in an average conformation that is essentially midway between the high energy eclipsed and low energy staggered conformations.

The observation of intermediate $^3J_{\alpha\text{H}\beta\text{H}}$ values for Cys³ is consistent with the observed HMBC intensities. The HMBC signal relating C³ β H₁ and C³CO is more intense than that relating C³ β H₂ and C³CO, indicating a more trans Cys³ β H₁-Cys³ β C-Cys³ α C-Cys³CO torsion and a more gauche C³ β H₂-C³ β C-C³ α C-C³CO torsion.

Stability of ReO-NAc-CGCG. To determine whether the nonradioactive complex would be able to withstand the conditions involved in SPPS, the stability of the ReO-NAc-CGCG complex was tested by a 2 h incubation in the cleavage/deprotection mix. This mix contains an 800-fold excess of free thiol groups, so this provides a rigorous stability test of the peptide–rhenium complex. The stability of this complex, as assessed by RP-HPLC, was such that no degradation was observed after 2 h. The stability of the ¹⁸⁶ReO-NAc-CGCG complex was tested by competition against various concentrations of L-cysteine. The complex showed essentially no degradation after 5.5 h in 1 mM cysteine, and 80% of the complex remained after 12 h in 10 mM cysteine.

Attachment of ReO-NAc-CGCG to a Bioactive Peptide Sequence. Two α -MSH-derived peptide sequences, [D-Phe⁷]- α -MSH_{5–10}-NH₂ and [Nle⁴,D-Phe⁷]- α -MSH (37), were N-terminally labeled with the ReO-NAc-CGCG moiety. In the peptide synthesis reactions, the rhenium was used as a blocking group, preventing the

Figure 1. ^1H NMR spectra of NAc-CGCG (top) and ReO-NAc-CGCG (bottom). Both spectra were acquired in 90% $\text{H}_2\text{O}/10\%$ D_2O at 298 K.

cysteine thiols from participating in side reactions. After cleavage/deprotection (see Experimental Procedures), the peptide products were subjected to C_{18} RP-HPLC.

In each case, the reaction yielded one major rhenium-containing product. Some unconjugated α -MSH fragment was also present since the reactions were carried out with an excess of α -MSH fragment present. The rhenium-containing product was more hydrophobic than the attached α -MSH sequences alone, thus simplifying purification of the final labeled product.

[D-Phe⁷]- α -MSH₅₋₁₀-NH₂ was also labeled with ^{186}ReO -NAc-CGCG via peptide synthesis techniques (see Experimental Procedures). The result of this reaction was a highly pure radiolabeled product (Figure 3). This product was easily separable from nonradioactive [D-Phe⁷]- α -MSH₅₋₁₀-NH₂ due to the relatively large difference in

hydrophobicity between the two compounds. The purity of product resulting from this synthesis strategy compares quite favorably to the product resulting from a postconjugate chelation strategy. The use of ^{186}ReO -NAc-CGCG as a preformed chelate precludes nonspecific binding of ^{186}Re to other uncharacterized sites within peptides.

Figure 3. HPLC profile showing the radioactive product of the ^{186}Re -NAC-CGCG-[D-Phe⁷]- α -MSH₅₋₁₀-NH₂ conjugation reaction. The radioactive product was shown to coelute with the previously characterized nonradioactive standard.

Table 4. EC₅₀ and K_i Values for Various α -MSH Analogs

compound	K _i (M)	EC ₅₀ (M)
α -MSH	8.8×10^{-10}	3.4×10^{-11}
[D-Phe ⁷]- α -MSH ₅₋₁₀ -NH ₂	4.6×10^{-8}	9.8×10^{-11}
ReO-NAC-CGCG-[D-Phe ⁷]- α -MSH ₅₋₁₀ -NH ₂	1.1×10^{-8}	1.1×10^{-9}
NAc-[Nle ⁴ ,D-Phe ⁷]- α -MSH	1.8×10^{-10}	1.1×10^{-11}
ReO-NAC-CGCG-[Nle ⁴ ,D-Phe ⁷]- α -MSH	3.0×10^{-10}	3.9×10^{-11}

Bioactivity and Receptor Binding Affinity. The bioactivity of these peptide-metal complexes was assayed by measuring stimulation of melanin production by B16 F1 murine melanoma cells (Figure 4). ReO-NAC-CGCG-conjugated [D-Phe⁷]- α -MSH₅₋₁₀-NH₂ and [Nle⁴,D-Phe⁷]- α -MSH peptides displayed a 4–10-fold reduction in melanin production compared to the uncomplexed parent peptides (Table 4). The EC₅₀ value for melanin production in response to [Nle⁴,D-Phe⁷]- α -MSH was found to be 1.1×10^{-11} M, a control value that is in good agreement with previously published values (36).

