Bioconjugate Chemistry

EDITORIAL: Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 1998 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the ninth volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are listed on the following page.

Spacers, Probability, and Yields

Donald M. Simons

Dade Behring Inc., P.O. Box 6101, M/S 709, Newark, Delaware 19714-6101. Received June 27, 1998

Spacers (linkers and bridgers) are extensively used in the synthesis of bioconjugates. This communication is concerned with spacers of the homobifunctional type—diols, diamines, dicarboxylic acids, etc.—in which the functional groups are equally reactive and sufficiently far apart that the reaction of one does not affect the reactivity of the other. In many cases, the first reaction carried out with such molecules is intended to derivatize, or to protect, only one functional group, leaving the other free for some subsequent reaction. No matter how these reactions are carried out, however, both diderivatized and unreacted spacers are always present in the final crude reaction mixture.

It is an almost universal custom among synthetic chemists to calculate a theoretical yield for the monoderivatized spacer as if it were the only product formed and to disregard the diderivatized product completely. However, information on the relative amounts of products present can at times be useful, particularly for cases in which the isolated yield of monoderivatized spacer turns out to be substantially less than anticipated. Comparison of the observed ratio of diderivatized spacer to monoderivatized spacer (r)[1] with the expected value (EV_r) can often distinguish which of the common causes of yield deficits—mechanical loss,[2] incomplete conversion, improper technique—is the predominant factor (Table 1).

In a homogeneous system, the expected values for the amounts of products formed in the reaction of a homobifunctional spacer with a monofunctional derivatizing agent are dictated by the chosen stoichiometry and the law of binomial distribution. (The law of binomial distribution may not apply in a heterogeneous reaction system.) Calculation of these values is straightforward and is the main subject of the following communication.

HOMOGENEOUS REACTION SYSTEMS

A reaction is regarded as homogeneous if both the homobifunctional spacer and its monoderivatized product remain in solution throughout the reaction. For purpose of illustration, consider the reaction of an equimolar mixture of a diamine and an acyl halide. Here, the amount of acyl halide used is just sufficient to react with exactly half of the total amine groups present.[3] If the reaction goes to completion, the probability that any given amine group will react (p) is 0.50. Correspondingly, the probability that any given amine group will not react (q) is $1 - 0.50 = 0.50$. These two probability values, identical in this particular case, are all that is needed to calculate the expected mole fractions of unreacted diamine (UND), diderivatized diamine (DID), and the desired monoderivatized diamine (MOD) in the final reaction mixture. Thus, the mole fraction of DID is obtained by multiplying the probability that one amine group in a molecule has reacted by the probability that the second amine group has also reacted:

$$\text{mole fraction of DID} = p \times p = p^2 = (0.50)^2 = 0.25$$

In similar fashion, the mole fraction of unreacted diamine is the product of the probabilities that both amine groups in a molecule have not reacted:

$$\text{mole fraction of UND} = q \times q = q^2 = (0.50)^2 = 0.25$$

The mole fraction of the desired monoderivative (MOD) is twice the product of the probability that one amine has reacted and the probability that the other amine has not reacted:

$$\text{mole fraction of MOD} = 2pq = 2 \times 0.50 \times 0.50 = 0.50$$

(The factor 2 is necessary because MOD can be formed in two different ways, that is, acyl halide can react at

Table 1. Use of Observed Ratio of Diderivatized Spacer to Monoderivatized Spacer (r) in Diagnosis of a Yield Deficit

r	probable cause for yield deficit[a]
equal to EVr[b]	mechanical loss
less than EV_r	incomplete conversion[c]
greater than EV_r	inadequate or improper mixing

[a] These guidelines can be subverted by use of impure reactants, by weighing errors, etc. [b] EV_r = expected value for r at complete conversion. [c] Incomplete conversion can result from a loss of derivatizing agent through side reactions (hydrolysis, etc.) as well as from incomplete reaction.

[1] Suitable values for r can often be obtained by analytical chromatography, which is especially convenient when the derivative group is a good chromophore. Because r is a ratio, the extinction coefficient is not required. If the derivative group is not a chromophore, a small sample of the reaction mixture can be treated with a large excess of a second chromophoric reactant. This then provides a measure of the ratio of unreacted spacer to monoderivatized spacer, which can be used in place or r. As a specific example, picrylsulfonic acid is a useful second chromophoric reactant for spacers of the diamine type.

[2] The term "mechanical loss" covers all those inevitable losses that occur during the manipulations required for transfer, purification, and isolation of the product. Even with good workup procedures and careful attention to details, it is difficult to reduce mechanical loss much below 8−10%.

[3] It is assumed that the reactants are mixed to homogeneity before any reaction takes place, that is, that the mixing is ideal. Ideal mixing can be approximated fairly closely for slow reactions but becomes increasingly difficult to attain as the reaction rate increases. Any deviation from ideal mixing always leads to a diminished yield of the monosubstituted derivative.

0.409	90
0.452	95
0.500	100

[a] Derivation of equation shown in footnote 4.

either of the two ends of the symmetrical diamine molecule to give the same product.) And finally, the expected value of *r* at complete conversion (EV_r) is

$$EV_r = p^2/2pq = p/2(1 - p) = 0.50$$

Multiplying each of the respective mole fractions by the initial moles of diamine actually used gives the moles of product formed (Scheme 1).

All of the above calculations are based on the assumption that the conversion of reactants to products is quantitative. Table 2 shows the relationship between the ratio of diderivatized spacer to monoderivatized spacer (*r*) and conversion (*x*). This relationship can also be expressed by the equation $x\ (\%) = 400r/(1 + 2r)$. In systems in which the reaction rate is not too fast, periodic measurement of *r* provides an elegantly simple method for following the kinetics.[4]

The true theoretical yield of monosubstituted product obtainable from the reaction of an *equimolar* mixture of a homobifunctional spacer and a monofunctional derivatizing reagent is 50 mol %. Further, one-half of the derivatizing reagent is lost through being converted to the disubstituted product. The efficiency can be increased by changing the stoichiometry, that is, by using a smaller ratio of derivatizing reagent to spacer. An example of this technique, taken from Aldenhoff et al. (*1*), describes the preparation of the monotrityl ether of triethylene glycol by reaction of trityl chloride (TrCl) with triethylene glycol (TEG):

> "To a stirred solution of triethylene glycol (75.09 g, 500.00 mmol) and 4-(dimethylamino)pyridine (0.38 g, 3.13 mmol) in 125 mL of anhydrous pyridine was added triphenylmethyl chloride (17.42 g, 63.50 mmol)[*sic*] in 10 portions during 3h. The solution was stirred for 16h under exclusion of moisture. Then, pyridine was removed (last traces were removed by coevaporation with toluene). The residue was taken up in dichloromethane and washed with saturated aqueous bicarbonate (three times) and water (three times). The organic layer was dried on magnesium sulfate, filtered, and concentrated to dryness under reduced pressure. The crude product was applied to a silica gel column. Elution with 1:1 petroleum ether/ethyl acetate afforded pure 1-(2′-O-triphenylmethylethoxy)-2-(2′-hydroxyethoxy)ethane (i.e., monotritylated triethylene glycol) as a viscous oil...yield, 20.56 g..."

(There is a minor uncertainty in the amount of trityl chloride used: 63.50 mmol requires 17.70 g instead of "17.42 g". The following calculations are based on 63.50 mmol.)

The probability that any given hydroxyl group has reacted (*p*) is numerically equal to the fraction of hydroxyl groups reacted. It is thus equal to the ratio of the equivalents of hydroxyl reacted (equal to the equivalents of trityl chloride used) to the total equivalents of hydroxyl initially present:[5]

$$p = 63.50/(2 \times 500.00) = 0.06350$$

The probability that any given hydroxyl group has not reacted (*q*) is, as always, $1 - p$:

$$q = 1 - 0.0635 = 0.9365$$

The expected mole fractions of the various products are calculated exactly as before:

[4] Derivation of $x\ (\%) = 400r/(1 + 2r)$. Consider the reaction of a homobifunctional spacer (*a* mole; 2*a* equiv) with an equimolar amount of a monofunctional derivatizing agent (MDA, *a* mole; *a* equiv). At time *t*, the conversion = *x* = the fraction of MDA reacted, and *ax* = the equivalents of MDA reacted. The value of *p* at time *t* is numerically equal to the fraction of spacer functional groups reacted. Thus, $p = ax/2a = x/2$. Substituting $x/2$ for *p* in $r = p/2(1 - p)$ gives $r = x/2(2 - x)$. Rearranging the last equation gives $x = 4r/(1 + 2r)$ or $x(\%) = 400r/(1 + 2r)$.

[5] General equations for calculation of probabilities in the reaction of *a* moles of homobifunctional spacer with *b* moles of monofunctional derivatizing agent: $p = b/2a$; $q = (1 - b/2a)$.

mole fraction of Tr-TEG-Tr $= p^2 = (0.06350)^2 =$ 0.004032

mole fraction of unreacted TEG $= q^2 = (0.9365)^2 =$ 0.8770

mole fraction of Tr-TEG $= 2\,pq = 2 \times 0.06350 \times$ 0.9365 $= 0.1189$

Scheme 2 shows a summary of the complete stoichiometry for this reaction.[6] The true theoretical yield of monotritylated triethylene glycol is 23.33 g. The actual yield reported (20.56 g) thus corresponds to 88.13% of the expected value. (If the amount of trityl chloride used was in fact 17.42 g (62.49 mmol), then the theoretical yield is 22.99 g and the recovery is 89.43%. Either way, this is obviously an excellent procedure for synthesis of the monotrityl ether of triethylene glycol.)

The foregoing calculations describe a bulk process, one in which the total amounts of the reactants are combined at the start. Aldenhoff et al. used an incremental process, adding the trityl chloride in 10 portions over a 3 h period. Both processes lead to the same final theoretical product distribution, however. A somewhat idealized summary of the incremental process is depicted in Table 3 in the form of a spreadsheet. [Instructions for reproducing the spreadsheet are given in a footnote to the table.[7]] In each step, the product distribution is calculated by applying the relevant probability values for the added increment to the products formed in the preceding step. For example, consider step 2 (The subscripts here refer to the step numbers, not row numbers or numbers of atoms or groups; the quantities are in moles):

cell F6: $\mathrm{TEG}_2 = {q_2}^2 \times \mathrm{TEG}_1$

cell G6: $\mathrm{Tr\text{-}TEG}_2 = (2 \times p_2 \times q_2 \times \mathrm{TEG}_1) + (q_2 \times \mathrm{Tr\text{-}TEG}_1)$

cell H6: $\mathrm{Tr\text{-}TEG\text{-}Tr}_2 = ({p_2}^2 \times \mathrm{TEG}_1) + (p_2 \times \mathrm{Tr\text{-}TEG}_1) + \mathrm{Tr\text{-}TEG\text{-}Tr}_1$

These equations state that the amount of Tr-TEG present at the end of step 2 is the sum of that newly formed from TEG_1 plus the residual amount—the amount *not* converted to $\mathrm{Tr\text{-}TEG\text{-}Tr}_2$—from step 1. In like fashion, the amount of Tr-TEG-Tr present at the end of step 2 is the amount newly formed from TEG_1 plus the amount formed from $\mathrm{Tr\text{-}TEG}_1$ plus the amount previously formed in Step 1 ($\mathrm{Tr\text{-}TEG\text{-}Tr}_1$). The spreadsheet format makes it easy to apply the formulas to each row in turn.

There is nothing particularly unique about the ten-step incremental process. The amount of each increment added can be decreased or increased and the table correspondingly lengthened or shortened without in any way affecting the final product distribution. It should be noted in this regard that a bulk process is an incremental process consisting of only one step.

In practical synthetic work, it is not necessary to either add increments in equal amounts nor drive the reaction to completion in any step except the last. The important factors are order of addition, reaction rate, and mixing technique. These are discussed in more detail later.

It is sometimes necessary to activate a homobifunctional spacer in order to link it to the desired reagent. Examples are the activation of a glycol with carbonyldiimidazole (CDI) followed by reaction with an amine to give a urethane, and activation of a dicarboxylic acid with isobutyl chloroformate (IBCF) followed by reaction with an amine to give an amide (mixed anhydride process) (Scheme 3). An interesting detail for reactions of this type is that the final product distribution is insensitive to the amount of activating agent used, so long as it lies in the range 1−2 mol/mol of homobifunctional spacer. First, consider the two extremes. Activation of 1 mol of a dicarboxylic acid spacer with 1 mol of isobutyl chloroformate ($p = 0.50$; $q = 0.50$) will give the expected binomial distribution: 0.25 mol of unreacted dicarboxylic acid, 0.25 mol of bis(mixed anhydride), and 0.50 mol of mono(mixed anhydride). Subsequent reaction with 1 mol of amine does not alter this distribution, thus yielding 0.25 mol of unreacted dicarboxylic acid, 0.25 mol of bisamide, and 0.50 mol of monoamide. Alternatively, activation of 1 mol of dicarboxylic acid with 2 mol of isobutyl chloroformate simply converts it to a new homobifunctional reactant; subsequent treatment with 1 mol of amine, followed by hydrolysis of excess mixed anhydride groups, will again give the same expected distribution: 0.25 mol of unreacted dicarboxylic acid, 0.25 mol of bisamide, and 0.50 mol of monoamide.

Consider now the activation of 1 mol of dicarboxylic acid with 1.5 mol of isobutyl chloroformate. Expected values for the activation step ($p = 1.5/2 = 0.750$; $q = 0.250$) are 0.0625 mol of unreacted dicarboxylic acid, 0.3750 mol of mono(mixed anhydride), and 0.5625 mol of bis(mixed anhydride). Subsequent treatment of this mixture with exactly 1 mol of amine gives the product distribution shown in Scheme 4. After hydrolysis of the excess mixed anhydride end groups, the reaction mixture contains 0.25 mol of dicarboxylic acid, 0.25 mol of bisamide, and 0.50 mol of monoamide, exactly as in the two preceding cases.

In a homogeneous system, no variation in experimental procedure can lead to a yield of monosubstituted spacer greater than that set by the stoichiometry and probability. However, procedure can drastically affect how closely the product distribution actually obtained approximates the expected values, particularly in those cases in which the reaction velocity is very fast. Order of addition is especially important. Visualize the consequences of slowly—slowly relative to the reaction rate—adding a solution of a diamine to a solution of an acyl halide. In the reactor, an excess of acyl halide over diamine will exist nearly to the point that half of the diamine has been added. Consequently, this half of the diamine becomes totally diacylated, and no more acyl halide remains to react with the second half. The final result is a mixture of diamide and unreacted diamine containing practically none of the monoacylated product. A more appropriate way to carry out this type of reaction is to add dropwise a solution of acyl halide (as dilute as possible) to a very vigorously agitated solution of diamine (as concentrated as possible, considering viscosity, solubility, etc.) at a temperature low enough to slow the rate of reaction substantially. The object again is to prevent

[6] General equations for calculation of expected values (moles) for products formed in the reaction of a moles of homobifunctional spacer with b moles of monofunctional derivatizing agent: Monosubstituted spacer $= b(1 - b/2a)$; disubstituted spacer $= b2/4a$; unreacted spacer $= (a - b + b2/4a)$. The sum of these three values is always equal to a, a detail useful for cross−checking the mass balance. When the derivatizing agent is present in excess, that is, $b > 2a$, these equations no longer have physical meaning.

[7] When set up as a spreadsheet, Table 3 is readily adaptable to any kind of addition process.

Scheme 2. Summary of Stoichiometry in the Preparation of the Monotrityl Ether of Triethylene Glycol by Reaction of Trityl Chloride (TrCl) with Triethylene Glycol (TEG)[a]

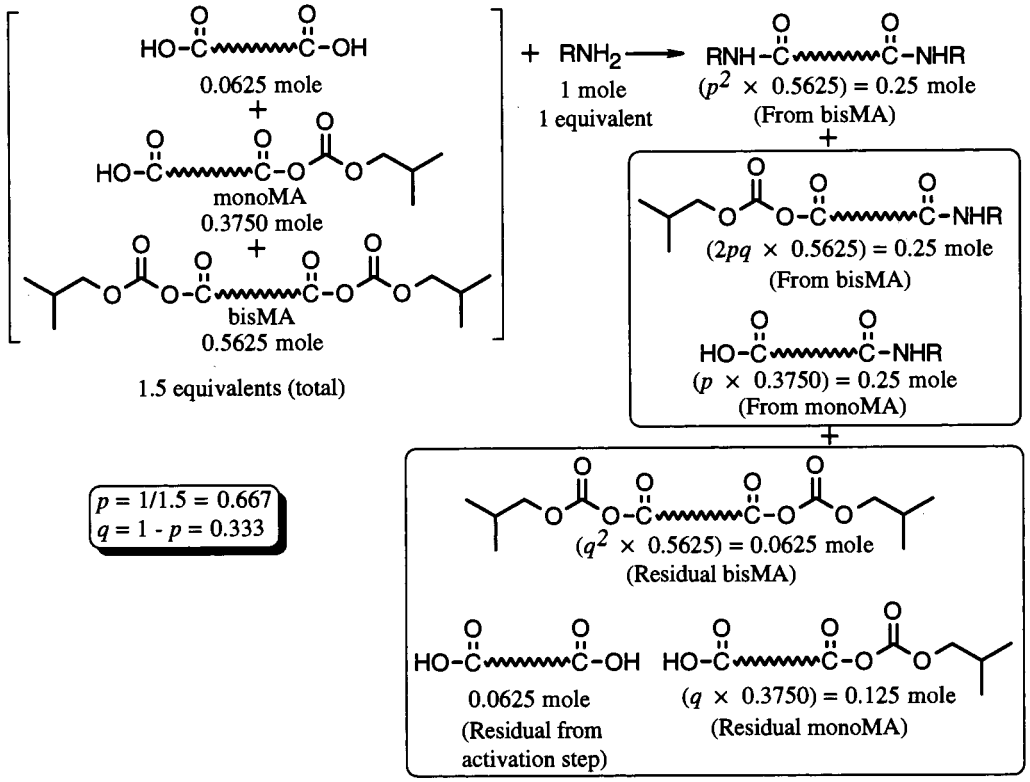
[a] Calculations using an Excel spreadsheet: enter the appropriate numerical values in row 4. Enter 0.006 35 in B5, select B5 and fill down to row 14 (step 10). Enter relative references in the cells of row 5 as shown. Select C5−H5 and drag fill handle to row 14. (The calculations are based on ideal mixing and quantitative reaction for each step.)

Scheme 3. Examples of Spacer Activation and Subsequent Derivatization[a]

[a] CDI = carbonyldiimidazole; IBCF = isobutyl chloroformate.



excess diacylation, since even here an excess of acyl halide over diamine can temporarily exist in the microenvironment around each newly added drop. It is therefore important that complete mixing takes place before any substantial amount of reaction has occurred.[8] An observed DID/MOD mole ratio (*r*) greater than the expected value (EV_r) is almost always the signature of a procedural problem.

HOMOTRI- AND HOMOPOLYFUNCTIONAL REACTANTS

The law of binomial distribution applies equally well to reactants with functionality greater than 2, subject again to the restriction that all the functional groups must be equally reactive. For example, the expected product distribution (mol fractions) from a reaction of equimolar quantities of a triamine and a monofunctional

[8] Depending on the case at hand, other options might include adding any catalyst, acid acceptor, etc., only after the primary reactants have been thoroughly mixed.

Scheme 4. Expected Values for the Reaction of 1 mol of Amine with 1 mol of Dicarboxylic Acid Previously Activated with 1.5 mol of Isobutyl Chloroformate[a]

[a] MA = mixed anhydride.

Table 4. Equimolar Reaction of a Homopolyfunctional Reagent (HPFR) Bearing *n* Functional Groups and a Monofunctional Derivatizing Reagent: Unreacted HPFR as a Function of *n*

n	unreacted HPFR (mole fraction)
2	0.2500
3	0.2963
4	0.3164
5	0.3277
6	0.3349
7	0.3399
8	0.3436
9	0.3464
10	0.3487
∞	0.3679

derivatizing agent are

$$p = 0.3333;\ q = 0.6667$$

$$\text{unreacted triamine} = q^3 = 0.2963$$

$$\text{monosubstituted triamine} = 3pq^2 = 0.4444$$

$$\text{disubstituted triamine} = 3p^2q = 0.2222$$

$$\text{trisubstituted triamine} = p^3 = 0.0370$$

A notable feature in the reaction of equimolar quantities of a homopolyfunctional reagent (HPFR) and a monofunctional derivatizing reagent is that the mole fraction of HPFR remaining unreacted *increases* as the number of functional groups (*n*) on the HPFR molecule increases, ultimately approaching the transcendental value 1/*e* (=0.367 879 441...) as a limit (Table 4).

Although these principles are relevant to conjugate syntheses with polyfunctional reagents such as the recently developed dendrimer reagents (*2*), they apply less well to proteins. In proteins, even functional groups of the same type possess widely differing reactivities due to the steric environment, different pK_a values, etc.

HETEROGENEOUS REACTION SYSTEMS

The above considerations apply to a homogeneous reaction, i.e., one in which both the homobifunctional spacer and its monoderivatized product remain in solution throughout the reaction. It is sometimes possible to find a solvent in which the reactants are soluble but the monoderivatized product is insoluble, precipitating as soon as it forms. Under these conditions, the law of binomial distribution no longer holds, and it is possible to get much higher yields than in a homogeneous system. A specific example of such a heterogeneous reaction system is encountered in the reaction of ethylene glycol bis(3-aminopropyl) ether [2997-01-5] with succinic anhydride in acetonitrile. The highly insoluble monoamide [144923-24-0] is obtainable in yields as high as 85% (*3*).

ACKNOWLEDGMENT

The author thanks his colleagues at Dade Behring Inc. for their many cogent comments, criticisms, and suggestions during preparation of the manuscript: Roger Bauer, William P. Bedzyk, Daniel V. Brown, Alan R. Craig, Pratap Singh, Richard W. Stout, John C. Thompson, and Chengrong Wang.

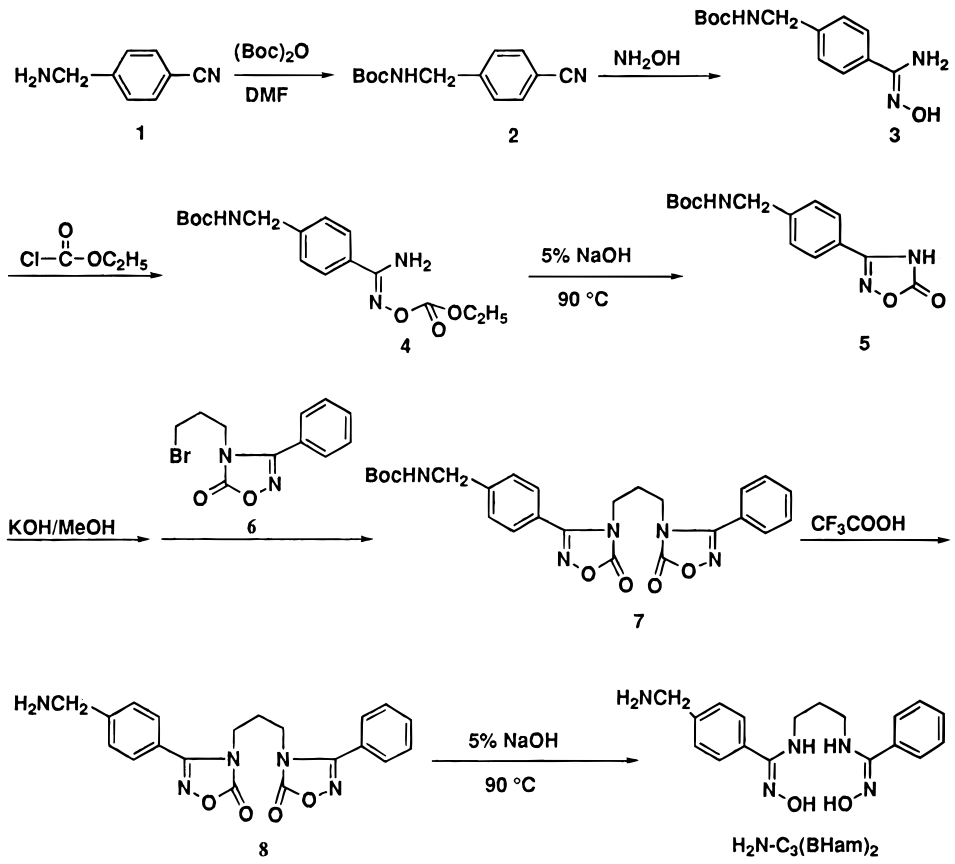
Received February 25, 1998; Revised Manuscript Received August 10, 1998

To develop chelating molecules that provide ^{99m}Tc-labeled polypeptides of high in vivo stability and high specific activities under mild reaction conditions, an asymmetrical bis(benzohydroxamamide) compound with an amine group, 4′-aminomethyl-*N*,*N*′-trimethylenedibenzohydroxamamide [$NH_2-C_3(BHam)_2$], was designed and synthesized. The amine residue of $NH_2-C_3(BHam)_2$ was converted to a maleimide group by reaction with *N*-succinimidyl-6-maleimidohexanoate, and the conjugation product was coupled to thiol groups of a monoclonal antibody against osteogenic sarcoma (OST7, IgG_1) pretreated with 2-iminothiolane to prepare $C_3(BHam)_2-$OST7. ^{99m}Tc radiolabeling of $C_3(BHam)_2-$OST7 was performed by the exchange reaction with [^{99m}Tc]glucoheptonate. [^{99m}Tc]$C_3(BHam)_2-$OST7 was further characterized using directly radioiodinated OST7 ([^{125}I]OST7) and [^{111}In]labeled OST7 with 1-[4-[(5-maleimidopentyl)amidobenzyl]ethylenediamine-*N*,*N*,*N*′*N*′-tetraacetic acid (EMCS−Bz-EDTA) as references. [^{99m}Tc]$C_3(BHam)_2-$OST7 was obtained with radiochemical yields of over 94% at protein concentrations as low as 0.2 mg/mL at room temperature for 1 h. [^{99m}Tc]$C_3(BHam)_2-$OST7 remained stable after incubation in freshly prepared murine plasma and in the presence of cysteine. Similar binding affinities to tumor cells were observed between [^{99m}Tc]$C_3(BHam)_2-$OST7 and [^{125}I]-OST7. When injected into normal mice, [^{99m}Tc]$C_3(BHam)_2-$OST7 exhibited radioactivity levels in the blood similar to [^{111}In]-EMCS−Bz-EDTA-OST7 up to 24 h postinjection with significantly faster elimination rate of the radioactivity from the liver. In nude mice bearing osteogenic sarcoma, no significant differences were observed in the radioactivity levels in the blood and the tumor between [^{99m}Tc]$C_3(BHam)_2-$OST7 and [^{125}I]OST7 at 24 h postinjection. These findings indicated that $C_3(BHam)_2$ provided ^{99m}Tc chelate of high stability at low concentrations even when conjugated to an intact antibody. Such characteristics render bis(hydroxamamide) compounds useful as chelating molecules for preparation of ^{99m}Tc-labeled polypeptides.

INTRODUCTION



Radiopharmaceuticals derived from low molecular weight polypeptides such as single-chain Fv fragment, octreotide, and chemotactic peptide have attracted attention for imaging of the sites of tumors, infection, and thrombosis (*1*−*3*). The rapid pharmacokinetic properties of these molecules enable target visualization at early postinjection intervals using radionuclides with short half-lives. ^{99m}Tc is an ideal radionuclide for scintigraphic imaging applications due to its excellent physical properties, low cost, and ready availability (*4*). Since most polypeptides do not possess binding sites to form ^{99m}Tc chelates of high in vivo stability, appropriate chelating molecules are incorporated into polypeptide molecules to prepare ^{99m}Tc-labeled peptides for in vivo applications.

Previous efforts directed toward the conjugation of ^{99m}Tc to polypeptides include the use of tetradentate ligands with N_3S or N_2S_2 ligand systems, which contain one or two thiol groups (*5*−*9*). While the thiol groups in the molecules facilitate the formation of mononuclear ^{99m}Tc complexes with high stability, the presence of the free thiol group may restrict the conjugation reactions with polypeptides and subsequent storage of the resulting bioconjugates. Protection of a thiol group was performed to conjugate a N_3S chelating molecule to an antibody fragment, which necessitated a deprotection step before

Scheme 1

^{99m}Tc complexation reaction (*9*). Exchange reactions between the free thiol groups of the chelating agents and disulfide bonds in peptides may also constitute a potential problem in the conjugation reactions. In addition, some chelating agents require harsh ^{99m}Tc complexation conditions (elevated temperatures or high pH) to prepare ^{99m}Tc chelates with high radiochemical yields (*10*−*12*). Thus, development of thiol-free chelating molecules that provide ^{99m}Tc complexes with high in vivo stability and high specific activities under mild complexation conditions would facilitate further application of ^{99m}Tc to a variety of polypeptides of interest for diagnostic nuclear medicine.

Hydrazino nicotinamide (HYNIC) is a representative thiol-free chelating agent, and applicability of this chelating agent for ^{99m}Tc labeling of polypeptides has been well demonstrated (*13*−*15*). HYNIC has been reported to act as a mono- or bidentate ligand and forms ^{99m}Tc chelates of high specific activity with high radiochemical yields in the presence of appropriate co-ligands such as glucoheptonate or tricine. We initiated a program to develop new thiol-free chelating molecules with a tetradentate ligand system. Previous studies suggested that *N*-hydroxy-carboximidamide (hydroxamamide, abbreviated as Ham)-based tetradentate ligands, bis(Ham), form ^{99m}Tc chelates with high stability and high specific activity with high radiochemical yields (*16*−*19*). These findings prompted us to design bis(Ham) derivatives with a functional group for the conjugation with polypeptides.

In the present study, an asymmetrical bis(benzohydroxamamide) compound with an amine group at the conjugation site, 4′-aminomethyl-*N*,*N*′-trimethylenedibenzohydroxamamide [$NH_2-C_3(BHam)_2$], was designed and synthesized as outlined in Scheme 1. The ability of $NH_2-C_3(BHam)_2$ as a chelating molecule for ^{99m}Tc-labeled polypeptides was estimated using a monoclonal antibody (mAb) against osteogenic sarcoma (OST7, IgG_1) as a model. For comparison, OST7 was labeled with radioiodine by direct iodination and with indium-111 (^{111}In) using 1-[4-[(5-maleimidopentyl)amidobenzyl]ethylenediamine-*N*,*N*,*N*′*N*′-tetraacetic acid (EMCS−Bz-EDTA) as the chelating agent. Chemical structures of each conjugate are illustrated in Figure 1.

MATERIALS AND METHODS

Reagents and Chemicals. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a JNM-500 (500 MHz) instrument (JEOL Ltd., Tokyo, Japan). Electron impact mass spectra (EI-MS) and fast atom bombardment mass spectra (FAB-MS) were obtained with a JMS-DX303HF mass spectrometer (JEOL Ltd.). Melting points were determined with a Yanaco Micro Melting Point Apparatus and were reported uncorrected. Na[^{125}I]I was obtained from Daiichi- Kagaku (Tokyo) and diluted with phosphate buffer (PB; 0.1 M, pH 7.4) to 0.37−3.7 MBq (0.01−0.1 mCi)/μL before use. $^{111}InCl_3$ [74 MBq (2 mCi)/mL in 0.02 N HCl] was supplied by Nihon-Medi-Physics (Tokyo, Japan). [^{99m}Tc]Pertechnetate ($^{99m}TcO_4^-$) was eluted in saline solution on a daily basis from Daiichi Radioisotope Labs. generators (Chiba, Japan). 3-Phenyl-4-(3-bromopropyl)-Δ^2-1, 2, 4-oxadiazolin-5-one (compound 6 in Scheme 1) was synthesized according to the procedures described previously (*19*). Both *N*-(ϵ-maleimidocaproyloxy)succinimide (EMCS) and EMCS−Bz-EDTA were purchased from Dojindo Labs (Kumamoto, Japan). 2-Iminothiolane (2-IT) was obtained from Nacalai Tesque, Inc. Kyoto, Japan). Size-exclusion HPLC was performed using a TSK guard column SW_{XL} (6.0 × 40 mm) connected to a TSK G3000SW_{XL} (7.8 × 300 mm) column, eluted with 0.1 M PB (pH 7.0) containing 0.3 M

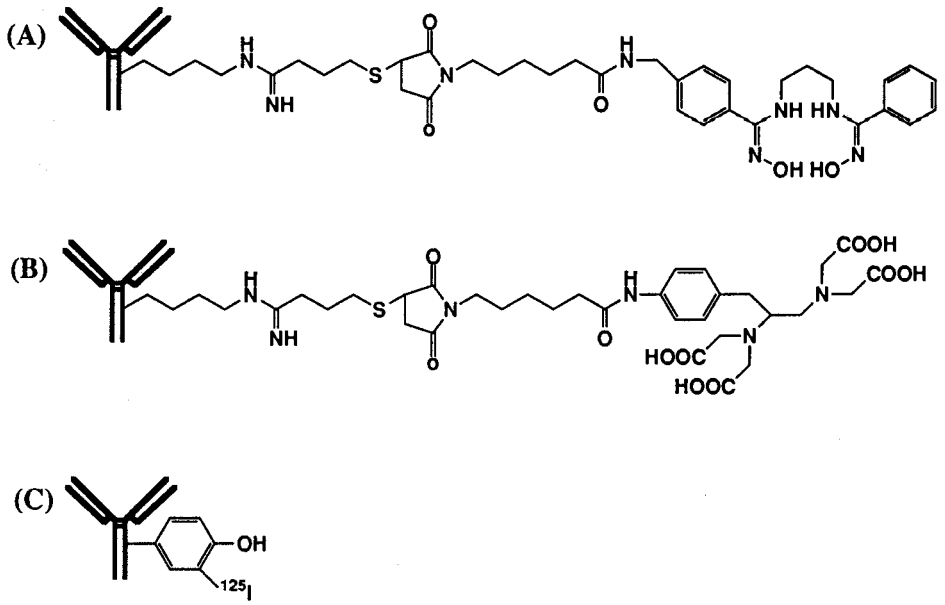

Figure 1. Chemical structures of $C_3(BHam)_2$−OST7 conjugate (A), EMCS−Bz-EDTA-OST7 conjugate (B) and ^{125}I-labeled OST7 (C).

sodium chloride at a flow rate of 0.5 mL/min. The eluent was monitored at 280 nm with an ultraviolet (UV) detector (Hitachi L-400 UV detector; Hitachi, Tokyo) and a well-type NaI (Tl) scintillation detector (Aloka PS-201; Aloka, Tokyo) coupled with a universal scalar (Aloka TCD 501). TLC analyses were performed with cellulose plates (Merck 5577) using 0.02 M phosphate-buffered saline (PBS, pH 7.0) as the developing solvent. Under these conditions, protein-bound radioactivity remained at the origin while $^{99m}TcO_4^-$ and [^{99m}Tc]cysteine moved with the solvent front. Cellulose acetate electrophoresis (CAE) was run on Separax SP (Joko, Tokyo) at a constant current of 0.8 mA/cm for 30 min in 0.072 M veronal buffer (pH 8.6). The migration distance of the antibody was determined by Ponceau 3R staining. To facilitate collection of urine and feces after administration of radiolabeled antibodies, mice were housed in metabolic cages (metabolica, MM type; Sugiyama-Gen Iriki Co. Ltd., Tokyo).

Tumor and mAb. KT005-cloned human osteosarcoma was maintained by serial subcutaneous transplantation in athymic nude mice. Female BALB/c athymic mice were implanted s.c. with 1−2 mm cubed pieces of KT005. Tumors of 0.2−0.5 g in weight at ca. 2 weeks postplantation were used in vivo study. Single-cell suspensions from xenografted tumors were used for the in vitro study *(20,21)*. The mAb against osteogenic sarcoma (OST7, IgG_1) was generated by a standard hybridoma technique, as described previously (*22*).

Synthesis of *p*-[*N*-(*tert*-Butoxycarbonyl)aminomethyl]benzonitrile (2). To a solution of *p*-(aminomethyl)benzonitrile (**1**, 10 g, 0.075 mol) in 60 mL *N,N′*-dimethyformamide (DMF) was gradually added a solution of $(Boc)_2O$ (17.4 g, 0.080 mol) in 50 mL of DMF, and the mixture was stirred at room temperature for 1 h. After removing the solvent in vacuo (30 mmHg), water (100 mL) was added to produce a white precipitate. The precipitate was collected and recrystallized from methanol−water (5:4) to produce compound **2** (17.5 g) in 99% yield. Mp 108−109 °C. ^{1}H NMR (DMSO-d_6): δ 7.479 (s, 1H, NH), 7.399−7.776 (m, 4H, aromatic H), 4.186 (s, 2H, NCH_2), 1.381 (s, 9H, $(CH_3)_3C$). EI-MS calculated for $C_{13}H_{17}N_2O_2$ (M^+): *m/z* 232. Found: 232. Anal. Calcd for $C_{13}H_{16}N_2O_2$: C, 67.22; H, 6.94; N, 12.06. Found: C, 67.46; H, 7.15; N, 11.85.

Synthesis of *p*-[*N*-(*tert*-Butoxycarbonyl)aminomethyl]benzohydroxamamide (3). A solution of free hydroxylamine was prepared by treating 13.8 g (0.20 mol) of hydroxylamine hydrochloride with 18 g (0.20 mol) of sodium bicarbonate in 100 mL of water. Compound **2** (36.8 g, 0.15 mol) in 100 mL of methanol was then added to the solution of free hydroxylamine, and the mixture was stirred at 60 °C for 8 h. After removing the solvent in vacuo, 100 mL of water was added to produce a white precipitate. Compound **3** was obtained after recrystallization of the precipitate from ethanol−water (1:1) with 94% (37.3 g) yield. Mp 152−153 °C. ^{1}H NMR (DMSO-d_6): δ 9.550 (s, 1H, OH), 7.364 (s, 1H, N*H*CH_2), 7.203−7.608 (m, 4H, aromatic H), 5.737 (s, 2H, NH_2), 4.120 (d, 2H, NHCH_2), 1.386 (s, 9H, $(CH_3)_3C$). EI-MS calculated for $C_{13}H_{20}N_3O_3$ (M^+): *m/z* 265. Found: 265. Anal. Calcd for $C_{13}H_{19}N_3O_3$: C, 58.85; H, 7.22; N, 15.84. Found: C, 59.08; H, 7.17; N, 15.70.

Synthesis of *p*-[*N*-(*tert*-Butoxycarbonyl)aminomethyl]benzamamide *O*-Ethoxycarbonyloxime (4). To a chilled solution of compound **3** (37 g, 0.14 mol) in 350 mL of dry acetone in an ice bath was slowly added 15.2 g (0.14 mol) of ethyl chlorocarbonate while maintaining the reaction temperature. A white precipitate of hydroxamamide hydrochloride was produced. While maintaining the reaction temperature at 0−4 °C, a solution of NaOH (5.7 g, 0.14 mol) in 100 mL of water was then gradually added. After stirring for 1 h at room temperature, the solvent was removed in vacuo. The solid residue was recrystallized from ethanol−water (1:1) to produce 37 g of compound **4** as white crystals (78%). Mp 109−110 °C. ^{1}H NMR (DMSO-d_6): δ 7.413 (s, 1H, N*H*CH_2), 7.270−7.631 (m, 4H, aromatic H), 6.749 (s, 2H, NH_2), 4.152 (d, 2H, NHCH_2), 4.175 (q, 2H, J = 7.32 Hz, OCH_2CH_3), 1.251 (t, 3H, J = 7.32 Hz, OCH_2CH_3), 1.386 (s, 9H, $(CH_3)_3C$). EI-MS calculated for $C_{16}H_{24}N_3O_5$ (M^+): *m/z* 337. Found: 337. Anal. Calcd for $C_{16}H_{23}N_3O_5$: C, 56.96; H, 6.87; N, 12.45. Found: C, 57.21; H, 6.96; N, 12.54.

Synthesis of 3-[*p*-(*N*-(*tert*-Butoxycarbonyl)aminomethyl)phenyl]-Δ^2-1,2,4-oxadiazolin-5-one (5). Compound **4** (36 g, 0.11 mol) was added to a solution of NaOH (17 g) in 300 mL of water, and the mixture was heated in a boiling water bath for 10 min. After the solution

became clear, the reaction mixture was cooled in an ice bath and acidified with acetic acid to produce a while precipitate. The precipitate was collected and recrystallized from ethanol−water (5:6) to yield 28 g of compound **5** as white crystal (87%). Mp 176−177 °C. ^{1}H NMR (DMSO-d_6): δ 7.441 (s, 1H, N*H*CH$_2$), 7.397−7.753 (m, 4H, aromatic H), 4.186 (d, 2H, NHC*H*$_2$), 1.385 (s, 9H, (CH$_3$)$_3$C). EI-MS calculated for $C_{14}H_{18}N_3O_4$ (M^+): *m/z* 291. Found: 291. Anal. Calcd. for $C_{14}H_{17}N_3O_4$: C, 57.72; H, 5.88; N, 14.42. Found: C, 57.61; H, 5.85; N, 14.28.

Synthesis of 3-[*p*-(*N*-(*tert*-Butoxycarbonyl)aminomethyl)phenyl]-3′-phenyl-4,4′-trimethylenedi-Δ^2-1, 2, 4-oxadiazolin-5-one (7). To a solution of compound **5** (15.5 g, 0.053 mol) in methanol (40 mL) was added a solution of KOH (3.0 g, 0.053 mol) in 50 mL of methanol. After stirring for 10 min, the solvent was removed in vacuo. The residue was dissolved in 80 mL of dry DMF, and 13.5 g (0.047 mol) of 3-phenyl-4-(3-bromopropyl)-Δ^2-1, 2, 4-oxadiazolin-5-one (*19*) was added. After 3 days of stirring at 50 °C, the precipitates were filtered off and the filtrate was evaporated in vacuo. Chloroform (30 mL) was added to the residue, and the organic phase was washed sequentially with 1.0 M NaOH and water. After drying over anhydrous $MgSO_4$, the solvent was removed in vacuo. The solid residue was crystallized from ethanol to give 14.9 g of compound **7** (57%) as white crystals. Mp 166−167 °C. ^{1}H NMR (DMSO-d_6): δ 7.415−7.699 (m, 9H, aromatic H), 4.228−4.241 (d, 2H, NH$_2$C*H*$_2$), 3.557−3.584 (m, 4H, C*H*$_2$CH$_2$C*H*$_2$), 1.746−1.774 (m, 2H, CH$_2$C*H*$_2$CH$_2$), 1.411 [s, 9H, (CH$_3$)$_3$C]. FAB-MS calculated for $C_{25}H_{28}N_5O_6$ (MH^+): *m/z* 493. Found: 493. Anal. Calcd for $C_{25}H_{27}N_5O_6$: C, 60.84; H, 5.51; N, 14.19. Found: C, 60.49; H, 5.56; N, 13.88.

Synthesis of 3-[*p*-(Aminomethyl)phenyl]-3′-phenyl-4,4′-trimethylenedi-Δ^2-1,2,4-oxadiazolin-5-one (8). Compound **7** (2.47 g, 0.005 mol) was dissolved in a mixed solution of trifluoroacetic acid (25 mL) and anisole (25 mL) at 0 °C. After stirring at room temperature for 1 h, the solvent was removed in vacuo. The residue was dissolved in water, and 1 N NaOH was added to bring the solution pH to ca. 9−10. A white precipitate was obtained after chilling the solution in an ice bath. Recrystallization of the precipitate from ethanol produced compound **8** (1.5 g, 74%). Mp 157−158 °C. ^{1}H NMR (DMSO-d_6): 7.485−7.704 (m, 9H, aromatic H), 3.551−3.584 (m, 4H, C*H*$_2$CH$_2$C*H*$_2$), 3.828 (s, 2H, NH$_2$C*H*$_2$), 1.724−1.1.783 (m, 2H, CH$_2$C*H*$_2$CH$_2$). FAB-MS calculated for $C_{20}H_{20}N_5O_4$ (MH^+): *m/z* 393. Found: 393. Anal. Calcd. for $C_{20}H_{19}N_5O_4 \cdot 1/2H_2O$: C, 59.7; H, 5.01; N, 17.4. Found: C, 59.96; H, 4.851; N, 17.17.

Synthesis of NH$_2$-C$_3$(BHam)$_2$. Compound **8** (1.0 g, 2.5 mmol) was added to 20 mL of 5% NaOH, and the mixture was heated with stirring at 90 °C for 10 min. After cooling to 0−4 °C in an ice bath, the reaction mixture was neutralized with 1 M HCl. A white precipitate was obtained after cooling the reaction solution on ice for several hours. The precipitate was collected and crystallized from ethanol to give 0.6 g (1.8 mmol) of NH$_2$−C$_3$(BHam)$_2$ as white crystals (72%). Mp 179−180 °C. ^{1}H NMR (DMSO-d_6): δ 9.705 (s, 2H, OH), 8.213 (s, 2H, N*H*$_2$-CH$_2$), 7.332−7.473 (m, 9H, aromatic H), 5.642−5.694 (m, 2H, *H*NCH$_2$CH$_2$CH$_2$N*H*), 4.037 (s, 2H, NH$_2$C*H*$_2$), 2.858−2.897 (m, 4H, HNC*H*$_2$CH$_2$C*H*$_2$NH), 1.366−1.392 (m, 2H, HNCH$_2$C*H*$_2$CH$_2$NH). FAB-MS calcd for $C_{18}H_{23}N_5O_2$ (MH^+): *m/z* 341. Found: 341. Anal. Calcd for $C_{18}H_{23}N_5O_2$: C, 63.32; H, 6.79; N, 20.51. Found: C, 63.42; H, 7.02; N, 20.28.

Preparation of C$_3$(BHam)$_2$−OST7 Conjugate. The conjugation reaction of NH$_2$−C$_3$(BHam)$_2$ with OST7 was performed according to the procedure described previously (*23*) with slight modifications as follows. To 0.5 mL of a solution of OST7 (9 mg/mL) in well-degassed 0.16 M borate buffer (pH 8.0) containing 2 mM ethylenediaminetetraacetic acid (EDTA) was added 25 μL of 2-IT (2 mg/mL) in the same buffer. After gentle agitation at room temperature for 1 h, excess 2-IT was removed by the centrifugation through gel-filtration columns packed with Sephadex G-50 (Pharmacia Biotech, Tokyo) equilibrated with 0.1 M PBS (pH 5.5) containing 2 mM EDTA. EMCS in DMF (50 μL, 40 mM) was added to an equal volume of NH$_2$−C$_3$(BHam)$_2$ (80 mM) in the same solvent. After stirring the reaction mixture for 30 min at room temperature, 20 μL of this solution was slowly added to the freshly thiolated OST7 solution (0.5 mL) and the reaction mixture was stirred gently at room temperature for 2 h. The solution was further agitated gently for 30 min after addition of iodoacetamide (20 μL, 10 mg/mL) to alkylate the unreacted thiol groups. The C$_3$(BHam)$_2$−OST7 conjugate was separated from unreacted small molecules using Sephadex G-50 column chromatography (1.5 × 37 cm) equilibrated and eluted with PBS (pH 7.0). The number of C$_3$(BHam)$_2$ chelates introduced per molecule of OST7 was estimated by measuring the number of thiol groups of OST7 before and after addition of the reaction mixture of EMCS and NH$_2$−C$_3$(BHam)$_2$ using 2,2′-dithiopyridine (*24*). C$_3$(BHam)$_2$−OST7 was characterized by SDS−PAGE using 4% stacking gels and 8% running gels according to the method of Laemmli under nonreducing conditions (*25*). After mixing with 4% SDS, the samples were immersed for 5 min in a boiling water bath and loaded on the gels at a concentration of 4.0 μg of protein per lane. Electrophoresis was performed with a current of 20 mA per gel until the bromophenol blue marker reached the bottom of the gel. After running, gels were stained with 0.02% Coomassie brilliant blue (CBB) R250 in 25% methanol/10% acetic acid, and subsequently destained by equilibrating with 5% acetic acid/2% glycerol.

^{99m}Tc Labeling of C$_3$(BHam)$_2$-OST7. C$_3$(BHam)$_2$−OST7 was labeled with ^{99m}Tc by reaction with [^{99m}Tc]-glucoheptonate. A freshly collected solution (3−4 mL) of $^{99m}TcO_4^-$ [1 mCi (37 MBq)/mL] was added to a vial containing lyophilized glucoheptonate (4 mg) and $SnCl_2$ (60 μg) under a nitrogen atmosphere and allowed to stand for 15 min at room temperature. Aliquots of this solution (200 μL) were added to the C$_3$(BHam)$_2$−OST7 solution (200 μL) of varying protein concentrations and incubated for 1 h at room temperature. Radiochemical purities of [^{99m}Tc]C$_3$(BHam)$_2$−OST7 were determined by TLC, CAE, size-exclusion HPLC, and SDS−PAGE. Autoradiography of the dried PAGE gels was carried out by placing them on X-ray film (Fuji Photo Film Inc., Tokyo, Japan) for 12 h.

Stability of ^{99m}Tc-Labeled C$_3$(BHam)$_2$-OST7. [^{99m}Tc]-C$_3$(BHam)$_2$−OST7 (0.2 mg/mL; 20 μL) was added to a tube containing 200 μL of freshly prepared murine plasma to a final protein concentration of 1.3×10^{-7} M. After incubating the solution at 37 °C for 6 and 18 h, the mixture was analyzed by CAE and TLC. Stabilities of [^{99m}Tc]C$_3$(BHam)$_2$−OST7 were also estimated in the presence of cysteine. A 10 μL aliquot of 1.2×10^{-6} M [^{99m}Tc]C$_3$(BHam)$_2$−OST7 in 0.1 M PBS (pH 7.0) was mixed with 10 μL of cysteine to make the final concentrations of cysteine in the range of 3.6×10^{-6} to 3.6×10^{-4} M. The mixture was incubated at 37 °C for 1 and 6 h and analyzed by TLC using 0.005 M PB (pH 7) as the eluent. In this TLC system, [^{99m}Tc]cysteine showed an

R_f value above 0.8, while [^{99m}Tc]C_3(BHam)$_2$−OST7 remained at the origin.

Preparation of [^{111}In]EMCS−Bz-EDTA-OST7 and [^{125}I]OST7. Conjugation of EMCS−Bz-EDTA to OST7 was performed by maleimide−thiol chemistry using 2-IT, and the conjugate was labeled with ^{111}In, as described previously (*24, 26*). The number of chelating agents attached per molecule of OST7 was 2.2 as determined by calculating the number of thiol groups per molecule of OST7 before and after conjugation with EMCS−Bz-EDTA. Radiochemical purity of [^{111}In]EMCS−Bz-EDTA-OST7 was over 92% as determined by CAE analysis. Direct radioiodination of OST7 was performed by the chloramine-T method (*27*). To 100 μL of OST7 (0.25 mg/mL) in 0.3 M phosphate buffer (pH 7.3) was added 2 μL of Na[^{125}I]I and 12.5 μL of chloramine-T solution (0.1 mg/mL) in the same buffer. After 10 of min incubation at room temperature, the reaction was terminated by addition of 3 μL of aqueous sodium bisulfite (0.7 mg/mL). [^{125}I]OST7 was purified by the centrifuged gel-filtration column method using Sephadex G-50 as described above. Radiochemical purity of the radioiodinated OST7 was over 97% as determined by CAE analysis.

Immunoreactivity Measurement. The immunoreactivities of [^{99m}Tc]C_3(BHam)$_2$−OST7 and [^{125}I]OST7 were determined as described previously (*20, 21, 23*). Single-cell suspensions from xenografted tumors [(1×10^4)−(1×10^7)] in 100 μL of Dulbecco's PBS were incubated with 100 μL of radiolabeled OST7s in microcentrifugation tubes (5.7 × 46 mm) for 2 h at 4 °C. After centrifugation at 10000*g*, the supernatant was aspirated off and the radioactivity was determined using an Aloka ARC-2000 auto-well γ system (Aloka, Tokyo).

In Vivo Studies. An aliquot of 120 μL of [^{99m}Tc]C_3(BHam)$_2$−OST7 [0.5 mCi (18.5 MBq)/0.2 mg/0.4 mL] or 50 μL of [^{111}In]EMCS−Bz-EDTA-OST7 [10 μCi (370 KBq)/40 μg/50 μL] was added to 3 mL of unmodified OST7 (0.2 mg/mL) in 0.1 M PBS (pH 7.0). The biodistribution of radioactivity after intravenous administration of each radiolabeled OST7 was monitored at 1, 3, 6, and 24 h postinjection into 5-week-old male ddY mice weighing 20−25 g (*28*). Groups of five mice each receiving ca. 20 μg of OST7 were used for the experiment (*20, 21, 23, 29*). Organs or tissues of interest were removed and weighed, and their radioactivities were determined using an Aloka ARC-2000 auto-well γ system.

An aliquot of 40 μL of [^{99m}Tc]C_3(BHam)$_2$−OST7 [0.5 mCi (18.5 MBq)/0.2 mg/0.4 mL] and 30 μL of [^{125}I]OST7 [1 μCi (37 KBq)/2.5 μg/10 μL] were added to 1 mL of unmodified OST7 (0.2 mg/mL). Athymic mice bearing osteogenic sarcoma were treated intravenously with 100 μL of the mixture. At 24 h postinjection, the animals were sacrificed and the organs or tissues of interest were removed and weighed, and the radioactivity in each organ or tissue was measured immediately for ^{99m}Tc and 3 days later for ^{125}I using an Aloka ARC-2000 auto-well γ system.

Statistical Analyses. Data are expressed as means (standard deviation) where appropriate. Results were statistically analyzed using unpaired Mann−Whitney test for in vivo studies. Differences were considered significant when p value was less than 0.05.

RESULTS

Synthesis of NH_2-C_3(BHam)$_2$. The asymmetrical bis(Ham) compound NH_2−C_3(BHam)$_2$ was synthesized according to the synthetic procedure reported previously for symmetrical bis(Ham) compounds (*19*). After protecting the amino group of *p*-(aminomethyl)benzonitrile (**1**) with Boc, the resulting compound **2** was reacted with hydroxylamine to prepare compound **3**. Treatment of compound **3** with ethyl chlorocarbonate gave compound **4**, which was cyclized to oxadiazoline derivative **5** by heating in alkaline solution. After conversion to the potassium salt, compound **5** was alkylated with compound **6** to produce an asymmetrical bis(oxadiazoline) precursor **7**. NH_2−C_3(BHam)$_2$ was obtained by deprotection of the Boc group by trifluoroacetic acid, followed by decyclization in alkaline solution. The overall yield was 19%.

Table 1. Radiochemical Yields of [^{99m}Tc]C_3(BHam)$_2$-OST7 at Different Antibody Concentrations

concentration of C_3(BHam)$_2$−OST7 conjugate (mg/mL)	labeling yields[a] (%)
2.0	98.1 ± 1.7
1.0	96.0 ± 1.5
0.5	94.5 ± 1.9
0.2	94.3 ± 1.7
unmodified OST7 (0.2 mg/mL)	<3

[a] ^{99m}Tc labeling was performed at room temperature for 1 h. Means ± s.d. of four experiments. Radiochemical yields were determined by CAE.

Preparation of ^{99m}Tc-labeled C_3(BHam)$_2$-OST7. C_3(BHam)$_2$−OST7 conjugate was prepared by converting the amine group of NH_2−C_3(BHam)$_2$ to a maleimide group with EMCS, followed by conjugation reaction of the maleimide groups with the thiol groups of 2-IT-modified OST7. The number of chelating agents attached per molecule of OST7 was estimated to be 1.9 by measuring the thiol groups of OST7 before and after the conjugation reactions (2.1 and 0.2, respectively). The amount of free thiol groups were negligible after treatment of the conjugate with iodoacetamide. The C_3(BHam)$_2$−OST7 conjugate showed a single elution profile on size-exclusion HPLC at a retention time identical to that of unmodified OST7 when measured at 280 nm (data not shown).

^{99m}Tc radiolabeling of the conjugate was performed by exchange reaction with [^{99m}Tc]glucoheptonate. Radiochemical yields of [^{99m}Tc]C_3(BHam)$_2$−OST7 at different antibody concentrations are summarized in Table 1. [^{99m}Tc]C_3(BHam)$_2$−OST7 was obtained in more than 95% radiochemical yields at antibody concentrations over 1 mg/mL. High radiochemical yields were also registered at lower antibody concentrations. Under these conditions, radioactivities associated with antibody fractions were less than 3% when unconjugated OST7 (0.2 mg/mL) was reacted with [^{99m}Tc]glucoheptonate. Figure 2 shows a CAE radioactivity profile of [^{99m}Tc]C_3(BHam)$_2$−OST7 when ^{99m}Tc labeling was performed at an antibody concentration of 0.2 mg/mL. Figure 3 shows a typical UV chromatogram of unmodified OST7 and a radiochromatogram of [^{99m}Tc]C_3(BHam)$_2$−OST7 when analyzed by size-exclusion HPLC. The radiochromatogram superimposed well on the spectrophotometric elution profile of unmodified OST7 at 280 nm.

SDS−PAGE profiles of ^{99m}Tc-labeled C_3(BHam)$_2$−OST7, C_3(BHam)$_2$−OST7 conjugate, and unmodified OST7 performed under nonreducing conditions are illustrated in Figure 4. The CBB-stained bands (B) of [^{99m}Tc]C_3(BHam)$_2$−OST7 (lane 1) and C_3(BHam)$_2$−OST7 (lane 2) showed single bands corresponding to unmodified OST7 (lane 3). The autoradiogram of [^{99m}Tc]C_3(BHam)$_2$−OST7 (A) showed a single radioactive band in the fraction identical to that of unmodified OST7.

Table 2 shows the time course of changes in antibody-bound radioactivity after incubation of [^{99m}Tc]C_3(BHam)$_2$−

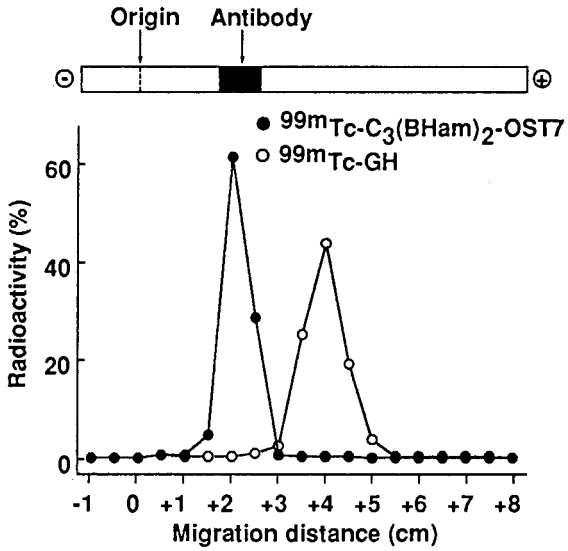

Figure 2. A typical radioactivity profile of [^{99m}Tc]C_3(BHam)$_2$−OST7 when analyzed by cellulose acetate electrophoresis.

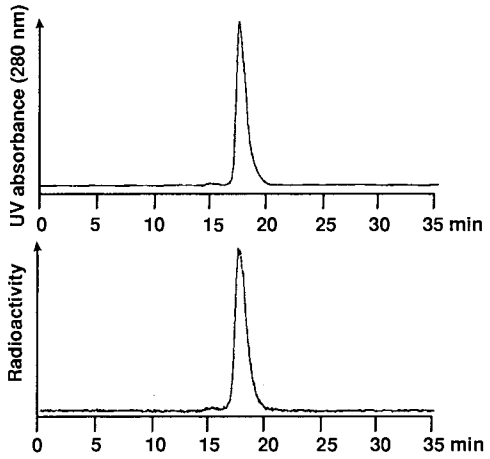

Figure 3. Size-exclusion HPLC profiles of the unmodified OST7 (UV 280 nm, top) and [^{99m}Tc]C_3(BHam)$_2$−OST7 (radioactivity, bottom).

OST7 in freshly prepared murine plasma at 37 °C. [^{99m}Tc]C_3(BHam)$_2$−OST7 showed only slight release of radioactivity after 18 h of incubation in plasma. Similar results were obtained by TLC analyses. Table 3 shows the radioactivity in the antibody fractions as a function of incubation time of [^{99m}Tc]C_3(BHam)$_2$−OST7 in buffered-solutions of different cysteine concentrations. [^{99m}Tc]C_3-(BHam)$_2$−OST7 remained stable after 6 h of incubation in the presence of 3.6×10^{-5} M cysteine. However, ca. 10% of the initial radioactivity was released from [^{99m}Tc]-C_3(BHam)$_2$−OST7 after 6 h of incubation in the presence of 3.6×10^{-4} M cysteine.

Immunoreactivity. Figure 5 shows the binding of [^{99m}Tc]C_3(BHam)$_2$−OST7 and [^{125}I]OST7 to KT005 cells as a function of cell number. No significant differences were observed in the cell-bound radioactivity between [^{99m}Tc]C_3(BHam)$_2$−OST7 and [^{125}I]OST7. No significant differences were observed in the cell-bound radioactivity between [^{99m}Tc]C_3(BHam)$_2$−OST7 and [^{125}I]OST7 when incubated with KT005 in the presence of varying concentrations of unmodified OST7 (data not shown).

In Vivo Studies. Table 4 shows the biodistribution of radioactivity after administration of [^{99m}Tc]C_3(BHam)$_2$−OST7 and [^{111}In]EDTA-Bz-EMCS−OST7 in normal mice. No significant differences were observed in the radioactivity levels of blood or spleen between [^{99m}Tc]C_3(BHam)$_2$−OST7 and [^{111}In]EDTA-Bz-EMCS−OST7 at all postinjection time points. [^{99m}Tc]C_3(BHam)$_2$−OST7 registered significantly ($p < 0.01$) lower radioactivity levels in the kidney and the liver at 24 h postinjection than those of [^{111}In]EMCS−Bz-EDTA-OST7. [^{99m}Tc]C_3(BHam)$_2$−OST7 also indicated higher levels of excretion radioactivity from the body as reflected by significantly higher amounts of radioactivity in the feces ($p < 0.01$). Low radioactivity levels were also observed in the stomach at all postinjection intervals.

Biodistributions of radioactivity after simultaneous administration of [^{99m}Tc]C_3(BHam)$_2$−OST7 and [^{125}I]-OST7 into nude mice bearing KT005 tumor cells are shown in Table 5. No significant differences were observed in radioactivity levels in the blood, lung, and the

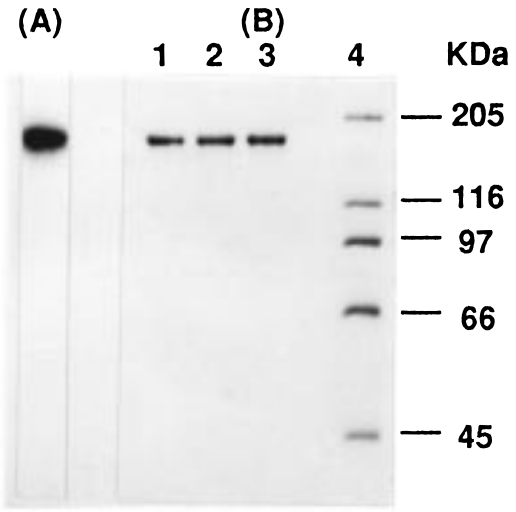

Figure 4. SDS−PAGE profiles of [^{99m}Tc]C_3(BHam)$_2$−OST7 (lane 1), C_3(BHam)$_2$−OST7 (lane 2), and unmodified OST7 (lane 3) as determined by CBB staining under nonreducing conditions. Molecular mass standards (lane 4) are myosin (205 kDa), *E. coli* β-galactosidase (116 kDa), rabbit muscle phosphorylase-*b* (97 kDa), bovine serum albumin (66 kDa), and hen egg white ovalbumin (45 kDa). The left lane (A) shows SDS−PAGE radioactivity profiles of [^{99m}Tc]C_3(BHam)$_2$−OST7 obtained by autoradiography.

tumor, although [^{99m}Tc]C_3(BHam)$_2$−OST7 showed slightly higher radioactivity levels in the liver, kidney, and intestine.

DISCUSSION

To assess the ability of tetradentate bis(Ham) ligands as chelating molecules for ^{99m}Tc labeling of polypeptides, bis(BHam) derivatives with polypeptide bindings sites were designed and synthesized. A prior study of ^{111}In labeling of antibodies using cyclic DTPA dianhydride as a chelating agent indicated that the induction of intramolecular cross-linking of antibodies interferes with ^{111}In complexation reaction with the DTPA moieties attached to antibodies and results in underestimation of the stability of ^{111}In-DTPA-labeled antibodies (*24*). For accurate estimation of bis(Ham) as a chelating molecule for ^{99m}Tc labeling of polypeptides, therefore, bis(BHam) derivatives with single polypeptide-binding sites were designed. We attempted to prepare bis(BHam) derivatives by a one-step reaction between 2-substituted 1,3-dibromopropanes with potassium 3-phenyl-Δ^2-1,2,4-oxadiazolin-5-one to introduce a functional group in the propylene backbone. However, the reaction of 2-substituted 1,3-dibromopropanes with the oxadiazoline derivative failed due to generation of propene derivative as the major product. Since the symmetrical bis(BHam) compounds can also be prepared after isolating monoalkylated hydroxamamide intermediates (*19*), similar synthetic procedures were employed for synthesis of the asymmetrical bis(BHam) derivative, NH_2−C_3(BHam)$_2$, as outlined in Scheme 1. Each intermediate compound was stable and easily purified by recrystallization. The final product, NH_2−C_3(BHam)$_2$, was a colorless crystal and was stable after storage for 1 year at 4−10 °C. The present synthetic procedure would allow versatile molecular design of asymmetrical bis(Ham) derivatives for further application to antibody fragments and peptides for diagnostic nuclear medicine.

[a] Expressed as percent injected dose per gram wet tissue. [b] Not significant. [c] Differences between [^{99m}Tc]C_3(BHam)$_2$-OST7 and [^{125}I]OST7 were analyzed by unpaired Mann−Whitney test. [d] Expressed as percent injected dose per tissue. [e] Not determined.

To estimate the ability of NH_2−C_3(BHam)$_2$ as a chelating molecule for polypeptides, stability estimation of ^{99m}Tc-labeled C_3(BHam)$_2$−OST7 should be performed using C_3(BHam)$_2$−OST7 that preserves the original immunoreactivity of the antibody. Among various procedures to conjugate amine compounds to polypeptides, we selected maleimide−thiol chemistry for lack of intra- or intermolecular cross-linking of polypeptide by this conjugation procedure (*23*, *24*, *26*, *29*). We attempted to purify the reaction product between NH_2−C_3(BHam)$_2$ and EMCS before the conjugation reaction with OST7. However, the purification of EMCS−NH_2−C_3(BHam)$_2$ from unreacted NH_2−C_3(BHam)$_2$ was found to be difficult using silica gel column chromatography due to high hydrophilic properties of the two compounds. While the reaction product of EMCS and compound **8** may be purified by column chromatography, decomposition of the maleimide group may proceed during hydrolysis of the oxadiazoline group. On the other hand, since deferoxamine was successfully conjugated to thiolated antibodies in situ without isolating the reaction product of deferoxamine and EMCS (*20*, *23*), similar procedures were employed for the preparation of C_3(BHam)$_2$−OST7. The stable linkage between OST7 and NH_2−C_3(BHam)$_2$ would also be useful to estimate the stability of ^{99m}Tc-bis(BHam) chelate in the OST7 conjugate for subsequent in vitro and in vivo studies. Since 2-IT was also utilized as a bifunctional chelating agent for ^{99m}Tc labeling of antibodies due to introduction of thiol groups *(30)*, the unreacted thiol

groups of OST7 were completely alkylated with iodoacetamide before ^{99m}Tc radiolabeling reactions. During conjugation and labeling, no fragmentation or dimerization of the antibody was observed (Figures 3 and 4). The lack of changes in immunoreactivity of OST7 was also confirmed by cell-binding studies (Figure 5).

Since $C_3(BHam)_2$ forms ^{99m}Tc complex over a wide pH range (*19*), complexation at pH of 7.0 was selected for physiological reasons. The exchange reaction with [^{99m}Tc]-glucoheptonate was selected to minimize the hydrolysis reaction of ^{99m}Tc during radiolabeling. High radiochemical yields were observed at final protein concentrations as low as 0.2 mg/mL after 1 h of incubation at room temperature as confirmed by size-exclusion HPLC and CAE analyses (Figure 3 and Table 1). Negligible amount of ^{99m}Tc incorporated into unmodified OST7 suggested selective complexation of ^{99m}Tc to $C_3(BHam)_2$ even when the chelate was covalently attached to high molecular weight polypeptides that possess endogenous ^{99m}Tc-binding sites such as imidazoles (*31*). This was supported by the selective complexation of ^{99m}Tc to bis(BHam) in the presence of an equimolar amount of IgG antibody (*19*). High stability of [^{99m}Tc]$C_3(BHam)_2$−OST7 was demonstrated by the almost unchanged antibody-bound radioactivity before and after incubation of [^{99m}Tc]$C_3(BHam)_2$−OST7 in murine plasma or in buffered-solutions containing varying amounts of cysteine (Tables 2 and 3). Although some decrease in the antibody-bound radioactivity was observed at high cysteine concentration, strong resistance of [^{99m}Tc]C_3(BHam)2-OST7 against cysteine transchelation was observed at a cysteine concentration similar to that in plasma (5×10^{-5} M). High stability of [^{99m}Tc]$C_3(BHam)_2$−OST7 in plasma and in the presence of cysteine also supported the selective complexation reaction of ^{99m}Tc to the $C_3(BHam)_2$ moiety in the $C_3(BHam)_2$−OST7 conjugate.

To further estimate in vivo stability, the biodistribution of the radioactivity after administration of [^{99m}Tc]$C_3(BHam)_2$−OST7 was compared with those of [^{111}In]-EMCS−Bz-EDTA-OST7 and [^{125}I]OST7. [^{111}In]EMCS−Bz-EDTA-OST7 was selected due to formation of ^{111}In chelate with high in vivo stability (*24, 32*) and conjugation procedure similar to those for [^{99m}Tc]$C_3(BHam)_2$−OST7. No significant differences were observed in the radioactivity levels in the blood between the two radiolabeled OST7s up to 24 h postinjection (Table 4), reinforcing the high stability of [^{99m}Tc]$C_3(BHam)_2$−OST7 in the blood. Low radioactivity levels in the stomach indicated the absence of reoxidation of ^{99m}Tc in $C_3(BHam)_2$−OST7 to $^{99m}TcO_4^-$ ion. The faster elimination rate of the radioactivity from the liver with [^{99m}Tc]$C_3(BHam)_2$−OST7 suggested that $C_3(BHam)_2$ might generate radiometabolites with much faster elimination rate from the lysosomal compartment of the liver after lysosomal proteolysis, as reflected by the higher radioactivity levels excreted from the body at 24 h postinjection. Since hepatobiliary excretion of the radioactivity was also observed after administration of [^{99m}Tc]$C_3(BHam)_2$ in mice (*19*), the rapid elimination rate of the radioactivity provides further evidence for the high in vivo stability of [^{99m}Tc]-$C_3(BHam)_2$−OST7, even after lysosomal proteolysis in the liver. The ability of $C_3(BHam)_2$ to form ^{99m}Tc chelate with high in vivo stability without impairing the biological reactivity of the parent polypeptides was confirmed by the similar tumor-to-blood ratios of the radioactivity between [^{99m}Tc]$C_3(BHam)_2$−OST7 and [^{125}I]OST7 in nude mice (Table 5). The slightly higher radioactivity levels of [^{99m}Tc]$C_3(BHam)_2$−OST7 in the liver, intestine, and kidney compared to those observed with [^{125}I]OST7 may reflect slightly slower elimination rates of radiometabolites derived from [^{99m}Tc]$C_3(BHam)_2$−OST7 than those of [^{125}I]OST7 (*32, 33*).

In conclusion, the findings in this study indicated that the newly designed $C_3(BHam)_2$ generated ^{99m}Tc-labeled antibodies with high in vivo stability at low protein concentrations with high radiochemical yields under mild reaction conditions, due to selective complexation of $C_3(BHam)_2$ with ^{99m}Tc. Such characteristics of $C_3(BHam)_2$ would render bis(Ham) derivatives useful as chelating molecules for ^{99m}Tc-labeled polypeptides. The absence of thiol groups in bis(Ham) molecules may also be advantageous for incorporation of ^{99m}Tc into peptides with disulfide bonds. Acceleration of the elimination rates from the liver and alternation of the excretion pathway from hepatobiliary to urine of [^{99m}Tc]$C_3(BHam)_2$ may constitute further program for clinical applications of the ligand system. The versatile synthetic procedure of bis(Ham) would be advantageous for such molecular design.

A procedure utilizing an activated ester approach for conjugation of unprotected hydroxamic acids to antibodies and peptides was recently reported. Here, an alternative method with advantages over the activated ester strategy is described. This protocol utilizes the hydrazone formation between a hydrazide derivative of the trihydroxamate ligand trisuccin and either a ketone derivative of antibody or the aldehyde groups, generated by oxidation of the carbohyrate residues. Thus, the trisuccin carboxylic acid (**1**) was derivatized with *tert*-butyl carbazate to the hydrazide **2**, and the protecting groups were removed by catalytic hydrogenation and acidolysis with TFA to afford the hydroxamate hydrazide **4**. Conjugation of **4** to monoclonal antibody CC49 was effected by two approaches: attachment through the amine (e.g., lysine) residues of the antibody or oxidation of the carbohydrate residues. The extent of conjugations were monitored by MALDI, through evaluation of the increases in molecular weights of the conjugates compared to the unconjugated antibody. The first approach utilizing a ketone linker (6-oxoheptanoic acid, OHA) which served as a hydrazide anchor, is being introduced in this report as a new technique for conjugation of hydrazide derivatives to proteins. The OHA approach proved to be a superior strategy over the aldehyde approach in the ease of the procedure and yield of protein recovery. It also had the advantage of yielding more control in adjusting the ligand-to-protein ratio and was therefore selected for protocol optimization. All conjugates resulting from both approaches were radiolabeled with ^{125}I and screened for their immunoreactivity. Furthermore, the conjugates prepared through the optimized OHA protocol were radiolabeled with both ^{99m}Tc and ^{125}I for which the radiolabeling yields and immunoreactivities are reported.

INTRODUCTION

Radiometal labeling of monoclonal antibodies (MAbs),[1] antibody fragments, and peptides has found a wide range of applicability in biology and medicine (*1*−*6*). A frequently used technique is the use of a heterobifunctional chelating agent which serves as a bridge between the metallic cation and the protein. Two requirements for such a linker to qualify as a potential labeling agent are (1) it should form metal chelation with high in vitro and in vivo stability, and (2) the linker as a whole should be biologically stable. Therefore, in addition to the metal complex stability, the overall usefulness of the labeled conjugate is dependent on the stability of the linker-protein bond (*7*−*9*). Premature cleavage of this bond may result in the release of the radionuclide before the construct reaches its intended target and will result in an insufficient target radioactivity dose for imaging or therapy, and an increase in background uptake in normal tissues. In an effort to design protein radiolabeling reagents capable of meeting these two requirements, we reported on the application of hydroxamate-derived bifunctional chelating agents (BCAs) to radiometal labeling of antibodies and peptides (*1*, *10*). Although the metal chelation of the hydroxamic acids had been well established, their utilization as BCAs was a new concept which turned out to be a challenging problem, due to the interference of the hydroxamate functionalities with the conjugation chemistries used for their attachment to a protein molecule. Our original procedure connected an O-benzyl-protected trihydroxamate, trisuccin, to MAbs, followed by removal of the benzyl groups by hydrogenation of the conjugate (*10*). Recently, we reported on an improved technique using the *o*-nitrophenol (ONP) activated ester of unprotected trisuccin (*11*). In this procedure, the fully deprotected hydroxamate was activated by ONP in the presence of a carbodiimide and used for the antibody conjugation without isolation. Due to the importance of the conjugation step and its effect on the subsequent application of the constructs, we continued our search for still better techniques. Our ultimate goal was a protocol in which stable derivatives of hydroxamic acids are conveniently and efficiently conjugated to the protein via a covalent bond which is stable under most

chemical and physiological conditions. Also of importance are the selectivity and site-targeting involved in the conjugation strategy. Electrophilic covalent coupling of BCAs to antibodies has traditionally been targeted at the amino terminal ends of polypeptide chains and ϵ-amino functions of the lysine residues, with the latter probably being the major site of reaction (*12*). A mechanistically different procedure for antibody conjugation of BCAs is utilization of the oxidized carbohydrate residues through Schiff base formation (*13, 14*). It has been postulated that derivatization of antibodies through this route would result in formation of conjugates with more preserved biological activities (*15*). The latter procedure was originally used for the attachment of horseradish peroxidase to an immunoglobulin (*16*) and was later extended to the conjugation of monoclonal antibodies (*12, 15*).

We report here two new protocols for the attachment of unprotected hydroxamate hydrazides targeted at two different sites of the MAb CC49, the lysine residues residing across the immunoglobulin molecule and the carbohydrate moieties of the hinge region. Although, in the case of this antibody, our results favor the former method, the latter protocol may also be useful for other glycoproteins and molecules containing oxidizable carbohydrate residues or suitable carbonyl functions. This, in turn, will have the benefit of reaction manipulation in tailoring a desired conjugation and more control on the reaction outcome.

EXPERIMENTAL PROCEDURES

General. The benzyl-protected trisuccin, **1**, was prepared as described previously (*10*). HPLC analyses were carried out on a Bio-Rad model 5000 Titanium system (Bio-Rad, Richmond, CA) equipped with model 1806 UV−vis detector and Beckman model 170 radioisotope detector, operated by ValueChrome software (Bio-Rad). For analytical SEC, a 7.5 mm × 25 cm G3000SW column (TosoHaas, Montgomeryville, PA) was used. PBS (10 mM) containing 10 mM Na_2SO_4 at pH 6.7 was used as solvent. Preparative SEC was carried out using sephadex G-25 columns (PD-10, Pharmacia Biotech AB, Uppsala, Sweden) eluted with DPBS. Mass spectra were run on an API III triple quadrupole mass spectrometer (PE-Sciex, Toronto, Ontario) in electrospray mode and PerSeptive Biosystems (Framingham, MA) Voyager Elite MALDI instruments. Microanalyses were performed by Atlantic Microlab (Atlanta, GA). *N*-Succinimidyl 6-oxoheptanoate was provided by Biolinx, Inc. (biolinx@aol.com). Metal-free purified water was obtained from a Milli-QF system (Millipore, Bedford, MA). Sodium [^{99m}Tc]-pertechnetate was purchased from Syncor (Birmingham, AL). ITLC was carried out on silica gel-impregnated glass fiber slides (Gelman Sciences, Ann Arbor, MI).

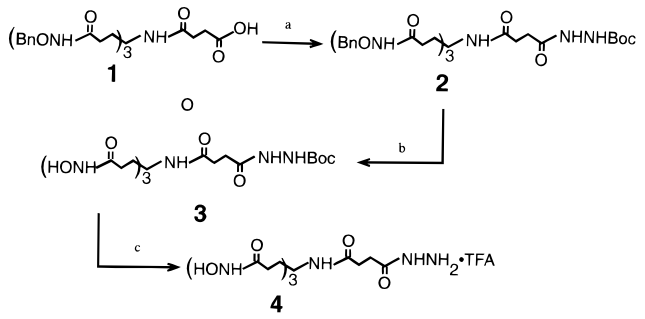
***N*-[Tris[2-[[*N*-(benzyloxy)amino]carbonyl]ethyl]-methyl]succinic *N′*-(*tert*-butyloxycarbonyl)hydrazide, 2.** To the solution of the trisuccin carboxylic acid **1** (500 mg, 0.75 mmol) in 10 mL of dry THF was added HOBT (102 mg, 0.75 mmol) and *tert*-butyl carbazate (Aldrich, 100 mg, 0.75 mmol). The mixture was cooled in an ice bath under argon and a solution of DCC (171 mg, 0.83 mmol) was added in small portions. The reaction was allowed to reach room temperature with stirring for 18 h. The solid was separated by filtration and the filtrate was concentrated in vacuo to an oily residue. The oil was redissolved in 50 mL of ethyl acetate, and the solution was washed with 10% citric acid, water, 10% $NaHCO_3$, and water. After drying over Na_2SO_4, the solvent was distilled in vacuo and the residue was charged into a silica gel column and eluted with chloroform and a 0 to 5% methanol gradient. Pooled fractions containing the product were distilled in vacuo and triturated with ether to afford 535 mg (92%) of a white powder. An analytical sample was prepared by crystallization from toluene/2-propanol (crystalline needles): mp 99.8−101.2 °C; 1H NMR (DMSO-d_6) δ 1.38 (s, 9H), 1.8 (m, 12H), 2.30 (m, 4H), 4.75 (s, 6H), 7.23 (bs, 1H), 7.35 (m, 15H), 8.65 (bs, 1H), 9.50 (bs, 1H), 10.95 (bs, 3H). Anal. calcd for $C_{40}H_{52}N_6O_{10}$: C, 61.84%; H, 6.75%; N, 10.82%. Found: C, 61.80%; H, 6.77%; N, 10.85%; ESMS (M + H) 777.

***N*-[Tris[2-[(*N*-hydroxyamino)carbonyl]ethyl]-methyl]succinic *N′*-(*tert*-butyloxycarbonyl)hydrazide, 3.** The hydrogenation procedure reported previously was used (*11*). Briefly, the protected hydroxamate **2** (500 mg, 0.71 mmol) was dissolved in 100 mL of HPLC-grade methanol and a slurry of 10% Pd/C (41 mg, 0.039 mmol) in methanol was added. The sealed flask was evacuated for 10 min with stirring and was charged with hydrogen gas at 10 psi, and the mixture was shaken for 65 h. The solvent was partially removed in vacuo to 10% of its original volume, the catalyst was removed by an Acrodisc syringe-tip 0.2 μm filter (Gelman Sciences, Ann Arbor, MI) and the solvent was distilled in vacuo. The light yellow glass was recrystallized from 2-propanol to obtain 310 mg (95%) of a white powder. mp 91.2−91.9 °C (dec). ^{1}H NMR (DMSO-d_6) δ 1.40 (s, 9H), 1.82 (m, 12H), 2.26 (m, 4H), 7.74 (bs, 1H), 8.64 (bs, 3H), 9.50 (bs, 1H), 10.30 (bs, 1H). Anal. Calcd for $C_{19}H_{34}N_6O_{10}$: C, 45.05%; H, 6.77%; N, 16.59%. Found: C, 45.15%; H, 6.79%; N, 16.60%. ESMS (M + H) 507.

***N*-[Tris[2-[[*N*-(hydroxy)amino]carbonyl]ethyl]-methyl]succinic hydrazide, 4.** Five milliliters of a mixture of trifluoroacetic acid, thioanisole, 1,2-ethanedithiol, and anisole (90:5:3:2, v/v) was added to the blocked hydrazide **3** (300 mg, 59 mmol) under argon and the resulting solution was allowed to stand at room temperature for 1 h. The solvent was distilled in vacuo and the solid residue was washed with hot 2-propanol to afford an off-white crystalline solid. The solid was dried in a vacuum over P_2O_5 to obtain 222 mg (92.5%) of the product. mp 79.3−82.6 °C (dec). ^{1}HNMR (DMSO-d_6) δ 1.78 (m, 12H), 2.32 (m, 4H), 7.28 (bs, 1H), 8.75 (bs, 2H), 10.30 (m, 4H). ESMS (M + H) 406.

Antibody Conjugation. Method A. The solution of the MAb CC49, reactive with the TAG-72 antigen expressed in carcinomas (*17*) (50 μL, 7 mg/mL), in DPBS was added to 300 μL of a 50 mM PBS buffer at pH 8.1. The resulting solution was stirred at 0 °C and the solution of OHA-NS (5.7 μg, 23.5 nmol) in 50 μL of DMF was added. After 90 min at 0 °C, the reaction was quenched by addition of 20 μL of 2 M glycine in the PBS buffer and the mixture was purified on a PD-10 column eluted with a 100 mM acetate buffer, pH 5.5. The elution was monitored by a UV flow-through detector, and the single MAb peak was collected in a 2 mL fraction. This was concentrated to 300 μL in a Centricon-50 concentrator (Amicon, Inc., Beverly, MA). To this solution, at room temperature and with stirring, was added the solution of the hydrazide **4** (0.12−1.2 μmol) in water (5−20 μL). The reaction mixture was stirred at room temperature for 90 min at which time 20 μL of $NaCNBH_3$ solution in water was added to a final concentration of 100 mM in $NaCNBH_3$. The resulting mixture was stirred gently at room temperature for 18 h followed by purification of the conjugate on a PD-10 column eluted with DPBS. The fraction containing the conjugate was concentrated to 300 μL as described above.

Method B. The solution of the MAb CC49 (50 μL, 7 mg/mL) in DPBS was added to 400 μL of 100 mM acetate buffer at pH 4.2 containing 0.3% EDTA. To this solution was added a solution of sodium periodate in water to a final molar ratio of 1000 with respect to the MAb (32 mM in $NaIO_4$). The mixture was stirred at 5 °C in the dark for 1 h followed by purification of the oxidized MAb on a PD-10 column eluted with 50 mM acetate buffer, pH 4.2. The MAb-containing fraction was concentrated to 200 μL in a Centricon-50 concentrator. A solution of the hydrazide **4** (0.12−1.2 μmol) in 200 mM acetate buffer at pH 5.5 was added to the MAb solution at room temperature with stirring, followed after 90 min by the addition of 15 μL of $NaCNBH_3$ in water to a final concentration of 100 mM in $NaCNBH_3$. The solution was stirred at room temperature for 18 h, and the conjugate was purified by gel filtration on a PD-10 column eluted with DPBS.



MALDI Analyses. Samples were analyzed in the positive mode on a Voyager Elite mass spectrometer with delayed extraction technology (PerSeptive Biosystems, Framingham, MA). The acceleration voltage was set at 25 kV, and 50−100 laser shots were summed. Sinapinic acid (Aldrich Chemical Co., Milwaukee, WI), dissolved in a 1:1 (v/v) mixture of acetonitrile:0.1% TFA, was used as the matrix. Bovine serum albumin (1 pmol/μL) was added as an internal standard. Equal volumes of sample and matrix were mixed on a smooth plate. The average of three measurements was used. For each reaction, the intact MAb was scanned as the control for evaluation of the following conjugation. In the OHA method, the molecular weight increase of the OHA-MAb intermediate was calculated using the unconjugated control. The molecular weight of this intermediate then served as the control to measure the increase in the molecular weight of the final product conjugate. Each difference in molecular weight was divided by the molecular weight of the corresponding linker to measure the linker:MAb ratio. For the SOX method, with no intermediate conjugate, the molecular weight difference between the final conjugate and the starting intact MAb was used.

Technetium-99m Radiolabeling. Sodium [^{99m}Tc]-pertechnetate (5 mCi in saline) was added to the solution of the MAb conjugate in DPBS. Under oxygen-free conditions, 25 μL of a 2 mg/mL solution of stannous chloride, containing 40 mg/mL of 2-hydroxy-2-methyl propionic acid, was added, and the mixture was incubated at 35 °C for 45 min. The labeled conjugate was then purified on a PD-10 column eluted with DPBS containing 0.1% HSA.

Iodine-125 Radiolabeling. A standard iodogen radiolabeling method was used (*18*). Briefly, 10 mg of iodogen was dissolved in 1 mL of chloroform, and 5 μL of this solution was dispensed into a vial containing a polystyrene bead. The bead was then dried under an argon flow. Sodium [^{125}I]-periodate (5 mCi/bead) was added, followed by 5× (v/v) of a pH 7.6 phosphate buffer. The MAb was added, the mixture was incubated for 15 min, and the labeled MAb was purified on a PD-10 column eluted with 0.1% HSA in DPBS.

Immunoreactivity Screening. Polystyrene beads (6.4 mm, specular finish) were coated with mucin (Sigma) in PBS (4.4 mg/100 mL) overnight and were washed and blocked with 0.1% HSA. For each assay, a control test tube containing no bead, as a counting standard for [^{99m}Tc]- or [^{125}I]-CC49, and a nonspecific binding tube containing the bead and 5 μL of a 5 mg/mL solution of the unlabeled MAb as a competitor of the labeled CC49, were used. Other tubes contained decreasing concentrations (1:2 to 1:200) of the unlabeled MAb. To all tubes were added 100 μL of the labeled MAb CC49 (12000−20000 cpm) followed by vortexing at room temperature for 1 h. All tubes, except the counting standard, were washed with DPBS, the beads were transferred into clean test tubes and were counted in a γ counter for 1 min. The percent of the radioactivity bound to the mucin-coated beads were calculated. The inverse of the percent binding values was plotted against the cold MAb concentrations. Extrapolation to infinite MAb concentration determined the percent immunoreactivity[2] of the labeled MAb CC49.

RESULTS AND DISCUSSION

Since the introduction of our first hydroxamate BCA, trisuccin (*10*), we have devoted considerable effort to develop a flexible and efficient conjugation protocol for the covalent attachment of unprotected hydroxamate ligands to proteins and peptides (*1, 11*). Our ultimate goal was establishing a protocol which uses a stable derivative of hydroxamic acids to target a specific function on the protein, generating a stable hydroxamate−protein bond with retention of both the biological activity of the protein or peptide moiety and the metal-chelating property of the hydroxamate ligand. The stability and shelf life duration of the BCA would be of importance especially for the development of a radiolabeling kit. Recently, we reported a procedure in which an *o*-nitrophenyl activated ester of the hydroxamic acid was used for conjugation to the amine residues of the MAb CC49, as well as a synthetic peptide, used as model proteins (*11*). In this report, we introduce a newer technique which utilizes a suitably functionalized yet stable derivative of trisuccin which is capable of conjugation to the same model protein under mild reaction conditions.

Synthesis. The hydrazide derivative of trisuccin was prepared in three steps from the protected carboxylic hydroxamate **1**, as shown in Scheme 1. Thus, compound **1** was coupled to *tert*-butyl carbazate by a standard DCC/HOBT reaction and the product **2** was hydrogenated to remove the benzyl protecting groups. This hydrogenation protocol had been developed previously (*11*) to minimize or eliminate the overreduction of the hydroxamate functions (*19*). All mass spectroscopic and NMR data indicated hydrogenation only to the desired extent with no overreduced products formed. Compound **3** was further deprotected by acidolysis to afford the final product **4**. All intermediates and the final product were analyzed

[2] The percent immunoreactivity refers to the fraction of the immunoreactive radiolabeled antibody as determined by its binding at infinite antigen excess.

by standard techniques which identified the expected structures. The overall yield of the synthesis was 72%.

Protein Conjugation. Two methods for the conjugation of **4** to the MAb CC49 were used: a linker-mediated technique (the OHA method, A), targeting the lysine residues of the protein, and an oxidation-mediated technique (the SOX method, B), targeting the carbohydrate residues of the antibody.

The OHA Method. The linker-mediated technique is a two-step process in which a hydrazide-binding molecule is first introduced into the protein to serve as the *anchor* for the incoming BCA. In the second step, a molar excess of the hydrazide-containing BCA is added to target the ketone function of the anchor. The rationale for this approach is based on two considerations: (1) the higher rate of condensation of the of hydrazide groups with ketones at the pH range of $5 < pH < 6$, and (2) the use of a large excess of the hydrazide with respect to the available protein $-NH_2$ groups. To optimize this procedure, we first carried out a number of conjugations to assess the general trend of the reaction and then used these results to optimize the protocol. Since the selected lysine residues of MAbs are readily available for conjugation and their modification, carried out under appropriate conditions, does not result in the loss of biological activity, we selected this residue to build the hydrazide-binding scaffold on the protein as shown in Scheme 2. Thus, *N*-succinimidyl 6-oxoheptanoate (OHA-NS, **5**) was selected as the bifunctional linker due to its ability to react with the lysine ϵ-amino groups through the activated ester moiety on one end and to a hydrazide through its ketone function, on the other. The OHA-NS was conjugated to MAb CC49 through standard N-hydroxysuccinimide active ester procedures. The reactions were generally complete within an hour or less and showed high coupling efficiencies, i.e., the experimentally measured number of linkers per MAb as compared to their theoretical values. It should be noted that while the kinetics of this reaction was not quantified, we observed that the number of linkers attached to the antibody, as measured by MALDI, did not increase any further by an increase in the incubation time. These data, for different OHA-NHS:CC49 mole ratios, are shown in Table 1. In the second step of the process, the hydroxamate hydrazide **4** was reductively coupled to the OHA−protein conjugate **6** in a low-pH medium to afford the final product conjugate **7**. The low pH of this reaction provides the advantage of a selective coupling between the hydrazide function of the hydroxamic BCA and the implanted ketone group of the OHA handle. While amines undergo only very slow reactions with ketones at pH 5.0−5.5, hydrazides condense quite readily with ketones at this pH range to produce the corresponding hydrazone (*20*). This selectivity is an important feature of the hydrazide functionality, which prevents the competing reaction of the endogenous amine functions of the protein.[3] These competing reactions may complicate the outcome of the conjugation process in the form of inter- or intramolecular protein condensations. To further stabilize the conjugate, the hydrazone bond was reduced under mild conditions with sodium cyanoborohydride, to the corresponding substituted hydrazide (*21*). The final product conjugates were analyzed by MALDI to evaluate the number of ligands incorporated into the protein molecule. These results for the conjugation of trisuccin hydrazide **4** to CC49 are shown in Table 2. Under the unoptimized conditions of Table 2, even at a high OHA:MAb ratio of 9, and at **4**:MAb ratios of 20 and below, the extent of conjugation was negligible. A larger difference in the molecular weights appeared at **4**:MAb ratios of >50, where the increase continued even at a lower OHA:MAb of 3.

Table 1. Conjugation Efficiencies of 4-CC49 Formation as a Function of OHA:MAb Mole Ratios[a,b]

conjugate	OHA:MAb[c]	OHA:MAb[d]	**4**:Mab[d]

The SOX Method. The in situ conversion of the carbohydrate moieties of an antibody to aldehyde groups by oxidizing agents, followed by reductive amination by an NH_2-containing molecule, has been reported (*14, 16*). In our earlier approaches, we attempted without much success to apply this technique to the conjugation of an aminohydroxamate to MAbs (*11*). We ascribed this lack of reaction to the low carbohydrate content of the IgGs (*22*) and did not further pursue the strategy. Interested in the development of conjugates with highly preserved immunoreactivities, we decided to investigate the oxidation method again, this time with a hydrazide (**4**) instead of an amine. This approach is shown in Scheme 3. Thus, the Mab CC49 was oxidized with sodium periodate in a low-pH acetate buffer to prevent self-condensation of the protein. After purification of the oxidized antibody, the trisuccin hydrazide **4** was added and the pH was raised to activate the hydrazide. Several reactions at different **4**:MAb ratios were carried out, and the conjugate product (**9**, Scheme 3) was analyzed by MALDI. In contrast to

[3] Safavy, A., unpublished results. The selective hydrazide-ketone coupling reported here has also been confirmed by our work on the synthesis of a conjugate of trisuccinn hydrazide with an 8-amino acid peptide, containing an unprotected lysine residue and the OHA linker on the N-terminal. No detectable coupling of the hydrazide with the side-chain amine of lysine was observed. These results will be submitted for publication shortly.

Scheme 3[a]

[a] (a) $NaIO_4$, acetate buffer, pH 4.2; (b) **4**, acetate buffer, pH 5.5, $NaCNBH_3$.

the OHA method, the oxidation reactions generally showed lower yields of final product recovery. Closer analyses of these reactions revealed that a considerable portion of the protein was lost due to self-condensation as evidenced by the formation of an insoluble precipitate. This loss of product was found to be pH dependent: to activate the amino groups of a BCA for condensation with an aldehyde, the pH of the solution has to be raised from the pH at which the antibody was oxidized. At this stage, the native amine residues of the protein may start condensing with the newly formed aldehydes, resulting in higher molecular weight aggregates. This may explain why our earlier attempts with an amino-trisuccin (*11*) were not successful. With the hydrazide **4**, however, it was possible to use a lower pH for the condensation reaction, and we were able to isolate the desired product, albeit at a low yield. Furthermore, it was found that the oxidation step of this approach was quite sensitive toward concentration of the oxidizing agent. At $NaIO_4$ concentrations above 50 mM, the MALDI showed considerable amounts of fragmentation of the MAb. An optimized protocol for conjugation of **4** to CC49 was, however, worked out, as shown in the Experimental Procedures, which resulted in a **4**:CC49 ratio of 2.5 and an immunoreactivity of 40% for the ^{125}I-labeled conjugate.

Optimization of the Conjugation Protocol. Because no special immunoreactivity advantages were realized from the oxidation method, we chose the OHA method for optimization and evaluated further modifications accordingly. The results of Table 1 (column 3, the OHA:MAb MALDI values) show that the average efficiency[4] of the first step, conjugation of OHA to the MAb, was 38.5 ± 2.8% at a buffer pH of 7.5. Increasing the pH to 8.1 increased this yield to 80 ± 20% as shown by the OHA:MAb ratios of Table 2 (column 2). The latter pH was therefore used for all OHA couplings which consistently showed coupling yields within the same range or higher (Table 3), according to the MALDI analyses. We further considered that the 7-carbon structure of OHA may impart some degree of lipophilicity which may pull the linker deep inside of the antibody molecule due to hydrophobic forces. This hydrophobic repulsion may, in turn, "*hide*" the ketone residue from a reactive collision with the incoming hydrophilic hydrazide. To overcome this problem, we increased the organic character of the reaction medium by lowering the ionization power of the reaction buffer and introducing 2-propanol as the cosolvent. Indeed, these modifications did increase the conjugation efficiency, as shown in Table 3. The measured ratios for conjugates 50:1 and 100:1 (**L** and **M** of Table 3, respectively), for instance, are higher or comparable to those for 500:1 and 1000:1 conjugates obtained under unoptimized conditions (**J** and **K** of Table 2, respectively). Compounds **L**−**P** (Table 3) were radiolabeled with both ^{99m}Tc and ^{125}I, for evaluation of their labeling efficiencies and immunoreactivities as shown in Table 4. The use of ^{125}I instead of a radiometal has the advantage of excluding the effects of the metallic cation and associated labeling chemistries on the immunoreactivity, thus revealing the pure effect of the BCA conjugation. These would constitute reference values against which the immunoreactivity of the radiometal-linked antibody could be compared. Immunoreactivities were estimated through a modified Lindmo assay (*23*). The RYs for ^{99m}Tc labeling of the conjugates and their specific activities increased with an increase in the L:MAb ratio while the RYs for iodinations did not significantly change indicating the lack of dependence of this labeling on the number of metal-chelating ligands. Interestingly, all immunoreactivities of the ^{99m}Tc-labeled antibodies were slightly lower than those for the ^{125}I-labeled conjugates. This observation may show an expected effect of the metal on the overall structure of the protein.

CONCLUSION

The work described in this report introduces two new strategies for the conjugation of unprotected hydroxamic acids to suitable proteins, peptides, and other molecules of biological and medicinal interest. The technique utilizes a new derivative of our trihydroxamate ligand, trisuccin, containing a hydrazide function and capable of forming a hydrazone with carbonyl-containing molecules. Two important advantages of this new method are (1) the use of a stable derivative of hydroxamic acids, as opposed to those with more limited stabilities (e.g., activated esters) (*11*), and (2) the chemical compatibility of the hydrazide and hydroxamate functionalities. Conjugation may be conducted through two different routes: in the ketolinker-mediated path, the hydroxamate hy-

[4] The average efficiencies (AEs) were calculated from the following equation: $AE = 100\{\sum(n, i=1)[(OHA:MAb)_E/(OHA:MAb)_T]/n\}$, where n is the number of conjugates in a series, $[OHA:MAb]_E$ and $[OHA:MAb]_T$ are the experimental and theoretical linker-to-MAb ratios, respectively.

drazide is directed to a carbonyl function, anchored on the protein molecule during a previous step; in the sugar oxidation route, the hydroxamate is directed toward the in situ generated aldehydes. These studies indicated that the former method was a more efficient technique which better preserved the structural integrity of the protein. As a whole, this new strategy may constitute a useful option in the covalent attachment of unprotected hydroxamates to molecules with biological, industrial, and synthetic applications.

Conjugation of Dipeptide to Fluorescent Dyes Enhances Its Affinity for a Dipeptide Transporter (PEPT1) in Human Intestinal Caco-2 Cells

Hiroshi Abe,[†] Momoko Satoh,[†] Seiji Miyauchi,[†] Satoshi Shuto,[‡] Akira Matsuda,[‡] and Naoki Kamo*[,†]

Revised Manuscript Received November 5, 1998

Dipeptide transporters in small intestine have a very wide substrate specificity, so that the transporter sometimes serves as a carrier for peptide-like compounds. We have synthesized dipeptide analogues conjugated at an ϵ-amino group of Lys in Val-Lys or Lys-Sar with fluorescent compounds such as fluorescein isothiocyanate and coumarin-3-carboxylic acid. Uptakes of these peptide analogues were examined by measuring intracellular accumulations into monolayers of the human intestinal epithelial cell line Caco-2 expressing the dipeptide transporter PEPT1. Kinetic analysis and effects of addition either of uncoupler (protonophore) or by Gly-Sar, one of the good substrates of PEPT1, revealed that fluorescent dipeptides were taken up by passive diffusion. In contrast, these analogues remarkably inhibited the Gly-Sar uptake by Caco-2 cells. Among the fluorescent analogues synthesized in this paper, Val-Lys(Flu) was the most potent competitive inhibitor against the Gly-Sar uptake with an inhibition constant of 5 μM. This value is the smallest among those ever reported: Val-Lys(Flu) has the highest affinity for PEPT1 among chemicals ever reported. The importance of the hydrophobic part of the substrate was pointed out.

INTRODUCTION

Dipeptide transporters in small intestine play an important role in the efficient absorption of small peptides following the digestion of dietary proteins (*1*). Due to the structural diversity of these oligopeptides, the peptide transporter is believed to have very broad substrate specificity. In some cases, this transporter serves as a carrier for pharmacological-active peptide-like compounds, which are exemplified by oral β-lactam antibiotics (*2*−*4*), the anti-neoplastic agent bestatin (*5*), and angiotensin-converting enzyme (ACE) inhibitors (*6*, *7*).

From a study on structure−activity relationship, Kramer et al. (*4*) proposed the essential structure of a substrate that is recognized and transported by the intestinal dipeptide/oligopeptide transporter. The requisite structure has the peptide core with a free negatively charged C-terminal group; a large extent of bulkiness of the side chain of the C-terminal amino acid is allowed, as exemplified by one of the substrates having high affinity, ACE inhibitor captopril (*6*, *7*). An N-terminal amino group or a weakly basic group at the N-terminals also seems essential (*8*); a wide variety in chemical structure or bulkiness of the side chain is allowed as true of the C-terminal.

The dipeptide transporter with large capacity and broad specificity could be used as a shuttle system to increase intestinal absorption of poorly absorbable drugs by conjugation of these drugs to a dipeptide or tripeptide core. On the basis of this idea, we synthesized conjugated dipeptide analogues: the ϵ-amino group of Lys in Val-Lys or Lys-Sar was conjugated with fluorescent dyes such as fluorescein isothiocyanate (FITC, abbreviated as Flu) or coumarin-3-carboxylic acid (Coum).[1] We chose these two peptides as a dipeptide core, since they might not be digested by peptidase in the intestine (*9*). The reason for our choice of Lys is the existence of an amino group at the ϵ-position to which we could easily add the fluorescent dye, a model of a poorly absorbing drug. The fluorescence of the bioconjugate allows easy assay of the accumulation of these peptide analogues into cells.

Unfortunately, contrary to our expectations, these fluorescent peptide analogues were not transported by PEPT1 in Caco-2 cells. Quite interestingly, however, the affinity of these analogues to PEPT1 was very high; Val-Lys(Flu) competitively inhibited the Gly-Sar uptake by Caco-2 cells with an inhibition constant of 5 μM. This figure is the smallest of all reported values for inhibitors and substrates of PEPT1: this fluorescent peptide analogue has the highest affinity for PEPT1 among chemicals ever reported.

MATERIALS AND METHODS

Materials. Carbonyl cyanide *m*-chlorophenylhydrazone (CCCP), Coum, and glycylsarcosine were purchased from Sigma Chemical Co. (St. Louis, MO). [^{14}C]glycylsarcosine ([^{14}C]Gly-Sar) (1.78 GBq/mmol) was purchased from Daiichi Pure Chemicals Co., Ltd. (Ibaraki, Japan).

The culture medium (RPMI 1640) and fetal bovine serum (FBS) were purchased from GIBCO BRL Life Technologies (Grand Island, NY). THF was purchased as a dehydrated solvent from Kanto Chemical Co. Inc. (Tokyo, Japan). DMF was distilled from CaH_2 at reduced pressure. Toluene and Et_2O were distilled from sodium metal/benzophenone ketyl. Unless otherwise stated, starting materials were obtained from commercial suppliers and were used without further purification. All amino acids used were L-isomer. Boc-Val and Boc-Lys(Cbz) were purchased from Peptide Institute, Inc. (Osaka, Japan). Lys(Cbz)-O*t*-Bu, Lys(Cbz)-OMe and Sar-O*t*-Bu were purchased from Kokusan Chemical Co. Inc. (Tokyo). FITC was purchased from Molecular Probes Inc. (Eugene, OR). Other chemicals used were of highest purity available.

Synthesis. *General Procedures.* ^{1}H NMR spectra were obtained on a JEOL EX270 or Bruker ARX500 and are given in parts per million (δ) relative to either tetramethylsilane or the solvent signal as internal reference ($CHCl_3$, 7.27 ppm; DMSO, 2.49 ppm). Splitting patterns are designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad. Analytical thin-layer chromatography was carried out on silica gel 60 (Merck, 70−230 mesh or 230−400 mesh). All reactions were performed under a nitrogen atmosphere, unless stated otherwise.

Synthesis of Dipeptide Analogues. Boc-Val-Lys(Cbz)-Ot-Bu (5). A mixture of Boc-Val (3.26 g, 15 mmol), Lys(Cbz)-O*t*-Bu·HCl (5.05 g, 15 mmol), HOBt (6.19 g, 30 mmol), and DMAP (1.83 g, 15 mmol) in DMF (120 mL) were stirred at 0 °C for 15 min; then WSCD·HCl (2.93 g, 15.3 mmol) was added. After 30 min, the reaction mixture was warmed to room temperature and stirred for a further 2 h. The mixture was diluted with EtOAc (300 mL) and washed successively with 0.6 M citric acid (150 mL), H_2O (150 mL), aqueous saturated $NaHCO_3$ (150 mL), H_2O (150 mL), and brine (100 mL), then dried (Na_2SO_4) and concentrated. The resulting residue was purified by column chromatography (SiO_2, 75:1 $CHCl_3$-MeOH) to give **5** (7.02 g, 87% as a white amorphous powder). ^{1}H NMR ($CDCl_3$, 270 MHz): 0.84 (3 H, d, J = 6.6 Hz, Val-CH_3), 0.93 (3 H, d, J = 6.6 Hz, Val-CH_3), 1.20−1.87 (24 H, m, Lys β, γ, δ −CH_2, 2 × *t*-Bu), 2.06−2.11 (1 H, m, Val β-CH), 3.11−3.25 (2 H, m, Lys ϵ-CH_2), 4.00 (1 H, dd, J = 6.2 Hz, Val α-CH), 4.44 (1 H, ddd, J = 3.8, 7.6, 8.7 Hz, Lys α-CH), 5.09 (2 H, s, PhCH_2), 5.21 (1 H, m, Val α-NH), 5.34 (1 H, br s, Lys ϵ-NH), 6.64 (1 H, d, J = 7.6 Hz, Lys α-NH), 7.35−7.38 (5 H, m, Ph).

*Boc-Val-Lys-Ot-Bu·HCl (**6**).* A solution of **5** (6.3 g, 11.8 mmol) in AcOH (250 mL) containing 10% Pd/C (500 mg) was stirred under atmospheric pressure of hydrogen for 4 h. The catalyst was filtered off by Celite filtration. The filtrate was diluted with toluene and concentrated until no AcOH remained. The crude oil was dissolved in MeOH−H_2O (10:1, 100 mL), and the solution was put on a Diaion WA-30 resin column (HCl form), which was developed with MeOH−H_2O (10:1). The eluent was concentrated, and the resulting residue was azeotroped with toluene (×2) to give **6** (5.0 g, 100% as a white solid). ^{1}H NMR ($CDCl_3$, 270 MHz): 0.93 (3 H, d, J = 6.6 Hz, Val-CH_3), 1.00 (3 H, d, J = 6.6 Hz, Val-CH_3), 1.14−1.89 (24 H, m, Lys β, γ, δ-CH_2, 2× *t*-Bu), 2.08−2.15 (1 H, m, Val β-CH), 3.07 (2 H, br, Lys ϵ-CH_2), 4.24 (1 H, dd, J = 5.3, 8.6 Hz, Val α-CH), 4.37−4.39 (1 H, m, Lys α-CH), 5.58 (1 H, d, J = 9.9 Hz, Val α-NH), 7.74 (1 H, d, J = 7.3 Hz, Lys α-NH), 8.27 (3 H, br, Lys ϵ-NH_3).

*Boc-Val-Lys(Flu)-Ot-Bu (**9a**).* FITC (269 mg, 0.690 mmol) was added to a solution of **6** (308 mg, 0.726 mmol) in DMF (20 mL), followed by Et_3N (101 μL, 0.724 mmol) at 0 °C, and the mixture was stirred at the same temperature for 15 min and then at room temperature for 30 min. The reaction mixture was diluted with EtOAc (50 mL) and washed successively with 0.6 M citric acid (40 mL), H_2O (30 mL), and brine (20 mL), then dried (Na_2SO_4) and concentrated. The resulting residue was purified by column chromatography (SiO_2 15:1:0.08 $CHCl_3$-MeOH−AcOH) to give **9a** (525 mg, 96% as a yellow powder). ^{1}H NMR (DMSO-d_6, 500 MHz): 0.83 (3 H, d, J = 6.9 Hz, Val-CH_3), 0.87 (3 H, d, J = 6.9 Hz, Val-CH_3), 1.23−1.77 (24 H, m, Lys β, γ, δ −CH_2, 2× *t*-Bu), 1.94 (1 H, m, Val β-CH), 3.51 (2 H, br, Lys ϵ-CH_2), 3.85 (1 H, dd, J = 7.9 Hz, Val α-CH), 4.14 (1 H, dd, J = 7.9, 13.4 Hz, Lys α-CH), 6.57 (2 H, dd, J = 2.0, 8.7 Hz, xanthene H-2′, H-7′), 6.60 (1 H, d, J = 8.8 Hz, Val α-NH), 6.61 (2 H, d, J = 8.7 Hz, xanthene H-1′, H-8′), 6.68 (2 H, d, J = 2.0 Hz, xanthene H-4′, H-5′), 7.18 (1 H, d, J = 8.3 Hz, H-3), 8.05 (2 H, m, Lys α-NH, Lys ϵ-NH_3), 8.24 (1 H, br, H-6), 9.85 (1 H, br, NH), 10.11 (2 H, s, 2× OH). FAB−HRMS calcd for $[C_{41}H_{50}N_4O_{10}S + H]^+$: 791.3325. Found: 791.3307.

*Val-Lys(Flu)·HCl (**10a**).* A mixture of **9a** (467 mg, 0.591 mmol) in THF (5 mL) and 4 M HCl/dioxane solution (30 mL) was stirred at room temperature for 30 min and evaporated under reduced pressure. The resulting residue was triturated with Et_2O and dried in vacuo to give **10a** (397 mg, 100% as an orange powder). ^{1}H NMR (CD_3OD, 270 MHz): 1.09 (3 H, d, J = 7.3 Hz, Val-CH_3), 1.12 (3 H, d, J = 7.3 Hz, Val-CH_3), 1.47−2.03 (6 H, m, Lys β, γ, δ −CH_2), 2.26 (1 H, m, Val β-CH), 3.66 (2 H, m, Lys ϵ-CH_2), 3.82 (1 H, d, J = 5.5 Hz, Val α-CH), 4.47 (1 H, m, Lys α-CH), 7.20 (2 H, dd, J = 2.2, 9.1 Hz, xanthene H-2′, H-7′), 7.34 (2 H, d, J = 2.2 Hz, xanthene H-4′, H-5′), 7.40 (1 H, d, J = 8.3 Hz, Ar H-3), 7.61 (2 H, d, J = 9.1 Hz, xanthene H-1′, H-8′), 8.12 (1 H, dd, J = 2.2, 8.3 Hz, Ar H-4), 8.57 (1 H, d, J = 2.2 Hz, Ar H-6). FAB−HRMS calcd for $[C_{32}H_{34}N_4O_8S + H]^+$: 574.3128. Found: 574.3143.

*Boc-Val-Lys(Coum)-Ot-Bu (**9b**).* WSCD·HCl (150 mg, 0.783 mmol) was added to a mixture of **6** (316 mg, 0.745 mmol), coumarin-3-carboxylic acid (149 mg, 0.783 mmol), and HOBt (300 mg, 1.49 mmol) in DMF (15 mL) at 0 °C. After 10 min, Et_3N (103 μL, 0.745 mmol) was added, and the mixture was stirred at the same temperature for 30 min. After the reaction mixture was stirred at room temperature for 2 h, it was diluted with EtOAc (40 mL) and washed successively with 0.6 M citric acid (30 mL), H_2O (20 mL), and brine (20 mL), then dried (Na_2SO_4) and concentrated. The residue was purified by column chromatography (SiO_2, 40:1 $CHCl_3$-MeOH) to give **9b** (394 mg, 92% as a white amorphous). ^{1}H NMR ($CDCl_3$ 270 MHz): 0.93 (3 H, d, J = 6.7 Hz, Val-CH_3), 0.98 (3 H, d, J = 6.7 Hz, Val-CH_3), 1.33−1.95 (24 H, m, Lys β, γ, δ −CH_2, 2 × *t*-Bu), 2.16 (1 H, m, Val β-CH), 3.46 (2 H, br, Lys ϵ-CH_2), 4.05 (1 H, m, Val α-CH), 4.40 (1 H, m, Lys α-CH), 5.18 (1 H, d, J = 8.6 Hz, Val α-NH), 6.68 (1 H, d, J = 7.3 Hz, Lys α-NH), 7.35−7.41 (2 H, m, H-8, H-6), 7.66 (1 H, m, H-7), 7.77 (1 H, m, H-5), 8.87 (1 H, m, Lys ϵ-NH_2), 8.96 (1 H, s, H-4). FAB−HRMS calcd for $[C_{30}H_{43}N_3O_8 + H]^+$: 574.3128. Found: 574.3143.

*Val-Lys(Coum)·HCl (**10b**).* The desired product **10b** (243 mg, 100% as a white powder) was obtained from **9b** (308 mg, 0.662 mmol) in a similar manner as described for the synthesis of **10a**. ^{1}H NMR (CD_3OD, 270 MHz): 1.07 (3 H, d, J = 7.1 Hz, Val-CH_3), 1.11 (3 H, d, J = 7.1 Hz, Val-CH_3), 1.50−2.01 (6 H, m, Lys β, γ, δ −CH_2), 2.23 (1 H, m, Val β-CH), 3.44 (2 H, m, Lys ϵ-CH_2), 3.74 (1 H, d, J = 5.5 Hz, Val α-CH), 4.46 (1 H, dd, Lys α-CH), 7.41−7.47 (2 H, m, H-6, H-8), 7.75 (1 H, ddd, J = 1.6, 7.1, 8.7 Hz, H-7), 7.85 (1 H, dd, J = 1.6, 7.9 Hz, H-5), 8.84 (1 H,

s, H-4), 9.05 (1 H, m, Lys α-NH). FAB−HRMS calcd for $[C_{21}H_{27}N_3O_6 + H]^+$: 418.1978. Found: 418.1976.

*Boc-Lys(Cbz)-Sar-Ot-Bu (**7**).* Compound **7** was prepared from Boc-Lys(Cbz) (2.2 g, 5.78 mmol) and Sar-O*t*-Bu·HCl (1.0 g, 5.5 mmol) using the procedure described for the synthesis of **5**. The crude product was purified by column chromatography (SiO_2, 10:1 $CHCl_3$-MeOH) to give **7** (2.79 g, 100% as a white solid). ^{1}H NMR ($CDCl_3$, 270 MHz) 1.13−1.89 (24 H, m, Lys *β*, *γ*, *δ* $-CH_2$, 2× *t*-Bu), 2.90−3.30 (5 H, m, Lys *ϵ*-CH_2, N−CH_3), 3.54−4.38 (2 H, m, Sar-CH_2), 4.39−4.75 (1 H, m, Lys α-CH), 5.00−5.20 (3 H, m, PhC*H*$_2$, Lys *ϵ*-NH), 5.24−5.49 (1 H, m, Lys α-NH), 7.26−8.06 (5 H, m, Ph).

*Boc-Lys-Sar-Ot-Bu·HCl (**8**).* The desired product **8** (2.10 g, 100% as a yellow oil) was obtained from **7** (2.6 g, 5.13 mmol) in a similar manner as described for the synthesis of **6**. ^{1}H NMR (DMSO-d_6, 270 MHz): 1.16−1.76 (24 H, m, Lys *β*, *γ*, *δ* −CH2, 2 × *t*-Bu), 2.73 (2 H, m, Lys *ϵ*-CH2), 2.81, 3.06 (3 H, m, N−CH_3), 3.62−4.18 (2 H, m, Sar-CH_2), 4.23−4.47 (1 H, m, Lys α-CH), 6.77−7.06 (1 H, m, Lys α-NH), 7.11−7.27 (5 H, m, Ph), 8.02 (3 H, br, NH_3).

*Boc-Lys(Flu)-Sar-Ot-Bu (**11a**).* Compound **11a** was prepared from **8** (1.1 g, 2.68 mmol) and FITC (954 mg, 2.45 mmol) using the procedure described for the synthesis of **9a**. The crude product was purified by column chromatography (SiO_2, 15:1:0.016 $CHCl_3$-MeOH−AcOH) to give **11a** (1.32 g, 71% as a yellow powder). ^{1}H NMR (DMSO-d_6, 500 MHz) 1.20−1.70 (24 H, m, Lys *β*, *γ*, *δ* $-CH_2$, 2 × *t*-Bu), 2.83, 3.09, 3.18 (3 H, m, N−CH_3), 3.49 (2 H, m, Lys *ϵ*-CH_2), 3.76−4.20 (2 H, m, Sar α-CH2), 4.42 (1 H, m, Lys α-CH), 6.54 (2 H, dd, J = 1.7, 8.9 Hz, xanthene H-2′, H-7′), 6.61 (2 H, d, J = 1.7 Hz, xanthene H-4′, H-5′), 6.67 (2 H, d, J = 8.9 Hz, xanthene H-1′, H-8′), 6.95 (1 H, m, Lys α-NH), 7.15 (1 H, d, J = 8.3 Hz, H-3), 7.75 (1 H, d, J = 7.9 Hz, H-4), 8.29 (1 H, s, H-6), 8.46 (1 H, m, Lys *ϵ*-NH), 10.27 (1 H, br, Ar−NH); FAB−HRMS calcd for $[C_{39}H_{46}N_4O_{10}S + H]^+$ 763.3012, found 763.3011.

*Lys(Flu)-Sar·HCl (**12a**).* The desired product **12a** (97 mg, 100% as an orange powder) was obtained from **11a** (122 mg, 160 *μ*mol) in a similar manner as described for the synthesis of **10a**. ^{1}H NMR (DMSO-d_6, 270 MHz): 1.35−1.85 (6 H, m, Lys *β*, *γ*, *δ* $-CH_2$), 2.89, 3.10 (3 H, m, N−CH_3), 3.50 (2 H, m, Lys *ϵ*-CH_2), 3.94−4.23 (2 H, m, Sar-CH_2), 4.43 (1 H, m, Lys α-CH), 6.48−6.67 (4 H, m, xanthene H-1′, H-8′, H-2′, H-7′), 6.74 (2 H, d, J = 1.7 Hz, xanthene H-4′, H-5′), 7.19 (1 H, d, J = 8.3 Hz, H-3), 7.86 (1 H, dd, J = 1.7, 8.3 Hz, H-4), 8.24 (3 H, br s, NH_3), 8.42 (1 H, s, H-6), 8.68 (1 H, br s, Lys *ϵ*-NH), 10.8 (1 H, br s, Ar−NH). FAB−HRMS calcd for $[C_{30}H_{30}N_4O_8S + H]^+$: 607.1862. Found: 607.1870.

*Boc-Lys(Coum)-Sar-Ot-Bu (**11b**).* Compound **11b** was prepared from **8** (702 mg, 1.71 mmol) and coumarin-3-carboxylic acid (341 mg, 1.79 mmol) using the procedure described for the synthesis of **9b.** The crude product was purified by column chromatography (SiO_2, 40:1 $CHCl_3$-MeOH) to give **11b** (790 mg, 85% as a white amorphous powder). ^{1}H NMR ($CDCl_3$, 270 MHz): 1.42−1.90 (24 H, overlapping m, Lys *β*, *γ*, *δ* $-CH_2$, 2 × *t*-Bu), 2.97, 3.13 (3 H, m, N−CH_3), 3.46 (2 H, m, Lys *ϵ*-CH2), 3.73−4.29 (2 H, m, Sar-CH_2), 4.41−4.69 (1 H, m, Lys α-CH), 5.31 (1 H, m, Lys α-NH), 7.33−7.41 (2 H, overlapping m, H-8, H-6), 7.63−7.70 (2 H, m, H-7, H-5), 8.81 (1 H, m, Lys *ϵ*-NH), 8.90 (1 H, s, H-4). FAB−HRMS calcd for $[C_{28}H_{39}N_3O_8 + H]^+$: 546.2815. Found: 546.2804.

*Lys(Coum)-Sar·HCl (**12b**).* The desired product **12b** (260 mg, 100% as a white powder) was obtained from **11b** (333.7 mg, 6.12 mmol) in a similar manner as described for the synthesis of **10a**. ^{1}H NMR (DMSO-d_6, 270 MHz): 1.53−1.79 (6 H, m, Lys *β*, *γ*, *δ* $-CH_2$), 2.88, 3.09 (3 H, m, N−CH_3), 3.39−3.30 (2 H, m, Lys *ϵ*-CH_2), 3.94, 4.18 (2 H, m, Sar-CH_2), 4.41 (1 H, m, Lys α-CH), 7.45 (1 H, ddd, J = 1.0, 7.6, 7.9 Hz, H-6), 7.52 (1 H, dd, J = 1.0, 8.6 Hz, H-8), 7.76 (1 H, ddd, J = 1.3, 7.6, 8.6 Hz, H-7), 8.00 (1 H, dd, J = 1.3, 7.6, 8.6 Hz, H-5), 8.71 (1 H, m, Lys *ϵ*-NH), 8.86 (1 H, s, H-4). FAB−HRMS calcd for $[C_{19}H_{23}N_3O_6 + H]^+$: 390.1665. Found: 390.1671.

*Boc-Val-Lys(Cbz)-OMe (**15**).* A mixture of Boc-Val (6.67 g, 30.7 mmol), Lys(Cbz)-OMe·HCl (8.47 g, 25.6 mmol), HOBt (10.5 g, 50.9 mmol), and 4-methylmorpholine (2.81 mL, 25.6 mmol) in DMF (170 mL) was stirred at 0 °C for 15 min. Then, WSCD·HCl (6.38 g, 33.3 mmol) was added to the solution. After 30 min, the reaction mixture was warmed to room temperature and stirred for 10 h. It was diluted with EtOAc (350 mL) and washed successively with 0.6 M citric acid (200 mL), H_2O (150 mL), aqueous saturated $NaHCO_3$ (200 mL), H_2O (150 mL), and brine (100 mL), dried (Na_2SO_4), and concentrated. The resulting residue was purified by column chromatography (SiO_2, 80:1 $CHCl_3$-MeOH) to give **15** (10.56 g, 83.7%) as white solid. ^{1}H NMR (DMSO-d_6, 500 MHz) 0.75 (3 H, d, J = 6.7 Hz, Val-CH_3), 0.79 (3 H, d, J = 6.7 Hz, Val-CH_3), 1.15−1.70 (15 H, Lys *β*, *γ*, *δ* $-CH_2$, *t*-Bu), 1.85 (1 H, m, Val *β*-CH), 2.90 (2 H, m, Lys *ϵ*-CH2), 3.53 (3H, s, CO_2CH_3), 3.75 (1 H, dd, J = 9.0 Hz, Val α-CH), 4.14 (1 H, dt, J = 5.9, 7.2 Hz, Lys α-CH), 5.53 (2 H, s, PhC*H*$_2$), 6.52 (1 H, d, J = 9.0 Hz, Val α-NH), 7.14 (1 H, t, J = 5.0 Hz, Lys *ϵ*-NH), 7.22−7.35 (5 H, m, Ph), 8.07 (1 H, d, J' = 7.2 Hz, Lys α-NH).

*Boc-Val-Lys-OMe (**16**).* A solution of **15** (4.96 g, 10.06 mmol) in MeOH (80 mL) containing 10% Pd/C (500 mg) was stirred under atmospheric pressure of hydrogen for 2 h. The catalyst was filtered off by Celite filtration. The filtrate was concentrated to give **16** (3.61 g, 100% as a white amorphous). ^{1}H NMR (DMSO-d_6, 500 MHz): 0.75 (3 H, d, J = 6.7 Hz, Val-CH_3), 0.79 (3 H, d, J = 6.7 Hz, Val-CH_3), 1.15−1.64 (15 H, m, Lys *β*, *γ*, *δ* $-CH_2$, *t*-Bu), 1.85 (1 H, m, Val *β*-CH), 3.00 (2 H, m, Lys *ϵ*-CH2), 3.54 (3 H, s, CO_2CH_3), 3.75 (1 H, dd, J = 8.0 Hz, Val α-CH), 4.16 (1 H, dt, J = 8.3 Hz, Lys α-CH), 6.56 (1 H, m, Val α-NH), 8.11 (1 H, m, Lys α-NH).

*Boc-Val-Lys(Flu)-OMe (**17a**).* Compound **17a** was prepared from **16** (2.80 g, 7.80 mmol) and FITC (3.04 g, 7.81 mmol) using the procedure described for the synthesis of **9a**. The crude product was purified by column chromatography (SiO_2, 13:1:0.14 $CHCl_3$-MeOH−AcOH) to give **17a** (4.13 g, 70.7% as a yellow amorphous): ^{1}H NMR (CD_3OD, 500 MHz) 0.93 (3 H, d, J = 6.7 Hz, Val-CH_3), 0.97 (3 H, d, J = 6.7 Hz, Val-CH_3), 1.38−1.94 (15 H, m, Lys *β*, *γ*, *δ* -CH_2, *t*-Bu), 2.02 (1 H, m, Val *β*-CH), 3.61 (2 H, br s, Lys *ϵ*-CH_2), 3.69 (3 H, s, CO_2CH_3), 3.91 (1 H, d, J = 6.9 Hz, Val α-CH), 4.45 (1 H, m, Lys α-CH), 6.54 (2 H, dd, J = 2.3, 8.7 Hz, xanthene H-2′, H-7′), 6.68 (2 H, m, xanthene H-1′, H-8′), 7.08−7.21 (3 H, m, Ar H-3, xanthene H-4′, H-5′), 7.75 (1 H, m, Ar H-4), 8.14 (1 H, br s, Ar H-6). $[C_{38}H_{44}N_4O_{10}S + H]^+$: 749.2856. Found: 749.2812.

*Val-Lys(Flu)-OMe·HCl (**18a**).* The desired product **18a** (445 mg, 94% yellow powder) was obtained from **17a** (500 mg, 0.668 mmol) in a similar manner as described for the synthesis of **10a**. ^{1}H NMR (CD_3OD, 270 MHz): 1.09 (3 H, d, J = 6.9 Hz, Val-CH_3), 1.11 (3 H, d, J = 6.9 Hz, Val-CH_3), 1.35−2.10 (6 H, m, Lys *β*, *γ*, *δ*-CH2), 3.39 (1 H, m, Val *β*-CH), 3.65 (3 H, s, CO_2CH_3), 3.70 (2 H, m, Lys *ϵ*-CH_2), 3.83 (1 H, d, J = 5.7 Hz, Val α-CH), 4.50 (1 H, m, Lys α-CH), 7.19 (2 H, dd, J = 2.3, 9.2 Hz, xanthene H-2′, H-7′), 7.33 (2 H, d, J = 2.3 Hz, xanthene H-4′, H-5′), 7.39 (1 H, d, J = 8.3 Hz, Ar H-3), 7.59 (2 H, d, J = 9.2 Hz, xanthene H-1′, H-8′), 8.12 (1 H, dd, J = 2.1, 8.3 Hz,

Ar H-4), 8.58 (1 H, d, $J = 2.1$ Hz, Ar H-6). FAB−HRMS calcd for $[C_{33}H_{36}N_4O_8S + H]^+$: 649.2332. Found: 649.2343.

*Boc-Val-Lys(Flu) (**19a**).* NaOH (5 M, 0.44 mL) was added dropwise to a solution of **17a** (1.5 g, 2.0 mmol) in MeOH/dioxane (8/2 mL) at 0 °C, and the mixture was stirred at room temperature for 2 h. The reaction mixture was diluted with EtOAc (200 mL) and washed successively with 0.6 M citric acid (150 mL), H_2O (100 mL), and brine (80 mL), dried (Na_2SO_4), and concentrated. The resulting residue was purified by flash silica gel column chromatography (4.5:1:0.1 $CHCl_3$-MeOH−AcOH) to give **19a** (1.3 g, 88% as a yellow powder). ^{1}H NMR (CD_3OD, 270 MHz): 0.92 (3 H, d, $J = 6.6$ Hz, Val-CH_3), 0.97 (3 H, d, $J = 6.6$ Hz, Val-CH_3), 1.28−2.06 (16 H, m, Lys β, γ, δ−CH_2, *t*-Bu, Val β-CH) 3.63 (2 H, m, Lys ϵ-CH_2), 3.94 (1 H, d, $J = 6.8$ Hz, Val α-CH), 4.43 (1 H, m, Lys α-CH), 6.54 (2 H, dd, $J = 2.4$, 8.7 Hz, xanthene H-2′, H-7′), 6.66 (1 H, m, Ar H-3), 6.68 (2 H, d, $J = 1.9$ Hz, xanthene H-4′, H-5′), 7.14 (2 H, d, $J = 8.2$ Hz, xanthene H-1′, H-8′), 7.76 (1 H, m, Ar H-4), 8.14 (1 H, br, Ar H-6). FAB−HRMS calcd for $[C_{37}H_{42}N_4O_8S + H]^+$: 735.2699. Found: 735.2723.

Cell Culture. Caco-2 cells (ATCC HTB-37) at passage 28 were purchased from the American Type Culture Collection. They were passaged in 75 cm^2 culture flasks (FALCON, Becton Dickinson and Co., Lincoln Park, NJ) in culture medium consisting of RPMI 1640 supplemented with FBS (15%), HEPES (5 mM), and $NaHCO_3$ (2 g/L) without antibiotics. The cells were maintained at 37 °C in an atmosphere of 5% CO_2. Cells between the 30th and 40th passage were used in this study. At approximately 80% confluence, cells were seeded using 0.02% EDTA and 0.05% trypsin at a density of 53 000 cells/cm^2 on 60 mm plastic culture dishes. The cells were fed fresh medium every 3 days and were used between the 14th and 16th day for the transport studies.

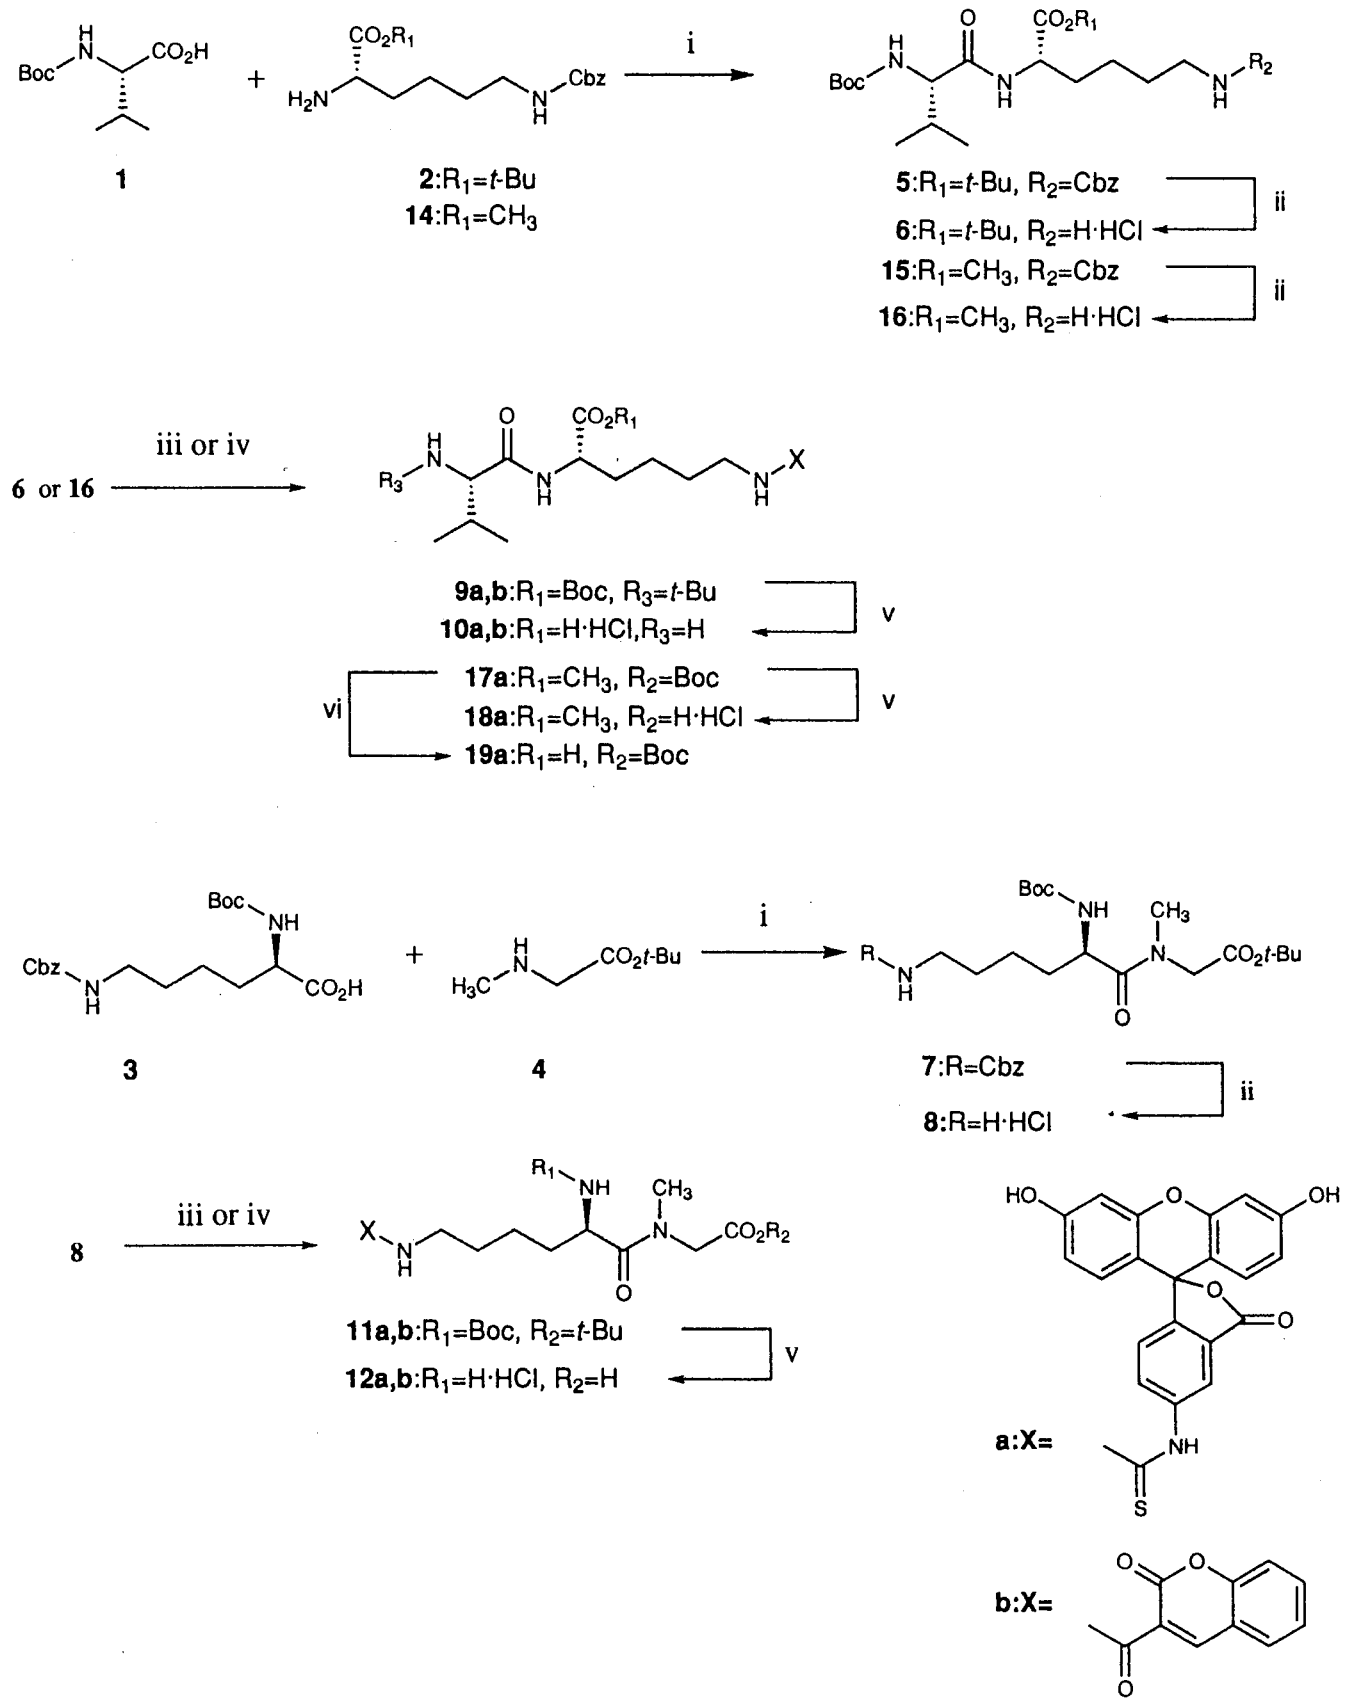
Uptake Experiments in Monolayer Caco-2 Cells. The uptake of [^{14}C]Gly-Sar by Caco-2 cells was measured. The composition of the incubation medium was 140 mM NaCl, 3 mM KCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM D-glucose, 5 mM MES (pH 6.0), or HEPES (pH 7.4). After removal of the culture medium, each dish was washed once with 5 mL of the incubation medium (pH 7.4) prewarmed at 37 °C and incubated with 2 mL of the same medium for 10 min at 37 °C. The cells were then incubated with 2 mL of incubation medium (pH 6.0) containing [^{14}C]Gly-Sar in the absence or the presence of inhibitors for a designated period at 37 °C. The medium was then aspirated off, and the dishes were rapidly rinsed twice with ice-cold incubation medium (pH 7.4). The cells were solubilized in 1 mL of 1 M NaOH followed by neutralization by 1 mL of 1 M HCl. The cell-associated radioactivity was determined in an ACSII scintillation counting cocktail (Amersham, Buckinghamshire England) by a liquid scintillation counter (LSC 2500, Packard).

The uptake of fluorescent dipeptide analogues was measured, unless otherwise indicated, in a similar manner as described above. The cells were solubilized in 1.5 mL of 1 M NaOH using a rubber policeman and neutralized by 1.5 mL of 1 M HCl. The extracted solution was centrifuged in a tabletop microfuge (Hitachi, Tokyo). The supernatant was diluted with 25 mM Tris-buffer (pH 9.6). The fluorescent intensity due to cell accumulation of fluorescein derivatives was determined with a Hitachi MPF-1 fluorometer (Hitachi, Tokyo) with emission at 520 ± 5 nm and excitation at 489 ± 5 nm. The fluorescent intensity by coumarin-3-carboxy derivatives was determined with emission at 410 ± 5 nm and excitation at 320 ± 5 nm. When the uptake of drugs was measured in the presence of CCCP, the cells were preincubated for 30 min at 37 °C with 1.5 mL of incubation medium (pH 6.0) containing 40 μM CCCP, and then incubated for the designated period at 37 °C with 1.5 mL of the incubation medium (pH 6.0) containing various drugs with 40 μM CCCP. The cells were then treated as described above.

The uptake of cepharosporins (cefadroxil and cephradine) was measured, unless otherwise indicated, in a similar manner as described above. The accumulation of cepharosporins was linear within 15 min, then the uptake rates were estimated from the slope. The cells were scraped with a rubber policeman into 1 mL of extraction solution (30 mM phosphate buffer pH 7.0/methanol, 50:50) and maintained for 1 h at room temperature. The extraction solution was centrifuged at 15 000 rpm in a tabletop microfuge (Hitachi, Tokyo Japan) for 15 min, and the supernatant was passed through a Millipore filter (SJGVL, 0.22 μm). The concentrations of cepharosporins in the filtrate were determined by a high-performance liquid chromatography L-6000 (Hitachi, Tokyo Japan) equipped with an UV detector L4000 (Hitachi Co.). The HPLC conditions were column, ERC ODS 6.0 mm inside diameter × 100 mm (ERC Inc., Saitama Japan); mobile phase, 50 mM phosphate buffer (pH 7.0)/methanol, 90:10 for cefadroxil and 70:30 for cephradine; flow rate, 0.8 mL/min; wavelength, 262 nm; injection volume, 20 μL; room temperature.

In all uptake measurements, unless otherwise indicated, values were corrected for the protein content. The protein content of the cell monolayers solubilized in 1.0 mL of 1 M NaOH was determined using a Bio-Rad protein assay kit (Bio-Rad Laboratories, Richmond, CA) with bovine serum albumin as a standard.

Kinetic Analysis of Gly-Sar Uptake. The uptake data of Gly-Sar were fitted to a Michaelis−Menten type equation with a nonsaturable component by an iterative nonlinear least-squares method using a MULTI program (*12*),



$$v_0 = \frac{V_{max}[S]}{K_m + [S]} + K_d[S] \quad (1)$$

where v_0 represents the initial uptake rate of Gly-Sar; V_{max}, the maximum uptake velocity; [s], the concentration of Gly-Sar; K_m, Michaelis constant; K_d, the coefficient of passive diffusion.

RESULTS AND DISCUSSION

Synthesis of the Fluorescent Dipeptide Analogues. Kramer et al. (*4*) reported that the minimum requirement of the chemical structure of substrates for recognition by the dipeptide transporter is the existence of the peptide bond, a free carboxyl group, and an α-amino group in N-terminal. Considering these structural requirements and the ease of preparing bioconjugates as described in the Introduction, Val-Lys and Lys-Sar were selected as the core of the dipeptide analogues, although recently it is shown that the existence of the peptide bond is not essential (*13*, *14*). It is also expected that these dipeptides are highly resistant to hydrolysis by peptidase owing to the bulky group of Val and to methylated amino groups of Sar. The strategy of the synthesis of fluorescent dipeptide analogues was conjugation of a fluorescent dye to ϵ-amino group of the dipeptides (see Scheme 1). Here, **a** represents FITC (Flu), and **b**, Coum. These fluorescent dyes were selected from the point that FITC is relatively large in the molecular size and Coum, small.

Scheme 1[a]

[a] Reagents: i, WSCD·HCl, HOBt, DMAP, DMF; (ii), 10% Pd/C, AcOH, then ion exchanger resin; iii, FITC, Et_3N, DMF; iv, Coumarin-3-carboxylic acid, WSCD·HCl, HOBt, Et_3N, DMF; v, 4 M HCl/dioxane.

Using proptected amino acids which are commercially available, desired products **10a**, **10b**, **12a**, **12b**, **18a**, and **19a** were synthesized by the usual reactions of peptide condensation and deprotection. Overall yield was **10a**, 84%; **10b**, 80%; **12a**, 71%; **12b**, 85%; **18a**, 56%; **19a**, 52%. It is noted that for removal of Cbz-protecting group from

5, **7**, and **15**, we chose acetic acid as a reaction solvent since the resulting product was unstable in a neutral solution and led to an undesired reaction of isomerization. After removal of Cbz-protecting group, the product was applied to a weakly acidic ion-exchange resin column to obtain **6**, **8**, and **16** as a hydrochloride salt. Protected Val-Lys(Flu), **18a**, and **19a** were synthesized to investigate the effect of amino or carbonyl group in Val-Lys(Flu) on the recognition by the dipeptide transporter.

Since the high purity of compounds **10a**, **10b**, **12a**, **12b**, **18a**, and **19a** was confirmed by NMR analysis, these compounds were used in the transport experiment without further purification. Fluorescein (Flu) is strongly fluorescent either in the conjugated or nonconjugated state. Although Coum itself has a little fluorescence, conjugation to dipeptide enhanced the quantum yield.

The fluorescent dipeptide analogues of Val-Lys(Flu) and (Flu)Lys-Sar were digested in the presence of cytosolic enzymes in Caco-2 cells, and analysis with aid of their fluorescence showed that the hydrolysis of Val-Lys or Lys-Sar occurred. The half-time was about 25 min for both. These analogues showed their inhibition on Gly-Sar uptake when they were added (see below): not the digested products but the analogues themselves exerted the inhibition.

Accumulation of Fluorescent Dipeptide Analogues by Caco-2 Cells. The uptake of (Flu)Lys-Sar and Val-Lys(Flu) was linear with respect to time within 20 min (data not shown); the rate of uptake was estimated by the accumulation in 15 min. (Coum)Lys-Sar and Val-Lys(Coum), on the other hand, were rapidly degraded to coumarin-3-carboxylic acid inside cells. We therefore were unable to determine the initial uptake of Coum analogues.

The kinetics of the Flu analogues was measured. The uptake of (Flu)Lys-Sar and Val-Lys(Flu) increased linearly and showed no saturation up to 2 mM with the increase in concentration: for (flu)Lys-Sar, uptake (pmol/mg/15 min) = (0.624 ± 0.016) × (concn in μM), $R = 0.996$, and for Val-Lys(Flu), uptake (pmol/mg/15 min) = (0.521 ± 0.02) × (concn in μM), R = 0.993. In Caco-2 cells, dipeptide is taken up by a symporter (co-transporter) with H^+ that is energized by an inwardly electrochemical potential difference of proton. If these Flu analogues are accumulated by the symporter, the uptake should cease or at least decrease with the addition of an uncoupler that dissipates the proton electrochemical potential. On the contrary, however, CCCP, the uncoupler, did not decrease the accumulation (see Figure 1). Gly-Sar is a substrate of a dipeptide transporter, PEPT1, that is expressed in Caco-2 cells (*10*, *11*). Gly-Sar did not inhibit the uptake of these analogues (see Figure 1). These three observations imply that (Flu)Lys-Sar and Val-Lys(Flu) are accumulated into cells via a passive diffusion. Figure 1 shows that addition of CCCP and Gly-Sar increased the accumulation of (Flu)Lys-Sar and Val-Lys(Flu). A plausible reason for this increase will be discussed later.

Kinetic Analysis of Active Gly-Sar Accumulation by Caco-2 Cells. Although Gly-Sar is known to be a substrate of PEPT1, we ourselves characterized Gly-Sar uptake by Caco-2 cells. The initial uptake rates were estimated by the slope of the total accumulation vs time; this slope was constant up to 15 min. Analysis with eq 1 gave the following values: V_{max} = 2.4 nmol/h/mg of protein, K_m = 0.86 mM, and K_d = 1.2 nmol/h/mg of protein. These values were consistent with those reported by others (*15*). Figure 1 shows that CCCP decreased the uptake of Gly-Sar, implying that this uptake requires a proton electrochemical potential. It is worth noting that

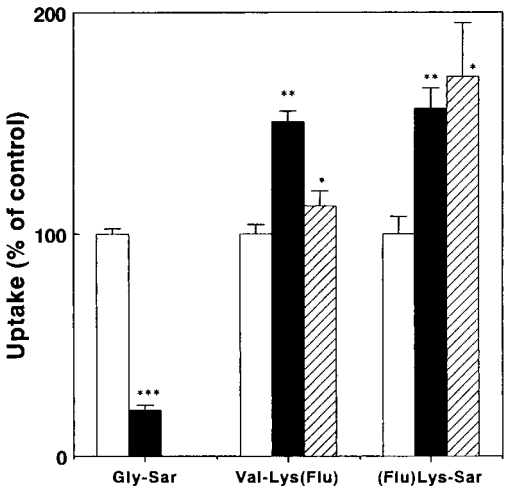


Figure 1. Effect of Gly-Sar and CCCP on the uptake of Val-Lys(Flu) and (Flu)Lys-Sar by Caco-2 cells. (*Leftmost columns*) Uptake of 100 μM Gly-Sar was measured in the absence (unfilled column) or presence (filled column) of 40 μM CCCP. (*Middle and rightmost columns*) Uptake of 200 μM Val-Lys(Flu) or (Flu)Lys-Sar was measured in the absence (unfilled column) or the presence(filled column) of 40 μM CCCP or of 10 mM Gly-Sar (striped column). The uptake was determined in 15 min incubation, then normalized by that for the value of corresponding control experiments. Each column represents the mean ± S. E. of three experiments. (***) $P < 0.005$; (**) $P < 0.01$; (*) $P < 0.05$, significant differences from the control using Student's *t*-test.

a single Michaelis−Menten term is enough to describe the uptake kinetics aside from the passive diffusion term. This would suggest the existence of only one transporter that transports Gly-Sar. This is consistent with the reported fact that Caco-2 cells functionally express PEPT1 as the only dipeptide transporter revealed by the Northern blot analysis (*16*).

Remarkable Inhibition of Gly-Sar Uptake by the Fluorescent Dipeptide Analogues. As described above, the fluorescent dipeptide analogues were not taken up by any transporters although these have a peptide bond. We next examined whether these analogues are recognized by the dipeptide transporter PEPT1 whose substrate is Gly-Sar. Inhibition of Gly-Sar uptake by these fluorescent dipeptide analogues was measured, and results (Figure 2) showed that these analogues strongly inhibited the uptake. It is noted that 1 mM Val-Lys(Flu) completely inhibited the Gly-Sar uptake. Cefalexin and cefadroxil are known to be transported by PEPT1 (*11*, *16*, *17*), but their inhibition was much weaker than the analogues.

To evaluate the kinetic type of inhibition by fluorescent dipeptide analogues, we performed Dixon plot analysis of Gly-Sar uptake by Val-Lys(Flu). Results are detailed in Figure 3 where the three lines cross at one point, indicating the competitive inhibition of Gly-Sar by Val-Lys(Flu) (*18*, *19*). The inhibition constant (K_i) was calculated to be 5 μM, which is the smallest value reported so far. The values of K_i or K_m reported for various peptide transport systems are in the range 1−10 mM (*17*, *20*, *21*). In other words, this compound has the highest affinity for PEPT1 among both inhibitors and substrates that have ever been reported.

We do not yet know the molecular mechanism of the inhibition by fluorescent analogues; do the analogues inhibit the binding of Gly-Sar or its intraprotein translocation? Two facts that (1) fluorescent analogues are transported by a passive diffusion mechanism and (2)

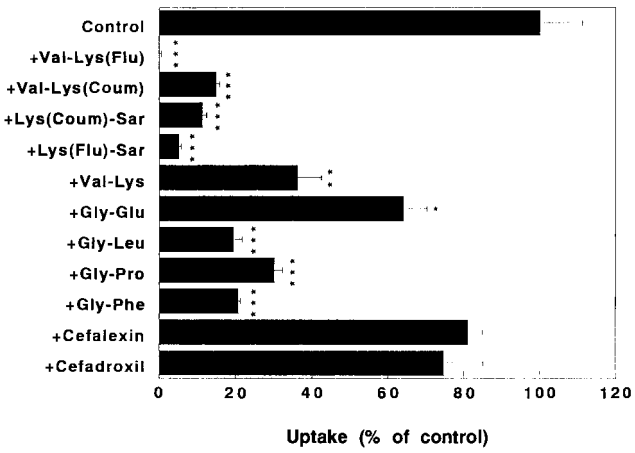

Figure 2. Effect of various fluorescent dipeptide-analogues, dipeptides or antibiotics on the uptake of Gly-Sar, a substrate of PEPT1. Uptake rate of 100 μM Gly-Sar was measured in the absence or the presence of 1 mM various fluorescent dipeptide-analogues, dipeptides or antibiotics. Initial uptake rates were determined using a linear regression of the linear portion in Gly-Sar uptake (measured at 5, 10, and 15 min). The uptake rate was normalized by that for the absence of fluorescent dipeptide-analogues. Each column represents the mean ± SE of three experiments. (***) $P < 0.005$; (**) $P < 0.01$; (*) $P < 0.05$, significant differences from the control using Student's *t*-test.

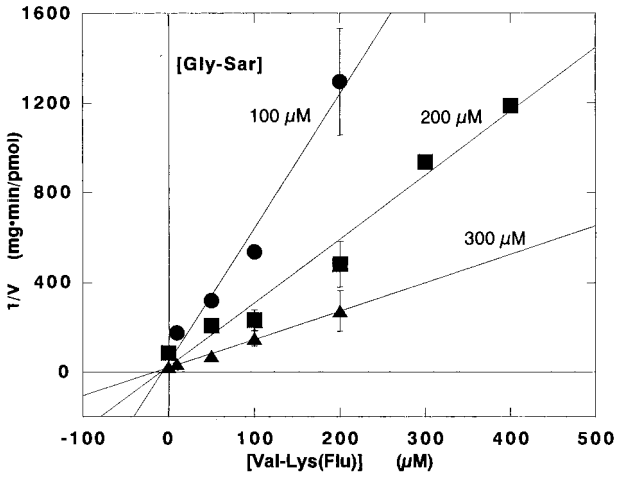

Figure 3. Dixon-Webb plot analysis for the inhibition of Gly-Sar uptake by Val-Lys(Flu) . The experiments were performed as described in the legend to Figure 1 in the presence of various concentrations of Val-Lys(Flu). Circles, squares and triangles represent 100, 200, and 300 μM Gly-Sar uptake rate, respectively. These rates were corrected for the passive diffusion (see eq 1). The inhibition of Gly-Sar upatake by Val-Lys(Flu) was analyzed by Dixon-Webb plot, showing the competitive inhibition. The K_i value was determined to be 5 μM from the intersection of the three lines. Each point represents the mean ± SE of three experiments.

inhibition is competitive suggest that these analogues strongly inhibit the binding of Gly-Sar to the transporter: the fluorescent analogues can bind the binding site of the transporter but they are not transported owing to their bulkiness. In this respect, Otto et al. (*22*) reported that a fluorescent dipeptide β-Ala-Lys-Nϵ-AMCA (AMCA is 7-amino-4-methylcoumarin-3-acetic acid) is transported by a dipeptide transporter of adenohypophysial folliculostellate cells. The reason that this fluorescent dipeptide is transported and our fluorescent dipeptide is not transported is not known.

What Chemical Features Enhance the Recognition by PEPT1? Inhibition of Gly-Sar uptake by several

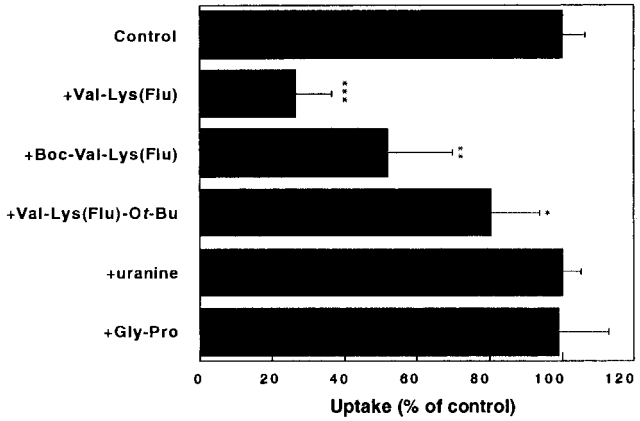

Figure 4. Effect of modification of the amino or carboxyl group in Val-Lys(Flu) on the Gly-Sar uptake. The experiments were performed as described in the legend to Figure 1. The uptake rate of 20 μM Gly-Sar was measured in the presence of 100 μM of each compound and was corrected for the passive diffusion. The uptake rate was normalized by that obtained in the absence of compounds. Each column represents the mean ± SE of three experiments. (***) $P < 0.01$; (**) $P < 0.05$; (*) $P < 0.1$, significant differences from the control using Student's *t*-test.

derivatives of Val-Lys(Flu) or related compounds was measured. The fluorescein (uranine) itself had no effect on the uptake, indicating that the peptide core of Val-Lys(Flu) is recognized by PEPT1. Figure 2 shows that an inhibition of Gly-Sar by Val-Lys is about 35% while the conjugation of Val-Lys to Flu inhibited it appreciably. Why does this conjugation increase the affinity although Flu is not recognized at all? The answer to this remains unclear. We can only point out the importance of the hydrophobicity of the dipeptide analogues. This tendency seems to appear in Figure 2; among Gly-X peptides, the order of inhibition by X is Phe > Leu > Pro > Glu, an order corresponding to hydrophobicity, although the differences are small. An experiment on the importance of hydrophobicity is now in progress in this laboratory.

We prepared two derivatives from Val-Lys: N-terminal-modulated Boc-Val-Lys(Flu) and C-terminal-modulated Val-Lys(Flu)-O*t*-Bu. As seen in Figure 4, the order of the inhibition is Val-Lys(Flu) > Boc-Val-Lys(Flu) > Val-Lys(Flu)-O*t*-Bu. This means that the carboxyl group might be more essential in the recognition by the peptide transporter than the amino group. This is consistent with the study on the intestinal absorption of cefixime and aminocephalosporin that do not have an α-amino group (*23*).

Possible Use of This Strong Inhibitor. We described here our successful preparation of a strong inhibitor of PEPT1. The inhibition constant is the smallest of those yet reported. The primary use of this strong inhibitor is to examine the possibility that some drugs can be transported via PEPT1. Our preliminary experiments were the initial uptake rate of 1 mM cefadroxil was 0.218 ± 0.004 nmol/min/mg of protein (mean ± SE, $n = 3$) and the addition of 200 and 500 μM Val-Lys(Flu) reduced 0.079 ± 0.001 (36.4% of the control) and 0.047 ± 0.001 (22.5%) nmol/min/mg of protein, respectively. Similarly, the rate of 1 mM cephradine was 0.200 ± 0.003 nmol/min/mg of protein (mean ± SE, $n = 3$) and the addition of 200 and 500 μM Val-Lys(Flu) reduced 0.091 ± 0.002 (45%) and 0.067 ± 0.001 (30%) nmol/min/mg of protein, respectively. These suggest that the present fluorescent analogue is the useful tool for this purpose. Second, the high affinity of the dipeptide analogues synthesized is applicable to the resin of the affinity chromatography; results in Figure 4 suggest that the

N-terminal should be linked to the resin. The high affinity of these analogues is also a powerful tool for purification of the dipeptide transporter.

Plausible Reasons Why CCCP Increases the Uptake of These Analogues. Figure 1 shows that CCCP increases the uptake of Val-Lys(Flu) and (Flu)Lys-Sar. If the uptake process requires energy, CCCP should show the reverse effect. There is no reason for the enhancement except the following: Val-Lys(Flu) is expelled by an energy-requiring efflux transporter in Caco-2 cells; the existence of an efflux transporter has been suggested (*24*, *25*). Results of Figure 1 suggest the high affinity of Val-Lys(Flu) to the efflux transporter, because this analogue is transported by passive diffusion so that its intracellular concentration might not be large. The reason Gly-Sar increases the uptake of Val-Lys(Flu) and (Flu)Lys-Sar is not yet clear. We are now analyzing this efflux transporter.

CONCLUDING REMARKS

We conjugated the dipeptide to fluorescent dyes. The resulting conjugates showed the highest affinity to the dipeptide transporter among those reported to date, although the conjugates are not transported by the transporter. Use of the high affinity of the analogues might help to characterize the transporter. As one reason for the high affinity, we pointed out the hydrophobicity; we should determine on a molecular basis whether this hypothesis is correct. We unfortunately failed to synthesize here the conjugated drugs that are transported by the transporter, and further study is needed to synthesize such chemicals which can improve the poor absorption in intestine.

ACKNOWLEDGMENT

We thank Dr. M. Sugawara in Department of Pharmacy, Hokkaido University Hospital for his guidance of HPLC experiments and Miss R. Tateoka for her assistance. This investigation was supported in part by a Grant-in-Aid from the Ministry of Education, Science, Sports and Culture of Japan.

Retention of Biologic Activity of Human Epidermal Growth Factor Following Conjugation to a Blood-Brain Barrier Drug Delivery Vector via an Extended Poly(ethylene glycol) Linker

Yoshiharu Deguchi, Atsushi Kurihara, and William M. Pardridge*

Department of Medicine, UCLA School of Medicine, Los Angeles, California 90095-1682. Received May 23, 1998; Revised Manuscript Received September 15, 1998

Human brain gliomas overexpress the receptor for epidermal growth factor (EGF), and radiolabeled EGF is a potential peptide radiopharmaceutical for imaging human brain tumors, should this peptide be made transportable through the blood-brain barrier (BBB) in vivo. Peptide drug delivery to the brain may be facilitated by conjugating peptide radiopharmaceuticals to BBB drug delivery vectors such as the OX26 monoclonal antibody (MAb), which undergoes receptor-mediated transcytosis through the BBB via the brain capillary endothelial transferrin receptor. EGF was biotinylated with NHS-XX-biotin, where NHS = *N*-hydroxysuccinimide and -XX- = bis (aminohexanoyl) spacer arm. The [^{125}I]EGF-XX-biotin rapidly bound to C6 rat glioma cells transfected with the human EGF receptor. However, no binding to the C6 EGF receptor was detected when the [^{125}I]EGF-XX-biotin was bound to a conjugate of streptavidin (SA) and the OX26 MAb. An alternative linker strategy using poly(ethylene glycol) (PEG) of 3400 Da molecular mass (PEG^{3400}) was evaluated, wherein EGF was monobiotinylated with NHS-PEG^{3400}-biotin. Attachment of the [^{125}I]EGF-PEG^{3400}-biotin to the OX26/SA conjugate did not impair binding of the construct to the EGF receptor in C6 glioma cells. The length of the -PEG- spacer arm and the -XX- spacer arm was >200 atoms and 14 atoms, respectively. These studies demonstrate that the use of the extended PEG linker releases steric hindrance of MAb transport vectors on binding of EGF to its cognate receptor on glioma cells. Attachment of EGF peptide radiopharmaceuticals to BBB drug delivery systems such as the OX26 MAb using extended PEG linkers allows for retention of the bifunctionality of the conjugate with binding to both EGF and transferrin receptors.

INTRODUCTION

Human gliomas overexpress the epidermal growth factor (EGF) receptor (*1*). Therefore, radiolabeled EGF is a potential peptide radiopharmaceutical that could be used to image human brain tumors (*2*), using standard external detection modalities such as single photon emission computed tomography (SPECT). However, EGF does not cross the blood-brain barrier (BBB) (*3*). The BBB is intact in the early stages of brain tumor growth and at the margins of the tumor (*4*), especially to larger molecular weight molecules such as peptides or antibodies (*5*). Therefore, the use of EGF as a peptide radiopharmaceutical for imaging human brain tumors will require a BBB drug delivery system.

Peptide drug delivery to the brain is facilitated by conjugation of a nontransportable peptide therapeutic to a BBB delivery vector (*6*). The latter is comprised of a modified protein or receptor-specific monoclonal antibody (MAb) that undergoes receptor-mediated transcytosis through the BBB in vivo. Peptide pharmaceuticals have been delivered through the BBB in rats using an anti-transferrin receptor MAb (*7*) and in Rhesus monkeys using an anti-insulin receptor MAb (*8*). However, it is possible that once a peptide radiopharmaceutical is conjugated to a BBB drug delivery system, the peptide will no longer bind with high affinity to its cognate receptor on brain cells. In this event, prior studies have used a cleavable (disulfide) linker for attachment of the peptide pharmaceutical to the BBB delivery vector (*9*). However, in this case, release of the peptide from the delivery vector requires cleavage of the disulfide to activate the peptide pharmaceutical. Since most disulfide reductase activity may be within the cytosol of cells (*10*), the use of a cleavable disulfide linker requires that the BBB delivery system contain an endosomal release function. A different conjugation strategy, which is examined in the present studies, is to employ an extended, poly(ethylene glycol) (PEG) linker between the peptide radiopharmaceutical and the BBB transport vector, in this case the OX26 MAb which is specific for the rat transferrin receptor. The use of the extended PEG linker increases the length of the linker from 14 atoms, which is the case for the conventional bis (aminohexanoyl) spacer arm, to >200 atoms, in the case of a PEG linker of 3400 Da.

EXPERIMENTAL PROCEDURES

Materials. Na[^{125}I] was supplied by Amersham (Arlington Heights, IL). Biotin-XX-NHS was supplied by Cal Biochem (San Diego, CA), where XX = bis (aminohexanoyl) spacer arm and NHS = *N*-hydroxysuccinimide. NHS-PEG^{3400}-biotin was obtained from Shearwater Polymers (Huntsville, AL). Chloramine T was purchased from MCB Reagents (Cincinnati, OH). Recombinant streptavidin (SA), recombinant human epidermal growth factor (EGF), and all other reagents were obtained from Sigma

Chemical Co. (St. Louis, MO). Vydac C4 (10 × 250 mm) reversed-phase HPLC columns were obtained from Separations Group (Hesperia, CA). TSK-gel G2000 SW_{XL} HPLC columns (7.8 × 300 mm) were obtained from TosoHaas (Montgomeryville, PA). High-Trap copper affinity columns (1 mL) and 1 × 30 cm Superose 12HR columns were obtained from Pharmacia (Piscataway, NJ). Centricon-30 microconcentrators were obtained from Amicon Corp. (Beverly, MA). C6 rat glioma cells transfected with the gene for the human EGF receptor (*2*) were kindly provided by Dr. Robert Fenstermaker of the Roswell Park Cancer Institute (Buffalo, NY), and these cells are designated C6EGFRp.

Preparation of [^{125}I]EGF-XX-biotin. NHS-XX-biotin (65 nmol in 10 μL of 100% dimethyl sulfoxide) was added in an 8:1 molar ratio to 50 μL of EGF (8.3 nmol in 0.05 M $NaHCO_3$, pH 8.3) and this mixture was incubated at room temperature for 60 min. The biotin-XX-EGF was directly iodinated by adding 6 μL (5 μg) to 20 μL of 0.3 M Na_2HPO_4, pH 7.0, followed by the addition of 2 mCi of ^{125}I and 10 μL (0.8 μg) of chloramine T. Following incubation at room temperature for 60 s, an additional 10 μL aliquot (0.8 μg) of chloramine T was added followed 60 s later by the addition of 50 μL (65 nmol) of sodium metabisulfite to terminate the iodination reaction. The mixture was then applied to a Sephadex G-25 gel filtration column followed by elution in 0.1 M Na_2HPO_4/0.15 M NaCl/pH 7.4/0.1% bovine serum albumin (BSA). The [^{125}I]EGF-XX-biotin was labeled to a specific activity of 548 μCi/nmol.

Preparation of [^{125}I]EGF-PEG^{3400}-biotin. NHS-PEG^{3400}-biotin (65 nmol in 100 μL of 0.05 M $NaHCO_3$) was added in an 8:1 molar ratio to 50 μg of EGF (8.0 nmol in 100 μL of 0.05 M $NaHCO_3$, pH 8.3) followed by incubation at room temperature for 60 min. Of this mixture, 20 μL was added to 20 μL of 0.3 M NaH_2PO_4 (pH 7.0) followed by the addition of 2 mCi of ^{125}I and 10 μL (0.8 μg) of chloramine T. After a 60 s incubation, an additional 10 μL (0.8 μg) of chloramine T was added, and 60 s later, the reaction was terminated by the addition of 50 μL (65 nmol) of sodium metabisulfite. Buffer A [0.05 M NaH_2PO_4/0.5 M NaCl/pH 7.0] was added to a volume of 1 mL and the mixture was then applied to a 1 mL High-Trap copper affinity column (*11*). The column was initially washed with 5 mL of water and charged with 0.5 mL of 0.1 M $CuSO_4$ followed by washing with 5 mL of water, followed by application of the sample. The column was washed with 10 mL of buffer A and the [^{125}I]EGF-PEG^{3400}-biotin was eluted with 5 mL of 50 mM imidazole in buffer A; 1 mL of this eluate (250 μCi) was added to a Centricon-3 microconcentrator and the volume was reduced to 200 μL by centrifugation at 7500 rpm (7500 g) for 40 min at room temperature. An aliquot of this fraction was then injected on the gel filtration HPLC column (see below) to determine the mobility of [^{125}I]EGF-PEG^{3400}-biotin. An aliquot was also injected into 2 Superose 12HR gel filtration columns in series and eluted with 0.01 M Na_2HPO_4/0.15 M NaCl/pH 7.4 at 0.5 mL/min, and 0.5 mL fractions were collected and detected at A_{220} by fast protein liquid chromatography (FPLC). The chemical identity of the EGF-[PEG-biotin]$_n$, where n = the number of PEG-biotin moieties per EGF, was determined by matrix assisted-laser desorption ionization mass spectrometry (MALDI). EGF-[PEG-biotin]$_3$ eluted at fractions 54−55 and constituted 7% of the total; EGF-[PEG-biotin]$_2$ and EGF-[PEG-biotin]$_1$ eluted at fractions 58−59 and 63−64 and constituted 35% and 43% of the total, respectively, and unconjugated EGF eluted at fractions 75−76 and comprised 15% of the total.

Preparation of EGF and OX26 MAb Conjugates. The conjugate of the OX26 MAb and recombinant streptavidin (SA) was prepared with a thiol-ether linkage as described previously (*12*). Briefly, 17 mg of OX26 MAb was thiolated with a 10:1 molar ratio of 2-iminothiolane; 7 mg of recombinant SA was activated with a 20:1 molar ratio of *m*-maleimidobenzoyl *N*-hydroxysuccinimide ester (MBS). The OX26/SA conjugate was labeled with 2.5 μCi of [^{3}H]biotin and was purified on a 2.6 × 92 cm column of Sephacryl S300HR (Pharmacia) followed by elution in 0.01 M Na_2HPO_4/0.15 M NaCl/pH 7.4/0.05% Tween-20 at 30 mL/h, and 3 mL fractions were collected. The conjugate peak was separated from either aggregates, unconjugated OX26 MAb, or unconjugated SA. The number of biotin-binding sites per OX26/SA conjugate was 3.3 ± 0.3, as determined with the [^{3}H]biotin binding assay (*12*).

The conjugate of OX26/SA and [^{125}I]EGF-PEG^{3400}-biotin was prepared by mixing 1 mL of the imidazole eluate from the High-Trap column containing 200 μCi of [^{125}I]EGF-PEG^{3400}-biotin (0.6 nmol) and 400 μg of OX26/SA (2.0 nmol). This volume was reduced to 0.2 mL with a Centricon-30 microconcentrator by centrifugation at 6300 rpm (5000 g) for 20 min at room temperature. The entire mixture was then applied to a TSK-gel G2000 SW_{XL} HPLC gel filtration column, followed by elution in 0.01 M Na_2HPO_4/0.15 M NaCl/pH 7.4/0.05% Tween-20 at a flow rate of 0.5 mL/min for 40 min, and 0.5 mL fractions were collected and counted for ^{125}I radioactivity. The conjugate of [^{125}I]EGF-PEG^{3400}-biotin bound to OX26/SA eluted at 7.0 mL from the column and this conjugate was subsequently used in the radioreceptor assays described below.

The conjugate of OX26/SA and [^{125}I]EGF-XX-biotin was prepared by mixing [^{125}I]EGF-XX-biotin (0.4 nmol) eluted from the Sephadex G-25 column with 60 μg of OX26/SA (0.30 nmol), followed by injection on the TSK G2000 SW_{XL} gel filtration HPLC column and elution as described above. The [^{125}I]EGF-XX-biotin bound to OX26/SA eluted at 7.0 mL from this column and was well separated from nonbiotinylated [^{125}I]EGF, which eluted at 11−12 mL.

C6EGFRp Radioreceptor Assays. C6EGFRp cells were grown in Dulbecco's modified Eagle medium (DMEM) with 4.5 g/L D-glucose, 4 mM glutamine, 10% fetal bovine serum, and 250 μg/mL G418, used as a selection agent, in 24-well cluster dishes. At 24 h prior to the radioreceptor assays, the medium was changed to DMEM with 4.5 g/L D-glucose, 1% fetal bovine serum, and 1 μM dexamethasone to induce expression of the EGF receptor (*2*). The assay was terminated by aspiration of medium, and washing wells with 0.01 M HEPES/0.15 M NaCl/pH 7.4 (HBS buffer). Radioreceptor assays were performed in the 24-well cluster dishes at 23 °C with 200 μL of final volume in the HBS buffer with 0.1% BSA. The wells contained 0.1 μCi/mL (0.18 nM) of [^{125}I]EGF conjugate and varying concentrations of unlabeled recombinant EGF ranging from 0.1 nM to 1 μM. Experimental incubations were performed from 15 to 120 min. The cell monolayer was solubilized by the addition of 0.5 mL of 1 N NaOH and incubated at 55 °C for 30 min or overnight at room temperature followed by counting for ^{125}I radioactivity and measurement of cell protein with the bicinchoninic acid (BCA) protein assay (Pierce Chemical Co.). Binding was expressed as percent of medium counts bound per milligram of cell protein and represents both surface bound and internalized ligand. Binding of the OX26/SA conjugate to C6 cells was confirmed by adding [^{3}H]biotin complexed to OX26/SA to cultured C6 cells; binding increased linearly with incubation time and was 4−5%/mgp at 60 min of incubation.

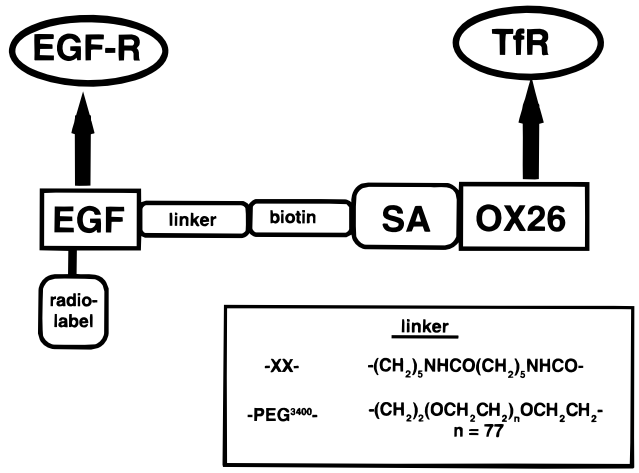

Figure 1. Structure of conjugate of EGF attached to the OX26 MAb using either a bis (aminohexanoyl) spacer arm (-XX-) or a 3400 Da poly(ethylene glycol) (PEG) spacer arm. The stable thioether linkage between OX26 and streptavidin (SA) is prepared in parallel with monobiotinylation of EGF using either NHS-XX-biotin or NHS-PEG^{3400}-biotin. The construct is prepared to ensure retention of the bifunctionality of the conjugate with binding to both the EGF receptor (EGF-R) via the EGF moiety or to the transferrin receptor (TfR) via the OX26 MAb moiety. The EGF is radiolabeled by iodination of EGF tyrosine residues. The length of the -XX- linker is 14 atoms and the length of the -PEG^{3400}- linker is >200 atoms.

RESULTS

The structure of the EGF/OX26 conjugate using a biotin/streptavidin linker is shown in Figure 1 for either the -XX- linker or the -PEG^{3400}- linker. The -XX- linker is 14 atoms long and the -PEG^{3400}- linker is >200 atoms long (Figure 1).

The binding of [^{125}I]EGF-XX-biotin to the C6EGFRp cells was avid and reached equilibrium by 60 min of incubation (Figure 2A) and was completely saturated by unconjugated EGF (Figure 2B). In contrast, conjugation of [^{125}I]EGF-XX-biotin to OX26/SA resulted in a more than 5-fold inhibition of binding of the EGF to the C6 cells (Figure 2A) and this binding was independent of unlabeled EGF added to the medium (Figure 2B). These results indicated that biotinylation, per se, of EGF did not impair binding to the EGF receptor, but attachment of EGF-XX-biotin to the OX26/SA drug delivery system essentially eliminated binding of the conjugate to the EGF receptor. Therefore, binding of the conjugate to the EGF receptor was assessed following the use of a PEG linker coupling EGF to OX26/SA.

The [^{125}I]EGF-PEG^{3400}-biotin eluted from TSK gel filtration HPLC column at a volume of 13.5 mL (Figure 3). However, after conjugation to OX26/SA, the [^{125}I]EGF-PEG^{3400}-biotin eluted at 7.0−7.5 mL from the column (Figure 3). Conjugation of EGF-PEG^{3400}-biotin to OX26/SA increased the molecular mass of the EGF construct from approximately 10 000 Da (Experimental Procedures) to 210 000 Da, since the OX26/SA has a size of 200 000 Da. The binding of [^{125}I]EGF-PEG^{3400}-biotin to the C6EGFRp cells was high (Figure 4A) and was comparable to the binding of the [^{125}I]EGF-XX-biotin (Figure 2A). The binding of [^{125}I]EGF-PEG^{3400}-biotin to the C6 cells was nearly completely displaced by the addition of unlabeled EGF to the medium, and the ED_{50} of this inhibition was approximately 1 nM (Figure 4B). This ED_{50} of EGF inhibition of the binding of [^{125}I]EGF-PEG^{3400}-biotin to the C6 cells approximates the ED_{50} of EGF inhibition of the binding [^{125}I]EGF-XX-biotin to these cells (Figure 2B). The conjugation of [^{125}I]EGF-PEG^{3400}-biotin to OX26/SA did not impair the binding of the EGF construct to the C6 cells (Figure 4A), and approximately 50% of the binding was inhibited by unlabeled EGF added to the medium (Figure 4B). The [^{125}I]EGF-XX-biotin or the [^{125}I]EGF-PEG^{3400}-biotin was metabolically stable during all radioreceptor assay incubations as the trichloroacetic acid (TCA) precipitability of medium ^{125}I radioactivity was >98% at all time points.

DISCUSSION

Human brain tumors frequently overexpress the EGF receptor (*13*, *14*). Radiolabeled monoclonal antibodies (MAb) to the EGF receptor have been used to image human gliomas in vivo (*15*). However, MAbs do not cross the BBB (*6*) and can image human brain tumors only when there is preexisting BBB disruption. For example, radiolabeled nonspecific MAbs image advanced human gliomas just as well as EGF receptor-specific MAbs, especially in patients with prior radiation therapy to the brain tumor (*15*), which causes BBB disruption (*16*). In the early stage of growth of a human brain tumor in an untreated patient, even metastatic tumors to brain (*17*),

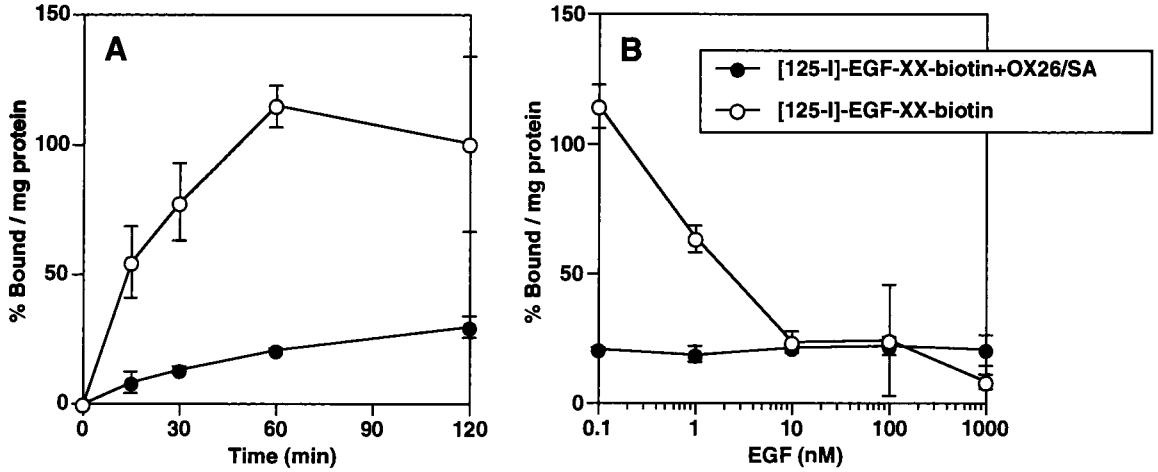

Figure 2. Radioreceptor assay showing binding of either [^{125}I]EGF-XX-biotin conjugated to OX26/SA (closed circles) or binding of [^{125}I]EGF-XX-biotin (open circles) to C6 rat glioma cells transfected with the human EGF receptor. Data are mean ± SE (n = 3 replicas at each point). (A) Time course of binding of either construct to the cells. (B) Saturation analysis was performed at 60 min incubations by adding varying concentrations of unlabeled recombinant EGF to the medium.

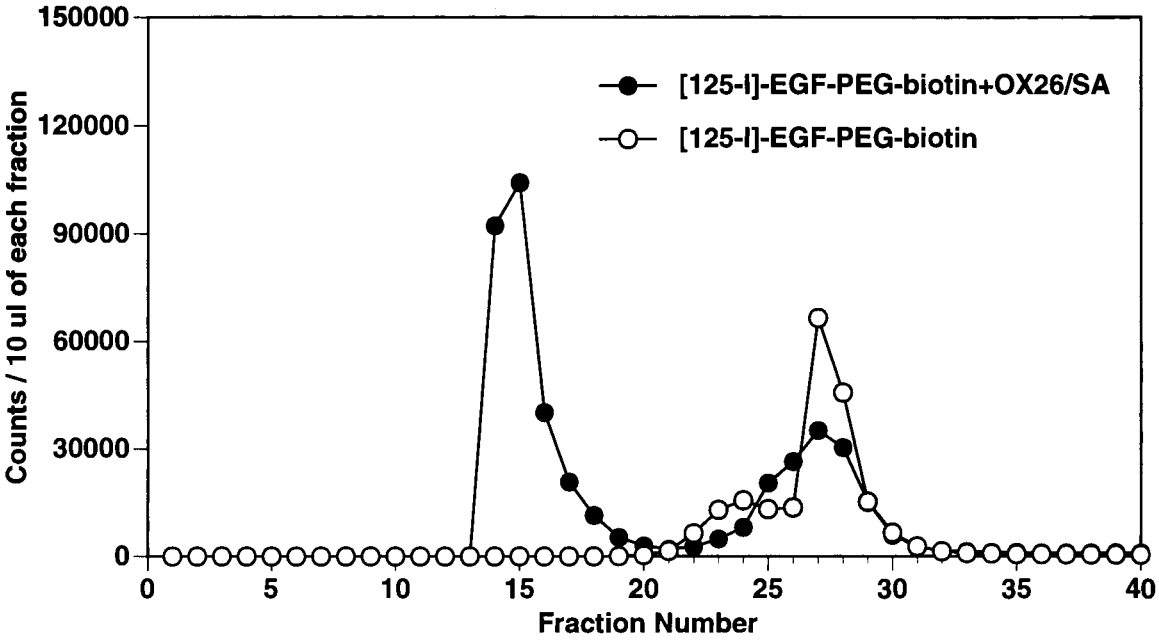

Figure 3. Elution of either [^{125}I]EGF-PEG^{3400}-biotin (open circles) or [^{125}I]EGF-PEG^{3400}-biotin conjugated to OX26/SA (closed circles) from a TSK-gel G2000 SW_{XL} gel filtration HPLC column. Each fraction was 0.5 mL and was accounted for ^{125}I radioactivity.

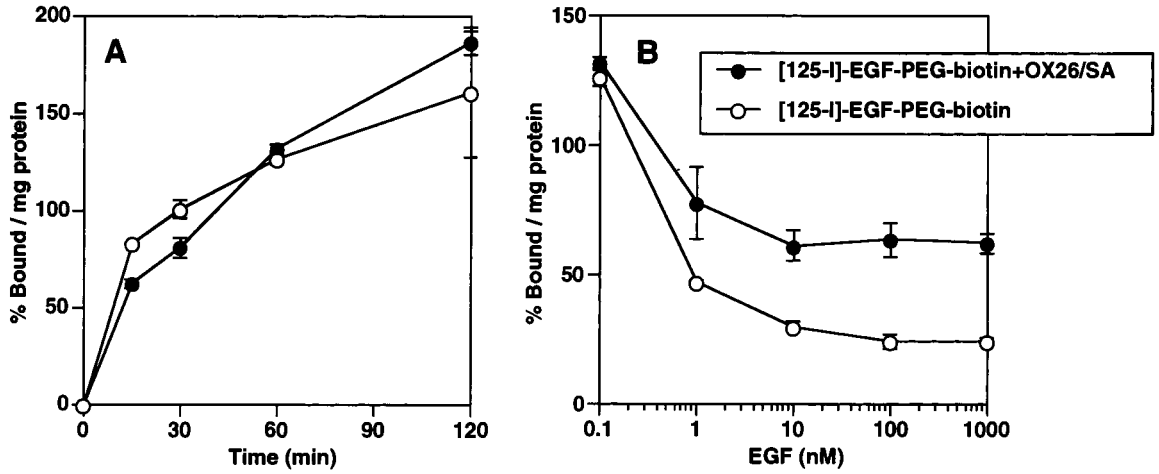

Figure 4. Radioreceptor assay showing binding of either [^{125}I]EGF-PEG^{3400}-biotin conjugated to OX26/SA (closed circles) or binding of [^{125}I]EGF-PEG^{3400}-biotin (open circles) to C6 rat glioma cells transfected with the human EGF receptor. Data are mean ± SE (n = 3 replicas at each point). (A) Time course of binding of either construct to the cells. (B) Saturation analysis was performed at 60 min incubations by adding varying concentrations of unlabeled recombinant EGF to the medium.

the BBB is intact, and it is at this stage that imaging and diagnosis of nascent brain tumors is most needed. Imaging of early brain tumors where the BBB is intact with either MAbs or peptide radiopharmaceuticals such as EGF requires the attachment of the tumor imaging agent to a BBB drug delivery system. The present studies make an initial evaluation of the molecular formulation required to attach EGF to a BBB transport vector in such a way that binding of the peptide to the EGF receptor is retained following conjugation to the delivery vector.

The results of these studies are consistent with the following conclusions. First, human EGF can be biotinylated with succinimide esters of biotin to target the ϵ-amino groups of lysine residues, with retention of ligand affinity for the EGF receptor. Second, when EGF-XX-biotin is conjugated to OX26/SA, the EGF no longer binds to the EGF receptor (Figure 2). Third, substitution of the 14 atom bis(aminohexanoyl) spacer arm between the biotin moiety and the EGF with a >200 atom extended poly(ethylene glycol) linker restores affinity of EGF for its cognate receptor despite conjugation of the peptide to the BBB delivery vector, OX26/SA (Figure 4).

Biotinylation of EGF with NHS-XX-biotin targets the ϵ-amino moiety of surface lysine residues. Murine EGF lacks internal lysine residues, but human EGF has 2 lysine residues at positions 28 and 48 (*18*, *19*). Although the amino terminus is also a target for biotinylation with succinimide esters, the biotinylation was performed at pH 8.3, which preferentially exposes the ϵ-amino moieties of lysine residues to the succinimide ester (*20*). The EGF-XX-biotin still binds to the human EGF receptor in transfected C6 rat glioma cells as EGF inhibits this binding with an ED_{50} of approximately 1 nM (Figure 2). The total binding of either [^{125}I]EGF-XX-biotin or [^{125}I]EGF-PEG^{3400}-biotin, expressed as percent bound per $(\text{milligram})_p$, is nearly identical to the total binding of unconjugated [^{125}I]EGF to the C6-$EGFR_p$ cells (*2*), indicating that neither biotinylation nor pegylation, per se, impairs ligand binding to the human EGF receptor. These results are consistent with earlier immunocytochemistry experi-

ments showing that biotinylated EGF binds to the EGF receptor in frozen sections of human glioma cells in vitro (*1*). Moreover, EGF-biotin detects the EGF receptor on human glioma cells immunocytochemically with a greater sensitivity than that achieved with monoclonal antibodies to the EGF receptor (*1*). The retention of ligand affinity for its cognate receptor following biotinylation on lysine residues, and the fact that mouse EGF lacks internal lysine residues (*18*, *19*), suggests that the lysine residues at positions 28 or 48 of human EGF do not participate in binding to the EGF receptor. However, when the OX26 MAb is conjugated to streptavidin via a stable thioether linkage and this complex is then bound to EGF-XX-biotin, the EGF no longer binds to the EGF receptor (Figure 2). These observations suggest that binding of EGF-XX-biotin to OX26/SA causes significant steric hindrance of binding of EGF to its cognate receptor. Although a vasoactive intestinal peptide (VIP) analogue has been successfully attached to OX26/SA with the biotin-XX-linker, and with retention of peptide affinity for the cognate receptor (*12*), the attachment of opioid peptides to OX26/SA with this linker eliminates peptide affinity for the opioid receptor (*9*). In the event that the non-cleavable (amide) -XX- linker eliminates ligand and receptor binding following attachment of the peptide to the delivery vector, previous studies have employed a cleavable (disulfide) -SS- linker between the biotin moiety and the therapeutic peptide. In this case, the peptide becomes biologically active with restoration of affinity for its cognate receptor following cleavage of the disulfide bond and release of the peptide from the OX26/SA delivery system (*9*). However, if the majority of the disulfide reductase resides in the cytosol of brain cells (*10*), it is necessary for the vector-SS-peptide conjugate to undergo release from the intracellular endosomal compartment following receptor-mediated endocytosis into the brain cell. In the absence of an obligatory endosomal release function built into the delivery system, the exposure of the conjugate to the cytoplasmic disulfide reductase may be minimal.

Given the potential limitations of either the noncleavable (amide) -XX- linker or the cleavable (disulfide) -SS- linker, there is a need for a third approach for conjugating peptide therapeutics to MAb-based BBB delivery systems that allows for retention of receptor affinity of the peptide therapeutic but does not require a disulfide cleavage. These requirements are satisfied with the use of an extended PEG linker between the biotin moiety and the peptide therapeutic. The radioreceptor assays in Figure 4 show that EGF-PEG^{3400}-biotin binds with high affinity to the EGF receptor, and the ED_{50} of EGF inhibition of this binding is 1 nM, which is identical to ED_{50} of EGF inhibition of EGF-XX-biotin binding to the EGF receptor (Figure 2). Therefore, the placement of the 3400 Da PEG moiety on a surface lysine residue of EGF does not impair peptide binding to the EGF receptor. When the EGF-PEG^{3400}-biotin is conjugated to OX26/SA, there is no impairment in the binding of the EGF to its cognate receptor on C6 glioma cells (Figure 4). The time course of EGF-PEG^{3400}-biotin binding to C6 glioma cells is identical with or without attachment to OX26/SA (Figure 4A). In addition, more than 50% of the binding of [^{125}I]-EGF-PEG^{3400}-biotin conjugated to OX26/SA is displaced by native EGF in the medium (Figure 4B). In the presence of saturating concentrations of EGF (>10 nM) there is still significant binding of [^{125}I]EGF-PEG^{3400}-biotin conjugated to OX26/SA (Figure 4B), and this residual binding is a result of conjugate binding to the transferrin receptor on the C6 glioma cells.

In summary, these studies describe the molecular formulation of an EGF peptide radiopharmaceutical that is conjugated to the OX26 MAb BBB drug delivery system, using an extended poly(ethylene glycol) linker between EGF and the biotin moiety. In contrast to a short bis(aminohexanoyl) -XX- linker, the PEG linker allows for retention of EGF binding to its cognate receptor on rat glioma cells. Many human brain gliomas overexpress the EGF receptor (*1*, *13*, *14*), and EGF peptide radiopharmaceuticals are potential imaging agents for detection of these tumors (*2*). However, EGF does not cross the BBB (*3*), which is consistent with the absence of EGF receptors on endothelial cells (*21*). An optimal use of EGF peptide radiopharmaceuticals to image human brain tumors may require a molecular reformulation of the peptide that involves conjugation to a BBB drug delivery vector.

Antibody-Directed Enzyme Prodrug Therapy with the T268G Mutant of Human Carboxypeptidase A1: In Vitro and in Vivo Studies with Prodrugs of Methotrexate and the Thymidylate Synthase Inhibitors GW1031 and GW1843

L. A. Wolfe, R. J. Mullin, R. Laethem, T. A. Blumenkopf, M. Cory, J. F. Miller, B. R. Keith, J. Humphreys, and G. K. Smith*

Glaxo Wellcome Research and Development Inc., Five Moore Drive, Research Triangle Park, North Carolina 27709. Received May 27, 1998; Revised Manuscript Received November 4, 1998

Antibody-directed enzyme prodrug therapy (ADEPT) is a technique to increase antitumor selectivity in cancer chemotherapy. Our approach to this technology has been to design a mutant of human carboxypeptidase A (hCPA1-T268G) which is capable of hydrolyzing in vivo stable prodrugs of MTX and targeting this enzyme to tumors on an Ep-CAM1-specific antibody, ING1. Through the use of this >99% human enzyme which is capable of catalyzing a completely nonhuman reaction, we hope to increase ADEPT selectivity while decreasing overall immunogenicity of the enzyme−antibody conjugate. In the current report, prodrugs of the thymidylate synthase inhibitors GW1031 and GW1843 and the dihydrofolate reductase inhibitor methotrexate were studied for their wild-type and mutant hCPA enzyme hydrolysis, their in vivo stability, and their use in therapy. Prodrugs with high k_{cat}/K_m ratios for mutated versus wild-type hCPA1 were examined in vitro for their stability in human pancreatic juice, and in vivo for their stability in mouse plasma and tissues. In addition, targeting and in vivo enzyme activity studies were performed with an ING1 antibody conjugate of the mutant enzyme (ING1-hCPA1-T268G). Finally, in vivo therapy studies were performed with LS174T tumors to demonstrate proof of principle. Results indicate that prodrugs can be synthesized that are selective and efficient substrates of hCPA1-T268G and not substrates of the endogenous CPA activities; this leads to excellent in vivo stability for these compounds. In vivo conjugate targeting studies showed that the antibody−enzyme conjugate was targeted to the tumor and enzyme was initially active in vivo at the site. Unfortunately therapeutic studies did not demonstrate tumor reduction. Experiments to determine reasons for the lack of antitumor activity showed that the enzyme activity decreased as a result of enzyme instability. The results offer encouragement for additional novel mutant enzyme improvements and additional in vivo studies on this unique approach to ADEPT.

INTRODUCTION

One of the problems associated with cancer chemotherapy is the lack of selectivity of drug for neoplastic cells over normal proliferating cells, and the resulting systemic toxicity (*1*, *2*). In an attempt to circumvent these problems, investigators have examined the potential of using monoclonal antibodies (mAbs)[1] that bind to tumor-selective antigens localized on the surface of neoplastic cells. This binding specificity can be exploited for tumor-specific delivery of materials conjugated to a targeting antibody. Cytotoxic drugs have been coupled to mAbs (*3*, *4*), and the resulting conjugates are more selective for tumor cells than are drugs alone. Toxicity also is reduced, allowing more drug to be used without affecting highly sensitive normal cells. However, low drug delivery is a problem generally associated with this approach. Efficient drug delivery is compromised by (a) the limitation caused by the number of drug molecules that can be attached to the antibody, (b) antigen density, (c) the limited diffusibility of conjugates compared to drugs alone due to differences in their sizes, and (d) poor internalization of conjugate. Because of these problems, investigators continue to look for alternate modes of therapy.

ADEPT has been proposed as a means to solve these problems (*5*−*10*). This technology involves selectively delivering an activating enzyme to the tumor site by conjugating it to a targeting antibody. This activating enzyme is then used to convert systemically administered

prodrug to drug at the tumor site. The catalytic potential of a targeted enzyme and the high potential prodrug concentration may overcome the low drug delivery problem. The toxic drug would be concentrated around the tumor, and its comparatively low molecular weight should allow for better tumor penetration than antibody−drug conjugates. In addition, this regional tumor-specific activation should lower systemic toxicity. An important decision that needs to be made with this type of therapy is what types of prodrugs and enzymes are to be employed. Although the need to find new active drugs still exists, it would also be of benefit to look at prodrugs of drugs currently used in the clinic since their toxicity and efficacy profiles are already understood. Enzymes that have been considered for ADEPT include both endogenous and nonendogenous types (*11*). One endogenous enzyme being investigated is alkaline phosphatase for the hydrolysis of phosphorylated prodrugs of phenol mustard (*12*), etoposide (*13*−*15*), and mitomycin C (*14*). Another enzyme is carboxypeptidase A for the hydrolysis of methotrexate prodrugs (*16*). Some nonendogeneous enzymes being used include cytosine deaminase for the conversion of 5-fluorocytosine to 5-fluorouracil (*17*) and the bacterial enzyme CPG2 for the cleavage of the glutamic acid moiety from prodrugs of alkylating agents (*18*).

The ADEPT approach is not without its problems. Use of endogenous enzymes may result in the hydrolysis of prodrugs at sites distal to the tumor site, thus increasing toxicity. By contrast, nonendogenous enzymes may generate an immune response which would interfere with multiple rounds of therapy. To address these problems, we recently reported an alternate approach to ADEPT. This strategy in its most generalized form uses an endogenous enzyme mutated at the active site to perform an otherwise nonendogenous reaction to convert an in vivo stable prodrug to active drug only at the targeted tumor. In our prototype example of the concept, the "novel endogenous enzyme" was based upon human CPA1. Binding pocket mutations were introduced into hCPA1 to alter the substrate specificity of the enzyme to allow for hydrolysis of novel prodrugs that were not substrates for wild-type hCPA (*19*). This "novel endogenous enzyme" should be less immunogenic than nonendogenous enzymes, and prodrug hydrolysis at sites distal to tumors should be better controlled than in systems based upon endogenous activities. Simultaneously we have attempted to match mutant enzyme constructs with prodrugs of methotrexate (*19*) and two promising active drugs, GW1031 (*20*) and GW1843 (*20*−*25*). In the current report, the most promising of the previously reported MTX prodrugs and novel prodrugs of two thymidylate inhibitors were studied in vitro and in vivo to determine the therapeutic potential of this approach.

MATERIALS AND METHODS

Chemicals. GW1031, GW1843, and all prodrugs were synthesized at Glaxo Wellcome Inc., Research Triangle Park, NC. ING1-TMT was obtained from Sterling Winthrop Immunoconjugates (Philadelphia, PA). ^{90}Y was purchased from Dupont NEN (Milford, MA). Methotrexate, HPA, trypsin, HPL, and L-glutamine were purchased from Sigma Chemical Co. (St. Louis, MO). RPMI-1640 tissue culture medium was purchased from Gibco BRL (Grand Island, NY), and FBS was purchased from JRH Biosciences (Lenexa, KY). Human serum was prepared in house from blood donors.

Kinetic Assays. Determination of the activity of hCPA1 and hCPA1-T268G on prodrugs was done by kinetic assays. Kinetic assays either were performed spectrophotometrically as described by Smith et al. (*19*) or were HPLC-based. HPLC assays were carried out in 0.5 mL reactions at 25 °C in assay buffer (25 mM Tris-HCl, 100 mM NaCl, pH 7.4). Reactions with varying concentrations of prodrug in buffer were preincubated at 25 °C for 3 min before reactions were initiated by addition of a known amount of human CPA enzyme. Aliquots (75 μL) of the reaction were withdrawn at predetermined times and stopped by the addition of 75 μL of 1 M perchloric acid. An aliquot of the acidified reaction (20 μL) was injected onto a Waters Nova-Pak C18 column, and the prodrug and drug were resolved with the following step gradient (solvent A = 0.1% aqueous trifluoroacetic acid, solvent B = 0.1% trifluoroacetic acid in acetonitrile): 18% B for 3 min, 18−50% B over 0.1 min, and 50% B for 3.9 min. Kinetic rates were determined from the linear portion of product vs time plots.

HPLC Analysis. HPLC analysis of in vivo samples consisted of using a 715 WISP autoinjector (Waters, Milford, MA), a constaMetric 4100 solvent delivery system (LDC Analytical, Riviera Beach, FL), a variable-wavelength spectroMonitor D detector (LDC) set at the absorbance maximum of each individual prodrug, and a 3.9 × 300 mm C18, 4 μm Nova-Pak or a C18, 10 μm μBondapak HPLC column equipped with a C18 guard column. Data acquisition and analysis were performed with a DS-80 microcomputer (Digital Specialities, Chapel Hill, NC). Prodrugs of GW1031 and GW1843 and the MTX prodrug 2-carboxyPhe were injected onto the Nova-pak column equilibrated at 5−20% acetonitrile containing 2% HOAc, pH 3.0, and run at a flow rate of 1 mL/min. A linear gradient was immediately run over 25−35 min to a final concentration of 50% acetonitrile, 2% HOAc, pH 3.0. Absorbance was monitored at 259−266 nm. All other prodrugs were injected onto the μBondapak column equilibrated with 16% acetonitrile, 5 mM Pic A, 10 mM $NH_4H_2PO_4$. A linear gradient of 16−50% acetonitrile was run over 30 min at 1 mL/min, and compounds were detected at 307 nm.

Stability in Human Pancreatic Fluid. Prodrugs were evaluated for their stability in activated human pancreatic fluid as described by Smith et al. (*19*). Briefly, prodrug stability was determined in diluted activated pancreatic fluid. After selected incubation times, prodrug hydrolysis was determined by HPLC.

Animals and Cell Lines. CD-1 nu/nu female mice (4−6 weeks old, 20−24 g) were purchased from Charles River Laboratories (Wilmington, MA). CB17 and Swiss nude female mice were purchased from Taconic Farms, Inc. (Germantown, NY). Mice were housed in microisolator cages (Lab Products Inc., Rockville, MD) in groups of up to four mice per cage. The human colon adenocarcinoma cell lines (WiDr and LS174T) were purchased from the American Type Culture Collection (Rockville, MD). Wein-133 cells, a B-cell lymphoma, were kindly provided by Dr. John Tite (The Wellcome Research Laboratories, Beckenham, U.K.). WiDr cells were grown in RPMI 1640, low-folate media supplemented with 10% charcoal-dialyzed FBS and with 10 nM calcium leucovorin (Glaxo Wellcome Inc., RTP, NC). Wein-133 cells were grown in RPMI 1640 containing 10% FBS with an additional 2.05 mM L-glutamine added.

Tumor Implantation. WiDr cells were implanted sc as a 0.15 mL solution of 1.5 × 10^6 cells in PBS. LS174T and Wein-133 cells were implanted as a 0.20 mL solution of 2 × 10^6 cells in 50% low-endotoxin matrigel (Col-

laborative Biomedical Products, Bedford, MA) in PBS. Wein-133 cells were implanted into 400 rad irradiated nude mice (Gammacell 40 irradiator, Nordion International Inc., Ontario, Canada). Tumors were allowed to grow to approximately 200−400 mg before animals were used for study.

In Vivo Drug Stability and Biodistribution. Mice bearing either WiDr, Wein-133, or LS174T tumors were dosed ip bolus or iv at 50 mg/kg by injecting 0.01 mL/g mouse with a 5 mg/mL solution of prodrug in PBS, pH 6−8. Animals were sacrificed after 30 min and 2 h, and the plasma, liver, kidney, small intestine and pancreas, large intestine, spleen, cecum, feces, and tumor tissues were collected. Plasma was frozen at −70 °C, and tissues were snap-frozen in liquid nitrogen and stored at −70 °C. Duplicate animals were sacrificed for each time point. Plasma was prepared for extraction by dilution (4-fold) with ice-cold 0.1 N HCl. Tissues were prepared for extraction by homogenization with a Polytron (Brinkmann Instruments, Westbury, NY) equipped with a PTA 7 generator in 5 volumes of ice-cold 0.1 N HCl. Drugs were subsequently extracted by adding 5 volumes of −20 °C acetonitrile to 2 volumes of the HCl homogenate. After a 5 min incubation on ice, samples were centrifuged at 12400*g* for 15 min. Supernatants were collected and diluted 3.57-fold with PBS to reduce the final acetonitrile concentration to 20%. Diluted supernatants were then analyzed by HPLC as described above. To account for drug recovery, control homogenates were spiked with drug, prodrug, or PBS prior to the acetonitrile extraction step. After correction for recovery of these standards, the levels of drug and prodrug and the stability of the prodrug were calculated.

Toxicity of MTX and Prodrugs in Mice. MTX prodrugs demonstrating good kinetic and in vivo stability profiles were compared to MTX for toxicity. Prodrugs were dosed iv into mice for 5 days, and a prodrug was considered toxic if weight loss exceeded 15%. CD-1 nu/nu female mice were dosed with MTX (2, 4, or 6 mg/kg), MTX-Phe (5, 15, or 45 mg/kg), MTX-2-cyclopentylPhe, MTX-3-cyclopentylPhe, or MTX-3-cyclopentylPhe (10, 20, or 40 mg/kg). Swiss nude mice were dosed with MTX (2.5, 4, or 5.5 mg/kg), MTX-cyclopentylTyr, or MTX-3-cyclobutylPhe (30, 40, or 50 mg/kg).

Radiolabeling of ING1 Antibody. ^{90}Y-Antibody conjugate, [^{90}Y]-TMT-ING1, was prepared from TMT-ING1 as follows. Using metal-free containers and pipets throughout, 3.8 μL of ^{90}Y (0.075 mCi, diluted with Ultrex water) was combined with 50 μL of ING1-TMT at 5 mg/mL (250 μg). The reaction was mixed and allowed to stand 60 min at 25 °C; 5 μL of 10 mM diethylenetriaminepentaacetic acid (DTPA) was added, mixed, and allowed to stand another 30 min. The reaction was purified through two 1 mL Biospin 30 columns (Biorad) equilibrated with Dulbecco's phosphate-buffered saline. Quality control was determined by thin-layer chromatography of a small aliquot on silica gel 60 (0.2 mm thickness; catalog no. 5735; E. Merck; mobile phase 5 g of ammonium acetate, 50 mL of H_2O, and 50 mL of methanol). The percent of the Biospin-purified material as chelate was typically over 95%. The purified material was diluted into 4.9 mL of 5 mg/mL ascorbate. Animals were dosed with 200 μL of ascorbate-diluted material.

Conjugation of Mutant hCPA to ING1. Antibody−enzyme conjugate ING1-hCPA1-T268G was prepared as described previously (*19*). Briefly, the process was carried out in three steps.

(A) Enzyme Modification. Four milligrams of mutant carboxypeptidase A was combined with 0.15 mg of Sulfo-SMCC (Pierce Chemical Co.) in 400 μL of PBS and was stirred for 45 min at 25 °C. The modified enzyme was then purified through a 1 × 13 cm G-25 medium column equilibrated with PBS.

(B) Antibody Modification. The full-length IgG_1 antibody ING1 was modified with the amine-reactive reagent 2-iminothiolane; 1.8 mg of antibody was combined with 0.22 mg of 2-iminothiolane in 1.3 mL of 50:50 PBS/0.1 M triethanolamine hydrochloride, 2 mM EDTA, pH 8.0, under anaerobic conditions. This was allowed to react with stirring for 1 h and 45 min, and the modified antibody was purified through a 1 × 13 cm G-25 medium column equilibrated with 0.02 M sodium acetate, 0.1 M NaCl, pH 5.8, bubbled with and maintained under a He atmosphere.

(C) Coupling of Modified Antibody with Modified Enzyme. The modified antibody was collected directly from the G-25 column into the solution of the modified carboxypeptidase A. The resulting mixture was then adjusted to pH 7.4 with NaOH, made anaerobic, and allowed to react with stirring at 4 °C for 18 h. After treatment with 0.3 mM mercaptoethanolamine at room temperature for 1 h, the conjugate was then concentrated to 1 mL on an Amicon PM10 membrane and then purified on Superose 12 HR 10/30.

In Vivo Targeting Studies. Targeting studies were done with radiolabeled antibody (ING1) alone and with antibody−enzyme conjugate (ING1-hCPA1-T268G). CB17 SCID female mice bearing LS174T tumors sc were dosed iv with 10 μg of [^{90}Y]-TMT-ING1. At 24, 48, 72, or 144 h after antibody administration, 100 mg tissue fragments were dissolved in 1 mL of Solvable tissue solubilizer solution (NEN Research Products, Boston, MA) at 55 °C for 48 h, followed by counting in 20 mL of Formula 989 scintillation cocktail (NEN). The second targeting experiment was designed to assay targeted CPA activity in tissues. Swiss nude female mice bearing LS174T tumors sc were dosed iv with 300 μg of ING1-hCPA1-T268G conjugate. At 6, 24, 48, or 72 h following dosing, plasma and tissues were collected and snap-frozen in liquid N_2 and stored at −80 °C. Plasma and tissues were diluted or homogenized in assay buffer and incubated (without centrifugation) in 20 μM MTX-3-cyclopentylTyr for varying times. Reactions were stopped with the addition of perchloric acid, and supernatants were analyzed by HPLC.

In Vivo Therapy Studies. Swiss nu/nu female mice bearing LS174T sc implants were dosed with 300 μg of ING1-hCPA1-T268G. After 24, 48, or 72 h, mice were dosed iv for 5 days with 30 mg/kg MTX-3-cyclopentylTyr. Mice were monitored for tumor regression.

Conjugate Activity (Post-Tumor Injection). Swiss nude female mice bearing LS174T tumors were dosed with 300 μg of ING1-hCPA1-T268G conjugate at three sites directly into the tumor. Mice were then dosed iv with 100 mg/kg MTX-3-cyclopentylTyr 30 min prior to sacrificing at 0.5, 6, 24, 48, or 96 h post-conjugate administration. Plasma and tumor were extracted and frozen in liquid N_2 and stored −80 °C. Samples were processed for prodrug and drug levels as described above.

In Vitro HCPA1 And Hcpa1-T268G Stability Studies. Wild type (hCPA1) and mutant (hCPA1-T268G) enzymes were studied for their stability at 0.1 mg/mL in PBS or human serum. Blood was collected from a healthy, normal volunteer. Serum was generated at room temperature, collected by centrifugation, and stored as aliquots at −70 °C. Enzyme was diluted from 1 mg/mL stocks (in 50 mM Tris, pH 7.4) directly into PBS, or

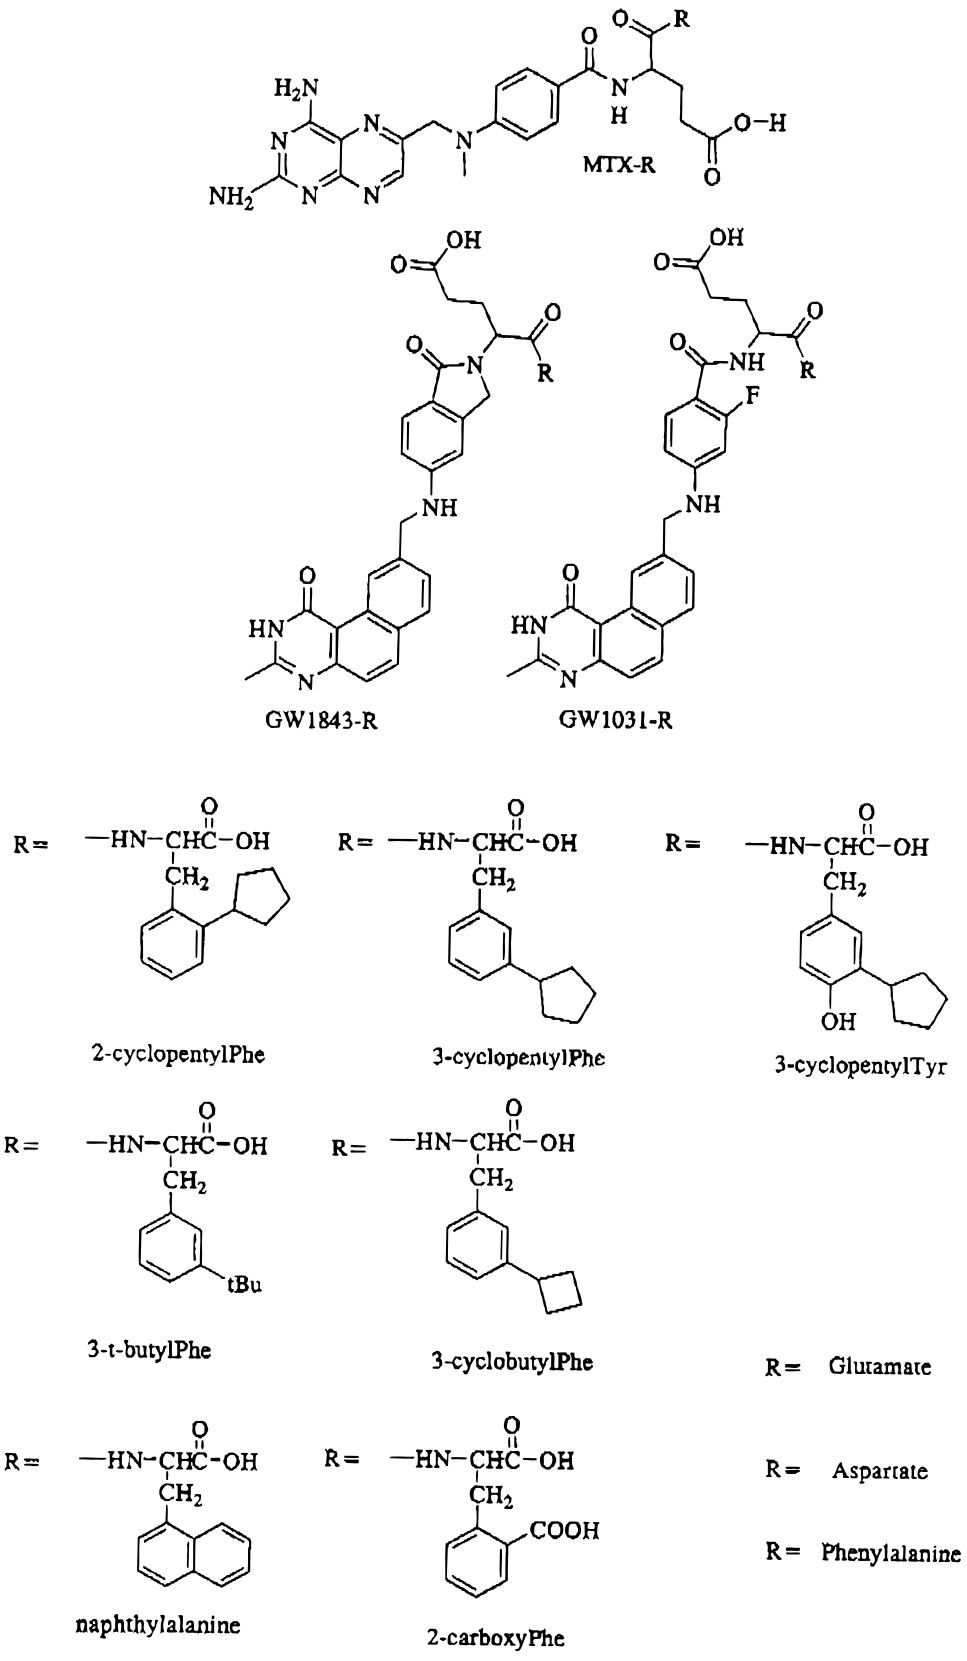

Figure 1. Prodrug structures.

human serum. Samples were then sterile-filtered into sterile screw cap centrifuge tubes for denaturation reactions. Sterility was maintained throughout the experiment. At specified times, samples were removed and assayed for CPA activity with hippurylphenylalanine as described previously (*19*).

RESULTS

Prodrugs under investigation were classified into four catagories (Figure 1 and Table 1). Class I prodrugs have natural, nonpolar amino acids and are substrates for wild-type CPA1. Class II prodrugs have natural, acidic amino acids. Class III prodrugs have nonnatural, bulky,

[a] All data from MTX prodrugs are reproduced from Smith et al. (*19*) and included here for comparison with in vivo data. [b] Class I: prodrugs with natural, nonpolar amino acids (substrates for wild-type CPA1). Class II: prodrugs with natural, acidic amino acids (substrates for wt carboxypeptidase G). Class III: prodrugs with nonnatural, bulky, aromatic amino acids (substrates for larger pocket mutants). Class IV: prodrugs with nonnatural, acidic, aromatic amino acids. [c] Pancreatic juice: numbers represent stability relative to MTX-Phe. [d] nd: not determined. [e] In Phe and Tyr prodrugs, position 2 = ortho and position 3 = meta.

aromatic amino acids and were designed to be substrates for larger-pocket hCPA mutants. Class IV prodrugs have nonnatural, acidic, aromatic amino acids and were designed as substrates for positively charged mutant carboxypeptidases.

Kinetic Assays. k_{cat} and K_m values for prodrugs of MTX were reported previously (*19*). Here, kinetic constants for the prodrugs of GW1031 and GW1843 were measured using wild-type (hCPA1) and mutant human CPA1 (hCPA1-T268G). Values were compared to those of MTX-Phe, a prodrug suggested by Vitols et al. (*26*) to have good potential in ADEPT. An ADEPT prodrug should show resistance to hydrolysis by endogenous enzymes such as wild-type hCPA1 and be easily hydrolyzed by an activating enzyme such as hCPA1-T268G. Therefore, desirable substrates for ADEPT would have much lower k_{cat}/K_m ratios with hCPA1 than that with hCPA1-T268G. In addition, a poor k_{cat}/K_m for hCPA2 also is needed (*19*). Our data (Table 1) indicate that while MTX-Phe demonstrated a extremely high k_{cat}/K_m ratio for hCPA1-T268G, it was also a very good substrate for hCPA1 and hCPA2. GW1031-Phe also had a similarly high k_{cat}/K_m for the wild-type enzyme, but GW1843-Phe was not hydrolyzed by either enzyme as efficiently as the other class I prodrugs. These data indicate that the class I prodrugs MTX-Phe and GW1031-Phe would not likely be good candidates in ADEPT since premature prodrug hydrolysis would likely occur in vivo. The other class I prodrug, GW1843-Phe, and all class II prodrugs tested were poor substrates for either the hCPA1 or the hCPA1-T268G enzyme. This poor hydrolysis with hCPA1-T268G in addition to the lack of specificity for the mutant enzyme over the wild-type enzyme indicates that these compounds are poor substrates in ADEPT with hCPA1-T268G. Class III prodrugs gave kinetic profiles where the k_{cat}/K_m for the mutant enzyme was much better than that observed with the wild-type enzyme. GW1031-naphthylAla, like MTX-naphthylAla reported previously (*19*), is a poor hCPA1 substrate but is an excellent hCPA1-T268G substrate. However, MTX-naphthylAla is an excellent substrate for hCPA2 as well, and therefore would be a poor ADEPT prodrug. With the exception of the naphthylAla prodrugs and MTX-2-cyclopentylPhe, class III prodrugs had no observed turnover of prodrug with hCPA1 (*19*). All class III MTX prodrugs showed some turnover with hCPA2, except MTX-3-cyclopentylTyr. However, observed turnover was modest with the exception of MTX-naphthylAla. The very high k_{cat}/K_m and specificity of class III prodrugs for hCPA1-T268G indicate that class III prodrugs show potential for ADEPT. The kinetic data from class IV prodrugs resembled that of class II prodrugs in that there was poor enzyme activity with both enzymes (*19*). Therefore, class IV prodrugs are not likely candidates for ADEPT with hCPA1-T268G. Based on the kinetic data, the top four prodrugs (all class III) are rank-ordered for stability versus the hCPA enzymes as MTX-3-cyclopentylTyr > MTX-3-cyclopentylPhe > MTX-3-*tert*-butylPhe > MTX-3-cyclobutylPhe.

Pancreatic Fluid Assays. In an attempt to model their in vivo stability, selected prodrugs were analyzed for their stability in activated human pancreatic fluid (*19*). MTX-Phe, a prodrug previously reported in the literature as having potential in ADEPT, was chosen as the prodrug with which others were compared. Higher relative stabilities in pancreatic fluid should correlate to an increase in in vivo prodrug stability. Results (Table 1) from the pancreatic fluid assay correlated fairly well with the kinetic data shown in the same table. Higher relative stability in pancreatic fluid paralleled resistance to hydrolysis by wild-type hCPA1 and hCPA2 in our kinetic assays (*19*). Based on the pancreatic fluid assays, the three best prodrugs are rank-ordered for stability as MTX-3-cyclopentylTyr > MTX-3-cyclopentylPhe > GW1031-2-carboxyPhe. The latter, which belongs to class IV, would not be a good prodrug with T268G. If more weight is given to the pancreatic fluid assay, which should be a better indication of in vivo stability than the kinetic assays, then the data indicate that MTX-3-cyclopentylTyr > MTX-3-cyclopentylPhe > MTX-3-cyclobutylPhe, MTX-3-*tert*-butylPhe. If a correlation of the pancreatic juice stability and the in vivo stability could be found, it would point to the former as a useful primary screen for in vivo stability of compounds. In vivo experiments were conducted to test this.

In Vivo Stability and Biodistribution. Fourteen prodrugs were examined for their stability (Table 2) and biodistribution in mice (Table 3). The compound suggested by Vitols et al. (MTX-Phe) showed poor stability

[a] Mice were dosed and samples processed as described in Table 2. Plasma and tissue prodrug levels were determined. Values are in nmol/g for tissue and μM for plasma. [b] Prodrug:MTX, MTX-Asp, MTX-2-cyclopentylPhe, MTX-3-cyclobutylPhe, MTX-3-cyclopentylPhe, MTX-3-*tert*-butylPhe, and MTX-3-cyclopentylTyr dosed iv; all others dosed ip. [c] Lg.Int: large intestine. [d] SIP: small intestine and pancreas. [e] Tumor: LS174T for MTX-3-cyclobutylPhe; WiDr for MTX-Phe; GW1031-Phe, GW1031-Glu, and Wein-133 for all others. [f] nd = no drug or prodrug detected.

in vivo, as expected, based on the kinetic and pancreatic fluid assay data. MTX-Phe was completely converted to drug in the small intestine and pancreas by 2 h (*19*). One other class I prodrug, GW1031-Phe, was similarly unstable, and the other, GW1843-Phe, was somewhat more stable than MTX-Phe in vivo, consistent with their CPA

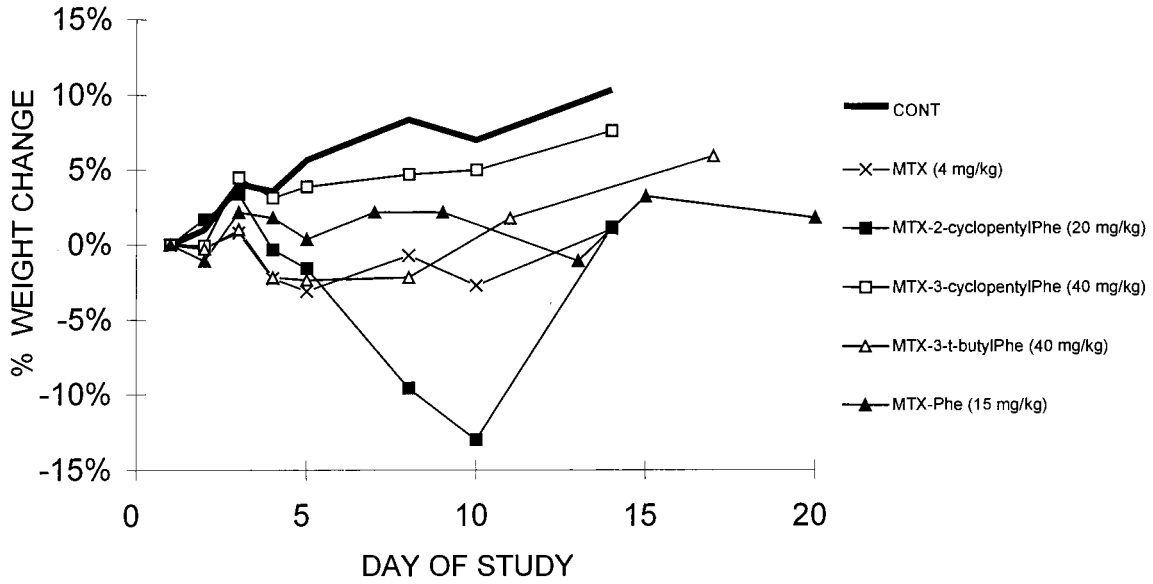

Figure 2. Toxicity of MTX and prodrugs in CD-1 nu/nu mice. CD-1 nu/nu female mice were dosed iv for 5 days with varying concentrations of MTX or selected class III prodrugs. A prodrug was deemed toxic if a 15% weight loss occurred. Doses shown for MTX and MTX-2-cyclopentylPhe were at the limit of toxicity. Doses for MTX-3-cyclopentylPhe and MTX-3-*tert*-butylPhe were the highest doses tested. Data are represented as percent weight change as a function of time.

substrate activity and pancreatic fluid stability. The two prodrugs tested in vivo from class II, GW1031-Glu and MTX-Asp, were more stable, again consistent with their stability from hCPA1 hydrolysis. Hydrolysis of these compounds was observed, however, particularly in tissues taken from the gut, where concentrations of CPA are the highest. Class III prodrugs generally gave better in vivo stability results than class I and class II. The exception was MTX-naphthylAla which is a substrate for wild-type hCPA2 and gave a profile similar to those of class I. The rest of the class III prodrugs are rank-ordered for stability as MTX-3-cyclopentylTyr > MTX-3-cyclopentylPhe > MTX-3-cyclobutylPhe > MTX-3-*tert*-butylPhe > MTX-2-cyclopentylPhe. Class IV prodrugs had similar stability profiles to MTX-3-cyclopentylTyr, the most stable class III prodrug. The biodistributions of class I, class II, and class IV prodrugs and the naphthylAla class III prodrugs indicate that the liver is the primary site of initial prodrug accumulation. The other class III prodrugs were found more in the small intestine and pancreas than the liver at the earliest time point tested. In all studies where feces were analyzed, the prodrug concentration in the feces after 2 h was higher than any tissue studied. This generally was the case after 30 min as well. All prodrug classes demonstrated rapid plasma clearance. This rapid biliary excretion was similar to that observed for MTX (*27*). Based upon kinetic data, pancreatic juice assays, and the in vivo stability and biodistribution results in mice, five prodrugs (MTX-Phe, MTX-2-cyclopentylPhe, MTX-3-cyclopentylPhe, MTX-3-*tert*-butylPhe, and MTX-3-cyclopentylTyr) were selected for mouse toxicity studies and compared to MTX.

Toxicity of MTX and Prodrugs in Mice. Selected prodrugs were evaluated in vivo for toxicity and compared to MTX (Figures 2 and 3). Toxicity was defined as death and/or a greater than 15% weight loss. In Figure 2, doses shown for MTX (4 mg/kg), MTX-Phe (15 mg/kg), and MTX-2-cyclopentylPhe (20 mg/kg) were at the limit of toxicity, and consistent with this, each produced a significant delay in weight increase at this dose. MTX-Phe resulted in 4 of 4 deaths at the dose above this limit (45 mg/kg). Doses for MTX-3-cyclopentylPhe (40 mg/kg) and MTX-3-*tert*-butylPhe (40 mg/kg) were the highest

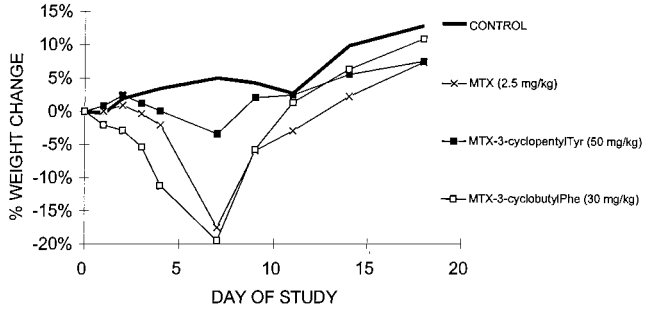

Figure 3. Toxicity of MTX and prodrugs in Swiss nude mice. Swiss nude female mice were dosed as described in Figure 2. The dose shown for MTX-3-cyclopentylTyr was the highest dose tested. The dose for MTX-3-cyclobutylPhe was the lowest dose tested and resulted in 2 of 3 deaths. The dose for MTX was the highest dose tested without toxicity. Data are represented as described in Figure 2.

doses tested; the latter compound produced a delay in weight increase. In Figure 3, the dose shown for MTX-3-cyclobutylPhe (30 mg/kg) was the lowest dose tested and resulted in 2 of 3 deaths. The dose for MTX (2.5 mg/kg) was the highest dose tested without toxicity. The dose for MTX-3-cyclopentylTyr (50 mg/kg) was the highest dose tested and had no toxicity. The data indicate that the in vivo stable prodrugs MTX-3-cyclopentylPhe, MTX-3-*tert*-butylPhe, and MTX-3-cyclopentylTyr could be safely dosed at 10−20 times the MTX maximum tolerated dose while the less stable prodrugs MTX-Phe, MTX-2-cyclopentylPhe, and MTX-3-cyclobutylPhe were toxic. These unstable and toxic prodrugs therefore would be less useful ADEPT prodrugs.

In Vivo Targeting Studies. Targeting studies were done to determine if an antibody−enzyme conjugate, ING1-hCPA1-T268G, which targets Ep-CAM-1 (*28*) on LS174T tumors, could be shown to target the tumor in vivo and if the enzyme moiety of the conjugate retained its catalytic activity in vivo. Desired results would be an accumulation of antibody−enzyme conjugate only at the tumor with a concurrent drop of plasma levels of conjugate. In vivo targeting studies were first done with ^{90}Y-labeled antibody to verify that ING1 targets LS174T. The data indicated that dosing with 10 μg of ING1 does target

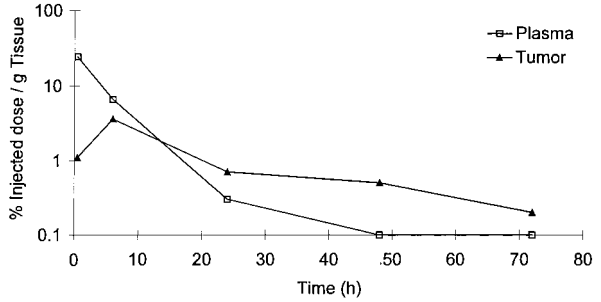

Figure 4. In vivo targeting of ING1-hCPA1-T268G in mice. Swiss nude female mice bearing LS174T tumors sc were dosed iv with 300 μg of ING1-hCPA1-T268G conjugate. At 6, 24, 48, or 72 h following dosing, plasma and tissues were collected and snap-frozen in liquid N_2 and stored −80 °C. Plasma and tissues were diluted or homogenized in assay buffer and incubated (without centrifugation) in 20 μM MTX-3-cyclopentylTyr for varying times. Reactions were stopped with the addition of perchloric acid, and supernatants were analyzed by HPLC. Data are reported as % injected dose/g of tissue as a function of time.

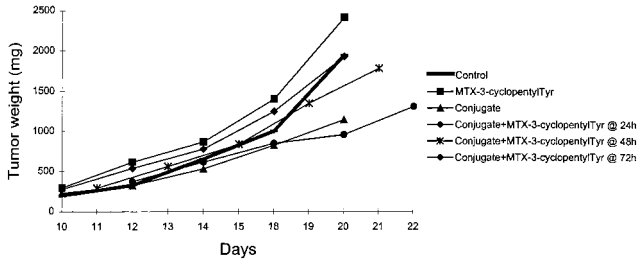

Figure 5. In vivo therapy study. Swiss nu/nu female mice bearing LS174T sc implants were dosed with 300 μg of ING1-hCPA1-T268G. After 24, 48, or 72 h, mice were dosed iv for 5 days with 30 mg/kg MTX-3-cyclopentylTyr. Mice were monitored for tumor growth using electronic caliper measurements.

LS174T with levels approaching 30% ID/g of tissue at 48 h while antibody levels in the liver were only 7% (data not shown). All other tissues studied (plasma, kidney, bone, and spleen) had less accumulation of antibody than tumor. Tumor-to-blood ratios were 1.0, 1.9, 4.4, and 19.6 at 24 h, 48 h, 72 h, and 144 h, respectively. Thus, ING1 targeted tumor and was cleared from circulation. A second targeting study was then performed by dosing with 300 μg of the ING1-hCPA1-T268G antibody−enzyme conjugate. Targeting studies with ING1-hCPA1-T268G (Figure 4) gave tumor-to-blood ratios of 2.7 at 24 h. As expected, conjugate levels in the blood dropped rapidly while levels in the tumor showed a much slower rate of decrease. The level of active conjugate found in tumor was approximately 1% ID/g of tissue. These data were encouraging, and an in vivo therapy study was designed.

In Vivo Therapy Study. An in vivo therapy study in Swiss nude mice bearing LS174T was performed using a single 300 μg dose of ING1-hCPA1-T268G followed by five daily doses of 30 mg/kg MTX-3-cyclopentylTyr. Prodrug dosing was commenced at 24, 48, or 72 h post-conjugate dose. Mice were monitored for tumor growth inhibition and compared to untreated mice. Results (Figure 5) indicate that under these conditions, the ADEPT was not efficacious.

Conjugate Activity (Post-Tumor Injection). In an attempt to determine why the therapy studied failed, the activity of ING1-hCPA1-T268G conjugate was studied as a function of time after direct injection into LS174T tumors. In this experiment, conjugate was injected into the tumor. Then immediately or 6, 24, 48, or 96 h later MTX-3-cyclopentylTyr was dosed systemically as in the therapy experiment. After another 30 min, animals were killed, and MTX and MTX-3-cyclopentylTyr levels were determined in tumor and plasma as described in the in vivo drug stability section. This protocol allowed determination of hCPA1-T268G activity. The results (Table 4) show absolute levels of these compounds as well as the inferred percent conversion of prodrug to drug at that site. It can be seen that prodrug was found in both the tumor and plasma at all time points. In addition, drug (MTX) was also found in the tumors at the early time points. The targeted enzyme converted 42.9, 30.1, and 0% of MTX-3-cyclopentylTyr to MTX at 0.5, 6, and 24 h, respectively. No MTX was found in the plasma at any time point. This indicates that the MTX found in the tumors was generated exclusively via the tumor-localized enzyme. In addition, since MTX was not found in tumors from (control) animals that were not dosed with conjugate, the prodrug was synthesized specifically by the targeted enzyme. This experiment then clearly shows that active enzyme was localized to the tumor by the ING1-hCPA1-T268G conjugate, and the activity was capable of producing MTX in situ. However, enzyme activity targeted to the tumor was lost by 24 h. Therefore, the result explains the lack of response in the in vivo therapy study since the earliest prodrug was dosed for therapy 24 h after conjugate administration. By then, conjugate activity would of been lost.

Table 4. Activity of ING1-T268G-CPA1 after Direct Injection into LS174T Tumors (% Conversion of MTX-3-cyclopentylTyr)[a]

time[b] (h)	plasma [MTX][c]	plasma [prodrug]	plasma % conv	tumor [MTX]	tumor [prodrug]	tumor % conv

[a] Swiss nude female mice bearing LS174T tumors were dosed with 300 μg of ING1-hCPA1-T268G conjugate at 3 sites directly into the tumor. Mice were then dosed iv with 100 mg/kg MTX-3-cyclopentylTyr at 0.5, 6, 24, 48, or 96 h post-conjugate administration. Mice were sacrificed 30 min following prodrug administration. Plasma and tumor were extracted and snap-frozen in liquid N_2 and stored at −80 °C. Samples were processed and analyzed by HPLC for prodrug concentration and stability (% conversion of MTX-3-cyclopentylTyr). [b] Time: time between conjugate dose and tissue extraction. [c] Concentration in μM (plasma) or nmol/g of tissue (tumor). [d] CTL: no conjugate control.

In Vitro Conjugate Stability Studies. We have reported that hCPA1-T268G is relatively stable at 37 °C (*19*). Therefore the complete loss of activity by 24 h was surprising. One possible explanation for the loss of conjugate activity in the therapy study is that serum factors may inactivate the enzyme. To test this, an in vitro 37 °C stability study was performed on both hCPA1 and hCPA1-T268G in PBS and in human serum. Results in Figure 6 show that, as we reported previously, the half-life for the wt hCPA1 was significantly longer in PBS than was that of hCPA1-T268G. This loss of stability upon mutation may derive from the destabilizing effect that cavity-creating mutations can produce (*29*). Surprisingly, however, the half-life of hCPA1 was reduced dramatically from 140 h in PBS to ∼24 h in human serum. The half-life of the hCPA1-T268G was also reduced by human serum, but not as dramatically, from 24 to ∼15 h. This inactivation of the enzyme in human serum resulted in 70% loss of hCPA1-T268G activity by 24 h and 90% loss of activity by 72 h. Thus, serum factors do inactivate the enzyme and can probably account for

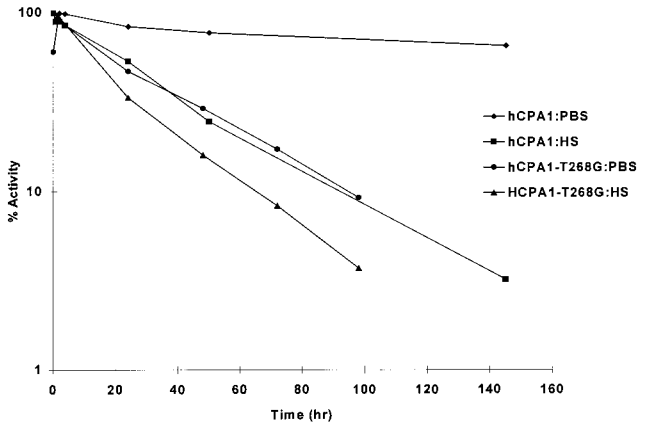

Figure 6. Stability of hCPA1 and hCPA1-T268G at 37 °C in vitro in PBS or human serum (HS). Wild-type (hCPA1) and mutant (hCPA1-T268G) enzymes were studied for their stability at 0.1 mg/mL in PBS or human serum. Enzyme was diluted directly into PBS or human serum. At specified times, samples were removed and assayed for CPA activity with hippurylphenylalanine. Data are shown as percent enzyme activity as a function of time.

some of the activity loss in vivo. However, since 30% activity remained at 24 h, the serum denaturation studies may not account for loss of all detectable activity in vivo at the tumor by 24 h. The stability of the enzyme under in vivo relevant conditions clearly warrants further study.

DISCUSSION

Our approach to ADEPT is to overcome the problem of enzyme selectivity vs immunogenicity by mutating a human enzyme to provide it with a nonendogenous activity, thereby minimizing immunogenicity and maximizing selectivity. The objectives of the current study were to examine the stability of four classes of prodrugs which would be suitable substrates for the novel mutant human enzyme hCPA1-T268G but would not be substrates for the wild-type hCPA1. The short-term biodistribution of these prodrugs was also determined in this effort. Selected prodrugs were then evaluated in vivo for their toxicity, elimination, and pharmacokinetic profiles. Finally targeting studies were done with antibody and antibody−enzyme conjugate in preparation for an in vivo therapy study.

Three assays were developed to examine prodrug stability. For a primary screen, kinetic assays were performed to generate k_{cat} and K_m values. The in vivo stabilities of prodrugs were then determined in mice. Compounds with both high and low k_{cat}/K_m ratios were studied in vivo to demonstrate a correlation between the kinetic and in vivo data. A third assay, human pancreatic fluid stability, was later developed as a simpler and perhaps more relevant reflection of prodrug stability in humans. This last assay was eventually used as a secondary screen prior to the more time-consuming in vivo study. Promising MTX prodrugs were dosed in mice up to 20 times the MTD of MTX to determine if a MTD of prodrug could be obtained. Targeting studies were done to demonstrate that our antibody was selective by targeting tumor better than normal tissue and that our antibody−enzyme conjugate was both selective and active. Finally, an in vivo therapy study was done.

The data indicate that we were able to generate very stable prodrugs of both the DHFR inhibitor MTX and the TS inhibitor GW1031 (MTX-3-cyclopentylTyr, MTX-carboxyPhe, GW1031-2-carboxyPhe, and MTX-3-cyclopentylPhe). The pancreatic fluid and in vivo screens produced the same trends for stability. It was expected that the stability of prodrugs in vivo or in pancreatic fluid would be predicted from the k_{cat}/K_m for the prodrug with hCPA1 and hCPA2. Generally, the hCPA1 kinetics alone were enough to predict in vivo and pancreatic fluid stabilities. The naphthylalanyl prodrugs of GW1031 and MTX, however, were much less stable in both the in vivo and pancreatic fluid assays than predicted from the kinetic data of hCPA1 alone. The lack of stability of these compounds in vivo, particularly in the small intestine and pancreas, seemed to suggest the presence of carboxypeptidases other than CPA1 in both mice and humans. Another CPA, CPA2, has been identified in rat (*30*) and human (*31*) but has yet to be reported in the cow (*32*). This enzyme prefers bulkier amino acids than CPA1. Indeed, we have shown previously that the MTX-naphthylalanine prodrug is hydrolyzed 1000 times more efficiently by hCPA2 than hCPA1 (*19*, *31*). We assume that CPA2 is the activity in mice and human pancreatic juice responsible for the hydrolysis of the naphthylalanyl prodrugs of GW1031 and MTX (*19*), and when it was included in the analysis, the stabilities of all compounds in vivo or in pancreatic fluid were readily predicted (*19*).

The highest in vivo stability, along with high hCPA1-T268G activity, was observed with the nonnatural, bulky, aromatic amino acid prodrug MTX-3-cyclopentylTyr, a class III prodrug. With the exception of the naphthylalanyl prodrugs as discussed above, this class in general showed the most promise for ADEPT with good in vivo stability and high hCPA1-T268G activity. Prodrugs of class IV, those with a nonnatural, acidic, aromatic amino acid substituent, and which were designed as substrates for mutant carboxypeptidases with positively charged active sites, also showed excellent in vivo stability. These compounds were, however, not good substrates for hCPA1-T268G, and efforts to produce an enzyme with an active site positive charge have thus far been unsuccessful (Table 1 and ref *19*). Nonetheless, their in vivo properties make them of continued interest. Compounds of class II, those prodrugs with an aspartate or glutamate substituent, were less stable in vivo, but considerably more stable than those of class I. As such they too may have utility if an appropriate enzyme can be produced. Finally, compounds of class I, those with a natural, nonpolar amino acid attached and which are substrates for wild-type CPA1, had low stability in vivo. These compounds would appear to have the lowest probable utility for ADEPT.

It is possible that semistable prodrugs could be used in ADEPT. Obviously, very stable prodrugs such as MTX-3-cyclopentylTyr would be best; however, prodrugs with partial degradation may still be useful if systemic toxicity can be avoided. For example, Senter et al. (*14*) using an alkaline phosphatase catalyzed system observed better antitumor activity with etoposide phosphate than etoposide, even though they observed prodrug hydrolysis in the absence of antibody−enzyme conjugate. In our case, the maximum tolerated dose of stable and semistable methotrexate prodrugs in mice was determined to ascertain how much endogenous degradation would be acceptable. Toxicity studies indicated that stable prodrugs such as MTX-3-cyclopentylTyr, MTX-3-cyclopentylPhe, and MTX-3-*tert*-butylPhe could be dosed at least 10−20 times the maximum tolerated dose of MTX. Semistable prodrugs such as MTX-2-cyclopentylPhe, as expected, were more toxic than our most stable prodrugs but less toxic than MTX alone.

Vitols et al. (*33*) reported the class I prodrug metho-

trexate-phenylalanine and showed in vitro that UCLA-P3 growth inhibition (ID_{50} values) of the prodrug in the presence of their CPA−mAb conjugate approached that of methotrexate. From these data, they inferred that methotrexate-phenylalanine would be an optimal ADEPT prodrug. However, our data indicate that class I prodrugs including methotrexate-phenylalanine are highly susceptible to in vivo degradation by endogenous enzymes, like CPA, and that using class I prodrugs designed for these enzymes would give unsatisfactory results. It is worthy of note, though, that although MTX-Phe was rapidly hydolyzed in vivo and as a result more toxic than the more in vivo stable prodrugs, its toxicity was still less than that of MTX, which may provide it some utility in ADEPT with hCPA1 or hCPA1-T268G.

Pharmacokinetic analysis showed that for all compounds, prodrug levels decreased rapidly in the plasma between 30 min and 2 h and followed this trend in almost all the tissues studied. The exceptions to this trend can probably be attributed to the variations typically seen between animals. Initial prodrug levels were high in the liver. This might be expected since the liver functions as a drug detoxification organ. The rapid biliary excretions of MTX and MTX prodrugs are responsible for the high prodrug levels in feces and small intestine and pancreas. This rapid excretion may be species-specific since the principle route of MTX clearance in humans is via the urine (*27*). The levels of prodrug found in tumor, while low, are consistent with the levels of methotrexate found in murine leukemias following ip dosage with the maximum tolerated dose of 3 mg/kg of methotrexate (*34*).

Metabolic cage studies were employed to monitor biliary excretion of class III prodrugs (data not shown). These studies indicated that class III prodrugs exhibit rapid fecal excretion with a small percentage of prodrug found in the urine. This fecal excretion is consistent with that of MTX (*27*).

We have previously demonstrated that ADEPT using a mutated human enzyme and novel prodrugs works in cell culture (*19*). In that study, HT-29 cells were exposed to varying levels of antibody−enzyme conjugate followed by varying concentrations of MTX-3-cyclopentylTyr. IC_{50}'s were determined and compared to MTX alone. The data demonstrated the efficacy of this variation on ADEPT in vitro. The current work extends those data further by including targeting studies and an in vivo therapy study.

ING1, an antibody that recognizes an epitope on Ep-CAM1 (*28*) on human colorectal carcinomas, was dosed into mice to determine antibody specificity. Data indicated a time-dependent drop in percent ID in all tissues studied. After plasma clearance, the levels were highest in the tumor, followed by spleen, liver, kidney, and bone. At 144 h, the latest time point tested, the tumor-to-blood ratio was 19. The in vivo targeting of the antibody−enzyme conjugate also showed an encouraging tumor-to-plasma ratio. At 24 h, a ratio of 2.7 was observed with ~1% ID/g of tumor found.

A possible explanation for the lack of a tumor response in vivo to therapy was instability of the conjugate. To test this hypothesis, a study was set up where conjugate was directly injected into the tumor, followed by a bolus dose of MTX-3-cyclopentylTyr. Then enzyme activity as a function of time postinjection was determined by monitoring percent prodrug hydrolysis 30 min after each prodrug injection time. The data suggested that the conjugate does suffer a time-dependent drop in activity in vivo. While there was in vivo enzyme activity present at up to 6 h post-conjugate injection, there was no detectable activity in vivo 24 h after injection. This explains the lack of antitumor activity in the in vivo therapy study since the earliest prodrug was dosed 24 h after conjugate administration. As shown in Figure 6, both wt- and T268G-hCPA1 were inactivated by human serum. Thus, a partial explanation for the loss of conjugate activity in vivo is inactivation by serum elements. (Preliminary experiments indicate that 5 mM mercaptoethanolamine in PBS can also accelerate denaturation of both wt- and T268G-hCPA1, resulting in loss of 50 and 75% activity by 18 h, respectively, which suggests that the serum factors may include thiols.) However, there appear to be additional features as well since at 37 °C in human serum, 30% of T268G-hCPA1 remained at 24 h and 10% remained at 72 h. Continued studies of this enzyme and its properties are warranted to enhance this promising approach to ADEPT. Further study using a different tumor model also may aid in determining if ADEPT works in vivo. In the current study, the human colon adenocarcinoma cell line LS174T was chosen based on the targeting ability of our ING1 antibody to it. Previous studies indicate that MTX, at nontoxic doses, only delays growth of LS174T tumors. Since one of the goals of ADEPT is to avoid the systemic toxicity seen during therapy while maintaining or improving efficacy, studies using a tumor model that responds better to MTX would help in determining the utility of ADEPT.

The development of mAbs represents an additional mode of cancer therapy and has led to the emergence of ADEPT. The novel approach we have taken, in which a mutant human enzyme is used for the conversion of stable prodrugs to their toxic form, appears to offer a high potential of success. This approach addresses two of the hurdles facing ADEPT. The use of a human enzyme should minimize the immunogenicity. The active site mutation will allow for the development of an exogenous enzymatic activity allowing for increased prodrug stability. The development of an antibody with better specificity in combination with a more stable antibody−enzyme conjugate would be beneficial and should give better antitumor results with MTX prodrugs in mice. Antitumor studies in mice using the other two antifolates, GW1031 and GW1843, are difficult because they exert their effect by inhibiting thymidylate synthase. This inhibition cannot take place in the presence of high circulating thymidine levels as observed in mice (*35*). For this reason, mouse antitumor studies were not done with prodrugs of these two antifolates.

Coupling of Nuclear Localization Signals to Plasmid DNA and Specific Interaction of the Conjugates with Importin α

Carole Ciolina, Gerardo Byk, Francis Blanche,† Vincent Thuillier,† Daniel Scherman, and Pierre Wils*

UMR 133 CNRS/Rhône-Poulenc Rorer and Rhône-Poulenc Rorer Gencell, Centre de Recherche de Vitry Alfortville, B.P.14, 13 quai Jules Guesde, 94403 Vitry-sur-Seine Cedex, France. Received June 5, 1998; Revised Manuscript Received October 23, 1998

The nuclear localization signal (NLS) of the SV40 large T antigen efficiently induces nuclear targeting of proteins. We have developed a chemical strategy for covalent coupling of NLS peptides to plasmid DNA. A *p*-azido-tetrafluoro-benzyl-NLS peptide conjugate was synthesized. This conjugate was used to covalently associate NLS peptides to plasmid DNA by photoactivation. Reporter gene was expressed after transfection of the plasmid−NLS conjugates in NIH 3T3 cells. The conjugates interacted specifically with the NLS-receptor importin α, but plasmid−NLS conjugates were not detected in the nucleus, by fluorescence microscopy, after cytoplasmic microinjection.

INTRODUCTION

Plasmids used for nonviral gene therapy are generally delivered as a complex with a variety of chemical or biochemical vectors to obtain maximal transfection efficiency. Among the various chemical vectors developed for gene transfer, cationic lipids are the most widely used (*1*). Nonviral gene transfer with cationic lipids can be divided into several steps (*2*): internalization of the DNA could occur via fusion at the cellular membrane or via endocytosis (*3*), then the plasmid diffuses to the nuclear enveloppe and enters the nucleus probably through the pore complexes. One of the steps limiting nonviral gene transfer efficiency is the entry of plasmid DNA from the cytoplasm into the nucleus (*2*, *4*−*6*).

The role of signal sequences for protein import into the nucleus is well documented (*7*, *8*). Proteins larger than 60 kDa are excluded from the nucleus unless they harbor a nuclear localization signal (NLS).[1] The NLSs usually comprise highly basic stretches of amino acids (*7*). Among the different NLSs, the NLS of the simian virus 40 (SV40) large T antigen has been extensively studied. This short peptide possesses five basic amino acids and efficiently induces nuclear targeting when conjugated to a nonkaryophilic protein of molecular mass up to 465 kDa (*9*). Moreover, nuclear import is increased when several independent SV40 large T antigen NLS peptides are conjugated to a protein (*10*). Karyopherin α is involved in nuclear protein import through association with nuclear localization signals in the cytoplasm, then binding to the nuclear pore complex (*11*, *12*). The 58 kDa mouse karyopherin α (called importin α or *m*-importin) binds to NLS sequence and then interacts with karyopherin *β* (also called importin *β*). The resulting complex binds to the nuclear pore (*13*) and is translocated through the pore in a mechanism involving the small GTPase Ran (*14*) and other proteins.

We developed a new methodology to covalently associate NLS peptides to DNA in which cationic NLS peptides are covalently bound to plasmid DNA by photoactivation. We report here the synthesis and characterization of these conjugates and demonstrate that they specifically interact with the NLS-receptor importin α.

EXPERIMENTAL PROCEDURES

Analytical and Semipreparative HPLC. Analytical and semipreparative HPLC were performed on a Merck-Hitachi gradient pump equipped with a AS-2000A autosampler, an L-6200A intelligent pump, and a UV−vis detector L-4000.

Method 1. For analytical separations, we used a column C18 Vydac 218 TP54 (Interchim, Montluçon, France) using a gradient of acetonitrile/water 0.1% TFA (from 0 to 41% acetonitrile in 25 min) with a flow rate of 1 mL/min during 25 min. For semipreparative separation, we used a column C18 Vydac-218 TP 1022 (10 mm) using a gradient of acetonitrile/water 0.1% TFA (from 5 to 50% acetonitrile in 40 min) with a flow rate of 7 mL/min during 40 min. Detection was by UV absorbance at 254 nm.

Method 2. The HPLC system used a 250 × 4.6 mm C8 Vydac column and a gradient of 5 to 50% acetonitrile over 40 min in 0.1 M triethylammonium acetate, pH 7.5 (flow rate = 1 mL/min). Detection was by UV absorbance at 250 nm.

Peptide Synthesis. The following peptides were synthesized: peptide *β*ACGAGPKKKRKV containing wild-type SV40 large T NLS (NLS) or peptide *β*ACGAGPKNKRKV containing mutant SV40 large T NLS (mNLS) or peptide CYGGPDEVKRKKKP containing SV40 large T NLS reverse sequence. Peptides were synthesized on Applied Biosystems 431A automatic synthesizer using a Rink amide resin as solid support and Fmoc strategy for amino acid assembly. A fluorescent molecular probe, Lissamine rhodamine B, was coupled manually in a separate flask at the N-terminal position of the NLS or mNLS peptides with a solution of dichloromethane containing 10 mol/equiv excess of Lissamine rhodamine B sulfonyl chloride (mixture of two isomers purchased from Aldrich), diisopropylethylamine (DIEA-pH 10), and

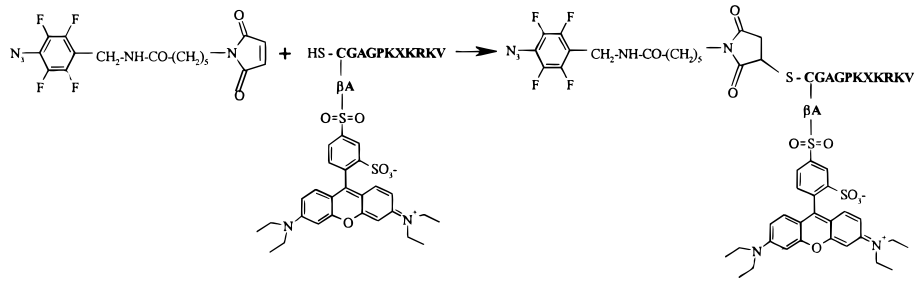
a catalytic amount of dimethylaminopyridine (DMAP). The peptides were cleaved from the Rink resin as usual and purified by HPLC. Analytical and semipreparative HPLC were performed as described above (method 1). The final purified products were analyzed by mass spectroscopy.

Lissamine-SO_2-βACGAGPKKKRKVNH_2 (HPLC, analytical, $R_t = 26.9$ min; semipreparative, $R_t = 28-31$ min; MH^+, 1782); Lissamine-SO_2-βACGAGPKNKRKVNH_2 (HPLC, analytical, $R_t = 25$ min; semipreparative, $R_t = 26-34$ min; MH^+, 1767).

Preparation of *p*-Azido-tetrafluoro-benzyl-peptide Conjugates. Lyophilized *N*-(4-azido-2,3,5,6-tetrafluorobenzyl)-6-maleimidylhexanamide [TFPAM-6 (Molecular Probes, Eugene, OR)] was dissolved in dimethyl sulfoxide (DMSO) at a concentration of 1 mg/mL. Lyophilized peptides were dissolved in 100 mM triethylammonium acetate, pH 7.5, at a concentration of 1 mg/mL. Equimolar quantities of TFPAM-6 and peptide were mixed at room temperature. The reaction was monitored by HPLC, and, after 2 h, the conjugate was purified by HPLC as described above (method 2). The conjugate was analyzed by mass spectroscopy. *p*-Azido-tetrafluoro-benzyl-lissamine-SO_2-βACGAGPKKKRKVNH_2 (HPLC, $R_t = 36$ min; MH^+, 2195); *p*-azido-tetrafluoro-benzyl-lissamine-SO_2-βACGAGPKNKRKVNH_2 (HPLC, $R_t = 38.9$ min; MH^+, 2181); *p*-azido-tetrafluoro-benzyl-CYGGPDEVKRKKKP (HPLC, $R_t = 26$ min; MH^+, 2018).

Covalent Coupling of Peptide Conjugates to ds-DNA. Plasmid pCMVLacZ (7257 bp) carries a cassette containing the enhancer-promoter from the immediate-early gene of cytomegalovirus (CMV) and the gene coding β-galactosidase. Plasmid DNA was purified using Wizard Megaprep kit (Promega, Madison, WI). *p*-Azido-tetrafluoro-benzyl-peptide conjugate was mixed with dsDNA (final concentration 0.3 μg/μL) at various molar excess depending on the assay. The mixture was cooled in an ice−water bath below a sun lamp (Rad Free UV lamp-365 nm, Schleicher and Schuell, Ecquevilly, France) and illuminated for 15 min in the dark. Excess *p*-azido-tetrafluoro-benzyl-peptide conjugate was removed by ion-exchange chromatography (PCR Purification kit, Qiagen, Hilden, Germany). The average number of fluorescent peptides attached to the DNA was determined with a Titertek Fluoroskan II Spectrofluorimeter with free and illuminated *p*-azido-tetrafluoro-benzyl-peptide conjugate for calibration curve (excitation, 544 nm; emission, 590 nm).



Preparation of Recombinant Importin α-GST Protein. Mouse importin α was cloned into pGEX-2T to produce a GST fusion protein: importin α-GST (*11*). The plasmid encoding the fusion protein was kindly provided by Dr. Y. Yoneda (Osaka University Medical School, Osaka, Japan). Importin α-GST was overexpressed in *Escherichia coli* strain BL21 grown in 1 L of LB medium, as previously described (*11*). Cells were harvested by centrifugation, washed with 100 mL of PBS and resuspended in 20 mL of buffer A [50 mM Tris-HCl, pH 8.3, 1 mM EDTA, 2 mM dithiotreitol, 0.5 M NaCl, and 200 μM Pefabloc (Boehringer, Manheim, Germany)]. Cells were disrupted by sonication at 4 °C during 30 min. The extract was clarified by centrifugation (15000*g*, 1 h). The recombinant protein was purified by affinity chromatography on glutathione-Sepharose 4B (Pharmacia, Uppsala, Sweden) equilibrated in buffer A. Glutathione-Sepharose 4B (8 mL) was cast in a HR10/10 column (Pharmacia, Uppsala, Sweden) connected to an HPLC system (Gilson 305). The clarified cell extract was loaded on the column at 0.5 mL/min. The column was washed with buffer B (20 mM HEPES-NaOH pH 7.3, 2 mM dithiotreitol, 1 mg/L leupeptin, 1 mg/L pepstatin, and 1 mg/L aprotinin). The column was incubated 10 min in buffer B containing 20 mM glutathione, after which the recombinant protein was eluted at 0.5 mL/min. The protein fractions are desalted on disposable Sephadex G-25 M columns (PD-10, Pharmacia, Uppsala, Sweeden) and eluted with 50 mM HEPES-NaOH, pH 7. Protein concentration was 0.6 mg/mL. The purity of the recombinant protein was assessed by denaturing polyacrylamide gel electrophoresis and Coomasie staining. Its identity was checked by Western blotting and probing with a polyclonal antiserum raised against the internal peptide: SEGYTFQVQDGAPGTFBF. The N-terminus of importin α-GST was also sequenced.

Importin α Binding Assay. All assays were performed using importin α-GST recombinant protein. Binding to importin α was performed according to Rexach and Blobel (*15*), with the following modifications: all assays were performed in binding buffer (20 mM HEPES, pH 6.8, 150 mM potassium acetate, 2 mM magnesium acetate, and 2 mM and 100 μg/mL bovine serum albumin). The GST fusion protein was incubated with glutathione-sepharose beads (Pharmacia Biotech, Uppsala, Sweden). Importin α-GST fusion protein (1 μg per 10 μL of beads) was incubated with beads in 0.5 mL of binding buffer for 30 min at room temperature. The beads were collected by centrifugation at 2000*g* for 30 s and were washed five times with 0.5 mL of binding buffer. Washed beads were resuspended in binding buffer with 1 vol of buffer/vol of beads.

The bead slurry (80 μL) was incubated with 2 μg of peptide−DNA conjugate, in 0.5 mL of binding buffer, for 30 min at room temperature. The beads were collected by centrifugation at 2000*g* for 30 s. The supernatant was removed and 30 μL was used to analyze the presence of the unbound DNA (this fraction is called the unbound fraction). The beads were washed five times with 0.5 mL of binding buffer and centrifugated at 2000*g* for 30 s. Finally, beads, corresponding to the bound fraction, were resuspended with 15 μL of electrophoresis loading buffer (0.05% bromophenol blue, 40% sucrose, 0.1 M EDTA pH 8, 0.5% sodium lauryl sulfate). The bound and unbound fractions were analyzed by electrophoresis on 0.8% agarose gel and DNA was stained with ethidium bromide for qualitative determination. Quantitative DNA evaluation in the unbound and bound fractions was obtained by resuspending beads in 160 μL of binding buffer and peptide−plasmid conjugate and dsDNA were measured according to the Picogreen ds DNA quantitation kit (Molecular Probes, Eugene, OR).

Transgene Expression Studies. NIH 3T3 cells were obtained from the American Type Culture Collection (ATCC CRL-1658). The cells were grown in Dulbecco's modified Eagle's medium (DMEM, Gibco, Grand Island, NY) containing 4.5 g/L glucose, supplemented with 2 mM glutamine, 100 units/mL penicillin, 100 μg/mL streptomycin, and 10% foetal bovine serum. Cells were grown at 37 °C in a 5% CO_2/air incubator. One day before the transfection assay, 24-well culture plates were seeded with 50 000 cells/well. Cationic lipid RPR 120535 (*16*) was used for the transfection assays. Plasmids were diluted in 150 mM NaCl at 20 ng/μL concentration, then mixed with a cationic lipid solution (0.12 mM). The DNA/cationic lipid complex was diluted in culture medium (Dulbecco's modified Eagle's medium) in the absence of serum and then added to the cells (0.5 μg of DNA and 3 nmol lipid/well). After 2 h at 37 °C in a 5% CO_2/air incubator, 10% foetal bovine serum was added to the cells. The cells were incubated for 48 h at 37 °C in a 5% CO_2/air incu-

TFPAM-6 Lissamine rhodamine B labeled peptide p-azido-tetrafluoro-benzyl-peptide conjugate

bator. The cells were washed twice with PBS and lysed with 250 μL of cell culture lysis reagent (Promega, Madison, WI). β-Galactosidase expression was measured according to the Lumigal β-Galactosidase genetic reporter system (Clontech, Palo Alto, CA). Light emission was measured by integration over 10 s using a Lumat LB9501 luminometer (EG and G, Berthold, Evry, France). Light emission was normalized to the protein concentration determined using the Pierce BCA assay (Pierce, Rockford, IL).

Microinjection Studies. CV-1 cells were kindly provided by Dr. S. Koutouzov (INSERM U25, Paris, France). Cells were cultured in Minimum Essential medium (MEM, Gibco, Grand Island, NY) supplemented with 2 mM glutamine, 100 units/mL penicillin, 100 μg/mL streptomycin, and 10% foetal bovine serum. Cells were grown at 37 °C in a 5% CO_2/air incubator on CELLocate microgrid coverslips (Eppendorf, Hamburg, Germany). The solution of DNA was injected into the cells via glass micropipets having tip diameters ranging from 0.3 to 0.7 μm (Femtotips, Eppendorf, Hamburg, Germany) at 1 μg/μL concentration. Injections were carried out under visual control on a fixed stage of an inverted phase contrast microscope (Axiovert 135, Zeiss, Le Pecq, France) using a Micromanipulator 5171 and Microinjector 5242 (Eppendorf, Hamburg, Germany). The average volume (0.1−0.2 pL) injected into each cell was determined by injecting [^{35}S]dATPαS into cells and measuring the radioactive content (*6*). These corresponded to an average of 6000−12000 plasmid molecules/cell. Following injection, the cells were incubated for 30 min to 6 h at 37 °C in a 5% CO_2/air incubator. The cells were washed three times with PBS, fixed for 20 min in 3% paraformaldehyde in PBS, and washed three times with PBS. Nuclei were then stained with 4,6-diamidino-2-phenylindole (DAPI), at a concentration of 0.1 μg/mL, for 15 min, and washed with PBS. The cells were mounted in Mowiol for examination. Slides were examined with a Zeiss Axiophot fluorescence microscope, with a 100× objective lens, coupled to a cooled CCD camera (Hamamatsu) and a Samba imaging software (Unilog, Meylan, France).

RESULTS

Preparation of *p*-Azido-tetrafluoro-benzyl-peptide Conjugates. Peptides containing wild-type SV40 large T NLS sequence (NLS) or mutant SV40 large T NLS (mNLS) were used. Introduction of a point mutation in the NLS sequence (asparagine instead of lysine) induces loss of NLS targeting activity (*9*). Scheme 1 illustrates the chemistry used to prepare *p*-azido-tetrafluoro-benzyl-peptide conjugates. The coupling step involves reaction of TFPAM-6 bearing a maleimide group with a peptide bearing a nucleophilic thiol residue (*17*). Equimolar quantities of the two reagents were used. Since TFPAM-6 absorbs at 250 nm, the conjugation chemistry was easily monitored by reversed-phase HPLC. After 2 h, the reaction was complete as shown by the disappearance of TFPAM-6 and of the starting peptide (Figure 1). The final product was analyzed by mass spectroscopy, which confirmed the disappearance of starting reagents, and the experimental mass was similar to the calculated mass. The yield of this reaction was

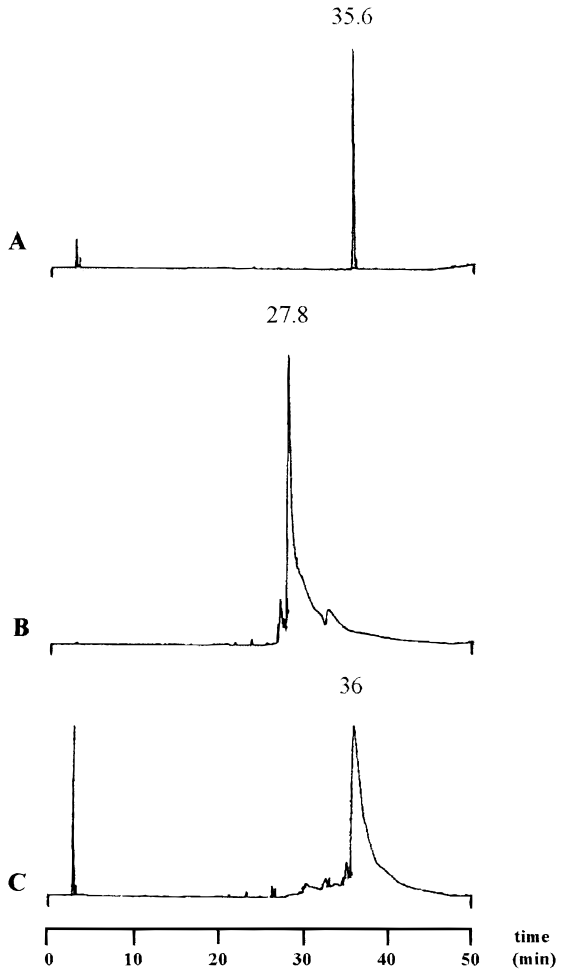

Figure 1. HPLC chromatograms of *p*-azido-tetrafluoro-benzyl-peptide conjugates. HPLC profiles of starting material and conjugate obtained after 2 h of reaction are shown. The molecules were analyzed by reversed phase HPLC using method 2 described in the experimental procedures (absorption wavelength = 250 nm). (A) TFPAM-6; (B) NLS peptide; (C) *p*-azido-tetrafluoro-benzyl-NLS peptide conjugate after 2 h of incubation.

90%. The peptides used were labeled with a fluorescent molecule, lissamine rhodamine B. The conjugate had the same fluorescent properties as the starting peptide (data not shown).

Covalent Attachment of Peptides to dsDNA. The *p*-azido-tetrafluoro-benzyl-peptide conjugates bearing either NLS or mNLS sequence were used to covalently modify plasmids by photoactivation. *p*-Azido-tetrafluoro-benzyl-peptide conjugates were mixed with dsDNA at peptide/DNA molar ratios varying between 5 and 1000 and illuminated at 365 nm. After purification on ion-exchange columns, the average number of peptide linked to the DNA could be measured by taking advantage of the peptide fluorescent labeling: by varying the *p*-azido-tetrafluoro-benzyl-peptide/DNA molar ratio during the coupling step, conjugates bearing an average number of 1 peptide/plasmid molecule to 300 peptides/plasmid (7257 bp) were obtained. During the last coupling step, 20% of the added *p*-azido-tetrafluoro-benzyl-peptide conjugates were found covalently linked with plasmid DNA after purification. For example, with a molar excess (NLS peptide/plasmid) of 500, the average number of NLS peptides linked per plasmid DNA was 100 ± 28 (six experiments). Plasmids modified with NLS and mNLS peptides are referred to as plasmid−NLS and plasmid−mNLS, respectively.

Characterization of Peptide−Plasmid Conjugates. Peptide−plasmid conjugates were analyzed by agarose gel electrophoresis as described in the Experimental Procedures. With 1−100 peptides/plasmid DNA molecule, there was no visible modification of plasmid DNA migration, and peptide−plasmid conjugates appeared on gels as supercoiled DNA. With higher numbers of peptides per plasmid DNA molecule, plasmid DNA migration delay was observed. No delay was observed when plasmid DNA was mixed with nonilluminated NLS peptides (data not shown).

The reporter gene expression was studied after transfection of NIH3T3 cells. Modified plasmids with 3−43 NLS peptides/plasmid DNA molecule expressed β-galactosidase. The increase of expression obtained with 3 NLS peptides/plasmid DNA is not significant. The expression was decreased by 60% with plasmids bearing 43 NLS peptides (Figure 2). Similar results were obtained with mNLS peptides (data not shown).

Importin α Binding Assay. Binding of the modified plasmids to importin α was studied on a importin α-GST fusion protein, using glutathione-sepharose beads, followed by agarose gel electrophoresis. Plasmid−NLS was detected in the bound fraction (interacting with the importin α-GST-beads) whereas nonmodified plasmid was all recovered in the supernatant (Figure 3). The same result was obtained with plasmid−mNLS instead of nonmodified plasmid (data not shown).

Double-stranded DNA in the fraction bound to importin α-GST was quantified using either the intrinsic fluorescence of the lissamine rhodamine B or, for higher sensitivity, using an intercalating fluorescent molecule, Picogreen reagent. Plasmid−NLS bound significantly more to importin α-GST beads than either plasmid-mNLS, nonmodified plasmid, or plasmid conjugated to reverse NLS peptide (VKRKKKP) (Figure 4A and data not shown). Moreover, no specific binding to importin α-GST was detected using neither plasmid prepared by mixing with *p*-azido-tetrafluoro-benzyl-NLS peptide conjugates, without further UV irradiation, nor plasmid prepared by mixing with a *p*-azido-tetrafluoro-benzyl-NLS peptide that had been irradiated prior to contact with DNA (Figure 4B). Hence, the binding of plasmid−

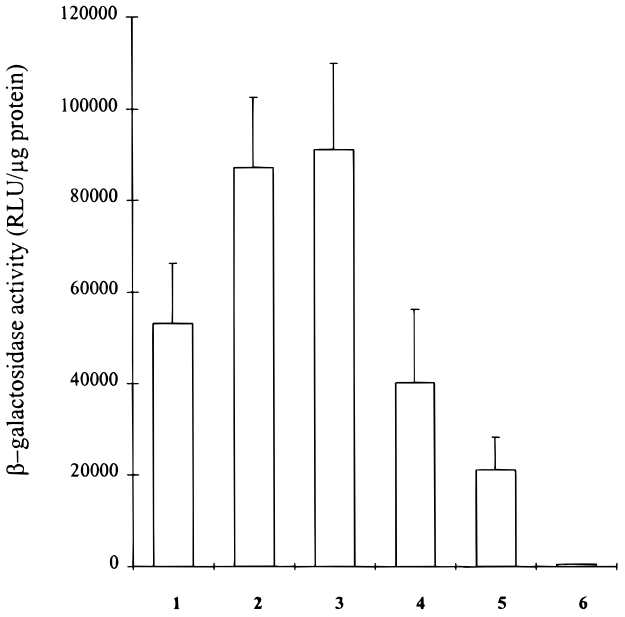

Figure 2. Transgene expression after transfection of plasmid−NLS conjugates. Nonmodified plasmid and plasmid−NLS conjugates were used for transfecting NIH3T3 cells with cationic RPR 120535. The β-galactosidase expression was evaluated after 24 h of incubation. (1) Nonmodified plasmid; plasmid−NLS with the following NLS peptide/plasmid molar ratio: (2) 3; (3) 8; (4) 16; (5) 43; (6) no plasmid. Values are means ± SD (n = 3).

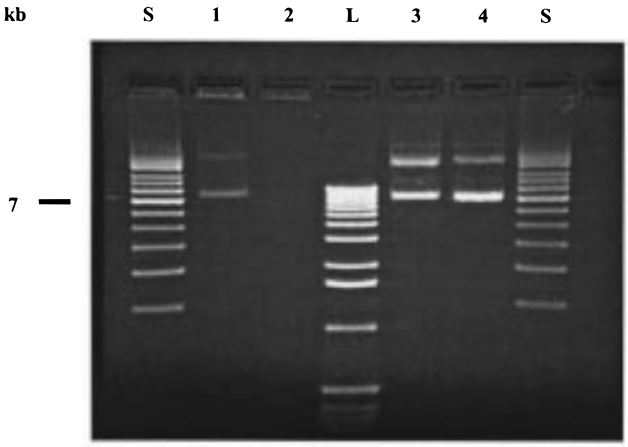

Figure 3. Interaction between importin α-GST and plasmid−NLS conjugates. Beads-immobilized importin α-GST (2 μg) was incubated for 30 min at room temperature with a plasmid conjugated to 66 NLS peptides (1 μg) (1 and 3) or nonmodified plasmid (1 μg) (2 and 4). Bound (1 and 2) and unbound (3 and 4) fractions were analyzed by 0.8% agarose gel electrophoresis and ethidium bromide staining. L = molecular weight marker for linear DNA fragments (1 kb ladder). S = molecular weight marker for supercoiled DNA fragments (1 kb ladder).

NLS to importin α is mediated by the specific interaction of nonmodified NLS peptide covalently bound to DNA and its receptor.

By increasing the ratio of *p*-azido-tetrafluoro-benzyl-NLS peptide, 2−26 NLS peptides were covalently attached to dsDNA. Plasmid interaction with importin α-GST increased with increasing number of peptides per plasmid (Figure 4C). By increasing this number up to 45 and 100, the quantity of dsDNA interacting with 2 μg importin α-GST fusion protein was 30 and 60 ng, respectively (data not shown).

Microinjection Studies. NLS-modified plasmids were microinjected into the cytoplasm of CV-1 cells. Plasmids with 100 NLS peptides/plasmid molecule were used. Cells

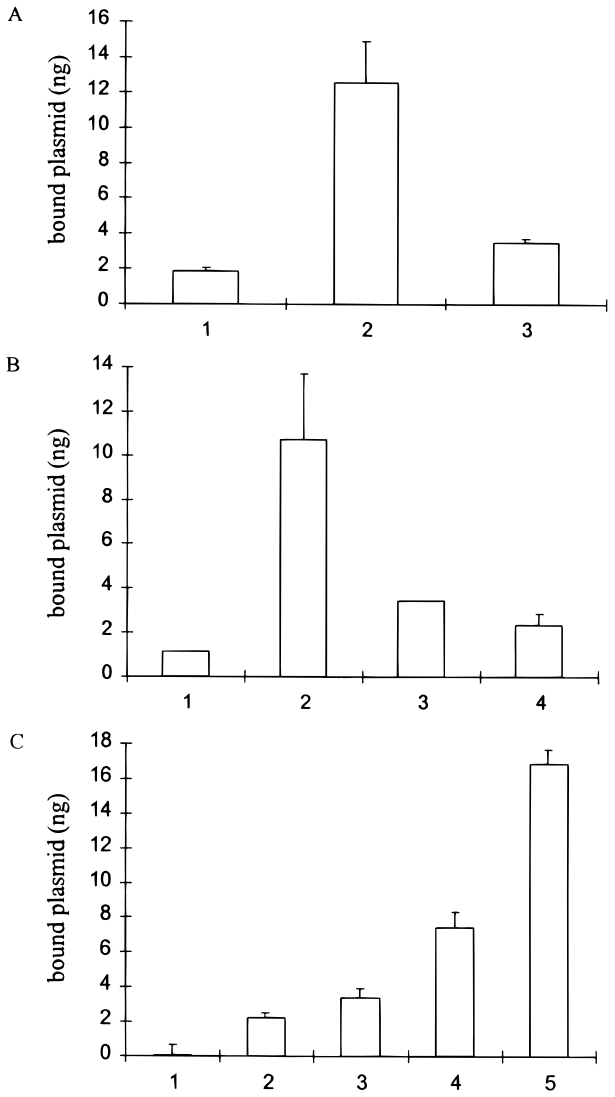

Figure 4. Quantitative analysis of plasmid−NLS conjugates binding to importin α-GST. Immobilized importin α-GST (2 μg) was incubated for 30 min at room temperature with the different conjugates (1 μg). DNA in the bound fractions was measured as described in the Experimental Procedures. were fixed after 30 min, 2 or 6 h, and nuclei were stained with DAPI. An intense cytoplasmic fluorescence was observed 30 min after microinjection into the cytoplasm, indicating that DNA could only be detected in the cytoplasm (Figure 5A). Cytoplasmic microinjection of NLS-conjugated BSA in the same conditions gave a high nuclear staining (data not shown). The DNA fluorescence pattern evolved 2 h after microinjection into the cytoplasm (Figure 5C): half of the stained cells showed the same intense fluorescent pattern observed at 30 min and the rest exhibited a single fluorescent spot in the cytoplasm. After 6 h, nearly all cells had only one residual fluorescent spot in the cytoplasm (Figure 5E).

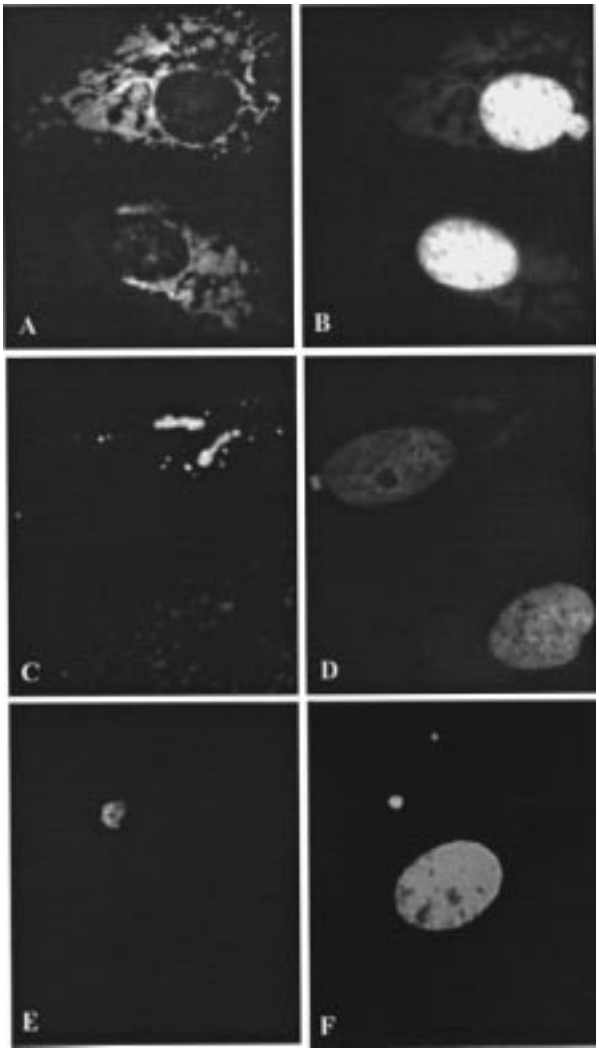

Figure 5. Cytoplasmic microinjection of plasmid−NLS conjugate. CV-1 cells were cytoplasmically microinjected with plasmid−NLS (100 NLS peptides/plasmid DNA molecule) and fixed after 30 min (A and B), 2 h (C and D), or 6 h (E and F). Fluorescent microscopy of plasmid−NLS (A, C, and E) and nuclei staining with 4,6-diamidino-2-phenylindole (B, D, and F) are shown.

DISCUSSION

Several methods for covalent attachment of molecules to nucleic acids have been developed and reported so far (*18*−*20*). Among them, the use of photoactive molecules, such as tetrafluorophenylazido groups, leads to an efficient photomodification of DNA (*21*). We have conjugated a cationic peptide, NLS from SV40 large T antigen, to a photoactive tetrafluorophenylazido-containing molecule. The NLS peptide had a sulfhydryl reactive group and the photoactive molecule, TFPAM-6, a maleimide group which reacted to give a photoactive NLS peptide. The peptide used had a fluorescent moiety, making it possible to follow the conjugation to plasmid DNA, to quantify the average number of peptides bound to DNA and to study the intracellular fate of the conjugates. Moreover, we found that the molecules labeled with lissamine rhodamine B are easier to purify and more chemically stable than those labeled with another fluorophore such as tetramethylrhodamine.

Covalent coupling of ligands to the DNA could cause transcriptional inactivation. According to a study on the expression of a biotinylated plasmid prepared with a similar photomodification chemistry, a plasmid with up

to 40 biotins coupled/plasmid retained 40% biological activity (*19*). Plasmids conjugated to NLS peptides by covalent coupling using a cyclopropapyrroloindole group were modified with 24−101 peptides/1 kb (*22*). With this number of peptides per plasmid, transgene expression was abolished. With the photoactive *p*-azido-tetrafluorobenzyl-peptide conjugates, lower levels of modification were obtained and the modified plasmids were still biologically active. With up to 43 peptides per plasmid DNA (7 kb), modified plasmids remained biologically functional. This result is in agreement with transgene expression data previously reported (*19*). It is also important to notice that plasmid−NLS conjugates appeared on gels as supercoiled DNA.

Using a binding assay, we showed that NLS peptides attached to dsDNA interacted with the NLS-binding protein, importin α. This interaction was specific and depended on the number of peptides conjugated to dsDNA. Our results show that NLS peptides are recognized despite the plasmid electrostatic properties. Plasmids associated to NLS peptides by covalent coupling were studied in digitonin-permeabilized cells (*22*). Nuclear accumulation of the plasmid DNA was observed and was dependent on the number of NLS peptides: peptide−plasmid conjugates bearing less than approximately 40 NLS/1 kb did not accumulate in the nucleus. In our experiments, we chose to couple a low number of peptides (less than 10 peptides/1 kb) in order to maintain a certain amount of transgene expression. Nuclear accumulation of plasmid DNA was also obtained in isolated male pronuclei with NLS peptides associated to plasmid DNA by electrostatic interactions (*23*).We demonstrate here that NLS peptides bound to DNA interact with their receptor: this recognition step is a prerequisite for import via the classical NLS-dependent pathway.

However, after microinjection in the cytoplasm, plasmid−NLS conjugates were not detected in the nucleus. These results are in agreement with microinjection data previously reported (*22*). Our microscopic studies suggest that microinjected plasmid−NLS conjugates are progressively degraded in the cytoplasm, since the staining observed gradually decreased with time. After 6 h, only one spot of fluorescent plasmid−NLS was detected, which probably corresponded to the site of injection. This suggests that the bulk of microinjected plasmid did not readily diffuse from the site of injection. It is possible that part of plasmid−NLS molecules could be sequestered in the cytoplasm as observed for naked DNA injected in myotubes (*5*).

In conclusion, we have designed a novel simple chemistry for coupling by photoactivation peptides to plasmid DNA. This technology allows the control of the number of peptides linked to DNA which is determinant for maintaining plasmid integrity and expression. Moreover, we show in the present work that a conjugate between a targeting NLS−peptide and plasmid−DNA is recognized by importin α NLS receptor. The present strategy could thus be used for coupling other ligands to plasmid DNA, study plasmid−ligand conjugate interaction with receptors. Since a fluorescent peptide could be coupled, the technology also allows to follow intracellular fate of the peptide−DNA conjugate.

ACKNOWLEDGMENT

This work was supported by a grant from the French Ministry of Research. We thank Dr François F. Clerc and his staff for peptide synthesis and Dr. Marc Vuilhorgne and his staff from the Structural Analysis Department of Rhône-Poulenc Rorer for mass spectroscopy analysis. We thank D.Bisch for importin α-GST purification.

A Fluorescent Radioiodinated Oligonucleotidic Photoaffinity Probe for Protein Labeling: Synthesis and Photolabeling of Thrombin

Catherine Berens,[†,‡] Pierre J. Courtoy,[‡] and Etienne Sonveaux*[,†]

Laboratoire de Chimie Thérapeutique et de Radiopharmacie, UCL 7340, 73 Avenue Emmanuel, Mounier, B-1200 Bruxelles, Belgium, and Unité de Biologie Cellulaire, UCL 7541, Christian de Duve Institute of Cellular Pathology, 75 Avenue Hippocrate, B-1200 Bruxelles, Belgium. Received June 10, 1998; Revised Manuscript Received October 1, 1998

To study the interactions between oligonucleotides and proteins, an original photoaffinity radiolabeling probe has been synthesized. Starting with a 5′-pyridyldithio-3′-amino-oligonucleotide, the photophore benzophenone was first coupled to the 3′ end, through acylation by an activated ester of benzoylbenzoic acid. A fluorescein molecule was grafted by alkylation of the free 5′-SH. This compound was finally radiolabeled with ^{125}I using IodoBeads. The selective photolabeling of thrombin in a complex protein mixture by the radioiodinated probe validates this strategy to identify oligonucleotide-binding proteins.

INTRODUCTION

The potential of oligodeoxyribonucleotides (ODNs) as antigene or antisense agents to inhibit protein expression, or as direct aptamers to proteins, is investigated increasingly. The best known examples of protein-binding ODNs are phosphodiester (PO) ODNs, featuring a G quartet, that inhibit the serine protease thrombin, a key blood-coagulation enzyme and, accordingly, a major target for anticoagulant therapy (Bock et al., 1992, Wang et al., 1993, Padmanabhan et al., 1993, Macaya et al., 1995, Shaw et al., 1995, Tsiang et al., 1995). Depending on their length and secondary structure (Tasset et al., 1997), G-quartet ODNs can bind either to the fibrinogen recognition or to the heparin-binding exosite of thrombin. Phosphorothioates (PS) ODNs, selected for their metabolic stability, avidly bind to various proteins such as recombinant soluble CD4 receptor, HIV-1 envelope glycoprotein gp120, HIV-1 reverse transcriptase, basic fibroblast growth factor (bFGF), acidic FGF, FGF-4, platelet-derived growth factor, vascular endothelial growth factor, laminin [reviewed by Stein (1995)] and more trivially, albumin (Greig et al., 1995). The sequence requirement for affinity is far less stringent for phosphorothioates than for phosphodiesters. In other words, PO−ODNs appear as unstable, but selective agents while PS−ODNs are more stable but less selective. 3′-Modified phosphodiester ODNs, resistant to 3′-exonuclease (the major serum nucleasic activity), probably feature a better compromise between stability and selectivity (Tidd and Warenius, 1989; Shaw et al., 1991).

The study of protein−ODN interactions was however not the initial focus in nucleic acid drug research. The major goal of ODNs is the antisense effect, i.e., the specific inhibition of translation of a (pre)mRNA, induced by a sequence-selective hybridization by Watson−Crick pairing with the antisense ODN. Nevertheless, whatever the nature of ODN backbone (be it PO, PS, or 3′-modified PO), an absolute requirement for an antisense effect is the cellular penetration of the ODN that presumably depends on receptor-mediated endocytosis, a process for which protein−ODN interactions are major determinants (Loke et al., 1989; Yakubov et al., 1989; Beltinger et al., 1995).

As protein−ODN interactions are so ubiquitous, we aimed at devising a standard procedure to synthesize ODN-affinity probes that would allow for specific and efficient labeling of target proteins. A photo-cross-linkable probe was favored because it could enable one to study in situ time-dependent phenomena such as the cellular penetration of ODNs. This tool would in particular prove valuable to characterize the series of protein associations of an antisense ODN on its journey from the cellular surface to the endosomes (early or late), and from the cytosol to the nucleus [reviewed by Akhtar and Juliano (1992)].

This report describes the synthesis, characterization, and radioiodination of an ODN coupled to the photophore benzophenone. This probe was further evaluated in vitro by photolabeling human and bovine thrombin. In cell biological experiments, this fluorescent ODN appears suitable for time-resolved (by flashing at different times) and space-resolved (by using confocal microscopy) chemoselective studies (by affinity labeling).

EXPERIMENTAL PROCEDURES

General. Unless otherwise stated, all reagents used for this study were of analytical grade. All buffers were made with milliQ water (Millipore). The 5′-pyridyldithio-3′-amino-oligonucleotide (ODN1, see Figure 1) was obtained by the method of Arar et al. (1995). The disulfide phosphoramidite building block and the suitably derivatized glass beads required for 5′ and 3′ modifications respectively are available from Glen Research (VA, Thiol Modifier C6 S−S and 3′-Amino-Modifier C7 CPG). High-performance liquid chromatography was performed on a Spectra Physics apparatus, using reversed-phase C18 columns (BioSil C18 HL 90-5S from Bio-Rad, or Adsorbosphere from AllTech) at a flow rate of 1 mL/min and a linear gradient of eluent B (triethylammonium acetate (TEAA) 0.1 M pH 7.0 in CH_3CN:H_2O, 60/40) in eluent A

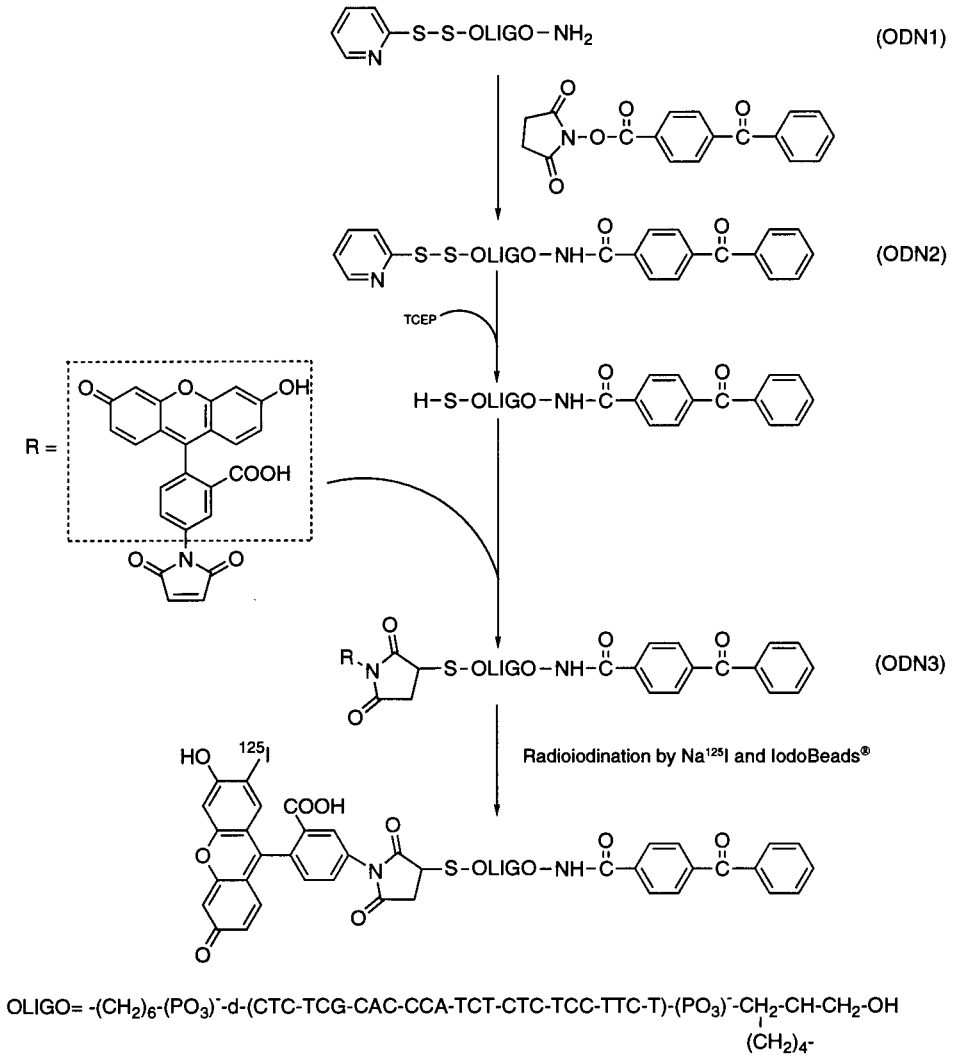

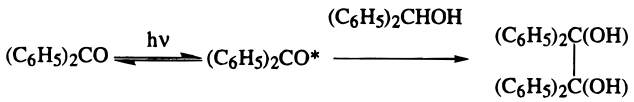

Figure 1. Structures and synthesis of ODNs. [TCEP is tris(2-carboxyethyl)phosphine].

(0.1 M TEAA, pH 7.0, in H_2O:CH_3CN, 95/5) from 0 to 100% over 60 min. Aqueous solutions were evaporated without heating on a Speed Vac centrifugal evaporator (Savant). The concentrations of purified ODNs were determined by UV spectroscopy at the maximum absorbance of the ODN (269 nm), using extinction coefficients calculated as described by Brown and Brown (1991).

For photo-cross-linking experiments, samples were exposed in open Petri dishes to illumination with three lamps (total power of 60 W, 30 W from above, 2 × 15 W lateral; Vilber Lourmat, Marne la Vallée, France, λ_{max} at 365 nm, no emission below 300 nm) at a distance of ~10 cm, or with only one 8 W lamp. To verify that the energy absorbed by the sample was sufficient to give a significant yield of cross-linking, a control reaction was used, based on the coupling, in a closed quartz cuvette, of 4.4 mM benzophenone with 0.1 M diphenylmethanol in benzene (quantum yield of ~0.5−1.0 in degassed solutions; Moore et al., 1961).

In these conditions, and using the 60 W lamp system, the half-life of benzophenone was ca. 18 min.

Synthesis of the ODN1−Benzophenone Conjugate (ODN2). ODN1 (30.3 nmol) was dissolved in 180 μL of 0.2 M borate buffer, pH 9. Two milligrams of 4-benzoylbenzoic acid *N*-hydroxysuccinimidyl ester (Sigma; total excess 200×) was solubilized in 20 μL of dry dimethylformamide (distilled on P_2O_5). Five aliquots (4 μL each) of this DMF solution were successively added to the stirred ODN solution, at 30 min intervals. The suspension was stirred for another 3 h after the last 4-benzoylbenzoic acid *N*-hydroxysuccinimidyl ester addition (total reaction time 5 h), centrifuged, and the supernatant filtered on a Nylon Acrodisc filter (0.45 μm, Gelman Sciences). This solution was precipitated with ethanol and the insoluble material redissolved in 200 μL of water. Pure ODN2 was isolated from this solution by HPLC (retention time = 25.5 min; yield 63%).

Synthesis of the Fluorescein−ODN2 Conjugate (ODN3). ODN2 (9.5 nmol) was dissolved in degassed phosphate buffer (100 mM, pH 7, 95 μL). A solution of tris(2-carboxyethyl)phosphine hydrochloride (TCEP, Sigma) in the same buffer (27.2 μg in 5 μL, 95 nmol, total excess 10×) was added to the ODN solution, and the stirred mixture was allowed to react in the dark under an argon atmosphere for 1 h. Nucleic acids were then precipitated by ethanol in order to eliminate the excess of unreacted TCEP, and the solid phase was dissolved in degassed phosphate buffer (180 μL). A solution of fluorescein-5-maleimide (Molecular Probes, 0.406 mg, 950

nmol, total excess 100×) in acetonitrile:water (1:1; 20 μL) was added to the solution of the reduced ODN2, and the mixture was stirred in the dark under an argon atmosphere for 30 min. ODN3 was first precipitated by ethanol and then purified by HPLC (retention time = 21.5 min; yield = 73%).

Radiolabeling of ODN3. Two IodoBeads (Pierce) were placed in an Eppendorf SafeLock tube, washed with phosphate buffer (0.1 M, pH 7.4, 3 × 1 mL), and covered with the same buffer (390 μL). A $Na^{125}I$ solution (10 μL, 1 mCi, Amersham) was carefully added to this suspension under a well-ventilated hood and allowed to react for 5 min. A solution of ODN3 (2.0 nmol) in phosphate buffer (0.1 M, pH 7.4, 100 μL) was then added. After 30 min of reaction, the supernatant was removed and mixed with a solution (500 μL) containing NaI (4.5 mg/mL) and $Na_2S_2O_3$ (4 mg/mL). The excess of radioiodine was eliminated by gel filtration on Sephadex G-25 (NAP-10, Pharmacia). After a concentration step (partial evaporation of the solution in a Speed Vac), an ethanol precipitation allowed one to obtain the radiolabeled ODN3 with a radiochemical purity of nearly 100% [paper chromatography assay on Whatman Chromatography Paper 1, 87 g/m^2, 0.16 mm thickness; mobile phase, methanol/water (7:3)].

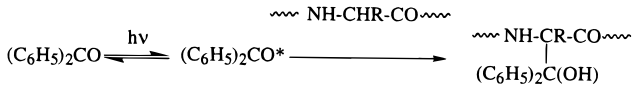

Photo-Cross-Linking of ODN3 to Human Thrombin. Human thrombin (176 pmol, ~3000 NIH units/mg of protein, Sigma) was dissolved in PBS−Ca^{2+} buffer (pH 7.4, 578 μL). An aqueous solution of radiolabeled ODN3 (22 μL, 176 pmol) was added. Half of this sample was exposed at 4 °C to UV irradiation in a Petri dish at a total power of 60 W. The other half was incubated in the dark (without being submitted to any UV irradiation). Aliquots submitted to both conditions were taken at different times ranging from 15 to 60 min. These aliquots were analyzed by a 5−15% SDS−PAGE (total amount of thrombin loaded per well = 100 ng). The gel was dried, exposed to a PhosphorImager intensifying screen, and read on a PhosphorImager apparatus (Molecular Dynamics, 410 A model) or autoradiographed.

Determination of the Photo-Cross-Linking Yield Using a Thrombin Aptamer. We used in this experiment Tasset's aptamer 60-18[29] [5′-AGT CCG TGG TAG GGC AGG TTG GGG T*GA CT-3′; K_d = 0.5 nM; Tasset et al. (1997)], which bears near the 3′ end an amino-modified T (indicated by an asterisk (*); Amino-Modifier C6 dT, Glen Research), to which a benzophenone moiety was coupled by the protocol used to obtain ODN2 (see above). Two parallel assays were conducted, involving (i) the 3′-amino aptamer 60−18[29] as a negative control and (ii) the 3′-benzophenone-derivatized aptamer 60-18[29]. Either 1.12 nmol of the 3′-amino aptamer 60-18[29] (solubilized in 10 μL of binding buffer, total excess 5×) or the same amount of the 3′-benzophenone-derivatized aptamer 60-18[29] was added to 7.5 μg of human thrombin (224 pmol, ~3000 NIH units/mg of protein, Sigma) solubilized in 740 μL of binding buffer (20 mM Tris acetate, pH 7.4, 140 mM NaCl, 5 mM KCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$; Bock et al., 1992; Macaya et al., 1995). Half of both mixtures was exposed at 4 °C to 60 W UV irradiation in Petri dishes, while the other halves were incubated at 4 °C in the dark. Aliquots were taken at time intervals ranging 15−120 min. These aliquots were analyzed by 5−15% SDS−PAGE (total amount of thrombin loaded per well = 500 ng) and revealed by silver staining.

Binding Selectivity of ODN3 for Bovine Thrombin. An aqueous solution of radiolabeled ODN3 (9.2 μL, 73.5 pmol) was added to bovine thrombin (7.3 nmol, ~75 NIH units/mg of protein, Sigma) dissolved in PBS-Ca^{2+} buffer (pH 7.4, 40.8 μL) and incubated at 4 °C in the dark for 2 h, before UV irradiation at 8 W for 15 min. An aliquot of this solution (containing 10 μg of thrombin) was analyzed by a 5−15% SDS−PAGE, and the gel was treated as above.

RESULTS AND DISCUSSION

Engineering of the Probe. To generate an appropriate probe to study ODN−protein interactions, a benzophenone−ODN conjugate was selected for several reasons [reviewed by Dorman and Prestwich (1994)]. (i) Benzophenone is excited at a wavelength (333 nm) that does not affect proteins. (ii) Benzophenone has a broad reactivity: its easily accessible n,π* diradicaloid triplet state is able to cross-link with amino acids residues, one typical reaction being the insertion into the α C−H bond as illustrated below [for a detailed discussion, see Deseke et al. (1998)]:

(iii) Since its unreacted triplet state simply returns to the ground state and does not react with water, benzophenone can be repeatedly excited. Contrary to the irreversibly destructed photophores such as azides, benzophenone derivatives can thus repeatedly absorb photons, until a productive reaction takes place. This property considerably facilitates experiments since benzophenone derivatives can be manipulated in subdued day light without problem. (iv) High yields of photo-cross-linking are usually obtained. Typical photo-cross-linking yields are 40−80% (Williams and Coleman, 1982; Mahmood et al., 1987; Shoelson et al., 1993; Thiele and Fahrenholz, 1993; Chaudhary and Prestwich, 1997). Such clear advantages make benzophenone a molecule of choice in engineering photo-cross-linking ODNs.

The ODN chosen for this study was a PO−ODN 25-mer complementary to the AUG initiation site of the *gag* gene of HIV-1 (Lisziewicz et al., 1994). Its sequence contains only one dG, and the ODN should have no more affinity for thrombin than a random 25-mer. This ODN was further selected because of the wealth of biological information available on its PS counterpart, the gene-expression modulator 91 (GEM 91), an anti HIV-1 former drug candidate from Hybridon (Lisziewicz et al., 1994). We indeed intended to use the probe for subsequent experiments on cells.

The radiolabeling procedure was of course a critical aspect. A standard 5′-^{32}P labeling using T4 polynucleotide kinase was not considered, because phosphatases are known to easily remove this label (Shaw et al., 1991). Tritium labeling (Graham et al., 1993) was also disregarded, because of the long exposure times needed to reveal this β-emitting radionuclide. Fluorescein is a phenolic compound able to incorporate the ^{125}I γ-emitting radionuclide in high yield. Moreover, a fluorescein appendage allows one to use confocal microscopy in experiments involving whole cells (Pichon et al., 1997). The 3′-end of the ODN being reserved for the grafting of benzophenone, fluorescein was attached at its 5′-end. Both 5′- and 3′-ends of our ODN were thus capped by unnatural residues. This protects the sequence against exonuclease degradation (Arar et al., 1995).

Synthesis and Radiolabeling of the Probe (Figure 1). The 5′-pyridyl-dithio-3′-amino PO−ODN (ODN1) was obtained by a standard solid-support synthesis. A practi-

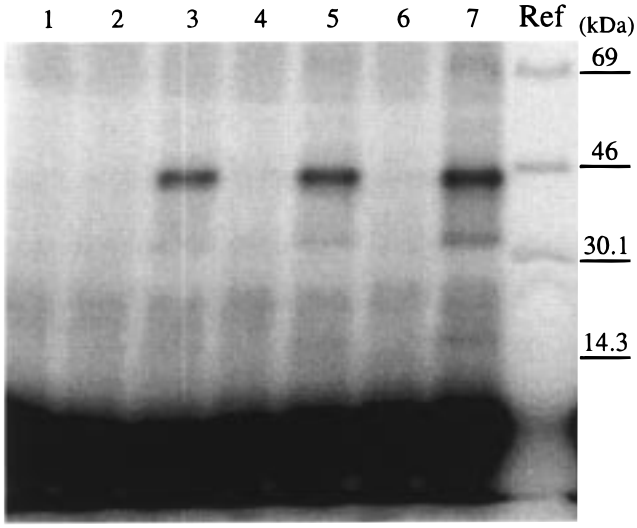

Figure 2. Photo-cross-linking of radioiodinated ODN3 to purified human thrombin. [^{125}I]ODN3 was incubated with thrombin without preincubation as explained in the text. Lane 1: starting time (0 min, no irradiation performed). Lanes 2, 4, and 6: incubation for 15, 30, and 60 min without irradiation. Lanes 3, 5 and 7: UV irradiation for 15, 30, and 60 min, respectively. Irradiation is necessary for photo-cross-linking to occur. The thrombin-ODN3 complex formed features a M_r of ca. 43 kDa, which corresponds to the sum of the MW of thrombin and ODN3.

cal way to monitor the reactions leading to ODN2 and ODN3 was reversed-phase HPLC. The coupling of ODN1, first with a benzophenone derivative and then with a fluorescein derivative, was in both cases associated with large changes in retention times, allowing for an easy recovery of the pure modified ODNs by semipreparative HPLC.

The grafting of benzophenone on the 3′-NH_2 of ODN1 was performed with a suspension of the insoluble 4-benzoylbenzoic acid N-hydroxysuccinimyl ester in an aqueous solution of the ODN. Assays of couplings in several binary solvents were unsuccessful. The chromatogram of the crude mixture was obscured by the presence of several byproducts derived from the acylating agent, but an ethanol precipitation greatly simplified the HPLC trace. Unreacted ODN1 (t_R = 18.1 min) and benzophenone-coupled ODN2 (t_R = 25.5 min, 63%) only subsisted.

The 5′-pyridyldithio moiety of ODN2 was reduced by a water-soluble phosphine. The 5′-HS−ODN was isolated by ethanol precipitation and immediately alkylated by fluorescein-5-maleimide. A new ethanol precipitation was necessary to remove the excess of the alkylating agent. The HPLC trace then showed only a low molecular weight contaminant (t_R = 18.7 min) followed by ODN3 (t_R = 21.5 min, baseline separation). The yield of the synthesis of ODN3 from ODN2 was 73%.

The radioiodination method used in this study was safe and efficient, reaching a specific radioactivity of 16 μCi/μg ODN (160.000 Ci/mol ODN or 18 × 10^{10} cpm/μmol ODN). For comparison, a specific radioactivity of the order of 12 × 10^7 cpm/μmol ODN would have been obtained if ODN3 had been tritiated by Graham's method (specific radioactivity accessible with Graham's protocol: ca. 4 × 10^7 cpm/μmol of purine; Graham et al., 1993). Sodium thiosulfate was added after radioiodination to quench any remaining electrophilic halogen species. Cold sodium iodide was also added to displace radioactive iodide anions possibly associated to the biopolymer by weak forces. A gel exclusion chromatography, followed by an ethanol precipitation, was then performed.

Photoaffinity Labeling of Human Thrombin. As long as no G-quartet is involved in the structure of ODN3, the dissociation constant of its complex with thrombin is estimated to be in the micromolar range or higher: K_d = 8.3 μM for a random library of 96-mers and 5.0 μM for

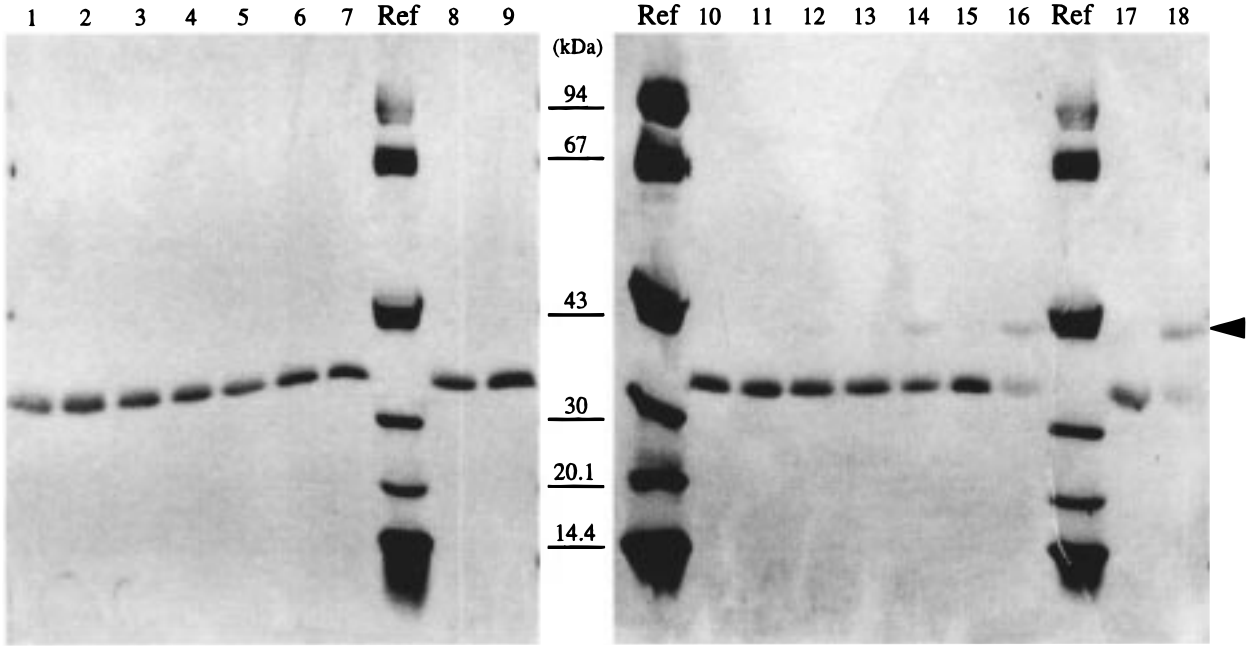

Figure 3. Silver-stained PAGE: yield of photo-cross-linking and necessity of a benzophenone residue for the photo-cross-linking to occur. Thrombin aptamer 60−18[29] was incubated with purified human thrombin, without preincubation as explained in the text. On the left, this aptamer was only 3′-protected by an amino function. On the right, the aptamer was bearing a 3′ benzophenone residue. Lanes 1 and 10: starting time (0 min, no irradiation performed). Lanes 2, 4, 6, 8, 11, 13, 15, and 17: incubation for 15, 30, 60 and 120 min without irradiation. Lanes 3, 5, 7, 9, 12, 14, 16, and 18: UV irradiation for 15, 30, 60, and 120 min, respectively. The presence of benzophenone and irradiation were necessary for the photo-cross-linking to occur (the product of which is indicated by an arrowhead at right). The yield of photo-cross-linking, measured by gel scanning, increased from 15% after 15 min of irradiation to 70% after 120 min.

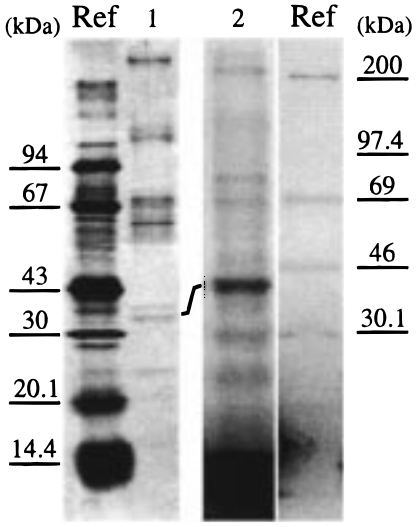

Figure 4. Binding selectivity of radioiodinated ODN3 for bovine thrombin in a crude preparation. Lane 1 is a silver staining of 400 ng of a crude bovine thrombin sample. Lane 2 is the PhosphorImager analysis of its photo-cross-linking with [^{125}I]ODN3. Markers for silver staining (from Pharmacia Biotech) are shown at left. Radiomarkers (from Amersham) are shown at right. The twisted bar between the two gels indicates band shift upon formation of a covalent complex.

a random library of 66-mers (Tasset et al., 1997); $K_d = 1$ μM for a 24-mer having a low propensity to form a G-quartet (ODN ***5*** of Macaya et al., 1995). The photo-cross-linking conditions used in this experiment were thus rather demanding as the complexed fraction of the ODN was probably as low as a few percent.

Figure 2 shows the results of the photolabeling of the purest commercially available human thrombin. No labeling was observed without irradiation. The maximum labeling yield was reached within 1 h. The intensity of the thrombin band decreased thereafter (data not shown), probably due to the photohydrolysis of the carbon−iodine bond releasing $^{125}I^-$ iodide anions (Wolf and Kharasch, 1961; Tejedor and Ballesta, 1983; Boule et al., 1984). As expected, the photo-cross-linking of thrombin increased its apparent molecular mass, from ca. 33.5 kDa to ca. 43 kDa, corresponding to the sum of the molecular masses of thrombin and ODN3. The association of ODN3 with thrombin was relatively rapid as a preincubation in the dark before irradiation had no effect on the intensity of the shifted band (data not shown).

Determination of the Photo-Cross-Linking Yield Using a High-Affinity Thrombin Aptamer. The irradiation of a dilute equimolar mixture of human thrombin with [^{125}I]ODN3 gave a low yield of labeled thrombin, as indicated by the ratio of the protein-associated radioactivity to the radioactivity migrating at the front of the PAGE (assumed to represent unreacted [^{125}I]ODN3; Figure 2). This could be due either to the very low equilibrium concentration of the thrombin−ODN3 complex, or to the inefficacy of the coupling reaction. The second hypothesis seemed unlikely, since yields are usually described as excellent. We nevertheless determined the efficacy of photo-cross-linking, using a conjugate of benzophenone with an aptamer featuring a high affinity for thrombin. Tasset's aptamer 60-18[29], whose K_d for thrombin is about 0.5 nM (Tasset et al., 1997), was coupled to a benzophenone molecule, and a mixture of thrombin with an excess of this conjugate was irradiated (in this case, human thrombin was calculated to be practically 100% in the form of its complex). We detected by silver staining on PAGE both unreacted thrombin and the thrombin−ODN covalent complex (Figure 3). The photo-cross-linking yield at a given irradiation time was determined as the amount of complex formed versus the total amount of thrombin. This yield increased with the irradiation time from 15% after 15 min to 70% after 2 h. The efficacy of the photochemical reaction was thus high, as expected.

A benzophenone moiety was necessary for the cross-linking to occur: even under irradiation, the underivatized aptamer formed no detectable SDS-stable complex with thrombin.

Binding Selectivity of ODN3 for Bovine Thrombin. As can be seen in Figure 4, ODN3 showed a chemoselectivity for bovine thrombin: despite this protein being only a minor constituent in a crude preparation, the major band observed resulted from the association of ODN3 with bovine thrombin.

Conclusion and Perpectives. We reported in this communication an efficient synthesis of a multipurpose ODN derivative. This probe was able to selectively photolabel a low-affinity protein using mild irradiation conditions after such a short time as 15 min. The probe was designed for time-resolved and space-resolved experiments on whole cells. We are currently using this tool for deciphering the process of ODN entry into mammalian cells.

ACKNOWLEDGMENT

C.B. was Aspirant of the Belgian Fonds National de la Recherche Scientifique. This work was supported by the French Agence Nationale de Recherche sur le SIDA, the Fonds des Sciences of the UCL (fellowship to C.B.), Fonds National de la Recherche Scientifique and the Belgian Federal Office for Scientific, Technical, and Cultural Affairs (Concerted Actions 172-94/99). The authors wish to thank Prof. M. Monsigny for a gift of ODN1 as well as for advice in synthesis, and Prof. Bernard Gallez for counseling in the radioiodination experiments.

Poly(ethylene glycol)-*block*-poly(L-lysine) Dendrimer: Novel Linear Polymer/Dendrimer Block Copolymer Forming a Spherical Water-Soluble Polyionic Complex with DNA

Joon Sig Choi, Eun Jung Lee, Young Hun Choi, Yong Joo Jeong, and Jong Sang Park*

Department of Chemistry, Seoul National University, San 56-1, Shillim-dong, Kwanak-ku, Seoul, 151-742, Korea. Received June 20, 1998; Revised Manuscript Received September 17, 1998

Methoxypoly(ethylene glycol)-*block*-poly(L-lysine) dendrimer was designed to form a water-soluble complex with plasmid DNA. The copolymer was synthesized by the liquid-phase peptide synthesis method. It was characterized by ^{1}H NMR and matrix-assisted laser desorption ionization-time-of-flight (MALDI-TOF) mass spectrum. Agarose gel electrophoresis and DNase I protection assay proved that this linear polymer/dendrimer block copolymer assembled spontaneously with plasmid DNA, forming a water-soluble complex which increased the stability of the complexed DNA. Atomic force microscopy of the complex was evaluated at various charge ratios showing that the copolymer/DNA complex was like a globular shape.

Block copolymers containing poly(ethylene glycol) (PEG) have been used in various drug delivery systems (*1*). PEG is a very attractive polymer in some aspects. The polymer is nontoxic, nonimmunogenic, and effective in solubilizing other hydrophobic polymers coupled to it (*2*). PEG has been conjugated linearly to polycationic polymers such as poly(L-lysine) (PLL) (*3*) and polyspermine (*4*) in order to improve solubility and gene transfer efficiency. Also, we have demonstrated that PEG-*graft*-PLL, a comb-shaped copolymer, showed improved cell viability and transfection efficiency in comparison with PLL (*5*).

The physicochemical characteristics of the methoxypoly(ethylene glycol) (mPEG)-*block*-PLL copolymer/nucleic acid complex have been recently studied. The shape and size distributions of the complex were reported to be dependent on the nature of PLL and/or the nucleic acid. In the case of the mPEG-*b*-PLL (10 kDa) complexed with plasmid DNA, a large size exceeding 100 nm was observed, forming a extended toroidal structure (*3*). In comparison, the mPEG-*b*-PLL (20 mer)/salmon testes DNA complex demonstrated that a smaller sized complex was dominant with a small fraction of secondary aggregates (*6*). Also, the mPEG-*b*-PLL (18 mer) was analyzed to form a small spherical nanoassociate with antisense oligonucleotide (ca. 60 nm) by the dynamic light-scattering method (*7*).

Many synthetic polycationic polymers were synthesized and tested for their potential utility in the field of gene therapy. Among them, dendrimers—hyperbranched macromolecules—were distinctive due to their defined structure and large number of surface amino groups. Polycationic dendrimers are capable of electrostatic interaction with polyanions, such as nucleic acids. Therefore, some dendrimers were introduced for the transfer of antisense (*8*) or plasmid DNA (*9*) in vitro and showed remarkable efficiency.

In keeping with the polymers mentioned above, we report herein a conceptually new approach that is designed to conjugate linear PEG with a dense globular macromolecule, PLL dendrimer. We present the characteristics of the complex formed by plasmid DNA and this linear polymer/dendrimer block copolymer that is composed of biocompatible mPEG and L-lysine.

We synthesized the mPEG-*b*-PLL dendrimer in which 16 surface amines were present (generation 4, Figure 1A). mPEG-amine (Sigma, St. Louis, MO) was used as the polymeric supporter, and the PLL dendrimer was prepared by repeated liquid-phase peptide synthesis (*10*) using fluoren-9-ylmethoxycarbonyl (Fmoc) chemistry. mPEG-amine (M_w = 5757, M_n = 5697, M_w/M_n = 1.01, determined by MALDI-TOF mass spectrum) was stirred with 4 equiv of *N*-hydroxybenzotriazole (HOBt), 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), *N*-α-*N*-ϵ-di-Fmoc-L-lysine (AnaSpec, Inc., San Jose, CA), and *N*,*N*-diisopropylethylamine (DIPEA), respectively, in anhydrous *N*,*N*-dimethylformamide (DMF). After the coupling reaction reached completion, the mixture was precipitated with 10-fold excess of cold ether and further washed two times with ether. Piperidine (30%) was used for deprotection of the Fmoc group of lysine. The reaction mixture was precipitated and washed with cold ether as mentioned above. From the reaction mixture, only mPEG-coupled products were precipitated in cold ether, and other byproducts were removed by washing with excess ether. To remove small traces of excess reagents, the precipitate was recrystalized in pure ethanol. The precipitates were dried in vacuo and prepared for further coupling reaction. The coupling and deprotection reactions were repeated four times. The amounts of *N*-α-*N*-ϵ-di-Fmoc-L-lysine, HOBt, HBTU, and DIPEA were doubled in each coupling reaction to meet the 4 equiv. Each reaction progress was monitored by ninhydrin test and ^{1}H NMR until completed.[1] The copolymer was dialyzed for 1 day against water using Spectra/Por dialysis membrane (molecular weight cutoff = 6000−8000, Spectrum, Los Angeles, CA) and collected by freeze drying. This linear polymer/dendrimer block copolymer was further characterized by MALDI-TOF

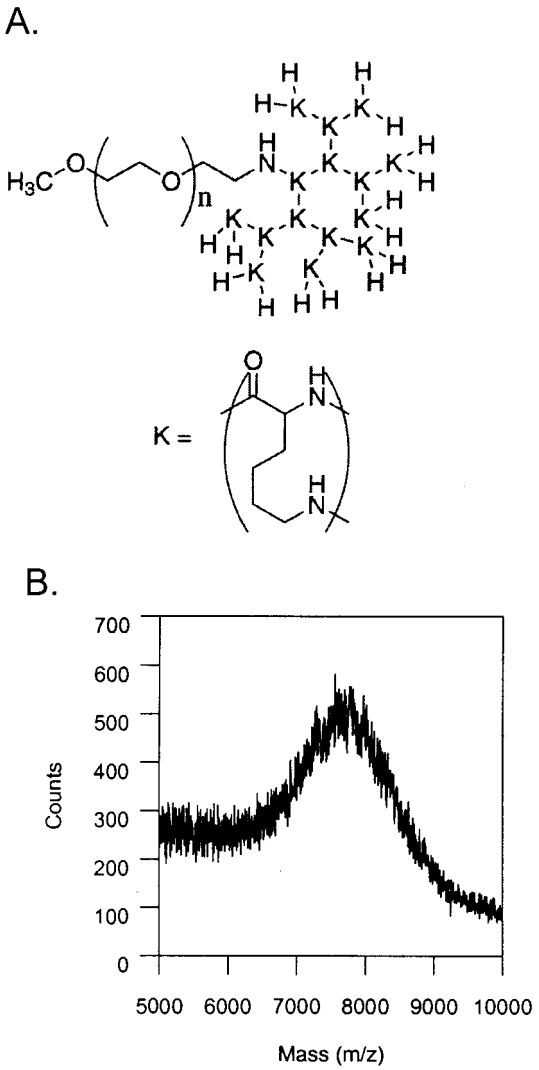

Figure 1. (A) Structural formula of mPEG-*b*-PLL dendrimer. (B) MALDI-TOF mass spectrum of the copolymer. The spectrum was obtained on a PerSeptive Biosystems instrument in the linear mode at 20 kV. The sample was dissolved in water containing 2,5-dihydroxybenzoic acid as a matrix.

mass spectrum (PerSeptive Biosystems, Inc., Framingham, MA) (Figure 1B). The M_w and M_n values of this copolymer were 7594 and 7553, respectively (M_w/M_n = 1.01).[2]

Figure 2 shows the agarose gel electrophoresis data of the copolymer/plasmid DNA associates. Complexes were formed at different charge ratios between the copolymer and pSV-β-gal plasmid DNA (Promega, Madison, WI) by incubation in 15 mM HEPES buffer (0.15 M NaCl, pH 7.4) at room temperature for 30 min. Each sample was then analyzed by electrophoresis on a 0.7% agarose gel containing ethidium bromide (0.5 μg/mL of gel). As the quantity of mPEG-*b*-PLL dendrimer increased, inhibition of migration into the agarose gel increased. At a cationic/anionic charge ratio of 2, complete retardation occurred (lane 3).

The shape and particle size distributions of the copolymer/plasmid complex at various charge ratios were examined by atomic force microscopy (NanoScope IIIa system, Digital Instruments, Inc., Santa Barbara, CA) under the same condition as reported previously with

[2] The M_w and M_n values of the product based on its structural formula were calculated to be 7678 and 7618, respectively.

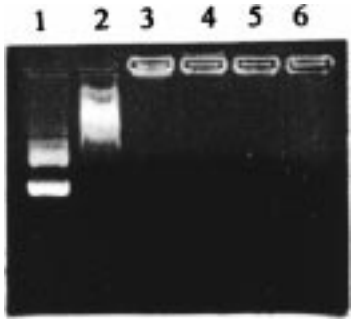

Figure 2. Analysis of complex formation at various charge ratios by agarose gel electrophoresis. pSV-β-gal plasmid DNA (1.0 μg) only (lane 1), charge ratio of copolymer/DNA = 1, 2, 3, 5, and 6 (lanes 2, 3, 4, 5, and 6, respectively). A total of 1.89×10^{15} negative charges are present per 1.0 μg of plasmid DNA, whereas the copolymer has 1.26×10^{15} charges/1.0 μg.

some modification (*3*). From the aqueous complex solution, 1−2 μL containing a final 10 μg/mL of plasmid DNA was deposited onto the surface of freshly split mica. After 1−2 min for adsorption, excess solution was removed by filter paper. The mica was further dried in room temperature and prepared for imaging. When the copolymer was mixed below the charge ratio enough to neutralize DNA, partially associated particles were observed (charge ratio of copolymer/DNA = 1, Figure 3A) as already shown in agarose gel electrophoresis (Figure 2, lane 2). Globular complexes were predominant in the case of charge ratio of copolymer/DNA = 2 (Figure 3B). When the charge ratio was raised to 4, even though a few further associated aggregates between some complexes were observed, most of the complexes were like globular shapes (Figure 3C). In both cases when the charge ratio of copolymer/DNA = 2 or 4, the size range was from ~50 to 250 nm. The average diameter was calculated to be 105 ± 67 nm (copolymer/DNA = 2, n = 30). It could be thought that the complex composed of the mPEG-*b*-PLL dendrimer/pSV-β-gal DNA forms an apparent globular structure, in contrast to the extended toroidal structures of the mPEG-*b*-PLL block copolymer/DNA complex (*3*). It was supposed that PLL dendrimer contained more condensed surface amines in a spatial arrangement than linear PLL and that the dendrimer behaved as a nondraining globular biopolymer (*11*), which led to the ability of this linear polymer/dendrimer block copolymer to form a spherical complex with plasmid DNA.

Nuclease resistance of the complexed DNA was examined at different charge ratios. After adding the copolymer to 4.0 μg of plasmid DNA at various charge ratios from 0 to 4 in 50 μL of 20 mM HEPES buffer (0.15 M NaCl, pH 7.4), the mixtures were incubated for 30 min at room temperature. After incubation, the mixtures were further incubated in the presence of 8.9 units of DNase I (Sigma, St. Louis, MO) for 20 min at room temperature. A total of 75 μL of stop solution (4 M ammonium acetate, 20 mM EDTA, and 2 mg/mL glycogen) was added to each mixture, which was kept in ice. After addition of 37 μL of 1% SDS, DNA was extracted with TE-saturated phenol/chloroform and precipitated by ethanol. The DNA was analyzed by 0.7% agarose gel electrophoresis (Figure 4). In the case of low charge ratios (lanes 2, 3, and 4), plasmid DNA was fragmented and linearized. The position of linearized plasmid DNA was compared with the molecular weight marker. But, nuclease resistance of the complexed DNA was improved much as the charge ratio of the copolymer/DNA increased up to 2 or 4 (lanes 5 and 6). No fragmentation was observed, and both supercoiled and open circular forms of plasmid DNA were obtained.

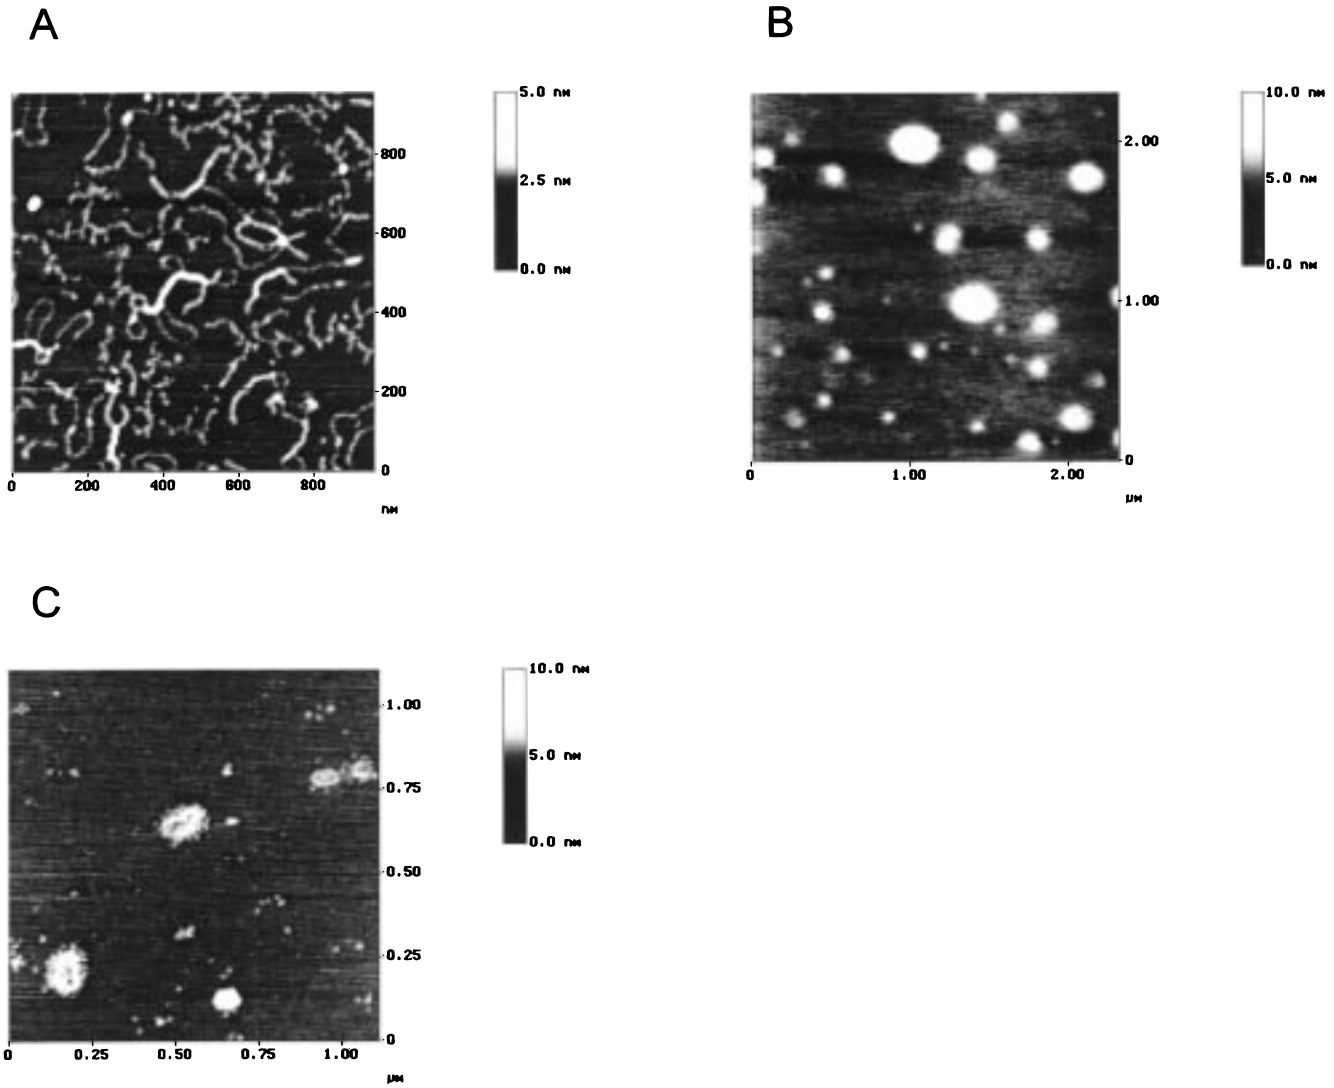

Figure 3. The atomic force microscopy images of the mPEG-*b*-PLL dendrimer/pSV-*β*-gal complex. Charge ratios of copolymer/DNA = 1, 2, and 4 (A, B, and C). The image mode was set to tapping mode. The white color indicates a height more than the designated nm above the mica surface. The *x* and *y* dimensions are scaled as shown.

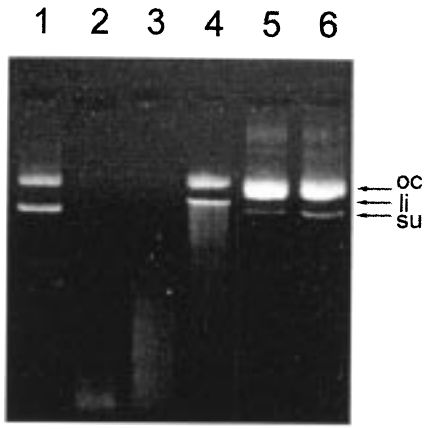

Figure 4. Stability of mPEG-*b*-PLL/plasmid DNA complexes to DNase I at various charge ratios. Undigested plasmid DNA (lane 1), Charge ratio of copolymer/DNA = 0, 0.5, 1, 2, and 4 (lanes 2, 3, 4, 5, and 6, respectively). The positions of the open circular (*oc*), linear (*li*), and supercoiled (*su*) forms are indicated on the right.

Moreover, the amount of supercoiled DNA increased as the charge ratio increased. Even though the complex could not completely protect the plasmid DNA, it is thought to be valuable in considering the recent report that the open circular form of plasmid DNA gave almost the same gene expression efficiency relative to supercoiled DNA (12).

In conclusion, it was proved that this novel linear/dendrimer block copolymer could self-assemble with plasmid DNA at physiological condition, forming a compact and water-soluble polyionic complex. The formed complex was found to take a globular shape with a relatively narrow size distribution. Nuclease resistance of the complex proved that the copolymer increased much the stability of the complexed plasmid DNA. In viewing the results obtained, this copolymer could be valuable in in vitro and/or in vivo delivery of genetic materials, such as antisense or plasmid DNA. Such a study is now in progress in our laboratory.

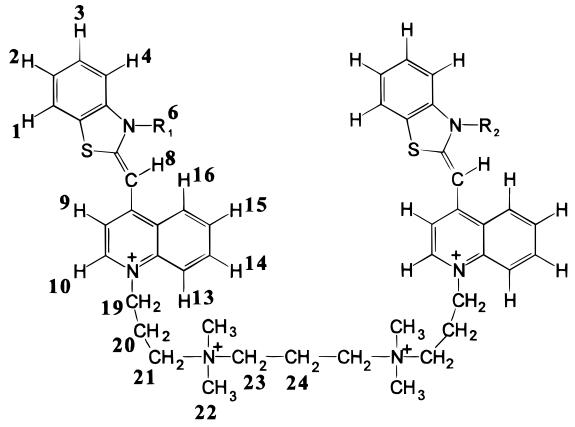
Bis-Intercalation of Homodimeric Thiazole Orange Dye Derivatives in DNA

Michael Petersen, Atef A. Hamed, Erik B. Pedersen, and Jens Peter Jacobsen*



Department of Chemistry, Odense University, Odense M, DK-5230 Denmark. Received June 20, 1998; Revised Manuscript Received November 17, 1998

The thiazole orange dye 1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis-4-[(3-methyl-2,3-dihydro-2(3H)-benzo-1,3-thiazolylidene)methyl]quinolinium tetraiodide (TOTO) binds to double-stranded DNA (dsDNA) in a sequence selective bis-intercalation. We have examined the binding of derivatives of TOTO with different substituents on the benzothiazole ring. The analogues are the following: 1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-[4-[3-(benzyl-2,3-dihydro-2-(3H)-benzothiazolylidene)methyl]quinolinium]-[4-[3-(methyl-2,3-dihydro-2-(3H)-benzothiazolylidene)methyl]-quinolinium]tetraiodide (TOTOBzl) and 1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis-4-[(3-ethyl-2,3-dihydro-2(3H)-benzo-1,3-thiazole)methyl]quinolinium tetraiodide (TOTOEt). In this paper, we report the synthesis of TOTOBzl and TOTOEt together with the one- and two-dimensional ^{1}H NMR investigations of complexes between these TOTO analogues and the dsDNA oligonucleotide d(CGCTAGCG)$_2$. Both analogues yield extremely stable complexes in which each chromophore is sandwiched between two base pairs in a (5′-CpT-3′):(5′-ApG-3′) site. The linker spans over two base pairs in the minor groove. The benzyl group in TOTOBzl and the ethyl groups in TOTOEt is pointing outward in the major groove.

INTRODUCTION

Interest in nonradioactive detection of nucleic acids has led to the search for DNA[1] stains that are stable under gel electrophoretic conditions. Recently, this has led to the synthesis and characterization of a family of homo- and heterodimeric DNA-binding dyes (Benson et al., 1993a,b; Rye et al., 1992). These dyes form highly fluorescent and stable noncovalent complexes with double-stranded DNA (dsDNA). Prominent among these are 1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis-4-[(3-methyl-2,3-dihydro-2(3H)-benzo-1,3-thiazolyl idene)methyl]quinolinium tetraiodide (TOTO, Scheme 1). The enhancement of the fluorescence quantum yield of TOTO upon complex formation with dsDNA is greater than 1000 (Rye et al., 1992), and $t_{1/2}$ for the dissociation of the dsDNA-TOTO complex under gel electrophoretic conditions is approximately 11 h (Benson et al., 1993a). This makes TOTO an excellent choice as a marker with a detection limit of ∼4 pg of DNA (Benson et al., 1993b).

Scheme 1. Numbering Scheme for TOTO, TOTOEt, and TOTOBzl

TOTO: $R_1 = CH_3$ $R_2 = CH_3$

TOTOBzl: $R_1 = CH_2Ph$ $R_2 = CH_3$

TOTOEt: $R_1 = CH_2CH_3$ $R_2 = CH_2CH_3$

We have used ^{1}H NMR spectroscopy to study the binding mode and sequence selectivity of TOTO with various dsDNA oligonucleotides and shown that TOTO binds via bis-intercalation preferentially to oligonucleotides containing the (5′-CTAG-3′)$_2$ binding site (Faridi et al., 1997; Hansen et al., 1996; Jacobsen et al., 1995; Spielmann et al., 1995; Stærk et al., 1997).

The solution structure of the complex of TOTO bis-intercalated in the (5′-CTAG-3′)$_2$ binding site of the d(5′-CGCTAGCG-3′)$_2$ oligonucleotide shows that the strong binding of TOTO is caused by the ability of the TOTO

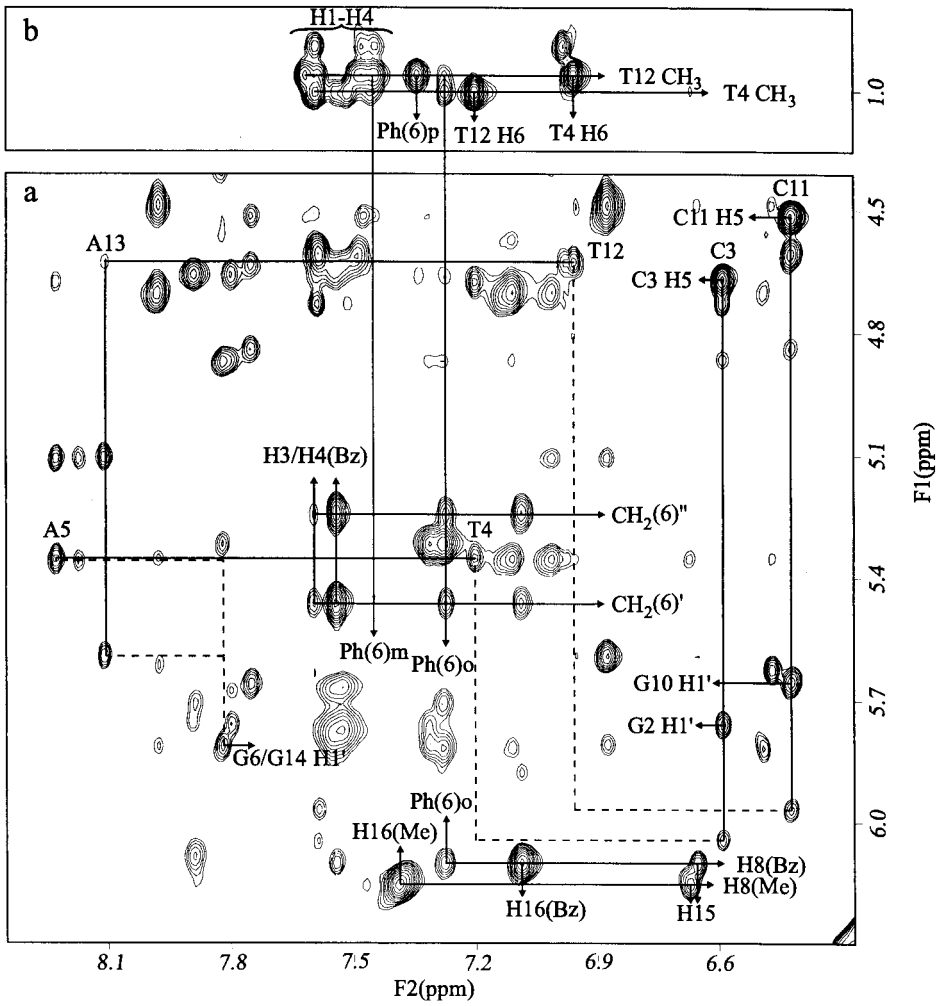

Figure 1. Parts of the 200 ms NOESY spectrum of the TOTOBzl complex recorded in D_2O. Note that the sample contains ca. 20% d(CGCTAGCG)$_2$−TOTO complex. (a) The aromatic to H1′ region. The sequential H1′(n − 1) − H6/H8(n) − H1′(n) connectivity pattern is shown for the 5′−G2-G6−3′ and 5′−G10-G14−3′ dsDNA segments with solid lines. Interruption due to bis-intercalation is shown with broken lines. Some TOTOBzl resonances are marked with solid arrows. (b) The aromatic to methyl region.

chromophores to adapt to the propeller twist of the nucleobases (Spielmann et al., 1995). This is possible since the benzothiazole ring can twist relative to the quinolinium ring due to the flexible cyanine methine bond between. The benzothiazole is intercalated between two pyrimidine bases and the quinolinium ring between the two purine bases. In contrast to other intercalators, the sequence selectivity of TOTO arises directly from the interaction of the intercalated chromophores with the nucleobases. Although the linker of TOTO adds significantly to the binding strength, it is only a spectator with respect to the sequence selectivity. The charged amino groups most probably contribute to the binding free energy by a nonspecific polyelectrolytic contribution.

In this paper, we present the results of one- and two-dimensional ^{1}H NMR studies of complexes between dsDNA and TOTO derivatives. We have synthesized 1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-[4-[3-(benzyl-2,3-dihydro-2-(3H)-benzothiazolylidene)methyl]-quinolinium]-[4-[3-(methyl-2,3-dihydro-2-(3H)-benzothiazolylidene)methyl]quinolinium] tetraiodide (TOTOBzl, Scheme 1) and 1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis-4-[(3-ethyl-2,3-dihydro-2(3H)-benzo-1,3-thiazole)methyl]quinolinium tetraiodide (TOTOEt, Scheme 1) and investigated their complexes with the oligonucleotide d(CGCTAGCG)$_2$. This oligonucleotide contains the (5′-CpT-3′):(5′-ApG-3′) and the (5′-ApG-3′):(5′-CpT-3′) sequences.

SYNTHESIS

The major problem in the synthesis of TOTOEt and TOTOBzl was to achieve proper 2-(methylthio)benzothiazolium salts to be used as starting materials for the synthesis of the intermediate monomeric cyanine dyes **6a** and **6b**. According to the procedure of Brooker et al. (1941, 1942), these 2-(methylthio)benzothiazolium salts should be condensed with the quinolinium salt **5** in the presence of triethylamine in methanol. For the synthesis of **6a**, it was decided to use *N*-ethyl-2-(methylthio)-benzothiazolium tetrafluoroborate (**3**) which could be easily obtained in a high yield from commercially available 2-(methylthio)benzothiazole (**1**) by alkylation with triethyloxonium tetrafluoroborate. When it was attempted to N-benzylate compound **1** by treatment with neat benzyl bromide at 100 °C for 12 h in order to obtain a proper benzothiazolium salt for the synthesis of **6b**, a demethylation reaction occurred and compound **2** was isolated in 51% yield. However, S-ethylation with triethyloxonium tetrafluoroborate afforded the adequate starting material **4**. In the final step, TOTOEt was obtained in 85% yield by condensing 2 equiv of the monomeric cyanine dye **6a** with 1 equiv of *N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediamine in dry methanol according to the procedure of Glazer and co-workers (Rye et al., 1992). Compound **7b**, believed to be formed in situ in this reaction, was also synthesized in a preparative

scale by reacting **6a** with an excess of *N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediamine. The so formed **7b** could then be used for an alternative synthesis of TOTOEt by condensation with **6a**. TOTOBzl was obtained in a similar way by condensing the compounds **6b** and **7a**.

RESULTS

The d(CGCTAGCG)$_2$−TOTOBzl Complex. *Spectral Data*. The line width observed in the 1D ^{1}H spectrum of the d(CGCTAGCG)$_2$−TOTOBzl complex is approximately 6−7 Hz indicating essentially no dynamic exchange between two or more complexes. The d(CGCTAGCG)$_2$−TOTOBzl complex arises from bis-intercalation in the (5′-CTAG-3′)$_2$ binding site. The amount of this complex is at least 100 times higher than the complex of TOTOBzl in any other site as seen from inspection of the spectra.

The dyad symmetry of the d(CGCTAGCG)$_2$ oligonucleotide is broken upon binding of TOTOBzl resulting in 16 spectroscopically distinct dsDNA residues and two distinct TOTOBzl chromophores henceforth designated as the Me-chromophore and the Bzl-chromophore. The protons of the dsDNA were assigned by conventional methods (Wüthrich, 1986; Feigon et al., 1983; Hare et al., 1983; Scheek et al., 1983, 1984; Boelens et al., 1985) while the TOTOBzl protons were assigned by the strategy usually employed for TOTO analogues (Spielmann et al., 1995).

Figure 1 shows the aromatic to H1′ part of a NOESY spectrum. The sequential connectivity pathway of the H1′(*n* − 1)-H6/H8(*n*)-H1′(*n*) resonances in the intercalation sites is shown with solid lines in Figure 1. Interruption due to intercalation in the 5′−C3pT4−3′ and the 5′−A5pG6−3′ (numbering of the dsDNA in Scheme 3) intercalation sites and similarly at the 5′−C11pT12−3′ and the 5′−A13pG14−3 intercalation sites is indicated with broken lines. The assignment of a few TOTOBzl protons is also indicated.

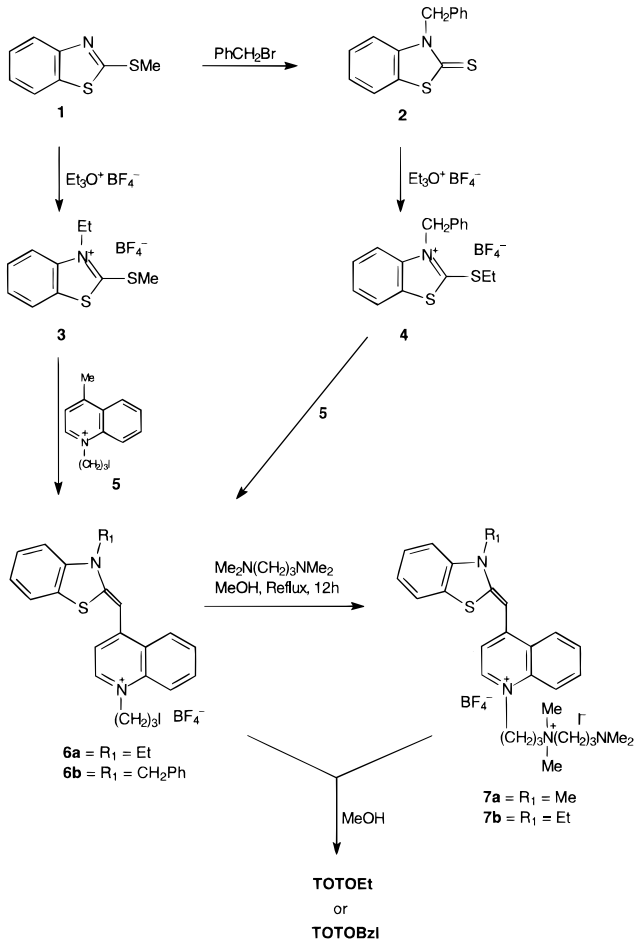
The interruption of the connectivity pathway combined with a multitude of intermolecular dsDNA-TOTOBzl cross-peaks unambiguously identifies binding in the (5′-CTAG-3′)$_2$ site. H13, H14, and H15 on TOTOBzl yield cross-peaks to A5 H2′/H2″ while H1 and H3 on TOTOBzl have cross-peaks to C3 H2′/H2″. These, and other, NOEs position the benzothiazole rings between C3/C11 and T4/T12 while the quinolinium rings are sandwiched between A5/A13 and G6/G14. The methyl group protons of T4/T12 have an upfield shift of 0.7 ppm and yield NOEs to H1−H4 on TOTOBzl implying that the methyl groups are positioned right above the benzothiazole rings.

The CH$_2$(6) protons on TOTOBzl give rise to two sharp resonances. It is only possible to identify three resonances from the phenyl ring of TOTOBzl; these resonances are identifiable as the ortho, meta, and para protons, respectively, by the magnitude of their NOESY cross-peaks to the methylene protons. The relative conformation of TOTOBzl in the complex is as shown in Scheme 1 as confirmed by prominent H8−H16 cross-peaks.

The NOESY spectra of the complex recorded in H$_2$O contain the normal Watson−Crick NOE connectivity pattern. Chemical shift values of labile protons are included in Table 1.

Intermolecular contacts between the *N*-methyl groups and A5/G6 confirm that the linker crosses the minor groove. The cross-peak pattern observed for the d(CGCTAGCG)$_2$−TOTBzl complex is very similar to that observed for the d(CGCTAGCG)$_2$−TOTO complex (Spielmann et al., 1995).

A ^{1}H,^{13}C-HSQC spectrum gave unambiguous assignment of the H3′ and H4′ protons of the dsDNA. However, not all H5′ and H5″ resonances could be assigned due to spectral overlap. Chemical shift values of all protons are shown in Table 1.



As we observe no exchange cross-peaks between the two strands of the dsDNA in the NOESY spectrum with a mixing time of 200 ms, we conclude that the d(CGCTAGCG)$_2$−TOTOBzl complex has a lifetime on the order of, or above, 200 ms.

Ligand−dsDNA NOE contacts. Interruption of the sequential connectivities in the C3pT4, A5pG6, C11pT12, and A13pG14 base pair steps are a clear indication that TOTOBzl bis-intercalates in the (5′−C3T4A5G6−3′):(5′−C11T12A13G14−3′) site. Intermolecular NOEs between T4 CH$_3$ and H1−H4(Me), T12 CH$_3$ and H1−H4(Bzl), A5 H1′, H3′ and H13−H15(Me), G6 H1′ and H13(Me) A13 H1′, H3′ and H13−H15(Bzl), and G14 H1′ and H13(Bzl) places the two benzothiazoles in the C3pT4 and C11pT12 pyrimidine base pair steps while the quinolinium rings are placed in the A5pG6 and A13pG14 purine base pair steps.

NOEs between a number of minor groove markers (H1′ and H2 of the adenosines in the intercalation site) and the polyamin(propylene)linker positions the linker of TOTOBzl in the minor groove of the dsDNA.

Observation of NOE contacts between protons on the phenyl ring and the methyl groups of T4 and T12 unequivocally places the phenyl ring in the major groove of the dsDNA. NOESY cross-peaks between the amino

protons of C3 and CH$_2$(6) and between the para proton of the phenyl ring and the methyl group of T12 show that the phenyl ring points toward the center of the oligonucleotide. The observed NOE contacts between the dsDNA and the phenyl ring of TOTOBzl are shown in Table 2.

Molecular Modeling. A total of 146 distance restraints were incorporated into RMD calculations; 87 of these restraints were found by the RANDMARDI procedure based on 97 NOESY cross-peak volumes; 33 restraints were qualitative restraints found by inspection of the NOESY spectrum with a mixing time of 200 ms and were conservatively chosen as strong (1.8−5.0 Å), medium (1.8−5.5 Å) or weak (1.8−6.0 Å). Four restraints were included to keep the ends of the dsDNA duplex in a B-DNA-like conformation. The remaining 22 of these restraints served to mimic Watson−Crick hydrogen bonding between the two DNA strands as justified by the NOESY spectrum recorded in H$_2$O. As an evaluation of the precision of the distances returned by RANDMARDI, the covalently fixed distances in TOTOBzl were left out of the distance reference file for MARDIGRAS. Consequently, the magnetization transfer for these protons are calculated and the distances returned can be used to evaluate the precision of the RANDMARDI procedure. Four of the 97 intensities used in the calculations stemmed from covalently fixed proton pairs in TOTOBzl and the distances returned for these proton pairs by RANDMARDI were in all cases in error of less than 0.3 Å relative to the covalently known "real" distances. This

[a] Found by RANDMARDI calculations. Qualitative distance restraints found by inspection of the NOESY spectrum with a mixing time of 200 ms are tabulated in parentheses.

lends credibility to the distances returned by RANDMARDI despite the sparse experimental data and justifies the inclusion of the 87 proton−proton distances in the RMD calculations. A detailed survey of the distance restraints is shown in Table 3.

Convergence. Twenty structures were generated for the dsDNA−TOTOBzl complex with B-DNA conformation as starting structure by RMD calculations. The 20 structures all converged to just one family of structures, and the pairwise root-mean-square (rms) deviation was 0.99 Å. We observed only two violations in excess of 0.2 Å but none in excess of 0.3 Å.

A model structure as the one here presented should not be mistaken for a high-resolution structure which requires a much larger set of experimental data. Due to the rather large number of restraints incorporated in the RMD calculations, the consideration of spin-diffusion effects in the RANDMARDI procedure, and the convergence after the RMD calculations, we have confidence in the model structure obtained and believe it to show a fairly precise "picture" of the structure of the TOTOBzl complex. Hence, we believe that the model structure enables us to determine various aspects of the local

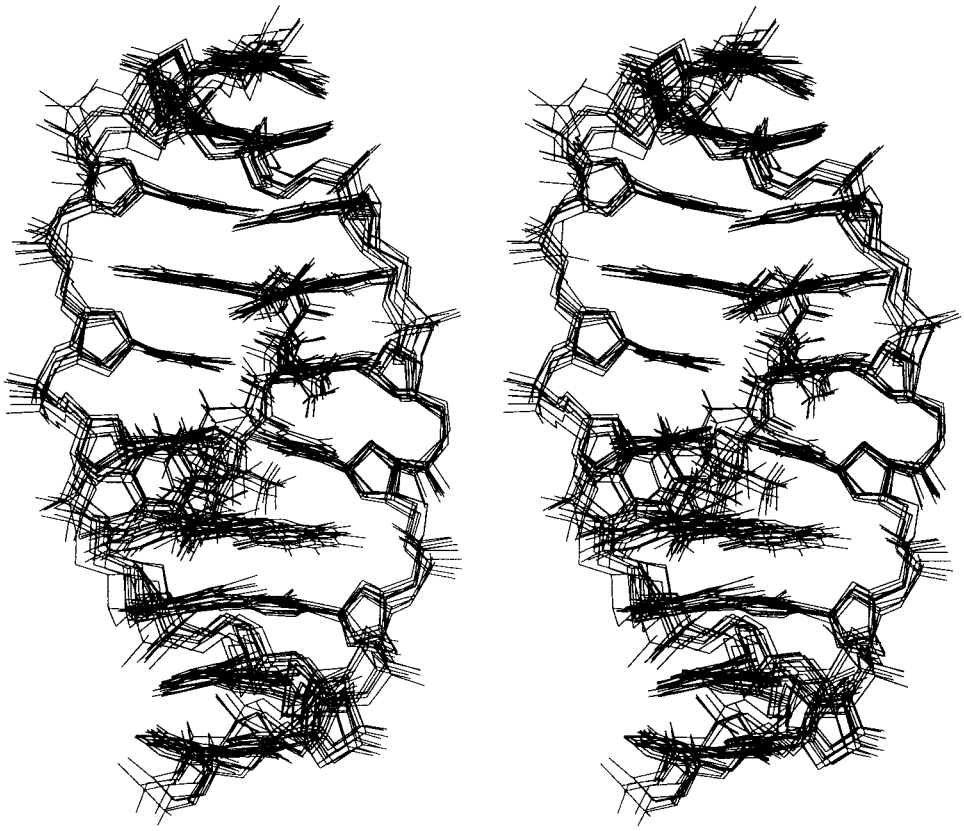

Figure 2. Stereoview of a superposition of 10 structures of the d(CGCTAGCG)$_2$−TOTOBzl complex looking into the major groove. Deoxyribose protons have been omitted for clarity.

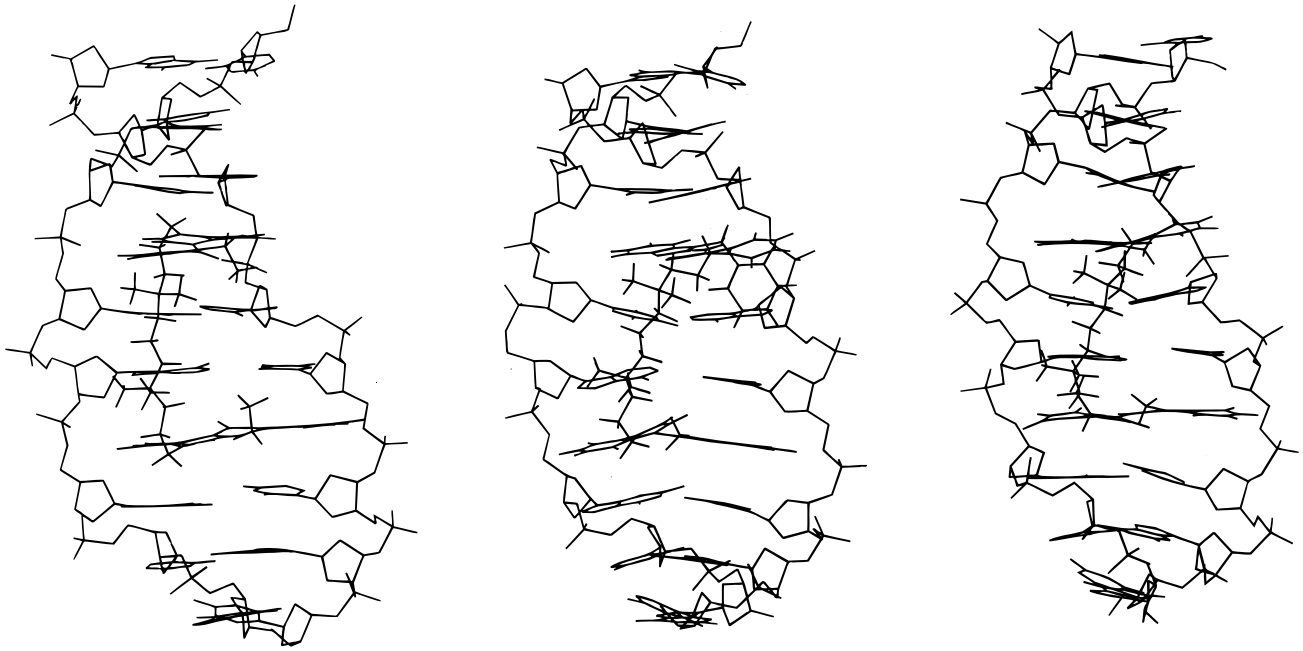

Figure 3. The complexes between d(CGCTAGCG)$_2$ and TOTO (left), TOTOEt (center) and TOTOBzl (right). The d(CGCTAGCG)$_2$-TOTO complex is reproduced from Spielmann et al. (1995). The d(CGCTAGCG)$_2$−TOTOEt complex is reproduced from Petersen and Jacobsen (1998).

structure of the complex. Views of the model structure are shown in Figures 2 and 3.

The d(CGCTAGCG)$_2$−TOTOEt Complex. The line width observed in the 1D ^{1}H NMR spectrum of the d(CGCTAGCG)$_2$−TOTOEt complex is just as narrow as for the TOTOBzl complex, indicating essentially no dynamic exchange between two or more complexes. Furthermore, only one resonance frequency is observed for the protons on each strand of the dsDNA and for each chromophore. This shows that the TOTOEt forms a single complex with d(CGCTAGCG)$_2$ with dyad symmetry. The d(CGCTAGCG)$_2$−TOTOEt complex arises from bis-intercalation in the (5′−CTAG−3′)$_2$ binding site. The amount of this complex is at least 100 times higher than any other complex as seen from inspection of the spectra. A full relaxation matrix analysis employing RAND-

MARDI (Liu et al.,1995) followed by restrained molecular dynamics calculations using cross-peak intensities in NOESY build-up experiments yielded a high-resolution structure of the d(CGCTAGCG)$_2$−TOTOEt complex. This work is reported elsewhere (Petersen and Jacobsen, 1998).

DISCUSSION

The sequence selectivity and the binding mode of the TOTO analogues to the dsDNA oligonucleotide examined in this work are very similar to those of TOTO. In the d(CGCTAGCG)$_2$ oligonucleotide, both TOTOEt and TOTOBzl bind exclusively to the (5′−CTAG−3′)$_2$ site.

Though the mode of binding and selectivity of TOTOEt, TOTOBzl, and TOTO is similar, there are interesting differences in the local structure of the dsDNA and the ligands. These differences are discussed below.

Description of the d(CGCTAGCG)$_2$−TOTOBzl Model Structure. The structure of the d(CGCTAGCG)$_2$−TOTOBzl complex shows that TOTOBzl bis-intercalates in the (5′−CTAG−3′)$_2$ site with the benzothiazole ring systems sandwiched in the CpT base pair steps and the quinolinium ring systems sandwiched in the ApG base pair steps. The N-benzyl group on the benzothiazole is placed in the major groove orientated toward the center of the oligonucleotide, and the polyamin(propylene)linker is in the minor groove. The dsDNA is in an overall B-DNA like conformation.

As can be gleaned from Figure 2 the nucleobases and the intercalating chromophores are fairly well-defined in the model structure while the N-benzyl group and the polyamin(propylene)linker cannot be accurately determined from the spectral data. The positions in the two grooves of the dsDNA are, however, beyond any doubt.

In the complex, the intercalating chromophores stretch across the dsDNA helix; T4 and T12 unstack from A5 and A13 to maximize van der Waals contacts with the intercalating chromophores. The methyl groups of the thymines are placed right on top of the benzothiazoles of TOTOBzl.

Cross-strand NOEs between T12 H3 and A5's amino protons and between the adenosine H2s and the thymidine H1s reveal that normal Watson−Crick base pairing is present in the intercalation site even though the adenosines and thymidines are unstacked.

For the uncomplexed d(CGCTAGCG)$_2$, no cross-peaks are observed between the thymine imino proton and the base-paired adenine amino protons due to exchange with the solvent. In the complex, cross-peaks are observed between T12 H3 and A5's amino protons. This is a testimony of the increased stability of the T12−A5 base pair due to intercalation of the Me-chromophore of TOTOBzl. Intriguingly, no cross-peaks are observed between T4 H3 and A13's amino protons. This can be explained by analysis of the model structure: A5 and T12 stack well with the ring systems of the intercalating Me-chromophore while T4 and A13 do not seem to make any appreciable stacking with the intercalating ring systems of the Bzl-chromophore. Therefore, the stability of the A5−T12 Watson−Crick base pair is enhanced relative to the stability of an A−T base pair in the uncomplexed dsDNA duplex.

Comparison of the Complexes of d(CGCTAGCG)$_2$ with TOTO, TOTOEt, and TOTOBzl. Bearing in mind that the model structure of the TOTOBzl complex is not a high-resolution structure, as are the structures determined of the TOTO and TOTOEt complexes, we refrain from discussing more detailed parameters such as helix parameters. Instead, we are making a qualitative comparison of the three complexes.

Table 4. Observed Twist between the Ring Systems of the Aromatic Chromophores in the TOTO, TOTOBzl, and TOTOEt Complexes and the Chemical Shift Values of the Protons Discussed in the Text

	twist angle[a] (deg)	thymidine H1′ [b]	$\Delta\delta$[c]	thymidine H6[b]	$\Delta\delta$[c]
TOTO	22	4.62	0.98	6.97	0.44
TOTOEt	6	4.96	0.64	7.08	0.33
TOTOBzl	1	5.35	0.25	7.20	0.21
TOTOBzl	25	4.62	0.98	6.96	0.45

[a] Twist angle between the two ring systems of the intercalating chromophore. [b] Chemical shift value of the specified proton on the thymidine adjacent to the intercalating chromophore, values are given (ppm). [c] Change in chemical shift relative to the free dsDNA.

In the three complexes, the dsDNA adopts an overall B-DNA-like geometry. A striking feature of the three complexes is the change in the angle around the cyanine methine bond of the intercalators (Figure 2). This angle defines the angle of the benzothiazole relative to the quinolinium ring. It appears that the substitution of ethyl and benzyl at the benzothiazole N-atom lowers this angle in the complexes relative to the complexes where a N-methyl is present at the benzothiazole (see Table 4).

As for chemical shifts, pronounced changes from free dsDNA are observed for the thymidine H6, H1′, H2′, H2″, and the adenosine H2 protons for the three complexes discussed. These protons are placed in the minor groove of dsDNA, and with the charged polyamin(propylene)-linker of the bis-intercalators "intruding" in this groove, it is to be expected that the electrostatic potential of the minor groove is profoundly altered in the complexes, resulting in changes of chemical shift values of protons positioned herein. The thymidine H6 and H1′ protons, however, seem to occupy exceptional positions as shown by the much different chemical shifts values for the three complexes (see Table 4).

The relationship between the value of the above-mentioned twist angle and the thymidine H6 and H1′ chemical shifts is evident as seen from Table 4. Although it appears that no simple relationship can account for the observations, the qualitative trend is clear that a large twist angle between the chromophores of the bis-intercalator leads to a large change in chemical shift for the thymidine H6 and H1′ protons relative to free dsDNA. Most striking are the results obtained for the TOTOBzl complex where each of the two intercalating chromophores display profoundly different behavior.

As the twist angle between the ring systems of the chromophores is enlarged, the overlap of the π-orbitals of the two ring systems diminishes, resulting in a quenching of the flow of π-electrons between the two ring systems, thus changing the ring current of the intercalating chromophore.

As neither the H2′ nor H2″ protons of the thymidine experience these different changes in chemical shifts it would seem that the change in "environment" for the H6 and H1′ protons is a local feature. This can be rationalized by the intercalating aromatic chromophore inducing a change in the ring current of the thymine ring and should be expected only to affect the protons in close proximity to this ring (Davies, 1978).

CONCLUSION

We have examined the complexes between d(CGCTAGCG)$_2$ and the bis-intercalators TOTOEt and TOTOBzl

resulting in a high-resolution structure of the d(CGCTAGCG)$_2$−TOTOEt complex and a model structure of the d(CGCTAGCG)$_2$−TOTOBzl complex. We have compared these complexes with the previously published high-resolution structure of the d(CGCTAGCG)$_2$−TOTO complex (Spielmann et al., 1995). Though the overall binding of the bis-intercalators are alike with nearest neighbor bis-intercalation in the (5′−CTAG−3′)$_2$ site, we are able to point out pronounced changes in the structure of the dsDNA upon binding of the different bis-intercalators.

There are no indications whatsoever that TOTOBzl or TOTOEt make less stable complexes than TOTO when bound to dsDNA. Our long-term objective of this work is to move the linker of the bis-intercalator from the minor groove to the major groove while retaining TOTO's sequence selectivity. The structure of the TOTOEt complex reveals that the benzothiazole N-ethyl group adopts a geometry near to perfect for the linking of the two chromophores in the major groove while the TOTOBzl complex shows that there is ample room to accommodate a benzyl group. This, thus, renders our goal a distinct future possibility.

EXPERIMENTAL PROCEDURES

Synthesis. *3-Ethyl-2-(methylthio)benzothiazolium Tetrafluoroborate (**3**).* Triethyloxonium tetrafluoroborate (1.90 g, 0.01 mol) in $CHCl_3$ (10 mL) is added with stirring to 2-(methylthio)benzothiazole (1.81 g, 0.01 mol) in $CHCl_3$ (50 mL) at −10 °C. The temperature was allowed to increase to 20 °C, and stirring was continued for 5 h. The precipitate was collected by filtration; yield 2.26 g (75%); mp 172−175 °C.

*3-Benzyl-2-(ethylthio)benzothiazolium Tetrafluoroborate (**4**).* A mixture of 2-(methylthio)benzothiazole (18.1 g, 0.1 mol) and benzyl bromide (51.1 g, 0.3 mol) was heated at 100 °C for 12 h. After cooling to room-temperature, ether (200 mL) was added under stirring and the precipitate of **2** was collected by filtration; yield 13.2 g (51%); mp 150−152 °C; lit. mp 149 °C (Reed et al., 1939). Et_3OBF_4 (1.90 g, 0.01 mol) in 50 mL CH_2Cl_2 was added dropwise to **2** (2.6 g, 0.01 mol) in 50 mL of CH_2Cl_2 at −10 °C with stirring. The temperature was allowed to increase to room temperature during 1 h and the mixture was stirred for 5 h. Compound **4** precipitated as pale yellow crystals on addition of ether; yield 3.3 g (88%); mp 165−168 °C. ^{1}H NMR (DMSO-d_6): δ 1.56 (t, 3H, J = 7.3 Hz, CH_3), 3.68 (q, 2H, J = 7.3 Hz, CH_2), 5.95 (s, 2H, CH_2), 7.31−8.45 (m, 9H, Ar). FAB MS: m/z 286 (M − BF_4). Anal. Calcd for $C_{16}H_{16}NS_2 \cdot BF_4$: C, 51.49; H, 4.32; N, 3.75. Found: C, 51.65; H, 4.09; N, 3.81.

*4-[(3-Ethyl-2(3H)-benzothiazolylidene)methyl]-1-(3-iodopropyl)quinolinium Tetrafluoroborate (**6a**).* Equimolar amounts of **3** and **5** were dissolved in absolute ethanol by heating. One equivalent of triethylamine was added, and the mixture was stirred at room temperature for 30 min. The title compound precipitated on addition of ether; yield 70%; recrystallization from acetone/ether; mp 250−252 °C. ^{1}H NMR (DMSO-d_6): δ 1.40 (t, 3H, J = 7.0 Hz, CH_3), 2.39 (quint, 2H, J = 7.0 Hz, CH_2), 3.35 (t, 2H, J = 7.0 Hz, CH_2), 4.65 (m, 4H, 2 × CH_2), 6.94 (s, 1H, =CH), 7.37−8.80 (m, 10H, Ar). FAB MS m/z 473 (M − BF_4). Anal. Calcd for $C_{22}H_{22}IN_2S \cdot BF_4 \cdot 0.5H_2O$: C, 46.42; H, 4.07; N, 4.92. Found: C, 46.65; H, 3.91; N, 4.89.

*4-[(3-Benzyl-2(3H)-benzothiazolylidene)methyl]-1-(3-iodopropyl)quinolinium Tetrafluoroborate (**6b**).* The title compound was synthesized from equimolar amounts of **4** and **5** in a similar way as **6a**; yield 65%; mp 237−247 °C (dec). ^{1}H NMR (DMSO-d_6): δ 2.38 (quint, 2H, J = 7.0 Hz, CH_2), 3.33 (t, 2H, J = 7.0 Hz, CH_2), 4.64 (t, 2H, J = 7.0 Hz, CH_2), 5.96 (s, 2H, CH_2), 6.99 (s, 1H, =CH), 7.29−8.64 (m, 15H, Ar). FAB MS: m/z 535 (M − BF_4). Anal. Calcd for $C_{27}H_{24}IN_2S \cdot BF_4 \cdot 0.5H_2O$: C, 51.37; H, 3.99; N, 4.44. Found: C, 51.56; H, 3.91; N, 4.44.

1,1′-[1,3-Propanediylbis[(dimethylimino)-3,1-propanediyl]]bis[4-[(3-ethyl-2(3H)-benzothiazolylidene)methyl]quinolinium Tetraiodide, TOTOEt. A suspension of **6a** and 0.5 equiv of *N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediamine in anhydrous methanol was heated at reflux for 24 h. Recrystallization from DMF/MeOH afforded the title compound as an orange-red solid: yield 85%; mp 248−251 °C (dec). ^{1}H NMR (DMSO-d_6): δ 1.42 (t, 6H, J = 6.8 Hz, 2 × CH_3), 2. 38 (m, 6H, 3 × CH_2), 3.19 (s, 12H, 4 × CH_3), 3.36 (m, 4H, 2 × CH_2), 3.71 (m, 4H, 2 × CH_2), 4.68 (m, 8H, 4 × CH_2), 6.93 (s, 2H, 2 × =CH), 7.35−8.82 (m, 20H, Ar). FAB MS: m/z 1203 (M − I). Anal. Calcd for $C_{51}H_{62}I_4N_6S_2$: C, 46.03; H, 4.70; N, 6.31. Found: C, 46.28; H, 4.85; N, 6.10.

1-[3-[[3-[Dimethyl[3-[4-[(3-methyl-2(3H)-benzothiazolylidene)methyl]quinolinio]-propyl]ammonio]propyl]dimethylammonio]propyl]-4-[(3-benzyl-2(3H)-benzothiazolylidene) − methyl]quinolinium Tetraiodide, TOTOBzl. Equivalent amounts of **6b** and **7a** in anhydrous methanol were refluxed for 12 h. TOTOBzl was precipitated by addition of ether and recrystallized from acetone/ether: yield 90%; mp 228−230 °C (dec). ^{1}H NMR (DMSO-d_6): δ 2.38 (m, 6H, 3 × CH_2), 3.19 (s, 12H, 4 × CH_3), 3.40 (m, 4H, 2 × CH_2), 3.72 (m, 4H, 2 × CH_2), 4.01 (s, 3H, CH_3), 4.70 (m, 4H, 2 × CH_2), 5.97 (s, 2H, CH_2), 6.90 (s, 1H, =CH), 6.97 (s, 1H, =CH), 7.30−8.90 (m, 25H, Ar). FAB MS: m/z 1251 (M − I). Anal. Calcd for $C_{55}H_{62}I_4N_6S_2 \cdot 4H_2O$: C, 45.53; H, 4.86; N, 5.79. Found: C, 45.49; H, 4.89; N, 5.81.

Sample Preparation. The purified oligonucleotide d(CGCTAGCG)$_2$ was purchased from DNA technology, Århus, Denmark, and used without further purification. TOTOEt and TOTOBzl are almost insoluble in water and the complexes with dsDNA was therefore made by the procedure described earlier (Jacobsen et al., 1995). The NMR samples were prepared by dissolving the complexes in 0.5 mL of 10 mM sodium phosphate buffer (pH 7.0), 0.05 mM NaEDTA, 0.01 mM NaN_3, and 0.1 mM DSS. For experiments carried out in D_2O the solid complexes, lyophilized three times from D_2O, were redissolved in 99.96% D_2O (Cambridge Isotope Laboratories). A mixture of 90% H_2O and 10% D_2O (0.5 mL) was used for experiments examining exchangeable protons. The samples were kept in NMR tubes under nitrogen. The final concentration of the complexes were ca. 2 mM.

NMR Experiments. NMR experiments were performed on a Varian Unity 500 spectrometer at 25 °C for the TOTOBzl complex and at 27 °C for the TOTOEt complex. NOESY spectra of the complexes were acquired in D_2O using 1024 complex points in t_2 and a spectral width of 5000 Hz. A total of 512 t_1 experiments were recorded using the States phase cycling scheme. The residual signal from HOD was removed by presaturation. For the TOTOEt complex, spectra with mixing times of 50, 100, 150, and 200 ms were recorded sequentially without removing the sample from the magnet. NOESY spectra of the TOTOBzl complex with mixing times of 100 and 200 ms were acquired at 750 MHz using 2048 complex points in t_2 and a spectral width of 7500 Hz on a Varian INOVA 750 spectrometer. NOESY spectra of the complexes in H_2O were obtained by using a NOESY pulse sequence where the last 90° pulse is replaced by a 1−1 jump-return pulse to suppress the solvent signal (Guéron and Plateau, 1982). The mixing times were 160 ms. In addition, a Watergate NOESY spectrum in H_2O

with a mixing time of 50 ms was recorded of the TOTOEt complex on a Varian Unity+ 500 spectrometer. The NOESY spectra in H_2O were acquired with a spectral width of 10 000 Hz in 2048 complex points using 512 t_1 experiments with 64 scans acquired in each t_1 experiment. NOESY spectra with mixing times of 500 ms were recorded of the free TOTOBzl and TOTOEt in DMSO-d_6.

TOCSY spectra of the complexes with mixing times of 30 and 90 ms were obtained in the TPPI mode using 1024 complex points in t_2 and 512 t_1 experiments with 64 scans each.

DQF−COSY spectra of the complexes were recorded using the States phase cycling scheme with 4096 complex points in t_2 and 1024 t_1 experiments with 64 scans each. Removal of the residual HOD signal was done by presaturation in all spectra.

^1H,^{13}C HSQC spectra in D_2O were recorded for both the complexes: the spectrum of the TOTOEt complex on a Varian Unity+ 500 spectrometer and the spectrum of the TOTOBzl complex on a Varian INOVA 750 spectrometer.

The acquired data were processed using FELIX (version 2.35, Biosym/MSI, San Diego, CA). The spectra were assigned by conventional methods (Wüthrich, 1986; Feigon et al., 1983; Hare et al., 1983; Scheek et al., 1983, 1984; Boelens et al., 1985).

Restrained Molecular Dynamics. The d(CGCTAGCG)$_2$ oligonucleotide and the TOTOBzl molecule were built in INSIGHTII (version 95.0, Biosym/MSI, San Diego, CA). TOTOBzl was manually docked into the model of B-form DNA to obtain the starting model for the structure refinement. The potentials for both DNA and TOTOBzl were assigned by the AMBER force field, modified to accommodate the benzothiazole sulfur atom of TOTOBzl.

The distance restraints obtained from RANDMARDI were incorporated into an energy minimization and a RMD procedure using DISCOVER (version 95.0, Biosym/MSI, San Diego, CA). An initial energy minimization was followed by 28 ps of restrained molecular dynamics: dynamics at 600 K for 4 ps, followed by cooling to 200 K in 50 K steps of 3 ps each. The final structure was then energy minimized to a maximum derivative of 0.01 Å.

The pseudo energy terms used to enforce the restraints were

$$E_{\mathrm{NOE}} = \begin{cases} k_1(r - r_1)^2 & \text{when } r < r_1 \\ 0 & \text{when } r_1 \le r \le r_2 \\ k_2(r - r_2)^2 & \text{when } r > r_2 \end{cases}$$

where r_1 and r_2 are the lower and upper distance bounds determined from the cross-peak volumes; k_1 and k_2 are the force constants. A lower force constant of $k_1 = 50$ kcal/(mol Å^2) and upper force constant of $k_2 = 25$ kcal/(mol Å^2) were employed. The width of the flat region of the potential well reflects the accuracy of a given constraint. A distance dependent dielectric, $\epsilon = r$, was employed to account for solvent effects.

Distance Restraints. *The Initial Model*. An initial model of the d(CGCTAGCG)$_2$−TOTOBzl complex was made with restraints found from the NOESY spectrum with a mixing time of 100 ms. Cross-peak volumes were converted to proton−proton distances by the isolated spin pair approximation (ISPA) using the volumes of covalently fixed dsDNA protons as references (cytosine H5−H6, 2.45 Å; deoxyribose H2′−H2″, 1.78 Å). All lower bounds were set to 1.8, and 1 Å was added to the distances determined to obtain the upper bounds. Distance restraints involving methyl and methylene protons were further loosened. In this manner, a total of 81 distance restraints were obtained (25 of these were intermolecular restraints). A further 22 distance restraints were included to mimic Watson−Crick base pairing. Three hydrogen bonds were included for each of the six C/G base pairs and two for both of the T/A base pairs. Lower and upper bounds were 1.7 and 2.1 Å, respectively. Thus, a total of 103 distance restraints were included in the RMD calculations.

A total of 20 structures were generated by the RMD protocol described above, all structures converged to just one family of structures. A representive structure of this family was chosen for further refinement by including restraints obtained by including a relaxation matrix analysis.

Relaxation Matrix Analysis. A total of 97 cross-peaks on the upper diagonal of the NOESY spectrum with a mixing time of 200 ms were integrated. The RANDMARDI variation of MARDIGRAS was employed to transfer the cross-peak volumes to proton−proton distance restraints taking spin diffusion into account (Borgias and James, 1990; Borgias et al., 1990; Liu et al., 1995). The RANDMARDI procedure generated 50 peak intensity sets and MARDIGRAS calculations were performed on each of those. A "noise level" of five times the measured volume of the weakest cross-peak was used in the RANDMARDI calculaions. Upper and lower bounds were calculated as the average interproton distance ± one standard deviation as found from the MARDIGRAS calculations.

A total of 97 cross-peak volumes were measured in FELIX; of those, 88 cross-peak volumes stemmed from interproton distances not detemined by the covalent geometry of neither the dsDNA nor the TOTOBzl. RANDMARDI returned 87 interproton distances for use in the RMD calculations, and 0.6 Å was added to all upper bounds for these distances before implementation as restraints. The average flat well potential width was 1.34 Å.

Cross-Linking Exogenous Bifunctional Peptides into Fibrin Gels with Factor XIIIa

Jason C. Schense[†,‡] and Jeffrey A. Hubbell*[,‡]

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125, and Department of Materials and Institute for Biomedical Engineering, ETH-Zürich and the University of Zürich, Moussonstrasse 18, CH-8044, Zürich, Switzerland. Received June 26, 1998; Revised Manuscript Received October 13, 1998

Bi-domain peptides with a factor XIIIa substrate in one domain and a bioactive peptide in another domain were covalently incorporated into fibrin gels during coagulation through the action of the transglutaminase factor XIIIa. The cross-linking characteristics were determined for two bi-domain peptides with factor XIIIa substrates based on fibrinogen, dYRGD*TIGEGQQHHLGG*-NH_2, and dLRGD*GAKDV*-NH_2, as well as one bi-domain peptide with a substrate sequence based on α_2-plasmin inhibitor, dL*NQEQVSPL*RGD-NH_2, and another with a nonbiological, oligolysine substrate, dLRGD-*KKKK*G-NH_2 (substrate domains in italic). Each of these peptides was able to cross-link into the fibrin gels during coagulation, with the peptide containing the factor XIIIa substrate based on α_2-plasmin inhibitor being incorporated at levels in excess of 8 mol/mol fibrinogen. The structural characteristics of these peptide-modified gels proved to be the same as those for a native fibrin gel. The bioactivity of the incorporated active factors was tested in a neuronal culture model with day 8 chicken dorsal root ganglia using two bioactive sequences, RGD and DGEA, and one inactive control sequence, RDG. Each of these peptides influenced the extension of neurites from the ganglia as expected, indicating that the incorporated factors retained their activity. With the use of soluble competitive inhibitors, it was shown that this effect was due to the covalently incorporated peptides. Through exploiting the role of factor XIIIa in coagulation, we have developed a method by which to impart the character of nonfibrin proteins, such as extracellular matrix proteins, to fibrin, a biological material with many potential therapeutic and academic applications.

INTRODUCTION

Fibrin is a biopolymeric gel that plays an important role in natural wound healing and medicine. Fibrin is formed by the enzymatic polymerization of fibrinogen at most sites of injury, and fibrin can be formed for therapeutic purposes either from purified fibrinogen or from processed blood plasma. Such therapeutic applications include use as an adhesive and sealant and as a vehicle for the local delivery of drugs (*1, 2*). A special feature of fibrin, both formed naturally and therapeutically, is that it is degraded and remodeled by cell-associated enzymatic activity during cell migration and wound healing (*3, 4*). As such, the material differs qualitatively from most synthetic biomaterials employed in medicine, in that there exists an active feedback from the cells in the healing response to the material (leading to degradation of the material) as well as from the material to the cells (providing a mechanical scaffold with biospecific adhesion sites for cell infiltration) (*5*). Our interest in fibrin relates to its use as a therapeutic material, and this report addresses methods by which to harness the enzymatic processes of coagulation to incorporate exogenous bioactive signals into the fibrin network. The processes by which fibrinogen is polymerized into fibrin and by which this fibrin is subsequently degraded have been well characterized. Initially, the protease thrombin cleaves the dimeric fibrinogen molecule at two symmetric sites. Once the fibrinogen is cleaved, a self-assembly step occurs in which the fibrinogen monomers come together and form a noncovalently cross-linked polymer gel via the proteolytic exposure of binding sites (*1*). Factor XIIIa, proteolytically activated from factor XIII by thrombin, may then covalently cross-link this polymer network (see below). Once a cross-linked fibrin gel is formed, the subsequent degradation of the fibrin network is tightly controlled. One of the key molecules in controlling the degradation of fibrin is α_2-plasmin inhibitor (*6*). This molecule is cross-linked to the α chain of fibrin through the action of factor XIIIa (*7*). By attaching to the gel, a high concentration of inhibitor can be localized to the gel. The inhibitor then acts by preventing the binding of plasminogen to fibrin (*8*) and by inactivating plasmin (*6*).

The enzyme factor XIIIa plays an important role in the formation and degradation of fibrin gels (*9*). Factor XIIIa is a transglutaminase, and the specific cross-linking mechanism has been elucidated (*10, 11*). Initially, the zymogen factor XIII is activated by thrombin cleavage to form the active transglutaminase factor XIIIa. This enzyme then proceeds to create primarily intermolecular cross-links between the γ chains in the fibrin network (*12, 13*). These covalent cross-links provide the fibrin gel with significantly greater stability and resistance to protease degradation. Furthermore, factor XIIIa has been shown to cross-link other proteins, including fibronectin to both fibrin (*14*) and collagen (*15*). For several proteins,

the exact amino acid sequence of the factor XIIIa substrate domain has been elucidated, including for fibrin (*12*), fibronectin (*16*), and α_2-plasmin inhibitor (*17*).

Fibrin is a very useful material in several biomedical applications. Its usefulness could be extended further, however, if one could alter the biological character of the fibrin by incorporating within it the biological activity of other proteins, such as those from extracellular matrix proteins including fibronectin, vitronectin, laminin, and collagen (*18*−*20*). In many cases, the bioactive domains, i.e., the regions of the proteins that bind to cell-surface receptors, are known, and these domains can be mimicked with synthetic linear and cyclic peptides (*21*, *22*). Two such sequences that were employed in this study were the tripeptide RGD, derived from many extracellular matrix proteins (*23*), which binds to a variety of integrin receptors (*24*), and the tetrapeptide DGEA, derived from collagen, which binds to the $\alpha_2\beta_1$ integrin (*25*).

Bi-domain peptides were designed and evaluated, with a factor XIIIa substrate in one domain and a bioactive region from fibronectin or collagen in another domain. The extent of incorporation of the exogenous peptide was determined, and the biological activity of such exogenous peptides was examined in the context of nerve regeneration. This technique has provided the ability to transfer biological activity from sources that are usually exogenous to fibrin gels, such as from extracellular matrix proteins, to create three-dimensional matrixes with numerous medical and biological applications.

EXPERIMENTAL PROCEDURES

Peptides and Proteins. Peptides were synthesized on solid resin using an automated peptide synthesizer (9050 Pep Plus Synthesizer, Millipore, Framingham) with standard 9-fluorenylmethyloxycarbonyl chemistry (*26*). All peptides were labeled with a fluorescent probe by including an α-dansylated leucine (Sigma, St. Louis) at the amino terminus of the peptide, except for dYRGD-*TIGEGQQHHLGG*-NH_2, which was dansylated off-line using dansyl chloride (*27*). All other reagents employed in peptide synthesis were purchased from Novabiochem (San Diego). A series of bifunctional peptides was synthesized that contained an RGD sequence coupled to a factor XIIIa substrate sequence (for clarity, the factor XIIIa substrate domains are always shown in italics). These peptides included dYRGD*TIGEGQQHHLGG*-NH_2 (d = dansylated amino acid; sequence from fibrinogen), dLRGD*GAKDV*-NH_2 (sequence from fibrinogen), dL*NQEQVSPL*RGD-NH_2 (sequence from α_2-plasmin inhibitor), and dLRGD*KKKK*G-NH_2 (nonbiological sequence including an oligomer of lysine). Two additional peptides were synthesized with the cross-linking domain from α_2-plasmin inhibitor, one containing a bioactive domain from collagen, dL*NQEQVSPL*DGEA-NH_2, and the other containing a biologically inactive control sequence, dL*NQEQVSPL*RDG-NH_2. Hydrophobic scavengers and cleaved protecting groups were removed by precipitation of the peptide in cold diethyl ether and dissolution in deionized water. After lyophilization, peptides were redissolved in 0.03 M Tris-buffered saline (TBS, pH 7.0) and analyzed using HPLC (Waters; Milford) on a size-exclusion column with TBS.

Fibrinogen solutions were prepared by dissolving fibrinogen (Fluka; Ronkonkoma) in deionized water at 8 mg/mL for 4 h. Dialysis (Spectrum, 6000−8000 MWCO; Laguna Hills) vs 400 vol of TBS, pH 7.4, for 24 h was used to exchange salts present in the protein solution. The resulting solution was then sterilized by filtering through a 0.22 μm syringe filter. The final fibrinogen concentration was determined by measuring the absorbance of the protein solution at 280 nm (*28*). TBS solutions at pH 7.0 that were made with either 50 mM Ca^{2+} or without any Ca^{2+} were sterilized by filtration though a 0.22 μm filter. Fresh thrombin solutions were made by dissolving thrombin (Sigma; St. Louis) in TBS at pH 7.0 at a concentration of 20 units/mL.

Fibrin Formation and Peptide Incorporation. Fibrin gels (200 μL) were made by mixing the four components such that final concentrations of 3.6 mg/mL fibrinogen, 2.5 mM Ca^{2+}, and 2 NIH units/mL of thrombin were obtained with various amounts of peptide added. This solution was allowed to gel for 60 min at 37 °C and 100% relative humidity. The gels were soaked in 0.3 M phosphate-buffered saline (PBS, pH 7.0) so that free peptide was allowed to diffuse out of the fibrin. In some experiments, the buffer was changed after the diffusion of free peptide reached equilibrium as indicated by spectrofluorimetric measurement of the dansyl signal.

To determine the amount of peptide incorporation, fibrin gels were degraded with 0.05 NIH units of plasmin (Sigma, St. Louis), and the resulting solution was analyzed using high-performance liquid chromatography (Waters; Milford). A size-exclusion column (Shodex, polyhydroxymethyl methacrylate packing; New York) was used that had a molecular mass range of 1−100 kDa. Samples were applied to the column and eluted in PBS. The resulting eluent was measured with both an inline ultraviolet and fluorescence detector to measure the presence of degraded fibrinogen and exogenous peptide (via the dansyl label), respectively.

Swelling. Fibrin gels were synthesized as described above with varying amounts of peptide. The gels were soaked in deionized water for 24 h and then weighed. Each gel was added to a preweighed culture dish and placed in a vacuum oven to dry. After all the water had been removed, the weight of the remaining gel was determined and the ratio of wet weight to dry weight was calculated.

Neurite Outgrowth. Dorsal root ganglia were dissected from 8 day old white leghorn chicken embryos (*29*). Ganglia were temporarily stored in modified neurobasal medium, consisting of insulin (5 μg/mL), transferrin (100 μg/mL), progesterone (6.3 ng/mL), putrascine (16.11 μg/mL), selenite (5.2 ng/mL), fibronectin (5 μg/mL), L-glutamine (0.5 mM), L-glutamate (25 μM), murine mouse nerve growth factor (20 ng/mL), 0.2% bovine serum albumin, and 1% antibiotic-antimycotic added to neurobasal medium (Gibco; Grand Island). Fibrin gels (400 μL) were polymerized as described above in the bottom of flat 24-well culture plates, except that the fibrin was polymerized around a dorsal root ganglion, such that one dorsal root ganglion was embedded three-dimensionally inside each gel. The dorsal root ganglia were cultured in 1 mL of modified neurobasal medium and the medium was changed at 3, 6, 9, and 24 h post seeding to wash out non-cross-linked peptide. Dorsal root ganglia were cultured in fibrin gels without added exogneous peptides (all values were normalized to this level of neurite extension in native fibrin), or with added dL*NQEQVSPL*DGEA-NH_2 or dL*NQEQVSPL*RGD-NH_2. As a control, dorsal root ganglia were cultured in fibrin gels with added dL*NQEQVSPL*RDG-NH_2 peptide, which is not biologically active. In each case, peptide was incorporated at 8 mol/mol fibrinogen. As additional controls, dorsal root ganglia were cultured in the three peptide-modified fibrin gels with the corresponding exogenous peptide

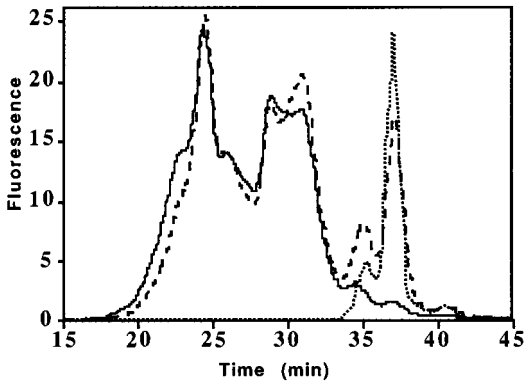

Figure 1. Fluorescence detection of chromatograms of plasmin-degraded gels. Size exclusion chromatography of a degraded gel with the peptide dL*NQEQVSPL*RGD (—) incorporated is shown. The second chromatogram shown (- - -) is identical to the first, except for the addition of free peptide after degradation of the gel with plasmin and the third chromatogram shown (···) represents free peptide eluted alone. The free peptide was observed to elute at longer times, corresponding to a lower molecular weight than the peptide incorporated during coagulation, demonstrating that peptide incorporated via the factor XIIIa substrate was covalently bound to the fibrin network.

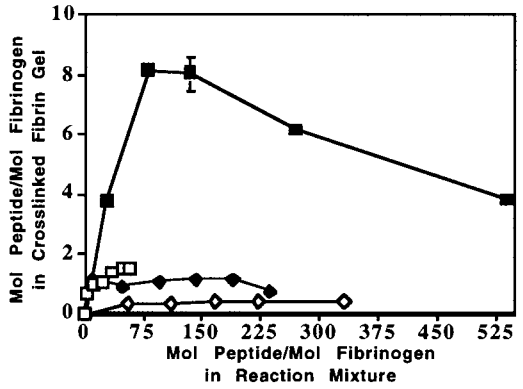

Figure 2. Incorporation of four bi-domain peptides with different factor XIIIa peptide substrates (italics). (■) dL*NQEQVSPL*RGD, from α_2-plasmin inhibitor, (◇) dLRGDAKDV, from fibrinogen, (□) dYRGD*TIGEGQQHHLGG*, from fibrinogen, and (◆) dLRGD*KKKK*G a nonbiological substrate, were each cross-linked into fibrin at a series of initial peptide concentrations, and the extent of incorporation is shown. Mean values and standard error of the mean are shown. The peptide dL*NQEQVSPL*RGD cross-linked more efficiently into the fibrin gel than the other three peptides, and achieved concentrations of up to 8.18 ± 0.09 mol of peptide/mol of fibrinogen.

added after gelation and throughout the culture duration (at 0.67 mg/mL) to serve as a soluble competitive inhibitor.

Images were collected at 24 and 48 h using light microscopy and digital image processing. At each time point, the average neurite length extending from each ganglion was measured as described elsewhere (*30*).

Statistics. Statistical analyses were performed using Statview 4.5. Comparative analyses were completed using analysis of variance (ANOVA) and Fisher's protective *t*-test at a 95% confidence level. Mean values and standard error of the mean are shown.

RESULTS

Calibration. Linear calibration curves were observed for both the incorporated peptides and the major components of the fibrin gels. Peptides were labeled with an α-dansylated amino acid, and this label was detected using an in-line fluorescence detector. Fibrinogen was degraded with plasmin and the correlation between the UV_{280} absorbance signal and protein concentration was determined. It was found the UV_{280} signal was linearly proportional to fibrinogen concentration for both degraded and nondegraded fibrinogen.

Measurement of Peptide Incorporation. To determine the extent of incorporation of the various bi-domain peptides into the fibrin network during coagulation, gels were formed, free peptide was permitted to diffuse out of the network, the fibrin was degraded with plasmin, and the degradation products were analyzed by HPLC to determine the amount of peptide (by fluorescence from the dansyl label) relative to fibrin (by UV absorbance) (Figure 1). Fibrin gels were synthesized and degraded, and the degradation products were analyzed by chromatography. The chromatogram obtained from a degraded, native fibrin gel with UV detection contained a single broad peak that eluted at 24 min (data not shown). The fluorescence signal was collected as well; however, the magnitude of the signal (from gels lacking exogenous peptide) was negligible (data not shown). Fibrin gels modified with different factor XIIIa substrate peptides were formed. The UV signals collected from these gels were consistently identical to that produced by native fibrin lacking exogenous peptides. However, for the peptide-modified gels, a large fluorescence signal appeared at an elution time later than the UV signal, appearing between 24 and 34 min (Figure 1, solid trace). When soluble peptide was added to the degraded peptide-modified fibrin gel, the fluorescence signal seen between 18 and 34 min was essentially identical to that seen in the degraded gel alone. However, the fluorescence signal seen between 34 and 39 min was increased (Figure 1, dashed trace), indicating that the added free peptide was eluting at a later time than peptide which had been incorporated during coagulation. These extra peaks, between 34 and 39 min, correlated directly with those observed for free peptide analyzed alone, in the absence of fibrinogen or fibrin degradation products (Figure 1, dotted trace).

The incorporation of four different bi-domain peptides, each with a different factor XIIIa substrate domain but the same bioactive domain, was determined as a function of exogenous peptide concentration during coagulation (Figure 2). The amount of peptide that was cross-linked into each gel was measured as described above. The bi-domain peptide with the cross-linking domain from α_2-plasmin inhibitor reached a maximum incorporated concentration of 8.18 ± 0.09 mol of peptide/mol of fibrinogen. It was possible to control the amount of peptide that was incorporated within the fibrin gel via the amount of peptide initially incorporated into the fibrinogen solution before coagulation. At initial peptide concentrations in excess of 135 mol of peptide/mol of fibrinogen, the ability of the peptide to cross-link into the gels decreased ($p < 0.05$). The cross-linking of dLRGD*KADV* and dYRGD*TIGEGQQHHLGG*, the two peptides with the fibrinogen factor XIIIa substrate domains, proved to be independent of initial peptide concentration, reaching levels of incorporation of 0.44 ± 0.03 and 1.53 ± 0.04 mol of peptide/mol of fibrinogen, respectively. The lysine oligomer substrate, dLRGD*KKKK*G, displayed a similar cross-linking profile and reached a maximum cross-linking density of 1.18 ± 0.05 mol of peptide/mol oof fibrinogen. When the average efficiency of incorporation (the fraction of exogenous peptide present in the coagulation mixture that was incorporated into the fibrin gel) was measured for each peptide, it was found that the factor XIIIa substrates with a glutamine at the active

Table 1. Extent of Incorporation and Efficiency of Bi-Domain Peptides Containing Different Factor XIIIa Substrates

peptide sequence (factor XIIIa substrate sequence in italics)	maximum cross-linking density (mol of peptide/ mol of fibrinogen)	maximum cross-linking efficiency (%)
dL*NQEQVSPL*RGD	8.18 ± 0.09	14 ± 0.6
dLRGD*AKDV*	0.44 ± 0.03	0.6 ± 0.1
dLRGD*KKKK*G	1.18 ± 0.05	12 ± 5
dYRGD*TIGEGQQHHLGG*	1.53 ± 0.04	29 ± 0.6

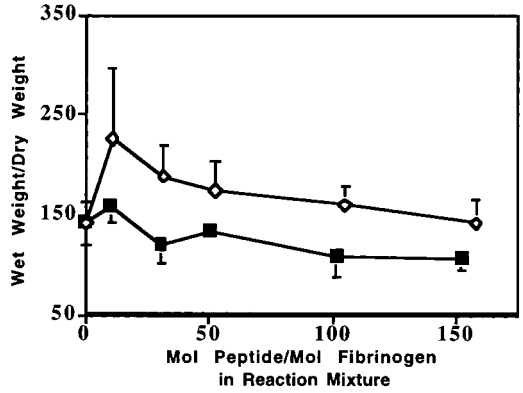

Figure 3. Swelling of the peptide cross-linked gels. Two different peptides, (■) dL*NQEQVSPL*RGD and (◇) dLRGDAKDV, were cross-linked into fibrin gels at a series of concentrations and the amount of swelling, determined by comparing the dry weight to the wet weight, is shown. Upon the basis of the initial volume and amount of material used, the swelling ratio at the time of synthesis before any contraction was 190. Mean values and standard error of the mean are shown. The change in swelling induced by incorporation of these two peptides was statistically insignificant ($p > 0.10$).

site were 3−30 times more efficiently incorporated than the lysine substrates (Table 1).

Swelling. As a measure of disruption of the fibrin network that might potentially occur as a result of the incorporation of exogenous peptide, the swelling of the fibrin gel was measured (Figure 3). Fibrin gels were polymerized as described above and modified separately with two factor XIIIa substrate peptides. The two substrates chosen were dLRGDG*KADV*, based on a fibrinogen substrate site, and dL*NQEQVSPL*RGD, based on the α_2-plasmin inhibitor substrate site. The influence of the incorporation of these peptides on the swelling of the resulting fibrin matrix was determined by comparing swelling to that of unmodified gels as well as to the initial ratio of water-to-protein, 190. When an unmodified fibrin gel was created, the ratio of wet weight to dry weight, 141.8 ± 20.7, was lower than the initial value in the fibrinogen solution before coagulation ($p < 0.05$). The swelling of peptide-modified gels proved to be similar to the swelling of unmodified fibrin gels and was independent of cross-linked peptide density for both peptides tested; no value for either peptide tested was statistically different than that for the unmodified gel ($p > 0.1$).

Neurite Extension. As a measure of the bioactivity of the exogenous peptide, incorporated via the factor XIIIa substrate domain of the bi-domain peptide, a neuronal cell culture model was employed in which neurites extend from dorsal root ganglia taken from day 8 chick embryos cultured within a three-dimensional fibrin network (Figure 4). Three peptides were individually cross-linked into fibrin and tested for their ability to interact with growing neurites in vitro. Each was a bi-domain peptide that contained the α_2-plasmin inhibitor

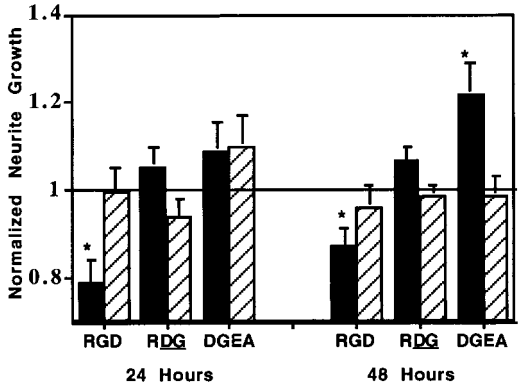

Figure 4. The effect of incorporated peptide at 8 mol of peptide/ mol of fibrinogen on neurite length within three-dimensional fibrin matrixes without (solid bars) and with (hatched bars), the indicated peptide added in soluble form to the culture medium. Neurite growth from day 8 dorsal root ganglia was normalized to growth in unmodified fibrin at 24 and 48 h culture time. All cross-linked peptides contained the substrate sequence dL*NQEQVSPL* and the active sequence as shown. Experiments were performed in triplicate with six dorsal root ganglia and mean values and standard error of the mean are shown; (*) $p < 0.05$ compared to unmodified fibrin. Cross-linking of RGD statistically lowered neurite extension, DGEA increased neurite extension and the inactive control peptide RDG had no effect on neurite extension. In each case, the effect of the cross-linked peptide was neutralized by the addition of the same peptide in soluble form as a competitive inhibitor.

sequence *NQEQVSPL* as the cross-linking substrate. Two active sequences, RGD and DGEA, and one control sequence, RDG, were attached to this factor XIIIa substrate. By incorporating 8 mol of peptide/mol of fibrinogen, statistically different neurite growth was obtained for both of the active sequences. At 24 and 48 h of culture, the incorporation of RGD into the fibrin reduced outgrowth ($p < 0.05$) relative to native fibrin by 21 ± 5.2% at 24 h and 13 ± 4.3% at 48 h. DGEA-modified gels proved to enhance neurite growth, increasing neurite length at 48 h of culture by 22 ± 7.0% ($p < 0.05$) relative to that in native fibrin. The cross-linking of the control peptide, RDG, into the fibrin did not affect the extent of neurite extension ($p = 0.22$). As a final control, peptides were added in the soluble phase in the culture medium as well as cross-linked into the gel to serve as competitive inhibitors. The resulting level of neurite growth returned to the level attained in native fibrin alone in all cases ($p > 0.21$).

DISCUSSION

Fibrin gels provide a unique platform as a biomaterial. In addition to being nontoxic as monomer, polymerized gel, or degraded gel, these materials are also able to interact biologically with cells, inducing proliferation or migration. However, many other proteins contain useful domains that fibrin lacks which would enhance the usefulness of fibrin as a biomaterial, e.g., in wound healing. Through the action of the transglutaminase, factor XIIIa, we sought to augment the native biological characteristics of fibrin to allow it to incorporate the characteristics of other useful proteins such as fibronectin, collagen, or laminin. Fibrinogen was obtained as a protein that was isolated from blood plasma. The transglutaminase zymogen factor XIII was present, as it usually is, as a copurified component in this fibrinogen preparation. Exogenous peptides were readily incorporated through the concerted action of thrombin and factor XIIIa during coagulation to covalently graft these bi-

domain peptides into the fibrin network. A sequence from α_2-plasmin inhibitor served as a particularly effective factor XIIIa substrate to accomplish this end.

Chromatographic analysis of the degradation products of peptide-modified fibrin gels provided information about the peptide incorporation process, allowing the determination of the amount of peptide incorporated as well as proof of the covalent nature of the incorporation. When peptide-modified and native fibrin gels were degraded by the fibrinolytic enzyme plasmin, multiple fragments of differing molecular weights were created. UV absorption was employed as the primary indicator of the presence of fibrin degradation products, and fluorescence measurement was utilized for detection of the exogenous peptide. These two measurements allowed unequivocal determination of the ratio of incorporated exogenous peptide to fibrin. Moreover, they provided strong evidence of covalent incorporation: when free peptide was added to degraded fibrin, it eluted at a low molecular weight, at a position identical to that of the free peptide in a single-component solution, whereas the peptide incorporated during fibrin polymerization eluted at a much higher molecular weight, indicating that it was covalently bound to the fibrin degradation fragments. This was true for all the exogenous peptides examined.

The various factor XIIIa substrates demonstrated different activities for incorporation into the fibrin network during gelation. Two substrate sequences were selected based on cross-linking domains on the γ chain of fibrinogen, one that contains a lysine substrate and one that contains a glutamine substrate. The lysine-based fibrinogen substrate displayed a relatively low maximum cross-linking density of 0.44 mol/mol fibrinogen and the density of incorporation saturated at this level at high concentrations in the fibrin precursor. The glutamine-based sequence could cross-link into the fibrin at a rather high density, 1.53 mol/mol fibrinogen, and the incorporation of this peptide also saturated at high reactant concentrations. The final cross-linking density may have been limited by the mechanism through which both of these peptides were incorporated into the fibrin. Namely, the sites at which these peptides cross-linked into the fibrin gel were the same as those used for intermolecular fibrin cross-linking, and thus the peptides had to compete directly with the polymerizing fibrin gel for the cross-linking sites. During the formation of a fibrin gel, precursor fibrils become ordered, placing the two fibrinogen cross-linking substrates into close proximity (*31*). This alignment enhances cross-linking of the fibrils and may have prevented these two peptides from efficiently competing for cross-linking sites. Interestingly, the fibrinogen-based substrate with a glutamine at the reaction site was incorporated at a more than 3-fold density ($p < 0.01$) and at a more than 48-fold efficiency ($p < 0.01$) than the fibrinogen-based substrate with a lysine at the reactive site.

A nonbiological substrate comprising a tetramer of lysine was also examined. The incorporation of this peptide reached a useful density of 1.18 mol/mol fibrinogen, with a maximum efficiency of 12%. Despite lacking a native substrate sequence, this oligomer was efficiently incorporated into the fibrin gel. This is consistent with studies that have demonstrated that the reactivity of the receptor amine for transglutaminase enzymes is more promiscuous than the glutamine. While small variations in amino acids flanking the glutamine residue in a native substrate can lead to significant changes in cross-linking specificity (*32*), the lysine residue is cross-linked sufficiently well that even nonbiological lysine substrates can be employed with high enzymatic activity (*33*, *34*).

Perhaps the most useful of the factor XIIIa substrates examined for the incorporation of exogenous peptides was a sequence based on the α_2-plasmin inhibitor cross-linking domain. A very high density of incorporation, more than 8 mol/mol fibrinogen in the fibrin gel was achieved. The nature of the cross-linking of the protein α_2-plasmin inhibitor appears to have features that make its factor XIIIa substrate very useful in incorporation of exogenous peptides into fibrin during gelation. The native protein is cross-linked into fibrin gels at a very high density, attaching at up to 17 separate sites on the α chain (*17*). By comparison with the maximum density of incorporation observed in this study of 8 mol of peptide/mol of fibrinogen, it may be that the truncated sequence dL*NQEQVSPL* with the fluorescent marker near the active amino acid does not serve as a substrate for all of these sites, or it may be that competition with contaminant α_2-plasmin inhibitor in the fibrinogen used (not assayed) limited incorporation. Another beneficial property of the factor XIIIa substrate from α_2-plasmin inhibitor is that these sites on the α fibrin chain are not used for intermolecular fibrinogen cross-links. Therefore, a peptide with this substrate would not need to compete with the fibrin itself for cross-linking sites. Interestingly, the chromatographic results obtained with the bi-domain peptide dL*NQEQVSPL*RGD are consistent with its incorporation into the α chain of fibrinogen. The peptide-containing peak (by fluorescence) obtained with this substrate eluted at consistently longer times (lower molecular weight) than those observed with the other three substrates. These smaller fibrin degradation fragments have been reported to be primarily degradation products of the α chain of fibrinogen (*35*, *36*). Previous work has shown that α_2-plasmin inhibitor cross-links only to one of the three chains in fibrinogen, the α chain (*37*, *38*), and the chromatographic result obtained in this study with the bi-domain peptide is consistent with this behavior. As a final feature of the nature of the cross-linking of the factor XIIIa substrate in α_2-plasmin inhibitor, α_2-plasmin inhibitor is known to continue to cross-link onto the fibrin matrix after the formation of the gel, allowing the fibrin gel to form unimpeded. Because of these natural traits, it would seem that the peptide was able to cross-link into the gel at a much higher density than the other substrates tested.

The swelling characteristics of the fibrin gel, specifically the water content, were used as an indication of the disruption of fibrin gel structure by the incorporation of exogenous peptides. The natural intermolecular cross-linking of fibrin limits the swelling of these gels in addition to providing stability. If the incorporation of exogenous peptide interferes with the formation of intermolecular fibrinogen cross-links, the water content in the gel should increase. As an example, two representative peptides were tested; namely a bi-domain peptide with the factor XIIIa substrate from fibrinogen, dLRGD-*GAKDV*, and a bi-domain peptide with the factor XIIIa substrate from the α_2-plasmin inhibitor sequence, dL*N-QEQVSPL*RGD. The amount of water absorbed by the gels comprising either of these peptides was not significantly higher than for a native fibrin gel, suggestive of little disruption of fibrin structure due to peptide incorporation. The peptide with the substrate from fibrinogen demonstrated relatively low incorporation levels, perhaps due to its inability to compete with the fibrin gel itself for enzymatic activity. It is thus likely that this rather subtle change in composition resulted in minimal alter-

ation in fibrin structure. The peptide containing the factor XIIIa substrate from α_2-plasmin inhibitor was incorporated at high levels, up to 8 mol/mol fibrinogen, however, the swelling of these gels remained unchanged as well. The natural role of α_2-plasmin inhibitor is to prevent proteolytic degradation of fibrin after it is cross-linked into the fibrin by factor XIIIa. Therefore, the cross-linking of this protein onto the fibrin is critical for gel stability and apparently is optimally arranged to minimize disruption of the gel structure. This property would appear to have been transferred to the peptide substrate as well, allowing it to cross-link at high densities without affecting the physical character of the fibrin.

A cell culture assay, in which neurites extend from the dorsal root ganglia of embryonic chicks through the fibrin matrix, was employed to assess the bioactivity of the incorporated peptides. All fibrin gels were modified with bi-domain peptides containing the factor XIIIa substrate sequence from α_2-plasmin inhibitor since this peptide had the greatest biological potential due to its high incorporation density. The fibrin gels modified with the exogenous peptides tested demonstrated significantly different neurite extension relative to native fibrin, with the associated active sequences providing the expected activity. Fibrin modified with the inactive control sequence, RDG, resulted in statistically identical neurite extension to that observed in native fibrin. Since the RDG sequence does not have any associated bioactivity, the only possible effect associated with peptide incorporation would be derived from physical changes to the fibrin gel. Incorporation of the this peptide did not affect neurite extension, indicating that any physical changes to the gel must have had a negligible effect in this cell culture model. The incorporation of RGD at 8 mol/mol fibrinogen into fibrin gels resulted in significantly shorter neurites at both 24 and 48 h. RGD modifies cell migration by acting as an adhesion site (*39*). Native fibrin contains two RGD domains per mole of fibrinogen, so this modification led to the formation of gels with 10 mol of RGD/mol of fibrinogen. By creating a material with so much adhesive character, it apparently became more difficult for the advancing neurite to migrate through the gel, leading to slower extension. This observed phenomenon is consistent with the observations of Palecek et al., who demonstrated that, in two dimensions, incorporation of high densities of adhesion ligand resulted in slower cell migration (*40*). This effect depended on the affinity of the ligand for its corresponding adhesion receptor and on cytoskeletal interactions. A sequence derived from collagen, DGEA, was also examined for bioactivity in this neurite extension model. This domain had been previously observed to enhance neurite extension (*41*); a similar observation in this present study suggests that this covalently incorporated exogenous peptide was indeed presented in a manner such that it was both available for receptor binding and biologically active. The control experiments with the peptides included in the culture medium as a soluble competitive inhibitor in which neurite extension was not significantly different than fibrin demonstrated that the observed biological activity was due exclusively to the covalently incorporated adhesion peptide.

Through the use of factor XIIIa, we have developed a consistent method through which the biological character of fibrin can be augmented with active factors, creating a material that can be optimized for various applications in medicine or cell biology. The specificity of the cross-linking enzyme allows us to have good control over the final incorporation density, allowing this material to be used for both therapeutic and academic applications.

Physicochemical Properties and O_2-Coordination Structure of Human Serum Albumin Incorporating Tetrakis(*o*-pivalamido)phenylporphyrinatoiron(II) Derivatives

Teruyuki Komatsu, Kazuyoshi Hamamatsu, Jian Wu, and Eishun Tsuchida*,†

Department of Polymer Chemistry, Advanced Research Institute for Science & Engineering, Waseda University, Tokyo 169-8555, Japan. Received July 16, 1998; Revised Manuscript Received October 12, 1998

Incorporation of tetrakis(*o*-pivalamido)phenylporphyrinatoiron(II) derivatives with a covalently linked axial imidazole (FeP) into human serum albumin (HSA) provides a new type of artificial hemoprotein (HSA-FeP) that binds and releases dioxygen reversibly under physiological conditions (in aqueous media, pH 7.4, 37 °C) and in a fashion similar to hemoglobin and myoglobin. The HSA host adsorbs a maximal eight FeP molecules, and their stepwise equilibrium constants (K_1-K_8) range from 1.2×10^6 to 1.3×10^4 M^{-1}. The major binding sites of the synthetic hemes are identical to those of hemin, bilirubin, and long-chain fatty acids. The red-colored solution of HSA-FeP was stored for three months at 4 °C and could be kept as a freeze-dried powder for more than six months. The solution properties [[HSA]: 5 wt %, FeP/HSA = 1−8 (mol/mol)] satisfy the physiological requirements for dioxygen infusion for potential clinical use; the specific gravity is 1.013, and the viscosity is 1.1 cP. Mixing the solution with human blood does not induce any coagulation and precipitation. On the basis of the gel permeation chromatography, CD spectroscopy, and IEF measurements, the molecular size, second-order structure, and surface charge distribution of the HSA-FeP conjugate are constant and independent of the binding numbers of heme molecules. Furthermore, the O_2-coordination structure of FeP embedded into certain hydrophobic domains of the albumin was confirmed by resonance Raman spectroscopy.

INTRODUCTION

In the bloodstream, serum albumin serves as a *shuttle* that transports an incredible variety of endogenous and exogenous compounds. Interest in this molecular binding led to research involving association studies of HSA with various ligands (Brown, 1976; Kragh-Hansen, 1981; Peters, 1975, 1985). Human serum albumin (HSA) was among the very first proteins crystallized in the microgravity environment of space (Carter et al., 1989, 1994; He et al., 1992). In contrast to the early conception of an oblate ellipsoid shape (140 × 40 Å), HSA is a unique heart-shaped molecule that can be approximated to be an equilateral triangle with sides of 8 nm and a depth of 3 nm. HSA has three homologue domains (I, II, and III) with nine loops formed by 17 disulfide linkages, and each domain is constructed of two subdomains (IA, IB, etc.). The majority of the compounds are bound at one or both sites within specialized cavities of the subdomains IIA and IIIA with typical equilibrium constants (K) ranging 10^6-10^4 M^{-1} (Kragh-Hansen, 1981a). For instance, bilirubin is primarily bound to a site within IIA. The binding behavior of several porphyrin derivatives to HSA has also been studied over the last two decades (Little et al., 1960; Beaven et al., 1974; Muller-Eberhand et al., 1975; Adams et al., 1980), because hemin released from hemoglobin is transported to the liver by albumin for metabolic processing. The primary binding site of hemin is located in the sequence 124−298 of HSA, corresponding to subdomains Ib−IIa (Hrkal et al., 1984), and the immobilization presumably involves coordination of a histidine residue to the central iron (Casella et al., 1993). The hemopexin in plasma definitely attaches to a free heme in both iron(II) and iron(III) states by an axial imidazole coordination (Muller-Eberhand and Morgan, 1975; Morgan et al., 1980; Lamola et al., 1981). One may expect some new functions of these albumin-heme conjugates, but little attention has been generated so far (Marden et al., 1989; Bonaventura et al., 1994).

We have recently found that a tetraphenylporphyrinatoiron(II) derivative with a covalently linked axial base, 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(α,α,α,α-*o*-pivalamido)phenylporphyrinatoiron(II) (FeP, Figure 1) (Tsuchida et al., 1994), is efficiently incorporated into the HSA molecule, providing an artificial hemoprotein which is able to bind and release dioxygen reversibly under physiological conditions (in aqueous media, pH 7.4, 37 °C) as hemoglobin (Komatsu et al., 1995; Tsuchida et al., 1997). The imidazole intramolecularly coordinated to the central iron plays a crucial role in the formation of a stable $Fe-O_2$ complex. We report herein the stepwise equilibrium constants for FeP association and the physicochemical properties of the obtained hybrid HSA-FeP. Furthermore, the axial base imidazole and the O_2-coordination structures of FeP embedded into certain domains of the albumin have been clarified by resonance Raman spectroscopy.

EXPERIMENTAL PROCEDURES

Materials and Methods. HSA-FeP with different FeP concentration was prepared according to our previously reported procedure (Tsuchida et al., 1997). An HSA was purchased from Bayer Co., Ltd. (Albumin Cutter, 5 wt %). Protoporphyrin IX disodium salts (PPIX) was gifted from Sato Pharmacy Co., Ltd. Phenol red and palmitic

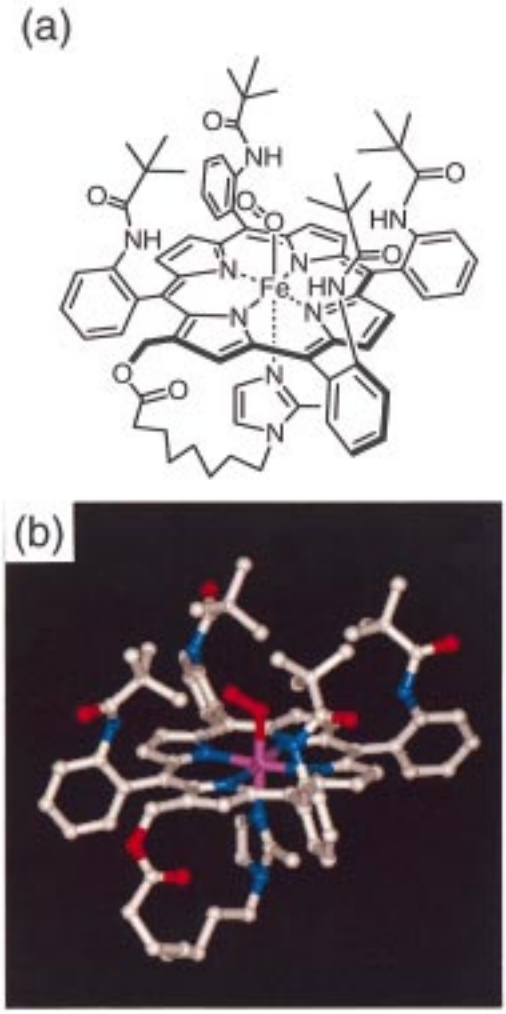

Figure 1. (a) Formula of FeP and (b) computer-simulated structure of dioxygenated FeP. Molecular dynamics and minimization (force field: esff) were performed using an Insight II system (Molecular Simulations Inc.). The structure was generated by alternative minimizations and annealing dynamic calculations from 1000 to 100 K.

acid were purchased from Kanto Chemical Co., Ltd. Pure water (Otsuka Pharmaceutical Co., Ltd.) was used for dilution for HSA and ethanol (>99.5%, Kanto Chemical Co., Ltd.) was for the solvent of FeP. UV−vis absorption spectra were obtained on a Shimadzu V-570 spectrometer.

Equilibrium Constants for FeP Binding to HSA. In the course of preparation of the HSA-FeP solution, the precipitated carbonyl FeP [FeP(CO)] was extracted with $CHCl_3$ and its concentration was determined by the absorption spectra (ϵ_{max} at 420 nm: 2×10^5 $M^{-1}cm^{-1}$). On the basis of the quantitative analysis of this free FeP-(CO) molecule in the solution prepared with different FeP/HSA mixing ratios (1−14 mol/mol), the equilibrium constants were determined using stepwise equilibrium models (Fletcher et al., 1970; Ashbrook et al., 1975).

Binding Sites of FeP in HSA. The association sites of FeP were determined from the competitive binding with other ligands which are well-known to bind the major sites of HSA. Palmitic acid, PPIX, instead of hemin, and phenol red, instead of bilirubin, were used as the inhibitors. The quantitative analysis of FeP was carried out with the hybrid HSA incorporating each inhibitor (molar ratio 1/1). The maximal binding numbers of FeP were decreased to less than the mixing ratio, if the FeP molecule could not displace the inhibitor in competitive binding.

Rheological Properties. The viscosity and density of the solution at 37 °C were measured with an Anton Parr OCR-D oscillatory capillary rheometer and density meter, where the sample in the measuring capillary was set into sinusoidal oscillations at a given frequency of 2 Hz. The shear rate ranged 0.58−358 s^{-1}. The HSA-FeP solution [[HSA]: 5 wt %, FeP/HSA = 4,8 (mol/mol)] was applied to all measurements. The human venous blood were drawn into EDTA containing tube just before use.

Physicochemical Properties. Circular dichroism (CD) spectra were obtained by a JASCO J-725 spectropolarimeter. The HSA concentration was 1.12 μM [FeP/HSA = 1, 4, 8 (mol/mol)], and quartz cuvettes with 1 mm and 10 mm thickness were used for measurements in the ranges 190−250 nm and 250−700 nm, respectively. Isoelectric points and molecular weights were measured by a Pharmacia Phastsystem using isoelectric focusing (IEF) in pH 3−9 Phast Gel IEF 3−9 and native PAGE in Phast Gel Gradient 8−25, respectively. The temperature during the electrophoresis was maintained at 15 °C and the sample concentrations were [HSA] = 3.75 μM. The used markers are Isoelectric Focusing Calibration Kit and LMW Electrophoresis Calibration Kit, respectively. Gel permeation chromatography was performed on a Shimadzu LC-8A chromatograph equipped with a SPD-10A UV−vis detector by using a Shodex GS-620HQ column at room temperature. The HSA-FeP solutions [FeP/HSA = 1, 4, 8 (mol/mol)] were applied to the measurements with phosphate-buffered saline (10 mM, pH 7.3) as the eluent.

Resonance Raman (RR) Spectroscopy. RR spectra were obtained with excitation of the 457.9 nm line of an NEC GLG2162 Ar^+ ion laser in a back-scattering geometry at 25 °C. All the spectra were recorded using a JASCO NRS-2000 laser Raman spectrometer equipped with a CCD multichannel detector. The preparation procedures of the deoxy and dioxygenated HSA-FeP [[HSA]: 5 wt %, FeP/HSA = 4 (mol/mol)] were reported elsewhere (Tsuchida et al., 1997). Calibration of the spectrometer was performed with indene.

RESULTS AND DISCUSSION

Binding Aspects of FeP to HSA. The maximal binding numbers of FeP to one HSA molecule were determined to be eight (Tsuchida et al., 1997). Our second interest in this albumin−heme complex was its nano structure. How strong and at which place are FePs bound in HSA? The binding constants are typically analyzed according to the Scatchard model (Beaven et al., 1974, Halfman and Nishida, 1992), we used, however, another means of analysis with a stepwise equilibrium model (Fletcher et al., 1970; Ashbrook et al., 1975). This model can incorporate many of the concepts in protein−ligand interaction, including cooperativity, the creation of new sites in the binding process, etc.; it is therefore the most satisfactory for protein-heme binding analysis. The magnitude of the binding constants for the FeP association with HSA (K_1−K_8) ranged 1.2×10^6 to 1.3×10^4 M^{-1} (Table 1) in which no cooperative relation was observed. These values are relatively low with respect to those of palmitic acid [K_1−K_8 = (6.2×10^7)−(3.8×10^5) M^{-1}] (Ashbrook et al., 1975) and hemin ($K_1 = 5.0 \times 10^7$ M^{-1}) (Beaven et al., 1974), which have Coulombic interactions with the albumin host through their carboxylic groups. The FeP molecules are probably incorporated into HSA

Table 1. Stepwise Equilibrium Constants of FeP Binding to HSA (M^{-1}) at 25 °C

K_1	K_2	K_3	K_4	K_5	K_6	K_7	K_8
1.2×10^6	7.8×10^4	6.6×10^4	5.3×10^4	2.3×10^4	1.8×10^4	1.7×10^4	1.3×10^4

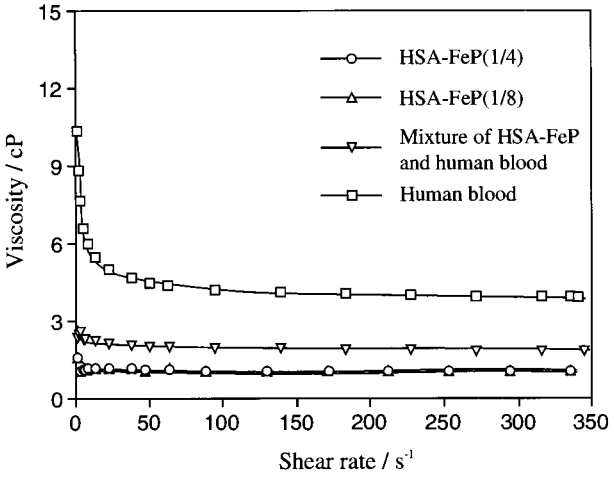

Figure 2. Shear rate dependence of the viscosity of HSA-FeP at 37 °C.

only by hydrophobic interactions, leading to a rather weak nonspecific binding.

The association sites of FeP were estimated from the competitive binding inhibition behavior by other well-known ligands which can bind the typical areas of HSA [palmitic acid (IIIB), PPIX instead of hemin (IB, IIA), and phenol red instead of bilirubin (IIA)]. At an FeP/HSA mixing ratio of 8, the binding numbers were significantly decreased to 7 in all cases; one of the binding regions of the synthetic heme is obviously occupied by the inhibitor ligands. Consequently, the primary binding sites of these ligands are identical to one of the FeP's sites. It is remarkable that the FeP binding was inhibited even by phenol red with a low K_1 of 3.9×10^4 M^{-1} (Kragh-Hansen, 1981b). One of the minor binding sites, at least a fifth one, was definitely blocked by a phenol red molecule.

Structure and Physicochemical Properties. The red-colored solution could be stored for three months at 4 °C; the turbidity at 700 nm was not changed (±4%), and no aggregation was observed for all samples prepared. Furthermore, the solution could be kept as a freeze-dried powder for more than 6 months. The long stability and no blood type, of course, become great advantages of this solution as a dioxygen infusion for potential clinical use.

The solution properties of HSA-FeP sufficiently satisfy the physiological needs. Specific gravities were all 1.013 [FeP/HSA = 1−8 (mol/mol)]. The viscosity behavior showed typical Newtonian type, and a value of 1.1 cP observed at a high shear rate of 230 s^{-1} was much lower than that of human blood (4.0 cP) (Figure 2). Furthermore, the HSA-FeP solution was mixed with fresh drawn human whole blood. The obtained suspension did not show any coagulation or precipitation, and its viscosity behavior was again Newtonian type (1.8 cP at 230 s^{-1}), displaying a good compatibility of HSA-FeP with human blood. The O_2-carrying solution with low viscosity may facilitate circulation and would permit a better exploition of collateral microcirculation.

The physicochemical properties of this artificial hemoprotein were studied. The isoelectric points (pI) of the HSA-FeP [FeP/HSA = 1∼8 (mol/mol)] were all found to be 4.8 from the IEF measurements, values that were exactly the same as that of HSA itself (Figure 3a). In the case of fatty acid binding, the pI value significantly decreased due to partial neutralization of the surface charge. Thus, it can be considered that FeP molecules interact nonspecifically with a part (most probably the hydrophobic region) of albumin, and its surface charge distributions are not influenced.

The native PAGE showed the same molecular sizes for all samples with different FeP binding numbers (Figure 3b). This was rather unexpected, because the molecular volume of FeP (1.3^3 nm^3 estimated by simulation, Figure 1b) is relatively bulky as a ligand for the host albumin. The morphology of HSA should be expanded after the FeP incorporation. GPC measurements also displayed very close peaks for HSA and HSA-FeP that could not be clearly distinguished. Carter (1994) reported some preliminary results on cocrystal structures of HSA with long chain fatty acids of laurate or palmitate in which three or more fatty acids bind to produce significant conformational changes in the albumin. The invariable molecular size of HSA-FeP obviously indicates the weak binding of FePs and conformational flexibility of the HSA molecule, somewhat like a sponge.

Circular dichroism (CD) spectroscopy provides information on the secondary and tertiary structures of HSA and conformation changes that ensue when FeP is bound. The spectral pattern showed typical double-minimum negative peaks in the ultraviolet region independent of

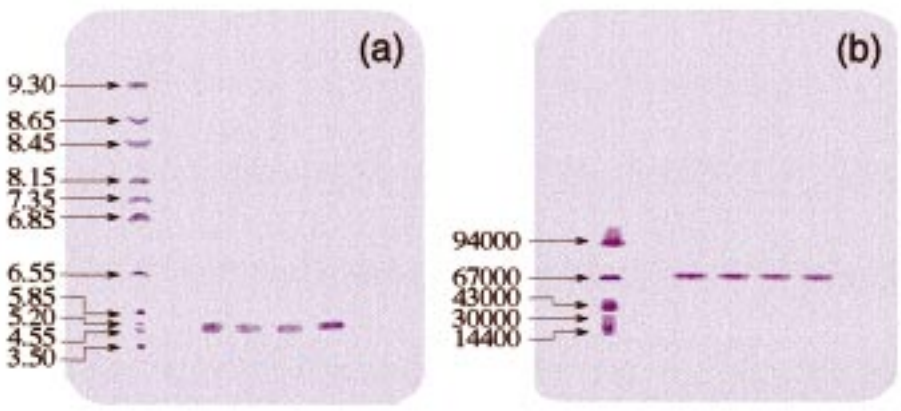

Figure 3. (a) IEF and (b) native-PAGE electrophoretic patterns of HSA and HSA-FeP solution. Lane 1, markers; lane 2, HSA; lane 3, HSA-FeP (1/1); lane 4, HSA-FeP (1/4); lane 5, HSA-FeP (1/8) from the left.