Receptor binding assays were performed on both ReO-NAC-CGCG-conjugated and unconjugated peptides (Figure 5). The ReO-NAC-CGCG-[Nle⁴,D-Phe⁷]- α -MSH and ReO-NAC-CGCG-[D-Phe⁷]- α -MSH₅₋₁₀-NH₂ conjugates exhibited a 1.5-fold decrease and a 4-fold increase in receptor binding affinity, respectively, compared to the parent uncomplexed peptide sequences (Table 4). Results from the melanin biosynthesis and receptor binding assays demonstrated that conjugation of ReO-NAC-CGCG to the N termini of the α -MSH analogs yielded minimal

Figure 5. Sigmoidal dose-response curves showing inhibition of binding of ^{125}I -Nle⁴,D-Phe⁷- α -MSH to B16 F1 murine melanoma cells by (▲) α -MSH, (□) [D-Phe⁷]- α -MSH₅₋₁₀-NH₂, (■) ReO-NAC-CGCG-[D-Phe⁷]- α -MSH₅₋₁₀-NH₂, (○) NAc-[Nle⁴,D-Phe⁷]- α -MSH, and (●) ReO-NAC-CGCG-[Nle⁴,D-Phe⁷]- α -MSH.

effects on both their biological activities and receptor binding affinities.

DISCUSSION

Certain bioactive peptides, including α -MSH (41), permit relatively bulky substitutions at their amino terminus. The ability to append a metal-peptide pre-chelate to a bioactive peptide sequence via SPPS could be advantageous in several respects. For example, such a procedure could simplify subsequent purification of a radiolabeled bioactive complex, since the labeled compound has quite different chromatographic characteristics compared with the unlabeled compound. This results in a radiotracer that is not contaminated with unlabeled peptide.

The peptide NAC-CGCG was used as a metal-binding moiety to coordinate rhenium. The results of the conformational analysis of ReO-NAC-CGCG demonstrate that the metal is coordinated by two cysteine sulfurs and two intervening amide nitrogens. The structure as a whole can be considered as consisting of three fused heterocycles (Figure 2), with ring 1 including Cys¹S and Gly²N heteroatoms and rings 2 and 3 numbered anti-clockwise from ring 1. There is a strong analogy between the structure of this compound and the structure of rhenium-bound mercaptoacetyl triglycine (MAG3) (26, 31, 43). Three crystal structures of metal-bound analogs of MAG3 are available in the Cambridge Crystallographic Database. Rings 2 and 3 of ReO-NAC-CGCG are directly comparable to the MAG3 structures, while ring 1 departs significantly from MAG3 geometry.

Alignment of ReO-NAC-CGCG ring 2 with the analogous ring of MAG3 (43), using the fit algorithm within the SYBYL molecular modeling program, resulted in an almost perfect alignment. Slight differences in alignment between ring 3 and the C-terminal ring of MAG3 can be accounted for by the lack of a planar peptide bond in ring 3 and by the replacement of the nitrogen donor in MAG3 with sulfur in ReO-NAC-CGCG.

The additional carbon atom in ring 1 relative to MAG3 results in a deviation from the square pyramidal coordination of the ReO core. Placement of the sulfur of Cys¹ in the plane of the other three donor atoms would yield a distorted coordination geometry in which the Cys¹S–Cys³S distance is shorter than it would be in an ideal square plane. Alternatively, the NMR data suggest a different conformation for ring 1 in which both Cys¹S and

Cys1 β C lie slightly below the plane of the other three donor atoms. ^{13}C and ^1H chemical shift data indicate that the β carbon of Cys1 lies below the plane of the other three donor atoms. It has been found previously that in technetium- and rhenium-containing compounds, groups in an *anti* configuration relative to the metal-oxo group tend to resonate upfield relative to analogous groups in a *syn* configuration (25, 44). That the sulfur of Cys1 is also located beneath this plane is supported by $^3J_{\alpha\text{H}\beta\text{H}}$ coupling data, suggestive of a *gauche/trans* relationship between the two Cys1 β protons and Cys1 αH . Confirmation of our model, however, awaits a crystal structure of the complex.

The stability of the ReO-NAC-CGCG complex enabled us to append it directly to the N termini of biologically active peptides using standard SPPS chemistry. Conjugation of the ReO-NAC-CGCG moiety to the N termini of the α -MSH analogs had a minimal effect on bioactivity and receptor binding affinity. The binding affinity of NAc-[Nle 4 ,D-Phe 7]- α -MSH decreased <2-fold upon addition of ReO-NAC-CGCG, indicating that the addition of spacer atoms between the coordinating moiety and the bioactive peptide sequence is not required. The binding affinity of the [D-Phe 7]- α -MSH $_{5-10}$ -NH $_2$ analog was actually seen to increase upon addition of ReO-NAC-CGCG, an effect that might be explained by the known preference for a hydrophobic moiety at the α -MSH N terminus.

The reduction in EC $_{50}$ and K_i values for the conjugated and parent [D-Phe 7]- α -MSH $_{5-10}$ -NH $_2$ analogs compared to the NAc-[Nle 4 ,D-Phe 7]- α -MSH analogs is directly attributable to differences in amino acid sequence length. The truncated [D-Phe 7]- α -MSH $_{5-10}$ -NH $_2$ fragment lacks the C-terminal three amino acids as well as the N-terminal four amino acids that are present in the wild-type hormone. Each of these sequences has been implicated as being important for the binding of the wild-type hormone to the murine α -MSH receptor (36). Although the smaller fragment has a lower binding affinity to the α -MSH receptor *in vitro*, its smaller size and increased hydrophilicity may benefit its biodistribution *in vivo*. Experiments to test this hypothesis are currently in progress.

CONCLUSION

The labeling of truncated α -MSH fragments with the ReO-NAC-CGCG chelate demonstrates that the Cys-Gly-Cys peptide sequence when complexed with rhenium can be used in SPPS as a preformed ^{186}Re bifunctional chelate. The resulting labeled bioconjugates showed specific binding affinity for the α -MSH receptor and were demonstrated to retain bioactivity. The synthesis of these compounds serves to show that preformed peptide-metal coordination compounds can be successfully incorporated into bioactive peptide sequences by conventional SPPS techniques. Further, the labeled product can be obtained in a highly pure form, easily purified away from potentially contaminating unlabeled peptide species. Whether the peptidic nature of the chelating moiety has any effect on the *in vivo* metabolism of the radiotracer is currently being investigated.

This method could provide a general means of labeling bioactive peptides with preformed radiolabeled chelates that contain a free -COOH group. Amino acid based chelates such as MAG3 could be labeled with ^{186}Re and then coupled to biologically active peptide sequences during automated synthesis. Likewise, this technique could be used to append radiolabeled N $_2$ S $_2$ heterocyclic chelates to peptides. The only requirements are that the chelate complex contains an activatable carboxylate group and is stable in the deblocking/deprotection mix.

Additionally, the use of a natural amino acid chelate has other possible benefits that can be realized using a postconjugate chelation approach. Cysteine-containing amino acid sequences such as Cys-Gly-Cys or Gly-Gly-Cys (29) can be genetically engineered into larger biomolecules such as antibody fragments. Recombinant fragments can then be radiolabeled under mild conditions, with increased labeling efficiency.

The pure radiolabeled peptide-rhenium complexes produced by the preformed chelate approach described here have the metal incorporated into the peptide structure at a specific, known position. In contrast, any postlabeling scheme, even of relatively small peptides, is likely to result in a mixture of labeled peptides, of which many are not N $_2$ S $_2$ rhenium conjugates and therefore have lower intrinsic stability. In the future, this method could provide a means of producing medically useful peptide radiopharmaceuticals of high specific activity and purity.