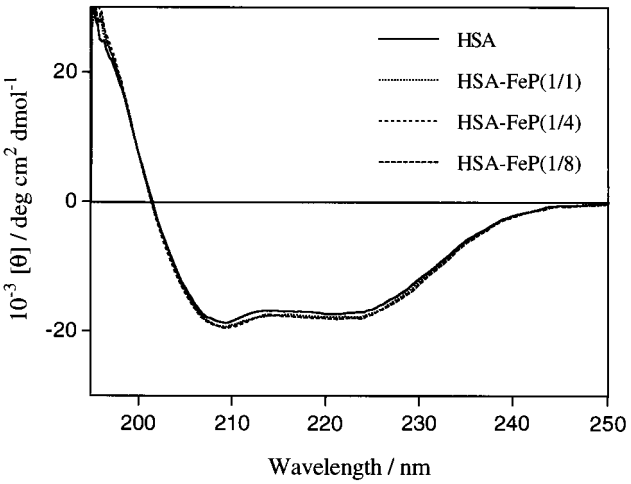

Figure 4. Circular dichroism spectra of the HSA-FeP solution at 25 °C.

the binding numbers of the FeP molecules from one to eight. There are no differences between the HSA-FeP series and HSA itself (Figure 4). The calculated α-helix content was approximately 52%, suggesting that the FeP association did not cause any second- and third-ordered structural changes in HSA. In general, the binding of the heme derivative to the albumin molecule is accompanied by a rise to an extrinsic negative Cotton effect in the Soret band region, because it binds to an albumin through a coordination between the imidazole of histidine and the central iron, allowing a high degree of immobilization (Beaven et al., 1974; Casella et al., 1993). HSA-FeP did not, however, show any CD bands in the Soret region. This observation again indicates a weak interaction between FeP and HSA as an apoprotein.

Attempts to measure the exact molecular mass of HSA-FeP from 67.8 kDa [FeP/HSA = 1 (mol/mol)] to 76.9 kDa [FeP/HSA = 8 (mol/mol)] by a time-of-flight mass spectroscopy with matrix-assisted laser desorption ionization system (Shimadzu Kompact MALDI-4) unfortunately failed. We detected only the 66.5 kDa peak of HSA itself. During the laser ionization, the weakly bound FePs were presumably dissociated from the HSA host. The nonspecific interaction between FeP and HSA was further studied using ultracentrifugation. In all cases, FeP sedimented together with albumin but redispersed again completely on shaking, giving a reddish homogeneous solution which showed the same absorbance at the 420 nm Soret band. We thus concluded that hydrophobic interactions are the major driving force of the FeP binding to HSA and that FeP incorporation does not induce any changes in the highly ordered structure and surface charge distribution of the albumin molecule.

Resonance Raman Studies of Axial Ligand Coordination to FeP Incorporated into HSA. The obtained HSA-FeP has the ability to bind dioxygen reversibly at 37 °C with a constant O_2-binding affinity [$P_{1/2}(O_2)$: 30 Torr], independent of the numbers of associated FePs (Tsuchida et al., 1997). The auto-oxidation reaction of the oxy state (λ_{max}: 548 nm) took place slowly, and the absorption band of 548 nm almost disappeared after 24 h, leading to formation of inactive hemin. The half-life ($\tau_{1/2}$) of the dioxygenated species was 8 h at 25 °C. We employed resonance Raman (RR) spectroscopy to characterize the O_2-coordination structure of the dioxygenated FeP in HSA. Soret band excitation of natural hemoproteins or synthetic porphyrinatoiron(II)s resulted in rich RR spectra consisting of totally symmetric vibrations of

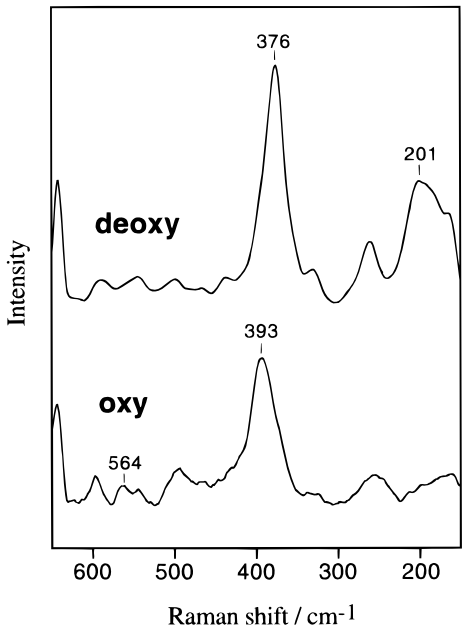

Figure 5. Resonance Raman spectra of the HSA-FeP solution at 25 °C.

the porphyrin macrocycle (Spiro et al., 1975). In the low-frequency RR spectra (<650 cm^{-1}) of the HSA-FeP under argon (i.e., the deoxy form), there is a medium band at 201 cm^{-1} (Figure 5). The five-coordinated species of FeP in CH_2Cl_2 also displayed a similar band at 205 cm^{-1} that has been assigned to the intramolecular coordinated iron−imidazole stretching mode, ν(Fe−N$_\epsilon$) (Wu et al., 1998). The covalently attached imidazole allowed the intramolecular iron−imidazole coordination of FeP even when embedded into a hydrophobic binding domain of the protein, where other peptide residues possibly coordinated to the central iron(II) may exist.

In addition, several porphyrin skeletal modes, that are sensitive to the spin state, have been identified (Burke et al., 1978). For instance, a relatively strong band around 360−395 cm^{-1} for tetraphenylporphyrinatoiron(II) derivatives has been assigned to a deformation mode of the porphyrin ring (ν_8) (Stein et al., 1984). The appearance of a ν_8 band at 376 cm^{-1} for HSA-FeP under argon represented the formation of the high-spin five-coordination state (Figure 5). Other strong bands at 1340−1390 cm^{-1} are generally assigned to a ν_4 frequency, a deformed pyrrole-ring breath-like mode (Oshio et al., 1984; Proniewicz et al., 1986), that depends on the electron density at the π^* antibonding orbital of the porphyrin (Abe et al., 1978). Hence, it is sensitive to the axial coordination state of the central iron. The ν_4 band of the deoxy HSA-FeP at 1356 cm^{-1} corresponding to the five-coordinated high-spin species immediately shifted to 1371 cm^{-1} after exposure to dioxygen. This observation indicated the formation of a six-coordinated low-spin dioxygenated species. At the same time, in the low-frequency region, the ν(Fe−O_2) vibration appeared at 564 cm^{-1}. This frequency mode represented the formation of dioxygenated heme with an end-on type coordinated dioxygen, similar to hemoglobin and myoglobin. All these peak changes have been observed to be reversibly dependent on the O_2 concentration. We concluded that the FePs having an intramolecular coordinated imidazole group obviously bind and release dioxygen in the HSA molecule.

In conclusion, human serum albumin incorporating synthetic hemes as O_2-binding sites provides an O_2-

carrying artificial hemoprotein as a hemoglobin analogue and shows unique physicochemical properties. The heme binding through hydrophobic interaction is relatively weak and does not lead to a change in the morphology and highly ordered structure, as well as the solution properties of HSA, independent of the binding numbers of FeP. The imidazole moiety coordinates to the central iron producing a five-coordinated high-spin species, and the complex forms a reversible and stable dioxygen adduct in HSA. Evaluation of the O_2-delivering efficacy in vivo is now underway using hemorrhagic shocked rats. HSA-FeP acts as a new O_2-carrying hemoprotein molecule capable of replacing hemoglobin in the bloodstream.

There is also current interest in recombinant HSA (rHSA), which has been recently manufactured by gene cloning and expression in *Pichia pastoris* (Sumi et al., 1993). A study on an rHSA−FeP conjugate as a totally synthetic O_2-carrier is also in progress.

Efficient Gene Delivery by a Peptide Derived from a Monoclonal anti-DNA Antibody

Alexandre Avrameas,*,† Thérèse Ternynck,‡ Leila Gasmi,† and Gérard Buttin†

Unité de Génétique Somatique (URA CNRS 1960) and Unité d'Immunocytochimie, Département d'Immunologie, Institut Pasteur, 28 rue du Dr Roux, 75724 Paris Cedex 15, France. Received July 9, 1998; Revised Manuscript Received October 12, 1998

We recently reported that translocating murine polyreactive anti-DNA antibodies can be used as vectors for the transfer of macromolecules into cells growing in culture. We show here that two such monoclonal antibodies (J20.8 and F4.1) conjugated to polylysine with a high (93) but not a low (19) number of lysine residues can transfer genes in the presence of serum. A 30 amino acid long peptide, VAYISRGGVSTYYSDTVKGRFTRQKYNKRA (peptide P3), corresponding to joined heavy-chain complementary-determining regions 2 and 3 of F4.1 antibody and carrying 19 lysine residues at its N-terminal, was found to be an efficient vector for the transfection of the luciferase gene into 3T3 and CCL39 cells in the presence of serum. Addition of 0.23 M glycerol during transfection considerably enhanced gene delivery. These results show that conjugation of a short polylysine tail converted a spontaneously internalizing peptide into a potent nontoxic plasmid vector.

INTRODUCTION

Nonviral gene delivery systems have been developed with the purpose to transfer foreign genes into cells (*1*−*3*). Cationic lipids, like dioctacethylaminodoglycylspermine (*4*) and *N*-(1-(2,3-dioeyloxy)propyl)-*N*,*N*,*N*-trimethylammonium chloride (*5*), and cationic polymers, such as poly(L-lysine) (pLK)[1] conjugates (*6*−*9*) or polyethylenimine (PEI) (*10*), were used as vectors in these experiments. pLK and PEI have also been linked through their amino groups to asialoglycoprotein, transferrin, insulin, immunoglobulin, folate, and lectins in order to achieve greater specificity in cell recognition, without interferring with DNA binding (*11*−*20*). Sometimes helper molecules, like chloroquine, glycerol, or fusogenic peptides, were used to facilitate the delivery of the complex into the cytosol (*17*, *21*−*25*). Chloroquine, a weak base which limits the degradation of DNA by lysozome enzymes, was found to enhance the polyfection (*26*) of cells mediated by pLK conjugates (*21*, *22*). Amphiphilic peptides exhibiting fusogenic properties in acidic medium were used to develop synthetic virus-like gene-transfer vectors (*24*, *25*). Although these helper molecules were inefficient when the transfection step was conducted in medium-containing serum, a peptide containing several histidines was recently reported to improve transfection efficiency without being impaired by the presence of serum (*27*).

Several studies have shown that anti-DNA autoantibodies obtained from humans and mice with lupus are able to penetrate into living cells (*28*−*30*). In a previous study, we showed (*31*) that monoclonal anti-DNA antibodies (mAbs) derived from a nonimmunized (NZB x NZW)F1 mouse accumulated in the nuclei of a variety of cells cultured in serum-containing medium and could be used as vectors for the intracellular transfer of haptens and proteins. Furthermore, we found that the polypeptide, VAYISRGGVSTYYSDTVKGRFTRQKYNKRA (P3), containing heavy-chain complementary-determining regions 2 and 3 (CDR2 and CDR3) from one of these mAbs (F4.1) translocated haptens and proteins across cell membranes but was not effective for gene transfer (*31*). Because these mAbs intensively complexed DNA and thereby altered the electrophoretic migration in agarose, their effectiveness in the transfer and expression of plasmids was also examined. As the DNA binding and translocation capacities of these mAbs are likely to be interdependent, specific conditions had to be defined for each mAb to avoid DNA immunoprecipitation while allowing plasmid transfer, and this idiosyncrasy gave rise to highly variable results from one experiment to another. In the present study, we tried to overcome this lack of reproducibility by using conjugates of these anti-DNA mAbs and pLK (*32*). Moreover, we explored the conditions necessary to obtain optimal polyfections with P3 carrying 19 lysines residues at its N-terminal position (K_{19}−P3). Indeed, because conjugation of low-molecular-weight pLK to a peptide or a polysaccharide (*33*, *34*) has been reported to generate useful carriers for nonviral gene delivery, we examined the possibility that addition of a short lysine tail could be sufficient to make P3 a plasmid vector. We compared the performances of this peptide with those of a peptide IGRIDPANGKTKYAPKFQDKATRSNYYGNSPS (P9.3), derived from an anti-DNA antibody H 9.3 which does not penetrate into cells (31), carrying also 19 lysine residues at its N-terminal position (K_{19}−P9.3). We also compared these peptides with another vector peptide bearing a tryptophan and a cysteine at its amino terminal

and 18 lysine residues coupled at its carboxyterminal ($CW-K_{18}$) (*33*). During polyfections in serum-containing medium, we tried to enhance gene delivery by $K_{19}-P3$ and $CW-K_{18}$ peptides by adding chloroquine or glycerol, and found that glycerol considerably improved delivery while chloroquine had only a very limited effect.

MATERIALS AND METHODS

Chemicals. Chloroquine, 1-ethyl-3(3-dimethylaminopropyl)carbodiimide, pLK hydrobromide 1000−4000 (average degree of polymerization 19) (pLK_{19}), and 15000−30000 (average degree of polymerization 93) (pLK_{93}) were purchased from Sigma (St. Louis, MO). PEI 25 (kDa) was from Aldrich (St Louis, MO) and glycerol from Prolabo (Paris, France). Luciferin (luciferase assay substrate), luciferase assay buffer, cell culture lysis buffer, and the complete luciferase assay system were from Promega (Madison, WI).

Preparation of mAb-Polylysine Conjugates. IgG2a F4.1 and J20.8 anti-DNA mAbs derived from the spleen of an (NZB × NZW)F1 lupus mouse and an IgG2a B7.14 not reacting with DNA mAb (negative control) were purified on a protein A-Sepharose column as previously described (*31*). pLK_{19} and pLK_{93} were coupled to mAbs with 1-ethyl-3(3-dimethylaminopropyl)carbodiimide as previously reported (*32*). Conjugates were passed through a protein A-Sepharose column and washed extensively with 1.5 M NaCl to eliminate free pLK. The column-bound conjugates were eluted with citric acid buffer, pH 2.9, and dialyzed against phosphate-buffered saline (PBS).

DNA Purification and Peptide Synthesis. pCMV-LUC plasmid (6.4 kb) carrying the firefly luciferase gene under the control of the human cytomegalovirus promoter was kindly provided by Dr. U. Hazan (Institut Cochin de Génétique Moléculaire, Paris, France). Plasmid DNA was prepared with the Qiagen plasmid Maxi Kit (Courtaboeuf, France) according to the manufacturer's protocols. Peptides $CW-K_{18}$, $K_{19}-P3$, and $K_{19}-P9.3$ were synthesized by Altergen (Strasbourg, France). Briefly, peptides were prepared by solid-phase peptide synthesis on Fmoc amino acid-*p*-alkoxy-benzyl-alcohol-resin (Wang resin). Cleavage was performed with trifluoroacetic acid (TFA); and peptides were purified on a semipreparative Eurosil Bioselect 5 μ 300A (1.6 × 25 cm) C_5 RP-HPLC column eluted at 1.1 mL/min with 0.1% TFA and a 10 to 70% acetonitrile gradient. Peptides were characterized by electrospray mass spectrometry using a VG BioQ triple quadrupole mass spectrometer [mass to charge (*m*/*z*) range 4000] upgraded by the manufacturer so that it gained Quattro II performance (Micromass Ltd, U.K., Altrincham). Scanning was performed in the range 400−1400 in 10 s. The extracting cone voltage was 50 V. The mass spectrometer was calibrated externally by using the horse heart myoglobine multiply charged ions. The mass spectra obtained for each peptide was for $K_{19}-P3$ (calcd 5908.2 Da, found 5908.3 Da), for $K_{19}-P9.3$ (calcd 61767.4 Da, found 61767.5 Da) and for $CW-K_{18}$ (calcd 2642.5 Da, found 2642.6 Da). Lyophilized peptides were dissolved in 0.15 mM NaCl and sterilized by passage through a 0.22 μm filter. To determine precisely the concentrations of the dissolved peptides, aliquots were hydrolyzed with 6 N HCl−0.2% phenol at 110 °C for 20 h in sealed tubes. Norleucine was added as the internal standard. Aliquots of the hydrolysates were analyzed on a Beckman 6300 amino acid analyzer.

Cells and Cell Culture. NIH 3T3 and CCL39 cells (respectively mouse embryo and hamster lung fibroblasts) were cultured in Dulbecco's modified Eagle's medium (DMEM) (Axcell) (St-Genis l'Argentière, France) containing 4 mM L-glutamine, 100 units/mL penicillin, and 0.1 mg/mL streptomycin (Gibco BRL) (Cergy Pontoise, France) (culture medium) and supplemented with 10% fetal calf serum (FCS) (complete medium). Cells were cultured at 37 °C in a humidified atmosphere (92% air and 8% CO_2).

Gel Retardation Assay. The preparation of pCMV-LUC/$K_{19}-P3$ complexes was carried out as follows. Plasmid/$K_{19}-P3$ complexes were prepared by adding 0, 0.005, 0.01, 0.02, 0.03, 0.04, and 0.06 nmol of $K_{19}-P3$ to 0.1 μg of pCMVLUC in 5 μL of 0.15 M NaCl. After 20 min of incubation at 20 °C, each sample was analyzed by electrophoresis for 1 h under 50 V/cm through a 0.8% agarose gel containing ethidium bromide (1 μg/mL of gel) to visualize DNA in a Tris-borate-EDTA buffer (45 mM Tris, 45 mM boric acid, and 1.2 mM EDTA), pH 8.6.

In Vitro Transfections with $pLK_{19}-mAb$ and $pLK_{93}-mAb$ Conjugates. 3T3 cells (8×10^4) were deposited into 24-well tissue culture plates the day before transfection. pCMVLUC-pLK_{19}-mAb or pLK_{93}-mAb conjugate polyplexes were made at the lowest plasmid/conjugate ratio (usually 1/6, w/w) able to completely block all DNA electrophoretic migration. pCMVLUC (2 μg) in 50 μL of 0.15 M NaCl was mixed with 12 μg of K_{19}-mAbs or K_{93}-mAbs (triplicate wells), and kept for 20 min at 20 °C. Just before transfection, cells were washed and incubated with 0.5 mL of complete medium or culture medium containing 2% FCS and 100 μM chloroquine. Polyplexes were added to the cells for 4 h at 37 °C in a humidified atmosphere (92% air and 8% CO_2). The medium was removed and cells were further incubated for 24 h at 37 °C in 1 mL of fresh complete medium.

In Vitro Transfections with $K_{19}-P3$, $K_{19}-P9.3$, or $CW-K_{18}$ Peptides. 3T3 or CCL39 cells (8×10^4) were deposited into 24-well tissue culture plates the day before transfection. Polyplexes were formed between pCMVLUC (3 μg) and different amounts of $CW-K_{18}$, $K_{19}-P3$, $K_{19}-P3$, or free pLK_{19} in 50 μL of 0.15 M NaCl and kept for 20 min at 20 °C. Just before transfection, cells were washed and incubated for various times with 0.5 mL of complete medium containing 0.23 M glycerol or not or culture medium containing 100 μM chloroquine and 2% FCS. Polyplexes were added to the cells for 1.25, 2.5, 5.5, and 24 h at 37 °C in a humidified atmosphere (92% air and 8% CO_2), the medium was removed, and cells were incubated for an additional 24 h at 37 °C in 1 mL of fresh complete medium. PEI (25 kDa) was used as previously described (*35*) at charge ratios (*26*) of 5 or 2.2 in the presence of glycerol. All experiments were run at least three times.

Luciferase Assay. Cells were washed twice with cold PBS. Lysis buffer (100 μL) (Promega) containing 1% Triton X-100 and 2 mM DTT were added to each well of a 24-well tissue culture plate. After 15 min, cell lysates were transferred into a microcentrifuge tube and briefly centrifuged at 13000 *g* to pellet large debris. The luciferase assay reagent (100 μL) containing luciferin was automatically injected into the cell lysate sample (15 μL). Luciferase relative light units (RLU) were recorded on a Lumat LB 9501 luminometer (Berthold Systems, Wildbach, Germany) with 10 s integration. The RLUs were normalized to milligrams of protein. Protein concentrations were determined using the Bradford assay (*36*) with bovine γ globulin as the standard with the Bio-Rad Protein Assay Kit (Ivry sur Seine, France). The number of RLU obtained with 15 μL of a 1 pg/mL luciferase solution was 4000.

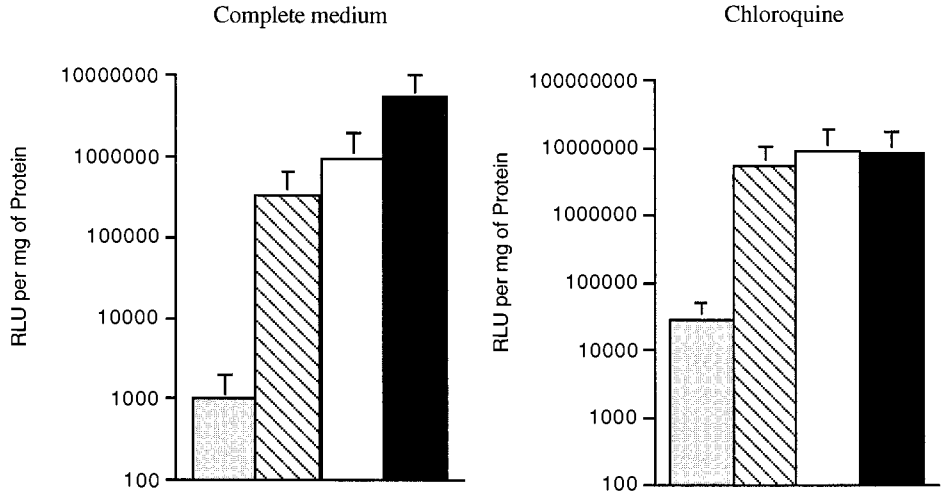

Figure 1. Polyfections of 3T3 cells with pLK_{93} (grey bar) and its conjugates with mAb J20.8 (J20.8-pLK_{93}) (white bar), (B7.14-pLK_{93}) (crosshatched bar), or F4.1 (F4.1-pLK_{93}) (black bar). pCMVLUC (2 μg) and 12 μg of either free pLK_{93}, J20.8-pLK_{93}, B7.14-pLK_{93}, or F4.1-pLK_{93} were combined in 50 μl of 0.15 M NaCl, and the reaction mixtures were incubated for 20 min at 20 °C. Each polyplex was tested in triplicate. Just before transfection, cells were washed and incubated with 0.5 mL of DMEM containing 10% FCS or 2% FCS and 100 μM chloroquine. Polyplexes were added to the cells for 4 h at 37 °C in a humidified atmosphere (92% air and 8% CO_2). The medium was removed and cells were further incubated for 24 h at 37 °C in 1 mL of fresh complete medium. After washing cells were lysed and the luciferase activity was determined. All experiments were carried out at least three times.

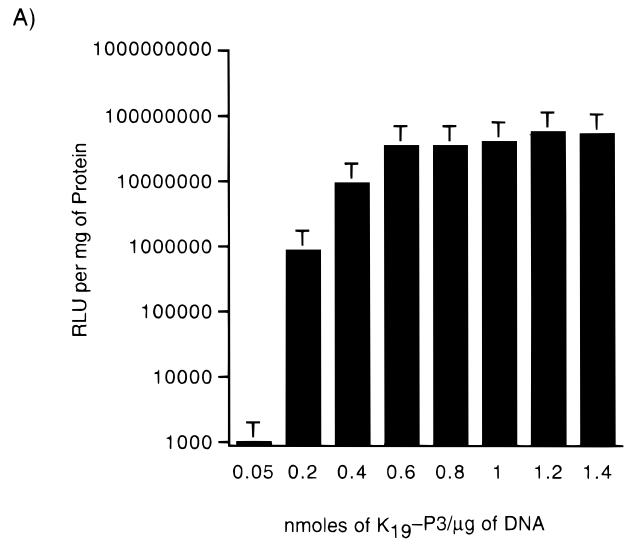
RESULTS

Polyfections with pLK_{19}−mAbs and pLK_{93}−mAbs. Transfection of 3T3 cells with pCMVLUC-pLK_{19}−F4.1 or pCMVLUC-pLK_{19}-J20.8 polyplexes at various plasmid/mAbs ratios failed to produce any major luciferase expression. The transfection potential of pCMVLUC-pLK_{93}-mAbs polyplexes was then tested. pLK_{93}-mAbs F4.1 J20.8 both showed high gene-transfer efficiency in complete medium in the absence of chloroquine (Figure 1). pLK_{93}-mAb F4.1 was 5 times more efficient than pLK_{93}-mAb J20.8 and at least 15 times more efficient than pLK_{93}-mAb IgG2a B7.14 used as negative control. Polyplexes formed with mAb had gene-transfer efficiencies 3−4 orders of magnitude higher than those formed with pLK_{93} alone. When the pLK_{93}-mAbs were tested for their gene-transfer efficiencies in medium containing 2% FCS and 100 μM chloroquine, 2- and 10-fold enhancements were noted, respectively, for pLK_{93}−F4.1 and pLK_{93}-J20.8. In contrast, a 16-fold and a 30-fold increase was, respectively, observed with pLK_{93}−B7.14 conjugate and free pLK_{93}.



Polyfection of 3T3 Cells with K_{19}−P3, K_{19}−P9.3, and CW−K_{18} Peptides. Luciferase reporter-gene expression was analyzed following transfection of 3T3 cells with the K_{19}−P3 peptide prepared at stoichiometric concentrations ranging from 0.05 to 1.4 nmol of peptides/μg of DNA. Gene expression increased with increasing peptide concentrations reaching a maximum at 0.6 nmol of peptide/μg of DNA that is a charge ratio of 4.4 (Figure 2A). This stoichiometry also corresponds to the optimum gene expression reported for CW−K_{18} (*33*), but does not coincide to the first complete retardation of all DNA in electrophoresis by the K_{19}−P3 peptide; this was obtained at a concentration of 0.2 nmol/μg of DNA (Figure 2B). Remarkably, 0.2 nmol/μg of DNA of CW−K_{18} peptide was also enough to obtain the full condensation of DNA observed with light scattering profile (*33*). At higher proportions, gene expression remained constant.

Kinetics of polyfections in complete medium without helper molecules at a 4.4 charge ratio showed no toxicity during 24 h of incubation with either K_{19}−P3, K_{19}−P9.3, or CW−K_{18} peptides. After 5.5 h of incubation, the luciferase reporter-gene expression was (2−3) × 10^7 RLU/mg of protein for K_{19}−P3 and (1−2) × 10^6 RLU/mg of protein for K_{19}−P9.3 or CW−K_{18} (Figure 3). After 24 h of incubation, transfection was, respectively, enhanced 4-, 10-, and 1.3-fold for CW−K_{18}, K_{19}−P9.3, and K_{19}−P3 peptides as compared to 5.5 h (Figure 3).

Polyfection in complete medium with K_{19}−P3 was 6 times lower than that obtained with PEI (Figure 4A). When the gene-transfer efficiencies of K_{19}−P3 and CW−K_{18} were tested in culture medium containing 2% FCS and 100 μM chloroquine, moderate 2-fold increase, comparable to that observed with pLK_{93}-mAb, was noted. Free pLK_{19} efficiency with or without chloroquine was, respectively, 5 and 100 times weaker than those of CW−K_{18} and K_{19}−P3 peptides.

Polyfection of CCL39 Cells with K_{19}−P3 and CW−K_{18} Peptides. 3T3 cells are a convenient classical model for transfection assays using nonviral vectors. However, because some cell lines are more refractory to transfection, we conducted comparative polyfections with 3T3 and CCL39 cell lines. Polyfection with K_{19}−P3 in complete medium resulted in the expression of 4 × 10^5 RLU/mg of protein in CCL39 cells (Figure 4B), a value that is 2 orders of magnitude lower than that detected with 3T3 cells (compare with Figure 4A). Indeed, absolute values of gene expression obtained with K_{19}−P3 or CW−K_{18} vectors were much lower in CCL39 cells than in 3T3. Their relative rates of gene-expression efficiency remained, however, constant, that is approximately 20 times higher for K_{19}−P3 in both 3T3 and CCL39 cells (compare panels A and B of Figure 4). Polyfections of CCL39 cells with PEI at a charge ratio of 5 also resulted in luciferase gene expression corresponding to no more than 10% of that obtained in 3T3 cells. Polyfections in culture medium containing 2% FCS and 100 μM chloroquine enhanced the expression of the luciferase gene by 3 and 10 times, respectively, with K_{19}−P3 and CW−K_{18} peptides. Free pLK_{19} with or without the addition of helper molecules failed to produce any major reporter gene expression.

Polyfection with K_{19}−P3 and CW−K_{18} Peptides in the Presence of 0.23 M Glycerol. Recent studies have demonstrated that the addition of 1.15 M glycerol during polyfection with DNA−transferrin−polylysine and DNA−

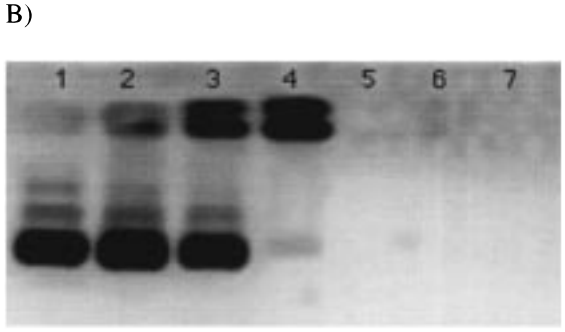


Figure 2. (A) Polyfection of 3T3 cells at various K_{19}−P3/plasmid ratios. Polyplexes between pCMVLUC (3 μg) and various amounts of K_{19}−P3 were made in 50 μL of 0.15 M NaCl (triplicate wells), and the solution was kept for 20 min at 20 °C. Just before transfection, cells were washed and incubated with 0.5 mL of complete medium. Polyplexes were added to the cells for 5.5 h at 37 °C. The subsequent steps were as those described in the legend to Figure 1. (B) Electrophoretic migration of pCMVLUC related to the plasmid/K_{19}−P3 molar ratio. Plasmid/K_{19}−P3 complexes were prepared by adding 0(1), 0.005 (2), 0.01 (3), 0.02 (4), 0.03 (5), 0.04 (6), and 0.06 (7) nmol of K_{19}−P3 for 0.1 μg of pCMVLUC in 5 μL of 0.15 M NaCl. After 20 min of incubation at 20 °C, each sample was analyzed by electrophoresis for 1 h under 50 V/cm through a 0.8% agarose gel containing ethidium bromide (1 μg/mL of gel) to visualize DNA in a Tris-borate-EDTA buffer (45 mM Tris, 45 mM boric acid, and 1.2 mM EDTA) pH 8.6.

polylysine complexes dramatically increases transgene expression (*23*, *37*). Using 3T3 cells, we found that 0.23 M glycerol was sufficient to maximize gene expression without the toxicity that we observed at 1.15 M when either K_{19}−P3 or CW−K_{18} peptides were used at a charge ratio of 2.2. When polyfections were carried out in 3T3 cells in the presence of 0.23 M glycerol, K_{19}−P3 was as efficient as PEI in the absence of glycerol (Figure 4A). In contrast, at a charge ratio of 2.2, PEI effectiveness decreased by almost 2 orders of magnitude while K_{19}−P3 remained at least equally effective (Figure 4A). Luciferase gene expression in CCL39 cells was increased by at least 1.5 orders of magnitude when polyfections mediated by K_{19}−P3 or CW−K_{18} peptides, but not by PEI, were performed in complete medium containing 0.23 M glycerol (Figure 4B). PEI effectiveness in the presence of glycerol was similar in both cell lines (Figure 4). In general, polyfections in the presence of 0.23 M glycerol except for PEI were much more effective (2−10 times)

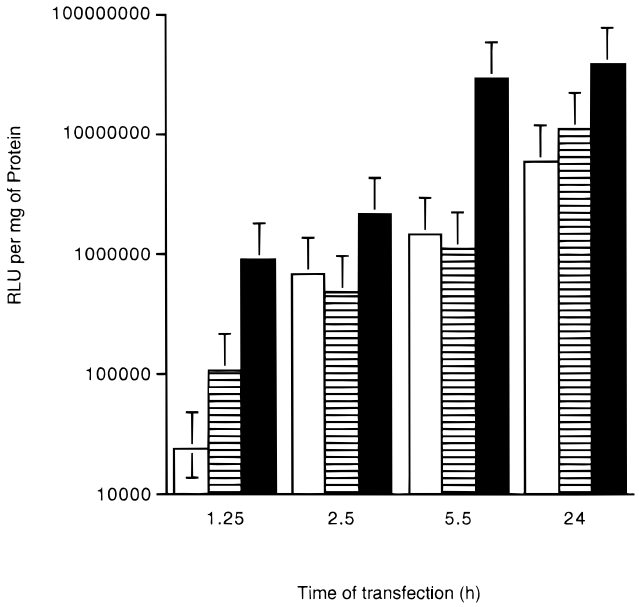

Figure 3. Polyfection of 3T3 cells incubated for various times with plasmid-peptide complexes. Polyplexes between 3 μg of pCMVLUC and 1.8 nmol of CW−K_{18} (white bar), K_{19}−H9.3 (crosshatched bar), or K_{19}−P3 (black bar) were made in 50 μL of 0.15 M NaCl (in triplicate wells), and the solution was kept for 20 min at 20 °C. Just before transfection, cells were washed and incubated with 0.5 mL of complete medium. Polyplexes were added to the cells for various times at 37 °C. The subsequent steps were as those described in the legend to Figure 1.

than those obtained in the presence of chloroquine (Figure 4A and B).

DISCUSSION

The naturally occurring polyreactive anti-DNA mAbs J20.8 and F4.1, recovered as hybridoma secretion products derived from the spleen cells of a nonimmunized mouse, penetrate and accumulate in the nuclei of a variety of cultured cells (*31*). In the present study, these antibodies conjugated to polylysine were tested as transfection vectors. mAbs-pLK_{19} conjugates were inefficient, probably because the proportion of lysine residues added was low by comparison to the long polypeptide chain of the mAbs. In contrast, conjugates of anti-DNA mAbs with pLK_{93} proved to be potential nonviral vectors for in vitro polyfections in the presence of serum. The observation that polyfection with J20.8 was 5 times lower than with F4.1 may be a reflection of each mAb's distinct kinetics of intracellular transit and/or its capacity to bind to distinct epitopes differently expressed at the cell surface (*38*). The experiments conducted with pLK_{93}-mAbs or free pLK_{93} showed toxicity for 3T3 cells (about 10−30%) which has not been analyzed but is presumably explained by the use of high molecular weight polydisperse poly-L-lysine (*39*).

Taken together, the above observations prompted us to substitute F4.1 mAb with the P3 peptide containing the heavy-chain CDR2 and CDR3 sequences of this antibody. P3 was previously shown to penetrate into various cell lines and to translocate proteins, but it failed to serve as a vector for delivery and expression of plasmid genes. The addition of 19 lysine residues to P3 generated an effective vector for gene transfer. In agreement with the reported properties of low-molecular-weight polylysine conjugates (*33*, *34*, *39*), K_{19}−P3 was not toxic. K_{19}−P3 turned out to be 10−20 times more efficient than CW−K_{18} peptide or than K_{19}−P9.3 peptide which was

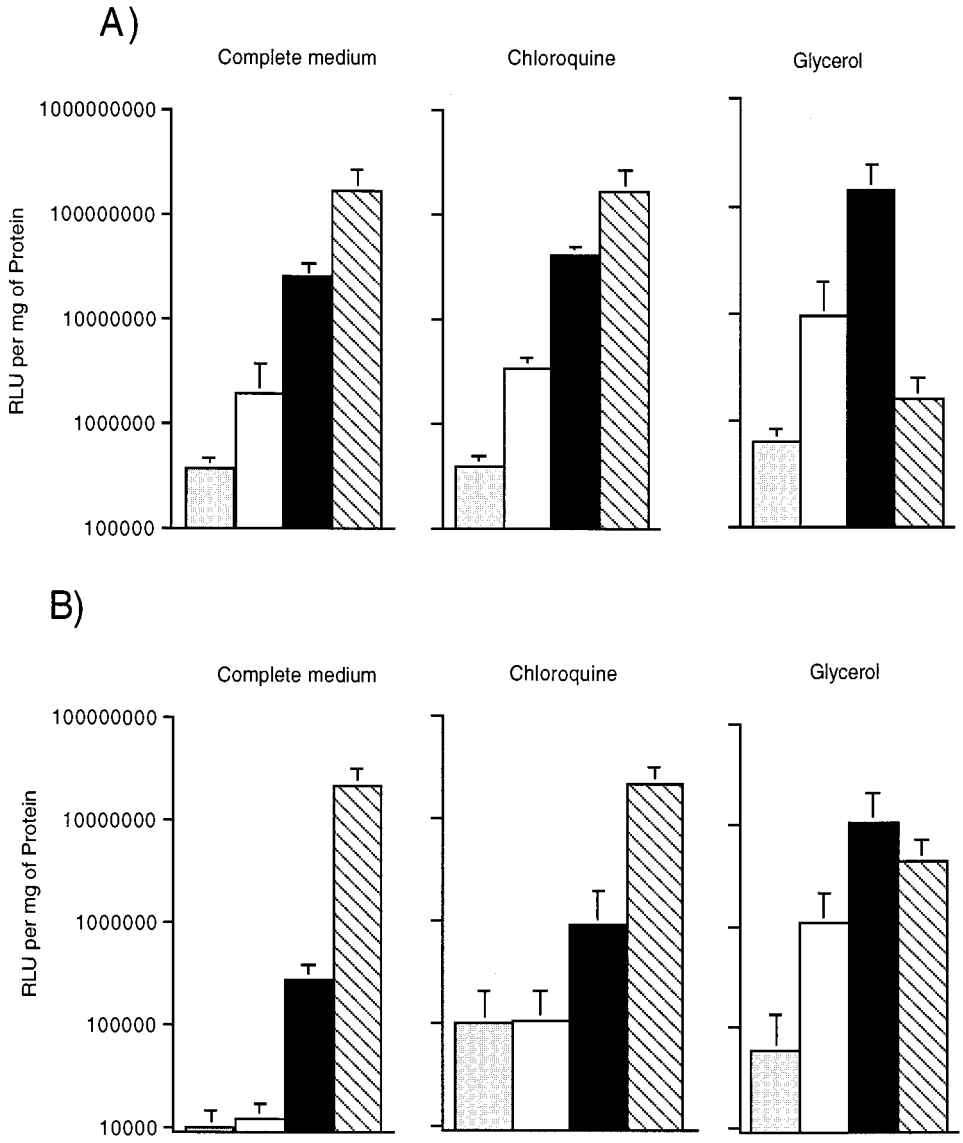

Figure 4. Polyfection of 3T3 (A) or of CCL39 (B) cells in the presence of helper molecules. Polyplexes formed between pCMVLUC (3μg) and 1.8 nmol and 0.9 nmol (in the presence of 0.23 M of glycerol) of either pLK_{19} (grey bar), $CW-K_{18}$ (white bar), or $K_{19}-P3$ (black bar) peptides, or 45 and 20 nmol (in the presence of 0.23 M of glycerol) of PEI (crosshatched bar). Polyplexes were made in 50 μL of 0.15 M NaCl, and the solution was kept for 20 min at 20 °C. Just before transfection, cells were washed and incubated with 0.5 mL of complete medium containing 0.23 M glycerol or not or culture medium containing 100 μM chloroquine and 2% FCS. Polyplexes were added to the cells for 5.5 h at 37 °C. The subsequent steps were as those described in the legend to Figure 1.

derived from a nonpenetrating anti-DNA antibody (H9.3) for gene transfer into 3T3 cells. Indeed, the values we observed in the present experiments for the expression of the luciferase gene driven by the $CW-K_{18}$ peptide in 3T3 cells (10^6 RLU/mg of protein) were comparable to those previously reported by Wadhwa et al. (*33*) for HepG2 cells. These results indicate that linking the mAb-derived P3 peptide to K_{19} makes a gene-delivery vector considerably more efficient than free K_{19}. Transfection of 3T3 cells gave 2−6% green cells when they were transfected with pCMV carrying the gene of the green fluorescent protein (data not shown).

In CCL39 cells, all attempted polyfections, even with PEI polyplexes, were less efficient although anti-DNA mAbs or P3 peptide penetrated into this cell line equally well as into 3T3 cells (*31*). This finding suggests that polyfection efficiency is not governed only by the ability of anti-DNA mAb conjugates or $K_{19}-P3$ to enter cells but also by the capacity of each cell line to transfer the DNA to the nucleus.

To enhance gene delivery by $K_{19}-P3$, we examined the possibility of adding chloroquine or glycerol helper molecules. Chloroquine did not markedly enhance polyfection. It is interesting to note that the recovery of luciferase activity after polyfections in the presence of glycerol at a 1.1 charge ratio was 2−3 orders of magnitude greater than without glycerol (data not shown), thereby confirming that the glycerol effect increased when the charge ratio of polylysine conjugates decreased (*37*). Glycerol stimulation of the activity of the cytomegalovirus promoter governing luciferase gene expression has been clearly ruled out (*37*). Evidence has been obtained to support the hypothesis that polylysine conjugates and glycerol may synergize their abilities to rupture membranes of internal vesicles, such as early endosomes (*37*). Our data do not evoke a likely mechanism of glycerol action, but the observation that chloroquine, unlike glycerol, did not greatly enhance polyfection by $K_{19}-P3$ remains consistent with the interpretation that glycerol enhances cellular uptake of the compact

polyplex particles (*23*). In our experiments, glycerol was used at 0.23 M, rather than 1.15 M as in previous studies (*23*), because at that relatively high concentration, significant toxicity was noted under our culture conditions.

Glycerol markedly improved gene delivery with peptides-K_{19}, but not with free pLK_{19}. This result is in contrast to those reported with free high-molecular-weight polydisperse polylysine (pLK_{250}), whose efficiency as a vector was enhanced by glycerol as was that of the transferrin-pLK_{250} conjugate (*24*). The difference may be attributable to the properties of the polyelectrolyte complexes arising from the complexation of DNA with polylysines of different molecular weights. The low-molecular-weight polylysines form condensates 20−30 nm in diameter, while pLK_{250} conjugates form condensates 100−200 nm in diameter (*39*), and thus they may need less glycerol to improve gene delivery than larger polyplexes. The addition of glycerol to the medium for K_{19}−P3 polyfection, as compared to complete medium, enhanced the efficiency of gene delivery 38 times in CCL39 but only 5 times in 3T3 cells. This finding suggests that glycerol is an efficient helper molecule, especially in cells that are poorly transfected, like CCL39 cells. Our data also demonstrated that a long peptide (30 amino acids) bound to K_{19} residues is a very efficient nontoxic gene vector able to preserve the property of low-molecular-weight polylysine to condense actively DNA into small particles. The rationale for constructing P3 peptide was to identify the specific sequences governing the internalization potential of a polyreactive mAb. Different CDR combinations from F4.1 and many other cell-penetrating anti-DNA mAbs can now be tested; some of them might possess selective capacities of internalization depending on the cell lines used. Indeed, preliminary experiments performed with several peptides derived from other translocating anti-DNA mAbs have shown different efficiencies and cell specificities for gene delivery. These observations prompt us to think that K_{19} conjugated to peptides naturally preselected in anti-DNA mAbs may represent an unlimited source of building blocks for gene-delivery vectors with different specificities.

ACKNOWLEDGMENT

We are grateful to Dr. U. Hazan, Institut Cochin de Génétique Moléculaire, for kindly providing the pCMV-LUC plasmid. A.A. received fellowships from Institut Pasteur-Weizmann Institut and Institut Pasteur-Canam. This work was supported in part by the Université Pierre et Marie Curie.

DNA Interaction and Photocleavage Properties of Porphyrins Containing Cationic Substituents at the Peripheral Position

Sashikumar Mettath,[†] Benjamin R. Munson,[†] and Ravindra K. Pandey*[,†,‡]

Photodynamic Therapy Center, Department of Radiation Biology and Department of Nuclear Medicene, Roswell Park Cancer Institute, Buffalo, New York 14263. Received July 29, 1998; Revised Manuscript Received September 23, 1998

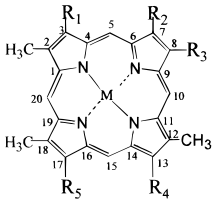
A series of mono- and disubstituted cationic porphyrins (**1**−**8**) were synthesized and investigated for their ability to bind and cleave DNA in the presence of light. In these porphyrins, the cationic substitutuents were introduced at various peripheral positions, i.e., the non-meso positions of the porphyrin system. The modes of binding of these porphyrins to DNA were investigated by UV−vis spectroscopy, circular dichroism, and an unwinding assay. The intrinsic binding constants K_b of these porphyrins to calf thymus DNA was found to be in the range 10^4-10^5 M^{-1}. Two of the zinc(II) complexes of non-meso-substituted cationic porphyrins (**5** and **8**) were found to bind to DNA via intercalation, which is in contrast to the previously reported outside-binding mode for the Zn(II) complexes of meso-substituted cationic porphyrins. Except for monocationic porphyrin **1** and Ni(II) dicationic porphyrin **6**, all the other porphyrins were found to be efficient photocleavers of DNA. The DNA photocleavage characteristics of this series of cationic prophyrins were found to depend on the structural characteristics of the poprhyrins such as (a) length of the side chain of the cationic substituents (**2** vs **4**), (b) the position of the side chain on the porphyrin ring (**4** vs **7**), and (c) the presence of the chelating metal in **3**, **5**, and **8** as compared to the nonmetallo porphyrins **2**, **4**, and **7**, respectively.

INTRODUCTION

Chemical agents which bind and cleave nucleic acids are potentially useful as reagents for accessing structural and genetic information, as well as for development of efficient chemical nucleases (*1*). Such compounds may also be useful as drugs for treatment of cancer, genetic diseases, and viral infections. Among such agents, cationic porphyrins such as meso-tetra-(4-*N*-methylpyridyl)porphyrin [T4MPyP] and its related analogues are known to bind as well as cleave DNA (*2*). Binding studies by others have shown that, in general, the free bases and Cu^{2+} and Ni^{2+} complexes of meso-substituted cationic porphyrins intercalate between the base pairs of the DNA as well as bind in the minor groove by an outside binding mode (*3*, *4*), whereas for Mn^{3+}, Fe^{3+}, Zn^{2+}, and Co^{2+} complexes of these porphyrins, due to the presence of axially bound ligands, intercalation is blocked and only outside binding occurs (*5*, *6*). DNA footprinting studies have shown that Mn^{3+}, Fe^{3+}, Zn^{2+}, and Co^{2} metallocomplexes of T4MPyP bind to the AT rich regions of DNA in the minor groove. The Ni and Cu complexes of T4MPyP were found to intercalate in GC rich regions and bind in the AT rich regions by outside binding mode (*7*−*10*). The affinity of binding to these two regions were different.

Fiel and co-workers found that Fe complexes of T4MPyP can be chemically activated to produce strand breaks in DNA (*11*). Studies by various groups have established that Fe^{3+}, Mn^{3+}, and Co^{2+} complexes of T4MPyP can be activated using a variety of oxidizing agents to produce strand breaks in the DNA (*12*−*14*). Conjugates of cationic manganese porphyrins with ellipticine (*15*, *16*), spermine (*17*), bis(benzimidazole) dye (*18*), peptide nucleic acid (*19*), and oligonucleotides (*20*, *21*) when activated by oxidizing agents have also been found to cleave DNA.

Porphyrins can also be activated by light to produce an effect on biological molecules, and such a methodology has been used in photodynamic therapy for treatment of cancer (*22*, *23*). Fiel and co-workers examined the light activated DNA cleavage property of meso-tetra(*p*-carboxyphenyl)porphine (T4MPyP) and found it to be an efficient cleaver (*24*). The DNA photocleavage properties of a series of cationic porphyrins including the zinc complexes, and porphyrin dimers were studied by Praseuth and co-workers (*25*). They found that the zinc complexes and the dimers were more efficient in cleaving DNA than the corresponding free bases and the monomers. Similarly, Munson et al. have demonstrated that cis and trans isomers of bis(*N*-methyl-4-pyridiumyl)-diphenyl porphyrin intercalates into DNA and also cleaves DNA in the presence of light (*26*).



A review of the literature showed that most of the cationic porphyrins studied for their DNA cleavage activity are metalloderivatives of porphyrins possessing cationic substituents at the meso positions and belong to the class of cleavers which needs an activating agent. The few exceptions in which the non-meso-substituted compounds have been studied for their DNA-cleaving abilities are the noncationic chlorins (*27*) and lutetium-(III) texaphrin (*28*). The aim of this work was to investigate the photocleavage and DNA-binding properties of a series of non-meso-substituted cationic porphyrins to further understand the characteristics needed for efficient cleavage of DNA in the presence of light. The structural characteristics of this series of porphyrins that

were varied to understand their effect on the DNA cleavage activity were (i) number of cationic substituents, (ii) the length of the carbon chain between the cationic group(s) and the porphyrin, (iii) the position of the cationic substituents on the porphyrin ring, and (iv) the effect of the coordinated metal.

MATERIAL AND METHODS

Synthesis of Porphyrins. The cationic porphyrins **1**−**8** (shown in Figure 1) were prepared from their respective porphyrins **9**−**16** (shown in Figure 2) by following the general scheme shown in Figure 3 (*29*). For the preparation of the moncationic porphyrin **1**, 8-vinyl porphyrin **9** obtained from dueteroporphyrin via a series of reactions, was used as the starting material. Reaction of **9** with Eschenmoser's salt [CH_2=$N^+(Me)_2I^-$] led to the formation of the dimethyl amino derivative, which on treatment with methyl iodide gave the desired cationic porphyrin **1**. Cationic porphyrins **2**−**8** were similarly prepared from porphryins **10**−**16**, respectively.

Porphyrin **15** in which the cationic substituents were introduced at the vinyl groups in diagonal position (ring A and ring C) to form porphyrin **7** was prepared by following the scheme shown in Figure 4 (*30*). In brief, the acetoxy methyl pyrrole **17** was condensed with the α-free pyrrole **18** in the presence of Montmorillonite K 10 and pyrromethane **19** was obtained in 85% yield (*31*). Reaction of **19** with TFA/triethyl orthoformate gave the

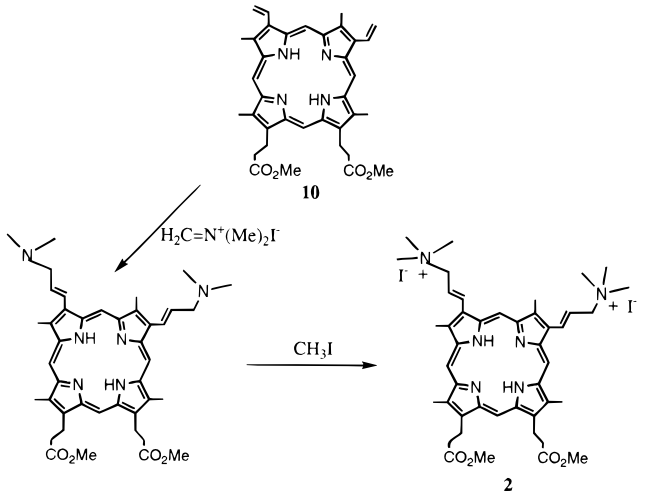

Figure 3. General scheme for the synthesis of non-meso-substituted cationic porphyrins.

monoformyl pyrromethane **20** in 70% yield. Hydrogenation of the benzyl ester functionality gave pyrromethane **21** as monocarboxylic acid, which on self-condensation under McDonald's reaction conditions produced bis(2-chloroethyl) porphyrin **22**. The chloroethyl functionalities were then converted to vinyl substituents by refluxing in NaOH/pyridine solution to obtain **16**. The divinyl free porphyin **15**, obtained upon removal of the zinc metal from porphyrin **16** was converted to the cationic porphyrin **7** by reaction with Eschenmoser's salt, followed by treatment with methyl iodide. All the new compounds were characterized by NMR and mass spectrometry analysis.

DNAs. Calf thymus DNA was purchased from Sigma Chemical and dissolved in BPES buffer (without NaCl) for the binding studies. Plasmid DNA used was the 4752 bp circular pCAT-control from Promega, amplified in *Escherichia coli* strain DH5α. The DNA was isolated and purified using cesium chloride and dissolved in TE buffer. Polydeoxyguanylic deoxycytidylic acid (poly[d(G.C)].poly[d(G.C)]) and polydeoxyadenylic thymidylic acid (poly[d(A.T)].poly[d(A.T)]) were purchased from ICN and were dissolved in BPES buffer (without NaCl) (*3*).

Hypochromicity Studies. All UV−vis spectrophotometric measurements were done on Genesys 5 spectrophotometer (5 nm spectral bandwidth). The hypochromicity in the Soret band of the cationic porphyrins caused by their interaction with calf thymus DNA and the polynucleotides poly[d(G.C)].poly[d(G.C)] and poly[d(A.T)].poly[d(A.T)] was determined as follows. Initially, visible absorption spectra of these porphyrins was determined at a concentration of $\sim 10^{-6}$ M. Calf thymus DNA, poly[d(A.T)].poly[d(A.T)] or poly[d(G.C)].poly[d(G.C)] was added in increments of 1−2 μL until no further decrease in the Soret band was observed. Buffer blanks were used to compensate for the dilution effect. The percentage hypochromicity was determined from the equation $(OD_f - OD_b/OD_f) \times 100$, where OD_f and OD_b represent the optical density of the free porphyrin and the mixture of free porphyrin and porphyrin bound to DNA, respectively.

Intrinsic Binding Constant K_b. The intrinsic binding constant K_b was determined by using the formula

$$[DNA]/(\epsilon_A - \epsilon_F) = [DNA]/(\epsilon_B - \epsilon_F) + 1/K_b(\epsilon_B - \epsilon_F)$$

where ϵ_A, ϵ_F, and ϵ_B correspond to A_{obsd}/[porphyrin], the extinction coefficient for the free porphyrin and the

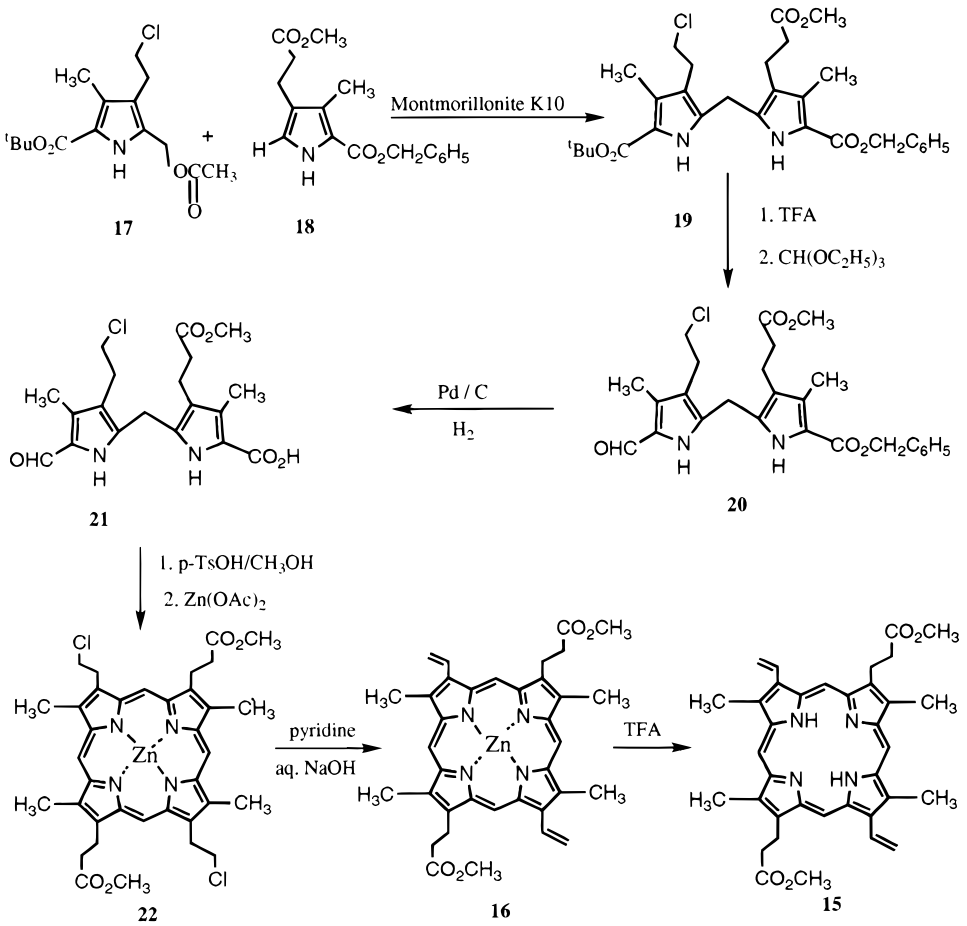

Figure 4. Synthetic strategy for the preparation of symmetrical porphyrins **15** and **16**.

extinction coefficient for the porphyrin complex in fully bound form, respectively. A plot of [DNA]/($\epsilon_A - \epsilon_F$) vs [DNA] will have a slope of 1/($\epsilon_B - \epsilon_F$) and a *y*-axis intercept equal to 1/K_b ($\epsilon_B - \epsilon_F$). The binding constant K_b was calculated from the ratio of the slope to the *y*-axis intercept.

Circular Dichroism (CD) Studies. CD spectra were recorded on a Jasco J-600 spectropolarimeter with a spectral bandwidth of 2 nm. The path length was 1 mm. The DNA (calf thymus DNA, poly[d(A.T)].poly[d(A.T)] or poly[d(G.C)].poly[d(G.C)]) was added to the porphyrins, and after an incubation period of 15 min, the samples were scanned in the visible region (320−480 nm). The *r* value, the ratio of the concentration of the porphyrins to the concentration of DNA, was less than 0.5. The baseline correction was applied using the buffer before scanning the samples.

DNA Unwinding Experiments. DNA unwinding assays were performed in two steps. First, closed supercoiled DNA (form I) pCAT (0.5 μg) was relaxed with wheat germ topoisomerase I (Promega Corp., Madison, WI). This was followed by a second topoisomerase-mediated relaxation in the presence of porphyrin. Specifically, topoisomerase I (2 units) was incubated at 37 °C for 30 min with 0.5 μg of form I pGS81 DNA first in the absence and then for 30 min in the presence of porphyrin in 25 μL of buffer containing 25 mM Tris-HCl, pH 7.9, 25 mM NaCl, 1 mM EDTA, 1 mM DTT, and 10% glycerol. The assay was stopped with 3 μL of 10% SDS and subjected to 1% agarose gel electrophoresis at 15 V for 20 h. After addition of the cationic porphyrin to DNA, care was taken to prevent exposure of the mixture to light.

Exposure of DNA/Porphyrin to Light. The solution of cationic porphyrins was added to the plasmid DNA in a 1.5 mL eppendorf microtube such that the *r* value was 0.5 or less. The tubes were placed 4 cm from a 15 W fluorescent daylight lamp and exposed to light for times ranging 0−90 min. The photoexposure ranged from 4.0 × (10^{-5} to 10^{-4}) J/cm^2 among various experiments. After exposure of the DNA to light, 1/10 volume of a solution of 50% glycerol containing 0.25% bromophenol blue was added to the DNA sample and loaded on to a 1% agarose gel and run in a TAE buffer system at 80 V for approximately 1.5 h. The agarose gel was then stained in ethidium bromide (0.25 μg/mL) and photographed. The photographs were analyzed using Image Quant software to quantify the amount of plasmid DNA (form I) remaining after treatment with light.

The singlet oxygen and hydroxyl radical quenching experiments were carried out in a manner similar to the cleavage reactions, with the addition of sodium azide (0.1 M) and mannitol (0.1 M), respectively. Sodium azide or mannitol was added at a final concentration of 0.1 M and exposed to light for varying amounts of time.

RESULTS AND DISCUSSION

Binding Studies. UV−vis absorption spectroscopy, CD spectroscopy, and DNA unwinding assays were used to evaluate the binding of non-meso-substituted cationic porphyrins **1**−**8** to DNA. In general, the hypochromic shift in the Soret band of the porphyrins upon interaction with the DNA indicate binding of the porphyrin to DNA; the sign of the ellipticity obtained in the visible range of the CD scan can point to the nature of the binding.

Table 1

porphyrin	Soret band (nm)	% hypochromicity with CT.DNA	K_b
2	385	29.8	2.32×10^5
3	410	25.4	2.52×10^4
4	385	28.6	3.10×10^5
5	409	49.0	1.12×10^5
6	388	42.7	0.88×10^5
7	382	33.5	0.81×10^5
8	406	41.0	1.34×10^5

Table 2

porphyrin	Soret band (nm)	% hypochromicity with poly dA.dT	% hypochromicity with poly dG.dC
2	385	15.0	28.7
3	410	9.7	5.5
4	385	21.5	35.9
5	409	14.0	25.0
6	388	12.9	22.6
7	382	32.2	41.4
8	406	29.6	46.4

Similarly, the unwinding assay has been used to examine the nature of binding of porphyrins to DNA as described below (*26*, *32*).

(a) UV−Vis Absorption Spectroscopy. A summary of changes in the Soret band of the porphyrins upon interaction with calf thymus DNA is shown in Table 1. These studies were done at an ionic strength (μ) of 0.17. Sodium chloride was excluded in these solutions. Addition of NaCl to these solutions was seen to decrease the hypochromic effects. Porphyrin **1** did not show any hypochromic shift. Porphyrins **5**, **6**, and **8** exhibited hypochromic shifts greater than 35%. All the other porphyrins showed hypochromic shifts in the absorption band in the range 25−33% (Table 1). However, no change in the absorption wavelength of the Soret band has been observed. The intrinsic binding constant, K_b for the binding of these porphyrins to calf thymus DNA was determined by the method reported in the literature (*33*−*35*). The binding constant for all the compounds **2**−**8** except **4** were found to be in the range of $\sim 10^5$; for **4** it was in the range of 10^4. However, because of the limitations imposed due to the aggregation of the cationic porphyrins, some variation in the value of the intrinsic binding constant, K_b cannot be ruled out. Attempts to find the number of binding sites by Scatchard plot proved to be difficult due to aggregation. Similarly, Sehlstedt et al. have also reported difficulty in finding the DNA binding constants of cobalt porphyrins due to aggregation effects (*36*). The hypochromic shift in the Soret band of the porphyrins upon interaction with copolymers poly-[d(A.T)].poly[d(A.T)] and poly[d(G.C)].poly[d(G.C)] was also determined and are shown in Table 2. The hypochromic shifts in the Soret band in the range 9.7−29.6% were observed upon binding of these porphyrins to poly-[d(A.T)].poly[d(A.T)] and in the range 5.5−46.4% upon unbinding to poly[d(G.C)].poly[d(G.C)].

(b) CD Studies. CD studies have been extensively used to study the binding of small molecules including porphyrins to DNA (*3*, *5*, *35*−*37*). In the visible range (320−480 nm), the porphyrins alone as well as the DNA by themselves do not show any ellipticity. However, an induced CD spectrum is obtained if there is a binding between the porphyrin and the DNA. The shapes of the curves obtained gave information about the nature of the binding. The mode of binding of the porphyrins **2**−**8** to calf thymus DNA, the copolymers poly[d(G.C)].poly-[d(G.C)] and poly[d(A.T)].poly[d(A.T)] were hence investigated by CD. None of these porphyrins showed any

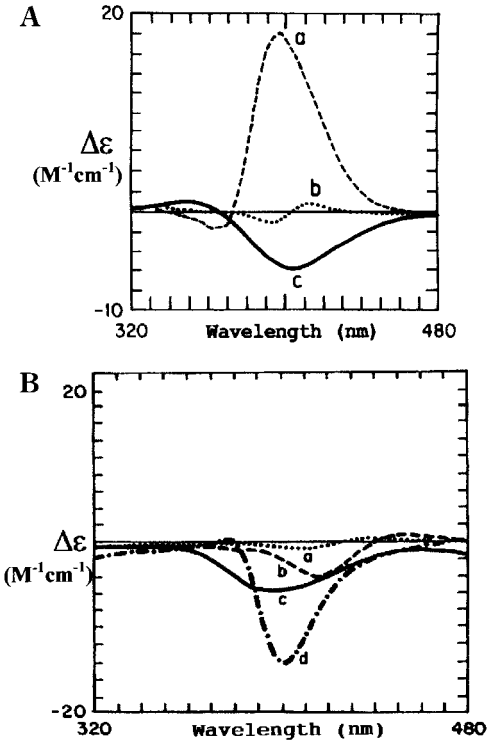

Figure 5. Visible CD spectra of CT. DNA in BPES/no salt buffer with porphyrins **2**−**8**. (A) **2** (line a), **3** (line b), **4** (line c). (B) **5** (line b), **6** (line d), **7** (line c), **8** (line a). $R < 0.5$, $\mu = 0.017$.

ellipticity in the visible range (320−480 nm) or in the UV range (220−300 nm). Interaction of the porphyrins **2**−**8** with calf thymus DNA and copolymers poly-[d(A.T)].poly[d(A.T)] and poly[d(G.C)].poly[d(G.C)] resulted in the formation of induced CD spectrums in the visible range (320−400 nm). The results of these interactions are shown in Figures 5 (interaction with calf thymus DNA), 6 (interaction with poly[d(A.T)].poly-[d(A.T)]), and 7 (interaction with poly[d(G.C)].poly-[d(G.C)]).

Porphyrin **2** (line a, Figure 5A) upon binding to calf thymus, DNA showed a strong positive peak centered at 396 nm, whereas compound **3** (line b, Figure 5A), the zinc complex, showed a weak positive peak and a weak negative peaks centered at 413 and 394 nm, respectively. Porphyrin **4** (line c, Figure 5A) and its metallocomplexes **5** (line b, Figure 5B) and **6** (line d, Figure 5B) all showed negative ellipticity; however, the intensity of the peaks as well as the wavelength at maximum peak height differed. Similarly, compound **7** (line c, Figure 5B) showed a strong negative peak upon interaction with calf thymus DNA. For the zinc complex **8**, a very weak ellipticity pattern was obtained, and changes in the *r* value did not cause any change in the shape of the spectra.

The visible CD spectrums obtained upon binding of porphyrins **2**−**8** with poly[d(A.T)].poly[d(A.T)] are shown in Figure 6. Porphyrin **2** upon interaction with poly-[d(A.T)].poly[d(A.T)] (line a, Figure 6a) showed a strong positive peak centered at 393.0 nm, whereas for porphyrins **3** and **4**, very weak and broad negative peaks (lines b and c in Figure 6A, respectively) were obtained. Compound **6** showed strong negative peaks centered at 402 nm (line b, Figure 6B), whereas compounds **5** and **8** exhibited broad peaks centered at 396 and 412 nm, respectively (lines a and d, Figure 6B). The interaction of compound **7** with poly[d(A.T)].poly[d(A.T)] did not result in any ellipticity.

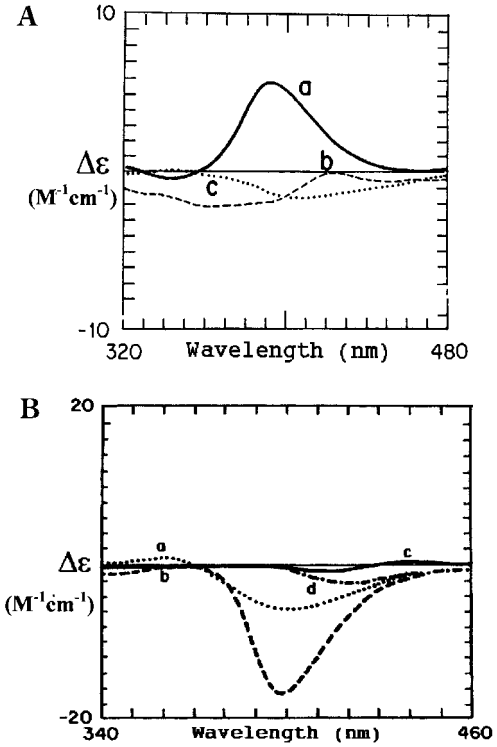

Figure 6. Visible CD spectra of poly[d(A−T)].poly[d(A−T)] in BPES/no salt buffer with porphyrins **2**−**8**. **(**A) **2** (line a), **3** (line b), **4** (line c). (B) **5** (line d), **6** (line b), **7** (line c), **8** (line a). R < 0.5, $\mu = 0.017$.

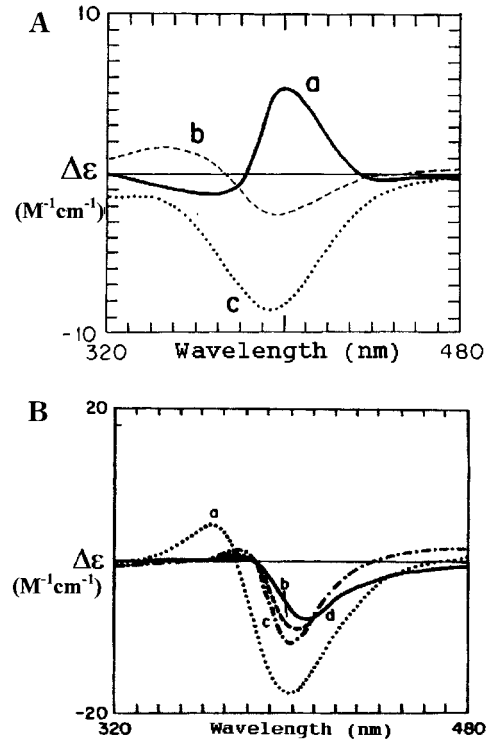

Figure 7. Visible CD spectra of poly[d(G−C)].poly[d(G−C)] in BPES/no salt buffer with porphyrins **2**−**8**. (A) **2** (line b), **3** (line a), **4** (line c). (B) **5** (line d), **6** (line b), **7** (line a), **8** (line c). R < 0.5, $\mu = 0.017$.

The interaction of porphyrins **2**−**8** with poly[d(G.C)]. poly[d(G.C)] is shown in the Figure 7. A strong positive peak was obtained in the visible CD spectra for compound **3** (line a, Figure 7A), upon binding to poly[d(G.C)].poly-[d(G.C)]. In the visible range, the binding of all the other porphyrins to poly[d(G.C)].poly[d(G.C)] resulted in negative ellipticity. These interactions are represented by lines b and c in Figure 7A, for **2** and **4**, respectively, and lines a−d in Figure 7B for the compounds **7**, **6**, **8**, and **5**, respectively.

(c) Unwinding Assay. The ability of compounds to intercalate to DNA can be checked by the unwinding assay using topoisomerase I (*26*, *32*). The DNA that is used in this assay is negatively supercoiled DNA. The supercoiled DNA is first converted to relaxed supercoiled DNA using topoisomerse I. The compounds were then added to interact with the DNA, and the assay was continued for 30 min in the presence of topoisomerase I. Compounds that intercalate into DNA induce supercoiling of DNA and, beyond a certain r value, complete supercoiling to negatively supercoiled DNA is obtained. The binding of porphyrins **2**−**8** were studied using unwinding assay and are shown in Figure 8 a−d. Porphyrins **2**, **3**, **4**, **6**, and **7** [porphyrins 2, 3, 4 (Figure 8, panels a−c), 6 (Figure 8D, lanes 11−13), and 7 (Figure 8D, lanes 2−4)], exhibit only a very weak unwinding of DNA, whereas porphyrins **5** (lanes 8−10, Figure 8D) and **8** (lanes 5−7, Figure 8D) caused complete unwinding to form supercoiled DNA. These unwinding assays indicate that compounds **5** and **8** are able to intercalate into DNA.

Photosensitized Cleavage of DNA. A convenient way to assess the ability of a cationic porphyrin to photocleave DNA is to measure the conversion of supercoiled DNA (form I) to form II (*26*). In the presence of light, all the cationic porphyrins, except **6** and **1**, were able to nick closed circular DNA (form I) to convert it into relaxed closed circular DNA (form II) in varying amounts. The amount of form II created depended upon the amount of exposure to visible light, the porphyrin that was used, and ratio of the concentration of the porphyin to that of the DNA. DNA (form I) was quantified by densitometry studies using Image Quanta software. Upon exposure to light for 90 min, all the porphyrins (r = 0.5), except **1** and **6**, were able to convert over 80% of DNA (form I) to DNA (form II) and not much difference in cleavage efficiency was observed. However, upon exposure to light for shorter time periods up to 60 min, differences in the efficiency of DNA cleavage by various porphyrins were observed. In the case of compound **5** (Figure 9b, lanes 13−16), within 15 min of exposure to light (lane 13), over 95% of the DNA (form I) was converted to form II, and 100% conversion was seen upon exposure to light for 60 min (lane 15). For compounds **2**, **3**, and **4**, the amount of DNA converted to form II in 15 min was 38.33, 49.81, and 50.93%, respectively, as shown in lanes 2, 7, and 12 of Figure 9a, respectively. Compounds **7** and **8** caused the conversion of 33.44 and 39.20% of the DNA form I to form II in 15 min (lanes 3 and 8 of Figure 9b, respectively). Compound **6 (**lanes 18−20**)**, the nickel complex, did not cause any cleavage of DNA (form I) even after exposure to light for an extended period of time (90 min). Similarly, the monocationic compound **1** also did not cause any cleavage of DNA (results not shown). The comparison of the DNA cleaving efficiencies of these porphyrins is shown in Table 3 (*37*).

The species responsible for causing the DNA cleavage is believed to be singlet oxygen. Singlet oxygen is generated upon transfer of energy from an excited porphyrin in the triplet state to oxygen in ground state (triplet state). The transfer of energy causes the conversion of oxygen to excited singlet state. The Ni complex **6** does not generate singlet oxygen, and this could explain the noncleavage of the DNA by this compound. For the other porphyrins, if singlet oxygen is the primary agent responsible for the cleavage of DNA, irradiation of the

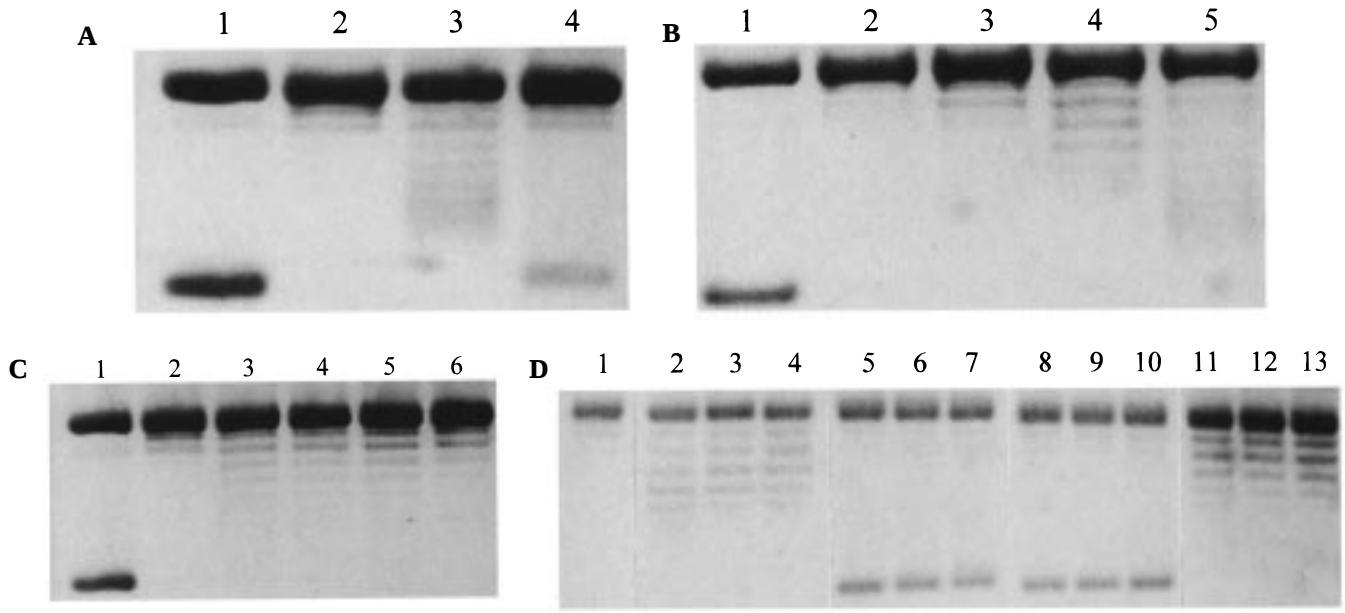

Figure 8. Agarose gel electrophoresis of supercoiled DNA relaxed by topoisomerase I in the presence of cationic non-meso-substituted porphyrins **2**−**8**. (A) Lane 1 is DNA form I and relaxed DNA. Lane 2 is control, DNA relaxed in the presence of topoisomerase I. Lanes 3 and 4, DNA relaxed in the presence of 19 and 38 μM of porphyrin **2**, respectively. (B) Lane 1 is DNA form I and relaxed DNA; lane 2 is control, i.e., DNA relaxed in the presence of topoisomerase I. Lanes 3−5 contain DNA relaxed in the presence of 14, 28, and 56 μM of porphyrin **3**, respectively. (C) Lane 1 is DNA form I. Lanes 2 and 6 are control, DNA relaxed in the presence of topoisomerase I. Lanes 3−5 DNA relaxed in the presence of 28, 42, and 60 μM of porphyrin **4**, respectively. (D) Lane 1 is control, DNA form I treated with topoisomerase I, lanes 2−4, DNA relaxed in the presence of 14, 10, and 7 μM of porphyrin **7**, respectively. Lanes 5−7, DNA relaxed in the presence of 14, 10, and 7 μM of porphyrin **8**, respectively. Lanes 8−10, DNA relaxed in the presence of 14, 10, and 7 μM of porphyrin **5**, respectively. Lanes 11−13 DNA relaxed in the presence of 14, 10, and 7 μM of porphyrin **6**, respectively.

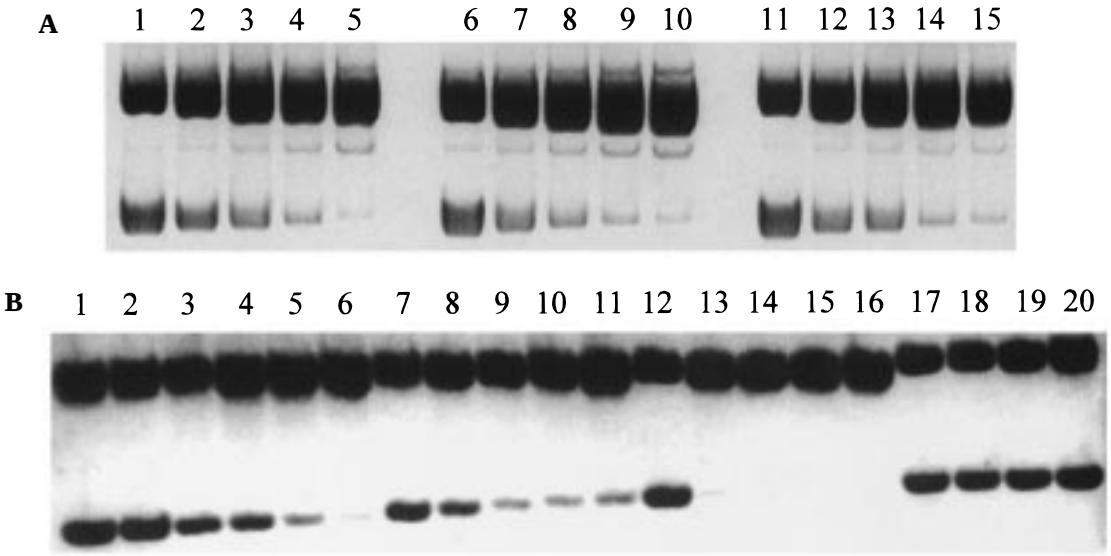

Figure 9. Agarose gel electrophoresis of plasmid DNA (form I) photosensitized with porphyrins **2**-**8**. Plasmid DNA (10 μL, 1 μg/10 μL) was added to eppendorf microtubes containing the porphyrins (10 μL, 75 μmol) and exposed to light for durations ranging 15−90 min and subsequently separated on 1% agarose gel. (A) Photocleavage of plasmid DNA (form I) by porphyrins **2**, **3**, and **4**. Lanes 1, 6, and 11 are controls and contain no porphyrins. Lanes 2−5: DNA + porphyrin **2**, treated with light for 15, 30, 60, and 90 min, respectively. Lanes 7−10: DNA + porphyrin **3**, treated with light for 15, 30, 60, and 90 min, respectively. Lanes 12−15: DNA + porphyrin **4**, treated with light for 15, 30, 60, and 90 min, respectively. (B) Photocleavage of plasmid DNA (form I) by porphyrins **5**, **6**, **7**, and **8**. Lanes 1, 7, 12, and 17 are controls and contains no porphyrins. Lanes 2−6: DNA + porphyrin **7** treated with light for 0, 15, 30, 60, and 90 min, respectively. Lanes 8−11: DNA + porphyrin **8** treated with light for 15, 30, 60, and 90 min, respectively. Lanes 13−16: DNA + porphyrin **5** treated with light for 15, 30, 60, and 90 min, respectively. Lanes 18−20: DNA + porphyrin **6** treated with light for 15, 60, and 90 min, respectively.

porphyrin−DNA complex in the presence of a singlet oxygen quencher should result in the decrease of the amount of DNA cleavage (*16*, *24*). As expected, a decrease in the cleavage of DNA was observed upon irradiation in the presence of sodium azide (100 mM), a well-known $^1O_2$ quencher (see Figure 10). No decrease in the cleavage was observed when the studies were done in the presence of equivalent concentration of NaCl (100 mM). DNA cleavage was also studied in the presence of hydroxyl radical scavenger mannitol (100 mM), and no discernible decrease in the cleavage of the DNA was observed (results not shown). These results indicate that singlet oxygen is the major species responsible for the cleavage of DNA.

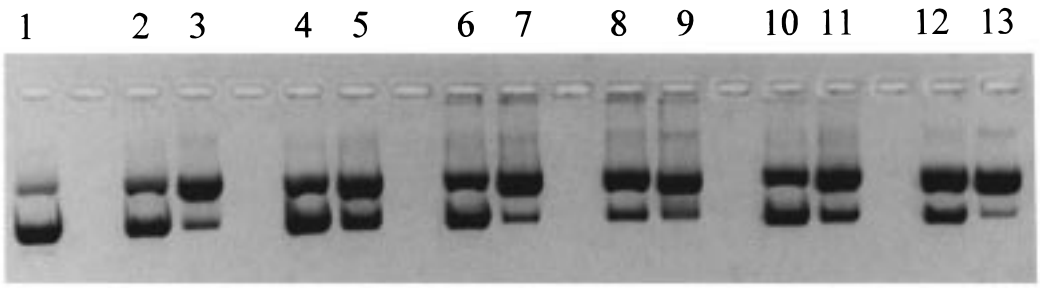

Figure 10. Agarose gel electrophoresis of plasmid DNA (form I) photosensitized with porphyrins **2**−**8** in the presence of 0.1 M sodium azide for 45 min. Lane 1 contains only DNA. Lanes 2 and 3: DNA photostosenstized with porphyrin **2** in the presence and absence of 0.1 M sodium azide, respectively. Lanes 4 and 5: DNA photostosensitized with porphyrin **3** in the presence and absence of 0.1 M sodium azide, respectively. Lanes 6 and 7: DNA photostosenstized with porphyrin **4** is the presence and absence of 0.1 M sodium azide, respectively. Lanes 8 and 9: DNA photostosensitized with porphyrin **5** is the presence and absence of 0.1 M sodium azide, respectively. Lanes 10 and 11: DNA photostosensitized with porphyrin **7** is the presence and absence of 0.1 M sodium azide, respectively. Lanes 12 and 13: DNA photostosensitized with porphyrin **8** in the presence and absence of 0.1 M sodium azide, respectively.

Table 3

porphyrin	% of DNA form I cleaved at 15 min	% of DNA form I cleaved at 60 min
1		
2	38.33	88.31
3	49.81	93.67
4	50.73	91.22
5	95.86	100
6		
7	33.44	80.44
8	39.20	80.27

Binding Characteristics. The hypochromicity values obtained for the interaction of compounds **5**, **6**, and **8**, with calf thymus DNA are 49.0, 42.7, and 41.0%. The hypochromicity values obtained for the other porphyrins are in the range 25.4−33.5%. In the literature, hypochromicity values greater than 35% have been considered as one of the characteristics of intercalators (*1*, *3*, *5*). Interaction of all the porphyrins, with poly[d(A.T)].poly[d(A.T)] and poly[d(G.C)].poly[d(G.C)], also resulted in hypochromic shifts in the absorbance of the Soret band. However, for all the porphyrins except **3**, higher hypochromicity value was obtained upon interaction with poly[d(G.C)].poly[d(G.C)] than poly[d(A.T)].poly[d(A.T)], probably indicating a slight preference for GC rich sites.

The nature of the binding of the porphyrins to the DNA has been generally interpreted from the shape of the induced CD bands obtained upon the interaction of the porphyrins with calf thymus DNA, poly[d(G.C)].poly[d(G.C)] and poly[d(A.T)].poly[d(A.T)]. In general, intercalation of the porphyrins is usually seen at GC-rich sites and is denoted by negative peaks in the CD spectrums with calf thymus DNA and poly[d(G.C)].poly[d(G.C)] (*3*, *5*, *38*−*40*), whereas outside binding has usually been observed at AT-rich sites and is denoted by positive peaks in the CD spectrums with calf thymus DNA and poly[d(A.T)].poly[d(A.T)] (*5*, *38*, *39*). The interpretations of the CD spectrums obtained for all porphyrins upon interaction with calf thymus DNA, poly[d(A.T)].poly[d(A.T)] and poly[d(G.C)].poly[d(G.C)] as well as the results from the unwinding assay can be interpreted as follows. (a) Porphyrin **2** shows a positive peak with calf thymus DNA (Figure 5a) and poly[d(A.T)].poly[d(A.T)] (Figure 6a) and weak positive and negative peaks with poly[d(G.C)].poly[d(G.C)] (Figure 7a), indicating an outside binding mode with preference to AT. The negative peak with poly dG.dC does point toward a small amount of binding at GC sites. The unwinding assay also indicates that this compound does not intercalate (Figure 8a). (b) Porphyrin **3** shows a weak positive peak and a weak negative peak with calf thymus DNA (Figure 5a), a weak negative peak with poly[d(A.T)].poly[d(A.T)] (Figure 6a), and a strong positive peak with poly[d(G.C)].poly[d(G.C)] (Figure 7a). Binding at GC-rich sites is generally by intercalation and indicated by a negative peak upon binding to poly[d(G.C)].poly[d(G.C)], hence the positive peak upon interaction with GC-rich sites could indicate an outside binding mode.

(c) Porphyrins **4**, **6**, and **7**; all three porphyrins show a strong negative peak in the visible CD with CT.DNA (Figure 5), a weak negative peak with poly[d(A.T)].poly[d(A.T)] (Figure 6), and a strong negative peak with poly[d(G.C)].poly[d(G.C)] (Figure 7). The nature of the peaks obtained indicate an intercalative mode of binding with preferential binding to GC-rich sites, with some binding to AT sites. However, the unwinding assays (Figure 8, panels c and d) indicate that these compounds are able to unwind the DNA to only a smaller extent. The combined results from these two assays point toward an outside binding mode with at GC-rich sites. (d) Porphyrin **5** shows a broad negative peak with calf thymus DNA and poly[d(A.T)].poly[d(A.T)] and a strong negative peak with poly[d(G.C)].poly[d(G.C)]. The CD spectrums indicate an intercalative mode of binding at GC-rich sites and also a weak binding at AT sites. However, the negative CD pattern upon interaction with poly[d(A.T)].poly[d(A.T)] is unusual as compared to meso-substituted porphyrins, wherein a positive ellipticity is obtained for binding at AT sites. The unwinding assay also indicates that this porphyrin does intercalate into DNA. (e) Porphyrin **8** shows very weak negative peak in the visible range spectrums with calf thymus DNA (Figure 5b) and poly[d(A.T)].poly[d(A.T)] (Figure 6b). A strong negative peak as well as a small positive peak is obtained in visible range with poly[d(G.C)].poly[d(G.C)] (Figure 7b). The negative peak obtained upon binding of **8** to poly[d(G.C)].poly[d(G.C)] indicates intercalation at GC sites. The small positive peak does point toward a small amount of outside binding at GC-rich sites. The unwinding assay also indicates an intercalative mode of binding.

DNA Cleavage Characteristics. The amount of DNA cleaved by the various porphyrins upon exposure to light for 15 and 60 min is shown in Table 3. The factors affecting the efficiency of DNA cleavage seem to be complex (*37*), however, certain porphyrins, structural characteristics needed for efficient cleavage of DNA can be elicited from these data. Among the factors that affect the cleavage efficiency are (a) the number of charges, (b) length and position of the side chain connecting the cationic substituent to the porphyrin macrocycle, and (c) the presence of chelated metal at the core of the porphyrin ring.

(a) Number of Charges. Our studies with various cationic porphyrins show that a minimum of two charges is needed for the binding and cleavage of DNA by cationic porphyins. For example, montocationic porphyrin **1** did not show any cleavage of DNA even after incubation with light 90 min under the condition used for all the other porphyrins.

(b) Length of the Side Chain of the Cationic Substituents. Dicationic porphyrins **2** and **4** are both linked to the porphyrin macrocycle by side chains at positions 3 and 8. However, in porphyrin **4**, the length of the side chain is extended by two more carbon atoms. This increase in the length of the side chain is seen to increase the efficiency of cleavage. Porphyrin **2** is able to convert 38.33% of DNA form I to form II and form III in the presence of light for 15 min; however, under the same conditions, porphyrin **4** is able to cleave 50.73% of DNA form I to DNA form II.

(c) Position of the Cationic Substituent on the Porphyrin System. In our attempts to understand the effect of the position of the cationic charges, porphyrins **4** and **7** were used as sensitizers. In porphyrin **4**, the charged group is substituted at positions 3 and 8, whereas in compound **7**, the charged groups are present at positions 3 and 13 of the porphyrin ring system. Porphyrin **4** converted 50.73% of the DNA form I to form II and form III in 15 min (Figure 9a, lane 12), and under the same conditions, porphyrin **7** was able to convert 33.44% of the DNA form I to form II (Figure 9b, lane 3).

(d) Effect of Chelated Metal. Compared to the nonmetalated analogues **2**, **4**, and **7**, the zinc analogues **3**, **5**, and **8** were found to have a higher efficiency of photocleavage of DNA.

CONCLUSION

The absorption, circular dichroism, unwinding assays, and the DNA photocleavage evidence from the present study shows that non-meso-substituted cationic porphyrins bind, as well as photocleave, DNA efficiently. On the basis of the DNA-binding studies and unwinding assays, it is suggested that the nature of binding of non-meso-substituted cationic porphyrins is different from that of the cationic meso-substituted pyridyl porphyrins. The results from the absorption spectroscopy, CD, and unwinding studies point toward intercalation as a mode of binding for the Zn(II) porphyrins **5** and **8**. The nature of the binding obtained for zinc porphyrins **5** and **8** is surprising, due to the presence of the nonplanar substituents as well as the presence of metal zinc, both of these characteristics are thought to block intercalation (*5*, *41*, *42*). Furthermore, the negative ellipticity obtained in the visible CD spectrums with calf thymus DNA and poly-[d(G.C)].poly[d(G.C)] for porphyrins **4**, **6**, and **7** indicate an intercalative mode of binding; however, this binding mode is not supported by unwinding assay. Again, the positive peak with poly[d(G.C)].poly[d(G.C)] and negative peak with poly[d(A.T)].poly[d(A.T)] for porphyrin **3** completely differ from the ellipticity obtained under similar conditions for meso-substituted cationic porphyrins. These studies show that the binding of porphyrins is complex, and from the presently existing model with meso-substituted cationic porphyrins, it is difficult to come to any precise conclusion regarding the binding mode obtained for non-meso-substituted cationic porphyrins. Clearly, further research in this area is needed to understand the binding characteristics of these types of porphyrins to DNA. To shed more light on the exact nature of the binding of these porphyrins to DNA, molecular modeling and DNA footprinting studies are underway.

ACKNOWLEDGMENT

We thank Drs. R. J. Fiel, T. J. Dougherty, and R. Shibata for their suggestions during this project. We also thank Drs. M. J. Levine and N. Ramasubbu (Research Center in Oral Biology, SUNY, Buffalo) for allowing us the use of Jasco J-600 spectropolarimeter (supported by Grant DE 08240).

(37) The factors influencing the relative photocleavage efficiencies of the different chromophores, other than their structural differences, are complex and could reflect affects such as binding affinities and singlet oxygen quantum yield. As suggested by one of the reviewers, another important factor that can effect the DNA cleaving efficiency is the exact number of porphyrin molecules bound to double stranded DNA, which is difficult to establish, due to aggregation effects.

Evaluation of the in Vivo Biodistribution of Indium-111 and Yttrium-88 Labeled Dendrimer-1B4M-DTPA and Its Conjugation with Anti-Tac Monoclonal Antibody†

Hisataka Kobayashi,‡ Chuanchu Wu,§ Meyoung-Kon Kim,‡ Chang H. Paik,‡ Jorge A. Carrasquillo,*,§ and Martin W. Brechbiel§

National Institutes of Health, Bethesda, Maryland 20892. Received August 4, 1998; Revised Manuscript Received September 29, 1998

We evaluated the in vivo biodistribution of indium- and yttrium-labeled second-generation polyamidoamine dendrimer (PAMAM) conjugated with 2-(*p*-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M), a derivative of DTPA. In addition, we conjugated PAMAM-1B4M to humanized anti-Tac IgG (HuTac) and evaluated its in vitro and in vivo properties. PAMAM-1B4M was labeled with ^{111}In at 37−48 MBq/mg (1.0−1.3 mCi/mg) or with ^{88}Y at 3.7−4.8 MBq/mg (0.1−0.13 mCi/mg), and an aliquot of radiolabeled conjugate was saturated with the corresponding stable yttrium or indium. Nontumor-bearing nude mice were injected intravenously with 55.5−66.6 kBq (1.5−1.8 μCi) of ^{88}Y-labeled PAMAM-1B4M or with 185 kBq (5 μCi) of ^{111}In-labeled PAMAM-1B4M. The mice were then sacrificed at 15 min, 90 min, 1 day, and 4 days postinjection. Then the PAMAM-1B4M was conjugated with HuTac and labeled with ^{111}In at 111−259 MBq/mg (3−7 mCi/mg). Another preparation of ^{111}In-labeled HuTac-PAMAM-1B4M was saturated with stable indium. Immunoreactivity of both preparations and biodistribution in normal mice 1 h after injection and in ATAC4 and A431 tumor-bearing mice 18 h after injection were evaluated and compared with those of ^{111}In-labeled 1B4M-HuTac. We noted significantly higher accumulations ($p < 0.05$) of ^{111}In-labeled and ^{88}Y-labeled unsaturated PAMAM-1B4M than saturated preparations in the liver, kidney, spleen, and bone at most time points. The whole-body clearance times of unsaturated preparations were significantly slower than those of saturated preparations at all time points, with the exception of 168 h for ^{111}In-labeled PAMAM-1B4M. The saturated preparation of ^{111}In-labeled HuTac-PAMAM-1B4M showed lower hepatic uptake (27 ± 2%ID/g) than the unsaturated (32 ± 2%ID/g), but greater than the HuTac-1B4M control (10 ± 0%ID/g). The splenic uptake showed 15 ± 1, 38 ± 5, and 8 ± 1%ID/g for the saturated, unsaturated, and control, respectively. The biodistribution of the dendrimer conjugated HuTac in normal organs of tumor-bearing mice was similar to nontumor-bearing mice. Specific tumor (ATAC4) uptake was higher than that in nonspecific tumor (A431). In conclusion, we evaluated the biodistribution of radiolabeled PAMAM-1B4M. We noted high accumulation in the liver, kidney, and spleen, which significantly decreased when the chelates were saturated with the stable element. A similar phenomenon was observed between unsaturated and saturated ^{111}In-labeled HuTac-PAMAM-1B4M, indicating that the PAMAM dendrimer had a detrimental effect on biodistribution.

INTRODUCTION

Starburst polyamidoamine (PAMAM)[1] dendrimers are a new class of highly branched spherical polymers that are highly soluble in aqueous solution and have a unique surface of primary amino groups (*1*, *2*). Compared with many other types of dendritic macromolecules that recently have been synthesized, PAMAM dendrimers are the only class of macromolecules that are unidispersed and show high charge densities restricted to the surface of the molecule (*3*). The defined structure and large number of surface amino groups of PAMAM dendrimers have led to their use as substrates for the attachment of chelating agents to antibodies (*2*, *4*, *5*) and in the preparation of novel magnetic resonance imaging (MRI) contrast agents (*6*). In addition, they have been used successfully to transfer nucleic acids into mammalian cells (*7*, *8*).

Radiolabeled antibodies have been extensively evaluated for radioimmunodetection and radioimmunotherapy of cancer (*9*−*11*). In addition to ^{131}I, ^{90}Y has been used for radioimmunotherapy (*12*−*14*). Initially, cyclic or mixed anhydride of diethylenetriaminepentaacetic acid (DTPA) was used for ^{90}Y labeling. Unfortunately, this chelate was not optimal since it prematurely released the ^{90}Y, which increased bone uptake (*15*, *16*). More stable chelates have since been generated (*17*, *18*) to address this problem. While 1,4,7,10-tetraazacyclododecane tetraacetic acid (DOTA), a macrocyclic chelating agent, has

excellent stability in vivo and in vitro for ^{90}Y, the metal−DOTA complex is slow to form (*16*, *19*). Approaches that may overcome this problem include prolonged incubation with the ^{90}Y or high doses of ^{90}Y, which may damage the antibody's immunoreactivity if radioprotectants are not used (*20*). Another approach is that of using higher temperature incubations (*21*), although in our experience, we have not been greatly successful with this approach (*2*), perhaps because of the DOTA variant that we utilized. Although large numbers of chelating groups can be conjugated to the antibody in an attempt to improve the kinetics, this often results in a drop in immunoreactivity (*22*). Problems similar to those encountered with ^{90}Y are likely to be encountered with α emitters, such as ^{212}Bi or ^{213}Bi that are being investigated for radioimmunotherapy. Previous work has attempted to take advantage of PAMAM dendrimers by conjugating multiple chelates to the dendrimer and attaching this dendrimer-chelate construct to the antibody through a single attachment site (*2*). Wu et al., using a second-generation ($G = 2$) PAMAM dendrimer, were able to attach either 2-(*p*-isothiocyanatobenzyl) (p-SCN-Bz)-DOTA or 2- (p-SCN-Bz)-cyclohexyl-diethylenetriaminepentaacetic acid (CHX) chelates to the dendrimer, and their preliminary in vitro results indicated a potential for greatly improving the radiolabeling kinetics and the specific activity of the ^{90}Y- or ^{212}Bi-labeled monoclonal antibody, a noted hindrance for the routine use of DOTA conjugated to antibodies in the conventional way (*2*). In addition, antibodies have been considered as targeting agents to be used with MRI. In this case, high molar concentrations are required with atom such as gadolinium (*6*). This study is an in vivo extension of our previous work (*2*).

We evaluated the biodistribution of a monoclonal antibody labeled with ^{111}In via a PAMAM dendrimer conjugated to 1B4M chelate (*16*). Because preliminary in vivo studies with this reagent showed large uptakes in liver and spleen, we evaluated the biodistribution of the PAMAM-1B4M labeled with ^{111}In and ^{88}Y, which was not conjugated to an antibody. In addition, we determined whether saturating the PAMAM-1B4M conjugate with stable indium or yttrium would alter its biodistribution. We chose to work with 1B4M rather than DOTA because of its greater availability and in order to provide proof-of-principal.

MATERIALS AND METHODS

Monoclonal Antibody. The anti-Tac IgG2a was produced and characterized as previously described (*23*). The humanized anti-Tac antibody (HuTac) was genetically constructed, as previously described, by combining the complementarity-determining regions of the murine anti-Tac antibody with the human IgG1κ framework and constant regions (*24*).

Conjugation of Chelates to Dendrimer. We used second-generation PAMAM dendrimer with an ethylenediamine core that possesses 16 amino groups and has a molecular mass of 3256 Da (Aldrich Chemical Co., Milwaukee, WI) (*1*). This dendrimer (10 μM in 10 mL of H_2O) was reacted with 240 μmol of 2-(*p*-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M) at 40 °C, adjusted to pH 9 with 1 M NaOH, for 24 h. One-half of the 1B4M was added at the beginning, and the remainder was added after 8 h as a solid form. The resulting preparations were purified by diafiltration using a stirred cell (Amicon Co., Beverly, MA) with a 3 kDa membrane (Omega 3K; Filtron Technology Co., Northborough, MA). This resulted in an average of 14.3 1B4M ligands on a dendrimer, as determined by a colorimetric assay (*25*). An average of one free amine was available for further chemical reaction and conjugation to the monoclonal antibody, as described below.

Conjugation of Dendrimer-Chelates with Antibody. The method of conjugation of PAMAM-1B4M with antibody was performed as previously described (*2*). Briefly, to provide a free thiol group, the remaining primary amine on the PAMAM-1B4M constructs was reacted with a 5-fold molar excess of sulfosuccinimidyl 6-[3′-(2-pyridyldithio)propionamido]hexanoate (sulfo-LC-SPDP, Pierce Chemical Co., Rockford, IL), in 0.1 M HEPES buffer, at pH 8.5 for 1 h at room temperature. A free sulfhydryl group was generated by reacting the above product with solid dithiothreitol for 15 min at a final concentration of 25 mM. The product was purified by diafiltration using a stirred cell (Amicon Co.) with a 3 kDa membrane (Omega 3K; Filtron Technology Co.).

The HuTac (5 mg/mL) was first reacted with sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SMCC; Pierce Chemical Co.) in bicarbonate buffer, pH 8.5, at room temperature for 20 min, at an initial sulfo-SMCC-to-HuTac ratio of 4:1. The unreacted reagent was removed by Sephadex G50 size-exclusion chromatography with aqueous 0.02M Bis-Tris/HCl and 0.1 M NaCl, pH 7.0, as eluant.

The thiol-containing PAMAM-1B4M construct was then conjugated with HuTac-SMCC at pH 7.0, at room temperature for 30 min, at a 1.5:1 molar ratio, respectively. HuTac-PAMAM-1B4M conjugates were separated from unmodified antibody, unreacted PAMAM-1B4M, and higher-molecular-weight species, which arose from multiple sulfhydryl groups attached to the dendrimer, by HPLC using a MONO Q anion-exchange column (5 × 600 mm, Pharmacia, Uppsala, Sweden) coupled in tandem with a TSK 3000SW preparative size-exclusion column (21 × 600 mm, Toso Haas, Tokyo, Japan) by a Pharmacia V7 valve eluted with 0.05 M PBS, pH 7.2, at a flow rate of 1.0 mL/min. The mean ratio of dendrimer to antibody was 0.8−1:1 (*2*). Isoelectric focusing experiments on a PhastGel IEF 3-9 (Pharmacia Biotech AB, Uppsala, Sweden) with the Phast System (Pharmacia Biotech AB) to determine the pI of PAMAM-1B4M were not successful because PAMAM-1B4M stayed at the site of application.

Radiolabeling of PAMAM-1B4M or HuTac-PAMAM-1B4M. Carrier-free $^{111}InCl_3$ was purchased from NEN DuPont (Boston, MA). Carrier-free ^{88}Y (Los Alamos National Laboratory, Los Alamos, NM) was further purified from metal contaminants by column extraction chromatography (*26*). The PAMAM-1B4M or HuTac-PAMAM-1B4M conjugates were reacted with ^{111}In or ^{88}Y at pH 5.5−6.5 for 30 min at room temperature as previously described (*2*, *16*, *18*, *26*). To remove any nonincorporated free radiometal, 10 μL of 0.1 M EDTA was added and purified by HPLC using a TSK 3000 SW size-exclusion column (Toso Haas) eluted with PBS, pH 7.2, at a flow rate of 1.0 mL/min. The resulting purified materials were referred to as "unsaturated" because on the average they had <1 radiometal (^{111}In or ^{88}Y) per molecule.

To evaluate the effect on biodistribution of saturating the 1B4M chelates, the PAMAM-1B4M or HuTac-PAMAM-1B4M was saturated with either nonradioactive indium or yttrium. Preparation method was the same as described above, except that excess cold indium or yttrium chloride was added to the reaction mixture and incubated for 5 min before the addition of EDTA and column purification. Radiolabeling yields were >85% for

all the conjugates, and their specific activities ranged from 3.7 to 4.8 MBq/mg (0.1−0.13 mCi/mg) for ^{88}Y-labeled PAMAM-1B4M; 37−48 MBq/mg (1.0−1.3 mCi/mg) for ^{111}In-labeled PAMAM-1B4M; and 111−259 MBq/mg (3−7 mCi/mg) for ^{111}In-labeled HuTac-PAMAM-1B4M.

All radiolabeled PAMAM-1B4M preparations, including the HuTac conjugates, were analyzed by HPLC using TSK 2000SW (Toso Haas) size-exclusion columns connected to an on-line γ detector (γRAM, IN/US Systems, Inc., Fairfield, NJ). The columns were eluted with 0.067 M PBS, 0.1 M KCl buffer (pH 6.8), with a flow rate of 0.5 mL/min. The same HPLC system was used to analyze collected urine.

Immunoreactivity. The immunoreactivity of the radiolabeled monoclonal antibody was determined by use of a modification of the cell-binding assay of Lindmo et al. (*27*) as we previously described (*28*). Aliquots of the ^{111}In-labeled HuTac-PAMAM-1B4M (3 ng/100 μL) were incubated for 2 h at 4 °C with 1×10^6 to 4×10^7 SP2/Tac cells. The cell-bound radioactivity was separated by centrifugation and counted in a γ counter. Nonspecific binding to the cells was examined under conditions of antibody excess (25 μg of nonradiolabeled anti-Tac antibody). As a control, we determined the immunoreactivity of ^{111}In-labeled 1B4M-HuTac.

Tumor-Bearing Animal Models. Tumor xenografts were generated with the ATAC4 cell line, which expresses the IL-2Rα receptor but does not secrete it into the circulation. This cell line was generated by genetically transfecting the plasmid encoding the IL-2Rα and a neomycin-resistant gene into receptor-negative A431 cells (*29*). The A431 cells, which were obtained originally from G. Todaro (National Institutes of Health, Bethesda, MD), are a human epidermoid carcinoma line that does not express IL-2Rα. Both cell lines were grown in RPMI 1640 medium (GIBCO Laboratories, Grand Island, NY) containing 10% fetal calf serum (GIBCO Laboratories, Grand Island, NY) and 0.03% L-glutamine, at 37 °C, in 5% CO_2, which was occasionally supplemented with 750 mg/mL sulfate Geneticin (GIBCO Laboratories) to avoid the growth of transformed ATAC4 cells. Tumor xenografts were established by s.c. inoculation of 4×10^6 ATAC4 and 5×10^6 A431 cells. The ATAC4 tumors in this study were 0.68 ± 0.31 g and the A431 were 0.55 ± 0.10 g in the HuTac-PAMAM-1B4M group and 0.76 ± 0.12 g for ATAC4 and 0.49 ± 0.14 g for the A431 tumor in the HuTac-1B4M control group.

Biodistribution Study. Biodistribution studies were performed in 5−6-week-old female athymic nude mice weighing 16−21 g (Harlan Sprague Dawley, National Cancer Institute, Frederick, MD). All studies were approved by the Clinical Centers' Animal Care and Use Committee. Mice were euthanized with CO_2 inhalation and exsanguinated by cardiac puncture prior to dissection. Aliquots of blood and all major organs were removed, weighed on an analytical balance, and the radioactivity was counted in a well-type γ counter (Autogamma, Packard Instrument Company, Downers Grove, IL). All data were decay corrected. When dual isotope studies were performed, the counts were corrected for decay and spillover. Under our counting conditions, ^{111}In (100−500 keV) had a 0.02% spillover and ^{88}Y (600−2000 keV) a 42% spillover into each other's window. The whole-body clearance was determined by summing the radioactivity measured in blood, individual organs, and in the remaining carcass. Random urine samples were taken shortly before sacrifice and analyzed with a size-exclusion HPLC system.

The biodistribution of ^{111}In-labeled unsaturated or saturated HuTac-PAMAM-1B4M was evaluated in two groups of three mice each. In addition, as a control, ^{111}In-labeled 1B4M-HuTac was injected into six mice. These groups of nontumor-bearing nude mice were sacrificed at 1 h after injection, and biodistribution studies were performed. In addition, two groups of three tumor-bearing mice each underwent a biodistribution study 18 h after injection of ^{111}In-labeled unsaturated HuTac-PAMAM-1B4M or ^{111}In-labeled 1B4M-HuTac.

Two groups of four mice each were injected i.v. with ^{111}In-labeled unsaturated [185 kBq (5 μCi)] or saturated [185 kBq (5 μCi)] PAMAM-1B4M and sacrificed at 15 min, 45 min, 90 min, 360 min, 24 h, 48 h, and 96 h after injection. Another two groups of four mice each received ^{88}Y-labeled unsaturated [62.9 kBq (1.7 μCi)] or saturated [55.5 kBq (1.5 μCi)] PAMAM-1B4M, and were then sacrificed at 15 min, 90 min, 24 h, and 96 h after injection. Biodistribution studies and whole-body clearance were performed as described above. In addition, urine was collected and analyzed at 15, 45, and 90 min to evaluate the urinary excretion of the radiolabeled PAMAM-1B4M.

To validate the reproducibility from one labeling to another, on the biodistribution of unsaturated and saturated PAMAM-1B4M, we co-injected ^{111}In-labeled and ^{88}Y-labeled unsaturated PAMAM-1B4M in one group of four mice and ^{111}In-labeled and ^{88}Y-labeled saturated PAMAM-1B4M in another group of four mice. The biodistribution was then evaluated at 15 min, 90 min, 24 h, and 96 h after injection.

To determine if the metal ion used to saturate the PAMAM-1B4M affected its biodistribution, cross-saturation studies were performed. PAMAM-1B4M trace-labeled with ^{111}In [185 kBq(5 μCi)] was saturated with cold yttrium, or ^{88}Y trace-labeled PAMAM-1B4M [55.5 kBq (1.5 μCi)] was saturated with cold indium. Mice were injected i.v. with these reagents and sacrificed at 15 min, 90 min, 24 h, and 96 h after injection. The biodistribution study was done as described above.

Statistical Analysis. We performed the statistical analysis using the one-way analysis of variance (ANOVA), with pairwise comparison using the Bonferroni method (Sigmastat, Jandel Scientific, San Rafael, CA).

RESULTS

Quality Control and Immunoreactivity. Radiochemical purity of all the ^{111}In-labeled HuTac-PAMAM-1B4M and ^{111}In-labeled or ^{88}Y-labeled PAMAM-1B4M preparations were >99% as determined by size-exclusion HPLC. Although the total binding was similar for both preparations, the nonspecific binding for the HuTac-PAMAM conjugates was higher and therefore had slightly lower immunoreactivity than that of the ^{111}In-labeled 1B4M-HuTac (Table 1) these immunoreactivity levels are similar to those we have observed for ^{125}I-labeled HuTac.

Biodistribution Studies. The ^{111}In-labeled unsaturated HuTac-PAMAM-1B4M showed higher hepatic and splenic accumulation than the ^{111}In-labeled saturated HuTac-PAMAM-1B4M (Table 2). However, the hepatic and splenic accumulation of ^{111}In-labeled saturated HuTac-PAMAM-1B4M was still significantly higher than that of ^{111}In-labeled 1B4M-HuTac ($p < 0.001$, Anova). The blood clearance of both unsaturated and saturated ^{111}In-labeled HuTac-PAMAM-1B4M were much faster than that of ^{111}In-labeled 1B4M-HuTac. Additional biodistribution studies were performed at 18 h to evaluate delayed kinetics and tumor uptake. As noted in the 1 h

Table 1. Immunoreactivity Test for ^{111}In-Labeled HuTac-PAMAM-1B4M and ^{111}In-Labeled 1B4M-HuTac

	^{111}In-labeled HuTac-PAMAM-1B4M (unsaturated)	^{111}In-labeled HuTac-PAMAM-1B4M (saturated)	^{111}In-labeled 1B4M-HuTac

[a] Data are expressed %ID/g ± SD.

biodistribution results in nontumor-bearing nude mice, the blood clearance of the ^{111}In-labeled HuTac-PAMAM-1B4M was faster than that of ^{111}In-labeled HuTac-1B4M. Although specific tumor uptake was seen at 18 h, the tumor uptake for the HuTac-PAMAM-1B4M was lower than that for HuTac-1B4M (Table 3).

The blood clearance of both ^{111}In- and ^{88}Y-labeled PAMAM-1B4M was rapid. The greatest concentrations of ^{111}In- and ^{88}Y-labeled PAMAM-1B4M were in the kidney, liver, spleen, and bone. There were very few differences in organ accumulation amounts of either the unsaturated ^{111}In- or the unsaturated ^{88}Y-labeled PAMAM-1B4M (Table 4). Significant differences between unsaturated and saturated preparations were seen in the biodistribution of both ^{111}In-labeled (Figure 1) and ^{88}Y-labeled PAMAM-1B4M (Figure 2). For both ^{111}In-labeled and ^{88}Y-labeled PAMAM-1B4M, saturation with their respective nonradioactive metals resulted in decreased activity of ^{111}In or ^{88}Y in the liver, kidney, spleen, and bone ($p < 0.05$).

The whole-body clearances were also significantly faster for saturated than unsaturated preparations radiolabeled with ^{111}In or ^{88}Y at all time ($p < 0.01$), except 168 h for ^{111}In-labeled PAMAM-1B4M (Figure 3). Both ^{111}In-labeled and ^{88}Y-labeled PAMAM-1B4M, unsaturated and saturated, were excreted into the urine, and HPLC analysis showed that the excreted products had the same retention time as the intact dendrimer (data not shown).

The co-injection studies with ^{111}In- and ^{88}Y-labeled unsaturated PAMAM-1B4M or ^{111}In- and ^{88}Y-labeled saturated PAMAM-1B4M showed similar biodistribution for these as for single isotopes (data not shown).

The ^{111}In-labeled PAMAM-1B4M saturated with cold yttrium showed significantly lower hepatic, renal, and splenic accumulations than either the ^{111}In-labeled unsaturated PAMAM-1B4M or the ^{111}In-labeled PAMAM-1B4M saturated with cold indium ($p < 0.05$; except in the spleen at 15 min). Although ^{88}Y-labeled PAMAM-1B4M saturated with cold indium showed lower hepatic

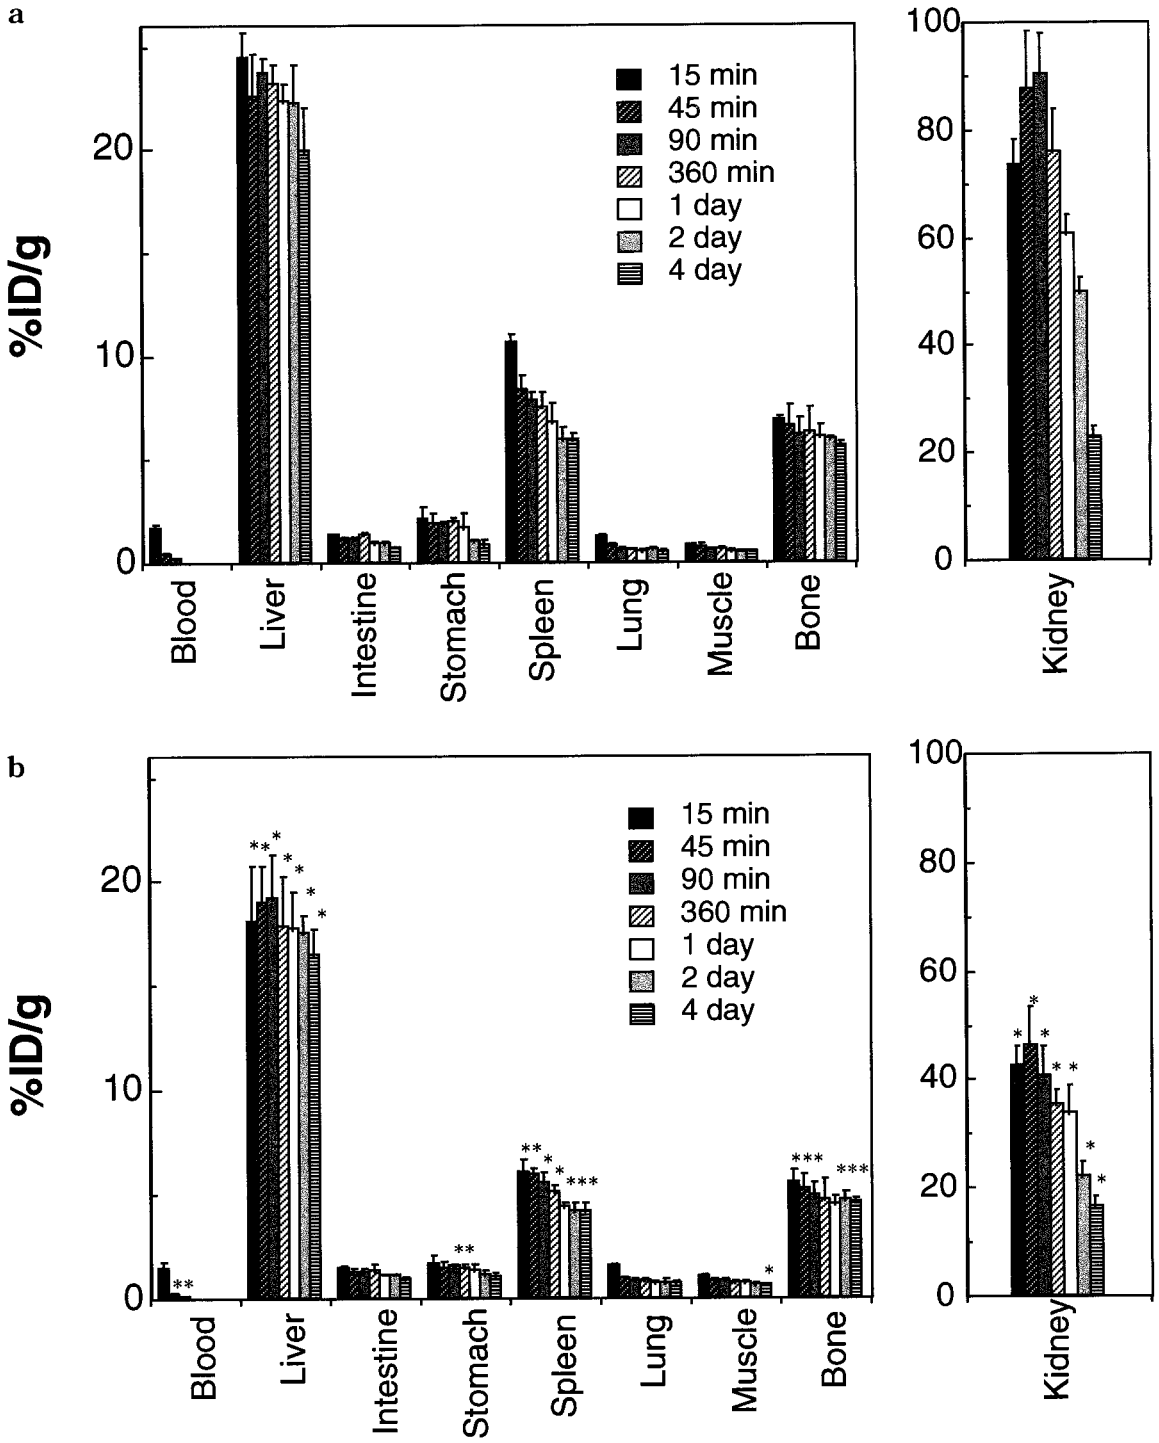

Figure 1. Plots of the biodistribution of ^{111}In-labeled PAMAM-1B4M (a) and ^{111}In-labeled PAMAM-1B4M saturated with cold indium (b). Nontumor-bearing nude mice were sacrificed in groups of four at 15 min, 45 min, 90 min, 360 min, 24 h, 48 h, and 96 h postinjection. The percentages of the injected dose per gram of tissue (%ID/g) in all major organs and in blood are shown. Data are expressed as means ±SD. The asterisks in panel b indicate significant differences ($p < 0.05$) compared with ^{111}In-labeled unsaturated PAMAM-1B4M.

and renal accumulations than ^{88}Y-labeled unsaturated PAMAM-1B4M ($p < 0.05$; except in the liver at 4 day), ^{88}Y-labeled PAMAM-1B4M saturated with cold indium showed higher hepatic and splenic accumulation than that saturated with cold yttrium ($p < 0.01$; except in the kidney at 90 min) (Table 4). The whole-body clearance showed that the saturated PAMAM-1B4M cleared more rapidly than the nonsaturated ($p < 0.01$; except for ^{111}In saturated with cold indium at 4 days) and that the PAMAM-1B4M saturated with yttrium cleared the fastest ($p < 0.01$) (Figure 3).

DISCUSSION

As far as we know, this is the first study to evaluate the biologic properties of an antibody that has been radiolabeled via a dendrimer-chelate combination. A few studies have investigated the use of antibody-dendrimer conjugates for tumor targeting (*2*, *4*, *30*). As expected from such work, attaching a dendrimer to the antibody had little effect on its immunoreactivity (*2*, *4*, *5*). Although retention of immunoreactivity is a prerequisite

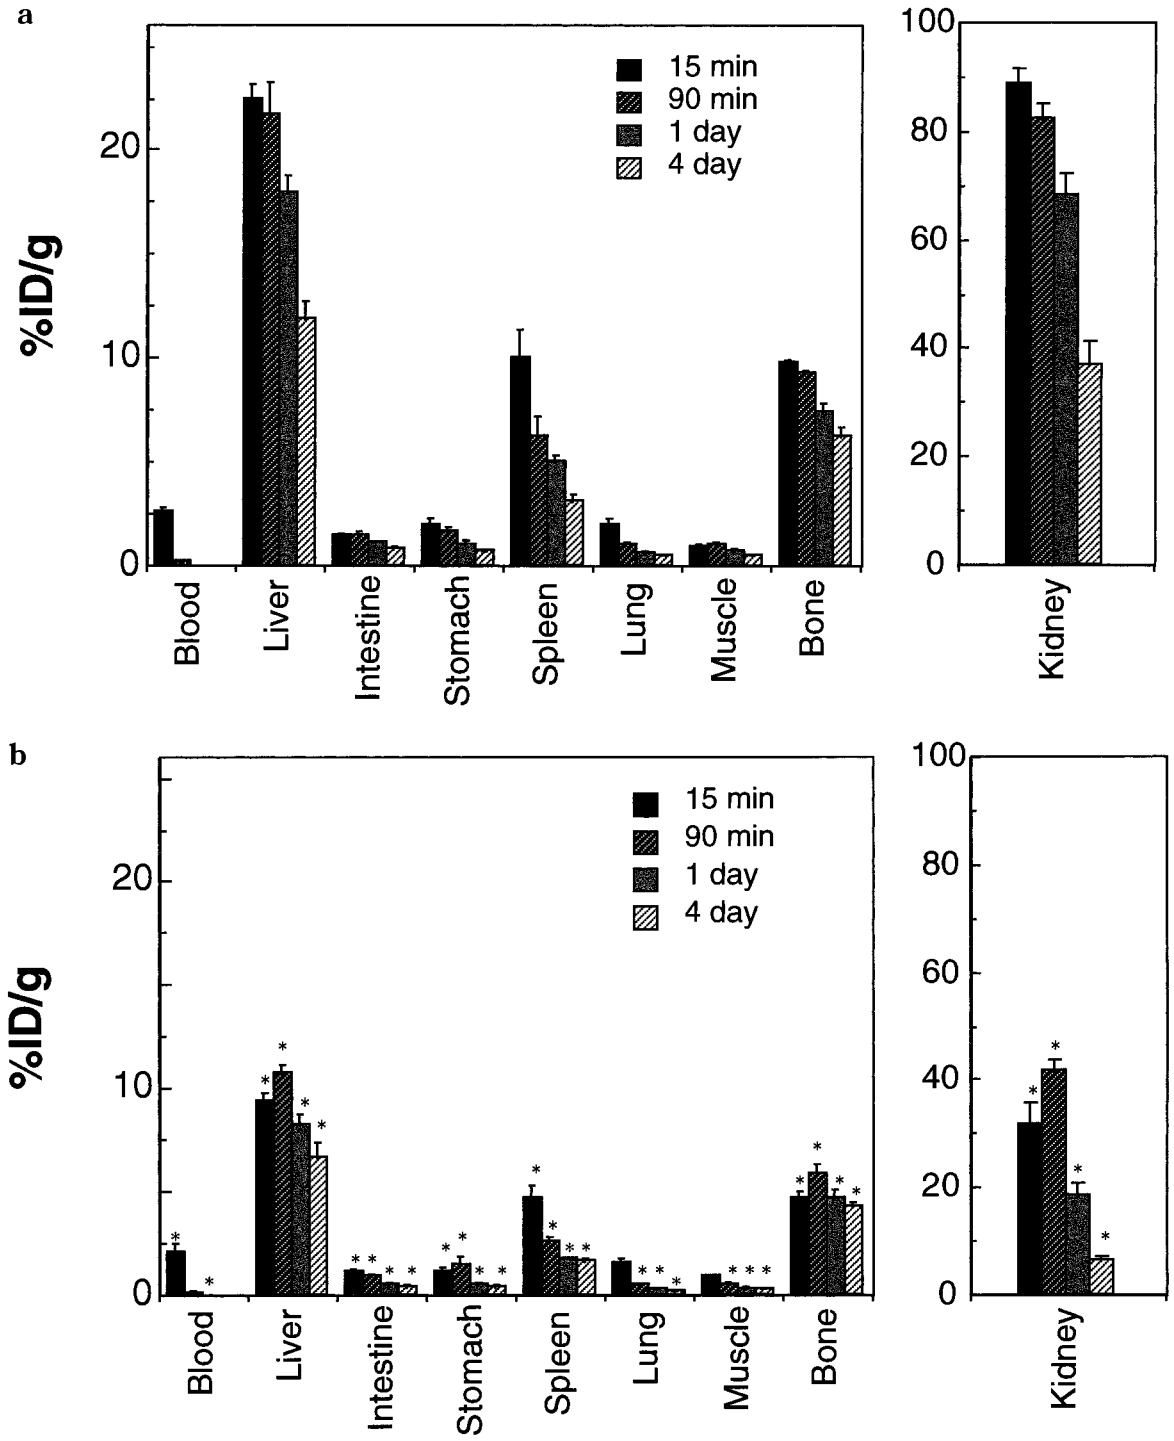

Figure 2. Plots of the biodistribution of ^{88}Y-labeled PAMAM-1B4M (a) and ^{88}Y-labeled PAMAM-1B4M saturated with cold yttrium (b) in nontumor-bearing mice. Animals were sacrificed in groups of four at 15 min, 90 min, 24 h, and 96 h postinjection. The percentages of the injected dose per gram of tissue (%ID/g) in all major organs and in blood are shown. Data are means ±SD. The asterisks in panel b indicate significant differences ($p < 0.05$) compared with ^{88}Y-labeled unsaturated PAMAM-1B4M.

when labeling an antibody, it is also important that the radiolabeling process not adversely affect the biodistribution.

Unfortunately, our results show that the ^{111}In-labeled HuTac-PAMAM-1B4M has altered clearance when compared to the HuTac conventionally labeled with ^{111}In. These altered kinetics were unfavorable because there was fast clearance from the blood and higher clearance into the liver and spleen. This was similar to what was reported by Barth et al., when they used a dendrimer labeled directly with Bolton−Hunter reagent (*4*). While this suggested that the faster clearance was related to the dendrimer itself, the alteration in clearance between saturated and unsaturated antibody conjugates suggested that additional factors related to the 1B4M metal complex itself were important. Roberts et al. evaluated the biodistribution in mice of [^{14}C]methylated dendrimers ranging from third to seventh generation (*31*). Their study of the methylated third generation dendrimer ($G = 3$), which is one generation larger than the one we studied, showed accumulation in liver, spleen, kidney, and pancreas. Methylated $G = 3$ has a molecular mass of 5.2 kDa, which is smaller than that of PAMAM-1B4M, ranging 7.6−9.3 kD. The surface charge on the methy-

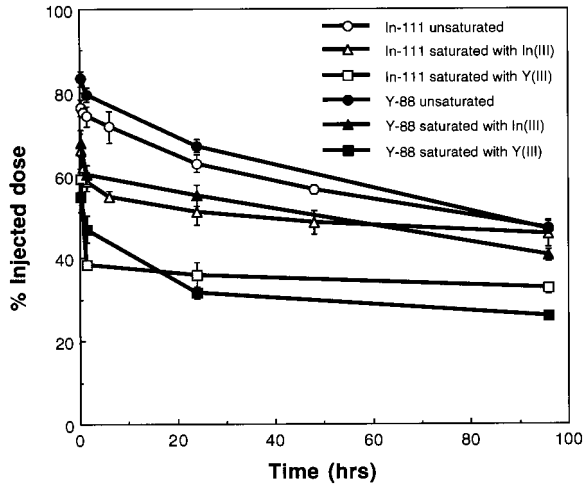

Figure 3. The whole-body retention of six preparations: ^{111}In-labeled (open symbols) or ^{88}Y-labeled (solid symbols); unsaturated (circles), saturated with stable indium (triangles) or saturated with stable yttrium (squares). Data are expressed as %ID retained in the whole body (means ± SD).

lated $G = 3$ is strongly positive. In contrast, unsaturated PAMAM-1B4M is strongly negative, although, after saturation with cold +3 metal ions, the overall charge is more positive. These differences in charge may be responsible for the higher accumulation of PAMAM-1B4M in the kidney and liver that we saw.

Other studies have evaluated the effect of alterations in pI on antibody biodistribution. ten Kate et al. (*32*) reported that changes in pI had a significant effect on antibody biodistribution. The pI change of an IgG resulted in faster blood clearance and less organ uptake. In addition, decreasing pI of small antibody fragments resulted in much lower renal accumulation than the unmodified dsFv fragment (*33*).

The altered kinetics of the ^{111}In-labeled HuTac-PAMAM-1B4M conjugate and the changes observed by saturating the 1B4M with cold radiometals directed us to evaluate the biodistribution of the PAMAM-1B4M with no antibody attached. Although the dendrimer itself is a polycation, in our studies, a mean of 14.3 1B4M groups were substituted, and therefore, this charge may be responsible for the fast clearance into liver and spleen. Saturation with cold metals caused a significant decrease in liver and spleen uptake and more rapid renal clearance. Among the most interesting aspects of this work is the greater effect of saturating the conjugate with yttrium rather than with indium in affecting the whole-body clearance of the PAMAM-1B4M. Our studies suggest that charge and molecular weight are not the only factors affecting biodistribution when cold radiometals were used for saturation, since the final charge and molecular weight should be similar whether indium or yttrium is used for saturation. Other studies show that, in the case of other branch polylysine structures, factors such as size or molecular configuration may affect biodistribution (*34*).

The exact changes in charge as a result of our modifications are complex. If one conjugates the 1B4M-DTPA to protein, the resulting change in charge is a sum of the −2 charge of the DTPA at physiological pH and the depletion of the +1 charge associated with the ϵ-amine of the lysine to which the ligand is now covalently linked via the newly formed thiourea structure. Radiolabeling with a +3 metal ion then returns the charge to the initial overall conditions. This of course neglects any charge balancing contributions of counterions such as H^+, Na^+, K^+, Ca^{2+}, etc. To assess the effect on charge due to the dendrimer, one must first assume that the 14 interior structural tertiary amines contribute to charge and that the 16 exterior primary amines are eliminated by use of one for linkage to protein with the remainder being used for 15 1B4M-DTPA molecules. The potential charge of this structure would be as high as −17, dropping to −14 after radiolabeling assuming just one ^{111}In atom per structure, and then finally after saturation with +3 metal ion becoming as high as +28. Again, these numbers neglect the presence of counterions. The effects of these changes in charge to the protein is strictly speculative and one must consider that while these may seem to be large swings in charge, the overall change to the entire protein charge, i.e., pI, may in fact be negligible, or at least be a local effect. While clearly there is a relationship between charge and organ deposition/clearance, the fact that the overall change in charge from negative to positive, i.e., unsaturated vs saturated, effected better results but not "normal" results would then imply that charge alone is not the determining factor and that other physical characteristics are involved. The lower generation level of PAMAM dendrimers may exhibit substantial back-folding of terminal groups into the dendrimer interior (*35, 36*). It is possible that the act of saturating the chelating surface with metals may inhibit the back-folding and keep the surface charge negative. Therefore, this saturation could decrease the interaction between cell membrane and the PAMAM-1B4M and possibly result in decreased hepatic and splenic uptake. In addition, this hypothesis could explain the difference of hepatic and renal uptake between yttrium and indium saturation if their atomic size differences affected the amount of back-folding. Whether this would happen in higher generation PAMAM dendrimers is not to be determined.

We used the 1B4M to chelate the indium and yttrium because these radiometals require a chelate that will hold the isotope tightly, since, if released from the chelate, these metals would have undesirable targeting and adverse dosimetry (*37*−*39*). In the case of ^{90}Y, the initial chelates used had been developed for ^{111}In, and their stability for ^{90}Y was suboptimal (*15*). As a result of advances in bifunctional chelate technology for ^{90}Y (*40*), several preclinical studies with new chelates indicate that isothiocyanatobenzyl derivatives of DTPA (SCN-Bz-DTPA) have greater stability for ^{90}Y than cyclic anhydride of DTPA, resulting in less bone uptake of ^{90}Y (*15, 41*−*43*). Although our studies were performed with 1B4M because of it greater availability, we believe that similar findings would be observed with DOTA or CHX chelates and therefore 1B4M use was adequate for proof-of-principal.

In conclusion, radiolabeled HuTac-PAMAM-1B4M has a different biodistribution than native HuTac. The faster blood clearance and greater liver and spleen accumulation are likely to be detrimental from an imaging and dosimetry point of view. While saturation of the conjugate with either indium or yttrium partially reversed the differences in biodistribution, its liver and spleen accumulation is still higher than that of native HuTac. Evaluation of the radiolabeled PAMAM-1B4M suggested that some of the uptake in liver and spleen depended on the conjugate itself. In the future we will evaluate other dendrimers which differ in their composition and that may have different physical characteristics.

ACKNOWLEDGMENT

We thank Dr. T. A. Waldmann of the Metabolism Branch, Division of Clinical Sciences, National Cancer

Institute, National Institutes Health, for kindly providing the HuTac.

Universal Isolation of Cross-Linked Peptides: Application to Neurofibrillary Tangles

Xiaohui Chen,[†,‡] Devayani Eswaran,[†,‡,||] Mark A. Smith,[§] George Perry,[§] and Vernon E. Anderson*[,‡]

Department of Biochemistry, Case Western Reserve University, 10900 Euclid Avenue, Cleveland, Ohio 44106-4935. Received August 11, 1998; Revised Manuscript Received October 19, 1998

A universal procedure to isolate cross-linked peptides has been demonstrated. The procedure relies on initially converting the ϵ-amino groups of lysine to dimethyl lysine by reductive methylation with sodium cyanoborohydride and formaldehyde. The lysine-modified protein is proteolytically cleaved and the resulting α-amino groups derivatized with methoxypoly(ethylene glycol)$_{5000}$ succinyl hydroxysuccinimide. Any unintentional derivatization of tyrosine side chains can be reversed by incubation under mildly alkaline conditions. The cross-linked polypeptides contain two poly(ethylene glycol)$_{5000}$ chains while non-cross-linked peptides contain a single poly(ethylene glycol)$_{5000}$ chain. The two populations of peptides can be separated by gel filtration chromatography. This procedure has been shown capable of isolating cross-linked peptides using glutathione, lysozyme, chemically cross-linked hemoglobin, and neurofibrillary tangles isolated from the brain of a case of Alzheimer's disease.

The determination of the sites of cross-links of proteins has been a central feature of protein structure determination from the initial work on insulin (Ryle et al., 1955). The location of disulfide cross-links has played a central role in the study of protein folding (Darby and Creighton, 1995, 1997). The use of cross-linking reagents, both specific (Wells and Yount, 1979) and nonspecific, e.g., Cervoni et al. (1994), has provided valuable information on the tertiary and quaternary structure of proteins. A wide variety of pathological processes including atherosclerosis and Alzheimer's disease have been characterized by the occurrence of proteinaceous deposits. It has been suggested that one cause of deposit formation and/or existence may be the generation of cross-linked proteins resulting in a decreased solubility and resistance to proteolytic removal of the aggregate (Munch et al., 1997).

Previous methods for isolating cross-links have relied on two separate approaches. The first is a prior knowledge of the chemical structure or property of the cross-link. Thus, fluorescent cross-linkers have been utilized (Mornet et al., 1985) to assist in the recovery of cross-linked peptides. Alternatively, careful characterization of a proteolytic peptide map can be used to identify new peptides following treatment with a cross-linker (Giorgianni et al., 1997).

Both of the classical approaches of isolating cross-links will fail when both the chemical mechanism of cross-linking is uncertain and the identity of the cross-linked proteins uncertain or derived from impure biological matrixes rendering the peptide maps inherently irreproducible. In this contribution, we describe a method and demonstrate its implementation at isolating an ensemble of cross-linked peptides to permit their further characterization by other analytical methods. This procedure, shown in concept in Scheme 1, relies on the obvious premise that cross-linked peptides will contain two α-amino groups while all other peptides will contain at most one α-amino group. To prevent the ϵ-amino groups of lysine from confounding the analysis, these amino groups must be derivatized prior to the proteolytic generation of the cross-linked peptides. A conceptually similar approach was taken by Jue and Doolittle (1985) to label the N-terminus of peptides.

The N-terminal derivatization suggested in Scheme 1 has three essential requirements: (1) the derivatization must be close to quantitative; (2) the product must permit the separation of peptides that contain one derivative from the cross-linked peptides which contain two of the derivatives, independent of what amino acid side chains are present in the peptide; and (3) the chemistry must result in the derivatization of only the α-amino group. In this contribution, we demonstrate that the *N*-hydroxysuccinimidyl ester of poly(ethylene glycol) succinate fulfills these three requirements and permits the universal isolation of cross-linked peptides.

MATERIALS AND METHODS

Chemicals. The methoxypoly(ethylene glycol)$_{5000}$ succinyl hydroxysuccinimide (PEG-*O-succinyl-O*−*Su*)[1] was purchased from Shearwater Polymers Inc. Sodium cyanoborohydride, succinic anhydride, chymotrypsin, Pronase, fluorescamine, sodium sulfite, bismuth nitrate, 5,5′-dithio bis(2-nitrobenzoic acid) (DTNB), trinitrobenzenesulfonate (TNBS), dithiothreitol (DTT), bovine insulin, and all amino acids, peptides, and buffers were purchased from Sigma Chemical Co. Potassium iodide

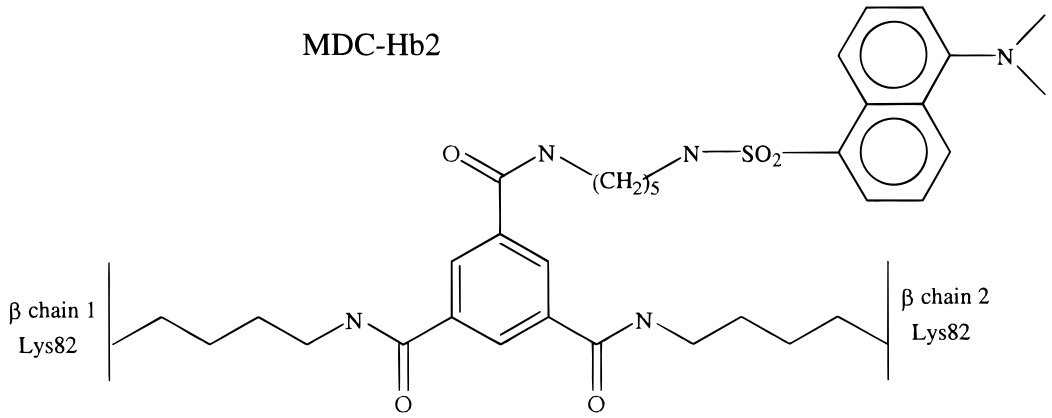
Scheme 1



was purchased from Aldrich Chemical Co. Hydroxylamine hydrochloride, acetic anhydride, ammonium acetate, sodium phosphate, sodium sulfate, sodium sulfite, sodium borate, sodium hydroxide, concentrated HCl, formaldehyde, acetone, and acetonitrile were purchased from Fisher Scientific. 2-Nitro-5-thiosulfobenzoate (NTSB) was synthesized as previously decribed (Thannhauser et al., 1987). Superdex 200 PG gel and PD-10 desalting columns were purchased from Pharmacia Biotech. Brain samples of cases of Alzheimer's disease case were from the CWRU brain bank. Hemoglobin was obtained from Dr. K. Magnus (Department of Biochemistry, CWRU). Hemoglobin cross-linked with a fluorescent cross-linker, MDC−Hb2 shown in Scheme 2, was a generous gift from Hemosol Inc. (Etobicoke, Canada) (Jones et al., 1993; Kluger et al., 1992; Schumacher et al., 1995).

Insoluble Paired Helical Filaments and Control Fractions. Hippocampus and temporal cortex with meninges and white matter removed from a case of Alzheimer's disease (77 year old) was homogenized in 5 vol of 50 mM Tris-HCl, pH 7.6 (buffer A), with 0.1 g of sodium dodecyl sulfate (SDS)/g of wet tissue. After centrifugation at 10000*g* for 4 h at 22 °C, the supernatant was removed, and the pellet was rehomogenized in buffer A with 1% SDS. After centrifugation at 25000*g* for 1 h, the pellet was again homogenized in buffer A with 1% SDS and 10% sucrose, layered over a gradient of 1.0, 1.2, and 2.0 M sucrose/buffer A, and centrifuged for 1 h at 72000*g*. The insoluble paired helical filament fraction at the 1.2−2.0 M interface was used in further experiments.

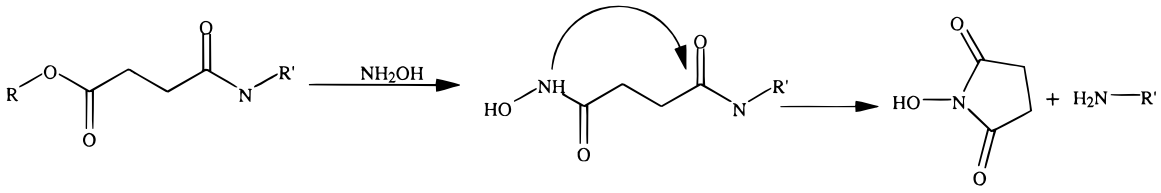
Gel Filtration Chromatography. A 420 mL Superdex 200 PG gel in a Pharmacia XK 26/100 column was used for most separations. In some early experiments, a 320 mL Pharmacia 26/60 HiLoad Superdex 200 PG gel filtration column was used. Constant flow was maintained with a Pharmacia P-500 FPLC system and the column effluent monitored with a 20 μL flow cell in an HP 8452A diode array spectrophotometer and constant volume fractions collected in an Isco Retriever II fraction collector.

Scheme 2

Modification of the Amino Group of the Cross-Linked Protein. Initial protection of protein lysine ϵ-amino groups as shown in Scheme 1 was accomplished by acetylation, succinylation, or reductive methylation, which proved to be most useful. Acetylation was accomplished by infusion of acetic anhydride at a flow rate of 0.9 μL/min using a syringe pump, into 1 mL of solution containing 1−3 mg of protein in 0.1 M phosphate buffer at pH 8.0 until a final concentration of 150 mM was achieved. The infusion procedure permitted the pH to be held constant at 8.0 by the manual dropwise addition of 1 M NaOH. Succinylation, after the method of Kooistra et al. (Kooistra et al., 1979), was achieved by addition of 1 mg of solid succinic anhydride to a 1 mL of solution containing 1−2 mg of protein in 0.1 M phosphate buffer at pH 8.0 with constant stirring. The pH of the solution dropped to 5.5, after 12 min, it was increased to 8.0 by titration with 1 M NaOH. Then, another addition of succinic anhydride was performed. This process was repeated for a total of five additions. The pH was increased to 8.0 at the end of each 12 min interval. Reductive methylation followed the procedure of Jentoft and Dearborn (1983). Formaldehyde and sodium cyanoborohydride were both added to a 1 mg/mL protein solution in 50 mM sodium phosphate buffer, pH 7.0, to final concentrations of 10 mM, and the was reaction allowed to proceed at ambient temperature for 24 h. The mixture was then dialyzed extensively against 0.2 M sodium phosphate buffer, pH 8.0, or alternatively desalted by elution with water through a PD-10 desalting column, preequilibrated with water.

The extent of the amino group modification was determined by detection of residual primary amines using a TNBS assay (Snyder and Sobocinski, 1975) or in later experiments with the more sensitive fluorescamine assay (Udenfriend et al., 1972).

Protease Digestion. The N-modified and desalted protein was then cleaved with the proteases chymotrypsin and Pronase to generate free amino termini. Except where noted, chymotrypsin was added first in a 1:50 (w:w) protease-to-protein ratio. The cleavage reaction was incubated for 5 h at 37 °C. Pronase was then added to the protein solution in a 1:50 (w:w) protease-to-protein ratio and incubated for 24 h at 37 °C. For the brain sample solution, only Pronase was added in a 1:25 (w:w) protease-to-protein ratio and incubated for 30 h at 37 °C.



Derivatization of the Proteolytically Liberated Peptide N-Termini with PEG-O-succinyl-O−Su. Following proteolysis, solid PEG-*O-succinyl-O−Su* was added into the above peptide solution with constant stirring to produce a concentration of 10 mg/mL. After 15 min, approximately 4 μL of 1 M NaOH was added to raise the pH back to 8.0. Then, an additional 10 mg/mL of PEG-*O-succinyl-O−Su* was added. This process was repeated to a total of seven PEG-*O-succinyl-O−Su* additions (final concentration of 70 mg/mL). The pH of the solution was increased to 8.0 by titration with 1 M NaOH at the end of each 15 min reaction.

Selective Hydrolysis of PEG-O-succinyl-O-Tyr. The modification of tyrosine with PEG-*O-succinyl-O−Su* revealed that the phenoxyl group of the side chain is derivatized to a small extent, forming the PEG-*O-succinyl-O*-Tyr phenyl ester. To unambiguously identify the doubly labeled peptides as cross-linked peptides, it is imperative to remove the PEG-*O-succinyl* tag from the side chain of tyrosine residues. After derivatizing the peptides with PEG-*O-succinyl-O−Su*, as described above, the phenyl ester linkage in PEG-*O-succinyl-O-Tyr* moiety was selectively hydrolyzed by titration to pH 11 with saturated trisodium phosphate. The reaction mixture was maintained at pH 11 for 30 min at ambient temperature and the reaction stopped by reducing the pH to 8.0 with acetic acid. This mild alkaline hydrolysis additionally hydrolyzes PEG-*O-succinyl-S−Cys* thiolesters but unfortunately will also cleave disulfide bonds. However, it does not hydrolyze the PEG-*O-succinyl* oxygen ester.

Separation of Peptides Containing either One or Two PEG_{5000} Chains. The PEG-*O-succinyl-O−Su* derivatized peptides were separated on a Pharmacia XK26/100 Superdex 200 PG gel filtration column, preequilibrated with 50 mM ammonium acetate, pH 5.0, and eluted with the same buffer. The PEG-*O-succinyl-O−Su* derivatized peptides (1 mL) were injected, and eluted at 1 mL/min, collecting 4 mL fractions. The gel filtration column was calibrated with PEG-*O-succinyl-O−Su* derivatized tryptophan and lysine nitroanilide which served as models for peptides containing either one or two PEG_{5000} chains, respectively. The tryptophan and lysine nitroanilide derivatives could be identified by their UV absorbance at 280 and 318 nm, respectively.

Quantitation of Disulfide Bonds. Fractions from the Superdex gel chromatography could be analyzed for disulfide bonds employing a 2-nitro-5-thiosulfobenzoate (NTSB) assay (Thannhauser et al., 1987). From each fraction, 1 mL was taken to dryness in a centrifugal vacuum concentrator, redissolved in 20 μL of water, and added into a 300 μL of NTSB assay solution, consisting of 250 μM NTSB, 50 mM glycine, 100 mM sodium sulfite, and 3 mM EDTA. The concentration of disulfide bonds

Scheme 3

was calculated from the increase in the 2-nitro-5-thiobenzoate (NTB) absorbance at 412 nm, $\epsilon_{412} = 13\ 600\ M^{-1}\ cm^{-1}$.

Hydroxaminolysis of PEG-O-succinyl-N-peptide. To permit further analysis of the fractions containing peptides with two PEG_{5000} chains, it is useful to be able to remove the N-terminal PEG-*O-succinyl* label. The treatment of the PEG-*O-succinyl*-labeled peptides with hydroxylamine, cleaves the PEG-*O-succinyl* ester, and the HONH-*succinyl-N*-peptide subsequently cyclizes releasing *N*-hydroxysuccinimide and the peptide with an unblocked amino terminus as shown in Scheme 3.

This cyclization of succinyl hydroxamate with cleavage of an amide is a known facile reaction (Notari, 1969). The reaction was monitored by following the release of ionized *N*-hydroxysuccinimide, $\lambda_{max} = 260$ nm. To effect this cleavage, *N*,*N*′-(PEG-*O-succinyl*)$_2$glutathione was isolated by chromatography and solid hydroxylamine was added to a final concentration of 0.8 M. The pH was adjusted to 9.5 with 1 M NaOH, and the reaction mixture held at 40 °C for 2 h (Notari, 1969). To analyze the time course of reaction, aliquots of the reaction at 30 min intervals up to 2 h were analyzed by gel filtration HPLC using a 30 cm Phenomenex Biosep SEC S2000 column eluted with 100 mM ammonium acetate buffer, pH 5, at a flow rate of 1 mL/min. The eluate was monitored at 280 nm and each 1 mL fraction analyzed for the presence of PEG by the addition of an equal volume of Dragendorff's reagent (0.11 M potassium iodide and 0.6 mM bismuth nitrate in 3.5 M acetic acid) (Rubia and Gomez, 1977) which generates an orange solution ($\lambda_{max} = 524$ nm) or precipitate in the presence of PEG.

Desalting Cross-Linked Peptides. Following hydroxaminolysis, the reaction mixture contained newly regenerated peptides, ammonium acetate, PEG_{5000}, hydroxylamine, and N-hydroxysuccinimide. To remove the PEG_{5000} and the excess hydroxylamine prior to further analysis, the solution was fractionated using a 1 g C_{18} solid-phase extraction column washed with 10 mL of 1 M sodium sulfate and 2 mL of water and eluted with 50% acetonitrile. Solid sodium sulfate was added to the peptide solution to a final concentration of 1 M prior to being loaded onto the solid-phase extraction column. Hydroxylamine and PEG_{5000} were removed by the wash, and the peptides were eluted in an elution volume of 1.5−2 mL of 50% acetonitrile.

RESULTS

Protection of ϵ-Amino Groups. Quantitative derivatization of lysine ϵ-amino groups has been accomplished by many procedures. In our hands, the best procedure was reductive methylation. This procedure had the benefits of retaining the positive charge for solubility while only chemically altering the protein amines, leaving Cys, His, and Tyr residues unmodified. To demonstrate that the conditions chosen successfully derivatized all of the ϵ-amino groups, lysozyme was chosen as a test protein. Following reductive methylation, less than 1% of the initially present amino groups was detected by fluorescamine assay. In all protein methylations monitored, the reaction with fluorescamine decreased by at least 99%. In the presence of aggregates, the potential exists that ϵ-amino groups could be inaccessible to both methylation and fluorescamine. However, extensive reaction times and elevated temperatures should prevent this from being a difficulty.

Derivatization of Amino Termini with PEG-O-succinyl-O−Su. The derivatization of the proteolytically generated α-amino groups was moderately successful. The aqueous derivatization with a hydroxysuccinimide ester represents a competition between hydrolysis and aminolysis. The pH of this reaction is the crucial parameter, lowering the pH makes the reaction more specific for amines and decreases the rate constant for hydrolysis at the price of increasing the required reaction time. We adopted a repetitive addition, titration scheme to neutralize the acid generated during hydrolysis of the excess reagent. In favorable cases, this repetitive procedure derivatized over 90% and, in the worst case, 70% of the amino groups, corresponding to a predicted complete derivatization of at least half of all cross-linked peptides.

Hydrolysis of PEG-O−Suc-O-Tyr. Control reactions with tyrosine indicated that some O-esterification of tyrosine with PEG-*O−succinyl-O−Su* occurred at pH 8.0. To define conditions required to hydrolyze PEG-*O−succinyl-O-Tyr*, the peptide YGGFL was intentionally N- and O-derivatized by raising the pH of the derivatization reaction. The O-Tyr ester hydrolysis can be monitored by following the appearance of tyrosine phenoxide at 292 nm (Edelhoch, 1967) and was shown to be complete in 30 min at pH 11. This mild alkaline hydrolysis effectively cleaves both phenyl and thiolesters while leaving the PEG-*O−Suc-N-peptide* ester and amide linkages uncleaved. Any histidine derivatization would generate an unstable acyl-imidazole that hydrolyzes at neutral pH.

Protein Hydrolysis. Proteolytic treatment with Pronase generates very small cross-linked peptides as it has endopeptidase activity as well as exopeptidase peptidase activities (Narahashi and Yanagita, 1967) which permits small modified peptides to be isolated (Catley et al., 1969). The use of more specific proteases such as trypsin will generate larger peptides that retain more sequence information. In our standard procedure the initial cleavage with chymotrypsin was introduced to enhance the efficacy of the Pronase cleavage.

Separation of Doubly and Singly Derivatized Peptides. The gel filtration separation of lysine nitroanilide and tryptophan derivatized with PEG-*O-succinyl-O−Su* on this column is shown in Figure 1. Lysine nitroanilide derivatized with two PEG_{5000} chains eluted between 239 and 277 mL and the tryptophan derivative containing a single PEG_{5000} chain eluted between 277 and 332 mL on the Superdex XK26/100 column. The elution volumes for peptides containing either one or two PEG_{5000} chains were relatively consistent and had a resolution of 1.2−1.3. These elution volumes compare to that of a globular protein with an M_r of 5−10 times the nominal molecular weight of the polymer. Insulin with three amino groups,

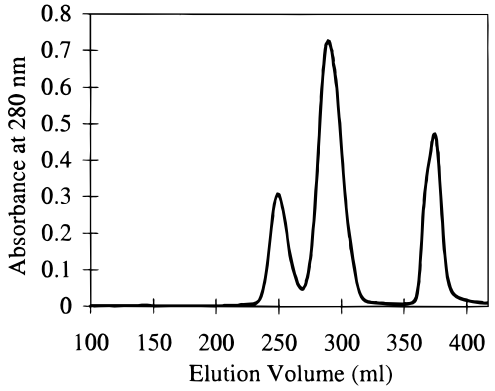


Figure 1. Gel filtration chromatogram of PEG-*O-succinyl-N*-Trp and N_α,N_ϵ-bis(PEG-*O*-succinyl-)lysine nitroanilide as singly and doubly labeled calibrators on an XK 26/100 Superdex 200PG column. The elution volumes of the tryptophan and lysine derivatives define the volumes for the elution of peptides containing either one or two PEG_{5000} chains, respectively. UV analysis of the fractions indicated that the first peak contained only the lysine derivative, the second peak contained the tryptophan derivative and the third peak was largely hydroxysuccinimide.

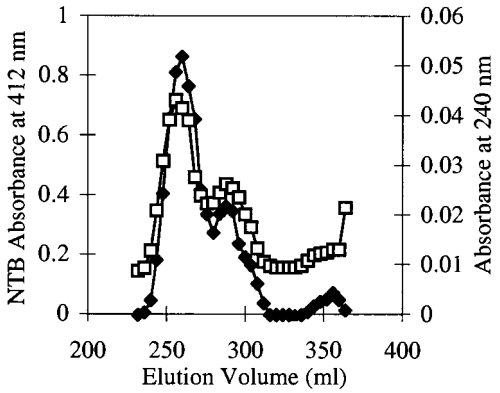

Figure 2. Gel filtration chromatogram of N_α,N_a'-bis(PEG-*O-succinyl*)glutathione by an XK 26/100 Superdex 200 PG column with the fractions monitored either by UV absorbance at 240 nm (□) or by using the NTSB assay for disulfide bonds (◆).

was derivatized with PEG-*O-succinyl-O−Su*. The triply derivatized insulin eluted well before the lysine nitroanilide standard. This early eluting triply labeled species was pooled, reduced with DTT, and then rechromatographed on the same gel filtration column. Two peaks were observed, one from the doubly labeled β-chain (the amino terminus and carboxy terminal lysine would both be derivatized) eluted and the other from the singly labeled α-chain. The coelution of the PEG-*O-succinyl*-derivative of the 21 amino acid insulin α-chain with the singly labeled standards suggests that the size of the derivatized oligopeptide will not significantly alter the chromatographic behavior of the PEG-*O-succinyl*-peptides.

Glutathione was used for the studies of both column recovery and derivatization efficiency. Glutathione was derivatized with PEG-*O-succinyl-O−Su* as described in the Materials and Methods. Derivatized glutathione was then chromatographed on the Superdex XK26/100 column. Using the NTSB assay for disulfide bonds, the recovery of cross-linked peptides was determined to be greater than 80%. The result with NTSB also showed that doubly labeled glutathione eluted between 236 and 276 mL and singly labeled glutathione eluted between 276 and 316 mL (Figure 2). The ratio of doubly labeled: singly labeled glutathione was 2.3:1. Thus, the efficiency

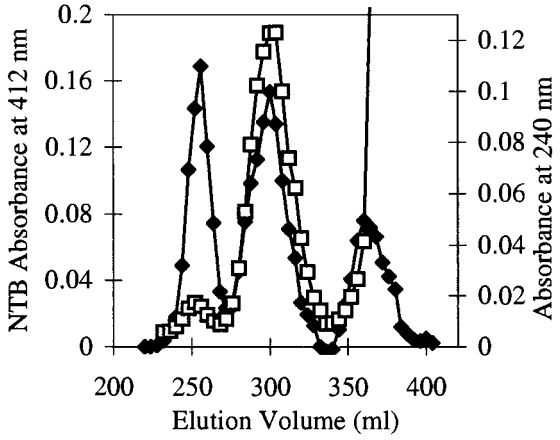

Figure 3. Gel filtration chromatogram of reductively methylated lysozyme, proteolytically digested, and derivatized with PEG-*O-succinyl-O−Su* monitored at 240 nm (□) or by NTSB assay for disulfide bonds (◆).

of derivatization of the glutathione amines was 85%. The pK_a of the α-amino group of glutathione of 8.5 is higher than expected for the α-amino peptides, so that the efficiency of derivatization of the α-amino groups of peptides at pH 8.0 might be anticipated to be better. The incomplete derivatization results from the competitive hydrolysis of PEG-*O-succinyl-O−Su* by water. While more complete derivatization might be anticipated with additional PEG-*O-succinyl-O−Su*, higher concentrations of PEG_{5000} become counterproductive in the subsequent chromatographic separation. The requirement for excess derivatizing reagent made it difficult to use an affinity matrix with their attendant low capacities for the chromatographic resolution singly and doubly labeled peptides.

Hydroxaminolytic Liberation of Cross-Linked Peptides from PEG-O-succinyl-N-peptide. Removal of PEG-*O-succinyl* moiety is desirable for planned sequencing studies of cross-linked peptides by Edman degradation or by mass spectrometry. Hydroxaminolysis was shown to remove the PEG-*O-succinyl* label from the derivatized peptides, as depicted in Scheme 3. The peptide MeOSuc-Ala-Ala-Pro-Val was used as a standard to determine the required reaction conditions. With peptides, the cleavage was additionally demonstrated by separating the liberated peptide from the polymeric PEG. Doubly labeled *N*,*N*′-(PEG-*O-succinyl*)$_2$-glutathione was subjected to hydroxaminolysis, and the products separated by HPLC gel filtration. Following hydroxaminolysis, the PEG elution volume increased from 11 to 13 min, consistent with the release from the doubly labeled peptide with a nominal M_r in excess of 10 000 to the elution volume of a standard monomeric PEG_{5000} while the glutathione eluted in the included volume. Analyses at varying times were consistent with the spectrophotometric studies, indicating that the hydroxaminolysis was complete in under 1 h.

Lysozyme. Lysozyme is cross-linked by four disulfide bonds. To demonstrate the method, peptides cross-linked by disulfides were isolated by the protocol outlined in Scheme 1. Lysozyme was methylated and desalted as described, digested with chymotrypsin and Pronase, and derivatized with PEG-*O-succinyl-O−Su*. The gel filtration chromatogram of the lysozyme derived peptides is shown in Figure 3. Each fraction was concentrated and then tested for disulfide bonds by using the NTSB assay. The ratio of underivatized: singly labeled: doubly labeled peptides was 2:2.1:1.5 based on the NTSB assay. The

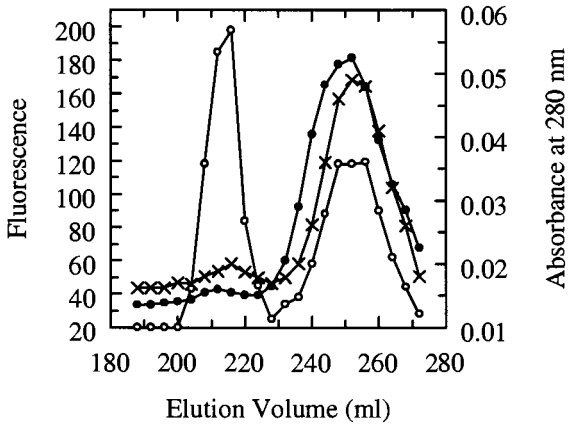

Figure 4. Gel filtration chromatograms of cross-linked and un-cross-linked hemoglobin by 26/60 Hiload Superdex 200 PG column, following reductive methylation, digestion with chymotrypsin and Pronase, and derivatization with PEG-*O-succinyl-O−Su*, followed by mild alkaline hydrolysis. The column fractions of the derivatized un-cross-linked hemoglobin peptides were monitored at 280 nm (×). The fractions of the derivatized cross-linked hemoglobin peptides were monitored by both UV at 280 nm (●) and the dansyl fluorescence at 550 nm (○) with excitation at 340 nm. The major fluorescent peak eluting around 215 mL elutes corresponds to the elution volume of peptides containing two PEG_{5000} chains by this column.

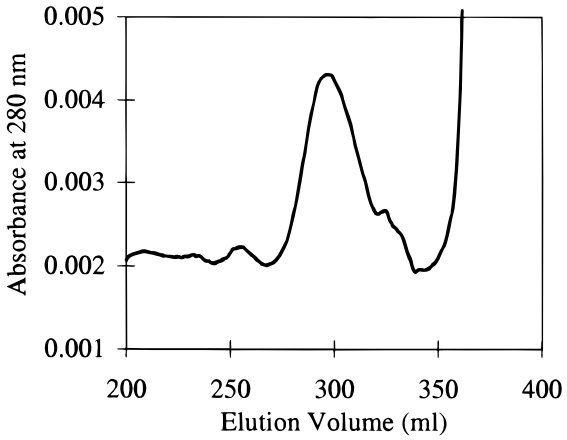

Figure 5. Gel filtration chromatogram of protein isolated from neurofibrillary tangles from Alzheimer disease that was reductively methylated, Pronase digested, PEG-*O-succinyl-O−Su* derivatized, and finally subjected to mild alkaline hydrolysis. The peptides eluted are monitored by absorbance at 280 nm. The peak eluting at 250 mL, elutes at the position expected for cross-linked peptides but not linear peptides. Unlike the previous examples this peak is small when compared to the monomeric fraction eluting at 300 mL because the cross-link is unknown and cannot be specifically detected.

apparent lower yield based on disulfide bonds, when compared with that of glutathione, may result from (1) free thiols generation from the cleavage of disulfide bonds since NTSB assay detects both free thiol and disulfide and (2) incomplete proteolysis. An inherent requirement of the protocol is that the proteolysis generates a new α-amino group in the sequence prior to the amino acid whose side chain participates in the cross-link. In lysozyme, Cys-6 forms a disulfide bond with Cys-127. To isolate a peptide with this cross-link, the proteolysis must cleave the peptide backbone before Cys-6 and between Cys-115 and Cys-127. Failure to proteolytically cleave before Cys-6 would result in cross-linked peptide with only one α-amino group because the N-terminal of lysozyme has been blocked by dimethylation. Thus, the apparent low efficiency may be a function both of disulfide cleavage and incomplete proteolysis. Even with this difficulty, this chromatogram clearly demonstrates the potential separation of a pool of cross-linked peptides obtained from a protein with intramolecular cross-links.

Hemoglobin. MDC−Hb2 (shown in Scheme 2) and control human hemoglobin were both treated according to Scheme 1 as follows: reductive methylation, desalting of protein, proteolytic digestion with chymotrypsin and Pronase, PEG-*O-succinyl-O−Su* derivatization, mild alkaline hydrolysis of labile PEG_{5000} esters, gel filtration chromatography, and fluorescent measurement of the collected fractions. The chromatograms of the cross-linked hemoglobin (3 mg) and un-cross-linked hemoglobin (3 mg) produced by monitoring the fluorescence at 550 nm with excitation at 340 nm and by monitoring the absorbance at 280 nm are shown in Figure 4. The peptides generated from proteolytic digestion of the cross-linked hemoglobin were separated by gel filtration column into three peaks, doubly labeled, singly labeled and underivatized peptides in the order of increased retention time. From the fluorescence assay of the fractions, it is obvious that the cross-linked peptide containing the dansyl group was concentrated in the first peak. This particular cross-linked protein was selected because (1) there is a single cross-link per 68 kDa hemoglobin tetramer and (2) the dansyl moiety on the cross-link can be identified by monitoring fluorescence, permitting the spectral identification of cross-linked peptides and their separation to be monitored.

In the control experiment, un-cross-linked hemoglobin was treated according to the same procedure. The chromatogram monitored by UV absorbance at 280 nm showed only one peak at the same retention time of the peptides containing a single PEG_{5000} chain, indicating that the protocol does not produce false positive signals by incorporation of two PEG_{5000} chains by unanticipated derivatization of amino acid side chains.

Insoluble Paired Helical Filaments of Alzheimer's Disease. An enriched fraction of paired helical filaments, the component structures of neurofibrillary tangles, from a case of Alzheimer's disease containing 0.4 mg of protein was treated by using the same procedure as for hemoglobin, except the fluorescence analysis of the chromatographic fractions was not required. The chromatogram obtained monitoring absorbance at 280 nm to detect peptides containing aromatic residues is shown in Figure 5. The peak with elution volume of 240−268 mL was that of the peptides containing two PEG_{5000} chains and are presumptively cross-linked peptides derived from neurofibrillary tangles. There were no disulfide bonds or free thiols detected in these fractions using the NTSB and DTNB assays, respectively. Therefore, the identification of peptides derivatized with two PEG_{5000} chains is suggestive of the existence of cross-link(s) in the neurofibrillary tangles. Further characterization of these putative cross-link(s) is being undertaken by mass spectrometry. Hydroxaminolysis will liberate the parent peptides and permit the reversed-phase HPLC-mass spectrometric characterization of this pool of peptides in our laboratory.

DISCUSSION

Cross-linking has proven to be a powerful method of studying protein structure, by demonstrating that the two cross-linked groups must, for the chemical reaction to have occurred, have been in close proximity. While cross-linked peptides can be identified when a control peptide map exists or when the cross-linker contains a detectable marker, neither of these restrictions applies when cross-linked peptides are sought from a biological

sample cross-linked by unknown processes. Scheme 1 presented a conceptual approach to isolating cross-linked peptides independent of the chemical nature or origin of the cross-link. All of the chemistry proposed is precedented and was substantiated in the studies reported.

The main issue presented in Scheme 1 is the selection of an amine-derivatizing reagent that will quantitatively react with the α-amino groups, including the secondary amine of proline, liberated by the partial hydrolysis of the protein backbone. Our initial concept was to use myristoyl isothiocyanate, as the development of Edman degradation has substantiated that derivatization of the amino terminal group with isothiocyanates can be quantitative and yet easily removed by acid-catalyzed cyclization. We envisioned a separation based on reversed-phase HPLC. The difficulties of peptide solubility both before and after derivatization prevented the realization of this approach. The choice of PEG-*O-succinyl-O−Su* as the derivatizing reagent was in response to difficulties in maintaining peptide and reagent solubility. The PEG_{5000} chain is miscible with water and imparts enhanced aqueous solubility to derivatized peptides and minimizes interactions with the gel filtration matrix. Alternative derivatization conditions or reactive PEG_{5000} substituent may permit an increase in the efficiency of the derivatization conditions. Incorporation of a radioactive label into the PEG, e.g., using [^{14}C]succinic anhydride to form the succinate ester, would permit the described assay to become a method of quantifying the isolated cross-links.

The second major consideration in Scheme 1 is the choice of proteolytic conditions. As noted, one of the virtues of reductive methylation of the ϵ-amino groups is that this derivatization is stable to acid hydrolysis. Thus, quantitative hydrolysis with 6 N HCl or weak acid hydrolysis would be possible, allowing the described method to isolate all acid-stable cross-links. This is potentially an important virtue for handling insoluble protein aggregates. A similar method exists based on α-amino acids ability to chelate diphenylborinic acid (Graham and Gallop, 1994). However, this approach has the absolute requirement that the protein be hydrolyzed completely to its constituent amino acids, preventing any sequence information from being retained in the cross-linked peptides.

Conclusion. A protocol has been proposed that permits the isolation of cross-linked peptides independent of the chemical nature of the cross-link. The validity of the key premise of this scheme, that the two amino termini of cross-linked peptides can be derivatized to permit separation from linear peptides, has been clearly demonstrated. Separation of PEG-*O-succinyl-O−Su*-derivatized peptides by gel filtration chromatography has been shown capable of isolating disulfide-bond cross-links from proteins of known sequence, a single fluorescent cross-linked peptide from the large number of proteolytic peptides of hemoglobin, and most provocatively, a potential pool of cross-linked peptides isolated from neurofibrillary tangles obtained from an Alzheimer's disease brain.

Received August 19, 1998; Revised Manuscript Received October 7, 1998

The diagnosis and staging of breast cancer could be improved by the development of imaging radiopharmaceuticals that provide a noninvasive determination of the estrogen receptor (ER) status of tumor cells. Toward this goal, we have synthesized a number of integrated "3+1" oxorhenium(V) complexes designed to mimic estradiol and a class of nonsteroidal estrogens, the tetrahydrochrysenes (THC). The monodentate component of the estradiol mimic is a *p*-hydroxyphenethyl thiol ligand with ethyl substituents at the benzylic and homobenzylic positions. Model complexes of this ligand were easily made, but steric hindrance of the secondary thiol prevented the formation of the complex with the disubstituted ligand. The three "3+1" oxorhenium(V) complexes prepared to mimic the THC class mimics represent the first pyridinedithiol rhenium complexes of their kind to be made. These complexes are quite stable to air and moisture. The target tridentate ligand was prepared from chelidamic acid, and the VT NMR of the rhenium complex displays interesting fluxional behavior. The binding affinities of these complexes for the estrogen receptor are low, and their lipophilicities are rather high. Nevertheless, our findings provide a further refinement of our understanding of ligand structure-binding affinity correlations for the estrogen receptor.

INTRODUCTION

Metastatic breast cancer is the most prevalent form of cancer of women in the United States and is the number one killer of women ages 40−55 (*1*). Recent figures show that a woman's lifetime risk of developing breast cancer is 1 in 8 (*2*). Early detection is imperative for breast cancer survival, as the 5 year survival rate for localized breast cancer is 96% (*3*). However, if the cancer has spread regionally, the survival rate drops to 75%, and distant metastases further reduce the survival rate to 20% (*3*). Clearly, better diagnostic techniques for early detection would increase survival.

Breast cancers that retain estrogen receptor (ER)[1] can usually be treated effectively by endocrine therapy, such as the use of the antiestrogen tamoxifen. In fact, about 60% of ER+ patients respond to endocrine therapy, whereas the response of ER− patients is much lower (*4*). However, only 70% of breast cancers are ER+; so, it is important to be able to determine the ER status of each tumor.

Current methods used to determine the ER status of breast tumor cells are invasive and do not fully account for cell heterogeneity. One way to eliminate the invasiveness and minimize the heterogeneity problems of current tumor ER assays would be to image breast tumors based on their content of ER, using positron-emission tomography (PET) or single photon emission computed tomography (SPECT). These techniques utilize the emission characteristics of certain radionuclides attached to radiopharmaceuticals that have appropriate distribution properties to image tissues. Considerable advances have been made in the development of steroids labeled with either fluorine-18 for PET imaging (*5*−*16*) or iodine-123 for SPECT imaging (*5*, *17*−*21*) of ER+ breast tumors. However, the radionuclide of choice for breast tumor imaging would be Tc-99m, due to its convenient 6 h half-life and its wide availability.

We have been interested in the development of Tc-99m-containing steroid mimics for use as imaging agents for receptor-positive breast tumors. In the "conjugated" or "pendant" design, a Tc-99m containing moiety is tethered to an existing steroid, such as progesterone or estradiol (**1**) (*22*−*29*). Such complexes are generally stable, but their large overall size can greatly affect their physical properties and their affinity for steroid receptors (*22*, *29*). Smaller complexes are produced by the alternative "integrated" approach, in which part of the steroid backbone itself is replaced by the requisite Tc-99m chelate (*30*−*32*). One way to incorporate Tc-99m into such integrated complexes is via the "3+1" design, in which a tridentate and monodentate ligand surround an oxometal core (*33*). The advantage of such a design is the well-established stability of many "3+1" complexes themselves (*27*−*29*, *33*−*35*), compared with that of the related 2+2 complexes. In addition, appropriately designed "3+1" complexes lack syn and anti stereoisomers that are often produced in the tetradentate oxorhenium and technetium complexes.

We report here the synthesis of several "3+1" oxorhenium complexes that are in the series of the estradiol mimic **2** and the tetrahydrochrysene (THC) mimic **4** (Figure 1). The syntheses involve rhenium as the surrogate metal for Tc-99m (*36*). As is illustrated in Figure 1, estradiol mimic **2** would contain a tridentate aliphatic ligand (where the heteroatom X could be a sulfur, oxygen, or alkyl nitrogen), intended to mimic the D-ring of estradiol. The monodentate ligand is aromatic, with a 2 carbon "spacer" separating the phenyl ring from the thiol, and is intended to mimic the A, B, and C rings of estradiol. The THC mimic **4** involves thiophenol as the

monodentate ligand and a unique pyridinedithiol as the tridentate ligand. In this case, both ligands are equally involved in mimicking the rings of THC.

EXPERIMENTAL SECTION

General. All reagents and solvents were obtained from Aldrich, Acros, Alfa Aesar, or Fisher. All reactions were performed under a nitrogen atmosphere unless otherwise indicated. THF was distilled from sodium/benzophenone immediately prior to use. Methylene chloride was distilled from CaH_2 prior to use. Triethylamine was dried by distillation from CaH_2 and stored over KOH. Dimethylformamide was distilled from and stored over 4 Å molecular sieves. MeOH was distilled from Mg/I_2 and stored over 3 Å molecular sieves. Hexanes were distilled from calcium sulfate (Drierite) before use in flash chromatography.

Reaction progress and flash chromatography was monitored by analytical thin-layer chromatography. Silica gel used in flash chromatography was 32−63 μm. Radial chromatography (Chromatotron, Harrison Research, model 7924T) was performed using a circular glass plate with a 2 mm depth of silica gel 60 PF_{254} (with gypsum). TLC plates were visualized using short-wave UV light (254 nm), potassium permanganate, or phosphomolybdic acid.

^1H and ^{13}C NMR were obtained at 400 or 500 MHz and are reported in parts per million relative to incomplete deuteration signals of $CDCl_3$, CD_3OD (CD_3 signal used), DMSO-d_6 or acetone-d_6. Mass spectra were obtained with a VG Instruments 70-VSE (EI, CI) or a VG Instruments ZAB−SE (FAB) mass spectrometer. Melting points are uncorrected. Elemental analyses were performed by the Microanalytical Service Laboratory of the University of Illinois.

4-Methoxyphenethyl Thioacetate (8a). MsCl (770 μL, 9.94 mmol) was added dropwise to a solution of 4-methoxyphenethyl alcohol (1.01 g, 6.63 mmol) and Et_3N (1.40 mL, 9.94 mmol) in THF (40 mL) at 0 °C. A white ppt of Et_3N hydrochloride formed immediately. The reaction was stirred for 1 h, at which time potassium thioacetate (2.27 g, 19.9 mmol) in DMF (10 mL) was added, resulting in an orange solution which turned red after several h. After 6 h, the reaction was stopped and concentrated, then dissolved in CH_2Cl_2 (60 mL). This was washed with saturated LiCl twice, followed by a wash with brine and then water (30 mL). The brine and water washes were separately back-extracted with CH_2Cl_2 (30 mL). The organics were then combined, dried over Na_2SO_4, filtered, and concentrated to a dark oil. Flash chromatography (60% CH_2Cl_2/PhH) and radial chromatography (30% EtOAc/Hex), followed by Kugelrohr distillation (125 °C, 0.9 mmHg) provided **8a** as a yellow oil (1.06 g, 76%). ^1H NMR ($CDCl_3$, 400 MHz): δ 2.33 (s, 3H, $-SCOCH_3$), 2.95 [ABq, J_{AB} = 7.3 Hz, $\Delta\upsilon$ = 119 Hz, 2H, $Ar(CH_2)_2SCOCH_3$], 2.95 [ABq, J_{AB} = 6.3 Hz, $\Delta\upsilon$ = 102 Hz, 2H, $Ar(CH_2)_2SCOCH_3$], 3.79 (s, 3H, $ArOCH_3$), 6.84 (d, J = 8.8 Hz, 2, ArH), 7.14 (d, J = 8.9 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 30.6, 30.7, 34.8, 55.2, 113.8, 129.5, 132.0, 158.2, 195.7. MS (EI, 70 eV): m/z 210 (M^+, 5), 134 (100), 121 (64). HRMS calcd for $C_{11}H_{14}O_2S$: 210.0715. Found: 210.0715.

4-Methoxyphenethyl Thiol (9a). A solution of 1 M HCl in MeOH/dioxane was prepared by diluting commercially available 4 M HCl/dioxane with freshly distilled, degassed MeOH. Following Okuno's procedure (*37*), 4 mL of this solution was added to **8a** (200 mg, 0.951 mmol) and the reaction was refluxed at 80 °C under Ar for 3 h. The reaction was then concentrated under high vacuum overnight, providing an orange oil which was Kugelrohr distilled (65 °C, 0.2 mmHg) to provide **9a** as a pungent-smelling yellow oil (70.1 mg, 44%). ^1H NMR ($CDCl_3$, 400 MHz): δ 1.37 (t, J = 7.8 Hz, 1H, −SH), 2.75 (m, 2H, $ArCH_2CH_2SH$), 2.87 (t, J = 7.3 Hz, 2H, $ArCH_2CH_2SH$), 3.80 (s, 3H, $ArOCH_3$), 6.85 (d, J = 8.7 Hz, 2H, ArH), 7.11 (d, J = 8.7 Hz, 2H, ArH). MS (CI, CH_4): m/z 168 (M^+, 22), 135 (100), 61 (23). HRMS calcd for $C_9H_{13}OS$: 169.0686. Found: 169.0687.

(4-Methoxyphenethylthiolato)(3-thiapentane-1,5-dithiolato)oxorhenium(V) (5a). A solution of bis(2-mercaptoethyl)sulfide (35.5 μL, 0.272 mmol) and **9a** (45.8 mg, 0.272 mmol) in CH_3CN (1 mL) was added dropwise to a solution of $[BnEt_3N]ReOCl_4$ (*38*) (146 mg, 0.272 mmol) in MeOH (1 mL) at 0 °C, followed by Et_3N (114 μL, 0.816 mmol). A brown solution immediately formed. After stirring for 1 h, the crude mixture was concentrated and purified by flash chromatography (CH_2Cl_2) to produce **5a** as a foamy red solid (78.7 mg, 55%). IR (NaCl): 959 cm^{-1} (Re═O); mp 51−53 °C (dec). ^1H NMR ($CDCl_3$, 400 MHz): δ 1.95 [ddd, J = 14.6, 10.1, 4.7 Hz, 2H, $-S(CH_2)_2S-$], 3.07−3.17 [m, 4H, $-S(CH_2)_2Ar-$], 3.80 (s, 3H, $ArOCH_3$), 3.91 [ddd, J = 10.2, 4.1, 1.5 Hz, 2H, $-S(CH_2)_2S-$], 4.00−4.06 [m, 2H, $-S(CH_2)_2S-$], 4.29 [ddt, J = 13.4, 4.9, 1.3 Hz, 2H, $-S(CH_2)_2S-$], 6.85 (d, J = 8.6 Hz, 2H, ArH), 7.24 (d, J = 8.6 Hz, 2H, ArH). MS (CI, CH_4): m/z 523 (M + H^+ for ^{187}Re, 3), 521 (M + H^+ for ^{185}Re, 2), 227 (19), 195 (51), 135 (100), 121 (20). HRMS calcd for $C_{13}H_{20}O_2S_4{}^{187}Re$: 520.9876. Found: 520.9893.

4-Hydroxyphenethyl Thioacetate (8b). Diisopropyl azodicarboxylate (4.27 mL, 21.7 mmol) was added dropwise to a solution of PPh_3 (5.70 g, 21.7 mmol) in THF (75 mL) at 0 °C. A white precipitate of the ylide formed, and the heterogeneous solution was stirred in an ice bath for 30 min. A solution of the 4-hydroxyphenethyl alcohol (1.00 g, 7.24 mmol) in THF was added slowly to the ylide, followed by thiolacetic acid (1.55 mL, 21.7 mmol). The reaction was stirred for 1 h at 0 °C, then room-temperature overnight, changing from a white to green to a golden yellow color during this time. The reaction was then concentrated and purified by flash chromatography twice (2.5% MeOH/CH_2Cl_2 and 2.5% acetone/CH_2Cl_2), yielding **8b** as a yellow oil (756 mg, 53%). ^1H NMR ($CDCl_3$, 400 MHz): δ 2.34 (s, 3H, $-SCOCH_3$), 2.95 [ABq, J_{AB} = 7.2 Hz, $\Delta\upsilon$ = 127 Hz, 2H, $Ar(CH_2)_2SCOCH_3$], 2.95 (ABq, J_{AB} = 6.1 Hz, $\Delta\upsilon$ = 110 Hz, 2H, $Ar(CH_2)_2SCOCH_3$), 6.07 (s, 1, ArOH), 6.80 (d, J = 8.3 Hz, 2H, ArH), 7.07 (d, J = 8.1 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 30.6, 30.8, 34.7, 115.3, 129.6, 131.8, 154.3, 197.3. MS (EI,

70 eV): *m*/*z* 197 (M + H, 44), 120 (100), 107 (66). HRMS calcd for $C_{10}H_{12}O_2S$: 196.0558. Found: 196.0558.

4-Hydroxyphenethyl Thiol (9b). Ten milliliters of 1 M HCl in MeOH/dioxane (vide supra) was added to **8b** (466 mg, 2.37 mmol), and the reaction was refluxed at 80 °C under Ar for 3 h. Following evaporation of the solution under high vacuum, Kugelrohr distillation (75 °C, 0.1 mmHg) provided **9b** as a near-colorless oil (338 mg, 92%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 1.37 (t, J = 7.7 Hz, 1H, S*H*), 2.75 [m, 2H, Ar(CH_2)$_2$SH], 2.85 [m, 2H, Ar(CH_2)$_2$SH], 4.70 (s, 1H, ArO*H*), 6.78 (d, J = 8.4 Hz, 2H, Ar*H*), 7.07 (d, J = 8.1 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 26.3, 39.2, 115.3, 129.8, 132.0, 153.9. MS (EI, 70 eV): *m*/*z* 154 (M^+, 27), 120 (81), 107 (100). Anal. Calcd for $C_8H_{10}OS$: C, 62.30; H, 6.54. Found: C, 62.28; H, 6.59.

(4-Hydroxyphenethylthiolato)(3-thiapentane-1,5-dithiolato)oxorhenium(V) (5b). A solution of bis(2-mercaptoethyl)sulfide (39.3 μL, 0.301 mmol) and **9b** (46.4 mg, 0.301 mmol) in CH_3CN (0.8 mL) was added dropwise to a solution of [BnEt_3N]ReOCl_4 (161 mg, 0.301 mmol) in MeOH (1 mL) at 0 °C under Ar, followed by Et_3N (1 drop). A red precipitate immediately formed. After stirring for 2 h at 0 °C, the crude mixture was concentrated and purified by radial chromatography (1% acetone/CH_2Cl_2) to produce a red residue. This was dissolved in CH_2Cl_2, and ether was slowly added over the top of the CH_2Cl_2 layer. Crystals immediately formed. After 24 h, the mixture was filtered to give **5b** as red crystals (37.4 mg, 24%). IR (KBr): 955 cm^{-1} (Re═O); mp 153−155 °C (dec). ^{1}H NMR (CD_2Cl_2, 400 MHz): δ 1.97 [ddd, J = 14.5, 10.4, 5.0 Hz, 2H, −S(CH_2)$_2$S−], 3.02 [m, 2H, Ar(CH_2)$_2$S−], 3.10 [ddd, J = 14.4, 13.2, 4.1 Hz, 2, −S(CH_2)$_2$S−], 3.95 [m, 2H, Ar(CH_2)$_2$S−], 4.29 [ddt, J = 13.4, 4.8, 1.2 Hz, 2H, −S(CH_2)$_2$S−], 5.19 (s, 1H, ArO*H*), 6.77 (d, J = 8.5 Hz, 2H, Ar*H*), 7.17 (d, J = 8.3 Hz, 2H, Ar*H*). ^{13}C NMR (CD_2Cl_2, 100 MHz): δ 38.8, 39.1, 44.1, 47.0, 115.3, 129.9, 132.9, 155.4. MS (FAB): *m*/*z* 509 (M^+ for ^{187}Re, 16), 507 (M^+ for ^{185}Re, 10), 307 (74), 289 (48), 154(100), 136 (94). HRMS Calcd for $C_{12}H_{18}O_2S_4{}^{187}$Re: 508.9747. Found: 508.9741.

2-(4-Hydroxyphenyl)butanoic Acid (12). Following the procedure by Aaron (*39*), sodium (1.58 g, 69.2 mmol) was added to a solution of naphthalene (8.87 g, 69.2 mmol) in THF (60 mL) and was stirred for 4 h with occasional sonication, during which time it turned the characteristic deep blue color. This was added to a solution of 4-methoxyphenylacetic acid (5.00 g, 30.1 mmol) in THF (70 mL) dropwise, which was then stirred for several h. The reaction was then cooled in an ice bath, and to it, EtBr (2.56 mL, 34.3 mmol) was added dropwise. The ice bath was removed, and the reaction was stirred overnight. It was then quenched with water (20 mL), concentrated, dissolved in ether, and extracted with 1 M Na_2CO_3 (3 × 25 mL). The extracts were washed with ether, then acidified and extracted with ether. The ether extracts were dried with Na_2SO_4, concentrated, and distilled (131 °C, 0.5 mmHg) to provide **11** as a yellow oil (5.28 g), which was used in the next step without further purification.

The yellow oil was refluxed with HBr (15 mL) and acetic acid (15 mL) for 16 h. It was neutralized with saturated Na_2CO_3, extracted into CH_2Cl_2, washed with saturated Na_2CO_3, and acidified with HCl. The aqueous washes were back-extracted with CH_2Cl_2. The organics were combined, dried with Na_2SO_4, and purified by flash chromatography (5% MeOH/CH_2Cl_2 to 10% MeOH/CH_2Cl_2) to give **12** as a slightly yellow solid (715 mg, 13% two-step yield): mp 125.5−129 °C. ^{1}H NMR (CD_2Cl_2/CD_3OD, 500 MHz): δ 0.87 (t, J = 7.4 Hz, 3H, −CH_3), 1.71 (dquin, J = 13.7, 7.4 Hz, 1H, −CH_2Me), 2.02 (dquin, J = 13.4, 7.5 Hz, 1H, −CH_2Me), 3.36 (t, J = 7.6 Hz, 1H, C*H*), 6.75 (d, J = 8.7 Hz, 2H, Ar*H*), 7.13 (d, J = 8.4 Hz, 2H, Ar*H*). ^{13}C NMR (CD_3OD, 100 MHz): δ 12.5, 27.8, 54.0, 116.2, 129.9, 131.7, 157.5, 178.5. MS (CI, CH_4): *m*/*z* 181 (M + H^+, 49), 163 (15), 149 (11), 135 (100), 121 (8), 107 (14). HRMS Calcd for $C_{10}H_{13}O_3$: 181.0865. Found: 181.0870.

2-(4-Hydroxyphenyl)butanol (13). A solution of **12** (180 mg, 0.924 mmol) in THF (10 mL) was added to a solution of LAH (4.33 mg, 4.7 mmol) in THF (1 mL), and the reaction was stirred overnight. The reaction was quenched with saturated potassium sodium tartrate, and the gummy aluminum salts from the reaction were filtered through Celite. Concentration, followed by radial chromatography (2.5−10% MeOH/CH_2Cl_2) provided **13** as an off-white solid (34.9 mg, 23%). ^{1}H NMR ($CDCl_3$/CD_3OD, 500 MHz): δ 0.80 (t, J = 7.4 Hz, 3H, −CH_3), 1.49 [ddq, J = 13.6, 9.5, 7.4 Hz, 1H, −CH(CH_2OH)CH_2-CH_3], 1.68 [dqd, J = 13.5, 7.4, 5.4 Hz, 1H, −CH(CH_2OH)-CH_2CH_3], 2.61 [ddt, J = 9.5, 8.4, 5.4 Hz, 1H, −C*H*(CH_2-OH)Et], 3.66 [dd, J = 10.8, 8.4 Hz, 1H, −CH(CH_2OH)Et], 3.75 [dd, J = 10.8, 5.5 hz, 1H, −CH(CH_2OH)Et], 6.75 (d, J = 8.7 Hz, 2H, Ar*H*), 7.02 (d, J = 8.6 hz, 2H, Ar*H*). ^{13}C NMR (CD_2Cl_2, CD_3OD, 100 MHz): δ 12.0, 25.4, 49.9, 67.5, 115.6, 129.4, 133.9, 155.5. MS (CI, CH_4): *m*/*z* 167 (M + H^+, 27), 149 (33), 135 (100), 107 (97). HRMS Calcd for $C_{10}H_{15}O_2$: 167.1072. Found: 167.1078.

2-(4-Hydroxyphenyl)butyl Thioacetate (14). DIAD (83.0 μL, 0.420 mmol) was added dropwise to a solution of PPh_3 (110 mg, 0.420 mmol) in THF (5 mL) at 0 °C. Following formation of the white ylide precipitate, the solution was stirred for 30 min, at which time a solution of **13** (34.9 mg, 0.210 mmol) in THF was added dropwise, followed by thiolacetic acid (1.54 mL, 21.6 mmol). The reaction was stirred for 1 h at 0 °C, then overnight at room temperature. The reaction was then concentrated, and purification by radial chromatography (1% acetone/CH_2Cl_2) provided **14** as a slightly yellow oil (33.3 mg, 71%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 0.78 (t, J = 7.4 Hz, 3H, −CH(CH_2SCOCH_3)CH_2CH_3], 1.56 (ddq, J = 13.5, 9.6, 7.4 Hz, 1H, −CH(CH_2SCOCH_3)CH_2CH$_3$], 1.78 (dqd, J = 13.5, 7.4, 5.0 Hz, 1H, −CH(CH_2SCOCH_3)CH_2CH$_3$], 2.29 (s, 3H, −SCOCH_3), 2.58 [dddd, J = 9.6, 8.4, 6.6, 5.0 Hz, 1H, −C*H*(CH_2SCOCH_3)Et], 3.04 (dd, J = 13.3, 8.5 Hz, 1H, −CH(CH_2SCOCH_3)Et], 3.21 [dd, J = 13.3, 6.6 Hz, 1H, −CH(CH_2SCOCH_3)Et], 5.56 (s, 1H, −O*H*), 6.79 (d, J = 8.5 Hz, 2H, Ar*H*), 7.01 (d, J = 8.5 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 12.0, 28.5, 30.6, 35.7, 46.4, 115.2, 128.7, 135.2, 154.3, 196.8. MS (CI, CH_4): *m*/*z* 225 (M + H^+, 7), 149 (100), 135 (23), 131 (36), 107 (48). HRMS calcd for $C_{12}H_{17}O_2S$: 225.0949. Found: 225.0950.

2-(4-Hydroxyphenyl)butanethiol (15). Five milliliters of 1 M HCl in MeOH/dioxane (vide supra) was added to **14** (18.5 mg, 0.0825 mmol), and the reaction was refluxed at 80 °C under Ar for 3 h. Following evaporation of the solution under high vacuum, Kugelrohr distillation (65 °C, 0.1 mmHg) provided **15** as a near-colorless oil which crystallized in the collection flask to a white solid (17.2 mg, 100%). mp 64−65.5 °C. ^{1}H NMR ($CDCl_3$, 400 MHz): δ 0.81 (t, J = 7.3 Hz, 3, −CH_3), 1.19 (ddd, J = 8.6, 7.5, 0.6 Hz, 1H, −S*H*), 1.57 (m, 1H −CH_2CH$_3$), 1.82 (m, 1H, −CH_2CH$_3$), 2.56 (m, 1H, C*H*), 2.74 (m, 2H, −CH_2SH), 4.73 (s, 1H, O*H*), 6.80 (d, J = 8.3 Hz, 2H, Ar-3H), 7.04 (d, J = 8.5 Hz, 2, Ar-2H). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 12.1, 28.3, 31.0, 50.3, 115.3, 129.0, 135.3, 154.1. MS (CI, CH_4): *m*/*z* 183 (M + H^+, 36), 149 (56), 135 (52), 107 (100), 89 (18). Anal. Calcd for $C_{10}H_{14}OS$: C, 66.65; H, 7.83. Found: C, 66.69; H, 8.08.

[2-(4-Hydroxyphenyl)butanethiolato](3-thiapentane-1,5-dithialato)oxorhenium(V) (6). A solution of **15** (19.3 mg, 0.106 mmol) and bis(2-mercaptoethyl)sulfide (13.0 μL, 0.106 mmol) in CH_3CN (0.6 mL) was added dropwise to a solution of $[BnEt_3N]ReOCl_4$ (56.8 mg, 0.106 mmol) in MeOH (1 mL). A reddish solid immediately precipitated from solution. To this was added Et_3N (1 drop), and the reaction was stirred at 0 °C for 1 h. The reaction was concentrated, then purified by radial chromatography (1% acetone/CH_2Cl_2) to give **6** as a red powder (17 mg, 31%). IR (KBr): 932 cm^{-1} (Re═O); mp 188−189 °C, dec. ^{1}H NMR (DMSO-d_6, 500 MHz): δ 0.71 (t, J = 7.4 Hz, 3H, −C*H*3), 1.54 (m, 1H, −CH_2CH$_3$), 2.21 [m, 2H, −S(CH_2)$_2$S−], 2.76 (m, 1H, CH), 3.01 [m, 2H, −S(CH_2)$_2$S−], 3.76 (dd, J = 12.8, 7.1 Hz, 1H, −CHCH_2S−), 3.86 (dd, J = 13.0, 7.5 Hz, 1H, −CHCH_2S−), 4.03 [m, 2H, −S(CH_2)$_2$S−], 4.27 [dt, J = 12.5, 6.1 Hz, 2H, −S(CH_2)$_2$S−], 6.67 (d, J = 8.4 Hz, 2H, Ar-3H), 7.00 (d, J = 8.4 Hz, 2H, Ar-2H), 9.11 (s, 1H, O*H*). ^{13}C NMR (d_6-DMSO, 125 MHz): δ 12.1, 27.8, 43.0, 43.1, 45.5, 49.2, 115.0, 128.4, 134.7, 155.6. MS (FAB): *m*/*z* 537 (M, ^{187}Re isotope, 3). HRMS calcd for $C_{14}H_{22}O_2S_4{}^{187}Re$: 537.0060. Found: 537.0054.

1-(*p*-Anisyl)-butan-2-one (17). Following the synthesis according to Myers (*40*), NaOMe (13.7 g, 253 mmol) was added in portions over a period of 3 h to a solution of distilled *p*-anisaldehyde (31.0 g, 228 mmol) and ethyl α-bromobutyrate (44.5 g, 228 mmol) with cooling in an ice bath. After stirring for 2 days, the crude reaction was diluted with water, acidified with acetic acid, and extracted with ether. The organics were dried over Na_2SO_4, filtered, and concentrated to a yellow oil. The oil was Kugelrohr distilled, and after a forerun of anisaldehyde was collected (∼10 g, 90 °C, 0.1 mmHg), the epoxides were collected (110−115 °C, 0.1 mmHg) to give **16** as a slightly yellow oil (39.4 g, 69%, 100% corrected). A smaller portion was further purified by radial chromatography (20% EtOAc/Hex) and redistilled to give analytically pure material. MS (CI, CH_4): *m*/*z* 251 ($M + H^+$, 12), 237 (16), 177 (100), 149 (16), 121 (10). Anal. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25. Found: C, 67.10; H, 7.04.

A solution of NaOH (6.92 g, 173 mmol) in EtOH (110 mL) was added to the epoxide and refluxed 3 h, at which time it was cooled and concentrated. It was then diluted with water (35 mL) and washed with ether (75 mL). This was followed by acidification with 6 M HCl and extraction with ether. The ether was then washed with water (2 × 50 mL) and water (50 mL) with a trace amount of $NaHCO_3$. The organics were dried over Na_2SO_4, filtered, and concentrated. The concentrate was then heated on an oil bath at 90−100 °C for 4 h, then 130 °C for 1 h. After cooling, the red oil was dissolved in ether (100 mL) and washed sequentially with 1 M NaOH (50 mL), water (2 × 40 mL), and brine (40 mL). The organics were dried over Na_2SO_4, and concentrated to an orange oil. Kugelrohr distillation (90 °C, 0.1 mmHg) provided **17** as a slightly yellow oil (21.2 g, 76%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 1.01 (t, J = 7.3 Hz, 3H, −CH_2CH_3), 2.45 (q, J = 7.3 Hz, 2H, −CH_2CH$_3$), 3.61 (s, 2H, ArCH_2COEt), 3.78 (s, 3H, −OCH_3), 6.85 (d, J = 8.8 Hz, Ar*H*), 7.11 (d, J = 8.8 Hz, 2H, Ar*H*). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 7.7, 34.9, 48.7, 55.1, 114.0, 126.4, 130.2, 158.5, 209.2. MS (EI, 70 eV): *m*/*z* 178 (M^+, 23), 121 (100), 91 (10), 78 (23), 57 (12). Anal. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92. Found: C, 74.20; H, 7.99.

4-(4-Methoxyphenyl)-3-hexanone (18). Following the procedure by Myers (*40*), EtI (28.1 mL, 351 mmol) was added dropwise to a slurry of **17** (20.9 g, 117 mmol) and NaOMe (12.6 g, 234 mmol) in an ice bath. The solution was then refluxed, adding excess EtI when needed to keep the reaction stirring. After 1 h, the reaction was cooled, concentrated, and diluted with 10 mL of water. This was then extracted with ether (30 mL). The ether layer was washed with 10% NaS_2O_3 (10 mL), water (10 mL), and brine (10 mL). The ether layer was then dried with Na_2SO_4, filtered, and concentrated to a yellow oil. Kugelrohr distillation (81 °C, 0.1 mmHg) provided **18** as a slightly yellow oil (21.4 g, 89%). A small portion was purified by radial chromatography (20% EtOAc/hexane) and redistilled to give analytically pure product. ^{1}H NMR ($CDCl_3$, 400 MHz): δ 0.80 (t, J = 7.4 Hz, 3H, −CHCH$_2$CH_3), 0.94 (t, J = 7.3 Hz, 3H, −COCH$_2$CH_3), 1.66 (dquin, J = 13.8, 7.5 Hz, 1H, −CHCH_2CH$_3$), 2.01 (dquin, J = 13.7, 7.3 Hz, 1H, −CHCH_2CH$_3$), 3.46 [t, J = 7.5 Hz, 1H, Ar−C*H*(Et)COEt], 2.37 (ABqq, J_{AB} = 7.3 Hz, $\Delta\nu$ = 16.7 Hz, J = 7.3 Hz, 2H, −COCH_2CH$_3$), 3.77 (s, 3H, ArOCH_3), 6.84 (d, J = 8.8 Hz, 2H, Ar*H*), 7.11 (d, J = 8.7 Hz, 2H, Ar*H*). ^{13}C NMR δ 7.8, 12.0, 25.2, 34.8, 55.1, 59.5, 114.0, 129.1, 131.1, 158.6, 211.4. MS (EI, 70 eV): *m*/*z* 206 (M^+, 14), 149 (100), 121 (44), 91 (13). Anal. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.88; H, 8.94.

4-(4-Hydroxyphenyl)-3-hexanone (19). HBr (15 mL) and acetic acid (15 mL) were added to **18**, and the mixture was refluxed for 5 h and then cooled. The reaction was diluted with water (40 mL) and extracted with ether (3 × 40 mL). The ether layer was washed with saturated $NaHCO_3$ until neutral to pH paper. The ether was then washed with 10% $Na_2S_2O_3$ (30 mL) and water (40 mL). The phenol was extracted with 1 M NaOH (2 × 40 mL), acidified with HCl, and extracted with ether (3 × 35 mL). The ether layer was washed with water (30 mL), brine (40 mL), then dried with Na_2SO_4, filtered, and concentrated to provide **19** as a brown solid (5.73 g, 88%): mp 64−65.5 °C. ^{1}H NMR ($CDCl_3$, 400 MHz): δ 0.80 (t, J = 7.3 Hz, 3H, −CHCH$_2$CH_3), 0.96 (t, J = 7.3 Hz, 3H, −COCH$_2$CH_3), 1.69 (dquin, J = 13.7, 7.6 Hz, 1H, −CHCH_2CH$_3$), 2.01 (dquin, J = 13.7, 7.3 Hz, 1H, −CHCH_2-CH$_3$), 2.42 (ABqq, J_{AB} = 7.4 Hz, $\Delta\nu$ = 18.4 Hz, J = 7.3 Hz, 2H, −COCH_2CH$_3$), 3.50 [t, J = 7.5 Hz, 1H, ArC*H*(Et)-COEt], 6.89 (d, J = 8.7 Hz, 2H, Ar*H*), 6.96 (s, 1H, ArO*H*), 7.05 (d, J = 8.5 Hz, 2H, Ar*H*). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 7.9, 12.0, 25.1, 35.0, 59.6, 115.7, 129.3, 130.4, 155.2, 213.7. MS (EI, 70 eV): *m*/*z* 192 (M^+, 16), 135 (100), 107 (55). Anal. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39. Found: C, 75.12; H, 8.40.

4-[4-(2-Methoxyethoxymethoxy)phenyl]-3-hexanone (20). To a solution of NaH (1.25 g, 31.2 mmol) and THF (20 mL), cooled to 0 °C, was added **19** (4.00 g, 20.8 mmol) slowly. After stirring for 30 min, MEMCl (7.25 mL, 41.6 mmol) was added slowly. This was stirred for 6 h at room temperature, then quenched with MeOH with cooling and concentrated. The residue was dissolved in 110 mL of ether, then washed with 15% NaOH (2 × 40 mL), water (40 mL), and brine (45 mL). The ether layer was dried over Na_2SO_4 and concentrated to a yellow oil. Flash chromatography (10% acetone/CH_2Cl_2) and radial chromatography (2.5% acetone/CH_2Cl_2) provided **20** as a slightly yellow oil (4.91 g, 84%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 0.79 (t, J = 7.4 Hz, 3H, −CHCH$_2$CH_3), 0.93 (t, J = 7.3 Hz, 3H, −COCH$_2$CH_3), 1.65 (dquin, J = 13.8, 7.5 Hz, 1H, −CHCH_2CH$_3$), 2.00 (dquin, J = 13.8, 7.3 Hz, 1H, −CHCH_2CH$_3$), 2.36 (ABqq, JAB = 7.3 Hz, $\Delta\nu$ = 16.1 Hz, J = 7.3 Hz, 2H, −COCH_2CH$_3$), 3.35 [s, 3H, CH_3O(CH$_2$)$_2$-OCH$_2$OAr], 3.46 [t, J = 7.4 Hz, 1H, ArC*H*(Et)COEt], 3.54 [m, 2H, CH$_3$O(CH_2)$_2$OCH$_2$OAr], 3.80 [m, 2H, CH$_3$O(CH_2)$_2$-OCH$_2$OAr], 5.23 [s, 2H, CH$_3$O(CH$_2$)$_2$OCH_2OAr], 6.97 (d, J = 8.9 Hz, 2H, Ar*H*), 7.10 (d, J = 8.5 Hz, 2H, Ar*H*). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 7.8, 12.0, 25.3, 34.9, 58.9,

59.5, 67.5, 71.5, 93.4, 116.4, 129.1, 132.5, 156.3, 211.4. MS (EI, 70 eV): *m/z* 280 (M^+, 8), 223 (38), 149 (4), 135 (9), 107 (10), 89 (100), 59 (88), 43 (33). Anal. Calcd for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63. Found: C, 68.30; H, 8.90.

4-[4-(2-Methoxyethoxymethoxy)phenyl]-3-hexanol (21). A solution of **20** (2.48 g, 8.85 mmol) in THF (10 mL) was added to a slurry of LAH (839 mg, 22.1 mmol) in THF (15 mL) at 0 °C. The reaction was warmed to room temperature and stirred for 1.5 h. It was quenched sequentially with 840 μL of water, 840 μL of 15% NaOH, and 2.5 mL of water. The white slurry was then passed through Celite and concentrated. Flash chromatography (10% acetone/CH_2Cl_2) provided **21** as a colorless oil (2.24 g, 90%). ^{1}H NMR ($CDCl_3$, 400 MHz, major diastereomer): δ 0.75 (t, J = 7.4 Hz, 3H, $-CH_3$), 0.95 (t, J = 7.4 Hz, 3H, $-CH_3$), 1.27 (d, J = 5.0 Hz, 1H, OH), 1.29 [ddq, J = 13.9, 8.2, 7.3 Hz, 1H, $-$CH(OH)CH_2-CH$_3$], 1.55 [dqd, J = 13.9, 7.5, 3.9 Hz, 1H, $-$CH(OH)-CH_2CH$_3$], 1.63 [ddq, J = 13.6, 10.3, 7.3 Hz, 1H, $-$CH-(CH_2CH$_3$)Ar], 1.75 [dqd, J = 13.6, 7.4, 4.9 Hz, 1H, $-$CH(CH_2CH$_3$)Ar], 2.43 [dt, J = 10.4, 5.2 Hz, 1H, $-$CH(Et)Ar], 3.36 [s, 3H, CH_3O(CH$_2$)$_2$CH$_2$OAr], 3.56 [m, 2H, CH$_3$O(CH_2)$_2$CH$_2$OAr], 3.61 [m, 1H, $-$CH(OH)Et], 3.82 [m, 2H, CH$_3$O(CH_2)$_2$CH$_2$OAr], 5.25 [s, 2H, CH$_3$O-(CH$_2$)$_2$CH_2OAr], 7.00 (d, J = 8.8 Hz, 2H, ArH), 7.11 (d, J = 8.6 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz, major diastereomer): δ 10.1, 12.2, 25.0, 27.8, 52.6, 58.9, 67.5, 71.6, 76.0, 93.5, 116.1, 129.8, 134.4, 155.9. MS (EI, 70 eV): *m/z* 282 (M^+, 1), 223 (30), 148 (56), 136 (36), 107 (19), 89 (100), 59 (92). HRMS Calcd for $C_{16}H_{26}O_4$: 282.1831. Found: 282.1841.

4-[4-(2-Methoxyethoxymethoxy)phenyl]-3-thioacetyl-hexane (22). Triethylamine (1.66 mL, 11.9 mmol) and MsCl (0.921 mL, 11.9 mmol) were added to a solution of **21** (2.24 g, 7.93 mmol) in THF (15 mL) and cooled to 0 °C in an ice bath. The reaction was stirred for 30 min at 0 °C, then for 1 h at room-temperature. Reaction was stopped and diluted with 20 mL of water. Following concentration, the aqueous layer was extracted with ether (1 × 40 mL, 1 × 15 mL). The organics were combined and washed with water (15 mL), dried with Na_2SO_4, and concentrated to a yellow oil (2.72 g, 91%). This was used in the next step without further purification.

The mesylate (361 mg, 0.960 mmol) was combined with tetrabutylammonium thioacetate [760 mg, 2.39 mmol, prepared according to Logusch (*41*)] in DMF (2 mL). This was heated at 50 °C overnight. The crude mixture was diluted with ether, washed with saturated LiCl, water, and brine, then dried over Na_2SO_4, filtered, and concentrated to a dark oil. This was purified by radial chromatography (0.5% acetone/CH_2Cl_2) to provide the thioacetate **22** as a yellow-orange oil (121 mg, 37%). ^{1}H NMR ($CDCl_3$, 400 MHz, major diastereomer): δ 0.68 (t, J = 7.4 Hz, 3H, CH_3), 0.84 (t, J = 7.3 Hz, 3H, CH_3), 1.24 [m, 1H, $-$CH(SCOCH$_3$)CH_2CH$_3$], 1.56 [m, 2H, $-$CH(SCOCH$_3$)CH_2-CH$_3$], 1.93 [dqd, J = 13.6, 7.4, 3.8 Hz, 1H, $-$CH(CH_2CH$_3$)-Ar], 2.34, (s, 3H, $-$SCOCH_3), 2.52 [ddd, J = 11.1, 8.6, 3.8 Hz, 1H, $-$CH(CH_2CH$_3$)Ar], 3.37 [s, 3H, CH_3O(CH$_2$)$_2$-CH$_2$OAr], 3.56 [m, 2H, CH$_3$O(CH_2)$_2$CH$_2$OAr], 3.68 [td, J = 8.9, 3.5 Hz, 1H, $-$CH(Et)Ar], 5.25 [s, 2H, CH$_3$O-(CH$_2$)$_2$CH_2OAr], 6.97 (d, J = 8.6 Hz, 2H, ArH), 7.08 (d, J = 8.6 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz, major diastereomer): δ 11.0, 12.2, 25.4, 26.4, 30.8, 50.8, 51.6, 59.0, 57.6, 71.6, 93.6, 115.9, 129.4, 135.6, 155.8, 195.9. MS (EI, 70 eV): *m/z* 340 (M^+, 1), 264 (40), 223 (51), 135 (21), 107 (15), 89 (100), 59 (75). HRMS calcd for $C_{18}H_{28}O_4S$: 340.1708. Found: 340.1709.

3-Mercapto-4-(4-hydroxyphenyl)hexane (23). Ten milliliters of 1 M HCl in MeOH/dioxane was added to **22** (121 mg, 0.350 mmol) and the reaction was refluxed at 80 °C under Ar for 3 h. Evaporation of the solvent under high vacuum provided a dark oil. Purification by radial chromatography (0.5% acetone/CH_2Cl_2) gave the thiol **23** as a yellow-orange oil (34.1 mg, 46%). ^{1}H NMR ($CDCl_3$, 400 MHz, major diastereomer): δ 0.73 (t, J = 7.3 Hz, 3H, CH_3), 0.95 (t, J = 7.3 Hz, 3H, CH_3), 1.26 [m, 1H, $-$CH(SH)CH_2CH$_3$], 1.31 (d, J = 7.2 Hz, 1H, $-$SH), 1.63 [m, 2H, ArCH(CH_2CH$_3$)CH(SH)CH_2CH$_3$], 2.03 [dqd, J = 13.5, 7.4, 3.8 Hz, 1H, $-$CH(CH_2CH$_3$)Ar], 2.50 [ddd, J = 11.0, 7.4, 3.5 Hz, 1H, $-$CH(Et)Ar], 2.87 [dtd, J = 9.2, 7.3, 3.5 Hz, 1H, $-$CH(SH)Et], 5.09 (s, 1H, Ar$-$OH), 6.78 (d, J = 8.3 Hz, 2H, ArH), 7.02 (d, J = 8.5 Hz, 2H, ArH). MS (CI, CH_4): *m/z* 211 ($M + H^+$, 40), 177 (100), 135 (72), 121 (14), 107 (80). HRMS Calcd for $C_{12}H_{19}OS$: 211.1157. Found: 211.1161.

2,6-Bis(thiacetomethyl)pyridine (25). DIAD (4.25 mL, 21.6 mmol) was added dropwise to a solution of PPh_3 (5.67 g, 21.6 mmol) in THF (100 mL) at 0 °C. Following formation of the white ylide precipitate, the solution was stirred for 30 min, at which time a solution of 2,6-pyridinedimethanol (1.00 g, 7.19 mmol) in THF/DMF was added dropwise, followed by thiolacetic acid (1.54 mL, 21.6 mmol). The reaction was stirred for 1 h at 0 °C, then overnight at room temperature. A green slurry developed immediately upon addition of the thiolacetic acid, which eventually changed to a yellow color. The reaction was then concentrated and purified by flash chromatography (5% MeOH/CH_2Cl_2) and radial chromatography (CH_2Cl_2 to 5% MeOH/CH_2Cl_2). Recrystallization from EtOAc/hexanes 3 times provided **25** as yellow crystals (980 mg, 53%): mp 46.5−47.5 °C. ^{1}H NMR ($CDCl_3$, 400 MHz): δ 2.36 (s, 6H, $-$SCOCH_3), 4.22 (s, 4H, ArCH_2SCOCH$_3$), 7.21 (d, J = 7.7 Hz, 2H, ArH), 7.56 (t, J = 7.7 Hz, 1H, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 30.2, 35.0, 121.6, 137.4, 157.0, 194.9. MS (CI, CH_4): *m/z* 256 ($M + H^+$, 100), 214 (55). Anal. Calcd for $C_{11}H_{13}NO_2S_2$: C, 51.74; H, 5.13; N, 5.49; S, 25.11. Found: C, 51.64; H, 5.19; N, 5.42; S, 25.07.

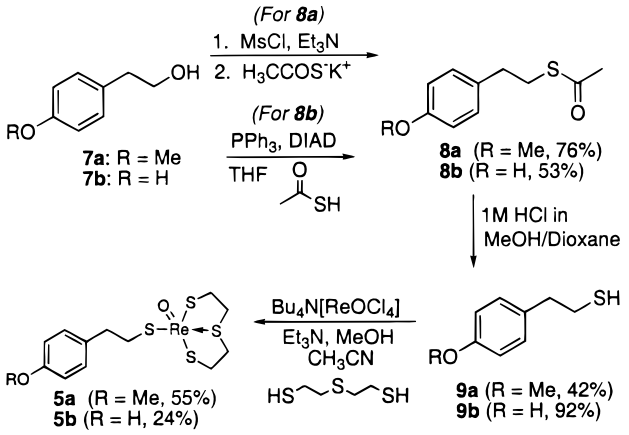
2,6-Dithiomethylpyridine Hydrochloride (26). Four milliliters of 1 M HCl in MeOH/dioxane (vide supra) was added to **25** (200 mg, 0.783 mmol) and the reaction was refluxed at 80 °C under Ar for 3 h. Evaporation under high vacuum provided **26** as a slightly yellow solid (144 mg, 89%). This solid was used in the next reaction without further purification. ^{1}H NMR (CD_3OD, 400 MHz) δ 4.09 (s, 4H, ArCH_2SH), 7.93 (d, J = 8.0 Hz, 2H, ArH), 8.48 (t, J = 8.0 Hz, 1H, ArH). MS (CI, CH_4): *m/z* 172 (M + H^+, 100), 138 (39).

(4-Hydroxythiophenolato)(2,6-dithiomethylpyridinato)oxorhenium(V) (4b). A solution of **26** (28.0 mg, 0.172 mmol) and 4-hydroxythiophenol (24.1 mg, 0.172 mmol) in CH_3CN (0.6 mL) and MeOH (0.4 mL) was added to a solution of [BnEt$_3$N]ReOCl$_4$ in MeOH (1 mL) under an Ar atmosphere. A brownish solution formed immediately, which intensified when Et_3N (95.9 μL, 0.688 mmol) was added. The reaction was stirred for 1 h, concentrated, and purified by radial chromatography (1% acetone/CH_2Cl_2) to give **4b** as a red solid (47.2 mg, 55%). IR (KBr): 962 cm^{-1} (Re═O); mp 108−112 °C (dec). Normal-phase HPLC [t_R = 8.6 min, 50% hexane/50% (5% IPA/CH_2Cl_2), UV detection] showed only one visible peak. ^{1}H NMR (acetone-d_6, 400 MHz): δ 4.8−5.6 (bm, 5H, $-$SCH_2pyr, ArOH), 6.89 (d, J = 8.7 Hz, 2H, $-$SArH), 7.53 (d, J = 8.7 Hz, 2H, $-$SArH), 7.70−7.88 (bd, 2H, pyrH), 7.97 (t, J = 7.7 Hz, 1H, pyr-4H). MS (EI, 70 eV): *m/z* 497 (M^+, 100), 372 (80). HRMS Calcd for $C_{13}H_{12}NO_2S_3{}^{187}$-Re: 496.9588. Found: 496.9581.

(4-Methoxythiophenolato)(2,6-dithiomethylpyridinato)oxorhenium(V) (4c). A solution of **26** (20 mg, 0.0927 mmol) and 4-methoxythiophenol (13.0 mg, 0.0927 mmol) in a 1:1 mixture of MeOH/CH_3CN (1 mL) was added dropwise to a solution of $[BnEt_3N]ReOCl_4$ in MeOH (1.5 mL). This was followed by the dropwise addition of Et_3N (52 μL, 0.371 mmol), and the reaction was stirred for 1 h, then warmed to 40 °C for 15 min. Concentration, followed by radial chromatography (CH_2Cl_2) provided **4c** as a dark red solid (18.5 mg, 39%). IR (KBr): 964 cm^{-1} (Re═O); mp 103 °C (dec). ^1H NMR (CD_2Cl_2, 500 MHz): δ 3.85 (s, 3H, Ar−OCH_3), 4.8−5.6 (m, 4H, pyr-CH_2S−), 6.96 (d, J = 8.8 Hz, −SAr*H*), 7.59 (d, J = 8.9 Hz, 2H, −SAr*H*), 7.78 (bd, 2H, pyr*H*), 7.97 (t, J = 7.7 Hz, 1H, pyr*H*). MS (FAB): m/z 511 (M + H^+ for ^{187}Re, 8), 509 (M + H^+ for ^{185}Re, 4), 141 (100). HRMS Calcd for $C_{14}H_{14}NO_2S_3{}^{187}Re$: 510.9744. Found: 510.9741.

Dimethyl Chelidamate (28). Using the procedure by Bradshaw (*42*), chelidamic acid (6.00 g, 32.8 mmol), MeOH (80 mL), and concentrated H_2SO_4 (1.2 mL) were combined and refluxed for 21 h. The reaction was cooled, neutralized with saturated Na_2CO_3, and reacidified with concentrated HCl. This was diluted with water (80 mL) and extracted with CH_2Cl_2 (1 × 100 mL, 2 × 50 mL). The organics were combined, dried with Na_2SO_4, filtered, and concentrated to a yellow solid. Two recrystallizations from MeOH gave **28** as a light yellow solid (3.51 g, 51%): mp 168.5−169.5 °C [lit. (*42*) 169−169.5 °C]. ^1H NMR ($CDCl_3$, 400 MHz): δ 3.96 (s, 6H, ArCO_2CH_3), 7.80 (bs, 2H, pyr*H*), 9.8−10.2 (bs, 0.4H, pyrO*H*), 11.4−11.9 (bs, 0.4H, pyrO*H*). MS (EI, 70 eV): m/z 211 (M^+, 100), 183 (71), 167 (15), 153 (96), 121 (52), 92 (64), 79 (8), 68 (14), 59 (31). Anal. Calcd for $C_9H_9NO_5$: C, 51.19; H, 4.30; N, 6.63. Found: C, 51.16; H, 4.24; N, 6.63.

Dimethyl 4-[(Tetrahydro-2-pyranyl)oxy]-2,6-pyridinedicarboxylate (29). To a solution of **28** (3.11 g, 14.7 mmol) in CH_2Cl_2 (44 mL) was added 3,4-dihydro-2*H*-pyran (6.72 mL, 73.6 mmol) and pyridinium *p*-toluenesulfonate (377 mg, 1.50 mmol). The reaction was stirred overnight at room temperature. The crude reaction mixture was washed with brine (2 × 15 mL) and water (20 mL), dried over Na_2SO_4, filtered, concentrated, and recrystallized from EtOAc/hexane to give **29** as white crystals (2.97 g, 68%): mp 119.5−121.5 °C [lit. (*42*) 120−121.5 °C]. ^1H NMR ($CDCl_3$, 400 MHz): δ 1.5−1.78 (m, 3H, THP), 1.82−2.04 (m, 3, THP), 3.61−3.80 (m, 2H, THP), 3.98 (s, 6H, pyrCO_2CH_3), 5.66 (t, J = 2.75 Hz, 1H, THP), 7.92 (s, 2H, pyr*H*). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 17.9, 24.7, 29.5, 53.1, 62.0, 96.3, 116.0, 149.6, 165.06, 165.12. MS (CI, CH_4): m/z 296 (M + H^+, 5), 240 (13), 212 (100), 85 (26), 57 (11). Anal. Calcd for $C_{14}H_{17}NO_6$: C, 56.94; H, 5.80; N, 4.74. Found: C, 56.80; H, 6.99; N, 4.73.



4-(Tetrahydro-2H-2-pyranyloxy)-2,6-bis(hydroxymethyl)pyridine (30). Following the procedure used by Scrimin (*43*), $NaBH_4$ (1.06 g, 28.1 mmol) was added to a solution of **29** in EtOH (90 mL). Crushed $CaCl_2$ (3.11 g, 28.1 mmol) was then added slowly to the reaction, producing a heterogeneous pink color. After stirring overnight, the reaction was diluted with water (100 mL), and the EtOH was removed by evaporation in vacuo. The residue was added to brine (100 mL), and extracted with $CHCl_3$ (4 × 200 mL). This was evaporated to a light green oil, which solidified upon standing under vacuum for several days, giving a crude mass of 1.53 g (69%). Recrystallization from EtOAc provides **30** as off-white crystals (1.14 g, 51%): mp 115−116 °C. ^1H NMR (CD_3OD, 500 MHz): δ 1.5−1.75 (m, 2H, THP), 1.8−2.0 (m, 3H, THP), 2.70 (bs, 2H, pyrCH_2O*H*), 3.58 (dtd, J = 11.3, 4.1, 1.5 Hz, 1H, THP), 3.77 (ddd, J = 11.4, 10.1, 3.2 Hz, 1H, THP), 4.61 (s, 4H, pyrCH_2OH), 5.55 (t, J = 3.2 Hz, 1H, THP), 6.89 (s, 2H, pyr*H*). MS (CI, CH_4): m/z 240 (M + H^+, 13), 222 (10), 184 (25), 156 (100), 85 (35). Anal. Calcd for $C_{12}H_{17}NO_4$: C, 60.24; H, 7.16; N, 5.85. Found: C, 59.93; H, 7.13; N, 5.85.

4-(Tetrahydro-2H-2-pyranyloxy)-2,6-bis(thioacetylmethyl)pyridine (31). Diisopropyl azodicarboxylate (2.30 mL, 11.5 mmol) was added slowly to a solution of PPh_3 (3.01 g, 11.5 mmol) in THF (75 mL) at 0 °C. Upon formation of the white ylide precipitate., the reaction was stirred for 30 min at 0 °C. A solution of **30** (1.08 g, 4.50 mmol) in THF/DMF was added to the reaction, followed by thiolacetic acid (820 μL, 11.5 mmol). The reaction was stirred for 1 h at 0 °C, then overnight at room temperature. The reaction was concentrated, redissolved in CH_2Cl_2 (60 mL), and washed with saturated LiCl (2 × 30 mL) and brine (1 × 30 mL). The organic layer was dried over Na_2SO_4, filtered, and concentrated. After three flash chromatography purifications (5% MeOH/CH_2Cl_2), the thioacetate **31** was isolated as a yellow oil (1.15 g, 72%). ^1H NMR ($CDCl_3$, 400 MHz): δ 1.24 (m, 2H, THP), 1.52−2.0 (m, 6H, THP), 2.34 (s, 6H, −SCOCH_3), 3.60 (dtd, J = 11.1, 4.0, 1.5 Hz, 1H, THP), 3.76 (m, 1H, THP), 4.14 (ABq, J_{AB} = 13.8 Hz, $\Delta\upsilon$ = 13.8 Hz, 4H, ArCH_2SCOMe), 6.86 (s, 2H, pyrH). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 18.2, 24.8, 29.7, 30.2, 35.4, 61.9, 95.7, 109.6, 158.4, 164.4, 194.9. MS (CI, CH_4): m/z 356 (M + H^+, 5), 300 (15), 272 (81), 247 (26), 205 (55), 161 (100), 147 (32), 119 (89), 85 (34), 57 (16). HRMS Calcd for $C_{16}H_{22}NO_4S_2$: 356.0997. Found: 356.0997.

[4-Hydroxy-2,6-bis(thiomethyl)pyridinato][4-hydroxythiophenolato]oxorhenium(V) (4a). A solution of 1 M HCl in MeOH/dioxane (1 mL) was added to **31** (50 mg, 0.141 mmol) and refluxed at 80 °C for 3 h under Ar. Concentration under high vacuum provided the dithiol HCl salt **32** as an extremely hygroscopic off-white solid, which darkened with time at room temperature. A solution of the thiol (25.2 mg, 0.113 mmol) and *p*-hydroxythiophenol (15.8 mg, 0.113 mmol) in 1:1 MeOH/CH_3CN (1 mL) was added to a solution of $[BnEt_3N]ReOCl_4$ in MeOH (1 mL) at 0 °C under Ar. This was followed by the dropwise addition of Et_3N (16 μL, 0.113 mmol), resulting in a dark solution. The reaction was warmed to room temperature for 45 min. Concentration, followed by radial chromatography (5−10% MeOH/CH_2Cl_2), provided a red, sticky oil, which when slowly evaporated from CH_2Cl_2 provided **4a** as red solid (22.5 mg, 39%). IR (NaCl): 965 cm^{-1} (Re═O); mp ∼100 °C (dec). ^1H NMR (DMSO-d_6, 400 MHz, 95 °C): δ 4.98 (ABq, J_{AB} = 17.6 Hz, $\Delta\upsilon$ = 195 Hz, 4H, pyrCH_2S−), 6.76 (d, J = 8.5 Hz, 2H, −SAr*H*), 7.25 (s, 2H, pyr*H*), 7.28 (d, J = 8.5 Hz, 2H, −SAr*H*). ^{13}C NMR ($CD_3OD/CDCl_3$, 100 MHz): δ 51.2, 106.7, 134.8, 138.0, 155.8, 168.8. MS (FAB): m/z 514 (M^+ for ^{187}Re, 3), 512 (M^+ for ^{185}Re, 2), 461 (100). HRMS calcd for $C_{13}H_{13}NO_3S_3{}^{187}Re$: 513.9615. Found: 513.9613.

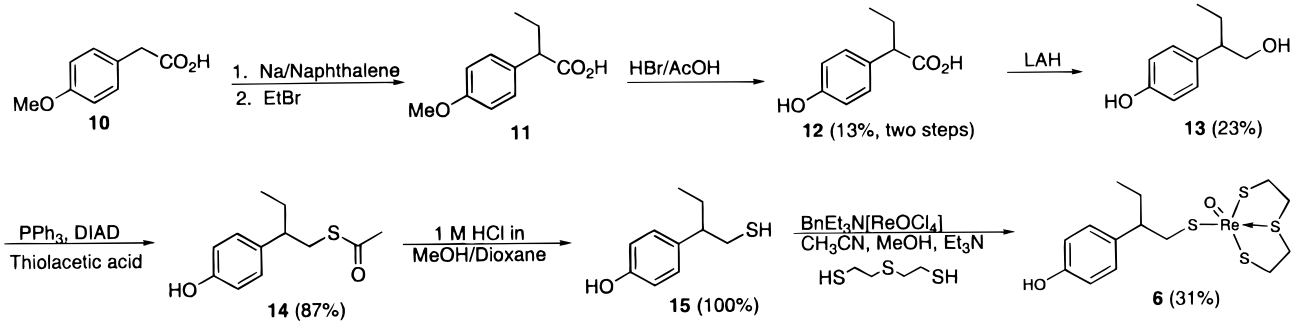
Measurement of the Octanol/Water Partition Coefficient. The log $P_{o/w}$ values were estimated from log k'_w values determined by reversed-phase HPLC following the method outlined by Minick (*44*). A Chromegabond C8 (5 mm, 60 Å, ES Industries) 15 cm × 4.6 mm column served as the stationary phase. The organic mobile phase was methanol containing 0.25% (v/v) 1-octanol, and the aqueous phase consisted of octanol-saturated water containing 0.25% (v/v) M MOPS (3-morpholinopropanesulfonic acid, Sigma) buffer and 0.15% (v/v) *n*-decylamine, adjusted to pH 7.4. The flow rate was 1 mL/min.

Scheme 1

Estrogen Receptor Binding Affinity. Receptor-binding affinity (RBA) values were determined by a competitive radiometric binding assay, using tritiated estradiol as the tracer and lamb uterus cytosol as the source of receptor, according to a previously established method (*45*).

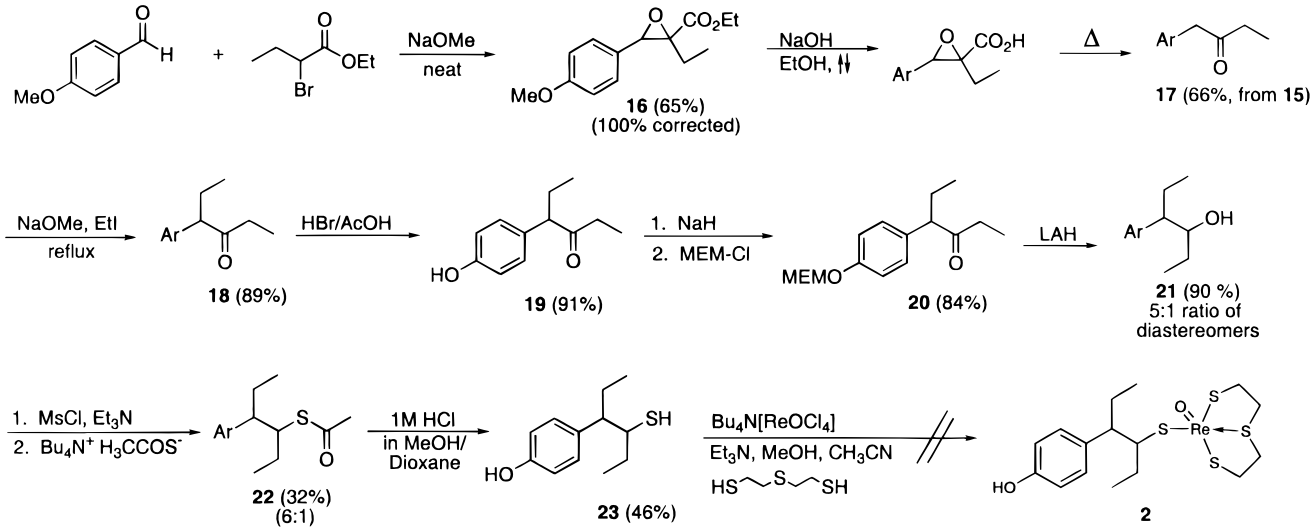
RESULTS AND DISCUSSION

Syntheses. *Synthesis of Complexes That Mimic Estradiol (**5ab**, **6**, and **2**).* Before the preparation of the precursor monodentate ligand for **2**, we first synthesized some model compounds which were intended to not only help us determine the route by which to introduce the thiol to monodentate ligands but also serve as a "reference" to compare relative-binding affinities to **2**. These complexes included one with a simple phenethyl thiol monodentate ligand (**5a,b**) and one with an ethyl group at the benzylic position of the monodentate ligand (**6**).



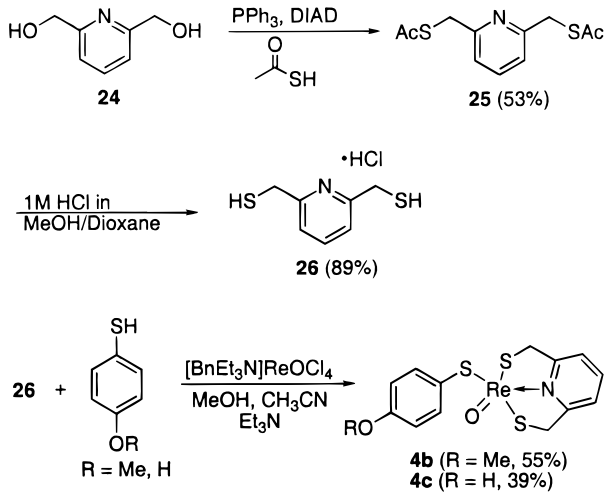
The synthesis of the first model systems **5a** and **5b** follows the straightforward route outlined in Scheme 1. Starting with the parent phenethyl alcohol (**7a**, **7b**), either Mitsunobu or mesylation-displacement with potassium thioacetate work well in generating the thioacetates **8a** and **8b**, respectively. Treatment of the thioacetate with anhydrous HCl in methanol/dioxane generates the free thiols **9a** and **9b** cleanly. Attempts to free the thiol under alkaline conditions (e.g., K_2CO_3 in MeOH/H_2O and LAH) only resulted in formation of the disulfide, even when strictly anaerobic conditions were observed. Complexation of these thiols with the commercially available bis(2-mercaptoethyl) sulfide and a readily available rhenium source, $Bu_4N[ReOCl_4]$ (*38*), furnished the desired complexes **5a** and **5b** in modest yields.

The synthesis of the monoethyl model system **6** is outlined in Scheme 2 and is analogous to the syntheses of **5a** and **5b**. Carboxylic acid **11** is prepared from *p*-methoxyphenylacetic acid (**11**), using a known literature procedure (*39*), and is used without purification in the deprotection step to afford phenol **12** in low yield. Reduction with LAH generates alcohol **13** in low yield because of difficulties in the workup. A Mitsunobu reaction on the alcohol provides the thioacetate **14** in good yield. The thiol **15** is then released in a manner analogous to **9a** and **9b**, and the complex is obtained without complication.



The attempted synthesis of desired complex **2** is described in Scheme 3. The skeleton for the monodentate ligand was generated by first reacting *p*-anisaldehyde and ethyl *a*-bromobutyrate in a Darzens reaction to afford the glycidic ester **16** in good yield (*40*). Saponification, followed by thermal decarboxylation produced ketone **17** in good yield (*40*). Ethylation of the more stable benzylic enolate with EtI as the solvent afforded the branched ketone **18** in excellent yield. Deprotection with HBr and AcOH produced the free phenol **19**, again in excellent yield (*40*). After reprotection with the MEM group, the protected ketone **20** was reduced by LAH reduction to generate the alcohol **21** as a 5:1 mixture of diastereomers by NMR (presumably 3R*,4S*:3R*,4R* according to Felkin-Ahn rules). We did not separate the diastereomers at this point because we chose to determine the relative-binding affinities of the diastereomeric mixture of rhenium complexes, not knowing which would be of higher affinity. If appreciable binding were observed, we then would have made efforts to separate the two diastereomers.

Mesylation of alcohol **21**, followed by displacement with thioacetate, generated the thioacetate **22** in low yield. A competing elimination reaction to produce the trisubstituted olefin and the difficulty of an S_N2 attack of the thioacetate on the highly hindered secondary carbon are thought to be responsible for the low yield. Typical Mitsunobu conditions to generate the thioacetate failed for this reaction. In addition, attempts to form the thiol via BuLi-assisted reductive fragmentation of a thioketal (derived from ketone **20**) failed (*46*), and reduction of the Lawesson's Reagent-produced thioketone (also derived from ketone **20**) was also unsuccessful. The thioacetate **22** was subjected to the same acidic conditions as in Schemes 1 and 2 to generate the thiol **23** in modest yield; the yield was again limited by acid-catalyzed formation of the olefin. However, in contrast to thiols **9ab** or **15**, when the thiol was subjected to the standard complexation conditions, complex **2** failed to form. Efforts to generate the complex by changing the temperature, order of reagent addition, and rhenium source also failed. It is believed that the difficulty in producing this complex is again due to the highly hindered nature of the secondary thiol used in the reaction, especially considering the fact that complexation of thiol **15**, which lacks just one of the



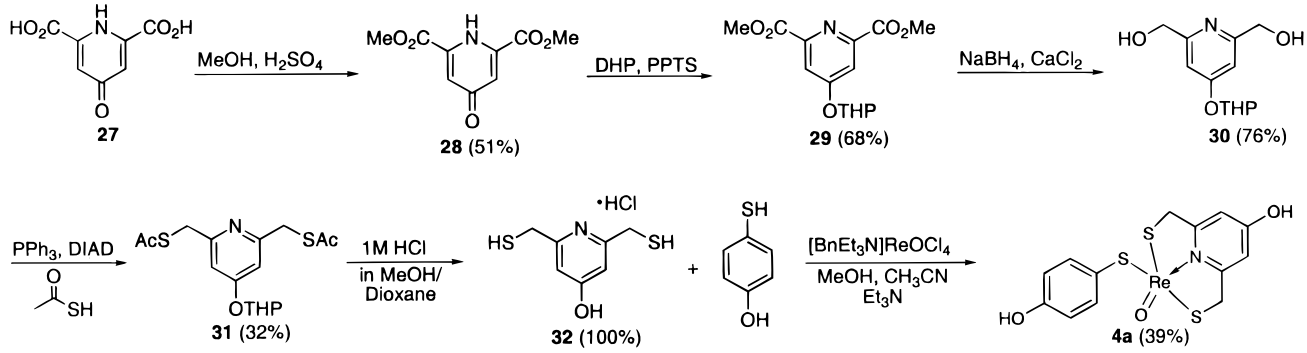
Scheme 2

Scheme 3

Scheme 4

ethyl groups, results in clean formation of complex **6** (Scheme 2).

*Synthesis of Complexes That Mimic a Tetrahydrochrysene Estrogen (**4a**−**c**).* Complexes **4a**−**c** were designed to mimic a tetrahydrochrysene (THC) estrogen (cf. Figure 1). The reasoning behind including complexes with and without the *p*-hydroxy functionality on the tridentate ligand was to compare the effect this would have on the relative-binding affinity. One would expect the binding to be appreciably higher in **4a** where both hydroxyls are present, as this best represents the THC that the complex is trying to mimic. Alternatively, when one removes the *p*-hydroxy group from the tridentate ligand (as in **4b** and **4c**) or protects the hydroxy on the monodentate ligand (**4b**), one should see a dramatic drop in binding affinity compared to **4a**.



We synthesized the tridentate pyridine dithiol ligand for **4b** and **4c**, which does not contain the *p*-hydroxy group, by starting with commercially available 2,6-pyridinedimethanol (**24**, Scheme 4). The Mitsunobu reaction was then used to transform the diol **24** into the dithioacetate **25** after recrystallization. Thioacetate **25** was then treated with anhydrous hydrochloric acid under argon to afford the dithiol **26** as the HCl salt in good yield. Subjecting the crude dithiol **26** to standard complexation conditions with either *p*-methoxythiophenol or *p*-hydroxythiophenol afforded the red complexes **4b** and **4c**, respectively.

A concern that we had prior to the successful formation of these complexes was that the planar aromatic pyridine would inhibit bonding of the tridentate ring to the oxorhenium core, because of the rigidity it enforces on the framework of the tridentate ligand. However, all complexation reactions involving this type of tridentate ligand went smoothly, and all of the complexes produced were stable to air and moisture for extended periods of time. To our knowledge, this is the first example of a benzylic dithiopyridine complexed to an oxorhenium center.

The synthesis of complex **4a** requires the use of a starting material which will eventually give a tridentate ligand having a *p*-hydroxy functionality. To this end, we started with commercially available chelidamic acid (**27**, Scheme 5). Esterification provides the diester **28**, which, upon protection of the phenol with DHP, gives the fully protected diester **29** (*42*). Although LAH was not effective in reducing the diesters, a mixture of $NaBH_4$ and $CaCl_2$ produced diol **30** in good yield (*43*). The thioacetates were then introduced by using the standard Mitsunobu conditions to give the dithioacetate **31**. Removal of the thioacetates under acidic conditions also conveniently removed the THP group, giving the desired tridentate dithiol **32** as the very hygroscopic HCl salt, in quantitative yield. The crude **32** was then subjected to the standard complexation conditions to give the novel rhenium complex **4a** in modest yield.

*Variable Temperature NMR Studies on the Fluxional 3+1 Complex **4a**.* An X-ray crystal structure of a complex similar to **4b** (where there is no *para* hydroxyl on the pyridine ring) shows that the arenethiolate ligand is bent toward one side of the molecule (*47*). Therefore, **4a** is asymmetric, and VT NMR studies on **4a** seem to confirm this observation (Figure 2). At −60 °C, the rotation of the arenethiolate ligand is slow on the NMR time scale, and the magnetically inequivalent benzylic and meta protons of the tridentate ligand appear as two sharp sets of AB quartets and two singlets, respectively. As the temperature is elevated, these peaks start to coalesce as the arenethiolate ligand flips back and forth more rapidly. This is evident at 16 °C where these signals are significantly broadened. At 95 °C, the rotation of the arenethiolate ligand is fast on the NMR time scale, and one observes a symmetric time-averaged structure. This is evident by the fact that the two singlets at −60 °C have now nicely coalesced into one singlet at 95 °C. Similarly,

Scheme 5

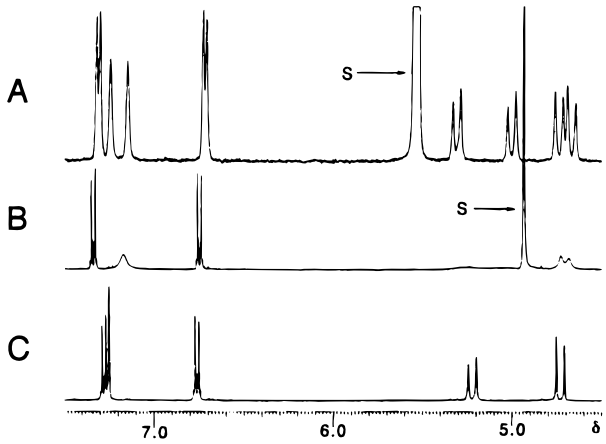


Figure 2. VT NMR of **4a** [A (CD_3OD, −60 °C); B (CD_3OD, 16 °C); C (DMSO-d_6, 95 °C)].

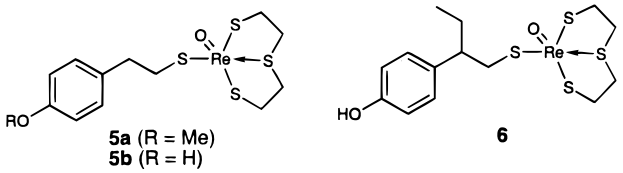
Table 1. Relative-Binding Affinity (RBA) and Log $P_{o/w}$ Values of Rhenium Complexes

complex	RBA (0 °C)	log $P_{o/w}$
1	100	3.98
5a	<0.006	
5b	0.018	
6	0.005	
4a	0.035	5.35
4b	<0.01	4.14
4c	0.01	3.46

the two sets of AB quartets at −60 °C have coalesced into one AB quartet at 95 °C.

Estrogen Receptor Binding Affinities and Lipophilicities. The ER binding affinities and lipophilicities of the rhenium complexes **5a**−**b**, **6**, and **4a**−**c** are shown in Table 1. The affinities were expressed as relative-binding affinities (RBA), where estradiol has a value of 100. RBA values were determined by a competitive radiometric binding assay at 0 °C, using lamb cytosol as the source for ER and [^{3}H]estradiol as the tracer. Unfortunately, all complexes showed only micromolar affinities for the ER. Considering the low RBA values of the estradiol mimic series, **5ab** and **6**, it is unlikely that the introduction of the second ethyl group would have changed the binding affinities dramatically had we been successful in preparing complex **2**. The THC mimic series (**4a**−**c**) also showed very low-binding affinities. There is a reasonable trend in the values, in that the complexes with one or more phenols show better RBA values than those without (**4a** > **4c** > **4b**). However, the significance of this trend at very low affinities is uncertain.

The lipophilicities of the THC mimics were determined by measuring their log $P_{o/w}$ values according to the method of Minick (*44*). The values of **4b** and **4c** (4.14 and 3.46, respectively) are rather similar to that of estradiol, while **4a**, which one would expect to be even more polar than **4c** because of the addition of a hydroxyl group, has a remarkably high log $P_{o/w}$ value of 5.35 by this method, even though normal-phase TLC and solubility in polar organic solvents show the opposite trend. The unique and not well-understood properties of this novel rhenium complex structure, especially its interactions with the reversed-phase HPLC column used to determine the log $P_{o/w}$ in this experiment, might contribute to this unexpected result. It is interesting to note, however, that Kung and co-workers reported a similar finding in comparing the log $P_{o/w}$ values of N_2S_2 oxotechnetium complexes of the diamine vs amine-amide type (*48*). The replacement of two hydrogens with an oxo substituent in this case resulted in an 8-fold increase in the log $P_{o/w}$ value.



CONCLUSIONS

We have described the synthesis of a number of novel "3+1" oxorhenium(V) complexes (**4a**−**c**, **5ab**, and **6**) for use as estrogen mimics and have determined their binding affinites for the estrogen receptor (ER). We were also able to synthesize the monodentate ligand **23** needed to prepare complex **2** (the best mimic of estradiol); however, the hindered nature of the thiol in **23** prevented this ligand from complexing with rhenium to form the desired complex. The relative-binding affinity (RBA) values of the estradiol model complexes (**5a**, **5b**, and **6**) are low (the highest value is 0.018% vs 100% for estradiol) and indicate that these complexes are not, in fact, good mimics of estradiol.

The series of pyridinedithiol complexes **4a**−**c** as mimics for THC have also been synthesized. These pyridinedithiol oxorhenium complexes are the first of their kind. The complexes are quite stable to air and moisture, and VT NMR studies reveal the fluxional nature of the arenethiolate ligand in these complexes. These complexes also have poor binding affinity to the ER. The lipophilicity of complexes **4b** and **4c** is fairly close to that of estradiol, while complex **4a** shows a log $P_{o/w}$ value much higher than expected. Even though molecular modeling suggests that the distance between the phenolic hydroxyl groups in complex **4a** is actually comparable to that of diethylstilbestrol compounds (*49*), the location of the polar and bulky square pyramidal oxorhenium core toward the center of a normally lipophilic region of steroidal and nonsteroidal estrogens might account for the low binding affinity observed for the THC class mimics (*30*).

The low binding affinity of all complexes described here is probably due to the poor geometric and electronic match between the complexes and the native ligands. Future work on these integrated complexes will involve

Chart 1

5a (R = Me)
5b (R = H)

6

the use of a chelate system whose geometry (e.g., square planar) and arrangement of polar moieties is more akin to that of the native ligands.

ACKNOWLEDGMENT

We are grateful for the support of this research through grants from the Department of Energy (DE FG02 86ER60401) and the National Institutes of Health (PHS 5 R01 CA25836). The assistance of Ms. Kathy E. Carlson in the receptor-binding experiments is appreciated. Helpful discussions regarding molecular modeling, log $P_{o/w}$ measurements, and X-ray crystal structures from Frank Wüst are also deeply appreciated. NMR experiments were performed in the Varian Oxford Instrument Center for Excellence NMR Laboratory (VOICE NMR Lab), in part funded by grants from the National Institutes of Health (PHS 1 S10 RR1044-01), the National Science Foundation (NSF CHE 96-0152), and the Keck Foundation. Mass spectral data were acquired on spectrometers purchased with funds in part from the Division of Research Resources, National Institutes of Health (RR 01575 and RR 04648), the National Science Foundation (PCM 8121494), and the National Institute of General Medical Sciences (GM27029).

TECHNICAL NOTES

Comparison of the Stability of Technetium-Labeled Peptides to Challenge with Cysteine

M. A. Stalteri,[†] S. Bansal,[‡] R. Hider,[‡] and S. J. Mather*[,†,‡]

Imperial Cancer Research Fund, Department of Nuclear Medicine, St. Bartholomew's Hospital, West Smithfield, London EC1A 7BE, U.K., and Department of Pharmacy, King's College, London, U.K. Received April 30, 1998; Revised Manuscript Received September 29, 1998

We have labeled a series of short peptides with technetium-99m either by direct labeling at pH 11 or by exchange from [^{99m}Tc]technetium glucoheptonate. Typical labeling yields obtained were as follows: *N*-acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2 (Acm = acetamidomethyl) 99%, *S*-benzoyl-mercaptoacetyltriglycine (*S*-Benzoyl-MAG3) 95%, mercaptoacetyldiglycine-NH_2 (MAG2-NH_2) 94%, MAG3 92%, *N*-acetyl-Aib-Aib-Cys-NH_2 (Aib = aminoisobutyric acid) 91%, Gly-Gly-Gly-Gly 90%, *N*-acetyl-Gly-Gly-Cys-Gly 87%, cyclo-1,4-(Gly-Gly-Gly-Gln) 40%, *S*-methyl-MAG2-NH_2 0%. In the absence of cysteine, all of the labeled peptides were quite stable in solution, with at least 80−90% of the labeled peptide remaining at 24 h. The order of stability of the labeled peptides to challenge with cysteine was found to be MAG3 > *S*-benzoyl-MAG3 > *N*-acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2 > *N*-acetyl-Aib-Aib-Cys-NH_2 > MAG2-NH_2 > *N*-acetyl-Gly-Gly-Cys-Gly > cyclo-1,4-(Gly-Gly-Gly-Gln) > Gly-Gly-Gly-Gly. The peptides without a sulfur donor were least stable to challenge with cysteine.

INTRODUCTION

Radiolabeled peptides have great potential as radiopharmaceuticals (Fischman, 1993; Thakur, 1995; Hom and Katzenellenbogen, 1997; Liu et al., 1997). Naturally occurring peptides are involved in many biological processes, where they may function as hormones, neurotransmitters, cytokines or growth factors. The low molecular weights of peptides, compared to other biomolecules such as antibodies and antibody fragments, result in faster localization and blood clearance. The rapid pharmacokinetics are ideal for labeling peptides with a radioisotope that has a short half-life, such as technetium-99m (Lister-James et al., 1997).

In previous work (Mather et al., 1995), we described the use of hybrid peptides which contain both receptor-binding and technetium-chelating amino acid sequences. Such peptides can easily be prepared by solid-phase synthesis techniques, and amino acid sequences designed to chelate technetium can be incorporated at sites where the biological activity will not be affected. This approach has also been used by Lister-James et al. (Lister-James et al., 1995, 1996; Pearson et al., 1996a,b) in the development of technetium-labeled somatostatin receptor-binding peptides and thrombus imaging peptides.

The renal function agent MAG3 was the first peptide-derived technetium chelator to be developed. Deprotonation of three of the amide nitrogens and deprotection/deprotonation of the sulfur during the labeling process gives an N3S triamide thiol ligand which forms a stable complex with a technetium(V) oxo core. MAG2 forms a similar type of complex with technetium-99m, acting as a tetradentate S,N,N,O donor ligand, with the terminal carboxyl group acting as an O donor (Johannsen et al., 1993). N4 donor tetrapeptides, such as tetraglycine, also form stable complexes with technetium-99m, with three deprotonated amide nitrogens and one amine nitrogen coordinated to technetium (Vanbilloen et al., 1995).

In previous work (Mather et al., 1995), we investigated the use of the peptide sequence Gly-Gly-Cys as a technetium chelator. Like MAG3, the Gly-Gly-Cys sequence can act as a triamide thiol ligand. Lister-James and coworkers have developed peptides with the technetium-chelating sequences Gly-Gly-Cys, Cys-Gly-Cys and Lys-Gly-Cys, which provide triamide thiol, diamide dithiol, and diamide amine thiol chelating ligands, respectively (Lister-James et al., 1996). Peers et al. are developing peptides for imaging inflammation using the *N*-dimethyl-Gly-Ser-Cys sequence as a technetium chelator (Peers et al., 1997). Peptide sequences therefore show great promise as chelators for technetium-99m. Factors such as the overall charge around the metal center or the side chains on the chelating amino acids may affect the biodistribution and receptor-binding affinity of technetium-labeled peptides, but the performance of a particular chelator will also depend on its ability to retain the technetium in vivo. Trans-chelation to other sulfur-containing ligands has been shown to be an important route of radiopharmaceutical instability (Pearson et al., 1996a). Thus, it would be useful to explore the technetium chelating abilities of different peptide sequences and the stability of their complexes.

In the present work, we have investigated the labeling,

solution stability, and stability to cysteine challenge of a series of peptides (Figure 1), including the sequences -Gly-Gly-Cys-, -Cys-Gly-Cys-, MAG3, and tetraglycine in order to compare their suitability as technetium chelators.

MATERIALS AND METHODS

Radioisotope. Sodium [^{99m}Tc]pertechnetate was obtained from an Amertec II technetium-99m generator (Amersham, UK).

Reagents for Peptide Synthesis. Tetraglycine was obtained from Sigma (Poole, U.K.). *S*-Benzoyl-MAG3 was obtained as a commercial kit (TechneScan MAG3, Mallinckrodt Medical, Petten, Holland). *p*-(9-Fluorenylmethoxycarbonyl-amino)-2,4-dimethoxybenzyl)phenoxyacetic acid (Rink amide linker), Tentagel resin, suitably protected Nα-9-fluorenylmethyloxycarbonyl (Fmoc) amino acids, and [2-(1*H*-benzotriazole-1-yl]-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU) were obtained from NovaBiochem (U.K.). Dimethylformamide (DMF) was freshly distilled by fractional distillation at reduced pressure. All organic solvents were of analytical reagent grade quality or better. 2-[(Triphenylmethyl)thio]acetic acid was prepared by reaction of mercaptoacetic acid with triphenylmethanol and boron trifluoride etherate in acetic acid according to published methods (Brenner et al., 1984).

Peptide Synthesis. Peptides were synthesized by solid-phase methods using a Milligen Biosearch 9050 Pepsynthesizer. Concentrations were performed under reduced pressure at temperatures of <30 °C. Positive FAB-MS were recorded on a double focused VG-Analytical 70-250S mass spectrometer. The FAB ions were produced by a beam of xenon atoms, 6 keV, from a matrix of 3-nitrobenzyl alcohol. HPLC was performed on a Waters Powerline System with a 990 photodiode array detector. The system was fitted with a Vydac reversed-phase C-18 column (218TP54) and a semipreparative column. Solvent system A was 0.1% trifluoroacetic acid (TFA) and B was 0.1% TFA in 90% acetonitrile; 10% water was employed for both analytical (1 mL/min) and preparative (5 or 7 mL/min) separations and detection was at 230 nm.

Synthesis of *N*-Acetyl-Aib-Aib-Cys-NH_2. Solid-phase synthesis was performed on Tentagel resin (1 g, 0.41 mequiv/g, 0.41 mmol). Nα-Fmoc deprotection was performed with a flow of 20% piperidine in DMF for 12 min. Fmoc-Cys(Trt)OPfp (Trt = trityl, Pfp = pentafluorophenyl) was coupled for 1 h in the presence of 1-hydroxybenzotriazole (HOBt), Fmoc-Aib-OH (4 equiv) was coupled for 2 h by recirculation after in situ preactivation with TBTU (3.9 equiv) and *N*-ethylmorpholine (NEM) (6 equiv), and N-terminal acetylation was performed with acetic anhydride (10% in DMF for 20 min). Each deprotection and acylation was followed by a DMF wash cycle for 15 min. After completion of the synthesis, the resin was washed with methanol (30 mL) then ether (30 mL) and dried in vacuo for 3 h. The peptide was cleaved from

the linker by treatment with TFA, water, phenol, triisopropylsilane (95:3:1:1, 15 mL, v/v) for 1 h followed by filtration, and the resin was washed with TFA (2 × 10 mL). The combined TFA solution was concentrated to dryness and the remaining material was precipitated by trituration with diethyl ether and then extracted with water. The crude product was obtained by lyophilization of the aqueous phase. The peptides MAG2-NH_2, *S*-methyl-MAG2-NH_2, *N*-acetyl-Gly-Gly-Cys-Gly, and *N*-acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2 were prepared in a manner similar to that described above.

MAG2-NH_2, FAB-MS $(M + Na)^+$: 228 calcd, 228 found. MAG3, FAB-MS $(M + Na)^+$: 286 calcd, 286 found.

N-Acetyl-Gly-Cys(Acm)-Gly-Cys(Acm)-Gly-NH_2, FAB-MS $(M+H)^+$: 579 calcd, 579 found.

Synthesis of cyclo-1,4-(Gly-Gly-Gly-Gln). Fmoc-Glu(OH)-OAll (All = allyl) was prepared by reaction of Fmoc-Glu(OtBu)-OH with allyl alcohol and diisopropylethylamine (DIPEA) followed by treatment with TFA according to published procedures (Kates et al., 1993). The Nα-Fmoc-Glu(OH)OAll was coupled to the Rink amide linker-Tentagel resin (0.27 mequiv/g, 1 g, 0.27 mmol) in DMF using TBTU (0.337 g, 1 mmol) and NEM (1.5 mmol), and the assembly of the peptide was completed as described above to afford Fmoc-Gly-Gly-Gly-Glu(Rink amide linker-Tentagel resin)-OAll. The allyl group from the α-carboxy group of the glutamate was removed by treatment with $Pd(PPh3)_4$ (2.7 mmol, 0.5 g) and HOBt (1.35 mmol, 40 mg), in a mixture of DMSO/DMF (1:1, 10 mL) under an argon atmosphere and in the dark for 18 h. On completion, the peptide-resin was filtered and washed with 0.5% DIPEA and 0.5% sodium diethyldithiocarbamate in DMF until the yellow coloration of the $Pd(PPh3)_4$ had been removed. The Nα-Fmoc group was removed with piperidine and the resin was washed with DMF. Cyclization of the peptide was performed with diisopropylcarbodiimide and HOBt, and the peptide was cleaved from the linker as described above and purified by HPLC.

FAB-MS$(M + Na)^+$: 320 calcd, 320 found.

High-Pressure Liquid Chromatography. Reversed-phase HPLC was performed using a Beckman System Gold dual pump system with a Beckman 166 UV detector at 220 nm, a 50 μL injection loop, and a Beckman Ultrasphere 5 μ ODS 4.6 mm × 25 cm column. Technetium-99m-labeled peptides were eluted at a flow rate of 1.0 mL/min using a 0.01 M sodium phosphate pH 6.0 (buffer A) to methanol (buffer B) gradient as follows: at $t = 0$ min, 5% B; $t = 3$ min, 5% B to 95% B over 10 min, linear gradient; $t = 13$ min, 95% B for 10 min; $t = 23$ min, 95% B to 5% B over 5 min, linear gradient; $t = 28$ min, 5% B for 2 min. Radioactivity was measured using a NaI(Tl) flow-through detector connected to a multichannel analyzer. The recovery was determined by collecting the eluate from the HPLC column for 30 min from the time of injection, and counting 1 mL aliquots in an LKB Wallac CompuGamma CS gamma counter, together with 1 mL aliquots of an appropriate dilution of the injectate.

Labeling with Technetium-99m. *Exchange Labeling.* A commercial glucoheptonate kit (Glucoheptoscint, Medgenix diagnostics, Fleurus, Belgium) containing 150 mg of sodium glucoheptonate, 50 mg of calcium glucoheptonate, 1.0 mg of stannous chloride dihydrate, and 0.3 mg of sodium sulfite was reconstituted with 2 mL of nitrogen-purged saline, divided into 200 μL aliquots and stored at −20 °C. A small amount of peptide was weighed accurately, and the appropriate amount of nitrogen-purged 0.5 M sodium phosphate buffer, pH 11, was added to give a 1 mg/mL peptide solution. The peptide solution was divided into 100 μL aliquots and stored at −20 °C. One hundred microliters of the reconstituted glucoheptonate kit was added to 100 μL of peptide solution. The mixture was vortexed, 100 μL of sodium [^{99m}Tc]pertechnetate (5−8 mCi) in saline was added, and the solution was either incubated at room temperature for 30 min or heated at 90 °C for 10 min in a shielded water bath, cooled to room temperature, and analyzed by reversed-phase HPLC.

Direct Labeling. Two microliters of a freshly prepared 113 mg/mL (0.5 M) solution of stannous chloride dihydrate in 1 M HCl was added to 100 μL of a 1 mg/mL peptide solution in 0.5 M sodium phosphate pH 11. One hundred microliters of sodium [^{99m}Tc]pertechnetate (5−8 mCi) in saline was then added, followed by 50 μL of 0.5 M sodium triphosphate. The solution was incubated at room temperature for 1 h, or heated at 90 °C in a water bath for 10 min, then analyzed by reversed-phase HPLC.

Labeling of *S*-Benzoyl-MAG3. *S*-Benzoyl-MAG3 was labeled essentially according to the manufacturer's instructions with 30 mCi of sodium [^{99m}Tc]pertechnetate in 4 mL of saline. The kit was then heated for 10 min in a boiling water bath, cooled to room temperature, and analyzed by reversed-phase HPLC.

Stability of Technetium-99m-Labeled Peptides. Peptides were labeled with technetium-99m as described above and analyzed by RP-HPLC. Eleven microliters of 0.5 M sodium phosphate buffer, pH 3, was added to 200 μL of technetium-99m-labeled peptide solution in order to adjust the pH to 7. The peptide solutions were then incubated at room temperature for 24 h. At various time points, aliquots of the solutions were removed and analyzed by RP-HPLC.

Cysteine Challenge. The pH of the technetium-99m-labeled peptide solutions was adjusted to pH 7 with 0.5 M phosphate buffer, and the solutions were diluted to a peptide concentration of 0.25 mg/mL. L-Cysteine hydrochloride monohydrate was dissolved in 0.5 M phosphate buffer to give 25 and 5 mg/mL solutions of cysteine with a pH of 7. Thirty microliters of each cysteine solution was added to 270 μL of labeled peptide solution, and the resulting solutions were incubated at 37 °C. The ^{99m}Tc-labeled peptides were not purified after labeling, and therefore tin and unlabeled peptides remained present in the solutions. The progress of the reactions was followed by RP-HPLC with radiometric detection.

RESULTS

Radiolabeling. The peptides shown in Figure 1 were labeled with technetium-99m either by direct labeling using stannous chloride dihydrate as the reducing agent or by exchange from [^{99m}Tc]technetium glucoheptonate using a commercial glucoheptonate kit. The reaction mixtures were either incubated at room temperature or heated to 90 °C for 10 min and then cooled to room temperature. *S*-Benzoyl-MAG3 was obtained as a commercial kit and was labeled by exchange from [^{99m}Tc]-tartrate with heating at 100 °C for 10 min. The labeling efficiencies were measured by reversed-phase HPLC with radiometric detection using a C18 column and a 0.01 M sodium phosphate pH 6.0 to methanol gradient. Typical labeling efficiencies for the peptides are given in Table 1, and HPLC radiochromatograms of the labeled peptides are shown in Figure 2. Peptides containing sulfur donors were labeled by transchelation from glucoheptonate or tartrate, whereas peptides without a sulfur donor were labeled by direct labeling. The peptides *N*-Acetyl-Aib-Aib-

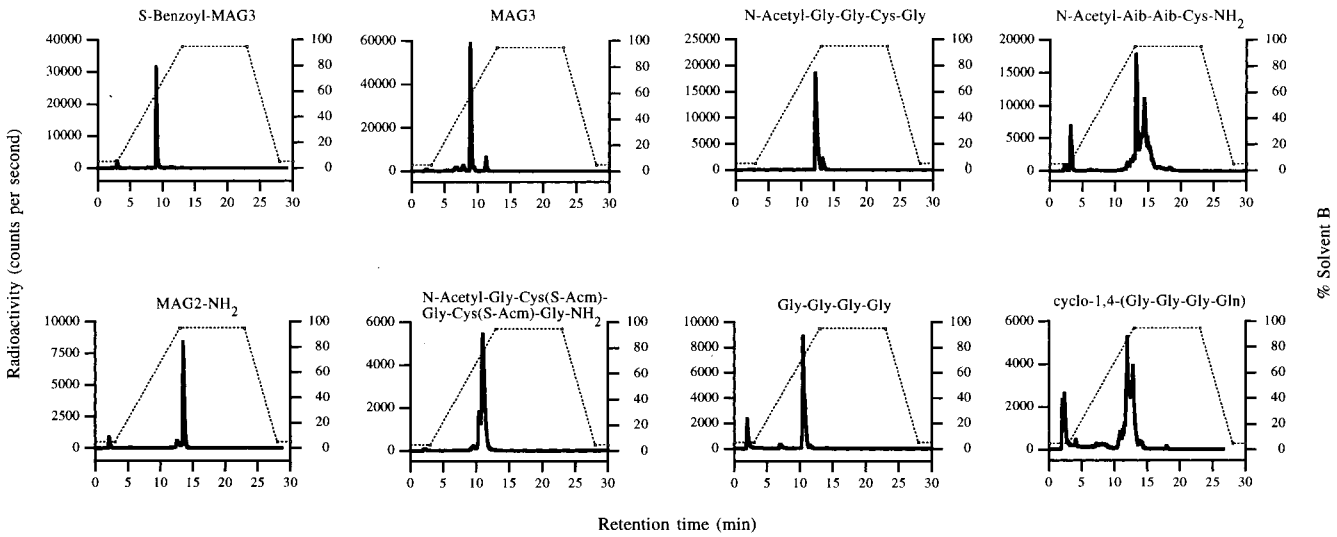

Figure 2. Reversed-phase HPLC radiochromatograms of the ^{99m}Tc-labeled peptides. Beckman Ultrasphere 5 μ ODS column; mobile phase 0.01 M sodium phosphate, pH 6.0 (A), methanol (B) gradient; flow rate 1.0 mL/min. (a) *S*-benzoyl-MAG3; (b) MAG3; (c) *N*-acetyl-Gly-Gly-Cys-Gly; (d) MAG2-NH_2; (e) *N*-acetyl-Aib-Aib-Cys-NH_2; (f) *N*-acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2; (g) Gly-Gly-Gly-Gly; (h) cyclo-1,4-(Gly-Gly-Gly-Gln).

Cys-NH_2, *N*-Acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2, and cyclo-1,4-(Gly-Gly-Gly-Gln) show more than one major peak in the HPLC radiochromatograms.

Typical labeling yields obtained were as follows: *N*-acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2 99%, *S*-benzoyl-MAG3 95%, MAG2-NH_2 94%, MAG3 92%, *N*-acetyl-Aib-Aib-Cys-NH_2 91%, Gly-Gly-Gly-Gly 90%, *N*-acetyl-Gly-Gly-Cys-Gly 87%, cyclo-1,4-(Gly-Gly-Gly-Gln) 40%, S-methyl-MAG2-NH_2 0%.

Stability of Technetium-99m-Labeled Peptides at pH 7. The pH of the labeled peptide solutions was adjusted to pH 7, and the solutions were incubated at room temperature for 24 h. The stability of the labeled peptides was monitored by RP-HPLC with radiometric detection. In the absence of cysteine, all of the labeled peptides were quite stable, with at least 80−90% of the labeled peptide remaining at 24 h.

Stability to Challenge with Cysteine. The stability of solutions of the labeled peptides at pH 7 and 37 °C to a challenge with cysteine at cysteine/peptide ratios of 2/1 and 10/1(w/w), corresponding to cysteine/peptide molar ratios in the ranges 3.4−6.0/1 and 17−30/1, was compared. The progress of the reactions was followed by HPLC. Figure 3 shows HPLC radiochromatograms of the reaction of technetium-99m-labeled *N*-acetyl-Gly-Gly-Cys-Gly with cysteine. The results of the cysteine challenge experiments are shown in Figure 4. The order of stability of the labeled peptides to challenge with cysteine was found to be MAG3 > *S*-benzoyl-MAG3 > *N*-acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2 > *N*-acetyl-Aib-Aib-Cys-NH_2 > MAG2-NH_2 > *N*-acetyl-Gly-Gly-Cys-Gly > cyclo-1,4-(Gly-Gly-Gly-Gln) > Gly-Gly-Gly-Gly. The peptides without a sulfur ligand were least stable to challenge with cysteine.

DISCUSSION

Five of the peptides we chose to study were triamide thiol ligands (Table 1). The other four peptides we studied included a triamide thioether, a diamide dithiol, a triamide amine and a tetraamide ligand, respectively. The peptides with a sulfur donor were labeled by transchelation from ^{99m}Tc-glucoheptonate or from ^{99m}Tc-tartrate in the case of *S*-benzoyl-MAG3. The peptides cyclo-1,4-(Gly-Gly-Gly-Gln) and Gly-Gly-Gly-Gly, which have a tetraamide and a triamide amine set of donors, respectively, were labeled by direct labeling at pH 11. High labeling yields were obtained for all the peptides except cyclo-1,4-(Gly-Gly-Gly-Gln) and *S*-methyl-MAG2-NH_2. All of the labeled peptides were stable in solution at pH 7.

In the case of the peptides *N*-acetyl-Aib-Aib-Cys-NH_2, *N*-acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2, and cyclo-1,4-(Gly-Gly-Gly-Gln), multiple unresolved peaks were present in the HPLC radiochromatograms. Square

pyramidal oxo-technetium complexes containing chiral centers on the ligand backbone may form diastereomers. (Liu et al., 1997). In the peptide cyclo-1,4-(Gly-Gly-Gly-Gln), the α carbon of the Gln residue is chiral. The Gln side chain can be either syn or anti with respect to the technetium-oxo core, thus diastereomers can be formed. *N*-Acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2 is a pentapeptide, and so more than one mode of coordination is possible. Diastereomers can be separated by HPLC, but the gradient we used was possibly too steep to resolve the various components.

Syn and anti isomers of square pyramidal complexes with a Tc-oxo core may show differences in stability and biodistribution (Vanbilloen et al., 1991), and it is therefore also possible that different isomers will show different stabilities to challenge with cysteine (Sharma, 1998). However, in the case of the peptides *N*-acetyl-Aib-Aib-Cys-NH_2, *N*-acetyl-Gly-Cys(*S*-Acm)-Gly-Cys(*S*-Acm)-Gly-NH_2, and cyclo-1,4-(Gly-Gly-Gly-Gln), which showed multiple unresolved components on HPLC analysis, we found no evidence that one of the components was more or less stable to cysteine than the others.

The low labeling efficiency obtained for cyclo-1,4-(Gly-Gly-Gly-Gln) may be due to the slow kinetics of labeling observed with macrocyclic ligands (Simon et al., 1981), or it may be due to the relative sizes of the technetium oxo core and the macrocyclic ring formed by the cyclic peptide. The 14 membered ring formed by the peptide may be either too small or too large for the technetium to be bound strongly in the plane of the four amide nitrogens. When the reaction mixture was monitored for several hours at room temperature after the initial heating step, the percent of labeled peptide was found to increase with time, from 40% at 30 min to 77% at 3 h. It is also possible that heating for 10 min is not enough to deprotonate the amide nitrogens. We obtained somewhat higher labeling yields at pH 12, but cleavage of peptide bonds is also more likely to occur at a pH greater than 11 (Bormans et al., 1995).

We chose to study the peptide *S*-methyl-MAG2-NH_2 in order to determine what effect, if any, the *S*-Me group would have on labeling and stability by comparison with MAG2-NH_2. Unprotected thiol groups are generally not stable and may oxidize to form disulfides, so it is more convenient to block the thiol with a protecting group (Bodanszky, 1988). Protecting groups such as *S*-benzoyl and *S*-acetamidomethyl are easily removed on heating to 100 °C for a short time (Liu and Edwards, 1995). However, some protecting groups, such as *S*-benzyl and *S*-benzamidomethyl, are more difficult to remove under the conditions used for radiolabeling (Bormans et al., 1995). We did not expect the *S*-methyl group of *S*-methyl-MAG2-NH_2 to be cleaved during the labeling, however the total failure of *S*-methyl-MAG2-NH_2 to label was somewhat unexpected. The N2S2 ligand *N*,2-methylthiobenzyl-*N*′-(1-oxo-2-mercapto-2-methyl)propyl ethylenediamine, which has one thiol sulfur donor, and one thioether sulfur donor forms a neutral complex with technetium (Oya et al., 1995). Thioether ligands coordinated to technetium are also found in technetium complexes of sulfur macrocycles (White et al., 1992).

Instability of radiolabeled peptides in vivo can occur through two principal routes; through proteolytic degradation of the peptide backbone by serum proteases or by transchelation of the technetium to other high-affinity binding sites. The first route of breakdown can be minimized by the use of unnatural amino acids such as D-optical isomers and through cyclization of the peptide.

The second route can be overcome by the use of suitable high-affinity chelators which prevent transfer of the radiolabel to other competing ligands in vivo. Since technetium shows a high affinity for sulfur-containing molecules, its tendency to transchelate in vivo can be modeled in vitro by challenge with the sulfur containing amino acid cysteine.

The peptides examined in this study fall into two clear categories as far as their stability to cysteine challenge is concerned. The thiol-containing ligands show much greater stability that those relying entirely on coordination by amide nitrogens. This suggests that sulfur-containing sequences would provide the chelators of choice for use in receptor-binding peptides. However, in addition to this requirement, this study points to a number of other desirable properties in a peptide technetium chelator which would help in the design of the optimal peptide sequence.

MAG3 shows greater stability than MAG2-NH2. Since the only difference between the two molecules is the terminal carboxylate, this group must assist the stability of the complex, either by unexpected involvement in coordination of the technetium or by steric hindrance of competing ligands attacking from the base of the pyramidal complex. This effect is also observed if the terminal amide nitrogen is acetylated as in the *N*-acetyl-gly-gly cys-gly sequence.

However, the presence of bulky substituents on the peptide backbone produces a marked increase in stability as can be observed in a comparison of *N*-acetyl-gly-gly cys-gly and *N*-acetyl-aib-aib-cys-gly. Such substituents will tend to promote the folding of the peptide in a manner which tends to favor coordination of the technetium with consequent increase in the stability of the complex.

The presence of two thiols in the sequence does not necessarily produce an advantage over one, since both the MAG3 complexes and *N*-acetyl-gly-cys-gly-cys-gly-NH2 show little or no instability in this assay. However, the dithiol sequence achieves this without the presence of the protective terminal carboxyl group. It seems likely therefore that in the absence of the carboxylate, two sulfurs are better than one.

The sequence showing the poorest stability to cysteine challenge was the open-chain tetraglycine sequence; however, cyclization of the peptide showed little if any increase in stability, perhaps, as suggested above, because the technetium is not fully located within the cage of the macrocycle.

The ultimate performance of a radiolabeled receptor-binding sequence will depend on a number of factors, in particular its affinity for the receptor, its pattern of biodistribution, and its in vivo stability. An advantage of the hybrid peptide approach is that the chelation sequence and the sequence responsible for receptor binding can be optimized independently. However, changes in both of these regions of the peptide are likely to result in an alteration in biodistribution since they will alter the hydrophilicity and possibly the resulting charge of the molecule. The rules which govern the influence of peptide structure on its biodistribution are not yet clearly understood and further studies on the factors which control this relationship are required before an optimal design for these radiopharmaceuticals can be realized.

CONCLUSION

Short peptide sequences can be incorporated into receptor-binding peptides to provide a radiolabeling site for technetium-99m. These peptides can be radiolabeled with high efficiency and high solution stability. Increased protection against possible loss of the radiolabel in vivo can be provided by the presence in the chelation sequence of either two sulfur atoms or one sulfur atom and a pendant carboxyl group on the terminal nitrogen. A further increase in stability is provided by the presence of bulky peptide side chains. This information will be of value in the design of optimized peptide chelators for technetium-99m.

ACKNOWLEDGMENT

We gratefully acknowledge the financial support of the Imperial Cancer Research Fund and the use the facilities of the Dominion House Centre for Clinical Research. We thank Angela Glenn for technical assistance with the peptide synthesis.

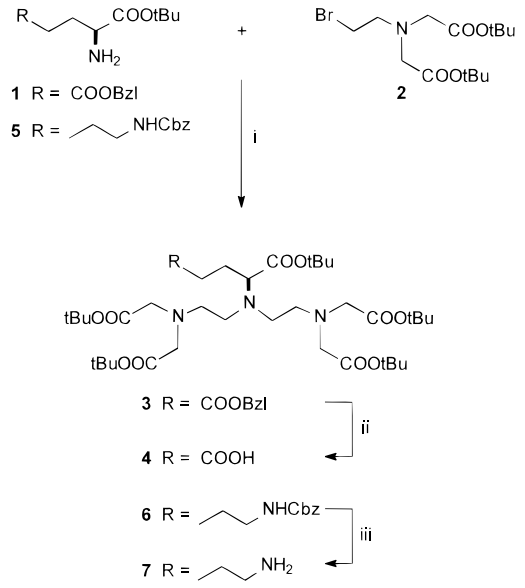
L-Glutamic Acid and L-Lysine as Useful Building Blocks for the Preparation of Bifunctional DTPA-like Ligands†

Pier Lucio Anelli,* Franco Fedeli, Ornella Gazzotti, Luciano Lattuada, Giovanna Lux, and Fabrizio Rebasti



Bracco spa, Milano Research Centre, via E. Folli 50, 20134 Milano, Italy. Received December 26, 1997; Revised Manuscript Received November 19, 1998

Bisalkylation of suitably protected L-glutamic acid and L-lysine derivatives with *tert*-butyl *N*-(2-bromoethyl)iminodiacetate **2**, followed by deprotection of the *ω* functional group affords *N*,*N*-bis[2-[bis[2-(1,1-dimethylethoxy)-2-oxoethyl]amino]ethyl]-L-glutamic acid 1-(1,1-dimethylethyl) ester **4** and N^2,N^2-bis[2-[bis[2-(1,1-dimethylethoxy)-2-oxoethyl]amino]ethyl]-L-lysine 1,1-dimethylethyl ester **7**. Such compounds feature a carboxylic or an amino group, respectively, which are available for conjugation with a suitable partner via formation of an amide bond. The conjugates, which can be prepared in this way, contain a chelating subunit in which all five acetic residues of DTPA are available for the complexation of metal ions. Direct bisalkylation of glycine with **2** promptly gives *N*,*N*-bis[2-[bis[2-(1,1-dimethylethoxy)-2-oxoethyl]amino]ethyl]glycine **11**. The latter allows to achieve conjugates in which the central acetic group of DTPA is selectively converted into an acetamide.

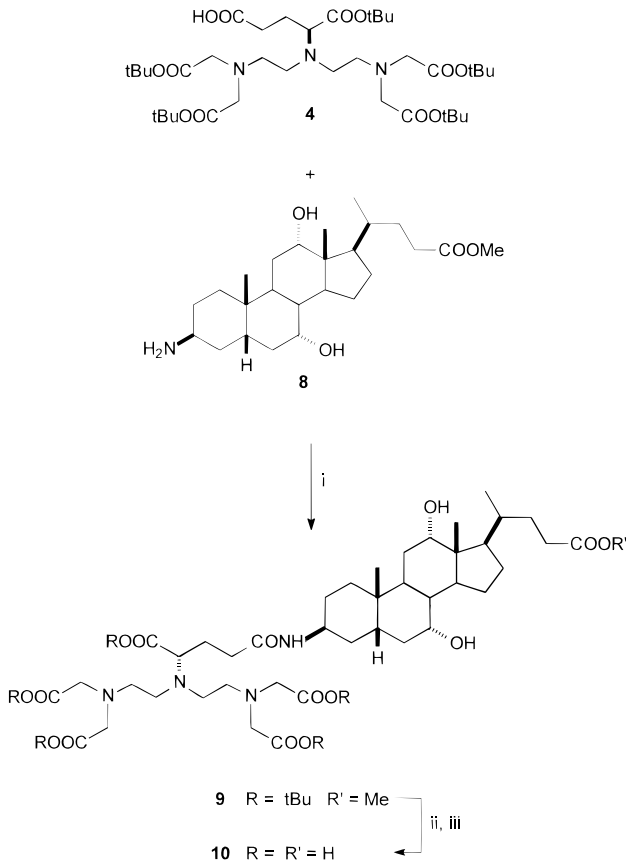
Diethylenetriaminepentaacetic acid (DTPA) is a very efficient chelating agent for the complexation of the gadolinium ion. The corresponding complex, due to its high in vivo stability, has been safely used as contrast agent in MRI over the past decade (*2*). Conjugation of DTPA-like ligands to macromolecules (*3*), iodinated synthons (*4*) or bile acids (*5*) has been recently pursued to achieve MRI contrast agents featuring improved organ specificity. The most popular way to conjugate DTPA to other molecules involves the conversion of one of the four equivalent carboxylic groups into a carboxamide via DTPA bisanhydride (*6*). Besides being not selective, due to the concomitant formation of some diamide (*7*), this methodology has the disadvantage of yielding conjugates containing a ligand weaker than DTPA. Indeed, such decrease in chelating ability of DTPA-like ligands in which one of the carboxylic group has been converted into a carboxamide is well-known (*8*).

Nevertheless, due to its chemical stability, amide bond is one of the preferred choices for the preparation of conjugates containing metal complexes which have to be administered in vivo. Therefore, we became interested in the preparation of DTPA ligands bearing either a carboxylic group or an amino group available for conjugation. Williams and Rapoport recently introduced a simple methodology which is a breakthrough in the synthesis of DTPA-like ligands (*9*). We have now found that L-glutamic acid and L-lysine, after suitable protections and using such methodology, conveniently yield functionalized DTPA pentaesters which are versatile intermediates for the preparation of conjugates of metal complexes. Since DTPA-like ligands have been proposed for the chelation of radionuclides [e.g., ^{111}In(III), ^{212}Bi(III), and ^{90}Y(III)] (*10*, *11*) we believe that the above intermediates could also be of some importance for the preparation of new radiopharmaceuticals.

Scheme 1[a]

[a] (i) **1** EtOH/H_2O, pH 8; for **5** MeCN/pH 8 phosphate buffer; (ii) H_2, 5% Pd/C, EtOH; (iii) H_2, 5% Pd/C, MeOH.

L-Glutamic acid 5-benzyl ester (*12*) was converted, with isobutene in dioxane in the presence of H_2SO_4, into the 1-*tert*-butyl 5-benzyl diester **1** (*13*), which was directly reacted with bromide **2** in EtOH/H_2O at pH 8 to afford hexaester **3** in only 31% yield (Scheme 1). The isolation of **3** in fair yields is related to the easy lactamization of both **1** and the monoalkylated intermediate. However, in our hands the dialkylation of **1** in homogeneous phase proved to be the best procedure, even better then the reaction under Rapoport's two-phase conditions (i.e., MeCN/pH 8 phosphate buffer). Cleavage of the benzyl ester protection of **3** by hydrogenolysis yielded the monoacid pentaester **4**.



On the other hand, to obtain a DTPA pentaester with a free amino group, commercially available N^6-Cbz L-

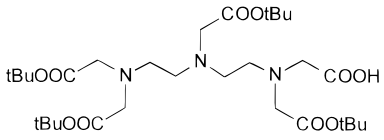
lysine was esterified in *tert*-butyl acetate in the presence of $HClO_4$ to afford **5**. Subsequent dialkylation with bromide **2** in MeCN/pH 8 phosphate buffer afforded protected pentaester **6**. Classical removal of the Cbz moiety by hydrogenolysis yielded the amino pentaester **7** (Scheme 1).[1] It must be stressed that Rapoport demonstrated that, under the reaction conditions that they developed for the dialkylation of amino esters, no racemization is observed. Pentaesters **4** and **7** can be easily reacted with substrates containing amino or carboxylic functionalities, respectively, and subsequently, the *tert*-butyl ester groups can be removed using routine methodologies. According to this strategy, conjugates containing DTPA subunits, in which all five acetic groups are available for complexation, are promptly achieved. Indeed, we synthesized ligand **10** by coupling of **4** to aminocholic methyl ester **8** (*14*) (Scheme 2). On complexation with Gd(III) ligand **10** gives rise to a complex which will be studied as MRI contrast agent in comparison with other bile acid conjugates (*5*). We also investigated the preparation of a synthon in which the acetic residue on the central nitrogen atom of DTPA can be selectively activated. Compound **11** has been recently prepared by hydrogenolysis of the corresponding mixed monobenzyl tetra-*tert*-butyl ester of DTPA **12** in its turn obtained through a synthetic route involving time consuming protection-deprotection of diethylenetriamine (*15*).



[1]Similarly, reaction of *O*-benzyl-L-serine *tert*-butyl ester with bromide **2** under Rapoport's conditions, followed by hydrogenolysis of the benzyl group, yielded a DTPA pentaester bearing an hydroxymethyl moiety on the central acetic residue. Such derivative can also be used for the preparation of conjugates.

11 R = H

12 R = Bzl

We found that dialkylation of glycine benzyl ester (*16*) with **2** directly affords pentaester **12** of DTPA which can be hydrogenated in MeOH in the presence of 10% Pd/C to give **11**. More surprisingly, we realized that dialkylation of glycine with **2** in $EtOH/H_2O$ at pH 10 straightforwardly leads to **11** in 70% yield after flash chromatography. Tetraester **11** is a very convenient intermediate for the synthesis of conjugates containing DTPA monoamide subunits. In this respect, the preparation of **11** appears less troublesome and quicker than that of the unsymmetrical tetraester **13**, which has been recently prepared with a six step synthesis (*17*).

13

It is noteworthy that DTPA polyesters **4**, **7**, and **11** are all prepared using bromide **2**, which indeed proved to be a very versatile intermediate.

A limit to the direct application of compounds **4**, **7**, and **11** for the preparation of conjugates is represented by the absence, in the substrate to which they have to be coupled, of chemical bonds labile under conditions of cleavage of the *tert*-butyl ester groups. This drawback can be circumvented, reacting **4** and **11** with either *N*-(2-aminoethyl)maleimide (*17*) or *S*-(2-pyridylthio)cysteamine (*18*) to give, after deprotection of the *tert*-butyl ester functions, bifunctional ligands which can be coupled to SH containing substrates (e.g., proteins). A similar strategy could be exploited for the use of **7**.

EXPERIMENTAL PROCEDURES

General Comments. All reagents were purchased from Fluka Chemie AG (Buchs, Switzerland), Aldrich (Milwakee, WI) and Merck KGaA (Darmstadt, Germany). ^1H and ^{13}C NMR spectra were recorded at 200 and 50 MHz, respectively, on a Bruker AC 200 spectrometer. Electrospray ionization was performed on a Finnigan TSQ 700 triple quadrupole mass spectrometer fitted with a Finnigan ESI interface, dissolving the samples in MeOH, H_2O/MeOH, or H_2O/MeCN. Optical rotations (10^{-1} deg cm^2 g^{-1}) were measured with a Perkin-Elmer 341 polarimeter. Melting points were determined with a Büchi 510 apparatus and are uncorrected. Preparative HPLC was performed on a Merck KGaA Prepbar 100 apparatus.

***N,N*-Bis[2-[bis[2-(1,1-dimethylethoxy)-2-oxoethyl]-amino]ethyl]-L-glutamic acid 1-(1,1-dimethylethyl) 5-(Phenylmethyl) Diester (3).** L-Glutamic acid 5-benzyl ester (*12*) (171 g, 0.72 mol) was added to a mixture of 98% H_2SO_4 (50.5 mL, 0.93 mol) in dioxane (500 mL) at 20 °C and the solution was stirred over 6 days under an isobutylene atmosphere (132 kPa). Crushed ice (720 g) was added to the reaction mixture, and then a solution of K_2CO_3 (128.5 g, 0.93 mol) in water (350 mL) was added dropwise over 1 h. The precipitate, containing the start-

ing monoester (60 g, 0.25 mol) and salts, was filtered and the solution freeze-dried. L-Glutamic acid 1-*tert*-butyl 5-benzyl diester **1** thus obtained (137.8 g; 0.47 mol; 65%) was dissolved in EtOH (780 mL) and water (170 mL) and bromoderivative **2** (*9*) (247 g; 0.7 mol) was added at 5 °C. The mixture was maintained at pH 8 by means of a pH-stat apparatus with 10 N NaOH. After 48 h at 5 °C and 98 h at 25 °C further, bromoderivative **2** was added (106 g, 0.3 mol). After 120 h at 25 °C and 22 h at 50 °C, the mixture was neutralized with 36% HCl and filtered. After evaporation of EtOH, the solution was diluted with water (300 mL) and extracted with *n*-hexane (1 × 1100 mL, 1 × 300 mL). The combined organic phase was washed with water (250 mL), dried, and evaporated. The residue (322 g) was purified by a first flash chromatography with 1:4 EtOAc/*n*-hexane followed by a second flash chromatography using CH_2Cl_2 → 1:12 Et_2O/CH_2Cl_2 as the eluent. Evaporation gave **3** (122.8 g, 0.147 mol, 31%) as a yellow oil. $[\alpha]_D^{20}$: −30.43 (*c* 5.5, $CHCl_3$). ^{1}H NMR ($CDCl_3$): δ 1.40 (s, 45H), 1.92 (m, 2H), 2.45 (m, 2H), 2.70 (m, 8H), 3.40 (m, 9H), 5.05 (s, 2H), 7.29 (m, 5H). ^{13}C NMR ($CDCl_3$): δ 24.7 (CH_2), 28.0 (CH_3), 28.1 (CH_3), 30.7 (CH_2), 50.0 (CH_2), 53.7 (CH_2), 55.8 (CH_2), 63.2 (CH), 65.9 (CH_2), 80.6 (C), 80.7 (C), 127.9 (CH), 128 (CH), 128.3 (CH), 136.0 (C), 170.3 (CO), 171.9 (CO), 173.1 (CO). ***N*,*N*-Bis[2-[bis[2-(1,1-dimethylethoxy)-2-oxoethyl]-amino]ethyl]-L-glutamic acid 1-(1,1-Dimethylethyl) Ester (4).** Pd (5%) on carbon (16 g) was added to a solution of **3** (121 g, 142 mmol) in EtOH (800 mL), and the suspension was stirred over 2 h under a hydrogen atmosphere (111 kPa) at 20 °C. The mixture was filtered over Millipore FH 0.45 μm, the solution evaporated and the residue purified by flash chromatography eluting with 1:2 EtOAc/*n*-hexane → EtOAc. Evaporation gave **4** (59.3 g, 56%) as a very viscous yellow oil. $[\alpha]_D^{20}$: −13.49 (*c* 2.3, $CHCl_3$). ^{1}H NMR ($CDCl_3$): δ 1.36 (s, 45H), 1.95 (m, 2H), 2.65 (m, 2H), 2.85 (m, 8H), 3.42 (s, 8H), 3.85 (dd, 1H). ^{13}C NMR ($CDCl_3$): δ 24.3 (CH_2), 27.9 (CH_3), 28.0 (CH_3), 31.6 (CH_2), 40.6 (CH_2), 53.0 (CH_2), 55.5 (CH_2), 63.6 (CH), 80.8 (C), 81.1 (C), 170.3 (CO), 171.1 (CO), 176.9 (CO). Anal. ($C_{37}H_{67}N_3O_{12}$) C, H, N. MS: *m*/*z* 746 $[M + H]^+$, 768 $[M + Na]^+$.

***N*^{6}-[(Phenylmethoxy)carbonyl]-L-lysine 1,1-Dimethylethyl Ester (5).** $HClO_4$ (70%, 19.5 mL) was added dropwise to a suspension of *N*^{6}-[(phenylmethoxy)-carbonyl]-L-lysine (56 g, 0.2 mol) in *tert*-butyl acetate (700 mL) to afford a clear solution. After 20 h, 10% Na_2CO_3-(aq) (600 mL) was dripped into the solution obtaining precipitation of the unreacted starting material which was filtered. NaOH (10 N) was added to adjust to pH 10 the aqueous phase then the organic phase was separated, washed with water (5 × 50 mL) and dried (Na_2SO_4). Evaporation gave **5** (53.5 g, 79%) as a colorless oil. $[\alpha]_D^{20}$: +8.88 (*c* 4.9, $CHCl_3$). ^{1}H NMR ($CDCl_3$): δ 1.30−1.80 (m, 15H), 3.10−3.35 (m, 3H), 4.90 (br s, 1H), 5.05 (s, 2H), 7.03 (m, 5H). ^{13}C NMR ($CDCl_3$): δ 22.6 (CH_2), 27.9 (CH_3), 29.5 (CH_2), 34.4 (CH_2), 40.7 (CH_2), 54.7 (CH), 66.3 (CH_2), 80.7 (C), 127.9 (CH), 128.3 (CH), 136.5 (C), 158.3 (CO), 175.2 (CO). Anal. ($C_{18}H_{28}N_2O_4$) C, H, N; H, calcd: 8.33. Found: 8.80. MS: *m*/*z* 337 $[M + H]^+$, 359 $[M + Na]^+$.

***N*^{6}-[(Phenylmethoxy)carbonyl]-*N*^{2},*N*^{2}-bis[2-[bis[2-(1,1-dimethylethoxy)-2-oxoethyl]amino]ethyl]-L-lysine 1,1-Dimethylethyl Ester (6).** Phosphate buffer (1 L; 2 M, pH 8) was added to a solution of compound **5** (81 g, 0.24 mol) and bromoderivative **2** (209 g, 0.59 mol) in CH_3CN (900 mL), and the mixture was vigorously stirred for 2 h. The two phases were separated and the aqueous phase replaced with fresh phosphate buffer (800 mL, 2 M, pH 8). After 48 h, the mixture was separated and the organic layer concentrated to dryness. The residue was dissolved in CH_2Cl_2 (1 L), washed with water (2 × 50 mL), dried (Na_2SO_4), and evaporated. The residue was purified by flash chromatography with 1:2 EtOAc/*n*-hexane to give **6** (190 g, 90%) as a very viscous yellow oil. $[\alpha]_D^{20}$: −26.40 (*c* 4.98, $CHCl_3$). ^{1}H NMR ($CDCl_3$): δ 1.20−1.80 (m, 51H), 2.75 (m, 8H), 3.20 (m, 3H), 3.40 (s, 8H), 5.10 (s + br s, 3H), 7.23 (m, 5H). ^{13}C NMR ($CDCl_3$): δ 23.1 (CH_2), 27.9 (CH_3), 28.1 (CH_3), 29.3 (CH_2), 40.6 (CH_2), 50.0 (CH_2), 53.4 (CH_2), 55.8 (CH_2), 63.7 (CH), 66.1 (CH_2), 80.4 (C), 80.5 (C), 127.7 (CH), 127.8 (CH), 128.2 (CH), 136.6 (C), 156.2 (CO), 170.4 CO), 172.5 (CO). ***N,N*-Bis[2-[bis[2-(1,1-dimethylethoxy)-2-oxoethyl]-amino]ethyl]glycine (11).**

Method a. Phosphate buffer (50 mL, 2 M, pH 8) was added to a solution of glycine benzyl ester (*16*) (2.44 g, 14.8 mmol) and bromoderivative **2** (11.5 g, 32.6 mmol) in CH_3CN (100 mL), and the mixture was vigorously stirred for 24 h. The mixture was separated, the organic phase evaporated, and the residue flash chromatographed with $CHCl_3$. The yellow oil obtained (6.5 g) was dissolved in MeOH (50 mL), and 10% Pd on carbon (0.7 g) was added. The suspension was stirred over 24 h under a hydrogen atmosphere at 20 °C. The mixture was filtered over Millipore FH 0.45 μm and evaporated to give **11** (4.87 g, 53%) as a yellow oil.

Method b. NaOH (10 M) (10 mL) was added to a solution of glycine (12 g, 0.160 mol) in water (100 mL) and 95% EtOH (100 mL) until pH 10 was reached. A solution of bromoderivative **2** (120 g, 0.341 mol) in 95% EtOH (100 mL) was added dropwise, maintaining at pH 10 by means of a pH-stat apparatus. After 18 h, EtOH was removed under reduced pressure, and the solution was acidified to pH 3.5 with 12 N HCl and extracted with CH_2Cl_2 (2 × 300 mL). The combined organic phases were washed with water (2 × 100 mL), dried (Na_2SO_4), and evaporated. The residue was purified by flash chromatography using CH_2Cl_2 → CH_2Cl_2/MeOH/25% NH_4OH-(ag) 150:13:1 as the eluent. Evaporation of the solvent gave a pale yellow oil which was treated with petroleum benzine (boiling range 60−80 °C; 3 × 400 mL) until **11** (69 g, 70%) was obtained as a white crystalline solid. mp 93 °C. ^1H NMR ($CDCl_3$): δ, 1.46 (s, 36H), 2.99 (t, 4H), 3.10 (br t, 4H), 3.45(s, 8H), 3.56 (s, 2H). ^{13}C NMR ($CDCl_3$): δ, 28.5 (CH_3), 51.2 (CH_2), 53.9 (CH_2), 56.4, (CH_2), 57.0 (CH_2), 82.0 (C), 170.8 (CO). Anal. ($C_{30}H_{55}N_3O_{10}$) C, H, N. MS: *m*/*z* 618 $[M + H]^+$, 640 $[M + Na]^+$.

Analysis of Nonlinear Quenching of Terbium(III):Dipicolinic Acid Complex Fluorescence by Chelators and Chelate-Conjugated Macromolecules

Charles G. Sanny* and Joseph A. Price

Department of Biochemistry/Microbiology, Oklahoma State University College of Osteopathic Medicine, 1111 West 17th Street, Tulsa, Oklahoma 74107. Received February 16, 1998; Revised Manuscript Received October 20, 1998

The terbium-dipicolinic acid complex (Tb(III):DPA) fluorescence quenching method of Ma, Hwang, and Lee [*Pharm. Res.* (1993) *10*, 204−207] was used at a lower initial concentration of Tb(III):DPA (0.2 μM compared to 1.0 μM) to minimize the concentration of chelate-conjugated macromolecules required for estimating concentrations of metal-binding sites. Fluorescence quenching by either EDTA, diethylenetriaminepentaacetic acid (DTPA), poly (L-lysine)-DTPA, or poly (L-lysine)-DTPA linked to mouse IgG (IgG-PL-DTPA) was nonlinear, suggesting initial binding of chelator results in minimal change in Tb(III):DPA complex fluorescence. On the basis of the law of mass action and nonlinear curve fitting, the data suggests a three-site binding model for Tb(III):DPA complex formation in which the binding of the first and second DPA produce the majority of complex fluorescence. Initial binding of chelators to the complex results in only slight decreases in fluorescence with the majority of fluorescence quenching resulting from dissociation of more than one DPA from the complex. Although fluorescence quenching was nonlinear, binding capacity of each chelator relative to either EDTA or DTPA (as suggested by Ma et al.) could be used to estimate the concentration of metal-binding sites consistent with concentrations reported in the literature using either radionuclides or nuclear magnetic resonance. Estimation of chelating groups on chelate-conjugated macromolecules at lower concentrations would minimize the amount of sample required for analysis during synthesis and isolation of chelate-conjugated macromolecules. The suggested model for the stoichiometry of Tb(III):DPA complex fluorescence may be useful in further refinement of methods for estimating chelator concentrations and for design of fluorescent probes for chelate-conjugated macromolecules.

INTRODUCTION

Chelate-conjugated macromolecules such as monoclonal antibodies linked to chelating polymers have become important tools for a wide variety of studies including radioimmunoimaging, radioimmunotherapy, NMR-tomography, and in vitro immunoassays (*1, 2*). Ma, Hwang, and Lee (*3*) have described a terbium−dipicolinic acid complex fluorescence quenching method for estimating chelating groups in chelate-conjugate macromolecules which is simple, rapid, and does not require radionuclides. This method was based on the assumptions that (1) the displacement of dipicolinic acid from the complex by stronger chelators is quantitative, (2) the resulting terbium−chelator complex is nonfluorescent, and (3) the reduction in fluorescence is linear with chelator or other chelate-coupled macromolecule concentration. To minimize the concentration of chelate-conjugated macromolecules required for analysis, the procedure of Ma et al. (*3*) was used at a lower concentration of terbium-dipicolinic acid complex (0.2 μM compared to 1.0 μM). Quenching by chelators and chelate-conjugated macromolecules at the lower initial concentration of the fluorescent complex was nonlinear. This communication describes the use of nonlinear analysis to estimate chelator concentrations at lower concentations than previously reported (*3*). Also, revised models are presented for turbium−dipicolinic acid complex fluorescence and for fluorescence quenching by chelators and chelate-conjugated macromolecules.

MATERIALS AND METHODS

Materials. Terbium(III) chloride hexahydrate and ethylenediaminetetraacetic acid (EDTA) were purchased form Aldrich Chemical Co. (Milwaukee, WI). Dipicolinic acid (pyridine-2,6-dicarboxylic acid) (DPA), diethylenetriaminepentaacetic acid (DTPA), poly L-lysine (PL25, 25 000 kDa), and *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid) (HEPES) and mouse IgG were purchased from Sigma (St. Louis, MO). Poly (L-lysine)-diethylenetriaminepentaacetic acid (PL25-DTPA) and PL25-DTPA linked to mouse IgG (IgG-PL25-DTPA) were prepared according to Manabe et al. (*4*) and Torchilin et al. (*5*), respectively.

Fluorescence Measurements. Fluorescence measurements were obtained using an RFM-2001 spectrofluorometer and standard cuvette holder from Photon Technologies International (Monmouth Jct., NJ) with excitation at 276 nm and emission from 470 to 510 nm. Fluorescence was determined from either the emission at 491 nm or the baseline corrected area of the emission peak from 477 to 507 nm.

Fluorescence measurements were normalized to percent fluorescence by the following equation:

$$\%F = F_{\text{sample}}/F_{\text{std}} \times 100 \quad (1)$$

10.1021/bc980018n CCC: $18.00 © 1999 American Chemical Society
Published on Web 12/03/1998

where %F is the normalized fluorescence, and F_{sample} and F_{std} are fluorescence of sample and of 0.2 μM Tb(III) in 1 μM DPA, respectively.

Standard curves of Tb(III):DPA complex fluorescence were obtained using Tb(III) concentrations ranging from 0 to 0.4 μM in 2 mM HEPES (pH 7.0, 0.9% NaCl) with either a DPA/Tb(III) ratio of 5 as recommended by Ma et al. (*3*), or at a constant concentration (2 μM) of DPA.

Fluorescence Quenching Measurements. Quenching of Tb(III):DPA complex fluorescence was measured using 0.2 μM Tb(III) in 2 mM HEPES (pH 7.0, 0.9% NaCl) containing DPA at a DPA/Tb(III) ratio of 5 as recommended by Ma et al. (*3*). Fluorescence measurements were obtained at increasing concentrations of either DTPA or EDTA from 0 to 1 μM or either PL25-DTPA (0−52 nM) or IgG-PL25-DTPA (0−44 nM).

Apparent Chelator-Binding Parameters and Stoichiometry of Fluorescence Quenching. Apparent binding constants and stoichiometry of fluorescence quenching by chelator were evaluated using the law of mass action for the reactions

$$(1)\ F_{cplx} + aS \leftrightarrow FS_a \text{ and } (2)\ F_{cplx} + bS \leftrightarrow NS_b:$$

$$K_{xa} = [FS_a]/([F_{cplx}][S]^a) \quad (2A)$$

$$K_{xb} = [NS_b]/([F_{cplx}][S]^b) \quad (2B)$$

where K_{xa} and K_{xb} are apparent association constants, $[F_{cplx}]$, $[S]$, $[FS_a]$, and $[NS_b]$ are the concentrations of the fluorescent complex, free terbium binding sites on chelator, fluorescent complex bound to chelator, and non-fluorescent turbium:chelator complex in the mixture, respectively, and a and b are reaction coefficients. The total number of chelator-binding sites in the reaction mixture can be defined as $cX_o = S + aFS_a + bNS_b$ where X_o is the initial molar concentration of chelator and c is the number of binding sites per chelator. By substitution, eqs 2A and 2B can be written as

$$K_{xa} = [FS_a]/([F_{cplx}][cX_o - aFS_a - bNS_b]^a) \quad (2C)$$

$$K_{xb} = [NS_b]/([F_{cplx}][cX_o - aFS_a - bNS_b]^b) \quad (2D)$$

Also,

$$\%F = p([F_{cplx}]_o - [NS_b]) \quad (3)$$

where $[F_{cplx}]_o$ is the initial concentration of the fluorescent complex and p is a fluorescence proportionality constant.

The amount of chelator required to produce a 50% decrease in fluorescence was estimated using a simple logistic dose−response function (LDR) of the form

$$\%F = \%F_{max}/[1 + ([X]_o/D_{50})^m] \quad (4)$$

where $\%F_{max}$ is the maximum percent fluorescence, $[X_o]$ is the initial concentration of chelator, D_{50} is the initial concentration of chelator resulting in 50% reduction of %F, and m is a slope factor (*6*).

Apparent DPA-Binding Parameters and Stoichiometry of Complex Fluorescence. A fluorescence titration curve was obtained using 0.2 μM $TbCl_3$ and increasing concentrations of DPA from 0 to 1 μM. Apparent binding constants and stoichiometry of DPA binding to Tb(III) to form a fluorescent complex were evaluated using the law of mass action for the reaction Tb(III) + nDPA⇔ $Tb(DPA)_n$:

$$K_n = [Tb(DPA)_n]/([Tb(III)][DPA]^n) \quad (5A)$$

$$K_n = [Tb(DPA)_n]/[([Tb(III)]_o - [Tb(DPA)_n])([DPA]_o - n[Tb(DPA)_n])^n] \quad (5B)$$

where K_n is an apparent association constant, $[Tb(DPA)_n]$, $[Tb(III)]$, $[DPA]$, $[Tb(III)]_o$, and $[DPA]_o$ are the concentrations of the fluorescent complex, free Tb(III), free DPA, initial Tb(III), and initial DPA in the mixture, respectively, and n is the reaction coefficient. Also, if %F is proportional to the concentration of $Tb(DPA)_n$, then

$$\%F = p[Tb(DPA)_n] \quad (6)$$

where p is a fluorescence proportionality constant.

Standard error of the curve fit. The standard error for each nonlinear regression curve fit [SE (fit)] was calculated as SE (fit) = square-root(sum of squares of the residuals/regression degrees of freedom). The residuals are the difference between the observed fluorescence and the calculated fluorescence. The regression degrees of freedom are the number of observations minus 1 minus the number of parameters in the curve-fit equation.

RESULTS

Standard curves of Tb(III):DPA complex fluorescence are shown in Figure 1. At a constant concentration of DPA (2 μM), the curve was linear throughout a Tb(III) concentration range 0−0.4 μM [$r^2 > 0.999$, SE (fit) = 4.1]. Within the same Tb(III) concentration range with a DPA/Tb(III) ratio of 5, complex fluorescence was approximately linear [$r^2 = 0.995$, SE (fit) = 11.9]; however, the curve deviated from linearity, suggesting complex dissociation.

Fluorescence quenching of the Tb(III):DPA complex by EDTA, DTPA, PL25-DTPA, and IgG-PL25-DTPA, respectively, are shown in Figures 2−5. EDTA, DTPA, and PL25-DTPA produced pronounced sigmoid-shaped quenching curves, suggesting initial binding of chelator results in minimal change in Tb(III):DPA complex fluorescence. The fluorescence quenching curves were modeled to law of mass action eqs 2A−D and 3 and to the logistic dose response eq 4. Curve-fit parameters are listed in Tables 1 and 2. Quenching equivalents defined as DTPA/X = $D_{50,DTPA}/D_{50,X}$ and EDTA/X = $D_{50,EDTA}/D_{50,X}$, where $D_{50,DTPA}$, $D_{50,EDTA}$, and $D_{50,X}$ are the D_{50} of DTPA, EDTA, and chelator X, respectively, are also listed in Table 2.

To determine Tb(III):DPA complex saturation conditions, 0.2 μM $TbCl_3$ was titrated with DPA up to a DPA/Tb(III) ratio of 5 as shown in Figure 6. The resulting saturation curve was modeled to the law of mass action (eqs 5A,B and 6). Curve-fit parameters were $n = 1.63$, $K_n = 29.0\ \mu M^{-n}$, and $p = 526\%F/\mu M$ [SE (fit) = 1.7]. At a DPA/Tb(III) ratio of 5, the observed %F(100) was approximately 95.1% of the maximum %F(105) predicted by eqs 5A,B and 6 for 0.2 μM Tb(III):DPA complex fluorescence.

DISCUSSION

Ma, Hwang, and Lee have described a fluorescence-quenching method using Tb(III) (1 μM) and dipicholinic acid (5 μM) for estimating chelating groups in chelate-conjugate macromolecules (*3*). This method of analysis was based on a fluorescence quenching model where Tb-(III) alone has low fluorescence, $Tb(DPA)_3^{3-}$ has strong fluorescence, and Tb(III) bound to chelator has no fluorescence. Fluorescence-quenching curves were fit to linear regression equations of fluorescence intensity and

initial chelator concentrations, with characteristic intercepts and slopes for each chelator. The relative number of molecules of different quenching reagents equivlent to one molecule of DTPA was calculated from the slopes of the quenching curves relative to the slope of the DTPA quenching curve.

In the current study, using higher sensitivity fluorometry and lower concentrations of Tb(III) (0.2 μM) and DPA (1 μM), fluorescence quenching by chelators was not linear (Figures 2−5) but rather sigmoidal suggesting

initial binding of chelator to the Tb(III):DPA complex may produce only small changes in fluorescence. The formation of a fluorescent Tb:DPA:chelator complex would be possible if there were coordination bonds not involved with chelator binding that could be filled by DPA. EDTA, for example, could occupy up to six out of eight coordination bonds leaving at least two available for DPA binding. At higher chelator concentations, the DPA would be

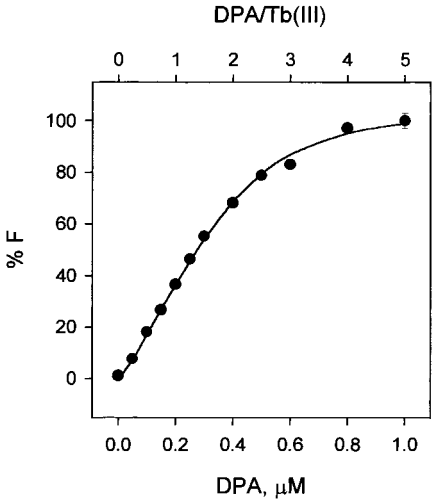

Figure 6. Fluorescence of $TbCl_3$ (0.2 μM) at increasing concentrations of DPA. Solid line, law of mass action curve-fit for Tb(III) + nDPA ↔ $Tb(DPA)_n$, % F = p*[$Tb(DPA)_n$]; $n = 1.63$, $K_n = 29.0\ \mu M^{-n}$, $p = 526\%$ F/μM.

displaced, resulting in complete quenching of fluorescence. Curves representing a nonlinear fluorescence quenching model (eqs 2A−D and 3; Table 1) are included in Figures 2−5. The stoichiometry of chelator binding as reflected by the reaction coefficients *a* and *b* listed in Table 1 suggests that approximately 1/3 of total chelator bound does not significantly change fluorescence of the Tb(III):DPA complex.

The potential formation of fluorescent Tb(III):DPA:chelator complexes is also supported by the fluorescence titration of Tb(III) with DPA (Figure 6). Stoichiometry of DPA binding to Tb(III) as evaluated using the law of mass action (eqs 5A,B and 6) suggests that maximum fluorescence may be achieved when less than 3 DPAs are bound per Tb(III) (i.e., $n = 1.6$). On the basis of a three-site binding model for Tb(III):DPA complex formation (Scheme 1), total fluorescence would depend on the concentration of each of three Tb(III):DPA complexes [i.e., Tb(III):(DPA), Tb(III):$(DPA)_2$, or Tb(III):$(DPA)_3$] and on the fluorescence proportionality constant for each complex. If fluorescence intensity depends primarily on one or two DPAs bound per Tb(III), then initial binding of chelator may significantly decrease the concentration of the Tb(III):DPA_3 complex by forming fluorescent Tb(III):DPA_2:chelator or Tb(III):DPA:chelator complexes, thus a change in fluorescence would be minimal. Subsequent changes in fluorescence at higher chelator concentrations could result when the Tb(III):$(DPA)_2$:chelator or Tb(III):(DPA):chelator complex concentrations decrease. The slightly sigmoidal shape of the fluorescence titration curve (Figure 6) would suggest that fluorescence of the Tb(III):DPA:chelator complex would be less than the Tb(III):$(DPA)_2$:chelator complex.

The values of the apparent association constants (K_{xa}, K_{xb}) listed in Table 1 for the binding of DTPA or EDTA to the fluorescent Tb(III):DPA complex are less than the reported values of the formation constants for the Tb(III):DTPA ($K_f = 5 \times 10^{13}\ \mu M^{-1}$) or Tb(III):EDTA ($K_f = 9 \times 10^{8}\ \mu M^{-1}$) complexes (*7*). Differences in values would be expected in this study where the binding of chelator to Tb(III) is in the presence of excess DPA which also binds to Tb(III), thus the apparent association constant for chelator binding to the fluorescent Tb(III):DPA complex would be less than the association constants for chelators binding to Tb(III) alone. The parameters in Table 1 are minimum values required to fit a model curve (eqs 2A−D and 3) to the observed data based on nonlinear least-squares analysis. Greater values for association constants are possible, although higher values would not necessarily improve the curve fit. The curve fit parameters are valid for the proposed reaction model (eqs 2A−D and 3), thus comparisons of reaction paramaters with others in the literature also requires a comparison of the reaction models used in calculating the association constants. The relative magnitudes of the binding constants determined in this study are consistent with published data (i.e. DTPA > EDTA ≫ DPA) (*7*).

The inclusion of the coefficient c (number of binding sites per chelator, Table 1) or the DTPA/X ratio (Table 2) provided means of evaluating the binding capacity of each chelator relative to DTPA. The relative binding capacity of each chelator was EDTA < DTPA < PL25-DTPA < IgG-PL25-DTPA. The weaker chelating ability of EDTA ($c = 0.57$; DTPA/X = 0.54) is to be expected from the fewer carboxyl groups available for chelation for EDTA (four) compared to DTPA (five) as suggested by Ma et al. (*3*). Also, the larger size of DTPA compared to EDTA may result in greater chelating ability of DTPA for lanthanide series ions.

Scheme 1. Three Site Binding Model for Tb(III):DPA Fluorescent Complex Formation[a]

A. Binding

1 $\%F_1 = p_1*[Tb(III):DPA] = p_1*K_1*[Tb(III)]*[DPA]$

2 $\%F_2 = p_2*[Tb(III):(DPA)_2] = p_2*K_1*K_2*[Tb(III)]*[DPA]^2$

3 $\%F_3 = p_3*[Tb(III):(DPA)_3] = p_3*K_1*K_2*K_3*[Tb(III)]*[DPA]^3$

[a] K_1−K_3, association constants; $\%F_1$ − $\%F_3$, complex fluorescence; p_1−p_3, fluorescence proportionality constants.

Fluorescence quenching by the chelate-conjugated macromolecules PL25-DTPA and IgG-PL25-DTPA reflects the expected higher binding capacity for these molecules. On the basis of the curve fit parameters *c* in Tables 1 and DTPA/X and EDTA/X in Table 2, PL25-DTPA and IgG-PL25-DTPA have approximately 14−15 and 18−29 times the binding capacity of DTPA and 25−26 and 33−54 times the binding capacity of EDTA, respectively. The data also suggests (based on DTPA/X and EDTA/X, Table 2) that up to two PL25-DTPAs may be bound per IgG. Fluorescence quenching by IgG-PL25-DTPA may also include Tb(III) and DPA binding to other sites on IgG, thus analysis of fluoresence quenching by IgG alone would be necessary to assess relative chelator concentration of chelate-conjugated IgG.

Estimates of chelating capacity by fluorescence quenching may underestimate the number of chelating groups in chelate-conjugated macromolecules. Tb(III) binding to PL25-DTPA as determined by fluorescence quenching suggests approximately 0.4−0.6 DTPA and approximately 1.0−1.1 EDTA equivalent Tb(III)-binding sites/kDa of PL25. Using ^{153}Gd(III) binding to PL14-DTPA (PL14 = 14 kDa), Manabe, Longley, and Furmanski (*4*) detected approximately 3 DTPA/kDa PL14. Torchilin et al. (*5*), using radiometric determination of ^{111}In(III) binding and nuclear resonance determination of Gd(III) binding to PLn-DTPA (PLn = 4, 14, or 55 kDa), conjugated monoclonal antimyosin antibody estimated from 1.6 to 5.4 cations bound/kDa PLn. As suggested by the data shown in Figures 2 and 3, approximately 1.5−2.0 DTPA/Tb(III) and >2.5 EDTA/Tb(III) are required to quench fluorescence, thus the actual number of chelating groups on PL25-DTPA or IgG-PL25-DTPA per kilodalton PL25 would be comparable to that reported by others.

In conclusion, as proposed by Ma et al. (*3*), the method of fluorescence quenching of the Tb(III):DPA complex by chelators is rapid, simple, and has merit in estimating low concentrations of chelating groups in chelate-conjugated macromolecules. Using high sensitivity fluorometry and lower initial concentrations of the Tb(III):DPA fluorescent complex, nonlinear curve fitting of fluorescence quenching facilitated the estimation of chelating groups at lower concentration limits. The estimation of chelating groups on chelate-conjugated macromolecules at lower concentrations would minimize the amount of sample required for analysis during synthesis and isolation of chelate-conjugated macromolecules for various procedures including radioimmunoimaging, radioimmunotherapy, NMR-tomography, and in vitro immunoassays. The data also suggested a model for the stoichiometry of Tb(III):DPA complex fluorescence consistent with the observed fluorescence quenching by chelators. An understanding of the mechanism of Tb:DPA complex fluorescence and fluorescence quenching would be useful in further refinement of methods for estimating chelator concentrations and for design of fluorescent probes.

Biotin-Conjugated Polychelating Agent

Vladimir P. Torchilin*

Center for Imaging and Pharmaceutical Research, Department of Radiology, Massachusetts General Hospital and Harvard Medical School, 149 13th Street, Charlestown, Massachusetts 02129. Received May 27, 1998

A procedure is described for preparing a polychelating agent−biotin conjugate through the interaction of biotin-maleimide with poly-L-lysine modified with multiple residues of diethylenetriaminepentaacetic acid and containing amino-terminal pyridylthio-propionate group. The conjugate can be easily loaded with multiple metal atoms, such as ^{111}In, and preserves its ability to specifically interact with avidin (as avidin-agarose). Polychelate-biotin conjugate may be used for signal amplification in visualization and analytical protocols involving the application of the avidin-biotin system.

The avidin-biotin system is well studied and used for different biochemical and biomedical applications including analytical ones, for review see ref *1*. Its application is based on the ability of avidin macromolecule to bind four biotin molecules with extremely high affinity ($K_d \approx 10^{-15}$ M). In particular, the authors of ref *1* mention the application of avidin-biotin complex in affinity chromatography, affinity cytochemistry, cell cytometry, blotting technology, immunoassay, histopathology staining, gene probes, and bioaffinity sensors. Avidin-biotin complex is also being used for targeted delivery of diagnostic and therapeutic agents. For the latter purpose, a ligand is modified either with avidin or with biotin and is then allowed to accumulate in a target area. Then, the pharmaceutical agent is administered as a conjugate with biotin (if avidin is accumulated in the target) or with avidin (if the target contains biotin) and concentrates locally in the desired area due to the fast formation of avidin-biotin complex. Since the in vivo stability of biotin association with various biological (macro) molecules was repeatedly confirmed (see, for example, refs *2* and *3* and references therein), the approach is currently finding growing application.

Recently, the (strept) avidin-biotin system was also used for the visualization of various pathological conditions including tumors (*4*, *5*). The approach is based on the observation that infected, inflamed, necrotic, and malignant areas are able to nonspecifically accumulate large protein molecules, such as immunoglobulins or albumin (*6*, *7*) or even nanoparticulates (*8*) via the mechanism of impaired filtration. It was suggested to use (strept) avidin itself or (strept) avidin-antibody conjugate as a tumor-accumulating substance, and after its preliminary injection and accumulation, to target (i.e., to visualize) the tumor with a biotin-associated label (*9*−*11*). Different heavy metal ions serve usually as those labels, such as ^{111}In and ^{99m}Tc (for γ-immunoscintigraphic visualization); Gd and Mn (for magnetic resonance imaging), or ^{186,188}Re and ^{90}Y (for tumor radiotherapy) (*10*).

Whenever biotin has to be modified with a reporter metal for in vitro or in vivo application, to couple metals with biotin, the latter is first chemically modified with a metal-chelating moiety (*11*). However, the insufficient ability to load biotin with a metal might be considered as one of the potential limitations of the proposed scheme. All techniques described so far involved the use of biotin carrying just a single chelating group, i.e. capable of binding just one metal atom, which results in the insufficient signal multiplication from biotin in both, in vitro and in vivo analytical (imaging) procedures. Thus, in vivo it should result in relatively low label accumulation in the target (tumor), especially when the size of the target is small and/or the quantity of avidin in the target is low. This makes γ- and MR-imaging as well as radiotherapy difficult enough, since the efficacy of all in vivo protocols depend on the quantity of a label delivered to the target. The sensitivity of various analytical in vitro protocols involving avidin-biotin application also might suffer because of insufficient biotin load with tracers.

This report describes an attempt to increase biotin load with a marker metal. With this in mind, the scheme was developed of biotin modification with single-terminus reactive chelating polymers containing multiple chelating groups and able to chelate firmly multiple metal atoms (their exact number in each particulate case can be controlled by the length of a chelating polymer). Such polymers were developed by us earlier for the modification of monoclonal antibodies used for γ-immunodiagnostics (*12*−*14*), see also ref *15* for review.

Materials. Biotin-maleimide [*N*-biotinoyl-*N*′-(6-maleimidohexanoyl)hydrazide, BMA], *N*-(carbobenzyloxy)-poly-DL-lysine (CBZ-PLL; MW 4000), diethylenetriaminepentaacetic acid cyclic anhydride (caDTPA), dithiothreitol (DTT), N-succinimidyl 3-(pyridyldithio) propionate (SPDP), guanidine chloride, and all solvents and buffer components were obtained from Sigma Chemical Co., St. Louis, Mo.[1] Prepacked 1 mL avidin-agarose columns (Immuno-Pure AffinityPak) were acquired from Pierce (Rockford, IL).

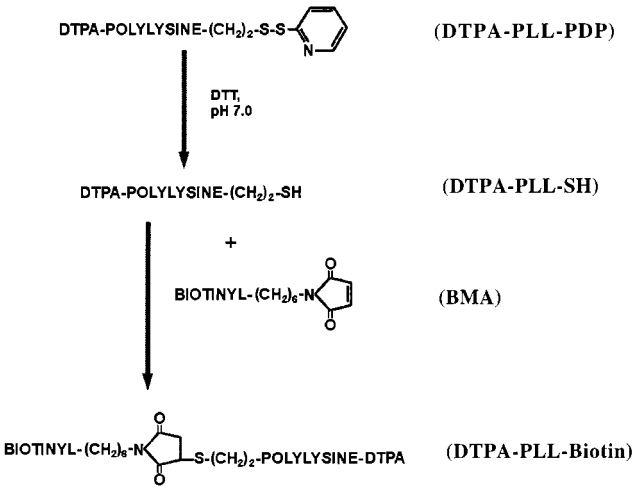

Figure 1. The scheme of DTPA-PLL-biotin synthesis. Starting DTPA-PLL-PDP was prepared as in ref 13.

Synthesis. N-Terminal-activated chelating polymer DTPA-PLL-PDP was prepared as in ref *14* by modification of the unprotected terminal amino group in CBZ-PLL with SPDP, subsequent deprotection of CBZ-PLL-PDP with HBr/CH_3COOH, and interacting free amino groups of PLL-PDP with caDTPA. For this purpose, 3.5 μmol of SPDP was reacted with 0.8 μmol of CBZ-PLL (MW 4000) in 350 μL of DMFA in the presence of 0.14 μL of triethylamine at 4 °C overnight. The product was precipitated with water and CBZ deprotected with 250 μL of 36% HBr in acetic acid. The resulting PLL-PDP was precipitated with diethyl ether and freeze-dried. DTPA residues were incorporated into PLL-PDP by reacting the latter with 50-fold molar excess of caDTPA at pH 8.2. In order to diminish possible cross-linking of PLL chains by bifunctional caDTPA, mixed DTPA anhydride can be used instead of caDTPA (*16*). However, HPLC analysis of DTPA-PLL-PDP obtained by both protocols provides similar patterns demonstrating the absence of olygomeric structures. As was demonstrated in our previous reports using the titration of remaining free amino groups with trinitrobenzene sulfonic acid of direct binding of ^{111}In (*12*−*14*, *17*), in such conditions 15−20 DTPA residues can be reproducibly incorporated into a single chain of DTPA-PLL(4000)-PDP.

To derivatize biotin with DTPA-PLL, DTPA-PLL-PDP (10 mg/mL in HEPES buffered saline, HBS, pH 7.0) was first reduced with 5 mM DTT in HBS for 2 h at room temperature. The product was purified from low-molecular-weight reactants by centrifugation on Sephadex G-10 minicolumn (Pharmacia). The resulting chelating polymer with free terminal SH-group was conjugated with BMA. For this purpose, 100 μg of DTPA-PLL-SH was incubated with 6 μg of BMA (added as 10% solution in DMSO), which corresponds to molar ratio DTPA-PLL-SH:BMA ca. 2:1, in 0.5 mL of HBS, pH 7.4, for 1 h at room temperature. The resulting DTPA-PLL-biotin (mixed with nonreacted DTPA-PLL-SH and BMA) was separated from low-molecular-weight reactants, including BMA, by centrifugation on Sephadex G-10 minicolumn. The synthesis scheme is presented in Figure 1.

DTPA-PLL-biotin (as a mixture with nonreacted DTPA-PLL-SH) and control DTPA-PLL-SH (same molar quantities as DTPA-PLL) were labeled with ^{111}In via the transchelation mechanism. For this purpose, 150 μL of 0.1 M citrate, pH 5.3, was added to 100 μg of each polymer in 0.5 mL of HBS, then polymer solutions were supplemented with ca. 300 μCi of ^{111}In (as $^{111}InCl_3$ in HCl and NEN) and incubated for 1 h at room temperature. Free ^{111}In was separated from ^{111}In-labeled polymers by centrifugation on Sephadex G-10 mincolumn.

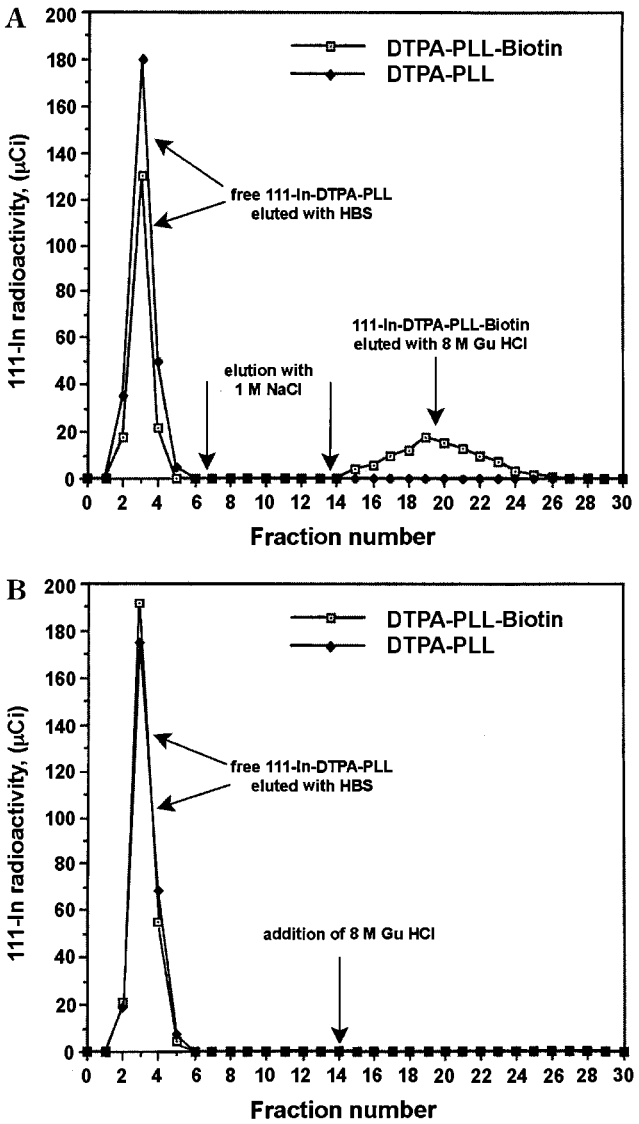

Figure 2. Chromatography of ^{111}In-labeled DTPA-PLL-biotin and control DTPA-PLL on avidin-agarose without (A) and with (B) column presaturation with free biotin. Column volume, 5 mL; samples were applied in 0.5 mL of HBS, pH 7.4 (other details in the text).

RESULTS AND DISCUSSION

Sephadex G-10 chromatography of ^{111}In-labeled samples demonstrated that both the eluate with DTPA-PLL-Biotin and eluate with DTPA-PLL-SH contained ca. 250 μCi of ^{111}In radioactivity (of ca. 300 μCi added to each sample). It proves efficient and similar labeling of chelates in both polymers.

To check the efficacy of biotin derivatization with DTPA-PLL, a gel-chromatography of both ^{111}In-labeled DTPA-PLL-Biotin and control DTPA-PLL-SH on avidine-agarose column equilibrated with HBS was performed. The results of this experiment are presented in Figure 2A. Upon washing column with HBS, all applied polymer-bound radioactivity was eluted in case of control chelating polymer, DTPA-PLL-SH. However, only 60% of applied radioactivity was eluted in case of labeled DTPA-PLL-Biotin. Forty percent of applied radioactivity remained on the column. This avidin-agarose-bound radioactivity

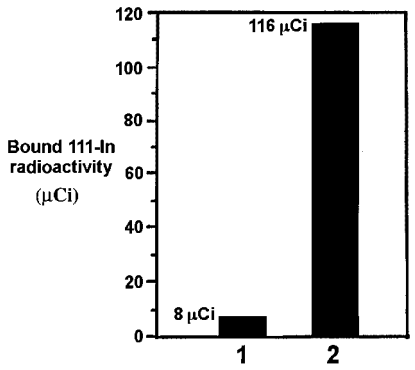

Figure 3. Radioactivity (^{111}In) binding with avidin-agarose via DTPA-biotin (1) and DTPA-PLL-Biotin (2). For conditions, see Figure 2.

cannot be eluted by washing the column with 1 M NaCI (which excludes any nonspecific interactions, such as electrostatic ones), but was eluted as a broad peak with 8 M guanidine chloride, which is known to slowly dissociate avidin-biotin complex (*18*). However, presaturation of the avidine-agarose column with pure nonlabeled biotin results in identical elution pattern for both polymers: HBS is able to elute all applied radioactivity for both, DTPA-PLL-biotin and control DTPA-PLL-SH (Figure 2B). It clearly proves that the reaction mixture after DTPA-PLL-biotin synthesis, together with nonbiotinylated DTPA-PLL, contains also polychelate-conjugated biotin which preserves its ability to specifically interact with avidin with very high affinity since, like in case of the native biotin-to-avidin interaction, only 8 M guanidine chloride is able to slowly dissociate the complex formed. Probably, negatively charged polychelator forms rigid rod-like "tail" attached to biotin "head" and does not create any steric hindrances for the biotin-to-avidin interaction. Since in the reaction mixture, DTPA-PLL-SH:BMA molar ratio was 2:1 and avidine-agarose adsorbs ca. 40% of applied reaction mixture (following the radioactivity data), we can easily calculate that the coupling yield of BMA and DTPA-PLL-SH is ca. 80% relative to BMA. Thus, even in the case of relatively low-molecular-weight PLL, it is possible to couple a PLL tail containing 15−20 DTPA residues (it means the same number of diagnostic or therapeutic metal atoms) to a single biotin molecule.

To prove the practical significance of polychelate-biotin and its superiority over traditional single chelate-modified biotin, we compared the quantity of radioactivity which can be delivered to the avidin-agarose column by ^{111}In-loaded DTPA-biotin (was purchased from Sigma as DTPA-α,ω-bis-biocytinamide) and DTPA-PLL-Biotin under similar conditions. Both reagents, taken in similar quantities as biotin, were incubated with the same quantity of ^{111}In in the same conditions, and reaction mixtures were directly applied onto identical avidin-agarose minicolumns. After washing columns with HBS (to remove all components containing no biotin moiety), the radioactivity remaining on both columns (i.e., attached to avidin via biotin residues) was measured. The results presented in Figure 3 clearly shows that DTPA-PLL-biotin is able to deliver to avidin-containing matrix almost 15 times more radioactivity than DTPA-biotin (which corresponds well with the presence of ca. 15 DTPA groups in DTPA-PLL-biotin compared with a single DTPA group in routine DTPA-biotin).

Thus, the possibility of increasing loading of biotin with metal (radio)isotopes via chelating polymers is demonstrated. Chelate-PLL-biotinyl conjugates (with various chelates) can be used to amplify the signal from avidin-bound biotin in various analytical systems in vitro and to enhance a diagnostic and/or therapeutic metal targeting to a preaccumulated avidin or avidinylated molecules in vivo. The medical application of this approach might be especially attractive, and one can speculate that the local metal concentration can be achieved suitable for γ-imaging, radiotherapy, and MR diagnostics of avidin-containing targets (tumors, infarcts, necrotic tissues etc.). Sure, additional in vivo studies have to be performed to investigate the pharmacokinetics of biotin-polychelate compared to biotin-monochelate (in particular liver uptake which might be higher for biotin-polychelate if the presence of DTPA residues will not compensate sufficiently positive charge of PLL) before making a more definite conclusion concerning the clinical (diagnostic) applicability of a new conjugate. However, the benefit of using biotin-polychelate conjugates is evident for in vitro analytical biochemistry, where it might be successfully applied as an amplification system in analytical procedures involving the use of the avidin-biotin system.

Received June 8, 1998; Revised Manuscript Received November 7, 1998

Enzyme-assisted synthesis and characterization are described for 3-O-β-D-glucuronides **1b**−**4b** of the aglycons *E*- and *Z*-2-cyano-*N*,*N*-diethyl-3-(3,4-dihydroxy-5-nitrophenyl)propenamide (entacapone), **1a** and **2a**, respectively, 3-(3,4-dihydroxy-5-nitrobenzylidene)-2,4-pentanedione (nitecapone) **3a** and 4′-methyl-3,4-dihydroxy-5-nitrobenzophenone (tolcapone) **4a**, and 1-*o*- and 2-*o*-glucuronides **5b** and **6b** of the aglycon 1,2-dihydroxy-4-nitrobenzene **5a**. Liver microsomes from rats pretreated with Aroclor 1254 were used as catalyst in the synthesis. Glucuronidation was regio- and stereoselective in the case of **1a**−**4a**; only one product was observed by HPLC, HPTLC, and NMR. The glucuronidation of 1,2-dihydroxy-4-nitrobenzene **5a** resulted in equal amounts of 1-O-β-D- and 2-O-β-D-glucuronides. Purification of the crude products by C_{18} solid-phase extraction and/or flash chromatography gave compounds **1b**−**6b** in 38−98% yields (50−84 mg). The structures of the glucuronides were characterized on the basis of UV and IR spectra and confirmed with FAB-MS and NMR spectroscopy.

INTRODUCTION

Nitrocatechol derivatives entacapone (E-isomer) **1a**, its Z-isomer (*Z*-entacapone) **2a**, nitecapone **3a**, and tolcapone **4a** (Figure 1) are potent inhibitors of catechol-*O*-methyltransferase (EC 2.1.1.6, COMT), with K_i values in the nanomolar range (*1*). Entacapone and tolcapone are used clinically as adjuncts in the L-DOPA therapy of Parkinson's disease (*2*). The main biotransformation reaction for these compounds is glucuronidation (*3*−*5*), catalyzed by UDP-glucuronosyltransferase, UGT, enzyme family (EC 2.4.1.17). Products of the enzymatic reactions represent the β-anomer. Futile cycling, including the glucuronidation and subsequent hydrolysis of the conjugates by β-glucuronidase, may affect the net glucuronidation in vivo (*6*, *7*) since microsomal β-glucuronidase (EC 3.2.1.31) egasyn complex is located within the lumen of the endoplasmic reticulum (*8*), as is the active site of UGTs (*9*). The hydrolysis of nitrocatechol glucuronides by β-glucuronidase from *Escherichia coli* in the intestine may also be of importance in vivo as suggested by the biliary excretion of nitrocatechol glucuronides (*10*).

Well-characterized reference glucuronides are needed for pharmacokinetic and toxicokinetic studies as well as for enzyme kinetic studies of both glucuronidation by UGTs and glucuronide hydrolysis by β-glucuronidase.

A variety of methods are available for the synthesis of β-glucuronide conjugates (*11*). Most synthetic methods yield mixtures of α- and β-anomers and side-products such as ortho ester.

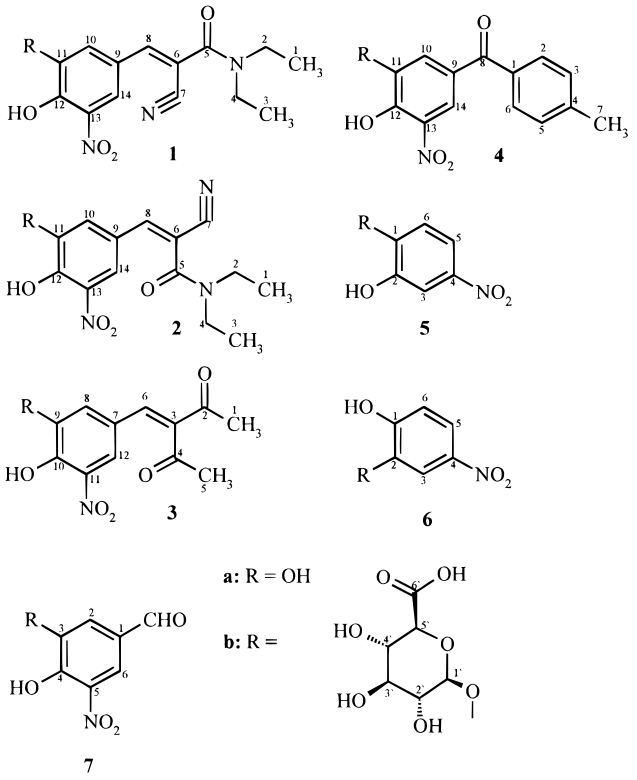

Figure 1. Structures of the nitrocatechol derivatives and their glucuronides.

Enzyme-assisted synthesis offers an alternative way of producing glucuronides. The advantage of biocatalyzed reactions is that the formation of solely the biologically relevant stereo- and regioisomeric products can be expected. Glucuronides have been prepared in laboratory scale by batch synthesis with microsomal enzyme sus-

This paper describes the synthesis and characterization of glucuronides of COMT inhibitors and some other nitrocatechols using rat liver microsomes as biocatalyst. Pure stereo- and regioisomeric glucuronides **1b−6b** were readily prepared in 50 mg scale, a quantity large enough for enzyme kinetic studies in vitro and for the reference standards required in pharmacokinetic and metabolism studies in vivo.

RESULTS AND DISCUSSION

Glucuronides of five nitrocatechol derivatives were prepared using liver microsomes from rats pretreated with Aroclor 1254 as biocatalyst. The purification by solid-phase extraction or flash chromatoraphy gave compounds **1b−6b** in 38−94% (50−84 mg) yields (Table 1).

The UGT activity in rat liver was increased by animal pretreatment with Aroclor 1254, which is a mixture of polychlorinated biphenyls. The specific UGT activities toward tolcapone and entacapone in liver microsomes from Aroclor 1254 (Aro) treated rats were 2- and 5-fold, respectively, relative to untreated or phenobarbital (PB)-treated rats. Glucuronidation may occur species dependently. Two glucuronides of nitecapone (*4*) and *Z*-entacapone (*3*) have been found in rat urine but only one glucuronide in human urine (*3, 4*). Surprisingly, only one glucuronide was formed for each aglycon **1a−4a** by liver microsomes from Aroclor 1254-treated rats. The observed regioselectivity of the reaction in vitro was not due to enzyme induction since only one glucuronide was produced with liver microsomes from untreated rats, too.

The glucuronidation of each nitrocatechol derivative was characterized by following the formation of the glucuronides **1b−6b** against time, protein concentration, and substrate concentration by HPLC. The reaction conditions were chosen by minimizing the amount of protein, maximizing the substrate concentration and optimizing against time.

An attempt was made to prepare nitecapone glucuronide **3b** by using rat liver microsomes immobilized to alginate beads (*14*). The reaction was incomplete resulting in low yield (38%). Further, the tight binding of the aglycon substrate and its degradation products to the matrix prevented repeated use of the beads.

The solubility of the aglycon substrates was in most cases (*Z*-entacapone, tolcapone, and 4-nitrocatechol) the rate-limiting factor of the glucuronidation, but entacapone inhibited its own glucuronidation at concentrations above 2 mM. This problem could be circumvented by adding the aglycon substrate to the reaction mixture in two portions after which the yield was increased from 50 to 76%.

During long incubations at pH 7.4, the side chain of entacapone **1a**, its Z-isomer **2a**, and nitecapone **3a** underwent nonenzymatic cleavage through *retro* aldol condensation. The product of the cleavage, 3,4-dihydroxybenzaldehyde **7a**, was also glucuronidated by rat liver microsomes. The identity of 3,4-dihydroxy-5-nitrobenzaldehyde glucuronide **7b** was determined by negative ion FAB mass spectrometry, $(M - H)^- = 358$. In the purification of **3b** by flash chromatography, the degradation product of the cleavage **7a** could not be fully separated from the glucuronide **3b**. Excess concentration of the aglycon substrate rather than the cosubstrate could not therefore be used in the synthesis of **3b**. The cleavage occurs in neutral conditions (*4*) and might have been prevented by lowering the pH of the reaction mixture.

D-Saccharic acid 1,4-lactone (SL) was included in the incubation medium to prevent cleavage of the generated glucuronides by endogenous β-glucuronidase. In the absence of SL, the cleavage of the glucuronides **1b−6b** was significant only after several hours of incubation.

The negative ion FAB spectra of the glucuronides **1b−6b** typically showed the loss of glucuronic acid. The deprotonated molecular ions $(M - H)^-$ and deprotonated aglycon fragments $(M - H - 176)^-$ were detected as diagnostic peaks. The exact masses obtained by high-resolution FAB mass spectrometry corresponded well with the calculated ones.

^1H and ^{13}C NMR spectra in D_2O were fully assigned on the basis of double quantum filtered correlation spectroscopy (DQF COSY), heteronuclear multiple quantum correlation (HMQC), and heteronuclear multiple bond connectivity (HMBC) spectra. For the sugar moiety, the DQF COSY spectra revealed the expected coupling network. The anomeric proton $H_{1'}$ was identified by the characteristic chemical shift near 5.2 ppm. The coupling constants between $H_{1'}$ and $H_{2'}$ (7 Hz) were in good agreement with the expected β-configuration. The site of glucuronidation was determined from the coupling between the anomeric proton $H_{1'}$ and the aromatic carbon of the glycosidic bond and from the absence or presence of long-range coupling between the aromatic carbon of the glycosidic bond and aromatic protons H_{10} and H_{14} in **1b−4b** (H_3, H_5, and H_6 in **5b** and **6b**). The NMR spectra confirmed the structures of the glucuronides **1b−6b** as stated in Figure 1.

For glucuronides **1b−4b**, the reaction was highly regioselective, producing 3-O-β-D-glucuronides in high yield. The glucuronidation of 4-nitrocatechol resulted in equal amounts of 1-O- and 2-O-glucuronides **5b** and **6b**. The products **1b−6b** were pure β-anomers and contained only minor amounts of the known impurities, indicating the superiority of the biocatalyzed reaction over chemical synthesis. In our laboratory this method has been successfully applied to the synthesis of glucuronides of other compounds, such as steroids and hydroxylated metabolites of polycyclic aromatic hydrocarbons, as well. The results will be reported elsewhere.

EXPERIMENTAL PROCEDURES

Chemicals. Entacapone, its Z-isomer, nitecapone, and tolcapone were from Orion Pharma (Espoo, Finland). All other reagents were of analytical grade. UDPGA, UDP, and SL were from Sigma Chemical Co. (St. Louis, MO).

Animal Treatment and Preparation of Microsomes. Eight adult male Wistar rats were obtained from the Helsinki University Breeding Center (Finland) and treated with as described previously (*19*). The treatment of the animals was approved by the local Ethical Committee for Animal Studies. Liver microsomes were prepared as described previously (*19*).

Table 2. Incubation Conditions for Glucuronides 1b−6b

[a] If two methods were applied consecutively, both are listed. [b] Solid-phase extraction (Bakerbond C_{18} Polar Plus, 3 g). [c] Flash-chromatography (Baker octadecyl 40 μm, 60 Å, 2.5 × 25 cm). [d] Methanol. [e] Acetonitrile.

Enzyme Reactions. All enzyme reactions were carried out in a water bath (37 °C) in 50 mM phosphate buffer (pH 7.4, 5 mM $MgCl_2$, 5 mM D-saccharic, acid 1,4-lactone) with continuous stirring and the reactions were stopped with 10% of ice-cold perchloric acid. The precipitated proteins were removed by centrifugation (3500 rpm, 10 min) and filtration (Schleicher & Schuell ME 25/21, 0.45 μm, Dassel, Germany) of the supernatants. The detailed reaction conditions are given in Table 2.

Purification of Glucuronides 1b−6b. Glucuronides **1b−6b** were purified by solid-phase extraction cartridges (Bakerbond C-18 Polar Plus 3 g) or by flash chromatography (Baker octadecyl 40 μm, 60 Å) in a 2 × 25 cm column (Table 3). After elution, organic solvents were evaporated by rotary evaporator and the aqueous residues were frozen and dried under vacuum with phosphorus pentoxide.

HPLC. (System 1) The formation of the glucuronides was followed by liquid chromatography (HP 1090 Liquid Chromatograph, Pye Unicam PU4020 UV detector and HP 35900 Interface) with a 3.9 × 150 mm Waters NovaPak C_{18} or Waters Symmetry C_{18} column and a Merck 4 × 30 mm precolumn packed with 5 μm LiChrospher RP-18. The detector was set to the UV absorption maximum of each aglycon substrate and glucuronide conjugate at pH 2.0. The flow rate was 1 mL/min. The mobile phase consisted of 5−30% acetonitrile in 0.5% acetic acid.

(System 2) The impurities in the glucuronides **1b−6b** were quantified with (Waters 510 HPLC Pump, Waters 717 plus Autosampler) Micra NPS, 3 μm, 4.6 × 33 mm C_{18} column and electrochemical detection (ESA Coulochem II, 5010 Analytical Cell) with electrode 1 set to 0 mV and electrode 2 set to 250 mV. The flow rate (5% ACN/ 20 mM phosphate buffer, 10 mM citric acid, pH 2.2, 0.15 mM Na_2-edetate) was 0.8 mL/ min.

(System 3) Entacapone glucuronide **1b**, its Z-isomer **2b**, and 4-nitrocatechol 1-O- and 2-O-glucuronides **5b** and **6b** contained small amounts of the other isomer as impurity and they were quantified by liquid chromatography (HP 1090 Liquid Chromatograph, Pye Unicam PU4020 UV detector and HP 35900 Interface) with a 3.9 × 150 mm Waters NovaPak C_{18} column and a Merck 4 × 30 mm precolumn packed with 5 μm LiChrospher RP-18. The mobile phase consisted of 20 mM ammonium acetate in 5−10% acetonitrile/water, and the flow rate was 1 mL/ min.

HPTLC. UDP, UDPGA, and SL contents of the products were determined by thin-layer chromatography by the method of Bansal and Gessner (*20*) but without radioactive label. Compounds **1b−6b** (50 μg) and 0.25−2.5 μg of UDP, UDPGA, and D-saccharic acid 1,4-lactone were applied on a Merck Silica gel 60 F_{254} HPTLC plate using the Linomat IV spray-on technique (Camag). After ascending chromatography in a Camag twin-trough chamber, the plates were scanned with a Camag TLC Scanner II controlled by a computer running Camag CATS software version 3.14.

UV−Vis, IR, and Mass Spectra. UV−vis spectra were recorded with a Philips PU8700 UV−vis spectrophotometer at pH 7.4 (50 mM phosphate buffer) and pH 2.0 (0.5% acetic acid). Molar absorptivities (ϵ) were calculated from 0.06 mM solutions. Infrared spectra were recorded with a Pye Unicam SP3-200 infrared spectrophotometer from KBr tablets. The fluorescence spectrum of nitecapone was also recorded at pH 7.4 and pH 2.0. FAB mass spectra were recorded on a JEOL JMS-HX100 instrument. Low-resolution spectra were obtained in negative ion mode using a 50/50 mixture of glycerol and DMSO as the matrix. Accurate mass measurements at a resolution of 5000 were made in positive or negative ion mode with use of glycerol as the matrix and reference compound.

NMR Spectra. For NMR spectroscopy the samples were deuterium exchanged twice by lyophilizing with excess D_2O. The final samples were prepared by dissolving the compounds (5−15 mg) in 0.7 mL of D_2O (Sigma 99.9% ^2H) in a 5 mm NMR tube. A small amount of acetone was added to the solution as an internal standard (^1H δ 2.225 ppm, ^{13}C δ 30.55 ppm). All spectra were recorded at 300 K (27 °C) on a Varian Unity 500 spectrometer. The HMQC spectra were recorded using the pulse sequence of Summers et al. (*21*). The delay for polarization transfer was set for an assumed ^1J(C, H) of 140 Hz and the delay after the BIRD portion of the pulse sequence was set to 200 ms. GARP-1 decoupling was used in the carbon channel during acquisition (*21*). The relaxation delay between scans was 1 s. The ^1H and ^{13}C spectra of glucuronides **1b−6b** were assigned based on DQF COSY, HMQC, and HMBC. HMQC and HMBC were used in concert to accomplish full ^1H and ^{13}C assignment.

Enzyme-Assisted Synthesis of Nitrocatechol Glucuronides and Physicochemical Characterization Data. *E-5-(2-Cyano-2-(N,N-diethylcarbamoyl)vinyl)-2-hydroxy-3-nitrophenyl-β-D-glucopyranosiduronic Acid,* ***1b***. The yield was 73 mg (76%). The product contained 0.4% entacapone, 0.04% *Z*-entacapone, 0.43% 3,4-dihydroxy-5-nitrobenzaldehyde, 0.73% *Z*-entacapone glucuronide, and less than 0.1% SL, UDP, and UDPGA.

ACKNOWLEDGMENT

We wish to thank the Technology Development Center in Finland (TEKES) for financial support and Orion Pharma for generously providing entacapone and its Z-isomer, nitecapone, tolcapone, and 3,4-dihydroxybenzaldehyde. We also wish to thank Professor Gösta Brunow for his helpful advice. The present work is associated with study project no. BMH4-97-2621 financed by the EU Biomed 2 program.

Paramagnetic Oligonucleotides: Contrast Agents for Magnetic Resonance Imaging with Proton Relaxation Enhancement Effects

Jennifer V. Hines,*,† Ghada M. Ammar,† Jill Buss,† and Petra Schmalbrock‡

Division of Medicinal Chemistry & Pharmacognosy, College of Pharmacy, and Department of Radiology, College of Medicine, The Ohio State University, Columbus, Ohio 43210. Received September 2, 1998

An antisense paramagnetic oligonucleotide analogue targeted to a model macromolecular receptor (5S rRNA) was prepared. The paramagnetic agent's relaxivity (dependence of the relaxation rate on paramagnetic agent concentration) in the presence and absence of the macromolecular receptor was measured at 1.5 and 6.3 T. The relaxivity of the targeted agent increased specifically in the presence of the macromolecular receptor (16% at 6.3 T and 15% at 1.5 T). This effect was specific for a paramagnetic oligonucleotide targeted to the receptor and was larger than the relaxivity enhancement due simply to receptor-induced viscosity differences. Maximizing this relaxivity enhancement of tumor targeted paramagnetic oligonucleotides will aid in contrast agent development for magnetic resonance imaging.

In addition to clinical assessment, cross-sectional diagnostic imaging procedures such as computed tomography (CT) and magnetic resonance imaging (MRI) are currently used to increase the accuracy of cancer diagnosis and staging. Currently approved MRI contrast agents either are tissue-nonspecific (Gd-DTPA, Figure 1) or target normal tissue providing only "cold" spot imaging (superparamagnetic iron oxide) which reduces their value in accurately detecting primary neoplasia or metastases (*1*−*3*). Development of cancer-targeted contrast imaging agents for providing "hot" spot MR imaging would improve the sensitivity of MRI for tumor detection over current methods. Biostable oligonucleotide analogues targeted to diseased tissue, either as an antisense agent to overexpressed mRNA (*4*) or as a ligand (aptamer) to a disease-specific receptor (*5*), have been investigated for other imaging methods but have not been thoroughly investigated as paramagnetic contrast agents for MRI. To optimize contrast agents for MRI, it is useful to maximize not only target localization but also the proton relaxation enhancement (PRE) (*6*) effect upon target binding. Maximizing the PRE effect increases the signal difference between targeted and nontargeted tissues, thus reducing toxicity by reducing the dose necessary for adequate contrast enhancement. We report the preparation of an antisense paramagnetic oligonucleotide targeted to a model macromolecular receptor and the demonstration of a specific PRE effect upon target binding. This information will aid in the development of paramagnetic oligonucleotide contrast agents for MRI.

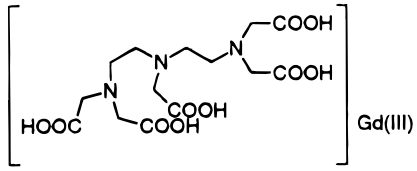

Figure 1. Gd-DTPA−diethylenetriaminepentaacetic acid.

MR contrast imaging relies on the effect a paramagnetic species has on the observed longitudinal and transverse relaxation rates ($1/T_1$ and $1/T_2$, respectively) of solvent (water) nuclei (*6*). Differential relaxation rates due to paramagnetic contrast agents can enhance the MR

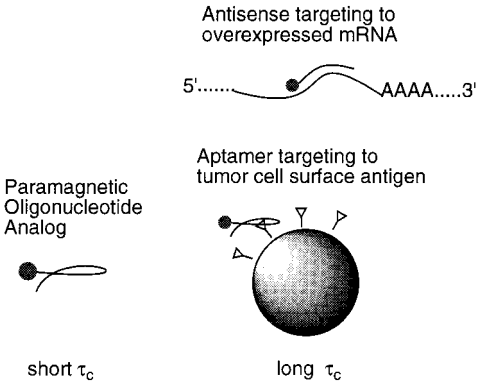

Figure 2. Antisense and aptamer-based targeting strategies.

image obtained and thus lead to better diagnosis. The relaxation rates are linearly dependent on the concentration of the paramagnetic species M where relaxivity (R_1) is defined as

$$(1/T_1)_{obs} = (1/T_1)_d + R_1[M] \quad (1)$$

where $(1/T_1)_d$ is the diamagnetic contribution to the observed relaxation rate $(1/T_1)_{obs}$.[1] A similar relationship applies to T_2 for R_2 relaxivity. The most widely investigated paramagnetic ions for T_1 contrast work are chelated Gd(III), Mn(II), and Fe(III).

The relaxivity is dependent on many factors, including magnetic field strength, correlation time (τ_c, tumbling rate in solution), and inner-sphere and outer-sphere water around the paramagnetic ion (*6*). Of particular importance is the fact that an increase in the correlation time of the paramagnetic species results in increased relaxivity. When the paramagnetic species is targeted to a macromolecular receptor and has a significant change in correlation time upon receptor binding, this leads to a proton relaxation enhancement (PRE) effect or increased relaxivity in the presence of the macromolecular receptor (*6*). Maximizing the PRE effect enhances the image contrast that can be achieved with a targeted contrast agent beyond that which can be achieved with currently available nonspecific agents.

Biopolymers such as paramagnetic antibodies targeted to tumor-specific antigens have been investigated for use as MRI contrast agents. The paramagnetic metal enhances the relaxivity (R_1) of bulk water, while the antibody provides tumor localization. Antibodies with only paramagnetic chelates attached, however, are not very effective contrast agents due to their large size, the lack of access of bulk water to the paramagnetic center, and very small correlation time change (and hence small relaxivity change) upon target binding (*6*). Only the superparamagnetic particle−antibody complexes are useful candidates. Porphyrins (*8*), liposomes (*9*), and polysaccharides (*10*, *11*) have also been investigated for tissue-specific delivery of relaxation agents. An alternative to these agents which has not been thoroughly investigated is the use of targeted paramagnetic oligonucleotide analogues.

Biostable oligonucleotide analogues can provide tumor-specific delivery of contrast agents (Figure 2) either as an antisense agent to mRNA overexpressed in a cancer cell (*4*) or as an aptamer to a cell surface (*12*). The main advantage of an oligonucleotide-based delivery agent over an antibody is size. Many oligonucleotide antisense agents and aptamers to complex targets have tight binding specificity contained within a relatively small piece of oligonucleotide (20−40 nucleotides ≅ 7−14 kDa) (*13*). Consequently, the correlation time of the free oligonucleotide analogue versus the oligonucleotide when bound to the target is different. This difference is sufficient to induce a PRE effect. The extent and lifetime of bound water in nucleic acids (*14*) can also be exploited to further enhance the PRE effect.

[1] Often, the terms $1/T_1$ and R_1 are used interchangeably; however, the explicit definition of relaxivity (R_1) is that shown in eq 1 (*6*) and is used accordingly throughout this paper.

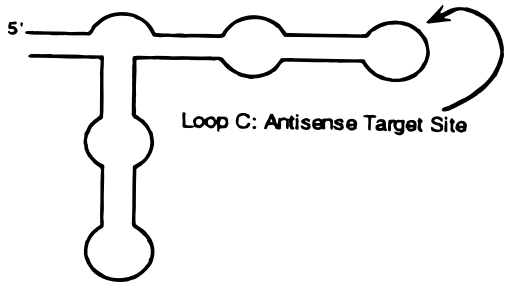

Figure 3. Secondary structure of 5S rRNA and antisense target site.

Our model system for investigating and ultimately optimizing the PRE effect for an antisense paramagnetic oligonucleotide uses 5S rRNA as the macromolecular target and a complementary 6mer sequence as the antisense agent. The *Escherichia coli* 5S rRNA was purchased and renatured (*15*). We chose the sequence 5′-CGGCAT-3′ (**ON-1**) which is complementary to nucleotides 39−44 in 5S rRNA (Figure 3) (*15*). We chose the sequence 5′-AAAAAA-3′ ($\mathbf{A_6}$) as a control to monitor relaxivity changes due to viscosity differences. Since there is no complementary binding site for $\mathbf{A_6}$ on 5S rRNA, relaxivity changes in the presence of 5S rRNA will depend only on viscosity changes due to the macromolecule. **ON-1** and $\mathbf{A_6}$ were purchased with a 5′-amino linker and reacted with DTPA dianhydride (**2**, Scheme 1). The resulting chelate conjugates were treated with $GdCl_3$ followed by size-exclusion chromatography and dialysis to prepare the paramagnetic−oligonucleotide chelate complexes. HPLC and MALDI-TOF analyses indicated there was pure product with no degradation or dimer formation. DTPA content was verified by spectrophotometric analysis (*16*).

On the basis of the correlation time of 5S rRNA (10 ns) (*17*) and of a 6mer oligonucleotide (1 ns) (*18*), there should be a significant change in the correlation time of the 6mer oligonucleotide chelate upon binding to the 5S rRNA target. Such a change in the correlation time should result in a PRE effect as discussed earlier. An electron spin resonance study with a TEMPO-modified single-stranded oligonucleotide showed that there was a change in the correlation time upon binding a complementary region of 5S rRNA (*19*).

The buffered renatured 5S rRNA (*15*) was used to prepare sample paramagnetic agent:5S rRNA ratios of 0:1, 0.25:1, 0.5:1, 0.75:1, and 1:1. Equivalent samples containing just buffered paramagnetic agent were also prepared. Inversion−recovery studies for measuring the T_1 values of the bulk water were carried out at 6.3 and 1.5 T. At 6.3 T, all buffered samples were in 95% D_2O/5% H_2O. Due to the sequential nature of the experiments, a full inversion−recovery experiment for determining each individual T_1 was prohibitively long. Consequently, the T_1s were estimated from the null spectrum of a 180−D_2−90−acquire pulse sequence where $T_1 = D_2/\ln 2$ (*20*). At 1.5 T, buffered samples in H_2O were placed in a 96-

[a] In 10 mM Tri- HCl (pH 6.9), 10 mM $MgCl_2$, 20 mM $Na_2B_4O_7$ buffer. Relaxation studies were performed at room temperature on a GE/Signa 1.5 T MR imager with the wrist coil as the receiver coil and the large volume body coil as the radio frequency transmitter. A single slice that was 4 mm thick was acquired corresponding to 40% of the sample height. The field of view was 12 cm × 9 cm and the matrix size 256 × 256 points. An inversion recovery fast spin-echo (IR-FSE) program was used with TIs (delay time for monitoring inversion recovery) of 50, 200, 300, 500, 700, 900, 1100, 1500, 1800, 2100, 2500, 3200, and 4000 ms with a constant TE (echo time) and TR (repetition time) of 16 and 8000 ms, respectively. [b] See the text for R_1 determination. Error estimated to be 5% based on replicate R_1 determinations. [c] Proton relaxation enhancement (% R_1 enhancement in the presence of a macromolecule); see the text. [d] At 0.006 mM in 5S rRNA.

well polypropylene tube array and surrounded by buffer to minimize magnetic susceptibility problems. To investigate the possibility of the nucleic acid binding to the well walls, which could potentially affect the relaxation measurements, duplicates of the samples were placed in wells previously treated with a siliconizing agent and then rinsed with 95% ethanol and air-dried.

To avoid difficulties with phase variation across the image, MR systems typically generate magnitude images. Thus, only the absolute value of the MR signal was measured. Images were analyzed using IDL (Research Systems Inc.), and the image intensities of each sample well (7 mm × 7 mm, 14 pixel × 14 pixel image) were measured over an area of 121 pixels. The intensities at different TIs were analyzed using SigmaPlot (Jandell Scientific). A nonlinear curve fit of the form

$$I_\tau = |I_\infty(1 - Ce^{-\tau/T_1})| \qquad (2)$$

was applied where τ is the delay time TI, T_1 is the spin−lattice relaxation time, I_τ is the image intensity at delay time τ (=TI), I_∞ is the image intensity when $\tau = \infty$, and $C \approx 2$. I_∞, C, and T_1 were treated as adjustable parameters. The resulting $1/T_1$ values were then plotted versus the paramagnetic agent concentrations. The relaxivity (R_1) was calculated for each experiment using a linear regression fit to the equation $(1/T_1)_{obs} = R_1x + b$, where $(1/T_1)_{obs}$ is measured in s^{-1} and x (the paramagnetic agent concentration) in millimolar. Using our experimental conditions for sample preparation, data acquisition, and analysis, the relaxivity measured for Gd-DTPA ($R_1 = 4.43$ mM^{-1} s^{-1} at 1.5 T) compares favorably with the literature value (*21*, *22*).

The antisense paramagnetic oligonucleotide targeted to 5S rRNA produced a 16% PRE effect at 6.3 T (Table 1) and a 15% PRE effect at 1.5 T (clinical MR field strength, Table 2). The nonspecific effect that viscosity changes would have on the observed relaxivity of the paramagnetic oligonucleotides due to the presence of a macromolecule was estimated two different ways. The R_1 of **ON-1−DTPA-Gd** in the presence of dextran (MW = 40 kDa ≅ 5S rRNA) was measured. The other viscosity control involved measuring the R_1 of **A_6−DTPA-Gd** in the presence of 5S rRNA. Both methods for estimating viscosity effects indicated the same enhancement of R_1 (3%, Table 1) in the presence of a macromolecule. On the basis of these controls, the enhancements simply due to viscosity were smaller than the PRE effects due to the targeted paramagnetic oligonucleotide binding to the 5S rRNA target. This indicates that a PRE effect can be observed when paramagnetic oligonucleotide analogues bind specifically to a macromolecular receptor. Maximizing this PRE effect will be useful in adding hot spot contrast to MR imaging with diseased tissue-targeted paramagnetic oligonucleotide analogues.

As mentioned above, in the 96-well array used for the MRI experiment we were concerned there might be some nonspecific attachment to the well sides. However, no significant difference in R_1 values was seen between the treated and the nontreated wells. An additional control was run to determine if there was any nonspecific attraction between Gd-DTPA and 5S rRNA. No significant difference in the R_1 values for Gd-DTPA in the presence (5.22 mM^{-1} s^{-1} at 6.3 T) or absence (5.20 mM^{-1} s^{-1} at 6.3 T) of 5S rRNA was detected. While the PRE for **A_6−DTPA-Gd** at 1.5 T was significantly smaller than that for **ON-1−DTPA-Gd**, we were somewhat surprised that it was larger than that at 6.3 T. It is possible that **A_6−DTPA-Gd** hydration differences for samples with and without 5S rRNA are affecting the PRE at 1.5 T more than at 6.3 T.

Since unchelated lanthanide ions and certain lanthanide complexes can lead to RNA degradation (*23*), we investigated whether any 5S rRNA degradation was occurring due to the paramagnetic oligonucleotides. UV

melting (*24*) of 1:1 **ON-1**−**DTPA-Gd**:5S rRNA and 1:1 **A_6**−**DTPA-Gd**:5S rRNA each showed a slight decrease in T_m ($\Delta T_m = 5$ °C) compared to that of 5S rRNA alone (approximate $T_m = 75$ °C). The predicted T_m for the **ON-1**−**DTPA-Gd**:5S rRNA duplex is 20 °C; however, the expected hyperchromicity upon melting would be very small relative to the 5S rRNA hyperchromicity and, thus, was not detected. Denaturing polyacrylimide gel studies for detecting full-length 5S rRNA and any degradation products were also carried out. Under the ratio and incubation time conditions used in the NMR and MRI studies, no degradation was observed. However, some degradation was observed at a ratio of 2:1.

While 5S rRNA degradation effects could affect the observed R_1 values, there was no difference in the degradation effects of **ON-1**−**DTPA-Gd** versus **A_6**−**DTPA-Gd** on 5S rRNA. Consequently, degradation does not appear to contribute to the observed difference in PRE between the targeted **ON-1**−**DTPA-Gd** and the viscosity control **A_6**−**DTPA-Gd**. The degradation is most likely due to gadolinium having one less ligand in the oligonucleotide−DTPA-Gd complexes than in Gd-DTPA, leading to an increased likelihood of free Gd^{3+} and nonspecific degradation. Since Gd-DTPA alone does not degrade 5S rRNA under the conditions used in the NMR and MRI studies or at a 2:1 ratio of paramagnetic agent: 5S rRNA as determined by UV melting and gel studies, we believe that utilizing a more stable chelate (DTPA isothiocyanate) (*25*) will reduce the degradation effects we are observing. This analogue allows full chelation of Gd^{3+} (stability constant equivalent to that of Gd-DTPA) with an added tether for conjugation to a macromolecule.

In summary, these studies indicate that paramagnetic oligonucleotides targeted to a macromolecule produce a PRE effect which is specific and greater than simple viscosity differences in the presence of the macromolecular receptor. Maximizing this PRE effect will lead to enhanced MR image contrast with paramagnetic oligonucleotides targeted to tumors since it enhances relaxivity without increasing the paramagnetic agent concentration. We are currently investigating the optimal biophysical features necessary to maximize the PRE effect of tumor-targeted biostable paramagnetic oligonucleotide analogues. Results from these experiments will be presented in due course.

^{99m}Tc-Labeled MIBG Derivatives: Novel ^{99m}Tc Complexes as Myocardial Imaging Agents for Sympathetic Neurons

Zhi-Ping Zhuang,[†] Mei-Ping Kung,[†] Mu Mu,[†] Catherine Hou,[†] and Hank F. Kung*[,†,‡]

Received November 29, 1997; Revised Manuscript Received October 1, 1998

Radioactive-iodine-labeled meta-iodobenzylguanidine (MIBG) is currently being used as an in vivo imaging agent to evaluate neuroendocrine tumors as well as the myocardial sympathetic nervous system in patients with myocardial infarct and cardiomyopathy. It is generally accepted that MIBG is an analogue of norepinephrine and its uptake in the heart corresponds to the distribution of norepinephrine and the density of sympathetic neurons. A series of MIBG derivatives containing suitable chelating functional groups N_2S_2 for the formation of $[Tc^{v}O]^{3+}N_2S_2$ complex was successfully synthesized, and the ^{99m}Tc-labeled complexes were prepared and tested in rats. One of the compounds, [^{99m}Tc]**2**, tested showed significant, albeit lower, heart uptakes post iv injection in rats (0.21% dose/g at 4 h) as compared to [^{125}I]MIBG (1.7% dose/g at 4 h). The heart uptake of the ^{99m}Tc-labeled complex appears to be specific and can be reduced by co-injection with nonradioactive MIBG or by pretreatment with desipramine, a selective norepinephrine transporter inhibitor. Further evaluation of the in vitro uptake of [^{99m}Tc]**2** in cultured neuroblastoma cells displayed consistently lower, but measurable uptake (approximately 10% of that for [^{125}I]MIBG). These preliminary results suggested that the mechanisms of heart uptake of [^{99m}Tc]**2** may be related to those for [^{125}I]MIBG uptake. If suitable ^{99m}Tc-labeled MIBG derivatives can be further developed, the prevalent availability of ^{99m}Tc in nuclear medicine clinics will allow them to be readily available for widespread application.

INTRODUCTION

In the past 15 years meta-iodobenzylguanidine (MIBG,[1] Figure 1) has attracted widespread acceptance as an imaging agent for studying norepinephrine neuronal function. Initially, radioiodine-labeled MIBG was developed as a norepinephrine analogue which localized in the adrenal medulla (*1*). The molecule was designed as a congener of an antihypertensive drug, guanethidine, whose pharmacological action is directly related to inhibition of the release of norepinephrine from adrenergic nerve endings. Using cloned cell lines (CV-1, green monkey kidney cells, and HeLa cells) expressing specific dopamine, norepinephrine, and serotonin transporters, MIBG uptake was reported to be mediated specifically by the norepinephrine transporter with a K_m value of 264 nM. The specific uptake was blocked by desipramine (DMI), a specific norepinephrine transporter inhibitor, and unaffected by dopamine and serotonin transporter inhibitors (*2*). As an analogue of norepinephrine, [^{131}I]-MIBG localizes in the tumors and provides a useful diagnostic tool of neuronal storage of norepinephrine (*1*, *3*). It was later discovered that [^{131}I]MIBG is useful as an agent for neuroendocrine tumor (neuroblastomas and pheochromocytomas) imaging and therapy (*4*).

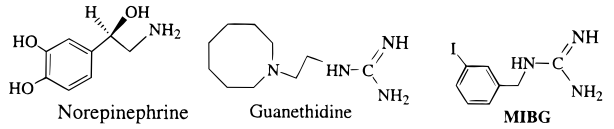

Figure 1. Chemical structures of norepinephrine, guanethidine, and meta-iodobenzylguanidine (MIBG).

One other important observation of using MIBG was that it also localized in myocardium (*5*). It was systematically established by the research group at the University of Michigan and others that the pharmacokinetics of MIBG are indeed related to norepinephrine uptake and release (*6*−*9*). Recent studies in denervated dog heart strongly suggested that the localization of MIBG reflected the integrity of adrenergic neurons. The cardiac scan at time points later than 1 h after injection of [^{123}I]MIBG provides a closed resemblance of the distribution of the sympathetic nerve endings (*9*−*11*). It was suggested that

assessment of the sympathetic nervous system by MIBG imaging may be important for patients with ventricular tachycardia, cardiomyopathy, and arrhythmia (*12*). Thus, MIBG scan may have predictable value for patients at risk of sudden death (*12*−*15*) and patients with diabetes (*16*, *17*). However, due to the limited supply of [^{123}I]MIBG, large-scale clinical studies are not readily achievable (*12*).

Due to the popularity of ^{99m}Tc routinely used in the clinical community, there is a strong need to develop ^{99m}Tc-based compounds, which can be used on a routine basis. Our successful development of [^{99m}Tc]TRODAT-1, a SPECT imaging agent targeting dopamine transporters (DAT) in humans (*18*), opened up a new avenue. The similar strategy aimed at developing ^{99m}Tc-labeled agents for other specific binding sites can be applied, by which they may provide important clinical applications. The $[Tc^{v}O]^{3+}N_2S_2$ complex was chosen for the initial attempt to prepare ^{99m}Tc-labeled MIBG derivatives because this complex has been successfully applied in the development of a brain perfusion imaging agent, [^{99m}Tc]ECD (ethylene cysteine dimer) (*19*−*21*), as well as for the DAT imaging agent, [^{99m}Tc]TRODAT-1 (*22*). Other ^{99m}Tc complexes may be possible, but in this initial report we are going to concentrate on the $[Tc^{v}O]^{3+}N_2S_2$ complexes.

If ^{99m}Tc-labeled MIBG derivatives can be successfully developed based on the same $[Tc^{v}O]^{3+}N_2S_2$ complex, the prevalent availability of ^{99m}Tc in nuclear medicine clinics will permit a widespread clinical application on patients with myocardial disease or various endocrine tumors. We report herein the initial effort in preparing novel ^{99m}Tc-labeled MIBG derivatives, which may potentially be valuable for routine clinical imaging study of the sympathetic nervous system of the heart.

EXPERIMENTAL PROCEDURES

General. Reagents used in the syntheses were purchased from Aldrich (Milwaukee, WI) or Fluka (Ronkonkoma, NY), and were used without further purification unless otherwise indicated. Anhydrous Na_2SO_4 was used as a drying agent. Reaction yields are reported without attempts at optimization. ^{1}H NMR spectra were obtained on a Bruker spectrometer (Bruker AC 200; 200 MHz). Chemical shifts are reported as δ values with chloroform or TMS as the internal reference. Coupling constants are reported in hertz. The multiplicity is defined by s (singlet), d (doublet), t (triplet), br (broad), and m (multiplet). Elemental analyses were performed by Elemental Analysis Laboratory, University of Pennsylvania. Mass spectrometry was performed by the Mass Spectrometry Center, University of Pennsylvania.

***N*-3-Cyanophenyl-2-(4′-methoxybenzyl)mercaptoacetamide (5).** A mixture of 3-aminobenzonitrile (1.18 g, 10 mmol), 2-(4-methoxybenzyl)mercaptoacetic acid (**4**, 2.12 g, 1 equiv), and DCC (2.18 g, 1 equiv) in CH_2Cl_2 (30 mL) was stirred under reflux overnight. After the mixture was cooled to room temperature, water was added and extracted with CH_2Cl_2. The organic extracts was dried and concentrated to give the crude product, which was purified by medium-pressure liquid chromatography (MPLC) (Hex:EtOAc = 5:1) to give 2.17 g of product (70%).

^{1}H NMR: 3.31 (2H, s, Ar-C$\underline{H}_2$-S-), 3.70 (3H, s, OC$\underline{H}_3$), 3.74 (2H, CO-C$\underline{H}_2$-S-), 6.78 (2H, dot, J = 8.6, 2.5 Hz, Ar$\underline{H}$), 7.18 (2H, d,t, J = 8.6, 2.5 Hz, Ar$\underline{H}$), 7.35−7.40 (2H, m, Ar$\underline{H}$), 7.54−7.63 (1H, m, Ar$\underline{H}$), 7.78 (1H, m, Ar$\underline{H}$), 8.4 (1H, br, CON$\underline{H}$).

Anal. ($C_{17}H_{16}N_2O_2S$): Calcd: C, 65.36; H, 5.16; N, 8.97. Found: C, 65.02; H, 5.08; N, 8.94.

3-Aminomethylphenyl-2-(4′-methoxybenzyl)mercaptoethylamine (6). To a suspension of LAH (0.72 g, 18.9 mmol) in THF (15 mL) was added dropwise a solution of **5** (1.19 g, 3.8 mmol) in THF (15 mL) at room temperature. The mixture was stirred under reflux for 1 h and stirred at room temperature overnight. Water (0.9 mL), NaOH (1 M, 0.9 mL), and additional water (2.7 mL) were added successively with caution to decompose excess LAH. The resulting mixture was stirred at room temperature for another 10 min, and the mixture was filtered through Celite. The filtrate was concentrated and purified by preparative thin-layer chromatography (PTLC) (CH_2Cl_2:MeOH:NH_4OH = 9:1:0.1) to give 633 mg of oil (55%).

^{1}H NMR: 2.68 (2H, t, J = 6.4 Hz, NHC$\underline{H}_2$), 3.27 (2H, t, J = 6.4 Hz, S-C$\underline{H}_2$), 3.68 (2H, s, Ar-C$\underline{H}_2$-S), 3.77 (2H, s, Ar-C$\underline{H}_2$-NH$_2$), 3.79 (3H, s, OCH_3), 6.47 (1H, d,d, J = 7.8, 2.0 Hz, Ar$\underline{H}$), 6.54 (1H, s, Ar$\underline{H}$), 6.65 (1H, d, J = 7.5 Hz, Ar$\underline{H}$), 6.84 (2H, d,t, J = 8.6, 2.8 Hz, Ar$\underline{H}$), 7.12 (1H, t, J = 7.7 Hz, Ar$\underline{H}$), 7.22 (2H, d,t, J = 8.6, 2.1 Hz, Ar$\underline{H}$).

Anal. ($C_{17}H_{22}N_2OS\cdot0.25H_2O$): Calcd: C, 66.52; H, 7.39; N, 9.13. Found: C, 66.70; H, 7.38; N, 8.98.

3-(*N*′-*tert*-Butoxycarbonyl)aminomethylphenyl-2-(4′-methoxybenzyl)mercaptoethylamine (7). To a solution of **6** (100 mg, 0.33 mmol) and Et_3N (0.1 mL) in CH_2Cl_2 (5 mL) was added dropwise a solution of $(Boc)_2O$ (72 mg, 1 equiv) in CH_2Cl_2 (2 mL) at 0 °C. The mixture was stirred at 0 °C for 1 h. Water was added, and the reaction mixture was extracted with CH_2Cl_2. The combined organic extract was dried, concentrated, and purified by PTLC (Hex:EtOAc = 3:2) to give 107 mg of product (80%).

^{1}H NMR: 1.47 (9H, s, Boc-H), 2.67 (2H, t, J = 6.4 Hz, NHC$\underline{H}_2$), 3.21 (2H, t, J = 6.4 Hz, S-C$\underline{H}_2$), 3.68 (2H, s, Ar-C$\underline{H}_2$-S), 3.79 (3H, s, OC$\underline{H}_3$), 4.22 (2H, d, J = 5.8 Hz, Ar-C$\underline{H}_2$-NH$_2$), 6.47 (1H, d, J = 6.7 Hz, Ar$\underline{H}$), 6.49 (1H, s, Ar$\underline{H}$), 6.62 (1H, d, J = 7.5 Hz, Ar$\underline{H}$), 6.85 (2H, d,t, J = 8.6, 2.8 Hz, S-Ar$\underline{H}$), 7.08 (1H, t, J = 7.6 Hz, Ar$\underline{H}$), 7.22 (2H, d,t, J = 8.6, 2.0 Hz, Ar$\underline{H}$).

Anal. ($C_{22}H_{30}N_2O_3S$): Calcd: C, 65.64; H, 7.50; N, 6.96. Found: C, 65.46; H, 7.57; N, 6.74.

***N*-3-(*N*′-*tert*-Butoxycarbonyl)aminomethylphenyl-*N*-2-(4′-methoxybenzyl)mercaptoethyl-2-chloroacetamide (8).** To a solution of **7** (100 mg, 0.25 mmol) and Et_3N (0.1 mL) in CH_2Cl_2 (5 mL) was added a solution of chloroacetyl chloride (34 mg, 1.2 equiv) in CH_2Cl_2 (1 mL) at 0 °C in an ice bath. The mixture was stirred at room temperature for 1 h. Water was added, and the reaction mixture was extracted with CH_2Cl_2. The combined extracts were dried, concentrated, and purified by PTLC (Hex:EtOAc = 1:1) to give 116 mg of product (97%).

^{1}H NMR: 1.45 (9H, s, Boc-H), 2.53 (2H, t, J = 7.6 Hz, NHC$\underline{H}_2$), 3.69 (2H, s, Ar-C$\underline{H}_2$-S), 3.81 (3H, s, OC$\underline{H}_3$), 3.78−3.85 (4H, m, S-C$\underline{H}_2$, COCH_2Cl), 4.32 (2H, d, J = 6.2 Hz, Ar-C$\underline{H}_2$-NH$_2$), 6.78 (2H, d,t, J = 8.6, 2.8 Hz, Ar$\underline{H}$), 7.07−7.72 (6H, m, Ar$\underline{H}$).

Anal. ($C_{24}H_{31}ClN_2O_4S\cdot0.5H_2O$): Calcd: C, 59.07; H, 6.61; N, 7.26. Found: C, 59.33; H, 6.54; N, 7.13.

***N*-3-(*N*′-*tert*-Butoxycarbonyl)aminomethylphenyl-*N*-2-(4′-methoxybenzyl)mercaptoethylaminoacetamide (10).** A mixture of **8** (390 mg, 0.81 mmol), 2-(4-methoxybenzyl)-mercaptoethylamine **9** (320 mg, 2 equiv), KI (50 mg, 0.3 mmol), and K_2CO_3 (500 mg, 4.5 equiv) in DMF (10 mL) was stirred at room temperature overnight. Water was added and the reaction mixture was extracted with a mixed solvent (CH_2Cl_2:MeOH = 9:1). The combined extract was dried, condensed, and purified by PTLC (CH_2Cl_2:MeOH = 95:5) to give 387 mg of product (74%)

^{1}H NMR: 1.45 (9H, s, Boc-H), 2.44−2.67 (6H, m, NHCH$_2$-, SCH$_2$-), 3.02 (2H, s, CO-CH$_2$-NH), 3.64 (2H, s, Ar-CH$_2$-S), 3.65 (2H, s, Ar-CH$_2$-S), 3.77 (6H, s, OCH$_3$), 3.70−3.83 (2H, m, CONCH$_2$-), 4.30 (2H, d, J = 5.9 Hz, ArCH$_2$NHBoc), 6.74−6.86 (4H, m,ArH), 6.98−7.39 (8H, m, ArH).

Anal. ($C_{34}H_{45}N_3O_5S_2\cdot 2H_2O$): Calcd: C, 60.42; H, 7.30; N, 6.21. Found: C, 60.89; H, 7.02; N, 5.72.

***N*-3-Aminomethylphenyl-*N*-2-(4′-methoxybenzyl)-mercaptoethyl-2-(4-methoxybenzyl)mercapto-ethylaminoacetamide (11).** Compound **10** (387 mg, 0.6 mmol) was dissolved in HCl−EtOAc (10 mL, 3 M), and the mixture was stirred at room temperature for 1 h. The solvent was removed, and the residue was dissolved in MeOH (1 mL). Water (5 mL) was added, and the solution was adjusted to pH 10 with concentrated NH_4OH. The resulting mixture was extracted with a mixed solvent (CH_2Cl_2:MeOH = 9:1). The combined extracts were dried, evaporated, and purified by PTLC (CH_2Cl_2:MeOH:NH_4OH = 9:1:0.2) to give 288 mg of product (88%).

^{1}H NMR: 2.42−2.67 (6H, m, NHCH$_2$-, SCH$_2$-), 3.03 (2H, s, Ar-CH$_2$-NH$_2$), 3.63 (2H, s, Ar-CH$_2$-S), 3.65 (2H, s, Ar-CH$_2$-S), 3.75 (6H, s, OCH$_3$), 3.79−3.83 (2H, m, CONCH$_2$-), 3.86 (2H, s, COCH$_2$N-), 6.76 (2H, d,t, J = 8.6, 2.9 Hz, ArH), 6.80 (2H, d,t, J = 8.6, 2.9 Hz, ArH-), 6.95−7.38 (8H, m, ArH).

Anal. ($C_{29}H_{37}N_3O_3S_2\cdot 1.5H_2O$): Calcd: C, 61.40; H, 7.11; N, 7.41. Found: C, 61.59; H, 6.96; N, 7.17.

***N*^{2}-3-{*N*-2-(4-Methoxy)benzylmercaptoethyl-*N*-2-[*N*′-2-(4-methoxy)benzylmercaptoethyl]aminoethyl}-aminobenzyl-*N*^{1},*N*^{3}-di-*tert*-butoxycarbonylguanidine (12).** To a suspension of LAH (28 mg, 0.73 mmol) in THF (3 mL) was added a solution of **11** (100 mg, 0.19 mmol) in THF (3 mL) dropwise at room temperature. The reaction mixture was stirred under reflux for 1 h after which one 1 drop of H_2O, 1 drop of NaOH (1 M), and 3 drops of H_2O were added successively to decompose the excess LAH. The resulting mixture was filtered, and the filtrate was concentrated to give 100 mg of crude product, 3-{*N*-2-(4-methoxy)benzylmercaptoethyl-*N*-2-[*N*′-2-(4-methoxy)benzylmercaptoethyl]aminoethyl}amino-benzylamine, which is pure enough for the next reaction without further purification.

^{1}H NMR: 2.53−2.76 (8H, m, S-CH$_2$-, NCH$_2$-), 3.65 (2H, s, Ar CH$_2$-S-), 3.68 (2H, m, Ar-CH$_2$-NH$_2$), 3.71 (2H, s, Ar-CH$_2$-S-), 3.78 (3H, s, OCH$_3$), 3.79 (3H, s, OCH$_3$), 6.49 (1H, d,d, J = 8.2, 2.3 Hz, ArH), 6.62 (2H, m, ArH), 6.80−6.87 (4H, m, ArH), 7.11−7.30 (5H, m, ArH).

A mixture of the amine obtained above (260 mg, 0.50 mmol) and 1,3-bis(*tert*-butoxycarbonyl)-2-methyl-2-thio-pseudourea (156 mg, 1 equiv) in THF (10 mL containing 0.2 mL of water) was stirred at 65 °C for 3 h. The solvent was removed, and the residue was purified by PTLC (CH_2Cl_2:CH_3OH = 93:7) to give 124 mg of product, **12** (33%).

^{1}H NMR: 1.46 (9H, s, Boc-H), 1.51 (9H, s, Boc-H), 2.52−2.80 (8H, m, -CH$_2$-), 3.32−3.46 (4H, m, -CH$_2$-), 3.60 (2H, s, Ar-CH$_2$-S-), 3.67 (2H, s, Ar-CH$_2$-S-), 3.77 (3H, s, OCH$_3$), 3.78 (3H, s, OCH$_3$), 4.52 (2H, d, J = 4.9 Hz, Ar-CH$_2$-NH-), 6.50 (1H, d,d, J = 8.1, 2.3 Hz, ArH), 6.58−6.65 (2H, m, ArH), 6.79−6.96 (4H, m, ArH), 7.04−7.32 (5H, m, ArH), 8.55 (1H, t, J = 4.5 Hz, Ar-CH$_2$-NH-), 11.52 (1H, s, NHBoc).

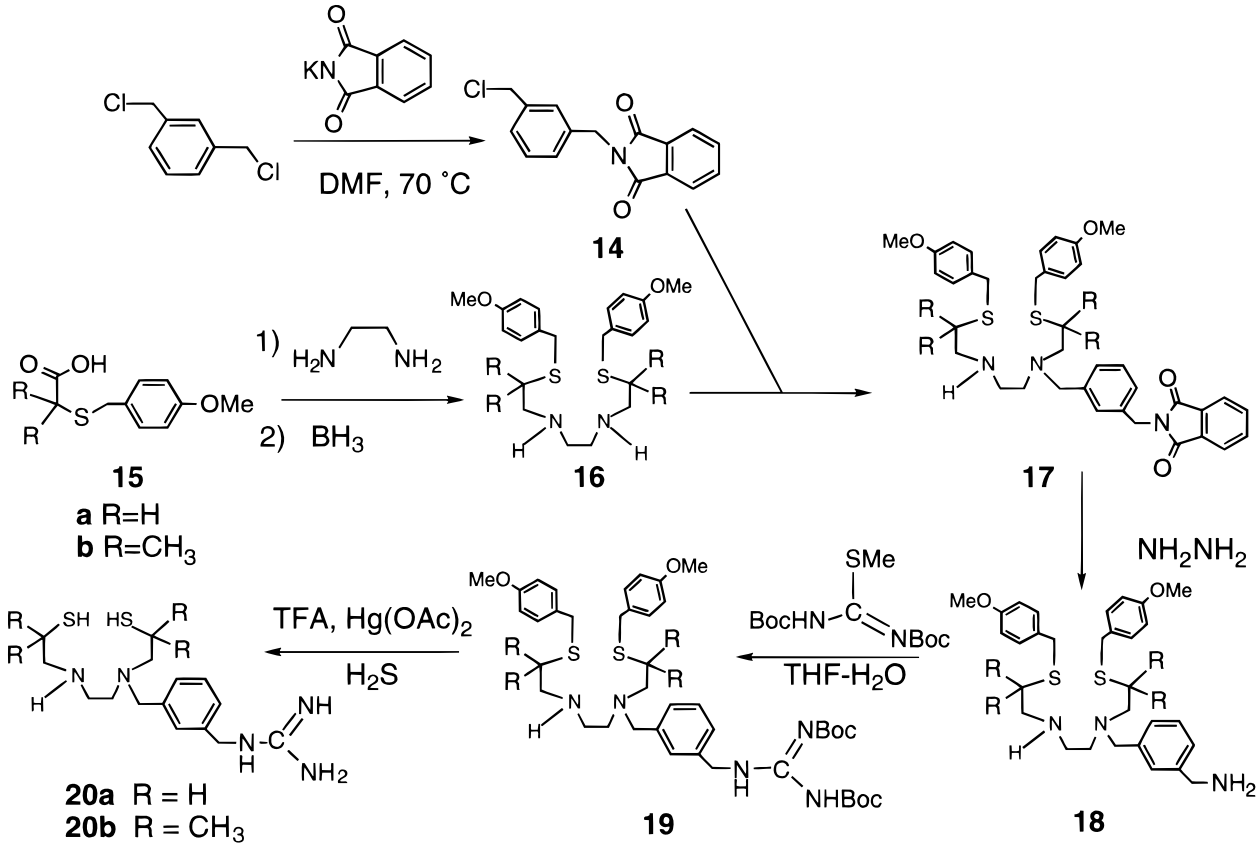
Radiolabeling Procedure. Unlabeled MIBG was prepared by the same two-step method employed for the synthesis of **13** and **20** from **11** and **18**. Labeling of MIBG with ^{125}I was performed by the ammonium sulfate, heat-mediated exchange procedure according to a published method (*1*). A generic description for preparation of all the ^{99m}Tc-labeled complexes is described as the following: A small amount of N_2S_2 ligand (1−2 mg) dissolved in 100 μL of EtOH was mixed with 200 μL of HCl (1 N) and 1 mL of Sn-glucoheptonate solution (containing 12 μg of $SnCl_2$ and 120 μg of Na-glucoheptonate, pH 6.67) and 50 μL of EDTA solution (0.1 N). [^{99m}Tc]Pertechnetate solution (100−200 μL; ranging from 1 to 3 mCi) was then added. The reaction was heated for 30 min at 100 °C, and cooled to room temperature. The reaction mixture was directly analyzed on either TLC (EtOH:concentrated NH_3 = 9:1) or ITLC SG (100% MeOH) to determine the purity of the product. For the animal study, the mixture was neutralized with phosphate buffer to pH 5.0. The ratio of the amount of ligand (a possible pseudo-carrier) to [^{99m}Tc]pertechnetate used for labeling was carefully monitored to result in a final dosing solution with less than 10 μg/Kg body weight/dose (*23*).

Partition Coefficients. Partition coefficients were measured by mixing ^{99m}Tc-labeled complexes or [^{125}I]MIBG with 3 g each of 1-octanol and buffer (pH 7.0 or 7.4, 0.1 M phosphate) in a test tube. The test tube was vortexed for 3 min at room temperature, and then centrifuged for 5 min. Two weighed samples (0.5 g each) from the 1-octanol and buffer layers were counted in a well counter. The partition coefficient was determined by calculating the ratio of cpm/g of octanol to that of buffer. Samples from the octanol layer were repartitioned until consistent partition coefficient values were obtained. The measurement was repeated 3 times.

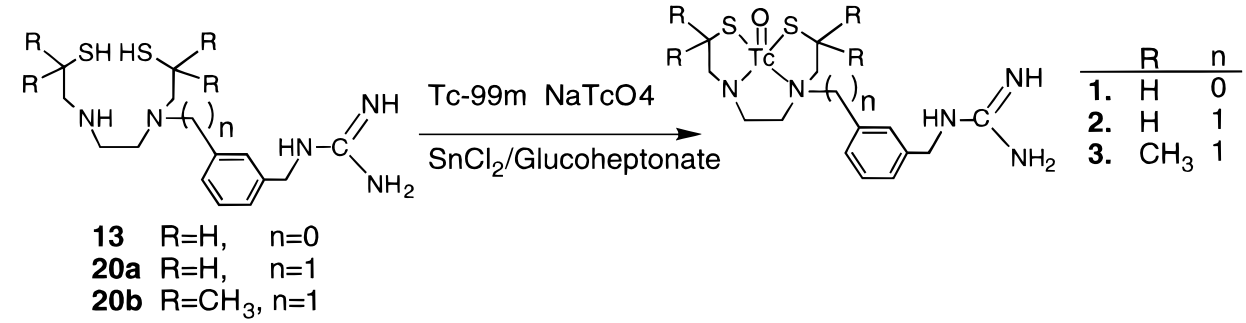
Biodistribution in Rats. Male Sprague-Dawley rats (225−300 g) allowed free access to food and water were used for in vivo biodistribution studies (*24*, *25*). While

Scheme 1



under ether anesthesia, 0.2 mL of a saline solution containing ^{99m}Tc-labeled agents (5−10 μCi) was injected directly into the femoral vein of rats, and the rats were sacrificed by cardiac excision at various time points postinjection. The organs of interest were removed and weighed, and the radioactivity was counted with an automatic gamma counter (Packard 5000). The percentage dose per gram of organ was calculated by a comparison of the tissue counts to suitably diluted aliquots of the injected material. For the dual-tracer experiment, [^{99m}Tc]**2** (5−10 μCi) and [^{125}I]MIBG (1−5 μCi) were coinjected together to the rats, and the biodistribution was performed as described. The samples were counted for ^{99m}Tc activity at the day of the experiment using the energy window of ^{99m}Tc (80−200 keV), and after a 3-day decay period, ^{125}I activity in the samples was determined and used without further decay correction. Blocking studies were carried out either by pretreating rats with desipramine (10 mg/kg, ip) 30 min prior to tracer injection or by coinjecting nonradioactive MIBG (1 mg/kg) together with the tracers.

Uptake Studies in Cultured Cells. The human neuroblastoma cell lines SK-N-SH (uptake-1 positive) and SK-N-MC (uptake-1 negative) (*26*) were purchased from the American Type Culture Collection (Rockville, MD). Cell uptake study was performed similar to that reported previously for MIBG and its related derivatives (*27*). Briefly, bulk quantities of cells were grown in Falcon tissue culture flasks (75 cm^2) at 37 °C in a 5% CO_2 humidified atmosphere. The culture medium was minimal essential medium (MEM) supplemented with glutamine, Earl's salts, sodium pyruvate, and 10% fetal bovine serum. The cells were seeded into 24-well plates [(2−4) × 10^5 cells/per well in 500 μL of medium] and incubated at 24 h at 37 °C. The transporters for dopamine (DAT) or norepinephrine (NET) expressed in the pig kidney cell line (LLC-PK1) were kindly provided by Dr. Rudnick (Yale University, New Haven, CT). These cells, grown as a monolayer culture as described (*28*), were seeded and incubated similarly to SK-N-SH cells. On the day of the experiment, [^{125}I]MIBG and [^{99m}Tc]**2** in the medium were incubated with cells in phosphate-buffered saline (PBS) for 60 min. The cells were solubilized with 500 μL of 0.5 N NaOH and then counted for the associated activity in a gamma counter (Packard 5000). Nonspecific activity was determined either by preincubating cells with DMI (50 μM) or by measuring tracer binding to SK-N-MC cells. Both methods gave similar results.



RESULTS

Synthesis of Ligands. Ligands **13**, **20a**, and **20b**, were prepared by reactions described in Schemes 1 and 2. For the synthesis of ligand **13**, a stepwise approach was used to build the N_2S_2 ligand system. The starting material, 3-aminobenzonitrile, was reacted with 2-(4-methoxybenzyl)mercaptoacetic acid, **4**, in the presence of DCC to produce the amide **5** in 70% yield. Reduction of the amide and the nitrile groups by LAH produced the desired amine **6** (55% yield). Selective protection of **6** with $(Boc)_2O$ resulted in **7** (80% yield). The protected amine, **7**, was acylated with chloroacetyl chloride by which the desired amide, **8**, was produced in 97% yield. Substitution of chlorine in **8** with 2-(4-methoxybenzyl)mercaptoethylamine, **9**, afforded **10** (yield 74%). Deprotection of the Boc group on **10** by acid gave amine **11** (yield 88%).

Scheme 2

Scheme 3

Reduction of the amide moiety of **11** followed by a selective alkylation of the primary amine of the reductive product with 1,3-bis(*tert*-butoxycarbonyl)-2-methyl-2-thiopseudourea in THF (*29*) introduced the guanidine moiety. This two-step reaction produced **12** in 33% yield. A one-pot reaction was used to remove both Boc and methoxybenzyl protection groups simultaneously. This was accomplished by treating **12** with TFA and $Hg(OAc)_2$ followed by treatment with H_2S to give the final product **13** (73%). The other two ligands, **20a** and **20b**, were prepared by reactions described in Scheme 2. To synthesize **20a** and **20b**, 2 equiv of α,α′-*m*-dichloroxylene was reacted with potassium phthalimide to give monophthalimide **14** in 70% yield. Monoalkylation of **16a** (*30*) or **16b** (*31*) by **14** produced the desired N_2S_2 derivatives **17a**,**b** directly. In this selective monoalkylation reaction, when 1 equiv of **16a** was used, the ratio of monoalkylation vs dialkylation was 2:1; when 2 equiv of **16a** was used in the same reaction, the ratio was increased to 4:1. In the case of preparation of **17b**, the reaction was much slower compared to that of **17a**, and no dialkylation product was detected even when 1 equiv of **16b** was used, which is likely due to the steric hindrance of tetramethyl substitution on **16b**. The yield of **17b** was improved from 33% to 66% by adding KI to the same reaction mixture. Hydrolysis of phthalimide of **17a** and **17b** with hydrazine afforded amines **18a** and **18b** in 79% and 86% yield, respectively. The same procedure for introducing the guanidine moiety as that reported for **13** was used to produce **20a** and **20b** in 37% and 68% yield, respectively.

Preparation of ^{99m}Tc-Labeled MIBG Derivatives. Preparation of ^{99m}Tc-labeled compounds from the free thiols, **13**, **20a**, and **20b**, was achieved by using stannous(II) glucoheptonate as the reducing agent for [^{99m}Tc]pertechnetate (Scheme 3). Formations of ^{99m}Tc-labeled complexes resulted in similar R_f values (0.1−0.2) as that of [^{125}I]-MIBG by a similar TLC method [Whatman silica gel plates (PESIL G/UV) under various solvent systems (data not shown)]. Using a solvent system of ethanol/concentrated NH_3 (9:1), the blank labeling reaction (without adding the ligand) showed one peak, most likely the ^{99m}Tc glucoheptonate peak with a R_f value of 0.8−0.9. The radiochemical purity of the final complexes evaluated on TLC (EtOH:concentrated NH_3 = 9:1) showed greater

than 95% purity (R_f = 0.15). Alternately, the formed complexes were evaluated on ITLC SG (Gelman Sciences) with 100% MeOH as the solvent. Without any chelating agent present, the reduced pertechnetate (most likely chemical form is TcO_2) moved slightly from the origin (R_f = 0.15). Formation of the ^{99m}Tc-labeled MIBG derivatives gave R_f values around 0.4, in contrast to the R_f value of 1.0 in the absence of the new ligands (data not shown). These results lend support to the formation of the proposed ^{99m}Tc-labeled complexes ([^{99m}Tc]**1**, [^{99m}Tc]**2**, and [^{99m}Tc]**3**). These complexes were stable up to 6 h in phosphate buffer (pH 5.0) when evaluated in the same TLC system at room temperature. It is important to note that the labeling reaction may produce isomers. Attempts were made to separate the ^{99m}Tc-labeled complexes on either TLC or HPLC (normal phase or reversed phase columns) with various solvent combinations but without any success. A more systematic effort is currently being made to identify possible isomers, which may not be detected by the TLC system described above.

Biodistribution Study of ^{99m}Tc-Labeled MIBG Derivatives in Rats. Lipophilicities, as measured by the partition coefficient (PC) between 1-octanol and pH 7.0 phosphate buffer, of these ^{99m}Tc-labeled complexes were comparable to that of [^{125}I]MIBG (PC = 1.1 for [^{125}I]MIBG and 1.99, 6.74, and 4.54 for [^{99m}Tc]**1**, [^{99m}Tc]**2**, and [^{99m}Tc]**3**, respectively). Preliminary biodistribution studies of these ^{99m}Tc-labeled MIBG derivatives showed reasonably good heart uptakes in rats (Table 1). The initial heart uptake of [^{99m}Tc]**3** (heart uptake 0.18 and 0.034% dose/g, at 2 and 30 min, respectively) clearly indicated that this compound is the least favorable one among all three ^{99m}Tc complexes in terms of penetrating the cell membrane to localize in heart tissues. It is likely that, despite the advantage of adding a tetramethyl group on the molecule, which increases the lipophilicity (may facilitate diffusion process), the bulk hindrance may play an even more important role in obstructing the ability of this molecule to cross the membrane. We therefore concentrated on studying compounds [^{99m}Tc]**1** and [^{99m}Tc]**2**, without the tetramethyl substitution groups. It appears that compounds [^{99m}Tc]**1** and [^{99m}Tc]**2** are both interesting, with similar heart uptakes at 2 and 30 min (0.52 and 0.24% dose/g for [^{99m}Tc]**1** and 0.67 and 0.41% dose/g for [^{99m}Tc]**2**, respectively). However, [^{99m}Tc]**2** displayed a higher heart-to-blood ratio (5.85) at 30 min as compared to that of [^{99m}Tc]**1** (0.65). Therefore, compound [^{99m}Tc]**2** was chosen for further studies in rats. It is interesting to note that these three ^{99m}Tc-labeled complexes displayed different uptakes in other organs such as lung and liver. [^{99m}Tc]**1** appeared to be more concentrated in these two organs and was slowly washed out as compared to [^{99m}Tc]**2** and [^{99m}Tc]**3**. In contrast, [^{99m}Tc]**1** displayed lower accumulation in kidney as compared to [^{99m}Tc]**2** and [^{99m}Tc]**3**.

The dual-tracer biodistribution study provides a direct comparison of heart uptake and washout between the ^{99m}Tc-labeled agent and [^{125}I]MIBG. Therefore, a dual-tracer experiment, the biodistribution of [^{99m}Tc]**2** and [^{125}I]MIBG, in Sprague-Dawley rats was carried out (Table 2). In these preliminary experiments using tracer doses, the loading doses for nonradioactive MIBG and also the ligands for making technetium complexes were kept below 10 μg/kg per rat per dose, so the concentrations of carrier or pseudo-carrier will not be sufficient to compete for the norepinephrine uptake sites (*23*). [^{99m}Tc]**2** displayed the desired heart uptake and slow washout (0.45% dose/g at 2 min and 0.21% dose/g at 4 h, respectively; see Table 2). However, in a direct comparison with [^{125}I]MIBG, the heart uptake of the ^{99m}Tc-labeled complex was approximately one-eighth of that for [^{125}I]MIBG (3.35 and 1.71% dose/g at 2 and 4 h, respectively). Unlike [^{125}I]MIBG, the contrast between heart vs blood at 4 h for [^{99m}Tc]**2** appeared to be lower (8.11 and 13.00 for [^{99m}Tc]**2** and [^{125}I]MIBG, respectively). The preliminary data are encouraging in that it is the first time a ^{99m}Tc-labeled MIBG derivative displays a measurable heart uptake. To specifically examine whether the heart uptake is related to norepinephrine distribution, we have performed the dual-tracer experiment in rats either by coinjecting nonradioactive MIBG (1.0 mg/kg) or by pretreating rats with desipramine (DMI, specific norepinephrine transporter blocker) prior to tracer injection. In rats with a coinjected loading dose of MIBG (1.0 mg/kg), the heart uptake of [^{125}I]MIBG was blocked by 47.5% at 2 h, while there was about 32.0% blockade of

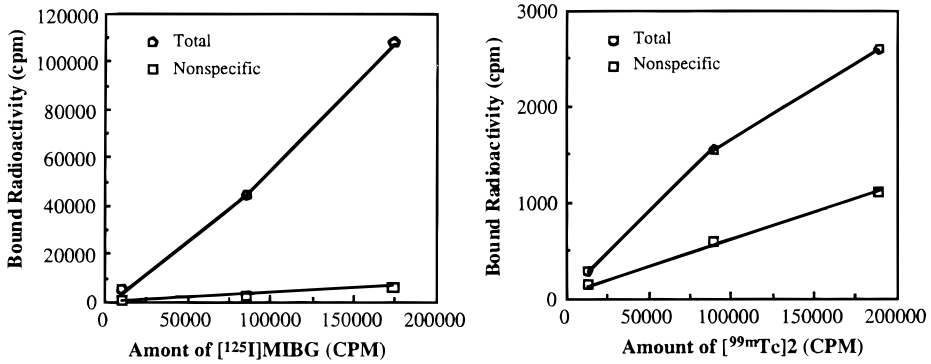

Figure 2. Uptake of [^{99m}Tc]**2** and [^{125}I]MIBG in SK-N-SH human neuroblastoma cells in vitro as a function of tracer concentration (in cpm). The data shown above were from a set of representative experiments.

heart uptake for [^{99m}Tc]**2** at the same time point (Table 3). This result suggests that the heart uptake of [^{99m}Tc]**2** may be related to the MIBG uptake.

To test the hypothesis that the binding of [^{99m}Tc]**2** is specific for norepinephrine transporters, rats were pretreated with desipramine (DMI; 10 mg/kg) ip for 30 min prior to tracer injection, and the same biodistribution was carried out (see Table 4). Even though the specific blockade for [^{99m}Tc]**2** is smaller than that of [^{125}I]MIBG (12% vs 32% reduction, respectively), the result is consistent with the notion that the new ^{99m}Tc-labeled complex, [^{99m}Tc]**2**, displayed specific binding to norepinephrine transporters.

Uptake Studies in Cells Expressing Monoamine Transporters. Cell uptakes of [^{99m}Tc]**2** were evaluated together with [^{125}I]MIBG in either SK-N-SH neuroblastoma cells or LLC-NET and LLC-DAT cells. [^{99m}Tc]**2** uptake by SK-N-SH cells, like [^{125}I]MIBG, increased as a function of input activity (Figure 2). The specific uptake of [^{99m}Tc]**2** was found, however, to be much lower than that of [^{125}I]-MIBG (about one-tenth). A higher nonspecific uptake of [^{99m}Tc]**2** (approximately 40% of total uptake) was observed in contrast to low nonspecific uptake for [^{125}I]-MIBG (10%). Interestingly, a similar specific uptake of [^{99m}Tc]**2** was also observed in LLC-NET cells but not in LLC-DAT cells (data not shown). The data are consistent with the results for [^{125}I]MIBG and related derivatives in the same SK-N-SH cells reported previously (*27*).

DISCUSSION

In the last 10 years, the localization of myocardial adrenergic nerve endings in normal subjects and patients with various cardiac diseases has been reported (*9*, *10*, *12*). MIBG in its ^{123}I-labeled form is the imaging agent of choice, and it is now commercially available in Japan and in Europe, which attests to its importance as a clinical diagnostic tool. MIBG initially was designed as an attempt to attach a more stable iodine at the meta position of benzenylguanidine as an adrenal medulla imaging agent (*1*, *3*). It is generally accepted that the iodine substitution at the paraposition is subjected to rapid in vivo deiodination. However, at the practical level, a comparable ^{99m}Tc-labeled MIBG derivative will provide a much wider clinical acceptance. In developing ^{99m}Tc-

labeled MIBG derivatives, in vivo deiodination is not a subject of concern; therefore, it is likely that the $[Tc^{v}O]^{3+}N_2S_2$ complex can be attached to benzylguanidine and both meta- and para-substituted ^{99m}Tc derivatives may be potentially useful.

We made the initial attempt to replace the iodo group at the meta position of MIBG with $[Tc^{v}O]^{3+}N_2S_2$ complex. Three complexes, [^{99m}Tc]**1**, -**2**, and -**3**, were prepared and tested. By substituting the iodo group with $[Tc^{v}O]^{3+}N_2S_2$ complex, the resulting ^{99m}Tc complexes displayed comparable lipophilicities as the parent MIBG molecule (reflected by comparable partition coefficients). However, the ^{99m}Tc complexes displayed a lower heart uptake in rats. It is possible that these complexes with enlarged molecular size due to $[Tc^{v}O]^{3+}N_2S_2$ complex prohibit their easy passage through the cell membranes.

Dual-tracer distribution studies clearly delineated that the ^{99m}Tc-labeled complex [^{99m}Tc]**2**, similar to [^{125}I]MIBG, was concentrated in the heart. It remained trapped in the heart for up to 4 h postinjection. Despite the lower amount of heart uptake, [^{99m}Tc]**2** closely resembled [^{125}I]-MIBG, i.e., displayed significantly reduced heart uptake when coinjected with nonradioactive MIBG or pretreated with desipramine, a norepinephrine transporter inhibitor. Two components of MIBG uptake have been identified: (a) the specific neuronal uptake-1 pathway mediated by NE transporters, which is blocked by desipramine (*6*); and (b) the nonspecific uptake-2 pathway (possibly by a simple diffusion mechanism). Both pathways are considered to be involved when [^{123}I]MIBG was used for myocardial imaging. It is likely that the heart uptake of ^{99m}Tc-labeled compound, [^{99m}Tc]**2**, derived from [^{125}I]-MIBG, also contained specific and nonspecific pathways and only the specific pathway can be blocked by pretreatment with desipramine (less than 20% for [^{99m}Tc]-**2**). The smaller percentage of the specific uptake-1 pathway observed with [^{99m}Tc]**2** could be likely due to the presence of the mixtures of diastereomers. It is also possible that only a certain structure conformation or configuration of the ^{99m}Tc complex can be preferably recognized by the specific uptake-1 pathway but not the other diastereomers. We attempted to separate different diastereomers using various HPLC columns and solvent combinations but without any success. Future efforts will be directed to the separation of individual isomers of the ^{99m}Tc complexes and the evaluation of the isolated isomer for their in vivo distribution.

The specific activity of radiolabeled MIBG appears to be important for the in vivo localization (*23*). An initial report by Wieland et al. used an exchange reaction for preparation of radiolabeled MIBG (*1*). The exchange reaction requires the use of a higher quantity of nonradioactive MIBG, which leads to a lower specific activity. Biodistribution studies in rats, as predicted, showed a substantially decreased heart uptake when nonradioactive carrier was added. The saturable uptake in the heart is consistent with the proposed mechanism of uptake and retention. Consistent heart uptake was observed in rats only when the loading nonradioactive dose was below 12 μg/kg (*23*). Recent studies showed that the no-carrier-added preparation, using the corresponding 3-trimethylsilylbenzylguanidine as the starting material, clearly suggested that the uptake in the heart of mice is carrier-dependent (*32*, *33*). It was also reported that in humans the heart uptake appeared to be higher when the no-carrier-added preparation of MIBG was used (the carrier-added preparation specific activity was 2 mCi/μmol for 5.4 mCi dose/70 kg man = 10.6 μg/kg). However, the image quality was not significantly improved in subjects receiving the no-carrier-added preparation of MIBG. It was suggested that the in vivo de-iodination might be more significant at a lower "carrier" dose (higher specific activity); therefore, the background level was higher. To avoid carrier effect, the loading dose for nonradioactive MIBG or unchelated technetium ligand used for the study was kept below 10 μg/kg per rat.

The uptake of MIBG into SK-N-SH cells by an active uptake-1 mechanism was reported previously (*2*). The substantially lower accumulation (one-tenth) of the ^{99m}Tc-labeled compound, [^{99m}Tc]**2**, as compared to that of MIBG in SK-N-SH cells, was observed (Figure 2). This lower cellular uptake is consistent with the finding of lower heart uptake in rat biodistribution (the heart uptake was one-eighth of that for MIBG). Further studies will endeavor to determine the specificity of the cellular uptake of these ^{99m}Tc-labeled complexes. It is suggested that an ideal Tc-99m-labeled agent should have the following properties: (i) A heart uptake of at least 0.75% dose/organ at 2 h post iv injection into rats (this is about 50% of that reported for [^{125}I]MIBG) and a heart vs blood ratio (percentage dose:gram ratio) $\geq$10 at 2 h postinjection. (ii) A specific heart uptake selective to norepinephrine storage sites (i.e., the uptake can be significantly reduced after pretreatment of "cold" MIBG or desipramine, DMI). The ^{99m}Tc-labeled analogue of MIBG should have a selective uptake similar to that of [^{125}I]-MIBG (at least 50% of the binding is related to selective norepinephrine distribution).

In conclusion, initial results of a series of novel ^{99m}Tc-labeled MIBG derivatives showed mixed results. At least in principle, it appears feasible to replace the iodine of MIBG with a $[Tc^{v}O]^{3+}N_2S_2$ complex. The heart uptake in rats for this series of compounds is relatively low (about one-eighth of that of MIBG). The other challenge is that the ligand may form several isomers of ^{99m}Tc complexes, resulting in differential biodistribution in vivo We are currently preparing additional compounds to ameliorate the deficiencies mentioned above, and we remain optimistic that agents with desirable properties could be developed in the future for imaging myocardial sympathetic neuronal functions

ACKNOWLEDGMENT

We thank Susan West and Laura Danich for their assistance in preparing the manuscript. This work was supported by the U.S. grants awarded by the U.S. Department of Energy (DOE-ER61657) and the National Institutes of Health (NS 18509).

Synthesis and Characterization of a Photoactivatable Glycoaryldiazirine for Surface Glycoengineering

Yann Chevolot,*,† Odile Bucher,‡ Didier Léonard,† Hans Jörg Mathieu,† and Hans Sigrist‡

Département des Matériaux, LMCH, Ecole Polytechnique Fédérale de Lausanne (EPFL), CH-1015 Lausanne, Switzerland, and CSEM (Centre Suisse d'Electronique et de Microtechnique SA), Jaquet-Droz 1, CH-2007 Neuchâtel, Switzerland . Received May 12, 1998; Revised Manuscript Received October 15, 1998

Biological systems make considerable use of specific molecular interactions. Many biomolecules involved in biorecognition are glycosylated, the carbohydrate moiety playing an essential role. Controlled surface glycoengineering is thus of crucial importance in biosensing, cell guidance, and biomedical applications. This study describes the synthesis of an aryldiazirine-derivatized galactose and the functionalization of surfaces by carbohydrates using photochemical immobilization techniques. A photoactivatable glycosylated reagent was synthesized by addition of thiogalactopyranose to the maleimide group of *N*-[*m*-[3-(trifluoromethyl)diazirin-3-yl]phenyl]-4-maleimidobutyramide (MAD) to give *N*-[*m*-[3-(trifluoromethyl)diazirin-3-yl]phenyl]-4-[3-thio (1-D-galactopyranosyl)succinimidyl]butyramide (MAD-Gal). The structure of the newly synthesized molecule was confirmed by UV spectroscopy, photoactivation, ^{1}H NMR, and ^{13}C NMR. MAD-Gal was immobilized on thin diamond films by photoactivation of the diazirine function (350 nm). Surface modification was investigated by XPS (X-ray photoelectron spectroscopy) and ToF-SIMS (time-of-flight secondary ion mass spectrometry). Imaging ToF-SIMS was applied to detect glycopatterns generated by mask-assisted lithography.

INTRODUCTION

Biological systems make considerable use of surface glycosylation. Indeed glycosylated molecules are involved in, for example, cell recognition (including species discrimination), blood group typing, blood coagulation cascade, and asialoglycoprotein recognition (*1*−*3*). Tissue engineering requires control of specific cell receptor interactions at material surfaces through oriented immobilization of biologically active molecules such as carbohydrates.

Carbohydrate immobilization is reported in the literature for galactose (*4*), melibiose (*5*), mannose (*5, 6*), lactose (*7*), starch (*8*), lactosaminide (*9*), and heparin (*5, 10*−*15*). This has been achieved mainly by thin-film adsorption (weak interactions) or by covalent binding. Adsorption of molecules through weak interactions (ionic in the case of heparin (*13*)) may reverse with time. Covalent immobilization was reported for polymer substrates by divinyl sulfone activation for mannose (*5*), reductive amination for melibiose on polyacrylamide (*5*), the bisorane method for lactose and *N*-acetylglucosamine (*5*), CNBr activation for heparin (*5*), reductive amination of nitrous acid treated heparin (*13*), and copolymerization for galactose (*4)* and lactosaminide (*9*). Galactose-derivatized polymers were used for the study of hepatocyte adhesion (e.g. PVLA,[1] poly(vinylbenzyl-β-D-lactonamide) (*7, 16*)). However, this kind of immobilization is not surface specific, unless coated. Furthermore, it is performed on polymeric materials and is not addressable. Photochemical procedures were applied for heparin (*10*−*12, 14, 15*) and dermatan (*14*) immobilization. Photoactivatable reagents generate very reactive intermediates that allow immobilization of the molecules onto various substrates, as well as addressable immobilization. Erdtmann et al. (*14*) used a nitrene generating reagent to achieve immobilization of heparin and dermatan on cellulose membranes. The membranes were first modified with 4-azido-1-fluoro-2-nitrobenzene. Guire (*10, 11*) immobilized heparin on polyurethane: albumin was first photoimmobilized on polyurethane, and heparin was then linked to albumin using 1-ethyl-3-[3-(dimethylamino)-propyl]carbodiimide chemistry. These strategies combine thermochemistry and photochemistry for surface immobilization. The development of a single step photochemical process would provide a more convenient tool for light addressable surface patterning.

Utilizing diazirine as a photoactivatable function, a reactive carbene is generated by thermochemical or light activation. The carbene may insert into C−H, C−C, C═C, N−H, O−H, and S−H bonds (*17*). Carbene-mediated target molecule binding has been reported for TiO_2/SiO_2 (*18*), silicon (*19, 20*), silicon nitride (*19*−*21*), diamond (*19, 20, 22*) and FEP-OH (hydroxylated fluorinated ethyleneepropylene) (*23*). Shergold et al. (*22*) used diazomethane, and Gao et al. (*18*) used an aryldiazirine-derivatized bovine serum albumin (T-BSA), while other investigations were carried out with the photoreagent MAD (*19*−*21, 23, 24*) (Figure 1). The energy used for photolabel

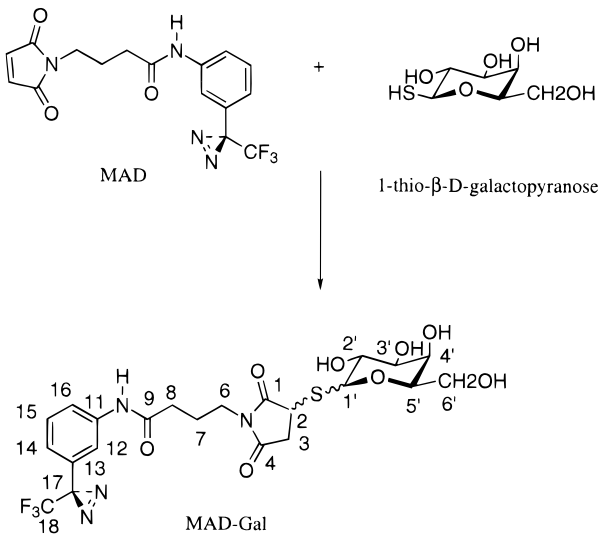

Figure 1. Reaction of 1-thio-β-D-galactopyranose with MAD, yielding *N*-[*m*-[3-(trifluoromethyl)diazirin-3-yl]phenyl]-4-(3-thio-(1-D-galactopyranosyl)succinimidyl)butyramide (MAD-Gal).

activation does not impair biological functions ((*24*) and unpublished results).

This work presents the derivatization of MAD with 1-thio-β-D-galactopyranose to give *N*-[*m*-[3-(trifluoromethyl)diazirin-3-yl]phenyl]-4-[3-thio(1-D-galactopyranosyl)-succinimidyl]butyramide (Figure 1). The parent molecule MAD provides a maleimide function, allowing the reaction with thiogalactopyranose. Both MAD and its derivative MAD-Gal contain the diazirine function that yields carbenes upon light activation at 350 nm. The synthesis, purification, and bulk analysis of MAD-Gal are described.

MAD-Gal was then immobilized on diamond. Due to its physical properties and biocompatibility (*25*−*27*), diamond and diamond-like carbon are widely used in biomedical applications. For example, thin film coatings are applied to stents and carbon is identified as a good substrate for biosensor applications (*28*). Therefore, surface modification of diamond functionalized by biological molecules to obtain specific interaction with analytes or cells is of great interest. Structured surfaces (photopatterning) can be used for probing or controlling interactions of cells or macromolecules at the surfaces of materials (i.e. implants and biosensing). The immobilization of MAD-Gal on diamond is confirmed by surface analysis techniques such as XPS (X-ray photoelectron spectroscopy) and ToF-SIMS (time-of-flight secondary ion mass spectrometry). Imaging ToF−SIMS is applied to detect glycopatterns generated by mask-assisted lithography.

EXPERIMENTAL SECTION

Materials. *Synthesis and Characterization.* MAD was synthesized according to Collioud et al. (*24*). 1-Thio-β-D-galactopyranose was purchased from Aldrich. Uvasol quality solvents (Merck) were used for chemical reactions. The HPLC grade solvents were purchased from Romil (Switzerland). Trifluoroacetic acid (TFA) was purchased from Sigma. MAD-Gal was purified by HPLC using a wide-pore butyl (C4) Bakerbond standard column (dimensions 4.6 × 250 mm; particle size 5 mm; Baker Inc., Phillipsburg, NJ) on a Bio-Cad system. The 1D ^{1}H NMR, 2D ^{1}H/^{1}H COSY NMR, ^{13}C NMR, and DEPT ^{13}C NMR spectra were collected at the University of Bern on a Bruker 500 MHz NMR using D_2O as solvent.

Surface Analysis. XPS analysis was performed under UHV conditions (~10^{-9} Torr) using a PHI 5500 (Perkin-Elmer, USA) system equipped with a hemispherical analyzer and a nonmonochromatized Mg Kα radiation source. The analyzed area was 0.12 mm^2, and spectra were recorded with a takeoff angle of 45° (with respect to the surface). Pass energies used for survey scans and high-resolution elemental scans were 93.5 and 23.5 eV, respectively. No sample charge-up was observed. For each sample, three areas were analyzed. For evaluation of the XPS spectra, the absolute peak areas were calculated using a parabolic interpolation routine, and background subtraction was applied. Resulting values were normalized to the step size to give the intensity in electronvolts per second. Sensitivity factors (S_i) were 0.296, 0.711, 0.477, 1.000, and 0.570 (*29*) for C 1s, O 1s, N 1s, F 1s, and S 2p, respectively. Atomic percentages of selected elements (x) were calculated using the above sensitivity factors and the equation: $X\% = (I_x/S_x)/(\sum I_i/S_i)$. Diamond chemical shift was chosen as the reference at 284.2 eV (*30*). It was confirmed with gold as internal standard.

ToF-SIMS was performed on commercial equipment from PHI-EVANS & Associates (described in (*31, 32*)) equipped with a pulsed FEI Ga^+ ion gun operated at 15 kV for high mass resolution. The sample surface was biased ±3 kV with respect to the grounded extraction electrode for positive/negative mode SIMS, respectively. The 800−850 pA dc ion beam current was pulsed at a 5 kHz repetition rate (pulse width of about 8 ns, as measured with the unbunched beam). The analyzed area was estimated to be a square of 84 μm × 84 μm. Spectra were acquired in the high mass resolution mode (bunched beam). The total ion dose for a typical spectrum was on the order of 9 × 10^{11} ions/cm^2, which is within the so-called "static" conditions (*33*). The mass resolution obtained for $Si^{+/-}$ on a Si wafer was $m/\Delta m$ > 3600 in the positive mode and >3000 in the negative mode. Normalized values were calculated by dividing the absolute intensity of secondary ions by the corrected total intensity (=total intensity from which intensities of H^{+-} of all inorganic peaks and of the main peaks of ubiquitous contaminants were subtracted). Images were also collected in the high mass resolution mode. The high mass resolution conditions were similar to those described above except for analyzed area (180 μm × 180 μm) and analysis time (20 min), but the ion dose was similar (8 × 10^{11} ions/cm^2).

Methods. *Synthesis of N-[m-[3-(Trifluoromethyl)diazirin-3-yl]phenyl]-4-[3-thio(1-D-galactopyranosyl)succinimidyl]butyramide.* 1-Thio-β-D-galactopyranose (1.5 mg) was dissolved in 150 μL of buffer A (20 mM citric acid, 35 mM Na_2HPO_4, 108 mM NaCl, 1 mM ethylenediaminetetraacetic acid (EDTA)) and 150 μL of ethanol. MAD (3.3 mg) was dissolved in 150 μL of ethanol and an additional 150 μL of buffer A. Both solutions were mixed. The mixture was stirred and allowed to react at room temperature for 90 min, to give MAD-Gal. The product was purified by HPLC. The HPLC flow rate was 2 mL/min. For gradient elution (0 min, 100% A; 5 min, 100% A; 20 min, 70% A; 30 min, 0% A; 40 min, 0% A), solvent B was added to solvent A (solvent A, 0.1% TFA in water; solvent B, 0.1% TFA in acetonitrile/water (4:1 by volume)). Detection was performed at 254 nm and fractions of the eluant were collected. ^{13}C NMR (D_2O chemical shift (δ) in parts per million): 179.14, 178.40, 177.99, 177.86, 173.30, 137.79, 129.53, 129.38, 122.46, 121.84, 118.32, 84.42, 84.27, 78.99, 78.91, 73.84, 73.66, 69.73, 69.68, 68.58, 68.49, 60.80, 60.69, 39.61, 38.66, 38.46, 37.71, 35.83, 33.57, 22.68, 22.57.

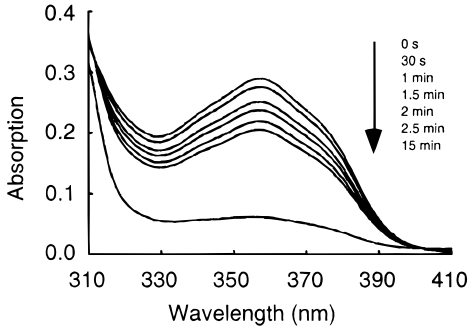

Figure 2. UV absorption spectra of MAD-Gal before and after irradiation for differing lengths of irradiation time.

Immobilization of MAD-Gal on Diamond. Hot filament CVD deposited thin-film diamond (*34*) was used as the substrate to exploit MAD-Gal immobilization. Pristine samples (5×5 mm^2) were washed (5 min ultrasonic bath in hexane and in ethanol) and dried for 2 h at room temperature under vacuum (~6 mbar). Then, MAD-Gal (10 μL, 0.25 mM in ethanol) was deposited as a droplet released from a syringe. The samples were dried for 2 h at room temperature under vacuum (30−40 mbar). They were irradiated for 20 min with the Stratalinker light source (0.95 mW/cm^2) and washed by ultrasound treatment twice in ethanol (5 min) and twice in hexane (5 min). The investigated samples are referenced as follows: **A** (washed surface), **B** (MAD-Gal deposited, no illumination performed before final washing), and **C** (MAD-Gal deposited, illumination and final washing). Patterning was performed with a mask consisting of 40 μm × 40 μm square windows separated by 40 μm bridges. MAD-Gal was deposited on the diamond surface before mask-assisted illumination and final washing.

RESULTS AND DISCUSSION

Chemical Characterization of MAD-Gal. The reaction between 1-thio-β-D-galactopyranose and MAD, yielding MAD-Gal, is displayed in Figure 1. HPLC analysis of the educts revealed a retention time of 37.41 min for MAD and approximately 15 min for 1-thio-β-D-galactopyranose, which was detected with 5,5′-dithiobis(2-nitrobenzoïc acid) (*35*). HPLC separation of the reaction mixture revealed a major peak with a retention time of 33.68 ± 0.07 min (88.2% of the total area). Minor byproducts with retention times of 33.06 ± 0.02 and 35.61 ± 0.02 min (0.6% and 11.2% of the total area, respectively), were observed. We suggest that they are products of the reaction of molecular oxygen with the thiols. During concentration of the eluant, thermal degradation may occur. Indeed, a peak with retention time of 35.99 min (10% area) was observed upon rechromatography of concentrated MAD-Gal. To avoid any thermal or light degradation of MAD-Gal, it was stored at −20 °C in the dark. MAD has shown to be stable over a period of at least 8 months under such conditions (*24*). In the immobilization experiments, MAD-Gal was dissolved in ethanol. Exposure to artificial light, unfiltered sunlight, or heat (over 30 °C) was avoided. These solutions were also stored at −20 °C.

The UV absorption spectrum of the product corresponding to the peak with the retention time of 33.68 min (major peak) shows an absorption band at 357 nm, characteristic of the diazirine function (*23*). Figure 2 indicates that the absorbance diminished with increasing light exposure at 357 nm, demonstrating exposure time dependent photoactivation and, thus, conversion of the diazirines into carbenes.

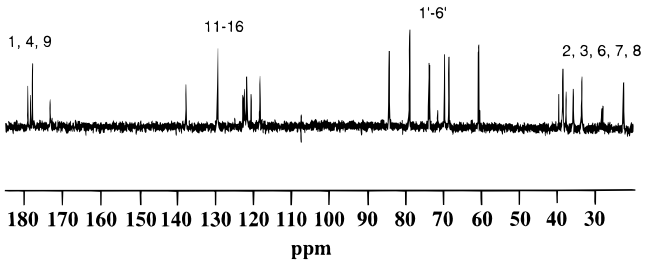

Figure 3. ^{13}C NMR overview spectrum of MAD-Gal.

In Figure 1, carbon and hydrogen atoms are numbered to facilitate the discussion of the NMR spectra. The ^{13}C NMR spectrum showed four separated areas corresponding to the ^{13}C nuclei of the amide function, the aromatic ring, the carbohydrate moiety, and the alkyl chain, respectively (Figure 3). The split signals of carbons 1, 2, 3, 4, 6, and 7 and of the carbohydrate moiety indicate the occurrence of two stereoisomers detected in similar proportions. Indeed, the sulfhydryl groups can attack the maleimide group above or below the plane of the ring, leading to two configurations of carbon 2. Consequently, the nuclei of both compounds in the vicinity of carbon 2 can appear at different chemical shifts. The DEPT (distortionless enhancement through polarization transfer) sequence analysis demonstrated that the peaks of the alkyl chain (22.57, 22.68, and 33.57 ppm) and C6′ (60.69 and 60.37 ppm, corresponding to the two isomers) correspond to secondary carbons. Other peaks appearing at 28.32, 27.99, 60.37, 71.52, 120.68, and 122.86 ppm were attributed to undefined contaminations.

The ^{1}H NMR spectrum of the purified product confirmed the presence of aromatic (6.5−7.5 ppm), alkyl (3.2−1.6 ppm), and carbohydrate protons (4.8−3.4 ppm) (Figure 4a). The ^{1}H/^{1}H COSY-NMR spectrum of MAD-Gal is displayed in Figure 4b. The two-proton signal at 1.8 ppm was connected with the peaks at 2.3 and 3.4 ppm. It was attributed to proton 7. The peak at 2.3 ppm was also a two-proton signal. Peaks at 2.3 and 3.4 ppm were attributed to proton 8 and proton 6, respectively. The two peaks at 4.1 and 4.2 ppm corresponded to $^1/_2$ of a proton signal each. The former was connected to the signal at 2.7 and 3.14 ppm, whereas the latter was connected to the peaks appearing at 2.8 and 3.14 ppm. According to the integration, peaks at 2.7 and 2.8 ppm represented the signal of a $^1/_2$ proton each. The wide peak at 3.14 ppm was a one-proton signal. Thus, the peaks at 4.1 and 4.2 ppm corresponded to H-2 in two configurations. The peaks at 2.7 and 2.8 ppm corresponded to H-3a (one for each stereoisomer), and the peak at 3.14 ppm consisted of two peaks (shown by COSY) and corresponded to H-3b. According to the integration, the peak at 4.4 ppm was also $^1/_2$ of a proton signal. The chemical shift corresponded to H-1′ of β-thiogalactopyranose. H-1′ for the second stereoisomer (also β) was at 4.7 ppm, within the water signal. Peaks between 3.9 and 3.4 ppm corresponded to protons 2′, 3′, 4′, and 5′.

In summary, the results confirmed the structure of MAD-Gal. NMR analyses sustain that the final product is a mixture of two stereoisomers detected approximately in the same quantities.