Kinetic Analysis of Sequence-Specific Alkylation of DNA by Pyrimidine Oligodeoxyribonucleotide-Directed Triple-Helix Formation

Matthew J. Taylor and Peter B. Dervan*

Arnold and Mabel Beckman Laboratories of Chemical Synthesis, Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received March 12, 1997*

Attachment of a nondiffusible bromoacetyl electrophile to the 5-position of a thymine at the 5'-end of a pyrimidine oligodeoxyribonucleotide affords sequence-specific alkylation of a guanine base in duplex DNA two base pairs to the 5'-side of a local triple-helical complex. Products resulting from reaction of 5'-³ETTTT^{Me}CTTTT^{Me}CTTTT^{Me}CTTTT-3' at 37 °C with a 29 base pair target duplex are determined by a gel mobility analysis to be oligonucleotides terminating in 5'- and 3'-phosphate functional groups, consistent with a mechanism involving alkylation, glycosidic bond cleavage, and base-promoted strand cleavage. The guanine-(linker)-oligonucleotide conjugate formed upon triple-helix-mediated alkylation at the N⁷ position of a guanine base in a 60 base pair duplex was identified by enzymatic phosphodiester hydrolysis of the alkylation products followed by reversed phase HPLC analysis. To determine the rate enhancement achieved by oligonucleotide-directed alkylation of duplex DNA, a comparison of rates of alkylation at N⁷ of guanine in double-stranded DNA by the *N*-bromoacetyloligonucleotide and 2-bromoacetamide was performed by a polyacrylamide gel assay. The reaction within the triple-helical complex on a restriction fragment was determined at 200 nM *N*-bromoacetyloligonucleotide to have a first-order rate constant k_1 of $(2.7 \pm 0.5) \times 10^{-5} \text{ s}^{-1}$ ($t_{1/2} = 7.2 \text{ h}$). The reaction of 2-bromoacetamide with a 39 base pair duplex of sequence corresponding to the restriction fragment targeted by triple-helix formation was determined to have a second-order rate constant k_2 of $(3.6 \pm 0.3) \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$. A comparison of the first-order and second-order rate constants for the unimolecular and bimolecular alkylation reactions provides an effective molarity of 0.8 M for bromoacetyl within the triple-helical complex.

INTRODUCTION

The design of sequence-specific DNA-cleaving molecules requires the integration of recognition and cleavage in a single molecule. Three approaches to the bifunctional design of these molecules include attachment of functional groups to DNA-binding molecules that can achieve oxidation of the deoxyribose backbone (1), electrophilic modification of the bases (2), or hydrolysis of the phosphodiester bond. Of these classes, DNA-binding molecules that perform electrophilic modification of the bases can provide additional specificity due to the different nucleophilicity of positions on the bases in DNA (e.g. N⁷ of guanine or N³ of adenine).

Oligonucleotide-directed triple-helix formation is one of the most powerful methods for the sequence-specific recognition of single sites within megabase pair double-helical DNA (3, 4). Pyrimidine oligodeoxyribonucleotides bind purine tracts in the major groove of DNA parallel to the purine Watson–Crick strand, through formation of specific Hoogsteen hydrogen bonds to the purine Watson–Crick bases (Figure 1). Specificity is derived from thymine (T) recognition of adenine–thymine (AT) base pairs (TAT triplet) and N³-protonated cytosine (C⁺) recognition of guanine–cytosine (GC) base pairs (C⁺GC triplet).

Efforts have been successful in the use of oligonucleotides for directing electrophiles to react at the N⁷-position of guanine in the major groove via triple-helix formation (5). Early examples utilizing 5'-aromatic chloroethyl-

Figure 2. Bromoacetyl electrophile is localized in the major groove by triple-helix formation proximal to a GC base pair (G) in the Watson–Crick duplex target site. Alkylation at N7 of guanine followed by depurination results in cleavage of the deoxyribose backbone.

otides equipped with *N*-bromoacetyl at the 5'-end react with one strand of a duplex DNA target site in very high yield (5c). Pyrimidine oligodeoxyribonucleotides bound in the major groove and equipped with a bromoacetyl moiety at the 5'-end position the electrophile proximal to a guanine 2 base pairs to the 5'-side of the target sequence. Reaction of the electrophilic carbon of *N*-bromoacetyl with N⁷ of the guanine base adjacent to the local triple helix results in covalent attachment of the oligonucleotide to the target sequence. Upon warming in the presence of base, depurination at the position of alkylation occurs and cleavage of one strand of the DNA backbone is observed (5c) (Figure 2).