Surface Photobonding and Surface Analysis. MAD-Gal was deposited on washed diamond surfaces. The solvent was removed under vacuum to avoid the reaction of carbenes with solvent molecules. Next, the diazirines were activated by light (350 nm) and modified surfaces were extensively washed. It was expected that

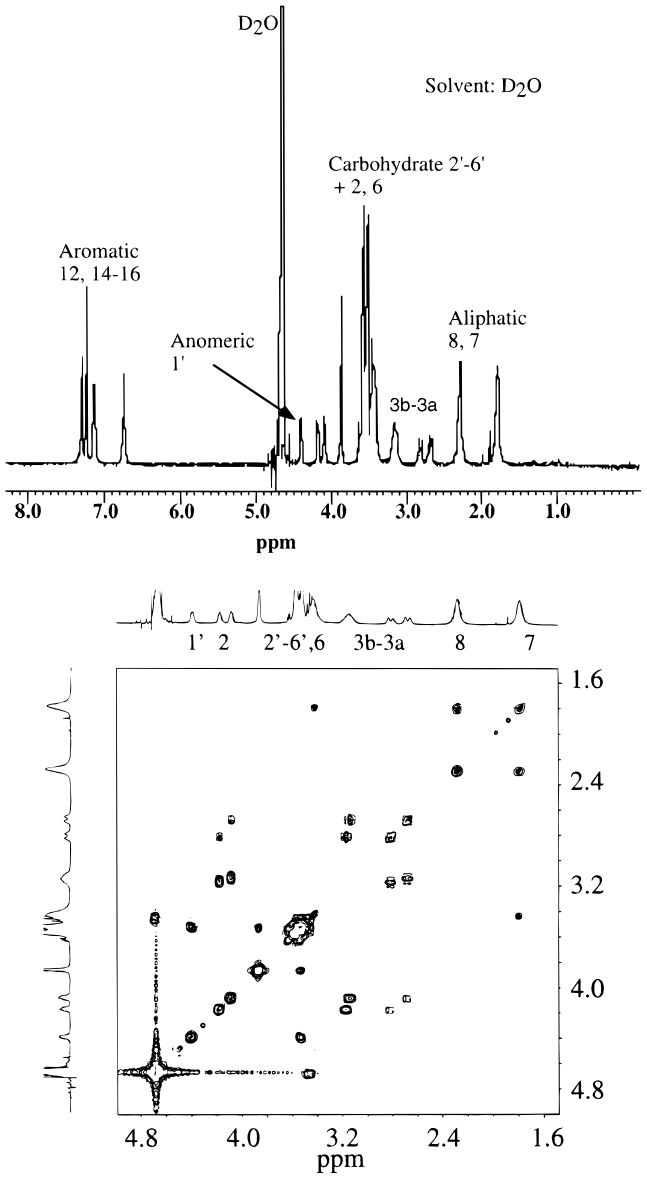

Figure 4. (a, top) ^{1}H NMR spectrum of MAD-Gal. (b, bottom) ^{1}H/^{1}H NMR COSY NMR spectrum of MAD-Gal.

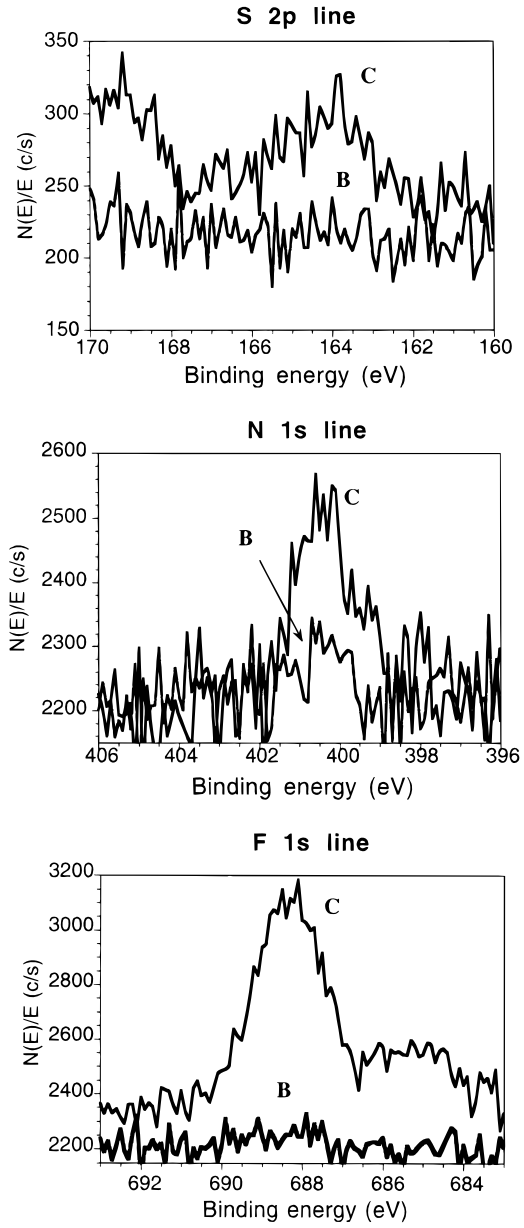

Figure 5. (a, top) S 2p XPS spectra of samples **B** and **C** (**B**, MAD-Gal on diamond, not irradiated, washed; **C**, MAD-Gal on diamond, irradiated and washed). The chemical shift corresponds to a C−S bond. S is only detected on sample **C**. (b, middle) N 1s XPS spectra of samples **B** and **C**. Nitrogen is only present on sample **C** (**B**, MAD-Gal on diamond, not irradiated, washed; **C**, MAD-Gal on diamond, irradiated and washed). The chemical shift corresponds to an amide. (c, bottom) F 1s XPS spectra of samples **B** and **C** (**B**, MAD-Gal on diamond, not irradiated, washed; **C**, MAD-Gal on diamond, irradiated and washed). Fluorine is only present on sample **C**. The chemical shift corresponds to a C−F bond. F is only detected on sample **C**.

this final washing step removed most of the physically adsorbed but not the covalently bound MAD-Gal molecules.

XPS wide scans of samples **A** and **B** exhibited intense photoelectron peaks at about 285 and 532 eV corresponding to the C 1s and O 1s lines. For sample **B**, on one area only, very low intensity peaks were observed around 400 and 688 eV corresponding to the N 1s and F 1s lines, respectively. According to the structure of the molecule (Figure 1), oxygen, fluorine, nitrogen, and sulfur were expected to be detected on diamond surfaces with grafted MAD-Gal. For sample **C**, XPS wide scans exhibited intense peaks corresponding to C 1s (285 eV), O 1s (532 eV), and F 1s (688 eV). Lower intensity peaks were observed at 165 and 400 eV corresponding to S 2p and N 1s, respectively. The binding energy of the S 2p line confirmed a C−S bond (Figure 5a) (*36*, *37*), and that of the N1s line corresponded to the chemical shift of an amide function (Figure 5b) (*38*). The F 1s chemical shift confirmed the presence of C−F (Figure 5c) (*36*, *38*). Results shown in parts a and b of Figure 5 indicated that XPS analysis of N and S on sample **C** was close to the instrumental detection limit (10^{12}−10^{13} molecules/cm^2).

The elemental compositions of samples **A**, **B**, and **C** are displayed in Table 1. For sample **A**, oxygen has an atomic percentage of 6%. Its presence at diamond surfaces can be explained by the fact that, during the hot filament CVD process, oxygen was incorporated to give a very complex surface with various functionalities (*39*, *40*): lactone, ether, carboxylic acid, and alcohol. The presence of oxygen on diamond surfaces was consistent with the various contributions in the C 1s envelope (data not shown) and the full width half maximum (fwhm) of diamond contribution to C 1s (*39*). Except on one area, the sample **B** spectrum did not exhibit fluorine or

Table 1. XPS C, O, N, F, and S Atomic Percentages for Samples A, B, and C[a]

	A	B	C
C	93.9 ± 0.6	92.3 ± 1.39	88.7 ± 1.7
O	6.0 ± 0.6	7.5 ± 1.05	9.8 ± 1.61
N	0 ± 0	0.42*	0.6 ± 0.07

O^-	200 ± 7.2	162 ± 2.1	184.9 ± 0.7
F^-	29 ± 2.53	6 ± 0.33	197 ± 3.1
CF_3^-	7 ± 0.75	0.7 ± 0.02	8.59 ± 0.29
S^-	1.87 ± 0.18	0.9 ± 0.05	10.3 ± 0.05
SO_4^-	0.78 ± 0.20	1.34 ± 0.07	1.47 ± 0.02
$C_4H_4NO_2^-$	0.07 ± 0.01	0.08 ± 0.01	1.05 ± 0.06
$C_5H_5O_2S^-$	0.11 ± 0.01	0.03 ± 0.00	0.15 ± 0.02

[a] The investigated samples are denoted as follows: **A**, washed surface; **B**, MAD-Gal deposited, no illumination performed before final washing; **C**, MAD-Gal deposited, Illumination and final washing. [b] Negative mode ToF-SIMS corrected total intensity ($\times 10^4$).

nitrogen, illustrating the efficiency of the washing step to remove physisorbed molecules. O and C atomic percentages were intermediate between those of samples **C** and **A**. The elemental composition of sample **C** was characterized by significant amounts of fluorine and nitrogen at the surface. Sulfur was also detected, but at a very low intensity, and the oxygen content was higher for sample **C** than for sample **B**. XPS data revealed an F/N ratio of 1.3, which was close to the theoretical value (1.5). However, the F/S ratio was higher than 3, indicating a possible partial loss of sulfur during XPS analysis.

Table 2 displays the corrected total intensity ($\times 10^4$, denoted "cor tot.") of negative mode ToF-SIMS spectra and normalized ToF-SIMS intensities (‰) of selected peaks for samples **A**, **B**, and **C**. F^-, CNO^- (an amide related ion), and CF_3^- fragments were related to the MAD moiety of the molecule (*20*). $C_4H_4O_2N^-$ (*20*) was identified as part of the succinimidyl group. S^- (not correlated to SO_4^-) and $C_5H_5O_2S^-$ were specifically related to the carbohydrate moiety (*41*, *42*). It should be noted that the mass resolution allowed the separation between S^- and O_2^- and between the peak at 129.01 amu ($C_5H_5O_2S^-$) and those appearing at 129.06 and 129.13 amu (not illustrated). Due to its high sensitivity, ToF-SIMS analysis revealed F where XPS analysis failed (samples **A** and **B**). Moreover, S was easily detected compared to XPS for sample **C**. All the characteristic ions of MAD-Gal showed lower intensities on sample **B** than on sample **C**. The results further confirmed that the washing procedure removed most of the physisorbed molecules.

The oxygen XPS signal and oxygen-containing ToF-SIMS ions were expected characteristic fragments of MAD-Gal. The data presented here (Tables 1 and 2) are of low information value, due to signals contributed by the substrate.

MAD-Gal surface patterning was performed using contact mode, mask-assisted lithography. Figure 6 presents the image of F^- ions and documents addressable immobilization of the photoreagent MAD-Gal. The figure shows three regions-of-interest (ROI) areas from which spectra were collected. Table 3 displays the normalized ToF-SIMS intensities (‰) of MAD-Gal characteristic ions for the three ROIs. ROIs 1 and 3 were light-exposed, whereas ROI 2 was a masked region. Areas where characteristic signatures of MAD-Gal were observed corresponded to the light-exposed domains. However, it was noted that the nonexposed ROI 2 exhibited detectable amounts of MAD-Gal fragments (higher than those observed on sample **B**), indicating the limitations of contact mode, mask-assisted patterning.

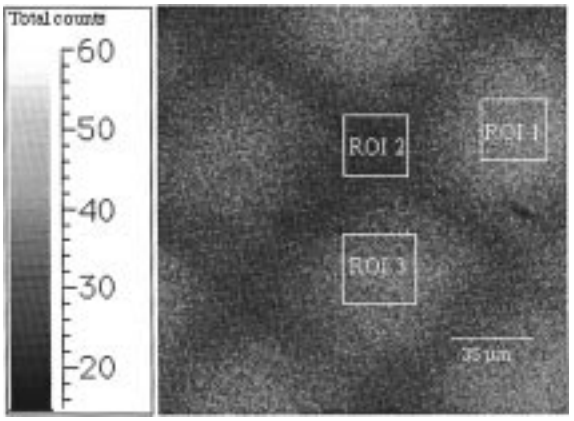

Figure 6. Negative mode ToF-SIMS image of F^- after mask-assisted patterning of MAD-Gal on thin film diamond. The pattern was generated with a mask consisting of 40 μm × 40 μm square windows separated by 40 μm bridges. The mask was placed on a MAD-Gal-coated diamond surface before irradiation. Negative ToF-SIMS images were recorded after irradiation and final washing of the surfaces.

Table 3. Negative Mode Normalized ToF-SIMS Intensities (‰) for the Spectra Corresponding to the Three Regions of Interest (ROIs) Displayed in Figure 6[a]

	ROI 1	ROI 2	ROI 3
F^-	141.3	97.7	145.3
CF_3^-	6.6	4.3	5.7
S^-	7.4	3.6	6.2
SO_4^-	1.0	1.1	0.8
CNO^-	12.7	8.8	12.0
$C_4H_4O_2N^-$	0.3	0.2	0.3
$C_5H_5O_2S^-$	0.1	0.01	0.1

[a] ROIs 1 and 3 were light-exposed, whereas ROI 2 was a masked region.

DISCUSSION

Great efforts are made in biomaterial science to generate bioactive surfaces with grafted oriented biomolecules. Molecular orientation is needed for biological interactions with modified surfaces. Carbohydrates are known to be involved in many biological phenomena. Linear and complex carbohydrate structures are present at biosurfaces in specific orientations and in defined structural (3-D) arrangements. In this study, oriented surface immobilization is implicated in the asymmetric molecular structure of MAD-Gal.

Maleimido groups are known to react readily with accessible sulfhydryl groups (*24*). Chemical and structural analyses have demonstrated that the addition of 1-thio-β-D-galactopyranose to MAD occurred at the maleimido group. The reaction produced two stereoisomeric glycosylated photoreagents. No attempts have been made to separate the isomers.

Diamond surfaces possess various types of surface functions (*39*) which figure as candidates for carbene

insertion. Surface analysis techniques provided strong evidence that MAD-Gal was successfully grafted to the diamond surface. The surface analyses and related phenomena are described in detail in (*42*). They also indicated that the applied wash procedure removed most but not all of the physically adsorbed molecules. A total of 10^{-8} mol/cm^2 (6.02×10^{15} molecules/cm^2) of MAD-Gal was deposited at the sample surfaces. The XPS signal of the molecule after photoimmobilization and washing was close to the detection limit of this technique. Therefore, the surface density of the molecule was estimated to be $10^{12}-10^{13}$ molecules/cm^2 (*20*). The efficiency of the grafting is estimated to be between 1% and 1‰. Optimization of the grafting will be considered. However, for future purposes (i.e. biological applications), such densities should not be a problem. Biomolecules can exhibit biological activity at very low concentration, as demonstrated by Massia et al. (*43*) in the case of surface-grafted peptides.

ToF-SIMS imaging allowed visualization of topically addressed MAD-Gal. However, the patterns obtained were not as distinct as expected. A possible explanation is the position of the mask during the illumination, which was positioned above but not close enough to the surface, and the diffraction of light under the mask.

In summary, the new photoreagent MAD-Gal was successfully synthesized as demonstrated by ^{13}C NMR, ^{1}H NMR, and UV absorption spectroscopy. Photoimmobilization of MAD-Gal on diamond surfaces via diazirine insertion was illustrated by XPS and ToF-SIMS surface analyses. The feasibility of surface patterning was demonstrated, although the lateral resolution was limited.

Biological tests are in progress to identify the remaining biological activity of photoimmobilized MAD-Gal molecules. Primary results with rat hepatocyte cultures are encouraging. However, the implicated surface orientation of MAD-Gal awaits further experimental documentation with biological systems.

Structure-Binding Relationships for the Interaction between a Vancomycin Monoclonal Antibody Fab Fragment and a Library of Vancomycin Analogues and Tracers

Maciej Adamczyk,* Jonathan Grote, Jeffrey A. Moore, Sushil D. Rege, and Zhiguang Yu

Diagnostics Division Organic Chemistry (9-NM), Abbott Laboratories, Building AP 20, 100 Abbott Park Road, Abbott Park, Illinois, 60064. Received November 6, 1998; Revised Manuscript Received December 23, 1998

A series of vancomycin analogues and tracers were synthesized, and their binding interactions with an anti-vancomycin Fab fragment were evaluated under mass transport limiting conditions using surface plasmon resonance detection. Differences observed in binding interactions were utilized to define the vancomycin structural elements critical for antibody recognition. Major structural regions of vancomycin shown to play an important role in anti-vancomycin Fab fragment recognition include two sugar moieties and one chlorinated phenyl ring. The *N*-methylleucyl residue, the carboxy terminal residue, and residues in the peptide-binding region of vancomycin have minimal impact on the anti-vancomycin Fab fragment/vancomycin binding interaction. The selection of an antibody with such binding properties plays a critical role in the development of a vancomycin immunoassay that employs stable calibrators and controls.

INTRODUCTION

The definition of a well-characterized immunoreagent has been expanded in recent years (*1, 2*). Haptens and tracers have been characterized traditionally for their identity and purity. Advances in electrophoresis, HPLC, and ESI and MALDI MS methods have permitted similar characterization of antibodies and immunoconjugates (*1, 3, 4*). Although important, such characterization is less critical to assay development than the structure−function relationships of the immunoreagents. This includes a more complete understanding of the molecular features critical for specific recognition between ligands (haptens and tracers) and antibodies. These molecular features can be identified through a rigorous evaluation of the binding interactions between antibodies and structurally modified haptens and tracers.

A method utilizing automated surface plasmon resonance technology has recently been demonstrated to be useful for studying the binding interactions between a monoclonal antibody Fab fragment and structurally modified ligands (*5, 6*). This method involves an immobilized ligand and a soluble ligand free in solution competing for binding sites on a single antibody Fab fragment. If high-density immobilized ligand surfaces are employed and the association rate between the antibody Fab fragment and the immobilized ligand is $\geq 1 \times 10^5$ M^{-1} s^{-1}, the observed binding will be limited by mass transfer (*7, 8*). Under such conditions, initial binding rates are directly proportional to the amount of free antibody Fab fragment (not bound to soluble ligand) in solution and independent of the interaction kinetics or analyte-ligand affinity. Measuring concentrations of free antibody Fab fragment in equilibrium solutions with different concentrations of structurally modified ligand allows one to determine binding affinities and relate these results to structural features critical for recognition.

Vancomycin (**1**, Figure 1) is the antibiotic drug of choice for the treatment of Gram-positive infections caused by methicillin resistant *Staphylococcus aureus* (*9*). It is also the treatment of choice in bacterial infections in patients allergic to β-lactam antibiotics (*10*). For the safe and effective use of this drug, quantitation of its levels in patient blood is required to maintain therapeutic levels (*11, 12*). Immunoassay techniques requiring structurally modified vancomycin tracers are frequently employed for this purpose. However, the antibiotic is rich in functionality from which to covalently attach signal-generating moieties. Here, we describe the preparation of several vancomycin analogues and tracers and the binding studies carried out on an automated BIAcore 2000 designed to evaluate the structural regions of vancomycin critical to recognition by an anti-vancomycin Fab fragment and those vancomycin regions which can be structurally modified with minimal impact to the binding interaction.

MATERIALS AND METHODS

Protein A Affinity-Pak columns and ImmunoPure Fab preparation kits, BupH phosphate-buffered saline packs, Slide-A-Lyzer 10K MWCO dialysis cassettes, the Micro BCA protein assay kit, and the Immunopure Mouse IgG $F(ab')_2$ fragment were obtained from Pierce (Rockford, IL). Microconcentrators were obtained from Millipore Corp. (Bedford, MA). Vancomycin (**1**) was obtained from the Chemical and Agricultural Products Division, Abbott Laboratories (Abbott Park, IL). Anti-vancomycin mAb was obtained from the Abbott cell culture facility (Abbott Park, IL) (*13*). (N^{α},N^{ϵ}-diacetyl)KdAdA tripeptide was obtained from Peninsula Laboratories (Belmont, CA). Aminocaproate-derivatized (N^{ϵ}-acetyl)KdAdA tripeptide was obtained from Research Genetics (Huntsville, Al). Biotin active ester (**2**) was prepared by the method of Wilchek (*14*). 6-Carboxyfluorescein active ester (**3**) was prepared by the method of Adamczyk et al. (*15*). Acridinium chemiluminescent label (**4**) was prepared following the general procedure of Mattingly et al. (*16, 17*).

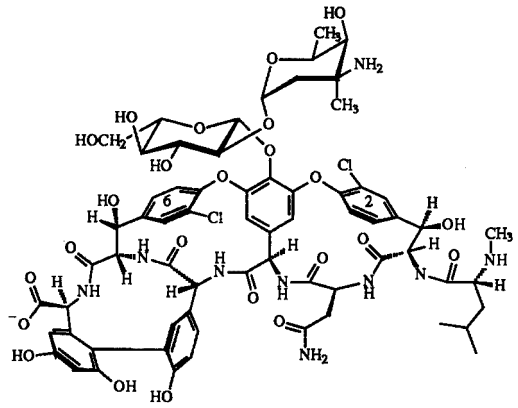

Figure 1. Structure of vancomycin.

Desvancosaminylvancomycin (**5**), aglucovancomycin (**6**), and *N*-acetylvancosaminylvancomycin (**7**) were prepared by the method of Kannan et al. (*18*). Ring-2 dechlorovancomycin (**8**) was prepared by the method of Harris et al. (*19*). Crystalline degradation product (CDP, **10**) was prepared by the method of Marshall (*20*). Ring-2 dechloroCDP (**12**) was prepared by the method of Harris et al. (*19*). All other reagents used in synthesis were obtained from Aldrich Chemical Co. (Milwaukee, WI) and utilized without further purification. Synthesized compounds were purified by HPLC [Waters (Millford, MA) Delta Prep 3000 Preparative Chromatography system equipped with a Lambda-Max 481 UV detector, a model 740 data module, and a 40 × 100 mm μBondapak C18 column]. Analytical HPLC was performed with the same system using an 8 × 100 mm μBondapak C18 column. HPLC columns were eluted with a linear gradient of 5 to 50% CH_3CN in 50 mM ammonium formate (solvent A) or isocratically in aqueous CH_3CN containing trifluoroacetic acid (v:v:v, CH_3CN/H_2O/TFA; solvent B) as noted. Elution profiles were recorded at 254 nm. Electrospray ionization mass spectrometry (ESI/MS) was carried out on a Perkin-Elmer (Norwalk, CT) Sciex API 100 Benchtop system employing the Turbo IonSpray ion source. Protein was analyzed by SDS−PAGE on a Bio-Rad Minigel system (Hercules, CA) utilizing 12.5% polyacrylamide gels (7 cm × 10 cm × 1 mm), followed by staining with Coomassie Blue. Surface plasmon resonance measurements were carried out on a BIAcore 2000 (BIAcore, Inc., Piscataway, NJ) automated system using CM-5 four-channel sensor chips. Reagents for the BIAcore instrument consisted of HBS buffer [10 mM Hepes (pH 7.4), 150 mM NaCl, 3.4 mM EDTA, and 0.05% surfactant P-20], a coupling kit containing *N*-hydroxysuccinimide (NHS), *N*-ethyl-*N*-(3-diethylaminopropyl)carbodiimide (EDAC), and 1 M ethanolamine hydrochloride (pH 8.5), all from BIAcore, Inc.

Preparation of AglucoCDP (11). Crystalline degradation product (CDP, **10**) (*20*) (100 mg, 0.069 mmol) in 1 N HCl (3 mL) was heated on a water bath for 1 h. The mixture was cooled to ambient temperature, and the solid was filtered off. The crude product was dissolved in saturated $NaHCO_3$, purified by preparative HPLC (solvent A over 20 min; flow rate, 45 mL/min), and lyophilized (45 mg, 57%). Analytical HPLC (solvent A over 20 min; flow rate, 2 mL/min): retention time, 9.4 min, 99%. ESI MS *m/z*: 1145 (MH^+).

General Procedure for Preparation of *N*-Vancosaminyl-Derived Vancomycin Tracers. To a solution of vancomycin (**1**) (482 mg, 0.33 mmol) in dry DMF (6 mL) were added active ester **2**, **3**, or **4** (0.36 mmol) and triethylamine (0.91 mL, 6.6 mmol). After stirring for 24 h at ambient temperature under N_2, the crude reaction mixtures were purified by preparative HPLC and lyophilized.

Compound **13** was obtained from **1** and biotin-active ester (450 mg, 81%). Preparative HPLC: solvent A over 20 min; flow rate, 45 mL/min. Analytical HPLC (solvent A over 15 min; flow rate, 2 mL/min): retention time, 9.4 min, 99%. ESI/MS *m/z*: 1674 (MH^+), 1305 (MH^+ − vancosaminylbiotin), 1143 (MH^+ − disaccharide − biotin), 554 (disaccharide + biotin + Na^+).

Compound **14** was obtained from **1** and 6-carboxyfluorescein-active ester (20 mg, 11%). Preparative HPLC: solvent B, 30:70:0.1; flow rate, 45 mL/min. Analytical HPLC (solvent B, 30:70:0.1; flow rate, 2 mL/min): retention time, 4.0 min, 99%. ESI/MS *m/z*: 1809 (MH^+), 904 (MH_2^{2+}), 1305 (MH^+ − vancosaminylfluorescein), 1143 (MH^+ − disaccharide − fluorescein), 665 (disaccharide + fluorescein).

Compound **15** was obtained from **1** and acridinium-active ester (409 mg, 70%). Preparative HPLC: solvent A over 20 min; flow rate, 45 mL/min. Analytical HPLC (solvent A over 20 min; flow rate, 2 mL/min): retention time, 10.4 min, 99%. ESI/MS *m/z*: 2016 (MH^+), 1305 (MH^+ − vancosaminylacridinium), 1143 (MH^+ − disaccharide − acridinium), 710 (disaccharide + acridinium).

General Procedure for Preparation of *N*-Methylleucyl-Derived Vancomycin Tracers. To a solution of vancomycin (**1**) (296 mg, 0.20 mmol) in DMSO (10 mL) were added biotin or 10-(3-sulfopropyl)-*N*-tosyl-*N*-(3-carboxypropyl)acridinium-9-carboxamide (0.20 mmol) and *N*-hydroxybenztriazole (33 mg, 0.24 mmol). Dicyclohexylcarbodiimide (206 mg, 1.0 mmol) was added, and the mixtures were stirred for 72 h at ambient temperature under N_2. The crude reaction mixtures were purified by preparative HPLC and lyophilized.

Compound **16** was obtained from **1** and biotin (136 mg, 40%). Preparative HPLC: solvent A over 20 min; flow rate, 45 mL/min. Analytical HPLC (solvent A over 20 min; flow rate, 2 mL/min): retention time, 9.4 min, 99%. ESI/MS *m/z*: 1675 (MH^+), 1531 (MH^+ − vancosamine), 1372 (MH^+ − disaccharide), 838 (MH_2^{2+}).

Compound **17** was obtained from **1** and 10-(3-sulfopropyl)-*N*-tosyl-*N*-(3-carboxypropyl)acridinium-9-carboxamide (190 mg, 35%). Preparative HPLC: solvent A over 20 min; flow rate, 45 mL/min. Analytical HPLC (solvent A over 15 min; flow rate, 2 mL/min): retention time, 12.1 min, 99%. ESI/MS *m/z*: 2016 (MH^+), 1874 (MH^+ − vancosamine), 1711 (MH^+ − disaccharide), 694 (*N*-methylleucylacridinium).

General Procedure for Preparation of Carboxyl-Derived Vancomycin Tracers. (A) Compound **9** was prepared according to the method of Sundram and Griffin (*21*). Briefly, to a solution of vancomycin (**1**) (500 mg, 0.35 mmol) and hexanediamine hydrochloride (196 mg, 1.04 mmol) in anhydrous DMSO/DMF (v:v, 1:1, 8 mL) at 0 °C were added HBTU (262 mg, 0.69 mmol) and diisopropylethylamine (480 μL, 2.76 mmol). After stirring for 72 h at ambient temperature, the crude reaction mixture was purified by preparative HPLC (solvent B, 17:83:0.0; flow rate, 40 mL/min) and lyophilized (228 mg, 43%). Analytical HPLC (solvent B, 17:83:0.0; flow rate, 2 mL/min): retention time, 7.9 min, 99%. ESI/MS *m/z*: 1548 (MH^+). (B) To a solution of compound **9** (19 mg, 12 μmol) in dry DMF (0.5 mL) were added active ester **2**, **3**, or **4** (12 μmol) and triethylamine (2 μL, 12 μmol). After stirring for 24 h at ambient temperature under N_2, the crude reaction mixtures were purified by preparative HPLC and lyophilized.

Compound **18** was obtained from **9** and biotin-active ester (9 mg, 31% based on recovered starting material). Preparative HPLC: solvent B, 20:80:0.05; flow rate, 40 mL/min). Analytical HPLC (solvent B, 20:80:0.05; flow rate, 2 mL/min): retention time, 6.1 min, 99%. ESI/MS *m/z*: 1797 ($M + Na^+$), 1775 (MH^+), 1632 (MH^+ − vancosamine), 1469 (MH^+ − disaccharide).

Compound **19** was obtained from **9** and 6-carboxyfluorescein-active ester (4 mg, 26% based on recovered starting material). Preparative HPLC: solvent B, 27:73:0.05; flow rate, 40 mL/min. Analytical HPLC (solvent B, 27:73:0.05; flow rate, 2 mL/min): retention time, 7.5 min, 99%. ESI/MS *m/z*: 1929 ($M + Na^+$), 1907 (MH^+), 1764 (MH^+ − vancosamine), 1600 (MH^+ − disaccharide).

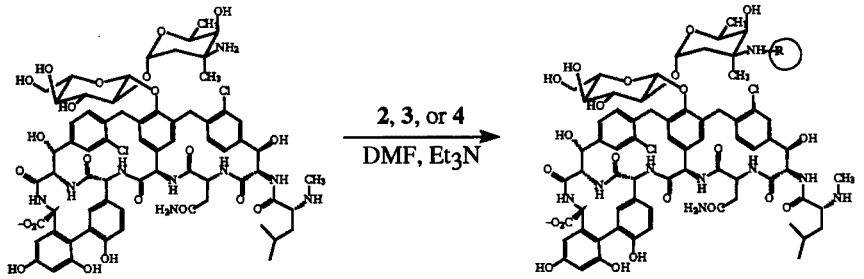
Compound **20** was obtained from **9** and acridinium-active ester (3 mg, 35% based on recovered starting material). Preparative HPLC: solvent B, 27:73:0.05; flow rate, 40 mL/min. Analytical HPLC (solvent B, 27:73:0.05; flow rate, 2 mL/min): retention time, 5.8 min, 99%. ESI/MS *m/z*: 2137 ($M + Na^+$), 2115 (MH^+), 1972 (MH^+ − vancosamine), 1810 (MH^+ − disaccharide).

Anti-Vancomycin Monoclonal Antibody Preparation. Anti-vancomycin mAb, which was raised against vancomycin coupled through the carboxylate to thyroglobulin via a 4-aminobutyrate linker (*13*), was purified on an Affinity-Pak Protein A column according to the manufacturer's protocol. Briefly, the cell culture medium containing mAb (25.4 mg) was clarified by centrifugation (3500*g*, 30 min) and filtered through a 0.2 μm filter, and the supernatant was applied to the Affinity-Pak Protein A column which had been equilibrated with 12 mL of IgG binding buffer. After washing with IgG binding buffer, the antibody was eluted with 6 mL of IgG elution buffer to a vial containing 1.0 mL of 1.5 M Tris buffer, pH 9.0. The purified IgG was dialyzed against PBS buffer (20 mM phosphate and 30 mM NaCl, pH 7.2) for 12 h at 4 °C and then concentrated to approximately 10 mg/mL in an Amicon Microcon-50 microconcentration device. The mAb concentration was 12.4 mg/mL as determined by the micro-BCA protein assay (*22*). The total recovery of the purified mAb was 18.6 mg.

Anti-Vancomycin Fab Fragment Preparation. The digestion of anti-vancomycin mAb was carried out with the ImmunoPure Fab preparation kit following the manufacturer's protocol. Briefly, purified anti-vancomycin mAb (∼12 mg) in digestion buffer (0.5 mL; 20 mM sodium phosphate, 10 mM EDTA, and 30 mM cysteine, pH 7.0) was incubated for 5 h in a 37 °C incubator shaker with immobilized papain in digestion buffer (0.5 mL). Papain-digested anti-vancomycin mAb was then passed through a preequilibrated immobilized protein-A column (2 mL) supplied with the kit to remove undigested mAb and the Fc fragment. The protein-A column was washed with an additional 13 mL of ImmunoPure binding buffer. The column flow-through and column washes containing the Fab fragment were pooled and dialyzed against PBS buffer for 12 h at 4 °C and concentrated in a Centriprep-10 concentration device. The concentration of the anti-vancomycin Fab fragment was 2.0 mg/mL as determined by the micro-BCA method using mouse IgG $(F_{ab}')_2$ as the standard. Purified anti-vancomycin Fab fragment was characterized by SDS−PAGE and LC/ESI mass spectrometry. The molecular masses of the heavy and light chains of the Fab fragment were 23 986 and 24 033 Da, respectively. All studies described were conducted with the Fab fragment of anti-vancomycin mAb to eliminate the complexity associated with the bivalency of the monoclonal antibody.

Preparation of Biosensor Surfaces. Immobilization of vancomycin analogue **9** or the aminocaproate-derivatized (N^{ϵ}-acetyl)KdAdA tripeptide via amine coupling to the CM-5 sensor chip was performed by a previously described method (*6*). Briefly, a continuous flow of HBS buffer at 10 μL/min was initiated over the biosensor surface. The carboxymethylated dextran matrix on the sensor surface was activated by a 3.5 min injection of a solution of 0.05 M NHS and 0.2 M EDAC. A solution of **9** or the aminocaproate-derivatized (N^{ϵ}-acetyl)KdAdA tripeptide (10 μM) and ethanolamine (990 μM; 1 mM total amine in HBS buffer) was then injected (7 min), followed by a 7 min injection of 1.0 M ethanolamine hydrochloride to block remaining unreacted active ester groups. Blank surfaces were generated under identical conditions omitting the ligand immobilization step.

Solution Competition Analysis of the Vancomycin Analogue/Anti-Vancomycin Fab Fragment Binding Interaction. Solution competition studies were carried out on a BIAcore 2000 following the general procedure previously described (*6*). Biosensor surfaces were regenerated after each injection with successive 1 min pulses of 6, 6, and 1.5 M guanidine hydrochloride. Initial rates of binding of anti-vancomycin Fab fragment to the biosensor surface were measured over a 15 s window beginning 20 s postinjection. Data were evaluated by nonlinear regression analysis using the solution affinity model built into BIAevaluation 3.0 software (BIAcore, Inc).



RESULTS

Preparation of Vancomycin Analogues and Tracers. Vancomycin analogues lacking the sugars or the ring-2 chlorine were prepared as previously described (*18*, *19*). Tracers **13**−**15**, containing a derivatized *N*-vancosaminyl carbohydrate moiety, were prepared in 11−81% yield by coupling vancomycin with the NHS active esters of biotin (**2**), 6-carboxyfluorescein (**3**), or 10-(3-sulfopropyl)-*N*-tosyl-*N*-(3-carboxypropyl)acridinium-9-carboxamide (**4**) and purification by preparative HPLC (Scheme 1). Vancomycin tracers **16** and **17**, bearing a derivatized *N*-methylleucyl moiety, were prepared in 40 and 35% yield, respectively, by coupling vancomycin with free biotin or acridinium acid in the presence of *N*,*N*′-dicyclohexylcarbodiimide and *N*-hydroxybenztriazole (Scheme 1). Analogue **9**, containing an aminoalkyl linker on the free carboxyl functionality of vancomycin, was prepared by the method of Sundram and Griffin (*21*). Coupling of **9** with the NHS active esters of biotin (**2**), 6-carboxyfluorescein (**3**), or 10-(3-sulfopropyl)-*N*-tosyl-*N*-(3-carboxypropyl)acridinium-9-carboxamide (**4**), as above, provided mixtures of the carboxyl and *N*-vancosaminyl carbohydrate derivatized vancomycin tracers. Repeated purifications by preparative HPLC provided pure carboxyl-modified tracers **18**−**20** in 26−35% yield (Scheme 1). Crystalline degradation product analogues were prepared following literature procedures or the general methodology described for preparation of vancomycin analogues. The structures of all vancomycin analogues and tracers and the CDP analogues utilized in this study are summarized in Table 1.

Preparation of an Immobilized Vancomycin Biosensor Surface. Initial attempts to generate a biosensor surface involved immobilization of vancomycin through the primary amine of the vancosamine sugar moiety via amine coupling to the activated carboxymethyl dextran surface of a CM-5 sensor chip. Subsequent binding studies with saturating amounts of anti-vancomycin Fab

fragment showed that these surfaces had minimal binding capacity and a relatively low affinity for the antibody fragment. In contrast, immobilization of vancomycin derivative **9**, containing the aminoalkyl linker from the free carboxyl functionality, under identical conditions to the activated carboxymethyl dextran surface provided biosensors with relatively high binding capacity ($RU_{max} \approx 4000$) and high affinity for anti-vancomycin Fab fragment. Additional binding studies of the anti-vancomycin Fab fragment to the immobilized aminoalkyl-modified vancomycin surface demonstrated the binding to be limited by mass transfer and suitable for use in the solution binding studies described below.

Determination of Binding Affinities of Vancomycin Analogues and Tracers for Anti-Vancomycin Fab Fragment. The binding affinity of anti-vancomycin Fab fragment for several vancomycin analogues and tracers was determined from solution competition experiments. Initially, known concentrations of anti-vancomycin Fab fragment (0−22 nM) were injected over the aminoalkyl vancomycin biosensor surface, and the initial rate of binding for each anti-vancomycin Fab fragment

concentration was determined. A plot of initial binding rate versus concentration of anti-vancomycin Fab fragment was fit using a 4-parameter logistic (general model in BIAevaluation 3.0) providing a standard curve. Several standard curves were generated during the course of these studies and all were identical within experimental error. A fixed concentration of anti-vancomycin Fab fragment (20 nM) was then mixed with 12 concentrations of each vancomycin analogue or tracer and allowed to reach equilibrium. The equilibrium mixtures were individually injected over the aminoalkyl vancomycin biosensor surface, and the concentration of free anti-vancomycin Fab fragment remaining was quantitated by determination of the initial rate of binding to the biosensor surface as described above. A plot of free anti-vancomycin Fab fragment versus total concentration of added analogue or tracer provides a competition curve. Figure 2 shows typical competition curves for studies conducted here. The data points represent the experimentally determined concentrations of free anti-vancomycin Fab fragment in equilibrium solutions at a given concentration of soluble analogue or tracer. The curves represent the best nonlinear fit of the data using eq 1 (solution affinity model in BIAevaluation 3.0 software)

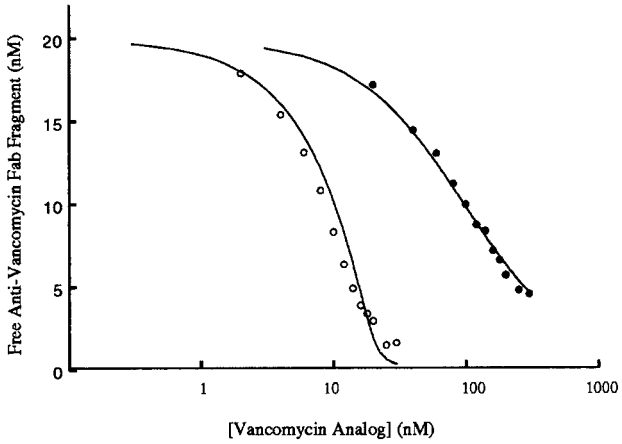

Figure 2. Solution competition curves for determination of equilibrium dissociation constants. Ring-2 dechlorovancomycin (**8**, ●); Biotinylated carboxyl-HDAvancomycin tracer (**18**, ○). The fixed concentration of anti-vancomycin Fab fragment was 20 nM.

$$\mathrm{Fab_f} = \frac{\mathrm{Fab_T} - A - K_D}{2} + \sqrt{\frac{(\mathrm{Fab_T} - A - K_D)^2}{4} - A \times \mathrm{Fab_T}} \quad (1)$$

where $\mathrm{Fab_f}$ is the concentration of free anti-vancomycin Fab fragment in equilibrium solutions, $\mathrm{Fab_T}$ is the total concentration of anti-vancomycin Fab fragment in solution (20 nM), A is the total concentration of added vancomycin analogue or tracer, and K_D is the equilibrium dissociation constant for the binding of the vancomycin analogue or tracer to anti-vancomycin Fab fragment in solution.

The structure-binding relationships for the interaction between vancomycin analogues and the anti-vancomycin Fab fragment, as measured by changes in the equilibrium dissociation constants (K_D), are summarized in Table 2. Vancomycin and the *N*-acetylvancosaminyl-derivatized vancomycin analogue (**7**) bind exceedingly tight with K_D values being outside the range for which the BIAcore instrument can accurately provide values from solution competition studies. Incorporation of the aminoalkyl linker on the free carboxyl functionality of vancomycin, providing **9**, which was used for preparation of the immobilized vancomycin biosensor surface, has minimal effect on the anti-vancomycin Fab fragment recognition in solution. Removal of the ring-2 chlorine atom from vancomycin results in a significant loss in binding recognition by the antibody fragment (cf. **8**). Cleavage of one or both of the carbohydrate rings from vancomycin by acid hydrolysis providing **5** and **6**, respectively, results in a further sequential loss in binding recognition by the antibody fragment with the loss of each monosaccharide. Anti-vancomycin Fab fragment binding interactions with vancomycin degradation products were extremely weak relative to the native antibiotic binding interaction. Crystalline degradation product (**10**) binds with a K_D of 488 ± 34 nM. Removal of the chlorine atom from the 2-position again results in a significant loss in binding recognition by the anti-vancomycin Fab fragment and, complete hydrolysis of the carbohydrate rings, providing **11**, results in a binding interaction with the anti-vancomycin Fab fragment too weak to be determined by the solution competition studies.

The structure-binding relationships for the binding interaction between vancomycin tracers and the anti-vancomycin Fab fragment, as measured by changes in the equilibrium dissociation constants (K_D), are summarized in Table 3. The binding interactions vary depending on the label contained on the tracer. However, *N*-methylleucyl- (**16** and **17)** and carboxyl-HDA-derived tracers (**18**−**20**) containing the same label bind the antibody fragment with similar affinities. In contrast, *N*-vancosaminyl-derived tracers (**13**−**15**) containing the equivalent label bind the antibody fragment substantially weaker.

Table 2. Structure-Binding Relationships for the Interaction between Vancomycin Analogues and the Anti-Vancomycin Fab Fragment[a]

analogue	equilibrium dissociation constant (K_D) (nM)
vancomycin (**1**)	≤0.2[b]
desvancosaminylvancomycin (**5**)	587 ± 27
aglucovancomycin (**6**)	42 000 ± 1000
N-acetylvancosaminylvancomycin (**7**)	≤0.2[b]
ring-2 dechlorovancomycin (**8**)	87 ± 4
carboxyl-HDAvancomycin (**9**)	0.32 ± 0.04
CDP (**10**)	488 ± 34
AglucoCDP (**11**)	≥50 000[c]
ring-2 dechloroCDP (**12**)	6000 ± 100

[a] Values are average equilibrium dissociation constants obtained from triplicate measurements. [b] K_D was too small to be reliably measured by solution affinity experiments. [c] K_D was too large to be reliably measured by solution affinity experiments.

Table 3. Structure-Binding Relationships for the Interaction between Vancomycin Tracers and the Anti-Vancomycin Fab Fragment[a]

	derivatization site (nM)		
derivative	*N*-vancosaminyl	*N*-methylleucyl	carboxyl-HDA
biotin	584 ± 19	≤0.2[b]	≤0.2[b]
fluorescein	76 ± 3	*c*	204 ± 6
acridinium	1200 ± 100	25 ± 0.7	26 ± 0.9

[a] Values are average equilibrium dissociation constants obtained from triplicate measurements. [b] K_D was too small to be reliably measured by solution affinity experiments. [c] Not determined.

Evaluation of a Vancomycin/KdAdA Tripeptide Binding Interaction on Anti-Vancomycin Fab Fragment Recognition. To further evaluate the topology of vancomycin critical for anti-vancomycin Fab fragment recognition, the role of residues located in the peptide-binding pocket of the antibiotic was investigated (Figure 3). For these studies an (N^{ϵ}-acetyl)KdAdA tripeptide containing an aminocaproate linker from the amino terminus was immobilized via amine coupling to an activated carboxymethyl dextran surface of a CM-5 sensor chip. Vancomycin (0.5 μM) binds to this surface (Figure 4). However, since the mass of the antibiotic is small, the instrumental response is relatively small (~50 RU at equilibrium). In contrast, injection of a vancomycin (0.5 μM)/anti-vancomycin Fab fragment (1 μM) complex, in which ≥99% of the vancomycin is bound by the antibody fragment, results in an approximately 10-fold increase in response due the increased mass of the complex (Figure 4). Anti-vancomycin Fab fragment alone has no affinity for the immobilized tripeptide surface (Figure 4). To further verify that the peptide and antibody-binding pockets of vancomycin were mutually exclusive, the vancomycin/anti-vancomycin Fab fragment solution binding interaction was reinvestigated under the conditions described above in the presence of (N^{a},N^{ϵ}-diacetyl)-KdAdA tripeptide (500 μM). The K_D value obtained for the vancomycin/anti-vancomycin Fab fragment binding interaction in solution in the presence of (N^{a},N^{ϵ}-diacetyl)-

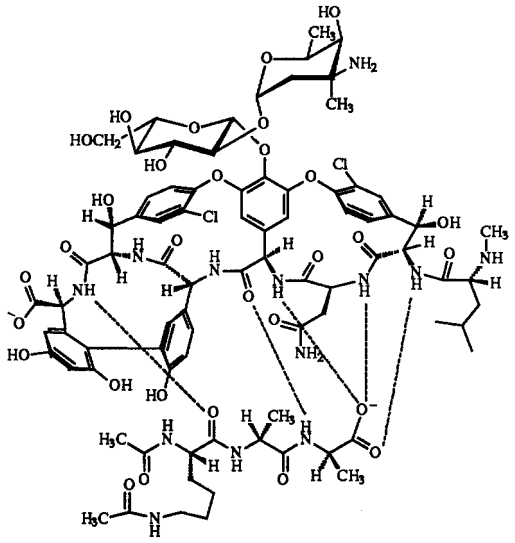

Figure 3. Proposed model for the binding interaction between vancomycin (**1**) and a cell wall peptide analogue (N^{α},N^{ϵ}-diacetyl)-KdAdA (*28*). Dashed lines indicate hydrogen bonds.

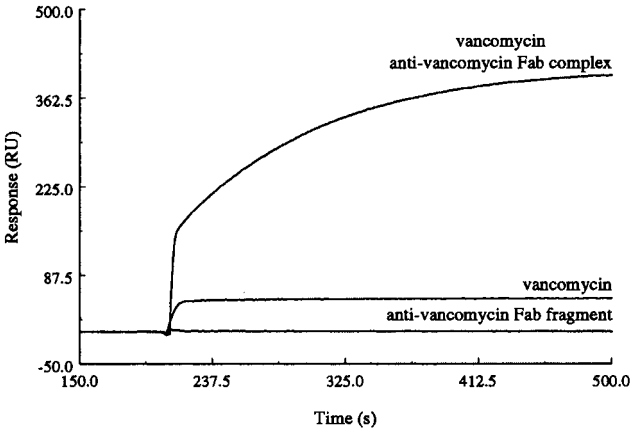

Figure 4. Binding of vancomycin, anti-vancomycin Fab fragment, and vancomycin/anti-vancomycin Fab fragment complex to aminocaproate-derivatized (N^{ϵ}-acetyl)KdAdA tripeptide biosensor surface.

KdAdA tripeptide was identical to the value obtained in the absence of the tripeptide (≤0.2 nM).

DISCUSSION

Reagent design plays an important role in rational immunoassay development. Specifically, the molecular architecture of an immunogen used for triggering an antigenic response is critical to the production of antibodies exhibiting the desired ligand binding characteristics. Important features of immunogen design can include the attachment site of a spacer arm to the ligand, the structure of the spacer arm, and the method employed for coupling the hapten to a carrier molecule. Likewise, some molecular features of the complementary ligand and labeled tracers will be important for recognition by the elicited antibody. The goal of tracer design is to produce ligands containing a signal-generating moiety, which exhibit diagnostically useful binding characteristics. Two approaches to immunoreagent design have been investigated. The design of homologous immunoreagents involves preparation of an immunogen and a tracer from the same hapten. Alternatively, in design of heterologous immunoreagents the immunogen and tracer are prepared from haptens with distinct points of attachment. In the present study, several vancomycin tracers (homologous and heterologous) were prepared, and their binding interactions with an anti-vancomycin Fab fragment were investigated. Several vancomycin analogues were also prepared and tested to further evaluate the structural regions of the antibiotic critical for recognition by the antibody fragment.

The inherent reactivity of vancomycin allows for the preparation of several analogues. Removal of the sugars from vancomycin occurs by mild acid hydrolysis (*18*, *20*). Crystalline degradation product (CDP, **10**) is formed in solution at ambient temperature by rearrangement of vancomycin with concomitant hydrolytic loss of ammonia (*23*). The antibiotic further contains several phenols that are susceptible to oxidative conditions and eight racemizable asymmetric centers. In contrast, the reactivity and complexity of vancomycin makes the preparation of tracers a challenge. As a result, literature reports of vancomycin tracers are limited, and no structural assignments have been provided (*24*−*26*). Tracers designed and synthesized here were derivatized on the vancosaminyl, *N*-methylleucyl, and carboxy terminal residues of vancomycin. The vancosaminyl and *N*-methylleucyl derivatized tracers (heterologous) were synthesized in good to moderate yield. The carboxyl derivatized tracers (homologous) were obtained in lower yields due to competing derivatization reactions yielding products, which were difficult to separate from the desired material. All tracers were isolated in >99% purity as determined by analytical HPLC. The structural assignments for all tracers were confirmed by mass spectral fragmentation patterns.

Aminoalkyl modified vancomycin (**9**) was immobilized on biosensor surfaces and utilized for all solution competition experiments. Analogue **9** contains two primary amines that can potentially react with the activated carboxymethyl dextran of a CM-5 sensor chip to produce a heterogeneous surface. Results obtained using underivatized vancomycin immobilized surfaces indicate that if coupling does occur via the primary amine of the vancosamine sugar moiety it is minor. Coupling of **9** results in a vancomycin-immobilized surface with high affinity and high-binding capacity for anti-vancomycin Fab fragment. This suggests the majority of coupling occurs via the primary amine of the aminoalkyl linker conjugated to the carboxy terminus of vancomycin. The possible generation of heterogeneous vancomycin biosensor surfaces in this manner does not effect the solution competition experiments, since all studies were conducted under mass transport limiting conditions with concentrations of free antibody fragment in equilibrium solutions being determined from a standard curve.

Solution competition studies show the antibody fragment binds vancomycin and the aminoalkyl modified vancomycin (**9**) with high affinity. However, hydrolysis of the two sugar moieties or removal of the ring-2 chlorine atom from vancomycin results in significant losses in binding affinity. The anti-vancomycin Fab fragment also exhibits minimal binding interactions with CDP analogues. In fact, binding interactions observed with CDP analogues and vancomycin analogues lacking the sugar moieties were outside the diagnostically relevant range for the vancomycin immunoassay (*13*). This is critical as assay specificity relies on the ability of the mAb to distinguish between vancomycin and its metabolites (i.e., CDP and other structurally similar compounds). The decreased binding recognition of the anti-vancomycin Fab fragment for CDP is attributed to a conformational change which occurs in the vancomycin to CDP transformation due to a ring expansion relieving the strain in

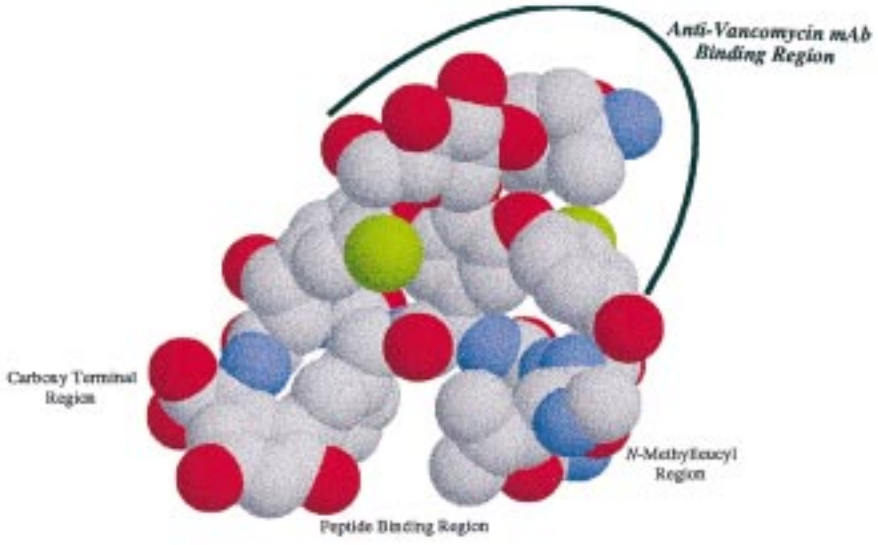

Figure 5. Space filling model of vancomycin showing a proposed anti-vancomycin mAb binding region. Color scheme: carbons (grey), chlorines (green), oxygens (red), and nitrogens (blue). Structure adapted from PDB file 1AA5 using SymApps 5.1 (Bio-Rad Laboratories).

the peptide backbone of the macrocycle (*23*). Crystalline degradation product (CDP, **10**) actually exists as an equilibrium mixture (2:3) of atropisomers differing in the orientation of the chlorine containing ring-2 residue (*23*). The orientation of the chlorine containing ring-2 residue in the major isomer differs from that in vancomycin by 180°. The minor isomer corresponds to the orientation found in vancomycin. The ring-2 orientation conversion is restricted in vancomycin. This reorientation of the chlorine atom in CDP can partially account for the decreased binding interaction observed with anti-vancomycin Fab fragment.

Results obtained for the binding interactions between vancomycin tracers and the anti-vancomycin Fab fragment are consistent with the vancomycin analogue binding studies. The *N*-methylleucyl and carboxy terminal residues of vancomycin can be structurally modified with minimal impact to the anti-vancomycin Fab fragment binding interaction. In contrast, derivatization of the vancosaminyl sugar residue of vancomycin with biotin, fluorescein, or acridinium labels results in a substantial loss in binding recognition by the antibody fragment. Interestingly, acetylation of the same vancosaminylamine does not affect the binding interaction. This suggests that the antibody-binding pocket may accommodate small structural modifications at the amino functionality and that the amine is not directly involved in the binding interaction.

Vancomycin manifests its antibiotic action by binding the carboxy terminal d-Ala-d-Ala peptides of the lipid-PP-disaccharide-pentapeptide intermediates involved in the biosynthesis of the bacterial cell wall peptidoglycan (*27*). This inhibits cross-linking of the chains in the growing cell wall peptidoglycan making the cell susceptible to lysis through osmotic shock. Binding of the carboxy terminal d-Ala-d-Ala peptides to vancomycin has been shown to occur in the concave pocket of vancomycin through five hydrogen bonds between the peptide and the amide backbone of the antibiotic (Figure 3) (*28*). To investigate the role this region played, if any, in anti-vancomycin Fab fragment binding recognition, we evaluated the vancomycin/anti-vancomycin Fab fragment binding interaction in the presence of KdAdA model peptides. Direct binding studies of a vancomycin/anti-vancomycin Fab fragment complex to an aminocaproate-derivatized (N^{ϵ}-acetyl)KdAdA tripeptide biosensor surface demonstrated the peptide and antibody fragment could bind vancomycin simultaneously. This observation was further confirmed by determination of the vancomycin/anti-vancomycin Fab fragment solution binding affinity in the presence of (N^{α},N^{ϵ}-diacetyl)KdAdA tripeptide. The results obtained were essentially identical to the value obtained in the absence of the tripeptide.

The selection of an anti-vancomycin mAb that binds vancomycin at a site independent from that of the peptide-binding site is notable. The degradation of vancomycin to CDP is relatively facile and can lead to problems associated with stability of immunoassay components (i.e., calibrators, controls, and tracers) and cross reactivity with degradation products. Certain peptidoglycan analogues have been shown to inhibit the degradation of vancomycin to CDP resulting in reagent stabilization (*29*). The mAb selected and utilized here not only is highly specific for vancomycin but can also be used in the presence of peptides that stabilize the assay components without interfering with the immunoassay (*13*).

A proposed antibody binding region consistent with all observations is shown in Figure 5. Major structural regions of vancomycin shown to be critical for recognition by the anti-vancomycin Fab fragment include the disaccharide moiety and the ring-2 chlorine atom. Additional structural features of vancomycin critical to recognition by the anti-vancomycin Fab fragment may exist but cannot be evaluated from the results obtained here.

CONCLUSION

A series of vancomycin analogues and tracers were synthesized, and their binding interactions with an anti-vancomycin Fab fragment were evaluated under mass transport limiting conditions using surface plasmon resonance. The results show that two sugar moieties and one chlorinated phenyl ring play important roles in the antibody binding interaction. The *N*-methylleucyl and carboxy terminal residues have minimal contact with the antibody binding pocket and can be structurally modified to generate tracers with little impact on the binding interaction. Additionally, KdAdA model peptides were

shown to bind to vancomycin at a site independent from that of the mAb-binding site and as a result can be used to stabilize immunoassay components.

High-Efficiency Intracellular Magnetic Labeling with Novel Superparamagnetic-Tat Peptide Conjugates

Lee Josephson, Ching-Hsuan Tung, Anna Moore, and Ralph Weissleder*

Center for Molecular Imaging Research, Massachusetts General Hospital, Boston, Massachusetts 02129.
Received October 19, 1998; Revised Manuscript Received January 4, 1999

A biocompatible, dextran coated superparamagnetic iron oxide particle was derivatized with a peptide sequence from the HIV-tat protein to improve intracellular magnetic labeling of different target cells. The conjugate had a mean particle size of 41 nm and contained an average of 6.7 tat peptides. Derivatized particles were internalized into lymphocytes over 100-fold more efficiently than nonmodified particles, resulting in up to 12.7×10^6 particles/cell. Internalized particles localized in cytoplasm and nuclear compartments as demonstrated by fluorescence microscopy and immunohistochemistry. Labeled cells were highly magnetic, were detectable by NMR imaging, and could be retained on magnetic separation columns. The described method has potential applications for in vivo tracking of magnetically labeled cells by MR imaging and for recovering intracellularly labeled cells from organs.

INTRODUCTION

Cell labeling with ferro/supermagnetic substances is an increasingly common method for in vitro cell separation (*1*). Magnetically labeled cells can also be detected by magnetic resonance imaging (*2*−*5*). Most current labeling techniques utilize one of two approaches: (i) attaching magnetic particles to the cell surface (*6*) or (ii) internalizing biocompatible magnetic particles by fluid phase endocytosis (*3, 5*), receptor mediated endocytosis (*7*) or phagocytosis (*2*). The first approach is limited to ex vivo use (*8*). The second approach is limited by the fact that many cells, such as lymphocytes, do not possess high-efficiency internalizing receptors and that the fluid phase pathway is relatively inefficient (*5*). It would therefore be highly desirable to develop a technique of high efficiency intracellular magnetic labeling for in vivo magnetic separation and/or imaging of a wide variety of cells. Such techniques are expected to be of particular importance as cell-based genetic therapies are being developed.

We hypothesized that a superparamagnetic iron oxide with a membrane translocating signal (MTS) peptide attached might be capable of producing high levels of cell internalization. Several MTSs have been described including the third helix of the homeodomain of Antennapedia (*9*), peptide derived from anti-DNA monoclonal antibody (*10*), VP22 herpes virus protein (*11, 12*), and HIV-1 tat peptide (*13*). HIV-1 tat protein is an 86 amino acid polypeptide and is essential for viral replication. It has been shown to freely travel through cellular and nucleic membranes (*14, 15*). Its membrane translocational property is dominated by a short signal, GRKKRRQRRR (amino acid residues 48−57). More recently, it has been demonstrated that the core peptide itself rather than the entire protein is capable of translocating a variety of molecules, including fluorescent probes (*16*), peptides (*17*), pathogenic epitopes (*18*), and proteins (*13, 19*−*21*). Here we report that tat peptide (residues 48−57) derivatized superparamagnetic iron oxide nanoparticles (41 nm) are internalized into cells over 100-fold more efficiently than has been reported to date. The novel compound may thus serve as a reagent for magnetic resonance imaging of cell trafficking and/or magnetic separation of in vivo homed cells.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. A peptide containing the translocation sequence of the tat peptide was synthesized on an automatic synthesizer (PS3, Rainin, Woburn, MA) by Fmoc chemistry using 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU)/*N*-hydroxybenzotriazole (HOBt) as activating agent. The peptide is referred to as tat(FITC). The sequence is Gly-Gly-Cys-*Gly-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg*- Lys-(FITC)-NH_2 (the italicized amino acids correspond to residues 48−57 of the tat protein). Fmoc-Lys(Dde) was anchored to 0.1 mmol of Rink amide MBHA resin (NovaBiochem, San Diego, CA) and followed with other amino acids, e.g., Fmoc-Arg(Pbf), Fmoc-Gln(Trt), Fmoc-Lys(Boc), Fmoc-Gly, and Fmoc-Cys(Trt). The N-terminal was finally capped with t-Boc-Gly. Thereafter, the Dde group on the C-terminal lysine residue was selectively removed with 10 mL of 2% hydrazine in DMF (2×3 min) and the deprotected amino group was reacted with 0.4 mmol of fluorescein isothiocyanate (FITC) (Aldrich, Milwaukee, WI) in 5 mL of DMSO/diisopropylethylamine (20% v/v) overnight. The peptide was cleaved by 5 mL of TFA/thioanisole/ethandithiol/anisole (90/5/3/2) and purified by C18 reversed-phase HPLC. MALDI-MS ($M + H)^+$: 2130.4 (calc.), 2130.3 (found).

Synthesis of Amine Terminated Cross-Linked Superparamagnetic Iron Oxide (CLIO−NH2) (II). A monodispersed superparamagnetic iron oxide colloid (MION) **I** was synthesized and cross-linked with epichlohydrin (Aldrich) to prepare **II** as described (*22*). Briefly, amination was achieved by the addition of 50 mL of concentrated ammonia/200 mL of the MION colloid, followed by heating at 37 °C overnight. The mixture was incompatible with ultrafiltration equipment, so low molecular weight materials were removed by dialysis against

10.1021/bc980125h CCC: $18.00 © 1999 American Chemical Society
Published on Web 02/26/1999

water using dialysis tubing (12−14K cutoff) (Spectra/Por, Laguna Hills, CA). Air was then bubbled through the colloid for 24 h at 37 °C. The colloid was subjected to pressure dialysis with the addition of 10 vol of 5 mM sodium citrate, pH 8. These steps fully oxidize any ferrous iron and remove traces of low molecular weight materials. Final concentration was 26 mg Fe/mL.

Synthesis of 2-Pyridyl Disulfide Derivatized Superparamagnetic Iron Oxide (III). To 1.2 mL of **II** (31.2 mg Fe, 557 μmol) was added 1.2 mL of 0.1 M phosphate buffer, pH 7.4, and 2 mL of *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) (Molecular Biosciences, Boulder, CO) in DMSO (25 mM, 50 μmol). The mixture was allowed to stand for 60 min at room temperature. Low molecular impurities were removed by PD-10 columns (Sigma Chemical, St. Louis, MO) equilibrated with 0.01 M Tris and 0.02 M citrate, pH 7.4 buffer. The pooled void volume of 4.4 mL was recovered, containing **III** at a concentration of 7 mg Fe/mL.

To measure the number of 2-pyridyl disulfide groups attached, 0.2 mL of the solution above was added to 0.2 mL of 0.05 M DTT in 0.1 M phosphate, pH 7.4. The mixture was allowed to stand for 30 min at room temperature. A microconcentrator, 30 kDa cutoff (Amicon, Beverly, MA) was used to separate the product of the reduction, pyridine-2-thione (P2T), from iron. The concentration of P2T was determined using an extinction coefficient at 343 nm of 8100 M^{-1} cm^{-1}. Results are expressed as the number of SPDP groups per particle, i.e., per crystal, assuming 2064 Fe atoms/crystal (*23*).

Synthesis of Superparamagnetic Iron Oxide-Tat-(FITC) (CLIO−Tat) (IV). To 2.3 mL of **III** (16.1 mg/Fe, 288 μmol) was added 1.9 mL of tat(FITC), (803 μM, 1.52 μmol, as determined by FITC absorbance, extinction coefficient of 73 000 M^{-1} cm^{-1} at 494 nm in 0.1 M phosphate buffer). The mixture was allowed to react overnight at room temperature. The solution was applied to PD-10 columns equilibrated as above and the excluded volume containing **IV** saved. To measure the number of tat(FITC) groups attached, the colloid was reacted with DTT and applied to a microconcentrator as above. Released peptide in the filtrate was quantitated using FITC fluorescence read against a standards of FITC.

^{111}In Labeling of IV. To permit **IV** to chelate indium, it was reacted with DTPA dianhydride (Aldrich). **IV** was exhaustively dialyzed against 2.5 mM citrate, pH 6.5 (Spectra/Por membrane, 12−14 kDa cutoff). To 0.6 mL of iron oxide (17.1 μmol of Fe, 8.28 nmol of crystal with 56 nmol of tat-peptide attached) were added 0.1 mL of 0.1 M tetraborate buffer, pH 8.5, and 0.2 mL of 0.14 mM DTPA dianhydride in DMSO (0.028 μmol). The reaction was allowed to proceed at room temperature for 60 min. Unreacted DTPA was removed by using a PD-10 column, equilibrated with 0.02 M sodium citrate, pH 6.5. The samples were applied to the columns which was spin for 5 min at 800*g*. To the filtrate was added 0.72 mCi of ^{111}In (NEN Life Sciences, Boston, MA), which was allowed to react for 3 h at room temperature. The separation procedure was repeated with 45−50% of the radioactivity passing through the column.

Cellular Uptake Assays. Lymphocytes were prepared from mouse spleen as previously described (*5*). Briefly, mice (n = 2) were sacrificed under general anesthesia by lethal intravenous injection of sodium pentobarbital (220 mg/kg, Anpro, Arcadia, CA) and their spleens removed using aseptic procedures. Lymphocytes were obtained by disrupting the spleen between sterile frosted histology slides and dispersed in RPMI 1640 medium (Cellgro, Mediatech, Washington, DC) supplemented with 10% fetal bovine serum. After an initial centrifugation, erythrocytes were lysed by resuspending the cell pellet in 0.83% ammonium chloride in distilled water. To remove the majority of the monocyte/macrophage population, the nonadherent cells were transferred into a new flask after 1 h and counted. This method yielded a cell population containing about 95% lymphocytes, as determined by morphology. Cells were counted and their viability was determined with the Trypan Blue exclusion assay.

The uptake of ^{111}In-labeled **IV** in mouse lymphocytes was measured as previously described (*5*). To determine the amount of superparamagnetic particle associated with cells, we used a simple cell binding assay. Cell suspensions (10^6 cells) were placed into plastic tubes containing 1 mL of the media with different concentrations of ^{111}In-**IV**. Cells were incubated at 37° C for 1 h and then washed three times by centrifugation through a step gradient of 40% Histopaque-1077 (Sigma) in Hanks' balanced salt solution (Mediatech). After the last centrifugation and aspiration of the supernatant, cell pellets were counted in a gamma counter (1289 Compugamma LS; Wallac, Turku, Finland).

Fluorescence Microscopy. Lymphocytes, natural killer (NK) cells, and HeLa cells were further used for fluorescent microscopy. HeLa cells were grown to confluence on glass cover slips in 12 well plates (Becton Dickinson, Bedford, MA). The culture MEM (Minimum essential medium) was replaced with 500 μL of **IV** in MEM media, 0.2 mg Fe/mL. Same amount of **IV** was added to cell suspensions of NK cells and mouse lymphocytes. After 30 min at 37 °C the cells were washed 3 times with HBSS and analyzed by fluorescence microscopy. All images were obtained using a cooled charge coupled device (Photometrics, Tucson, AZ), operated via a linked Power Macintosh 7600/120 computer.

Immunohistochemical Stain for Dextran. To evaluate cellular localization of **IV**, HeLa cells were plated on glass cover slips in a 12 well plate at 60% confluency 24 h before the experiment. Cells were incubated with **IV** for 1 h at 20 μg of Fe, washed extensively with HBSS and fixed with MeOH:acetone (1:1) mixture for 10 min at −80° C. After fixation cells were incubated with anti-dextran IgA antibody W1329 (generous gift from Dr. Glaudemans) (*24*), followed by incubation with secondary biotinylated goat anti-mouse IgA antibody (Sigma). Biotin was probed for with avidin peroxidase (Bio-Rad, Hercules, CA). The color reaction was revealed with DAB Fast substrate tablets (Sigma).

Physical Properties of the Superparamagnetic Iron Oxide Particles. Relaxivity, iron concentration, and size by light scattering were measured as described (*23*). Special phantoms were constructed for NMR imaging that consisted of 10^7 cells embedded in agar to prevent drying and susceptibility artifacts. Freshly isolated lymphocytes were labeled with **IV** or **I**, and sedimented cell pellets were resuspended in 30 μL of warm agarose and placed into holes previously stenciled into the agarose. Each well was then sealed with an additional 0.5 mL of agarose. NMR imaging was performed with a 1.5 T superconducting magnet (Signa 5.0; GE Medical Systems, Milwaukee, WI) using a 5 in. surface coil. The imaging protocol consisted of coronal T1 weighted spin−echo (SE 300/11 where the first number represents the repetition time, TR, and the second number the echo time, TE), T2 weighted SE (SE 2000/102) or T2* gradient echo sequence (Steady-State Free Precession pulse sequence with TR/TE 50/60 and a flip angle of 20°) representative of commonly used pulse sequences in

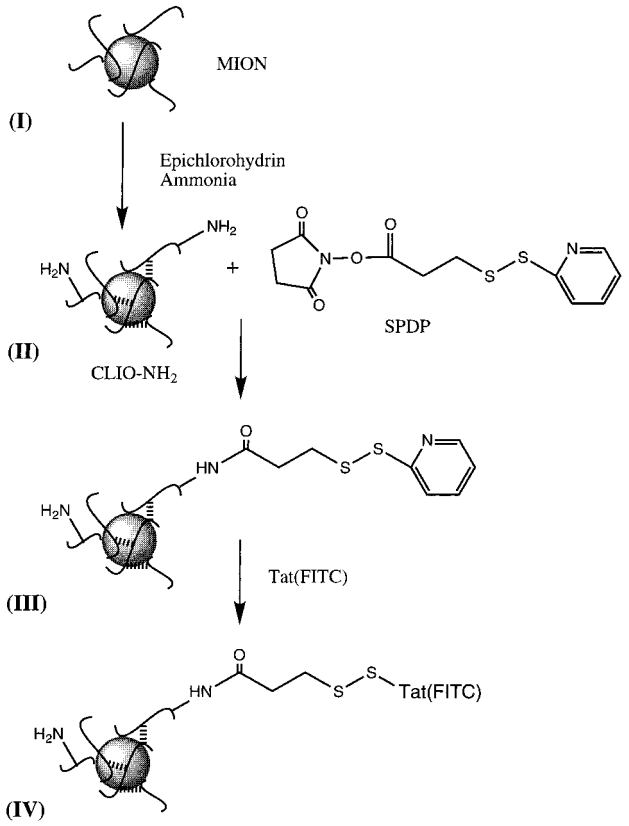

Figure 1. Synthetic scheme of superparamagnetic iron oxide-Tat peptide conjugate

clinical imaging. Slice thickness was 3 mm. The field of view (FOV) was 10 or 12 cm^2, using an 256 × 192 imaging matrix and 2−4 acquisition averages.

RESULTS AND DISCUSSION

A variety of MTS peptides have been used as vectors to carry various payloads into cells (*10, 25*−*27*). These reports inspired us to test whether MTS conjugated to nanometer sized superparamagnetic iron oxide particles could be used for intracellular magnetic cell labeling. Among the reported MTS peptides, HIV-1 tat is unique in that it is one of the shortest MTS signals. Tat peptides have been used to internalize different compounds into cells, such as peptides (*17*) and proteins (*13, 19*−*21*). Although it has been reported that tat peptide with extensions on both ends has a higher efficiency (*13*), we chose to use the shortest tat peptide (residues 48−57) (*17*) for our conjugate. The tat peptide was modified to carry a fluorescein isothiocyanate (FITC) tag, to follow the peptide during conjugation and as a marker for fluorescence microscopy. A Gly-Gly-Cys peptide was incorporated to the N-terminus to introduce a mono reactive sulfhydryl group.

The fluorescent peptide was attached to the amino group of a cross-linked dextran iron oxide (**1**) using SPDP (Figure 1). Reacting **II** with SPDP, the amino groups on **II** were converted to sulfhydryl groups, which were initially protected with 2-pyridyl disulfide. The degree of substitution was determined by reduction with DTT followed by ultrafiltration to free solutions of iron. Measuring the specific absorption of the released pyridine-2-thione at 343 nm, an average of 14 sulfhydryl groups was determined per particle.

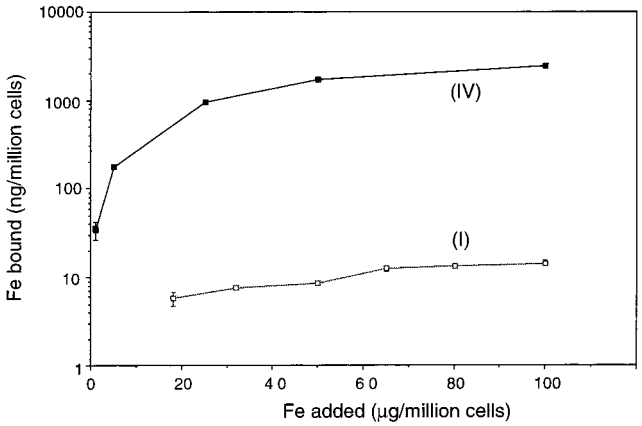

Figure 2. Uptake of **IV** and **I** by mouse lymphocytes at 37 °C for 1 h. **I** was prepared as described in ref *5*. Note the logarithmic *Y* axis. Cellular uptake of control peptide-particles were similar to **I** (data not shown).

Tat(FITC) was attached to activated **III** at pH 7.4 through a disulfide exchange reaction. After separating the free peptide from the conjugate **IV** by a size-exclusion column, a small portion of **IV** was used to determine the number of tat(FITC) per particle using the DTT reduction reaction and ultrafiltration. Released peptide was quantitated by determining FITC fluorescence against a FITC standard at 494 nm. An average of 6.7 peptides were thus attached per particle.

The physical properties of the superparamagnetic iron oxide colloids involved in this study are summarized in Table 1. No significant difference in the particle size was observed after peptide attachment. In addition, the similar relaxivity (values) of **II**, **III**, and **IV** indicate that the magnetic property of the colloid is unaffected by the reactions performed to attach tat(FITC).

A high cellular uptake of **IV** could be demonstrated in all three cell types tested in this study: murine lymphocytes, human natural killer cells and HeLa cells. With murine lymphocytes, the uptake of radioactive **IV** was quantified and compared to **I** (*5*) (Figure 2). Over a wide concentration range, the uptake of **IV** was about 100-fold higher than that of a conventional nonmodified magnetic particle. At the highest concentration of **IV** employed, 100 μg of Fe/million cells, there was an uptake of 2535 ng of iron/million cells corresponding to 12.7 × 10^6 particles/cells. Under similar conditions but using **I**, mouse peritoneal macrophages internalized 970 ng (*2*), while splenic lymphocytes, human and rat lymphocytes took up only 18.7, 27.9, and 11.5 ng, respectively (*5*). The concentration dependence of the uptake of **IV** was such that even at 20 μg of Fe/million cells, mouse lymphocytes internalized 981 ng/million cells (Figure 2), an amount equivalent to that obtained with macrophages at 100 μg of Fe/million cells.

Table 1: Physical Properties of Superparamagnetic Iron Oxide Colloids

compd	surface	size (nm)	2-pyridyl per particle	tat(FITC) per particle	R1[a]	R2[a]

IV	cross-linked dextran-tat(FITC)	41.3	ND	6.7	22.3	71.9

[a] mM^{-1} s^{-1}.

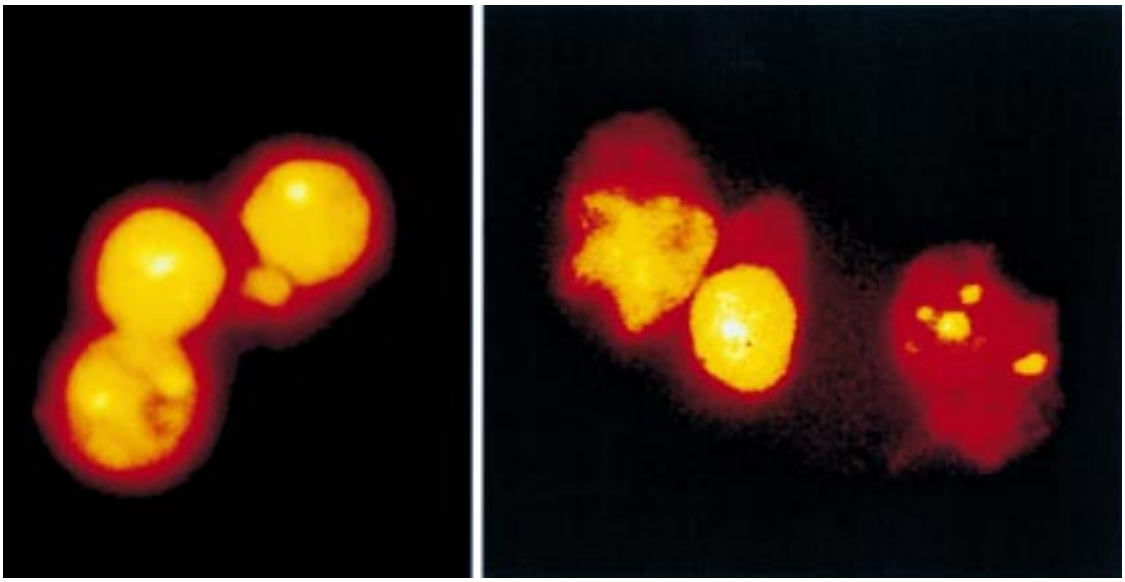

Figure 3. Fluorescence microscopy of murine lymphocytes (left) or activated human NK cells (right) 30 min after incubation with **IV**. The label is clearly contained within lymphocytes, particularly the nucleus and nucleoli. The shape of activated NK is slightly irregular representing terminal tufts. No significant intracellular fluorescence was observed when cells were labeled with FITC-**II** under identical conditions (not shown).

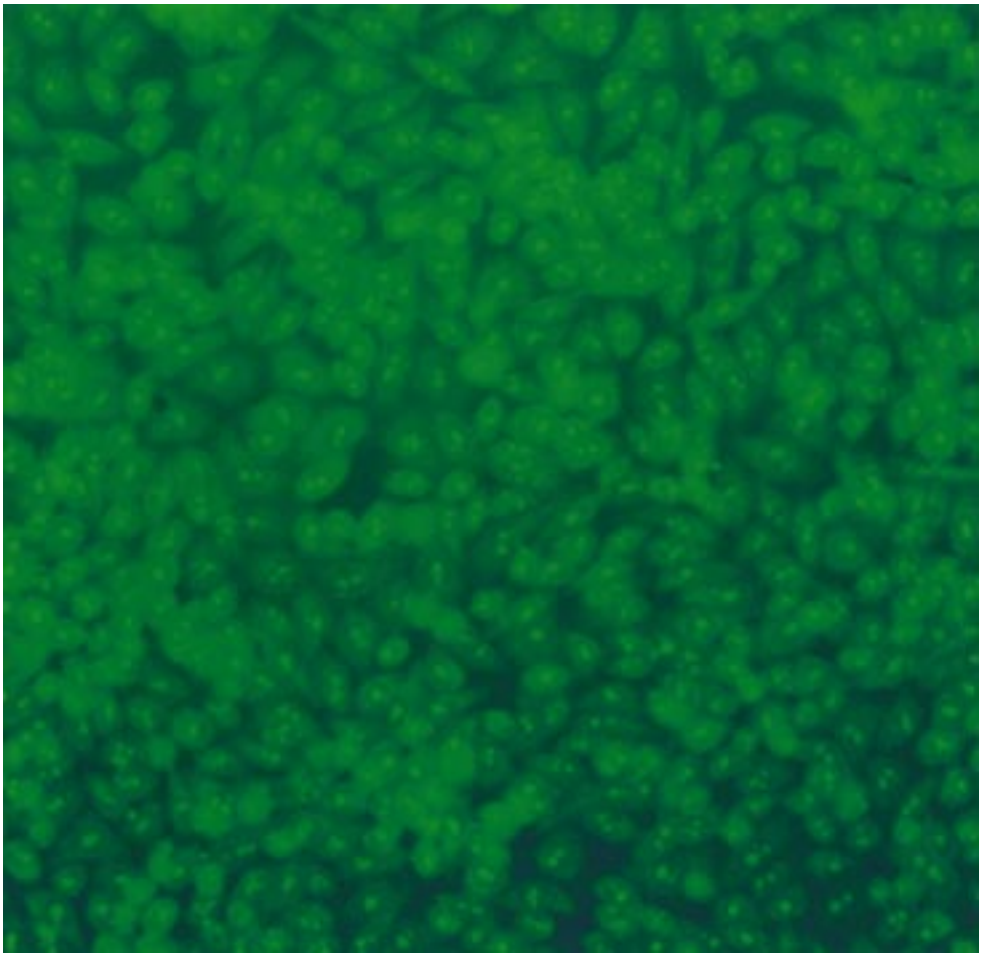

Figure 4. Fluorescence microscopy of HeLa cells incubated with **IV**.

Figure 3 shows the intracellular distribution of **IV** by fluorescence microscopy in murine lymphocytes and activated human NK cells. Fluorescence signal was distributed in the cytoplasm with particularly high concentrations in the nucleus and nucleolus. There was a notable lack of punctate staining as is observed with lysosomal accumulation where receptor-mediated or fluid phase endocytosis pathways are used for magnetic cell labeling (*5*). Intracellular location of **IV** was also examined in HeLa cells, which are commonly used in studies of MTS biology. Figure 4 shows HeLa cells after an incubation of 30 min with a concentration of 0.2 mM of Fe **IV**. A pronounced nuclear accumulation was observed in virtually all cells examined. Cells were not fixed to

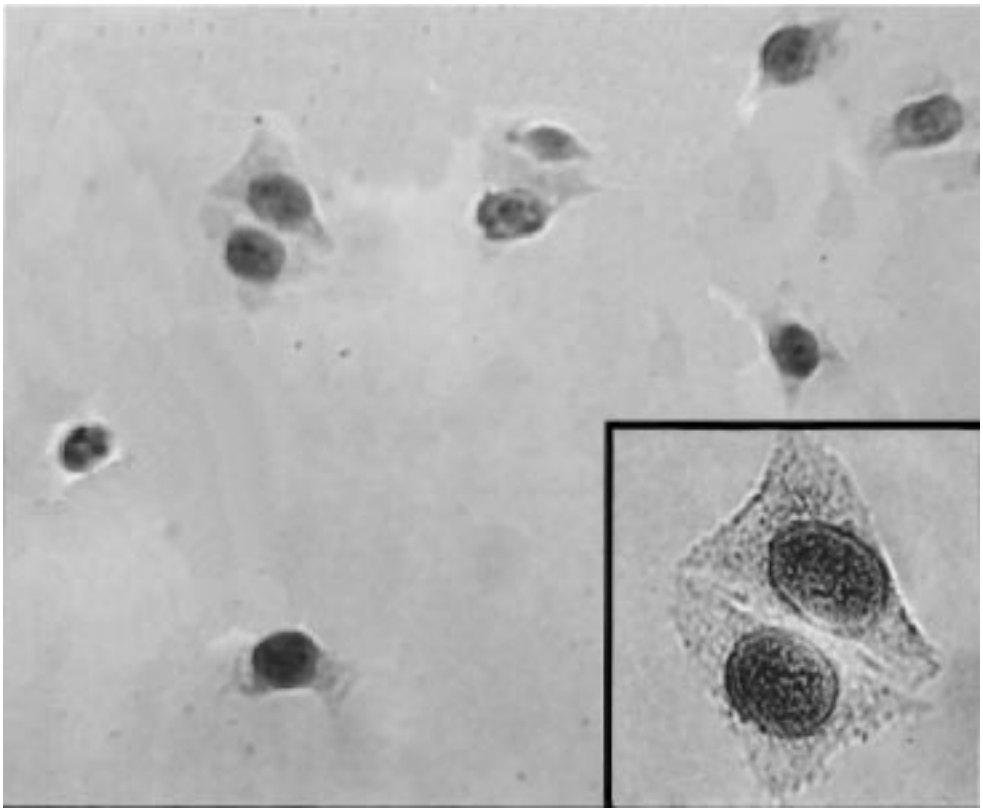

Figure 5. Anti-dextran staining of HeLa cells incubated with **IV**. (Inset) Magnification at 600×. The brown reaction product represents dextran within cell and the nucleus.

avoid possible alterations due to the fixing procedure. No significant cellular internalization was observed for the control compounds consisting of GRGDSPGGCK(FITC)-NH_2-**II** conjugate or FITC-**II**.

The linkage between the superparamagnetic iron and tat (FITC) peptide of conjugate **IV** is a reversible disulfide bond. Under physiological conditions, it is possible that the peptide is released from the particle. Although the fluorescence signal was clearly intracellular, we performed additional experiments to exclude the possibility of peptide dissociation. Briefly, cells were stained for dextran using a monoclonal antibody (*24*). As shown in Figure 5, dextran was concentrated in and distributed through the nucleus thus confirming internalization of the entire construct **IV**. This suggests that the uptake and nuclear localization of **IV** seen by fluorescence microscopy corresponds to the intact particle and not the dissociated peptide-tat (FITC).

Finally, we compared the magnetic effects of cellular internalization of **IV** and **I**. These studies were performed with lymphocytes incubated with either compound and then subjected to MR imaging using different pulse sequences. Figure 6 summarizes these results. Signal intensity differences were most marked with the T2 and T2* weighted sequences as predicted by theory. For example, **IV**-labeled cells produced a much lower signal intensity than did **I**-labeled cells (Figure 6). These results are entirely consistent with quantitative cell uptake studies (Figure 2) and attest to the feasibility of MR imaging of labeled cells. Furthermore, 95% of lymphocytes labeled with **IV** were retained on magnetic separation columns whereas cells labeled with **I** were not (data not shown).

We describe the synthesis and properties of a functionalized, biocompatible iron oxide particle containing multiple copies of a membrane translocating tat peptide.

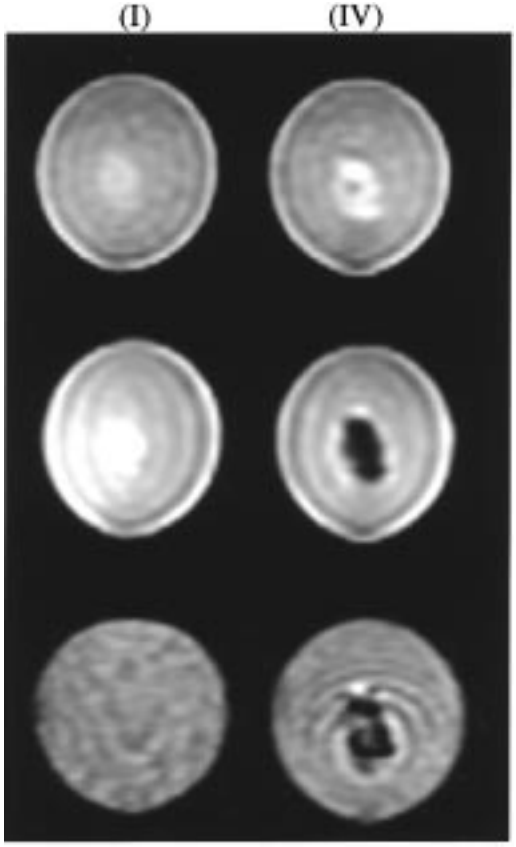

Figure 6. Comparative NMR imaging of **I** or **IV** labeled lymphocytes. (Top) T1 weighted spin−echo sequence (SE 300/11); middle T2 weighted sequences (FSE 2000/102); (bottom) T2* weighted sequence (SSFP 50/60/20°). Each well measures 2 cm in diameter and each agar plug contains a 20 μL insert with 10^7 labeled cells. Cell concentration and incubation conditions among the two samples are identical.

To the best of our knowledge, our study is the first to show that relatively short MTS signals can internalize entire nanometer sized magnetic particles into cells. A second type of tat (FITC) conjugate was synthesized devoid of the C-terminal GGC sequence. Both conjugates were internalized in a similar manner (data not shown). Utilizing the above-described approach, a variety of studies are currently being conducted to further explore the exact mechanism of cellular internalization of **IV** conjugates. Preliminary trypan blue exclusion toxicity studies showed no cellular toxicity at incubation concentrations used for MR imaging (up to 30 μg of Fe). Apart from more elaborate toxicity studies, additional MR imaging studies are underway to determine the threshold of cell detection by NMR imaging. Initial feasibility studies have also shown that magnetically labeled cells are indeed recoverable by magnetic cell separation technique after intravenous administration.

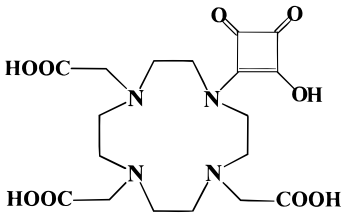
Macromolecular Gd(III) complexes may find useful application as contrast agents for magnetic resonance angiography (MRA). Herein two novel systems are reported, namely $Gd(DO3ASQ)_3-lys_{16}$ and $Gd(DO3ASQ)_{30}-orn_{114}$. Their syntheses are based on the ability of the squaric acid moiety to act as a linker between the DO3A (1,4,7,10-tetraazacyclododecane-1,4,7-triacetic acid) chelate moiety and the polyamino acidic chain. Moreover, the squaric acid participates in the coordination cage of the Gd(III) ion. The investigation of ^1H and ^{17}O NMR relaxation processes of solvent water nuclei allowed a detailed characterization of the systems under study. $Gd(DO3ASQ)_{30}-orn_{114}$ displays a remarkable ability to enhance the water proton relaxation rate of its solutions, and it may be considered as potential contrast agent for MRA applications.

INTRODUCTION

The search for macromolecular Gd(III) complexes (*1*, *2*) has been an important issue in the past decade of development of contrast agents (CA) for magnetic resonance imaging (MRI) (*3*−*5*). This interest is even stronger now that magnetic resonance angiography (MRA) is becoming a procedure of widespread use. These macromolecular systems provide both an enhanced ability to catalyze solvent proton relaxation rates [through the occurrence of a long molecular reorientational time τ_R (*6*, *7*)] and an increased lifetime of the CA in the circulating blood by avoiding the extravasation typical of the small-sized Gd(III) complexes commonly employed in MRI investigations. It was earlier reported that an easy way to attach a chelating moiety to a macromolecule consists of forming an amide linkage with the reaction of an amino group on the macromolecule and the bis(anhydride) derivative of DTPA. This procedure has been used to prepare systems such as $(GdDTPA)_n$−albumin and $(GdDTPA)_n$−polylysine (*8*, *9*).

The main drawback in the use of the bifunctional dianhydride DTPA stems from the occurrence of undesiderable intra- and intermolecular cross-linking reactions. Intermolecular cross-linking may be reduced by the use of low protein concentrations, but this has no effect on intramolecular cross-linking, which represents a major risk in the case of highly flexible macromolecules such as polylysine (*10*). The diconjugation of DTPA is expected to cause a large reduction of the thermodynamic stability of the metal complexes as proved in a detailed study on model systems (*11*). The search has then been addressed to methods that preclude diconjugation of the chelate, for instance, through the use of the monoanhydride derivative of DTPA (*12*). However, as outlined also by other authors (*10*), the synthesis of the latter ligand appears to be difficult to reproduce and the yields are invarianty low. For the same purpose other authors have dealt with functionalized DOTA chelates (*13*). Again, the employed procedures are rather laborious and troublesome. On this basis, the need for a monoreactive chelate derivative that would enable extensive and specific activation of amino groups in macromolecules is still vivid.



The effectiness of paramagnetic CAs is represented by their relaxivity (r_{1p}); that is, the water proton relaxation rate of a 1 mM solution of the Gd(III) chelate, that, at the magnetic fields usually employed in MRI (0.5−1.5 T), is roughly proportional to the molecular reorientation time (τ_R) of the complex. Unfortunately, the relaxivity of such systems is not as high as one would expect on the basis of their molecular weights. Possible causes for such behavior may be either the occurrence of internal motions that reduce the effective molecular reorientation time or the presence of a relatively long exchange lifetime (τ_M) of the coordinated water molecule or both. As far as the exchange of the water molecule coordinated to the Gd(III) ion is concerned, the enhancement of the solvent relaxation rate (R_{1p}^{is}) is "quenched" when τ_M is longer than the relaxation time of these protons (T_{1M}) (*14*).

Indeed, a number of bis(amide) DTPA Gd(III) complexes have been reported to have τ_M values of ∼1 μs at room temperature (*15*), whereas other DTPA- and DOTA-like (1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid) Gd(III) complexes display shorter τ_M values (*14*). On this basis, it was deemed of interest to explore alternative routes to obtain conjugates between macromolecular substrates and Gd(III) chelate moieties different from DTPA-amide. Since it has been recently reported that squaric esters readily react with amino groups (*16*), under mild conditions, we decided to explore

their use in the formation of stable linkages between Gd(III) complexes and NH_2 moieties on macromolecular substrates. Furthermore, once the squaric ester derivatives are bonded to an amino nitrogen of a tetraazacyclododecane macrocycle as in DO3ASQ and DO3ASQ-est ligands (Scheme 1), they may show coordination properties analogous to those displayed by an acetate arm in the parent DOTA ligand.

EXPERIMENTAL PROCEDURES

Syntheses. *Synthesis of 10-(2-Ethoxy-3,4-dioxo-1-cyclobutenyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triacetic Acid, (Tri)-tert-Butyl Ester (**3**).* To a stirred solution of the triester (**1**) [1,4,7,10-tetraazacyclododecane-1,4,7-triacetic acid, (tri)-*tert*-butyl ester] (*17*), kindly provided by Bracco (Bracco S.p.A., Milano, Italy) (3.3 g, 6.1 mmol) in ethanol (50 mL) is added a solution of diethyl squarate (1.24 g, 7.73 mmol) in one portion. The resulting mixture is stirred overnight at room temperature and then evaporated in vacuo. The product is purified by column chromatography (SiO_2, $CHCl_3$/acetone 50:50 → 10:90), yielding 3.60 g (92.7%) of **3** as a light yellow viscous oil: ^{1}H NMR (300 MHz, $CDCl_3$) δ 4.72 q[2H] (J = 7.1 Hz), 3.93 t[2H] (J = 6.0 Hz), 3.78 t[2H] (J = 6.0 Hz), 3.26 s[2H], 3.25 s[4H], 2.98 m[4H], 2.72 m[8H], 1.42 s[27H], 1.30 t[3H] (J = 7.1 Hz); ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 189.0, 182.1, 176.1, 172.0, 170.6, 81.0, 69.2, 58.0, 57.6, 56.7, 55.6, 54.8, 54.6, 53.2, 53.0, 52.1, 52.0, 49.6, 48.7, 28.1, 15.8; IR (neat) 2979, 2932, 2848, 1797, 1731, 1714, 1613 cm^{-1}; MS(CI), m/z 640 (MH^+), 611 (−CO); R_f (TLC) = 0.78 (SiO_2, acetone).

Synthesis of 10-(2-Hydroxy-3,4-dioxo-1-cyclobutenyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triacetic Acid (Trifluoroacetate) (DO3ASQ). To a stirred solution of the tetraester **3** (3.27 g) in THF (20 mL) is added concentrated HCl (37%, 2.5 mL), and the mixture is stirred for 24 h at room temperature. Diethyl ether (20 mL) is slowly added to form a two-phase system, which is allowed to stand at room temperature overnight. The crystalline product DO3ASQ is isolated by filtration, washed with diethyl ether, and dried in vacuo. The product is recrystallized from water, obtaining 2.88 g: mp 223−225 °C (dec); ^{1}H NMR (D_2O, 200 MHz) δ 4.25 m[4H], 3.60 m[4H], 3.48 m[4H], 3.46 s[6H], 3.08 m[4H]; ^{13}C NMR (D_2O, 50.3 MHz) δ 198.6, 190.0, 184.2, 179.4, 170.5, 56.4, 55.6, 55.2, 54.1, 52.2, 49.3; IR (Nujol mull) 3500−2500 (bb), 1813, 1751, 1694, 1665 cm^{-1}.

Synthesis of 10-(2-Ethoxy-3,4-dioxo-1-cyclobutenyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triacetic Acid (Trifluoroacetate) (DO3ASQ-est). A solution of compound **3** (204.0 mg, 0.3194 mmol) in trifluoroacetic acid (1 mL) was stirred overnight at room temperature. After evaporation to dryness, the residue was dissolved in methanol (1 mL); slow addition of diethyl ether (10 mL) caused the precipitation of DO3ASQ-est as a white powder, which was collected by centrifugation, washed with diethyl ether, and dried in vacuo (140.7 mg): mp 170−175 °C (dec); ^{1}H NMR (D_2O, 200 MHz) δ 4.65 q[2H] (J = 7.0 Hz), 3.82−3.51 m[10H], 3.16−3.00 m[12H], 1.36 t[3H] (J = 7.1 Hz).

Syntheis of Polylysine Conjugate. Polylysine hydrobromide (**5**, 49.1 mg; Sigma, St. Louis, MO) is dissolved in 250 μL of H_2O; triethylamine (500 μL) is added to the clear solution and, after 5 min, a solution of the tetraester **4** (33.6 mg) in 750 μL of ethanol is added in one portion. The mixture is stirred at room temperature for 72 h, with the disappearance of **4** (SiO_2, $CHCl_3$/MeOH 9:1) monitored by TLC. The mixture is evaporated in vacuo and the residue dissolved in neat trifluoroacetic acid (3 mL) and stirred overnight at room temperature; the solution is evaporated, and the residue is dissolved in 1 mL of methanol. By slow addition of a 4-fold volume of diethyl ether, the conjugate (**7**) precipitated as a white amorphous powder, which was collected by centrifugation, repeatedly washed with diethyl ether, and dried in vacuo (yield = 69.7 mg).

The presence of unconjugated DO3ASQ monomer has been ruled out on the basis of HPLC analysis. The experimental setup of HPLC analysis is as follows: Hamilton PRP-1 column (5 μm, 250 × 4 mm), UV detector at 260 nm, isocratic elution with a 10:90 mixture of acetonitrile/TBOH, 0.02 M, pH 6.5 by H_2SO_4; elution flux = 1 mL/min. The samples were derivatized by treatment with a 0.01 M $CuSO_4$ solution.

Synthesis of Polyornithine Conjugate. Polyornithine hydrochloride (**5**, 51.6 mg; Sigma) is dissolved in 500 μL of H_2O; triethylamine (500 μL) is added to the clear solution and, after 5 min, a solution of the tetraester **4** (60.9 mg) in 500 μL of ethanol is added in one portion. The mixture is stirred at room temperature for 72 h, with the disappearance of **4** (SiO_2, $CHCl_3$/MeOH 9:1) monitored by TLC. The mixture is evaporated in vacuo and the residue dissolved in neat trifluoroacetic acid (3 mL) and stirred overnight at room temperature; the solution is evaporated, and the residue is dissolved in 1 mL of methanol. By slow addition of a 4-fold volume of diethyl ether, the conjugate (**7**) precipitated as a white amorphous powder, which was collected by centrifugation, repeatedly washed with diethyl ether, and dried in vacuo (yield = 72.7 mg).

The absence of unconjugated DO3ASQ monomer has been checked by HPLC as described above for the polylysine conjugate.

Preparation of the Gd(III) Complexes. The complexation has been carried out by adding stoichiometric amounts of $GdCl_3$ to the aqueous solutions of the ligands at neutral pH and at room temperature. The formation of the complex has been followed by measuring the solvent proton relaxation rate ($1/T_1$). The presence of an excess of free Gd(III) ions, which yields a noticeable increase of the observed relaxation rate, may be quickly removed by centrifugation of the solution brought to basic pH.

NMR Measurements. The longitudinal water proton relaxation rate was measured by using a Stelar Spin-

master spectrometer [Stelar, Mede (PV) Italy] operating at 20 MHz, by means of the standard inversion−recovery technique (16 experiments, 2 scans). A typical 90° pulse width was 3.5 μs, and the reproducibility of the T_1 data was ±0.5%. The temperature was controlled with a Stelar VTC-91 air-flow heater equipped with a copper−constantan thermocouple (uncertainty of ±0.1 °C).

The proton $1/T_1$ NMRD profiles were measured over a continuum of magnetic field strength from 0.00024 to 1.2 T (corresponding to 0.01−50 MHz proton Larmor frequency) on the Koenig−Brown field-cycling relaxometer installed at the NMR relaxometry laboratory of the University of Torino (Italy). The relaxometer works under complete computer control with an absolute uncertainty in $1/T_1$ of ±1%. Details of the instrument and of the data acquisition procedure may be found elsewhere (*18*).

Variable-temperature ^{17}O NMR measurements were recorded on a JEOL EX-90 (2.1 T) spectrometer, equipped with a 5 mm probe, by using a D_2O external lock. Experimental settings were as follows: spectral width = 10000 Hz, pulse width = 7 μs, acquisition time = 10 ms, 1000 scans, and no sample spinning. Solutions containing 2.6% of ^{17}O isotope (Yeda, Israel) were used. The observed transverse relaxation rates (R^{O}_{2obs}) were calculated from the signal width at half-height. The ^{1}H and ^{13}C NMR spectra of the ligands were performed on a Bruker AC-200 spectrometer (7.1 T). *tert*-Butyl alcohol (1%) was used as internal reference ($\delta^{1H} = 1.29$ ppm, $\delta^{13C} = 31.3$ ppm, and $\delta^{31P} = 0$ ppm) for ^{1}H/^{13}C NMR spectra recorded using as solvent D_2O (99.8%, Merck, Darmstadt, Germany).

THEORY

^{1}H Water Relaxation Rate. The longitudinal water proton relaxivity r^{H}_{1p} is defined as the paramagnetic contribution to the observed water proton relaxation rate (R^{H}_{1obs}) of a 1 mM solution of the paramagnetic metal complex:

$$r^{H}_{1p} = R^{H}_{1obs} - R^{H}_{1d} \quad (1)$$

In eq 1 R^{H}_{1d} is the water proton relaxation rate in the presence of an equimolar amount of a diamagnetic analogue of the paramagnetic compound which, for diluted solutions, may be made equal to the value of 0.38 s^{-1}, that is, the relaxation rate of pure water at 298 K. The observed relaxivity results from contributions arising from water molecules in the inner- and outer-coordination spheres of the metal ion:

$$r^{H}_{1p} = r^{His}_{1p} + R^{Hos}_{1p} \quad (2)$$

r^{His}_{1p} deals with the contribution arising from the exchange of the water directly coordinated to the paramagnetic metal ion and is given by

$$R^{His}_{1p} = (Cq/55.6)(T^{H}_{1M} + \tau^{H}_{M}) \quad (3)$$

where C is the molar concentration of the complex, q the hydration number, T^{H}_{1M} the longitudinal relaxation time of the inner-sphere water protons, and τ^{H}_{M} their residence lifetime. The Solomon−Bloembergen theory (*19*) describes the magnetic field dependence of T^{H}_{1M}, which, for a Gd(III) chelate, is given by

$$\frac{1}{T^{H}_{1M}} = \frac{2}{15}\frac{2\gamma_H^2 g_e^2 \mu_B^2 S(S+1)}{r_H^6}\left[\frac{3\tau_{c1}}{1+\omega_H^2\tau_{c1}^2} + \frac{7\tau_{c2}}{1+\omega_S^2\tau_{c2}^2}\right] \quad (4)$$

where S is the electron spin quantum number [$^7/_2$ for Gd(III)], γ_H is the proton nuclear magnetogyric ratio, μ_B is the Bohr magneton, g_e is the Landè factor for the free electron, r_H is the distance between the metal ion and the inner-sphere water protons, ω_H and ω_S are the proton and electron Larmor frequencies ($\omega_S = 658\omega_H$), respectively, and τ_{ci} ($i = 1, 2$) are the correlation times related to the modulation of the electron−proton dipolar coupling. Such an interaction may be modulated by the reorientation of the paramagnetic species, τ_R, by the residence lifetime of the inner-sphere water molecule (τ_M) and by the electronic relaxation times, T_{iE}.

$$\tau_{ci}^{-1} = \tau_R^{-1} + \tau_M^{-1} + T_{iE}^{-1} \quad (5)$$

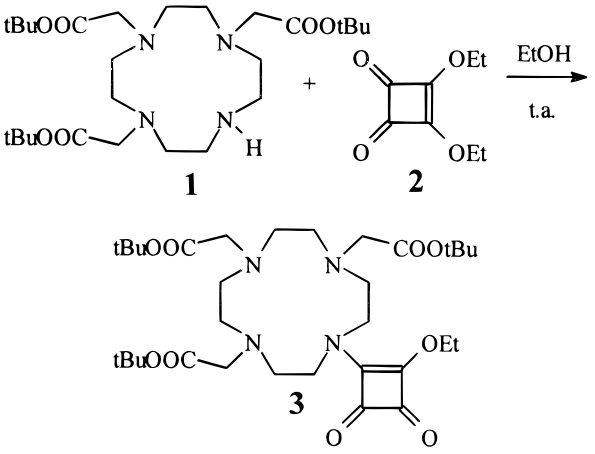
In analogy with the nuclear relaxation time also the electronic relaxation processes depend on the magnetic field strength. For Gd(III) complexes T_{iE} are related to the modulation of the zero field splitting (ZFS) of the electronic spin states due to the dynamic distortions of the ligand field interaction and, according to the Blombergen−Morgan theory (*20*), their magnetic field dependence is given by the following equations:

$$T_{1E}^{-1} = \frac{1}{25}\Delta^2\tau_v[4S(S+1) - 3]\left(\frac{1}{1+\omega_S^2\tau_v^2} + \frac{4}{1+4\omega_S^2\tau_v^2}\right) \quad (6)$$

$$T_{2E}^{-1} = \frac{1}{50}\Delta^2\tau_v[4S(S+1) - 3] \times \left(3 + \frac{5}{1+\omega_S^2\tau_v^2} + \frac{2}{1+4\omega_S^2\tau_v^2}\right) \quad (7)$$

where Δ^2 is the trace of the square of the transient ZFS tensor and τ_v is the correlation time related to its modulation. The outer-sphere term, R^{Hos}_{1p}, describes the contribution arising from the water molecules diffusing near the paramagnetic chelate and, according to the model of Hwang and Freed (*21*), may be related to the minimum distance between the metal and the diffusing water molecules, a, the relative solute−solvent diffusion coefficient, D, and the electronic relaxation times, T_{iE}

$$R^{Hos}_{1p} = C^{os}\left(\frac{1}{aD}\right)[7J(\omega_S) + 3J(\omega_H)] \quad (8)$$



where C^{os} is a constant (5.8×10^{-13} s^{-2} M^{-1}) and the dependence on the electronic relaxation times is expressed in the non-Lorentzian spectral density functions $J(\omega_i)$.

^{17}O Water Relaxation Rate. The residence lifetime of a water molecule directly coordinated to a paramagnetic metal ion (τ^{O}_{M}) may be evaluated by measuring the temperature dependence of the paramagnetic contribution (R^{O}_{2p}) to the observed ^{17}O water solvent transverse relaxation rate

$$R^{O}_{2p} = R^{O}_{2obs} - R^{O}_{2d} \quad (9)$$

where, in analogy with ^{1}H measurements, the diamagnetic term R^{O}_{2d} is measured on a solution containing a diamagnetic analogue of the chelate of interest. (We used ^{17}O NMR data of LaDOTA.) R^{O}_{2p} is related to τ^{O}_{M} through

Scheme 2

the values of $\Delta\omega_M^O$ (which is the ^{17}O chemical shift difference between coordinated and bulk water molecule) and R_{2M}^O (which is the transverse relaxation rate of the coordinated water oxygen) (*22*):

$$R_{2p}^O = \frac{qC}{55.6}\tau_M^{O-1}\frac{R_{2M}^{O\,2} + \tau_M^{O-1}R_{2M}^O + \Delta\omega_M^{O\,2}}{(R_{2M}^O + \tau_M^{O-1})^2 + \Delta\omega_M^{O\,2}} \quad (10)$$

The temperature dependence of $\Delta\omega_M^O$ is described by the equation

$$\Delta\omega_M^O = \frac{g_e\mu_B S(S+1)B_0}{3k_B T}\frac{A}{\hbar} \quad (11)$$

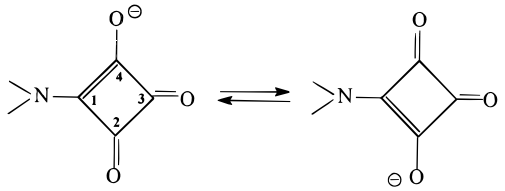
where B_0 is the magnetic field strength (2.11 T in this work) and $A/\hbar$ is the Gd-^{17}O scalar coupling constant [the value of which for polyaminocarboxylate Gd(III) complexes may be reasonably fixed to -3.8×10^6 rad s^{-1}].

For relatively small-sized Gd(III) chelate and at the field of 2.11 T used in this work, R_{2M}^O is dominated by the electron−nucleus scalar interaction:

$$R_{2M}^O = \frac{1}{3}\left(\frac{A}{\hbar}\right)^2 S(S+1)\left(\tau_{E1} + \frac{\tau_{E2}}{1+\omega_S^2\tau_{E2}^2}\right) \quad (12)$$

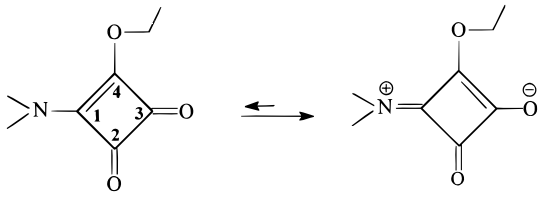
$$\tau_{E2}^{-1} = T_{iE}^{-1} + (\tau_M^O)^{-1} \quad (13)$$

Finally, the temperature dependence of R_{2P}^O is expressed in terms of the Eyring relationship for τ_M^O and τ_v



$$(\tau_j)_T^{-1} = \frac{(\tau_j^{-1})^{298.15}T}{298.15}\exp\left[\frac{\Delta H_j}{R}\left(\frac{1}{298.15} - \frac{1}{T}\right)\right] \quad (14)$$

where j refers to the two different dynamic processes involved (j = v, M) and ΔH_j is the corresponding activation enthalpy.



RESULTS AND DISCUSSION

Synthesis of the Ligands DO3ASQ and DO3ASQ-est. The ligands reported herein were prepared starting from diethyl squarate **2** (Scheme 2). The reactivity of this compound toward amines has been already investigated (*23*−*25*). Diethyl squarate may be selectively converted into the corresponding mono- or bis(amide)s (*26*, *27*) simply by varying the experimental conditions. Reaction of a slight excess of diethyl squarate **2** with DO3A−*tert*-butyl ester (**1**) in ethanol at room temperature gave, after silica gel chromatography, nearly quantitative yields of tetraester **3**.

Scheme 3

Scheme 4

The ligand **4** was obtained in good yield by reacting **3** with concentrated HCl/THF at room temperature, which promotes the simultaneous hydrolysis of the *tert*-butyl and ethyl ester groups.

^{13}C NMR Characterization of DO3ASQ and DO3ASQ-est Ligands. The ^{13}C NMR spectra of DO3ASQ and DO3ASQ-est provide useful insights to predict the coordination properties of these ligands. In fact, whereas the chemical shifts of the ^{13}C resonances of the macrocyclic ring and of the acetate arms (see Experimental Procedures) are very similar in the two ligands, a noticeable difference exists as far as the cyclobutenedione (squaric) group resonances are concerned. In DO3ASQ the squaric acid moiety gives raise to three resonances with the relative intensity ratio of 1:2:1 at 197.1 (C-3), 189.7 (C-2 and C-4), and 183.2 (C-1) ppm, respectively, owing to the delocalization of the negative charge (Scheme 3) as outlined by the remarkable downfield shift of C-3 with respect to C-2/C-4. On the other hand, in the case of DO3ASQ-est, there are four, equally intense, squaric ester derivative resonances at 190.3 (C-2), 184.8 (C-1), 175.4 (C-4), and 174.5 (C-3) ppm, respectively. Because it is well established that a heteroatom substituent (alkoxy or amino) deactivates the nonadjacent carbonyl group through resonance delocalization (*28*, *29*), the contribution of this resonance form A-2, reported in Scheme 4, is also evident from the large upfield shift of C-3. Thus, the strong upfield shift of C-3 suggests a large decrease of its carbonylic character, which is consistent with a shift in the equilibrium represented in Scheme 4. Besides the squaric acid resonances, the overall ^{13}C NMR spectrum of the DO3ASQ-est, recorded at 25 °C, supports this hypothesis as it shows 18 different signals resulting from the hindered rotation around the bond between carbon (C-1) of the squaric ester moiety and the macrocyclic nitrogen (i.e., vinylogous amide functionality).

Thus, we expect that in DO3ASQ the squaric moiety may participate in the chelation of a Ln^{3+} ion through the negatively charged oxygen at one of the equivalent C-2 or C-4 sites, whereas in DO3ASQ-est the coordination might involve either the oxygen of the carbonyl C-2 functionality or the estereal oxygen.

Chelation of the Gd(III) ions from both DO3ASQ and DO3ASQ-est occurs instantaneously, at room temperature, by mixing equimolar solutions of the reagents.

^{1}H and ^{17}O Relaxometric Investigations of DO3ASQ and DO3ASQ-est Gd(III) Complexes. The

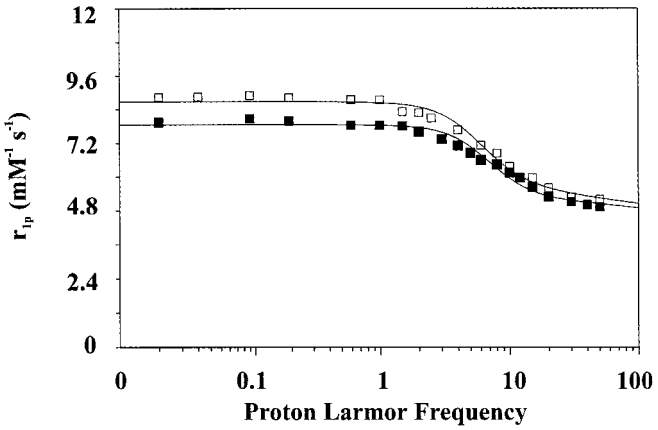

Figure 1. $1/T_1$ NMRD profile of a 1 mM aqueous solution of GdDO3ASQ (■) and GdDO3ASQ-est (□) at 25 °C and pH 7. The solid curves through the data points were calculated with the parameters of Table 1. The lower curves represent the outer sphere contributions to the overall relaxivity.

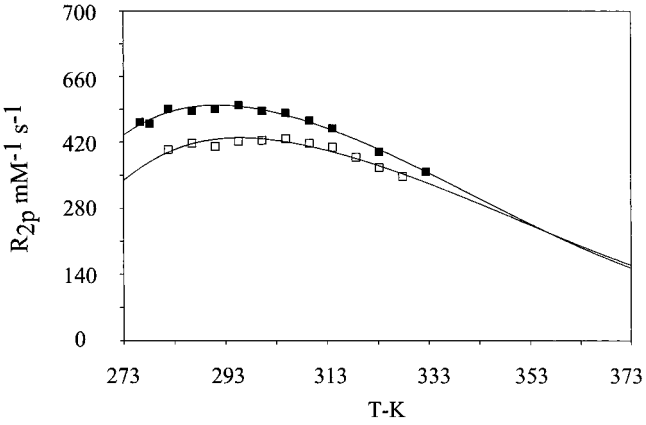

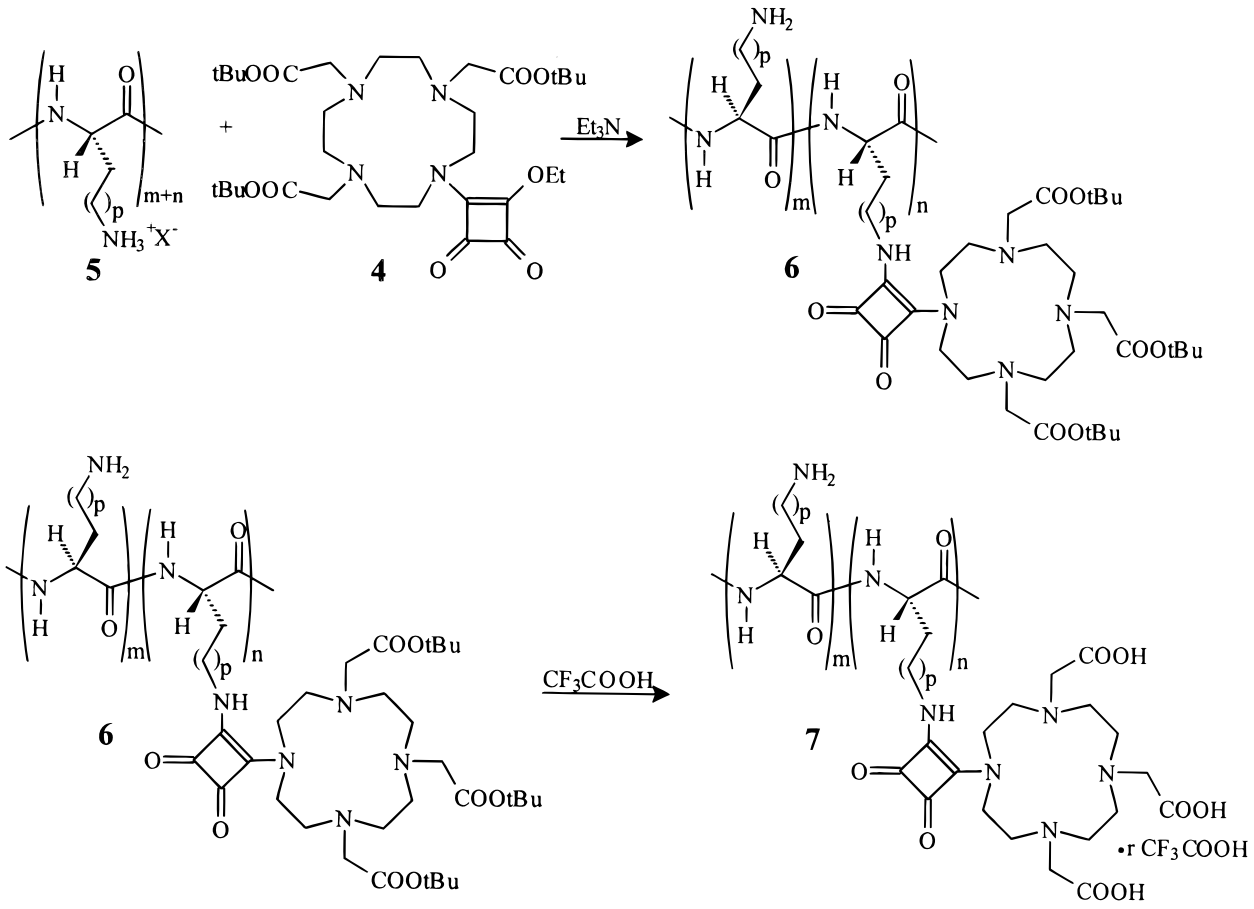

Figure 2. Temperature dependence of the transverse water ^{17}O relaxation rate at 2.1 T and pH 7 for 50 mM solution of GdDO3ASQ (■) and GdDO3ASQ-est (□). The solid curves through the data points were calculated with the parameters of Table 1.

relaxivities at 20 MHz and 25 °C of GdDO3ASQ and GdDO3ASQ-est are 5.3 and 5.6 mM^{-1} s^{-1}, respectively, that is, in the upper range of values for related polyamino polycarboxylate Gd(III) complexes containing one coordinated water molecule (q = 1) (*5*, *14*). The NMRD profiles of GdDO3ASQ and GdDO3ASQ-est (Figure 1) closely resemble those obtained for a number of DOTA-like Gd(III) complexes, and Table 1 shows the parameters obtained by fitting the experimental data to the Solomon−Bloembergen−Morgan and Freed equations. Thus,

Scheme 5

the occurrence of $q = 1$ implies that the squaric acid moiety is involved in the coordination scheme of these complexes.

A parameter particularly important for the forthcoming application of these complexes is represented by the residence lifetime of the coordinated water molecule at the metal site (τ_M). As has been demonstrated in several recent publications (*15*, *30*, *31*), the exchange rate of the coordinated water molecule (τ_M^{O-1}) may be accurately determined by the measurement of the solvent water $^{17}O-T_2$ at variable temperature. In fact, the temperature dependence of R_{2M}^O may be fitted in terms of the temperature dependence of τ_M^O, τ_v, and $\Delta\omega_M^O$. In Figure 2 the R_{2p}^O data for GdDO3ASQ and GdDO3ASQ-est measured over an extended temperature range are reported, and the calculated values of the relevant parameters obtained from the fitting procedure to the above-reported theory are shown in Table 1.

From this procedure we obtained, at 298 K, τ_M values of 134 ns for GdDO3ASQ and 200 ns for GdDO3ASQ-est. These values are similar to those reported for other DTPA- and DOTA-like Gd(III) complexes and are almost 1 order of magnitude shorter than those obtained at the same temperature for the corresponding complexes with bis(amide)−DTPA ligands. Thus, although still far from optimum τ_M values of 10−20 ns, which ensure maximum relaxation enhancement (*14*) for systems with long τ_R and T_{1E}, the exchange lifetime of the coordinated water in these Gd(III) chelates of squaric acid containing ligands should not represent a limiting factor in attaining a relaxation enhancement for conjugates in which the paramagnetic moiety is attached to macromolecular substrates of molecular mass up to 30−40 kDa.

Synthesis of the Conjugates with Polylysine and Polyornithine. The tetraester **3** (Scheme 5) was employed for the synthesis of polylysine−DO3ASQ and polyornithine−DO3ASQ conjugates. For this purpose we chose two polyamino acids endowed with a large difference in the number of monomeric units in their chain, that is, polylysine ($n = 16$) and polyornithine ($n = 114$). The "second amidation step" implied the reaction with an amino group in the presence of a base (generally a tertiary amine). Due to the low solubility of polylysine and polyornithine in solvents other than water, the coupling reaction was run in a water/ethanol mixture, in the presence of triethylamine. The reaction of the two polymers with **3** required 72 h to reach completion; the two conjugates were isolated by adding diethyl ether to a methanolic solution of the crude hydrolysis product. All of the added chelate bound almost quantitatively to yield $(DO3ASQ)_n-lys_{16}$ and $(DO3ASQ)_m-orn_{114}$ respectively. n and m numbers were estimated to be ∼3 and ∼30 on the basis of the observation that all of the added compound **3** was consumed. These numbers have been confirmed by the results of the titration with Gd^{3+} ions (vide infra). The number of chelate moieties on each polyamino acidic chain is an average value as we have not attempted any separation of the reaction products. The conjugates so obtained were directly used for the complexation of the paramagnetic ion.

Synthesis and Relaxometric Characterization of DO3ASQ−lys$_{16}$ and DO3ASQ−orn$_{114}$ Gd(III) Complexes. The dropwise addition of a $GdCl_3$ solution to 1 mM aqueous solutions of $(DO3ASQ)_n-lys_{16}$ and $(DO3ASQ)_m-orn_{114}$ at room temperature led to the prompt chelation of the metallic ions by the chelate moieties on the polyamino acidic substrate. The formation of the macromolecular complex has been monitored

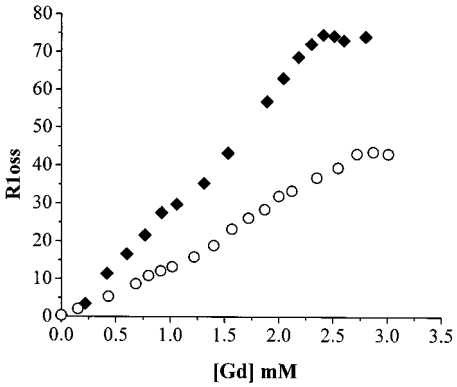

Figure 3. Longitudinal water proton relaxation rate of 0.078 mM $(DO3ASQ)_{30}-orn_{114}$ (◆) and 1 mM $(DO3ASQ)_3-lys_{16}$ (○) ligand solutions as a function of the Gd(III) ion concentration added to solutions.

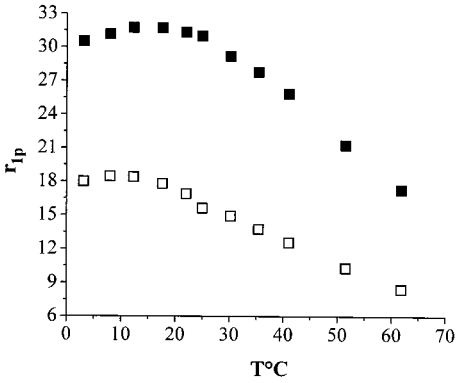

Figure 4. Temperature dependence of the longitudinal proton relaxivity at 20 MHz and pH 7 of $Gd(DO3ASQ)_{30}-orn_{114}$ (■) and $Gd(DO3ASQ)_3-lys_{16}$(□) water solutions.

by measuring the relaxation time of the water protons. Each addition of Gd(III) ions corresponds to an increase of the observed relaxation rate (not a linear increase as the successive coordination of metal ions causes a progressive increase of the molecular weight and an eventual change in the overall polymer structure). The titration end point (Figure 3) is clearly detected and allows us to establish the relative metal chelate/polyamino acid ratio, thus yielding the following stoichiometries: $Gd(DO3ASQ)_3-lys_{16}$ (MW ≅ 5000) and $Gd(DO3ASQ)_{30}-orn_{114}$ (MW ≅ 35000); their relaxivities are 15.6 and 31.0 mM^{-1} s^{-1}, respectively. To get more insight into the understanding of the various parameters determining the observed relaxivities of these paramagnetic macromolecular complexes, we measured both the temperature dependence of proton r_{1p} at 0.47 T and the temperature dependence of $^{17}O-R_2$ at 2.1 T. From the data reported in Figure 4, it is clearly shown that from room to high temperature, the relaxivities of $Gd(DO3A)_3-lys_{16}$ and $Gd(DO3A)_{30}-orn_{114}$ are not limited by τ_M; that is, the condition $T_{1M} > \tau_M$ holds (eq 1). At lower temperatures the decreased exchange rate and the concomitant shortening of T_{1M} (as a consequence of the elongation of τ_R) yield the typical flattening of the profile of r_{1p} versus T, expected for systems whose $\tau_M > T_{1M}$. This is confirmed by analyzing the water $^{17}O-R_{2p}$ variable temperature profiles (Figure 5) from which the τ_M values obtained for both macromolecular complexes are relatively short and similar to those determined for the free Gd complexes. Table 2 shows that the other parameters and the reorientational correlation time (τ_R) display values comparable to those of the free complexes. This finding supports the view that each Gd ion owns one water molecule, pointing

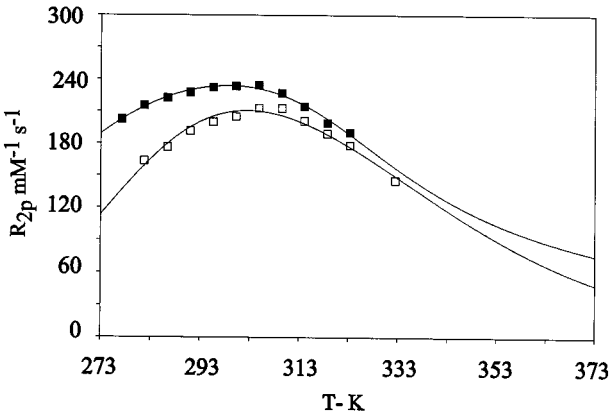

Figure 5. Temperature dependence of the transverse water ^{17}O relaxation rate at 2.1 T and pH 7 for 11.0 mM solutions of $Gd(DO3ASQ)_{30}$−orn_{114} (■) and $Gd(DO3ASQ)_3$−lys_{16} (□). The solid curves through the data points were calculated with the parameters of Table 2.

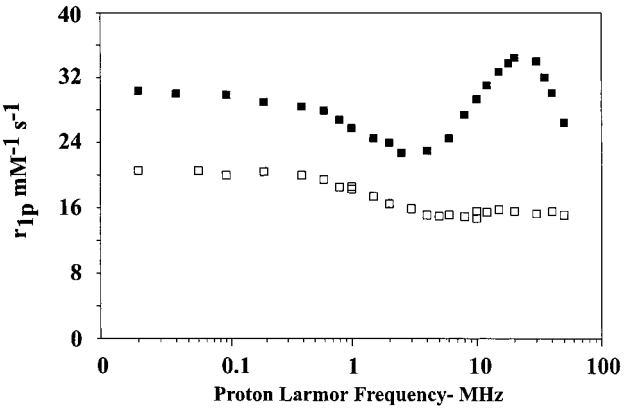

Figure 6. $1/T_1$ NMRD profile of a 1 mM aqueous solution of $Gd(DO3ASQ)_{30}$−orn_{114} (■) or $Gd(DO3ASQ)_3$−lys_{16} (□) at 25 °C and pH 7.

out that the squaric group maintains its ability to coordinate the metal ion. The linkage to the polyamino acidic residue yields to the transformation of one of the $C_{(2/4)}$−O bonds of the squaric acid moiety into a C−N bond; thus, it seems likely that the coordination to the Gd(III) center occurs through the carbonyl (C-2) functionality. On this basis it seems likely that an analogous binding scheme may occur also in the case of the monomeric GdDO3ASQ-est.

The NMRD profiles of $Gd(DO3A)_3$−lys_{16} and $Gd(DO3A)_{30}$−orn_{114} (Figure 6) show a relaxivity increase at ∼20−30 MHz typical of slowly tumbling paramagnetic systems. Only in the case of $Gd(DO3A)_{30}$−orn_{114} does the NMRD profile display the shape of the relaxivity peaks commonly found for paramagnetic protein conjugates. Furthermore, the extent of the observed relaxivity enhancements is not proportional to the molecular weights of the two systems to suggest that large internal motions overlap the reorientational processes of the whole molecules. As in the case of the noncovalent paramagnetic adducts with albumin, the data in the low-field region of the NMRD profile cannot be fitted with the r_{1p} values calculated on the basis of the Solomon−Bloenbergen−Morgan theory. Likely, the high relaxivities observed in the 0.01−3 MHz region are indicative of additional contributions arising mainly from water molecules bound to the surface of the macromolecular substrate in the proximity of the paramagnetic center (*32*, *33*).

CONCLUDING REMARKS

In summary, the results herein reported show that, for the formation of conjugates with macromolecular substrates, an easy alternative to the use of DTPA anhydride is now available leading to Gd(III) chelates that display quite good relaxivities and do not suffer the limitation of the long exchange lifetime. Particularly interesting is the $(GdDO3ASQ)_{30}$−orn_{114} conjugate, which has an r_{1p} value, at 39 °C, of 26.5 mM^{-1} s^{-1}, significantly higher than the r_{1p} values reported by Brasch et al. for other macromolecular CAs such as $(GdDTPA)_n$−polylysine (r_{1p} = 13.1 mM^{-1} s^{-1}) and $(GdDTPA)_n$−albumin (r_{1p} = 14.4 mM^{-1} s^{-1}), respectively (*1*).

Furthermore, with respect to the use of DTPA−bis(anhydride), there is the advantage that, by applying the method herein described, no cross-linking between the macromolecular chain occurs. The easiness found in the anchoring procedure of the chelate moiety to the macromolecular substrates suggests that this route based on squaric acid conjugates may find a wide generalization. As far as the specific substrates considered in this work are concerned, polyamino acidic chains containing a high number of Gd(III) chelates may be used as high relaxivity markers for systems able to target selected tissues or organs.

ACKNOWLEDGMENT

Financial support from Bracco S.p.A. (Milano, Italy), CNR, and MURST is gratefully acknowledged. This work was carried out under the scheme of the EU-COST-D8 Program and the EU-BIOMED II-MACE Project. We gratefully acknowledge the stimulating discussion with Prof. I. Bertini, C. Luchinat, L. Casella, and their collegues.

Synthesis and Characterization of Photoreactive Insulin-like Growth Factor 1 Derivatives for Receptor Analysis

Marlies Fabry*

Deutsches Wollforschungsinstitut an der RWTH Aachen e.V., 52062 Aachen, Germany. Received May 19, 1998; Revised Manuscript Received September 23, 1998

Recombinant human insulin-like growth factor 1 (hIGF-1) was reacted with 4-azidosalicylic acid (Asa) to synthesize photoreactive IGF-1 derivatives. Depending on the time of reaction and the Asa/IGF-1 ratio, a mixture of mono-, bis-, and trisacylated derivatives and one tetraacylated derivative was produced, which was separated by reversed-phase HPLC. HPLC, PAGE, and MALDI mass spectrometry were used to determine the degree of the acylation and location of the photolabel insertion. After iodination of the three monoacylated photoreactive IGF-1 derivatives, the specific labeling of the receptor could be proved. Together with a comparative investigation in which B29-Asa−insulin was used, the results suggest corresponding contact areas for IGF-1 and insulin with the insulin receptor ectodomain.

INTRODUCTION

Insulin-like growth factor 1 (IGF-1)[1] is a growth factor that exhibits structural and functional homology to insulin. The single-chain protein consists of 70 amino acids forming four peptide domains: the B (1−29), C (30−41), A (42−62), and D domains (63−70). The A and B domains are structurally homologous to the insulin A and B chains; the C domain corresponds to the C peptide of proinsulin, while the D domain does not have an equivalent in proinsulin or insulin. As in insulin, six cysteine residues form three disulfide links (Rinderknecht and Humbel, 1978; Blundell et al., 1983). Whereas IGF-1 has a key function in the regulation of cellular proliferation and differentiation, insulin regulates a broad spectrum of metabolic processes. The action of both polypeptide hormones is mediated by the interaction with their specific membrane receptors.

Like their ligands, the insulin and IGF-1 receptor exhibit a remarkable homology with regard to their amino acid sequence and molecular structure. Both receptors have the same heterotetrameric $\alpha_2\beta_2$ structure. The ligand-binding α-domains are completely extracellular and have a cysteine-rich domain. The β-subunits cross the plasma membrane and contain the cytoplasmatic phosphotyrosine kinase domain. Ligand binding induces autophosphorylation of the receptors and subsequently phosphorylation of cytoplasmatic proteins (Ullrich et al., 1985, 1986; Ebina et al., 1985).

Despite the high degree of homology of the ligands as well as the receptors, insulin and IGF-1 exhibit only weak cross reactivity. The affinity of binding of each ligand to the receptor of the other ligand is about 1% (Kjeldsen et al., 1991; Schumacher et al., 1991). Nevertheless, cross reactivity and homology between ligands and receptors suggest an analogous mechanism of ligand−receptor interaction for IGF-1 and insulin.

Photoaffinity labeling is a powerful chemical approach in structural biology (Kojro et al., 1993; Zhou et al., 1997) and has already proven to be very useful in the identification of the area of binding of insulin to its receptor (Wedekind et al., 1989; Yip, 1992; Fabry et al., 1992; Whaugh et al., 1989; Kurose et al., 1994). Analogous studies with the IGF-1 receptor should now provide additional information about the ligand specificity. In this paper, the preparation and characterization of photoreactive IGF-1 derivatives are reported. These derivatives were used to label IGF-1 receptors and to further investigate the IGF-1 and insulin receptor systems.

MATERIALS AND METHODS

Chemicals. Recombinant human insulin-like growth factor 1 (hIGF-1) was a donation from Lilly Research Laboratories (Indianapolis, IN). HPLC-grade acetonitrile, TFA, and TPCK−trypsin were from Merck. Carrier-free ^{125}I was purchased from Amersham. 4-(Azidosalicyloyl)-*N*-hydroxysuccinimide ester was synthesized as described elsewhere (Fabry and Brandenburg, 1992). Human IGF-1 receptor was isolated from transfected NIH-3T3 fibroblasts (Lammers et al., 1989). Clones of transfected CHO-K1 cells that overexpress the IR921 protein were selected. This is the soluble ectodomain of the human insulin receptor in which the heterotetrameric $(\alpha\beta_0)_2$ receptor was truncated following residue 921 (Schaefer et al., 1992).

Preparation of Asa−IGF-I Derivatives. Asa-OSu was dissolved in DMF (90 μg/10 μL) and added in 4 portions to a 70 μL solution containing 500 μg of IGF-1 dissolved in 0.1 M sodium phoshate buffer (pH 7.4) which was being stirred at room temperature protected from light. After 5−10 min, the reaction was quenched with 10 μL of ethanolamine. The mixture was separated on a Sephasil C-18 SC 2.1/10 column using the SMART system (Pharmacia) and a gradient from 20 to 48%

acetonitrile in 0.1% TFA over the course of 90 min. The proteins were detected by measuring the absorbance at 214, 256, and 280 nm. Fractions were collected automatically into 0.5 mL Eppendorf tubes and lyophilized by SpeedVac vacuum centrifugation.

Degree of Acylation and Location of the Photolabel. The different Asa−IGF-1 derivatives separated by reversed-phase HPLC were analyzed by acid−urea PAGE with 8 M urea and 0.9 M acetic acid at pH 4 using a 15% polyacrylamide gel (Poole et al., 1974) and MALDI mass spectrometry to determine the degree of acylation. The mass spectra were obtained on a Bruker Biflex III TOF instrument (Bruker-Franzen Analytik, Bremen, Germany) equipped with a 337 nm nitrogen laser using sinapinic acid as the matrix, acetonitrile/TFA as the solvent, and standard experimental parameters (3 ns pulse duration, linear mode, 100−150 laser spots). To locate the position of the photolabel, IGF-1 and the monoacylated products were digested with trypsin after reduction and carboxymethylation (Honegger and Humbel, 1986). The digests were subjected to MALDI mass spectrometry to evaluate the change of the fragmentation pattern compared to that of unlabeled IGF-1. For reduction and carboxymethylation of disulfide bonds, the lyophilized proteins (10 μg) were dissolved in 20 μL of 6 M guanidinium hydrochloride, 0.5 M Tris, and 5 mM EDTA (pH 8.5) containing 40 nmol of dithiothreitol, flushed with nitrogen, and kept at room temperature in darkness for 3 h. Then, 400 nmol of iodoacetic acid was added, and the solution was further incubated under nitrogen for 2 h. The reaction was stopped by addition of 2 μL of mercaptoethanol. The proteins were desalted by reversed-phase HPLC with the same column using a 90 min gradient from 16 to 48% acetonitrile in 0.1% TFA at a flow rate of 100 μL/min and dried. The reduced products were identified by acid−urea PAGE. The enzymatic cleavage was performed by addition of 0.5 μg of TPCK−trypsin to the proteins dissolved in 30 μL of 0.1 M ammonium bicarbonate (pH 8), followed by incubation at room temperature for 18 h. To stop the reaction, 0.1% TFA was added and proteins were dried by SpeedVac vacuum centrifugation and washed with water twice. The digestion products were then studied with MALDI mass spectrometry.

Radioiodination/Iodine Analysis. IGF-1 and the Asa−IGF-1 derivatives were iodinated according to the chloramine T method (Yip et al., 1993) with the following modification of reaction conditions; 4 μg of IGF-1 or the derivative was dissolved in 20 μL of 0.4 M sodium phosphate buffer (pH 7.5), and then 100 μCi of carrier-free ^{125}I (IMS 30, Amersham) was added. Iodination was started by addition of 5 μL of chloramine T (100 ng/1 μL of 0.04 M sodium phoshate buffer) and continued for 3 min at room temperature. The reaction was stopped by adding 10 μL of tyrosine (0.2 mg/mL) and KI (1 mg/mL). The reaction mixture was applied to a SepPak C-18 cartridge (Waters Corp.) that had been equilibrated with 0.1% TFA/acetronitrile (90/10 v/v). After washing, the iodinated derivatives were eluted with 60% acetronitrile in 0.1% TFA into 50 mM ammonium bicarbonate, lyophilized, and stored at −20 °C. To define the ^{125}I position, approximately 50 000 cpm carboxymethylated protein was digested with TPCK−trypsin as described above, and the digest was separated by reversed-phase HPLC with a gradient of 15 to 40% acetonitrile in 0.1% TFA over the course of 100 min at a flow rate of 100 μL/min.

Assay of IGF-1 Receptor Binding. Binding of [^{125}I]-IGF-1 to plasma membranes of NIH-3T3 cells (50 μg of protein/sample) and competition with IGF-1 and the Asa−IGF-1 derivatives were assessed as described previously (Schumacher et al., 1991). Plasma membranes were prepared according to a previously published procedure (Breiner et al., 1993).

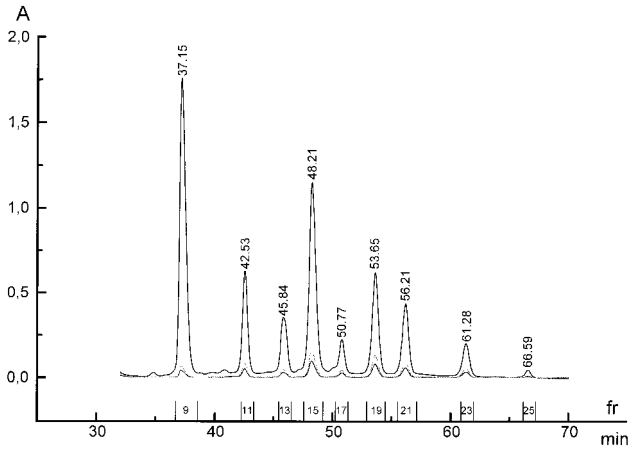

Figure 1. Reversed-phase HPLC separation of the reaction mixture of 4-(azidosalicyloyl)-*N*-hydroxysuccinimide (Asa-OSu) with IGF-1. Fifty micrograms of the reaction mixture was loaded onto a C-18 column and separated with a flow rate of 100 μL/min using a 20 to 48% acetonitrile gradient over the course of 90 min. Proteins were monitored at 215, 256, and 280 nm. IGF-1 and the Asa derivatives were identified by acid−urea PAGE (Figure 2) and MALDI mass spectrometry (Table 1).

Photoaffinity Labeling. Plasma membranes (protein content of at least 30 μg) prepared from NIH-3T3 fibroblasts or IR921 were incubated with the photoreactive IGF-1 derivatives (approximately 500 000 cpm, 2.95 nM) in 50 μL of KRH buffer [50 mM Hepes, 13 mM NaCl, 5.1 mM KCl, and 1.3 mM Mg_2SO_4 (pH 7.8)] at 15 °C for 90 min. Membrane pellets were washed once with KRH buffer and photolyzed by irradiation with three flashes (each 1000 Ws) of an UV flash apparatus ("Lizzy", Raytest) in 20 μL of KRH buffer. When the soluble IR921 was labeled, noncovalently bound ligand was removed by precipitation with polyethylene glycol and γ-globulin after photolysis (Fabry et al., 1992). The membrane pellets were solubilized in SDS sample buffer in the presence of dithiothreitol and analyzed by SDS−PAGE (7.5%). Gels were dried prior to autoradiography.

Time Course of the Tryptic Digestion of the Photoaffinity-Labeled Ectodomain. IR921 was labeled with B29-Asa−insulin and B27-Asa−IGF-1. Digestion was carried out with 30 μg/mL TPCK−trypsin at room temperature (reaction times indicated). Aliquots were taken, and the reaction was stopped by addition of Laemmli sample buffer and heating for 5 min at 95 °C and analyzed by SDS−PAGE (12.5%).

RESULTS AND DISCUSSION

Preparation of Asa−IGF-1 Derivatives. By reaction of the photoreagent, the *N*-hydroxysuccinimide ester of 4-azidosalicylic acid, with unprotected IGF-1, four free amino groups, the α-amino group in B1 and the three ϵ-amino groups of B27-, D65-, and D68-lysine, can be substituted. The resulting mixture of reaction products, varying in degree and site of acylation, can be separated by reversed-phase HPLC due to differences in charge and hydrophobicity (Figure 1).

Proteins were detected at the leading wavelength of 214 nm. Two secondary wavelengths at 256 and 280 nm were of interest for the detection of aromatic or modified amino acids. Since the photolabel also absorbs at 256 and 280 nm, the absorbance ratios A_{214nm}/A_{256nm} and $A_{214nm}/$

Table 1. Absorbance Ratios of the HPLC Fractions for Reaction of Asa-OSu with IGF-1 (Figure 1)[a]

HPLC fraction	A_{214nm}/A_{256nm}	A_{214nm}/A_{280nm}	A_{256nm}/A_{280nm}	assumed number of photogroups
9	45.0	28.0	0.63	0
11	12.9	8.1	0.7	1
13	16.2	10.4	0.64	1

[a] Absorptions were simultaneously monitored at 214, 256, and 280 nm.

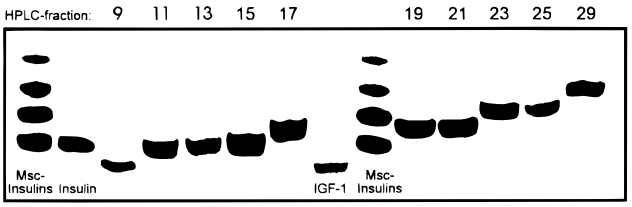

Figure 2. Acid−urea PAGE of the HPLC fractions, and reaction of Asa-OSu with IGF-1 (Figure 1). Msc-insulins are a standard mixture of differently charged insulins. Fraction 9 contains unmodified IGF-1 with the same mobility as the standard IGF-1. Fractions 11, 13, and 15 correspond to monoacylated, fractions 17, 19, and 21 to bisacylated, and fractions 23 and 25 to trisacylated Asa−IGF-1, and fraction 29 corresponds to tetraacylated Asa−IGF-1.

A_{280nm} change characteristically with the degree of acylation (Table 1). Thus, a first classification of the products according to their degree of acylation was possible. Fraction 9 exhibits the typical absorption characteristics of native IGF-1 ($45A_{214nm}/A_{256nm}$ and $28A_{214nm}/A_{280nm}$).

The acid−urea PAGE (Figure 2) confirmed that fraction 9 contained IGF-1 and fractions 11, 13, and 15 the monoacylated products, followed by three bisacylated IGF-1 derivatives (fractions 17, 19, and 21), and two trisacylated products (fractions 23 and 25). When the reaction was carried out with a 5-fold excess of active ester and a reaction time of 5 min, 29% of the IGF-1 was not modified, 41% monoacylated, 23% bisacylated, and 4% trisacylated. With the same Asa-OSu/IGF-1 ratio and a longer reaction time, there was actually less educt, but the amount of more highly acylated products increased considerably: 4% nonacylated IGF-1 and 11% monoacylated, 33% bisacylated, 46% trisacylated, and 7.5% tetraacylated IGF-1 derivatives (see Figure 2, fraction 29).

For native IGF-1, the mass determined by MALDI mass spectrometry corresponds to the calculated mass. For the Asa−IGF-1 derivatives, mass shifts of 1−3-fold minus 28 Da were found in addition to the expected data.[2] The mass spectrum for B27-Asa−IGF-1 is given in Figure 3. This mass shift can be explained by a partial photoactivation of the aryl azides effected by the laser energy of the spectrometer during measurement leading to the formation of nitrene with elimination of nitrogen and possibly an addition of two atoms of hydrogen. Normally, this reaction leads to a covalent binding to the receptor.

Location of the Photolabel. Tryptic digestion of reduced IGF-1 leads to the formation of six fragments, T1−T6 (Rinderknecht and Humbel, 1978; Honegger and Humbel, 1986). The substitution sites of the photolabel at B1-glycine, B27-lysine, or D65/D68-lysine are within

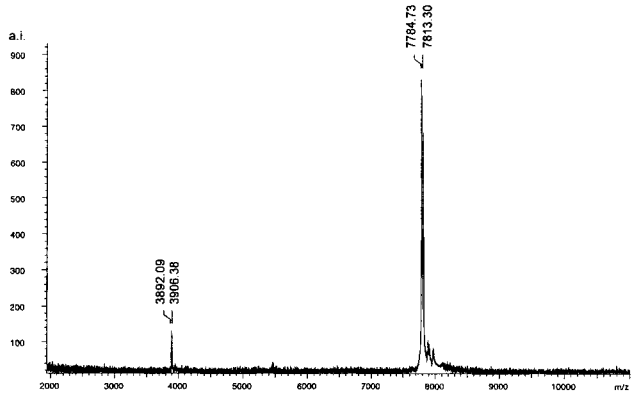

Figure 3. MALDI mass spectrum of B27-Asa−IGF-1 (calculated mass of 7810.3 Da; fraction 11 of the reversed-phase HPLC separation, Figure 1). In addition to the observed mass of 7813.3 Da, a second peak with a mass 28.6 Da lower and the corresponding doubly protonated proteins were detected. The spectrum was recorded using sinapinic acid as the matrix.

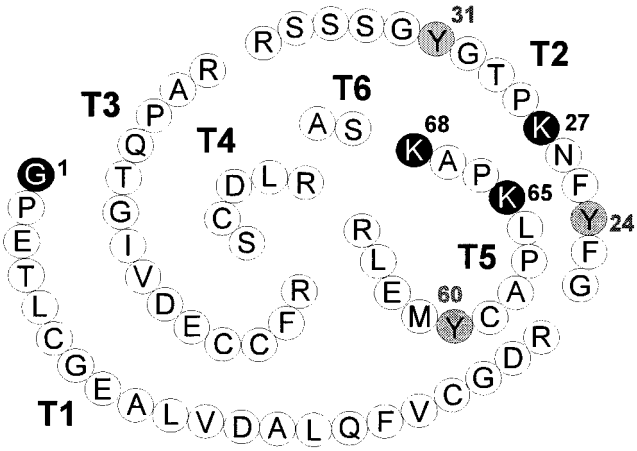

Figure 4. Amino acid sequence of IGF-1 showing tryptic peptides T1−T6, the acylation sites of the photolabel Asa (black), and the positions of iodination (gray).

tryptic fragments T1, T2, or T5, respectively (Figure 4). The mass values of the fragments are changed characteristically due to substitution.

IGF-1 and the three monoacylated IGF-1 derivatives were reduced, carboxymethylated, and treated with trypsin after reversed-phase HPLC purification. The peptides were analyzed by MALDI mass spectrometry.

Under the conditions used, trypsin cleaved IGF-1 and its derivatives completely and as expected.[3] Additionally, at the sequence position S^{C35}-R^{C36}-R^{C37}-A^{C38}, a shifting of the cleavage occurred. As a result, tryptic fragment T2 with two C-terminal arginines and tryptic fragment T3 without the N-terminal arginine were found. At the second position with two arginine residues in sequence, L^{A54}-R^{A55}-R^{A56}-L^{A57}, cleavage occurred only between the two arginines.

The mass analyses of the tryptic fragments of the three monoacylated IGF derivatives confirmed the complete elimination of nitrogen from the photofragments. In fraction 11, a mass shift of the tryptic fragment T2 from 1668.78 to 1803.76 Da was observed, corresponding to the activated photogroup (Figure 5). In fraction 15, this caused a shift of the mass of fragment T1 from 2310.28 to 2445.07 Da. Due to the acylation at D68-lysine, no tryptic cleavage of the peptide of fraction 13 was possible.

[2] Interested investigators can request molecular mass data from Fabry@dwi.rwth-aachen.de.

[3] Molecular mass data also available via e-mail from Fabry@dwi.rwth-aachen.de.

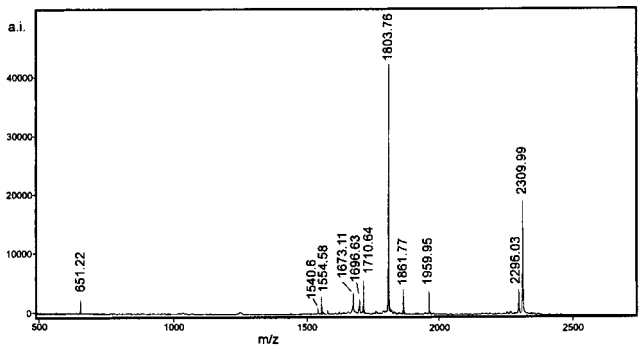

Figure 5. MALDI mass spectrum of the tryptic peptide map of B27-Asa−IGF-1. In addition to the native tryptic peptides, a peak at *m*/*z* 1803.76 corresponding to the photofragment T2 with Asa in position B27 was observed. The spectrum was recorded using α-cyano-4-hydroxycinnamic acid as the matrix.

Therefore, this photofragment was enlarged not only by the mass of the activated photogroup but also by the two C-terminal amino acids serine and alanine. As a result, it could be confirmed that fraction 11 contained B27-Asa−IGF-1 (t_R = 42.53 min, Figure 1), fraction 13 D68-Asa−IGF-1 (t_R = 45.84 min), and fraction 15 B1-Asa−IGF-1 (t_R = 48.21 min). The derivative acylated in position B27 was of special interest, because here the photogroup is directly located within the postulated binding area (Blundell et al., 1983).

Radioiodination and Analysis of the Position of ^{125}I. To verify that after tryptic digestion of radioactive IGF−receptor conjugates the resulting binding fragments are still detectable, the insertion of iodine was investigated. Iodine can be inserted onto three tyrosine residues in positions 24, 31, and 60 (Figure 4), as well as into the photolabel itself. Under the conditions used, radioiodination of IGF-1 results in the formation of three monoiodo isomers and radioiodination of the mono-Asa−IGF-1 derivatives forms four isomers.

To clarify the site of iodination, radiolabeled IGF-1 and the three mono-Asa−IGF-1 derivatives were reduced, carboxymethylated, and digested with trypsin. Since fragments T1 and T3 only contain phenylalanine, fragment T5 only contains tyrosine, and fragment T2 contains phenylalanine as well as tyrosine, typical absorbance ratios were obtained. The elution profile given in Figure 6 and the assignment were identical to the tryptic peptide map of Honegger and Humbel (1986), who determined the primary structure of the hormone isolated from bovine serum. The tryptic mapping of [^{125}I]IGF-1 revealed the presence of three radioactive peaks. They correspond to tryptic fragment T5 with iodine in position tyrosine 60 and to fragment T2, one with iodine in position tyrosine 24 and one in position tyrosine 31 (Figure 4). When the photolabel is inserted into position B1, tryptic fragment T1 that is not radioactive without the photolabel now is radioactive. Therefore, the reversed-phase HPLC separation of the tryptic map of B1-Asa−IGF-1 shows a fourth radioactive peak neighboring fragment T1 (Figure 6, t_R = 74.4 min); here, 30% of the iodine was inserted into the N-terminal photolabel (Figure 6, histogram). Fragments T2 and T5 are radioactive without photolabel, but the elution time of the photofragments is much longer compared to those of the radioactive fragments without photolabel. Iodine is inserted into position tyrosine 60 of B27-Asa−IGF-1 to a small extent; iodination of tryptic fragment T2 (with two tyrosine residues and one photogroup) is strongly preferred. For fragment T5, insertion of the photolabel in D65/D68 increases the iodine uptake from 11 to 21%.

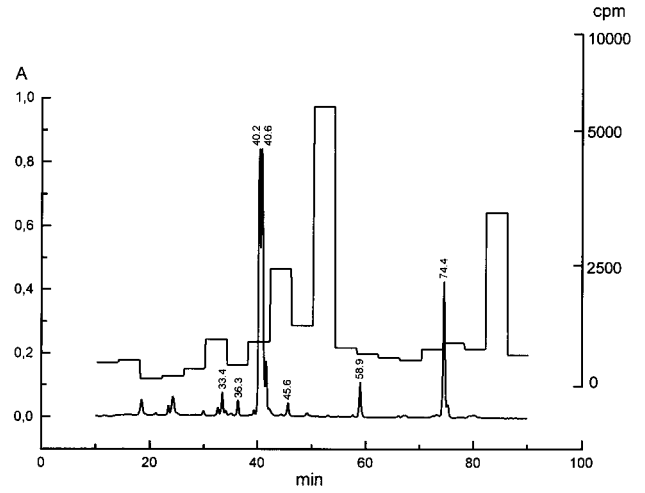

Figure 6. Reversed-phase HPLC separation of the tryptic peptide map of carboxymethylated IGF-1 (lower UV curve) with the corresponding radioactivity profile of B1-Asa−IGF-1 (upper histogram). The digest was fractionated on a C-18 column at a flow rate of 100 μL/min using a 10 to 40% acetonitrile gradient over the course of 100 min. Fractions (400 μL) were collected, and the amount of radioactivity was counted.

Table 2. Receptor Binding of Native IGF-1 and Asa−IGF-1 Derivatives

HPLC fraction	derivative	$K_D \pm$ SD (nM)	relative biological binding affinity (%)

23	tris-Asa−IGF-1	12 ± 1.68	6.3
25	tris-Asa−IGF-1	9.2 ± 1.47	7.9
27	tris-Asa−IGF-1	18 ± 1.62	4.1
29	tetra-Asa−IGF-1	15 ± 1.05	4.8

As a conclusion, it can be expected that after tryptic digestion of the covalent hormone−receptor conjugate binding fragments are still detectable because the point of receptor labeling and ^{125}I would not be separated.

Receptor Binding Studies. To determine the binding characteristics of the photo-IGF-1 derivatives, saturation binding experiments were carried out with [^{125}I]IGF-1 on plasma membranes of NIH-3T3 cells that overexpress wild-type IGF-1 receptors (Table 2). The binding affinities of the three monoacylated photo-IGF-1 derivatives differed considerably, indicating the importance of the substituted positions for receptor binding. The severest impairment of receptor binding was caused by a modification of position B27, which is within the postulated binding area. The derivative acylated in position B1 showed an even slightly higher binding affinity than native IGF-1, indicating that this position is not significantly involved in receptor binding. The binding affinity of the derivative with modification of the C-terminal D domain was intermediate. As expected, the binding affinity decreased with a further increase in the degree of acylation, with the exception of a bisacylated derivative that showed a rather low binding affinity of 4.8% compared with that of IGF-1.

Photoaffinity Labeling. Figure 7A shows the results of the photoaffinity labeling of plasma membranes of NIH-3T3 cells overexpressing the human IGF-1 receptor with the three mono-Asa−IGF-1 derivatives analyzed by SDS−PAGE. Specifically labeled bands with M_rs of

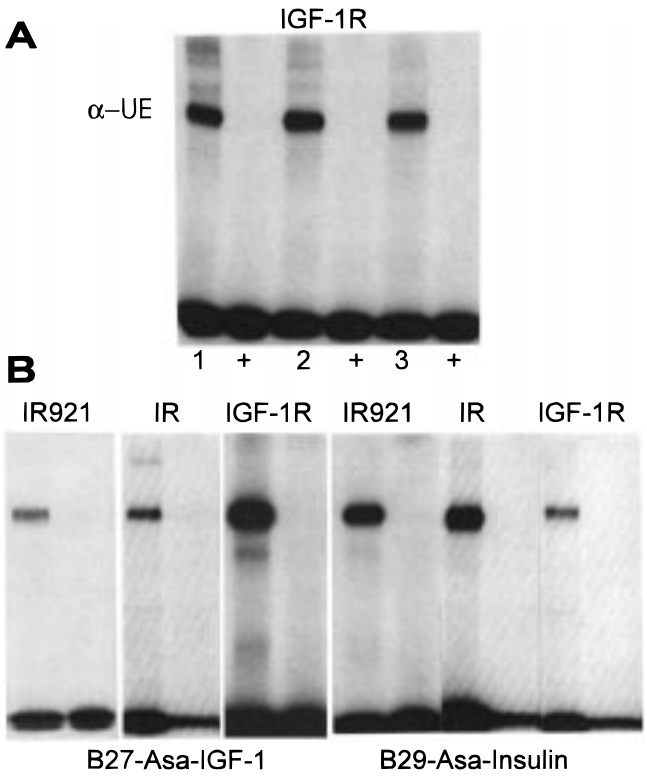

Figure 7. (A) Photoaffinity labeling of the IGF-1 receptor with B27-Asa−IGF-1 (1), D65/D68-Asa−IGF-1 (2), and B1-Asa−IGF-1 (3). Lanes marked with + are protein labeling (control) with an excess of IGF-1 (10^{-5} M). (B) Photoaffinity labeling of the IGF-1 receptor (IGF-1R), insulin receptor (IR), and insulin receptor ectodomain (IR921) with B27-Asa−IGF-1 and B29-Asa−insulin, as analyzed by SDS−PAGE under reducing conditions and autoradiography.

120 000 Da correspond to the hormon binding α-subunit. The B1-, B27-, and D65/D68-Asa−IGF-1 derivatives revealed no detectable difference in the degree of labeling of the receptor. The efficiency of photolabeling was approximately 10% (calculated as the extent of incorporation of radioactivity into the IGF-1 receptor α-subunit vs the total amount of radioactivity applied onto SDS−PAGE). In Figure 7B, the photoaffinity labeling of insulin receptor ectodomain (IR921), native insulin (IR), and IGF-1 receptors (IGF-1R) of NIH-3T3 cells with B27-Asa−IGF-1 and B29-Asa−insulin is compared. Photo-IGF-1 labels the insulin receptor and vice versa; photoinsulin also labels the IGF-1 receptor. The soluble ectodomain is strongly labeled by insulin (maximum of 40%) but only weakly by IGF-1 (approximately 5%).

The tryptic peptide maps of the photoinsulin and IGF-1 IR921 conjugates are very similar (Figure 8). SDS−PAGE of the cleavage products under reducing conditions indicated for labeling with photoinsulin major fragments of 97, 72, 59, 31, 28, and 22 kDa and for labeling with photo-IGF-1 of 94, 68, 58, 32, 29, 24, and 23 kDa. For both labels, weak bands at 43 and 13 kDa were also observed. The high correspondence of the digestion pattern indicates identical fragments and thus identical binding areas.

The synthesis of a series of photoreactive hormone derivatives for cross-linking described here will facilitate the construction of a detailed interaction map of the insulin and IGF-1 receptors and their ligands. Synthesis and radioiodination of the ligands as well as photoaffinity labeling of the receptors are possible within a short period of time. The method presented is a powerful tool for detecting and comparing specific binding areas of ligands and their receptors.

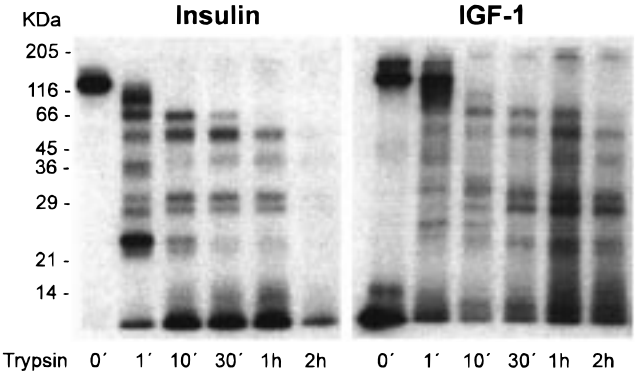

Figure 8. Time course of the tryptic digestion of the insulin receptor ectodomain labeled with B29-Asa−insulin and B27-Asa−IGF-1. Receptors were photoaffinity labeled as described in Materials and Methods. At the indicated time points, aliquots were withdrawn and analyzed by SDS−PAGE (12.5%) and autoradiography.

ACKNOWLEDGMENT

We thank Lilly Research Laboratories (Indianapolis, IN) for providing recombinant human insulin-like growth factor 1 (hIGF-1) and Dr. E. Schaefer (Quality Controlled Biochemicals, Hopkinton, MA) for the insulin receptor ectodomain IR921. The NIH-3T3 cell lines overexpressing the human IGF-1 and insulin receptor were kindly provided by Prof. A. Ullrich (MPI für Biochemie, Martinsried, Germany). I thank Dr. D. Waidelich (PerSeptive Biosystems, Wiesbaden, Germany) for the mass spectra of the tryptic digests and Mr. S. Rütten for his technical assistance. This work was supported by a Lise Meitner Grant from the Ministry of Higher Education and Research of the State of North Rhine-Westphalia.

Optimized Conditions to Couple Two Water-Soluble Biomolecules through Alkylamine Thiolation and Thioetherification

Laurent Meunier, Sylvain Bourgerie, Roger Mayer, Annie-Claude Roche, and Michel Monsigny*

Glycobiologie, Centre de Biophysique Moléculaire, CNRS, Rue Charles Sadron, 45071 Orléans Cedex 02, France. Received June 16, 1998; Revised Manuscript Received October 5, 1998

A simple method for introducing, in buffered saline, a reactive sulfhydryl group on water-soluble molecules bearing an alkyl-amino group is described. This method is based on the use of two water-soluble reagents: 2-iminothiolane and 6,6′-dithiodinicotinic acid. The first one is open upon reaction with an amino group, and the generated thiol group is immediately protected by action of the second reagent. The optimal conditions were determined by taking into account the stability and the reactivity of both reagents with regards to pH and temperature. This method was validated through two applications, the substitution of bovine serum albumin with a bromoacetyl peptide and the substitution of an amino link at the 5′ end of an oligonucleotide by reaction with either a fluorescent tag, iodoacetamidofluorescein, or a bromoacetyl peptide, upon reduction of the protected disulfide bridge with a third water-soluble reagent, namely tris(2-carboxyethyl)phosphine.

INTRODUCTION

A number of molecules, including antibodies (Carlsson et al., 1978; Duncan et al., 1983; Karacay et al., 1997), enzymes (Yoshitake et al., 1979), liposomes (Lasch et al., 1987), or toxins (Lambert et al., 1985) have been thiolated and then substituted with other molecules.

One of the procedures used for the preparation of protein conjugates is to link the two partners through either a disulfide bridge or a thioether bond. Heterobifunctional reagents such as *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) (Carlsson et al., 1978), *S*-acetyl thioacetic acid (Duncan et al., 1983), or homocysteine thiolactone (Leanza et al., 1992) are commonly used to add a thiol group to a protein.

Alternatively, 2-iminothiolane, which reacts with an amino group and generates a free thiol group (Traut et al., 1973; Jue et al., 1978; Singh et al., 1996) can be used. King et al. (1978) used a mixture of 2-iminothiolane and dithiodipyridine to prepare protein conjugates via an intermolecular disulfide bond, dithiopyridine being used to protect the generated thiol groups. The advantage of 2-iminothiolane over SPDP is that it is more hydrophilic and preserves a positive charge on lysine side chains. Indeed, with 2-iminothiolane, the surface charge distribution of the protein is unperturbed (Jue et al., 1978), whereas with SPDP the positive charge of the free lysine residue is lost upon substitution; this induces a decrease in the solubility of the substituted protein. However, as shown earlier and especially by Singh et al. (1996), the adduct obtained upon reaction of 2-iminothiolane on an amino group is labile as long as the thiol group is free. It is therefore very useful to immediately substitute the thiol group by adding a protective reagent such as dithiodipyridine (King et al., 1978). However, dithiodipyridine, which must be used in large excess, is unfortunately slightly water soluble; in contrast, 6,6′-dithiodinicotinic acid is highly water soluble, and therefore, it may be used in a high concentration without requiring the presence of any organic solvent. Upon reaction of 6,6′-dithiodinicotinic acid with a thiol group, the carboxylated pyridinethione released is easily titrated thanks to its high absorbance at 344 nm (Grassetti et al., 1969), as in the case of pyridinethione.

We describe a simple, optimized method for the derivatization of a protein and of an oligonucleotide in buffered saline by introducing a thiol-reactive group on these molecules. This method is based on the use of three water-soluble reagents, namely 2-iminothiolane, 6,6′-dithiodinicotinic acid, and tris(2-carboxyethyl)phosphine (TCEP). The two first reagents used in conjunction led to a protected thiol derivative. Then, the use of TCEP together with halogeno-acetyl derivatives led to the substitution of molecules of interest with either a fluorescent tag or a peptide.

EXPERIMENTAL PROCEDURES

Materials. 2-Iminothiolane, tris(2-carboxyethyl)phosphine, iodoacetamidofluorescein, or lissamine rhodamine sulfonyl chloride were purchased from Molecular Probes (Leiden, The Netherlands); 6,6′-dithiodinicotinic acid, dithiodipyridine, triisopropylsilane, iodoacetamide, ϵ-amino caproic acid, DABCO and 5,5′-dithiobis(2-nitrobenzoic acid or Ellman's reagent) were from Aldrich (Saint Quentin Fallavier, France).

An 5′-alkylamine pentacosanucleotide $^{+}NH_3$-$(CH_2)_6$-O-PO_2-$^{5'}$CTC TCG CAC CCA TCT CTC TCC TTC T$^{3'}$-PO_2-O-$(CH_2)_{12}$OH phosphodiester (specific for a sequence encompassing the gag AUG of HIV) was kindly provided by Drs. U. Asseline and N. T. Thuong (CBM-CNRS, Orléans, France).

Fluorescein-labeled serum albumin (F-BSA) and rhodamine-labeled serum albumin (R-BSA) were prepared by allowing fluorescein isothiocyanate (isomer-I) or lissamine rhodamine sulfonyl chloride to react with bovine serum albumin as previously described (Roche et al., 1983; Monsigny et al., 1984).

Peptide Synthesis. The SV40 karyophilic peptide YPKKKRKVEDPR (M_r 1665), an NLS peptide (Yoneda et al., 1987), and the KDEL peptide YGEEDTSEKDEL (M_r 1533), a reticulum endoplasmic retention signal (Munro and Pelham, 1987), were prepared by solid-phase synthesis on an Applied 433 A synthesizer (Foster city, CA) using an Fmoc strategy starting from a 4-(hydroxymethyl)phenoxymethyl resin and monitoring the coupling efficiency by conductimetry. At the last step, bromoacetic anhydride reacted with the N_α-amino terminal group to form the N_α-(bromoacetyl)-protected peptide-resin (Arar et al., 1995). The peptides were further deprotected and released from the resin by incubation in a trifluoroacetic acid/water/phenol/triisopropylsilane mixture (88:5:5:2) for 3 h. After precipitation and washing with *tertio*-butylmethyl ether, the peptides were dried under reduced pressure. The bromoacetyl peptides were characterized by matrix-assisted laser desorption ionization time-of-flight mass spectrometry using a Finnigan MAT Lasermat 2000 instrument (San Jose, CA) and an α-cyano-4-hydroxycinnamic acid matrix (Aldrich). Their purity was checked by capillary electrophoresis on a P/ACE 5500 instrument (Beckman, Fullerton, CA) equipped with a P/ACE diode array detector and a fused-silica capillary equilibrated in sodium borate buffer, pH 8.6 (Kit Beckman).

pH and Temperature Influence on the Stability and on the Reactivity of 2-Iminothiolane. The 6,6′-dithiodinicotinic acid (5 mM) was dissolved in 1 mL of 50 mM sodium borate buffer containing 2 M sodium acetate, in the presence or in the absence of ϵ-amino caproic acid (20 mM). The pH was adjusted between 8.0 and 9.2 by adding 0.5 N NaOH. One micromole of 2-iminothiolane (from a freshly prepared 73 mM stock solution) was added, and the reaction was performed either at 25 °C or on ice.

After different incubation times, the amount of released sulfhydryl groups was determined by measuring the absorbance of carboxylated pyridinethione [ϵ_{344nm} = 10 000 according to Grassetti et al. (1969)].

Synthesis of F-BSA-NLS Using 2-Iminothiolane and 6,6′-Dithiodinicotinic Acid. F-BSA (0.3 μmol) was dissolved in 4 mL of 50 mM sodium borate buffer, pH 9.0, containing 2 M sodium acetate. A solution of 6,6′-dithiodinicotinic acid (45 μmol) in 1 mL of the buffer was adjusted at pH 9.0 by addition of 0.5 N NaOH. Then, 2-iminothiolane (30 μmol) was added. The mixture was incubated for 12 h on ice. F-BSA-(dithionicotinic acid)$_n$ was purified by gel filtration on an Ultrogel GF 05 column (50 × 2 cm) (Sepracor, Villeneuve-la-Garenne, France) eluted with a *n*-butanol/water (5:95) mixture at 4 °C. The fluorescent fractions were collected.

After freeze-drying, F-BSA-(dithionicotinic acid)$_n$ (0.28 μmol, 93% yield) was dissolved in 4 mL of 50 mM sodium phosphate buffer, pH 8.0, containing 2 M sodium acetate. The mixture was degassed by freezing at −20 °C and then thawing under reduced pressure. The solution was maintained under argon throughout the reaction to prevent air oxidation of sulfhydryl groups. The disulfide bridges were reduced with TCEP (4.5 μmol) at 25 °C then bromoacetyl-peptide NLS (8 μmol) was added in 2 M sodium acetate and 50 mM sodium phosphate buffer, pH 8.0. The mixture was stirred for 4 h. Remaining thiol groups were substituted by adding an excess of iodoacetamide (30 μmol) in 200 μL DMF (5% of the buffer volume), and the solution was stirred further for 2 h. The F-BSA-NLS was purified at 4 °C by gel filtration on Ultrogel GF 05 equilibrated with water containing 5% *n*-butanol. The number of peptides linked to F-BSA was estimated by electrophoresis in an 8% polyacrylamide gel (Laemmli, 1970) in the presence of 0.1% SDS. After freeze-drying, 0.255 μmol of F-BSA-NLS was collected which represented a yield of 85%.

Synthesis of F-Oligonucleotide Using 2-Iminothiolane and 6,6′-Dithiodinicotinic Acid. A 5′-hexylamine phosphodiester oligonucleotide (0.125 μmol) was dissolved in 0.5 mL of 2 M sodium acetate and 50 mM sodium borate buffer pH 9.0. 2-Iminothiolane (12.5 μmol) and 6,6′-dithiodinicotinic acid (19 μmol) were added in 0.5 mL of the same buffer adjusted at pH 9.0. The mixture was incubated on ice, and the oligonucleotide thiolation was monitored by HPLC.

Analyses were carried out using a Waters system (Saint-Quentin-en-Yvelines, France) with a Millennium software, on a Nova-Pack C18 (Waters) column (0.4 × 15 cm; particle size, 10 μm), with a linear gradient from 5 to 30% solvent B in solvent A over 30 min (flow rate 1 mL/min; solvent A: 95% 0.1 M triethylammonium acetate (TEAA), pH 7.0/5% acetonitrile; solvent B, 5% 0.1 M TEAA, pH 7.0/95% acetonitrile). The elution was monitored by UV absorbance at 260 nm using a Waters photodiode array detector.

The thiolated oligonucleotide was precipitated by adding 2.5 vol of ethanol. The precipitate was then dissolved in distilled water and loaded onto a Biogel P2 column (20 × 1 cm) (Bio-Rad, Oxfordshire, England) eluted with 5% *n*-butanol. Fractions containing the oligonucleotide were pooled and, upon freeze-drying, stored at −20 °C.

The thiolated oligonucleotide, dissolved in 0.5 mL of 2 M sodium acetate, 50 mM phosphate buffer, pH 8.0, was reduced with 2 equiv of TCEP (0.25 μmol). Iodoacetamidofluorescein (20 equiv) was dissolved in the same buffer and slowly added to the oligonucleotide solution under stirring. The reaction was performed under argon at 25 °C for 3 h. To remove the fluorescein excess, the oligonucleotide was precipitated by adding 2.5 vol of ethanol. The fluoresceinylated oligonucleotide was purified by chromatography on Biogel P2 or by HPLC before its characterization by mass spectrometry. The negative ion electrospray mass spectra were obtained using a Platform quadrupole mass spectrometer (VG Biotech, Fisons Instruments, Altrincham, U.K.) equipped with an electrospray atmospheric pressure ionization source.

Synthesis of Oligonucleotide-KDEL Peptide Conjugate Using 2-Iminothiolane and 6,6′-Dithiodinicotinic Acid. The 5′-hexylamine phosphodiester oligonucleotide was thiolated as described above. All the solutions used were degassed under reduced pressure and then gassed with argon. The reduction of the dithionicotinic acid-oligonucleotide and the coupling reaction with the KDEL peptide bearing a N_α-bromoacetyl reactive group were simultaneously conducted. The thiolated oligonucleotide (0.125 μmol dissolved in 0.5 mL of 2 M sodium acetate, 50 mM phosphate buffer pH 8.0) was mixed with the N_α-bromoacetyl-KDEL peptide (1.25 μmol dissolved in 0.25 mL of the same buffer) and with TCEP (0.25 μmol in 7 μL of the same buffer). The reaction was stirred under argon for 3 h. The oligonucleo-peptide-KDEL was purified by HPLC on a LiChrospher 100 RP-18 E (Merck) column (10 × 250 mm; particule size, 10 μm) with a linear gradient from 10 to 30% solvent B in solvent A over 30 min (flow rate 3 mL/min; solvent A,

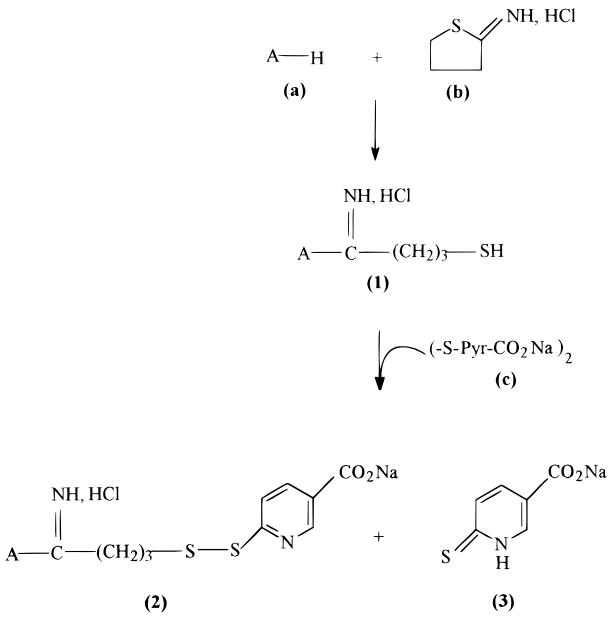

Figure 1. Scheme of the reaction of 2-iminothiolane (b) with an amine bearing molecule (a) (A = R-NH) or water (A = OH) followed by substitution with 6,6′-dithiodinicotinic acid (c). **1**, a thiolated compound; **2**, a dithionicotinic acid-substituted compound; and **3**, the carboxylated pyridinethione released. It should be noted that there is a large excess of 2-iminothiolane and 6,6′-dithiodinicotinic acid over the concentration of the amine and therefore the amount of carboxypyridinethione obtained is much larger than that expected from the reaction with the thiolgroup linked to the aminogroup.

95% 0.1 M triethylammonium acetate (TEAA), pH 7.0/5% acetonitrile; solvent B, 5% 0.1 M TEAA, pH 7.0/95% acetonitrile). The elution was monitored by UV absorbance at 260 nm using a Waters photodiode array detector. The oligonucleo-peptide was then characterized by a polyacrylamide (15%) gel electrophoresis, using a 10 cm long slab for 3 h under 70 V, in a tris-borate-EDTA buffer (TBE), pH 8.0. The oligonucleotides were then stained with methylene blue.

Microinjection into Somatic Cells and Confocal Microscopy Analysis. HeLa cells (10^5 cells/well) were grown for 24 h on CELLocate microgrid coverslips (Eppendorf, Hamburg, Germany). Both R-BSA and F-BSA-NLS were co-injected at 5 mg/mL into the cytosol of cells by using a microinjector 5242 and a micromanipulator 5170 (Eppendorf, Hamburg, Germany). Cells were incubated for 30 min at 37 °C in complete medium (DMEM supplemented with 10% FBS) in a 5% CO_2 air atmosphere. Cells were then fixed with 2% *p*-formaldehyde in PBS for 30 min and were mounted in PBS/glycerol (1:1, v/v) containing 1% DABCO as an antifading agent (Johnson et al., 1982). Cells were observed with a MRC 1024 confocal microscope (BioRad, Oxfordshire, U.K.) equipped with a Nikon Optiphot epifluorescence microscope (Nikon, Tokyo, Japan) and a 60× Planapo objective (numerical aperture 1.4).

RESULTS

Stability and Reactivity of 2-Iminothiolane Related to pH and Temperature. The thiolation scheme of an amino group with 2-iminothiolane and 6,6′-dithiodinicotinic acid is presented in Figure 1. Each molecule of dithiodinicotinic acid which reacts with a molecule containing a sulfhydryl group releases one molecule of carboxylated pyridinethione.

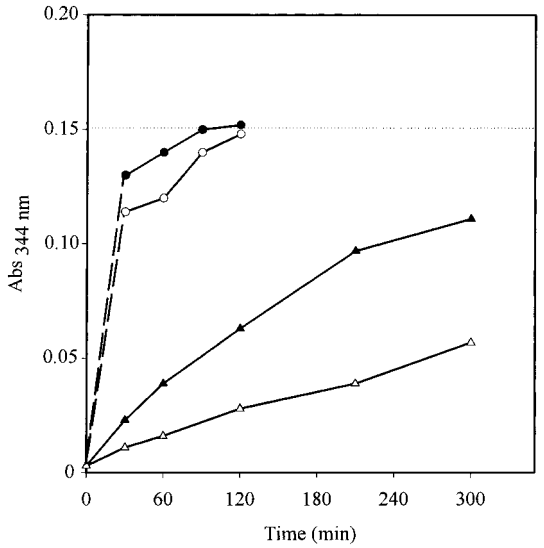

Figure 2. Hydrolysis and aminolysis of 2-iminothiolane at pH 8.6 and 25 °C in the presence (●) or in the absence (○) of ϵ-amino caproic acid, and at pH 8.6 on ice in the presence (▲) or in the absence (△) of ϵ-amino caproic acid. The absorbance of carboxylated pyridinethione released was measured at 344 nm.

The optimal conditions leading to the substitution of an ϵ-amino group were determined by using ϵ-amino caproic acid as a model compound. The stability and the reactivity of 2-iminothiolane were checked in the absence or in the presence of ϵ-amino caproic acid.

The coupling reaction was conducted in the presence of a high ionic strength buffer, 2 M sodium acetate; indeed, 2-iminothiolane was found to be less susceptible to degradation when it was kept in such a high ionic strength buffer. The extent of the reaction was monitored by measuring the absorbance increase at 344 nm. The rapid increase of the absorbance at 344 nm of a solution of 2-iminothiolane and 6,6′-dithiodinicotinic acid at pH 8.6 and 25 °C (Figure 2), in the absence of ϵ-amino caproic acid, indicated a spontaneous hydrolysis of 2-iminothiolane. However, in the presence of ϵ-amino caproic acid, the increase in absorbance was slightly faster showing that 2-iminothiolane was both aminolyzed and hydrolyzed (Figure 2). The spontaneous hydrolysis at pH 8.6, in the absence of ϵ-amino caproic acid was slower at low temperature (on ice) allowing a more efficient aminolysis (Figure 2).

To determine the optimal coupling conditions, the reaction was performed on ice at pH between 8.0 and 9.2 (Figure 3). The 6,6′-dithiodinicotinic acid was found to be quite stable on ice and at pH around 9.2. Concerning 2-iminothiolane, its rates of both hydrolysis and aminolysis increased with pH but the aminolysis reaction appeared to be optimal when the reaction was conducted at pH 9.0. At higher pH, the rate of hydrolysis increased faster than that of aminolysis. On these bases, the optimized conditions are those conducted on ice at pH 9.0 in a high salt buffered solution.

Preparation of F-BSA-NLS. 2-Iminothiolane and 6,6′-dithiodinicotinic acid were used to add thiol reactive groups to a protein (F-BSA). After 12 h of incubation under optimized conditions (pH 9.0, on ice) and purification by gel filtration, the number of sulfhydryl groups added to F-BSA, determined on an aliquot of F-BSA-(dithionicotinic acid)$_n$ by measuring the amount of carboxylated pyridinethione released upon reduction with TCEP, was found to be about 15. When the reaction was conducted at pH 8.0, the substitution was less efficient

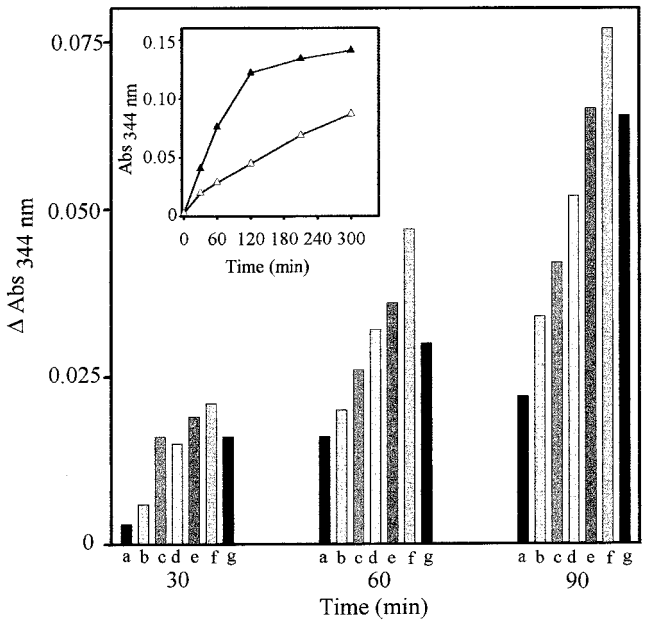

Figure 3. Time-course studies of the reaction of 2-iminothiolane with ϵ-amino caproic acid on ice at pH 8.0 (a); pH 8.2 (b); pH 8.4 (c); pH 8.6 (d); pH 8.8 (e); pH 9.0 (f); pH 9.2 (g). ΔAbs is the difference between the absorbances of the released carboxylated pyridinethione at 344 nm in the presence and in the absence of ϵ-amino caproic acid. Inset: monitored time-course studies of the release of carboxylated pyridinethione at pH 9.0 on ice. The absorbance of released carboxylated pyridinethione was measured at 344 nm in the presence (▲) or in the absence (△) of ϵ-amino caproic acid.

by a factor of 0.7. The number of NLS peptide linked to F-BSA through a thioether bond was determined by electrophoresis in SDS−polyacrylamide gel. Under reducing and denaturing conditions, the electrophoretic mobility of F-BSA-NLS decreased with the number of peptides bound. An average of 10 NLS peptides was found to be bound on one F-BSA molecule. A control study using the bromoacetyl-peptide-NLS with native nonthiolated BSA to estimate the extent of the reaction of bromoacetyl-peptide on lysine and histidine residues was performed at pH 8.0 and 9.5: no substitution could be evidenced upon monitoring the migration of the protein in SDS−PAGE.

To assess the intracellular fate of the F-BSA-NLS conjugate, F-BSA-NLS and R-BSA were co-injected into the cytosol of HeLa cells. The F-BSA-NLS, as expected, was localized in the nucleus within 30 min incubation at 37 °C, whereas R-BSA stayed in the cytosol (Figure 4) showing that the F-BSA-NLS conjugate, prepared as described above, was selectively and efficiently transported through the nuclear pore to the nucleus.

Derivatization of an Oligonucleotide on its 5′ End. The same method was used to introduce a thiol group on a phosphodiester oligonucleotide substituted with an amino group on its 5′-end. The reaction was monitored by HPLC (Figure 5). The thiolated oligonucleotide (peak 2) was eluted 2 min after the oligonucleotide (peak 1). After 7 h, about 60% of the oligonucleotide was thiolated and the reaction was almost completed after 12 h (Figure 5B). By comparison, the reaction with dithiodipyridine instead of 6,6′-dithiodinicotinic acid appeared less efficient: only 60% of oligonucleotide was thiolated after 12 h. It is important to notice that due to the low solubility of dithiodipyridine in aqueous solvent, dithiodipyridine had to be previously dissolved in dimethylformamide and added to the oligonucleotide which was in aqueous solution. The final concentration in dimethylformamide was 30%. Conversely, using 6,6′-dithiodinicotinic acid, there was no need of any organic solvent.

The sulfhydryl group may be used to couple an oligonucleotide to another molecule with a reactive group such as a sulfhydryl or a bromoacetyl group leading to either a disulfide bridge or a thioether linkage, respectively. To test the reactivity of the thiolated oligonucleotide, 20 equiv of iodoacetamidofluorescein in 2 M sodium acetate and 50 mM sodium phosphate buffer at pH 8.0 was added to a solution of dithionicotinic acid-oligonucleotide conjugate reduced with 2 equiv of TCEP. Under these conditions, the reaction was complete within 3 h. The fluorescent oligonucleotide was purified by HPLC (Figure 6) before characterization by mass spectrometry. The experimental mass of the fluorescent oligonucleotide (8195 ± 2 Da) was in agreement with the calculated mass (8196.6 Da).

In the same manner, a N_α-bromoacetyl-peptide containing a KDEL motif was coupled to the thiolated oligonucleotide reduced with 2 equiv of TCEP. The reaction was stopped after 3 h and the oligonucleopeptide was characterized by polyacrylamide (15%) gel electrophoresis. The purified oligonucleo-peptide (Figure 7, lane 3) had a migration slower than that of the oligonucleotide protected with dithionicotinic acid derivative (Figure 7, lane 1). After 3 h, the major compound was the expected oligonucleo-peptide; a small amount of the monomeric-reduced oligonucleotide, which had not reacted with the peptide, was however still present (Figure 7, lane 2). It should be emphasized that, under these conditions, the dithionicotinic acid-oligonucleotide derivative did not lead to any significant amount of a dimeric oligonucleotide (Figure 7, lane 1).

DISCUSSION

The present report describes an optimized and simple technique for obtaining water-soluble conjugates based on the use of two selected water-soluble reagents: 2-iminothiolane to add a reactive thiol group on a compound bearing an aminoalkyl residue and 6,6′-dithiodinicotinic acid to immediately protect the newly generated thiol.

Dealing with highly hydrophilic components such as proteins or oligonucleotides, it is worthwhile to define efficient conditions which avoid any organic solvent. 2-Iminothiolane is very soluble in aqueous solution and, therefore, can be easily used in a large excess without adding any organic solvent.

Dithiodipyridine has been used in conjunction with 2-iminothiolane to introduce dithiopyridyl groups into proteins (King et al., 1978). Unfortunately, dithiodipyridine has a limited water solubility; it is therefore usually dissolved in an organic solvent such as dimethylformamide or methanol. Conversely, sodium 6,6′-dithiodinicotinate is highly soluble in aqueous solution. Furthermore, 6,6′-dithiodinicotinic acid was preferred to another thiol reagent such as the Ellman's reagent [5,5′-dithiobis(2-nitrobenzoic acid)] because, in preliminary experiments the substitution of thiolated BSA led to precipitation of the adduct. In addition, the dithiopyridine derivative upon reduction led to a single thiol, the released protecting group becoming a nonreactive pyridinethione derivative. Conversely, upon reduction, dithionitrobenzoic acid derivative led to two thiols: one born by the molecule of interest, and the other by the released protective group.

TCEP was used to reduce quantitatively disulfide bridges of small molecules (Burns et al., 1991) leading

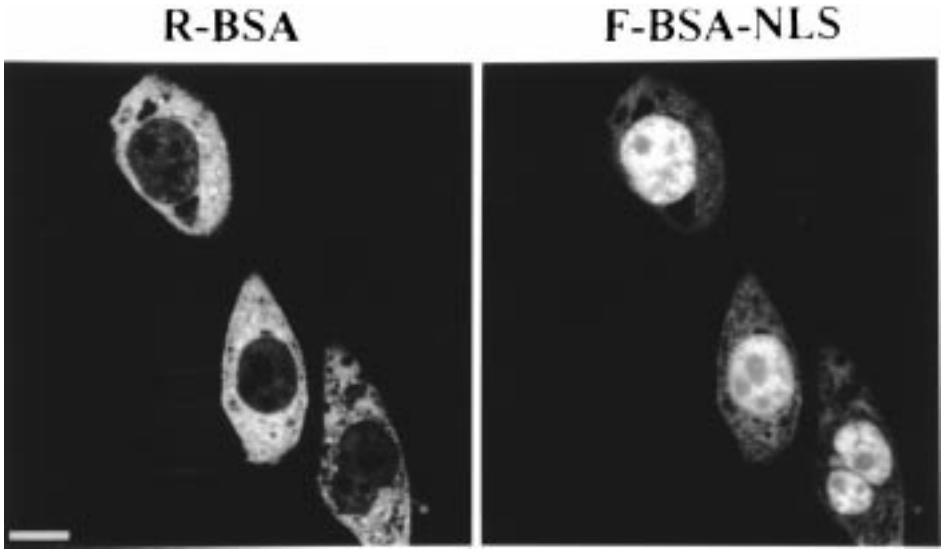

Figure 4. HeLa cells, co-injected with both F-BSA-NLS and R-BSA, in their cytoplasm were then incubated for 30 min at 37 °C in DMEM containing 10% FBS and then observed in a confocal microscope after fixation as described in the Experimental Procedures. Scale bar, 10 μm.

to two thiols; acting on an alkyldithionicotinic acid, TCEP leads to a free alkylthiol and to carboxypyridinethione. Initially, the reduction was performed for 30 min at pH 7.0 before adding the thiol reagent (Arar et al., 1995). Under those conditions, optimized for the use of TCEP, we were unable to form a fluorescent oligonucleotide (results not shown). The thiol adduct formed by the reaction of an amine with iminothiolane is rapidly converted to nonthiol products with a loss of ammonia as shown by Singh et al. (1996), except when it is substituted; therefore, it is important to increase the rate of the reaction. For this reason, the reaction was performed at pH 8.0, and both the reduction and the substitution of the newly formed thiol were simultaneously conducted. Therefore, the optimal conditions are a compromise to take into account the relative instability of both the iminothiolane adducts and TCEP. Indeed, TCEP is stable at or below pH 7.0; it is slowly oxidized in water at higher pH. However, by adding both a slight excess of TCEP and a larger excess of a thiol reagent (iodoacetamidofluorescein) at the same time, at pH 8.0, the reduction was complete and the formation of a stable thioether was fast enough to efficiently avoid any substantial rearrangement of the primary iminothiolane adduct. Under similar conditions, TCEP was found to reduce the dithionicotinic acid linked to a protein such as thiolated BSA or thiolated immunoglobulin. The reduction of the intramolecular disulfide bridges under nondenaturing conditions is unlikely. In control experiments, thiolated human IgG treated with TCEP was not dissociated in subunits upon subsequent denaturation in the presence of SDS (results not shown). In addition, TCEP was selected among a series of reducing agents such as mercaptoethanol, thioglycolic acid, and dithiothreitol for three main reasons: the first one is because TCEP is hydrophilic and highly water soluble, the second one is that the reduction is roughly stoichiometric with regards to the concentration of dithiodinicotinic acid, and the third one because TCEP is oxidized into a nonreactive TCEPoxide making the reaction strictly irreversible. The two last characteristics are specific to such a compound

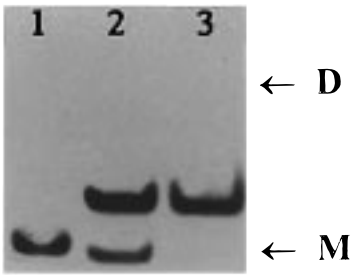

Figure 7. Polyacrylamide gel electrophoresis of oligonucleotide and derivatives conducted for 3 h on a 15% polyacrylamide gel, 10 cm long at 7 V/cm. and are not shared with the reducing agents containing free thiol groups.

Several previous papers described different methodologies to incorporate thiol groups into proteins by using 2-iminothiolane. Jue et al. (1978) showed that 2-iminothiolane was quite stable at pH 8.0 at 7 °C; they also showed that sulfhydryl groups were slowly exposed in the absence of any primary amine at 25 °C at the same pH. Lasch et al. (1987) used 2-iminothiolane at pH 8.5 and 23 °C to thiolate liposomes, and Singh et al. (1996) used it at pH 8.0 on ice to thiolate BSA. Tarentino et al. (1993) used 2-iminothiolane for the introduction of a sulfhydryl group into oligosaccharyl-glycosylamines deriving from asparagine-linked glycans at pH 8.8 at 25 °C. Under their conditions, we were unable to introduce more than a few sulfhydryl groups onto F-BSA (results not shown).

The optimal conditions in using 2-iminothiolane were determined. At 25 °C, 2-iminothiolane was found to be almost totally degraded within 1 h. Conversely, when the reaction was performed at low temperature, about 17 protein amino groups were substituted. The optimal pH was found to be around 9.0. This optimal pH allowed the addition of 15 thiol groups on F-BSA by using a 100-fold excess in thiolation reagent; this excess corresponds to 1.8-fold excess based on the number of lysyl residues in BSA. In their study on the decay of thiol groups in a sample of BSA modified with 2-iminothiolane, Singh et al. (1996) introduced two thiol groups per BSA at pH 8.0 on ice using a 42-fold molar excess of 2-iminothiolane per molecule of BSA.

In addition to the thiolation of a protein, the thiolation of a 5′-ω-hexylamine oligonucleotide derivative was investigated. For the ϵ-amino groups of a protein or for the single ω-alkylamino group of an oligonucleotide, the reactivity even at pH 9.0 requires a large excess of 2-iminothiolane and therefore an excess of a thiol-specific reagent to protect the newly added thiol. Because of the high pK of an ϵ-amino group (around 10.5), the pH must be as high as possible. But because spontaneous hydrolysis of 2-iminothiolane when the solution is strongly basic, the optimal pH is lower than the pK of the acceptor amino group. Furthermore, the rate of the spontaneous hydrolysis of 2-iminothiolane increased more rapidly with an increase in temperature than that of aminolysis; therefore, by working at low temperature (close to 0 °C), the spontaneous hydrolysis is slow enough to allow an efficient aminolysis in the presence of ϵ-amino groups. Finally, because the rate of the spontaneous hydrolysis of 2-iminothiolane at pH 9.0 is not negligible even at low temperature, an excess of 2-iminothiolane is required to ensure a high yield of substitution of the ϵ-amino groups or ω-amino groups. The optimal conditions described here allow the substitution of about one-fourth of the ϵ-amino groups of a protein such as BSA, and almost quantitatively (about 95%), the amino group of the hexylamine linked to an oligonucleotide.

Alternatively, Gaur et al. (1989) shows in a short note that it is possible to introduce a protected thiol group on an alkylamine at the 5′ end of an oligonucleotide in hydroorganic solvent (a mixture of water and acetonitrile) by using a very large excess of 500-fold SPDP and an acylating catalyst.

The method described in the present paper was mainly developed with the aim to substitute water-soluble biomolecules such as proteins or oligonucleotides with ligands or recognition signals in a high yield by avoiding the use of any organic solvent. The yield of the substitution of oligonucleotides and BSA was not dependent on the oligonucleotides used nor on the BSA batches used. Concerning the substitution of proteins, the use of three water-soluble reagents, namely 2-iminothiolane, 6,6′-dithiodinicotinic acid, and tris(carboxyethyl)phosphine, allows a very efficient thiolation of the amino groups and finally a high substitution of the protein with molecules of interest such as a peptide. Because the primary thiolation reaction does not require any organic solvent and does not neutralize the positive charge of the protein amino groups, the highly thiolated protein obtained remains very water-soluble. Concerning the oligonucleotides, the thiol derivatives are much more easily substituted than the alkylamine derivatives. Therefore, when an oligonucleotide has to be substituted twice, the best way is to use commercially available oligonucleotide derivatives with an alkylamine at one end and a protected alkylthiol at the other end. The first step is the linkage of a substituant on the thiol group, the second step is the addition of a new thiol group by reaction of 2-iminothiolane on the available alkylamine and its temporary protection with the water-soluble dithiodinicotinic acid, and finally, the third step is the addition of the second substituant on the newly added thiol derivative. This bisubstituted oligonucleotide can bear two substituants linked by two thioether bonds or two substituants linked by both a thioether bond and a disulfide bond.

Tresyl-Mediated Synthesis: Kinetics of Competing Coupling and Hydrolysis Reactions as a Function of pH, Temperature, and Steric Factors

Jeffrey J. Sperinde, Benjamin D. Martens, and Linda G. Griffith*

Massachusetts Institute of Technology, Department of Chemical Engineering and Division of Bioengineering and Environmental Health, MIT 66-466, 25 Ames Street, Cambridge, Massachusetts 02139. Received June 19, 1998

Kinetic parameters have been measured for coupled nucleophilic and solvolytic reactions of 2,2,2-trifluoroethanesulfonyl (tresyl)-modified poly(ethylene glycol) based on a system of coupled differential equations implied by recently proposed elementary reaction mechanisms. Fitted kinetic parameters were found to be strong functions of pH, temperature, and steric factors. To maximize the total yield of coupled amine as well as the fraction of secondary amine linkages, our model predicts that it is desirable to run tresyl coupling reactions at low temperatures at pH ~8.0, depending on the amine pK_a for primary, unhindered amines. For branched primary amines, our data favor room temperature at a slightly higher pH.

INTRODUCTION

Nearly two decades ago, 2,2,2-trifluoroethanesulfonyl chloride (tresyl chloride) was introduced as a more reactive alternative to *p*-toluenesulfonyl chloride (tosyl chloride) in activating hydroxyl groups to covalent modification for the preparation of affinity chromatography supports (Nilsson and Mosbach, 1981). Tresyl chloride has found wide use in solid support activation as well as extensive use in poly(ethylene glycol) (PEG) activation for PEG modification of small drugs and proteins for biological stabilization and immuno-modulation (Harris, 1992).

It had long been assumed that the reaction mechanism for tresyl-mediated coupling was identical to that of tosyl chloride and other sulfonyl chlorides where the substituted sulfonyl acts as a leaving group. Recently, it has been suggested that alternative mechanisms may prevail. Demiroglou et al. (1994) proposed a mechanism in which the sulfonyl sulfur is retained throughout the entire coupling reaction. On the basis of experimental evidence, Gais and Ruppert (1995) as well as King and Gill (1995, 1996) corrected this postulated mechanism to include nucleophile addition by an β-elimination/Michael-type addition reaction. The present understanding of tresyl reactions in aqueous media includes three pathways (Scheme 1): hydrolysis, nucleophilic displacement, and β-elimination/addition.

Experimental work regarding tresyl-chloride-mediated coupling has been focused on determining the molecular structure of reaction products, yet for practical application of tresyl-mediated coupling, it is necessary to know how reaction conditions may affect the coupling yield. Here, we report effective rate constants for the recently elucidated reaction network for tresyl-mediated coupling, using PEG-Tr as a model. We further examine the effects of temperature, pH, and steric factors that affect yields of the reaction products.

The central goal of this research was to define rate constants useful in predicting coupling rates, product distributions, and product yields for tresyl-mediated coupling based on fundamental parameters such as pH, temperature, steric effects, and nucleophilic amine pK_a. It has recently been shown that pH can play a large role in hydrolysis rates and coupling products (King and Gill, 1996). Here, we sought to define the role of pH, temperature, and steric effects through the measurement of apparent rate constants that might be representative of the elementary reaction mechanisms involved in tresyl-mediated coupling of amine nucleophiles to tresylated PEG.

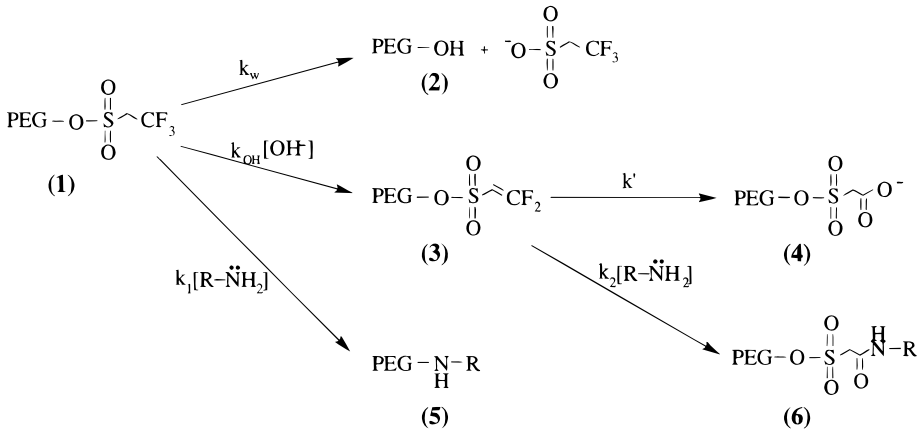
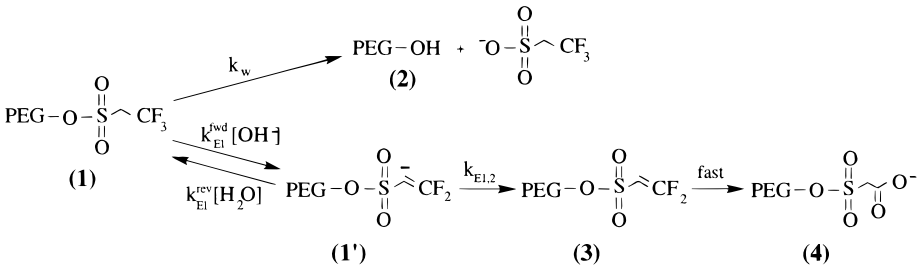
MATERIALS AND METHODS



Poly(ethylene glycol) (MW = 6000) was purchased from Fluka. Tresyl chloride (2,2,2-trifluoroethanesulfonyl chloride), L-phenylalanine (Phe), and N^2-(carbobenzyloxy)-L-lysine (αCBZ-Lys) was from Aldrich. Glycyl-DL-phenylalanine (Gly-Phe) was from Sigma.

Synthesis of Tresylated PEG (1). The general synthesis procedure for PEG tresylation is detailed elsewhere (Sperinde and Griffith, 1997), employing a method similar to that of Nilsson and Mosbach (1984). In the present study, dihydroxyl PEG (6000 MW) was used as the starting material. Briefly, the tresylation was performed in a dried solution (over molecular sieves previous to tresylation) of PEG$-OH_2$ in methylene chloride (10 mL/g PEG) under argon with triethylamine as an acid acceptor. Purified PEG-Tr_2 was obtained by successive reprecipitations from acidified methanol, using decreasing concentrations of acid. Residual triethylamine was found to be 0.02 wt % by ^{1}H NMR. On the basis of sulfur elemental analysis, tresylation was approximately 100%, with 3.08 g/mmolTr [52.2% C, 8.54% H, 1.04% S]. Each tresyl group (=[1], see Scheme 1) of PEG-Tr_2 is assumed to react independently; therefore, designations "PEG-Tr" and "PEG-Tr_2" are used interchangeably.



Isolated Hydrolysis Reaction. Progress of the hydrolysis reaction was monitored by continuous titration. A weighed amount of PEG-Tr_2 (about 50 mg) was added to a measured volume (about 100 mL) of Milli-Q water. The solution was stirred continuously. Dilute potassium

Scheme 2

hydroxide (20 mM) was added as needed to maintain the pH within 0.05 units of desired pH as measured by a standard calomel electrode. The amount and time of addition of each acid aliquot was recorded. Continuous titration experiments were run at 22 ± 1 °C with pH 6.0, 7.0, 7.5, 8.0, 8.5, and 9.0 and at 4 ± 0.2 °C with pH 8.0, 8.5, and 9.0. Each continuous titration reaction was monitored for 80 min. For slower reactions at 4 ± 0.2 °C with pH 5.0, 6.0, and 7.0, base was required much less often to maintain the desired pH. In these three conditions, the rate of acid evolution was measured by the rate of pH change, where the pH was always maintained within ±0.1 pH units of the desired level. These three slower reactions were run at higher PEG-Tr_2 concentrations (about 2 mg/mL) and were maintained over a number of days, with frequent recalibration of the pH meter.

The measurement of moles of base added to maintain constant pH was used to calculate moles of tresyl groups consumed. By reaction stoichiometry, 4 mol of base is required to neutralize the acid evolved by the conversion of R-Tr to R-$OSO_2CH_2COO^-$, and 1 mol of base is required to neutralize the hydrolysis of R-Tr to R-OH and $^-OSO_2CH_2CF_3$. The fractional conversion of tresyl groups (X_{Tr}) was calculated on the basis of the weight of PEG-Tr_2 used in each experiment (measured to ±0.1%), using the value of 3.08 g of PEG/mmol of Tr noted above, confirmed by total hydrolysis of PEG-Tr_2.

Simultaneous Coupling/Hydrolysis Reaction. A measured amount of PEG-Tr to make a final concentration of 40 mM in tresyl was added to a solution 100 mM in primary amine and 400 mM in potassium phosphate at the desired pH. The extent of the coupling reaction was measured as a function of time by periodic sampling of the reaction solution by a HPLC Hitachi L-7200 autosampler. The aliquot was immediately injected onto one TSK G4000PW and one TSK G2000PW column in series. The mobile phase was 0.50 M sodium chloride with 10 mM potassium phosphate and 4% acetonitrile at pH 4 delivered by a Hitachi L-7100 pump. Detection was by a Hitachi L-7420 UV−vis detector at 260 nm where PEG-Tr has an insignificant absorbance. For each measurement, the fraction of amine bound to PEG was calculated as the integral of absorbance at 260 nm for the PEG peak (first to elute) divided by the total integral (PEG peak + free amine peak). Amines examined include glycyl-phenylalanine, phenylalanine, and α-CBZ-lysine. All amines were examined at 4 and 22 °C.

Algorithm for Rate Constant Fitting. Whereas analytical solutions to rate equations were unavailable, rate constants were fit using standard Fortran models extracted from Numerical Recipes (Press et al., 1986). The rate constants were fit by an iterative process. A fourth-order Runge−Kutta routine was used to generate data for conversion as a function of time from a set of guessed rate constants. This generated data was then compared with measured data to calculate a new set of more accurate rate constants. A Levenberg−Marquardt (LM) χ-squared minimization routine generated this new guess. The same Runge−Kutta routine was used within the LM routine as well to calculate the necessary partial derivatives ($\partial\chi/\partial k_i$) for each rate constant, k_i. This process was repeated iteratively until χ was approximately minimized ($\chi_{n+1}/\chi_n < 0.0001\%$).

The data were separated for rate constant analysis by nucleophile ($n = 3$) and by temperature ($n = 2$). For each of these six data groups, rate constants were optimized by the LM method for all pHs simultaneously.

RESULTS AND DISCUSSION

A number of reaction pathways for tresylated species have recently been elucidated, yet kinetic data which could be used to maximize desired products is somewhat limited. The goal of this work is to measure apparent rate constants for a reaction network that describes the set of possible reactions for the displacement of tresyl groups by primary amines in an aqueous environment as a

function of pH temperature and steric factors. This has been undertaken in two steps. First, in the absence of an amine nucleophile, rate constants for hydrolysis and hydroxyl-mediated tresylate conversion were measured. Second, with knowledge of the solvent-mediated reactions, rate constants for coupling of various primary amine species were measured by fitting to a kinetic model consistent with known reaction mechanisms.

Rate Constants for Hydrolytic Processes. King and Gill have shown that the ethyl trifluoroethanesulfonate in the absence of a nucleophile will hydrolyze to different species depending on the solution pH (King and Gill, 1996) as can be inferred from Scheme 2. They reported data at 25 °C supporting a traditional sulfonate ester hydrolysis pathway (first-order rate constant = k_w) at low pH and reversible E1cB reaction at high pH (pseudo-first-order rate constant = $k_{OH}[OH^-]$) in which the first step is rate limiting. Given the set of reactions in Scheme 2, the disappearance of PEG-Tr (1) can be written as

$$-\frac{d[PEG-Tr]}{dt} = (k_w + k_{OH}[OH^-])[PEG-Tr]$$

where

$$k_{OH} = \frac{k_{E1}^{fwd} k_{E1,2}}{k_{E1}^{rev}[H_2O] + k_{E1,2}}$$

The integrated form of this equation in terms of conversion ($\equiv X_{Tr}$) is

$$-\ln(1 - X_{Tr}) = (k_w + k_{OH}[OH])t = k_{h,app}t$$

where

$$X_{Tr} = 1 - \frac{[PEG-Tr]}{[PEG-Tr]_0}$$

This equation implies that a plot of $-\ln(1 - X_{Tr})$ versus time would be linear, with the slope equal to (k_w + $k_{OH}[OH^-]$). By varying the pH, unique values for k_w and k_{OH} can be computed. Data for hydrolysis reactions are plotted in Figure 1 at 4 °C for pH 8−9 and 22 °C for pH 6−9.

Our data for the hydrolysis of tresylated PEG at 4 and 22 °C supports the model given in Scheme 2. Linearity of the $\ln(1 - X_{Tr})$ plot (Figure 1) confirms that the first hydrolysis step is rate limiting under almost all conditions studied. The pH 9.0, 22 °C reaction deviates somewhat from linearity, indicating that one or more of the multiple steps between 3 and 4 of Scheme 1 may be limiting in the high pH regime.

To derive rate constants k_w and k_{OH}, the apparent hydrolysis rate $k_{h,app}$ was fit by a least-squares method to $k_{h,app} = k_w + k_{OH}[OH^-]$ separately for 4 and 22 °C as shown in Figure 2. Table 1 shows the rate constants fit to the data in Figure 2.

The hydrolysis rate constant k_w was found to be a stronger function of temperature than k_{OH}, the apparent rate constant for the addition−elimination pathway. The low-temperature dependence of k_{OH} may point to a significant influence of k_{E1}^{rev}, consistent with a reversible E1cB mechanism. Because k_w is of a similar order of magnitude as $k_{OH}[OH^-]$ around room temperature and slightly basic pHs, this difference in temperature dependence might allow for the control of the distribution of products by manipulating pH and temperature. This will depend on the kinetics of S_N2 nucleophilic displacement discussed below.

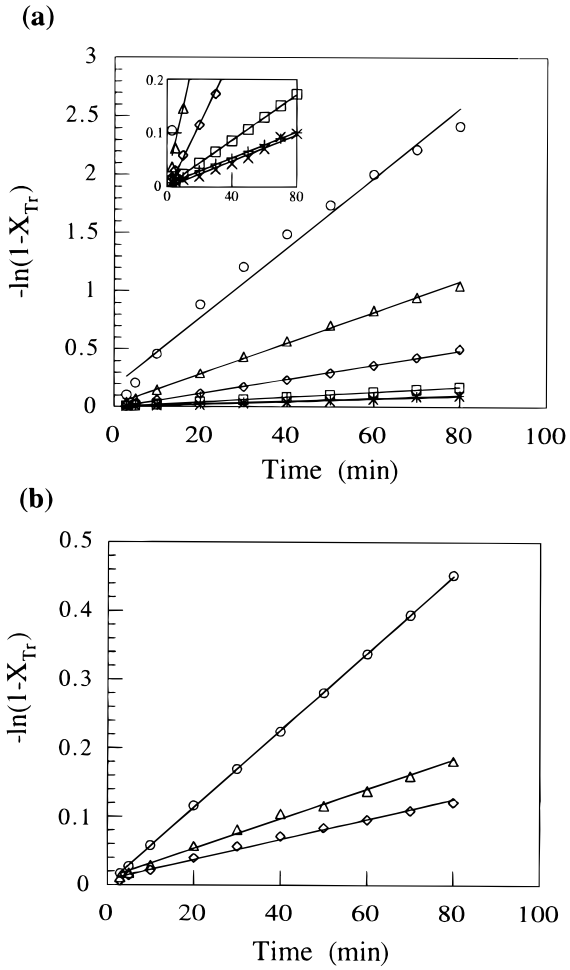

Figure 1. Hydrolysis reaction at 22 °C (1a) at pH 6.0 (×), pH 7.0 (+), pH 7.5 (□), pH 8.0 (◇), pH 8.5 (△), pH 9.0 (○), and 4 °C (1b) at pH 8.0 (◇), pH 8.5 (△), and pH 9.0 (○). All reactions were followed by titration as detailed in the Materials and Methods. Conversion of tresyl groups ($X_{Tr} = 1 - [1]/[1]_0$) was calculated on the basis of the initial concentration of tresyl groups for each experiment.

Development of a Tresyl-Mediated Coupling Model. It has been suggested that there are at least two pathways by which nucleophilic amines can couple to tresylated species (Scheme 1) [Gais and Ruppert, 1995; King and Gill, 1995; ref 6 in King (1996)]. The first pathway involves an S_N2 nucleophilic displacement, similar to that which is observed for other sulfonate leaving groups. This S_N2 pathway is thought to be minor or undetectable at very high pH (King and Gill, 1996). At high pH, the second pathway has been observed that is thought to go through an addition−elimination intermediate (3) (King and Gill, 1995). This intermediate can undergo further modifications to an inactive product (4), or it can react with an amine to give a coupled product (6).

The apparent first-order rate dependence of the addition−elimination pathway for hydrolysis suggests that $k' \gg k_{OH}[OH^-]$. This implies that as 3 is formed it is rapidly converted to a mixture of 4 and 6, such that [3] ≪ [1]. We can describe the fraction of 3 that becomes 6 as α, given by the following approximation:

$$\frac{d[6]}{dt} \approx \alpha(k_1[OH^-][1])$$

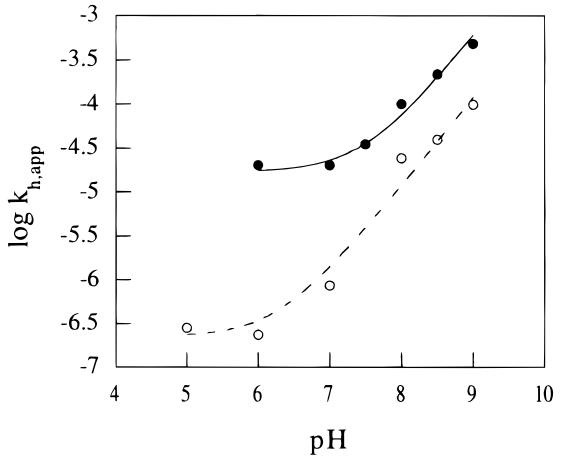

Figure 2. Least-squares fit for hydrolysis reaction ($k_{h,app} = k_w + k_{OH}[OH^-]$) for 22 °C (●) and 4 °C (○). Values of $k_{h,app}$ are taken from the slopes of curves in Figure 1 for faster reactions (points where log $k_{h,app} > -5$) and from the rate of pH change (see Materials and Methods) for slower reactions (points where log $k_{h,app} < -5$).

where

$$\alpha = \frac{k_2[\mathrm{N:}]}{k_2[\mathrm{N:}] + k'}; \; [\mathrm{N:}] \equiv \text{unprotonated amine}$$

As suggested by the hydrolysis experiments, the above assumption should hold at least for pH ≲9.0. Because reactions governed by k_2 and k' are downstream of the rate-limiting step, (1 → 3), the absolute magnitudes of k_2 and k' cannot be measured independently. Only the ratio k_2/k' can be calculated.