More recently, alkylation of both strands of double-helical DNA has been demonstrated (6). Pyrimidine oligonucleotides modified at both the 5'-end (for same-strand alkylation) and 3'-end (for opposite-strand alkylation) with aromatic chloroethylamines cross-link short double-helical DNA at guanine bases separated by 22–26 base pairs in 80% yield (6b). *N*-Bromoacetyl oligonucleotides bind adjacent inverted purine tracts on double-helical DNA by triple-helix formation and alkylate single guanine positions on opposite strands (6a). Double-strand cleavage at a single site within yeast chromosome III occurs in 85–90% yield, demonstrating the utility of this nonenzymatic approach for atom-specific reaction and cleavage of megabase pair double-helical DNA. Further design of these systems will undoubtedly benefit from an understanding in quantitative terms of what has been gained in reaction rate and specificity upon covalent attachment of electrophiles to oligonucleotides for alkylation of DNA.

We report here a product and kinetic analysis of pyrimidine oligonucleotide-directed bromoacetyl alkylation of double-stranded DNA. Products of N⁷ alkylation of guanine in the target duplex DNA and the pyrimidine-rich Hoogsteen strand of the bound triple-helical complex are characterized. Rate constants for the alkylation reaction at N⁷ of guanine within the triple-helical complex and the reaction of 2-bromoacetamide with N⁷ of guanine within duplex DNA are determined, allowing for an estimate of the effective molarity of bromoacetyl obtained upon attachment of the electrophile to the Hoogsteen strand of a local triple-helical complex.

EXPERIMENTAL PROCEDURES

¹H NMR and ¹³C NMR spectra were recorded at 300 MHz on a General Electric QE 300 Spectrometer. Chemical shifts were recorded in parts per million using the proteo NMR solvent as a reference. Biochemical manipulations were carried out according to standard procedures (7) unless otherwise noted. Adenine-specific (8) and guanine-specific (7) sequencing reactions were performed as previously described. Radioactive nucleotides were purchased from Amersham and ICN. T4 polynucleotide kinase, calf alkaline phosphatase, Klenow fragment, and glycogen were obtained from Boehringer Mannheim. *Hind*III was obtained from New England Biolabs. *Ssp*I was obtained from Gibco/BRL. Terminal transferase was obtained from USB. Dimethyl sulfate, piperidine, and 2-bromoacetamide were obtained from Aldrich. Purity of 2-bromoacetamide was verified by ¹H NMR. Acrylamide was purchased from Bio-Rad. Cobalt hexamine trichloride was obtained from Fluka. Snake venom phosphodiesterase (type VIII) was purchased from Sigma. NAP-5, NAP-25, and NICK columns were purchased from Pharmacia. All reagents were used without further purification unless otherwise noted. High-resolution FAB mass spectra were obtained at the California Institute of Technology Chemistry/Biology Mass Spectrometry Facility. Matrix-assisted laser desorption/ionization time of flight mass spectra were obtained at the Protein and Peptide Microanalytical Facility at the California Institute of Technology.

High-pressure liquid chromatography (HPLC) was performed on a Hewlett-Packard 1090 liquid chromatograph with a HPLC 3D Chemstation. Analytical reversed phase HPLC was performed on a Vydac 201HS reversed phase HPLC column. Oligonucleotide purification was accomplished on a Pharmacia LKB FPLC using a ProRPC HR 16/10 reversed phase column (160 mm × 10 mm). Ion retardation resin (AG 11A8) and cation exchange cellulose (Cellex-CM) were purchased from Bio-Rad. Reversed phase resin (LiChroprep RP-18) was purchased from EM Separations.

Synthesis and Purification of Oligonucleotides.

Oligonucleotides were synthesized on an Applied Biosystems Model 380B DNA synthesizer using standard phosphoramidite chemistry (9) and deprotected with concentrated NH₄OH at 55 °C for 24 h. Following lyophilization, purification of 5'-OH-oligonucleotide was achieved using denaturing polyacrylamide gel electrophoresis. Purification of the 5'-O-dimethoxytrityl oligonucleotide was achieved using reversed phase FPLC (solvent A, 100 mM ammonium acetate, pH 7.0; solvent B, 40% acetonitrile in solvent A). Following lyophilization of appropriate fractions and removal of the dimethoxytrityl protecting group (80% acetic acid for 20 min followed by lyophilization), purification of the deprotected oligonucleotide was achieved by reversed phase FPLC. Following purification, oligonucleotides were desalted on a Sep-Pak car-

tridge (Waters) and quantitated by UV-vis spectroscopy (extinction coefficients in $M^{-1} \text{ cm}^{-1}$: dT = 8 700, dG = 11 500, dA = 15 400, dC = 7 400).