The rate constants k_w and k_{OH} are known from the previous section (Table 1). Here we will fit k_1 and k_2/k' for each amine species at each temperature, based on measured coupling data for a set of model amines. On the basis of Scheme 1 and the above approximation, we can write the following differential equations that describe the concentrations of the reaction components as a function of time:

$$\frac{\mathrm{d}[1]}{\mathrm{d}t} = (k_w + k_{OH}[OH^-] + k_1[\mathrm{N:}])[1]$$

$$\frac{\mathrm{d}[2]}{\mathrm{d}t} = k_w[1]$$

$$\frac{\mathrm{d}[4]}{\mathrm{d}t} = (1 - \alpha)k_{OH}[OH^-][1]$$

$$\frac{\mathrm{d}[5]}{\mathrm{d}t} = k_1[\mathrm{N:}][1]$$

$$\frac{\mathrm{d}[6]}{\mathrm{d}t} = \alpha k_{OH}[OH^-][1]$$

$$\frac{\mathrm{d}[\mathrm{N}]_{total}}{\mathrm{d}t} = -(k_1[\mathrm{N:}] + \alpha k_{OH}[OH^-])[1]$$

The $[OH^-]$ concentration was calculated using the measured pH and the ion product of water, K_w, at the appropriate temperature (see Table 2):

$$[OH^-] = K_W(T) \times 10^{pH}$$

Table 1. Hydrolysis Rate Constants

temp (°C)	k_w (10^{-6} s^{-1})	k_{OH} (10^3 s^{-1} M^{-1})
4	0.22	68
22	17.0	78.3

Table 2. Ionization Constants

temp (°C)	pK_w[a]	pK_a Gly-Phe	pK_a Phe	pK_a αCBZ-Lys
4	14.78	8.6	9.6	11.3
22	14.08	8.1	9.1	10.7

[a] pK_w from Marshall and Franck (1981). The amine pK_as at 4 and 22 °C were calculated as explained in the text from literature values at 25 °C for glycylphenylalanine (Biester and Ruoff, 1959) and phenylalanine (Nevenzel et al., 1949). The pK_a of the αCBZ-Lys was assumed to be similar to lysine (Ellenbogen, 1952) and 6-aminohexanoic acid (Smith and Smith, 1942), which have similar pK_as.

The concentration of unprotonated amine was calculated from an algebraic variant of the Henderson–Hasselbach equation as

$$[\mathrm{N:}] = [\mathrm{N}]_{total}\frac{10^{\{pH - pK_a(T)\}}}{1 + 10^{\{pH - pK_a(T)\}}}$$

Both K_w and the pK_a for each amine species vary with temperature (Table 2). The pK_as for the various amine species were adjusted for temperature based on the van't Hoff equation by

$$pK_a(T_2) = pK_a(T_1) - \log\left\{\exp\left[-\frac{\Delta H°}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)\right]\right\}$$

The temperature adjustments to the pK_a are significant, yet small enough to allow for use of approximate values for $\Delta H°$. For example, variations in $\Delta H°$ on the order of 10 kJ/mol imply differences in pK_a of only 0.1 pH unit at 4 °C. The heat of ionization for the α-amine of phenylalanine was taken as 44 kJ/mol (Izatt et al., 1961). The heat of ionization for the α-amine of glycylphenylalanine was also approximated as 44 kJ/mol based on the observation that chemical substituents removed from the α-amine have little effect on the $\Delta H°$. For example, enthalpy literature values for similar molecules such as glycine (King, 1951), glycylglyine (Smith and Smith, 1942), and phenylalanine (above) were all given as 44 kJ/mol. The heat of ionization for the α-amine of α-CBZ-lysine was assumed to be similar to α-dimethyllysine (Marini et al., 1971) at 52 kJ/mol. Heat capacities, defined as the change in $\Delta H°$ with temperature, were assumed to be insignificant based on typical literature values. For example, the heat capacity for a prototypical α-amine of glycine (King, 1951) predicts only a 0.2 kJ/mol difference in $\Delta H°$ between 4 and 22 °C.

To test the robustness of this tresyl reaction network model, we chose to experimentally study three model amine compounds (Figure 3)—a high pK_a species, αCBZ-lysine; a low pK_a species, glycyl-phenylalanine; and a more sterically hindered amine of intermediate pK_a, phenylalanine—to probe for possible steric inhibition. On the basis of the results from the hydrolysis experiments, a pH range of 7.5–8.5 was chosen for study so that $k_{OH}[OH^-]$ is of the same order as k_w for maximum resolution of the various pathways. Experiments at room temperature (22 °C) and in a 4 °C cold room were conducted to measure the effects of temperature.

Figure 4 shows measured reaction time courses and curves predicted by the model for the three model amines at three pHs and two temperatures. The best-fit rate

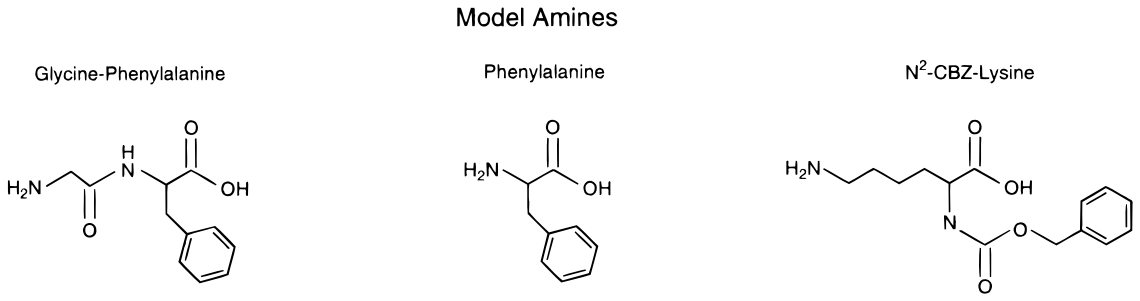

Figure 3. Model primary amines used in coupling studies. Compounds were chosen to span a range of pK_as (see Table 2). Glycine-phenylalanine, phenylalanine, and αCBZ-lysine were chosen as models for peptidyl N-termini, branched amines, and protein surface-presented lysines, respectively.

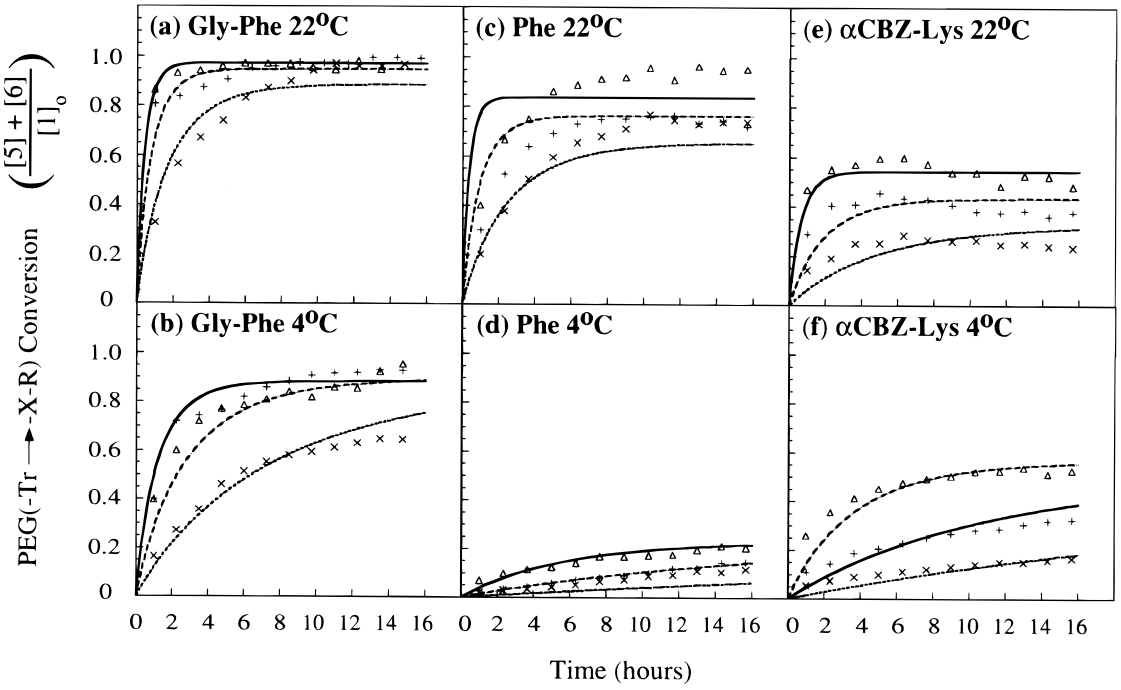

Figure 4. PEG(−Tr → −X−R) conversion data and model fit for the reaction PEG-Tr + H_2N−R → PEG−X−R where X = (NH) or [$OSO_2CH_2C(O)NH$]. Each panel (a−f) is fit by a single set of rate constants to the mechanism prescribed in Scheme 1. Data [symbols, (×) pH 7.5; (+) pH 8.0; (△) pH 8.5] and model predictions [lines, pH 7.5 (- - -); pH 8.0 (— —); pH 8.5 (—)] are given for Gly-Phe at 22 °C (1a), Gly-Phe at 4 °C (1b), Phe at 22 °C (1c), Phe at 4 °C (1d), αCBZ-Lys at 22 °C (1e) and αCBZ-Lys at 4 °C (1f). Conversion data [=([5] + [6])/$[1]_o$] was measured as the fraction of tresyl groups converted to PEG−N−R.

Table 3: Tresyl-Mediated Coupling Effective Rate Constants

	Gly-Phe		Phe		αCBZ-Lys	
rate constant[a]	4 °C	22 °C	4 °C	22 °C	4 °C	22 °C
k_1 (10^{-2} s^{-1} M^{-1})	0.48(0.02)	0.69(0.05)	0.16(0.01)	3.1(0.2)	25(2)	29(2)
k_2/k' (10^2 M^{-1})	13(6)	*b*	*c*	0.63(0.16)	12(6)	5.4(1.3)

[a] Rate constants are given as value (standard deviation). The large standard deviation in the case of k_2/k' for αCBZ-Lys at 4 °C reflects a relative insensitivity of the fit to this parameter.

constants from the χ-squared minimization fitting routine are given in Table 3. The model reaction network (Scheme 1) was able to fit the observed data quite well considering that a single set of rate constants were fit to all pH values simultaneously. In all cases, the model was able to capture the long time behavior trend as a function of reaction pH, as well as the final conversion. The transient behavior was also fit acceptably well in all cases, with the exception of phenylalanine at 22 °C (Figure 4c). The transient portion of Figure 4c suggests a weaker dependence on pH than predicted with [N:] as the driving force, possibly due to an effect of the proximity of the carboxylate group to the nucleophilic amine.

Temperature Effects. The reaction temperature can have a profound influence on the kinetics and product distribution in tresyl-mediated reactions as illustrated in Figure 4. In general it can be said that room-temperature reactions lead to higher total coupling yields. Yet, our data suggest that the distribution of the coupled products, 5 and 6, can also be affected by temperature.

Our data suggest that at lower temperatures, a higher proportion of 5 is formed relative to 6. This is evident from the temperature influence on the initial step of the reaction. Whereas k_w and k_{OH} appear to have significant temperature dependencies, k_1 appears to be only slightly affected by temperature. This suggests that lowering the temperature serves to increase the relative yield of 5. The ratio of k_2/k' is also a function of temperature. The apparent activation energy of k_2 is higher than that of the hydrolysis rate constant, k', as suggested by our data

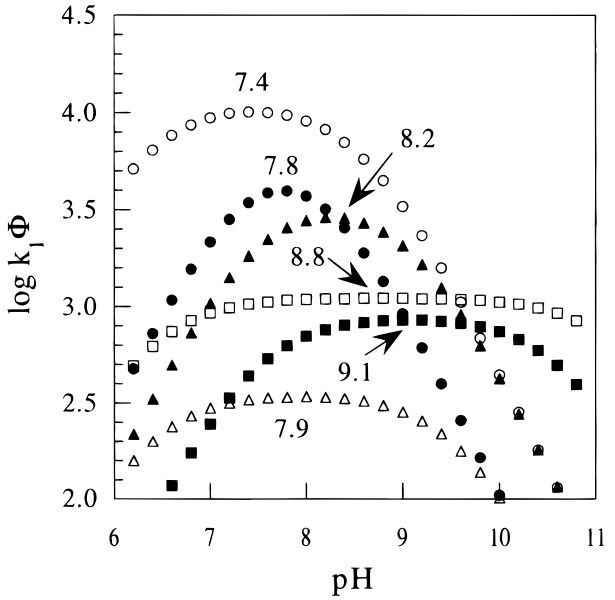

Figure 5. Plot of relative rates of reactions with PEG-Tr in terms of $k_1\Phi$ (see text). Curves at given at 4 °C (open symbols) and 4 °C (filled symbols) for Gly-Phe (○/●), Phe (Δ/s) and αCBZ-Lys (□/■) The pH where $k_1\Phi$ is a maximum is indicated (numeral) for each curve. Maximal $k_1\Phi$ predicts an optimal pH for (1 → 5)-type coupling.

(Table 3). Thus, our data indicate that higher temperatures yield more 6 relative to 4. It should be noted that higher temperatures also contribute to increased hydrolysis through the (1 → 2) pathway.

Temperature also has a small, but significant effect on pK_w and the pK_as of the amines as shown in Table 2.

pH Effects. Increasing the pH of the reaction solution increases the rate of conversion of tresyl species, through the addition−elimination pathway as well as the amine-nucleophilic displacement pathway shown in Scheme 1. Increasing the hydroxyl concentration increases the flux through the addition−elimination pathway (1→ 3). Increasing the pH also has the effect of creating a larger concentration of unprotonated amines, increasing the amine-nucleophilic displacement as well as the conversion of 3 to 6.

The reaction pH has an especially strong influence on the initial fate of 1. A detailed analysis and discussion of similarly competing pH-dependent reactions can be found in the literature (King et al., 1992, 1994). In the present case, the relative values of k_w, $k_{OH}[OH^-]$, and k_1-[N:] must be considered to optimize the amount of 5 formed relative to 2 and 3. This can be quantified as

$$\frac{\text{rate}_{1\to5}}{\text{rate}_{1\to2} + \text{rate}_{1\to3}} = \frac{k_1[\text{N:}]}{k_w + k_{OH}[OH^-]} = k_1[\text{N}]_{total}\Phi$$

where

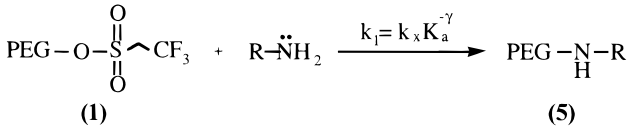
$$\Phi = \frac{\dfrac{[\text{N:}]}{[\text{N}]_{total}}}{k_w + k_{OH}[OH^-]}$$

The parameter Φ then expresses the relative rates as a function of pH, regardless of the absolute concentration of amine and the particular value of k_1 and $[N]_{total}$. In Figure 5 we show a plot of $\log(k_1\Phi)$ versus pH for the three model amines at 4 and 22 °C. By solving for $\partial\Phi/\partial pH = 0$, the pH that maximizes Φ is found to be

$$pH|_{max\Phi} = \frac{pK_w + pK_a + \log\left(\dfrac{k_w}{k_{OH}}\right)}{2}$$

This defines the optimal pH for (1 → 5)-type coupling. It can be seen from Figure 5 that $\Phi(pH|_{max\Phi})$ increases with decreasing pK_a, predicting a lower required amine concentration, but longer reaction times. Decreasing temperature has the effect of somewhat increasing $\Phi(pH|_{max\Phi})$ as well as $pH|_{max\Phi}$.

On the basis of Scheme 1, the interplay of the pH effect on hydroxyl and unprotonated amine concentration can be separated into three regimes: $[OH^-] \ll k_w/k_{OH}$, $[OH^-] \approx k_w/k_{OH}$, and $[OH^-] \gg k_w/k_{OH}$. At low pHs, only hydrolysis (1 → 2) and nucleophilic substitution (1 → 5) are significant, yet a large concentration of the amine species will be needed to favor addition over hydrolysis due to the low fraction of unprotonated amines at low pH. In the intermediate regime, all three pathways can be significant; however, the (1 → 5) pathway can be made dominant with a lower amine concentration than is needed for the later low pH regime. In the high pH regime, hydrolysis is insignificant relative to the first step in the addition−elimination pathway (1 → 3). This regime can prove to be impractical because $[OH^-]$ increases faster than [N:] with increasing pH, requiring a large excess of amines.



In our model, we have attempted to represent all reactions in terms of possible elementary reactions. However, in the case of k_1, in particular, our data suggests that there might be a dependence on the amine pK_a that would not be consistent with the assertion that k_1 is an elementary reaction. It can be seen from Table 3 that k_1 increases with pK_a. This trend acts in the opposite direction but with a smaller magnitude than the pK_a dependence imposed by using [N:] as the effective amine dependence. Attempts to fit the data with $k_1[N]_{total}$ as the driving force failed to yield a fit comparable to that of k_1[N:] as the driving force.

In an attempt to fit all the data for k_1 to a single rate relation, an empirical model was developed for the S_N2 reaction as shown in Scheme 3. This empirical rate equation fits the data of all temperatures, reaction pHs, and amines except for the phenylalanine 4 °C reaction, possibly for steric reasons. The correlation of the empirical rate equation with the measured values for k_1 is illustrated in Figure 6. It is interesting to note that the k_1 dependence on $K_a^{-0.63}$ is invariant with temperature, although only limited data is available at 4 °C. The consistency of this empirical relation across the variety of amines may indicate a slightly different dependence than the concentration of unprotonated amine, [N:].

Steric Effects. Phenylalanine was expected to be the most sterically inhibited. The effect was most noticeable at 4 °C (Figure 4d). This is best illustrated in Figure 6, where the phenylalanine 4 °C reaction is well removed from the trends established by all other rate constants. It is also possible that steric factors rather than the pK_a dependence supported above may account for the higher values of k_1 for αCBZ-Lys as compared to glycyl-phenylalanine 4 °C.

Control of Product Distribution. It could be argued that the relative amount of 5-type, 2° amine linkages and 6-type, sulfonyl linkages may be more important than total yields, especially since 6-type linkages may be subject to slow hydrolytic cleavage. In general, it would be desirable to maximize the number of 5-type, secondary amine linkages. Our model predicts that reactions run

Scheme 3

[b] k' was found to be negligible as compared to k_2 under the conditions examined. [c] k_2 was found to be negligible as compared to k' under the conditions examined.

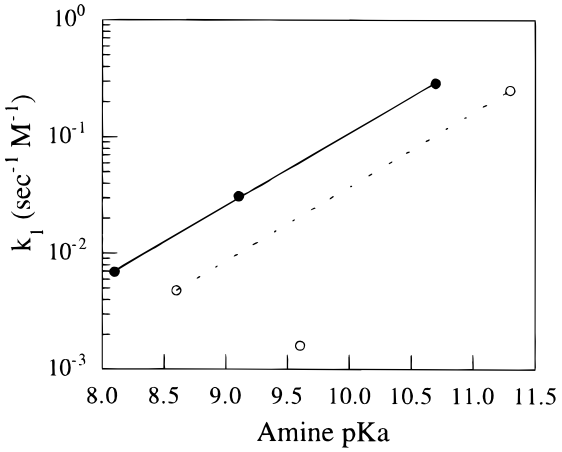


Figure 6. Empirical correlation (see Scheme 3) for rate constant k_1 at 22 °C (●) and 4 °C (○) with the amine pK_a (see Table 2) fit to $k_1 = k_x K_a^{-\gamma}$ where k_x(22 °C) = 6.4 × 10^{-8} M^{-1} s^{-1}, k_x(4 °C) = 1.6 × 10^{-8} M^{-1} s^{-1}, γ(22 °C) = 0.62, and γ(4 °C) = 0.63. Fit at 4 °C (- - -) is included to illustrate the similarity in γ to the fit at 22 °C (—) even though the data point at pK_a = 9.6 is omitted due to suspicion of steric influences.

at 4 °C would have more secondary amine bonds than at 22 °C for a given amine concentration. In general, the fraction of secondary amine linkages increases with increasing amine concentration by increasing the rate of 1 → 5 relative to 1 → 2 + 3.

The distribution of 4 and 6 from 3 is best described by α. At any given time, α is the instantaneous fraction of 3 that will become 6:

$$\alpha = \frac{k_2[\mathrm{N:}]}{k_2[\mathrm{N:}] + k'} = \frac{\dfrac{\mathrm{d}[6]}{\mathrm{d}t}}{\dfrac{\mathrm{d}[4]}{\mathrm{d}t} + \dfrac{\mathrm{d}[6]}{\mathrm{d}t}}$$

Because α is a function of [N:], its value changes as the reaction progresses. To compare values of k_2 for the three model amines at both temperatures, it is instructive to compare the initial value of α. α will tend to decrease somewhat from its initial value as free amines are consumed. Figure 7 shows α(t = 0) for the 18 curves examined. The value of α was found to be consistently larger at 22 °C than at 4 °C. For any given amine, the initial value of α is a increasing function of reaction pH through the dependence of [N:] on the solution pH. α was found to be a decreasing function of pK_a, with a value approaching unity for 100 mM glycyl-phenylalanine at 22 °C, suggesting that the driving force for this coupling pathway has a stronger dependence on solution pH than is exerted through [N:].

CONCLUSIONS

With the judicious choice of reaction temperature and pH, tresyl-mediated couplings can be achieved with high yields. To maximize the total yield and the fraction of secondary amine linkages, our model predicts that it is

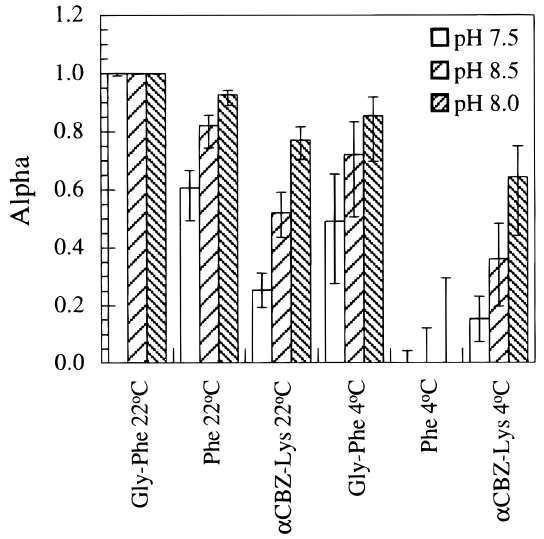

Figure 7. Plot of the initial distribution of products from ref *3*, given as α (= $\mathrm{rate}_{3\to6}/\mathrm{rate}_{3\to4+6}$), based in Scheme 1 and measured rate constants, k_2/k'. Because α is a function of the concentration of the nucleophilic species [N:], α is expected to be a function [N:], and will decrease with time proportional to the depletion of [N:]. Error bars are 95% confidence intervals.

desirable to run tresyl coupling reactions at lower temperatures around pH 8, depending on the amine pK_a as specified by the above equation for $\mathrm{pH}|_{\max\Phi}$ and illustrated in Figure 5. Although total yields ([5] + [6]) may be higher at elevated pH levels (Figure 4), 6-type amide linkages may be unstable over prolonged periods in aqueous environments. Where reactions must be run at higher temperatures due to solubility limitations, maximal secondary amine linkages are predicted at slightly higher pH levels to overcome the higher rate of hydrolysis (k_w).

Where the choice of nucleophilic amine is possible, it is advantageous to use an amine of low pK_a to maximize the concentration of the unprotonated species. This points to an advantage of coupling peptides via an N-terminal glycine rather than through an ϵ-amine group of a lysine residue.

When coupling to tresylated species via a lysyl ϵ-amine is necessary, as may be the case with certain proteins, low temperature at pH ∼8.8 is indicated (Figure 5). In this case high concentrations of amine are necessary, even beyond the 100 mM amine used here, to achieve high yields of secondary amine linkages. Beyond pH ∼8.8, additional tresyl conversion (Figure 4) is predicted to be largely through 6-type amide linkages.

In some applications, it may be the nucleophilic amine that is limiting, rather than the tresyl-activated species. Such a case is encountered in attaching pendant PEG chains to proteins or small molecules. When the tresylated species is used in large excess, it can be seen from Scheme 1 that the 1 → 3 pathway (∼[Tr]) can quickly become dominant over the 1 → 5 pathway (∼[N:][Tr]). This raises the concern that the limited number of amines might be consumed in a 3 → 6 reaction, disfavoring 1 → 5. To maximize secondary amine linkages in this case, it is advantageous to run under conditions where α is small (Figure 7), i.e., at a somewhat lower pH than prescribed by Figure 5.

Received June 25, 1998; Revised Manuscript Received December 21, 1998

To produce a series of model membrane proteins, bovine pancreatic trypsin inhibitor (BPTI) has been modified by specifically attaching reporter groups to Lys-15 and fatty acids or hydrophobic peptides at the N-terminus. Lys-15 of BPTI was protected by trypsin bound to BPTI, then *O*-methylisourea (OMIU) was used to guanidinate all unprotected lysines. The N-terminal amine was then reacted with several saturated fatty acid anhydrides from 8 to 18 carbons in length, or with an SMCC cross-linker. Cysteine-containing hydrophobic peptides, cleaved from resin in the presence of sodium dodecyl sulfate (SDS), were then attached to the protein via the N-terminal cross-linker. The methods described yield a unique, chemically modified protein which can carry site-specific modifications at two distinct residues. The resulting proteins are ideal for diffusional or partitioning studies on model and biological membranes.

INTRODUCTION

We are interested in generating a series of unobtrusive, fluorescently labeled, model transbilayer proteins and fatty-acylated proteins capable of spontaneously inserting into the hydrophobic core of membranes in order to measure accurately the insertion and diffusion of membrane proteins and assess the factors influencing these processes. To accomplish this goal, we have devised methods for site-specifially attaching fatty acids or hydrophobic peptides, along with reporter groups to bovine pancreatic trypsin inhibitor (BPTI).[1] The choice of BPTI as the carrier protein was based on the stability of the protein, its compact structure, and its high aqueous solubility.

To attach peptides specifically to the N-terminus of BPTI, Ebina et al. (1989) and Moll and Thompson (1994) have both utilized *O*-methylisourea (OMIU) to derivatize the four lysine residues of BPTI. OMIU has been used extensively and has been shown to be very specific in its reactivity toward only the ϵ-amino groups of lysine and not N-terminal α-amines (Hughes et al., 1949; Chervenka and Wilcox, 1956). Derivatization of BPTI with OMIU thus yields a protein with all four lysine residues guanidinated (G-BPTI) and the N-terminal amine available for the attachment of peptides, fatty acids, or other groups. To create a second specific labeling site, we protected lysine-15 of BPTI with trypsin. Following guanidination of the BPTI/trypsin complex with OMIU, a fatty acid or cross-linker was attached specifically to the N-terminus of BPTI. Upon dissociation of the trypsin, lysine-15 of BPTI was labeled with an amine-reactive reporter group. Other, less specific strategies for dual protein modifications have been reported previously (Babbitt et al., 1984; Amir and Haas, 1987); however, such strategies generally are specific for only certain modifications or subsequent chromatographic separation of multiple products is required.

The cleavage and handling of hydrophobic peptides is difficult due to their insolubility and propensity to irreversibly aggregate. Moll and Thompson (1994) attached polyalanine peptides to G-BPTI by employing detergents during both the cleavage from the resin and attachment to G-BPTI. We have employed a similar strategy here to attach other, more hydrophobic peptides to guanidinated, trypsin-protected BPTI (K15-G-BPTI).

The N-hydroxysuccinimide ester of palmitic acid has usually been used in the presence of detergents to chemically attach fatty acids to proteins (Lee and Kim, 1995; Huang et al., 1980; Babbitt and Huang, 1985). Detergents, however, can pose difficult purification problems. As an alternative, we have developed a novel tetrahydrofuran (THF) based solvent system which eliminates the need for detergents. As acylating reagents we employed fatty acid anhydrides which are commercially available in a variety of chain lengths.

We describe here, methods for the synthesis and cleavage of hydrophobic peptides, and novel strategies for the site-specific attachment of these hydrophobic peptides or fatty acids to the N-terminus of trypsin-protected, guanidinated BPTI (K15-G-BPTI). We show that trypsin can effectively protect lysine-15 of BPTI from guanidination by OMIU and thereby provide a second specific site for the attachment of a reporter group. Figure

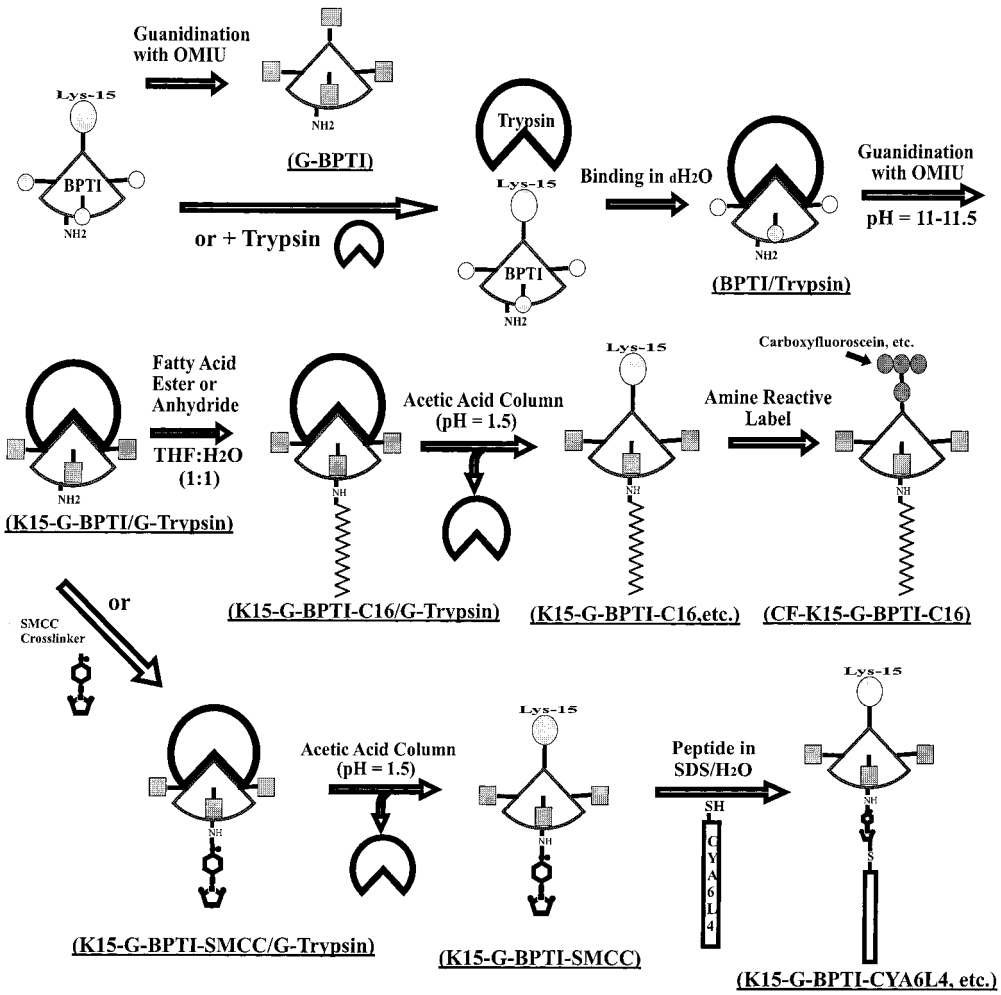

Figure 1. A diagram depicting the steps involved in site-specifically attaching fatty acids, hydrophobic peptides, and reporter groups to BPTI. Lysine residues are depicted as circles, and homoarginine residues as squares. Each step in the synthesis was characterized using reversed-phase HPLC and/or MALDI and ESI mass spectrometry. The names used in reference to each structure are indicated below the corresponding structures.

1 outlines the strategy of the chemical modifications described in this paper. The resulting proteins are ideal for experiments such as membrane diffusion studies or partitioning studies due to their small size, stability, and well-defined structure and composition. In a more general sense, these methods yield a unique carrier protein site-specifically modified at two separate sites.

MATERIALS AND METHODS

Materials. Bovine pancreatic trypsin inhibitor (BPTI) was purchased from Bayer Corporation (Kankakee, IL). Fisher Scientific (Pittsburgh, PA) supplied the barium hydroxide, glycine, sodium chloride, and calcium chloride. Sephadex CM-25 ion-exchange resin and Sephadex G-50 super fine gel filtration resins were obtained from Pharmacia (Uppsala, Sweden), and Spectra/Por 3 regenerated cellulose dialysis membranes (3500 MWCO) were obtained from Spectrum (Houston, TX). *N*-α-Benzoyl-L-arginine-*p*-nitroanilide (L-BAPA), *N*-Hydroxybenzotriazole (HOBt) and all Fmoc amino acids were obtained through Bachem (King of Prussia, PA). Arg-C and Lys-C endoproteinases were obtained from Boehringer Mannheim Corp. (Indianapolis, IN). OMIU, trypsin (type III, bovine pancreas), Trizma-HCl and the N-hydroxysuccinimide ester of palmitic acid (NHS-palmitate), all amino acids, sodium bicarbonate, bromocresol green, ammonium bicarbonate, boric acid, ferric chloride, ninhydrin, TRIZMA base, and all fatty acid anhydrides were purchased from Sigma Chemical Co. (St. Louis, MO). 5-(and 6-)-Carboxyfluorescein was purchased from Molecular Probes (Eugene, OR). TLC plates were from Analtech (Newark, DE). Sulfo-SMCC heterobifunctional crosslinker was purchased from Pierce (Rockford, IL). Tritiated acetic anhydride was purchased from Amersham (Arlington Heights, IL). 2-(1H-Benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), and Nα-Fmoc-Nϵ-tBoc-lysine Wang resin were purchased from Nova Biochem (San Diego, CA). Peptide amide resin (PAL) was purchased from Perseptive Biosystems (Framingham, MA). All other reagents were obtained from Aldrich (Milwaukee, WI).

Guanidination of BPTI/Trypsin Complex with OMIU. The method used to guanidinate the lysine residues of the BPTI/trypsin complex was similar to that of Chervenka and Wilcox (1956) with some modifications. One hundred milligrams of BPTI was dissolved in 10 mL of water and combined with 368.5 mg of trypsin yielding a BPTI to trypsin ratio of 1:1. Twenty grams of OMIU was dissolved in 40 mL of deionized water with stirring at room temperature. This solution was then put on ice, and 40 g of barium hydroxide (anhydrous) was added while stirring. The solution was diluted with water to a final volume of 200 mL. This solution was then centrifuged twice at 10 000 rpm for 20 min, and the supernatants were saved. The pH of the supernatant was then decreased to 11.4 by addition of concentrated hydrochloric

acid. The BPTI/trypsin solution was then added to the OMIU solution on ice and allowed to react for 7 days with stirring at 4 °C. Following the 7 day period, the reaction mixture was dialyzed and purified on a CM-25 ion-exchange column using a 0.02 M glycine buffer (pH 10.5) and eluted with a 0 to 1 M NaCl gradient. The lyophilized complex was then chromatographed on a Sephadex G-50 super fine gel filtration column (1.5 × 45 cm) using an ammonium bicarbonate buffer at pH 7.8. Yields for the K15-G-BPTI/G-trypsin complex were greater than 70%. To dissociate K15-G-BPTI from G-trypsin, the complex was chromatographed on a Sephadex G-50 super fine column (1.5 × 45 cm) equilibrated with a 100 mM acetic acid buffer at pH 1.5 (Ebina et al., 1989). Protein absorbance was monitored at 280 nm. Yields of K15-G-BPTI from this column were always greater than 95%. The purified K15-G-BPTI was characterized by MALDI−TOF and ESI mass spectrometry and amino acid analysis.

Digestion and Sequencing of K15-G-BPTI. K15-G-BPTI was reduced and carboxymethylated as described by Crestfield et al. (1963). Lys-C digestion of the protein was performed by dissolving 0.15 μmol of K15-G-BPTI (reduced and carboxymethylated) and 0.1 mg of Lys-C endoproteinase in 1 mL of buffer containing 5 mM tris and 2 mM EDTA at pH 8.5. The digestion was carried out for 16 h at 37 °C and monitored by MALDI−TOF mass spectrometry. Collision activated dissociation electrospray ionization mass spectrometry (CAD ESI-MS) was used to sequence peptides of interest.

Acylation of G-BPTI and K15-G-BPTI/G-Trypsin with Fatty Acid Anhydrides. A total of 1.5 μmol of G-BPTI or 0.5 μmol of K15-G-BPTI/G-trypsin was dissolved in 1 mL of 100 mM phosphate buffer (pH 7.8). A total of 100 μmol of acid anhydride was then dissolved in 1 mL of THF and added to the protein solution while stirring. For the anhydrides of caprylic acid and capric acid (which are liquids at room temperature), the reagents were added to protein solutions to which 1 mL of THF had already been added. After a reaction time of 1 h, the protein was precipitated by addition of excess THF. Those reactions involving myristic-, palmitic-, and stearic acid anhydrides were performed in a 50 °C water bath to increase the reactivity and solubility of the anhydrides. Yields for the palmitoylated and myristoylated proteins were between 10 and 20%, approximately 30% for C12-G-BPTI, and over 70% for C8-G-BPTI and C10-G-BPTI.

Gel Filtration Chromatography of Acylated G-BPTI and K15-G-BPTI/G-Trypsin. Following reaction with fatty acid anhydrides, G-BPTI samples were dissolved in 1−2 mL of 5% acetic acid and chromatographed on a Sephadex G-25 column (1.5 × 25 cm) equilibrated with the same. The protein eluted in the void volume and was collected and lyophilized. Following the acylation reaction, K15-G-BPTI/G-trypsin samples were dissolved in 2−3 mL of 50 mM ammonium bicarbonate (pH 7.9) and were chromatographed on a Sephadex G-50 column (1.5 × 45 cm) equilibrated with the same buffer. The intact complexes were lyophilyzed then dissolved in 1−2 mL of 100 mM acetic acid (pH 1.5), allowed to equilibrate for 20 min, and chromatographed on a Sephadex G-50 super fine column (1.5 × 45 cm) equilibrated with the same buffer (Ebina et al., 1989). Protein absorbance was monitored at 280 nm during all runs.

Fatty-Acylated G-BPTI and K15-G-BPTI Analysis and Purification by Reversed-Phase HPLC. All solvents were vacuum filtered using an Amicon 0.25 micron filter and degassed under reduced pressure. Solvent A consisted of 0.1% trifluoroacetic acid (TFA) in glass-distilled water. Solvent B consisted of acetonitrile: 1-propanol:iso-butyl alcohol in a ratio of 2:5.5:2.5 plus 0.1% TFA. Samples were dissolved in deionized water and diluted in half with 0.2% TFA. A Zorbax 300SB-C3 semipreparative reversed-phase column (9.4 mm × 25 cm) (MAC-MOD Analytical Inc., Chadds Ford, PA) was used for all purifications. The HPLC system consisted of a Beckman System Gold programmable solvent module 126 and detector module 166, interfaced with an NEC PC-8300 computer. The linear gradient used for purifying the acylated proteins started at 30% B and increased to 90% B over 10 min. Peaks of interest were *immediately* diluted with water and frozen in liquid nitrogen for lyophilization.

Attachment of sulfo-SMCC Cross-Linker to G-BPTI and K15-G-BPTI/G-Trypsin Complex. A total of 1.5 μmol of G-BPTI or 0.5 μmol of K15-G-BPTI/G-trypsin was dissolved in 1 mL of 100 mM phosphate buffer at pH 7.8. To this was added 4 mg of sulfo-SMCC cross-linker, and the reaction was stirred for 10−15 min. The reaction mixture was then chromatographed on a Sephadex G-50 column (1.5 × 45 cm) equilibrated with 100 mM acetic acid at pH 1.5. In initial experiments, the K15-G-BPTI/G-trypsin complex was first chromatographed on a Sephadex G-50 column (1.5 × 45 cm) equilibrated with 50 mM ammonium bicarbonate (pH 7.8) to determine if the complex remained intact following the attachment of the cross-linker.

Synthesis of Hydrophobic Peptides. Fmoc-based automated synthesis was performed on a Symphony peptide synthesizer (Protein Technologies Inc., Tucson, AZ) on low substitution Wang or Pal resins (0.15−0.20 mmol/g). Capping was performed with acetic anhydride following each coupling cycle. Following automated synthesis, the final residues were attached manually. The peptides were radiolabeled by either capping with tritiated acetic anhydride following the final coupling reaction or by using tritiated Fmoc-leucine amino acids which were synthesized using established protocols involving a trimethylsilyl intermediate (Chang et al., 1980; Bolin et al., 1989). Peptides containing N-terminal cysteines were synthesized using a PAL resin affording an amide group at the C-terminus.

Cleavage of Peptides Using Sodium Dodecyl Sulfate (SDS). The solution used to cleave the peptides from the resin was a modified form of that used by Moll and Thompson (1994) and consisted of 950 μL of trifluoroacetic acid (TFA), 25 μL of water, 25 μL of triethylsilane or triisopropyl silane, and 2−5 mg of SDS. The supernatant containing the cleaved peptide was then separated from the resin, and the TFA was reduced to a volume of 100 μL under a stream of dry nitrogen. A total of 1.5 mL of *cold* TBMether was then added, and the solution was stored at −20 °C for 30 min. (To reduce any peroxides present, the TBMether was distilled over $LiAlH_4$ and cooled to −20 °C immediately before use.) The peptide/SDS precipitate was pelleted in a microfuge. The ether was then removed and the pellet dried under nitrogen. The pellet was placed under high vacuum for 30 min to remove any residual ether.

Coupling of Peptides to (K15)-G-BPTI-SMCC. The peptide/SDS complex was immediately dissolved in 1 mL of 100 mM phosphate buffer at pH 6.6. A total of 1.5 μmol of G-BPTI-SMCC or 0.5 μmol of K15-G-BPTI-SMCC was then added to the peptide solution and incubated at room temperature for 1 h. The reaction was stopped by flash freezing the solution in liquid nitrogen followed by lyophilization.

Gel Filtration of (K15)-G-BPTI-Peptide/SDS Complex. To separate the (K15)-G-BPTI-Peptide conjugate from the SDS, gel filtration was performed using a Sephadex G-25 column and PFH buffer. The (K15)-G-BPTI-Peptide/SDS complex was dissolved in 1−3 mL of PFH buffer (depending on the solubility of the sample), loaded on the column and chromatographed at a flow rate of 0.1 mL/min. Protein absorbance was monitored at 280 nm and radioactivity was measured using liquid scintillation. The protein peak was then diluted with water and lyophilized. The method of Sokoloff and Frigon (1981) was used to assay for the presence of SDS.

Gel Filtration and Refolding of the (K15)-G-BPTI-Peptide Conjugate. Initial separation of G-BPTI-Peptide from G-BPTI was achieved using a Sephadex G-50 column (1.5 × 120 cm) equilibrated with 50 mM ammonium bicarbonate (pH 7.8). Following the elution of the proteins, the fractions were kept as dilute solutions overnight. Peaks of interest were then lyophilized.

HPLC Purification of G-BPTI-Peptide Conjugates. The HPLC system used to separate the unmodified protein from that with attached peptide was the same as described above. However, the gradient was more shallow consisting of a change in organic phase from 10 to 30% over 30 min. It was found to be crucial to freeze the purified proteins in liquid nitrogen immediately following elution from the column. If fractions were allowed to stand for more than 30 min before freezing, the resulting lyophylized proteins were mostly insoluble.

Labeling of G-BPTI and K15-G-BPTI-C16,14,12 with ^{3}H-NSP. K15-G-BPTI-C16,14,12 samples were dissolved in 0.5 mL of 100 mM borate buffer (pH 9.5). G-BPTI-C16,14,12 proteins were then added to these samples until the absorbance at 280 nm was greater than 0.5 absorbance units (∼0.6 mM). ^{3}H-NSP (150 μCi) was then dissolved in 150 μL of THF and added to the proteins while stirring. An additional 75 μCi of NSP was added to the reaction after 20 min. After 1 h, the reaction was quenched by addition of 1.5 mL of 1 M hydroxylamine (pH 9) and equilibrated for 1 h. G-BPTI samples were prepared in the same manner, except that a phosphate buffer at pH 7.8 was used in place of the borate buffer. Following treatment with hydroxylamine, the samples were purified on a Sephadex G-25 column (1.5 × 25 cm) equilibrated with 5% acetic acid. The purified samples were then characterized by MALDI−TOF mass spectrometry and liquid scintillation.

Fluorescent Labeling of K15-G-BPTI-C16 at Lys-15. A total of 30 μmol of K15-G-BPTI-C16 was dissolved in 250 μL of phosphate buffer (100 mM, pH 7.9), while 2 mg of 5-(and 6-)-carboxyfluoroscein, succinimidyl ester (CF) was dissolved in 200 μL of dry DMF. Twenty-five microliters of the CF was added dropwise, very slowly, to the protein solution stirring in a minireaction vessel. The reaction vessel was covered in foil and the reaction was allowed to proceed for 1 h at which time 25 μL of 3 M hydroxylamine (pH 8.5) was added to quench the reaction and cleave any esters which may have formed with tyrosine side chains. The entire sample was then diluted with phosphate buffer to 2 mL and desalted on a Millipore spin concentrator (5000 MWCO). The product was characterized by UV spectroscopy and MALDI−TOF mass spectrometry.

RESULTS

Guanidination of BPTI/Trypsin Complex. Figure 2A shows that on a cation-exchange column, the fully guanidinated BPTI (M_r = 6684) elutes at a higher NaCl concentration than K15-G-BPTI (M_r = 6641). Gel filtration was also performed to show that the peak corresponding to fully guanidinated BPTI (NaCl concentration of 0.45−0.55 M) consisted of unassociated G-BPTI and G-trypsin, while the larger peak (NaCl concentration of 0.3−0.4 M) contained protein present as intact complex. These results demonstrate that ion exchange chromatography provides an effective means for separating the dissociated proteins from intact complex and thereby a means for purifying the fully guanidinated G-BPTI from the trypsin-protected K15-G-BPTI.

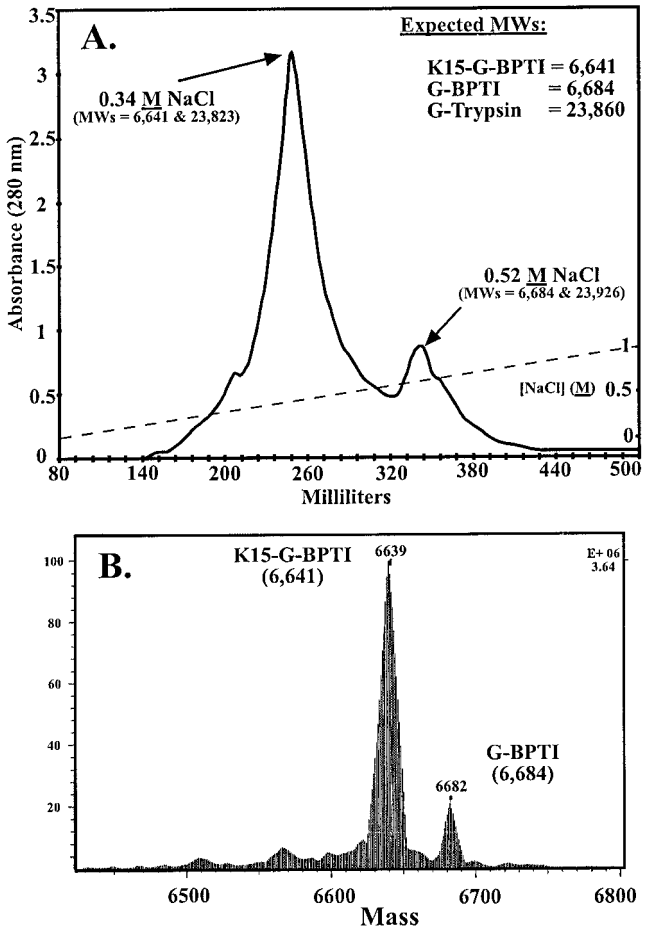

Figure 2. (A) Elution profile obtained for the K15-G-BPTI/G-trypsin complex on a Sephadex CM-25 cation exchange column (0.02 M glycine, pH 10.5) with a gradient of 0 to 1 M NaCl. For each peak, the NaCl concentration is given, as well as the relative molecular mass (MW in figure) of each molecular species eluting in that peak. The relative molecular masses calculated for the three expected derivatives are also given. (B) ESI mass spectrum obtained for the lower relative molecular mass species from the 0.34 M NaCl peak in panel A. The relative molecular masses expected for each peak are given below the names of the two protein derivatives.

Figure 2B shows the ESI mass spectrum obtained for K15-G-BPTI. The major peak at 6639 corresponds to the relative molecular mass of 6641 expected for BPTI with one unguanidinated lysine residue. The peak at 6682 indicates that a small fraction of fully guanidinated BPTI had reassociated with trypsin during the derivatization reaction. This was not surprising since the pK_a of homoarginine is well above 11.5 and under the reaction conditions used, the guanidinium group on a derivatized lysine-15 would therefore possess a positive charge facilitating the formation of a salt bridge with aspartic acid 189 in the active-site pocket of trypsin.

Protease Digestion and CAD Sequencing of K15-G-BPTI. To verify that lysine-15 was the sole, underiva-

tized lysine residue on K15-G-BPTI, an Arg-C endoproteinase digestion was performed. While analyzing the mass spectrum from the digest, we discovered that Arg-C endoproteinase had not only cleaved at arginine residues, but had also cleaved after the guanidinated lysine residues. Since the digestion at these homoarginine residues was incomplete, as well as unexpected, the resulting mass spectrum of the digest was difficult to interpret.

We therefore decided to use Lys-C endoproteinase to digest K15-G-BPTI. Since Lys-C cleaves C-terminal to lysine residues, only one cleavage site at lysine-15 was expected. Figure 3A shows the primary structure of BPTI with the expected Lys-C cleavage site indicated at lysine-15. Figure 3B shows the MALDI−TOF mass spectrum of the Lys-C digest of K15-G-BPTI. The peaks at 1844 and 5178 correspond, respectively, to peptides consisting of residues 1−15 and 16−58 of BPTI. The presence of these peptides indicates that K15-G-BPTI was cleaved at lysine-15. The peaks at 2205 and 2910 were not assigned and are not consistent with cleavage at any of the lysine residues. Thus, it was concluded that the only remaining lysine residue on K15-G-BPTI had to be lysine-15. Control digests of native BPTI showed products consistent with cleavage at all four lysine residues.

Since unassigned peaks were observed during the Lys-C digest, we decided to use collision activated dissociation (CAD) sequencing of the 1844 peptide from the Lys-C digest to confirm that it did indeed consist of residues 1−15 of BPTI (Figure 3C). Since fragmentation of peptides occurs preferentially at amide bonds in CAD experiments, the peaks resulting from the fragmentation were analyzed for relative molecular masses corresponding to cleavages at those bonds. The insert of Figure 3C shows the sequence of BPTI from residues 1−15. The relative molecular masses above the sequence correspond to those expected for peptides resulting from single cleavages of the peptide at each residue starting from arginine-1. The relative molecular masses below the sequence correspond to those expected for peptides resulting from single cleavages of the peptide at each residue starting at lysine-15. Unfortunately, when using this method, preferential cleavage tends to occur on the N-terminal side of proline residues resulting in a significant fraction of peptides corresponding to double cleavages. The second row of relative molecular masses above the sequence correspond to those expected for peptides initially cleaved at proline residues.

The CAD sequencing data showed that large peaks occurred at 920 and 921 as a result of the preferential cleavage of the BPTI peptide between glutamate-7 and proline-8. The appearance of these and other peaks corresponding to fragmentation products expected from the given sequence, indicates that the Lys-C endoproteinase cleavage product weighing 1844 did correspond to residues 1−15 of BPTI. The results from the Lys-C cleavage and sequencing, coupled with the ESI mass spectra, conclusively show that trypsin effectively protects lysine-15 of BPTI from guanidination and that all other lysines on BPTI, as well as on trypsin, became fully guanidinated during the derivatization with OMIU.

Fatty Acylation of K15-G-BPTI/G-Trypsin Complex. The (50% THF)/(50% aqueous phosphate buffer, pH 7.8) utilized here for attaching the fatty acid anhydrides proved essential in maintaining the solubility of both the anhydrides and proteins without the need for detergents. BPTI has been shown to be stable in 70% methanol, 70% ethanol, and 50% acetone (Kassel, 1970). We have demonstrated here that both the inhibitor and the

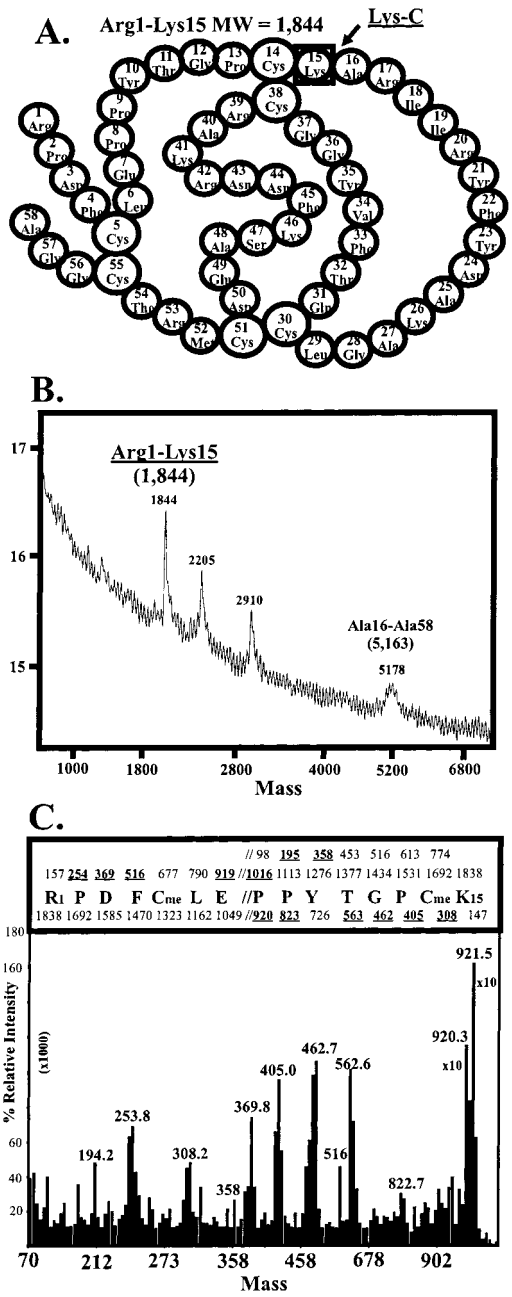

Figure 3. (A) Primary structure of BPTI, the expected site of cleavage of K15-G-BPTI by Lys-C endoproteinase and the calculated relative molecular mass for the peptide resulting from such a cleavage. (B) MALDI−TOF mass spectrum obtain from the Lys-C cleavage of K15-G-BPTI. (C) Graphical display of the data obtained from the CAD sequencing of the 1844 relative molecular mass peptide from panel B. Each labeled peak corresponds to a cleavage product consistent with values calculated from the first 15 residues of BPTI. The insert displays the sequence of the first 15 residues of BPTI with the relative molecular mass calculated for fragmentation of the peptide at each respective peptide bond. Since fragmentation occurred preferentially at proline-8, the relative molecular masses calculated for double fragmentations at this site are given on a second line above the sequence. The peptide fragments observed in the spectrum are in bold and underlined.

inhibitor/trypsin complex are stable in 50% THF. The use of THF aided in the purification of the derivatized proteins as well, since addition of excess THF precipitates the proteins which can then be simply collected as a pellet.

By performing the reaction at pH 7.8, we were able to eliminate nearly all acylation of tyrosine residues (pK_a

≈ 10). Other studies have also shown that at pH values below 8, α-amino groups are much more reactive than ϵ-amino groups (Rana and Meares, 1990; Wetzel et al., 1990). Thus, a pH of 7.8 significantly enhanced the selectivity of the acylation reactions described here. The yields, however, ranged from over 70% for G-BPTI-C8 and -C10 to only about 10% for G-BPTI-C14 and -C16. In preliminary experiments using a borate buffered system (pH 8.5 or 9.5), we have obtained yields of nearly 100% (data not shown). Although multiple tyrosine residues were found to be acylated, such side reactions were reversible with hydroxylamine. Thus, once these reaction conditions have been refined, much higher yields should be realized in future experiments.

Following acylation of the K15-G-BPTI/G-trypsin complex, gel filtration revealed that a small fraction (always less than 5%) of the complex does dissociate during the course of the reaction. However, these proteins were easily purified from the intact complex. Figure 4A displays the elution profile obtained for a palmitoylated K15-G-BPTI/G-trypsin complex on a pH 1.5 acetic acid column used to dissociate the complex. Under these conditions, almost all of the complex dissociated and the K15-G-BPTI-C16 was well resolved from the dissociated trypsin. The disparity in peak size is due to the much larger absorbance of trypsin at 280 nm. Unlike previous studies (Ebina et al., 1989), these conditions provide a complete dissociation of the complex in one chromatographic run. Figure 4B shows an HPLC elution profile obtained for K15-G-BPTI-C16 following dissociation of the complex on the acetic acid column, while Figure 4C shows the MALDI-MS obtained for K15-G-BPTI-C16 following HPLC purification. Both indicate that the product is clean and is modified as expected.

Reversed-Phase HPLC of Acylated Proteins. The solvent system employed was based on that used by Moll and Thompson (1994) to purify polyalanines attached to G-BPTI. The final mobile phase (or solvent B) used in our experiments consisted of 20% acetonitrile, 55% 1-propanol, and 25% iso-butanol. Isobutanol is quite nonpolar with a relative polarity of 3.0 (water = 10.2), however, at this concentration was miscible with water and was found to improve resolution and shorten the retention time of the proteins. A very steep gradient of 6% B/min was also found to enhance resolution. Figure 5 displays the elution profile of each of the acylated-G-BPTIs examined and shows that all of the acylated proteins are well resolved from the unmodified G-BPTI (see also Figure 4B).

Site-Specific Attachment of Reporter Groups. To show that these acylated proteins can be used in a fluorescence recovery after photobleaching (FRAP) experiment or other experiments requiring a fluorescent label, it was necessary to show that lysine-15 could be labeled with an amine-specific fluorophore. The NHS-ester of 5-(and 6-)carboxyfluoroscein (CF) was chosen due to its high quantum yield, low cost, wide use as a general fluorophore, and its susceptibility to bleaching, which is important for FRAP experiments. Both mass and absorbance spectra indicated that the ratio of attachment of the fluorophore to K15-G-BPTI-C16 was 1:1.

Initial attempts at labeling K15-G-BPTI-C16 with tritiated *N*-succinimidyl propionate (^{3}H-NSP) were unsuccessful. The pK_a of the ϵ-amino group on lysine-15 is between 9.8 and 10.4 (Mathews and van Holde, 1990), and thus, the phosphate buffer initially used at pH 7.8 could not deprotonate the ϵ-amine which is necessary for its reaction with ^{3}H-NSP. Morrison et al. (1986) have shown that there is a very significant difference in the

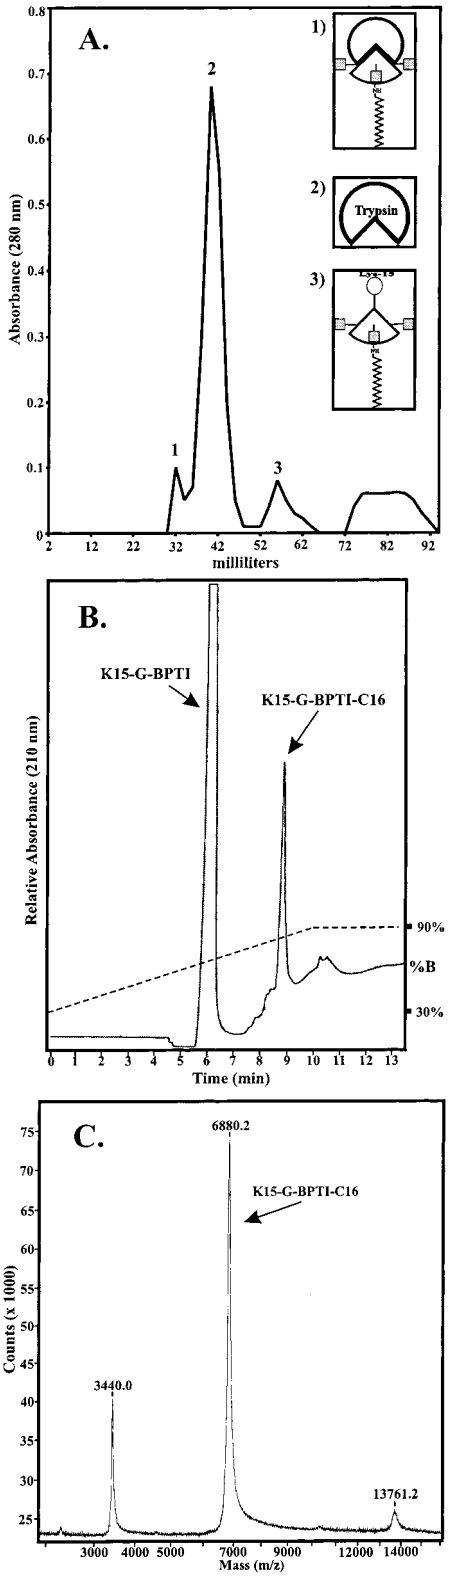

Figure 4. (A) Elution profile obtained for a palmitoylated K15-G-BPTI/G-trypsin complex on a Sephadex G-50 superfine column (1.5 × 45 cm; 100 mM acetic acid, pH 1.5). Protein absorbance was monitored at 280 nm. The peaks are numbered and the structures (from Figure 1) corresponding with the relative molecular masses measured in each peak are indicated. (B) C-3, reversed-phase HPLC elution profile obtained for K15-G-BPTI-C16 from acetic acid column in Figure 4A. The organic phase (B) consisted of acetonitrile:1-propanol:isobutanol (2:5.5:2.5). (C) MALDI-MS of K15-G-BPTI-C16 HPLC peak. Relative molecular mass calculated for [M + H$^+$] (6880.0). The peak at 3440 corresponds to [M + 2H$^+$], and the peak at 13 761.2 corresponds to a gas-phase dimer.

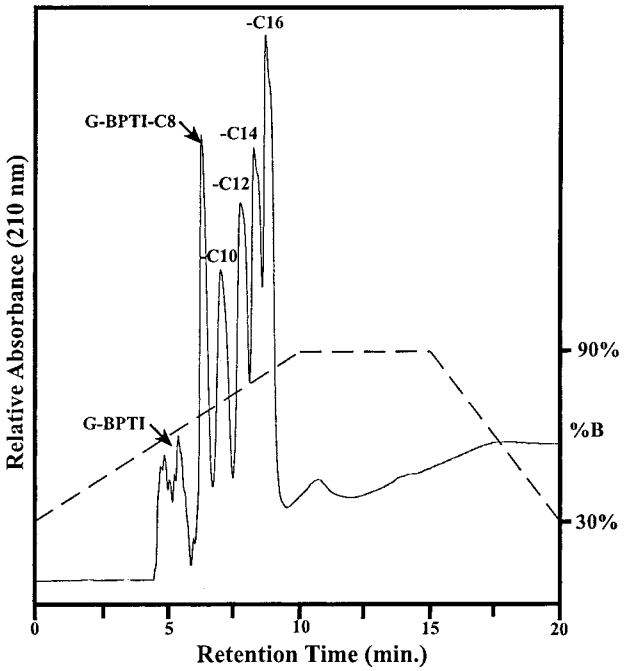

Figure 5. Elution profile obtained on a C-3 reversed-phase HPLC column (9.4 × 250 mm) for a series of G-BPTI proteins N-terminally acylated with fatty acids ranging in length from 8 to 16 carbons. The organic phase (B) consisted of acetonitrile: 1-propanol:isobutanol (2:5.5:2.5). The retention times for each of the proteins are as follows: G-BPTI, 5.3 min; G-BPTI-C8, 6.4 min; G-BPTI-C10, 7.1 min; G-BPTI-C12, 7.8 min; G-BPTI-C14, 8.4 min; G-BPTI-C16, 8.8 min; and G-BPTI-C18, 9.5 min (G-BPTI-C18 not shown in Figure 5). The peaks around 5 min correspond to G-BPTI and to excess TFA introduced during dilution of the samples.

reactivity of NSP with coagulation factor X between pH 7.5 and 9.0. Thus, a borate buffer at pH 9.5 was employed. The reaction proceeded well at this pH; however, in addition to the amide bond at lysine-15, esters were formed with tyrosine residues. These esters were easily cleaved with hydroxylamine yielding a molecule radiolabeled specifically at lysine-15.

Labeling of the α-amine of G-BPTI proved much less problematic due to its lower pK_a. This lower pK_a allowed the reaction to be performed in phosphate buffer at pH 7.8 with no labeling observed at tyrosine residues. The difference in labeling between G-BPTI and K15-G-BPTI-C16 at pH 7.8 indicates that the labeling indeed occurred at the N-terminus of G-BPTI and Lysine-15 of K15-G-BPTI-C16, respectively.

Attachment of sulfo-SMCC to G-BPTI and K15-G-BPTI/G-Trypsin. During the initial course of these reactions, mass spectra indicated the addition of a second linker to some proteins after 10 min. Since the half-life of the NHS-ester was determined to be around 4 min, the species appearing after 10 min was assumed to be due to the reaction of the maleimide group on SMCC with a cysteine residue on G-BPTI. The lag time before the attachment of the second cross-linker supports this assumption, since it is also reasonable that under these conditions, the attachment of a cross-linker to a cysteine residue involved in a disulfide bridge would take longer than the reaction of an NHS-ester with a free amino group.

Therefore, to reduce the fraction of proteins with a second cross-linker attached, the time of the reaction was limited to 10−15 min. It was found that, in this time frame, approximately 30−50% of the total protein received one cross-linker and approximately 10% received two. No proteins with three cross-linkers were observed. Gel filtration showed that the complex remained intact, indicating that lysine-15 remained protected during the reaction. Experiments monitoring the stoichiometry of attachment of free cysteine with the proteins indicated only one reactive maleimide group per protein.

Due to the significant hydrolysis of maleimide groups above pH 8 (Ishikawa et al., 1983), acidic conditions were used during purification of G-BPTI-SMCC and K15-G-BPTI-SMCC. The stability of the maleimide at acidic pH was particularly convenient since it was necessary to dissociate the K15-G-BPTI/G-trypsin complex on a gel filtration column at pH 1.5 (see Figure 4).

Peptide Cleavage Procedures. The method used to cleave the hydrophobic peptides from resin was a modified version of that described by Moll and Thompson (1994) to cleave polyalanine peptides. The goal of our study was to develop a cleavage procedure that could be performed on small amounts of resin, allowing the peptides to be coupled to proteins within a few hours following cleavage. Such a method would eliminate the need for further reduction of cysteine residues on the peptides and allow for cleavage of only necessary amounts of peptide such that unneeded peptide could be kept protected and attached to resin.

Performing cleavages on small resin samples of 20−30 mg (3−4.5 μmol of crude peptide) and using dry nitrogen to remove most of the cleavage solution made it possible to couple peptides to G-BPTI within 2 h of cleavage. Triethylsilane and water were used as scavengers because their volatility allowed them to be easily removed following cleavage. By performing all steps in 1.5 mL eppendorf tubes, microfuges could be used for pelletting the peptides making the procedure quicker and more convenient than methods used in the past. An important step in the procedure proved to be the distillation of TBMether immediately before precipitation of the peptide/SDS complex. Prior to distillation, TBMether can contain peroxides which will oxidize cysteine residues.

Synthesis/Characterization of K15-G-BPTI-Peptide Conjugates. To separate the peptide−protein conjugate from the SDS following the coupling reaction, a propionic acid, formic acid, and water (PFH) buffer was used. Figure 6A shows the elution profile obtained for K15-G-BPTI-CYA_6L_4 using this column. The majority of the radioactivity elutes with the protein, indicating that a significant amount of peptide was attached to the protein. The peak corresponding to the acridine orange assay for SDS indicates that the protein is well resolved from the detergent-containing fractions. All syntheses yielded elution profiles very similar to Figure 6A, indicating that this method completely dissociates SDS from the proteins.

Figure 6B shows the elution profile for the same K15-G-BPTI-CYA_6L_4 protein on a Sephadex G-50 gel filtration column. The protein−peptide conjugate elutes slightly ahead of the unmodified protein as indicated by both the protein absorbance and tritium profiles. This column also serves to separate the protein from any unattached peptides as evidenced by the small radiolabeled peak around 145 mL corresponding to residual peptide. Dilution of the proteins on this column facilitated the refolding of denatured forms of the protein that were observed during HPLC purification.

Many different peptides were attached to G-BPTI and K15-G-BPTI using these methods. Peptides attached included CYA_6, CYA_6L_2, $CYA_6L_2A_2$, CYA_6L_4, and $CYA_{14}L_2A_6$. Yields varied from around 80% for attachment of

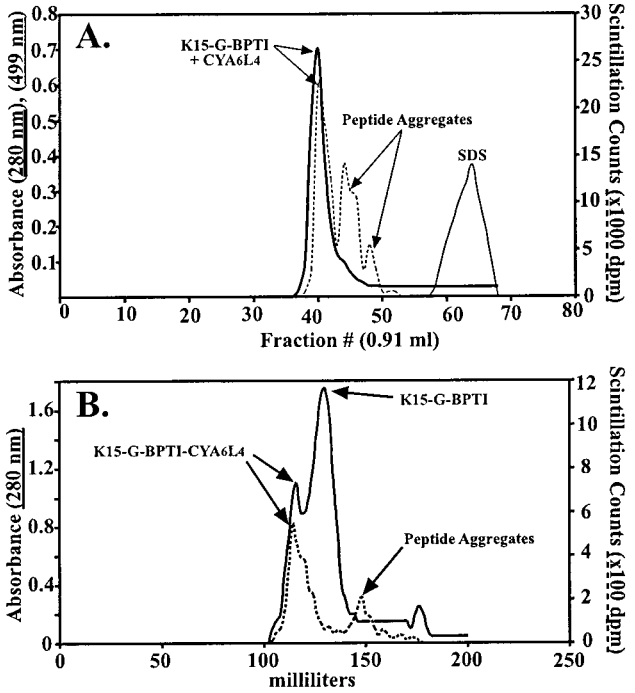

Figure 6. (A) Elution profile obtained on a Sephadex G-25 superfine column (1.5 × 25 cm; propionic acid:formic acid:water, 2:1:2) of the reaction mixture used to couple CYA_6L_4 to K15-G-BPTI-SMCC. Protein and peptide absorbance was measured at 280 nm (solid, bold line), and radiolabeled peptide was assayed using liquid scintillation (dotted line). SDS was assayed by partitioning of SDS/acridine orange complexes into toluene and subsequent absorbance of the complexes at 499 nm (solid, line). (B) Elution profile for the main 280 nm peak from panel A on a Sephadex G-50 superfine (1.5 × 120 cm; 50 mM ammonium bicarbonate, pH 7.8) gel filtration column. Protein and peptide absorbance was measured at 280 nm (solid line), and radiolabeled peptide was assayed by liquid scintillation (dotted line).

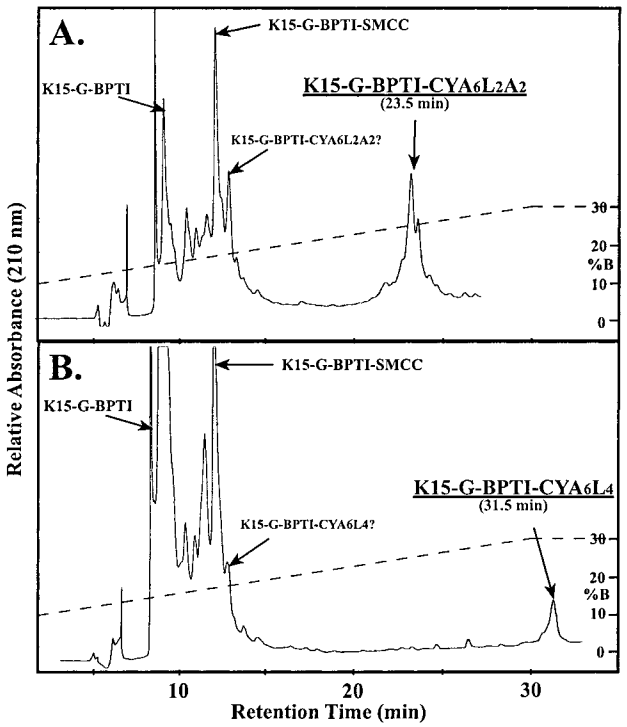

Figure 7. HPLC elution profiles obtained for (A) K15-G-BPTI-$CYA_6L_2A_2$ and (B) K15-G-BPTI-A_6L_4 on a C-3 reversed-phase column (9.4 × 250 mm). The organic phase consisted of acetonitrile:1-propanol:isobutanol (2:5.5:2.5).

CYA_6 and 60% for $CYA_6L_2A_2$ to less than 1% for the attachment of $CYA_{14}L_2A_6$. The predominant factor limiting coupling of the peptides to K15-G-BPTI was the concentration of peptides' free sulfhydryl groups. Thus, yields could be improved dramatically if the yields of full-length peptide were increased.

HPLC Purification of K15-G-BPTI-Peptide Conjugates. Figure 7 shows the HPLC elution profile for K15-G-BPTI-$CYA_6L_2A_2$, and K15-G-BPTI-CYA_6L_4. Using G-BPTI as an internal standard, it was observed that the yield for K15-G-BPTI-CYA_6L_4 was much lower than that for K15-G-BPTI-$CYA_6L_2A_2$. Since the peptides were capped following each coupling cycle, only full-length peptides should have possessed an N-terminal cysteine residue. Thus, the lower yield was primarily due to a lower yield of full-length peptide, which reduced the concentration of peptide containing free sulfhydryls.

The appearance of two peaks for K15-G-BPTI-$CYA_6L_2A_2$ was a concern; however, ESI mass spectrometry verified that the protein in each peak has the expected relative molecular mass of 8024. Also, since the K15-G-BPTI-$CYA_6L_2A_2$ from these peaks was shown to be a good inhibitor of trypsin (data not shown), it was assumed that the two peaks must simply corresponded to two slight structural isoforms of the same protein.

DISCUSSION

The goal of these studies was to create a series of unobtrusive, fluorescently labeled, model transbilayer proteins and fatty-acylated proteins capable of spontaneously inserting into the hydrophobic core of membranes. To create such a protein, we have developed methods for chemically modifying BPTI to contain two specific, reactive sites. To either site, an amine-reactive reporter group may be attached. We have developed methods for coupling fatty acids specifically to the N-terminus without the need for detergents. As an alternate procedure, we have also developed methods for handling and specifically linking hydrophobic peptides to the N-terminus.

To create two specific sites on BPTI for attachment of different groups, we protected Lys-15 of BPTI from modification with OMIU by binding trypsin to the inhibitor. The coupling of a trypsin protection strategy with derivatization by OMIU was unique and significant in two respects. First, these studies are the first time that a derivatization has been performed on a BPTI/trypsin complex above pH 10.0. Second, OMIU does not derivatize the α-amino group of the N-terminus, which results in a BPTI molecule (K15-G-BPTI) with two sites available for the attachment of labels, peptides, fatty acids, or other moieties. Past studies using trypsin to protect lysine-15 employed reagents that modified all unprotected amino groups, thus eliminating the possibility for a second site-specific modification (Ebina et al., 1989; Elkana, 1974). Also, since trypsin survives the modification and stays complexed with K15-G-BPTI, trypsin can be used to further protect lysine-15 during the attachment of other groups to the N-terminal α-amino group. These studies show that trypsin does effectively protect Lys-15 from derivatization and extend to a higher pH, data from past studies showing the extreme stability of the complex formed between BPTI and trypsin (Lazdunski et al., 1974; Levilliers et al., 1970; Delaage and Lazdunski, 1968).

The reaction conditions and reagents used here to fatty acylate the N-terminus of G-BPTI and K15-G-BPTI/G-trypsin are unique in several respects. The use of THF to maintain the solubility of the reagents provides a means for reacting hydrophilic proteins with hydrophobic

fatty acid esters and anhydrides without detergents. This solvent system eliminates the need for dialysis or excessive washing of the protein as described in other methods (Robert et al., 1993; Lee and Kim, 1995; Huang et al., 1980; Babbitt and Huang, 1985) and simplifies purification by allowing the modified protein to be precipitated with excess THF. The use of fatty acid anhydrides for the acylation of G-BPTI is also unique and establishes a simple method for attaching various lengths of fatty acids to proteins and peptides, since the anhydrides of fatty acids of up to 22 carbons in length are commercially available. At pH values below 8, these methods could provide a general means for specific N-terminal fatty acylation of proteins.

To attach hydrophobic peptides to BPTI, we have developed methods for the cleavage and handling of hydrophobic peptides and the attachment of these types of peptides to K15-G-BPTI via an SMCC cross-linker attached at the N-terminus (K15-G-BPTI-SMCC). The entire cleavage process takes only 2 h which allows the peptides to be conjugated to the K15-G-BPTI-SMCC before significant oxidation of cysteine residues can occur. These procedures eliminate the need for further reduction of cysteine-containing peptides prior to conjugation with K15-G-BPTI-SMCC. Unlike past methods (Moll and Thompson, 1994), our methods make small-scale cleavages practical allowing unused peptide to remain resin bound. Although further studies, including peptide mapping, should be performed to ensure the absolute specificity of cross-linker and peptide attachment, our results indicate that these methods can be used to attach very hydrophobic peptides to the N-terminus of K15-G-BPTI and that the stoichiometry of attachment is 1:1.

The methods described here provide a realistic means for producing model membrane proteins containing N-terminal fatty acyl groups or hydrophobic peptides. Because BPTI is a small, stable, highly soluble protein, it is expected to have minimal interactions with any other membrane proteins. Since the site of attachment of fluorescent labels and other reporter groups at lysine-15 is on the opposite pole of K15-G-BPTI, these groups should not effect membrane binding or diffusion. Moll and Thompson (1994) studied the partitioning of peptide−G-BPTI conjugates prepared in a manner very similar to those described here and found them satisfactory as biophysical probes. We have also examined the membrane binding and self-association properties of the fatty-acylated proteins described here (Pool and Thompson, 1998). Both studies attest to the utility of these proteins as model systems for studying protein−membrane and protein−protein interactions.

ACKNOWLEDGMENT

The authors would like to thank Dr. Mike Kinter and Dr. Nicholas Sherman for their assistance in obtaining and interpreting the mass spectral data, Linda Beggerly for her assistance in synthesizing the hydrophobic peptides, and David Singleton for critical reading of the manuscript. This work was supported by NIH Grants GM-14628 and GM-23573.

Labeling of Monoclonal Antibodies with Diethylenetriaminepentaacetic Acid-Appended Radioiodinated Peptides Containing D-Amino Acids†

Serengulam V. Govindan,*,‡ M. Jules Mattes,§ Rhona Stein,§ Bill J. McBride,‡ Habibe Karacay,‡ David M. Goldenberg,§ Hans J. Hansen,‡ and Gary L. Griffiths‡

Immunomedics, Inc., 300 American Road, Morris Plains, New Jersey 07950, and Garden State Cancer Center, 520 Belleville Avenue, Belleville, New Jersey 07109. Received June 26, 1998; Revised Manuscript Received November 18, 1998

The optimal use of radioiodinated internalizing monoclonal antibodies (mAbs) for radioimmunotherapy necessitates the development of practical methods for increasing the level of retention of ^{131}I in the tumor. Lysosomally trapped ("residualizing") iodine radiolabels that have been previously designed are based mostly on carbohydrate−tyramine adducts, but these methods have drawbacks of low overall yields and/or high levels of mAb aggregation. We have developed a method using thiol-reactive diethylenetriaminepentaacetic acid (DTPA)−peptide adducts wherein the peptides are assembled with one or more D-amino acids, including D-tyrosine. Two such substrates, R-Gly-D-Tyr-D-Lys[1-(*p*-thiocarbonylaminobenzyl)DTPA], referred to as IMP-R1, and [R-D-Ala-D-Tyr-D-Tyr-D-Lys]$_2$(CA-DTPA), referred to as IMP-R2, wherein R is 4-(*N*-maleimidomethyl)cyclohexane-1-carbonyl, were synthesized by preparing functional group-protected peptides on a solid phase, selectively derivatizing the lysine side chain with 1-(*p*-isothiocyanatobenzyl)DTPA or DTPA dianhydride (CA-DTPA), deprotecting other functional groups, and finally derivatizing the peptide's N-terminus so it contained a maleimide group. Radioiodinations of the peptides followed by conjugations to disulfide-reduced mAbs, carried out as a one-vial procedure, resulted in 32−89% overall yields, at specific activities of 1.8−11.1 mCi/mg, with less than 2% aggregation. Two internalizing mAbs, LL2 (anti-CD 22 B-cell lymphoma mAb) and RS7 (an anti-adenocarcinoma mAb which targets EGP-1 antigen), labeled with this procedure exhibited a 2−3-fold better cellular retention in Ramos and Calu-3 tumor cell lines, in vitro, respectively, compared to the same mAbs radioiodinated with the chloramine-T method. The rationale for the new approach, syntheses, radiochemistry and in vitro data are presented.

INTRODUCTION

The current status of radiolabeled mAbs[1] in cancer diagnosis and therapy, and possible approaches for improved methods, have been discussed in recent reviews (*1*−*3*). Among the significant issues to consider are the role of mAb metabolism after internalization in tumor cells and the subsequent fate of the attached radionuclide, because this process affects tumor dosimetry (*4*). Radioiodine is released from the cell as iodotyrosine after lysosomal processing of radioiodinated mAbs, while a radiometal label on mAbs is trapped in lysosomes after such processing (*4*, *5*). With radioiodinated mAbs, the residence times of the nuclide in tumor and tumor-to-nontumor discrimination are reduced, and in the case of ^{131}I, the dosimetric advantage of the isotope's 8 day half-life is diminished. This scenario potentially applies to most mAbs which bind to the tumor cell surface, since it has been shown in in vitro studies that most bound mAbs are catabolized with a half-life of 1−2 days (*4*, *6*). The need to develop practical methods to enhance the residence time of radioiodine in tumors is therefore compelling.

To increase the residence time of radioiodine inside cells, mAbs have been labeled with radioiodinated nonmetabolizable carbohydrate−tyramine adducts. Dilactitoltyramine (DLT; *7*−*9*) and tyraminecellobiose (TCB; *10*) are two substrates of this class which have been frequently utilized for this purpose. After mAb processing,

the radioiodinated carbohydrate metabolite is trapped ("residualized") in lysosomes. Stein et al. (*9*) have observed a >3-fold advantage in the level of tumor cell retention of [^{125}I]DLT-labeled mAbs RS7 and RS11 in vitro over a 69 h period, and a pronounced dosimetric (*9*) and therapeutic (*11*) advantage in animal experiments in which the Calu-3 lung carcinoma cell line was used, compared to data obtained using the same antibodies radioiodinated with the chloramine-T method. Similar advantages were reported by Mattes et al. (*12*) in the [$^{125/131}$I]DLT labeling of anti-lymphoma antibody LL2. Ali et al. (*10*) have reported improved tumor retention of radio-
iodine when mAbs were labeled with radioiodinated TCB.

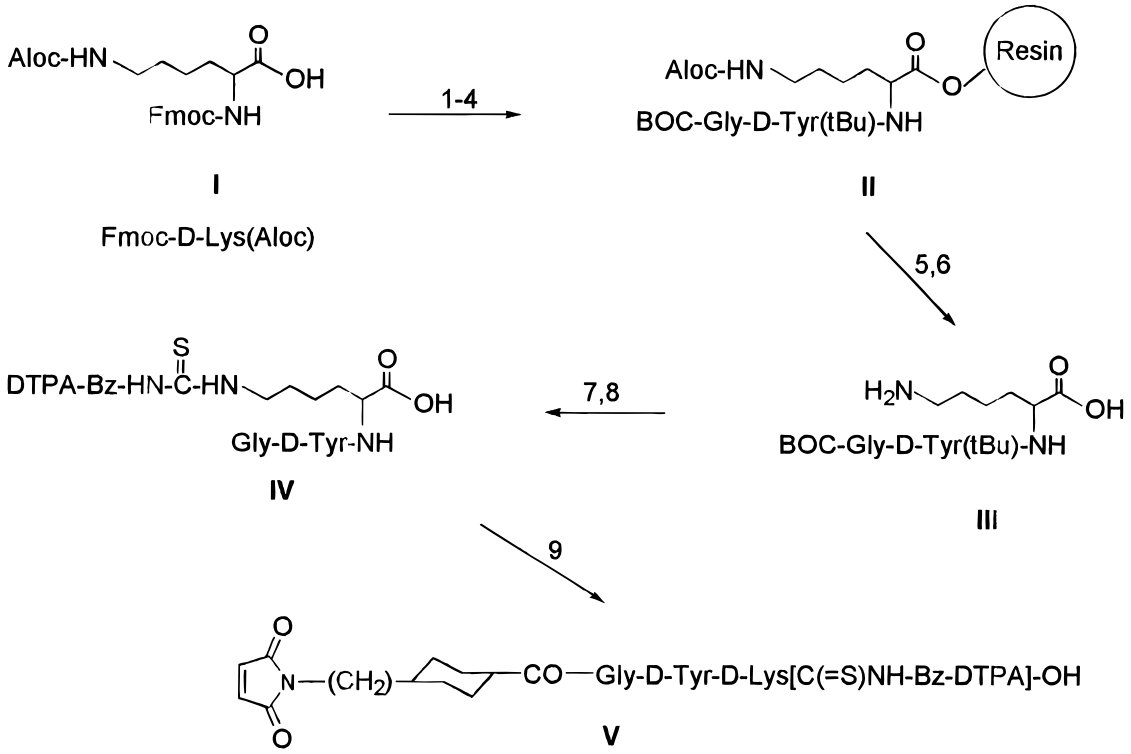
However, these carbohydrate-based iodine radiolabels have certain practical drawbacks. In the case of DLT, the level of overall radioiodine incorporation into mAbs is only 3−6% (*9*, *12*) which results in very low specific activities. With TCB, the conjugation to mAbs makes use of cyanuric chloride as the cross-linker, which produces 10−25% mAb aggregation (*10*). In both cases, the mAb labeling is a multistep procedure. These limitations may impede further development of these agents for clinical use.

Another reported method involves using *N*-succinimidyl 5-iodo-3-pyridinecarboxylate (SIPC), as exemplified in the labeling of the anti-epidermal growth factor variant III mAb L8A4 (*13*). The major intracellularly trapped low-molecular mass catabolite, after internalization and processing of the radiolabeled mAb−antigen complex, was found to be a 5-iodonicotinic acid−lysine conjugate. The level of intracellular retention, in the HC2 20 d2 cell line, of L8A4 mAb radioiodinated by the SIPC method was 68% higher at 2 h than that of the same mAb radioiodinated with the iodogen method, although this difference was reduced at the 20 h time point. In vivo, the amounts of tumor-associated radioactivities in athymic mice bearing HC2 20 d2 xenografts were 25% higher for the mAb labeled with SIPC than for the iodogen mode of radioiodination at time points up to 48 h, but the levels were equalized for both the labels at the 72 h time point. However, the former label also cleared faster from normal organs and thus gave rise to better tumor-to-organ ratios (*13*).

Radiometalated mAbs constitute another class of residualizing labels. The radionuclides from indium- and yttrium-labeled mAbs, for instance, are residualized in the lysosomes in the form of the lysine adducts of the respective metal chelates (*14*). The metal chelators in these cases are usually aminopolycarboxylates, such as EDTA or DTPA.

The goal of this study was to devise a practical method for the production of residualizing radioiodine, based on what was known about the residualization of metal chelates. We hypothesized that if an aminopolycarboxylate, such as DTPA, were attached to the ϵ-amine of D-lysine, and the latter was further elaborated by sequential couplings to one or more D-amino acids, including D-tyrosine, the result would be a DTPA-attached peptide wherein the peptide bonds would be relatively resistant to the action of proteases in the lysosomes. The N-terminus of the peptide could be coupled to a cross-linker, such as sulfo-SMCC, carrying a thiol-reactive group. Radioiodination of such an entity, followed by conjugation to a thiol-containing mAb, could generate a residualizing iodine label, while concurrently enabling the desired yield and specific activity enhancements in radiolabeling.

This work was carried out mainly using internalizing mAbs LL2 and RS7. LL2 is a pan-B-cell mAb, whose binding is restricted to B cells, and is one of a number of mAbs that belong to the CD22 cluster (*15*, *16*). Its internalization has been studied (*12*, *17*). RS7, an internalizing mAb, targets epithelial glycoprotein EGP-1, which is expressed in a number of carcinoma cell lines (*18, 19*). LL2 belongs to the IgG_{2a} isotype, while RS7 belongs to the IgG_1 class. In this report, we describe the syntheses of two bifunctional substrates,[2] IMP-R1 and IMP-R2, the radiochemistry of mAb labelings, and a proof of concept that radiolabeling internalizing mAbs using these radioiodinated peptides leads to enhanced retention of radioiodine in tumor cells.



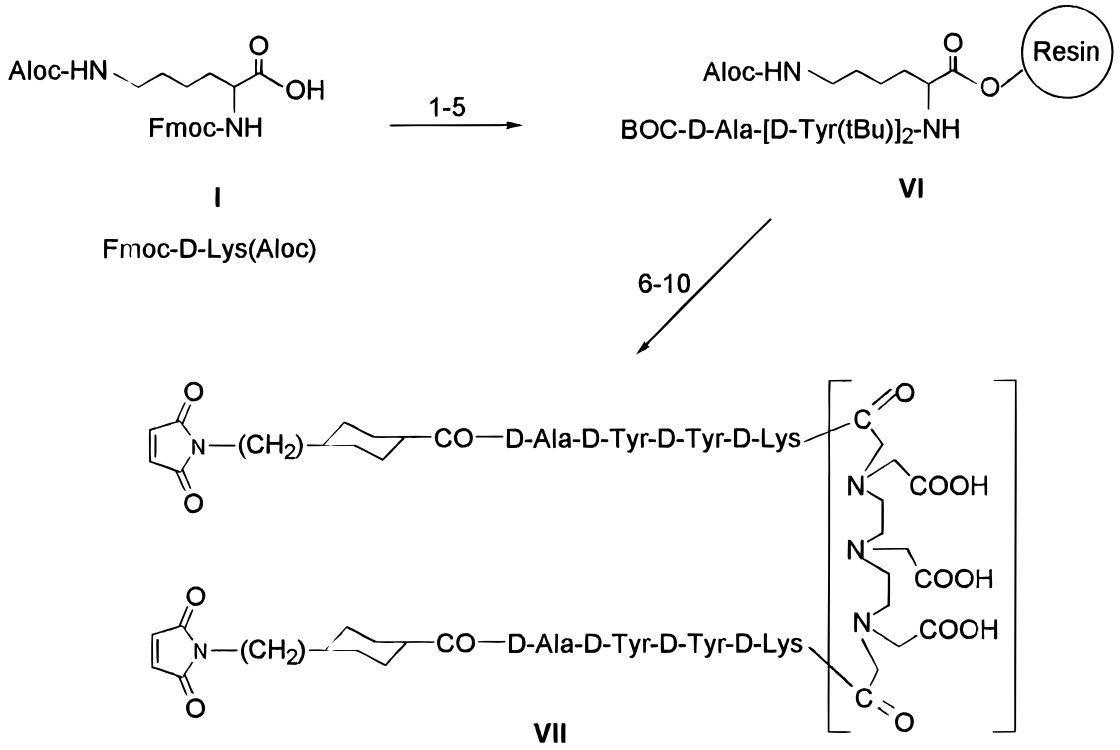
EXPERIMENTAL PROCEDURES

General Procedures. Monoclonal antibodies were obtained from Immunomedics' and the Garden State Cancer Center's antibody production laboratories. 2-Chlorotrityl chloride resin and protected D-amino acids were obtained from Advanced ChemTech (Louisville, KY) and used as received. Sulfo-SMCC was purchased from Pierce (Rockford, IL) and Molecular Biosciences, Inc. (Boulder, CO). All other chemicals and solvents (high-purity grade) were obtained from Advanced ChemTech, Aldrich Chemical Co. (Milwaukee, WI), Fisher Scientific (Pittsburgh, PA), and J. T. Baker (Phillipsburg, NJ). Na^{125}I, Na^{131}I, and $^{111}InCl_3$ were purchased from NEN Life Science Products (Boston, MA). All nonaqueous reactions were carried out under argon or nitrogen. Electrospray mass spectral (ESMS) data were obtained from Mass Consortium (San Diego, CA) and were recorded using either a Hewlett-Packard 1100 MSD or an API 1 Perkin-Elmer SCIEX electrospray mass spectrometer. Exact mass determinations by high-resolution mass spectra were obtained using FAB on a VG ZAB-VSE mass spectrometer. Amino acid analyses were carried out at the Scripps Research Institute Core facility (La Jolla, CA). Analytical HPLC analyses of peptides were carried out using a Waters PrepLC 4000 system using a Nova Pak C-18 (4 μm, 8 mm × 100 mm) Radial Pak cartridge, equipped with a UV detector (220 nm), and using a gradient elution consisting of buffers A (0.1% aqueous TFA) and B (9:1 acetonitrile/water in 0.1% TFA). [The gradient was as follows: 100% A changing to 100% B over the course of 10 min (linear gradient) at a flow rate of 3 mL/min, changing to a flow rate of 5 mL/min at 10.1 min, and remaining isocratic at 100% B at this flow rate for the next 5 min.] Unless otherwise stated, purified peptides were found to be eluted essentially as single peaks under these HPLC analytical conditions. Preparative HPLC was performed on a Waters PrepLC 4000 system using a Delta Pak C-18 (15 μm, 100 Å, 4 cm × 31 cm) or Nova Pak C-18 (6 μm, 60 Å, 2.5 cm × 20 cm) preparative HPLC column. HPLC analyses of radiolabeled mAbs were carried out on an analytical Bio-Sil 250 size-exclusion column, in series with a guard column (both from Bio-Rad Laboratories, Hercules, CA), using 0.2 M sodium phosphate buffer (pH 6.8) as the mobile phase at a flow rate of 1 mL/min, with in-line UV (280 nm) and radioactivity detection. Cell lines were obtained from American Type Culture Collection (Rockville, MD), cultured as previously described (*9*, *12*), and were routinely tested for mycoplasma by the Mycotect assay (Life Technologies, Gaithersburg, MD).

Synthesis of IMP-R1 (Scheme 1). Fmoc-D-lysine-(Aloc) (0.325 g) was dissolved in anhydrous dichlo-

[2] IMP-R1 and IMP-R2 were previously referred to as "DPep" and "DDipep", respectively.

Scheme 1[a]



[a] (1) 2-Chlorotrityl chloride resin, DIEA, CH_2Cl_2, 18 h; (2) 20% piperidine/DMF; (3) Fmoc-D-Tyr(tBu), activated with HOBt and DIC, DIEA, step 2; (4) BOC-Gly, activated with HOBt and DIC, DIEA; (5) $[(C_6H_5)_3P]_4Pd$, Bu_3SnH; (6) 1:1:8 HOAc/CF_3CH_2OH/CH_2Cl_2, 3% TFA; (7) ITC-Bz-DTPA, pH 8.5; (8) TFA; (9) sulfo-SMCC, pH 7.0−7.2, 1 h.

romethane (5 mL) and mixed with DIEA (0.55 mL). The solution was mixed with 0.5 g of 2-chlorotrityl chloride resin at room temperature for 18 h. The resin was filtered, washed with solvents, and dried in a stream of nitrogen. The rest of the steps for the synthesis of resin-bound BOC-Gly-D-Tyr(tBu)-D-Lys(Aloc) followed standard Fmoc protocol (*20*, *21*) utilizing, sequentially, Fmoc-D-tyrosine(tBu) and BOC-glycine. The Aloc protecting group was removed by adding a solution of 0.1547 g of tetrakis-(triphenylphosphine)palladium(0) in a mixture consisting of dichloromethane (40 mL), acetic acid (2 mL), and DIEA (5 mL), followed by the addition of tributyltin hydride (5 mL). After 1 h, the filtered resin was washed with solvents, dried, and treated with 10 mL of 1:1:8 acetic acid/trifluoroethanol/dichloromethane, containing 3% TFA, for 1 h. The peptide, cleaved from the resin, was collected by filtration of the reaction mixture. Solvent removal furnished the protected peptide **III** as a gummy material which was essentially pure as determined by HPLC (>95%), and was used as such. It had a retention time (HPLC) of 7.10 min. The electrospray mass spectrum exhibited an M + H peak at *m/e* 523 (positive ion mode) and an M − H peak at *m/e* 521 (negative ion mode). This product (53 mg, 0.1 mmol) was derivatized with ITC-Bz-DTPA (0.2 mmol) in water (pH 8.5) at 37 °C for 4 h. HPLC analysis indicated ~65% conversion. Preparative purification via reverse-phase HPLC furnished 30 mg of the precursor of **IV** as a colorless solid. It had a retention time (HPLC) of 7.54 min. The mass spectrum exhibited an M + H peak at *m/e* 1063 (positive ion mode) and an M − H peak at *m/e* 1061 (negative ion mode). This material was then treated with 0.8 mL of a mixture consisting of TFA (2 mL), dichloromethane (0.5 mL), 0.12 mL of 1:3 (v/v) ethanedithiol/anisole, and 0.06 mL of water and the mixture stirred for 1 h at room temperature, and the product (**IV**, >98% pure as determined by HPLC) was precipitated with diethyl ether. It had a retention time (HPLC) of 5.31 min. Mass spectrum: M + H at *m/e* 907, M − H at *m/e* 905. Exact mass: calcd for M + Na 929.3327, found 929.3370 (mass spectrum). Amino acid analysis, found (expected): Gly, 1.05 (1); Tyr, 0.92 (1); Lys, 0.95 (1). The intermediate **IV** (25 mg) was reacted with a 5-fold molar excess of sulfo-SMCC in 0.1 M sodium phosphate (pH periodically adjusted to be in the range of 7.0−7.2) for 1 h. The reaction proceeded with ~50% efficiency (HPLC). Preparative reverse-phase HPLC yielded IMP-R1 (**V**). It had a retention time (HPLC) of 6.36 min. Electrospray mass spectrum: M+H at *m/e* 1126 (positive ion mode) and M−H at *m/e* 1124 (negative ion mode). Additionally, the mass spectra exhibited peaks at *m/e* 1186 and 1184 in the two ion modes, respectively, which were about 30% of the intensity of the main mass peak (see Results and Discussion). Exact mass: calcd for M + H 1126.4423, found 1126.4381 (mass spectrum). A repetition of the last step using >95% pure sulfo-SMCC gave IMP-R1 whose mass spectrum showed a negligible peak at *m/e* M + H + 60.

Synthesis of IMP-R2 (Scheme 2). The resin-bound Fmoc-D-Lys(Aloc) was elaborated to **VI** via treatment with two successive D-tyrosine(tBu) units followed by BOC-D-alanine. After the Aloc group removal, the ϵ-amine at the C-terminus of the resin-bound peptide was reacted with a 6-fold molar excess of CA-DTPA in DMF, added in portions over the course of 1 h. After workup involving filtering and washing the resin with solvents, the final peptide was cleaved from the resin under mild acidic conditions. The product was purified by preparative reverse-phase HPLC. Cleavage of BOC and tBu protecting groups using TFA/dichloromethane/anisole produced the precursor to the title compound. It had a retention time (HPLC) of 5.44 min. Electrospray mass spectrum: *m/e* 1445 (M + H). Exact mass: calcd for M + Na

Scheme 2[a]

[a] (1−3) Steps 1−3 of Scheme 1; (4) step 3 of Scheme 1; (5) BOC-D-Ala, activated with HOBt and DIC, DIEA; (6 and 7) steps 5 and 6 of Scheme 1; (8) DTPA dianhydride, DMF, Et_3N; (9 and 10) steps 8 and 9 of Scheme 1.

1466.6456, found 1466.6489 (mass spectrum). Amino acid analysis, found (expected): Ala, 2.10 (2); Tyr, 3.69 (4); Lys, 2.22 (2). This intermediate was further derivatized with a 10-fold excess of sulfo-SMCC as described previously. Purification by preparative reverse-phase HPLC yielded IMP-R2 (**VII**). It had a retention time (HPLC) of 6.99 min. Electrospray mass spectrum: *m/e* 1883 (M + H). In addition, a peak at *m/e* 1943 (M + H + 60) was observed (see Results and Discussion). Reaction yields were estimated by HPLC analyses of reaction mixtures. The precursor to the DTPA-coupled peptide was obtained in >95% yield, and the coupling to CA-DTPA gave ~80% yield; the TFA deprotection proceeded in >95% yield, and the final derivatization with sulfo-SMCC resulted in ~40% conversion.

Stock aqueous solutions (0.75−1.24 mM, pH 5.6) of the peptides were aliquoted in several vials and stored frozen (−80 °C). For radioiodinations, 5−7 μL (~6 nmol) of the peptide solution was used.

Radioiodination and Conjugation to mAb-SH. *DTT Reduction of mAbs.* Intact IgG of LL2 (0.55 mL, 13 mg/mL) or RS7 (0.55 mL, 9 mg/mL) was mixed with 0.55 mL of 0.1 M sodium phosphate (pH 7.0), 0.11 mL of 0.5 M sodium borate buffer (pH 8.5), and 6 μL of a freshly prepared DTT solution (2.6 M). The solution was purged with argon to exclude the presence of air, incubated at room temperature for 30 min, and purified with centrifugation SEC (*22*) on two successive 3 mL columns of Sephadex G50/80 in 0.1 M sodium phosphate (pH 6.6). Another method involved mixing 0.1 mL of IgG (8−10 mg/mL) with 6 μL of 0.1 M aqueous EDTA (pH 7) and 6 μL of 40 mM DTT, purging with an inert gas such as argon, incubating at 37 °C in a water bath for 40−50 min, and purifying as described above.

Iodogen Method. Twenty microliters of a diluted solution of PBS [0.8 mL of water and 0.02 mL of 0.5 M PBS (pH 7.5)] was added to 3−5 μL of $Na^{125}I$ (2 mCi) in the activity vial. Buffered $Na^{125}I$ was transferred into a septum-sealed 1 mL vial containing the peptide solution (5−7 μL, 6 nmol) and a coating of iodogen (60 μg). The vial was shaken every 5 min for 20−30 min, and the solution was syringed out into a second septum-sealed vial containing a (4-hydroxyphenyl)acetic acid solution (40 mM, 1.5 μL). After 2−5 min, DTT-reduced antibody (0.5 mg) was added and the vial contents were incubated for a further 40 min. [Although DTT reduction was carried out on ~1−7 mg scale for convenience, only a small portion was used for conjugating to radioiodinated IMP-R1 or -R2.] The rest of the processing and purification were as described below for the chloramine-T method.

Chloramine-T (CT) Method. To $Na^{125}I$ (2 mCi) in the activity vial were added PBS (0.5 M, pH 7.5, 20 μL), a peptide solution (5−7 μL, 6 nmol), and aqueous chloramine-T (4.4 mM, 20 μL). After 1−2 min, piperidine (14 mM, 20 μL), (4-hydroxyphenyl)acetic acid (5 mM, 20 μL), and potassium iodide (5 mM, 20 μL), each in water or 50 mM sodium phosphate (pH 7.5), were added sequentially, and the mixture was incubated for 1 min. Reduced IgG (0.2−0.5 mg) was then added, and the mixture was incubated for 20−30 min. Finally, aqueous sodium tetrathionate (50 mM, 20 μL) was added and the mixture incubated for 5 min. The iodination mixture was diluted with 0.25 mL of a solution of 40 mM PBS/10 mM sodium iodide, containing 0.02% sodium azide and 0.1% gelatin (pH 7.0), and transferred onto a 3 mL size-exclusion column of Sephadex G50/80 equilibrated in 50 mM PBS (pH 7.0). The vial was further rinsed, and the rinse was also transferred. Purification was carried out via centrifugation SEC.

Radiolabelings of mAbs with ^{111}In, [^{125}I]DLT, and $^{125/131}I$ (CT Method). These labelings were carried out as reported (*9*, and references therein). For ^{111}In labelings, conjugates of RS7 and LL2 intact mAbs with ITC-Bz-DTPA were used, unless otherwise stated.

Immunoreactivity (IMR). Comparisons of IMRs of the various RS7 preparations were carried out via a direct cell binding assay as described previously (*18*). Antigen-expressing cells (typically ME180 cells) were washed with PBS (Dulbecco's PBS without calcium and magnesium), and the cell suspension (100 μL) was mixed with labeled mAb (~50000 cpm) and 25 μL of either an unlabeled irrelevant mAb or an unlabeled specific mAb (RS7). A minimum of a 100-fold excess of unlabeled mAb was used. After incubation for 1 h at 4 °C with shaking, the mixture was diluted with PBS containing 1% horse serum, cells were pelleted for 5 min at 400*g*, and the amount of radioactivity associated with the pellet was counted. Data from triplicate experiments were computed as average percentages of specific bindings. Results obtained at two or three cell concentrations were compared to determine if a plateau of mAb excess had been reached.

In Vitro Antibody Retention Experiments. These studies were carried out as described in detail in published work (*6, 9*). Raji, Calu-3, and ME180 cell lines were grown in RPMI 1640 medium (Gibco, Grand Island, NY) supplemented with 5% fetal bovine serum, 5% horse serum, penicillin, streptomycin, glutamine, and sodium pyruvate (Gibco). All incubations were carried out in tissue culture medium at 37 °C. Confluent cells in 96-well plates were incubated with 5×10^5 cpm of labeled antibody for 2 h and then washed four times with media by centrifugation. Tissue culture medium (0.2 mL) was added, and incubation was continued for specified times as indicated in the Results. Cells remained viable for at least 3 days. At indicated times, 0.1 mL of the medium was removed, and after washing via centrifugation, the cells were solubilized with 2.0 M NaOH to determine the amounts of cell-bound radioactivity. After the total counts per minute were determined in the culture medium, iodinated mAbs were precipitated with 5 mL of cold 10% trichloroacetic acid, the indium samples were precipitated with 10 mL of methanol with the use of 1.0 mg of bovine IgG as a carrier protein, and the precipitates were collected by centrifugation. The amounts of precipitable radioactivity and soluble radioactivity in the supernatant were thus determined. The extents of antigen-specific bindings, determined by adding a large excess of unlabeled specific mAbs (50 μg/mL) in control wells, were >90%. Each mAb processing experiment was carried out in triplicate unless otherwise stated.

RESULTS

Solid-phase peptide syntheses were carried out utilizing a standard Fmoc strategy (*20, 21*). The functional group-protected peptide was assembled on the 2-chlorotrityl chloride resin; the Aloc group was selectively deprotected by a Pd(0)-mediated reaction (*23*), and the peptide was cleaved from the resin under mild acidic condition. This was followed by the derivatization of the lysine side chain, the cleavage of BOC and tBu groups, and finally the reaction of the amine terminus with sulfo-SMCC. Differential protections of the ϵ-amine of D-lysine and the peptide's N-terminus, with Aloc and BOC protecting groups, respectively, which were cleaved under different conditions, enabled differential derivatizations of the amines. The methods used for peptide bond formation are known to cause negligible racemization (*21*).

The intermediates prior to SMCC derivatization, in both IMP-R1 and IMP-R2, were characterized by electrospray mass spectra, by exact mass analyses, by high-resolution mass spectrometry, and by amino acid analyses. After derivatization with the cross-linker, both the bifunctional substrates exhibited M + H + 60 peaks (estimated to be 30%) in the electrospray mass spectra in addition to the expected mass peaks, as a result of an impurity (M + 60) present at the same level in the particular lot of sulfo-SMCC used.[3] This suggested that in the particular lot of the cross-linker used, perhaps the maleimide group's functional purity was compromised by a 1,4-addition of acetic acid, or some other entity with a molecular mass of 60 Da, to the same.[3] The consequence of the presence of a M + 60 side product is in the lowering of the observed overall radioiodination−conjugation yield, but does not otherwise affect the utility aspect of the radiolabeled conjugates. The preparation of IMP-R1 was repeated when >95% pure sulfo-SMCC (including maleimide purity) was made available from a different commercial source. As expected, the mass spectrum of this preparation of IMP-R1 exhibited only a negligible level of the previously seen impurity.

Disulfide reduction was carried out using DTT. Reduced IgGs (3.8−5.6 mg/mL) were estimated to contain 8.84 thiols (for LL2) and 8.95 thiols (for RS7) per IgG molecule by Ellman's assay (*24*), corresponding to the breakage of four disulfide bonds. Under a variety of conditions, using up to 250 molar equiv of DTT, 8−9 thiols per IgG were produced (not shown). Using 2-mercaptoethanol, the number of thiol groups produced per IgG was 4−5, but the final radioiodinated mAbs derived thereof were not different from those derived from the DTT-reduced IgGs in terms of in vitro and in vivo characteristics (not shown).

Radiolabeling consisted of peptide radioiodination and subsequent conjugation to reduced IgG. Only the combined yield of the radioiodination and the conjugation steps (overall yield) was determined routinely. Overall yields were based on the amount of radioactivity recovered after purification by centrifugation SEC. The radioactive material obtained after purification was determined to be the relevant mAb, based on the retention time on analytical SE-HPLC. In a few cases where the HPLC analyses showed the presence of a slower-eluting component (low-molecular mass entity, such as a labeled peptide not completely removed by the purification method, usually <5%), overall yields were appropriately corrected. Specific activities were calculated from the amount of radioactivity in the purified final material and the antibody content in the same. The latter was derived from the amount of mAb used, and correcting for the customary loss of ~5% of the protein on the size-exclusion column. On a few occasions, we also determined the peptide radioiodination yields by analytical size-exclusion HPLC. The HPLC sample consisted of an aliquot of radiolabeling mixture prior to quenching with (4-hydroxyphenyl)acetic acid, which was treated with sodium metabisulfite to reduce reactive iodine to sodium iodide. Panels A and B of Figure 1 show the results from size-exclusion radio-HPLC analyses of $Na^{125}I$ and the reaction mixture of [125I]IMP-R1 radioiodination, respectively. Areas under the broad peptide peak and the sodium iodide peak in the HPLC chromatogram of IMP-R1 radioiodination (Figure 1B) are seen integrated in a 7:3 ratio, indicating a 70% incorporation of radioiodine in the peptide. The mAb conjugation yield was not determined separately, but was computed from the overall and radioiodination yields. For instance, a high overall yield

[3] The supplier concurred with our finding about the specific product lot (communication of April 14, 1998). A conversation with the supplier indicated that that lot of the material contained acetate.

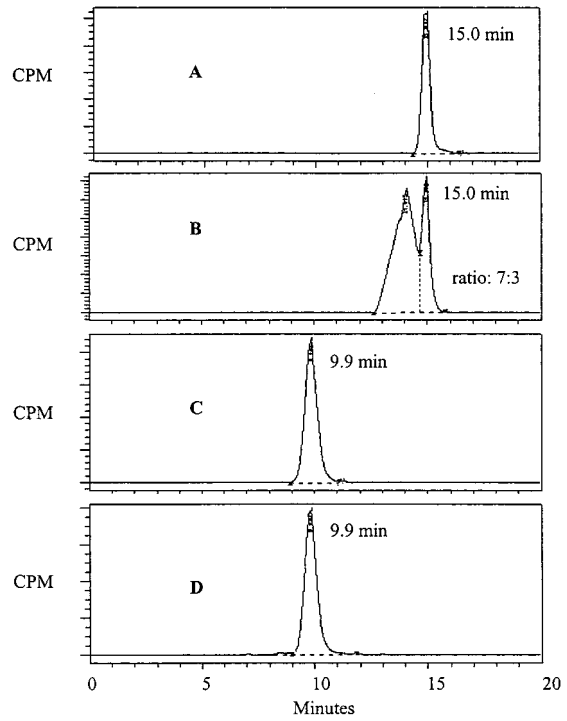


Figure 1. Analytical size-exclusion HPLC analyses, with radiomatic detection, of representative radioiodinations. (A) $Na^{125}I$. (B) [^{125}I]IMP-R1 radioiodination mixture (chloramine-T method), treated with sodium metabisulfite. Although a baseline separation is not achieved, the sodium iodide peak can be distinguished from the broad peptide peak. (C) Purified [^{125}I]-IMP-R1−RS7. (D) Purified [^{125}I]IMP-R2−RS7.

(74−89%), when IMP-R2 was used, implied a minimum average of 85% yield for each of the two steps. Panels C and D of Figure 1 display radio-HPLC traces of purified [^{125}I]IMP-R1−RS7 and [^{125}I]IMP-R2−RS7, respectively. The recoveries from the HPLC columns were judged to be good, based on empirical correlations of the amounts of radioactivity injected onto the HPLC column with the millivolt outputs, and comparing the same with historical data. In one instance, the actual recovery, as determined for purified [^{125}I]IMP-R1−RS7, was quantitative.

Table 1 contains incorporations, specific activities, and levels of aggregation (determined from HPLC) for representative labelings of LL2 and RS7 mAbs which are the internalizing mAbs of focus in this study. Table 1 also gives two entries (14 and 15) of data obtained with a CEA mAb, MN-14 (*25*), and LL1 which is another internalizing anti-lymphoma mAb (*26*), to demonstrate the generality of the labeling method. The control experiment (entry 16) served to ensure that, when the described procedures were used, nonspecific labeling of mAb was negligible (less than 0.5%) when the peptide was not present. The data in Table 1 fall into three distinct patterns. (i) When iodogen was used for the radioiodination of IMP-R1, the overall yield was 21−30% (entries 1−4). (ii) The CT-mediated labeling of IMP-R1 offered better overall labeling yields (32−44%) at specific activities of 1.7−2.0 mCi/mg (entries 5−9). (iii) The CT-mediated iodination of IMP-R2 gave much enhanced yields and specific activities (>74% yield, 5−11 mCi/mg; entries 10−15). The level of aggregation was usually less than 2%. A level of aggregation of about 5% was seen in some initial LL2 labelings with [^{125}I]IMP-R1 using the iodogen method, but this was not observed subsequently (not shown).

In a single radiolabeling of RS7 carried out with a newer preparation of IMP-R1 (the latter prepared using >95% pure sulfo-SMCC), an overall yield of ∼42% was achieved with a doubling of the specific activity from 2 to 4 mCi/mg.

Table 1. Overall Incorporations, Specific Activities, and Aggregate Content of Purified [^{125}I]IMP-R1/R2−mAb-SH Conjugates for Representative Labelings[a]

	substrate	mAb-SH	mCi used	% yield[b]	mCi/mg[c]	% aggregation[d]

[a] Chloramine-T as the oxidant in peptide iodination unless otherwise stated. [b] Overall isolated yield. [c] Specific activity of the purified product. [d] Determined by HPLC analysis. [e] Iodogen as the oxidant in peptide labeling. [f] No peptide was used in this control. [g] N/A, not applicable.

Immunoreactivities (IMRs) of labeled RS7 preparations were determined with a direct cell binding assay (*18*). Representative data of percent average bindings (with <5% variations from the mean, in each case, of triplicate data) were 69.3 and 65.7% for [^{131}I]RS7(conventional label), 78.4 and 72.6% for [^{125}I]IMP-R1−RS7, 72.3 and 58.2% for [^{125}I]DLT−RS7, and 52.1 and 43.9% for [^{111}In]-RS7, with numbers in each set corresponding to binding at 2×10^7 and 1×10^7 cells/mL, respectively. In a separate experiment (with no blocking performed), the percent average bindings from duplicate data were 73.1, 69.4, and 66.3% for the [^{125}I]IMP-R2 label and 75.3, 70.7, and 56.2% for the conventional ^{131}I label, with numbers in each set corresponding to binding at 2×10^6, 1×10^6, and 5×10^5 cells/mL, respectively.

Results from in vitro antibody retention experiments are shown in Figures 2−4. In Figure 2A, we compare the processing of [^{125}I]IMP-R1−LL2 with that of [^{125}I]LL2 (CT) by Raji cells. At 45 h, the amount of cell-bound radioactivity for IMP-R1 label was 37.9% of the initially bound value, which was 2 times that for the conventional (CT) label. Panels B and C of Figure 2 pertain to intact and degraded mAbs in the supernatant, respectively, for the two labels compared. In a different experiment (not shown in the figure), the amounts of Raji cell-retained radioactivity, up to 5 days, were compared for three groups of radiolabeled LL2: (i) [^{125}I]IMP-R1−LL2, (ii) [^{111}In]LL2, prepared by labeling IMP-R1 with ^{111}In acetate, followed by coupling to DTT-reduced LL2, and (iii) [^{125}I/In]IMP-R1−LL2 which was prepared by first labeling LL2 with [^{125}I]IMP-R1, followed by labeling with excess indium acetate (cold). Retentions, expressed as the average of three measurements (with the spread within 5% of the mean), were as follows: for [^{125}I]IMP-R1−LL2, 94.7 (2 h), 66.8 (18.5 h), 63.8 (26 h), 51.1 (48 h), and 35.4% (115 h); for [^{111}In]IMP-R1−LL2, 89.2 (2 h), 69.4 (18.5 h), 68.1 (26 h), 49.8 (48 h), and 34.1% (115 h); and for [^{125}I/In]IMP-R1−LL2, 95.2 (2 h), 66.5 (18.5 h), 59.6 (26 h), 49.0 (48 h), and 33.5% (115 h).

Panels A−C of Figure 3 show the Calu-3 cell binding data for RS7 preparations containing [^{125}I]IMP-R1, [^{125}I]-

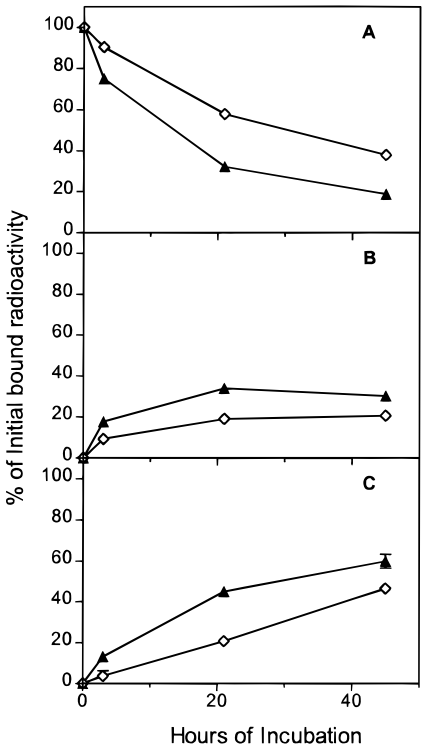

Figure 2. Processing of radiolabeled LL2 bound to Raji cells in vitro. LL2 was labeled with either [125I]IMP-R1 (◇) or 125I by the chloramine-T method (▲). (A) Amount of cell-bound radioactivity in counts per minute. (B) Counts per minute released intact into the supernatant. (C) Counts per minute released degraded into the supernatant. Results shown are average of triplicate data; standard deviations for most data are low and are not readily seen.

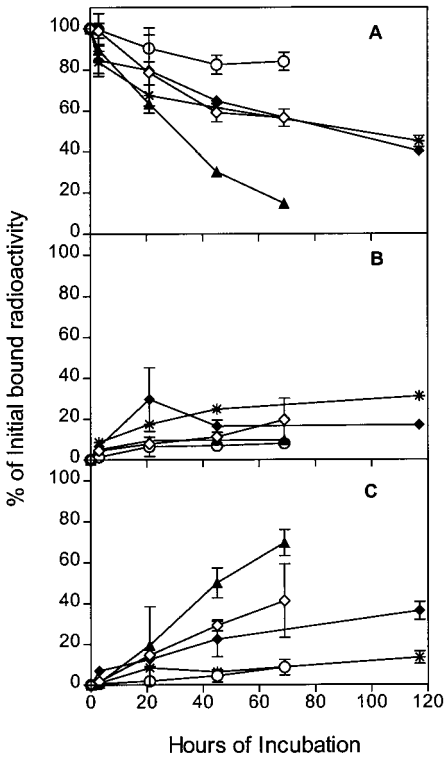

Figure 3. Processing of radiolabeled RS7 bound to Calu-3 cells in vitro. RS7 was labeled with [125I]IMP-R1 (◇), [125I]IMP-R2 (*), [125I]DLT (◆), [111In]benzyl-DTPA (○), or 125I by the chloramine-T method (▲). (A) Amount of cell-bound radioactivity in counts per minute. (B) Counts per minute released intact into the supernatant. (C) Counts per minute released degraded into the supernatant. Results shown are means ± standard deviations of triplicate data.

IMP-R2, [125I]DLT, conventional 125I and 111In labels. Figure 3A shows that at 69 h, the amount of cell-bound radioactivity of the IMP-R1 label is 46% of the amount of the initially bound radioactivity, which is 3 times that of the 14.7% observed for the conventional (CT) label. The tumor cell retentions of the residualizing radioiodine labels derived from IMP-R1, IMP-R2, and DLT are similar and are markedly better than that of the conventional label. The 111In label is seen to be somewhat better than the residualizing iodine labels in this set of experiments.

Panels A−C of Figure 4 show the comparisons of [125I]-IMP-R1, [125I]IMP-R2, [125I]DLT, 125I (CT), and [111In]-benzyl-DTPA labels in the ME180 cell line. As can be seen, the processing patterns of the 111In label and the IMP-R2- and DLT-based radioiodine labels of RS7 are quite similar, and distinctly different from that of the CT-based iodine label of RS7. The [125I]IMP-R1 label is somewhat less well retained than the other three residualizing labels, although it is still retained twice as well as a conventional iodine label as judged from the 69 h cell-bound counts per minute levels. Both Calu-3 (lung adenocarcinoma) and ME180 (cervical carcinoma) cell lines express RS7 antigens, but the antigen density on ME180 is 3 times that on Calu-3. For in vitro analyses, either cell line is conveniently used (*9*, *18*, *19*).

The stabilities of mAbs, labeled with radioiodinated IMP-R1 and IMP-R2 substrates, in cell culture media were determined by TCA precipitation. This revealed an average loss of label of 3%/day and 1%/day, when IMP-R1 and IMP-R2 methods are used, respectively, in various culture media (data not shown).

DISCUSSION

The lysosomal processing of mAbs to the level of amino acids results in the escape of the conventional iodine label of mAbs in the form of iodotyrosine (*5*, *27*). Since the particular label would not be expected to alter the metabolic pathway of mAb itself, it can be concluded that mAbs carrying residualizing labels are likewise processed to the level of amino acids and that the lysosomal retention of residualizing labels must be in the form of low-molecular mass catabolites. It has been suggested (*8*) that carbohydrate-based residualizing labels, such as iodo-TCB or iodo-DLT, are lysosomally trapped because these (i) cannot be digested by lysosomal hydrolases, (ii) are relatively large in size, with molecular masses of >500 Da, and (iii) are hydrophilic. All these factors collectively render the label membrane-impermeable. In the case of metal−DTPA conjugates of mAbs, the final catabolite, metal−DTPA−lysine (*14*), is also a residualizing label for the same reasons. Designing a residualizing radioiodine label modeled on metal−DTPA, as described herein, is attractive in that the DTPA molecule provides polar groups, hydrophilicity, and a size contribution.

It is evident that many other types of residualizing radioiodine labels could be created, which may be functionally similar to those described in this report. The key requirement is that the putative metabolite containing the residualizing label meets the requisite criteria (*8*) for membrane impermeability. We have not yet determined which features of our labels are essential for residualization. More specifically, we do not know if DTPA is a requirement, since certain peptides composed of D-amino acids would probably be effective residualizing labels

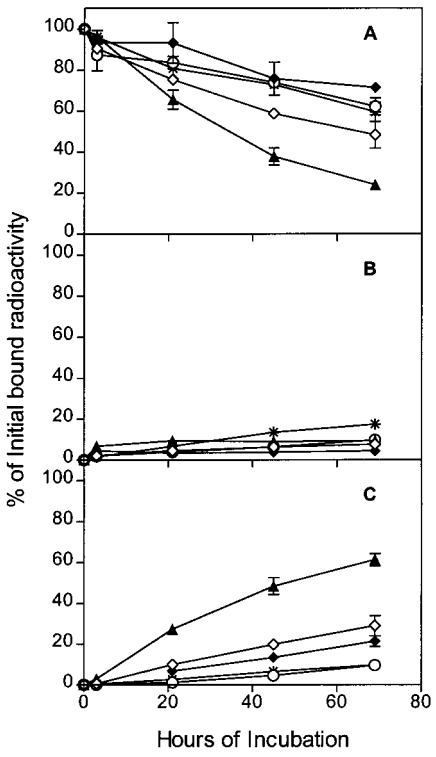

Figure 4. Processing of radiolabeled RS7 bound to ME180 cells in vitro. RS7 was labeled with [^{125}I]IMP-R1 (◇), [^{125}I]IMP-R2 (*), [^{125}I]DLT (◆), [^{111}In]benzyl-DTPA (○), or ^{125}I by the chloramine-T method (▲). (A) Amount of cell-bound radioactivity in counts per minute. (B) Counts per minute released intact into the supernatant. (C) Counts per minute released degraded into the supernatant. Results shown are means ± standard deviations of triplicate data.

themselves. Likewise, we do not know how many amino acids, conjugated to DTPA, are required to achieve good retention; it is possible that tyrosine alone would be sufficient. Considering that many of the residualizing labels are retained intracellularly to similar extents, we did not find a need to further optimize the label design. Rather, our primary goal was to solve the problems that have inhibited the use of the previous residualizing iodine labels for RAIT, namely, low iodination efficiency and low specific activity, and this was achieved. One question is whether iodo-D-tyrosine, coupled to mAbs, can itself be a residualizing label. It is known that iodo-D-tyrosine and iodotyramine are less efficient substrates than iodo-L-tyrosine for the enzyme deiodinase (*28*). However, many studies have clearly demonstrated that the metabolism of mAbs to the level of amino acids is the major factor contributing to reduced retention of internalized radioiodinated mAbs in the tumor, with deiodination playing a minor role, if any (*5*, *27*−*29*). Therefore, if iodinated D-tyrosine is used as a label for mAbs, protein catabolism in lysosomes may also lead to the escape of iodo-D-tyrosine through the lysosomal membrane.

Once the enhanced retention of the [^{125}I]IMP-R1 label was established, we attempted to further improve the mAb radioiodination yields by increasing the tyrosine and the maleimide contents in the peptide. In this respect, the DTPA dianhydride (CA-DTPA) reagent presented an opportunity to readily introduce multiple tyrosines and maleimides on the peptide template. All that was needed was synthesis of a tetrapeptide containing two tyrosines and linking the same to both ends of CA-DTPA, and this was the basis for the preparation of IMP-R2. In fact, the use of IMP-R2, which is also a residualizing label, resulted in substantially higher yields and specific activities of radioiodinated mAbs (Table 1). The type of attachment of DTPA to lysine was not expected to influence residualization, since previouly published work had shown that metalated DTPA−mAb conjugates with either thiourea (*27*) or amide (*14*) bonding of DTPA to mAb lysines generated effective residualizing labels.

Disulfide-reduced mAbs are frequently used for site-specific conjugations since this method offers several advantages, including a minimal impact on immunoreactivity (*30*). IgG_1 and IgG_{2a} classes are known to possess four interchain disulfide bonds and numerous intrachain disulfide bonds, and the interchain bonds are held together by noncovalent forces in addition to the four disulfide bonds (*31*). The intrachain disulfides are inaccessible to reduction by thiol-containing agents even when a high molar excess of the reductant is used. With an up to 250-fold excess of DTT, the cleavage of only four disulfide bonds, corresponding most likely to the four interchain disulfides, is found to occur with the Ellman's assay in this study. This is similar to the results reported for mAb BR96 (*30*). The mAb is found to retain its molecular structure even after the reduction of the four interchain disulfide bonds, as evidenced by SE-HPLC analyses in this study and by SE-HPLC and nondenaturing SDS−PAGE analyses in the work of Willner et al. (*30*).

In initial experiments, the peptide was radioiodinated using iodogen as the oxidant, but this procedure was subsequently replaced by the use of chloramine-T (CT) radioiodination. This resulted in a simpler one-vial method, reduced the process time, and increased the overall yield. To minimize potential damage to the antibody due to CT, piperidine (a secondary amine) was added prior to the conjugation step so that the amine, not the reactive groups in the antigen binding region of the mAb, was chlorinated (*32*). Peptide radioiodination by either iodogen or CT methods led to mAb products which behaved similarly in vitro and in vivo (not shown), but the shorter duration of the CT method improved the conjugation yield, possibly by limiting the degradation of the maleimide group at the labeling pH of 7.5.

The lack of significant aggregation in these radiolabelings, particularly when substrate IMP-R2 was used, is interesting. Substrate IMP-R2 offers the opportunity to cross-link thiol groups from two mAb molecules. Intermolecular cross-linking is possibly inhibited by unfavorable stereoelectronic factors. Also, SDS−PAGE analyses indicated the absence of mAb interchain cross-linking by the two maleimide groups of IMP-R2 (not shown).

Antibody immunoreactivity (IMR) is known to be only minimally affected by the method of conjugation to hinge-region cysteines (*30*). Indeed, IMRs of all radiolabeled RS7 preparations were very similar. Although IMR determinations were not carried out with LL2 preparations, the strong binding seen in the in vitro cell binding experiments as well as in in vivo targeting experiments (not shown) was indicative of the preservation of IMR of LL2 labeled by radioiodinated IMP-R1 or IMP-R2.

The better cellular retention of indium versus residualizing radioiodine labels ([^{125}I]DLT, [^{125}I]IMP-R1, and [^{125}I]IMP-R2) on RS7 in the Calu-3 cell bindings (Figure 3) appears to be contrary to our earlier findings of the similarity of [^{125}I]DLT and [^{111}In]Bz-DTPA labels in vitro and in vivo (*9*). The explanation of this discrepancy must await further experimentation. In the ME-180 cell bindings, however, [^{125}I]IMP-R2, [^{125}I]DLT, and [^{111}In]Bz-DTPA labels on RS7 were seen to be processed similarly,

with the [125I]IMP-R1 label being released somewhat faster. The residualizing iodine labels were retained significantly better than a conventional iodine label in both cell lines. In this study, we have not directly determined either the form in which radiolabels were retained by cells or the subcellular site at which they were retained. However, it can be logically expected that the low-MW lysosomal catabolites in this work would be similar to those in other documented studies (*14*, *27*), and are very likely to contain the iodo-D-Tyr-D-Lys(DTPA) residue.

It must be pointed out that TCA precipitation of supernatants in cell binding studies effectively distinguishes between intact and degraded mAb, with a radioiodine label produced by the chloramine-T method, but with the [I]IMP-R2 label, some of the degradation products are also likely to be precipitated, as indicated by partial precipitation (~25%) of the cysteine adduct of IMP-R2, prepared as a control. In this case, TCA precipitation provides a minimum estimate of the extent of degradation, and an overestimate of the amount of mAb released intact; therefore, the amount of cell-bound radioactivity, as well as the amount of total radioactivity released into the supernatant, provides the most reliable indication of retention. Whether this is also the case with the IMP-R1 label remains to be determined, although the profiles of the intact and the degraded forms of radioactivity released into the supernatant when IMP-R1 is used suggest that the degraded form of the radioactivity is probably not precipitable.

The question of whether a metal (such as indium)−DTPA, rather than unchelated DTPA, should be part of the DTPA−peptide structure was addressed in one of our early experiments. We examined IMP-R1 labeled with 125I alone, with 125I and cold indium acetate, and with 111In acetate. Each of these IMP-R1 radiolabels was conjugated to disulfide-reduced LL2, and the processing by Raji tumor cells in vitro was studied. The tumor cell retentions were almost identical in all three cases. This implied that incorporation of indium in the label design was not a prerequisite for residualization to occur, perhaps because the metal ions present inside the cells or in the medium were themselves available for chelation by the DTPA substructure of the peptides.

In the in vitro studies, we did not examine directly the internalization of the mAb, but rather the retention of the radiolabel which is a function of both internalization and catabolism. Clearly, it is the accumulation of radiolabel in the target cell that is the major consideration for RAIT. Moreover, methods commonly used to assay mAb internalization appear to be unreliable when some residualizing radiolabels are used, as the following example suggests. Lymphoma tumor cells, bound by the labeled mAb [125I]DLT−LL1, were extracted at low pH (under conditions used for extraction of surface-bound mAb) 21 h after mAb binding to the cell surface, a time when virtually all of the mAb had been catabolized (*26*) and the retained radiolabel colocalized with lysosomes (*33*). We found that the majority of the label, shown to be low-MW degradation products by TCA precipitation, was extracted from the cells by treatment with pH 2.0 or 2.5 buffers.[4] Some of the low-pH buffers also caused death of more than half the cells, as determined by exclusion of trypan blue. While cell death could of course allow the release of an intracellular label, we noted that one of the buffers that did not cause substantial cell death still extracted the majority of the [125I]DLT from its intracellular site. We conclude that low-pH treatment may extract intracellular material from cells, possibly by cell toxicity.[4]

In summary, the yield and the specific activity levels obtained in mAb radioiodinations using IMP-R1 and IMP-R2, as well as the enhanced tumor cell retentions observed in in vitro experiments, bode well for the DTPA−peptide approach in the design of residualizing radioiodine. However, the particular choice of the radioiodinating agent for RAIT is not necessarily restricted to these substrates. This flexible peptide approach can be adapted to the synthesis of a number of bifunctional substrates differing in the tyrosine content, the maleimide content, the number of amino acids, and the mode of attachment to DTPA, to maximize mAb radioiodination yields as well as therapeutic indices in in vivo applications. Progress along these lines, together with the details of a series of paired-label in vivo experiments involving RS7 and LL2 mAbs labeled with IMP-R1, IMP-R2, DLT and conventionally (CT method) based radioiodine labels, will be described elsewhere.

Design, Synthesis, and Spectroscopic Properties of Peptide-Bridged Fluorescence Energy-Transfer Cassettes

Yanlong Li† and Alexander N. Glazer*

Departments of Chemistry and Molecular and Cell Biology, University of California, Berkeley, California 94720.
Received July 6, 1998; Revised Manuscript Received December 1, 1998

A general partial solid-phase synthetic scheme was developed for the synthesis of energy-transfer cassettes with the donor and acceptor dyes bridged by a peptide. In these cassettes, 6-carboxyfluorescein (Fam) served as a donor. For the second dye, 6-carboxy-X-rhodamine (Rox) was used as a fluorescent acceptor or erythrosin B as a quencher. Different peptides bearing Rox at the amino terminus and Fam linked through different diamines to the carboxyl terminus were synthesized to examine the effects of the chain length and rigidity on energy-transfer efficiency. The ratio of emission intensities at 605 nm of the acceptor dye (ROX) in the cassette Rox-GPPPEPPP-*p*-xylylenediamine-Fam versus free ROX with 488 nm excitation was ~14 and is similar to that obtained for optimized oligonucleotide primers bearing the same dyes [Ju, J., Ruan, C., Fuller, C. W., Glazer, A. N., and Mathies, R. A. (1995) *Proc. Natl. Acad. Sci. U.S.A. 92*, 4347−4351].

INTRODUCTION

In recent years, we have developed sets of fluorescence energy-transfer (ET)[1] primers for DNA sequencing and mapping (reviewed in refs *1* and *2*). In these primers, a donor dye is attached to the oligonucleotide at the 5′ end, and the acceptor is attached to a modified thymidine internal in the primer sequence. ET cassettes are superior to single dye-labeled probes because the large acceptor-dependent Stokes shifts allow excellent rejection of adventitious autofluorescence, Raleigh and Raman scattering at the emission wavelength of the acceptor, and because multiplex assays can be carried out by using sets of labels with a common dye as a donor and different dyes as acceptors. In addition, we have developed a general method to tag primers of any sequence with ET-coupled fluorophores using a universal ET cassette which contains a polydideoxyribose phosphate spacer and can be incorporated at the 5′ end of an oligonucleotide primer by conventional automated synthesis (*3*).

Other universal ET cassettes would be useful; ones that could be coupled to any molecule of interest. Such general ET cassettes would need to embody the following components: (i) a donor dye; (ii) an acceptor dye; (iii) a conformationally constrained bridge of readily varied length connecting the donor and acceptor dyes; and (iv) a functional group for attachment of the cassette to target molecules.

We describe here a preliminary examination of alternative ET cassettes which employ 9-phenylxanthene dyes as donor and acceptors (or quenchers) and conformationally constrained peptide derivatives as the bridging moieties. Peptides are particularly attractive bridge candidates because of the convenience of solid-phase synthesis and the availability of a wide range of building blocks. Indeed, peptides bearing donor dyes and quenchers are widely used for proteinase assay (e.g., refs *4*−*13*).

EXPERIMENTAL PROCEDURES

All chemicals were purchased from Aldrich (Milwaukee, WI) except where otherwise indicated. Erythrosin B-5-isothiocyanate and the NHS esters of the 5-carboxy isomers of Fam and Rox were purchased from Molecular Probes (Eugene, OR). Peptides on Merrifield resin were obtained through custom synthesis performed by SynPep (Dublin, CA). Chymotrypsin was purchased from Sigma (St. Louis, MO).

Synthesis of Erythrosin B-Ala-Phe-Ala-Gly-NH-C2-NH-Fam. Erythrosin B isothiocyanate (~4 mg) was dissolved in DMSO (0.2 mL) and added to the peptide AFAG-Merrifield resin (~2 mg of peptide) in an Eppendorf tube. DIPEA (5 μL) was added to this mixture. After vortexing for 2 h, a few resin beads were removed and checked by the Kaiser test for the completeness of dye coupling (*14*). When the reaction was complete, the supernatant was removed by centrifugation. After three sets of alternating washes with DMSO (1.0 mL) and methanol (1.0 mL), the resin beads were added to 30% (v/v) ethylenediamine in methanol (0.2 mL). After vortexing for 2 h, the supernatant was transferred to a fresh Eppendorf tube. Ether (2 mL) was added to precipitate the labeled peptide, erythrosin B-AFAG-NH-C2-NH_2. The precipitate was redissolved in DMSO (0.2 mL) and the

[1] Abbreviations: Fam, 5-carboxyfluorescein; Rox, 5-carboxy-X-rhodamine; DIPEA, *N*,*N*-diisopropylethylamine; DMSO, dimethyl sulfoxide; DMF, *N*,*N*-dimethylformamide; ET, energy transfer; NHS, *N*-hydroxysuccinimide; TEAA, triethylamine acetate; tBoc, *tert*-butyloxycarbonyl; tBu, *tert*-butyl; TFA, trifluoroacetic acid; MMT, monomethoxytrityl. 1× TBE buffer, 89 mM Tris/89 mM boric acid/2 mM EDTA, pH 8.0. The standard one-letter amino acid abbreviations used are E, L-Glu; F, L-Phe; G, Gly; P, L-Pro. Dye-labeled peptides are named systematically by the abbreviation of the first dye (at the N terminus) followed by one letter abbreviations for the amino acid residues, the abbreviation for the diamine and the abbreviation for the second dye (at the C terminus). The ethylenediamine linker was abbreviated as HN-C2-NH.

peptide derivative reprecipitated to remove residual ethylenediamine. The NHS ester of Fam (~2 mg) was dissolved in DMSO (0.2 mL) and added to erythrosin B-AFAG-NH-C2-NH_2 followed by DIPEA (5 μL). After vortexing for 2 h, ethyl acetate (2 mL) was added to precipitate the doubly labeled peptide, erythrosin B-AFAG-NH-C2-NH-Fam. The precipitate was dissolved in methanol, and the doubly labeled peptide purified by reversed-phase HPLC. In the HPLC solvent, the erythrosin B-AFAG-NH-C2-NH-Fam peak showed two visible absorbances at 529 and 495 nm with a A_{529nm}:A_{495nm} ratio of 0.755. In 1× TBE, the erythrosin B absorbance was negligible relative to that of Fam.

Rox-Gly-Pro-Pro-Glu-Pro-Pro-NH-C2-NH-Fam. Ethylenediamine in methanol (30% v/v; 0.2 mL) was added to tBoc-GPPE(-tBu)PP-Merrifield resin (~5 mg of peptide) to give tBoc-GPPE(-tBu)PP-NH-C2-NH_2. This product was then labeled with NHS ester of FAM (~8 mg) to give tBoc-GPPE(-tBu)PP-NH-C2-NH-Fam. After precipitation with ethyl acetate, tBoc-GPPE(-tBu)PP-NH-C2-NH-Fam was added to 75% (v/v) TFA in dichloromethane (0.3 mL) and allowed to deprotect for 1 h. The product, GPPEPP-NH-C2-NH-Fam, was precipitated with ether (2 mL). Addition of the NHS ester of Rox (~5 mg) in DMF (0.1 mL) and DIPEA (5 μL) to GPPEPP-NH-C2-NH-Fam produced Rox-GPPEPP-NH-C2-NH-Fam.

Alternatively, 4-methoxytrityl chloride (~0.5 g) was dissolved in dichloromethane (0.5 mL) and added to GPPEGG-Merrifield resin (~5 mg of peptide). Pyridine (0.5 mL) was added to the above mixture. While stirring, the mixture was heated at 45 °C for 48 h. After completion of the reaction, the peptide was treated as described above to give MMT-GPPEPP-NH-C2-NH_2. The rest of the synthesis was performed as described above except that deprotection was performed with 3% (v/v) TFA in dichloromethane for 5 min.

Mass spectrometry of Rox-GPPEPP-NH-C2-NH-Fam gave $(M + 1)^+$ of 1510 (corresponding to the calculated mass of 1509) and a ratio of A_{495nm} (FAM):A_{585nm} (Rox) of 0.816.

Rox-Gly-Pro-Pro-Glu-Pro-Pro-*p*-xylylenediamine-Fam. This compound was synthesized following the scheme for Rox-GPPEPPNH-C2-NH-Fam except that *p*-xylylenediamine, $C_6H_4(CH_2NH_2)_2$, was used for cleavage. Rox-GPPEPP-*p*-xylylenediamine-Fam purified by HPLC had a ratio of A_{495nm} (FAM):A_{585nm} (Rox) of 0.873.

Rox-Gly-Pro-Pro-Pro-Glu-Pro-Pro-Pro-*p*-xylylenediamine-Fam. This compound synthesized as described for Rox-GPPEPP-*p*-xylylenediamine-Fam except that GPPPEPPP-Merrifield resin was used as the starting material. Rox-GPPPEPPP-*p*-xylylenediamine-Fam purified by HPLC had a ratio of A_{495nm} (FAM):A_{585nm} (Rox) of 0.896.

Hydrolysis of Erythrosin B-AFAG-NH-C2-NH-Fam by Chymotrypsin. Chymotrypsin (0.25 mg) was added to a solution of erythrosin B-AFAG-NH-C2-NH-Fam (1.0 mL, A_{498} = 0.12/cm) in 0.1 mM $CaCl_2$, 50 mM Tris-HCl, pH 8. A control solution was prepared leaving out chymotrypsin. The fluorescence emission spectra of both the sample and the control solutions were measured after 24 h incubation at 37 °C.

Chromatography. HPLC was performed on a Waters 991 system with a photodiode array detector. All runs were carried on a Bio-Rad C18 column (4.6 × 250 mm) with a flow rate of 1.0 mL/min. Purification was performed with a linear gradient from 50% methanol and 50% 0.05 M TEAA to 100% methanol in 10 min. Peaks were collected manually and the solvent removed by vacuum-drying.

Mass Spectrometry. Low-resolution fast-atom bombardment mass spectrometry was performed by Mass Spectrometry Center of University of California, Berkeley.

Absorbance and Fluorescence Spectroscopy. All absorbance spectra were measured in 1× TBE buffer (unless otherwise specified) with a Perkin-Elmer Lambda 6 UV−vis spectrophotometer. The ratio of the extinction coefficients of free Fam at 495 nm to that of free Rox at 585 nm is 1.01. The absorbance of Rox at 495 nm is 7.5% of its absorbance at 585 nm, whereas Fam contributes no absorbance at 585 nm. The ratios of Fam-to-Rox absorbance given for the ET cassettes are corrected for the Rox contribution at 495 nm. Fluorescence emission spectra were collected on a Perkin-Elmer MPF-44B spectrofluorimeter with excitation at 488 nm. The sample absorbance at A_{max} in 1× TBE ranged between 0.010 and 0.012/cm. The bandwidth of the excitation and emission slits was set to 3.0 nm.

RESULTS

In their classic test of the Förster prediction (*15*) that the rate constant for energy transfer is proportional to the inverse sixth power of the distance between the donor and acceptor, Stryer and Haugland (*16*) synthesized oligomers of L-proline as spacers of defined length carrying an α-naphthyl group at the carboxyl end as a donor and a dimethylaminonaphthalenesulfonyl group at the imino end as an acceptor. The synthesis was carried out by the Merrifield solid-phase method, and the acceptor was attached to the imino end of the peptide before release from the resin. Treatment with hydrazine was then used to release the peptide derivative and to provide a reactive group at the carboxyl terminus for the attachment of the donor. However, we found that 9-phenylxanthene dyes subjected to this synthetic procedure were unstable under the conditions of hydrazinolysis.

To address this problem, we examined the use of diamines in place of hydrazine to introduce the attachment site for a dye. Since, in principle, different diamines could be used to effect the release of the peptide, this allowed examination of the effect of the portion of the bridge immediately proximal to one of the dyes on the efficiency of the energy-transfer process. Preliminary experiments showed that primary amines that are liquids or are readily soluble in organic solvents, such as ethylenediamine, 1,3-diaminopropane, and *p*-xylylenediamine, all cleaved 9-phenylxanthene dye-peptide conjugates efficiently from the resin without adverse effect on the dye.

In an initial test of the procedure, we synthesized erythrosin B-AFAG-NH-C2-NH-Fam (Figure 1). This compound was designed with a donor (Fam) and a quencher (erythrosin B) and a chymotrypsin-sensitive Phe−Ala bond to show that this synthetic procedure would be readily applicable to the synthesis of energy-transfer peptides of the type widely used for proteinase assays. The fluorescence emission of Fam at 525 nm was quenched >95% in erythrosin B-AFAG-NH-C2-NH-Fam. A 24 h incubation with chymotrypsin restored the fluorescence emission to 90% that of free 6-carboxyfluorescein (Figure 2).

Figure 3 presents the synthetic scheme for the preparation of peptides which carry Fam as a donor and Rox as acceptor and in which the γ-carboxyl group on a glutamyl residue is available for the conjugation of the ET cassette to a target molecule. With tBoc-GPPE(-tBu)-PP-Merrifield resin as starting material, ethylenediamine

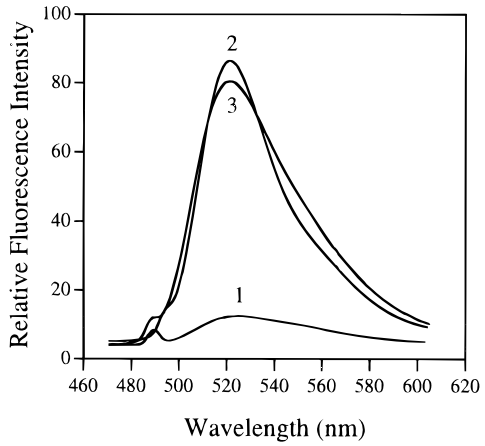

Figure 2. Fluorescence emission with 488 nm excitation of Erythrosin—AFAG-NH-C2-NH-Fam before (curve 1) and after (curve 3) hydrolysis by chymotrypsin. Curve 2 shows the fluorescence emission of an equimolar solution of free Fam. See the Experimental Procedures for details.

cleavage introduced a free amino group at the C-terminus. After conjugation to Fam, the peptide was deprotected with 75% TFA for 1 h to remove the tBoc from the N-terminus. The free N-terminal amine then readily reacted with Rox NHS ester. When a monomethoxytrityl (MMT) group was used to protect the N-terminal amine, deprotection was achieved with 3% TFA in 5 min. The latter procedure is more compatible with syntheses that may involve dyes unstable under strongly acidic conditions. The product Rox-GPPEPP-NH-C2-NH-Fam was obtained with both synthetic schemes (Figure 3). The mass of Rox-GPPEPP-NH-C_2-NH-Fam matched the proposed structure. Rox-GPPEPP-*p*-xylylenediamine-Fam and GPPPEPPP-*p*-xylylenediamine-Fam were synthesized following the same procedure with *p*-xylylenediamine for cleavage from the resin and GPPEPP or GPPPEPPP as the peptide sequences.

When excited at 488 nm, the compound Rox-GPPEPP-NH-C_2-NH-Fam showed strong emission from Rox at 605 nm, but also significant residual fluorescence emission from the donor Fam at 525 nm (Figure 4a). In contrast, Rox-GPPEPP-*p*-xylylenediamine-Fam offered a negligible donor residue emission (Figure 4b). Increase in donor—acceptor separation by two additional prolyl residues in Rox-GPPPEPPP-*p*-xylylenediamine-Fam gave the

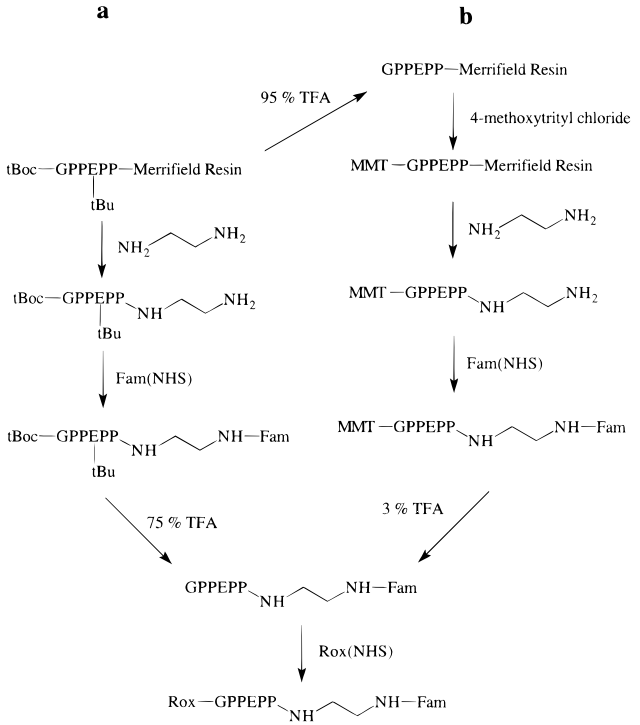

Figure 3. Synthetic schemes for Rox—GPPEPP-NH-C2-NH-Fam.

most pronounced increase of Rox emission on 488 nm excitation, over 13 times that of equimolar free Rox (Figure 4c).

DISCUSSION

We present here a straightforward general procedure which depends largely on solid-phase synthesis for the production of ET peptide cassettes. The novel feature of this procedure is the use of diamines both to release the peptide from the resin and to provide a primary amino group at the C-terminus of the peptide for facile addition of a dye.

This procedure allows the synthesis of ET peptide cassettes varying only in the nature of the diamine at the C-terminus. Surprisingly, different diamines have a substantial impact on the fluorescence emission properties of the ET cassette. With 488 nm excitation, Rox-GPPEPP-NH-C2-NH-Fam and Rox-GPPEPP-*p*-xylylenediamine-Fam (Figure 4, panels a and b) show similar enhancement of Rox fluorescence emission at 605 nm (relative to equimolar free Rox). However, Rox-GPPEPP-NH-C2-NH-Fam shows significant emission from the Fam donor, whereas the donor emission in Rox-GPPEPP-*p*-xylylenediamine-Fam is virtually completely quenched. Thus, the structure (and possibly the rigidity) of the portion of the ET cassette proximal to a dye has a disproportionately large effect on the spectroscopic properties of the cassette. It is customary to link dyes to oligonucleotides (*1, 2*) and the like through long aliphatic tethers. The result reported here suggests that systematic studies of the influence of the structure of these tethers on the fluorescence properties of the ET cassettes would be worthwhile.

Studies of ET cassettes with oligonucleotide and oligodideoxyribose phosphate spacers (*3, 17—20*) have yielded the unexpected result that both the efficiency of energy transfer, as measured by quenching of donor emission, and the intensity of fluorescence emission from the acceptor increase with longer donor—acceptor spacing,

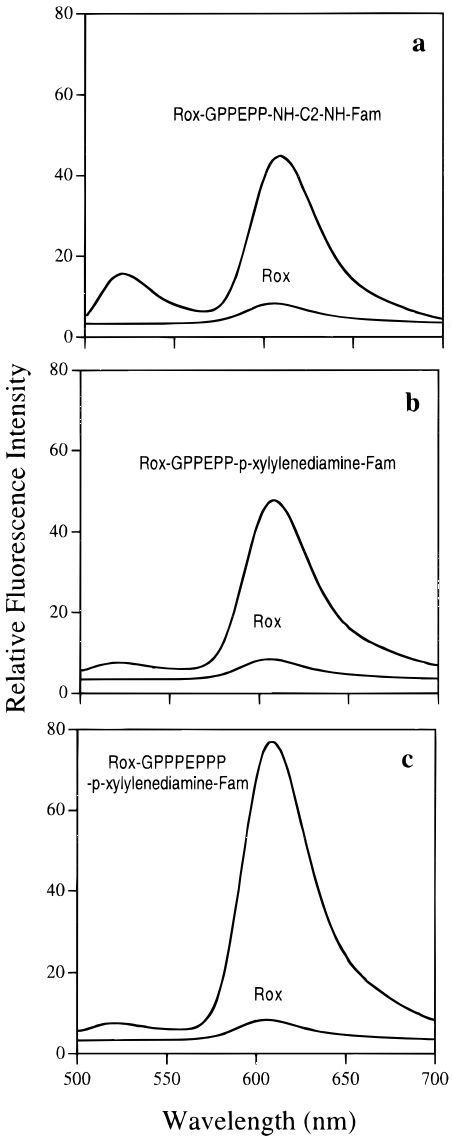

Figure 4. Comparison the fluorescence emission on 488 nm excitation of peptide ET-cassettes with that of an equimolar solution of free Rox. (a) Rox−GPPEPP-NH-C2-NH-Fam versus Rox. (b) Rox−GPPEPP−*p*-xylylenediamine-Fam versus Rox. (c) Rox−GPPPEPPP−*p*-xylylenediamine-Fam versus Rox.

reaching a maximum at a chain length of 8−10 monomer units (*17*−*19*). The inverse result is predicted by the Förster equation (*15*), and such expectation is validated by studies of donor−acceptor pairs bridged by a rigid backbone (*16*). The anomalous behavior of cassettes with oligonucleotide and polydideoxyribose phosphate spacers is attributable to their conformational flexibility which may allow for close contact of donor and acceptor in some conformers with consequent quenching of the emission.

In this report, we examine the dependence of energy transfer in Fam/Rox oligopeptide cassettes on the structure of the spacer separating the dyes. Here, as in oligonucleotide and polydideoxyribose phosphate spacers studied earlier, peptide length-dependent variation in the orientation factor (κ^2) is not likely to be significant because the 9-phenylxanthenes are attached to the oligopeptides through bonds that do not hinder their mobility. Experimental support for this assertion is provided by Stryer and Haugland (*16*), who concluded that a dansyl group attached to the imino end of proline oligopeptides had a fast rotational mobility independent of that of the oligopeptide moiety. They therefore used the average value of κ^2, i.e., 2/3, in the energy-transfer calculations for oligoproline peptides varying in length (*16*). Eisinger and co-workers (*21*, *22*) reached the same conclusion for chromophores attached to polypeptide chains that have little or no secondary or tertiary structure.

The two peptides Rox-GPPEPP-*p*-xylylenediamine-Fam and Rox-GPPPEPPP-*p*-xylylenediamine-Fam differ only in the length of the Pro-containing segments. Both of these ET peptides show near-complete quenching of donor emission. However, the longer peptide, Rox-GPPPEPPP-*p*-xylylenediamine-Fam, gave significantly greater enhancement of Rox fluorescence emission (Figure 4c). The ratio of emissions for 488 nm excitation for this ET cassette versus free ROX approaches 14 and is similar to the ratio of 14 obtained for optimized oligonucleotide primers bearing the same dyes (*2*). The difference in the absorbance spectra of Rox-GPPEPP-*p*-xylylenediamine-Fam (A_{495nm}:A_{585nm} = 0.873) and Rox-GPPPEPPP-*p*-xylylenediamine-Fam (A_{495nm}:A_{585nm} = 0.896) is consistent with lesser dye-dye interaction in the longer ET cassette.

The conformational aspects of the Pro-Pro or Pro-Pro-Pro segments of the oligopeptides deserve a brief comment. Pro is unique among amino acids in that the side chain is bonded covalently to the nitrogen atom of the peptide group. Therefore, the backbone at a Pro residue within an oligopeptide chain has no amide hydrogen for participation in hydrogen bonding or in resonance stabilization of the peptide bond of which it is a part. The cyclic five-membered ring also imposes rigid constraints on rotation about the N−C^{α} bond of the backbone. Pro residues, therefore, do place major constraints on the conformation of the oligopeptide backbone. However, even the Pro-Pro and Pro-Pro-Pro segments of these oligopeptides most likely exist in alternative conformations since the trans form of imide bond involving Pro is only slightly favored (4:1) over the cis form (*23*). These segments are too short to assume a helical conformation. The oligopeptide portion of each of the two ET cassettes thus exists as a population of conformers each varying in the separation between the donor and acceptor dyes.

In conclusion, as for ET primers with oligonucleotide spacers, for ET peptide-based cassettes with partially flexible regions, the optimum donor−acceptor separation will need to be established empirically.

Comb-Type Prepolymers Consisting of a Polyacrylamide Backbone and Poly(L-lysine) Graft Chains for Multivalent Ligands

Shoichiro Asayama, Atsushi Maruyama,* and Toshihiro Akaike

Department of Biomolecular Engineering, Tokyo Institute of Technology, 4259 Nagatsuta, Midori, Yokohama 226-8501, Japan. Received August 17, 1998

The comb-type copolymers consisting of a polyacrylamide (PAAm) backbone and poly(L-lysine) (PLL) graft chains have been prepared as the "prepolymer" for designing multivalent ligands. To regulate the length and density of the clusters of primary amino groups, the N^{α}-carboxyanhydride of N^{ϵ}-carbobenzoxy (CBZ)-L-lysine was first polymerized using *p*-vinylbenzylamine as an initiator. The resulting poly(CBZ-L-lysine) macromonomer was then radically copolymerized with AAm, followed by the deprotection of amino groups. For the model study, the reactive clusters of primary amino groups were completely converted into anion clusters by the reaction with succinic anhydride. The model multivalent ligands having the biotin label on the PAAm backbone were prepared by the terpolymerization of the macromonomer, AAm, and the biotin derivative having a vinyl group. The enzyme-linked immunosorbent assay showed that the biotin with no spacer on the PAAm backbone was recognized by the avidin−peroxidase conjugate specifically. Therefore, the highly sensitive detection of the interaction between cells and various model multivalent ligands was possible. The selective labeling onto the PAAm backbone revealed that the converted anion clusters of graft chains interacted exclusively with the cell and that the backbone was inert to the interaction with the cell. These results indicate that the various PAAm-*graft*-PLL comb-type copolymers with the defined length and density of the PLL-*grafts* are the potential prepolymers to investigate and to optimize the affinity of the multivalent ligands for receptors.

INTRODUCTION

Cell-surface receptors interact with their specific ligands such as growth factors, hormones, neurotransmitters, cell adhesion molecules, and extracellular matrices (*1*). These receptor−ligand interactions are mainly driven through the combination of electrostatic attraction, hydrogen bonds, and van der Waals attractive force (*2*). Interestingly, in the case of an asialoglycoprotein receptor (ASGP-R[1]), the affinity of the galactosylated protein for the ASGP-R on hepatocytes is enhanced by increasing the number of the galactose residues on the protein (*3*−*6*). Furthermore, the particular geometry of a few galactose residues considerably increases the affinity of the galactosylated ligand for the ASGP-R on the hepatocytes (*7*, *8*).

We reported previously that the multivalent β-galactose ligands of a polystyrene derivative, poly[*N*-(*p*-vinylbenzyl)-4-*O*-β-D-galactopyranosyl-D-gluconamide] [PVLA, poly(vinylbenzyl-β-D-lactonamide)], are recognized by the ASGP-R on the surface of the hepatocytes; namely, the PVLA is found to be an artificial cellular matrix as the useful substratum for hepatocyte culture (*9*−*12*). When a culture dish is coated with a high density of PVLA, the hepatocytes attached on the dish remain spherical and show low DNA synthesis activity. In contrast, the hepatocytes on the coated dish with a low density of PVLA show spread morphology but high DNA synthesis activity (*13*). The particles covered with the PVLA are also recognized by the hepatocytes (*14*, *15*). The particle covered with the high density of β-galactose residues is promptly internalized by ASGP-R-mediated endocytosis, whereas the low density of β-galactose residues on the particle permits the binding to the hepatocyte without internalization (*16*). In these cases, the surface density of β-galactose residues is shown to be influential in the cellular responses and ligand binding. However, the influence of the size and distribution of the galactose cluster is not precisely estimated. The multivalent effect may occur in a variety of receptor−ligand interactions of cell adhesion molecules (*17*−*20*) such as P-selectin recognizing anionic glycoproteins (*21*−*24*).

In this study, we have designed the "prepolymer" for the multivalent ligands which have the well-controlled clusters of ligand molecules. The prepolymer consists of a polyacrylamide (PAAm) (*25*) backbone and poly(L-lysine) (PLL) graft chains. The clusters of primary amino groups on the PLL-*grafts* offer chemical modification sites, so that the amino groups can be converted into galactose clusters by the reaction with lactonolactone (*12*). The length and density of these clusters are properly characterized and controlled by varying the length of the PLL macromonomer or by varying the feed ratio for the

copolymerization with AAm. The various PAAm-*graft*-PLL comb-type copolymers are, therefore, expected to be useful in investigating and optimizing the affinity of the multivalent ligands for receptors.

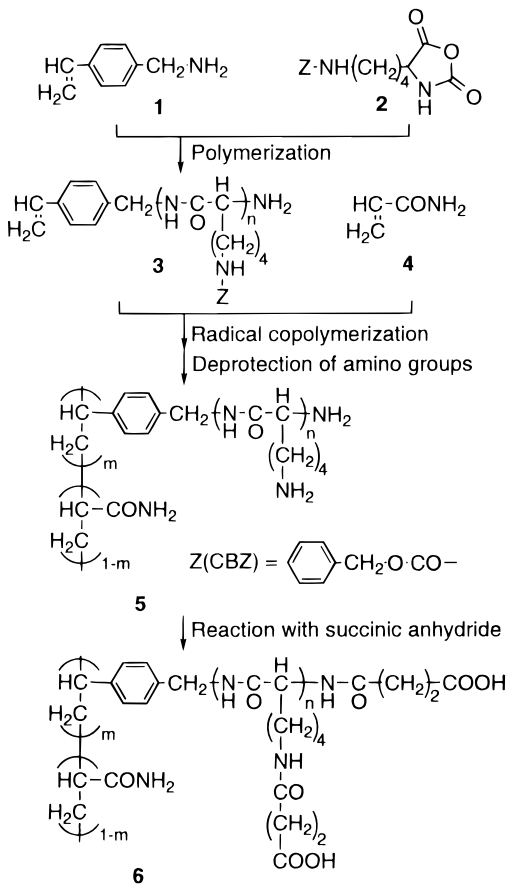
EXPERIMENTAL PROCEDURES

Materials. Acrylamide (AAm) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan) and was crystallized from benzene. Hexane was from Kanto Chemical Co., Inc. (Tokyo, Japan) and was washed with concentrated sulfuric acid to remove olefin, followed by water, drying, and distilling over sodium under nitrogen. Ethyl acetate (from Kanto) was dried with K_2CO_3, followed by distilling and redistilling over acetic anhydride to convert ethanol into ethyl acetate under nitrogen. Tetrahydrofuran (THF) was from Kanto and was dried with KOH, followed by distilling over *n*-butyllithium under nitrogen. *N*,*N*-Dimethylformamide (DMF) was from Kanto and was distilled under reduced pressure over $MgSO_4$. (+)-Biotin was purchased from Wako. Streptavidin−horseradish peroxidase conjugate and *o*-phenylenediamine dihydrochloride (OPD) were purchased from Gibco Bethesda Research Laboratories (Grand Island, NY). All other chemicals of a special grade were used without further purification.

Synthesis of Poly[N^{ϵ}-carbobenzoxy (CBZ)-L-lysine] Macromonomers. The N^{α}-carboxyanhydride (NCA) of CBZ-L-lysine (**2**) was prepared in THF, followed by crystallization from THF/hexane and recrystallization from ethyl acetate/hexane according to the method proposed by Daly and Poché (*26*). The NCA (**2**) was dissolved in dehydrated DMF. *p*-Vinylbenzylamine (**1**; VBA) (*27*) was dissolved in dehydrated DMF and added to the solution of **2**. The polymerization reaction was performed with 2.5 g of CBZ-L-lysine NCA (**2**) in 25 mL of DMF at the monomer (**2**)/initiator (**1**) molar ratios of 3, 5, 10, or 20 (for 36 h at 48 °C). The reaction mixture was then poured into a 20-fold volume of diethyl ether. Precipitate was collected by centrifugation and washed with diethyl ether, followed by drying in vacuo.

Synthesis of the Biotin Derivative Having a Polymerizable Group. First, biotinyl-*N*-hydroxysuccinimide ester was prepared from biotin (**7**) and *N*-hydroxysuccinimide (NHS) by coupling with dicyclohexylcarbodiimide (DCC) (*28*). Each reactant was dissolved at 0.07 M concentration in DMF and incubated for 16 h at 50 °C. The mixture was cooled to room temperature, the dicyclohexylurea was filtered off, and the filtrate was dried on a rotary evaporator. The residue was crystallized from 2-propanol. The resulting active ester of biotin and VBA (**1**) were dissolved at 0.06 M concentration in DMF and incubated for 22 h at 25 °C. The mixture was diluted with a 19-fold volume of H_2O, and the precipitate was collected by filtration, followed by washing with H_2O (to remove resulting NHS and unreacted **7**) and diethyl ether (to remove unreacted **1**). The residue was crystallized from DMF/H_2O mixture.

Synthesis of PAAm-*graft*-PLL Comb-Type Copolymers. The resulting macromonomer (**3**) and AAm (**4**) were dissolved in 2.5 mL of DMF at the total monomer concentration of 100 mg/mL. In the case of biotinylation, 5 mg of the resulting biotin monomer (**8**) was added to the above mixture. The radical copolymerization reaction was carried out for 2−4 h at 47 °C in a sealed glass ampule using 10 mM 2,2′-azobis(2,4-dimethylvaleronitrile) (V-65) as an initiator. After the reaction, the content was poured into a large excess of ethanol, and precipitate was dried in vacuo. The crude polymers were dissolved in trifluoroacetic acid (TFA), followed by the addition of thioanisole to deprotect CBZ-amino groups. The final concentrations of thioanisole and the polymer were 0.3−1 M and 20−100 mM (based on the CBZ groups), respectively. The deprotection reaction was carried out for 2.5−3.0 h at 25 °C. The reaction mixture was poured again into a large excess of ethanol. Precipitate was redissolved in TFA and poured into ethanol repeatedly. The precipitate was dried in vacuo, dissolved in water, and obtained by freeze-drying.



Succinylation of PAAm-*graft*-PLL Comb-Type Copolymers. The resulting copolymer (**5**) or biotinylated **5** was dissolved in 1 mL of H_2O at the concentration of 50 mg/mL, the pH of which was increased to 10 by the addition of triethylamine (TEA). The DMF solution (150 μL) of succinic anhydride (60 mg) was subsequently added to the copolymer aqueous solution. The mixture was incubated for 3 h at 25 °C. The above DMF solution of succinic anhydride was added again to the mixture, the pH of which was adjusted to 10 with TEA. The resulting mixture was further incubated for 1 day at 25 °C. The degree of amino group modification was examined by the spectrophotometric amino group determination with trinitrobenzenesulfonic acid (TNBS) (*29*). The reaction mixture was dialyzed against distilled water using a Spectra/Por 7 membrane (molecular weight cutoff = 10^3), followed by freeze-drying.

Gel Permeation Chromatography (GPC). GPC was carried out using a JASCO 880-PU pumping system (Tokyo, Japan) at a flow rate of 1.0 mL/min at 25 °C with Ultrahydrogel 500 and Ultrahydrogel 250 columns (Japan Waters Ltd., Tokyo, Japan). The aqueous solution containing 0.5 M CH_3COOH and 0.3 M Na_2SO_4 was used as a mobile phase. Three hundred microliters of 1 mg/mL samples was injected into the columns. Eluate was detected by a UV (wavelength = 274 nm) detector (875-UV, JASCO), a refractive index (RI) detector (830-RI, JASCO), and a multiangle light scattering detector (Dawn-DSP, Wyatt Technology Co., Santa Barbara, CA).

^{1}H NMR Spectroscopy. Each polymer was dissolved in $(CD_3)_2SO$ (DMSO-d_6) or D_2O (99.8 atom % D; Merck, Darmstadt, Germany). ^{1}H NMR spectra (400 MHz) were obtained by a Varian Unity 400plus spectrometer (Palo Alto, CA) at a probe temperature of 298 K. The chemical shifts are expressed as parts per million using internal DMSO (δ = 2.5 ppm in DMSO-d_6) or HDO (δ = 4.7 ppm in D_2O) molecules as a reference.

Enzyme-Linked Immunosorbent Assay (ELISA) Measuring Polymer−Cell Interaction. Endothelial cells (ECV304, ATCC CRL1998) were seeded in tissue culture wells and allowed to grow to confluence in M199 medium (Gibco) supplemented with 10% heat-inactivated fetal bovine serum. The binding assays between the polymers and the cells were performed in a Sumilon multiwell plate (No. MS-8096F, Sumitomo Bakelite Co., Ltd., Tokyo, Japan) as below. First, the cells were washed once with an isotonic and low-ionic incubation buffer (285 mM sucrose, 10 mM Hepes, 0.9 mM $CaCl_2$, 0.5 mM $MgCl_2$). The confluent cells were incubated with 100 μL/well of the buffer containing each polymer (1 mg/mL) for 2 h at 4 °C. The wells were then washed once with the buffer, followed by the addition of 100 μL of the peroxidase-conjugated streptavidin in the buffer (1 μg/mL). After 1 h of incubation at 4 °C, the wells were washed three times with the buffer. Finally, 100 μL of 1 mg/mL OPD solution (in 50 mM citric acid, 100 mM Na_2HPO_4 buffer, pH 5.0) containing 0.02% H_2O_2 was added to the well as a substrate. Fifty microliters per well of 1.5 M

Scheme 1. Synthesis of PAAm-*graft*-PLL Comb-Type Copolymers

H_2SO_4 was added to stop the enzyme reaction after the incubation at room temperature. The absorbance at 492 nm was measured with an MTP-120 microplate reader (Corona Electric Co., Ltd., Ibaragi, Japan).

Estimation of the Dependence of the Succinylated PAAm-*graft*-PLL (PAAm-*graft*-PLLS) Cell Binding on the Ionic Strength of the Medium. As stated above, the endothelial cells were seeded and washed once with the isotonic and low-ionic incubation buffer. The PAAm-*graft*-PLLS was dissolved in the isotonic buffer containing 10 mM Hepes, 0.9 mM $CaCl_2$, 0.5 mM $MgCl_2$, and various sucrose/NaCl mixtures (285 mM/0 mM, 230 mM/27.5 mM, 155 mM/65 mM, 80 mM/102.5 mM, or 5 mM/140 mM) being added to the cells. These cells were incubated with 100 μL/well of each buffer containing PAAm-*graft*-PLLS (10 μg/mL) for 2 h at 4 °C. The wells were washed once with the isotonic and low-ionic incubation buffer. One hundred microliters of the peroxidase-conjugated streptavidin in the low-ionic buffer (1 μg/mL) containing 1 mg/mL bovine serum albumin was added to the wells. After the incubation for 1 h at 4 °C, the wells were washed three times with the low-ionic buffer. One hundred microliters of a 1 mg/mL OPD solution containing 0.012% H_2O_2 was then added to the well, followed by the measurement of the absorbance at 492 nm.

RESULTS AND DISCUSSION

Synthesis of Poly(CBZ-L-lysine) Macromonomers. To synthesize the graft copolymers (Scheme 1), we chose the macromonomer method (*30*) because it has several advantages over other methods. The length (molecular weight) of the polyamino acid macromonomer is easy to control by varying the feed ratio of monomers to the initiator having a polymerizable functional group. The density of graft chains is also controllable by varying the feed ratio of the macromonomer to comonomers. Therefore, the structure of graft chains would be well-defined and characterized. Furthermore, we are able to vary the properties of backbone polymers by replacing comonomers (*31*).

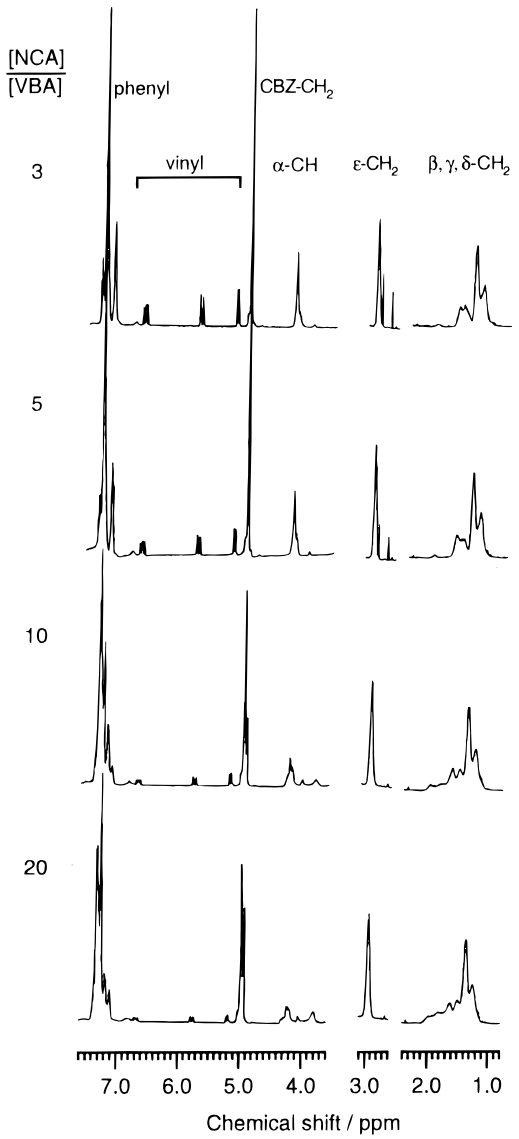


Figure 1. ^{1}H NMR spectra of poly(CBZ-L-lysine) macromonomers in DMSO-d_6. The feed ratio of monomer (NCA) to initiator (VBA) is represented.

Poly(CBZ-L-lysine) macromonomers (**3**) were prepared by the polymerization of CBZ-L-lysine NCA (**2**) using VBA (**1**) as an initiator. The polymerization progressed homogeneously in the solvent of dehydrated DMF. The polymers were purified by precipitating into diethyl ether. The vinyl groups were preserved in the resulting polymer (**3**), which was confirmed by ^{1}H NMR spectroscopy (Figure 1) in DMSO-d_6: δ 5.2 (doublet), 5.8 (doublet), and 6.7 (quartet). The signals of CBZ-L-lysine were also identified: δ 1.2−1.8 (β-, γ-, and δ-methylene protons), 3.0 (ϵ-methylene protons), 4.3 (α-methine protons), 5.0 (CBZ-methylene protons), and 7.2−7.4 (phenyl protons). From the signal ratio of vinyl protons and lysine protons, the number-average degree of polymerization (P_n) of **3** was determined. The result is shown in Table 1. The P_n of **3** almost corresponded with the feed ratio of monomer (**2**) to initiator (**1**). Therefore, it is possible to vary the

average length of the poly(CBZ-L-lysine) macromonomer (**3**) as the graft chain of PAAm-*graft*-PLL comb-type copolymer (**5**).

Synthesis of PAAm-*graft*-PLL Comb-Type Copolymers. At first, we attempted to deprotect CBZ-amino groups of the macromonomer (**3**) before the copolymerization reaction. However, the undesirable side reaction of vinyl groups occurred when the deprotection was carried out in the TFA/thioanisole mixture. Accordingly, we deprotected CBZ-amino groups after the copolymerization. The radical copolymerization of **3** with AAm (**4**) using the initiator of an azo compound, V-65, was carried out in DMF at 46 °C. During the reaction, a precipitate gradually appeared. After the copolymerization, the mixture was poured into a large excess of ethanol to precipitate the resulting polymer (**5**), together with unreacted **3**, and to remove unreacted **4**. The removal of the unreacted macromonomers (**3**) from the copolymers (**5**) in this step was difficult because the solubility of **3** was similar to that of **5**. Eventually, we were unable to find any selective solvents for the purification. Therefore, we isolated the copolymers after the deprotection of CBZ-amino groups. Because deprotected **3** was soluble in ethanol, the copolymers were isolated by the precipitation into ethanol after the deprotection. Figure 2 shows the representative GPC profiles of the resulting copolymer (**5**) detected by either absorbance at 274 nm (A_{274}) or RI. The A_{274} was mainly attributed to the terminal phenyl groups of the graft chains. The GPC profiles therefore validated the incorporation of the macromonomer (**3**) in the copolymer (**5**) and the removal of unreacted **3**. The number-average molecular weight of the each copolymer determined by GPC was $\sim 3 \times 10^4$. The ^{1}H NMR spectra (Figure 3) of the copolymer showed the characteristic signals of both PLL-*graft* and PAAm backbone: δ 1.4−1.8 (methylene protons of PAAm), 2.1−2.4 (methine protons of PAAm), 3.0 (ϵ-methylene protons of PLL), and 4.3 (α-methine protons of PLL). No residual

[a] Initiator, 10 mM V-65; reaction temperature, 46 °C; solvent, 2.5 mL of DMF; reaction time, 2 h (samples 1, 4, and 7), 3 h (samples 2, 5, and 8), 4 h (sample 3), and 4.5 h (samples 6 and 9). [b] The deprotection reaction of CBZ-amino groups was carried out in TFA/thioanisole mixture at 25 °C: 0.27 M thioanisole/19 mM CBZ, 2.5 h reaction (samples 1, 4, and 7); 0.54 M thioanisole/45 mM CBZ, 2.75 h reaction (samples 2, 5, and 8); and 1.1 M thioanisole/95 mM CBZ, 3.0 h reaction (samples 3, 6, and 9).

CBZ groups were detected in the final polymer samples, indicating the successful deprotection of amino groups. From the signal ratio of the PLL-*grafts* and the PAAm backbone, the content (mole fraction) of **3** in the copolymer was determined. As the mole fraction of **3** in feed increased, the mole fraction in the copolymer increased (Table 2). Furthermore, various macromonomers (**3**) with different P_n were copolymerized. Thus, it is possible to obtain the various PAAm-*graft*-PLL comb-type copolymers (**5**) with the well-controlled length and density of graft chains by using the macromonomer method.

Modification of the Amino Groups of the PAAm-*graft*-PLL Comb-Type Copolymers. We examined the reactivity of the amino groups of the graft chains. Here the acylation of the graft chains by succinic anhydride

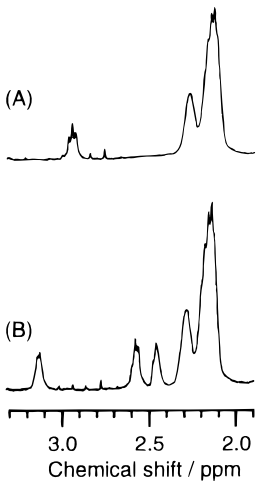

Figure 4. Change in the ^{1}H NMR spectra of the PAAm-*graft*-PLL comb-type copolymer (sample 6 in Table 2) by the reaction with succinic anhydride: (A) before and (B) after the reaction.

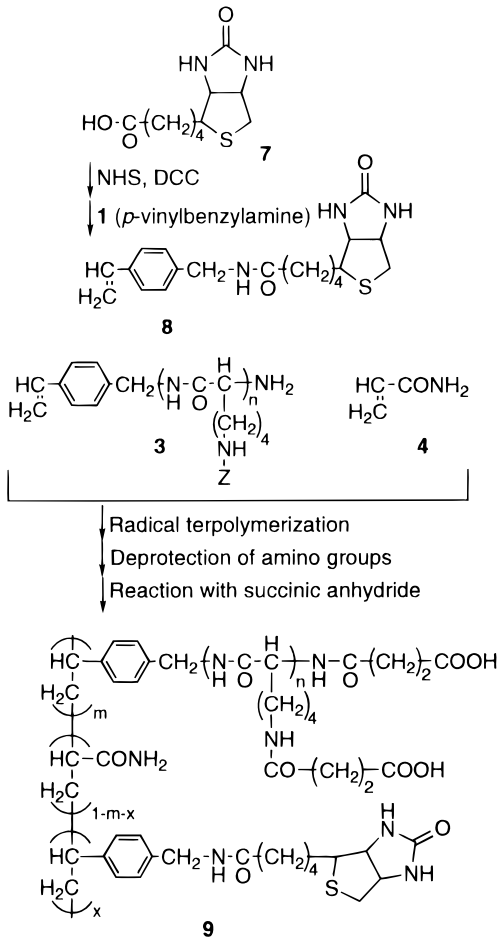
was examined. The PAAm-*graft*-PLL (**5**) was dissolved in water, and the pH of the solution was increased to 10 by TEA. The succinic anhydride dissolved in DMF was added to the aqueous solution of the PAAm-*graft*-PLL, which was insoluble in DMF. Thus, the succinylation reaction was carried out in the mixture of water and DMF. The complete succinylation of the amino groups of the graft chains was confirmed by the spectrophotometric amino group titration with TNBS (*29*). Figure 4 shows the ^{1}H NMR spectra of the resulting polymer (**6**) purified by dialysis. After the succinylation (Figure 4B), the signal of ϵ-methylene protons of the PLL-*grafts* shifted downfield (from δ 3.0 to 3.2), and the signals of the methylene protons of succinic acid appeared (δ 2.4−2.6). These results proved the complete succinylation of the amino groups again. The amino groups of the graft chains retained high reactivity, so that the graft chains are expected to be modified with ligand molecules such as β-galactose (unpublished results).

PAAm-*graft*-PLL Comb-Type Copolymers Having the Biotin Label on the Backbone. To analyze the interaction between cells and the comb-type copolymers, we intended to label the PAAm-*graft*-PLL with biotin, which is detected by ELISA using avidin (biotin-binding protein) (*32*). The comb-type copolymer PAAm-*graft*-PLL has two segments, that is, the nonionic backbone of PAAm and the PLL-*graft*. We prefer to incorporate biotin molecules into the PAAm backbone rather than into the PLL-*graft* to minimize the influence on the avidin−biotin binding and the interaction between the PLL-*graft* and the receptor. For the biotin-labeling, the biotin derivative (**8**) having a polymerizable group was prepared and terpolymerized with the poly(CBZ-L-lysine) macromonomer (**3**) and AAm (**4**) (Scheme 2).



First, the carboxyl group of biotin (**7**) was activated in DMF using NHS and DCC. The active ester of biotin was then reacted with VBA (**1**), resulting in the monomer (**8**) having a vinyl group. The biotin monomer (**8**) was terpolymerized with the macromonomer (**3**) and AAm (**4**). After the deprotection of amino groups, the ^{1}H NMR spectra of the resulting terpolymer were obtained (results not shown). From the signal ratio of methine protons (2.1−2.4 ppm) of the PAAm backbone and ϵ-methylene protons (3.0 ppm) of the PLL-*grafts*, the content (mole fraction) of **3** in the terpolymer was determined (Table 3). However, the ^{1}H NMR signal of **8** in the terpolymer was not detected, presumably because of considerably low feed and thereby low content in the terpolymer. The

Scheme 2. Biotinylation of PAAm-*graft*-PLL Comb-Type Copolymers

complete succinylation of the biotinylated PAAm-*graft*-PLL was also carried out in the same way as succinylating the unlabeled PAAm-*graft*-PLL.

Detection of the Interaction between Cells and the Biotinylated PAAm-*graft*-PLLS Comb-Type Copolymers by ELISA. We examined whether the interaction between cells and the PAAm-*graft*-PLLS comb-type copolymers was detected by ELISA. Figure 5 shows the detection of the biotinylated PAAm-*graft*-PLLS (**9**) bound to adherent cells by ELISA using peroxidase-conjugated streptavidin (*33*). The biotinylated PAAm-

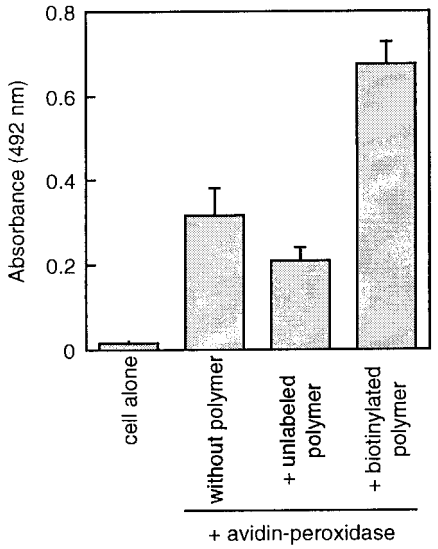

Figure 5. Detection of the interaction between adherent cells and the biotinylated PAAm-*graft*-PLLS comb-type copolymers by ELISA using the peroxidase-conjugated streptavidin. The biotin-labeled (sample 3 in Table 3) or unlabeled (sample 6 in Table 2) PAAm-*graft*-PLLS was added to confluent endothelial cells at 4 °C, as described under Experimental Procedures, followed by the addition of the peroxidase-conjugated streptavidin. After washing, the substrate (OPD + H_2O_2) was added and the color development was read as the absorbance at 492 nm. Symbols and error bars represent the mean and standard deviation of the measurements made in quadruplicate wells.

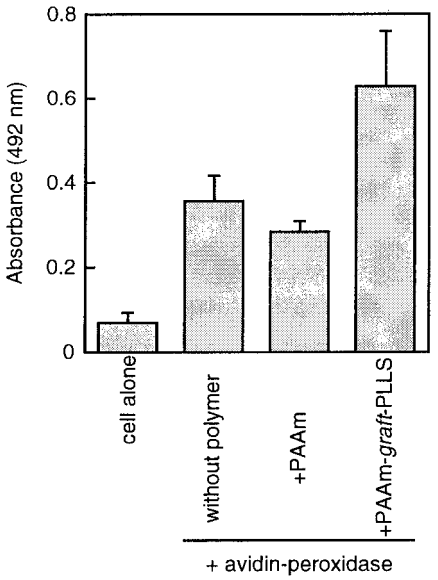

Figure 6. Binding assay between endothelial cells and polymers by ELISA. The binding of the PAAm-*graft*-PLLS (sample 1 in Table 3) or PAAm (sample 7 in Table 3) was determined by the color development of the substrate as described in Figure 5. Symbols and error bars represent the mean and standard deviation of the measurements made in quadruplicate wells.

graft-PLLS (**9**) and not unlabeled copolymer (**6**) showed significant absorbance over the background level. The PAAm-*graft*-PLLS bound to the cells was, therefore, detectable by ELISA using the peroxidase-conjugated streptavidin.

To evaluate the role of graft chains in the binding to the cell, we carried out a set of the ELISA experiments with the PAAm-*graft*-PLLS comb-type copolymer and PAAm homopolymer. As shown in Figure 6, the biotinylated PAAm was not detected. Therefore, the graft chains played a major role in the binding to the cell,

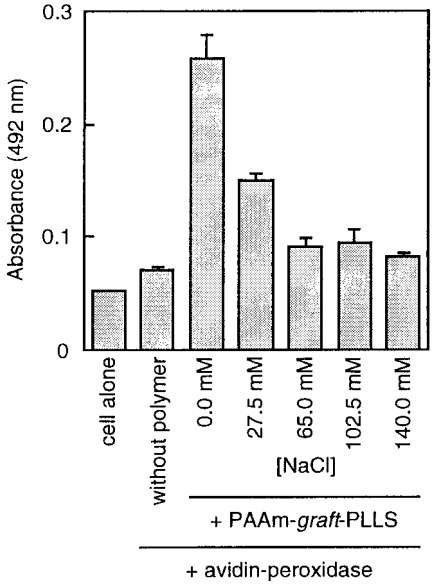

Figure 7. Effect of the ionic strength of the medium on the interaction between endothelial cells and the PAAm-*graft*-PLLS comb-type copolymers. The PAAm-*graft*-PLLS (sample 3 in Table 3) was added to confluent endothelial cells at 4 °C in the isotonic solution containing the indicated concentration of NaCl, as described under Experimental Procedures. The binding of the PAAm-*graft*-PLLS was determined by the color development of the substrate (the absorbance at 492 nm). Symbols and error bars represent the mean and standard deviation of the measurements made in quadruplicate wells.

whereas the PAAm backbone presumably had no interaction with the cell surface.

The ionic interaction between the graft chains and the cell surface was considered the major driving force for the binding to the cell, so that we estimated the effect of the ionic strength of the medium on the interaction of the PAAm-*graft*-PLLS with the cell (Figure 7). The PAAm-*graft*-PLLS was highly bound to the cell under low ionic strength conditions (0 mM NaCl and 285 mM sucrose). However, the increase in the ionic strength of the medium drastically reduced the binding of the PAAm-*graft*-PLLS, leading to almost no binding at physiological ionic strength (140 mM NaCl and 5 mM sucrose). These results proved that the electrostatic attraction between PLLS-*grafts* and the cell surface mainly mediated the binding of the PLLS-*graft* to the cell. In other words, the nonspecific interaction of the PAAm-*graft*-PLLS with the cell was negligible under physiological salt conditions.

Conclusion. We have synthesized the various PAAm-*graft*-PLL comb-type copolymers with the defined length and density of graft chains by using the macromonomer method. The PAAm-*graft*-PLL was synthesized as the "prepolymer" for multivalent ligands. We can introduce the various types of ligand molecules into the graft chains, via the primary amino groups, with certain chemicals such as lactonolactone (*12*) to form ligand clusters. In this paper, the complete modification of the graft chains with succinic anhydride was achieved for the model study to explore the interaction between a cell surface and the resulting polymer having anion clusters (PAAm-*graft*-PLLS). To detect the interaction between the cell surface and the model multivalent ligands having the anion clusters, we prepared the biotin monomer, labeling the prepolymer on the PAAm backbone. By ELISA, we confirmed that the anion clusters of the graft chains worked exclusively for the interaction with the cell and that the PAAm backbone was inert to the interaction with the cell. The anion clusters of the model

multivalent ligand may interact with cation cluster sites [e.g., P-selectin (*21*−*24*, *34*)] or anionic sites [via Ca^{2+} bridges (*35*)] on the cell surface under low ionic strength conditions. From a practical point of view, the nonspecific interaction of the model multivalent ligand PAAm-*graft*-PLLS with the cell was negligible under physiological salt conditions, so that we expect the multivalent effect of ligands to be properly extracted by incorporating ligands of interest into the PLL-*grafts*.

The multivalent effect has been studied by conjugating ligand molecules to soluble polymers or insoluble polymer matrices. In these cases, however, it is difficult to control the density and distribution of ligands. Indeed, the increase of ligand density must result in the formation of the clustered domain of ligands, so that we are unable to distinguish between cluster effect and density effect. The various PAAm-*graft*-PLL comb-type copolymers with the defined length and density of the PLL-*grafts* are the potential prepolymers to investigate and to optimize the affinity of the multivalent ligands for receptors.

^{99m}Tc-Labeling and in Vivo Studies of a Bombesin Analogue with a Novel Water-Soluble Dithiadiphosphine-Based Bifunctional Chelating Agent

Srinivasa R. Karra,[†] Roger Schibli,[†,‡] Hariprasad Gali,[†,‡] Kattesh V. Katti,[†] Timothy J. Hoffman,[†,§,∥] Chris Higginbotham,[∥] Gary L. Sieckman,[∥] and Wynn A. Volkert*[,†,∥]

Department of Radiology, Department of Chemistry, and Department of Medicine, University of Missouri—Columbia, Columbia, Missouri 65211, and H. S. Truman Memorial Veterans Hospital, Columbia, Missouri 65212. Received August 19, 1998; Revised Manuscript Received December 2, 1998

Recent progress in the synthesis of water-soluble phosphine ligand systems and their corresponding ^{99m}Tc complexes prompted the development of a new bifunctional chelating agent (BFCA) based on a tetradentate dithiadiphosphine framework (P_2S_2-COOH). The detailed synthesis of this new BFCA is described here. The corresponding ^{99m}Tc complex, ^{99m}Tc−P_2S_2-COOH, can be formed in >95% yield. To demonstrate the potential of this chelate to efficiently label peptides, ^{99m}Tc−P_2S_2-COOH was coupled to the N-terminal region of the truncated nine-amino acid bombesin analogue, 5-Ava-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH_2 [BBN$^{(7-14)}$], to form ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$. Conjugation to the peptide was performed in borate buffer (pH 8.5) by applying the prelabeling approach in yields of >60%. In competitive binding assays, using Swiss 3T3 mouse fibroblast cells against [^{125}I-Tyr^4]bombesin, Re−P_2S_2−BBN$^{(7-14)}$ exhibited an IC_{50} value of 0.8 ± 0.4 nM. The pharmacokinetic studies of ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ and its ability to target tissue expressing gastrin-releasing peptide (GRP) receptors were performed in normal mice. The ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ exhibited fast and efficient clearance from the blood pool (0.6 ± 0.1% ID, 4 h postinjection) and excretion through the renal and hepatobiliary pathways (56.4 ± 8.2 and 28.1 ± 7.9% ID, 4 h postinjection, respectively). Significant uptake in the pancreas was observed (pancreatic acini cells express bombesin/GRP receptors), producing pancreas:blood and pancreas:muscle ratios of ca. 22 and 80, respectively, at 4 h postinjection.

INTRODUCTION

Small receptor-avid peptides have attracted considerable interest for use in thrombus, inflammation, and tumor imaging and tumor treatment (*1*, *2*, and references cited therein). A number of malignant tumors overexpress certain types of receptors on their surface which make them potential targets for imaging and therapy with radiolabeled synthetic antagonists and agonists. The 14-amino acid peptide bombesin (BBN) isolated from the skin of the amphibian Bombina and related gastrin-releasing peptides (GRP) exhibit an enhanced response in a variety of tumor tissues, e.g., in small cell lung, prostate, breast, and colon cancer (*3*−*6*). Analogues of bombesin with modified structures exhibited a similar or even higher affinity for these receptors (*7*−*9*). Today, corresponding synthetic peptides can be readily generated through automated solid phase techniques. For our studies, we produced and used the nine-amino acid bombesin analogue BBN$^{(7-14)}$ as a vehicle to target GRP receptors (Figure 1). The peptide BBN$^{(7-14)}$ has proved in the literature to be a potent GRP agonist. It can be radiolabeled with $^{123/131}$I or ^{105}Rh for potential nuclear medical applications by virtue of its retention of a high binding affinity for GRP receptors (*10*, *11*). We introduced an additional spacer function in the form of 5-aminopentanoic acid to the N-terminal region of the peptide to avoid interference of the chelating moiety with the receptor binding C-terminus of the peptide.

Most of the bifunctional chelating agents reported in the literature for labeling biomolecules with ^{99m}Tc and $^{186/188}$Re are based on N_2S_2 or N_3S frameworks. Sometimes, harsh reaction conditions (e.g., high temperatures and extended reaction times) are required to form the corresponding complexes with high specific activity or the labeling efficiency is low. Furthermore, these chelate moieties can exhibit often unfavorable physicochemical characteristics (e.g., high lipophilicity), which can play a critical role in maintaining high receptor binding affinity and in tumor uptake and also in the rate and route of clearance of a biomolecule from target and nontargeted tissues. The hydrazinonicotinamide (HYNIC) ligand system in combination with coligands offers today the only important alternative to the NS systems (*12*, *13*).

Our group is focused on the development of hydrophilic chelating moieties to achieve efficient clearance of the ^{99m}Tc or ^{188}Re conjugate from the blood pool through the kidneys into the urine with low retention of the radioactivity in the liver and the kidney. Initial in vitro and in vivo studies with water-soluble dithiadiphosphine ligand systems (Figure 2, I) and their corresponding technetium and rhenium complexes, synthesized in our laboratory, showed that they are highly soluble and

I **II**

Figure 2. Structure of the model, dithiadiphosphine ligand P_2S_2 (I) and structure of the bifunctional dithiadiphosphine ligand P_2S_2-COOH (**4a**) (II) used for the studies.

stable in aqueous solutions (*14*−*16*). The excellent water solubility is facilitated by the positive overall charge of the chelate and by the four hydroxymethyl groups on the phosphine functionalities. The combination of sulfur and phosphorus exhibits enhanced σ-donor and good π-accepting properties for stabilizing the metal center. We recently developed the P_2S_2-COOH (**4b**) BFCA based on the dithiadihydroxymethylphosphine framework shown in Figure 2 (II). The complex with ^{99m}Tc demonstrated excellent in vitro and in vivo stability and the desirable clearance and excretion properties (*17*).

This study describes the synthesis and the radiolabeling of the new BFCA **4b** and demonstrates the utility of **4b** in labeling small bioactive peptides. The procedure of labeling BBN$^{(7-14)}$ with ^{99m}Tc−P_2S_2-COOH and the in vitro and in vivo behavior of the conjugate M−P_2S_2−BBN$^{(7-14)}$ (M = ^{99m}Tc or Re) are also presented.

EXPERIMENTAL PROCEDURES

Materials. All chemicals were obtained from either Aldrich Chemical Co. or Fisher Scientific. Diethyl (3-bromopropyl)phosphonate was synthesized utilizing Arbuzov Reaction and refluxing triethyl phosphite in a 10-fold excess of 1,3-dibromopropane for 1 h and then purified by vacuum distillation. DL-6,8-Dihydrothioctic acid and $ReO_2(py)_4Cl$ were synthesized according to the literature procedures (*18*, *19*). The Fmoc-protected amino acids were purchased from Nova Biochem. The chemicals and solvents were of reagent grade and were used without further purification. Na[$^{99m}TcO_4$] was eluted from a ^{99}Mo/^{99m}Tc generator (Mallinckrodt Medical, Inc.) using 0.9% saline. CF-1 normal mice were purchased from Taconic Labs. Swiss 3T3 mouse fibroblast cell lines were obtained from American Type Culture Collection (ATCC) and maintained and grown in the University of Missouri Cell and Immunology Care facilities. The [^{125}I-Tyr^4]-bombesin was purchased from DuPont Merck Pharmaceuticals. The peptide was synthesized on a Synergy 432A personal peptide synthesizer from Applied Biosystems.

Nuclear magnetic resonance spectra were recorded on a Bruker ARX-300 spectrometer. The ^{1}H and ^{13}C chemical shifts are reported relative to residual solvent protons as a reference, while the ^{31}P shifts are reported relative to an external reference of 85% H_3PO_4. IR spectra were recorded on a Mattson Galaxy Series FTIR 3000 spectrometer. FAB-mass spectral analyses were performed by the mass spectrometry laboratories at Washington University (St. Louis, MO). HPLC analyses were performed on a Waters 600E system equipped with a Waters 486 tunable absorption detector, a radiometric detector system, and a Waters 746 Data Module integrating recorder. HPLC solvents consisted of H_2O containing 0.1% trifluoroacetic acid (solvent A) and acetonitrile containing 0.1% trifluoroacetic acid (solvent B). For the radiochemical experiments (analysis and purification), a C-18 Hamilton PRP-1 column (10 μm, 150 mm × 4.1 mm) was used. The HPLC gradient system started with 95% A/5% B from 0 to 2 min followed by a linear gradient from 95% A/5% B to 50% A/50% B from 2 to 17 min. The gradient remained at 50% A/50% B for 9 min before ramping back to 95% A/5% B at 26 min. The flow rate was 1.5 mL/min. For the purification and quality control of the peptide, a C-18 Phenomenex Jupiter column (250 mm, 10 μm) was used. The gradient started with a linear gradient from 95% A/5% B to 30% A/70% B over the course of 25 min.

Preparation of Compound 1. A suspension of 60% NaH in mineral oil (6.5 g, 0.16 mol) was placed in a 1 L two-necked flask fitted with a septum and a N_2 inlet. The mineral oil was extracted with dry hexane (3 × 25 mL). The remaining NaH was suspended in dry THF (100 mL). Dihydrolipoic acid (10.5 g, 0.05 mol) in THF (15 mL) was added dropwise under N_2 via a syringe at 0 °C. The suspension was stirred for 30 min. Diethyl (3-bromopropyl)phosphonate (27.2 g, 0.10 mol) in THF (200 mL) was added slowly while the mixture was constantly being stirred. After 1 h, the excess NaH was quenched with 5 N HCl (50 mL). THF was removed under reduced pressure, and 500 mL of dichloromethane was added to the residue. The organic layer was washed with water (3 × 25 mL) and brine (100 mL) and dried over anhydrous Na_2SO_4. After removal of the solvent, the crude product was purified on a silica gel column (98:2 dichloromethane/methanol). The yield was 25.6 g (90%): LR-FAB-MS *m*/*z* 565.4 [M + 1]$^+$; IR (NaCl cell) 1724 cm^{-1} (s, $\nu_{C=O}$); ^{1}H NMR ($CDCl_3$) δ 4.17−4.13 (m, 8H), 2.79−2.66 (m, 8H),

2.36 (t, 2H), 2.15−1.99 (m, 4H), 1.90−1.3 (m, 8H), 1.36 (t, 12H); ^{13}C NMR ($CDCl_3$) δ 180.4, 61.4 (d, J = 6.4 Hz), 61.3 (d, J = 6.4 Hz), 44.5, 36.8, 34.5 (d, J = 13.8 Hz), 32.3 (d, J = 18.2 Hz), 30.5 (d, J = 18.2 Hz), 28.8, 26.4, 25.57, 24.23 (d, J = 141.4 Hz), 24.18 (d, J = 141.4 Hz), 22.6 (d, J = 4.4 Hz), 22.2 (d, J = 4.4 Hz), 16.2 (d, J = 6.0 Hz); ^{31}P NMR ($CDCl_3$) δ 31.8 (s), 31.6 (s).

Preparation of Compound 2. *N*-Methylmorpholine (2.3 g, 0.022 mol) and isobutyl chloroformate (3.1 g, 0.022 mol) were added to a solution of **1** (11.3 g, 0.02 mol) in dry THF (100 mL) at −15 °C under N_2. After 10 min, a solution of aniline (2.0 g, 0.022 mol) in THF (25 mL) and triethylamine (2.2 g, 0.22 mol) in THF (25 mL) were added at −15 °C. The mixture was allowed to warm to room temperature and stirred for 2 h. The precipitate of *N*-methylmorpholine hydrochloride was filtered, and the solvent was removed. The crude product was purified on a neutral alumina column (70:30 chloroform/hexane). The yield was 10.9 g (85%): LR-FAB-MS m/z 640.3 $[M + 1]^+$; IR (NaCl cell) 1657 cm^{-1} (s, $\nu_{C=O}$);^{1}H NMR ($CDCl_3$) δ 8.85 (br s, 1H), 7.62 (d, 2H, J = 7.6 Hz), 7.28 (dd, 2H, J_1 = 12.0 Hz, J_2 = 7.6 Hz), 7.05 (t, 1H, $J_1 = J_2$ = 7.4 Hz), 4.09 (m, 8H), 2.75−2.52 (m, 8H), 2.4−2.35 (2H), 2.0−1.5 (m, 15H), 1.33 (t, 6H, $J_1 = J_2$ = 7.1 Hz), 1.32 (t, 6H, $J_1 = J_2$ = 7.1 Hz); ^{13}C NMR ($CDCl_3$) δ 171.7, 138.7, 128.4, 123.3, 119.5, 61.4 (d, J = 5.9 Hz), 44.4, 36.9, 34.5, 34.3, 32.2 (d, J = 17.7 Hz), 30.8 (d, J = 17.7 Hz), 28.7, 26.0, 24.2 (d, J = 140.5 Hz), 24.1 (d, J = 142.6 Hz), 22.7 (d, J = 4.2 Hz), 22.2 (d, J = 4.3 Hz), 16.2 (d, J = 5.9 Hz); ^{31}P NMR ($CDCl_3$) δ 31.5 (s), 31.4 (s).

Preparation of Compound 3. Compound **2** (6.4 g, 0.01 mol) was dissolved in dry diethyl ether (100 mL) and the mixture placed in a 500 mL flask fitted with a reflux condenser. The solution was cooled to 0 °C, and 1 M $LiAlH_4$ in ether (15 mL, 0.15 mol) was added dropwise via a syringe under N_2. After the mixture was stirred at room temperature for 30 min, the reaction mixture was diluted with diethyl ether (200 mL). Then, a saturated solution of Na_2SO_4 (25 mL) was added at 0 °C to quench the excess $LiAlH_4$. The organic layer was cannulated and the ether removed under reduced pressure at room temperature to give the crude diphosphine **3**, which was used without further purification: ^{31}P NMR ($CDCl_3$) δ −137.5 (s).

Preparation of Compound 4a. The crude diphosphine **3** was dissolved in degassed ethanol (15 mL). A solution of 37% formaldehyde (9 g, 0.1 mol) in ethanol (5 mL) and 5 mL of 30% HCl was added, and the mixture was stirred for 10 min under N_2 at room temperature and then refluxed for 5 h. The solvents were removed under reduced pressure to give the crude (hydroxymethyl)phosphonium chloride **4a**. The crude product was purified with a reverse phase Sep-Pak C-18 column using a water/methanol gradient. The yield was 3.0 g (45%): LR-FAB-MS m/z 573.6 $[M - Cl]^+$; ^{1}H NMR (D_2O) δ 4.49 (m, 12H), 2.75−2.5 (m, 7H), 2.45−2.20 (m, 6H), 2.0−1.20 (m, 12H); ^{13}C NMR (D_2O) δ 180.0, 51.1 (d, J = 54.5 Hz), 45.1, 34.8, 34.7, 32.7 (d, J = 15.9 Hz), 31.2 (d, J = 15.8 Hz), 29.3, 26.6, 25.2, 22.4 (d, J = 4.1 Hz), 21.9 (d, J = 4.1 Hz), 13.7 (d, J = 41.2 Hz), 13.6 (d, J = 41.1 Hz); ^{31}P NMR (D_2O) δ 28.6 (s).

Preparation of Compound 4c. A solution of compound **4a** (901 mg, 1.48 mmol) in water (100 mL) was added to a solution of $[ReO_2(py)_4]Cl$ (py = pyridine) (200 mg, 0.37 mmol) in water (25 mL), and the reaction mixture was refluxed for 5 h. The reaction solution was concentrated and purified on a reverse phase Sep-Pak C-18 column (35 cm^3, 10 g) using a water/methanol gradient to obtain pure compound **4c** as a purple viscous oily liquid. The yield was 148 mg (55% based on Re): LR-FAB-MS m/z 694.9 $[M - Cl]^+$; IR (NaCl cell) 3333 (bs, ν_{O-H}), 1724 (s, $\nu_{C=O}$), 912 (s, ν_sO═Re═O), 795 cm^{-1} (s, ν_{as}O═Re═O); ^{1}H NMR (D_2O) δ 4.30 (m, 8H), 3.43 (br s, 4H), 3.20 (br s, 1H), 2.90 (br t, 2H), 2.45 (br m, 5H), 2.19 (br t, 6H), 1.66 (br m, 2H), 1.31 (br m, 4H); ^{13}C NMR (D_2O) δ 179.1 (s), 59.4 (s), 58.9 (s), 58.5 (d), 58.0 (d), 49.9 (s), 38.4 (s), 37.2 (s), 34.0 (s), 33.3 (s), 33.1 (s), 30.1 (s), 24.5 (s), 24.2 (s), 20.9 (s), 17.8 (d), 17.5 (d); ^{31}P NMR (D_2O) δ −7.9 (d, J_{PP} = 12 Hz), −8.8 (d, J_{pp} = 12 Hz).

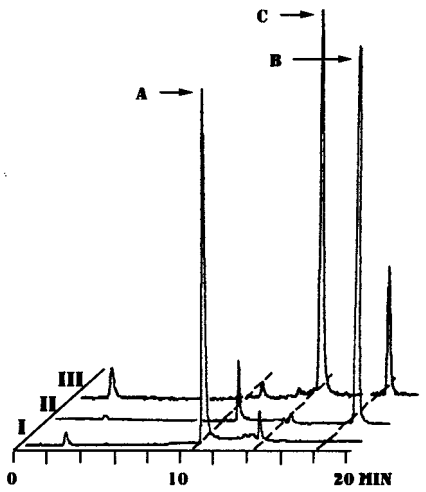

Figure 3. ^{99m}Tc HPLC traces of the products formed during the labeling procedure: (A) ^{99m}Tc−P_2S_2-COOH, (B) ^{99m}Tc−P_2S_2−PFP, and (C) ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$. A reverse phase C-18 column was used for the characterization and purification of the compounds.

^{99m}Tc-Labeling of 4b. For the preparation of the ligand, 5 mg (8.2 μmol) of **4a** was dissolved in 1 mL of H_2O. One hundred microliters of a 1 M $NaHCO_3$ buffer solution (pH 9) was added to produce **4b**. Thirty microliters of the stock solution of **4b** was added to 500 μL of Na[$^{99m}TcO_4$] in saline and the mixture vortexed. The technetium was reduced by addition of 10 μL of a degassed, presaturated stannous tartrate solution to form ^{99m}Tc−P_2S_2-COOH within 10 min at room temperature. The formation of the product was confirmed by reverse phase HPLC (>95% yield). The retention time of Na[$^{99m}TcO_4$] was 1.2 min, whereas ^{99m}Tc−P_2S_2-COOH had a retention time of 10.9 min (Figure 3, I).

Activation of the Acid Functionality of ^{99m}Tc−P_2S_2-COOH. The carboxylic acid group of ^{99m}Tc−P_2S_2-COOH was activated with pentafluorophenol (PFP) using 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide methiodide (EDC) to form ^{99m}Tc−P_2S_2−PFP ester. Ten milligrams of EDC (0.3 mmol) and 6 mg of PFP (0.3 mmol in 100 μL of acetonitrile) were added to 500 μL of a freshly prepared ^{99m}Tc−P_2S_2-COOH solution in a 10 mL test tube. The reaction mixture was vortexed for 1 min and kept at room temperature for 20 min. The solution was centrifuged for 2 min, and the aqueous layer was separated from the oily drops of PFP containing >80% of the initial activity in the form of ^{99m}Tc−P_2S_2−PFP. The product was separated from the excess PFP by HPLC after dissolving the oily drops in 200 μL of acetonitrile. The activated ester had a retention time of 18.1 min (Figure 3, II), whereas PFP had a retention of 20.4 min (monitored at 254 nm) on the reverse phase HPLC system. The aqueous layer contained 20% of the initial radioactivity in form of ^{99m}Tc−P_2S_2−PFP (ca. 60%) and some unreacted ^{99m}Tc−P_2S_2-COOH (ca. 40%).

Coupling of ^{99m}Tc−P_2S_2−PFP Ester to BBN$^{(7-14)}$. The pH of a previously HPLC-purified solution of ^{99m}Tc−

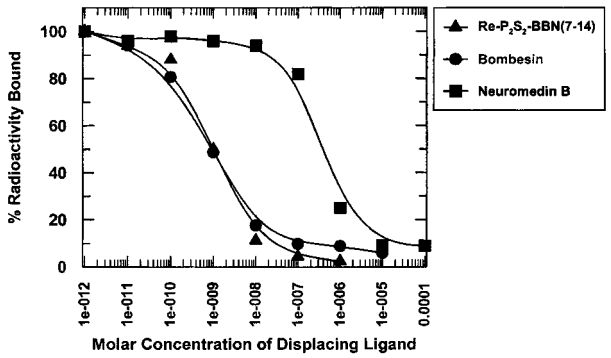

Figure 4. Competitive binding of peptide Re−P_2S_2−BBN$^{(7-14)}$ vs [^{125}I-Tyr^4]bombesin using Swiss 3T3 mouse fibroblast cells. Competitive binding of bombesin and Neuromedin B vs [^{125}I-Tyr^4]bombesin in the same cell line performed as controls which have IC_{50} values of 4 and 1000 nM, respectively (*22*).

P_2S_2−PFP was adjusted to 8.5 using borate buffer (0.1 M). Approximately 1 mg of BBN$^{(7-14)}$ (0.9 μmol) was added to a 500 μL aliquot of a ^{99m}Tc−P_2S_2−PFP solution and the reaction mixture vortexed for 1 min and incubated for 30 min at room temperature. The reaction was monitored by reverse phase HPLC. The final product [^{99m}Tc−P_2S_2−BBN$^{(7-14)}$] was separated from excess BBN$^{(7-14)}$ using the standard HPLC gradient. The conjugate exhibited a retention time of 14.6 min (Figure 3, III), whereas the free BBN$^{(7-14)}$ exhibited a retention time of 12.3 min. The coupling yields were usually between 70 and 80% as determined radiometrically.

Preparation of the Re Analogue of the Conjugate. The Re−P_2S_2−BBN$^{(7-14)}$ was synthesized by solid phase peptide synthesis. ReO_2−P_2S_2-COOH was introduced in the last step of the peptide synthesis. After the peptide was cleaved from the resin, the product was purified by reverse phase HPLC. The molecular constitution of Re−P_2S_2−BBN$^{(7-14)}$ was confirmed by FAB mass spectroscopy. The FAB mass spectral analysis confirmed the presence of a $[O{=}Re{=}O]^+$ core. This is in agreement with the observation made by Smith et al. for similar Re(V) complexes with P_2S_2 ligands (*15*). The conjugate exhibited a retention time of 15.2 min (monitored at 350 nm): FAB-MS *m/e* (M + 1) calcd 1616.89, found 1616.4.

In Vitro Binding Assay of Re−P_2S_2−BBN$^{(7-14)}$. In vitro BBN−receptor binding capabilities of the labeled peptide were assessed utilizing displacement binding assays conducted at 37 °C in Swiss 3T3 fibroblast cells with a method similar to that designed by Mahmoud et al. (*20*). The IC_{50} value was determined for the non-radiolabeled Re−P_2S_2−BBN$^{(7-14)}$ analogue by analyzing displacement of bound [^{125}I-Tyr^4]bombesin (Figure 4). In vitro binding assays were performed under identical conditions using active BBN and Neuromedin B as positive and negative controls, respectively (Figure 4).

Biodistribution of ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ in Normal Mice. Normal CF-1 mice (average weight, 25 g) were used for the biodistribution studies (Tables 1 and 2). The pH of the HPLC-purified ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ solution was adjusted to physiological conditions using a 0.01 M phosphate buffer (pH 7.4). Aliquots (80−100 μL) of the labeled peptide solution (55−75 kBq) were injected into each animal via the tail vein. Tissues and organs were excised from the sacrificed animals 30 min, 1 h, and 4 h postinjection. The organs and tissue were weighed; the activity was counted in a NaI counter, and the percent injected dose per organ and the percent injected dose per gram were calculated. The % ID in whole blood was estimated assuming a blood volume of 6.5% of the total body weight. Receptor blocking studies were also carried out where excess BBN$^{(7-14)}$ was administered to animals for in vivo saturation of GRP receptors prior to injection of ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ (Tables 3 and 4). In these studies, each animal received a subcutaneous injection of 1 mg of BBN$^{(7-14)}$ dissolved in 100 μL of a mixture of saline/acetonitrile/DMF (90:5:5) 35 min prior to the injection of ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$. Control (unblocked) animals received an injection of 100 μL of the solvent mixture without BBN$^{(7-14)}$ 35 min prior to the injection of ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$. The animals were sacrificed 30 min postinjection and the tissues removed, weighed, and counted as previously described.