Synthesis and Analysis of *N*-Bromoacetyloligonucleotides. Fmoc-protected aminonucleoside (5c) was incorporated at the 5'-end of the oligonucleotide 5'-TTT^{Me}-CTTTT^{Me}C^{Me}CTTT^{Me}CTTTT-3' as the 5'-O-DMT-3'-phosphoramidite with a modification of standard coupling protocols. The last coupling step in the oligonucleotide synthesis was performed with a 0.15 M solution of the β -cyanoethyl phosphoramidite in tetrahydrofuran (distilled from calcium hydride) on a 1 μmol scale. Following deprotection at 55 °C for 15 h, the 5'-O-DMT-oligonucleotide was purified by reversed phase FPLC, deprotected, and further purified by reversed phase FPLC. Acylation of the resulting oligonucleotide-amine was then performed. Ten nanomoles of oligonucleotide was dissolved in 10 μL of 200 mM borate buffer, pH 8.9. Ten microliters of a 30 mM solution of freshly prepared *N*-hydroxysuccinimide bromoacetate in *N,N*-dimethylformamide (stored over molecular sieves) was added, the resulting solution mixed well, and, after 30 s, diluted to 0.5 mL with water and passed through an NAP-5 column (Sephadex G-25, equilibrated with water). Following elution with 1.0 mL of water, the *N*-bromoacetyloligonucleotide was quantitated by UV-vis spectroscopy (extinction coefficient of 153 000 $M^{-1} \text{ cm}^{-1}$ determined from the sum of dT = 8 700, dT^E = 8 700, and 5-methyl-dC = 5 700) and stored at -20 °C. The reaction was judged quantitative by HPLC analysis of enzyme degradation products. To the oligonucleotide were added 18 μL of water, 2.5 μL of 10 \times dephosphorylation buffer (500 mM Tris-HCl, 1 mM EDTA, pH 8.5), 2.5 μL of 2 M MgCl_2 , and 2 μL of snake venom phosphodiesterase (2 units/0.7 mL of enzyme). Following incubation at 37 °C for 2 h, samples were filtered (0.2 μm Nylon-66 membrane, Rainin) and 23.5 μL was injected. HPLC conditions: Vydac C₁₈ 201HS reversed phase column preequilibrated to 50 °C; solvent A, 100 mM ammonium acetate, pH 6.0; solvent B, acetonitrile; gradient, 0–10 min at 0% B, 10–40 min to 5% B, 40–60 min at 5% B, 60–70 min to 10% B, 70–85 min at 10% B, 85–90 min to 0% B. Retention times and relative peak areas: 5-methyl-2'-deoxycytidine 5'-monophosphate, 10.3 min, 2.6; thymidine 5'-monophosphate, 15.0 min, 14.6; hydroxy-(linker)-thymidine, 35.2 min, 0.2; bromo-(linker)-thymidine, 52.6 min, 0.8. Mass spectrum of *N*-bromoacetyloligonucleotide (MALDI-TOF): calcd 5934.9, found 5935.7.

5'-³²P-End Labeling of the 29 Base Pair Duplex. Fifty picomoles of single-stranded oligonucleotide 5'-GCTAGTAAAGAAAAGGAAAGAAAAGTCG-3' was labeled with ³²P at the 5'-end by treatment with 45 units of T4-polynucleotide kinase and [γ -³²P]dATP γ P for 45 min at 37 °C. Following phenol/chloroform extraction, ethanol precipitation, and hybridization with 100 pmol of complementary single-stranded oligonucleotide, the 5'-³²P-end-labeled duplex was subjected to 14% nondenaturing polyacrylamide gel electrophoresis, visualized by autoradiography, excised from the gel, and eluted with 200 mM NaCl/1 mM EDTA at 37 °C overnight. The DNA was filtered (0.45 μm), ethanol precipitated, passed through a NICK column (Sephadex G-50, equilibrated with water), and stored at -20 °C.

3'-³²P-End Labeling of 29 Base Pair Duplex. Fifty picomoles of single-stranded oligonucleotide 5'-GCTAGTAAAGAAAAGGAAAGAAAAGTCG-3' was labeled with [α -³²P]ddA α P at the 3'-end by treatment with 85 units of terminal deoxynucleotidyl transferase and [α -³²P]ddATP α P for 45 min at 37 °C. Unincorporated nucleotide was removed by passage through a NICK column (Sephadex