RESULTS AND DISCUSSION

The crucial molecular building block for the bifunctionalization of the P_2S_2 ligand system is the commercially available DL-α-lipoic acid. The bifunctional ligand **4a** was produced in four steps outlined in Scheme 1. The synthetic procedure for forming the P_2S_2 backbone is identical with that applied for the underivatized P_2S_2 ligand (Figure 2, I) described by Smith et al. (*15*). The carboxylic acid was protected with aniline for the reduction step of the phosphonate groups using a procedure described by Barton et al. (*21*). The (hydroxymethyl)-phosphonium chloride **4a** was prepared by formylation of the P−H bonds of **3** in oxygen-free ethanol in the presence of excess aqueous formaldehyde and hydrochloric acid. In the same step, the carboxylic acid function was deprotected.

The new compounds, **1**, **2**, and **4b**, were characterized by ^{1}H, ^{13}C, and ^{31}P NMR and IR spectroscopy and mass spectrometry. Compound **3**, which is an intermediate, was characterized by ^{31}P NMR spectroscopy only. Ligands **4a,b** are highly soluble in water. The formation of the phosphonium salt of the ligand **4** has two advantages.

(1) Purification of the phosphonium salt **4a** is more convenient than that of **4b**. (2) Due to the formation of the phosphonium salt, the P^{III} centers are protected against oxidation, and the ligand can be stored under aerobic conditions for a long period of time. This is an important advantage for a kit formulation in which ligand systems with (hydroxymethyl)phosphine groups are used. **4a** can be readily converted into **4b** by adding small amounts of a base before complexation with a metal center. It is noteworthy that **4b** is oxidatively stable even under high levels of dilution in aqueous media for several hours, which was confirmed in the ^{31}P NMR experiments.

The prelabeling approach was selected to radioactively conjugate the peptide, as difficulties were encountered in activating the carboxylic acid in **4a,b**. ^{99m}Tc−P_2S_2-COOH can be produced either by direct reduction of Na[$^{99m}TcO_4$] with stannous tartrate in the presence of **4b** (total ligand concentration in the samples is on the order of 10^{-5} M) or by the ligand exchange reaction starting with [^{99m}Tc]gluconate and **4b** at room temperature (*17*). In both cases, the complex was efficiently produced (>95%) as a single species which was confirmed by HPLC (Figure 3, I). However, we were only able to form the active ester complex ^{99m}Tc−P_2S_2−PFP in good yields in the absence of the trans-chelating gluconate ligand. Therefore, only direct reduction of the ^{99m}Tc center in the presence of **4b** was employed for these studies. ^{99m}Tc−P_2S_2−PFP was produced in good yields (>90%) in a 0.9% saline solution using an excess of EDC and PFP at room temperature. The HPLC profile again showed the formation of a single species (Figure 3, II). ^{99m}Tc−P_2S_2−PFP is remarkably stable under acidic conditions and could be purified and collected by HPLC where only minor reformation of ^{99m}Tc−P_2S_2-COOH was observed 2 h after collection of ^{99m}Tc−P_2S_2−PFP. For the final labeling step of BBN$^{(7-14)}$, the pH of the purified ^{99m}Tc−P_2S_2−PFP solution was adjusted to 8.5 using a 0.1 M borate buffer. An aliquot of 500 μL of the ^{99m}Tc−P_2S_2−PFP solution was added to 1 mg of the peptide and the mixture incubated at room temperature. HPLC profile III, shown in Figure 3, revealed that after 30 min ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ was formed as a single species in approximately 80% yield. Extension of the incubation time did not lead to the complete formation of the conjugate due to the decomposition of the remaining ^{99m}Tc−P_2S_2−PFP back to ^{99m}Tc−P_2S_2-COOH. The labeled peptide was separated from unlabeled BBN$^{(7-14)}$ by HPLC and collected into 0.1 M phosphate buffer to achieve physiological pH conditions for use in animal studies.

To evaluate the biological activity of the labeled peptide in vitro, the ability of the nonradioactive conjugate Re−P_2S_2−BBN$^{(7-14)}$ to bind to the GRP receptors on Swiss 3T3 mouse fibroblast cells was examined. The cell binding studies were carried out using [^{125}I-Tyr^4]bombesin as the competitive BBN analogue. The results of the experiments shown in Figure 4 demonstrated the high binding affinity of Re−P_2S_2−BBN$^{(7-14)}$. The IC_{50} value was determined to be 0.8 ± 0.4 nM and is comparable with those of bombesin and its analogues that are considered to have sufficiently high binding affinity for potential use as targeting vectors for GRP receptor-expressing cancers in vivo.

Results of the in vivo biodistribution experiments with ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ in normal mice are summarized in Tables 1 and 2. The conjugate ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ exhibited rapid clearance from the blood pool (0.6 ± 0.07% ID at 4 h postinjection) and nontargeted tissues. The excretion of the radioactivity from the body occurs in both the renal (56.5 ± 8.20% ID, 4 h postinjection) and the hepatobiliary (liver and intestines, ca. 35% ID, 4 h postinjection) pathways. Only small amounts of activity were retained in the kidneys 4 h postinjection (1.3 ± 0.15% ID). There was some retention of the conjugate in the liver (5.3 ± 0.80% ID, 4 h postinjection). The amount of radioactivity found in the stomach, an indication of an in vivo decomposition of a ^{99m}Tc conjugate and the reformation of [$^{99m}TcO_4$]$^-$, was negligible (0.4 ± 0.10% ID, 4 h postinjection). This provides important evidence that the P_2S_2 ligand system is capable of stabilizing ^{99m}Tc even under in vivo conditions. A significant uptake of radioactivity was observed in the pancreas (4.7 ± 0.53 or 17.4 ± 3.40% ID/g, 1 h postinjection), demonstrating the ability of ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ to target in vivo GRP-expressing cells (acini cells in the pancreas express GRP receptors that are accessible to the blood stream). The pancreas:muscle and pancreas:blood ratios (based on % ID per gram) reached a maximum of 80 and 22, respectively, at 4 h postinjection. Furthermore, receptor blocking studies with BBN$^{(7-14)}$ confirmed the specificity of BBN$^{(7-14)}$ or ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ toward the GRP receptors. The difference in the uptake of ^{99m}Tc−P_2S_2−BBN$^{(7-14)}$ in the pancreas with and without subcutaneous injection of 1 mg of BBN$^{(7-14)}$ is significant (0.6 ± 0.33 and 6.5 ± 0.25% ID, respectively). The uptake of the ^{99m}Tc-labeled peptide in all other organs and tissue was not affected by the blocking experiment (Tables 3 and 4).

CONCLUSION

The detailed synthesis and characterization of the first water-soluble, bifunctional chelator **4a,b** based on a P_2S_2 framework is presented. Furthermore, the ability of the novel BFCA to form an in vitro and in vivo stable complex with ^{99m}Tc and its utility for the radiolabeling of receptor-avid peptides are demonstrated. Although the prelabeling procedure with ^{99m}Tc−P_2S_2-COOH is time-consuming, a P_2S_2 chelating system might, in the future, serve as a potential alternative to the known tetradentate N_2S_2, N_3S, and HYNIC ligand systems. In fact, recent experiments showed that the synthetic precursor **3** (after deprotection of the acid function) can be efficiently attached to the N-terminal function of peptides. The hydroxymethyl functions are subsequently introduced to the $[H_2P]_2S_2$ peptide conjugate to achieve the favorable in vivo characteristics of the chelating moiety. This enables in the future a more convenient postlabeling approach of a P_2S_2-functionalized peptide.

Electroactive oligodeoxynucleotides (ODNs) with specific base sequences have a potential application as electrical sensors for DNA molecules. To this end, a phosphoramidite that bears a 9,10-anthraquinone (AQ) group tethered to the 2′-O of the uridine via a hexylamino linker, 2′-*O*-[6-[2-oxo(9,10-anthraquinon-2-yl)amino]hexyl]-5′-*O*-(4,4′-dimethoxytrityl)uridine 3′-[2-(cyanoethyl)bis(1-methylethyl)-phosphoramidite] (**3**), has been synthesized and used to prepare three ODNs with tethered AQs using standard phosphoramidite chemistry. The synthetic methodology thus allows the synthesis of ODNs with electroactive tags attached to given locations in the base sequence. Cyclic voltammetric behavior of these AQ−ODN conjugates was examined in aqueous buffer solutions at a hanging mercury drop electrode. At slow sweep rates, nearly reversible two-electron waves characteristic of an adsorbed anthraquinone/hydroquinone redox couple was observed for all of the AQ−ODN conjugates. Approximate Langmuirian isotherms were found for the AQ−ODNs with molecular footprints, calculated from the saturation coverages, that scaled with molecular size. The cyclic voltammetric response of the duplexes formed from the AQ−ODNs and their complementary ODN was complicated by the competitive adsorption of the individual ODNs and possibly the duplex species as well.

INTRODUCTION

The exquisite selectivity provided by Nature in the formation of DNA double helices via Watson−Crick hydrogen-bonded base pairs is arguably unmatched among molecular recognition strategies. Hybridization of complementary oligonucleotides, if confined to a small volume element or interface, is the basis of a selective nucleic acid sensor using conventional (e.g., radiochemical) means of distinguishing double-helix from single-strand (ss) structures (*1*). Much of this research is highly interdisciplinary, involving both the synthesis of modified oligonucleotides and their study by different physicochemical techniques (*2*). The use of fluorescent oligonucleotide probes is well established and the basis of commercial DNA analyzers. Reviews of the older literature on this topic are available (*3*, *4*), and a summary of recent attempts to improve detection of the hybridization event was given by Thiel et al. (*5*), who used surface plasmon resonance imaging to differentiate between ss- and ds-DNA.

A modified electrode surface in which an electroactive probe has been incorporated would have many attractive features common to modern electroanalytical techniques. These include in situ analysis of small volumes and possibly no requirement for washing of excess reactants from the surface reaction layer. Ideally, a surface-attached oligodeoxynucleotide (ODN) with an attached electroactive group would mimic natural DNA, which gives well-defined faradaic signals for ss-DNA and not ds-DNA (*6*−*8*). An ideal tag for this purpose would give a persistent signal, preferably electrochemically reversible, in a potential region well removed from where natural DNA and RNA are electroactive, such that the signal could be easily interrogated in a sensor configuration. ODNs with attached electroactive groups or tags have been described by several groups (*9*−*13*). These applications have involved chromatographic separation of the ss- and ds-DNAs with electrochemical detection of the tag, although Xu and Bard used electrochemical luminescence to detect ds-DNA with an end-tethered Ru(bpy)$_3^{2+}$ group (*14*).

The above strategy can be contrasted to other electrochemical means of detecting ds-DNA that have appeared in recent years, many of which involve the use of electroactive intercalators that selectively bind to double-helix structures. Most of these methods require the addition of a solution species, the intercalator, to perform the analysis. Thus, hybridization can be detected by the preconcentration or binding of the intercalator to a surface-confined DNA molecule, which leads to an increase in the signal. Transition metal complexes, which bind to DNA to give electroactive complexes (*15*−*17*), have been used in this manner (*16*, *18*−*21*), as have a variety of other species, including a Hoechst dye (*22*), ethidium (*23*), methylene blue (*24*), daunomycin (*25*), and aromatic amines (*26*). Other electrochemical approaches involve the enhancement of the electrocatalytic current for oxidation of ds-DNA by intercalating redox couples (*27*−*30*), use of the Fe(CN)$_6^{3-/4-}$ couple as a permeability marker (*31*), and an attenuation of the poly(pyrrole) doping process by a tethered oligonucleotide in the double-helix form (*32*).

Described below are the synthesis and electrochemical behavior of ODNs with 9,10-anthraquinone (AQ) groups

tethered to the 2′-O of a uridine unit (see Scheme 1). While this work focuses on the electrode reactions, others have prepared ODNs with tethered quinone groups for different applications. An increase in stability has been noted for nucleic acid duplexes modified at the sugar 2′-position (*33*), including several studies in which pendant AQ groups were used (*34*−*36*). Rokita and co-workers have used tethered quinones for photochemical methylation of DNA with known sequences at specific sites (*37*, *38*), and Gasper and Schuster found photooxidation of GG sites in a DNA double helix possessing an end-tethered anthraquinone group (*39*). Cohen and co-workers utilized 5′-linked AQ−ODNs to demonstrate that AQ derivatives can be delivered to target nucleic acids (mRNA or DNA) (*40*). AQ tags were chosen for the present study since they can withstand the conditions required for the solid-phase synthesis of ODNs (*33*, *39*), while also exhibiting a two-electron electrode reaction characteristic of the quinone/hydroquinone couple. The formal potential of this couple is well separated from potentials of redox reactions associated with the ODNs. In addition, the electrochemical signal provides a means of studying interfacial electron and proton transfer reactions of immobilized oligonucleotide probes on electrode surfaces.

EXPERIMENTAL PROCEDURES

All reactions were monitored by thin-layer chromatography (TLC). Adsorption chromatography was carried out using E. Merck silica gel products: (a) TLC on 0.2 mm aluminum-backed plates or (b) column chromatography using 230−400 mesh silica gel. Visualization of the TLC plates was achieved with 254 nm UV light and by spray-heat development using a *p*-anisaldehydesulfuric acid reagent (*41*). The solvent systems for adsorption chromatography were (A) 1:1 ethyl acetate/hexanes, (B) 95:5 dichloromethane/methanol, (C) 3:1 ethyl acetate/hexanes, (D) 9:1 dicholoromethane/methanol, (E) 99:1 dichloromethane/methanol, and (F) 65:35:trace ethyl acetate/hexanes/triethylamine. All reactions were carried out under a nitrogen atmosphere unless otherwise indicated. Solvents were evaporated under an aspirator vacuum at about 25 °C unless otherwise indicated. Elemental analyses were furnished by Atlantic Microlab, Inc. (Atlanta, GA). ^{1}H and ^{13}C NMR spectra were recorded at 400.13 and 100.61 MHz, respectively, unless stated otherwise. ^{19}F NMR spectra were recorded on a JEOL FX90Q spectrometer at 84.24 MHz using an external standard of trifluoroacetic acid-*d*. ^{31}P NMR spectra were recorded at 161.9 MHz using an external standard of phosphoric acid (85%) at 37 °C.

Positive ion electrospray mass spectra of the modified nucleosides were acquired on a Quattro-II quadrupole instrument (Micromass Inc., Manchester, U.K.) by infusion (5 μL/min) of a ca. 1 μM solution of the analyte in methanol. Data were averaged in the "multichannel acquisition" mode over a 2 min acquisition period. Conversely, negative ion electrospray mass spectra of the unmodified ODNs were obtained on the same instrument by infusion (5 μL/min) of a ca. 1 μM solution of the analyte in 1:1 methanol/water that contains 0.15% triethylamine. The averaging of the data was performed as described above.

The AQ−ODNs were synthesized using a Perspective Biosystems Expedite 8901 Nucleic Acid Synthesis System (PE Applied Biosystems, Foster City, CA)

Preparative reversed-phase HPLC on the monotritylated AQ−ODNs was performed on a Waters 600E instrument (260 nm) equipped with a Waters Delta Pak C4 column (7.8 mm × 300 mm) and a Waters 991 integrator (Waters Corp., Milford, MA). The solvent systems used for reversed-phase HPLC were (G) 50 mM triethylammonium acetate at pH 7.0 and (H) acetonitrile. The gradient system employed was 95:5 G:H for 5 min with a linear increase to 4:6 G:H over the course of 50 min (method A) using a flow rate of 2.5 mL/min. The purity of the AQ−ODNs was determined utilizing a Waters Delta Pak C4 column (3.9 mm × 300 mm) and the same gradient system as described above at a flow rate of 1.5 mL/min (method B).

Additional analysis of the AQ−ODNs was conducted with capillary gel electrophoresis (CGE). A 100 μL aliquot of the ODN (0.2 OD) was injected into a Beckman P/ACE System 5000 Capillary Gel Electrophoresis unit, coupled to a UV−vis detector (Beckman and Coulter, Inc., Fullerton, CA) that was equipped with a column (27 cm in total length with an effective length of 20 cm) of 12% linear polyacrylamide in a buffer of 7 M urea and 0.2 M bis tris borate. A voltage of 500 V/cm was supplied to the column at ca. 40 °C. A typical analysis was completed in 12 min (method A).

Prior to acquisition of the negative ion electrospray mass spectra of the AQ−ODNs on a HP 59987A series II API 5989A mass spectrometer (Hewlett-Packard Co., Palo Alto, CA), ca. 0.5 OD was desalted by osmosis from water that contained ammonium hydroxide using a Millipore VS 0.025 μm filter (Millipore Corp.). After 1 h, the purified sample was then dissolved in 1:1 2-propanol/water (100 μL). Before the sample was infused into the spectrometer, a 2.5 μL aliquot of piperidine (100 mM) was added.

A Shimadzu UV-2101PC UV−vis scanning spectrophotometer was used to determine the ϵ_{max} of the novel AQ−ODNs (Shimadzu Corp., Kyoto, Japan). Melting points of the ODNs were determined using an HP model 8452A diode array spectrophotometer equipped with an HP model 89090A Peltier temperature controller (Hewlett-Packard Co.).

The electrochemical studies were performed using a hanging mercury drop electrode (HMDE) purchased from EG&G (Oak Ridge, TN). The electrode area was 0.0225 cm^2 for most of the voltammetric experiments; details are given elsewhere (*42*). The reference electrode was a Ag/

AgCl wire immersed directly in the test solution. A Cypress model CS-2Ra (Cypress Systems, Inc., Lawrence, KS) potentiostat was used. Calculation of the cyclic voltammograms was carried out using software supplied by CH Instruments, Inc. (Cordova, TN).

Materials and Solvents. Solutions of nonmodified phosphoramidites (0.1 M) were used as purchased from PE Applied Biosystems. 5′-d(ATG CAT TCT GCC CCC AAG AG)-3′ (**7**) was supplied by Operon Technologies, Inc. (Alameda, CA). The other unmodified ODN 5′-d(CTC TTG GGG GCA GAA TGC AT)-3′ (**6**) was furnished by Isis Pharmaceuticals (Carlsbad, CA). The entire amount of the ODNs was diluted to 10 mL with sterile deionized water. Anhydrous solvents were prepared as follows. Dichloromethane and pyridine were distilled from calcium hydride at atmospheric pressure, and 1,4-dioxane was distilled from lithium aluminum hydride.

9,10-Anthraquinone-2-carboxylic Acid 2,3,4,5,6-Pentafluoro Phenyl Ester (9). To a solution of **8** (2.1 g, 7.9 mmol) in dichloromethane (50 mL) at 0 °C were added DCC (0.67 g, 4.3 mmol) and 2,3,4,5,6-pentafluorophenol (0.90 g, 4.3 mmol). The suspension was allowed to warm to room temperature overnight. The crude reaction mixture was adsorbed onto silica gel and submitted to column chromatography (hexanes), affording **9** as a pale yellow solid (1.25 g, 45%): mp 197−205 °C; R_f = 0.91 (solvent A); ^{1}H NMR ($CDCl_3$) δ 7.88 (m, 2H), 8.37 (m, 2H), 8.50 (d, 1H, J = 8.15 Hz), 8.58 (dd, 1H, J = 1.52 Hz, J = 8.09 Hz), 9.13 (d, 1H, J = 1.33 Hz); ^{19}F NMR ($CDCl_3$) δ −152.35 (d, 2F, J = 18.31 Hz), −157.23 (t, 1F, J = 21.98 Hz), −161.98 (dd, 2F, J = 18.31 Hz, J = 21.98 Hz); ^{13}C NMR ($CDCl_3$ and 2 drops of DMSO-d_6) δ 127.19, 127.69, 129.34, 131.59, 133.13, 133.72, 134.34, 134.84, 137.01, 160.92, 181.35, 181.68. Higher-order resonances associated with the pentafluoro moiety are between δ 120 and 150. Anal. Calcd for $C_{21}H_7F_5O_4$: C, 60.30; H, 1.69. Found: C, 60.23; H, 1.71.

2′-*O*-[6-[2-Oxo(9,10-anthraquinon-2-yl)amino]hexyl]-5′-*O*-(4,4′-dimethoxytrityl)uridine (10). To a solution of **9** (1.0 g, 2.4 mmol) in dichloromethane (40 mL) at 0 °C was added pyridine (0.19 mL, 2.4 mmol). Compound **4** (*43*) (1.4 g, 2.2 mmol) was then added. After 50 min, the reaction mixture was allowed to warm to room temperature for a further 3 h. The crude reaction mixture was then adsorbed onto silica gel and subjected to flash chromatography (solvent C), which afforded a pale yellow, glassy material **10** (1.6 g, 83%): R_f = 0.44 (solvent B); ^{1}H NMR (DMSO-d_6) δ 1.34 (bm, 4H), 1.54 (bm, 4H), 3.07−3.50 (bm, 3H, obscured by the H_2O signal), 3.50−3.67 (overlapping resonances, 3H), 3.71 (s, 6H), 3.98 (bs, 1H), 3.91 (bs, 1H), 4.18 (t, 1H, J = 5.23 Hz), 5.11 (bs, 1H, exchanges with D_2O), 5.28 (d, 1H, J = 8.04 Hz), 5.81 (d, 1H, J = 3.15 Hz), 6.88 (d, 4H, J = 8.65 Hz), 7.11−7.50 (overlapping resonances, 9H), 7.73 (d, 1H, J = 8.04 Hz), 7.91 (dd, 2H, J = 3.36 Hz, J = 5.21 Hz), 8.04−8.41 (overlapping resonances, 4H), 8.61 (s, 1H), 8.88 (t, 1H, J = 4.80 Hz), 11.35 (bs, 1H, exchanges with D_2O); ^{13}C NMR (DMSO-d_6) δ 26.28, 28.89, 29.04, 54.99, 62.58, 68.47, 69.82, 79.12, 80.91, 82.60, 85.87, 87.14, 101.43, 113.20, 125.42, 126.75, 126.96, 127.68, 127.84, 129.73, 132.73, 132.99, 134.39, 134.56, 135.05, 135.32, 139.50, 140.14, 144.60, 150.25, 158.10, 162.95, 164.44, 182.06; ESIMS calcd for $C_{51}H_{48}N_3O_{11}$ 878.3, found $[M + Na]^+$ 902.1 and $[M + K]^+$ 918.0. Anal. Calcd for $C_{51}H_{48}N_3O_{11}\cdot 2H_2O$: C, 66.95; H, 5.73; N, 4.59. Found: C, 66.96; H, 5.57; N, 4.44.

2′-*O*-[6-[2-Oxo(9,10-anthraquinon-2-yl)amino]hexyl]-uridine (5). Compound **10** (0.33 g, 0.38 mmol) was stirred with a 3% (v/v) dichloroacetic acid/dichloromethane solution (7 mL) for 10 min. The crude reaction mixture was subjected to flash chromatography (solvent A → ethyl acetate, followed by dichloromethane → E) to afford a pale yellow amorphous powder **5** (0.13 g, 60%). Lyophilization with 1,4-dioxane afforded an off-white, fluffy solid: R_f = 0.39 (solvent D); ^{1}H NMR (DMSO-d_6) δ 1.31 (bm, 4H), 1.53 (bm, 4H), 3.40−3.63 (overlapping resonances, 6H), 3.86 (dd, 2H, J = 2.28 Hz, J = 4.56 Hz), 4.06 (dd, 2H, J = 5.28 Hz, J = 5.9 Hz, signal collapses to a triplet upon the addition of D_2O), 5.02 (d, 1H, J = 5.9 Hz, exchanges with D_2O), 5.10 (t, 1H, J = 5.14 Hz, exchanges with D_2O), 5.63 (dd, 1H, J = 2.06 Hz, J = 7.87 Hz), 7.76−8.10 (overlapping resonances, 3H), 8.13−8.43 (overlapping resonances, 4H), 8.64 (bd, 1H, J = 2.54 Hz), 8.90 (t, 1H, J = 5.08 Hz), 11.31 (s, 1H); ^{13}C NMR (DMSO-d_6) δ 25.32, 26.45, 29.07, 29.23, 60.74, 68.59, 69.92, 81.34, 85.31, 86.39, 101.98, 102.05, 125.80, 125.90, 127.02, 127.37, 133.24, 133.30, 139.79, 140.65, 140.77, 163.49, 165.04, 182.46. Anal. Calcd for $C_{30}H_{31}N_3O_9\cdot 0.5C_4H_8O_2$ (1,4-dioxane): C, 61.83; H, 5.67; N, 6.76. Found: C, 61.87; H, 5.78; N, 6.60.

2′-*O*-[6-[2-Oxo(9,10-anthraquinon-2-yl)amino]hexyl]-5′-*O*-(4,4′-dimethoxytrityl)uridine 3′-[2-(Cyanoethyl)bis(1-methylethyl)phosphoramidite] (3). Compound **10** (1.12 mmol, 0.98 g, dried in vacuo for 12 h) was dissolved in dichloromethane (ca. 1 mL) that was added under a blanket of argon. To the solution were added diisopropylammonium tetrazolide (1.13 mmol, 2.0 g) and 2-(cyanoethyl)-*N*,*N*,*N*′,*N*′-tetraisopropyl phosphorodiamidite (2.25 mmol, 0.14 g). After being stirred overnight, the crude reaction mixture was purified by column chromatography (solvent F), which afforded the phosphoramidite **3** (0.750 g, 64%): R_f = 0.36 (solvent F); ^{31}P NMR ($CDCl_3$) δ 150.89; FABMS calcd for $C_{60}H_{66}N_5O_{12}P$ 1079.45, found $[M + H]^+$ 1080.11 and $[M + Na]^+$ 1102.23.

General Procedure for the Synthesis of 2′-O-Modified AQ−ODNs 1a−c and 2. All of the AQ−ODNs were synthesized (2 μmol scale)—at least two batches were prepared of each modified ODN—using standard instrument chemistry with the exception of the step of incorporating the modified uridine moiety. This was accomplished by coupling the growing oligomer twice per cycle (5 min for each cycle) utilizing an acetonitrile solution of phosphoramidite **3** (0.08−0.1 M). At the end of the synthetic sequence, the final DMT group was left intact. After treatment with ammonium hydroxide (28−30%) for ca. 16 h at 55 °C, the CPG was removed by filtration through a Gelman 0.45 μm nylon acrodisc syringe filter (Pall Gelman Sciences, Ann Arbor, MI). The crude ODNs were purified employing reversed-phase HPLC (method A). Final detritylation was accomplished with acetic acid (80%) for ca. 30 min. The trityl residues and excess salt were removed by passing the AQ−ODNs through a column of Sephadex G-25 (Sigma, St. Louis, MO). Analytical details of AQ−ODNs were as follows.

5′-d(AU*G CAT TCT GCC CCC AAG AG)-3′ (1a): t_R = 21.77 min (HPLC using method B); t_R = 4.12 min (CGE using method A); ESIMS calcd for $C_{213}H_{262}N_{75}O_{121}P_{19}$ m/z 6397.4, found m/z 6398.8.

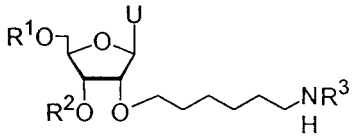
5′-d(ATG CAT TCU* GCC CCC AAG AG)-3′ (1b): t_R = 19.97 min (HPLC using method B); t_R = 5.89 min (CGE using method A); ESIMS calcd for $C_{213}H_{262}N_{75}O_{121}P_{19}$ m/z 6397.4, found m/z 6398.6.

5′-d(AU*G CAT TCU* GCC CCC AAG AG)-3′ (1c): t_R = 22.84 min (HPLC using method B); t_R = 8.16 min (CGE using method A); ESIMS calcd for $C_{233}H_{279}N_{76}O_{125}P_{19}$ m/z 6732.7, found m/z 6732.9.

5′-d(GAU*CT)-3′ (2): t_R = 34.72 min (HPLC using method B); t_R = 7.98 min (CGE using method A); ^{1}H NMR (D_2O) δ 5.84−5.88 (overlapping resonances, 3H), 5.98 (d,

1H, $J = 7.55$ Hz), 6.13 (d, 1H, $J = 6.45$ Hz), 6.10−6.30 (overlapping resonances, 3H), 7.53 (d, 1H, $J = 6.59$ Hz), 7.74 (s, 1H), 7.80−7.90 (overlapping resonances, 4H), 8.07−8.15 (overlapping resonances, 3H), 8.20 (s, 1H), 8.24 (s, 1H), 8.34 (d, 1H, $J = 1.78$ Hz); ^{31}P NMR (D_2O) δ −0.32, −0.28, −0.11, 0.11; ESIMS calcd for $C_{69}H_{80}N_{18}O_{33}P_4$ m/z 1813.4, found m/z 1813.2.

Determination of the Concentration of the Novel ODNs 1a−c. To accurately determine the concentration of AQ−ODNs **1a**−**c**, a stock solution of 20−60 ODs of each of the modified oligomers (dependent on the amount available) was prepared in sterile, deionized water (10 mL). The contribution of AQ to the ϵ_{260} for modified AQ−ODN **1a** was added to the ϵ_{260} for 5′-AUG CAT TCT GCC CCC AAG AG-3′, which was calculated from the nearest-neighbor effect (*44*). The ϵ_{260} of AQ was determined to be 26 400 M^{-1} cm^{-1} by subtracting the ϵ_{260} of uridine from the ϵ_{260} of monomer **5**. Thus, the ϵ_{260} of **1a** was determined to be 214 000 M^{-1} cm^{-1} (260 nm). By measuring the absorbance at 260 nm, we found the concentration of the stock solution of **1a** to be 2.09×10^{-5} M. Similarly, the concentrations of the stock solutions of **6** ($\epsilon_{260} = 194\,000$ M^{-1} cm^{-1}) and **7** ($\epsilon_{260} = 188\,000$ M^{-1} cm^{-1}) were determined to be 2.04×10^{-5} and 2.83×10^{-5} M, respectively.



Electrochemical Studies. Cyclic voltammetry (CV) was carried out using aqueous buffers containing NaCl at various concentrations. For the pH studies on compounds **2** and **5** (see below), 0.125 M phosphate and acetate buffers were used for pH <7 and Britton−Robinson (BR) (*45*) buffers were used for pH >7. The latter buffer system was also used for the determination of the adsorption isotherms at pH 7.15. Before measurements were taken, solutions were purged with purified nitrogen that had been passed through a column containing Mn(II) oxide dispersed on a vermiculite support to remove oxygen.

Hybridization Conditions. Hybridization solutions were prepared by mixing equimolar aliquots (ca. 50 μL) of the stock solutions with 2−3 mL of buffer solution. Temperature profiles were obtained by heating the cell to 90 °C for 10 min, followed by slow cooling in 1 °C increments while measuring the absorbance at 260 nm. Once confirmation of duplex formation was achieved, CV was performed on the solution as described above. Initial experiments used either the pH 7.15 BR buffer solution containing 0.25 M NaCl and 3.6 mM EDTA or a 0.01 M ammonium acetate/0.001 M ammonium chloride buffer. The ammonium acetate buffers were chosen to mimic the conditions of Bayer et al. (*46*), who detected duplexes in solution using electrospray mass spectroscopy (albeit at higher concentrations). The latter experiments were performed in 0.1 M phosphate buffer (pH ∼7) containing 0.05 M NaCl and 5 mM EDTA. In the latter procedure, melting curves were obtained for solutions before exposure to the HMDE conditions, and the voltammetric behavior was compared to that of an identical solution that was not thermally cycled. Spurious voltammetric waves were obtained for solutions of **1a** and **6** that had been exposed to the HMDE conditions before thermal cycling.

RESULTS AND DISCUSSION

Synthesis of 2′-O-Modified ODNs. Entry into the novel oligomers **1a**−**c** and **2** was crucial for this study (refer to Scheme 1). The key intermediate in the synthetic sequence was the electroactive phosphoramidite **3** (Scheme 2). Additionally, the strategy provided access to the free nucleoside **5** that was required to establish the experimental conditions required to observe the distinctive electrochemical signature of the quinone moiety. Initially, the 3-(3-methyl-1,4-naphthoquinon-2-ylsulfanyl)propionyl reporter group of Chatterjee and Rokita (*38*) was employed. However, when the precursor to the conjugates was subjected to concentrated ammonia, to mimic the final deblocking step in the synthesis of ODNs (*47*), deleterious side reactions took place. Accordingly, an AQ tag was employed in this work since these conjugates are known to survive the conditions of the oligonucleotide synthesis (*34*, *40*).

Scheme 3[a]

[a] (a) DCC, 2,3,4,5,6-pentafluorophenol, CH_2Cl_2, 0 °C → room temperature over the course of 12 h; (b) **4**, pyr, CH_2Cl_2, 0 °C for 50 min, room temperature for 3 h; (c) 3% (v/v) $Cl_2CHCOOH$ in CH_2Cl_2, 10 min; (d) diisopropylammonium tetrazolide, 2-(cyanoethyl)-*N*,*N*′,*N*′,*N*-tetraisopropyl phosphoramidite, CH_2Cl_2, room temperature for 12 h; (e) automated ODN synthesizer.

Compound **9** was synthesized utilizing DCC to condense **8** with 2,3,4,5,6-pentafluorophenol (Scheme 3). Addition of **9** to **4** (*43*) in the presence of pyridine secured the modified nucleoside **10**. With this essential intermediate in hand, (a) phosphoramidite **3** was prepared using

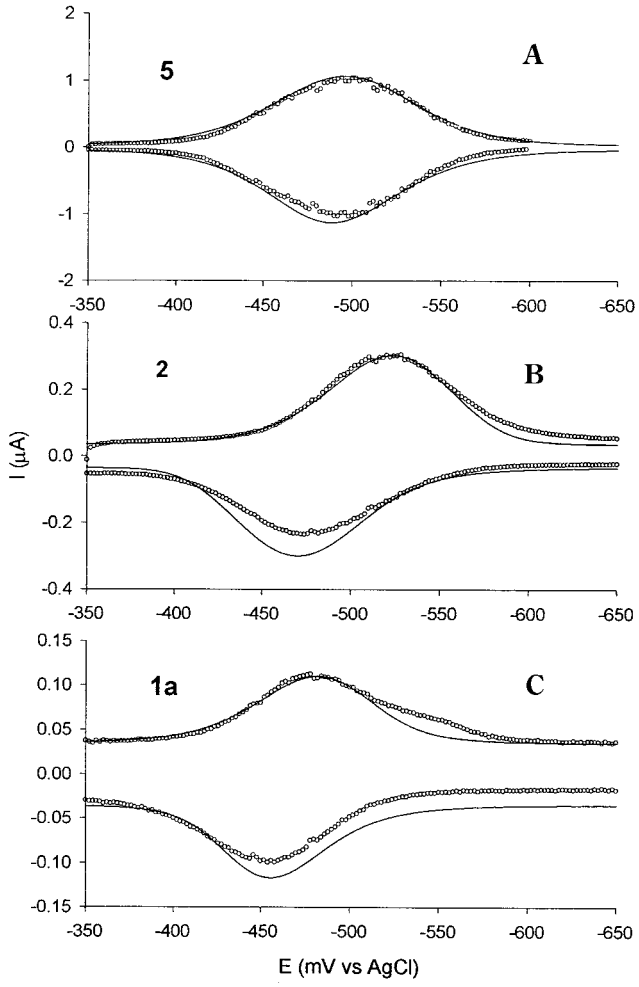

Figure 1. Typical cyclic voltammograms (○) of compounds (A) **5** (pH 7.15), (B) **2** (pH 7.77), and (C) **1a** (pH 7.15) at 100 mV/s with accompanying EE mechanism simulations (solid lines). Simulation parameters were as follows: (A) $k_{s1} = 100\ s^{-1}$, $k_{s2} = 20\ s^{-1}$, $E°_1 = -0.475$ V, and $E°_2 = -0.510$ V; (B) $k_{s1} = 100\ s^{-1}$, $k_{s2} = 2\ s^{-1}$, $E°_1 = -0.510$ V, and $E°_2 = -0.490$ V; and (C) $k_{s1} = 100\ s^{-1}$, $k_{s2} = 5\ s^{-1}$, $E°_1 = -0.470$ V, and $E°_2 = -0.470$ V.

standard methodology (*43*) and (b) removal of the 4,4′-dimethoxyltrityl (DMT) group was readily achieved with a 3% (v/v) dichloroacetic acid in CH_2Cl_2 (*47*) solution to afford free ribonucleoside **5**. A standard protocol was performed to obtain AQ–ODNs **1a**–**c** and **2** from **3** on an automated oligonucleotide synthesizer (*48*). Prior to removal of the final DMT group, the resulting oligomers were purified using reversed-phase HPLC.

Cyclic Voltammetry. Before studies were carried out on oligomers **1a**–**c**, cyclic voltammetry was performed on aqueous buffer solutions of **2** and **5**. Immediately upon extrusion of a HMDE into a dilute aqueous solution of these AQ–ODNs, the presence of an adsorbed layer of electroactive AQ was indicated by the appearance of a voltammetric wave with a wave shape indicative of a redox process for a surface-confined species. Typical voltammograms are shown in Figure 1. These voltammograms are similar to those reported by Forster, in both position and shape, for related simple AQs on HMDEs (*49*). Thus, it appears that the AQ groups readily adsorb on and remain in close electrical contact with the mercury surface despite the presence of the oligonucleotide substitutent.

The cyclic voltammograms of 20-mers **1a**–**c** were similar to those of **2** and **5**, except that the magnitudes of the current and the corresponding surface charge were smaller. Figure 1C shows a typical cyclic voltammogram for **1a**, which has an AQ group tethered to the second nucleotide from the 5′-phosphate end of the base sequence. The shapes of the voltammetric waves for all the compounds studied at sweep rates of less than ca. 1 V/s were symmetrical, or nearly so, with peak separations ($E_p^{anod} - E_p^{cath}$) of a few millivolts and minimal faradaic current at potentials on the wings of the voltammogram. These observations are consistent with formation of a self-assembled layer on the electrode surface. It will be argued below that these films must possess a fair degree of order as well.

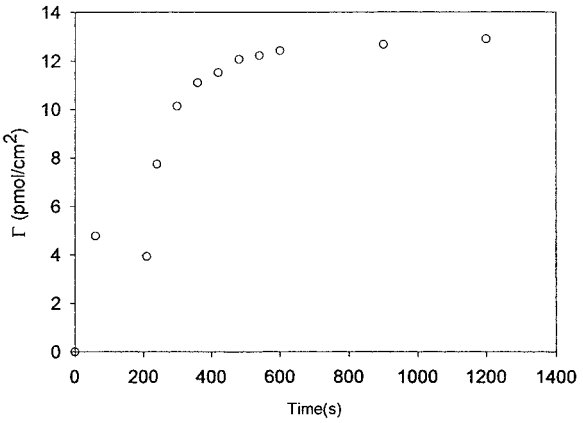

Figure 2. Surface coverage vs exposure time of the HMDE drop to 0.4 μM **1a** BR buffer (pH 7.15).

The voltammograms in Figure 1, which do not have ideal Nernstian shapes for an *n*-electron process, have been fit to a simple global EE mechanism (i.e., two successive electron additions) (*50*). This approach gave good fits to the slow sweep rate voltammograms of all the conjugates, including the splitting that was evident in the cyclic voltammograms at pH values of less than ca. 6 and the narrowing of the voltammograms at pH >7. In this simple analysis, it is assumed that the electron additions would be accompanied by protonation steps. It is realized that the formal potentials and rate constants used in these calculations are necessarily not unique. A more detailed analysis of the electrode kinetics for these surface layers will be published elsewhere.

With time after the extrusion of a new mercury surface, the magnitude of the waves for all the AQ species increased, and then leveled off, reaching a plateau after 5–10 min, while maintaining an approximately constant shape. This behavior is shown in Figure 2, where the surface coverage was calculated using the charge necessary to reduce the adsorbed species from Faraday's law in the usual fashion. At the sweep rates of these experiments, an *n* value of 2 was assumed for the reduction of the AQ moiety.

$$AQ + 2H^+ + 2e^- \rightleftarrows AQH_2 \qquad (1)$$

The solutions used to obtain the data of Figure 2 contained an excess of EDTA to scavenge metal ions, in particular adventitious Hg(II) species which are difficult to eliminate in HMDE voltammetry. The cathodic current evident as a shoulder on the negative side of the peak voltammogram of **1c** in Figure 1 is likely due to the reduction of accumulated Hg(II). In the absence of EDTA, the cathodic charge continued to increase with time, and the wave shape changed, indicative of overlapping redox processes. This behavior is attributed to the reduction of the Hg(II) species accumulated by the oligonucleotide

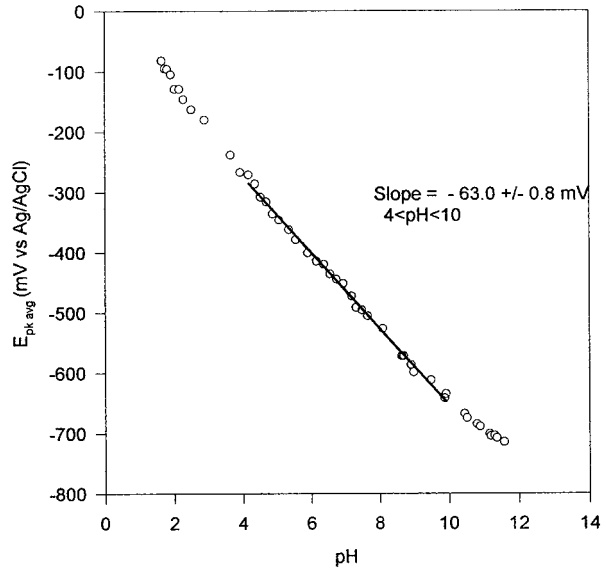

Figure 3. Average peak potential [$(E_{pk}^{a} + E_{pk}^{c})/2$] pH study for compound **5**.

surface layer. The ability of nucleic acids to coordinate mercury species is well documented (*51*).

The pH dependence of the $E^{o\prime}$ [$=(E_{pk}^{a} + E_{pk}^{c})/2$] for the AQ/$AQH_2$ couple of compound **5** is shown in Figure 3. The response is close to 60 mV/pH unit over a wide pH range. This is consistent with the two-electron, two-proton stoichiometry of eq 1 and with the Pourbaix diagrams of simple anthraquinones (*52*). A similar behavior was obtained for pentamer **2**. Due to the limited amounts of the 20-mers that are available, full pH studies were not carried out for these compounds, but the peak potential data were consistent with Figure 3 and eq 1. The fact that the apparent $E^{o\prime}$ values exhibited a lack of gross dispersion indicates that the surface layers possess a fair degree of order with respect to the location of the AQ/AQH_2 couple.

Adsorption Isotherms. The concentration dependence of the voltammograms for all of the AQ−ODN conjugates was examined in neutral pH phosphate buffer solutions. Limiting saturation surface coverages were seen at concentrations in the micromolar range, indicating a high affinity of all of the compounds for the mercury electrode surface. This is not surprising in view of the known affinity of the purine and pyrimidine bases, native DNA and RNA (*7*), and the AQ unit itself for mercury electrode surfaces. Figures 4 and 5 show the Γ versus concentration behavior for compounds **5** and **1a**, respectively, along with fits to the simple Langmuir adsorption isotherm model.

Although the agreement with the Langmuir model is not perfect, the fits are good enough to provide a means of comparing the AQ−ODN conjugate voltammetry as a function of chain length and degree of substitution. First, the molecular footprints calculated from the limiting Γ_{max} values

$$\text{footprint} = (\Gamma_{max} N_{av} \times 10^{-14})^{-1}\ \text{nm}^2/\text{molecule} \quad (2)$$

scale with the size of the *n*-mers and the degree of substitution; see Table 1. The sizes of the footprints per substituted uridine ring indicate a closely packed surface layer.

The footprint calculation of eq 2 assumes that the *n* value of the electrode reaction is two for compounds **1a**, **1b**, **2**, and **5**, and four for compound **1c**, which possesses

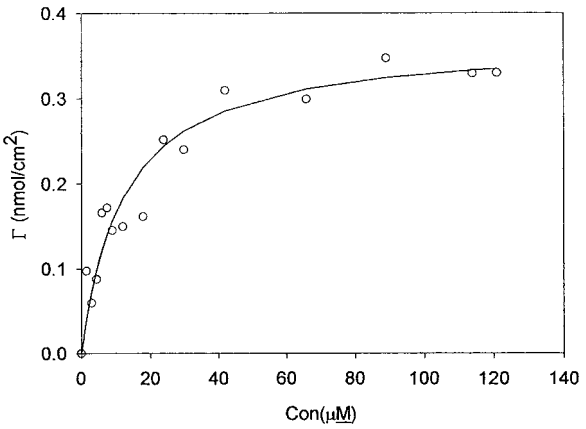

Figure 4. Adsorption isotherm of compound **5** in pH 7.15 BR buffer with 0.25 M NaCl (○). The line is a calculated Langmuir isotherm where $\Gamma_{max} = 0.369$ nmol cm^{-2} and $\beta = 1.01 \times 10^5$ M^{-1}.

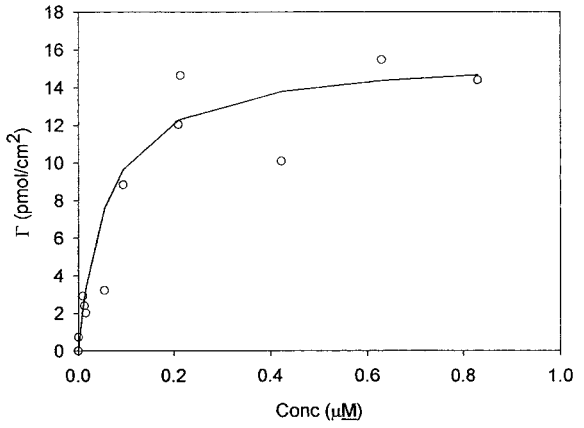

Figure 5. Adsorption isotherm of compound **1a** in pH 7.15 BR buffer with 0.25 M NaCl (○). The line is a calculated Langmuir isotherm where $\Gamma_{max} = 15.7$ pmol cm^{-2} and $\beta = 1.7 \times 10^7$ M^{-1}.

Table 1. Langmuir Adsorption Isotherm Parameters for AQ Conjugates at Hg in pH 7.1 Buffer Solution

	footprint (nm²/molecule)	β (M^{-1})	ΔG_{ads} (kJ/mol)
2	0.48	1.01×10^5	−28
5	1.99	7.9×10^7	−45
1a	11.0	8.50×10^6	−40
1b	10.5	2.69×10^7	−42
1c	11.1	3.2×10^7	−43

two pendant AQ groups. Significantly, the footprint for the latter was in agreement with those of the other 20-mers, indicating that both AQ groups were involved in the electrochemical reactions. At faster sweep rates, a splitting of the cathodic wave was seen in the voltammograms of the disubstituted 20-mer.

The packing density of **5**, ca. 0.5 nm²/molecule, is on the order of magnitude expected for a much smaller benzohydroquinone based on van der Waals radii (*53*). This indicates that the AQ group in the adsorbate is oriented in an edge-pendant configuration with respect to the electrode surface. The observed reversibility of the electrode reaction also suggests that the AQ groups are close to the mercury surface. It should be noted that the charge under the voltammetric waves decreased significantly at faster sweep rates (up to 30−50% of the charge for the voltammograms of Figure 1). This is indicative of kinetic limitations on the electrode reaction which are beyond the scope of this report. However, possible kinetic limitations would decrease the surface charge and in-

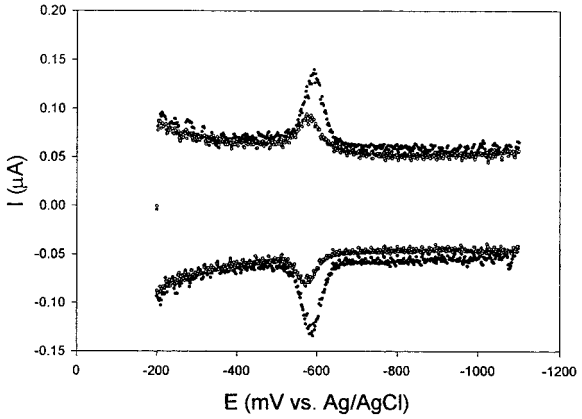

Figure 6. Cyclic voltammogram of (●) **1a** and (○) **1a** and complementary strand **6** in 0.01 M NH_4Ac and 0.001 M NH_4Cl, with a sweep rate of 0.1 V s^{-1}, a 0.0225 cm^2 HMDE, and an accumulation time of 5 min.

crease the calculated values of the footprints, which assume a two-electron *n* value.

The Langmuirian behavior of the Γ data also affords a quantitative measure of the affinity of the molecules for the electrode surface via the following relationship between the free energy of adsorption (ΔG_{ads}) and the Langmuir energy coefficient (β):

$$\Delta G_{ads} = -RT \ln(\beta) \tag{3}$$

The large absolute values of the negative free energy of adsorption for the AQ bioconjugates indicate a strong affinity of the mercury surface for these single-strand DNA molecules.

Competitive Adsorption of ODNs. Several experiments were performed to examine the effect of hybridization of the DNA chain on the voltammetric response. The results from one such experiment are shown in Figure 6, which shows the voltammogram of **1a** in the absence and presence of an equimolar concentration of its complementary strand, compound **6**, in an ammonium acetate buffer solution. In the presence of the complementary strand, the electrochemical signal was attenuated significantly, while the wave shape remained approximately constant. However, this result is complicated by the competitive adsorption displacement of the tagged 20-mer from the electrode surface by the untagged chain. In the buffer solution of Figure 6, essentially identical behavior was observed when a noncomplementary sequence, compound **7**, was added to the solution.

The facile competitive nature of the adsorption process is demonstrated by the experiment whose results are depicted in Figure 7. Here the voltammetric charge for **1a** was measured as a function of the amount of added untagged 20-mer in phosphate buffer solution. Within a few seconds, apparent equilibrium surface coverage by both compounds is observed. The data are in agreement with the following equation for competitive Langmuirian adsorption of two species with identical saturation surface coverages (*54*).

$$\Gamma_1 = \frac{\Gamma_s \beta_1 C_1}{1 + \beta_1 C_1 + \beta_2 C_2} \tag{4}$$

This equation can be rearranged into the following linear form

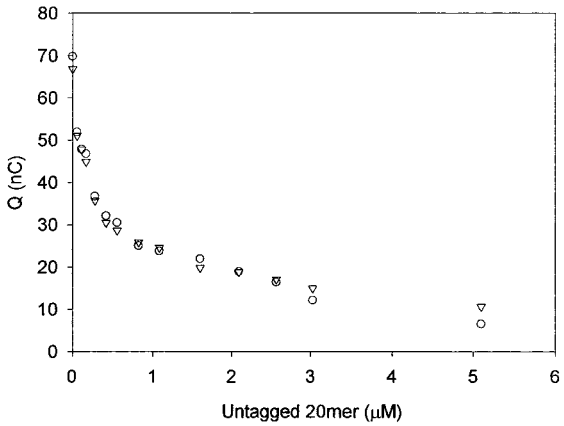

Figure 7. Competitive adsorption study of compounds **1a** and **7** at a HMDE. Conditions were 0.216 μM **1a** in pH 7.15 BR buffer, with 0.25 M NaCl and 3.6 mM EDTA: (○) cathodic charge or (▽) anodic charge.

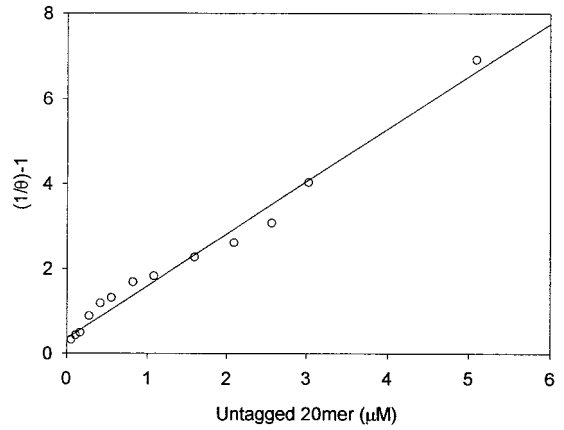

Figure 8. Linear competitive adsorption model.

$$\frac{1}{\theta_1} - 1 = \frac{1}{\beta_1 C_1} + \frac{\beta_2 C_2}{\beta_1 C_1} \tag{5}$$

where C_1 is the concentration of the tagged 20-mer **1a**, C_2 is the concentration of the added untagged 20-mers (**6** or **7**), and θ_1 is the fractional surface coverage of the tagged compound. The corresponding plot is shown in Figure 8. Calculation of the relative β values from the slope of the line in Figure 8 reveals that the untagged 20-mer is adsorbed less strongly than the tagged 20-mer by 4 kJ/mol.

Effect of Duplex Formation. The surface state of these AQ−ODNs in the presence of its complementary strand, i.e., adsorbed ss-DNA versus adsorbed ds-DNA, is difficult to establish in the absence of additional information. The possibility exists that a duplex structure of these ODNs would unzip and adsorb on the mercury electrode in the single-strand form. There is ample precedent for this in the classical work of Palecek on native DNA electrochemistry (*7*), and the large negative free energy of adsorption could provide the driving force for this process. In addition, the crowded packing of these molecules on the electrode surface may not allow enough space for surface hybridization (*55*).

To confirm that a duplex was present in the solutions containing both a tagged 20-mer and its complementary strand, the melting/annealing process was followed by monitoring the UV absorption spectrum as a function of temperature. Figure 9 shows a cooling absorbance trace for a solution of **1a** and its complementary strand, which exhibits a melting point at 66 °C. Interestingly, the

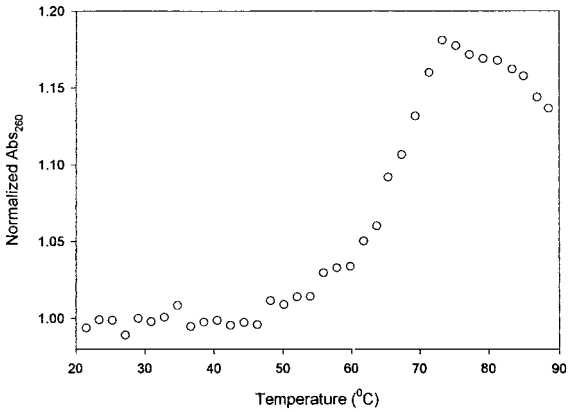

Figure 9. Typical melting curve for 0.35 μM **1a** and **6** in pH 6.83 0.1 M phosphate buffer, with 0.1 M NaCl.

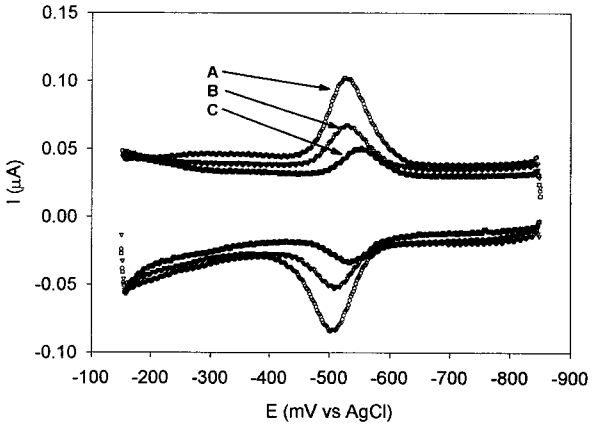

Figure 10. Cyclic voltammogram of **1a** with complementary 20-mer **6**: (A) 0.695 μM **1a** in pH 7.4 phosphate buffer (0.1 M), with 0.05 M NaCl and 5 mM EDTA; (B) addition of an equal amount of compound **6** at room temperature; and (C) after heating to 90 °C and cooling to room temperature. The sweep rate was 0.1 V s^{-1}.

melting temperatures of the untagged duplex, i.e., **6·7**, and the duplexes of the AQ−ODNs were approximately the same, indicating that the tethered AQ group is not intercalated in the duplex structure. In pH 7.4, 0.1 M phosphate buffer containing 0.05 M NaCl and 5 mM EDTA, the T_m (ΔT_m) values were 66.4, 68.3 (1.9), 68.4 (2.0), and 69.1 (2.7) °C for the duplexes of **6** with **7**, **1a**, **1b**, and **1c**, respectively. Somewhat larger ΔT_m values were seen for 2′-O-modified ribonucleotides with an intercalating substituent, 2-aminoanthraquinone, tethered on shorter linker arms (*35*).

Cyclic voltammetry experiments carried out in parallel with the melting curves gave further support to the competitive nature of the adsorption equilibria that are at play at the electrode surface. In these experiments, solutions containing equimolar amounts of a tagged AQ−ODN and either its complementary (**6**) or a noncomplementary (**7**) ODN species were split into two parts and subjected to both CV and UV−vis analysis. The resulting voltammograms for compound **1a** are shown in Figures 10 and 11 for a pH 7.4 phosphate buffer. The cyclic voltammograms marked A in these figures were obtained with solutions containing **1a** at a concentration sufficient to give a limiting surface coverage of the AQ−ODN. Addition of the complementary strand to the solution resulted in an attenuation of the signal; refer to the cyclic voltammogram marked B in Figure 10. However, this result cannot be distinguished from simple competitive adsorption of an untagged ODN since essentially identical behavior was seen when the experiment was repeated with a noncomplementary sequence; see the cyclic voltammogram marked B in Figure 11.

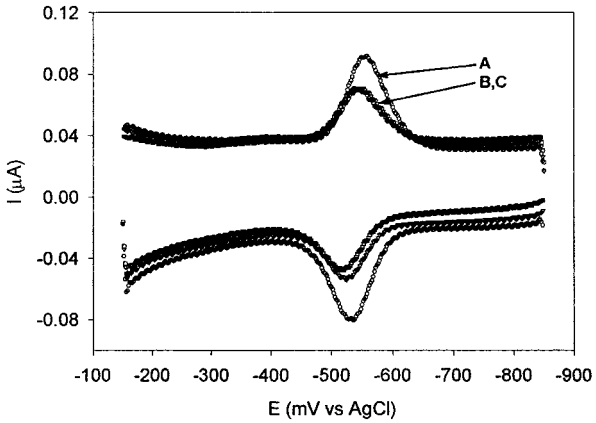

Figure 11. Cyclic voltammogram of **1a** with noncomplementary 20-mer **7**. Conditions were the same as those described in the legend of Figure 10.

Significantly, however, when the solution containing **1a** and its complement was annealed at 90 °C, followed by slow cooling to room temperature, the resulting cyclic voltammogram obtained on the solution was further attenuated and shifted to slightly more negative potential; see the cyclic voltammogram marked C in Figure 10. The corresponding cyclic voltammogram obtained for the control solution with the noncomplementary species **7** (cyclic voltammogram marked C in Figure 11) was not attenuated. These results are best understood if the hybridization is slow in these dilute solutions at room temperature. In this case, the attenuation seen in the cyclic voltammograms marked B in Figures 10 and 11 could be due to competitive adsorption as described above.

While the further attenuation seen in the cyclic voltammogram marked C in Figure 10 appears to be related to formation of the duplex species in solution, the physical phenomenon responsible for this effect is not clear. One possibility is that the duplex **1a·6** species is electroinactive or not adsorbed on the electrode surface and that the signal obtained after solution hybridization is due to adsorbed **1a** in equilibrium with a decreased concentration of **1a** in the bulk of the solution. Alternatively, the duplex **1a·6** might adsorb on the electrode with a footprint that is larger than the combined footprints of the tagged and untagged 20-mers. More likely, the duplex **1a·6** is electroactive, but has a smaller adsorption coefficient (β) than the single-strand ODNs since the DNA bases are not free to interact with the surface, so that when the duplex is formed in solution, the surface layer is no longer at saturation coverage. In any case, the possibility of a simple in situ electrochemical detection of the hybridization event based on these results is problematic without a different strategy and further modification of the electrode surface.

CONCLUSIONS

(1) We have demonstrated that AQ−ODNs, which bear one or more reporter groups, can be prepared with a modified uridine moiety in any location in a specific sequence utilizing standard phosphoramidite methodology.

(2) The AQ conjugates form compact surface layers on Hg electrodes with molecular footprints, calculated from the saturation coverages, that scale with molecular size.

The cyclic voltammetry is consistent with rapid electron transfer and little dispersion of $E^{\circ\prime}$ values. This indicates that the AQ groups are located in a uniform position in a compact surface layer and are not insulated from the electrode surface since facile transfer of electrons through the adsorbed ss-DNA layer is unlikely.

(3) The cyclic voltammetric response of the ds-AQ−20-mers is complicated by the competitive adsorption of the individual ss-20-mers and possibly the ds-20-mers as well. At room temperature in aqueous buffer solutions, equilibrium surface coverages are established more rapidly than the hybridization kinetics, which are much slower than the CV time scale.

(4) Accumulation of adventitious Hg(II) ions is a problem, which has not been fully realized in previous work, when HMDEs are used for voltammetric sensing of DNA.

Revised Manuscript Received December 21, 1998

Multiple sialic acid (SA) residues conjugated to a linear polyacrylamide backbone are more effective than monomeric SA at inhibiting influenza-induced agglutination of red blood cells. However, "polymeric inhibitors" based on polyacrylamide backbones are cytotoxic. Dendritic polymers offer a nontoxic alternative to polyacrylamide and may provide a variety of potential synthetic inhibitors of influenza virus adhesion due to the wide range of available polymer structures. We evaluated several dendritic polymeric inhibitors, including spheroidal, linear, linear-dendron copolymers, comb-branched, and dendrigraft polymers, for the ability to inhibit virus hemagglutination (HA) and to block infection of mammalian cells in vitro. Four viruses were tested: influenza A H2N2 (selectively propagated two ways), X-31 influenza A H3N2, and sendai. The most potent of the linear and spheroidal inhibitors were 32−256-fold more effective than monomeric SA at inhibiting HA by the H2N2 influenza virus. Linear-dendron copolymers were 1025−8200-fold more effective against H2N2 influenza, X-31 influenza, and sendai viruses. The most effective were the comb-branched and dendrigraft inhibitors, which showed up to 50000-fold increased activity against these viruses. We were able to demonstrate significant ($p < 0.001$) dose-dependent reduction of influenza infection in mammalian cells by polymeric inhibitors, the first such demonstration for multivalent SA inhibitors. Effective dendrimer polymers were not cytotoxic to mammalian cells at therapeutic levels. Of additional interest, variation in the inhibitory effect was observed with different viruses, suggesting possible differences due to specific growth conditions of virus. SA-conjugated dendritic polymers may provide a new therapeutic modality for viruses that employ SA as their target receptor.

INTRODUCTION

Influenza virus is a highly contagious, enveloped RNA virus which is responsible for several severe pandemics (Mulder and Hers, 1972). Two envelope glycoproteins, hemagglutinin (HA) and neuraminidase (NA), determine the antigenic specificity of viral subtypes (Lamb and Krug, 1996). The virus is highly mutagenic, and frequent alterations in HA glycosylation leading to altered antigenicity are considered to be responsible for the episodic resurgence of influenza. The capacity to modify viral antigenic sites enables influenza virus to overcome inhibitory effects of neutralizing antibodies and elude many anti-viral compounds including neuraminidase inhibitors (Lamb and Krug, 1996; Schulze, 1997).

The first step of infection by influenza virus is the binding of the viral HA to sialic acid receptors on the host cell, followed by receptor-mediated endocytosis of the virus into the cell (Wiley and Skehel, 1987). One potential approach to anti-viral therapy involves the inhibition of virus/host cell binding via blocking of the viral receptor (Kiefel et al., 1996; Weis et al., 1988). Ideal preventative agents must be nontoxic to mammalian cells, broadly specific across viral subtypes and cost effective. Previous reports have demonstrated that millimolar concentrations of solubilized monomeric sialic acid (SA) prevent influenza A agglutination of chicken erythrocytes (cRBC), presumably by binding to the HA molecule on the virus (Pritchett and Paulson, 1987; Weis et al., 1988). However, host cell viral receptor sialyl moieties have great lateral mobility on the cellular surface, allowing each influenza virion to use the estimated 300−600 envelope hemagglutinin spikes to develop strong polyvalent binding to host cell receptors (Choi et al., 1997; Weis et al., 1988). Thus, while the binding of soluble α-sialoside monomeric derivatives to hemagglutinin is very weak ($K_D \approx 2$ mM), cooperative interaction allows influenza virus attachment to the surface of an erythrocyte with K_D (HA) over $<10^{-12}$ M (Pritchett and Paulson, 1987; Sauter et al., 1989). Nonphysiological and potentially toxic concentrations of soluble monomeric SA are required to competitively disrupt this polyvalent interaction and prevent viral internalization into the cells. Moreover, soluble monomeric SA is vulnerable to enzymatic breakdown when exposed to biological fluids. Soluble monomeric SA also must compete with host sialosides attached to glycoproteins and glycolipids, and its use is therefore unlikely to be an effective strategy to prevent viral infection (Pritchett and Paulson, 1987).

To circumvent these problems, multiple sialyl moieties were conjugated to a synthetic polymer backbone to provide a polyvalent inhibitor. With this strategy, the

polymeric inhibitor molecule can potentially interact with many HA moieties on a single virus, leading to increased binding affinity. In addition, the sialyl moiety is more stable when conjugated to polymer in a manner similar to the higher stability of immobilized enzymes (Trevan, 1980). Whitesides and co-workers have successfully conjugated SA residues to a polyacrylamide backbone, and this material demonstrates enhanced inhibition of viral agglutination of cRBC at concentrations between $10^{-4}-10^{-7}$ M SA in solution (Choi et al., 1997; Mammen et al., 1995; Spaltenstein and Whitesides, 1991). This demonstrated that coupling SA to a synthetic polymer backbone can enhance the inhibition of viral adhesion of SA 25-fold greater than the best naturally occurring inhibitor (Mammen et al., 1995). However, we have found linear polyacrylamide to be toxic to mammalian cells and the acrylamide monomer is a potent neurotoxin in animals (Mangan and Snyder, 1978; Schaumburg et al., 1989; Spencer and Schaumburg, 1975), and this limits its utility in vivo.

Roy and co-workers tried an alternative multivalent approach to influenza virus inhibition, attaching sialic acid groups to the periphery of several generations of small polylysine dendrimers (Roy et al., 1993). It was found that as the number of surface sialic acid moieties was increased from 2 to 16 (along with the dendrimer size), the potency of the inhibitors increased to approximately that of Whitesides' much larger polysialoside inhibitors. It seemed that the branching architecture could hold advantages over the more conventional linear inhibitors such as increased polyvalent binding with reduced toxicity. Further explorations of this concept with other relatively small, dendritic carbohydrate inhibitors have allowed improvements in lectin binding (Roy, 1996). Recent results from the same group suggest that PAMAM dendrimers above G1 have superior lectin binding properties (Zanini et al., 1998).

The objective of this study was to assess the efficacy of novel polymer-based decoys to prevent viral adhesion and infection. In analyzing these agents, we hope to identify structure−function relationships in these inhibitors. The present approach uses inert, nontoxic and structurally well-defined dendritic polymers conjugated with sialic acid as polyvalent inhibitors of viral adhesion. We screened a variety of these polymer conjugates for the ability to prevent adhesion of several strains of virus. We also confirmed for the first time that these polymer conjugates could prevent viral infection in mammalian cells.

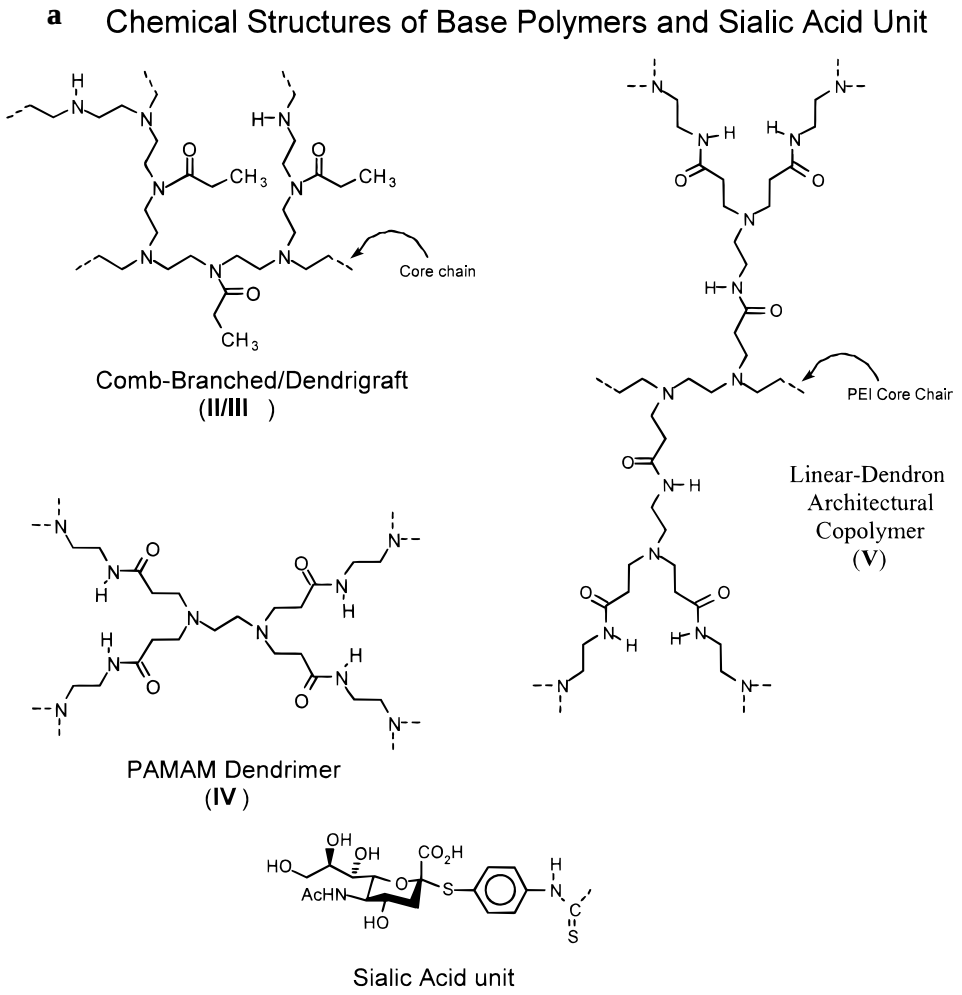
MATERIALS AND METHODS

Virus and Antisera. Influenza virus A/AA/6/60 (H2N2) strain passaged in mice and another passaged in chickens (Herlocher et al., 1996) were graciously donated by Dr. Hunein Maassab (Department of Public Health, University of Michigan, Ann Arbor, MI). X-31 (A/Aichi/2/68 × A/PR/8/34) influenza A H3N2 virus was kindly provided by Mr. Alan R. Douglas, NIMR, London, United Kingdom. Sendai/52 virus was obtained from ATCC (Rockville, MD). Viruses were propagated in embryonated chicken eggs using standard methods described elsewhere (Barrett and Inglis, 1985). Infectious allantoic fluid was collected and centrifuged at 2000−3000 rpm for 10 min. The supernatant was cultured on blood agar to screen for potential bacterial contamination. As an extra precaution, the supernatant was passed through a 0.2 mm filter and stored in aliquots of 10^8 pfu/mL at −80 °C.

Ferret anti-influenza A H2N2 polyclonal antibody was donated by Dr. Hunein Maassab (Department of Public Health, University of Michigan, Ann Arbor, MI). Rabbit anti-X31 polyclonal antisera was graciously provided by Alan R. Douglas (NIMR, London, United Kingdom).

Dendritic Polymers. Linear polyacrylamide polymers were synthesized similar to previous reports using a modified form with the same SA group (Choi et al., 1997; Roy et al., 1992). Synthesis of comb-branched (Figure 1, structure II) and dendrigrafts (Figure 1, structure III) polymers (Tomalia et al., 1991), spheroidal dendrimer (Figure 1, structure IV) (Kim et al., 1996; Roy, 1996; Roy et al., 1993, 1994; Tomalia et al., 1985), and linear-dendron architectural copolymers (Figure 1, structure V) (Yin et al., 1998) were accomplished as reported elsewhere.

Briefly, linear polyethyleneimine (PEI) required for the construction of the comb-branched, dendrigraft (Tomalia et al., 1991), and linear-dendron architectural copolymers (Yin et al., 1998) was obtained by either partial (30%, for the first two architectures) or full (for the latter) acid hydrolysis of polyethyloxazoline (PEOx). The PEOx was in turn prepared by the living cationic polymerization of ethyl oxazoline, initiated by methyl *p*-toluenesulfonate.



Comb-branched (G0) polymers were prepared by grafting living cationic PEOx chains (initiated as above) onto linear PEI. Reiteration of the hydrolysis and grafting steps led to dendrigraft polymers of increasing generation (Figure 1, structure II). Linear-dendron architectural copolymers were prepared by employing the methyl acrylate Michael addition/EDA amidation sequence used for the PAMAM synthesis (see above) with linear PEI as the core instead of EDA. This led to a polymer consisting of a PEI core functionalized with PAMAM dendrons along its length (Figure 1, structure V).

PAMAM dendrimers (Tomalia et al., 1985) were prepared by Michael addition of methyl acrylate to ethylenediamine (EDA), followed by amidation of the tetraester product with an excess of EDA to produce the G0 product. Continued similar alternating Michael addition/amidation reactions with the G0 product (and succeeding generations) led to PAMAM dendrimers of the desired generation, with primary amine end groups (Figure 1, structure IV). Those PAMAM dendrimers listed in Table 1b with variable degrees of conjugation contain a mixed hydroxyl/amine surface.

The conjugation of sialic acid to the backbone dendritic polymers was carried out by reacting primary or secondary amine groups of the polymers with a protected, isothiocyanate-derivatized sialate. Deprotection of the blocking groups led to polymers conjugated to sialic acid groups via an aromatic thiourea linker (Zanini et al., 1998).

Backbone polymers were characterized by ^{1}H and ^{13}C NMR spectroscopy, SEC-RI, MALDI MS, and MALLS. The conjugates were characterized by UV−vis and ^{1}H and ^{13}C NMR spectroscopy. Molecular weights of dendrigraft conjugates were calculated from amide hydrolysis and grafting efficiencies, as determined by ^{1}H NMR. Ultraviolet spectroscopy was utilized for quantitative measurement of the chromophore-linked sialic acid molarity at a wavelength of 248−250 nm. Decoy polymers were reconstituted with sterile Dulbecco's PBS (D-PBS) (Life Technologies, GibcoBRL, Gaithersburg, MD), mixed overnight on a tube rotator at room temperature, and stored at 4 °C.

Hemagglutination Inhibition Assay (HAI). Assays were performed with 0.5% chicken red blood cells (cRBC) as previously described (Kendal and Dowdle, 1986) with minor modifications. *N*-Acetylneuraminic acid type IV (Sigma Chemical Co.) was employed as internal monomer

with 0.1 M sodium phosphate and 0.13 M sodium chloride in double distilled water with the final pH adjusted to 7.4.

MDCK Cellular Toxicity Assay. Madin Darby Canine Kidney (MDCK) cells (American Type Culture Collection [ATCC], Rockville, MD) were grown to a monolayer in 96-well microtiter plates in Minimal Essential Medium (MEM) Eagle (Mediatech, Inc., Herndon, VA), 10% fetal bovine serum (Hyclone, Logan, UT), 0.1 mM MEM Nonessential Amino Acids Solution, 2 mM L-Glutamine, 1.0 mM MEM sodium pyruvate, 100 units/mL Penicillin 100 μg/mL Streptomycin (Life Technologies, GibcoBRL, Gaithersburg, MA). MDCK cells were washed with Dulbecco's PBS (D-PBS) and incubated with 100 μL of the virus/potential inhibitor mixture diluted in serum free medium for 1 h. Cells were visually inspected for cytopathic effect using an inverted microscope and quantification of cell viability was performed using the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) spectrophotometric assay (Watanabe et al., 1994; Schulze, 1997) read at 595 nm with an ELISA reader.

Enzyme-Linked Immunosorbant Assay (ELISA) Infection Assays. All polymeric inhibitors were standardized to 5×10^{-3} M SA and incubated with an equal volume of influenza virus at a final concentration of 5.0

$\times 10^7$ pfu/mL for 30 min at 37 °C. The monomeric SA was diluted in serum free MEM and 1 M HEPES solution to a neutral pH. Polymeric inhibitors were diluted in serum free MEM to the desired concentration and incubated with MDCK cells as described below.

An ELISA was used to detect and quantitate soluble viral proteins in the supernatant from the infected cells. MDCK cells were prepared as described in the MDCK cellular toxicity assay above. Culture media were removed and cells were washed with sterile D-PBS. A total of 100 μL of the inoculum was added to each well and incubated for one hr at 37 °C with 5% CO_2. One hour later, the inoculum was replaced with fresh serum-free culture medium and incubated for 24 h at 37 °C in 5% CO_2.

Culture media from virus-infected MDCK cells were transferred to another 96-well microtiter plate pretreated with 0.5% glutaraldehyde for 1 h at 56 °C. Plates were then washed with PBS and blocked with 1% dry milk in PBS for 30 min at 37 °C. A total of 100 μL of ferret anti-influenza A antibody (1:1000 dilution) was added to the wells for 1 h at 37 °C. The wells were washed four times with washing buffer (PBS and 0.05% Tween-20) and incubated with goat anti-ferret biotinylated antibody (Kirkegaard and Perry Laboratories, Gaithersburg, MA) for 30 min at 37 °C, then washed four times again and incubated with streptavidin-peroxidase (Sigma), washed again, and then incubated with 1-Step turbo TMB-ELISA substrate (Pierce, Rockford, IL). The reaction was stopped with 1 N sulfuric acid and plates were read at a wavelength of 450 nm in an ELISA reader.

Data Analysis. All experiments were done in triplicate. Significance testing using the Student's *t*-test and regression analysis was done using Microsoft Excel SR-1, 1997, software. Significance was defined with $\alpha = 0.05$. Significance in the hemagglutination inhibition assay was defined as at least a 4-fold change in titer.

RESULTS

The concentration of monomeric SA that effectively inhibited viral agglutination of cRBC was determined. Free SA at a concentration of 4×10^{-3} M was shown to inhibit agglutination of cRBC caused by three different influenza viral strains and sendai virus. In subsequent hemagglutination inhibition assays, a concentration of 4×10^{-3} M SA was used as a standard concentration of free sialic acid for comparison with the polymeric agents.

Linear Polyacrylamide Polymers. Preliminary studies showed that three of four linear polyacrylamide polymers (Figure 1, structure I) were 64−128-fold more effective (concentrations $\sim 10^{-4}$ M) at inhibiting influenza A H2N2 (chicken passaged) virus agglutination of cRBC than the monomeric SA on a molar basis as measured in the HAI assay (Table 1a). The strongest inhibitor of these four was the compound with 20% of available binding sites conjugated to SA. Those with either higher or lower levels were less effective. However, these polymeric inhibitors were extremely toxic to MDCK cells at 10^{-6} M concentration (1000-fold lower than the effective HAI concentration; data not shown) and therefore could not be evaluated in the infectivity study.

Spheroidal Dendrimers. Of the spheroidal polyamidoamine (PAMAM) dendrimers (Figure 1, structure IV) tested, only one compound was more effective on a molar basis of polymer (32-fold) than monomeric SA at inhibiting cRBC agglutination of influenza A H2N2 (chicken passaged; see Table 1b). None of the spheroidal dendrimers were found to be effective at blocking sendai virus adhesion. Unconjugated generation five spheroidal dendrimers tested as a control also showed no ability to block viral adhesion.

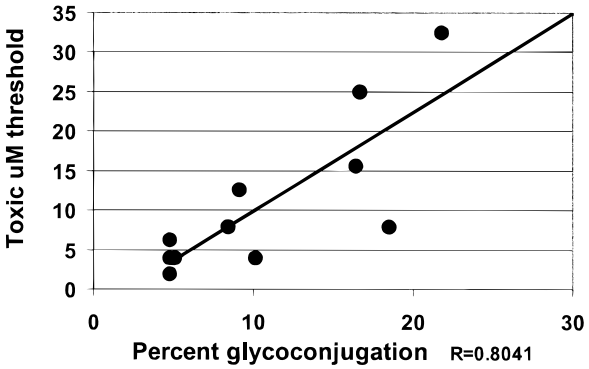

Figure 2. Inverse relationship between toxicity to MDCK cells and percentage SA conjugation of protonated primary and/or secondary amine binding termini observed for linear-dendron architectural copolymers (Figure 1, structure V). Those with all of the available primary amine sites conjugated to SA were nontoxic to mammalian cells.

Linear-Dendron Architectural Copolymers. On the basis of this information, we sought to determine if a nontoxic, linear backbone structurally similar to polyacrylamide could be equally effective in preventing viral cRBC agglutination. To test this hypothesis, we constructed 12 branched polyethylenimine-PAMAM linear-dendron architectural copolymers (Figure 1, structure V) with varying amounts of sialic acid moieties conjugated to the primary amine termini and screened them for efficacy in the HAI assay. These polymers, intended to be rod-shaped, at higher generations have the tree-like branching structure of PAMAM dendrons attached to the linear backbone (Figure 1, structure V). When these polymeric inhibitors had all of the primary amine groups conjugated to sialic acid, they were up to 1000-fold more effective at preventing cRBC agglutination caused by influenza A H2N2 (mouse passaged), H3N2 (X-31), and sendai viruses when compared to monomeric SA at the same molarity of sialic acid in solution (M SA, Table 1c). Hemagglutination by X-31 influenza and sendai viruses in particular was highly susceptible to the inhibitory effects of these conjugates. In contrast, these polymers failed to prevent agglutination of cRBC caused by the influenza A H2N2 (chicken passed) virus. Conjugates with 30% or less sialyl conjugation were ineffective with all tested viruses. We observed a negative correlation between the percentage of sialyl conjugation and cytotoxicity with these polymers (Figure 2). The unconjugated polyethylenimine backbone was cytotoxic to mammalian cells in vitro, while structures with 100% sialic acid conjugation at the same concentrations were not.

Comb-Branched and Dendrigraft Polyethylenimine Polymers. In the next set of experiments, we tested the efficacy of sialic-acid-conjugated comb-branched and dendrigraft (Figure 1, structures II and III) polymers to inhibit HA mediated by influenza and sendai viruses. These polymeric inhibitors are constructed of many chains of polyethylenimine in a "branch upon branch" comblike structure and have sialyl moieties conjugated to secondary amines. Those polymers with approximately 50% of secondary amines conjugated to sialic acid demonstrated a significant inhibition of cRBC agglutination caused by X-31 and sendai viruses at molar concentrations up to 50000-fold lower SA molarity than monomeric SA (Table 1d). These conjugates showed only moderate inhibition of cRBC agglutination caused by influenza A

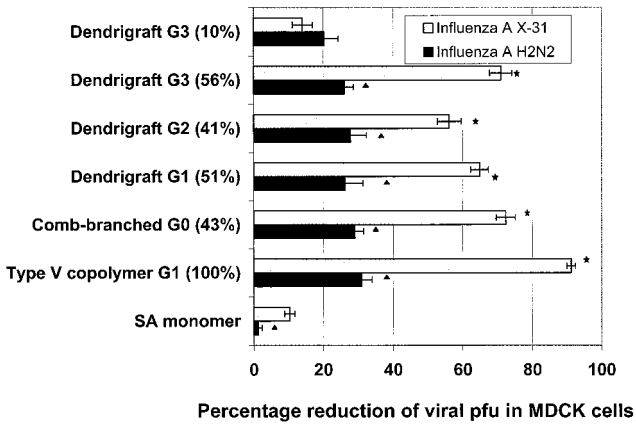

Figure 3. Percentage reduction of influenza A H2N2 (mouse passaged) and influenza A H3N2 (X-31) virus (pfu/well) treated with linear-dendron architectural copolymers (structure V), comb-branched (structure II), and dendrigraft (structure III) polymers on MDCK cells using ELISA. Numbers in parentheses represent percent SA conjugation to free amine binding sites on the polymer backbone. Note the viral strain variation in susceptibility to the inhibitors. All samples were standardized to 5×10^{-3} M SA. (★) Significantly less virus isolated from cells treated with decoy polymers than from virus treated with the unconjugated polymer backbone or monomeric SA ($p < 0.001$). (▲) Significantly different amounts of virus isolated from cells infected with either influenza A H2N2 or X-31 virus treated with the same inhibitor ($p < 0.05$).

H2N2 (mouse passaged) virus and were not effective in preventing cRBC agglutination of the influenza A H2N2 (chicken passaged) virus. Those with less than 13% of amines conjugated to sialyl groups were ineffective with all tested viruses. None of the tested comb-branched or dendrigraft polymeric inhibitors, regardless of the percentage of sialyl conjugation, were toxic to MDCK cells, even at concentrations as high as 1 mM SA (data not shown).

Prevention of Influenza Infection. On the basis of the HAI screening data, we attempted to determine if the most effective inhibitors (Figure 1, structures II, III, and IV) would be able to prevent viral infection of MDCK cells cultured in vitro. Using ELISA to measure the infection levels, buffered monomeric 2.5 mM SA showed a significant difference in inhibitory effect on X-31 virus infection compared to influenza A H2N2 (mouse passaged) virus (10 and 2%, respectively, $p < 0.05$). Several sialic-acid-conjugated comb-branched, dendrigraft, and linear-dendron architectural copolymers significantly ($p < 0.001$) inhibited influenza H2N2 (mouse passaged) and X-31 virus infection at 2.5 mM SA concentration (Figure 3). Inhibition data obtained from ELISA correlated well with those obtained from the HAI assay. Polymeric architectures that did not inhibit hemagglutination (e.g., dendrigraft G3 [10%]) consistently failed to show inhibitory effect on either X-31 or influenza A H2N2 (mouse passaged) viral infection of MDCK cells as tested in the ELISA. X-31 virus was significantly more susceptible to the dendrimer inhibitors than the influenza A H2N2 (mouse passaged) virus ($p < 0.01$). The reduction of X-31 virus ranged from 55% to over 90%, while for influenza A H2N2 the range was 23−35%. This significant viral variation to dendritic polymer inhibition observed during the in vitro infection assay was comparable to that which was observed in the HAI assay.

Unexpectedly, the unconjugated PEI polymer backbone (0.17 mM) showed some ability to inhibit (<20%) influenza A H2N2 (mouse passaged) virus infection in the MDCK cellular infection assay as determined by ELISA. However, this effect was not seen with the X-31 virus (<6%).

DISCUSSION

It is theorized that a significant proportion of the estimated 300−600 hemagglutinin glycoprotein spikes on an influenza virion must be blocked to effectively prevent viral adhesion to target cells (Mammen et al., 1995). Due to the low-affinity interaction between monomeric SA and viral HA, high concentrations of monomeric SA would be required to inhibit influenza virus. However, these concentrations are not biologically or medically feasible due to rapid enzymatic breakdown of the SA monomer (Kelm and Schauer, 1997) and the potential tissue toxicity of the high concentrations of SA. Spherical dendrimers are capable of inhibiting influenza viral agglutination of cRBC, as are linear polyacrylamide polymers. Due to their cellular toxicity, however, linear polyacrylamide polymers could not be evaluated in the infection assay. Linear-dendron architectural copolymers and dendrigraft polymers (Figure 1, structures V and III, respectively) were approximately 50 000 times stronger inhibitors of influenza viral agglutination of cRBC than monomeric SA and approximately 500 times stronger than other types of polymeric inhibitors. For the first time, it has been shown that sialic-acid-conjugated dendritic polymers are capable of inhibiting viral infection of mammalian cells in vitro and do not exhibit cytotoxicity at potentially therapeutic concentrations.

The action of SA-conjugated polymers is not fully understood (Mammen et al., 1995). These structures may act as decoy molecules with a high polyvalent binding to the hemagglutinin glycoprotein spikes and therefore compete with the host cell receptor binding by blocking virus adhesion. Some reports suggest that the cooperative interaction of SA moieties dramatically increases binding affinity to the virus (Choi et al., 1997; Mammen et al., 1995, 1998). In addition to this effect, we believe another factor also may contribute to inhibit viral adhesion to the host cell: the backbone of the virus-bound polymeric inhibitor provides a mass effect that may interfere with interactions between the virus and cell. It is also thought that these hydrophilic polymers have a large hydration effect, increasing nonspecific steric inhibition. Together, the specific affinity of HA for SA receptors and backbone hindrance may be inhibiting virus absorption in a synergistic manner.

Specific variations in dendritic polymer architecture selectively enhance the ability to inhibit virus. Spheroidal dendrimer architecture (Figure 1, structure IV) has a fixed, rigid size and shape, which may limit its ability to interact with the virus. These dendrimers are relatively small (1−10 nm) when compared to influenza virus (∼120 nm). Thus, it may take many more dendrimer inhibitors per virion in solution to block virus adhesion to the target cell. Linear-dendron architectural copolymers (Figure 1, structure V) are larger and more flexible than the spherical polymers and, therefore, potentially interact with the virus more efficiently. It is also possible that the unbound backbone and polymer groups block additional binding sites between virus and target by preventing the interaction. Comb-branched polymers and dendrigrafts (Figure 1, structures II and III) have a scaffolding-type of structure that combines the exponential surface binding capacity of the spherical dendrimers and the plasticity of the linear-dendron architectural copolymers (Figure 1, structure V). These dendritic

polymers theoretically have the ability to conform and wrap around receptor sites maximizing steric hindrance. However, the addition of excess branches may lead to entanglement of the SA-bound branches and actually limit virus/receptor interaction. The early generation (G0, G1) linear-dendron architectural copolymers and dendrigrafts (Figure 1, structures V and III, respectively) show the same ability to inhibit virus as hyperbranched, later generation (G2, G3) inhibitors (when standardized to the same SA molarity concentration). Thus, the advantage offered by the additional branching rapidly diminishes.

Only those dendrimers with all of the exterior primary and/or secondary amine binding sites conjugated to sialyl groups were effective at inhibiting viral adhesion and infection. One explanation is that the dendrimer polyvalent attraction to viral HA is only strong enough to effectively compete with the host cell receptors when maximally conjugated. An alternative hypothesis is that the protonated primary amines create charge repulsion between the decoy inhibitor and the virus (or create internal ionic binding between carboxylates and amines within decoy conjugates). With spheroidal dendrimers or linear-dendron architectural copolymers (Figure 1, structures IV and V), all of the amine sites within the polymer are exposed and able to be conjugated. However, with comb-branched and dendrigraft polymers (Figure 1, structures II and III), only approximately 50% of the amine sites are available to undergo conjugation, with the remaining sites buried within the polymer. The minor inhibition of influenza H2N2 viral infection in tissue culture by the unconjugated PEI backbone may be attributable to a type of nonspecific binding.

Initial PAMAM structures contained varying ratios of hydroxyl/SA moieties based on previous reports of ideal mole fractions of SA/acrylamide ranging from 0.05 to 0.6 (Choi et al., 1997; Spaltenstein and Whitesides, 1991). However, we found no correlation between the partial degree of sialyl moiety conjugation of the PAMAMs and the ability to prevent viral adsorption to cRBC. Due to their lack of activity in our HAI screening assay, these structures were not included in further studies. Also, given our finding that maximal conjugation of the larger polymers was required for any anti-viral activity, we hypothesize that 100% conjugation of the PAMAMs would be required for them to become effective. However, at this time, we do not have the capability to consistently synthesize higher generation PAMAM dendrimers with 100% conjugation. Both the degree of sialic acid conjugation and the polymer size appear to influence the ability of the polymer to inhibit influenza via polyvalent binding forces and steric hindrance. Investigation into these concepts is ongoing.

Creating polymeric inhibitors that are not toxic or irritating to tissues can be problematic. The polyacrylamide backbone causes significant cytotoxic effect to tissue culture cells, and the monomer is a known neurotoxin to humans. Conjugating all of the primary amine termini with SA mitigated the toxicity of a polyamine backbone and this suggests that the amino groups are responsible for the observed cellular damage. The potential inhibitor diversity with this polymer backbone is therefore somewhat limited due to this factor. However, when the PEI backbone is used to create a scaffold type of structure, as with dendrigraft polymers, the toxicity is markedly reduced. This may be because of internalization (i.e., sheltering) of the unreacted, protonated amines and the presence of secondary amine sites instead of primary.

Strain variation may be as important as the differences between polymeric inhibitors. Strain-specific viral variation to anti-viral therapy has been observed many times in the literature (Hartley et al., 1997; Kiefel et al., 1996; Schulze, 1997). Alternations or mutations in glycosylation of the HA glycoprotein of influenza virus are responsible for changes in virulence and, ultimately, resistance to previously protective antibodies (Lamb and Krug, 1996). Because influenza A virus must adhere to the target cell through the HA−SA interaction to cause infection, it was theorized that these polymeric inhibitors could be used to block this interaction, regardless of the specific viral antigenicity. However, significant variation was seen in influenza H2N2 strains when a given parent virus was passaged in a different host. These viruses have distinct phenotypic and genotypic characteristics, and specific point mutations have been identified which are common to all virulent viruses but absent from attenuated viruses (Herlocher et al., 1996). The virus-specific hemagglutinins in these two strains have not yet been sequenced, but may help explain the differences in susceptibility to dendritic polymers. Sendai virus in the closely related *Paramyxoviridae* family shares affinity for sialyl receptors on host cells. This virus allows further evaluation of polymeric sialyl receptor and viral hemagglutinin interaction. Sendai virus is the most susceptible to the effects of the dendritic polymer inhibition, suggesting that differences in the hemagglutinin are responsible for altered affinity to sialyl moieties and possible conformational changes in the structure of the glycoprotein. There are many SA structures found in nature (Kelm and Schauer, 1997). Influenza A typically binds to α-2,3-linked or α-2,6-linked SA, while sendai virus uses α-2,3-linked and α-2,8-linked SA as receptors. The significant viral variation in susceptibility to polymeric inhibitor inhibition seen in this study was not expected and must be further evaluated. On the basis of our findings, it is clear that one needs to evaluate several strains of influenza virus when assessing the efficacy of potential influenza inhibitors.

In conclusion, this study has shown that variations in dendritic architecture have a profound effect on the potency of sialate-based polymeric viral inhibitors. In addition, the effectiveness of the inhibitors increases with the degree of sialic acid substitution on the "surface" of these polymers. For a given inhibitor, we saw significant variation in the degree of inhibition for each virus, effects that will require further study for a more complete understanding. Finally, a significant reduction in cell toxicity was observed for those inhibitors based on dendritic architecture (when compared to those based on linear polymers) and with increasing SA surface substitution.

ACKNOWLEDGMENT

This work was supported by DARPA (Defense Advanced Research Project Agency) Contract MDA 972-1-007 of the Unconventional Pathogen Countermeasures Program and National Institutes of Health (NIH) Training Grant RR0 7008-21. The authors wish to thank Dr. H. Maassab for his generous donation of influenza virus, antisera and chicken erythrocytes, Mr. A. R. Douglas for his kind donation of X-31 virus and antisera, Y. Zhu for her preparation of type (V) copolymer backbones, Dr. M. Anderson for her work with viral propagation, and P. and L. Balogh for their help with polymer illustrations.

Monoclonal Antibody Conjugates of Doxorubicin Prepared with Branched Linkers: A Novel Method for Increasing the Potency of Doxorubicin Immunoconjugates

H. Dalton King,*[,†] Derek Yurgaitis,[†] David Willner,[†] Raymond A. Firestone,[†,‡] Michael B. Yang,[§] Shirley J. Lasch,[§] Karl Erik Hellström,[∥] and Pamela A. Trail[§]

Bristol Myers Squibb Pharmaceutical Research Institute, 5 Research Parkway, Wallingford, Connecticut 06492, and Princeton, New Jersey, 08543. Received August 28, 1998; Revised Manuscript Received December 28, 1998

Immunoconjugates of monoclonal antibody BR96 and Doxorubicin have been prepared using a novel series of branched hydrazone linkers. Since each linker bound to the mAb carries two DOX molecules, the DOX/mAb molar ratios of these conjugates were approximately 16, twice that of those previously prepared with single-chain hydrazone linkers. The conjugates were stable at a physiological pH of 7, but released DOX rapidly at lysosomal pH 5. The branched series of BR96 conjugates demonstrated antigen-specific cytotoxicity, and were more potent in vitro than the single-chain conjugate on both a DOX (4−14-fold) and mAb (7−23-fold) basis. The results suggest that, by using the branched linker methodology, it is possible to significantly reduce the amount of mAb required to achieve antigen-specific cytotoxic activity. In this paper, the synthesis and in vitro biology of branched chain immunoconjugates are described.

Monoclonal antibody conjugates have been shown to be effective targeting vehicles for cytotoxic drugs such as doxorubicin (*1*). We have previously demonstrated the antitumor activity of BR96-DOX conjugates in the treatment of human tumor xenografts in mice and rats (*2*, *3*). The BR96 mAb identifies a Lewis y (Le^y)-related tumor-associated antigen expressed at high density on the majority of human carcinomas (*4*). BR96 is rapidly internalized following antigen-specific binding (*4*, *5*). The BR96-DOX conjugates employed a hydrazone linkage to C-13 of DOX (*6*−*8*) and a thioether linkage to the mAb (*2*, *9*). Hydrazones of this nature are stable at normal physiological pH 7, but once internalized into the acidic compartment of endosomes/lysosomes, hydrolysis occurs liberating free DOX (*6*, *7*). The thioether linkage is formed by the reaction of BR96 thiol groups, generated by mild DTT reduction of four interchain disulfides, with the linker **1**. Therefore, the observed molar ratio (DOX/mAb) of these first generation BR96 conjugates was typically 8 (*2*, *9*). BR96-DOX conjugates produced antigen-specific antitumor activity and were more potent, were more active, and produced less systemic toxicity than unconjugated DOX in vivo (*2*, *3*, *9*).

We have previously demonstrated that it is possible to increase the potency of lysine-linked SPDP-hydrazone conjugates by increasing the DOX/mAb molar ratio from 1 to 8 (*10*). When the molar ratio was increased beyond 8, significant losses in antigen-specific binding were observed. A similar loss in both binding avidity and antigen-specific potency was observed by other investigators as molar ratios of directly linked DOX conjugates exceeded 10 (*11*).

In the studies described here we evaluated the potential to increase the potency of BR96-DOX conjugates by attaching more than one drug per thiol group generated on the mAb. This approach employs a *branched* linker (Scheme 1), carrying two hydrazide functional groups for the attachment of DOX. With the single branch point, MR's are expected to approach 16, twice that of the prototype conjugate BR96-DOX. For these conjugates to be effective, they must maintain binding avidity and be capable of undergoing acid-catalyzed hydrolysis at rates similar to that of BR96-DOX (*9*).

For the branched linkers **2** and **3**, we used L-glutamic acid as the synthetic template to attach the required functionality. The two carboxyl groups were converted to hydrazides for DOX attachment, and the amino group was extended to a maleimide for mAb thiol group attachment. The length of the maleimide tether was varied (n = 2, 3, and 5) to evaluate solubility and other subtle aspects of conjugate synthesis. To avoid potential crowding of the DOX moieties, we also synthesized an extended series **3** in which a β-alanyl unit was inserted at each glutamic acid carboxyl group. Finally, to evaluate the susceptibility of a typical branched linker to enzymatic degradation, we synthesized a D-glutamic acid analogue of **2b** (Schemes 2 and 3).

EXPERIMENTAL PROCEDURES

General. All reactions utilizing nonprotic solvents were carried out under inert N_2 atmosphere. Reaction solvents were freshly opened Aldrich "Sure-Seal" quality. All other solvents and reagents were reagent grade and used without further purification. Bio-Beads SM-2 chromatographic support was supplied by Bio-Rad Laboratories. ^{1}H NMR and ^{13}C NMR spectra were obtained at

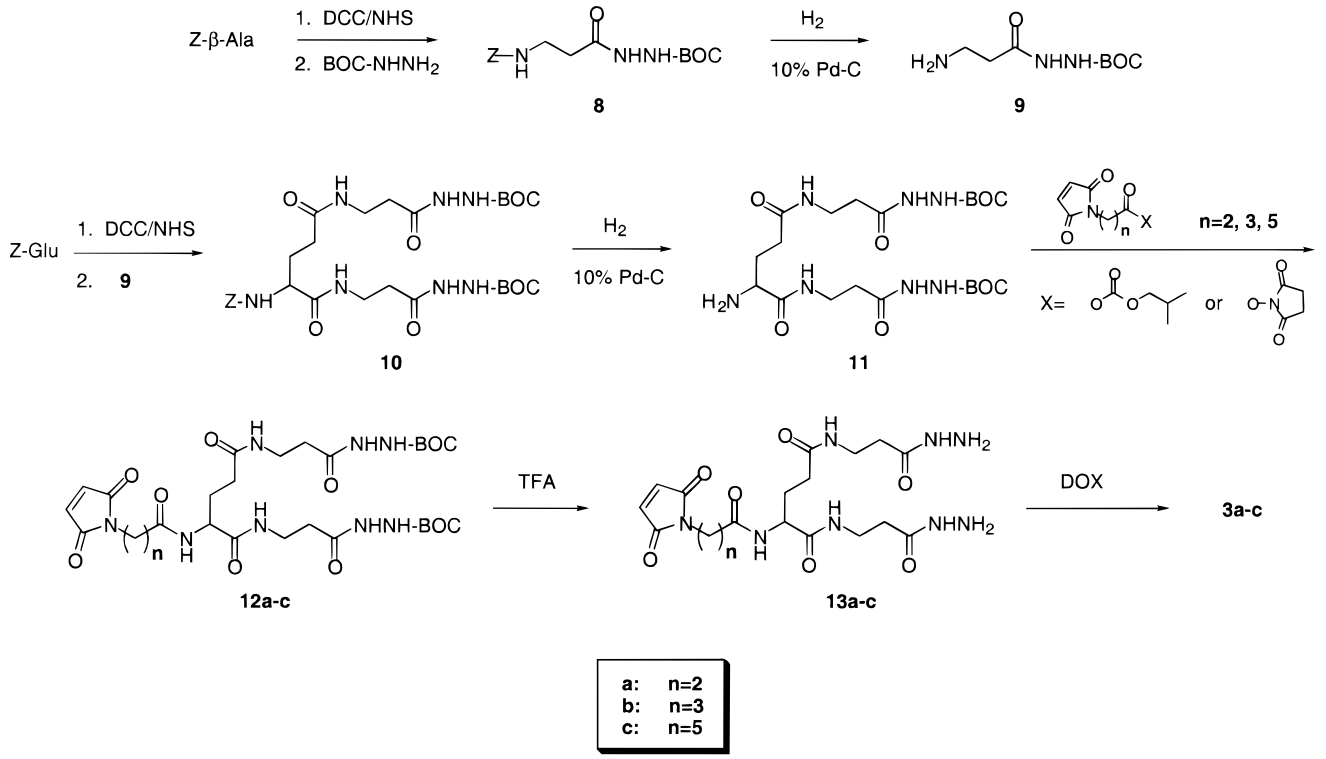
300 and 75 MHz, respectively, in the indicated solvents. Internal referencing was used and chemical shifts are reported in ppm. FTIR's were obtained as KBr pellets. Melting points are uncorrected. Elemental analyses were provided by Oneida Research Services.

TLC was carried out on Analtech silica gel GHLF plates, generally with 10−20% MeOH in methylene chloride as the eluting solvent, and visualized with UV light and chemical staining. Flash chromatography was carried out on Merck silica gel 60 (230−400 mesh). Routine HPLC of synthetic compounds was performed on a Perkin-Elmer 410 Pump and LC-235 Detector. HPLC columns were supplied by Phenomenex (IB-Sil 5 C-18). All compounds were homogeneous by TLC and/or HPLC.

HPLC Analysis of Conjugates. SEC−HPLC analysis of conjugates was carried out on a Toyo Soda 5u TSK column (3000SW XL, 300 mm × 7.5 mm) equipped with a 5u TSK (3000SW XL, 40 mm × 6.0 mm) guard column. Samples were eluted at a flow rate of 1.0 mL/min with isocratic 0.2 M KH_2PO_4, 0.9% NaCl, pH 6.8, and monitored at 280 and 495 nm.

HIC−HPLC analysis was carried out on a Biorad Biogel TSK-phenyl-5-PW column (75 mm × 7.5 mm). Samples were eluted under a 35 min gradient of 100% buffer A to 100% buffer B at 1.0 mL/min. Buffer A was 2 M NaCl, 25 mm NaH_2PO_4 (pH 7.0). Buffer B was 80% 50 mM NaH_2PO_4 (pH 7.0), 10% 2-propanol, and 10% acetonitrile. Eluant was monitored at 280 and 495 nm.



SYNTHESIS

***Z*-Glutamyldi(Boc)hydrazide 4.** *Z*-Glutamic acid (42.20 g, 150 mmol) and *N*-hydroxysuccinimide (34.53 g, 300 mmol) were dissolved in 150 mL of DMF at 0 °C under dry N_2. A 0.5 M solution of dicyclohexylcarbodiimide in methylene chloride (600 mL, 300 mmol) was added dropwise over a 1 h period with stirring. The reaction was stored at 4 °C in the refrigerator for 18 h. Dicyclohexylurea precipitate (65.48 g, 98%) was filtered, and the filtrate was added directly to solid *tert*-butylcarbazate (39.65 g, 300 mmol). After being stirred at room temperature for 48 h, the reaction was rotary evaporated to an oil, which was redissolved in 300 mL of ethyl acetate/200 mL of ether. The organic layer was extracted three times with 200 mL of 10% citric acid, 3 times with 200 mL of saturated aqueous sodium bicarbonate, and once with 100 mL of brine. The organic layer was dried over sodium sulfate and rotary evaporated to a foam. Flash chromatography was carried out on silica gel (4 in. × 19 in.) with ethyl acetate−hexane 2:1, 12 L. Pure fractions containing product **4** were pooled and concentrated to a foam by rotary evaporation to yield, after drying under high vacuum, 55.24 g (72%).

^{1}H NMR ($CDCl_3$): δ 1.44 and 1.47 (2s, 18H), 1.9−2.4 (bm, 4H), 4.32 (bm, 1H), 5.06 (dd, J = 12, 16 Hz, 2H), 5.55 (d, J = 6 Hz, 1H), 6.5 (bd, 2H), 7.31 (bm, 5H), 9.6 (s, 1H), and 9.9 (s, 1H). Mass Spec.: FAB 510 ($M + H^+$), 532 ($M + Na^+$), 548.1 ($M + K^+$). Anal.: $C_{23}H_{35}N_5O_8$ C, H, N.

***Z*-(D)-Glutamyldi(Boc)hydrazide D-4.** This compound was prepared on an identical scale by a method

Scheme 3. Synthesis of Series 3

similar to that used for **4**. Flash chromatography was carried out on silica gel (4 in. × 18 in.) with the following gradient: (1) CH_2Cl_2, 2 L, (2) CH_2Cl_2-methanol 25:1, 4 L, and (3) CH_2Cl_2−methanol 9:1, 6 L. Yield of D-**4** was 59.11 g (77%).

^{1}H NMR ($CDCl_3$): δ 1.44 and 1.47 (2s, 18H), 1.9−2.4 (bm, 4H), 4.32 (bm, 1H), 5.06 (dd, J = 12, 16 Hz, 2H), 5.57 (d, J = 7 Hz, 1H), 6.6 (m, 2H), 7.31 (bm, 5H), 9.60 (s, 1H), and 9.87 (s, 1H). Mass Spec.: FAB 532 $(M + Na^+)$, 549 $(M + K^+)$. Anal.: $C_{23}H_{35}N_5O_8$ C, H, N.

Glutamyldi(Boc)hydrazide 5. *Z*-Glutamyldi(Boc)-hydrazide **4** (19.59 g, 38.44 mmol) was hydrogenated along with 2 g of 10% Pd−C in 200 mL of MeOH at 50 psi for 3 h. The reaction was filtered through Celite and rotary evaporated. The resulting foam was dried under high vacuum to yield **5** (14.40 g, 100%).

^{1}H NMR (d_4-methanol): δ 1.42 and 1.45 (2s, 18H), 1.9 (bm, 2H), 2.35 (t, J = 7 Hz, 2H), 3.34 (t, 7 Hz, 1H). Mass Spec.: DCI 376 $(M + H)^+$. Anal.: $C_{15}H_{29}N_5O_6 \cdot 0.5H_2O$ C, H, N.

(D)-Glutamyldi(Boc)hydrazide D-5. This compound was prepared from D-**4** (23.05 g, 45.2 mmol) by an similar procedure to that used for **5**. Crude product was purified by flash chromatography on silica gel (2 in. × 20 in.) with the following gradient: (1) CH_2Cl_2−methanol 25:1, 600 mL, (2) CH_2Cl_2−methanol 9:1, 6 L, and (3) CH_2Cl_2−methanol 8:2, 4 L. Pure fractions were pooled and rotary evaporated. Drying under high vacuum yielded pure D-**5** (13.51 g, 80%).

^{1}H NMR (d_4-methanol): δ 1.46 and 1.47 (2s, 18H), 1.94 (bm, 2H), 2.33 (t, J = 7 Hz, 2H), 3.34 (t, J = 7 Hz, 1H). Mass Spec.: FAB 376 $(M + H)^+$, 398 $(M + Na)^+$, 414 $(M + K)^+$. Anal.: $C_{15}H_{29}N_5O_6 \cdot 0.5H_2O$ C, H, N.

Maleimidopropionylglutamyldi(Boc)hydrazide 6a. Maleimidopropionic acid (636 mg, 3.76 mmol) and *N*-hydroxysuccinimide (476 mg, 4.14 mmol) were dissolved in 10 mL of DMF at 0 °C. A 0.5 M solution of DCC in CH_2Cl_2 (7.6 mL, 3.8 mmol) was added and the reaction allowed to stand for 20 h at 4 °C. After filtration of the DCU precipitate, the filtrate was added to **5** (1.27 g, 3.38 mmol) and the mixture was stirred at room temperature for 2.5 days. Solvents were partially removed by rotary evaporation. The oil was dissolved in 100 mL of ethyl acetate, then extracted three times with 100 mL of 10% citric acid, three times with 100 mL of saturated aqueous sodium bicarbonate, and three times with 100 mL of H_2O. The organic layer was dried over sodium sulfate and rotary evaporated to a foam. This was purified by flash chromatography on silica gel (2 in. × 11 in.) with CH_2Cl_2−acetic acid−methanol 93:2:5. Pure fractions were pooled, rotary evaporated, and dried under high vacuum to yield **6a** as a foam (1.22 g, 69%).

^{1}H NMR (d_4-methanol): δ 1.46 (s, 18H), 2.01 (m, 2H), 2.33 (t, 7 Hz, 2H), 2.51 (t, J = 7 Hz, 2H), 3.76 (t, J = 7 Hz, 2H), 4.34 (t, J = 7 Hz, 1H), 6.80 (s, 2H). Mass Spec.: FAB 549.4 $(M + Na)^+$, 565.3 $(M + K)^+$. Anal.: $C_{22}H_{34}N_6O_9 \cdot 2HOAc$ C, H, N.

Maleimidobutyrylglutamyldi(Boc)hydrazide 6b. This compound was prepared by a method analagous to that used for **6a** from maleimidobutyric acid (1.9 g, 10.3 mmol). Crude product was purified through a plug of silica gel with CH_2Cl_2−acetic acid−methanol 93:2:5, rotary evaporated, and dried under high vacuum to yield **6b** as a foam (3.50 g, 63%).

^{1}H NMR (d_4-methanol): δ 1.36 and 1.37 (2s, 18H), 1.77 (p, J = 7 Hz, 2H), 2.00 (bm, 2H), 2.14 (t, J = 7 Hz, 2H), 2.26 (t, J = 7 Hz, 2H), 3.43 (t, J = 7 Hz, 2H), 4.26 (t, J = 7 Hz, 1H), 6.71 (s, 2H). Mass Spec.: 541 $(M + H)^+$, 563 $(M + Na)^+$, 579 $(M + K)^+$. Anal.: $C_{23}H_{36}N_6O_9 \cdot 0.75H_2O$ C, H, N.

Maleimidobutyryl-(D)-glutamyldi(Boc)hydrazide D-6b. Maleimidobutyric acid (1.832 g, 10.0 mmol) was dissolved with *N*-methylmorpholine (1.21 mL, 11.0 mmol) in 60 mL of dry THF under N_2 at 0 °C. Isobutylchloroformate (1.30 mL, 10.0 mmol) was added dropwise, followed 10 min later by the addition of (D)-Glutamyldi-(Boc)hydrazide (D-**5**) (3.754 g, 10.0 mmol). Stirring was continued for 1 h at 0 °C. The reaction was rotary

evaporated to a foam, which was then dissolved in 150 mL of EtOAc. The organic layer was washed two times with 100 mL of 10% citric acid and two times with 100 mL of saturated $NaHCO_3$. The organic layer was concentrated to a foam, which was purified by flash chromatography on silica gel (2 in. × 11 in.) with CH_2Cl_2−acetic acid−methanol 95:2:3, 2 L, followed by CH_2Cl_2−acetic acid−methanol 93:2:5, 1 L. Pure fractions were pooled and rotary evaporated to a foam. Drying under high vacuum yielded **6b** (3.25 g, 60%).

^{1}H NMR (d_4-methanol): δ 1.45 and 1.46 (2s, 18H), 1.86 (p, J = 7 Hz, 2H), 2.09 (bm, 2H), 2.24 (t, J = 7 Hz, 2H), 2.35 (t, J = 7 Hz, 2H), 3.52 (t, J = 7 Hz, 2H), 4.35 (t, J = 7 Hz, 1H), 6.81 (s, 2H). Mass Spec.: 563 $(M + Na)^+$, 579 $(M + K)^+$. Anal.: $C_{23}H_{36}N_6O_9 \cdot 0.75H_2O$ C, H, N.

Maleimidocaproylglutamyldi(Boc)hydrazide 6c. This compound was prepared by a method analagous to that used for **6a** from maleimidocaproic acid (4.22 g, 20 mmol). Crude product was purified by flash chromatography on silica gel (2 in. × 10 in.) with 4 L of CH_2Cl_2−acetic acid−methanol 97:1:2. Pure fractions were pooled, rotary evaporated, and dried under high vacuum to yield **6c** as a foam (6.40 g, 56%).

^{1}H NMR (d_4-methanol): δ 1.2 (p, J = 7 Hz, 2H), 1.40 (s, 18H), 1.5 (m, 4H), 2.0 (bm, 2H), 2.14 (t, J = 7 Hz, 2H), 2.28 (t, J = 7 Hz, 2H), 3.41 (t, J = 7 Hz, 2H), 4.29 (t, J = 7 Hz, 1H), 6.72 (s, 2H). Mass Spec.: FAB 569 $(M + H)^+$, 591 $(M + Na)^+$, 607 $(M + K)^+$. Anal.: $C_{25}H_{40}N_6O_9 \cdot 0.5H_2O$ C, H, N.

Maleimidopropionylglutamyldihydrazide Ditrifluoroacetate 7a. Maleimidopropionylglutamyldi(Boc)-hydrazide **6a** (1.50 g, 2.85 mmol) was stirred in 15 mL of CH_2Cl_2/trifluoroacetic acid (1:1) under N_2 for 1.5 h. Solvents were removed by rotary evaporation. Ether was added and coevaporated three times, and then the resulting solid was triturated with ether. The solid was filtered and dried under high vacuum to yield **7a** (1.6 g, 100%).

^{1}H NMR (d_4-methanol): δ 1.99 and 2.16 (2m, 2H), 2.41 (t, J = 7 Hz, 2H), 2.53 (t, J = 7 Hz, 2H), 3.80 (dt, J = 2, 7 Hz, 2H), 4.38 (dd, J = 5, 4 Hz, 1H), 6.81 (s, 2H). Mass Spec.: FAB 349.2 $(M + Na)^+$, 365.1 $(M + K)^+$. Anal.: $C_{12}H_{18}N_6O_5 \cdot 2.8$TFA C, H, N.

Maleimidobutyrylglutamyldihydrazide Ditrifluoroacetate 7b. This compound was prepared by a similar procedure from **6b** (3.50 g, 6.47 mmol). Yield of **7b** was 3.8 g (100%).

^{1}H NMR (d_4-methanol): δ 1.87 (p, J = 7 Hz, 2H), 2.0 and 2.2 (2m, 2H), 2.27 (t, J = 7 Hz, 2H), 2.44 (m, 2H), 3.53 (t, J = 7 Hz, 2H), 4.42 (dd, J = 5, 4 Hz, 1H), 6.82 (s, 2H). Mass Spec.: FAB 341 $(M + H)^+$, 363 $(M + Na)^+$, 379 $(M + K)^+$. Anal.: $C_{13}H_{20}N_6O_5 \cdot 3.15$TFA C, H, N.

Maleimidobutyryl-(D)-glutamyldihydrazide Ditrifluoroacetate D-7b. This compound was prepared by a similar procedure from D-**6b** (2.06 g, 3.81 mmol). Yield of D-**7b** was 2.2 g (100%).

^{1}H NMR (d_4-methanol): δ 1.79 (p, J = 7 Hz, 2H), 1.9 and 2.1 (2m, 2H), 2.18 (t, J = 7 Hz, 2H), 2.37 (m, 2H), 3.45 (t, J = 7 Hz, 2H), 4.35 (dd, J = 5, 4 Hz, 1H), 6.73 (s, 2H). Mass Spec.: FAB 341 $(M + H)^+$, 363 $(M + Na)^+$, 379 $(M + K)^+$. Anal.: $C_{13}H_{20}N_6O_5 \cdot 2.5$TFA C, H, N.

Maleimidocaproylglutamyldihydrazide Ditrifluoroacetate 7c. This compound was prepared by a similar procedure from **6c** (5.96 g, 10.5 mmol). Yield of **7c** was 6.3 g (100%).

^{1}H NMR (d_4-methanol): δ 1.22 (p, J = 7 Hz, 2H), 1.52 (m, 4H), 1.92 and 2.09 (2m, 2H), 2.18 (t, J = 7 Hz, 2H), 2.35 (m, 2H), 3.41 (t, J = 7 Hz, 2H), 4.35 (dd, J = 5,4 Hz, 1H), 6.72 (s, 2H). Mass Spec.: FAB 369 $(M + H)^+$, 391 $(M + Na)^+$, 407 $(M + K)^+$. Anal.: $C_{15}H_{24}N_6O_5 \cdot 2.5$TFA C, H, N.

Maleimidopropionylglutamyldihydrazone of Doxorubicin 2a. Maleimidopropionylglutamyldihydrazide ditrifluoroacetate **7a** (600 mg, 1.07 mmol) and DOX·HCl (1.24 g, 2.14 mmol) were dissolved in 600 mL of methanol over a period of 3 h. The reaction was concentrated to 100 mL by rotary evaporation, then stirred for 3 days. The reaction was further concentrated to 12 mL and eluted on an LH-20 column (2 in. × 10 in.) with methanol. Chromatography was repeated in the same system on mixed fractions. The purified product was rotary evaporated to a red film and dried under high vacuum to yield **2a** (776 mg, 50%).

^{1}H NMR (d_4-methanol): (selected peaks) δ 1.34 (2d, J = 7 Hz, 6H), 4.07 (2s, 6H), 6.79 (s, 2H), 7.5−8.0 (m, 6H). Mass Spec.: FAB 1375.4 $(M - H)^-$. Ionspray: 1377.2 (MH^+). HRMS: calculated $(M + Na)^+$ 1399.4506; observed 1399.4455. Anal.: $C_{66}H_{72}N_8O_{25} \cdot 2HCl \cdot 3.0H_2O$ C, H, N.

Maleimidobutyrylglutamyldihydrazone of Doxorubicin 2b. This compound was prepared by a similar procedure from **7b** (1.00 g, 1.76 mmol) and DOX·HCl (2.05 g, 3.53 mmol). Yield of **2b** was 1.32 g (51%).

^{1}H NMR (d_4-methanol): (selected peaks) δ 1.33 (2d, J = 7 Hz, 6H), 4.06 (2s, 6H), 6.80 (s, 2H), 7.5−8.0 (m, 6H). Mass Spec.: FAB 1392 (MH^+), 1413.4 $(M + Na)^+$, 1429 $(M + K)^+$. Ionspray: 1392.5 $(M + H)^+$, 1414.4 $(M + Na)^+$. HRMS: calculated $(M + Na)^+$ 1413.4663; observed 1413.4609. Anal.: $C_{67}H_{74}N_8O_{25} \cdot 2HCl \cdot 4.0H_2O$ C, H, N.

Maleimidobutyryl-(D)-glutamyldihydrazone of Doxorubicin D-2b. This compound was prepared by a similar procedure from D-**7b** (570 mg, 1.00 mmol) and DOX·HCl (1.34 g, 2.30 mmol). Yield of D-**2b** was 420 mg (30%).

^{1}H NMR (d_4-methanol): (selected peaks) δ 1.30 (2s, 6H), 4.07 (2s, 6H), 6.80 (s, 2H), 7.5−8.0 (m, 6H). Mass Spec.: FAB 1392.0 (MH^+), 1414.9 $(M + Na)^+$, 1429.7 $(M + K)^+$. HRMS: calculated $(M + Na)^+$ 1413.4663; observed 1413.4603. Anal.: $C_{67}H_{74}N_8O_{25} \cdot 2HCl \cdot 3.5H_2O$ C, H, N.

Maleimidocaproylglutamyldihydrazone of Doxorubicin 2c. This compound was prepared by a similar procedure from **7c** (298 mg, 0.50 mmol) and DOX·HCl (580 mg, 1.00 mmol). Yield of **2c** was 510 mg (68%).

^{1}H NMR (d_4-methanol): (selected peaks) δ 1.34 (2s, 6H), 4.08 (2s, 6H), 6.76 (s, 2H), 7.5−8.0 (m, 6H). Mass Spec.: FAB 1420 (MH^+), 1442.3 $(M + Na)^+$. Ionspray: 1419.6 $(M + H)^+$. HRMS: calculated $(M + Na)^+$ 1441.4976; observed 1441.4924. Anal.: $C_{69}H_{78}N_8O_{25} \cdot 2HCl \cdot 4H_2O$ C, H, N.

***Z*-β-Alanyl(BOC)hydrazide 8.** *Z*-β-Alanine (8.93 g, 40 mmol), *tert*-butylcarbazate (5.29 g, 40 mmol), and EDCI (8.00 g, 42 mmol) were stirred in 200 mL of CH_2Cl_2 for 1.5 h at room temperature. The reaction was extracted three times with 200 mL of 0.1 M acetic acid, twice with 200 mL of saturated aqueous sodium bicarbonate, and once with 200 mL of water. The organic layer was dried over sodium sulfate, rotary evaporated, and dried under high vacuum to yield **8** as a foam, 12.42 g (92%).

^{1}H NMR (d_6-DMSO): δ 1.38 (s, 9H), 2.25 (t, J = 7 Hz, 2H), 3.19 (q, J = 7 Hz, 2H), 4.99 (s, 2H), 7.3 (m, 6H), 8.21 (s, 1H), 9.56 (s, 1H). Mass Spec.: FAB 338 $(M + H)^+$. Anal.: $C_{16}H_{23}N_3O_5$ C, H, N.

β-Alanyl(BOC)hydrazide 9. 8 (15.25 g, 45.2 mmol) was hydrogenated at 50 psi in 200 mL of methanol with 3 g of 10% Pd−C for 4 h. The reaction was filtered

through Celite, rotary evaporated, and dried under high vacuum to yield **9** as a hygroscopic foam, 9.2 g (100%).

^{1}H NMR (d_4-methanol): δ 1.40 (s, 9H), 2.32 (t, J = 7 Hz, 2H), 2.88 (t, J = 7 Hz, 2H). Mass Spec.: FAB 204.2 $(M + H)^+$. Anal.: $C_8H_{17}N_3O_3 \cdot 0.5H_2O$ C, H, N.

***Z*-Glutamyldi[*β*-alanyl(Boc)hydrazide] 10.** *Z*-Glutamic acid (3.86 g, 13.7 mmol) and *N*-hydroxy succinimide (3.17 g, 27.5 mmol) were dissolved in 80 mL of DMF at 0 °C under dry N_2. A 0.5 M solution of dicyclohexylcarbodiimide in methylene chloride (55 mL, 27.5 mmol) was added, and the reaction was stored at 4 °C for 24 h. Dicyclohexylurea precipitate was filtered, and the filtrate was added to **9** (6.00 g, 29.5 mmol). After the mixture was stirred at room temperature for 15 h, the reaction was rotary evaporated to an oil, which was redissolved in 150 mL of ethyl acetate. The organic layer was extracted three times with 100 mL of 10% citric acid, 3 times with 100 mL of saturated aqueous sodium bicarbonate, and three times with 100 mL of brine. The organic layer was dried over sodium sulfate and rotary evaporated to a foam. Flash chromatography was carried out on silica gel (2 in. × 11 in.) with 1 L of CH_2Cl_2/methanol 25:1 followed by 3 L of CH_2Cl_2/methanol 9:1. Pure fractions containing product **10** were pooled and concentrated to a foam by rotary evaporation to yield, after drying under high vacuum, 6.70 g (75%).

^{1}H NMR ($CDCl_3$): δ 1.42 (s, 18H), 2.03 and 2.32 (2m, 8H), 3.5 (m, 4H), 4.35 (t, J = 7 Hz, 1H), 5.05 (dd, J = 18 Hz, 2H), 6.22 (d, J = 7 Hz, 1H), 6.49 (d, J = 18 Hz, 2H), 7.30 (s, 5H), 7.42 (m, 1H), 7.58 (m, 1H). Mass Spec.: DCI 652 $(M + H)^+$, 674 $(M + Na)^+$, 690 $(M + K)^+$. Anal.: $C_{29}H_{45}N_7O_{10}$ C, H, N.

Glutamyldi[*β*-alanyl(Boc)hydrazide] 11. *Z*-Glutamyldi[*β*-alanyl(Boc)hydrazide] **10** (3.52 g, 5.40 mmol) was hydrogenated along with 1 g of 10% Pd−C in 75 mL of MeOH at 50 psi for 2 h. The reaction was filtered through Celite and rotary evaporated. The resulting foam was dried under high vacuum to yield **11** (2.77 g, 99%).

^{1}H NMR (d_4-methanol): δ 1.46 (s, 18H), 1.91 (m, 2H), 2.25 (t, J = 7 Hz, 2H), 2.42 (q, J = 8 Hz, 4H), 3.35 (t, J = 8 Hz, 1H), 3.44 (m, 4H). Mass Spec.: FAB 518 $(M + H)^+$, 540 $(M + Na)^+$, 556 $(M + K)^+$. Anal.: $C_{21}H_{39}N_7O_8 \cdot 1.5H_2O$ C, H, N.

Maleimidopropionylglutamyldi[*β*-alanyl(Boc)hydrazide] 12a. Maleimidopropionic acid (399 mg, 2.36 mmol) and *N*-hydroxy succinimide (272 mg, 2.36 mmol) were dissolved in 30 mL of CH_2Cl_2/3 mL of DMF at 0 °C. A 0.5 M solution of DCC in CH_2Cl_2 (4.7 mL, 2.36 mmol) was added and the reaction mixture stirred for 3 h at room temperature. After filtration of the DCU precipitate, the filtrate was added to **11** (1.10 g, 2.13 mmol) and the reaction mixture stirred at room temperature for 1 day. Solvents were removed by rotary evaporation. The oil was purified by flash chromatography on silica gel (2 in. × 10 in.) with 500 mL of CH_2Cl_2, 2 L of CH_2Cl_2/methanol 95:5, and 2 L of CH_2Cl_2/methanol 9:1. Pure fractions were pooled, rotary evaporated, and dried under high vacuum to yield **12a** as a foam (850 mg, 60%).

^{1}H NMR (d_4-methanol): δ 1.46 (s, 18H), 1.82 and 2.04 (2m, 2H), 2.23 (t, J = 8 Hz, 2H), 2.40 (m, 4H), 2.52 (t, J = 7 Hz, 2H), 3.45 (m, 4H), 3.78 (t, J = 7 Hz, 2H), 4.20 (dd, J = 8 Hz, 1H), 6.81 (s, 2H). Mass Spec.: FAB 669 $(M + H)^+$, 691 $(M + Na)^+$, 707 $(M + K)^+$. Anal.: $C_{28}H_{44}N_8O_{11} \cdot 2H_2O$ C, H, N.

Maleimidobutyrylglutamyldi[*β*-alanyl(Boc)hydrazide] 12b. This compound was prepared by a similar procedure from maleimidobutyric acid (432 mg, 2.36 mmol). Yield of **12b** was 800 mg (55%).

^{1}H NMR (d_4-methanol): δ 1.46 (s, 18H), 1.87 (m, 3H), 2.08 (m, 1H), 2.24 (m, 4H), 2.41 (m, 4H), 3.45 (m, 6H), 4.23 (dd, J = 8 Hz, 1H), 6.82 (s, 2H). Mass Spec.: FAB 683 $(M + H)^+$, 705 $(M + Na)^+$, 721 $(M + K)^+$. Anal.: $C_{29}H_{46}N_8O_{11} \cdot 1.5H_2O$ C, H, N.

Maleimidocaproylglutamyldi[*β*-alanyl(Boc)hydrazide] 12c. Maleimidocaproic acid (453 mg, 2.14 mmol) and *N*-methylmorpholine (239 mg, 2.36 mmol) were dissolved in 25 mL of dry THF under Ar at −5 °C. Isobutylchloroformate (263 mg, 1.93 mmol) was added. After 5 min, **11** (1.0 g, 1.93 mmol) was added as a THF solution and the reaction mixture stirred for 3 h with warming to room temperature. Ethyl acetate (150 mL) was added, and then the solution was extracted three times with 75 mL of 10% citric acid, three times with 75 mL of saturated aqueous sodium bicarbonate, and three times with 75 mL of water. The organic layer was dried over sodium sulfate, then passed through a plug of silica gel with CH_2Cl_2/methanol 9:1. The purified product was rotary evaporated and dried under high vacuum to give **12c**, 800 mg (58%).

^{1}H NMR (d_4-methanol): δ 1.30 (m, 2H), 1.46 (s, 18H), 1.60 (m, 4H), 1.88 and 2.06 (2m, 2H), 2.22 (t, J = 7 Hz, 4H), 2.41 (t, J = 7 Hz, 4H), 3.44 (m, 6H), 4.24 (dd, J = 9 Hz, 1H), 6.80 (s, 2H). Mass Spec.: FAB 711.4 $(M + H)^+$, 733.2 $(M + Na)^+$, 749.3 $(M + K)^+$. Anal.: $C_{31}H_{50}N_8O_{11} \cdot 1.0H_2O$ C, H, N.

Maleimidopropionylglutamyldi[*β*-alanylhydrazide] 13a. Maleimidopropionylglutamyldi[*β*-alanyl(Boc)-hydrazide] **12a** (850 mg, 1.27 mmol) was stirred in 15 mL of CH_2Cl_2/trifluoroacetic acid (1:1) under N_2 for 1.5 h. Solvents were removed by rotary evaporation. Ether was added and coevaporated three times, and then the resulting solid was triturated with ether. The solid was filtered and dried under high vacuum to yield **13a** (890 mg, 100%).

^{1}H NMR (d_4-methanol): δ 1.83 and 2.02 (2m, 2H), 2.23 (t, J = 7 Hz, 2H), 2.52 (q, J = 7 Hz, 6H), 3.47 (m, 4H), 3.78 (dt, J = 7, 3 Hz, 2H), 4.13 (dd, J = 5, 4 Hz, 1H), 6.82 (s, 2H). Mass Spec.: FAB 469.0 $(M + H)^+$, 491.1 $(M + Na)^+$, 507.1 $(M + K)^+$. Anal.: $C_{18}H_{28}N_8O_7 \cdot 3.75TFA \cdot 0.25Et_2O$ C, H, N.

Maleimidobutyrylglutamyldi[*β*-alanylhydrazide] 13b. This compound was prepared by a similar procedure from **12b** (800 mg, 1.17 mmol). Yield of **13b** was 840 mg (100%).

^{1}H NMR (d_4-methanol): δ 1.88 (m, 3H), 2.06 (m, 1H), 2.26 (t, J = 7 Hz, 4H), 2.51 (t, J = 7 Hz, 4H), 3.50 (m, 6H), 4.18 (dd, J = 5, 4 Hz, 1H), 6.82 (s, 2H). Mass Spec.: FAB 483.2 $(M + H)^+$, 505.1 $(M + Na)^+$, 521.1 $(M + K)^+$. Anal.: $C_{19}H_{30}N_8O_7 \cdot 3.5TFA \cdot 0.25Et_2O$ C, H, N.

Maleimidocaproylglutamyldi[*β*-alanylhydrazide] 13c. This compound was prepared by a similar procedure from **12c** (800 mg, 1.13 mmol). Yield of **13c** was 870 mg (100%).

^{1}H NMR (d_4-methanol): δ 1.31 (p, J = 7 Hz, 2H), 1.61 (m, 4H), 1.85 and 2.03 (2m, 2H), 2.24 (t, J = 7 Hz, 4H), 2.50 (t, J = 7 Hz, 4H), 3.47 (m, 6H), 4.19 (dd, J = 5, 4 Hz, 1H), 6.80 (s, 2H). Mass Spec.: Ionspray 511.1 $(M + H)^+$, 533.0 $(M + Na)^+$. Anal.: $C_{21}H_{34}N_8O_7 \cdot 2.75TFA \cdot 0.25Et_2O$ C, H, N.

Maleimidopropionylglutamyldi[*β*-alanylhydrazone] of Doxorubicin 3a. Maleimidopropionylglutamyldi[*β*-alanylhydrazide] ditrifluoroacetate **13a** (1.0 g, 1.44 mmol) and DOX·HCl (1.68 g, 2.88 mmol) were dissolved in 600 mL of methanol over a period of 3 h. The reaction was concentrated to 100 mL by rotary evaporation, then stirred for 1 day. After further concentration to 10 mL, elution on an LH-20 column (2 in. × 10 in.) with

methanol/DMF (1:1) was carried out. The purified product was concentrated by rotary evaporation and precipitated by the addition of acetonitrile. The red solid was isolated by centrifugation and dried under high vacuum to yield **3a** (450 mg, 20%).

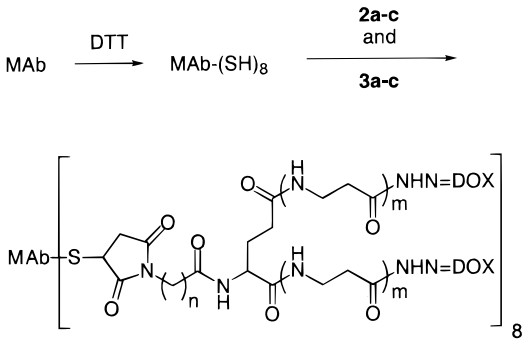
^{1}H NMR (d_4-methanol): δ 1.29 (2bd, 6H), 4.04 (s, 6H), 6.80 (s, 2H), 7.5−8.0 (m, 6H). Mass Spec.: Ionspray 1519.6 $(M + H)^+$, 1541.2 $(M + Na)^+$. HRMS: calculated $(M + Na)^+$ 1541.5249; observed 1541.5187. Anal.: $C_{72}H_{82}N_{10}O_{27}$·2HCl·7H_2O C, H, N.

Maleimidobutyrylglutamyldi[β-alanylhydrazone] of Doxorubicin 3b. This compound was prepared by a similar procedure from **13b** (280 mg, 0.395 mmol). Chromatography was carried out on an LH-20 column (1 in. × 15 in.) with methanol/DMF (1:1). The purified product was concentrated by rotary evaporation and precipitated by the addition of acetonitrile. The red solid was isolated by centrifugation and dried under high vacuum to yield **3b** (325 mg, 51%).

^{1}H NMR (d_4-methanol): δ 1.30 (m, 6H), 4.04 (s, 6H), 6.78 (s, 2H), 7.4−8.0 (m, 6H). Mass Spec.: FAB 1533.7 $(M + H)^+$, 1555.5 $(M + Na)^+$, 1572.4 $(M + K)^+$. Anal.: $C_{73}H_{84}N_{10}O_{27}$·2HCl·7H_2O C, H; N; calcd, 8.08; found, 7.41.

Maleimidocaproylglutamyldi[β-alanylhydrazone] of Doxorubicin 3c. By using the procedure of **3b**, we prepared this compound from **13c** (148 mg, 0.20 mmol). Yield of **3c** was 162 mg (50%).

^{1}H NMR (d6-DMSO): δ 1.20 (m, 6H), 4.0 (s, 6H), 6.95 (s, 2H), 7.5−8.1 (m, 6H). Mass Spec.: FAB 1561 $(M + H)^+$, 1583.4 $(M + Na)^+$, 1599.9 $(M + K)^+$. Anal.: $C_{75}H_{88}N_{10}O_7$·2HCl·7H_2O C, H, N.



CONJUGATE SYNTHESIS

Monoclonal Antibodies. BR96 is a chimeric (mouse/human IgG1) mAb which identifies a Le^y-related tumor-associated antigen expressed on carcinomas of the lung, colon, breast, and ovary. The mAb is rapidly internalized following antigen-specific binding (*2*, *4*, *9*). Doxorubicin immunoconjugates of various DOX/mAb molar ratios were prepared with both chimeric BR96 and control human IgG.

Thiolation. *Method A*. On a scale ≤3 g, BR96 and IgG were reduced by a previously reported method (*9*). In a typical example, 1.54 g of BR96 (180 mL at 53.4 μM, 9.6 μmol) was deoxygenated by cycling several times between vacuum and Ar atmosphere. This was then treated with 34 mM DTT (2.0 mL, 68.0 umol in Ar-bubbled PBS, pH 7.0) and stirred at 37 °C under Ar for 3 h. Removal of low molecular weight compounds was accomplished by ultrafiltration against PBS, pH 7.0, in an Amicon stirred cell at 4 °C. A 400 mL Amicon cell was fitted with an Amicon YM30 filter (molecular weight cutoff 30000) and charged to 40 psi with Ar. Cell eluant was monitored for thiol content with Ellman's reagent (*12*) until a baseline reading at 412 nm was obtained. Concentrations of protein and thiol groups were determined according to the previously reported method (*9*). In this example, 1.47 g of reduced BR96 (190 mL at 48.57 μM mAb, 412.7 μM thiol) was obtained, for a yield of 95% and a thiol titer of 8.5 mol of thiol groups/mol of BR96.

Method B. On a scale >3 g, the same procedure was utilized for the DTT reaction, with the exception that the mAb solutions were deoxygenated by bubbling with Ar. Purification after DTT reduction was accomplished by ultrafiltration in a Filtron Minisette unit. The Minisette was fitted with two Filtron 30K cassettes and was connected to a Watson Marlow 604S pump with Bioprene tubing. The mAb solution was ultrafiltered at 0 °C under Ar against Ar-bubbled PBS, pH 7.0 (eluant flow rate 100−150 mL/min, 25 psi backpressure), while continually monitoring eluant for thiol content as above. In a typical example, a 6.6 g batch of BR96 (550 mL at 75.3 μM) yielded 6.1 g of reduced BR96 (800 mL at 47.6 μM mAb, 398 μM thiol) for a yield of 92% and thiol titer of 8.4 mol of thiol groups/mol of BR96.

Conjugation. The following procedure, for the conjugation of BR96 and **2b**, is typical of that used for all linkers cited herein. To reduced BR96 from Method A (125 mL, 6.07 μmol mAb, 51.5 μmol thiol) was added dropwise at 0 °C under Ar a solution of **2b** (93 mg, 67.2 umol) in 5 mL of Ar-bubbled H_2O. After being stirred for 30 min, the reaction mixture was filtered through a 0.22μ sterile filter. Conjugate was purified at 4 °C by percolation (approximately 2 mL/min) through a 1 in. × 36 in. Bio-Beads column (initially prepared by swelling and packing in methanol, then equilibrated in H_2O, and finally PBS, pH 7.0). The purified conjugate was filtered again through a 0.22μ sterile filter to yield 155 mL of BR96-**2b** (BR96, 39.13 μM; DOX, 589.0 μM; MR, 15.1 mol of DOX/mol of BR96; yield, 100%). Conjugate was frozen in liquid N_2 and stored at −80 °C. Conjugation results for all linkers **2** and **3** are shown in Scheme 4 and Table 1.

(**2**-**3**) and treated for 10 min with 100 mL of 2-mercaptoethanol. Solvent was removed under vacuum and the residue washed with Et_2O. Complete conversion to the thioether was verified by ^1H NMR and a shift in HPLC retention time.

Determination of Hydrolysis Kinetics of 14−16. Stock solutions (10 mM) of **14**−**16** were freshly prepared in H_2O. Aliquots were diluted to a final concentration of 30 mM in either 100 mM NaOAc, pH 5.0, or 100 mM Na_2HPO_4, pH 7.0, then incubated (stoppered test tube) at 37 °C in a thermostat-regulated H_2O bath. RP−HPLC was used to monitor the formation of DOX in solution and the disappearance of starting materials until equilibrium was reached. Conditions for the analyses were 50 mL injection; Phenomenex IB−Sil 5 C-18 column; mobile phase 44:56 H_2O−MeOH with 6% NH4OAc; flow rate 1.5 mL/min; UV detection 235 nm. Free DOX was quantitated by integrating the 7.5 min peak (positively identified by comparison to a DOX standard) and represented as the percent of total DOX in solution vs time. Half-lives for the appearance of DOX were calculated from these curves and are listed in Table 2.

Determination of Conjugate Hydrolysis Kinetics. Conjugates at approximately 10 mg/mL were diluted 1:3 into either 100 mM NaOAc, pH 5.0, or 100 mM Na_2HPO_4, pH 7.0. The solutions were placed into a temperature-controlled (37 °C) autosampler for RP−HPLC. Samples were taken and analyzed automatically at timed intervals by the autosampler. Conditions for the analyses were Jones Chromatography Apex C-18 5μ column; mobile phase 70:30 MeOH−30mM ammonium phosphate, pH 4.5; flow rate 1.5 mL/min; fluorescence exitation 233 nm, emission 570 nm; UV detection 235 nm. DOX·HCl standards were analyzed before and after the experiment. The results are expressed as percents of total DOX released. Half-lives for the appearance of DOX were calculated from these curves and are listed in Table 2.

In Vitro Cytotoxicity Assays. In vitro cytotoxicity assays were performed as described previously (*10*) using the BR96 expressing human lung carcinoma line L2987 (*2*). Briefly, monolayer cultures of L2987 cells were harvested and resuspended to 1×10^5/mL in RPMI-1640 containing 10% heat inactivated fetal calf serum (RPMI-10%FCS). Cells (0.1 mL/well) were added to each well of 96 well microtiter plates and incubated overnight at 37 °C in a humidified atmosphere containing 5% CO_2. Medium was removed from the plates and serial dilutions of DOX or mAb-DOX conjugates added to the wells. All dilutions were performed in quadruplicate. Cells were exposed to DOX or mAb-DOX conjugates for 2 h at 37 °C in a humidified atmosphere of 5% CO_2. Plates were centrifuged (200*g*, 5 min), the drug or conjugate removed, and the cells washed 3× with RPMI−10% FCS. The cells were cultured in RPMI−10% FCS (37 °C, 5% CO_2) for an additional 48 h. At this time the cells were pulsed for 2 h with 1.0 μCi/well of [^{3}H]thymidine (New England Nuclear, Boston, MA). Cells were harvested onto glass fiber mats (Skatron Instruments, Inc.,Sterling, VA), dried, and filter bound [^{3}H]thymidine radioactivity determined (β-Plate scintillation counter, Pharmacia LKB Biotechnology, Piscataway, NJ). Inhibition of [^{3}H]thymidine uptake was determined by comparing the mean CPM for treated samples with that of the mean CPM of the untreated control.

RESULTS AND DISCUSSION

Linker Synthesis. The branched linkers were synthesized using L- or D-glutamic acid as a convenient template. The two carboxyl groups of glutamic acid were converted to hydrazides, either directly as in **2** (Scheme 2), or via an extended β-alanine spacer as in **3** (Scheme 3). The amino group of glutamic acid was extended using an amide linkage with maleimidoalkanoic acids of varying length to introduce a terminal maleimide group.

The two series of linkers **2** and **3** were synthesized by parallel procedures. For the **2** series, *Z*-Glu was doubly activated with DCC/NHS to give the bis-succinimdyl carbonate which was directly coupled with *tert*-butyl carbazate to give **4**. Catalytic hydrogenation gave the free amine **5**. The maleimidoalkanoyl tether was attached to **5** by either of two amide coupling methods, yielding **6a**−**6c**. The unprotected bis-hydrazides **7a**−**7c** were generated by treatment with 50% TFA in CH_2Cl_2. Condensation of **7a**−**7c** with DOX in MeOH in the presence of catalytic TFA[1] was monitored by RP−HPLC, which showed that the reaction progressed through a monohydrazone species to give bis-hydrazones **2a**−**2c**. The final products were generally isolated in good yield and purity after chromatography on Sephadex LH-20 in methanol (*13*). Included in this series is one D-analogue, D-**2b**, which was synthesized by an identical procedure from *Z*-D-Glu.

In the **3** series, the hydrazide linkage was initially installed on the β-alanine unit before attachment to *Z*-Glu. Thus, *Z*-β-Ala was activated with DCC/NHS and coupled to *tert*-butyl carbazate to give **8**. Catalytic hydrogenation generated **9**, which was coupled to *Z*-Glu in a manner similar to that used for **4** to generate the extended bis-hydrazide **10**. Continuing the parallel sequence, **10** was elaborated to the extended bis-hydrazones **3a**−**3c**.

Our earliest attempt at the synthesis of glutamyldihydrazides made use of the attachment of a maleimidoglycine unit to **5** to give **6** ($n = 1$), with the ultimate goal of extension to **2** ($n = 1$). In a similar manner, **12** ($n = 1$) was synthesized.[2] It was felt that linkers with short tethers would be the most H_2O soluble. We unexpectedly found that **6** ($n = 1$) was unstable in methanol. NMR studies showed that it decomposed with a $T_{1/2}$ of about 24 h at room temperature to yield a maleamate. By contrast, **12** ($n = 1$) was completely stable, as were all

[1] Prior experience with the synthesis of unbranched DOX hydrazones has shown TFA to be an effective catalyst in this reaction (*8*). Advantageously bound TFA, from the previous synthetic step, acted as catalyst in the preparation of **2a**-**2c**.

[2] Data not shown.

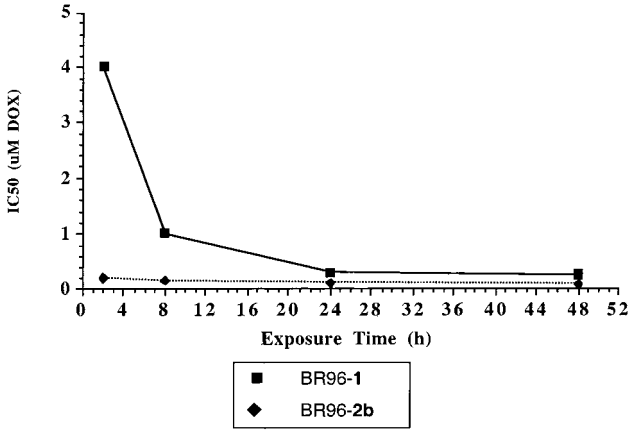

Figure 1. Relative in vitro potencies of branched and linear conjugates evaluated as a function of in vitro exposure time.

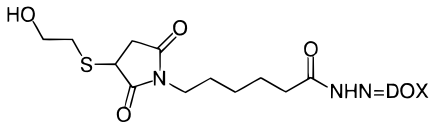
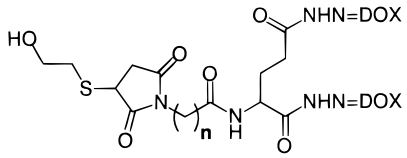


compounds with $n \geq 2$. Appparently **6** ($n = 1$) is a uniquely activated electrophile toward protic solvolysis by virtue of the hydrazide groups at close proximity. Because methanol was a crucial solvent during later stages of the syntheses, we decided to abandon maleimidoglycine linkers in general. Ultimately, this proved to be inconsequential in regard to solubility, since all members of the **2** and **3** series which were synthesized were fully soluble in H_2O as HCl salts.

Conjugation of Linkers to Monoclonal Antibodies. We have previously shown that mild treatment of BR96 with DTT reduces a maximum of 4 interchain disulfide bonds to yield 8 thiol groups, which, upon reaction with the single-chain maleimide **1** gave immunoconjugates with MR's equal to 8 (*9*). The reduction procedure is generally applicable and was used with minor modifications in this work to generate immunoconjugates of branched linkers. Thus, mAb (either BR96 or control IgG) was treated with a 7-fold excess of DTT with exclusion of O_2 at 37 °C for 3 h. For syntheses ≤3 g, reduced mAb was purified by diafiltration in an Amicon stirred cell device. For larger scale syntheses (3−9 g), a Filtron minisette was used. In either case removal of small molecules was rapid (about 3 h for the Amicon device and 30 min for the Filtron minisette) and efficient, generating SH titers of about 8 for BR96 and 10 for IgG. Conjugation of a 1.3 molar excess of branched linkers (based on SH titer) for 30 min at 0 °C was followed by chromatography on Bio-Beads to remove unreacted linker. MR values of 14−16 DOX/mAb were obtained for the **2** series, consistent with the SH titer generated. Protein recoveries were generally good with yields in the range of 85−100%. For reasons not readily apparent, lower MR values were obtained for the **3** series than for the **2** series. Results for some representative immunoconjugates are summarized in Table 1.



In our earlier work, we reported that BR96-DOX, prepared from the single-chain linker **1**, was a single molecular entity with molecular weight 160000 (*9*). Conjugates prepared from **2** and **3** also were shown by SEC−HPLC to be monomeric, usually containing <5% aggregate. In this study we also used HIC chromatography to verify the absence of unreacted Ab. Finally, these immunoconjugates were shown by RP−HPLC to contain <2−3% unconjugated DOX or DOX linker (Table 1).

Hydrolysis Kinetics. We have previously shown that **1** and its mAb conjugates are stable at pH 7, yet hydrolyze rapidly at pH 5 to release free DOX (*9*). In this study, it was also necessary to examine the hydrolytic

16b n=3
16c n=5

stability of branched linkers **2** and **3**. For this purpose we decided to convert our linkers **1**−**3** to thioether derivatives **14**−**16** (Scheme 5) by reaction with 2-mercaptoethanol. The thioethers were more soluble in aqueous buffers than their parent maleimides and more closely mimicked the mAb conjugate, which itself is a thioether. The conversion of thioethers **14**−**16** to DOX was followed at pH 5 and 7 by RP−HPLC, and $T_{1/2}$ values calculated for disappearance of starting material. Results are summarized in Table 2.

Within each series of linkers, $T_{1/2}$ values are equivalent and show that there is no effect due to the length of the tether. It is interesting to note that **15** (derived from the compact series **2**) is considerably more stable at pH 5 and 7 than **16** (derived from the extended series **3**). It is possible that stacking interactions are greater for **15** and that attack by water on the hydrazone bond is hindered due to steric constraints. Furthermore, it is seen that **16** hydrolyzes at a rate equal to that of the single-chain linker **14** (derived from **1**) at both pH values. This observation is consistent with **16** adopting a more extended conformation, similar to **14**, where the hydrazone bond is less hindered to attack by water.

We also examined the hydrolysis rates of the actual conjugates derived from **2** and **3** as a function of pH. In this case, RP−HPLC was used to monitor the levels of free DOX in solution generated over time from the immunoconjugate. Results from Table 2 show that the same trends are maintained as for the thioether derivatives, albeit at rates 2−10× faster at pH 5. General acid catalysis provided by acidic residues on the protein may account for the increase in hydrolysis rates. Stereochemistry of the Glu residue has no effect on conjugate hydrolysis rates. Immunoconjugates derived from **2** are about twice as stable as those of **3** or **1** (our prototype

single-chain linker) at pH 5, a factor which is probably not significant in vivo. We believe that a $T_{1/2}$ of 5−7 h is sufficient for efficient release of DOX within the tumor lysosome.

In Vitro Potency of Linear and Branched DOX Hydrazone Conjugates. The in vitro potency of immunoconjugates prepared with different branched linkers is shown in Table 3. The conjugates evaluated in this study had molar ratios which ranged from 7.0 to 15.3, contained <5% aggregate, and retained ≥95% binding activity relative to mAb BR96. When the concentration of DOX required to produce 50% cytotoxicity was evaluated, the branched BR96-DOX conjugates were 4−14-fold (IC_{50} values of 0.2−0.58 μM equivalent DOX) more potent than the linear BR96-**1** conjugate (2.8 μM DOX equivalent DOX) on an equivalent DOX basis. The branched BR96-DOX conjugates were as potent as unconjugated DOX, whereas the linear BR96-**1** conjugate was approximately 20-fold less potent. As shown in Table 3, the increased potency of the branched chain conjugates on a DOX basis coupled with the increased DOX/mAb molar ratios of these conjugates translates into a 7−23-fold increase in potency on a mAb basis. For example, the IC_{50} of the branched D-**2b** conjugate (0.015 μM mAb) was 20-fold lower than that of the linear **1** conjugate (0.3 μM mAb). We conclude, therefore, that branched BR96-DOX conjugates deliver an increased concentration of DOX per molecule of BR96, resulting in a significant increase in the in vitro potency of the conjugate on both a DOX and mAb basis.

The mechanism responsible for the >2-fold increase in in vitro potency corresponding to the doubling of the DOX/mAb molar ratio is not clear at this time. However, in additional in vitro experiments (Figure 1), the relative potencies of the branched and linear conjugates were evaluated as a function of the in vitro exposure time. These studies demonstrated that the enhancement in potency of branched conjugates was seen only following exposure times of ≤2h (the standard exposure time for these assays). With longer exposure times, 8−24 h, the branched conjugates were approximately twice as potent as the linear **1** conjugate. These data suggest either that the branched conjugates are internalized more rapidly than the linear conjugates or that DOX is more rapidly released from the branched conjugates in lysosomes following internalization.

The branched and linear chain BR96-DOX conjugates demonstrated antigen-specific cytotoxicity; however the specificity ratios of the branched conjugates were much higher than the linear conjugates. BR96-DOX conjugates were significantly more potent than IgG-DOX conjugates prepared at a similar molar ratio using the same linker.

CONCLUSION

In this work, we have introduced the novel concept of branched DOX hydrazone linkers for mAb conjugates. With a single branch point, these linkers have enabled us to successfully synthesize conjugates with mole ratios twice that of conjugates derived from similar single-chain DOX linkers. The new conjugates were generally obtained in good yield and were found to contain little or no aggregates, unreacted mAb, unreacted DOX hydrazone linkers, or free DOX. They demonstrate appropriate hydrolysis kinetics, releasing DOX rapidly at pH 5 while stable at pH 7. Conjugates derived from series **3** hydrolyze at the same rate at pH 5 as BR96-DOX, which is about twice as fast as those derived from series **2**. Neither this factor nor others such as the length of the maleimide tether or the configuration of the Glu residue are reflected, though, in in vitro cytotoxicity. The BR96 branched hydrazone conjugates were more potent than the linear DOXHZN conjugate on both a DOX (4−14-fold) and a mAb (7−23-fold) basis. These data suggest that utilizing the branched hydrazone methodology offers a potential advantage in conjugate potency and provides a means to significantly reduce the amount of mAb required to achieve activity. The in vivo biology of the branched chain conjugates is the subject of a later manuscript.

ACKNOWLEDGMENT

We acknowledge Michael Walker (BMS-Wallingford) and Y. Pendri (BMS-New Brunswick) for their assistance in various aspects of this work, and the BMS Analytical Chemistry Group (Ed Pack, Sadia Abid, and Tony Spears) for chromatographic assistance. Finally, we thank Drs. Dinesh Vyas and Terry Doyle for their support.

Received September 11, 1998; Revised Manuscript Received November 30, 1998

Conjugates of three components, folic acid−poly(ethylene glycol)−distearoylphosphatidylethanolamine (FA−PEG−DSPE), derived from PEG with molecular masses of 2000 and 3350 Da were synthesized by a carbodiimide-mediated coupling of FA to H_2N-PEG−DSPE. The conjugates were characterized by ^1H NMR, MALDI-TOF, and HPLC analysis of enzymatic cleavage with carboxypeptidase G. As a prototype of a folate receptor (FR)-targeted system, the conjugates were formulated at 0.5 mol % phospholipid in hydrogenated phosphatidylcholine/cholesterol liposomes with or without additional methoxyPEG2000−DSPE. In vitro binding studies were performed with sublines of M109 (murine lung carcinoma) and KB (human epidermal carcinoma) cells each containing high and low densities of FR. FA−PEG−DSPE significantly enhanced liposome binding to tumor cells. The best binding was observed when FA−PEG liposomes contained no additional mPEG−lipid. In fact, our experiments showed that the presence of mPEG on liposomal surfaces significantly inhibited FA−PEG−liposome binding to FR. Increasing the molecular mass of the PEG tether from 2000 to 3350 Da improved the FR binding, particularly in the case of mPEG-coated liposomes. The FA−PEG liposomes bound to M109-HiFR cells very avidly as demonstrated by the inability of free FA (used in a 700-fold excess either at the beginning or at the end of the incubation) to prevent the cell binding. This is in contrast to the 5−10-fold lower cell binding activity of mPEG−FA compared to that of free FA, and likely to be related to the multivalent nature of the liposome-bound FA. Only 22% of FA−PEG3350 and 32% of FA−PEG3350/mPEG cell-associated liposomes could be removed by exposure to pH 3, conditions that dissociate FA−FR, suggesting that more than two-thirds of the bound liposomes were internalized during incubation for 24 h at 37 °C. FA-targeted liposomes also show enhanced nonspecific binding to extracellular tissue culture components, a phenomenon especially relevant in short incubation time experiments.

INTRODUCTION

Recent advances in the design of liposomes based on surface modification with poly(ethylene glycol) (PEG)[1] have resulted in new formulations of small (<100 nm), long-circulating vesicles (*1*). The brush-like coat of PEG molecules attached to liposomal bilayer builds up a sterically repulsive shield that protects the liposome surface from nonspecific opsonization by plasma proteins, thus interfering with liposome recognition and clearance from circulation by the macrophages of the reticuloendothelial system (*2*, *3*). The improved pharmacokinetic properties of these PEG-grafted liposomes (*4*), and specifically their long circulation time, result in increased levels of localization into tumor tissues with high microvascular permeability (*5*). However, these liposomes remain mostly in the extracellular fluid and are not taken up by tumor cells (*6*).

For efficient drug delivery, a carrier system should facilitate not only tumor localization but also intracellular access. Therefore, significant effort has been focused on exploiting natural endocytosis pathways for targeting macromolecules or particulate carriers into living cells. The methodology has generally involved the chemical coupling of a normally endocytosed ligand to the carrier, followed by exposure of the resulting conjugate to receptor-bearing cells. Using this strategy, a variety of ligands such as antibodies, growth factors, or cytokines have served as vehicles for introducing drugs, proteins, and nucleic acids into target cells (*7*). In the case of ligand-mediated targeting of PEG-grafted liposomes, it is advantageous to link the ligand moieties to distal end groups of the PEG chains (*8*−*11*). It has been demonstrated recently using a surface forces apparatus that linking via a long PEG spacer expands the receptor-accessible range by almost the entire length of the fully stretched PEG tether (*12*). This may offer a major targeting advantage compared to ligand attachment

directly to phospholipid (PL) membrane. In another example, it was shown that incorporation of sialyl Lewis X−PEG2000−DSPE into unilamellar liposomes resulted in a striking enhancement in the level of binding to E-selectin, 3 orders of magnitude higher than that of the free oligosaccharide ligand (*13*).

Antibody targeting to erbB2-overexpressing human carcinomas, using anti-erbB2 monoclonal antibody-bearing hydrazide−PEG liposomes (immunoliposomes), was examined by our group (*14*). We obtained specific and pronounced binding of immunoliposomes to erbB2-overexpressing cells in vitro. However, failure of the antibody-targeted liposomes to induce internalization by target cells was probably a major factor preventing the translation of specific binding into improved antitumor efficacy of doxorubicin-loaded immunoliposomes (*15*). Confirming the importance of internalization, Park et al. (*16*) have observed enhanced therapeutic efficacy with doxorubicin encapsulated in liposomes targeted with an anti-erbB2 antibody Fab fragment that causes liposome internalization into several breast cancer cell lines.

In recent years, it has been demonstrated that receptor-mediated uptake of the vitamin folic acid (FA) could also be exploited to facilitate entry of an attached molecule, macromolecule, or liposome into cells (*10*, *17*−*19*). Notably, it has been reported that the covalent conjugation of FA to liposomes through a PEG spacer permitted avid uptake of liposomes by KB cells (human nasopharyngeal cancer cell line) (*10*, *20*−*22*). The binding of these FA-targeted liposomes to KB cells could be competitively inhibited by excess free FA or by an antiserum against the FA receptor, demonstrating that the interaction is mediated by the cell surface FA-binding protein. The folate receptor (FR) is a glycosylphosphatidylinositol-linked membrane glycoprotein of 38 kDa located in caveolae that participates in the cellular accumulation of folates in a number of epithelial cells through the process of potocytosis (*23*−*25*). In this process, ligand-bound receptor is sequestered in caveolae, followed by internalization into postcaveolar plasma vesicles, released from the receptor via an intravesicular reduction in pH, and subsequently transported into the cytoplasm for polyglutamation. Ligand-free receptor is then recycled to the cell surface by reopening of the caveolae (*25*, *26*). A soluble form of the receptor, the folate-binding protein, was first described 30 years ago (*27*).

Cell surface receptors for folic acid are generally overexpressed in human cancer cells. The human FR happens to be largely overexpressed in ovarian cancer (80−90% of the cases), where it constitutes a useful marker (*28*−*30*). Enhanced expression of human FR has also been reported in malignant cell lines (>20-fold) (*31*), in human brain tumors (*31*), and in lung tumors (*32*). In addition, the receptor has been mapped to 11q13 (*31*), a region amplified in more than 20% of the samples from head and neck and breast tumors. In normal human tissues, detectable FR has a limited distribution, mainly in kidneys, lungs, choroid plexus, and placenta. The receptors in each of these tissues, except placenta, are localized in the apical membrane surface, i.e., facing away from the blood (toward urine, airway, and CSF) and hence inaccessible to FA conjugates administered intravenously (*19*). These observations suggest that the receptor may be a useful target for the development of selective cancer therapy.

Here we describe the synthesis and characterization of a folate−PEG−distearoylphosphatidylethanolamine (FA−PEG−DSPE) conjugate and summarize our in vitro findings with methoxy-PEG (mPEG)-grafted liposomes bearing the above conjugate specifically designed for targeting to the FR. Our results are in agreement with previous reports pointing at the feasibility of targeting liposomes using a FA ligand (*19*). However, we also find that the liposome mPEG coating interferes significantly with liposome binding and uptake by cells expressing FR at a high level. Optimal liposome−cell association was obtained when liposomes were prepared with a small fraction of the FA−PEG conjugate and no additional mPEG coating. When FA was conjugated using a longer polymer chain, PEG3350, liposome interaction with target cells was enhanced compared to that with the shorter PEG2000 tether commonly used for liposome coating.

MATERIALS AND METHODS

Synthesis and Characterization of FA−PEG−DSPE and mPEG−FA. Folic acid (Fluka, 100 mg, 0.244 mmol) was dissolved in DMSO (4 mL). Amino-PEG2000−DSPE (*33*) (400 mg, 0.14 mmol) and pyridine (2 mL) were added to the FA−DMSO solution followed by dicyclohexylcarbodiimide (130 mg, 0.63 mmol). The reaction was continued at room temperature for 4 h. TLC on silica gel GF (75:36:6 chloroform/methanol/water) showed a new spot ($R_f = 0.57$) due to the formation of the product. The disappearance of amino-PEG−DSPE ($R_f = 0.76$) from the reaction mixture was confirmed by ninhydrin spray. Pyridine was removed by rotary evaporation. Water (50 mL) was added to the reaction mixture. The solution was centrifuged to remove trace insolubles. The supernatant was dialyzed in Spectra/Por CE (Spectrum, Houston, TX) tubing (MW cutoff of 300 000) against saline (50 mM, 2 × 2000 mL) and water (3 × 2000 mL). The dyalizate, containing only the product (single spot by TLC), was lyophilized and the residue dried in vacuo over P_2O_5. The yield was 400 mg (90%). Exactly the same protocol was used to prepare FA−PEG−DSPE from H_2N-PEG3350−DSPE. In a similar procedure, FA was attached to mPEG2000-NH_2 (*34*). The product, mPEG−FA, was purified on a silica gel (70−200 mesh, 60 Å) column using a stepwise gradient of methanol (10 to 80%) in chloroform and then chloroform/methanol/water (65:30:5) for the elution of the pure product.

UV Analysis. Folate content values determined by quantitative UV spectrophotometry of the conjugates in methanol (0.05 mg/mL) using FA the extinction coefficient ϵ value of 27 500 M^{-1} cm^{-1} at a λ_{max} of 285 nm. The following FA content values were calculated: 0.29 mmol/g (94% of the theoretical value, 0.31 mmol/g) for FA−PEG2000−DSPE, 0.21 mmol/g (97% of the theoretical value, 0.22 mmol/g) for FA−PEG3350−DSPE, and 0.40 mmol/g (98% of the theoretical value, 0.41 mmol/g) for mPEG2000−FA.

^{1}H NMR (360 MHz, DMSO-d_6/CF_3CO_2D, ~10:1 v/v) for FA−PEG−DSPE: δ 0.84 (t, CH_3, 6H), 1.22 (s, CH_2, 56H), 1.49 (m, CH_2CH_2CO, 4H), 2.1−2.3 (overlapping 2 × t, CH_2CH_2CO and m, CH_2 of Glu, 8H), 3.2 (m, CH_2CH_2N, 4H), 3.50 (s, PEG, ~180H and ~300H for derivatives of PEG2000 and -3350, respectively), 4.02 (t, CH_2OCONH, 2H), 4.1 (dd, *trans*-PO_4CH_2CH, 1H), 4.3 (dd, *cis*-PO_4CH_2CH, 1H), 4.37 (m, α-CH, 1H), 4.60 (d, 9-CH_2N, 2H), 5.15 (m, PO_4CH_2CH, 1H), 6.65 (d, 3′,5′-H, 2H), 7.65 (d, 2′,6′-H, 2H), 8.77 (s, C7-H, 1H).

^{1}H NMR (360 MHz, DMSO-d_6/CF_3CO_2D, ~10:1 v/v) for mPEG−FA: δ 1.85−2.1 (m, β-CH_2 of Glu, 2H), 2.3 (m, γ-CH_2 of Glu, 2H), 3.11 (m, CH_2CH_2N, 4H), 3.50 (s, PEG, ~180H), 4.3 and 4.37 (minor and major α-CH_2 of Glu,

1H), 4.60 (9-CH_2N, 2H), 6.65 (d, 3′,5′-H, 2H), 7.66 (d, 2′,6′-H, 2H), 8.77 (s, C7-H, 1H).

Mass Spectra (MALDI-TOFMS). The spectra were obtained by Charles Evans & Associates (Redwood City, CA) with a PHI-EVANS MALDI triple electrostatic analyzer time-of-flight mass spectrometer (desorption laser operating at 337 nm, with a 600 ps pulse width), utilizing gentrinsic acid as a matrix material. The spectra exhibited a bell-shaped distribution of 44 Da-spaced lines centered at 3284 Da for FA−PEG2000−DSPE (calculated molecular mass of 3200 Da), 4501 Da for FA−PEG3350−DSPE (calculated molecular mass of 4540 Da), and 2400 Da for mPEG−FA (calculated molecular mass of 2423 Da).

HPLC Monitoring of CPG-Mediated Cleavage. An HPLC system, Shimadzu 10 A, equipped with a Phenomenex Prodigy C8 (4.6 mm × 50 mm) column was used at a flow rate of 1 mL/min, while monitoring at a λ of 285 nm. For analysis of FA−PEG−DSPE, the system was used in isocratic mode, with methanol/10 mM sodium phosphate at pH 7.0 (92:8 v/v). The conjugate eluted as a single peak with a retention time of 5.7 min. Analysis of mPEG−FA was performed in a gradient mode, using 10 mM sodium phosphate (pH 7.0) with methanol (0 to 35% over the course of 25 min). The conjugate eluted as a single peak with a retention time of 19.6 min. In both cases, it was possible to follow the enzymatic cleavage of pteroate from the FA moiety of the conjugates by the decrease in the total conjugate peak area. A solution of FA−PEG−DSPE (0.1 mg/mL) was prepared in 150 mM Tris buffer (pH 7.3). An aliquot (10 μL) of this solution was injected into the HPLC system to obtain the time zero peak integration. Enzyme carboxypeptidase G (CPG, Sigma, 1 unit) was added to the FA−PEG−DSPE solution. The resulting solution was incubated at 30 °C, and aliquots (10 μL) were injected into the HPLC system at different time intervals. The rate of enzymatic hydrolysis is rather fast initially, but it slows after incubation for 4 h. Additional 1 unit aliquots of CPG were added to the reaction mixture at 4 and 20 h time points. Data were collected for up to 27 h. Despite the prolonged incubation times and multiple additions of the enzyme, the size of the conjugate peak did not diminish beyond 20% of the initial integration value, indicating that 80% of the FA−PEG−DSPE was γ-carboxyl-linked. The experiment performed with mPEG−FA as a substrate showed that ~90% of the FA residues in this conjugate were γ-carboxyl-linked.

Liposome Preparation. Hydrogenated soybean phosphatidylcholine (HSPC) was from Avanti Polar Lipids (Birmingham, AL), and cholesterol (Chol) was from Sigma (St. Louis, MO); methoxyPEG2000−DSPE (mPEG−DSPE) was prepared as described previously (*35*). Liposomes with six different compositions (molar ratios in parentheses) were tested here: HSPC/Chol/FA−PEG-2000−DSPE (99.5:70:0.5), HSPC/Chol/FA−PEG3350−DSPE (99.5:70:0.5), HSPC/Chol/mPEG−DSPE (99.5:70:0.5), HSPC/Chol/FA−PEG2000−DSPE/mPEG−DSPE (92.5:70:0.5:7), HSPC/Chol/FA−PEG3350−DSPE/mPEG−DSPE (92.5:70:0.5:7), and HSPC/Chol/mPEG−DSPE (92.5:70:7.5). Since all preparations contained HSPC, Chol, and DSPE, we will refer to them by their type of FA−PEG/mPEG content (for a schematic diagram, see Figure 1). All liposome preparations were spiked with a trace amount of [^{3}H]Chol-hexadecyl ether (NEN, Boston, MA). Liposomes were made by hydration at 55−60 °C of either a thin dry lipid film obtained by rotary evaporation of a chloroform/methanol (1:1) lipid solution or a freeze-dried lipid "cake" obtained by lyophilization of a *tert*-butyl alcohol lipid solution. The buffer was 5% dextrose/15 mM Hepes (pH 7.4) at a concentration of 50−100 μmol of PL/mL. The course of hydration was followed by high-pressure extrusion through double-stacked polycarbonate membranes with pore sizes from 1.0 to 0.05 μm using a stainless steel device from Lipex Biomembranes (Vancouver, BC). Liposomes were sterilized by filtration through 0.22 μm cellulose membranes. Liposome characterization included the PL concentration based on phophorus content, the FA concentration based on the UV absorbance of folic acid at 285 nm after liposome disruption in sodium dodecyl sulfate solution (10%), the vesicle size as determined by dynamic laser scattering, and, in some preparations, free fatty acid content to check for PL hydrolysis. All liposome preparations had a mean vesicle size between 70 and 90 nm with a standard deviation of <25% and a unimodal size distribution. PL hydrolysis was not detected in the preparations tested here.

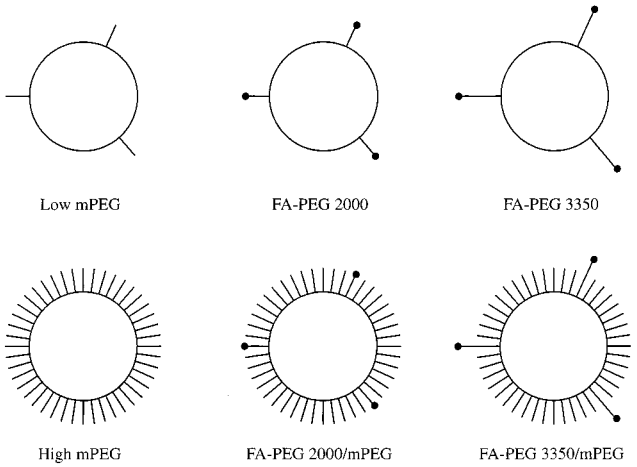

Figure 1. Schematic diagram of the liposome formulations tested in this study emphasizing the presence or absence of FA−PEG−DSPE with a short (PEG2000) or long (PEG3350) spacer arm and the presence or absence of mPEG.

Cell Culture and Binding Studies. *Medium.* Cells were cultured in normal or FA-free RPMI medium (RPMI-1640, Biological Industries, Beyt Haemek, Israel), with 10% fetal bovine serum (GIBCO, Grand Island, NY), 2 mM glutamine, 50 units/mL penicillin, and 50 μg/mL streptomycin. The concentration of FA in the serum-containing FA-free medium is only 3 nM, as opposed to 2.26 μM (1 mg/L) under normal culture conditions. Cells were routinely passed by treatment with a trypsin (0.05%)/EDTA (0.02%) solution in calcium- and magnesium-free phosphate-buffered saline (PBS).

Cell Lines. M109, a murine lung carcinoma line of BALB/c mice (*36*), and a subline of these cells, M109R, displaying multidrug resistance (an approximately 100-fold increased resistance to doxorubicin) were used in most of the experiments. Both cell lines express in vitro low amounts of FA receptors and are therefore referred to as M109-LoFR and M109R-LoFR, respectively. By culturing these cells in FA-free medium for several passages, we obtained two sublines expressing a high amount of FA receptors and adapted to grow under low-FA conditions with generation doubling times similar to the lines of origin. They are referred to as M109-HiFR and M109R-HiFR, respectively, to emphasize the overexpression of folic acid receptors.

KB cells, a human nasopharyngeal epidermal carcinoma (*37*), were also grown in low-FA medium to obtain cells overexpressing folic acid receptors, KB-HiFR cells.

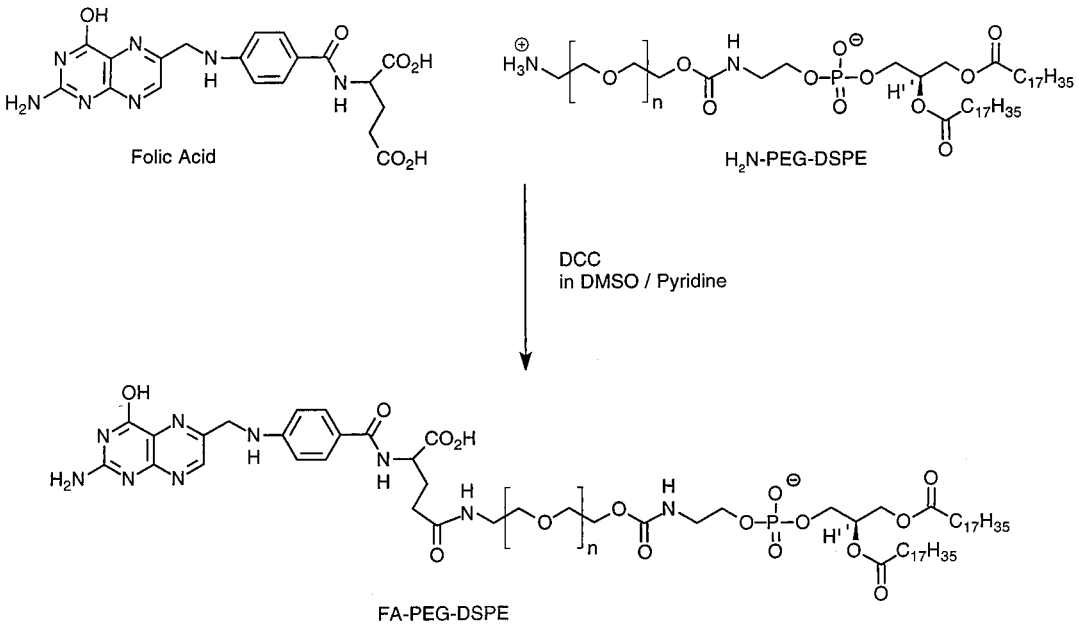

Figure 2. Synthesis of the FA−PEG−DSPE conjugate. Only the structure of the main product, the active γ-carboxyl-linked conjugate, is shown ($n \approx 45$ for PEG2000, $n \approx 76$ for PEG3350).

Other cell lines used in this study are A375, a human melanoma line, and normal human fibroblasts which were kindly provided by the Genetics Department of Hadassah Hebrew University Hospital.

Cell Binding of Free Folate or Liposomes. Binding was assayed through measurement of the level of cell-associated liposomal [^{3}H]Chol or [^{3}H]FA (Amersham, U.K.). Forty-eight hours prior to an assay, 5×10^5 cells were seeded per 35 mm dish, to obtain a concentration of about 10^6 cells/plate. Plates preincubated with medium and serum for 2 days, without cells, were used as controls. For the assays, plates were washed twice with FA-free RPMI medium, and incubated at 37 °C with 1 mL of FA-free RPMI medium containing 0.1 μM radiolabeled FA or liposomes in amounts of 30−300 nmol of PL. After incubation, the plates were rinsed three times with 2 mL of ice-cold PBS, and the radiolabels were extracted with 1 mL of 0.5 N NaOH overnight, followed by neutralization with 1 mL of 0.5 N HCL. To analyze exclusively radioactivity associated with cells, cells were released from plates with the trypsin/EDTA treatment, washed three times with PBS, and then extracted following the same procedure. The amount of radioactivity was determined by liquid scintillation counting. On the basis of the specific ratio of counts per minute per PL for each liposome formulation, the results were translated into picomoles of PL per 1 million cells.

For acid wash treatment following binding, each dish was washed twice with acidified saline (pH 3), followed by washing with PBS, and then the compound extracted as described above.

For treatment of cells with phosphatidylinositol-phospholipase C (PI-PLC), 2-day-old cell monolayers were rinsed twice with FA-free RPMI medium and incubated for 60 min at 37 °C with 0.1 unit/mL PI-PLC (Boehringer, Mannheim, Germany) in 1 mL of FA-free RPMI medium. Each dish was rinsed twice with FA-free RPMI medium and assayed for FA or liposome binding as described above.

In experiments performed with cells in suspension, cells from monolayers were released with the trypsin/EDTA treatment, followed by three washes (7 min, 500*g* centrifugation) in FA-free RPMI medium. The suspended cells ($1-10 \times 10^6$ cells/mL) were incubated with radiolabeled free FA or liposomes (concentration as indicated for each experiment) for 30 min to 24 h in 5 mL plastic tubes. Unbound material was removed by four washes with PBS.

RESULTS

Preparation and Characterization of FA Conjugates. Folate−PEG−DSPE conjugates were prepared, as shown in Figure 2, via a dicyclohexylcarbodiimide-mediated coupling of FA to H_2N-PEG−DSPE. The starting amino-PEG lipids were synthesized from PEG with molecular masses of 2000 and 3350 Da according to the previously described method (*33*). Using the same coupling method, we also prepared the mPEG−FA conjugate. This material represents FA conjugated to PEG with a molecular mass of 2000 Da without the PL moiety. The structures of the purified conjugates were corroborated by ^{1}H NMR, MALDI-TOFMS, and UV analysis. Since carbodiimide-activated FA can couple with H_2N-PEG−DSPE via either α- or γ-carboxyl groups of its glutamate residue, and it is known that only the γ-conjugate is capable of binding to the FR, it was important to determine the relative amounts of each α- and γ-carboxyl-linked conjugate. Our HPLC assay did not separate the two isomeric conjugates. It was previously shown that the α-conjugates of FA are inert with respect to carboxypeptidase G (CPG), while the γ-conjugates are subject to pteroate-glutamate cleavage at an appreciable rate (*18*, *38*, *39*). The enzymatic cleavage was followed by disappearance of the conjugate peak by HPLC. This reaction proceeded up to 80% conversion despite prolonged incubation times and multiple additions of the enzyme, indicating that FA−PEG−DSPE contained 80% γ-linked and the remaining 20% α-linked conjugates. Using the same approach (HPLC followup of CPG cleavage), we determined that ~90% of the mPEG−FA was linked through the γ-carboxyl group. These proportions of α- and γ-products are consistent with the previously reported results obtained with the FA−desferal conjugate synthesized under similar conditions (*18*).

Binding and Uptake of Free FA by M109 and Other Cell Lines. As indicated in Materials and Meth-

Table 1. Binding of Folic Acid to Various Cell Lines in Culture Plates[a]

cell line	folic acid (fmol/10^6 cells)
M109-LoFR	20 ± 6
M109-LoFR[b]	25 ± 13
M109R-LoFR	27 ± 10
M109-HiFR	678 ± 255
M109R-HiFR	2179 ± 430
KB-LoFR	456 ± 79
KB-LoFR[b]	6725 ± 323
KB-HiFR	9730 ± 79
A375	168 ± 33
NHF	45 ± 3

[a] Incubation time of 30 min at 37 °C. [b] After incubation in FA-depleted medium for 24 h.

ods, three of the cell lines tested here (M109, M109R, and KB cells) were induced to upregulate their FA receptors by consecutive passages in FA-depleted medium (3 nM FA). This resulted in three cell sublines referred to as HiFR with a 20−80-fold increase in FA binding capacity compared to those of the parental cell lines, which are known as LoFR (Table 1). We also used normal human fibroblasts in early passage, and a human melanoma line A375, to obtain a spectrum of different cell lines with a broad range of receptor expression levels (Table 1). When the lines with the lowest (M109-LoFR) and highest (KB-HiFR) amount of receptors are compared, differences in FA binding capacity up to 485-fold were observed.

All of the above experiments were carried out with a 30 min incubation with FA at 37 °C in FA-depleted medium. M109-LoFR and KB-LoFR cells were also assayed for FA binding following 24 h of incubation in FA-depleted medium (Table 1). Under these conditions, M109-LoFR did not upregulate the amount of FA binding. In contrast, KB-LoFR showed a 15-fold increase in the level of FA binding, indicating rapid upregulation of receptor expression.

In further experiments used to characterize the binding of FA with the FR-overexpressing M109-HiFR cell line, we made the following observations (data not shown).

(i) The extent of binding is directly proportional to the number of cells in the range of 10^5 to 1.5×10^6 cells/plate.

(ii) Monolayer cultures of M109R-HiFR cells pretreated with PI-PLC lose 99% of their FA receptors, as shown by the binding assay with FA, indicating that the overexpressed FR is bound to the cell membrane by a glycophospholipid anchor. In contrast, trypsin treatment does not damage the FR, as indicated by the fact that (a) radiolabeled FA binds to a similar extent to plated cells and to suspension cells after trypsinization and (b) cell-bound radiolabeled FA is almost fully recovered (91 ± 11%) after trypsinization.

(iii) Only 2 ± 1% of the FA remains bound to M109R-HiFR cell monolayers following acid wash (pH 3), indicating that the binding of FA to the overexpressed receptors is pH-sensitive. To prevent internalization, the FA binding assay took place at ∼1 °C for 30 min. When M109R-HiFR cells were incubated for 4 h at 37 °C with radiolabeled FA, and then submitted to acid wash, 30−40% of the ligand is retained by cells. This is most likely the fraction of FA ligand that is internalized by cells, thus avoiding the pH-induced dissociation from the receptor.

Competition Binding Study with FA, mPEG−FA, and Free PEG. In this experiment, M109R-HiFR cells were exposed to a constant amount of radiolabeled FA at a concentration of 0.1 μM and increasing concentrations of "cold" FA, mPEG−FA, and free PEG (from 0.1 to 100 μM). Both the PEG2000 and mPEG2000−FA used here were freely water-soluble, not lipid-linked, compounds. The latter derivative can be viewed as a monovalent version of FA−PEG2000−liposome as depicted in Figure 1. As seen in Figure 3, mPEG−FA was less effective than free FA in competing with radiolabeled FA, suggesting that the attachment of PEG to the vitamin molecule diminishes by 5−10-fold the extent of binding of FA to the receptor, whereas free PEG did not inhibit binding at all.

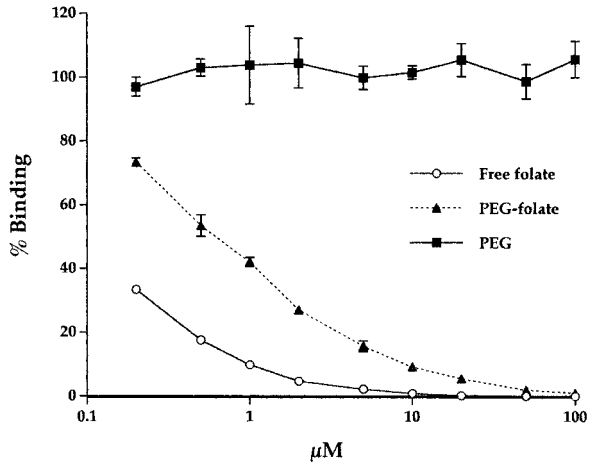

Figure 3. Competition study of binding to cellular folate receptor with free folic acid, free PEG2000, and the mPEG2000−FA conjugate. Radiolabeled FA was added at a concentration of 0.1 μM to M109R-HiFR cell monolayers which were incubated at 37 °C for 30 min with or without the competitors at the concentrations shown.

Enhanced in Vitro Cell Binding of FA-Targeted Liposomes. The liposome formulations tested were as described in Materials and Methods and as schematically depicted in Figure 1. Since the plain (nontargeted) high-mPEG and low-mPEG formulations behaved similarly in vitro, data are presented only for the high-mPEG liposomes which is the formulation with Stealth properties most commonly used in vivo (*1*). Folate-targeted liposomes contained the FA−PEG−DSPE conjugate derived from PEG with a molecular mass of 2000 or 3350 Da at a molar fraction of ∼0.5% of total liposomal PL.

The binding of radiolabeled FA-targeted liposomes and nontargeted liposomes was assayed on monolayer cultures of M109R-HiFR and M109-LoFR cells at 37 °C for 24 h. Figure 4A shows the amounts of liposomes bound to trypsin-released cells, expressed as the amount of PL per 1 million cells. The level of binding of plain mPEG liposomes was very low and similar for both high- and low-FA receptor cell lines. The targeted formulation with the highest binding efficiency was FA−PEG3350 (26-fold increase over that of nontargeted liposomes). Addition of mPEG (7% of PL) to the formulation or shortening of the PEG tether from 3350 to 2000 reduced the level of binding substantially. The level of binding was always greater for M109-HiFR cells than for M109-LoFR cells, regardless of the type of FA-targeted liposome used, although the differences were much less striking than those seen in Table 1 with free FA binding. The highest-affinity liposomal formulation, FA−PEG3500, showed the lowest relative increase of binding (∼30%) when the LoFR and HiFR cells were compared.

Figure 4B presents the results obtained when similar experiments were performed with KB cells. Once again, the addition of mPEG reduced the efficiency of binding,

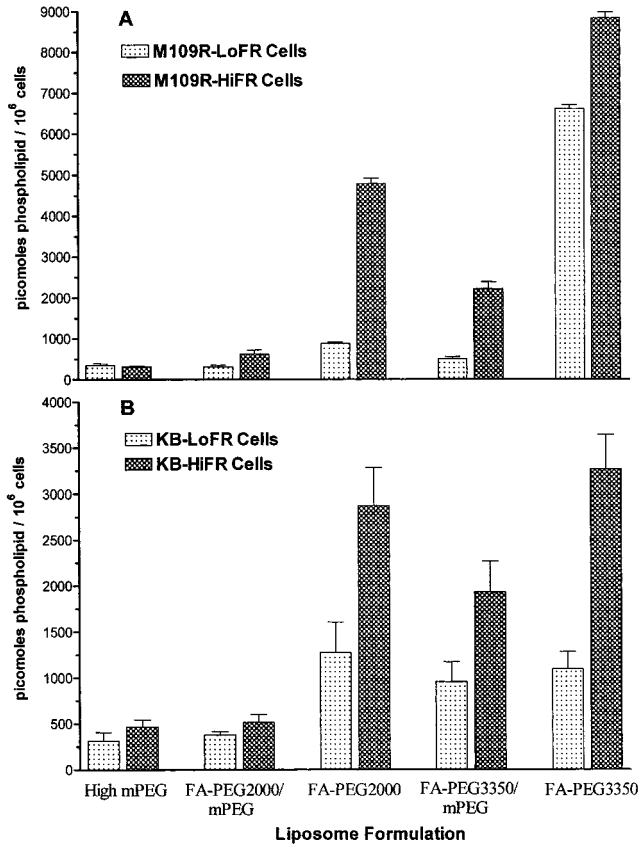

Figure 4. Binding of various FA-bearing and control liposomes to M109-LoFR and M109R-HiFR cells (A) and to KB-LoFR and KB-HiFR cells (B). The results were obtained after incubation for 24 h at 37 °C in the presence of 300 nmol of PL/mL. Cells were seeded 48 h prior to liposome exposure. See Figure 1 for the designation of various liposome formulations.

Table 2. Inhibition of Binding of FA-Bearing Liposomes to M109R-HiFR Cells by Free FA of Acid Wash[a]

	% inhibition	
liposomal formulation	FA−PEG3350	FA−PEG3350/mPEG
1 mM FA at time 0[b]	46 ± 8	86 ± 6
1 mM FA after 24 h[c]	2 ± 3	8 ± 4
acid wash after 24 h[d]	22 ± 2	32 ± 5

[a] M109R-HiFR cells were incubated for 24 h with 300 nmol/mL of FA liposomes. [b] Results obtained after the continuous presence of free folic acid from time 0. [c] Results obtained after folic acid was added for 2 h after incubation for 24 h with liposomes. [d] Results obtained after cells were washed with acid saline (pH 3) after incubation for 24 h with liposomes.

and in the presence of mPEG, FA−PEG3350 was markedly superior to FA−PEG2000. However, when mPEG was absent, the use of the longer PEG spacer did not appreciably increase the level of binding to KB cells. Also, the differences between KB-HiFR and KB-LoFR were in some instances smaller than in the case of M109 cells, a finding related perhaps to the rapid upregulation of FR receptors in KB cells during the 24 h incubation period (Table 1).

Effects of Acid Wash and Competition with FA on Cell Binding and Internalization of FA−PEG Liposomes. To determine if the cell-associated liposomes are cell surface-bound or internalized into cells, an acid wash with saline (pH 3) was performed at the end of the binding assay. The results shown in Table 2 indicate that only 22% of the FA−PEG3350 and 32% of the FA−PEG3350/mPEG liposomes could be removed, which means that more than two-thirds of the cell-associated liposomes have been internalized by M109-HiFR cells. Also shown in Table 2 are results from competition studies with 1 mM folic acid (~700-fold excess compared to the concentration of liposome-bound FA) either at the beginning or at the end of the binding assay. It was found that folic acid only partially inhibits liposome binding, especially when the higher-affinity, mPEG-free liposomes were used. When FA was added at the end of liposome incubation, it was unable to displace any significant amount of FA-bearing liposomes from the cells despite the fact that, according to acid wash experiments, approximately 20−30% of the liposomes were still bound to the cell surface. These experiments demonstrate the greater binding avidity of FA−PEG liposomes over free FA for the cellular FR, which is in contrast to 5−10-fold less efficient binding of the monovalent analogue, mPEG−FA. The stronger binding of FA liposomes is probably related to the multivalent presentation of FA residues on the liposomal platform.

Nonspecific Binding of FA-Targeted Liposomes to Extracellular Components. Unexpectedly, during the course of this study we observed substantial and rapid (within 30 min) binding of FA-presenting liposomes to serum and extracellular components adhered to tissue culture plates. Although most of our investigations on this effect were carried out with the FA−PEG/mPEG liposome formulation (results shown in Table 3), it should be noted that the nonspecific binding to extracellular plate components was observed with FA−PEG liposomes as well.

When binding of free FA to monolayer cultures was assayed by direct extraction from the plates without detaching the cells, the results were similar to those obtained when extraction was performed from trypsin-detached cells; i.e., 92 ± 2% of the total amount of FA bound to the plate was actually cell-associated after incubation for only 30 min. In contrast, after a short incubation time of 30 min, FA-bearing liposomes exhibited a high level of binding to nontrypsinized plates and a minimal level of binding to trypsin-released cells, accounting for only 6 ± 3% of the total counts bound to the nontrypsinized plate. In these experiments, most of the liposomes were released from the plate by trypsin treatment and were found in the cell-free supernatant, indicating that the binding site is extracellular and trypsin-sensitive, in direct contrast to that of cellular FR (data not shown). Moreover, there was no difference in the amounts of binding of FA-targeted liposomes when plates with HiFR and LoFR M109 cells were compared (Table 3). We also observed substantial binding of FA-targeted liposomes to serum-coated, cell-free plates. Plain, nontargeted, liposomes did not adhere to plates or cells under the same conditions (Table 3), indicating that the FA residue of targeted liposomes was responsible for this type of binding.

When the incubation time is prolonged from 30 min to 4 and 24 h, the level of specific cellular binding of FA-targeted liposomes increases gradually while the level of nonspecific extracellular binding remains unchanged or even decreases. At 24 h, FR-mediated cellular binding accounts for 50 to >90% of the total liposome binding to the plate, depending on the type of FA liposome tested.

To determine whether the binding of FA-targeted liposomes to extracellular components of cell culture plates is due to an extracellular FR present in serum and/or shed by cell monolayers, we examined their binding to plates coated with folate binding protein (Sigma), which is the soluble form of the FR. No binding of the FA−PEG/mPEG liposomes was observed, despite the fact

Table 3. Binding of FA-Bearing Liposomes, Control Nontargeted Liposomes, and Free FA to Plates with Serum Components or Monolayer Cell Cultures[a]

plates	liposomes (pmol of PL/plate)		free FA (fmol/plate)
	plain high mPEG	FA−PEG2000/ mPEG	
uncoated, cell-free	7 ± 4	31 ± 4	not detectable
serum-coated, cell-free	8 ± 3	809 ± 72	4 ± 3
laminin-coated, cell-free	3 ± 4	6 ± 8	1 ± 1
folate binding protein-coated, cell-free	6 ± 8	26 ± 12	1034 ± 56
M109-LoFR cells,[b] serum coated	25 ± 13	2564 ± 677	20 ± 6
M109R-HiFR cells,[b] serum coated	22 ± 12	2496 ± 868	2179 ± 430
M109R-HiFR laminin-coated[c]	18 ± 3	25 ± 6	1817 ± 252

[a] In a 35 mm empty plastic dish with incubation for 30 min at 37 °C. Liposome concentration of 30 nmol of PL/mL. [b] Two day monolayer confluent cultures (about 10^6 cells/plate) grown in medium with 10% fetal bovine serum. [c] About 10^6 cells attached to laminin-coated plates for 4 h in serum-free medium.

that free FA binds avidly in the same assay (Table 3). To investigate further the involvement of serum or cell-secreted proteins (unrelated to FR), we used laminin-coated plates. Within 4 h of incubation on laminin-coated plates and serum-free medium, M109-HiFR cells are firmly attached and spread. This enabled us to carry out liposome binding experiments before secreted or shed cellular components accumulate in the extracellular medium, and without the confounding factor of serum proteins. The level of binding of FA-targeted liposomes to laminin-coated plates was extremely low, and equivalent to only about 1% of the amount of binding to the same cell monolayers grown for 48 h with serum (Table 3).

These results support the contention that the extracellular binding component is present in serum and its level increases significantly in the presence of products shed from cell monolayers. The extracellular binding is likely to be related to a nonspecific binding of FA liposomes to proteins of the plate extracellular matrix, perhaps an opsonizing effect due to the recognition of an acidic carboxyl group on the surface of FA-targeted liposomes. This notion is further supported by the observation that free glutamic acid (1 mM) competes effectively with the binding of FA liposomes to the extracellular plasma component, but not with the cellular FR binding (data not shown).

DISCUSSION

The need to develop targeted liposomes with PEG coating is derived from our strategy for liposome targeting to tumors which consists of two steps: an initial step of extravasation into the tumor interstitial fluid based on the "Enhanced Permeability and Retention" effect (*40*) followed by a second step of direct interaction with a receptor on the membrane of tumor cells leading to internalization of liposome contents (*41*). The first step of tumor localization requires liposomes to be long-circulating, stable, and small, probably <100 nm in diameter (*5*), such as a class of PEG-coated liposomes referred to as Stealth (*1*). Extravasation is the rate-limiting step for tumor localization and should not be affected by a small-sized targeting ligand directed to the tumor cell (*14*, *15*). However, once liposomes reach the tumor cell microenvironment, the targeting effect may play an important role in facilitating the intracellular delivery of liposome contents.

The FA receptor has been proposed as a target for cancer drug delivery and immunotherapy (*17*, *31*, *42*, *43*). For liposome-mediated delivery in particular, Lee and Low have pioneered this approach using FA as a ligand attached to the PL bilayer of liposomes through a PEG spacer. Their work with KB cells overexpressing FA receptors has demonstrated the feasibility and efficiency of this targeting system (*10*, *20*, *44*). The advantages of FA-mediated targeting include the small size of the ligand, as opposed to the bulkiness, and potential immunogenicity of proteins (*45*), and the internalization of the ligand−receptor complex which should facilitate intracellular delivery of the therapeutic agent. In addition, FR overexpression is common as the α-isoform in malignant tumors of epithelial origin, and as the *β*-isoform in malignant tumors of nonepithelial origin (*46*), suggesting that this approach can be applied to a wide spectrum of neoplastic diseases. The main concern of FA targeting is the potential damage to normal tissues which generally express low to moderate amounts of the *β*-isoform of FR (*46*, *47*), an issue which needs to be evaluated.

Our approach to the synthesis of PEG−FA conjugates, in particular FA−PEG−DSPE, involved carbodiimide-mediated coupling of FA to readily attainable H_2N-PEG derivatives. This constitutes a cleaner and more straightforward approach to the target conjugates in comparison to the previously published examples (*10*, *20*). We also provide here, for the first time, a complete chemical characterization of these conjugates, including NMR, MALDI-MS, UV, and HPLC-mediated followup analysis of the CPD cleavage. According to these criteria, the conjugate preparations were highly pure (>94%) and contained predominantly (≥80%) the biologically active, *γ*-carboxyl-linked, form of FA. Folate−PEG−DSPE conjugates were incorporated into liposomes with or without additional mPEG−DSPE. As discussed in detail elsewhere (*48*), this method is preferable to conjugation of the ligand to preformed liposome (*10*).

In the experiments reported here, we examined the FA-mediated targeting of liposomes using a similar PEG spacer approach of Lee and Low (*10*, *20*, *44*), although the liposome tracer was different, a radiolabeled nondegradable cholesterol ether molecule which is a component of the liposome bilayer in this study, as opposed to encapsulated calcein or doxorubicin used by Lee and Low. This study demonstrates clearly that coupling of FA to the extremities of PEG chains grafted on liposomes is an effective way of targeting liposomes to tumor cells, especially when these cells overexpress FR, increasing the level of liposome cell binding by 26-fold. This is achieved with only about 100−250 FA−PEG residues per vesicle exterior. The estimated number of vesicles internalized by each tumor cell is very large, in the range of 50000−100000, stressing the potential of this approach for intracellular delivery of large payloads. Of note, the increase in the level of liposome binding and/or targeting is also important in the case of tumor cells not submitted to repeated passages in FA-depleted medium for further overexpressing FR. As a result, HiFR and LoFR M109

cells, which show enormous differences (80-fold, Table 1) with regard to the level of uptake of free FA, differ only by a relatively small factor (1.3−5.4 depending on the PEG tether with or without additional mPEG, Figure 4) when the uptake of FA-bearing liposomes is examined. This cannot be related to a difference in affinity of the respective ligands since mPEG−FA actually shows a lower affinity for the FR than for free FA (Figure 3). One likely explanation of these results is that a large part of the overexpressed receptors plays no essential role in liposome binding (estimated number of receptors per M109-HiFR cell is approximately 1 million). The number of liposomes which can interact with FR-enriched membrane areas in the vicinity of caveolae is physically limited. Once bound, a liposome may encompass an area of the cell membrane in which the number of FR exceeds the number of the liposomal FA residues, therefore rendering a fraction of the FR superfluous. Therefore, under in vitro conditions of liposome excess, an equivalent number of liposomes may bind to cells having a large difference in the number of FR.

Our experiments point at a clear interference of mPEG coating, which is mainly needed to combine extended systemic circulation in vivo with the targeting effect of FA. This interference of mPEG coating was more pronounced with FA−PEG2000−DSPE than with FA−PEG3350−DSPE. The longer arm of the latter ligand probably enables a better interaction with the FR away from the shielding effect of the mPEG2000 coating. The interference of the grafted mPEG with FA−PEG recognition by its receptor was much more marked for M109-HiFR cells than for KB-HiFR cells (4.0- vs 1.7-fold binding inhibition, respectively, using FA−PEG3350−DSPE, Figure 4), suggesting that the cell type is an important factor. This is worth noting in light of the results of Lee and Low (*20*, *44*), who reported equally effective cell binding regardless of the additional mPEG coating, using high-FR-expressing KB cells. In any case, the mPEG−lipid content might be an important variable in determining the liposome cell binding properties.

Recently, Kirpotin et al. (*49*) found that the binding activity of immunoliposomes was negatively affected in a dose-dependent fashion by the actual amount of mPEG present on the liposome surface, but only when the Fab′ ligand was linked to the lipid anchor directly. When the antigen was bound through a PEG spacer, mPEG−lipid content had no effect on the antigen binding activity. Inhibition of receptor binding by mPEG grafted to the same liposome surface as the ligand has been previously reported for cases involving both large, protein-based ligands (*8*, *11*, *49*, *50*) and also small molecules (*51*, *52*). In the current study, for the first time, we observed the negative effect of grafted mPEG on the binding of a PEG-tethered ligand, FA−PEG, even though the length of the PEG tether was equal or even greater than that of the mPEG. This is a somewhat surprising finding, in light of our previous experience with sialyl Lewis X−PEG2000 liposomes (SLX content of 0.5−5 mol %), which exhibited markedly enhanced E-selectin binding with minimal influence of the mPEG2000−DSPE content in the 4.5−0 mol % range (*13*). Furthermore, the FA−PEG binding inhibition caused by grafted mPEG is difficult to rationalize in light of previous measurements of the thickness of the mPEG2000 steric barrier (≤50 Å) (*53*−*55*) and the PEG2000-tethered ligand−receptor interaction range (≈150 Å) (*12*), although the latter measurement was taken in the absence of additional mPEG. Perhaps the explanation lies in the nature of the ligand itself, for example, in its potential to form hydrogen bonds with PEG, thus contributing to the PEG-tethered FA being shielded in the PEG layer surrounding the liposome.

Finally, our observations on the nonspecific binding of FA-targeted liposomes to extracellular components underscore the need for a cautious evaluation of the in vitro binding assays. The in vivo relevance of this nonspecific binding as a factor interfering with specific targeting is still uncertain and needs to be clarified in biodistribution studies of FA-targeted liposomes in tumor-bearing animals.

Duplex Recognition by Oligonucleotides Containing 2′-Deoxy-2′-fluoro-D-arabinose and 2′-Deoxy-2′-fluoro-D-ribose. Intermolecular 2′-OH−Phosphate Contacts versus Sugar Puckering in the Stabilization of Triple-Helical Complexes

Christopher James Wilds and Masad José Damha*

Department of Chemistry, Otto Maass Chemistry Building, McGill University, 801 Sherbrooke Street West, Montreal, Quebec, Canada H3A 2K6. Received September 24, 1998;
Revised Manuscript Received December 1, 1998

To gain insight into the origins of the large binding affinity of RNA toward target duplexes, 2′-deoxy-2′-fluororibonucleic acid (2′F-RNA) and 2′-deoxy-2′-fluoroarabinonucleic acid (2′F-ANA) were tested for their ability to recognize duplex DNA, duplex RNA, and RNA−DNA hybrids. 2′F-RNA, 2′F-ANA, and the corresponding control single-stranded (ss) DNA strands were shown to form triple-helical complexes only with duplex DNA and hybrid DNA (Pu)−RNA (Py), but not with duplex RNA and hybrid RNA (Pu)−DNA (Py). In contrast, an RNA third strand recognized all four possible duplexes (DD, DR, RD, and RR) as previously demonstrated by Roberts and Crothers [(1992) *Science 258*, 1463−1466]. The 2′F-RNA (C3′-endo) strand exhibited significantly reduced affinity for duplexes compared to an unmodified RNA (C3′-endo) strand. These findings are consistent with the intermolecular 2′-OH−phosphate contact mechanism proposed by Escudé et al. [(1993) *Nucleic Acids Res. 24*, 5547−5553], as a ribo 2′-F atom should not interact with a negatively charged phosphate. In addition, they emphasize the role of the 2′-OH ribose as a general recognition and binding determinant of RNA. The 2′-F arabino modification (2′F-ANA, C2′-endo) led to a considerable increase in the binding affinity for duplex DNA, as compared to those of DNA and 2′F-RNA third strands. This is likely to be the result of a greater population of C2′-endo pucker of the 2′F-ANA compared to DNA. The enhancement observed for 2′F-ANA strands toward duplex DNA is comparable to that observed with 2′-OMe RNA. Since 2′F-ANA has been shown to be more resistant to nuclease degradation than DNA, these results are likely to stimulate experimental work on arabinose derivatives in laboratories concerned with targeting DNA sequences in vivo ("antigene" strategy).

INTRODUCTION

The ability of single-stranded (ss) DNA or RNA to hybridize complementary nucleic acids, in a sequence-specific manner, is a fundamental characteristic of these molecules (*1*). The familiar double-helical structure of DNA is a consequence of this type of association (*2*). Of special interest are the hybridization properties of modified nucleic acids because of their potential use as molecular biology probes (*3*), and as chemotherapeutic agents that form double-stranded complexes with target mRNA ("antisense" approach; *4*). Interest in modified oligonucleotides has recently intensified due to the realization that they can be used as "antigene agents" forming intermolecular triplexes with DNA sequence (*5*−*7*). Several nucleic acid triple helices have been characterized, which fall into two distinct classes depending on the orientation of the third strand. In the more common triplex pattern known as the "pyrimidine" (or "parallel") motif, pyrimidine-rich oligonucleotides bind parallel to the purine strand of the target duplex, forming *T*·AT and C^+·GC triplets (*5*−*7*), while in the alternative "purine" (or "antiparallel") triplex motif, purine-rich third strands bind in an antiparallel orientation, generating *G*·GC, *A*·AT, and *T*·AT triads (*8*, *9*).

Investigations from several laboratories have established that the chemical nature of the sugar rings has a dramatic influence on the stability of triplexes (*10*−*13*). For example, in pyrimidine motif triplexes, a more stable triplex is formed when the third strand is RNA rather than DNA. In addition, a third RNA strand forms a stable triplex with all duplex combinations (i.e., DD, DR, RD, and RR, where the first letter represents the purine strand and the second the pyrimidine strand), whereas a third DNA strand forms a stable triplex only with DD and DR duplexes. The structural basis for these effects is unknown. Possible explanations include (a) a specific intermolecular contact of the 2′-OH group of the RNA third strand with proximal phosphate groups of the underlying Watson−Crick duplex (*12*) and (b) different sugar puckering forms of RNA and DNA (*5*, *14*). Thus, with some exceptions, the DNA sugars generally assume a C2′-endo conformation, while RNA sugars generally assume a C3′-endo conformation (*1*). Interestingly, these puckering modes seem to prevail in triple-helical complexes. For example, C2′-endo sugars are mainly observed in triple helices formed with a DNA strand, while C3′-endo sugars are mainly found in triple helices containing an RNA third strand (*15*−*17*).

Cuenoud and co-workers examined recently the properties of 2′-*O*-alkylamino RNA with regard to binding to duplex DNA, and found that this modification led to a considerable increase in the binding affinity compared

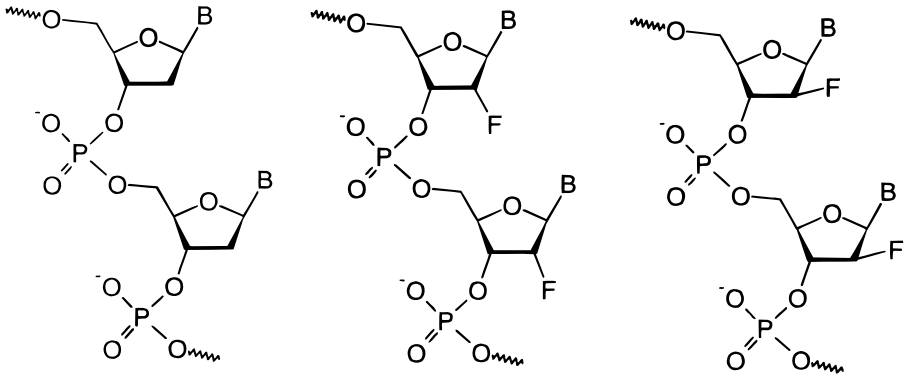

Figure 1. Structures of DNA, 2′-deoxy-2′-fluororibonucleic acid (*R*′, **1**), and 2′-deoxy-2′-fluoroarabinonucleic acid (*A*′, **2**) strands.

to that of an unmodified DNA third strand (*18*). While these findings are consistent with the proposed intermolecular OH−phosphate contact (i.e., a 2′-*O*-alkyl-NH_3^+−phosphate interaction should be stronger than a 2′-OH−phosphate interaction), they do not rule out mechanism b. The sugar conformation of 2′-*O*-alkylamino RNA is unknown, as is its ability to associate with duplex DR, RD, and RR. Our laboratory has recently reported on arabinonucleic acids (ANA), the 2′-epimer of RNA, with regard to triplex formation (*14*). The inversion of configuration at the 2′-stereocenter led to a significant decrease in the binding affinity compared to that of the RNA third strand. Moreover, the ANA strand was able to hybridize only to DD and DR duplexes, and not to RD and RR duplexes. Thus, in terms of binding properties, ANA mimics DNA, not RNA. Since the loss of stability may be due to the disruption of the 2′-OH−phosphate contact, and/or a change in the sugar conformation to C2′-endo (observed often in arabinonucleotide residues; *14*, and references therein), it is difficult to ascertain the nature of the observed effects. It is important to understand the role that sugar conformation has on triplex stability so that puckering and intermolecular contact effects can be distinguished from one another. A thorough understanding of these factors is crucial for the design of future generation oligonucleotide analogues.

To help identify the role played by sugar conformation, we have examined the properties of 2′-deoxy-2′-fluororibonucleic acids (2′F-RNA, **1**) and 2′-deoxy-2′-fluoroarabinonucleic acid (2′F-ANA, **2**) with regard to triplex formation (Figure 1). Since 2′F-RNA lacks the protic 2′-OH group and its puckering is C3′-endo, like that of natural RNA, it provides a unique opportunity to clarify the stabilizing influence of RNA strands on triple-helical complexes. The 2′F-arabino modification should stabilize the C2′-endo form (*14*, *19*) and thus serves as a reference point for evaluating the importance of sugar puckering (C3′-endo vs C2′-endo) in the stabilization of triple helices (Figure 2). Our results are described below.

EXPERIMENTAL PROCEDURES

General Methods. Molar extinction coefficients for oligonucleotides were calculated from those of the mononucleotides and dinucleotides according to nearest-neighboring approximations (*20*). The values for the hybrid hairpins were assumed to be the sum of their D and R components: DD, 26.5; DR, 27.1; RD, 26.7; RR, 27.7; *D*, 9.1; and *R*, 9.6 ($\times 10^4$ M^{-1} cm^{-1}). Molar extinction coefficients for 2′F-ANA and 2′F-RNA strands (*A*′ and *R*′) were assumed to be the same as that of the corresponding DNA strand (9.1 $\times$ 10^4 M^{-1} cm^{-1}). Complexes were prepared by mixing equimolar amounts of interacting strands, e.g., *R*′ and hairpin DD, and lyophilizing the resulting mixture to dryness. The resulting pellet was then redissolved in the buffer. The solutions were at a concentration of 2 μM in each strand, with 100 mM NaOAc and 1 mM EDTA (pH 5.5). The solutions were then heated to 80 °C for 15 min, cooled slowly to room temperature, and stored at 4 °C overnight before measurements were taken. Melting curves were determined using a Varian Cary model 1 UV spectrophotometer equipped with a Peltier temperature programmer for automatically increasing the temperature at a rate of 0.5 °C/min. Melting temperatures (T_m) were calculated from the first derivative of the melting curves. Gel electrophoresis (mobility shift assays) and CD measurements were carried out as described previously (*14*).

Oligonucleotide Synthesis. 1′-(2-Deoxy-2-fluoro-β-D-arabinofuranosyl)thymine (2′F-aT) and 1′-(2-deoxy-2-fluoro-β-D-arabinofuranosyl)cytosine (2′F-aC) were synthesized according to published procedures (*21*, *22*). They were elaborated to the 5′-*O*-(4-monomethoxytrityl)-3′-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite derivatives of 2′F-aT and 2′F-aC(N^4-Bz) according to literature procedures (*23*). 1′-(2′-Deoxy-2′-fluoro-β-D-ribofuranosyl)-thymine (2′F-rT) and its 5′-*O*-(4,4′-dimethoxytrityl)-3′-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite derivative were a gift from Y. Sanghvi (Isis Pharmaceuticals) (*24*). The β-anomeric configuration of these nucleoside derivatives was established with two-dimensional nuclear Overhauser effect (nOe) experiments (NOESY). For example, the NOESY spectrum of 2′F-rT displayed both H2′/H6 (moderate) and H3′/H6 (strong) correlations, as expected, whereas only the H3′/H6 correlation was observed with 2′F-aT. Also consistent with the β-configuration at the glycosidic bond is the observation of nOes between H4′ and H1′ for both 2′F-rT and 2′F-aT (data not shown). 5′-*O*-(4,4′-Dimethoxytrityl)-2′F-rC(N^4-Bz) 3′-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite was purchased from Glen Research (Sterling, VA).

Oligonucleotides 2′F-RNA (*R*′) and 2′F-ANA (*A*′) were synthesized on an Applied Biosystems 381A synthesizer using slight modifications of our published protocols (*14*). Couplings proceeded in good yields (>90%) as judged by the trityl assay. The oligomers were isolated by polyacrylamide gel electrophoresis (PAGE) followed by gel filtration (desalting) on a Sephadex G-25 column (*23*).

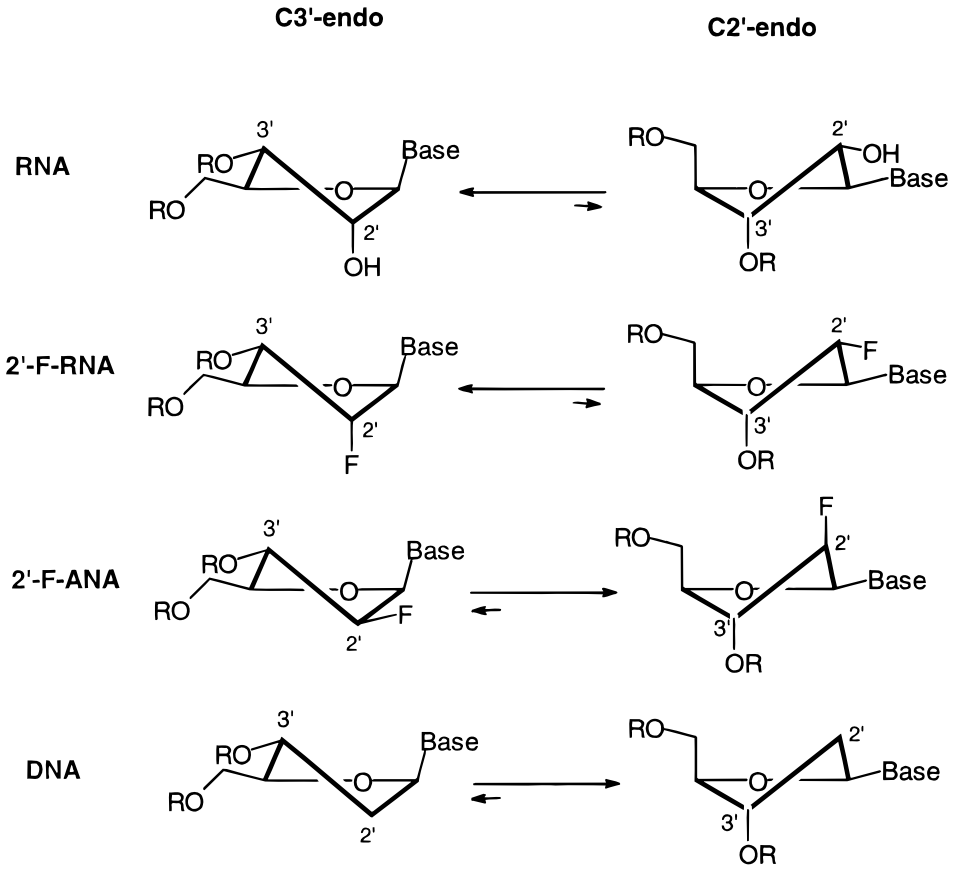

Figure 2. Sugar puckering conformational equilibrium for RNA, 2′F-RNA, 2′F-ANA, and DNA. In the most stable conformations of 2′F-RNA (C3′-endo) and 2′F-ANA (C2′-endo), the 2′-F atom is pseudoaxial and gauche with respect to ring oxygen O4′ ("gauche effect").

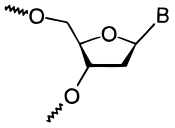
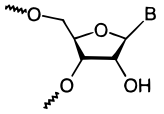
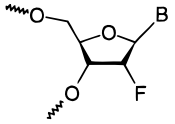
Isolated yields were 10−20 A_{260} units (ca. 1 mg). The isolated product gave satisfactory MALDI-TOF mass spectra (*A′*, calcd M^+ 3682.5, found M^+ 3681.7; *R′*, calcd M^+ 3682.5, found M^+ 3681.3). The hairpin duplexes DR, RD, and RR and the control strand *R* were synthesized according to the method of Damha and Ogilvie (*23*). The DD hairpin and *D* sequence were obtained commercially.

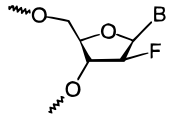
RESULTS AND DISCUSSION

Experimental Design. Experiments were carried out with polypyrimidines *R′* and *A′* and hairpin target duplexes having all four possible duplex combinations with each of the two duplex strands composed of either DNA or RNA (i.e., DD, DR, RD, and RR; Figure 3). The known DNA (*D*) and RNA (*R*) third strands served as controls. This experimental design was selected since Roberts and Crothers had used it successfully in analyzing the effects of the DNA and RNA composition of pyrimidine motif triple helices (*10*). Triple helix formation was monitored via native gel electrophoresis (*25*; Figure 4A,B) and CD (*10*; Figure 5A,B), whereas the melting behavior of complexes was assessed by obtaining UV melt curves (Figure 6A,B and Table 1).









As previously demonstrated (*10*), the RNA (*R*) third strand formed a triple-helical complex with all four duplexes, whereas the DNA (*D*) strand formed a triplex only with duplex DD and DR. This was indicated by the presence of two transitions in the absorbance versus temperature profile of single stands and duplex mixtures (e.g., *D* + DD and *R* + DD; see Figure 6). The low-temperature transition corresponds to dissociation of the third strand from the target duplexes, whereas the high-temperature transition corresponds to the melting of the

Figure 3. Base sequence of hairpin duplexes (DD, DR, RD, and RR) and third strands (D, R, *A′*, and *R′*) selected for study. DNA sequences are shown in bold.

hairpin duplexes (*10*). These assignments are based upon the observations that the low-temperature transition disappears at neutral pH (due to destabilization of C^+·GC triads), and the fact that only the high-temperature transition is observed when a solution of duplex alone was heated under identical conditions. These results were confirmed by native polyacrylamide gel electrophoresis and CD (data not shown).

Table 1

third strand		Δ T_m / triad	
type	structure	DD target	DR target
DNA		0	0
RNA		+ 1.8	+ 2.8
2'F-RNA		- 0.3	+0.4
2'F-ANA		+ 0.8	+ 0.7

2′F-RNA (*R*′) versus RNA (*R*) as a Third Strand. The CD spectra of a 1:1 mixture (5 °C) of *R*′ and DD and of *R* and DD are quite similar in the region of 240−320 nm, suggesting that *R*′ and DD and *R* and DD triplexes have similar helical conformations (Figure 6A). This was also true for the CD spectra of *R*′ and DR and of *R* and DR (Figure 6B). The differences are mainly located in the region around 280 nm, where the (+) band of the *R*′ triplexes is blue shifted and greater in magnitude than that observed for the *R* triplexes.

If the 2′-OH groups of RNA (*R*) third strands were indeed positioned to interact specifically with nearby phosphate groups, one might expect that replacing the 2′-OH group with a 2′-F group would destabilize the triplex. If puckering was the most important effect, however, one may actually observe stabilization of the complex since the C3′-endo sugar population of 2′F-RNA (*R*′) is larger than that of RNA (*26*). Thermal dissociation data for the triplex formed from *R*′ and DD and *R*′ and DR in fact support the proposed intermolecular contact, since the ribo 2′-F modification significantly reduced the affinity of *R*′ for the duplexes to a level similar to that of the DNA third strand (Table 1). For example, the temperature at which *R*′ dissociates from duplex DD is only 36 °C, a value significantly lower than that observed for the *R* strand (62 °C). Also significant is the finding that *R*′, like *D* strands (and unlike *R* strands), is unable to form a stable triplex with RD and RR (Figure 4A). We conclude that the 2′-OH ribose group, not the C3′-endo pucker of third strands, is essential for the formation of *R* and RD and *R* and RR triple helices.

2′F-ANA (*A*′) versus DNA (D) as a Third Strand. As shown in Table 1, the 2′-F arabino sugar modification (C2′-endo) led to an increase in the binding affinity compared to that of the unmodified DNA (C2′-endo), although the magnitude of the effect was smaller than that observed for RNA (*R*). It is also worth noting that *A*′ strands and 2′-O-methylated RNA display comparable triplex binding enhancement with respect to *D* third strands (*15*, *18*, *27*). The higher affinity of 2′F-ANA (*A*′) compared to *D* for DD and DR duplexes is consistent with expectations of a more preorganized state (higher percentage of C2′-endo population) of the *A*′ strand relative

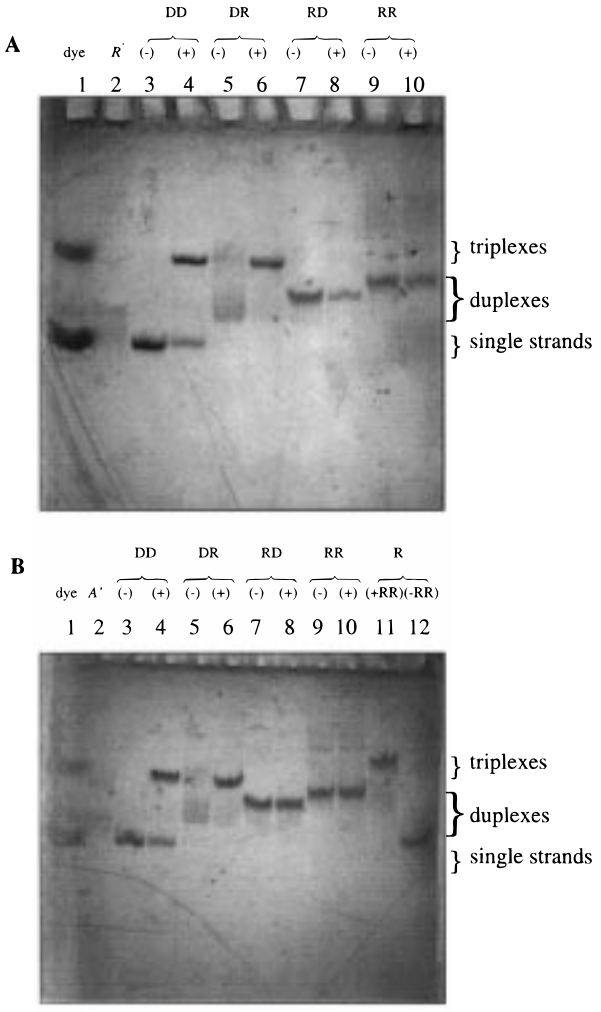


Figure 4. Gel shift mobility assay under nondenaturing conditions, with 20% polyacrylamide at 4 °C and pH 5.0. The marker dyes are xylene cyanol (XC) and bromophenol blue (BPB). Hairpins either alone (−) or in the presence (+) of 2′F-RNA (A) or 2′F-ANA (B) are indicated. Evidence of the formation of the control triplex R·RR is seen in lane 11 of Figure 4B.

to the *D* strand (*14*, *19*), whereas the stabilizing effect seen for 2′-OMe RNA is most likely hydrophobic in nature (*15*, *27*).

Also shown in Figure 5 (panels C and D) are the CD spectra of 1:1 mixtures of *A*′ and DD and of *A*′ and DR at 5 °C, along with the spectra of the control *D* and DD and *D* and DR mixtures. The spectra of the triplexes containing *A*′ strands are characterized by (+) bands that are blue-shifted relative to the *D* triplexes. In the case of *A*′ and DR, the CD spectrum is dominated by a very large molar ellipticity of the (+) band (e.g., compared to the CD spectra of *A*′ and DR and *D* and DR; Figure 5D) which may be attributed to a more effective $\pi-\pi$ overlap of the base triplets.

As in the case for *D* strands, only triplexes derived from *A*′ and DD and from *A*′ and DR, but not from *A*′ and RR and *A*′ and RD, were observed (Figure 4B). Thus, the entropic advantage exhibited by *A*′ strands over *D* strands is not sufficient to effect binding to RR or RD under the conditions used. In the case for the two triplexes that do not form (*A*′ and RD and *A*′ and RR), only the transition corresponding to the self-association of the *A*′ strand ($T_m \simeq 44$ °C) is seen at low temperatures (data not shown). This self-associating structure of *A*′ is evident because of the presence of numerous bands in a

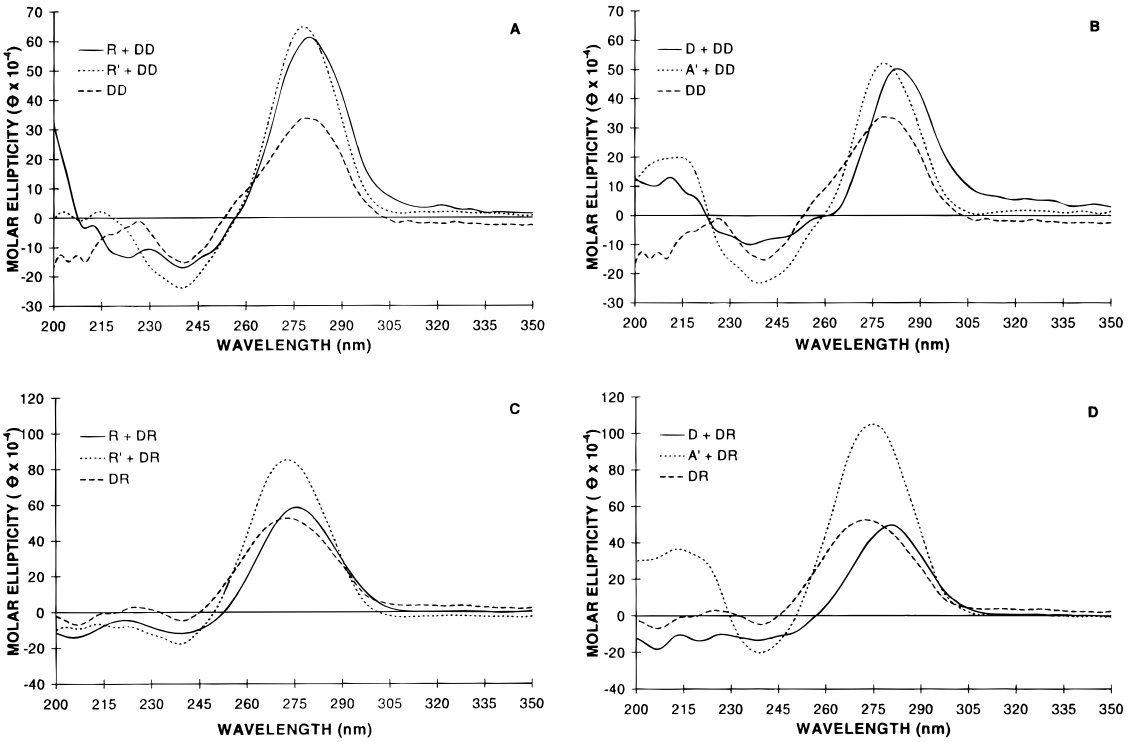

Figure 5. (A−D) Circular dichroism (CD) of hairpin duplexes and triple-helical complexes. The concentration is 2 μM in each strand, and the buffer is 100 mM sodium acetate and 1 mM EDTA (pH 5.5).

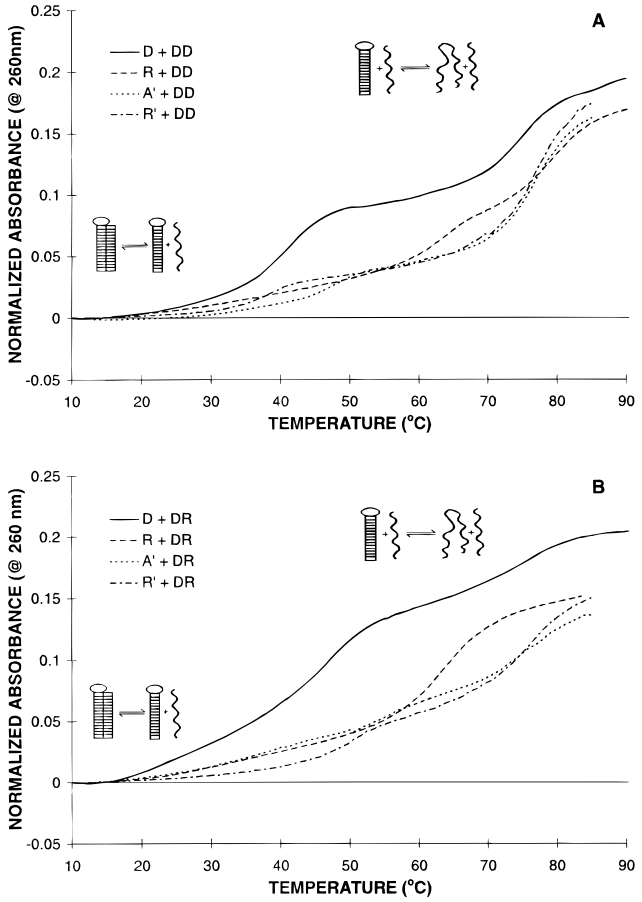

Figure 6. (A and B) Ultraviolet (UV) melting curves of complexes (2 μM) in 100 mM sodium acetate and 1 mM EDTA (pH 5.5). The cartoons indicate the transition from triplex to duplex plus third strand, and from the latter to completely dissociated complexes.

gel run under nondenaturing conditions (e.g., Figures 4B and 7B). This property is shared with the corresponding *D* (*10*), ANA (*16*), and 2′F-RNA strands, but not with RNA or 2′,5′-linked RNA (*28*) strands which appear as a single, well-defined band under the same conditions. The self-associating structures of *D* and other deoxycytidine-rich sequences have been described in detail (*10*, *29*), and are believed to be complexes in which the cytosines are base paired ($C{\cdot}C^+$).

SUMMARY

Our findings are consistent with the work of Escudé and co-workers, who proposed that interactions between the 2′-hydroxyl group of an RNA third strand and the phosphates of the polypurine strand play an important role in determining the relative stabilities of pyrimidine motif triple-helical complexes (*12*). In addition, they emphasize the role of the 2′-OH ribose as a general recognition and binding determinant of ribonucleic acids. An important observation made from this study was that 2′F-ANA shows considerable binding affinity for duplex DNA, relative to DNA and 2′F-RNA third strands. Since 2′F-ANA (*30*) and ANA (*31*) elicit RNaseH activity when bound to single-stranded RNA (*32*) and bind to duplex DNA (this work and ref *14*), our results are likely to stimulate experimental work on arabinose derivatives in laboratories concerned with targeting DNA and RNA sequences in vivo (antigene and antisense strategies).

ACKNOWLEDGMENT

This research was supported by a grant from the National Science and Engineering Council of Canada (NSERC-Strategic Program). We also gratefully acknowledge postgraduate scholarships from NSERC and FCAR to C.J.W. We also thank the referees for thoughtful criticism and suggestions, and A. Noronha for assistance in experiments and in preparing the manuscript. The

TECHNICAL NOTES

Quantitative Analysis of Derivatized Proteins Prepared with Pyridyl Disulfide-Containing Cross-Linkers by High-Performance Liquid Chromatography

Dong Hee Na, Byung Ho Woo, and Kang Choon Lee*

Drug Targeting Laboratory, College of Pharmacy, SungKyunKwan University, 300 Chonchon-dong, Jangan-ku, Suwon City 440-746, Korea. Received March 11, 1998; Revised Manuscript Received November 30, 1998

Determination of the introduced moieties into derivatized proteins is an essential step in the preparation and quality control of chemically defined immunoconjugates. For the derivatized proteins using pyridyl disulfide-containing cross-linkers such as *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) and 4-succinimidyloxycarbonyl-α-methyl-α-(2-pyridyldithio)toluene (SMPT), the derivatization degree (ratio of pyridyl disulfide moieties to protein) has been traditionally determined by measuring the absorbance of both the derivatized protein and 2-thiopyridone (2-TP) released from the dithiothreitol (DTT) treatment (spectrophotometric method). This method, however, causes several problems including false high and low determinations of the protein and 2-TP, respectively, low selectivity, poor reproducibility, and relatively large amounts of sample consumption. A quantitative determination method of the derivatization ratios using bovine serum albumin derivatized with SPDP and SMPT as the model system has been developed. The concentration of protein and 2-TP released from the DTT treatment of derivatized proteins was determined directly without consideration of different reagents used and their concentrations. The present HPLC method was proved to be better in terms of accuracy, selectivity, and reproducibility with micro sample consumption. Moreover, this HPLC method can be directly applied to all derivatized proteins prepared with pyridyl disulfide-containing cross-linkers.

INTRODUCTION

The majority of immunoconjugates including immunotoxins consisting of monoclonal antibody and toxin have been synthesized according to chemical methods with cleavable heterobifunctional cross-linkers (*1*−*4*). A major concern in immunoconjugate research is the synthesis and testing of the heterogeneous mixture without proper separation and characterization of the chemically defined immunoconjugates. Recently, there is increasing interest among pharmaceutical scientists in developing specific and reproducible chemical methods in the preparation of immunotoxins and appropriate controls and validatable assays (*5*). Determination of the introduced moieties into the protein derivatized with cross-linkers is therefore an essential step in the preparation and quality control of chemically defined immunoconjugates (*6*−*7*).

The derivatization degree (ratio of pyridyl disulfide moieties to protein) of the derivatized proteins prepared with pyridyl disulfide-containing cross-linkers (*8*−*20*) has been traditionally determined by using the spectrophotometric method (SP method), which measures the absorbances of both protein derivatized and 2-thiopyridone (2-TP) released from the derivatized protein by reaction with dithiothreitol (DTT) at 280 and 343 nm, respectively (*8*). This method, although simple, raises several concerns including false high or low determination of the protein and 2-TP concentration, respectively, low selectivity, and poor reproducibility due to the spectral interference of the introduced moieties (*9*, *10*). In addition, it requires a large amount of sample consumption. Furthermore, this method has not been modified appropriately for all of the derivatized proteins prepared from different cross-linkers. Pyridyl disulfide moieties of the derivatized protein from different cross-linkers, for example, (2-pyridyldithio)-propionate (PP) from *N*-succinimidyl 3-(2-pyridyldithio)-propionate (SPDP) and α-methyl-α-(2-pyridyldithio)-toluene (MPT) from 4-succinimidyloxycarbonyl-α-methyl-α-(2-pyridyldithio)toluene (SMPT), have their own absorbance at 280 nm (A_{280}) in addition to protein. Therefore, these moieties may exert different effects on the A_{280} in protein assay (*8*, *9*).

In this study, we developed a quantitative determination method of the derivatization ratios of protein modified with pyridyl disulfide-containing heterobifunctional cross-linkers by measuring the protein and 2-TP using size exclusion and C-18 reversed phase HPLC, respectively. This new HPLC method was compared with the SP method using bovine serum albumin (BSA) derivatized with SPDP and SMPT as the model system.

MATERIALS AND METHODS

Materials. BSA (fraction V) and DTT were obtained from Sigma (St. Louis, MO). BSA was further purified by using a Sephadex G-100 column, and the purified fraction (MW 66000) was used. SPDP and SMPT were purchased from Pierce (Rockford, IL). 2-Thiopyridone (2-

Published on Web 02/17/1999

mercaptopyridine) was obtained from Aldrich (Milwaukee, WI), and HPLC grade methanol was purchased from J. T. Baker (Phillipsburg, NJ). All other materials were of reagent grade.

BSA Conjugation with SPDP and SMPT. Each of 0−16 molar excess of SPDP or SMPT solutions (20 mM in dimethyl sulfoxide) was added to 1 mL of BSA (5×10^{-2} mM) in 10 mM phosphate buffer containing 0.15 M NaCl (PBS, pH 7.4). The reaction mixtures were incubated for 30 min at room temperature, and the excess of reagent was then removed by gel filtration on a Sephadex G-25 column (Sigma) equilibrated with PBS. Fractions with an absorbance >1.0 at 280 nm (~8 mL) were collected and used in the assay. The derivatization ratio was determined by measuring the concentration of both BSA and 2-TP released by DTT treatment of the derivatized BSA using both the SP and HPLC methods described below.

SP Method. This method was performed as described previously (*8*). In brief, BSA concentration was determined by measuring the A_{280} using a Spectronic 1201 UV−vis spectrophotometer (Milton Roy, Rochester, NY). The amount of pyridyl disulfide moiety (PP or MPT) in the derivatized BSA was determined by measuring the absorbance of 2-TP at 343 nm (A_{343}), which was released by adding 20 μL of 1 M DTT in deionized water to the derivatized BSA solution (980 μL) after 1 h of incubation at room temperature. The molar concentration of 2-TP was calculated using its molar extinction coeffcient $E_{343} = 8.08 \times 10^3\ M^{-1}\ cm^{-1}$ (*21*). In the determination of the molar concentration of BSA, an erroneously high BSA concentration due to pyridyl disulfide moieties was corrected by subtracting the A_{280} contribution of the pyridyl disulfide moieties (2-pyridyl disulfide structure) in the derivatized BSA from the total A_{280} using the equation

$$\text{pyridyl disulfide moieties/1 molecule of BSA} = A_{343} \times 40.3/(A_{280} \times 8.08 - A_{343} \times 5.10) \quad \text{(a)}$$

The molar extinction coefficient of BSA at 280 nm was measured as $E_{280} = 4.03 \times 10^4\ M^{-1}\ cm^{-1}$ using purified BSA described under Materials. E_{280} of pyridyl disulfide moiety (PP or MPT) in the derivatized BSA was adopted as used previously without correction as $E_{280} = 5.10 \times 10^3\ M^{-1}\ cm^{-1}$ (*8*, *9*, *11*, *19*, *21*).

HPLC Method. The concentration of BSA of the derivatized BSA was determined by a size exclusion HPLC using a BIOSEP SEC-S2000 column (300 × 7.8 mm, Phenomenex). PBS (pH 7.4) was used as a mobile phase, and the flow rate was 1 mL/min. Each 20 μL of standard and sample solutions was injected onto the HPLC, and the effluent was detected at 215 nm. The concentration of 2-TP released from the derivatized BSA solution by DTT treatment was determined by a reversed phase HPLC using a LiChrospher 100 RP-18 column (125 × 4.0 mm, 5 μm, Merck, Darmstadt, Germany) at 343 nm. The mobile phase was composed of distilled water with a linear gradient of 0−30% (v/v) methanol for 10 min. The flow rate of the mobile phase and the injection volume were 1 mL/min and 20 μL, respectively. A Gynkotek HPLC system with model 480 pumps, a model GINA50 autosampler, a model UVD340S photodiode array detector and Gynkosoft (Gynkotek, Munich, Germany) was adopted.

RESULTS AND DISCUSSION

The important point of the required and ideal characteristics of immunotoxin conjugates is that the cross-linking process must minimize the deactivation and polymerization of both the antibody and toxin. In general, the chemistry of bioconjugation gives rise to various structures, resulting in a heterogeneous population of products that are difficult to separate from each other (*5*, *22*, *23*). These products usually consist of a major component containing equimolar amounts of antibody and toxin and several other conjugates with two or more toxin molecules per molecule of antibody. This heterogeneity results from the introduction of varying numbers of derivatized moieties per molecule of antibody (*24*). Due to the nature of the chemical reaction between the *N*-succinimidyl or hydrazide groups of the cross-linkers and the primary amino or carbohydrate groups of the antibody, the populations of antibody molecules substituted with none, one, two, three, and more than three pyridyl disulfide groups are obtained and the microenvironment of the protein attached linker will most likely affect the conjugation of antibody with toxin. Thus, it is very important to reproducibly determine the extent of derivatization exactly.

To determine the derivatization degrees of modified proteins by cross-linkers, both protein and pyridyl disulfide moieties of derivatized proteins must be assayed precisely. Determination of protein by measuring A_{280} adopted in the SP method is not strictly quantitative and is fairly adequate for crude protein mixtures, because this assay is based on the strong absorbance of tyrosine, phenylalanine, and tryptophan residues. Different proteins may therefore have widely varying molar extinction coefficients, and the absorbance must be partially corrected for interfering substances in the range of 0.2−2 mg/mL (*25*). Because all of the pyridyl disulfide moieties of derivatized proteins have their own A_{280} values, an erroneously high protein concentration is obtained when calculation is done on the basis of absorbance at 280 nm.

For the SPDP-derivatized BSA, the additional A_{280} by the pyridyl disulfide moieties has been calculated using the molar extinction coefficients of the PP moiety in derivatized BSA at 280 nm ($E_{280} = 5.10 \times 10^3\ M^{-1}\ cm^{-1}$). This E_{280} value of the PP moiety in the derivatized protein is not a measured value but a calculated value from the absorbance of SPDP or 2,2′-dipyridyl disulfide (2-Py-S−S-Py) (*8*, *21*). This means that the SP method must be validated and confirmed by the experimental method. Also, the SP method has not been modified adequately for different derivatized proteins prepared from different cross-linkers. Different pyridyl disulfide moieties of the derivatized proteins are obtained depending upon the cross-linkers used, for example, (2-pyridyldithio)propionate (PP) from SPDP and α-methyl-α-(2-pyridyldithio)-toluene (MPT) from SMPT. Therefore, if the concentration of BSA of the SMPT-derivatized BSA is determined in the same manner as in SPDP derivatization, false high protein concentrations may result due to differences in the contribution of A_{280} between PP from SPDP and MPT from SMPT (*9*, *11*, *19*).

To assess the effect of the introduced moiety on the A_{280} value of derivatized BSA, the absorbance of each derivatized BSA prepared from different ratios of cross-linkers to BSA and fractionated by size exclusion HPLC was measured using the SP method. Higher ratios of the cross-linker to BSA resulted in higher A_{280} (data not shown). In the case of SMPT derivatization, the additional absorbance from pyridyl disulfide moieties introduced was higher than that of SPDP derivatization, resulting from the methyl toluene moiety in addition to the PP moiety. Therefore, specific equations for different

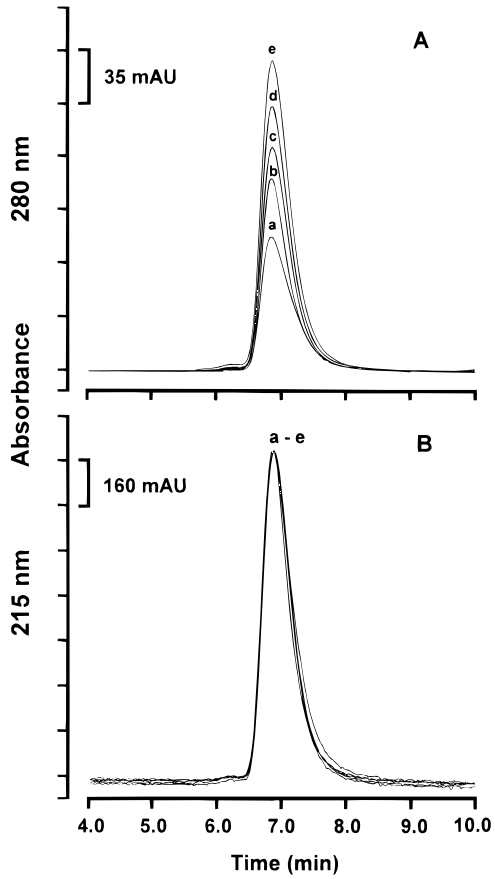

Figure 1. Size exclusion HPLC chromatograms of SPDP-derivatized BSA prepared from 0 to 8.7 molar excess of SPDP: (A) 280 nm detection; (B) 215 nm detection; (a) underivatized BSA; (b−e) SPDP-derivatized BSA (SPDP/BSA molar ratio: b, 1:1; c, 2.6:1; d, 5.0:1; e, 8.7:1).

derivatized proteins must be confirmed to determine the accurate derivatization ratios.

In the HPLC method, the detection wavelength was set at 215 nm, which was sensitive to the peptide bonds. To determine the effect of the pyridyl disulfide moiety on the detection wavelengths, the HPLC chromatograms obtained at both wavelengths of 215 and 280 nm were compared (Figure 1). In contrast to the increased absorbance as a result of increased concentration of cross-linkers at 280 nm, no additional absorbance of the introduced moieties into the derivatized protein was observed at 215 nm. This means that no correction is needed to measure the protein concentration regardless of the cross-linkers and reaction conditions used. Therefore, this HPLC method may be applied to all of the derivatized proteins prepared with pyridyl disulfide-containing cross-linkers. In addition, the detection sensitivity of protein at 215 nm was 13 times higher than that at 280 nm. From the HPLC method, the correlation coefficient of the detector linearity was found to be >0.999 over the concentration range 1.5−15.2 μM in 10 mM PBS (pH 7.4)

The introduced moieties, PP from SPDP and MPT from SMPT, have been routinely quantitated by measuring the difference in the absorbance before and after DTT treatment of derivatized proteins at 343 nm using the molar extinction coefficient $E_{343} = 8.08 \times 10^3\ M^{-1}\ cm^{-1}$ without separation of 2-TP from the reaction solution. However, it is laborious to obtain reproducible data because the value of A_{343} of 2-TP is variable depending upon the reaction conditions, for example, pH, reagents used and

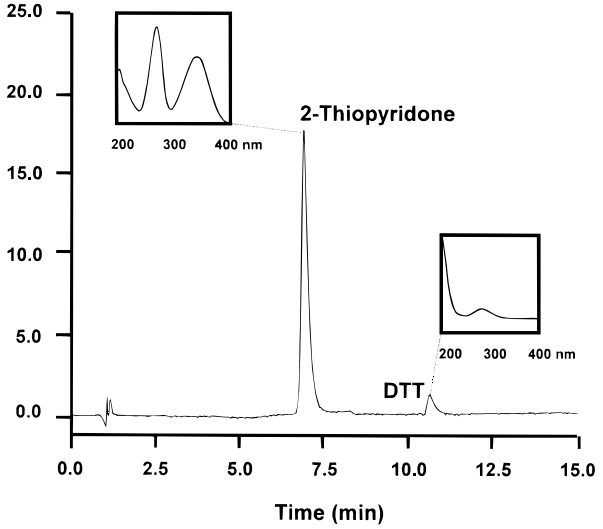

Figure 2. Reversed phase HPLC chromatogram of SPDP-derivatized BSA treated with DTT at 343 nm and the identification of the peak by photodiode array detection: (Insets) absorbance curves of 2-thiopyridone and DTT.

their concentrations, and proteins derivatized (*7*, *8*, *21*, *26*). Moreover, this method was found to be unreliable because the DTT treatment changes the absorbance at 280 nm, resulting in small baseline changes at 343 nm that are of an order of magnitude similar to those expected for the released 2-TP (*10*). In fact, the HPLC chromatogram of the reaction mixture shows the presence of the DTT peak detected at 343 nm (Figure 2), indicating that DTT used as a reducing agent might cause falsely high concentrations of 2-TP, especially for proteins with a low degree of derivatization and high concentrations of DTT under the SP method. As an alternative method, the measurement of sulfhydryl groups in the DTT-treated derivatized protein using Ellman's reagent has its own limitation, due to possible damage of endogenous disulfide bonds and unfavorable effects of the reaction conditions (*8*, *10*).

In the present HPLC method, the concentration of 2-TP released from the DTT treatment of SPDP- or SMPT-derivatized BSA was determined with photodiode array detection at 343 nm. 2-TP was well resolved as shown in Figure 2. The linearity was observed over the range of 2−80 μM in 10 mM PBS (pH 7.4), with the correlation coefficient being >0.999. Using this HPLC method, 2-TP released from other proteins prepared with various pyridyl disulfide-containing cross-linkers may be determined quantitatively without any interference from the reagents or reaction conditions used.

The derivatization ratios determined according to the SP and HPLC methods were compared (Table 1). The ratios of the SPDP-derivatized BSA were comparable between these two methods. However, there was a significant difference in the derivatization ratios for the SMPT-derivatized BSA. At low derivatization ratios <1, these differences were relatively small. However, the differences became significant at higher derivatization ratios. The derivatization ratios from the SP method were determined to be lower than those from the HPLC method. The reason for this might be due to the falsely high BSA concentration caused by a partial correction for the contribution of MPT moiety on the A_{280} by using the correction factor of PP instead of MPT. For both derivatized BSAs, the HPLC method showed better reproducibility than the SP method. In the HPLC method, intraday ($n = 5$) and interday ($n = 6$, data not shown)

16	4.72 ± 0.09	1.90	7.98 ± 0.26	3.24	6.78 ± 0.12	1.77

[a] Ratio from the conventional E_{280} value of introduced moiety; $E_{280} = 5.1 \times 10^3$ M^{-1} cm^{-1}. [b] Ratio from the new E_{280} value of introduced moiety; $E_{280} = 8.6 \times 10^3$ M^{-1} cm^{-1}. [c] Reaction ratio = cross-linker/BSA.

coefficients of variation (CV) ranged from 1.01 to 4.38% in SPDP-derivatized BSA and from 0.46 to 1.77% in SMPT-derivatized BSA, respectively. In the SP method, intraday ($n = 5$) and interday ($n = 6$, data not shown) CVs ranged from 1.89 to 12.25% in SPDP-derivatized BSA and from 1.65 to 4.82% in SMPT-derivatized BSA, respectively.

These results indicate that the SP method, although simple, is not quantitative and may be suitable for the SPDP-derivatized protein. To apply the SP method to SMPT-derivatized protein, a new molar absorption coefficient of MPT moiety at 280 nm was calculated as $E_{280} = 8.6 \times 10^3$ M^{-1} cm^{-1} on the basis of the data obtained by using the HPLC method. Consequently, in SMPT-derivatized BSA, the derivatization ratio can be calculated by using the equation (Table 1):

$$\text{MPT moieties/1 molecule of BSA} = A_{343} \times 40.3/(A_{280} \times 8.08 - A_{343} \times 8.60) \quad \text{(b)}$$

Likewise, a specific equation may be constructed for any derivatized protein prepared by an individual pyridyl disulfide-containing heterobifunctional cross-linker.

In conclusion, we have developed a quantitative HPLC method to determine the derivatization ratios of the modified protein prepared by pyridyl disulfide-containing heterobifunctional cross-linkers. In contrast to the SP method, the concentration of the protein and 2-TP released from the DTT treatment of derivatized proteins can be assayed directly without interference from different reagents (proteins, cross-linkers, and DTT) and their concentrations. This HPLC method was proved to be better in terms of accuracy, selectivity, and reproducibility, requiring micro sample consumption. Therefore, this HPLC method may be directly applied to other derivatized proteins prepared with pyridyl disulfide-containing cross-linkers.

Thiol-Reactive Luminescent Chelates of Terbium and Europium

Jiyan Chen and Paul R. Selvin*

Physics Department and Center for Biophysics, University of Illinois, Urbana, Illinois 61801.
Received September 17, 1998; Revised Manuscript Received November 18, 1998

Thiol-reactive lanthanide complexes have been synthesized that are luminescent when bound to terbium and/or europium. The complexes consist of a diethylenetriaminepentaacetate (DTPA) chelate covalently joined through one amide bond to a chromophore, carbostyril 124, and via a second amide bond to a maleimide, bromoacetamide, or pyridyldithio moiety. Site-specific attachment and characterization of the complexes attached to DNA-activating protein NtrC, to various sites on myosin, or to DNA are presented. The compounds coordinate a surprisingly large number of ligation sites of terbium when a hydrazide spacer is used between the chelate and thiol-reactive moiety, although this extra ligation can cause quenching when europium is used. Synthesis is a simple two- or three-step reaction, and purification is straightforward. The compounds should be useful as nonisotopic replacements, as long-lifetime probes in imaging, and as donors in luminescence resonance energy transfer. They are examples of a wide class of chelates that can be made conjugatable via readily available hetero- or homo-bifunctional linkers.

INTRODUCTION

Luminescent lanthanide chelates are of interest in time-resolved fluorescence assays (reviewed in refs *1* and *2*) as long-lifetime (millisecond) probes to increase contrast in fluorescence imaging when autofluorescence is a problem (*3*, *4*) and as donors in resonance energy transfer experiments (*5*−*12*). The chelate of diethylenetriaminepentaacetic acid covalently joined to a chromophore, 7-amino-4-methyl-2(1*H*)-quinolinone (also named carbostyril 124 or cs124), makes an excellent donor in energy transfer experiments (*7*, *8*, *10*) and can be conjugated to amine-containing macromolecules via either the anhydride or isothiocyanate forms (*13*). The conversion of one or even two DTPA[1] carboxyl groups to amides does not affect the coordination (*14*), and a sufficiently high binding constant is maintained for most purposes. Pyridyldithio forms of DTPA and triethylenetetraaminehexanoic acid, which are luminescent with europium, have been made previously by placing the reactive moiety on the chromophore (*15*). Other thiol-reactive chelates have also been developed (*16*).

Here we present the synthesis of maleimide, bromoacetamide, and pyridyldithio forms of DTPA−cs124 for reaction with thiols. We have recently used the maleimide form in energy transfer experiments on the muscle protein myosin (*17*). The synthesis is a simple two- or three-step reaction in which the dianhydride of DTPA is first reacted with the 7-amino of cs124 and then with a hetero-bifunctional compound containing an amino on one end and a thiol-reactive moiety on the other end. Alternatively, the second anhydride can be reacted with a diamino compound, which is then further reacted with an NHS−thiol reactive cross-linker. When the linker contains a hydrazide, under favorable conditions we find the carbonyl can ligate the lanthanide, resulting in a higher terbium quantum yield.

EXPERIMENTAL METHODS

Chemicals and Materials. The following were purchased from Aldrich: diethylenetriaminepentaacetic acid dianhydride (caDPTA); 7-amino-4-methyl-2(1*H*)-quinolinone (also named carbostyril 124 or cs124); anhydrous dimethyl sulfoxide, dimethylformamide, and hydrazine (Sure/Seal bottles); triethylamine (dried by activated molecular sieves before use); ethylenediamine (redistilled); C18-silica on glass-backed TLC plates (150 μm layer thickness); 3-maleimidopropionic acid *N*-hydroxylsuccinimide ester; acetonitrile (99.93%, HPLC grade). Glacial acetic acid and ammonium hydroxide were purchased from Fisher Scientific. *N*-Hyroxysuccinimidyl bromoacetate was purchased from Molecular Biosciences (Boulder, CO). Glutathione (reduced form) was purchased from Sigma. 3-(2-Pyridyldithiol)propionyl hydrazide (PDPH) was purchased from Pierce. ϵ-Maleimidocaproic acid hydrazide−HCl (EMCH) was from Bioaffinity Systems (Roscoe, IL). cDNA for the cys73 mutant of myosin regulatory light chain (RLC) was the generous gift of Dr. Susan Lowey. NtrC (mutant D54C) was the generous gift of Dr. Michael Nohaile. Distilled and deionized water (18 MΩ cm^{-1}) was used throughout. All glassware was washed with a mixed acid solution and thoroughly rinsed with deionized, distilled water (*18*). All plastic labware was purchased from Bio-Rad (metal-free). All chemicals were of the purest grade available.

Purification. Reverse-phase high-performance liquid chromatography was performed at room temperature on a Waters model 600 system with a Dynamax 60 Å C_{18} column (10 or 25 mm i.d. × 250 mm, Rainin, at 3 or 8

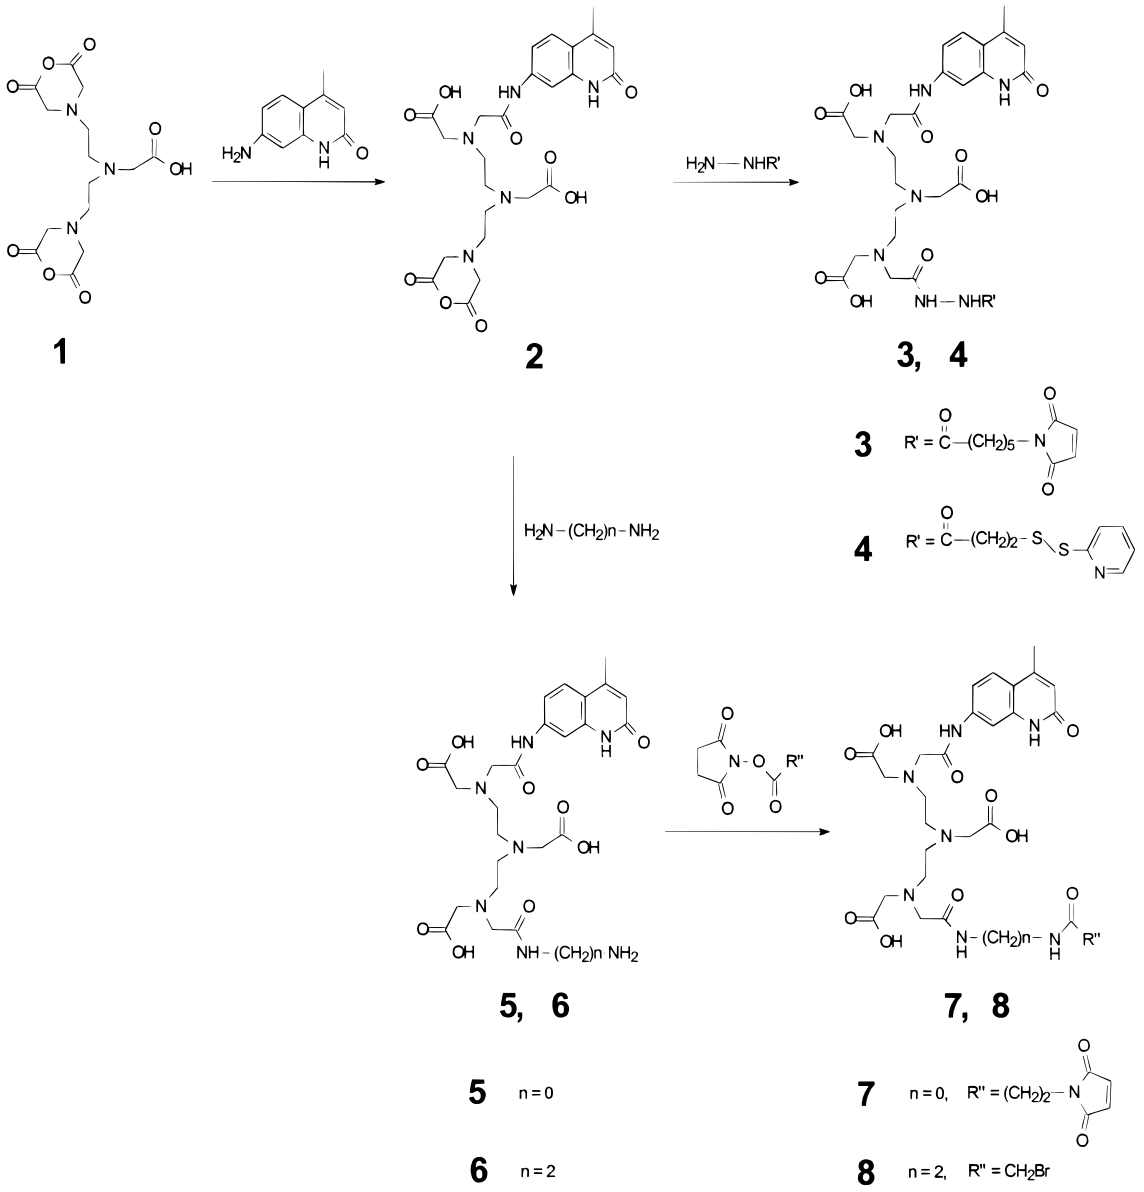

Figure 1. Synthetic reaction scheme for thiol-reactive DTPA−cs124 chelates.

mL/min, respectively) using a linear gradient (solvent A = 0.1 M triethylammonium acetate, pH 6.5; solvent B = acetonitrile). Fractions were vacuum-dried at room temperature, and the powder was stored at −80 °C.

Spectroscopy. Time-resolved and gated luminescence measurements were made on a laboratory-built spectrometer described previously (*8*, *10*), employing a 5 ns excitation pulse at 337 nm followed by time-resolved detection of lanthanide emission (*8*, *10*).

Synthesis (Figure 1). *DTPA−cs124−EMPH (**7**).* caDTPA (**1**) (50 mg, 141 μmol) was dissolved in 0.5 mL of anhydrous DMSO. Triethylamine (20 μL, 141 μmol) dried over molecular sieves was added to the caDTPA−DMSO solution. A solution of cs124 (19 mg, 109 μmol, 0.77 equiv in 0.5 mL of anhydrous DMSO) was added dropwise. The reaction was carried out at room temperature for 30 min, and then 10.7 μL of anhydrous hydrazine (282 μmol, 2 equiv) was added to above the reaction mixture. Fifteen minutes later, one-third of the solution was added to solid 3-maleimidopropionic acid *N*-hydroxysuccinimide ester (25 mg, 2 equiv) at room temperature and the reaction quenched after 30 min by adding 7 mL of aqueous triethylammonium acetate (TEAA) (0.1 M, pH 6.5). The remaining two-thirds of the solution was stored at −80 °C for future reaction. Alternatively, the intermediate product DTPA−cs124−hydrazide (**5**) was first purified by HPLC, redissolved in DMSO, and reacted with *N*-hydroxysuccinimide ester as above. This eliminated contaminating DTPA−$(cs124)_2$ in the final product (see directly below).

The reactions were monitored by C18 RP-TLC. When acetonitrile/TEAA (2:8, v/v) was used as RP-TLC developing system, the R_f values of DTPA−cs124, DTPA−cs124−hydrazine, and DTPA−cs124−hydrazine−maleimide were 0.67, 0.60, and 0.40, respectively. The final product was purified by HPLC using a 40-min linear gradient, from 10 to 20% solvent B. Three major peaks with 12.2, 17.6, and 20.2 min retention times were collected and characterized as DTPA−cs124, DTPA−$(cs124)_2$, and DTPA−cs124−hydrazine−maleimide (DTPA−cs124−EMPH), respectively. [HPLC purification of the intermediate product, DTPA−cs124−hydrazine, when done, eliminated the $(DTPA-cs124)_2$ peak from the final reaction.] FAB-MS (glycerol matrix) of the 20.2 min retention time peak shows mass (MH^+) of 715.2686 (found); 715.2687 (calculated). The product was dried on

a Speed-vac and stored either at −80 °C in solid form or in TEAA buffer at ∼30 mM DTPA−cs124−EMPH.

The thiol reactivity of the DTPA−cs124−EMPH was tested by adding an excess of solid glutathione (reduced form) with a solution of DTPA−cs124−EMPH in 0.1 M TEAA (pH 6.5) at room temperature for 1 h and then checked on RP-TLC and MS. The RP-TLC showed the DTPA−cs124−EMPH peak disappeared and a more rapidly moving peak appeared; high-resolution FAB-MS (glycerol as matrix) of the reaction mixture showed 1022.35; 1022.35 (calcd). These results indicate complete reaction of starting material into product.

*DTPA−cs124−EMCH (**3**).* To a solution of caDTPA (27.6 mg, 77 μmol) in 1 mL of DMSO was added dropwise cs124 (13.5 mg, 77 μmol) in 200 μL of DMSO, and the mixture was vortexed immediately. Two or four hours later, solid EMCH (27.6 mg,105 μmol) was added, and the mixture was vortexed until the EMCH had dissolved. The reaction proceeded overnight and was then frozen at −70 °C until purification. Immediately before HPLC purification, 9× volume of 0.5 M triethylammonium acetate, pH 6.5, was added to quench the reaction. The product was purified by reverse-phase HPLC using a 30 min linear gradient from 10 to 45% solvent B at 3 mL/min. The product was collected as a well-resolved peak at 22 min and immediately frozen and lyophilized to dryness. Yield was ∼25%, estimated by HPLC profile. FAB-MS: *m/e* 757 (glycerol matrix).

*DTPA−cs124−EDA−Bromoacetamide (**8**).* DTPA−cs124−ethylenediamine (**6**) (DTPA−cs124−EDA) was synthesized as reported previously (*13*). To a solution of DTPA−cs124−EDA (5.9 mg, 10 μmol, containing about an equal amount of DTPA−cs124) in 1 mL of TEAA (0.1 M, pH 8.5) was added *N*-hydroxysuccinimidyl bromoacetate (NHS-Br, 10 mg, 3 equiv). With vigorous stirring, the white solid of NHS-Br was dissolved gradually in the reaction solution over a few minutes at room temperature. The reaction was complete in 30 min. The R_f value of DTPA−cs124−EDA−bromoacetyl (DTPA−cs124−EDA−Br) was 0.45 [C18 RP-TLC in acetonitrile/TEAA (2:8, v/v)]. The newly formed compound showed full reactivity with glutathione (reduced form), monitored by RP-TLC. The final product was purified by HPLC (45-min linear gradient, from 10 to 25% solvent B at 8 mL/min), and the peaks at 18.8 and 25.2 min retention times were collected and characterized as DTPA−cs124 and DTPA−cs124−EDA−Br. High-resolution FAB-MS (glycerol as matrix) of the 25.2 min retention time peak shows 712.1942 (found); 712.1942 (calcd)

*PDPH−DTPA−cs124 (**4**).* Cs124 (10.5 mg, 60 μmol) was dissolved in 0.3 mL of dry DMSO and added dropwise to a 0.9 mL solution of caDTPA (21 mg, 61 μmol) in dry DMSO and allowed to react at room temperature for 45 min. Solid PDPH (10.7 mg, 47 μmol) was added to 1 mL of the above solution and allowed to react for >2.5 h at room temperature. Solid caDTPA (1.1 mg, 3 μmol) was occasionally added in an attempt to bind any residual free cs124 or PDPH. The reaction was quenched by addition of an equal volume of 400 mM sodium bicarbonate, pH 7.0. Purification was by HPLC (gradient: 0−14% solvent B from 4 to 14 min, 14−20% solvent B from 14 to 84 min, at 8 mL/min). The product at 51 min was dried on a Speed-vac, redissolved in water, passed through a C18 Sep-Pak (Waters), eluting with 50:50 acetonitrile/water and dried to give a white powder. The product was identified by FAB mass spectrometry, UV−vis, and lanthanide luminescence. Reaction with 2.4× glutathione (20 mM sodium bicarbonate, pH 7.0) resulted in increased absorbance in the 310−380 nm range due to release of the absorbing pyridyl group [$\epsilon_{343} = 8.1 \times 10^3\ M^{-1}\ cm^{-1}$ (*19*)], indicating nearly quantitative reaction with the PDPH moiety. FAB-MS, *m/e* 758.

Addition of Metal. $TbCl_3$ or $EuCl_3$ was added to the chelate in a 0.9:1 mole ratio at >0.1 mM concentration at pH 6−7, usually in 0.1 M TEAA, pH 6.5, buffer and allowed to bind on ice for ∼15 min. The complex was either stored at −80 °C or used immediately for reaction with biomolecules.

Coupling to Biomolecules. Coupling of Tb−DTPA−cs124−EMPH with the regulatory light chain of myosin, a 20 kDa calmodulin-like protein has been described (*17*), although we now routinely omit the reductant TCEP. We have also coupled it to a cysteine mutant of RLC (cys73) (*20*) at 25 μM protein with a 5-fold excess of chelate and to a single-cysteine mutant (D54C) of NtrC protein, a 20 kDa protein for which the atomic structure has been solved by NMR (*21*). Tb−(Eu−)DTPA−cs124−EDA−Br was coupled to heavy meromyosin (HMM), a 400 kDa fragment of myosin (∼14 μM protein), at a ratio varying from 2:1 to 10:1, and the reaction was carried out on ice overnight in 20 mM Mops, pH 7.0/5 mM $MgCl_2$. The excess lanthanide chelates were removed by passing the reaction mixture through a Sephadex G-25 size exclusion column. Tb−EMCH−DTPA−cs124 was reacted with a DNA (5′-$HSCH_2CH_2NHPO_3$−CCT-AGC-CAG-TGG), containing a free thiol at the 5′ end [introduced by coupling of cystamine via a slight modification of the method of Chu and Orgel (*22*)], and HPLC purified.

RESULTS AND DISCUSSION

Figure 1 shows the synthetic pathway for the various thiol-reactive chelates. HPLC, mass spectra, reaction with small or large thiol-containing molecules, and lanthanide luminescence all prove the chelates' structures and reactivities. The products were generated either in a two-step (one-pot) reaction, where DTPA dianhydride was first reacted with cs124 and then to an amine-thiol cross-linker (such as EMCH or PDPH), or via a three-step (one- or two-pot) procedure where a DTPA−cs124−diamine compound was generated and the free amine converted into a thiol-reactive entity via reaction with an NHS-thiol cross-linker. The former has greater simplicity but was not always possible. In particular, we made DTPA−cs124−EMPH both ways, but with the two-step reaction, HPLC retention of the DTPA−cs124−EMPH was similar to that of the byproduct DTPA−$(cs124)_2$, and more significantly, dramatically different yields were found, possibly due to variability in the purity of the starting EMPH material.

General Overview. The excited-state lifetime and emission spectra of Tb^{3+} and Eu^{3+} in the thiol-reactive chelates are shown in Table 1 and Figures 2 and 3. Figure 3 shows that both lanthanides have the usual sharply spiked emission spectrum. Table 1 and Figure 2 show that the lifetimes of both lanthanides are, as expected, in the millisecond range. The exact lifetimes depends on the lanthanide, chelate, and linker between maleimide and chelate and what they are attached to. For lanthanides, one of the main determinants of lifetime is the number of waters bound to the lanthanide (*23*). DTPA or DTPA−cs124 coordinates eight of nine possible sites, and the remaining site is filled by a water molecule, which reduces the excited-state lifetime through vibrational quenching. Surprisingly, for the chelate derivatives reported here, this last site can be filled by the carbonyl oxygen of the hydrazide (but not ethylenediamine) linker (see also Coordination Sites). For terbium, this is advan-

Table 1. Lifetimes of Thiol-Reactive Europium and Terbium Complexes in H_2O and D_2O, Their Ratio, and the Number of Coordinated Waters in the Lanthanide Primary Sphere[a]

lanthanide complexes[a]	τ_{H_2O} (ms)	τ_{D_2O} (ms)	τ_{H_2O}/τ_{D_2O}	no. of waters

[a] The measurements for the free reactive chelates were taken in 20 mM MOPS/5 mM $MgCl_2$, pH 7.0, at room temperature. Numbers in parentheses are for Eu^{3+}; those not in parentheses are for Tb^{3+}. [b] Data from ref *24*. [c] DTPA−cs124−AH = DTPA−cs124−acetic hydrazide = $CH_3CONHNH_2$−DTPA−cs124. Synthesis followed the general protocol outlined in Figure 1: reaction of caDTPA with cs124 followed by addition of an excess of $CH_3CONHNH_2$ and HPLC purification. [d] Tb^{3+} lifetime decreases *slightly* when conjugated to proteins (see Figure 1). [e] Free chelate. Tb lifetimes are major component. There was a minor short-lifetime (<0.5 ms) component as well. [f] Conjugated to NtrC in buffer defined above (footnote *a*) such that there is <1 Tb chelate per protein. [g] Conjugated to glutothione. Lifetime indicates ligation of carbonyl hydrazide from linker is not occurring. Conjugated to DNA it is highly quenched due to extra ligation (data not shown). [h] Conjugated to single-stranded 12-mer DNA in 20 mM $MgCl_2$/50 mM NaCl/10 mM Tris, pH 8.0. [i] Unconjugated compound showed very large concentration-dependent quenching. To achieve the reported Tb lifetimes required titrations down to 5 nM. Tb lifetime was biexponential, with 75% of population corresponding to long-lifetime reported; shorter lifetime was ≈0.5 ms. Eu lifetimes could not be accurately determined at these concentrations. The results for Eu are reported in the presence of glutothione, which displaced the pyridyl group of PDPH, produced a large (>200-fold) increase in signal, and largely eliminated the concentration quenching.

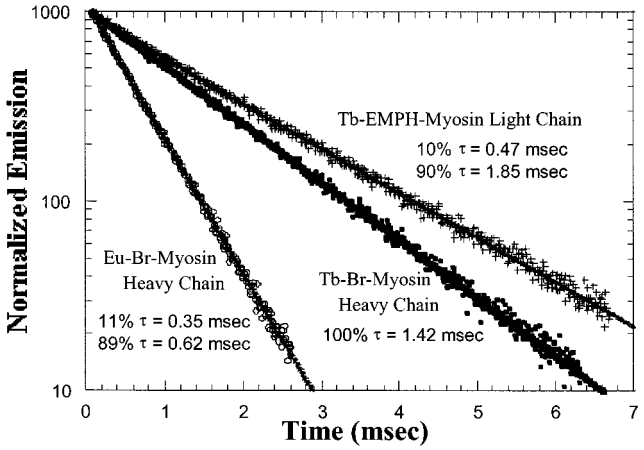

Figure 2. Lifetime of Tb^{3+} and Eu^{3+} bound to seven or eight attached to myosin fragments.

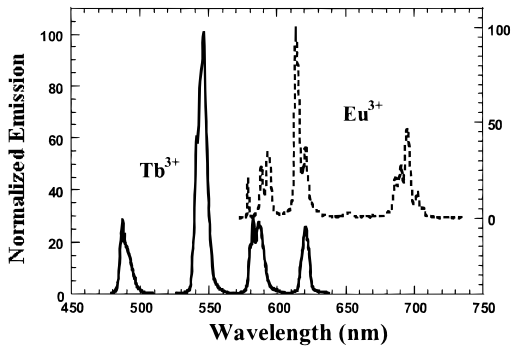

Figure 3. Normalized Tb and Eu emission spectra in DTPA−cs124−EDA−Br. Tb^{3+} and Eu^{3+} display their characteristic sharply spiked spectra. Free chelate dissolved in 20 mM Mops, pH 7.0/5 mM $MgCl_2$ at a concentration of 0.5 μM. Resolution is 0.3 nm, excitation was at 40 Hz of 3.4 μJ/pulse at 337 nm for Eu, 2.0 μJ/pulse for Tb; integration time is 1 s for Tb and 10 s for Eu. Note that signal is normalized. Tb emission is considerably brighter (roughly 20×) than Eu emission. Eu spectrum is displaced for clarity of presentation.

tageous. However, for europium, with one exception (PDPH bound to glutathione), this ligation causes very large quenching, presumably through vibrational deactivation. Single-exponential lifetimes (as opposed to biexponential) are also advantageous, and the bromoacetamide chelate produces this, whereas the maleimide can be either single exponential or biexponential, depending on the biomolecule attachment site and solvent conditions. In all cases, coupling to thiol-containing biomolecules could be monitored by comparing the absorbance of the cs124 when coupled to DTPA (12000 M^{-1} cm^{-1}) at 337 nm to that of the biomolecule (typically 260 nm for DNA, 280 nm for proteins). [The absorption spectra has been reported (*24*).] For DTPA−cs124−PDPH, coupling could also be monitored by the release of the pyridylthio group. Reaction with the RLC was also monitored by MALDI mass spectroscopy.

Specific Thiol-Reactive Forms. *Maleimide.* The maleimide form has the advantage of quick and efficient reaction with thiols. Tb−DTPA−cs124−EMPH was previously attached to the regulatory light chain of myosin and used successfully as a donor in resonance energy transfer experiments in myosin (*17*) (see Figure 2). To further characterize this reaction, we have now performed mass spectrometry (MALDI) on the chelate bound to a single-cysteine (cys73) mutant of RLC. Two peaks of molecular weight of 20002.9 and 19285.2 in approximately 4:1 ratio were found (data not shown). The former is labeled RLC, and the latter is unlabeled RLC. Note that the difference in mass is 717.7, in excellent agreement with the mass of EMPH−DTPA−cs124. The mass spectrometery data also show that labeling is efficient (∼80% yield based on relative peak heights) and, as expected for a maleimide, is likely highly specific for thiols as only one chelate per protein is bound. Previous energy transfer measurements using this chelate-labeled protein further indicate that the label is bound specifically to cysteine-108 (*17*). The excited-state lifetime of Tb in this reaction was biexponential, with a minor, short-lifetime component and with a major long-lifetime component of ∼1.8 ms at room temperature (2.0 ms at 4 °C) (Table 1 and Figure 2). The brightness of the terbium−maleimide when bound to RLC was equivalent to or slightly brighter than that of free Tb−DTPA−cs124 (the unreactive, no linker parent compound), which we have previously shown to have a 2 pM detection limit.

In addition, the EMPH or EMCH chelate was reacted with thiolated DNA, with NtrC, and with the heavy chain of myosin at cysteine-707. When attached to the 5′ end of thiolated DNA, Tb−DTPA−cs124−EMPH went from biexponential to single exponential at higher salt. With

NtrC it was also biexponential, although in both cases the short-lifetime component was a minority (10−20%). Finally, because the maleimide forms were made using a hydrazide linker, the number of waters bound to the terbium was decreased in most cases (discussed further below), which results in longer lifetime (>1.8 versus 1.5 ms without hydrazide; Table 1), higher quantum yield, and brighter emission compared to those without the extra ligation. Europium in the EMPH linker was highly quenched under conditions where extra ligation was present, such as bound to the 5′ end of thiolated DNA, but displayed its usual 0.6 ms unquenched lifetime in H_2O-based buffer when extra ligation did not occur (see Table 1, footnote *g*).

Bromoacetamide. The bromoacetamide form has the distinct advantage of being single exponential with terbium and either single exponential with europium or at worst having a minor (10%) quenched component (Figure 2). The terbium brightness in the unconjugated bromoacetamide chelate (**8**) was equivalent to the unreactive form (Tb−DTPA−cs124 with no linkers). We found, however, the reactivity of bromoacetamide chelates to be significantly less than that of maleimides. It was sufficiently reactive with cysteine-707 on myosin, a site that is known to be highly reactive, but was not sufficiently reactive for labeling the regulatory light chain of myosin.

PDPH. The PDHP−DTPA−cs124 reacts rapidly with thiols to form a reducible disulfide bridge, with the release of pyridylthio. Because the PDPH chelate contains a hydrazide linker, it displays the long lifetime with terbium. Interestingly, this probe appears to be a useful reagent for the detection of glutathione or possibly other small thiol peptides, as it is highly quenched in the absence of glutathione and has a 200-fold intensity increase in its presence.

Coordination State. The number of waters bound to the primary ligation sphere can be calculated by comparing the lifetimes in H_2O and D_2O and using the equation of Horrocks and Sudnik (*23*). The results are shown in Table 1. Recently, Parker et al. have shown that ligated amide N−H bonds can deactivate the excited state of Eu^{3+} with an efficiency equivalent to approximately one-sixth that of a ligated OH bond, so the number of water molecules reported in Table 1 is likely overstated by about this amount (*25*). By comparing the free DTPA−cs124 to DTPA−cs124−acetic hydrazide it can be seen that the number of water molecules decreases for terbium, which we interpret as being due to the ligation of the amide−carbonyl in the hydrazide linkage. This ligation is advantageous, as mentioned above, in that it increases the terbium quantum yield and also results in 1.8-fold higher intensity. The ligation is fairly weak (order of kT) as it is temperature dependent, with lifetime increasing from 1.85 ms at room temperature to ∼2.0 ms at 4 °C for the EMPH derivative. For the DTPA−cs124−EMCH chelate this ligation is even weaker. This weak ligation is not surprising given that it arises from a seven-membered ring formation. Slight changes, such as using an ethylenediamine instead of hydrazine or using DTPA−cs124−triglyceride (*24*) eliminates this extra ligation. Similar subtle changes exist depending on what is bound to at the end of the hydrazine linkage. For example, unconjugated DTPA−cs124 hydrazine−maleimide compounds do not display this extra ligation, whereas we have found that when conjugated to certain proteins, the extra ligation occurs. Surprisingly, this hydrazide ligation tends to efficiently quench the europium excited state, with the exception of Eu bound to DTPA−cs124−PDPH coupled to glutathione (Table 1).

In summary, we have made a number of different thiol-reactive forms of the luminescent lanthanide chelate DTPA−cs124. The maleimide form (**7**) appears to be the most versatile with terbium as it is highly reactive, specific, and bright. A drawback is its biexponential excited-state lifetime when conjugated to some biomolecules. The bromoacetamide derivative overcomes this drawback when it is sufficiently reactive. Overall, the synthetic route is simple and amenable to modification such that a wide variety of different linker lengths can be readily made. These have already been shown to be useful donors in resonance energy transfer experiments in which specific reaction with protein thiols is required.

ACKNOWLEDGMENT

This work was supported initially by NIH Grant AR44420 and later by Amersham Inc. We thank Dr. Michael Nohaile for the gift of NtrC protein and Dr. Susan Lowey for the gift of cDNA for mutant RLCs. We also thank Dr. Ming Xiao for assistance in RLC labeling and Dr. Handong Li for assistance with mass spectroscopy.

Total Solid-Phase Synthesis of 1,4,7,10-Tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic Acid-Functionalized Peptides for Radioimmunotherapy

James J. Peterson, Roger H. Pak, and Claude F. Meares*

Department of Chemistry, University of California, One Shields Avenue, Davis, California 95616-5295.
Received September 25, 1998; Revised Manuscript Received December 12, 1998

A convenient approach to the functionalization of peptides with the macrocyclic 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) moiety has been developed. Protected components (using *tert*-butyl or *tert*-butyloxycarbonyl groups) of both the peptide and the chelate were assembled on the same solid resin support. Deprotection and cleavage of the resin-bound DOTA−peptides were performed in one step using a trifluoroacetic acid cleavage mixture to yield free DOTA−peptide amides.

INTRODUCTION

Bifunctional chelating agents derived from the macrocyclic 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA)[1] have been used for studies in vivo due to the extraordinary stability of its complexes with many useful metals under physiologic conditions (*1*−*4*). Introduction of peptide/protein conjugation functionality to DOTA can originate either from the ring methylene carbons (*4*−*6*) or, more simply, through one of the four carboxylates of the macrocycle (*3*, *6*, *10*).[2] For the latter strategy, activation of a carboxylate group with isobutyl chloroformate (*7*−*9*) allows conjugation to a peptide (*10*). The DOTA should be monofunctionalized to prevent cross-linking of peptides. One disadvantage of this method is the low solubility of DOTA (<20 mM) (*8*, *10*) in anhydrous organic solvents.[3] We were able to circumvent this difficulty by synthesizing DOTA stepwise on the peptide N-terminus, using solid-phase synthesis methodology (Scheme 1). The selectivity in the *alkylation* of polyazamacrocycles (*12*) and the high solubility (>4 M) of the macrocycle cyclen in an appropriate organic solvent were also important.

EXPERIMENTAL PROCEDURES

Reagents. Fmoc-protected amino acids and BOP reagent for manual synthesis were purchased from BACHEM California, Inc. Fmoc-protected amino acids in 1 mmol cartridges, HMP resin, and reagents for automated synthesis (using "FastMoc" chemistry) were purchased from ABI. Cyclen sulfate, anhydrous NMP, anhydrous DMF, bromoacetyl bromide, chloroacetyl chloride, *tert*-butyl-2-bromoacetate, redistilled DIEA, piperidine, acetic anhydride, NBP, and HOBt were purchased from Aldrich Chemical Co. PEGA Rink amide resin was purchased from Nova-Biochem. Polypropylene chromatography columns (fritted) used for solid-phase peptide synthesis were purchased from Bio-Rad (parts 731-0003 and 732-1010). TFA and TIPS were purchased from Acros Organics or Fisher Scientific. Ammonia gas was purchased from Matheson. All buffers and cleavage cocktails were made using pure water (18 MΩ cm^{-1} resistivity). The ninhydrin test kit was purchased from ABI.

High-Performance Liquid Chromatography. For analytical HPLC, a Dynamax 60 Å (8 μm, 4.6 mm × 250 mm) C_{18} reversed-phase column was used at a flow rate of 1 mL/min. For semipreparative HPLC, a Phenomenex Magellan 100 Å (5 μm, 10 mm × 250 mm) C_{18} reversed-phase column was used at a flow rate of 3 mL/min. HPLC buffers are as follows: buffer system A, 0.068 M NH_4OAc (pH 4.8) versus CH_3CN; and buffer system B, 0.1% TFA/H_2O versus 0.1% TFA/CH_3CN. Eluting samples were detected at 280 nm unless otherwise indicated. For gradient 1, hold at 0% CH_3CN for 5 min and proceed to 50% by 35 min. For gradient 2, hold at 20% CH_3CN for 5 min and proceed to 50% by 23 min. For gradient 3, hold at 25% CH_3CN for 5 min and proceed to 50% by 25 min. For gradient 4, hold at 0% CH_3CN for 5 min, proceed to 50% in 10 min, and proceed to 70% in 15 min. Samples collected during HPLC were lyophilized at least twice on a Savant model SVC-100H Speed-Vac lyophilizer before analysis.

NMR Spectroscopy. ^1H NMR spectra were recorded on a General Electric QE 300 spectrometer at 300 MHz. Chemical shifts are reported relative to HDO (4.80 ppm) or $CHCl_3$ (7.26 ppm).

[1]Abbreviations: ABI, Applied Biosystems, Inc.; BOP, (benzotriazolyloxy)tris(dimethylamino)phosphonium hexafluorophosphate; cyclen, 1,4,7,10-tetraazacyclododecane; DCM, dichloromethane; DIEA, diisopropylethylamine; DOTA, 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid; ESI-MS, electrospray ionization mass spectrometry; Et_2O, diethyl ether; F*, (*S*)-*p*-nitrophenylalanine; Fmoc, fluoren-9-ylmethyloxycarbonyl; HMP, hydroxymethylphenoxy resin; HOBt, 1-hydroxybenzotriazole; NMP, 1-methyl-2-pyrrolidone; NBP, (nitrobenzyl)pyridine; NO_2Phe, (*S*)-*p*-nitrophenylalanine; PEG, polyethylene glycol; PEGA, bis(2-acrylamidoprop-1-yl) polyethylene glycol cross-linked dimethylacrylamide and mono(2-acrylamidoprop-1-yl)-(2-aminoprop-1-yl) polyethylene glycol (800); SPPS, solid-phase peptide synthesis; TIPS, triisopropylsilane.

[2]This is a very practical alternative, since the resulting loss of metal−chelate stability (*8*) has been found to be insignificant in serum (with ^{111}In or ^{90}Y), or when subjected to DTPA challenge (*3*).

[3]The purity and counterion form of DOTA must be carefully defined and reliable. For example, we purchased DOTA that was only 25% pure as determined with a ^{57}Co metal binding assay (*11*).

[a] Range of purities found by integration of the peak area of an HPLC trace (detection at 280 nm) for different batches (at least two) of each DOTA−peptide. [b] For peptides **1**−**7**, we used gradient 1 and buffer system A, while for peptides **8** and **9**, we used gradient 4 and buffer system B. [c] The purified yield is based on the substitution level of completed peptide resins. [d] Milder conditions used for synthesis (chloroacetyl chloride). [e] Mass calculations are for the $[M + 2H]^{2+}$ species. [f] Due to a distribution of charged states for this species, the spectrum was deconvoluted using MaxEnt software to determine the mass on the true mass scale.

Mass Spectrometry. ESI-MS was performed on a Fisons Instruments VG Quattro triple-quadrupole spectrometer using an eluent of 0.1% HCOOH/49.95% H_2O/49.95% CH_3CN at a flow rate of 5 μL/min. The cone voltage was set to 50 V. The source temperature was set to 80 °C. Calibration of the mass scale was performed using a solution of PEG 300, PEG 600, and PEG 1000 as a calibration standard. Molecular weights of multiply charged peptides were determined by mathematical transformation (deconvolution) of the electrospray spectra to a true mass scale spectrum using the maximum entropy transformation algorithm MaxEnt.

Peptide Synthesis. Peptides were synthesized using either a multiple parallel manual synthesis apparatus (peptides **1**−**7**, see Table 1) or an ABI model 430A automated peptide synthesizer (peptides **8** and **9**). All parent peptides were fully characterized by amino acid analysis and mass spectrometry before the parent peptide−resin was subjected to DOTA functionalization.

Parallel Manual Synthesis of Peptide−Resins 1−7. Using the multiple synthesis apparatus described previously (*13*), 17 peptides were manually synthesized in parallel within 10 days. Standard Fmoc SPPS was carried out according to the preactivation method of Hudson et al. (*14*). A simple method of assaying the activity of the HOBt esters used for SPPS was also employed (*13*).

PEGA Rink resin (10 g, 2 mmol, stored in CH_3OH) was delivered to a 250 mL polypropylene-fritted reaction vessel fashioned from a Bio-Rad Polyprep Column. Dry argon was introduced to the reaction column from below the frit to bubble-stir the slurry using the frit as a bubbler. The resin was washed with 4 × 60 mL of DCM (5 min/wash) and then with 5 × 60 mL of DMF (5 min/wash). Solvent was drained through the frit into a vacuum filter flask using positive argon pressure from above the swollen resin. Fmoc-L-NO_2Phe-OH (4.51 g, 10.4 mmol) and HOBt (1.41 g, 10.4 mmol) were placed in a dry pear-shaped flask and dissolved in 25 mL of dry DMF. To this solution was added 2.61 mL of redistilled DIEA (15 mmol). BOP reagent (5 g, 11.3 mmol) was dissolved in a separate dry pear-shaped flask with 5 mL

of dry DMF and syringed into the Fmoc-L-NO_2Phe-OH solution. After preactivation for 10 min, a 20 μL aliquot containing the active ester was checked for acylating activity and the Fmoc-L-NO_2Phe active ester solution was added to the swollen resin in the polypropylene reaction column. After 2.5 h, the peptide−resin tested nearly negative for free amines (<5 μmol/g) as determined by using the ABI ninhydrin test kit. After 3 h, the resin was washed with 5 × 60 mL of dry DMF and residual amines were capped using 2 mL of acetic anhydride (21 mmol) and 1 mL of DIEA (5.7 mmol) in a total slurry volume of 125 mL. After 1.5 h, the resin was washed with 5 × 60 mL of DMF (5 min/wash) and then treated with 20% piperidine in DMF in a total slurry volume of 125 mL for 20 min. The resin was then washed with 5 × 100 mL of DMF (5 min/wash).

Two more cycles of coupling and deprotection as described above were utilized until the common resin L-Ala-Gly-L-NO_2Phe-PEGA Rink was constructed. The resin was then portioned equally into 17 smaller 50 mL reaction vessels fashioned from 50 mL polypropylene conical flasks and Bio-Rad disposable polypropylene columns (part 732-1010). These reaction vessels were fitted to an 18-reaction vessel capacity multiple SPPS apparatus, and the balance of each peptide was synthesized in parallel at a rate of one amino acid per day. Each night, resins were stored in DCM in their amino-terminal form. At the conclusion of the syntheses, resins were stored in their amino-terminal form in ethanol at −20 °C. Resins were not dried, but stored swollen in solvent according to the manufacturer's suggestions. Completed resins were found to swell to 0.16 g/mL in DMF (average of four measurements). To determine the final substitution level for each resin, ninhydrin analyses (average of five measurements) were performed at the conclusion of the syntheses.

Synthesis of Peptide−Resins 8 and 9 by Automated Peptide Synthesis. Two peptide−resins were synthesized on an ABI model 430A automated peptide synthesizer on a 0.1 mmol scale using the manufacturer's "FastMoc" methodology, which involves HBTU activation of amino acids. Solid support was PEGA Rink amide resin (0.05 mmol/g). An automated resin sampler was programmed to aliquot samples of resin after coupling steps were completed. These resin samples were typically in the range of 3−5 mg and were tested by ninhydrin analysis (ABI test kit) to determine the completeness of coupling which was determined to be >98% for all steps. Peptide−resin **9**, Fmoc-GKLLKLLLKL*p*YKKLLKLLK−PEGA Rink, was initially synthesized with a free hydroxyl on the Tyr residue, which was subsequently protected as the *tert*-butyl phosphotriester upon global phosphorylation using the method of Perich (*15*). All other Fmoc-amino acids were incorporated with side chain protecting groups. After synthesis was complete, Fmoc-peptide−resins were stored at −20 °C in anhydrous NMP until further use. Immediately prior to subsequent alkylation steps, the Fmoc-peptide−resins were amino-terminus deprotected by treatment with 5 mL of 20% piperidine/DMF for 5 min followed by another treatment for 10 min. The peptide−resin was then washed with 5 × 5 mL of DMF (5 min/wash) and 5 × 5 mL of NMP (5 min/wash).

Preparation of Cyclen Free Base. Cyclen sulfate (5.12 g, 13.9 mmol) was stirred vigorously in DCM (125 mL) in a 250 mL round-bottom flask fitted to a reflux condenser and septum for the gas inlet tube and vent needle. Ammonia gas was filtered and dried through a 300 mm × 50 mm column of KOH pellets and bubbled into the suspension (being stirred) for 9 h. The precipitated $(NH_4)_2SO_4$ was filtered off, and the supernatant was again treated with ammonia gas for an additional 2 h. The flask was sealed and the mixture allowed to stir overnight. A second batch of $(NH_4)_2SO_4$ precipitate was filtered off, and the supernatant was rotary evaporated to give white cyclen free base in quantitative yield. ^{1}H NMR ($CDCl_3$): δ 2.61 (s). ESI-MS: *m*/*z* calcd $(M + H)^+$ 173.2, found 173.5.

Cyclen Recovery Procedure. Excess cyclen in DCM, which had been recovered after reaction with alkylating peptide resin (see below), was concentrated by rotary evaporation and recycled to the free base. As an example, 1.6 g of recovered cyclen oil was taken up in 80 mL of CH_3OH, and 15 mL of concentrated HCl was added dropwise. The mixture was then stirred for 6 h, and the CH_3OH was rotary evaporated. Cyclen hydrochloride was then converted to the free base in the same manner as cyclen sulfate (see above). Peptide **2** DOTA−GFQGVQ-FAGF*-NH_2 was synthesized using recycled cyclen.

General Synthesis of DOTA−Peptides. A general method for the synthesis of DOTA−peptides is shown by example using the synthesis of DOTA−GGFLGLGAGF*-NH_2. All other DOTA−peptides followed a similar synthetic procedure.

Step 1. Acylation with Bromoacetyl Bromide. NH_2-GGFLGLGAGF*−PEGA Rink resin (0.59 g, 92 μmol) was washed with 5 × 5 mL of dry NMP. The resin slurry volume was adjusted to 5.8 mL with NMP and vortex mixed. To the vortexing slurry were added 80 μL (460 μmol) of DIEA, and then 180 μL (2 mmol) of bromoacetyl bromide. The resin was vortex mixed for 1 h, and washed with 5 × 5 mL of dry NMP and 10 × 5 mL of dry DCM. A 5 mg sample of resin was assayed by ninhydrin for free amines and found to be negative for free amines (<5 μmol/g). A 1 mg sample was removed and treated with NBP (3 g in 60 mL of acetone). The yellow resin turned royal blue upon treatment with NH_3(g), indicating the presence of alkylating species (the reactive bromoacetyl moiety).

Alternate Step 1. Acylation with Chloroacetyl Chloride. NH_2-GGVLRAGFK−PEGA Rink resin (0.1 g, 16 μmol) was washed with 5 × 2 mL of dry NMP. The resin slurry volume was adjusted to 1.1 mL and the slurry vortex mixed. To the vortexing slurry were added 80 μL (115 μmol) of DIEA, and then 29 μL (364 μmol) of chloroacetyl chloride. The resin was vortex mixed for 72 min, and then washed with 5 × 2 mL of dry NMP and 10 × 2 mL of dry DMSO. A 5 mg sample of resin was assayed by ninhydrin for free amines and found to be negative for free amines (<10 μmol/g). A 1 mg sample was removed and soaked with NBP (3 g in 60 mL of acetone) for 30 min at 35 °C. The yellow resin turned violet upon treatment with NH_3(g), indicating the presence of alkylating species (the reactive chloroacetyl moiety).

Step 2. Immobilization of Cyclen by the Haloacetyl-Peptide−Resin. The bromoacetyl-GGFLGLGAGF*−PEGA Rink resin was gravity drained and vortex mixed. Over a period of less than 10 s, 1.4 mL of 4.3 M cyclen free base in dry DCM was added to the resin that was being vortexed. This gave a total volume of 5.4 mL for a final cyclen concentration of 1.1 M. The slurry was vortex mixed for 2.5 h, checked for alkylating species via NBP test (negative), and washed with 6 × 5 mL of dry DCM (the washes pooled for the recycling procedure), 5 × 5 mL of dry DMSO (to remove any insoluble cyclen mixed salts), and 5 × 5 mL of dry NMP. A 43 mg sample of the cyclen−peptide−resin was removed, washed with 8 × 5 mL of DCM, and dried with flowing argon gas. Standard

peptide cleavage (see below) resulted in a product that was purified on HPLC (gradient 1, buffer system A). The major peak was collected and determined to be cyclen−GGFLGLGAGF*-NH_2. HPLC purity: 69%. ESI-MS: *m/z* calcd for $C_{53}H_{82}N_{16}O_{13}$ $(M + H)^+$ 1151.7, found 1151.0; calcd for $(M + 2H)^{2+}$ 576.4, found 576.2.

Step 3. Alkylation of Immobilized Cyclen−Peptide with tert-Butyl 2-Bromoacetate. The slurry volume of cyclen−GGFLGLGAGF*−PEGA Rink resin was adjusted to 5.3 mL with dry NMP. DIEA (366 μL, 2.1 mmol) and then *tert*-butyl 2-bromoacetate (310 μL, 2.1 mmol) were added to give final concentrations of 0.35 M. The resin was vortex mixed for 13.5 h, and then washed with 5 × 5 mL of DMF and 6 × 5 mL of DCM. An analytical sample of resin was removed and the product cleaved from the resin (see below). After collection of product fractions from C_{18} HPLC (gradient 1, buffer system A), ESI-MS of the cleaved DOTA−peptide amide indicated completion of the reaction and the absence of significant impurity corresponding to incomplete alkylation. The remaining resin was then dried by flowing argon over the drained bed for several hours.

Step 4. Cleavage of the DOTA−Peptide Amide from Solid Support and HPLC Purification. The dried DOTA−peptide−resin was weighed (0.576 g, 82 μmol), and a cleavage cocktail of TFA, TIPS, and H_2O (95:2.5:2.5, v/v) was added (10 mL). After vortex mixing for 2.5 h, the eluent was collected and the resin was washed with 5 × 4 mL of cocktail. The combined eluents were rotary evaporated to approximately 500 μL. Cold Et_2O (10 mL) was added and the solution cooled for 30 min at −20 °C. The precipitate was centrifuged at 800*g* at 4 °C for 5 min. The Et_2O was decanted and the pellet resuspended in another 10 mL of cold Et_2O. This centrifuge/wash procedure was repeated for a total of five washes. The precipitate was dried under vacuum and weighed (70 mg). The precipitate was taken up in 5 mL of 20% DMSO/water, filtered through a 0.45 μm membrane, and HPLC analyzed using gradient 1 with buffer system A on a Dynamax analytical C_{18} column. The major peak (retention time of 29 min) comprised 54% of the integrated chromatogram. The crude material was HPLC purified using gradient 2 with buffer system A on a Magellan C_{18} semipreparative column (retention time of 13 min). The product was lyophilized twice. The yield was 25 mg, or 19 μmol (23% based on ninhydrin-quantitated substitution of 156 μmol/g × 0.91 for *t*-Bu-DOTA−GGFLGL-GAGF*−resin).[4] ESI-MS: *m/z* calcd for $C_{59}H_{88}N_{16}O_{19}$ $(M + H)^+$ 1325.6, found 1325.7; calcd for $(M + 2H)^{2+}$ 663.3, found 663.7. Amino acid analysis confirmed the correct composition of amino acids. A stock solution of DOTA−GGFLGLGAGF*-NH_2 was prepared in 1:1 DMSO/0.1 M triethylammonium acetate, and the concentration was determined with a ^{57}Co metal binding assay (11.7 mM). This value compared well with the spectrophotometrically determined value (13.4 mM) obtained from absorbance at 280 nm when 2.5 μL of this stock was diluted in 500 μL of 0.1 M sodium phosphate (pH 7.0) using an ϵ of 9050 M^{-1} cm^{-1} (280 nm) for *p*-nitrophenylalanine at pH 7.

RESULTS

A variety of peptide−resins were synthesized, by manual and automated methods, for use as scaffolds for the construction of the DOTA moiety on their amino termini. The crude unmodified peptides, when cleaved from the resin, were typically >90% pure as determined by HPLC.

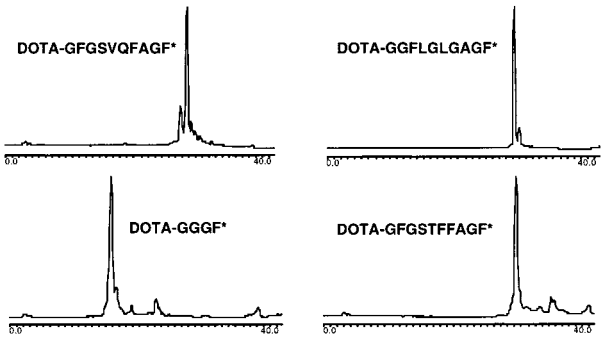

Figure 1. HPLC chromatograms of the crude cleavage products for several DOTA−peptide amides on an analytical C_{18} column. All DOTA−peptide amides were deprotected and cleaved from PEGA Rink amide resin using a cleavage cocktail of 95% TFA/2.5% TIPS/2.5% H_2O. After precipitation from cold Et_2O, DOTA−peptides were dissolved in 20% DMSO/H_2O and filtered before HPLC analysis. The major peak in each chromatogram was determined to be the desired product.

Functionalization of the amino terminus of the peptide−resin was provided through the use of the bifunctional bromoacetyl bromide or chloroacetyl chloride. Since the acyl halide functionality is much more reactive than the alkyl halide with respect to amine nucleophilic attack, acylation was the preferred reaction pathway. Initial acylation experiments using peptide−HMP resins (polystyrene-based) followed by cyclen alkylation resulted in a complex mixture of byproducts. Analysis of the bromoacetyl-peptide−HMP resins using 1.1 M NH_3 as the nucleophile showed that simple polystyrene-based peptide−resins treated with bromoacetyl bromide were poor alkylating agents in DCM when compared to peptide−poly(ethylene glycol) acrylamide resins. We therefore used the PEGA−Rink resins as the solid phase for our peptide syntheses.

Milder reaction conditions in which chloroacetyl chloride was used were also successful, despite the less reactive chloroacetyl electrophile. Preliminary tests of the alkylation step in which NH_3 was used as the nucleophile showed that the chloroacetyl group is significantly less reactive toward NH_3 than the bromoacetyl group in DCM. Nevertheless, alkylation of cyclen by the chloroacetyl group was accomplished in both DMSO and DCM. Recovery of unreacted cyclen was further simplified by the fact that the resulting cyclen mixed salt was in the hydrochloride form and required one less step for recycling to the free base form.

During the cyclen alkylation step, it was feared that a considerable amount of cross-linked peptide−cyclen−peptide products might have resulted since cyclen has four nucleophilic sites. However, products such as peptide−DOTA−peptide were not detected by mass spectrometry (sub-picomole limits of detection). Rather, the most significant impurity for the multistep DOTA functionalization of peptide−resin was typically one with a mass corresponding to underalkylation of immobilized cyclen−peptide by *tert*-butyl 2-bromoacetate (i.e., two groups instead of three). The purity of the cleaved DOTA−peptides as measured by integration of their HPLC chromatograms was high enough to yield useful amounts of pure material. Table 1 displays the sequences, HPLC purities, yields, and ESI-MS data of the DOTA−peptide amides. Figure 1 displays the HPLC

[4]The factor of 0.91 is derived from the fact that *t*-Bu-DOTA adds to the weight of the peptide resin, and the substitution level of 156.1 μmol/g must be adjusted accordingly to 142 μmol/g.

chromatograms of several of these DOTA−peptide amides.

DISCUSSION

Peptide linkers can potentially improve the efficacy of targeting radionuclides to tumors (*10*, *13*); practical synthesis of peptides bearing strong metal-binding groups makes it possible to test various strategies efficiently. A combined procedure where both the DOTA and the DOTA-linked peptide amide are synthesized on a single support offers many advantages. The peptidyl solid support can be thought of as a purification column, eliminating the costly and laborious HPLC steps utilized to purify the chelate, the peptide, and the chelate-modified peptide. The time to synthesize one DOTA−peptide amide is significantly reduced, since byproducts and unreacted starting materials are simply eluted during the wash steps. The procedure can take as little as 4 days from bare PEGA Rink resin to HPLC-purified DOTA−peptide.

The gravimetric yields of DOTA−peptide realized with this method are not yet characteristic of what can be expected of SPPS. For example, solid-phase synthesis yields of the peptides alone are typically >90%. However, the DOTA−peptide yields are comparable to those realized with other methods where only one of multiple sites on a macrocycle is modified. Using a solid-phase chemistry solvent such as DCM provides practical advantages for the use of cyclen in our synthetic route. Not only does the resin swell effectively in DCM, but also cyclen is highly soluble in this solvent, allowing us to use the principle of excess and avoid cross-linking. The recovery of unreacted cyclen is also easily and rapidly accomplished in DCM. The use of *tert*-butyl 2-bromoacetate (*16*) affords a carboxyl-protected DOTA moiety which, when utilized in an orthogonal protection scheme, allows further manipulation of the resin-bound peptide. This may prove useful in the synthesis of peptides with multiple functionalities.

The variety of peptides that have been DOTA-functionalized on the solid phase testifies to the general utility of this synthetic route. Milligram quantities of DOTA peptides have been rapidly and efficiently made and purified. These DOTA−peptides can be further investigated for use in radioimmunoconjugates or targeted delivery vehicles for radioisotopes.

Molecular Chaperone-Like Activity of Hydrogel Nanoparticles of Hydrophobized Pullulan: Thermal Stabilization with Refolding of Carbonic Anhydrase B

Kazunari Akiyoshi,* Yoshihiro Sasaki, and Junzo Sunamoto*

Department of Synthetic Chemistry and Biological Chemistry, Graduate School of Engineering, Kyoto University, Yoshida-Hommachi, Sakyo-ku, Kyoto 606-8501, Japan. Received October 26, 1998

We have been studying the formation of hydrogel nanoparticles by the self-aggregation of hydrophobized polysaccharide and the effective complexation between these nanoparticles as a host and various globular soluble proteins as a guest. This paper describes a new finding that refolding of the heat-denatured enzyme effectively occurs with the nanoparticles and β-cyclodextrin according to a mechanism similar to that of a molecular chaperone. In particular, the irreversible aggregation of carbonic anhydrase B (CAB) upon heating was completely prevented by complexation between the heat-denatured enzyme and hydrogel nanoparticles formed by the self-aggregation of cholesteryl group-bearing pullulan (CHP). The complexed CAB was released by dissociation of the self-aggregate upon the addition of β-cyclodextrin. The released CAB refolded to the native form, and almost 100% recovery of the activity was achieved. The thermal stability of CAB was drastically improved by capture of the unfolded form which was then released to undergo refolding.

Most proteins irreversibly aggregate upon heating. Molecular chaperones selectively trap heat-denatured proteins (*1*−*3*) or their intermediates in refolding (*4*, *5*) to prevent their irreversible aggregation. The host chaperone releases the protein in a refolded form through a change in the conformation of the complex with the aid of ATP and another co-chaperone. Chaperonins, which have multiple subunits and a cage-like structure, are a well-investigated family of molecular chaperones (*6*). For example, GroEL acts as a host in macromolecular self-assembly by enclosing a folding intermediate protein as a guest in its central hydrophobic cavity (*6*). This is an interesting example of host−guest chemistry in a macromolecular system.

Surfactants (*7*, *8*) and cyclodextrins (*9*) are known to prevent the aggregation of the partly intermediate protein that is formed in the refolding process and in heat denaturation. Gellman et al. demonstrated an interesting system for protein refolding via the sequential use of low molecular weight surfactants and cyclodextrins as a stripping agent (*10*). In their system, however, it is sometimes difficult to completely remove the surfactant after treatment. Water-soluble polymers such as poly(ethylene oxide) (*11*) and polyamino acids (*12*) also prevent protein aggregation, although their efficiency is low.

The amphiphilic nature of proteins, especially their

hydrophobicity, is important in the complexation between a chaperone and denatured protein. To mimic or simulate the function of molecular chaperones, we newly designed an amphiphilic hydrogel nanoparticle that behaves as a host for a guest protein. Hydrophobized polysaccharides such as cholesteryl group-bearing pullulan (CHP) spontaneously form hydrogel nanoparticles in water by intra- and/or intermolecular self-aggregation (*13, 14*). Furthermore, these hydrogel nanoparticles spontaneously complex with various soluble proteins or enzymes in water (*15*−*17*). In these cases, we have observed several different types of complexation, as follows. Type I: Enzymes such as α-chymotrypsin or horseradish peroxidase are complexed by polysaccharide nanoparticles at room temperature or physiological temperature and lose their enzyme activity in the complex (*15*). Type II: Enzymes are complexed in the native form and retain their activity even in the complex, for example, lipase (unpublished result). In both cases, the complexed proteins gain substantial thermal stabilization due to fixation of the proteins or enzymes in the hydrogel matrix of the nanoparticles.

In this work, we newly report another interesting type of complexation: Type III. In this case, carbonic anhydrase B (CAB) was complexed quantitatively by the nanoparticles in a heat-denatured form above its denaturation temperature (55 °C). Another interesting and important finding is that complexed CAB was effectively (almost quantitatively) released in its refolded native form in the presence of β-cyclodextrin. This is similar to the two-step mechanism of a molecular chaperone, that is, capture of a heat-denatured protein and release of the refolded protein. In addition, this system provided effective thermal stabilization of CAB. In this paper, we describe this unique behavior of hydrogel nanoparticles of CHP self-aggregate, which is different from those previously reported for the immobilization and stabilization of enzymes or proteins in an ordinary polymer matrix.

The preparation and characterization of CHP nanoparticles have been reported elsewhere (*13, 14*). Cholesteryl group-bearing pullulan (CHP-108−0.9, where the molecular weight of the parent pullulan was 108 000 and the degree of substitution of the cholesteryl moiety per 100 glucose units was 0.9) was used in this study. The average hydrodynamic radius (R_H) of the nanoparticles was approximately 18 nm by dynamic light scattering. The apparent molecular weight (8.2×10^5) and the aggregation number of the self-aggregate (approximately 7) were determined by the static light-scattering method. The root-mean-square radius of gyration (R_G) was 15.1 nm. The association of cholesteryl moieties provides noncovalently cross-linked points in hydrogel nanoparticles (*14*).

The heat-induced aggregation of CAB (molecular weight 30 000, 0.06 mg/mL, 2 μM) was investigated by the light-scattering method at 400 nm in the absence and presence of CHP. When CAB was heated above its denaturation temperature (55 °C) to 63 °C, aggregation started within 5 min (Figure 1). The hydrophobic portions of globular protein are exposed upon partial unfolding of the protein under heating. This results in aggregation of the protein. This aggregation of CAB was significantly prevented in the presence of CHP nanoparticles. When the molar ratio of CHP nanoparticles to CAB was above 0.2, the solution was optically clear even after heating at 63 °C for 40 min. In contrast, the parent pullulan did not show the same behavior even at a rather high concentration of pullulan. Thus, CHP nanoparticles effectively prevented the aggregation and sedimentation of heat-denatured CAB. This effect is similar to the behavior of a molecular chaperone in nature.

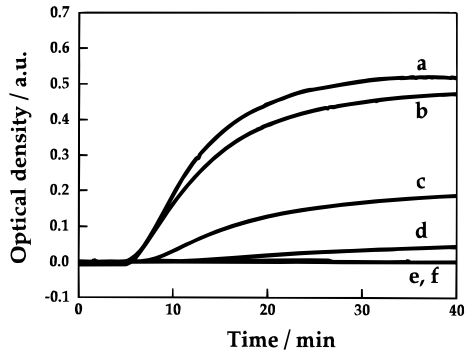

Figure 1. Self-aggregation of CAB in the presence of CHP nanoparticles and pullulan at 63 °C: (a) free CAB (0.06 mg/mL, 2 μM). (b) Pullulan (molecular weight 108 000), 0.15 mg/mL. (c) CHP nanoparticles (0.082 mg/mL, 0.1 μM as CHP nanoparticles concentration): CAB (0.06 mg/mL, 2 μM) = 0.05:1 (as a molar ratio). (d) CHP nanoparticles: CAB = 0.1:1. (e) CHP nanoparticles: CAB = 0.2:1; and (f) CHP nanoparticles, CAB = 1:1.

A mixture of the CHP nanoparticles (2 μM, as a molar per nanoparticle) and CAB (2 μM) was incubated at 70 °C for 10 min and then cooled to 25 °C. Quantitative complexation between CAB and the CHP nanoparticles was confirmed by high-performance size-exclusion chromatography (HPSEC, Superdex 200HR column, Pharmacia, UV detection at 280 nm) (data not shown). No spontaneous dissociation of CAB was observed even after storage for a week at room temperature. The CHP nanoparticles did not complex with native CAB at 25 °C even after incubation for 32 h. The secondary structure of native CAB consists of 6.6% α-helical and 30.9% β-forms (*17*). With the CHP−CAB complex, the proportions of the helical and β-forms were computationally estimated to be 24.6% and 12.0%, respectively, on the basis of the CD spectrum. The heat denaturation and subsequent complexation of CAB with CHP nanoparticles induced a large conformational change in its secondary structure. Goto and co-workers previously pointed out the possibility that the α-helical intermediate of denatured protein is a nonhierarchical intermediate of β-sheet proteins such as CAB (*18*). CHP nanoparticles may capture the heat-denatured intermediate of CAB.

The change in the mean residual ellipticity of CAB was investigated in the presence of CHP as a function of temperature at 222 nm. The mixture of CAB and CHP nanoparticles was gradually heated from 25 to 70 °C at 0.17 °C/min and then cooled to 25 °C at the same rate (Figure 2). No significant change was observed in the secondary structure of CAB upon heating to 40 °C. At around 50 °C, however, the ellipticity showed a large sigmoidal decrease. This temperature coincides with the denaturation temperature of CAB. CHP nanoparticles themselves do not show any structural change even after heating to 70 °C. The nanoparticles selectively and effectively complex only with heat-denatured CAB. The increased hydrophobicity of the denatured unfolded protein may prefer complexation with amphiphilic hydrogel nanoparticles compared to the completely folded native protein.

The dynamics of a chaperone function are controlled by suitable effectors (*6*). ATP interacts with the chaperone−protein complex and induces a conformational change in the chaperone to release the bound protein, accompanied by complete refolding, and the original protein

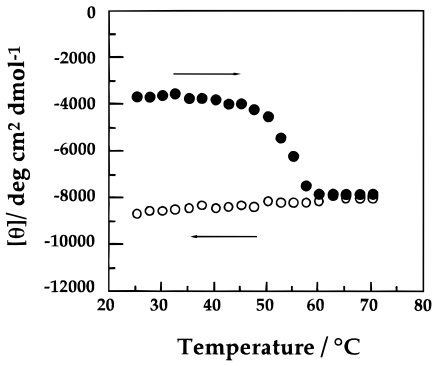

Figure 2. Mean residual ellipticity (θ) at 222 nm as a function of temperature in 50 mM Tris-sulfate (pH 7.5). A solution mixture of CAB and CHP nanoparticles was heated from 25 to 70 °C at 10 °C/h and then cooled to 25 °C: [CHP nanoparticles] = [CAB] = 15 μM.

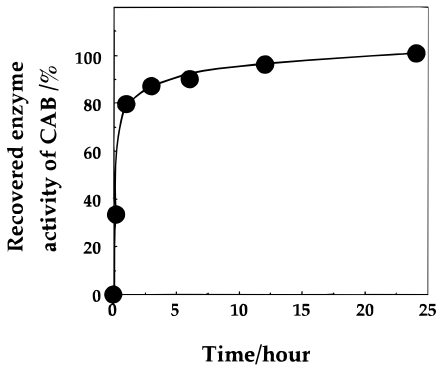

Figure 3. Recovery of enzyme activity of complexed CAB in the prescence of β-cyclodextrin (3 mM) at 25 °C in 50 mM Tris-sulfate buffer (pH 7.5).

activity is fully recovered. CHP self-aggregates undergo dissociation with the addition of β-cyclodextrin (*19*). The cross-linking domains provided by the hydrophobic cholesteryl groups are destructed upon encapsulation of the cholesteryl moiety by the β-cyclodextrin cavity. Destruction of the nanoparticles subsequently induces the release of complexed CAB. To the CHP−CAB complex, which was prepared by mixing the CHP nanoparticles (2 μM) and CAB (2 μM) at 70 °C for 10 min, was added β-cyclodextrin (3 mM), and the mixture was kept for 24 h at 25 °C. HPSEC analysis of the reaction mixture showed a complete release of free CAB (data not shown) from the complex under these conditions. Figure 3 shows the recovery of the enzyme activity of CAB with the addition of β-cyclodextrin as a function of incubation time.[1] Complexed CAB (2 μM) did not show any enzyme activity in the absence of β-cyclodextrin. However, with the addition of β-cyclodextrin (3 mM) to the complex (CHP, 2 μM), 90% of the enzyme activity recovered after 6 h, and recovery was almost 100% after 24 h. The mixture of CAB and CHP nanoparticles was heated for 10 min at various temperatures and then cooled to 25 °C. The enzyme activity that remained after the addition

[1] An aliquot containing CAB was heated at 70 °C for 10 min in 50 mM Tris, pH 7.5, and then chilled to room temperature for 10 min. A dry acetonitrile solution (0.2 mL) of 10 mM *p*-nitrophenylacetate (pNPA) was added to 1.8 mL of the sample solution (CAB, 1.8 μM in 50 mM Tris-sulfate, pH 7.5). After 20 s of mixing, an increase in the *p*-nitrophenolate concentration was monitored by the absorbance at 400 nm as a function of time. The percent recovery of enzyme activity was calculated on the basis of the initial velocity of the activity of native CAB (*20*).

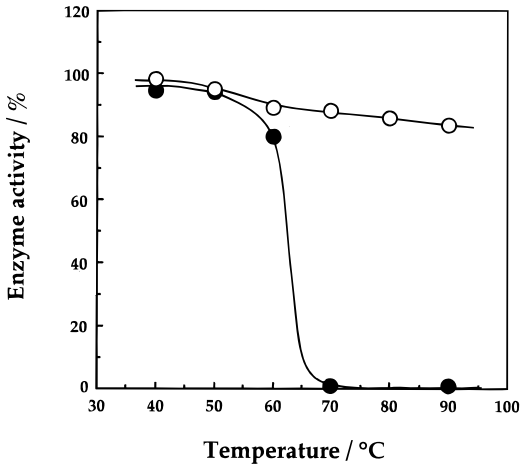

Figure 4. Stability of CAB in the presence of CHP nanoparticles at various temperatures. The mixture of CAB (2 μM) and CHP nanoparticles (2 μM) was treated for 10 min at various temperatures. The *p*-nitrophenyl acetate hydrolysis by CAB was monitored at 25 °C in 50 mM Tris-sulfate buffer, pH 7.5, after the addition of β-cyclodextrin.

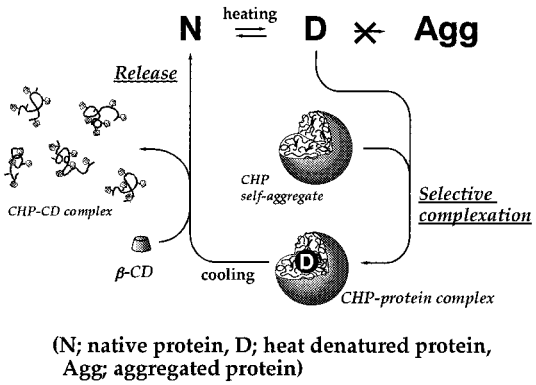

Figure 5. Schematic representation of controlled association between CHP nanoparticles and CAB.

of β-cyclodextrin was investigated (Figure 4). The irreversible heat denaturation of CAB was effectively prevented by complexation with CHP nanoparticles even at higher temperatures. As a result, the thermal stability of CAB was drastically enhanced in this system.

In conclusion, in this study, we mimicked the complex function of a molecular chaperone using a relatively simple system consisting of CHP self-aggregate nanoparticles and β-cyclodextrin. Figure 5 shows a schematic two-step mechanism, that is, the capture of heat-denatured unfolded protein and the release of the refolded form. Through this processes, the enzyme gains significant thermal stabilization. This is a novel method for the thermal stabilization of enzymes using the well-controlled association with a simple macromolecule. Protein refolding in urea or GuHCl-induced denaturation system is under investigation using a similar hydrophobized polysaccharide system.

Synthesis of Novel Europium-Labeled Estradiol Derivatives for Time-Resolved Fluoroimmunoassays

Niko Meltola,*,† Piitu Jauria,†,‡ Petri Saviranta,† and Heikki Mikola§

University of Turku, Medical Physics and Chemistry and Department of Biotechnology, P.O. Box 123, FIN-20521 Turku, Finland, and Wallac Oy, P.O. Box 10, FIN-20101 Turku, Finland . Received January 26, 1998; Revised Manuscript Received November 30, 1998

The *O*-(5-carboxypentyl)-, *O*-(4-aminobutyl)-, *O*-(6-aminohexyl)oximes of 2- and 4-formylestradiol as well as the 4-carboxyethylthioether derivative of estradiol were synthesized. These estradiol derivatives were characterized using IR-, ^{1}H-, and ^{13}C NMR spectroscopy. All synthesized estradiol derivatives were labeled with europium chelates. These "tracers" were purified and tested in a competitive time-resolved fluoroimmunoassay with monoclonal antibody (SSI 57-2) raised against the 6-*O*-(carboxymethyl)oxime-bovine serum albumin derivative of estradiol. All the tested europium-labeled estradiol-4-derivatives were bound by the antibody, whereas tracers linked via position 2 were not recognized by this antibody. It was observed that tracers conjugated via C-4 gave more sensitive standard curves than tracers conjugated via C-6. Especially, the estradiol-4-thioether derivative was found to be highly useful in time-resolved fluoroimmunoassays of estradiol while using this antibody.

INTRODUCTION

In many biochemical applications, haptens coupled covalently to other molecules are needed (*1*). For example, in affinity chromatography and in immunoassays, haptens coupled covalently onto either a solid matrix, a carrier molecule, or a label molecule are used. The coupling site, the chemical structure of the linkage, and the length of the spacer arm between the hapten and the label or the carrier molecule play important roles in the biochemical recognition reactions (*1*−*3*). Usually before coupling, a spacer arm and/or a suitable reactive group has to be introduced to the hapten molecule. In steroid immunoassay procedures and in antibody rising *O*-(carboxyalkyl)oximes, hemisuccinates, carboxyalkyl ethers, and thioethers are frequently used to couple the steroids to proteins or to the label molecule (*1, 4*).

For the raising of anti-steroid antibodies, steroids conjugated to macromolecular carriers have to be used as immunogens. The specificities of the antibodies obtained partly depend on the nature of the linkage and the coupling site of the steroid on the carrier. We have studied the binding properties of a monoclonal anti-estradiol antibody (SSI 57-2) using time-resolved fluoroimmunoassay. In these assays, we used estradiol derivatives labeled with europium chelates, which give a strong, long decay-time fluorescence, creating high specific activity in the labeled immunoreagents (*5*−*7*). The monoclonal antibody used here has been raised against 6-oxoestradiol 6-(*O*-carboxymethyl)oxime-bovine serum albumin immunogen. This immunogen has a distorted steroid core compared to free estradiol because of the double bonding of the nitrogen to position C-6 (*8*). The used anti-estradiol antibody has a much higher affinity to derivatives linked via C-6 than to free estradiol (*9*) mainly due to the bridge effect also described elsewhere (*8, 10*). It was our aim to design new estradiol derivatives that behave as similarly to free estradiol as possible while using this antibody. Because of the aromatic A ring of estradiol, conjugations to the A ring do not cause any distortions in the core structure. In addition, our previous studies (*9*) show that this anti-estradiol antibody has 90% cross-reactivity to estradiol-4-derivative, which means that the antibody binds estradiol and estradiol-4-derivatives by almost the same selectivity. On the basis of the reasons above, we describe here the synthesis of some estradiol 4-alkyloxime and 4-thioether derivatives and their labeling with a europium chelate. These europium-labeled estradiol derivatives, called tracers, were briefly tested in a competitive time-resolved fluoroimmunoassay with the monoclonal anti-estradiol antibody in order to study their binding to the antibody and, thus, to find a useful estradiol derivative to be used as a panning antigen.

EXPERIMENTAL PROCEDURES

Materials. The reagents for syntheses were purchased from either Aldrich-Chemie, Fluka, Sigma, or E. Merck and used without further purification. Europium-labeled 6-oxoestradiol 6-(*O*-carboxymethyl)oxime (abbreviated as E2-6-CMO-Eu), the europium chelates used for labeling (*11*), and aminooxyalkylamines (*12*) and aminooxyalkanoic acids (*13*) were obtained from Wallac. The solvents

were p.a. grade from either E. Merck, Aldrich-Chemie, or Lab-Scan and were used as received unless otherwise stated. NMR spectra were recorded on either JEOL JNM-LA400 or JEOL JNM-A500 spectrometers using deuterated chloroform as a solvent and tetramethylsilane as internal standard. Mass spectra (MS) were recorded on a VG7070E spectrometer and IR spectra on a Perkin-Elmer 1600 FTIR spectrophotometer. The UV spectrum was recorded on a Shimadzu UV-2100 spectrophotometer. Thin-layer chromatography (TLC) plates and silica gel for short-column chromatography were obtained from E. Merck. Purification of the europium-labeled estradiol derivatives was performed using a Superdex Peptide column (Pharmacia) with UV detection at 276 nm (Uvicord UV Monitor from Pharmacia). The murine anti-estradiol antibody; SSI 57-2 (IgG_1, κ) was obtained from Statens Seruminstitut (Denmark). Rabbit anti-mouse IgG microtitration plates, 1234 DELFIA fluorometer, DELFIA assay buffer, DELFIA wash solution, and DELFIA enhancement solution were from Wallac.

4- and 2-Formylestra-1,3,5(10)-trien-3,17β-diol (2 and 3). A solution of ethylmagnesium bromide was prepared from magnesium turnings (410 mg, 16.9 mmol) and ethyl bromide (1.27 mL, 16.9 mmol) in sodium-dried diethyl ether (115 mL). 17β-Estradiol (**1**) (1.00 g, 3.67 mmol) in anhydrous toluene (270 mL) was added dropwise to this solution. Paraformaldehyde (0.88 g, 29.4 mmol) and triethyl phosphate were then added to the mixture. The mixture was heated at 80 °C for 20 h. Hydrochloric acid (5%) was added, and layers were separated. The aqueous layer was extracted with toluene/diethyl ether (1/1 v/v). Combined organic extracts were washed with water, dried over magnesium sulfate, filtered, and evaporated to dryness. The residue was chromatographed on a short silica gel column. Elution with chloroform (technical grade) gave a mixture of 4- and 2-formyl-17β-estradiol (**2** and **3**) 688 mg (62%).

*4-Formyl-17β-estradiol (**2**).* ^{1}H NMR (δ ppm): 12.00 (1H, s, ArOH), 10.38 (1H, s, CHO), 7.49 (1H, d, J = 8.9 Hz, H-1), 6.79 (1H, d, J = 8.9 Hz H-2), 3.74 (1H, m, H-17), 0.79 (3H, s, CH_3-18).

*2-Formyl-17β-estradiol (**3**).* ^{1}H NMR (δ ppm): 10.79 (1H, s, ArOH), 9.81 (1H, s, CHO), 7.43 (1H, s, H-1), 6.70 (1H, s, H-4), 3.74 (1H, m, H-17), 0.80 (3H, s, CH_3-18). IR (film): 3413, 2931, 2869, 1653, 1571, 1488, 1239 cm^{-1}.

4-Formylestra-1,3,5(10)-trien-3,17β-diol 4-[*O*-(5-carboxypentyl)]oxime (4) and 2-formylestra-1,3,5-(10)-trien-3,17β-diol 2-[*O*-(5-carboxypentyl)]oxime (5). A mixture of 4- and 2-formyl-17β-estradiol (**2** and **3**) (52.8 mg, 0.176 mmol) was dissolved in pyridine (0.5 mL), and 6-(aminooxy)hexanoic acid hydrobromide (40.0 mg, 0.176 mmol) was added. According to TLC (dichloromethane/methanol 10/1, v/v) the reaction occurred immediately. The reaction mixture was stirred overnight at room temperature and hydrochloric acid was added. The solution was extracted with ethyl acetate. The organic layer was washed with water and dried over sodium sulfate. After filtration, the solution was evaporated to dryness and purified by preparative TLC (2 mm silica gel plate) using dichloromethane and methanol (10/1, v/v) as an eluent. Extraction with dichloromethane/methanol (5/1, v/v) gave a mixture of desired 4- and 2-carboxypentyloxime derivatives (**4** and **5**) 48.8 mg (64%).

*4-Carboxypentyloxime Derivative (**4**).* ^{1}H NMR (δ ppm): 10.34 (1H, s, ArOH), 8.54 (1H, s, $-$CH$=$N$-$), 7.25 (1H, d, J = 8.8 Hz, H-1), 6.80 (1H, d, J = 8.8 Hz, H-2), 4.16 (2H, m, $=$N$-$O$-$CH$_2-$), 3.74 (1H, t, H-17), 0.78 (3H, s, CH_3-18).

*2-Carboxypentyloxime Derivative (**5**).* ^{1}H NMR (δ ppm): 9.66 (1H, s, ArOH), 8.11 (1H, s, $-$CH$=$N$-$), 7.02 (1H, s, H-1), 6.69 (1H, s, H-4), 4.16 (2H, m, $=$N$-$O$-$CH$_2-$), 3.74 (1H, t, H-17), 0.77 (3H, s, CH_3-18). IR (film): 3430, 2933, 2870, 1728, 1393, 1260 cm^{-1}.

4-Formylestra-1,3,5(10)-trien-3,17β-diol 4-[*O*-(6-Aminohexyl)]oxime (8) and 2-formylestra-1,3,5(10)-trien-3,17β-diol 2-[*O*-(6-aminohexyl)]oxime (9). A mixture of 4- and 2-formyl-17β-estradiol (**2** and **3**) (100 mg, 0.33 mmol) was dissolved in pyridine (1.5 mL), and 6-(aminooxy)hexylamine hydrochloride (379 mg, 1.66 mmol) was added. The reaction was complete in 1 h. Pyridine was evaporated and the residue was purified by preparative TLC using chloroform/methanol (10/3, v/v) as eluent. Extraction with the same solvent gave a mixture of 4- and 2-aminohexyloxime derivatives (**8** and **9**) 75 mg (54%).

*4-Aminohexyloxime Derivative (**8**).* ^{1}H NMR (δ ppm): 8.55 (1H, s, $-$CH$=$N$-$), 7.25 (1H, d, J = 8.8 Hz, H-1), 6.80 (1H, d, J = 8.8 Hz, H-2), 4.15 (2H, m, $=$N$-$O$-$CH$_2-$), 3.70 (1H, t, H-17), 0.77 (3H, s, CH_3-18).

*2-Aminohexyloxime Derivative (**9**).* ^{1}H NMR (δ ppm): 8.12 (1H, s, $-$CH$=$N$-$), 7.04 (1H, s, H-1), 6.69 (1H, s, H-4), 4.15 (2H, m, $=$N$-$O$-$CH$_2-$), 3.70 (1H, t, H-17), 0.77 (3H, s, CH_3-18). IR (film): 3376, 2928, 2863, 1628, 1385, 1265 cm^{-1}.

4-Formylestra-1,3,5(10)-trien-3,17β-diol 4-[*O*-(4-aminobutyl)]oxime (10) and 2-formylestra-1,3,5(10)-trien-3,17β-diol 2-[*O*-(4-aminobutyl)]oxime (11). A mixture of 4- and 2-formyl-17β-estradiol (**2** and **3**) (30 mg, 0.1 mmol) was dissolved in pyridine (1.0 mL), and 4-(aminooxy)butylamine hydrochloride (28 mg, 0.2 mmol) was added. The reaction mixture was stirred overnight at room temperature. Pyridine was evaporated and the residue was purified by preparative TLC using chloroform/methanol (10/3, v/v) as eluent. Extraction with the same solvent gave a mixture of 4- and 2-aminobutyloxime derivatives (**10** and **11**) 18 mg (47%).

*4-Aminobutyloxime Derivative (**10**).* ^{1}H NMR (δ ppm): 8.55 (1H, s, $-$CH$=$N$-$), 7.25 (1H, d, J = 8.8 Hz, H-1), 6.81 (1H, d, J = 8.8 Hz, H-2), 4.17 (2H, m, $=$N$-$O$-$CH$_2-$), 3.73 (1H, t, H-17), 0.78 (3H, s, CH_3-18).

*2-Aminobutyloxime Derivative (**11**).* ^{1}H NMR (δ ppm): 8.12 (1H, s, $-$CH$=$N$-$), 7.03 (1H, s, H-1), 6.70 (1H, s, H-4), 4.17 (2H, m, $=$N$-$O$-$CH$_2-$), 3.73 (1H, t, H-17), 0.78 (3H, s, CH_3-18). IR (film): 3332, 2923, 2871, 1627, 1385, 1265 cm^{-1}.

4,5-Epoxy-17β-hydroxyestran-3-one (17). 19-Nortestosterone (**16**) (980 mg, 3.57 mmol) was dissolved in methanol (100 mL) and the solution was cooled to 5 °C. Aqueous NaOH (5.4 mL, 4 M) and H_2O_2 (0.54 mL, 30%) were added, and the mixture was allowed to stand at 5 °C for 3.5 h. The solution was acidified with glacial acetic acid (2 mL), concentrated to 30 mL, diluted with water, and extracted with ethyl acetate. The organic layer was washed with $NaHCO_3$ (5% aq) and water, dried over sodium sulfate, and evaporated to dryness. The crude product (970 mg, 93%) was used for the next synthesis step without further purification.

^{1}H NMR (δ ppm): 3.66 (1H, t, J = 8.5 Hz, H-17), 3.04 (1H, s, H-4), 0.78 (3H, s, CH_3-18). ^{13}C NMR (δ ppm): 206.82 (C-3), 81.56 (C-17), 67.50 (C-5), 61.75 (C-4). IR (film): 1705 cm^{-1}.

4,5-Epoxy-17β-hydroxyestr-1-en-3-one (18). The crude 4,5-epoxy-17β-hydroxyestran-3-one (**17**) (900 mg, 3.10 mmol) was dissolved in 2-methyl-2-propanol (200 mL). Acetic acid (3 mL, glacial) and selenium dioxide (688 mg, 6.20 mmol) were added to the solution. The mixture was refluxed under nitrogen atmosphere for 42 h, filtered

through a Celite layer, and the filtrate was evaporated to dryness. The residue was dissolved in ethyl acetate, washed 3 times with $NaHCO_3$ (5% aq), washed once with water, and dried over sodium sulfate. After removal of the solvent, the product was purified by short-column chromatography on silica gel (petroleum ether/ethyl acetate, 5/2, v/v). Yield: 382 mg (43%).

^{1}H NMR (δ ppm): 6.77 (1H, dd, J = 10.5 and 5.4 Hz, H-1), 5.95 (1H, dd, J = 10.5 and 1.2 Hz, H-2), 3.65 (1H, t, J = 8.5 Hz, H-17), 3.24 (1H, s, H-4), 2.61 (1H, dd, J = 10.7 and 5.4 Hz, H-10), 0.82 (3H, s, CH_3-18). ^{13}C NMR (δ ppm): 196.03 (C-3); 148.32 (C-1); 124.95 (C-2); 81.52 (C-17); 63.86 (C-5); 61.91 (C-4). IR (film): 1682 cm^{-1}.

3,17β-Dihydroxyestra-1,3,5(10)-trien-4-(2-carboxyethyl)thioether (19). 4,5-Epoxy-17β-hydroxyestr-1-en-3-one (**18**) (415 mg, 1.44 mmol) was dissolved in methanol (4 mL), and Tris-HCl-buffer (4 mL, 0.2 M, pH 7.5) and mercaptopropionic acid (250 μL, 3.5 mmol) were added. The pH of the reaction mixture was adjusted to 9.0 with sodium hydroxide, and the mixture was stirred at 62 °C for 20 h. The mixture was washed with ethyl acetate, and the product was precipitated from aqueous layer by adjusting pH to 2.5 with hydrochloric acid. The product was filtered off, washed with water and dried in a vacuum desiccator. Yield: 411 mg (76%).

^{1}H NMR (δ ppm): 7.42 (1H, d, J = 8.5 Hz, H-1), 6.81 (1H, d, J = 8.5 Hz, H-2), 3.70 (1H, t, J = 8.5 Hz, H-17), 2.88 (2H, t, J = 7.1 Hz, Ar−S−CH_2−), 2.54 (2H, t, J = 7.1 Hz, −CH_2COOH), 0.77 (3H, s, CH_3-18). ^{13}C NMR (δ ppm): 174.19 (−COOH); 155.31 (C-3); 141.45 (C-5); 132.95 (C-10); 127.80 (C-1); 116.93 (C-4); 111.82 (C-2); 81.22 (C-17). IR (film): 1700 cm^{-1}. MS: 376 (M^+); 304 (M − CH_2CH_2COOH); 272 (M − SCH_2CH_2COOH). UV (EtOH): λ_{max} = 293 nm.

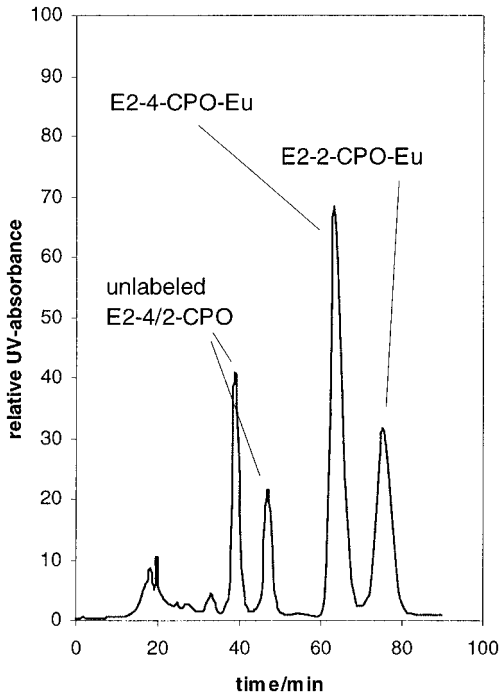
Labeling of Carboxy and Amino Derivatives of Estradiol with Europium Chelate. The carboxy derivatives of estradiol were labeled with 4-aminobenzyldiethylenetriaminetetraacetic acid europium chelate in a mixture of dioxane and 4-morpholineethanesulfonic acid buffer (0.5 M, pH 5.5) using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide as an activator. The reaction mixture was stirred for 2 h at room temperature, evaporated to dryness and the product was purified by preparative TLC using acetonitrile/water (2/1, v/v) as an eluent (*3*).

The amino derivatives of estradiol were labeled with 4-isothiocyanatobenzyldiethylenetriaminetetraacetic acid europium chelate in pyridine/water/triethylamine (90/15/1, v/v/v). After reaction (2 h), the solution was evaporated to dryness and the product was purified by preparative TLC using acetonitrile/water (2/1, v/v) as an eluent (*4*).

All the labeled estradiol derivatives were further purified on a Superdex Peptide column using 0.05 M Tris-HCl buffer [pH 7.5, containing 0.05 M NaCl and 20% (v/v) acetonitrile] as eluent. The fractions were detected by UV absorption at 276 nm and checked for europium content by DELFIA enhancement solution and time-resolved fluorometer as described later. The chromatogram of europium-labeled estradiol 4- and 2-carboxypentyloxime derivatives is shown by way of an example in Figure 1. The retention times of all europium-labeled estradiol derivatives obtained using a flow rate of 1 mL/min are given in Table 1.

Time-Resolved Fluoroimmunoassays. The synthesized and purified europium-labeled estradiol derivatives were tested in a time-resolved fluoroimmunoassay (*4*). Assays were carried out by adding 200 μL of anti-estradiol antibody (5 ng/mL) to prewashed rabbit anti-mouse IgG microtitration wells and, after a 2 h incubation, washing the wells four times with wash solution (DELFIA Platewash). The tracer solution (200 μL) was added, and after 2 h incubation, the unbound tracer was washed away. Enhancement solution (200 μL) was dispensed into the wells and incubated for 30 min in order to release the europium ion from the chelate into the solution and enhance the fluorescence. The enhanced fluorescence signal was then measured with the 1234 DELFIA research fluorometer. All the dilutions of antibody, estradiol and tracers were made in assay buffer and all the measurements were made in duplicate.

The affinity constants were determined by Scatchard analysis (*14*) of binding data obtained from the immunoassays described above. The amount of binding sites was titrated with increasing concentrations (0.05−20 nM) of labeled estradiol derivatives.



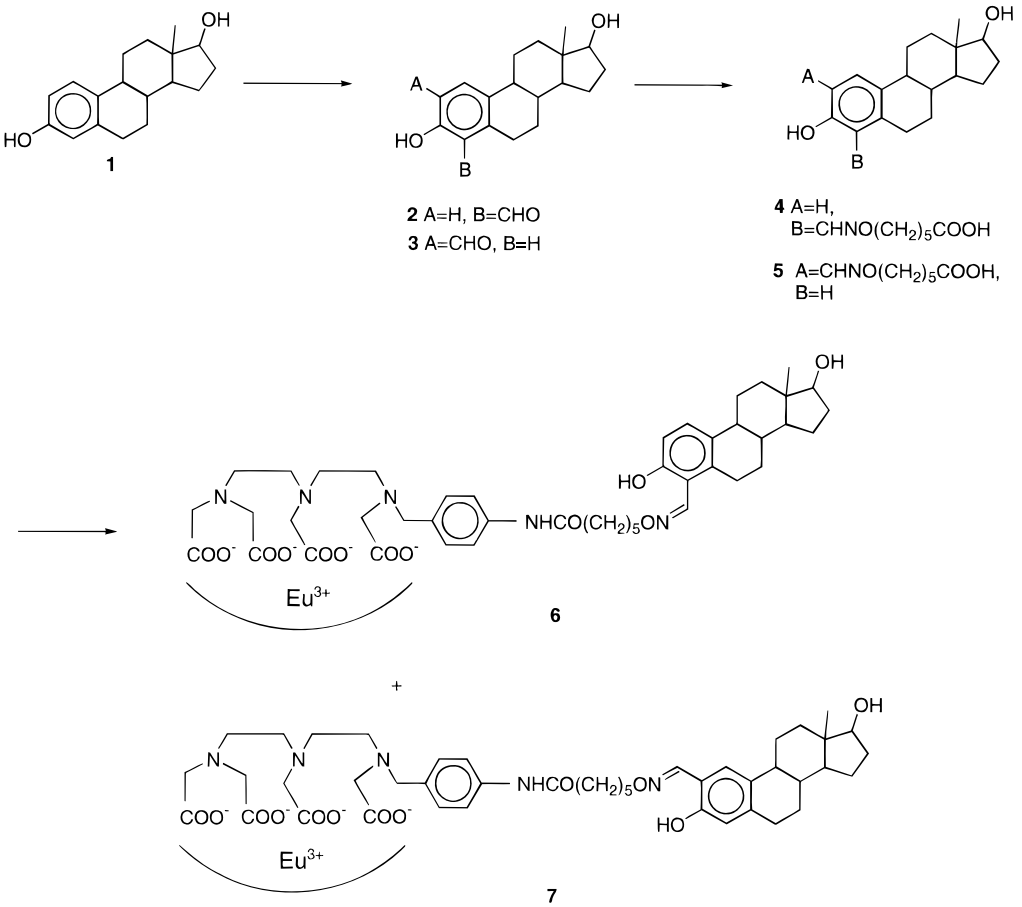


Figure 1. Purification of europium-labeled estradiol-4- and 2-carboxypentyloximes (E2-4-CPO-Eu and E2-2-CPO-Eu) (**6**, **7**).

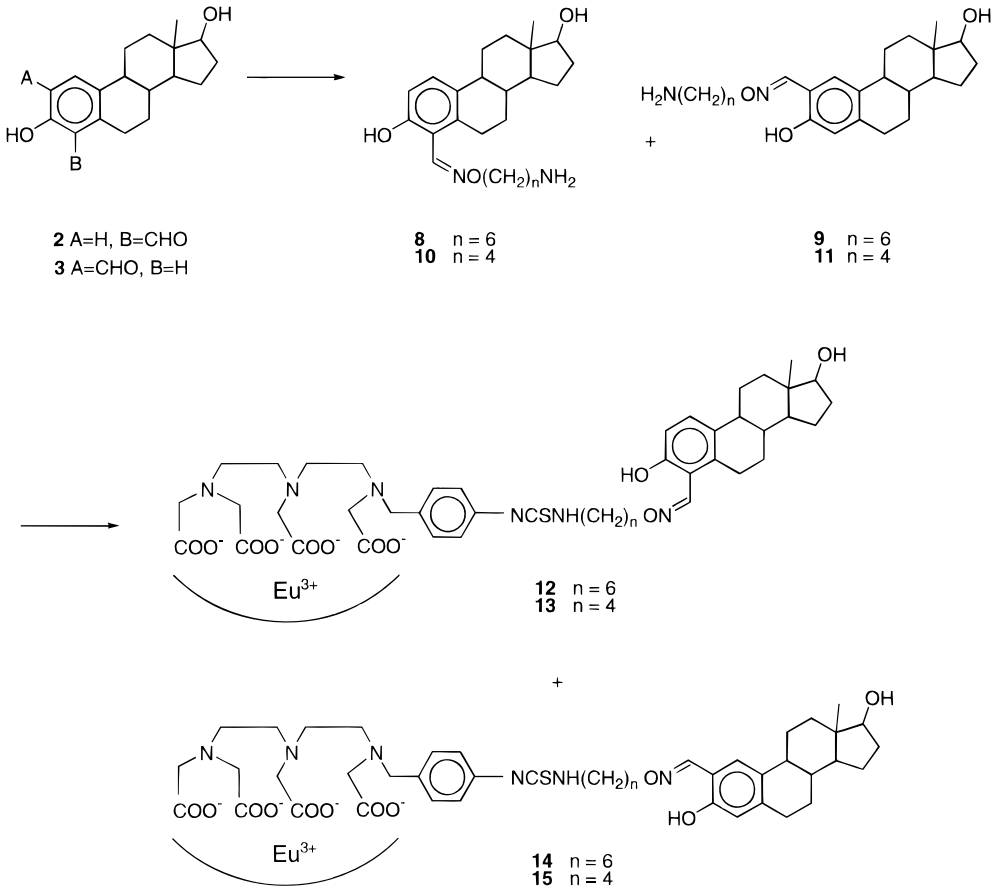
Table 1. Retention Times of Europium-Labeled Estradiol Derivatives at Purification with Superdex Peptide Column

name	abbreviation	retention time (min)
4-formylestra-1,3,5(10)-trien-3,17β-diol 4-[*O*-(5-carboxypentyl)] oxime europium chelate	E2-4-CPO-Eu	63
2-formylestra-1,3,5(10)-trien-3,17β-diol 2-[*O*-(5-carboxypentyl)] oxime europium chelate	E2-2-CPO-Eu	75
4-formylestra-1,3,5(10)-trien-3,17β-diol 4-[*O*-(6-aminohexyl)] oxime europium chelate	E2-4-AHO-Eu	91
2-formylestra-1,3,5(10)-trien-3,17β-diol 2-[*O*-(6-aminohexyl)] oxime europium chelate	E2-2-AHO-Eu	106
4-formylestra-1,3,5(10)-trien-3,17β-diol 4-[*O*-(4-aminobutyl)] oxime europium chelate	E2-4-ABO-Eu	55
2-formylestra-1,3,5(10)-trien-3,17β-diol 2-[*O*-(4-aminobutyl)] oxime europium chelate	E2-2-ABO-Eu	61
estra-1,3,5(10)-trien-3,17β-diol 4-(2-carboxyethyl)thioether europium chelate	E2-4-CET-Eu	30

Scheme 1. Synthesis of Europium-Labeled Estradiol-4- and 2-Carboxypentyloximes (6, 7)

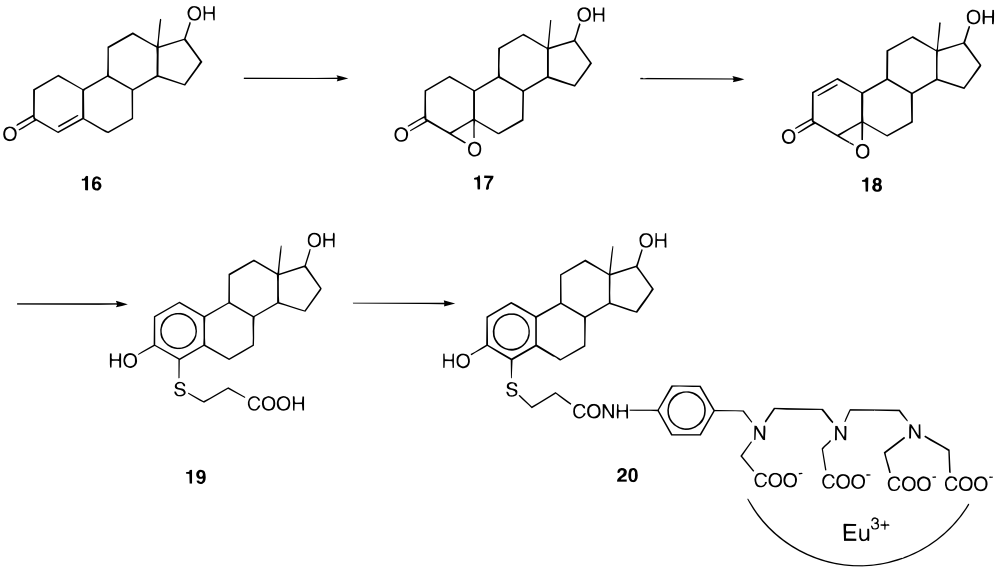
The standard curves for estradiol were obtained with competitive fluoroimmunoassay using double antibody technique (*4*), in which the anti-estradiol antibody was captured on to the solid phase by secondary antibody (anti-mouse IgG), whereafter estradiol standards were added together with the tracer to the wells. Estradiol inhibits the binding of the labeled derivative, resulting in a descending standard curve.

RESULTS AND DISCUSSION



Syntheses. On the basis of our previous good experiences with oxime-type spacers (*4*, *12*, *15*), we synthesized estradiol-4 derivatives starting with the introduction of a formyl moiety into position 4. Selective formylation of estradiol into position 2 has been published by Brueggemeier et al. (*16*); however the regioisomeric 4-formylestradiol could not be obtained by this route. Pert et al. (*17*) have published the synthetic route for 2- and also for 4-formylestradiol. The synthesis of 4-formylestradiol seemed laborious, and the overall yield was quite low. The procedure that Xie et al. (*18*) have used for the formylation of 17α-ethynylestradiol seemed attractive, because in this procedure there is no need of protective groups, and both 2- and 4-formyl-17α-ethynylestradiol were obtained in a single step in relative good yield. We used the same procedure for the synthesis of 2- and 4-formylestradiol (Scheme 1). The reaction occurred smoothly and the product obtained was as expected, a mixture of 4-formylestradiol (**2**) and 2-formylestradiol (**3**) with a total yield of 62%. Total separation of these two isomers was laborious and unnecessary at this stage. For partial purification, we used a short silica gel column where the faster moving 4-formylestradiol (**2**) could be enriched from 1/5 to 3/2 for further reactions.

Introduction of the oxime linkers (Schemes 1 and 2) was performed by dissolving a mixture of formylestradiol into pyridine and adding aminooxy compounds into the solution (*12*). The reaction was complete in a few minutes due to the relatively high reactivity of the salicylaldehyde-type formylestradiol. The reaction mixture was stirred at room temperature for longer period to make sure there was no starting material left. The reaction conditions were not optimized and better results may be obtained by using another solvent or temperature. All estradiol-oxime derivatives, except for europium-labeled ones, were characterized as a mixture of two isomers using ^{1}H NMR and IR spectroscopy.



The thioether derivative (**19**) was synthesized (Scheme 3) starting from 19-nortestosterone (**16**) using previously published methods (*19*, *20*). The 19-nortestosterone (**16**) was converted to its epoxy derivative (**17**) by oxidation with alkalic hydrogen peroxide. The 4,5-epoxy-17β-hydroxyestran-3-one was obtained in 93% yield and was used for the next synthesis step without further purification. Oxidation with selenium oxide gave the desired 4,5-epoxy-17β-hydroxyestr-1-en-3-one (**18**) with 43% yield after purification by short-column chromatography. The previous two reactions were scaled up and compounds **17** and **18** were obtained in approximately the same yields (90 and 40%) as before. The mercaptopropionic acid was introduced into the 4,5-epoxy-17β-hydroxyestr-1-en-3-one (**18**) by modifying the method of Ghaffari et al. (*21*). The product (**19**) was obtained in 76% yield. The estra-1,3,5(10)-trien-3,17β-diol 4-(2-carboxyethyl)thioether (**19**) was characterized using ^{1}H NMR, ^{13}C NMR, IR, and UV spectroscopy. Mass spectrometry was also used to confirm the desired structure.

All the synthesized estradiol amino and carboxy de-

rivatives were labeled with europium chelate and purified using first preparative TLC and then HPLC on a Superdex Peptide column (Table 1 and Figure 1).

Tracer Testing. For testing of the tracers, we used a buffer-based model system. The results from the affinity measurements, analyzed according to the Scatchard equation (*14*), are shown in Figure 2. As expected, the affinity of the anti-estradiol antibody to europium-labeled 6-oxoestradiol-6-CMO used as an internal standard was the highest because it was the immunogen used to raise the antibody. Estradiol-4-derivatives have considerably lower affinity as shown in Figure 2 and Table 2. In general, antibodies are expected to have lower affinity to steroids, which differ from the immunogen with regard to positions where direct contact is made with antibody side chains (*22*). The chemical structure of the linkage between the label and steroid also affects the process of the antibody recognition (*2*). This has also been observed in our studies. The antibody had a higher affinity to the thioether derivative than to the oxime derivatives when coupled to position C-4 of estradiol (Figure 2). This can be explained by hydrogen bond between oxime-nitrogen

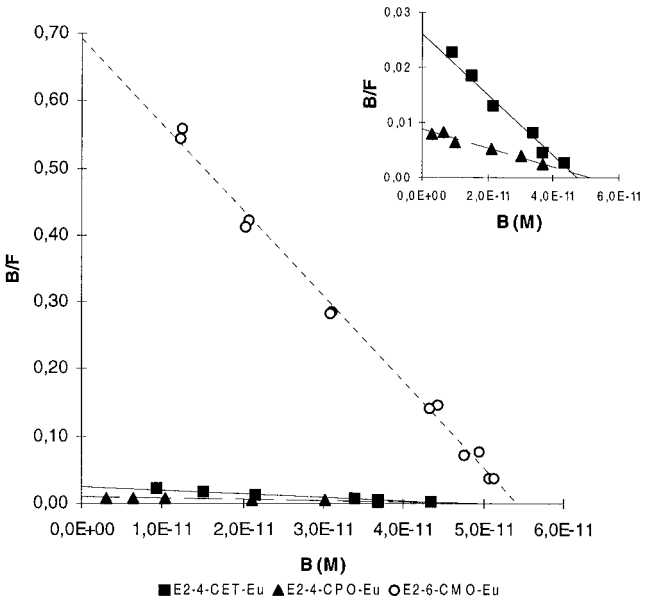

Figure 2. Scatchard analysis of equilibrium binding data for an anti-estradiol antibody. The plot includes only one oxime-derivative by the way of an example. Each point is the mean of two determinations.

Table 2. IC_{50} Values, Signal Levels, and Affinities of the Tested Estradiol Tracers

tracer	IC_{50}[a] (nM)	corr B_o[b] (cps)	bg[c] (cps)	K_a (M^{-1})
E2-6-CMO-Eu	8.1	37 068	477	1.3×10^{10}
E2-4-CPO-Eu	4.0	36 182	5148	1.7×10^{8}
E2-4-AHO-Eu	4.9	43 288	12 222	1.9×10^{8}
E2-4-CET-Eu	6.1	35 773	729	5.5×10^{8}
E2-4-ABO-Eu	7.8	34 366	10 978	1.6×10^{8}

[a] IC_{50} values are determined as estradiol concentration for 50% displacement of maximum binding in the absence of unlabeled estradiol. [b] Signal in the absence of unlabeled estradiol. [c] Instrumental background and nonspecific binding.

and 3-hydroxyl group, which obviously has a negative effect on antibody recognition.

In summary, all the tested europium-labeled estradiol-4-derivatives were bound by the antibody (SSI 57-2), whereas tracers linked via position 2 were not recognized by this antibody. This was anticipated because in the previous studies (*9*), the same antibody had only slight cross-reactivity with estradiol-2-derivatives. Figure 3 shows estradiol standard curves with three different tracers. The curves show a trend in sensitivity depending on the position of the linkage. Tracers conjugated via C-4 give more sensitive standard curves than tracers conjugated via C-6. This can also be seen in Table 2, where IC_{50} values are lower when using tracers conjugated via C-4. The reason for higher background signal with oxime derivatives is unspecific binding, resulting partly from the higher tracer concentration needed because of the lower affinity of these derivatives.

Our results demonstrate that the new estradiol derivatives synthesized here, especially the thioether derivative, are useful tracers in the immunochemical characterization of the anti-estradiol Mab SSI 57-2. Because this antibody is a representative of a large group of monoclonal antibodies raised with estradiol-6-CMO conjugates, we foresee that our tracers will be potentially suitable for the other Mabs, too. Furthermore, as these new conjugates do not exhibit considerable bridge effect (unlike the 6-CMO derivatives), they could be used as panning antigens in the search of improved anti-E2-6-CMO antibody variants from large mutant libraries using

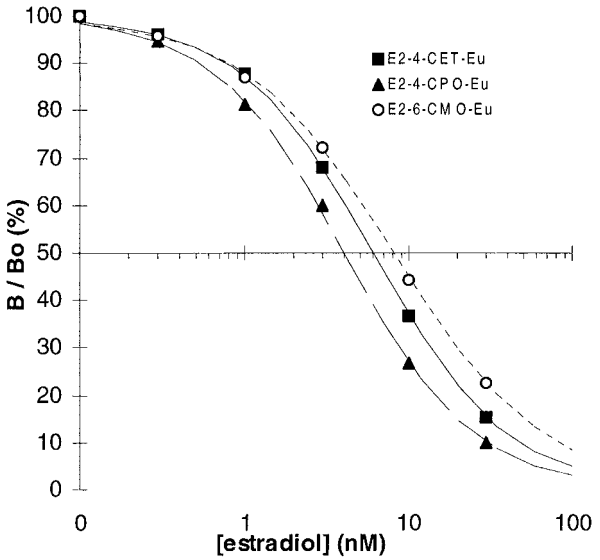

Figure 3. Estradiol displacement curves with different europium-labeled estradiol derivatives in the time-resolved fluoroimmunoassay. *B* is binding at the estradiol concentration indicated, B_o is maximum binding without unlabeled estradiol.

the phage display technology (*23*). When used as a panning antigen, these estradiol derivatives can be conjugated with biotin instead of a europium chelate. We are currently using such biotinylated estradiol-4-thioether derivative for the panning of a mutant phage library derived from Mab SSI 57-2 (to be published elsewhere).

Carlos Haya Hospital, Malaga, Spain. Received February 3, 1998; Revised Manuscript Received December 18, 1998

Conjugates of poly-L-lysine (PLL) containing a penicillin or a penicilloyl residue were prepared and characterized by ^{1}H NMR and by size-exclusion (SE) HPLC. These conjugates were used in a radio allergo sorbent tests (RAST) test for the determination of allergy toward β-lactams. The chemiometric evaluation of the data indicates that allergy to amoxycillin is different from allergy to the other β-lactams tested. Furthermore, careful chemical characterization of the conjugates appears to be crucial to obtain meaningful information from the RAST data.

INTRODUCTION

Despite a recent claim suggesting the overestimation of allergy to penicillin (*1*), most research groups agree with the importance of this pathology (*2*), which may cause severe health problems (*3*).

Hypersensitivity reactions to β-lactams are the most frequent type of adverse drug reaction mediated by an immunological mechanism (*4*, *5*). Penicillin allergy has been deeply studied and considered to be the model for drug allergy (*6*−*8*).

Penicillins are low molecular weight substances which are not themselves antigenic but give rise to a number of different antigenic determinants either by metabolism in vivo or by breakdown in vitro before administration (*9*).

In early studies with benzylpenicillin in man and animals (*10*, *11*), it was demonstrated that penicillin interacts covalently with serum proteins (*12*) forming immunogenic conjugates (*13*) which can produce severe anaphylactic reactions.

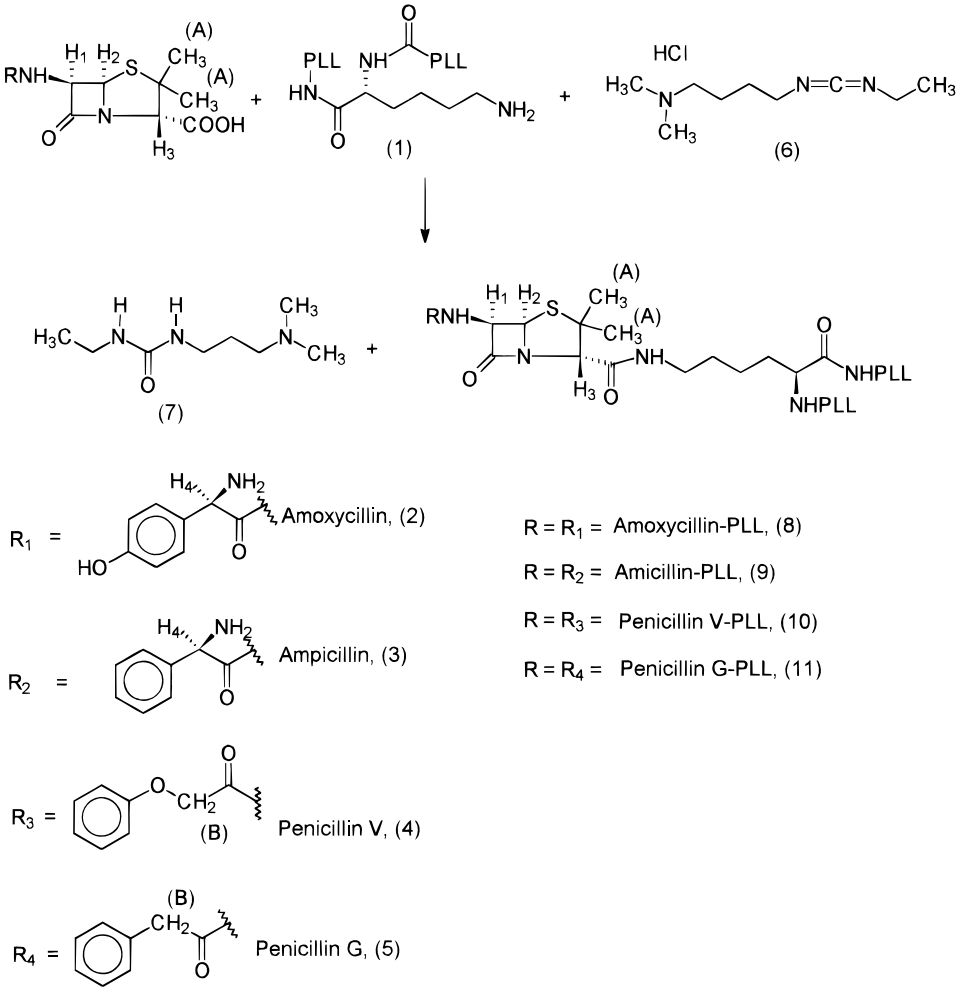
The major antigenic determinant is the penicilloyl group derived from the cleavage of the β-lactam ring of penicillin (*12*), and many allergic reactions to penicillin are due to antibodies specific to this group (*14*). Other β-lactam cleavage products may also act as haptens and are known as "minor determinants" (*15*). These are associated with the majority of the severe immediate reactions to penicillin G (*16*). Human IgE to penicillin itself has been clearly documented in a previous paper (*17*).

Skin tests are often used for the diagnosis of penicillin allergy (*18*−*21*). These appear to be positive in approximately 60% of predictive cases in allergic reaction to penicillin or its derivatives (*22*). The materials used for "in vivo" tests are essentially penicillin−poly-L-lysine conjugates (*23*). Several "in vitro" tests for the determination of allergy to penicillin derivatives are also based on penicillin−protein conjugates (*24*). Penicillin-related RAST requires a carrier-drug structure to present the drug molecule to the specific antibody (*25*). These conjugates are not generally chemically well characterized, and this has a consequence in the uncertainty about the structure of the determinant(s).

A chemical characterization of these compounds is also necessary since penicillin conjugates with tissue macromolecules (proteins, carbohydrates, and lipids) are the compounds which elicit antibody formation (*26*, *27*). Moreover, knowledge of the structure of the antigenic determinants of penicillin conjugates may allow the preparation of monovalent derivatives which could be used to desensitize patients prior to administration of the drug (*28*).

EXPERIMENTAL PROCEDURES

Instrumentation. NMR spectra were measured in D_2O at 25 °C using a Bruker AC300 instrument. HPLC analyses were performed with a Waters 600E HPLC. The detector was a Hewlett-Packard 1040 Diode Array Detector. The γ-counter was a Packard Cobra instrument.



Reagents. Poly-L-lysine (L-PLL) hydrobromide ($n \approx 145$) was purchased from Sigma Chemicals, *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide (ECDI) was an Aldrich product; all the β-lactam antibiotics were Farmitalia Carlo Erba products. Membranes for dialysis were Spectra/Por products. Paper disks were activated with cyanogen bromide. Labeled, affinity purified, anti-human IgE from goat was a Pharmacia product.

Preparation of the Conjugates. A total of 0.09 mmol of β-lactam was added to a solution of L-PLL (*1*) (13 mg, 0.0007 mmol) in 5 mL of 0.2 M aqueous buffer, pH 7.2 (K_2HPO_4/KH_2PO_4) (or 0.2 M aqueous buffer, pH 8.5 for K_2HPO_4/KH_2PO_4), and the resulting solution was stirred

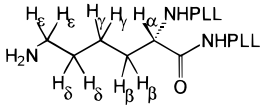
Scheme 1



at 4 °C. After 5 min, 17 mg (0.09 mmol) of *N*-(3-dimethylaminopropyl)-*N′*-ethylcarbodiimide (*10*) was added, and this solution was stirred at 4 °C for 12 h. Low molecular weight reagents and byproducts were removed by dialysis for 120 h at 4 °C with a 3500 Da cutoff membrane. The product was then obtained by lyophilization.

Radio Allergo Sorbent Test (RAST). RAST assays were carried out as previously described (*25*, *29*, *30*). Cyanogen bromide activated cellulose disks were used as the solid phase. The disks were bound to different conjugates. This was made in duplicate using 30 μL of serum and 30 μL of radiolabeled anti-IgE antibody (Pharmacia, Uppsala, Sweden). Results obtained were expressed as percentage of label uptake respect to the maximum counts after subtracting the uptake of the respective carrier single disk. Optimal cutoff points between positive and negative were determined by receiver operator control curves (ROC) using a negative control group of subjects with no history of allergy to penicillin and a negative skin test to all the penicillin determinants (*31*).

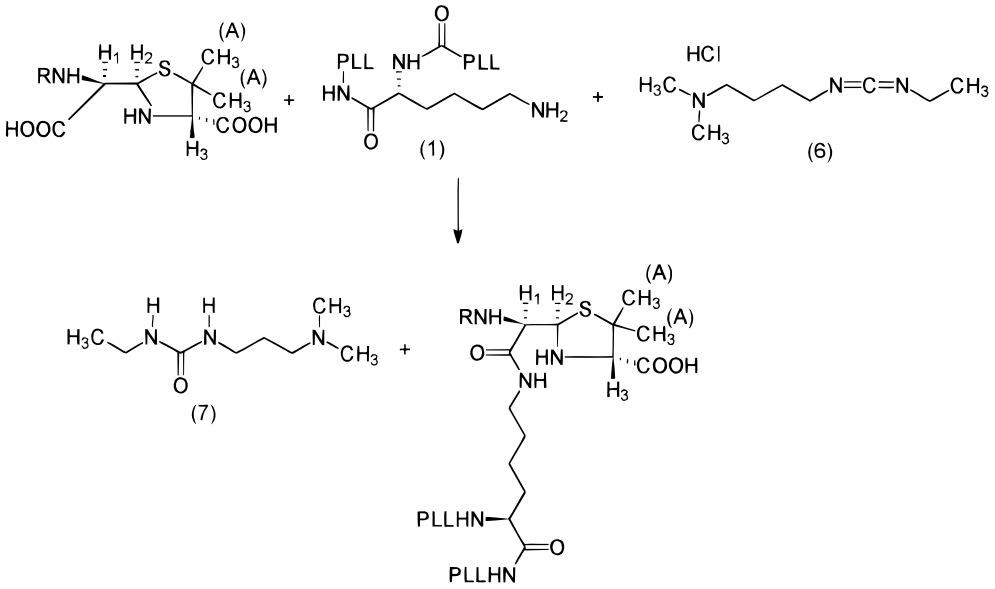
RESULTS AND DISCUSSION

The reaction of poly-L-lysine (L-PLL-NH_2), **1**, average MW, 20 kDa (*32*) with excess penicillins [amoxycillin (**2**, AXO), ampicillin (**3**, AMP); penicillin V (**4**, PV); penicillin G (**5**, PG)] (Scheme 1) was performed at pH 7.2, in the presence of the water-soluble carbodiimide **6** (ECDI) (*33*), and gave, after extensive dialysis at 0 °C, the conjugates **8**−**11**. These were constituted of a family of poly-L-lysines derivatized at the primary amino group at C_ϵ with a β-lactam fragment. The lysine residue resonated as shown in Table 1. This resulted from the ^{1}H NMR spectrum in D_2O.

Table 1

PLL	H_α	H_β	H_γ	H_δ	H_ϵ
Amoxycillin-PLL, **8**	4.25 (t)	1.75 (m)	1.40 (t)	1.75 (m)	3.00 (t)
Ampicillin-PLL, **9**	4.25 (t)	1.75 (m)	1.40 (t)	1.75 (m)	3.00 (t)
Penicillin V-PLL, **10**	4.30 (t)	1.75 (m)	1.45 (m)	1.75 (m)	3.00 (s)
Penicillin G-PLL, **11**	4.30 (m)	1.70 (m)	1.40 (m)	1.70 (m)	3.00 (s)

The NMR signals of the β-lactam-derived part of the molecule are shown in Table 2, together with the signals of the parent β-lactam. In the preparations performed at pH 7.2 and 4 °C, H_1 and H_2 appeared in the region δ 5.20−5.60, respectively, with a $J = 5-7$ Hz. Hence, they were in the same position and had the same multiplicity as the corresponding protons in the starting materials. In particular, the coupling constants showed also that the chirality at C_6 and C_7 had been retained. The aromatic hydrogens of the penicillin residue appeared at δ 7.30−7.50 as multiplets. These attributions were confirmed by ^{1}H-COSY experiments.



The integration of the aromatic protons and H_α suggested that the family of derivatized poly-L-lysine mol-

penicilloyl G-PLL, **15**	16.0	6.24

ecules constituting the conjugate contained the hapten density shown in Table 3. This evaluation of hapten density of a polypeptide or a protein turned out to be by far more precise that the spectrophotometric determination.

It has been pointed out that a too low percent haptenization of the protein carrier lowers the effectiveness of the conjugate in eliciting Wheal-and-Flare in penicillin-sensitized human subjects (*34*). Using penicilloylated bovine serum albumin (BSA) as the immunizing antigen in mice, it was found that an epitope number higher than 11 penicilloyl residues/protein molecule induces significant antibody formation after a single injection, whereas 0.6 penicilloyl residues/BSA molecule do not induce penicilloyl-specific antibodies (*35*).

When the reaction of the β-lactam was performed at alkaline pH (8.5), this resulted in the formation of a different type of conjugate **12**−**15**. In fact, Table 1 shows the opening of the β-lactam ring, thus allowing the conjugation with L-PLL via the carboxylic acid resulting from the cleavage of the β-lactam ring (Scheme 2). In the reaction of amoxycillin **2** at pH 8.5, the resulting mixture was constituted of amoxycilloyl-PLL **12,** 60%, and a complex mixture of other ring fission products (Scheme 2).

Other authors have prepared penicillin−L-polylysine conjugates. The alkaline pH was generally used. In particular, a recent synthetic method (*36*) forms a benzylpenicilloyl−L-polylysine (BPO-L-PLL), and this conjugate has been used in the determination of IgE antibodies to the BPO determinant (*30*).

All the conjugates previously described were then used in a RAST (*37*). The conjugates were immobilized in paper disks and used to test the presence of human IgE antibodies in the sera of some 30 patients known to be allergic to penicillins. Ten sera had been shown by conventional clinical tests to be only specific to amoxycillin (group A), 10 other sera were shown by conventional clinical tests to be specific only to penicillin G (group B), and further 10 sera where shown by conventional clinical tests to be positive to both amoxycillin and penicillin G (group C). The results are shown in Table 4.

The principal component analysis (PCA) (*38*) was used to evaluate the information contained in the experimental data (distribution, clusters, outliers, etc.) and the relationships among the variables. PCA was performed on the experimental data (30 patient sera × 8 β-lactams, Table 4); the first three principal components explain 95% of the total data variability.

The meaning of the PCs and the relationships among the variables were evaluated from the two biplots PC1 vs PC2 and PC1 vs PC3 (i.e., the contemporary scatter plot of both loadings and scores). The first component is the allergenic power of all the combined considered drugs (81% of explained variance); the second component is the

[a] Results were expressed as percentage of label uptake respect to the maximum counts of radiolabeled anti IgE added.

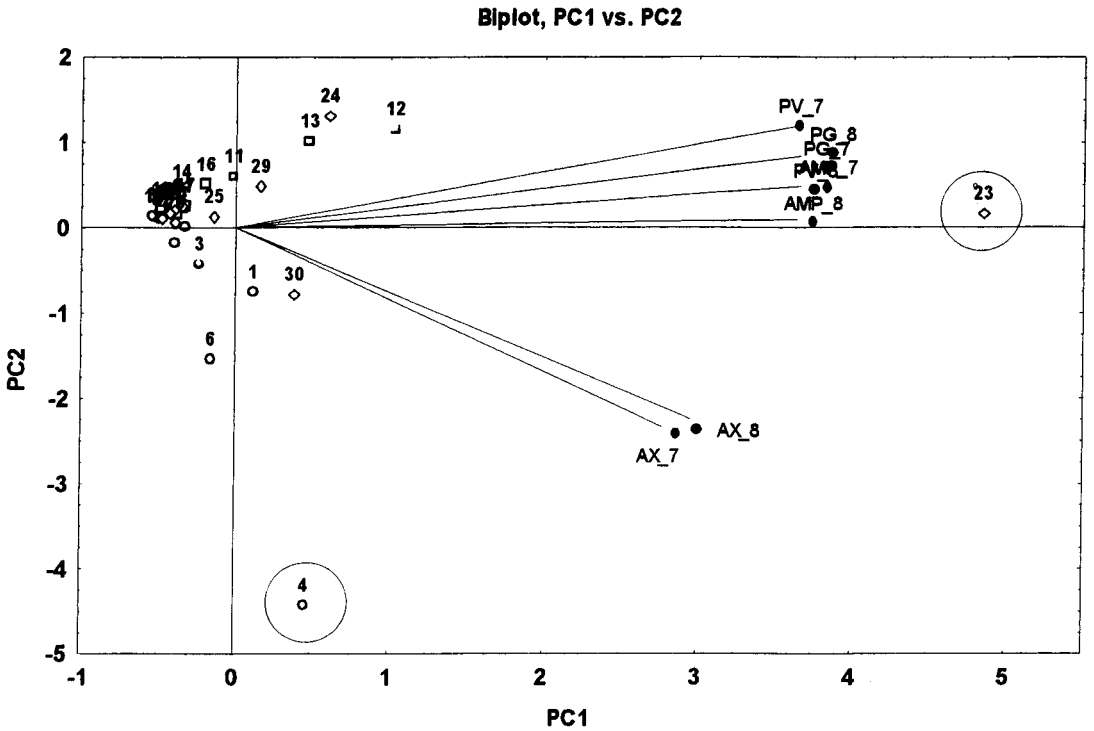

Figure 1. Biplot PC1 vs PC2. Variables in black (loadings); samples (patient sera) are divided in allergic to amoxycillin (circles), allergic to penicillin G (squares), and allergic to both drugs (rhombs). Patients 4 and 23 are highlighted with a big circle.

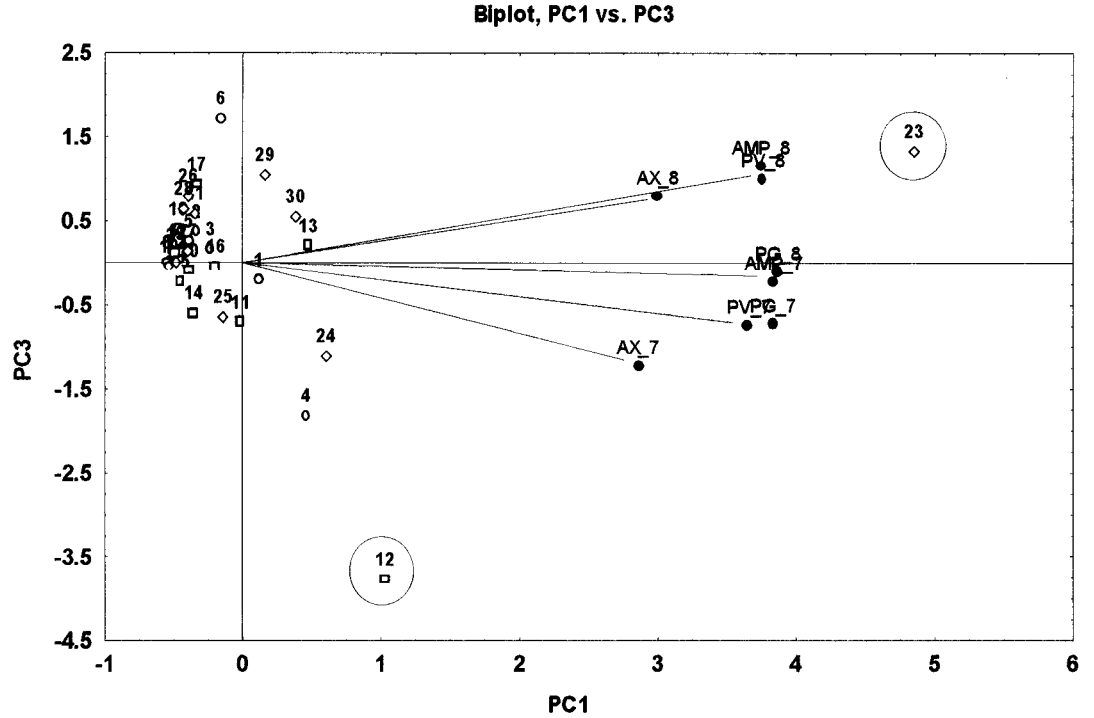

Figure 2. Biplot PC1 vs PC3. Variables in black (loadings); samples (patient sera) are divided in allergic to amoxycillin (circles), allergic to penicillin G (squares), and allergic to both drugs (rhombs). Patients 12 and 23 are highlighted with a big circle.

different action of amoxycillin with respect to the remaining β-lactams (11% of explained variance, Figure 1).

Concerning the patients, the analysis highlights patient 23 as the most allergic to all the β-lactams. Furthermore, patient 4 is characterized by a strong reactivity to amoxycillin (Figure 1).

The third component (4% of explained variance) shows the different behavior exhibited by the conjugates prepared at pH 7.2 in comparison with those prepared at pH 8.5, in particular related to amoxycillin (Figure 2). This component shows the high sensitivity to conjugates prepared at pH 7.5 for patient 12.

In conclusion, the in vitro determination of human IgE antibodies to β-lactams shows that patients may have both anti-penicillyl and anti-penicilloyl IgE antibodies. The chemometric evaluation of the data indicates that allergy to amoxycillin is different from allergy to the other β-lactams tested. Furthermore, careful chemical characterization of the conjugates appears to be crucial to obtain meaningful information from the RAST data.

ACKNOWLEDGMENT

This work was supported by NATO Contract CRG-971196 and by a CNR grant. We thank our students Aldo Comi, Luciana Monti, and Barbara Avogadro for their collaboration in the experimental work.

Closo-Dodecaborate(2-) as a Linker for Iodination of Macromolecules. Aspects on Conjugation Chemistry and Biodistribution

Vladimir Tolmachev,*[,†,‡] Jacek Koziorowski,[§,∥] Igor Sivaev,[⊥] Hans Lundqvist,[†] Jörgen Carlsson,[†] Anna Orlova,[§] Lars Gedda,[†] Pär Olsson,[†] Stefan Sjöberg,[§] and Anders Sundin[#]

Division of Biomedical Radiation Sciences, Box 535, S-751 21, Uppsala University, Uppsala, Sweden, Uppsala University PET-Centre, Uppsala University, Uppsala, Sweden, Department of Organic Chemistry, Uppsala University, Uppsala, Sweden, Nesmeyanov Institute of Organo-Element Compounds, Moscow, Russia, RRC "Kurchatov Institute", Moscow, Russia, and Institute for Medical Radiobiology, Paul Scherrer Institut, Villigen, Switzerland. Received March 18, 1998; Revised Manuscript Received January 29, 1999

Boron-containing compounds like *closo*-dodecaborate(2-) are in theory suitable for radioactive labeling with halogens. The boron−halogen bond is stronger than carbon−halogen bond and is not likely to be recognized by deiodinating enzymes in vivo. Peptides and proteins may be conjugated with various *closo*-dodecaborate(2-)-containing ligands, and thereafter, the conjugate can be iodinated. Since *closo*-dodecaborate(2-) is more avidly iodinated than tyrosine in moderately acidic media, such conjugates may be directly labeled on the boron part with radioisotopes of iodine using the standard Chloramine-T procedure. Mercapto-undecahydro-*closo*-dodecaborate(2-) (BSH) was reacted with the double bond of allyldextran to form a boronated dextran compound of the molecular size of about 70 kDa. This compound, in the text denoted as Dx-BS, and cesium dodecahydro-*closo*-dodecaborate(2-) were labeled using iodine-125. The two compounds were administered to rats in order to study their in vivo stability. The results indicate that iodinated Dx-BS is stable for about 20 h in vivo. The degradation rate, as indicated by thyroid uptake, was found low. [^{125}I]Iodo-*closo*-dodecaborate(2-), which is a possible degradation product of [^{125}I]Dx-BS-I, was rapidly excreted in urine without significant accumulation in any organ.

INTRODUCTION

Iodine isotopes play a fundamental role both in biomedical research and in clinical practice (Dewanjee, 1992), and a variety of decay schemes for these different iodine isotopes allow for a wide range of applications in the field of nuclear medicine. A convenient radionuclide for laboratory studies and for radioimmunoassay is ^{125}I [$T_{1/2}$= 60 days,100% electron capture (EC)] (Cleeland et al., 1976), while ^{131}I ($T_{1/2}$= 8 days, β^-) is the most frequently used isotope for systemic radionuclide therapy (Wilbur et al., 1989; O'Doherty et al., 1993; Press et al., 1996; Troncone and Rufini, 1997). ^{123}I ($T_{1/2}$=13.3 h, 100% EC) is widely used for diagnostic purposes in γ-scintigraphy and SPECT [see, e.g. Killen et al. (1989), Kulkarni and Corbett (1990), and Kusic et al. (1990)]. In the past few years, there has been a growing interest in the long-lived positron emitter ^{124}I ($T_{1/2}$= 4.2 days, 23% β^+) for labeling of macromolecules as positron emission tomography (PET) tracers (Arbit et al., 1995; Carnochan et al., 1994; Young et al., 1995).

It has been advocated that the use of radioiodine is advantageous compared with radiometals for labeling of antibodies intended for in vivo applications (Larson and Carrasquillo, 1988). During the past decade, radioiodinated antibodies have been used both for radioimmunodetection (Delaloye et al., 1986; Bischof-Delaloye et al., 1989; Gasparini et al., 1994) and for radioimmunotherapy (RIT) (Knox, 1995; Lashford et al., 1988).

A problem associated with in vivo applications of radioiodinated radioimmunoconjugates is the loss of the iodine label from the targeting compound in a tumor (Zalutsky and Narula, 1988; Zalutsky et al., 1989; Wilbur et al., 1989). This process is probably the reason for the lower tumor accumulation of radioiodine than radiometals as shown in a number of dual-labeling studies (Khaw et al., 1986; Bischof Delaloye et al., 1997; Meijs et al., 1997). It was believed for a long time that the structural similarity between iodotyrosines and the thyroid hormones, which are substrates for deiodinases, was the major cause for the loss of radioiodine from monoclonal antibodies (mAbs) in vivo (Zalutsky, 1988; Khaw et al., 1986). For this reason, alternative strategies for protein radioiodination were sought to provide iodination sites on the mAbs, with a high C−I bond strength, which are dissimilar in structure to iodotyrosines and thyroxine (Garg et al., 1991). This search resulted in the development of various radioiodinating reagents which contained radioiodine attached to a nonphenolic benzene ring (Zalutsky and Narula, 1987; Zalutsky and Narula, 1988; Wilbur et al., 1989), 4-methyl-benzoate (Garg et al., 1993), pyridinecarboxylate (Garg et al., 1991), or vinyl moiety (Hadley and Wilbur, 1990) instead of a tyrosine-like moiety.

The same concept was initially the basis of this study where derivatives of *closo*-dodecaborate dianion were chosen as linkers for attachment of iodine to targeted conjugates. The rationale for this approach was (1) *closo*-dodecaborate(2-) may be easily iodinated (Knoth et al., 1964; Srebny and Preetz, 1984; Haeckel and Preetz, 1995; Wilbur et al., 1995); (2) the B−I bond is stronger than the C−I bond (220 kJ/mol versus 209 kJ/mol) (Kerr, 1992); (3) Derivatives of *closo*-dodecaborate(2-) can be conjugated to biomolecules (Holmberg and Meurling, 1993; Gedda et al., 1996); and (4) the assumption that no enzymatic system exists in laboratory animals or in human for detachment of iodine from boron.

One strategy in our laboratory in the development of compounds for tumor targeting is the use of dextran conjugated to a target-seeking moiety to create a spacer to attach therapeutic radionuclides or other cytotoxic substances at a suitable distance from the antigen- or receptor-binding site. Receptor-specific proteins and shorter peptides, like mAbs or their fragments, epidermal growth factor (EGF), and somatostatin may be conjugated to dextran without destroying the receptor specificity (Holmberg et al., 1994a,b; Andersson et al., 1991; Lövqvist et al., 1993; Olsson et al., 1994; Zhao et al., 1998). Dextran may also protect peptides from fast biodegradation (Andersson et al., 1991, 1992; Carlsson et al., 1994; Lindström and Carlsson, 1993).

To evaluate the stability of the iodine−boron bond in vivo, we used compound 4 (Dx-BS) in this study. This compound was radioiodinated and injected intravenously in rats. It has been shown previously that Dx-BS may be conjugated with EGF, and that such a conjugate, without iodine label on boron, binds to cultured glioma cells (Gedda et al., 1996). The biodistribution in rats of iodinated *closo*-dodecaborate(2-), an expected catabolite of Dx-BS, was also investigated.

A general problem in the design of radioimmunoconjugates is the choice of labeling strategy. In the present experiment, there were two possible approaches: (1) to label *closo*-dodecaborate(2-) with iodine first and then attach it to the dextran-containing targeted conjugate and (2) to bind *closo*-dodecaborate(2-) to the conjugate and then iodinate.

In the first case, the position of the label is more predictable, but the conjugation-labeling yield is generally lower than that of direct halogenation. The second approach probably leads to a higher yield, but suffers from the risk of iodinating the tyrosine residues of the peptide part, which is often vulnerable to biodegradation. This drawback may, however, be overcome if *closo*-dodecaborate(2-) is iodinated at a lower pH, i.e., under conditions when the tyrosine ring is not so easily iodinated (Knight and Welch, 1978). To study the feasibility of such an approach, a competitive iodination of *closo*-dodecaborate(2-) and tyrosine was performed at different pH-values of the reaction mixture.

The aims of the study were (1) to develop a convenient method for no-carrier added labeling of *closo*-dodecaborate(2-) and its derivatives with iodine, (2) to evaluate the possibility to direct the iodine label to boron but not to tyrosine, via pH variation during labeling, (3) to evaluate the in vivo stability of the iodine label on *closo*-dodecaborate(2-), and (3) to study the pharmacokinetics of [^{125}I]Dx-BS-I and of [^{125}I]iodo-*closo*-dodecaborate(2-).

MATERIALS AND METHODS

Materials. ^{125}I (3.7 GBq/mL) for labeling was from Amersham Int. plc., Little Chalfont, Buckinghamshire, U.K. Cesium carbonate was heated at 300 °C during 60 min and dissolved in methanol to a concentration of 5 mg/mL before use. Water solutions of Chloramine-T (4 mg/mL) and sodium metabisulfite (4 mg/mL) (Sigma Chemical Co., St. Louis, MO) were prepared immediately before iodination. IodoGen (Pierce, supplied by Soccochim SA, Lausanne, Switzerland) was dissolved in methylene chloride (1 mg/mL), 100 μL of the solution was added into 300 μL ReactiVials (Pierce, supplied by Soccochim SA, Lausanne, Switzerland), and the solvent was evaporated under a gentle stream of nitrogen, leaving a thin film of IodoGen.

NAP-5 columns (Sephadex G-25 gel, Pharmacia, Sweden) were used for separation of labeled dextran from low-molecular-weight components.

Radioactivity measurements were done with an automatic γ counter (LKB Wallac Oy, Turku, Finland).

The radio-TLC identity of the compounds was assessed by coelution with corresponding cold standards.

Preparation of Dx-BS. The Dx-BS compound (76 kDa dextran, 40−50 boron cages/dextran molecule) was produced as described by Gedda et al. (1996). Briefly, 2 g of 70 kDa dextran, 0.5 g NaOH, and 20 mg $NaBH_4$ were mixed in 15 mL of distilled water at 40 °C. Allyl bromide (3.5 g, 2.5 mL) was added and the reaction allowed to proceed at 60 °C for about 3 h. After neutralization, the allyldextran was purified by precipitation with ethanol three times, then lyophilized and stored at −70 °C. The degree of allyl substitution was calculated by elemental analysis of carbon and hydrogen in the allylated and native dextran (Gedda et al., 1996).

For attachment of boron cages, 20 mg of BSH and 20 mg of $(NH_4)_2S_2O_8$ were mixed with 20 mg of allyldextran dissolved in 200 μL of distilled water. The reaction continued for 2 h at 50 °C with stirring. Then, dextran-BSH was purified from uncoupled BSH and other low-molecular-weight compounds on a NAP-5 column (equilibrated with distilled water). The high-molecular-weight fraction (first 900 μL) was eluted instead of the recommended 1.0 mL, to avoid any contaminants of low-molecular-weight compounds. The amount of boron added to the dextran was determined with ICP-AES, and substitution rates were calculated (Gedda et al., 1996). Dx-BS was dissolved in 0.25 M phosphate buffered saline (PBS), pH 7.5, to a concentration of 20 mg/mL and stored frozen before use.

Iodination of Dx-BS Conjugate. [^{125}I]Iodide solution (5 μL) was mixed with 20 μL of Dx-BS solution and 20 μL of PBS and 10 μL of Chloramine-T solution in water were added. After vortexing, the mixture was incubated at room temperature for 5 min and then quenched by adding 20 μL of sodium metabisulfite solution.

Alternatively, 10 μL of Dx-BS was mixed with 80 μL of citrate buffer (pH 4.0) in the IodoGen coated vessel, and 5 μL of [^{125}I]iodide was added. After vortexing, the mixture was incubated at room temperature during 5 min, and the high-molecular-weight fraction was separated from unreacted iodine without quenching using gel-filtration.

Separation of iodinated Dx-BS from low-molecular-weight components was performed on a NAP-5 column equilibrated with PBS. After passing of the void volume (500 μL), fractions of 200 μL were collected. The radioactivity in each fraction, as well as reaction vial and the column, was measured to determine the labeling yield. The high-molecular- weight fractions were pooled and diluted in PBS for use in the biodistribution experiments.

One problem was found in the purification step of [^{125}I]-Dx-BS-I after the labeling since 30% of the added

radioactivity was retained in the NAP-5 column. Washing the column with more buffer did not elute more radioactivity. Free iodine is easily eluted, and the remaining radioactivity was most likely attached to Dx-BS nonspecifically interacting with the column matrix. Pretreating the column with nonlabeled *closo*-dodecaborate(2-) did not help. Work is in progress to develop another size-exclusion chromatographic method that will avoid this problem and that will increase the total labeling yield.

Iodination of Cesium *Closo*-Dodecaborate(2-). Solution of potassium dodecahydro-*closo*-dodecaborate(2-) in water (10 μL, 10 mg/mL) was mixed with 30 μL of PBS and 5 μL of [^{125}I]iodide. After addition of 10 μL of Chloramine-T solution and vortexing, the mixture was incubated during 5 min at room temperature. The reaction was quenched with 20 μL of sodium metabisulfite solution.

The iodinated *closo*-dodecaborate(2-) was purified as follows: 150 μL of water was added to the reaction mixture, and *closo*-dodecaborate(2-) was precipitated with 20 μL of tetraphenylphosphonium chloride. The mixture was passed through a 0.45 μm filter, and the residue was washed with 500 μL of water. More than 90% of the initial iodine radioactivity was associated with the residue. After drying over phosphorus pentoxide, the residue was redissolved in 600 μL of acetonitrile. A total of 400 μL of water was added, and acetonitrile was evaporated under a gentle flow of argon. The newly formed residue was filtered out, washed with water (400 μL), and dried during 4 h over phosphorus pentoxide. After redissolving in 600 μL of methanol, *closo*-dodecaborate(2-) (both labeled and unreacted) was precipitated with the solution of cesium carbonate in methanol. After additional washing with methanol, the residue was redissolved in water and used for injection in experimental animals. Quality control was performed on Silica gel coated TLC aluminum plates (Merck) using methylene chloride:acetone (1:4) as an eluent. R_f values were found: 0.71 for iodinated dodecaborate, and 0.41 for iodide.

Competitive Iodination of *Closo*-Dodecaborate-(2-) and Tyrosine. Tyrosine and sodium *closo*-dodecaborate(2-) (100 μL of each) were added from 5 mg/10 mL of stock solutions into a ReactiVial coated with 10 μg of IodoGen. The molar amount of tyrosine was 0.276 μmol and that of sodium *closo*-dodecaborate(2-) 0.266 μmol. Tyrosine and *closo*-dodecarborate(2-) was dissolved in one of the following: (a) 0.1 M phosphate buffer, pH 7; (b) 0.1 M borate buffer, pH 9; (c) 0.1 M citrate buffer, pH 4; (d) 0.1 M phosphate buffer, pH 6; (e) 0.1 M acetate buffer, pH 5; or (f) 0.1 M borate buffer, pH 8. After careful mixing, 10 μL of [^{125}I]iodide in 0.1 M phosphate buffer, pH 7, was added to the vial, and the reaction mixture was incubated at room temperature. After 1 and 5 min of incubation, aliquots were taken for radio-TLC analysis. TLC analysis was performed on silica-coated glass plates (Merck, Silica gel 60 F254) using methylene chloride:acetone (1:3) as eluent. Radiochromatograms were quantitatively evaluated using Berthold tracemaster 20 (Berthold AG, Regensdorf, Switzerland) radio-TLC scanner. In these conditions R_f values were [^{125}I]-monoiodotyrosine, about 0; [^{125}I]iodide, 0.6; *closo*-dodecaborate(2-) and [^{125}I]iodo-*closo*-dodecaborate(2-), 0.81.

Animal Experiments. Twenty-three male Sprague−Dawley rats (BK Universal AB, Stockholm, Sweden) weighing 240−300 g were used. The animals were housed in an isolated room at 25 °C, constant air humidity, and a 12 h light/12 h dark cycle. They were fed ad libitum with sterilized water and standard pellet diet. For anesthesia, Inactin (5 mg/mL, 0.25 mL/100 g of body weight) was administered intraperitoneally. Under anesthesia, an incision was made in the right groin and the femoral vein was isolated and cannulated with a plastic catheter. About 0.25 MBq (0.25−0.30 mL) of [^{125}I]Dx-BS-I (n = 11) or [^{125}I]iodo-*closo*-dodecaborate(2-) (n=12) was administered intravenously to each rat using 1 mL syringes. After injection, the catheter was rinsed with saline. The radioactivity of each syringe was measured before and after injection. Samples of each labeled compounds were taken as standards for the distribution study.

The animals were sacrificed under anesthesia by desanguination and dissected in groups of three rats and with occasional groups of two rats at 0.5, 1, 3, and 6 h after injection and in the [^{125}I]Dx-BS-I experiment also at 20 h. At each time-point, blood and urine were drawn, and various organs and tissues were collected. The samples were weighed and measured for radioactivity corrected for background. Accumulation of the radioactivity in each organ was calculated as the percent injected dose per gram.

Table 1. Iodination of Sodium *Closo*-Dodecaborate(2-) Using IodoGen at Different pH

pH	buffer	iodination yield (%)[a]
4	citrate-phosphate	88−95
5	acetate	87−88
6	phosphate	90−97
7	phosphate	85−87
7.4	phosphate buffered saline	96−97
8.1	phosphate	44−45
9.1	borate	27−28

[a] The iodination yields were determined using radio-TLC, as described in the text.

Table 2. Competitive Iodination of Tyrosine and *Closo*-Dodecaborate(2-)[a]

pH	percent of iodine incorporated into tyrosine	percent of iodine incorporated into *closo*-dodecaborate(2-)	ratio of iodinated tyrosine to iodinated *closo*-dodecaborate(2-)
4	13	87	0.15
5	12	89	0.13
6	42	58	0.72
7	70	30	2.33
8	93	7	13.3
9	94	6	15.6

[a] A mixture of tyrosine and cesium *closo*-dodecaborate(2-) was iodinated using IodoGen at different pH. The iodination yields were determined using radio-TLC, as described in the text.

RESULTS

Labeling Chemistry. The labeling yield of *closo*-dodecaborate dianion, assessed by radio-TLC, was 85−97% in the pH range 4−7.4, but decreased at higher pH (Table 1). The yield was similar using Chloramine-T and IodoGen, giving the same yield at 1 and 5 min of incubation. The unreacted iodine was identified through TLC-analysis as free iodide. The labeling yield was found to be independent of pH within the range 4−7.4. The main factor influencing the labeling yield was the quality of [^{125}I]iodide. "Old" iodide samples, which had been stored for 2 months or more, gave lower iodination yield. Radio-TLC analysis of such samples showed that appreciable amounts of radioactivity had R_f values different from the R_f of iodide.

The results of the competitive iodination of tyrosine and dodecaborate are given in Table 2. Note the different pH dependencies between labeling of tyrosine and *closo*-

[a] Mean ± SD (n = 3).

dodecaborate(2-), and that even in a moderately acidic water solution, the radioiodine label was preferentially bound to *closo*-dodecaborate(2-) rather than to the tyrosine residues.

The labeling of Dx-BS conjugate was equally efficient at pH 7 and 4. Typically, about 60% of the eluted radioiodine was associated with the high-molecular-weight fraction.

Distribution of [^{125}I]Iodo-*Closo*-Dodecaborate-(2-). The tissue distribution of [^{125}I]iodo-closo-dodecaborate(2-) is presented in Table 3. [^{125}I]Iodo-*closo*-dodecaborate(2-) was not accumulated in any organ, and the uptakes in most tissues were very low. The high ^{125}I content in the kidneys and urine indicated a rapid elimination of [^{125}I]iodo-*closo*-dodecaborate(2-) by urinary excretion. The radioactivity concentration in blood decreased quite rapidly after the injection to an "intermediate" level. The fact that the uptake in heart and lungs was somewhat higher than in the other normal tissues merely reflects the high blood volume of these organs. Note that there was no accumulation of radioiodine in the stomach and in the thyroid. Hence, throughout the observation time, the iodine content of the thyroid was lower than that in blood, and tended to decrease over time (Figure 2). The radioactivity uptake in the stomach, generally considered to represent free iodide, was 0.28 ± 0.057% ID at 30 min and 0.23 ± 0.02% ID at 1 h after injection.

Distribution of [^{125}I]-Dx-BS-I. The distribution of [^{125}I]-Dx-BS-I in various organs and tissues is given in Table 4. The radioactivity was accumulated to a high degree in kidney, liver and spleen. The uptakes in these organs reached maximum values between 3 and 6 h after injection and then slowly decreased. The radioactivity was mainly excreted through the kidneys but radioactivity was detected in the feces 20 h after injection. No appreciable accumulation of radioactivity was observed in the other organs. The thyroid uptake increased over the observation time. However, the value of the thyroid uptake was only 0.073 ± 0.003% ID at 20 h after injection.

DISCUSSION

During the past few years, knowledge regarding dehalogenation mechanisms of iodinated compounds in vivo has increased considerably. Directly radioiodinated proteins, after cellular uptake, undergo catabolism accompanied by a rapid loss of cell-bound radioactivity. This is mainly due to a fast membrane transport of iodotyrosine, whereas free iodide accounts for a minor part of the cellular radioactivity losses (Geissler et al., 1992; Press et al., 1996; Stein et al., 1997). Procedures have been suggested to overcome this problem, e.g., by the use of so-called residualizing labels based on aryl carbohydrate adducts (Ali et al., 1990). A small molecule, stable to metabolic degradation, is labeled with radioiodine after which it is attached to the main molecule, e.g., a targeting peptide or protein. After internalization, the protein may still undergo degradation, but the labeled products are not easily excreted from the cell. Radioiodinated dilac-

titol-tyramine or tyramine-cellobiose seem in this aspect more promising than nonphenolic linkers in order to enhance cellular retention of radioiodine (Stein et al., 1997; Reist et al., 1995).

So far, indirect labeling methods have been used, i.e., the residualizing linkers are first radiolabeled and then conjugated, often with a low efficiency, which is the main disadvantage. Thus, Stein et al. (1997) stated that the delivery of absorbed dose using [^{131}I]dilactitol-tyramine was limited by the low conjugation efficiency of prelabeled linker. Low conjugation yields, 30−40%, and a possible aggregation of antibodies when using tyramine-cellobiose were observed by Reist et al. (1995).

Thus, it would be of advantage to do the conjugation step first, i.e., targeting molecule to residualizing linker. After a purification step that hopefully can separate the conjugate from starting material, the conjugate could then be directly labeled. The advantages should be that the starting material is well characterized, the labeling is fast and gives high labeling yields, and also the final purification step is simple. However, the labeling conditions must preferably direct the label to the linker molecule and not to the rest of the conjugate. Furthermore, the biological function of the conjugate must not be severely affected.

An example of such a direct labeling procedure was recently suggested at our laboratory. A conjugate of mouse epidermal growth factor and dextran modified with tyrosine, (mEGF)-dextran-tyrosine, was iodinated using the Chloramine-T method (Zhao et al., 1998). Since the dextran contained more tyrosine (5−15) than the mEGF (5), the radioactive label was concentrated to the dextran-tyrosine part (65−75%). The intracellular retention of radioiodine delivered by such a conjugate was improved in comparison with a homologous mEGF-dextran labeled only in the peptide part thus proving that dextran-tyrosine has a residualizing function. However, this method can be applied only if the targeting molecule contains no or a few tyrosine residues.

In this study, we suggest a new type of residualizing linker, dextran conjugated with *closo*-dodecaborate(2-), which permits direct labeling. Nonradioactive iodo-derivatives of *closo*-dodecaborate were studied and characterized earlier (Knoth et al., 1964; Srebny and Preetz, 1984; Haeckel and Preetz, 1995; Wilbur et al., 1995). Boron-containing compounds are interesting since the boron−iodine bond is stronger than the carbon−iodine bond and no enzymatic system in vivo is known to cleave this bond. *Closo*-Dodecaborate(2-) can, as shown here, easily be labeled with iodine at various pH using standard methods such as Chloramine-T or IodoGen. A new labeling strategy may then be applied where the conjugation step [*closo*-dodecaborate(2-)-sugar to protein] is the first step. At pH 5, a rather mild labeling condition for most proteins, a high labeling yield is obtained for the *closo*-dodecaborate(2-) residues, whereas the protein tyrosine is poorly labeled (Table 1). Since the radioiodination yield of *closo*-dodecaborate does not depend on pH, the difference in the yields in competitive experiments, which were performed for nearly equimolar amounts of tyrosine and *closo*-dodecaborate, should be due to different impact of pH variation on the iodination kinetics of these two compounds.

The stability test, using [^{125}I]Dx-BS-I as a model compound, was designed to prove the stability of the radioactive label bound to the *closo*-dodecaborate(2-) in vivo. Dextran per se is known to be resistant to metabolic degradation (Mowry and Millican, 1953). Previous studies of our group have shown that both tritium and radioiodine labels attached to the dextran part of targeting conjugates possess an enhanced stability after intracellular uptake (Andersson et al., 1991; Zhao et al., 1998). In vivo, dextran is accumulated in lysosomes after kidney uptake (Christenses and Maunsbach, 1981). Dextran might also undergo liver uptake mediated by receptors for asialoglycoproteins (Nishikawa et al., 1992) when injected in rats at doses below 1 mg/kg of body weight. The interaction with these receptors leads to internalization and quick degradation of glycoproteins in lysosomes (Duncan and Welch, 1993). Thus, [^{125}I]Dx-BS-I administered at low amounts in vivo could be exposed to lysosomal digestion, but the carbohydrate backbone is assumed to be stable to degradation and will not readily be excreted from the cells. Loss of the radioactivity from liver and kidney may then be ascribed mainly to cleavage of boron−iodine bond or to detachment of [^{125}I]iodo-*closo*-dodecaborate(2-) from dextran.

The expected in vivo distribution of [^{125}I]Dx-BS-I was verified in the animal studies. High radioactivity uptake was found in liver and kidneys reaching a maximum at 3−6 h after injection. At this time the blood pool was cleared of [^{125}I]Dx-BS-I. Thereafter, a small decrease in kidney and liver radioactivity was observed that probably corresponded to exocytosis or a degradation and slow release of radioactivity. The thyroid uptake of radioactivity increased over time but was only 0.072 ± 0.003% ID at 20 h. This is low in comparison with previous results on thyroid accumulation of iodine in mice after injection of various mAbs and fragments iodinated by other techniques. Zalutsky and Narula (1987) reported radioactivity uptake of 1.39 and 2.37% ID in mouse thyroid at 24 h when injecting iodinated IgG labeled by the use of ATE and IodoGen, respectively. Although the comparison is made between different rodent species, the difference is considerable and supports the assumption that the iodine is firmly attached to the boron compound.

Liver and kidney are organs where the highest rate of radioiodine loss is expected (Khaw et al., 1986). Our data

Table 4. Tissue Distribution of Radioiodine after Administration of [^{125}I]Dx-BS-I in Rats

	% ID/g tissue[a]				
tissue	0.5 h	1 h	3 h	6 h	20 h
blood	2.724 ± 0.402	0.394 ± 0.026	0.307 ± 0.083	0.182 ± 0.039	0.098 ± 0.005

[a] Mean ± SD ($n = 3$ or $n = 2$).

indicate that the dextran-associated label was stable after internalization. A comparison was made to a directly labeled peptide, [^{125}I]mEGF, which was tested in the same Sprague−Dawley rats using a similar experimental protocol (Scott-Robson et al., 1991) as for the [^{125}I]Dx-BS-I. After receptor-mediated uptake, iodinated mEGF is efficiently transported into the intracellular compartment (Todderud and Carpenter, 1989). We assume that [^{125}I]Dx-BS-I is transported to the same compartments, the lysosomes, and is exposed to similar degradation conditions. The rapid blood clearance of [^{125}I]mEGF is an advantage since the organ loss of radioactivity directly reflects the degradation rate and is not obscured by blood radioactivity. The comparison of data shows a fast degradation of [^{125}I]mEGF, e.g., more than a 3-fold decrease of the liver radioactivity during 2 h, whereas the radioactivity loss of [^{125}I]Dx-BS-I was minor.

[^{125}I]Iodo-*closo*-dodecaborate(2-), a probable degradation product of the conjugate, was found to be rapidly eliminated from the circulation and excreted in urine without accumulation in any organ. The radioactivity uptake in the stomach, generally considered to represent free iodide, was 0.23 ± 0.02% ID at 1 h after injection. In distribution studies performed in mice (Zalutsky and Narula, 1988; Garg et al. 1991), the uptake of free radioiodine in the stomach was in the range 14−25% at 1 h after injection. Although the comparison is made between two species, the difference between the previous studies in mice and the present experiment, i.e., 2 orders of magnitude, is persuasive. This indicates that in the clinical situation the degradation products will probably not contribute to the background, which might improve the tumor to normal tissue ratio.

Systemic injection of dextran leads to an elevated uptake in liver, spleen, and kidney. It is possible that this will also be true for, e.g., a tumor-seeking peptide and that a part of the conjugate will be directed to these organs, thus competing with the desired tumor uptake. However, Nishikawa et al. (1992) have shown in rats that the hepatic uptake of dextran may be receptor mediated, and the co-injection of nonlabeled dextran could therefore decrease the liver uptake considerably if such receptors are present in humans. Since dextran is nontoxic (Molteni, 1979), an injection of a large amount of dextran before injection of dextranated targeting conjugates is possible.

Generally, increased and prolonged uptake in excretory organs is typical for residualizing labels. A similar effect of prolonged retention of the residualizing label in liver, spleen, and kidney was reported by Reist et al. (1995) when they compared a distribution of mAb H10 labeled by IodoGen and by tyramine-cellobiose. Longer hepatic and renal retention of metal chelates, which are residualizing labels, in comparison with iodine have been observed in numerous dual label studies (Khaw et al., 1986; Meijs et al., 1997; Schott et al., 1992; Ryser et al., 1992). Prolonged retention of ^{111}In in liver and kidney was the reason for Larson and Carrasquillo (1988) to state that conventional iodine label is better for certain applications than metal label, despite better accumulation of radioindium in tumor sites. Several studies (Press et al., 1996; Duncan and Welch, 1993; Behr et al., 1998) suggest that protracted renal and hepatic retention is provided by the same mechanism, which provides prolonged retention of residualizing label inside tumor cells. For this reason, this problem can be alleviated only by modification of the pharmacokinetics of the whole targeted radioconjugate to prevent capture in liver and kidney. Thus, promising results were obtained in decrease of kidney accumulation of radiometal labeled peptides using lysine or poly-lysine (Behr et al., 1998; De Jong et al., 1995; Bernard et al., 1997; De Jong et al., 1998). However, the problem is far from solved at the moment. It is possible that in the future the kind of label will be chosen for a given patient on a basis of individual optimization.

The present study indicates that radioiodinated [^{125}I]Dx-BS-I conjugated to a tumor-seeking molecule can provide a stable residualizing iodine label which, if applied to a relevant targeting agent, will be of interest for imaging and therapy.

New Use of Cyanosilane Coupling Agent for Direct Binding of Antibodies to Silica Supports. Physicochemical Characterization of Molecularly Bioengineered Layers

Sandrine Falipou, Jean-Marc Chovelon,*,† Claude Martelet,† Jacqueline Margonari,‡ and Dominique Cathignol‡

Laboratoire d'Ingénierie et Fonctionnalisation des Surfaces, CNRS/UMR 5621, Ecole Centrale de Lyon, BP163 69131 Ecully Cedex, France, and INSERM, Unité 281: Recherches sur la Détection et le Traitement de la Prolifération Tissulaire par Agents Physiques. 151, Cours Albert Thomas 69424 Lyon Cedex 03, France.
Received April 10, 1998; Revised Manuscript Received February 4, 1999

A simple protocol to fix biological species to silica-based surfaces (silica microbeads and glass slides), using a bifunctional silane reagent (3-cyanopropyl dimethyl chlorosilane), is presented. This silane reagent was used without further derivatization. This system led to strong, but not covalent, linkage of antibodies through their glycosylated regions (OH groups) to solid supports. The use of a microsized sample revealed that the coupling process depends not only on physicochemical interactions but also on steric phenomena, and in this case, it was shown that a molecule acting as a spacer was required for more efficient cell fixation. Here, monoclonal mouse antibodies against the CD45 molecule expressed on rat lymphocytes (MAR anti CD45 Ab) were linked to lymphocytes, and as spacers, sheep anti-mouse antibodies (SAM Ab) were immobilized on silica surfaces, allowing the cells to stick to the floating hollow silica microbeads by simple incubation. Under such conditions, a single microbead can fix several cells. The potential of this hollow, low-density support is in ultrasound applications, for the destruction by cavitation phenomena of cells selectively fixed onto such a support. Such a study can serve as a basic model for various microbiosystems involving cell manipulation.

INTRODUCTION

Since the first work of Nelson and Griffin (*1*), fixing biologicals onto a variety of solid inorganic supports has become a widely used technique.

A great number of biomedical applications, especially diagnostic, involve binding biospecies (antigen, antibody, and enzyme) to various solid matrixes. For example, biosensing applications require the biospecies involved to be grafted onto silicon, polymers, or metallic-based materials (*2*, *3*). For immunoaffinity chromatography, functionalized beads are required. The various functionalization methods are often tedious, rather expensive, and can denature the biological species (*4*). Moreover, the efficiency of the grafting processes must often be characterized through topographical studies (atomic force microscopy) or analytical investigations. For this purpose, substrates such as mica or glass slides with similar reactivity and with a well-controlled surface state (low roughness) are used (*5*, *6*).

Various chemical reagents can be used to modify surfaces in order to immobilize proteins (*7*). For example, surfaces can be activated with reagents such as BrCN or derivatized with linkers such as triazines, epoxy, aryl azides, isothiocyanates, *N*-hydroxysuccinimides, silanes, etc. Bifunctional silanes with a $(MeO)_3Si(CH_2)_nX$ structure, where X represents a reactive moieties such as an amine or a glycidoxy group, were used extensively in the 1970s as coupling agents to link proteins to various inorganic solid supports (*8*). Very often, after silanization, the reactive moieties must be derivatized prior to protein immobilization. This additional step is not always easy to realize and a direct coupling procedure without the use of an intermediary step would be of interest.

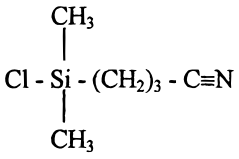

Figure 1. Bifunctional silane reagent: 3-cyanopropyl dimethyl chlorosilane.

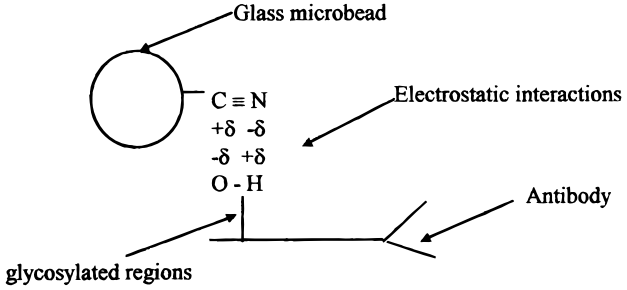

Figure 2. Antibody coupling to silica or glass surfaces.

In this paper, a simple protocol to fix biological species to silica-based surfaces by using a bifunctional silane reagent (3-cyanopropyl dimethyl chlorosilane, cf. Figure 1) is presented. This silane reagent was used without further derivatization. Such a system has already been shown to induce a strong, but not covalent linkage, of antibodies to solid supports, through their glycosylated regions (OH groups) (cf. Figure 2) (*9*). Moreover, antibodies fixed onto a cyanosilanized silica substrate have been

found to resist acid washing. During such treatments, a partial reorganization of the antibody layer was observed, inducing an increase in antibody activity (*10*).

The efficiency of such a silanization process resulting in a high rate of immobilized antibodies on the silica surfaces has been demonstrated by using glass slides which allow various methods of physicochemical characterization.

Subsequently, antibodies anchored on floating silica hollow microbeads were proved to be able to recognize CD45 rat cells.

The originality of this study is that such hollow, low-density silica microbeads have never been used before. This solid support was chosen because it is inexpensive and could also be used in ultrasound applications. Cavitation could be used for the destruction of cells in vitro (*11*): gas bubbles in the suspension could collapse and damage cell membranes causing their death. Thus, acoustic cavitation could be used as an alternative medical therapy for cancer treatment. F. Prat et al. (*12*) obtained subsequent hepatic lesions in vivo in the rabbit by acoustic cavitation, coupling the injection of artificial bubbles in the liver with ultrasonic treatment. It is worth noting that pressures generated during the collapse could attain tens of thousands of bars (*13*).

EXPERIMENTAL SECTION

Reagents. 3-Cyanopropyl dimethyl chlorosilane was purchased from Aldrich and was used as received. According to the suppliers, its purity was 95%, the remaining 5% being mainly composed of disilane form, which resulted from the condensation of the molecule, and was nonreactive toward the surface. The following commercial analytical grade reagents were used: sulfuric acid and potassium dichromate from Merck, tetrahydrofuran from Sigma, xylene from Carlo Erba, and 2-methylbutane from Aldrich.

Low-density hollow silica microbeads (SDT-60:0.6 g cm^{-3}) were obtained from NewMet.

The sulfochromic solution was prepared by mixing 15 g of potassium dichromate, 5 mL of deionized water, and 80 mL of 96% concentrated sulfuric acid.

Purified sheep anti-mouse monoclonal antibody, purified mouse anti-rat CD45RC (clone OX22) monoclonal antibody, and biotin-conjugated mouse anti-rat CD45RC (clone OX22) monoclonal antibody were obtained from Pharmingen. A FITC-conjugated $F(ab')_2$ fragment of goat anti-mouse antibody was purchased from Dako. Ficolite was obtained from Dutscher.

Phosphate-buffered saline (PBS), bovine serum albumin (BSA), and Tween 20 were from Sigma, carbonate/bicarbonate buffer was prepared by mixing Na_2CO_3 0.1 M and $NaHCO_3$ 0.1 M and adjusting the pH to 9.4. Barbital (Veronal) buffer was prepared by dissolving 4.12 g of sodic veronal and 0.8 g of veronal in 1 L of distilled

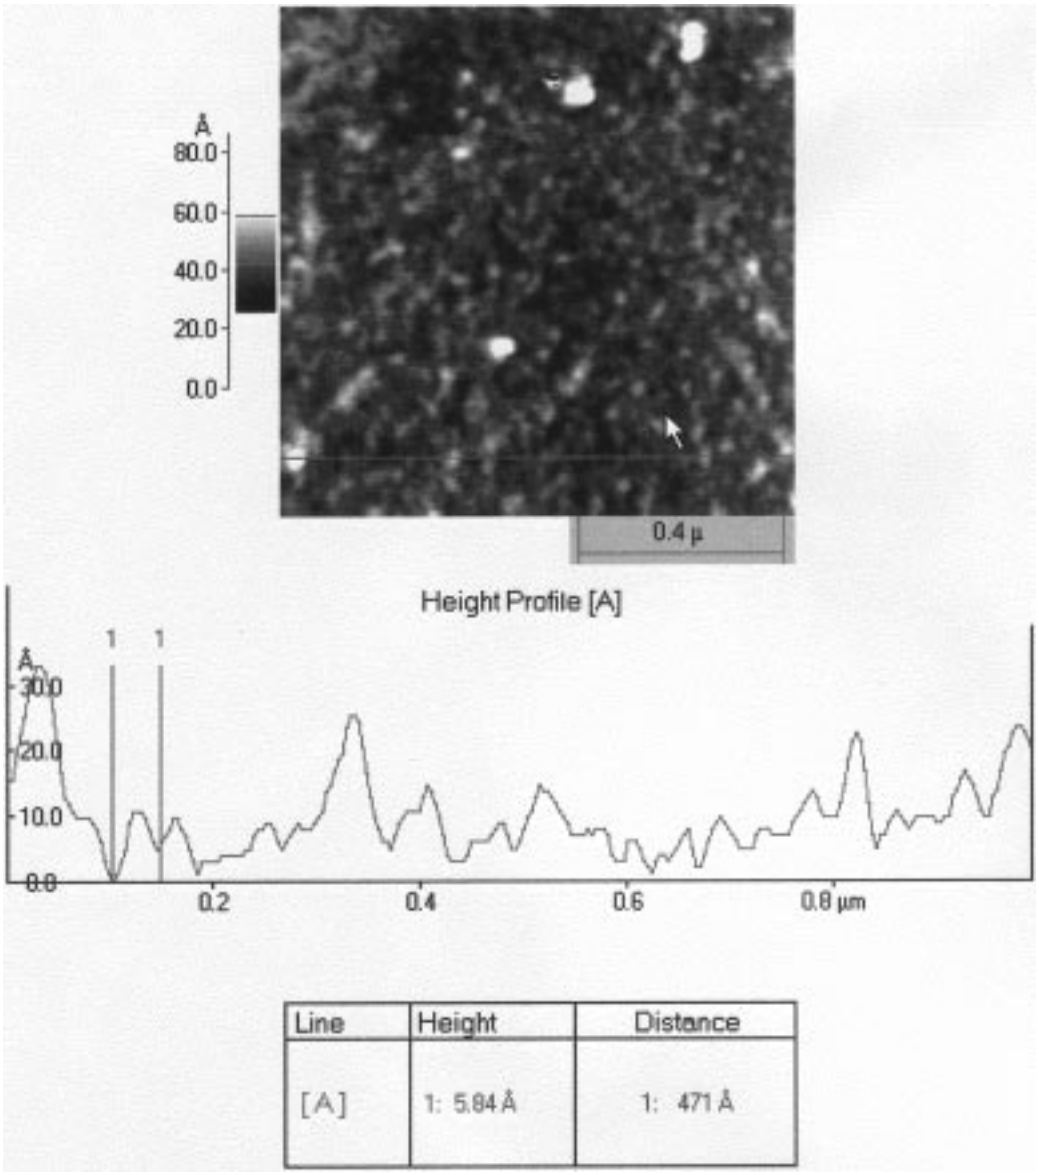

Figure 5. AFM image of silanized surface and profile corresponding to the line shown in the image. The height and the distance are measured between lines 1.

water and adjusting the pH to 8.6. Citrate buffer was prepared by mixing 1.78 g of Na_2HPO_4, 0.7 g of citric acid, and 134 mL of distilled water.

Sample Surface Preparation. Silica surface cleaning and hydroxylation are important in the grafting process. Glass slides were first degreased under ultrasonic stirring with acetone. Due to the difficulties of handling them, silica microbeads were not degreased before the hydroxylation treatment. This first step is not critical, as grease residues should be completely eliminated in the following which involves strong oxidizing reagents.

Glass slides and floating silica microbeads were treated with sulfochromic solution for 30 min at 70−80 °C to remove any coatings or contaminates and to create hydroxyl reactive functions at the surface. Glass slides were washed with deionized water and dried by a pure nitrogen stream. The washing procedure used for microbeads is more critical since they are far more difficult to handle than glass slides. After the sulfochromic treatment, the microbeads were allowed to float to the top of the suspension while the underlying fluid was drawn off. Then deionized water was added to the microbeads which were once again allowed to float. This process was repeated until the sulfochromic solution was completely eliminated. Then, the microbeads were partially dried at 100 °C in air.

Silane Activation (Figure 3). After the cleaning process, the glass slides and microbeads were dried at 140 °C under vacuum (0.1 Pa) for 2 h in order to remove the physisorbed water (Figure 4).

For the glass slides, pure silane was introduced under nitrogen atmosphere whereas the microbeads were first placed in a solution of 5×10^{-2} mol of silane in 2-methyl butane, to ensure that they would be well wetted. For the latter, the solvent was removed in the following step under vacuum.

The condensation reaction on the silica sample was performed in sealed vessels under vacuum for 48 h at 70 °C.

The excess silane was eliminated by washing with THF, xylene, and deionized water. The glass slides were blown dry with dry nitrogen, whereas the microbeads, were allowed to dry in air at ambient temperature. Although the cleaning and the treating processes are slightly different for each substrate, the surface reactivities to silane reagents are assumed to be quite similar.

Of course, the possibility that solvent may penetrate the cyanosilane molecules of the microbeads is not excluded.

Contact Angle Measurements on Planar Substrates. As the silanized surfaces are more hydrophobic compared to the hydroxylated ones, the efficiency of the silanization process can be controlled by measuring the contact angles.

Contact angles were measured by the sessile drop method on a Digidrop instrument. (GBX Scientific Instruments).

Measurements were made on drops of pure water deposited at 22 °C under an atmosphere saturated with humidity to obtain reproducible conditions.

A video camera equipped with an image analyzer visualized the shape of the drop and gave the contact angle between water drop and silica surface.

The reported contact angles are the average of at least 15 drops for each surface treatment. The macroscopic homogeneity of the surface structure can be estimated by its standard deviation. These measurements are used to control each sample at each step of the silanization process by reference to the values obtained for at least 3 samples and 15 drops of distilled water.

Atomic Force Microscopy. Atomic force microscopy (AFM) images were obtained in air using a Park Scientific Instrument (Autoprobe). V-shaped cantilevers (PSI) with a normal spring constant of 0.05 N m^{-1} and a pyramidal Si_3N_4 tip were used in this study. Either 100 $\times$ 100 μm^2 or 5 $\times$ 5 μm^2 scanners were used. Images were flattened with only a second order correction. Images were taken in the contact or tapping modes.

Surface evolution was tracked using root-mean-squared surface roughness (rms), measured for each step of the silanization and antibody fixation processes.

Infrared Spectroscopy on Microbeads. Methods previously described do not allow the characterization of microspherical substrates. Infrared measurements were made by the Service Central d'Analyses of the CNRS on a Nicolet 20SXC instrument (diffuse reflection mode). Results were given after accumulations of 2048 scans.

Immobilization of Immunological Species on Silanized Substrates and Analysis of Ab Content by Competitive ELISA Assay: Use of Glass Slides for Technical Purposes. Mouse anti-rat CD45RC antibody was placed on silanized slides of defined surfaces at concentrations ranging from a few nanograms per milliliter to several micrograms per milliliter. Antibodies were allowed to adsorb for 1 h at 37 °C and 1 night at 4 °C in a wet atmosphere. Various buffers for dilution and washing were studied: phosphate-buffered solution, pH 7.4 (PBS),

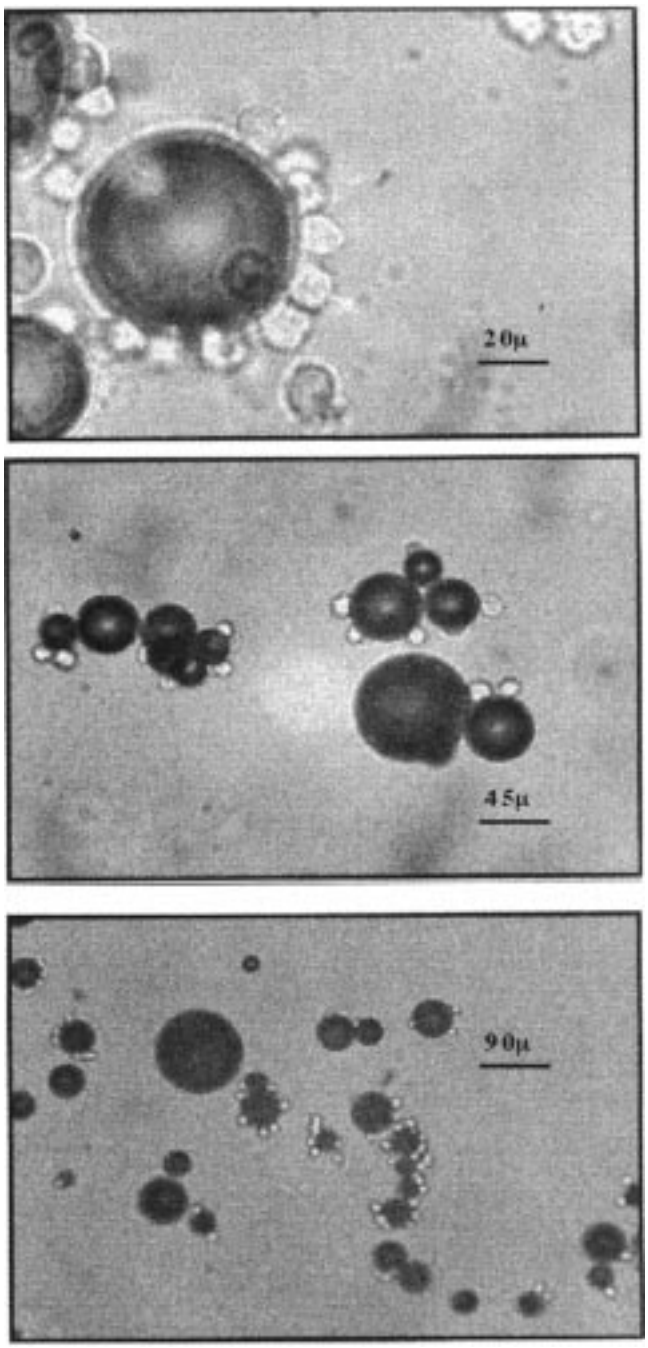

Figure 9. Photographs of cells around silica microbeads.

phosphate-buffered solution/bovine serum albumine at pH 7.4 (PBS/BSA) and carbonate/bicarbonate at pH 9.4.

Concentrations of less than 5 μg/mL could not be obtained by direct enzymatic methods of quantification (for example with a goat anti-mouse horseradish peroxidase monoclonal). Thus, a competitive technique was used in association with the amplified visualization of antibody fixation (an enzymatic reaction with biotinylated mouse antibody and a streptavidin/enzyme complex for binding).

First the optimum optical density curve for biotinylated anti CD45 dilutions was defined. The dilution which gave 50% of the maximal OD was retained.

Second, optical density was tested when nonbiotinylated anti-CD45 antibody dilutions were added to the previously defined biotinylated anti-CD45 dilution.

Finally, the same competition analysis was carried out for the glass slides: the glass slides and 400 μL Mouse anti-CD45 in concentrations ranging from a few nanograms per milliliter to several micrograms per milliliter were incubated with constant agitation for 1 h at 37 °C and 1 night at 4 °C. The quantity of nonbound antibodies remaining in the liquid was measured by competing with biotin-conjugated antibody at the previously determined concentration, and the results obtained by comparison with the curve defined at the second step were read at 492 and 620 nm. The difference between the total amount used for incubation and the residual one after incubation represented the amount of absorbed antibodies per surface unit.

Preparation of Rat Lymphocytes for Cell-Immobilization Experiments. Fresh rat blood (approximately 15 mL) was collected and heparinized. The blood was diluted by half, and 15 mL of diluted blood was added to 50 mL centrifuge tubes containing 15 mL of Ficolite. The tubes were then centrifuged at 1000*g* for 13 min at ambient temperature to obtain a cell density gradient. The resulting layer of peripheral blood lymphocytes, which possess CD45 antigen on their surface, was delicately removed from each tube and pooled.

Cells were washed in PBS containing albumin (PBS/BSA 1%) and spun down 3 times for 13 min at 500*g* and low temperature. A batch of four tubes, each containing 1×10^7 cells in 50 μL of PBS/BSA, was prepared, and 100 μL of a 5 μg/mL dilution of anti-CD45 antibody was added to each tube before incubation for 30−60 min at 4 °C.

After washing in PBS/BSA, cells were counted with a hemocytometer for viability.

Immobilization of Cells onto Silica Microbeads. The experiments and control were carried out using silanized or nonsilanized substrates and different fixation modes were tested using monoclonal mouse anti rat antibodies, which recognize CD45 molecules expressed on rat lymphocytes. Another biochemical link was tested with the insertion of an antibody between the complex cells/CD45 and the substrate SAM Ab.

In all cases, cells were added to the microbeads in a ratio higher than 5×10^5 cells/mg of microbeads.

The volume was 500 μL to 1 mL, and the microbeads and cells were incubated for 2 h at 4 °C with agitation. After incubation, centrifuging at 450−500*g* allowed microbeads to float to the top of the suspension whereas nonfixed cells fell to the bottom. Then, the effluent was drawn off. Floating microbeads were observed under the microscope and photographs of the cell were taken.

RESULTS AND DISCUSSION

Silanization Process. Considering the geometry of the silica beads, classical methods of characterization of the silanization cannot be applied. Of these methods, the contact angle measurements offer the most significant wettability test when pure fluids and smooth surface are used. So, to evaluate the wettability after silanization on flat sample, glass slides were used.

Such silica-based samples should behave similarly to microbead ones.

For silane-treated and untreated glass slides, Table 1 summarizes contact angle results at equilibrium.

When no treatment was applied, the value obtained showed great standard deviation ($\theta = 34.2 \pm 7°$), reflecting the heterogeneity of the surface.

The surface of glass slides, when treated by hot sulfochromic solution, is almost totally wetted by water ($\theta < 15°$) demonstrating the efficiency of such a cleaning procedure. Surface hydrophilicity is due to the presence

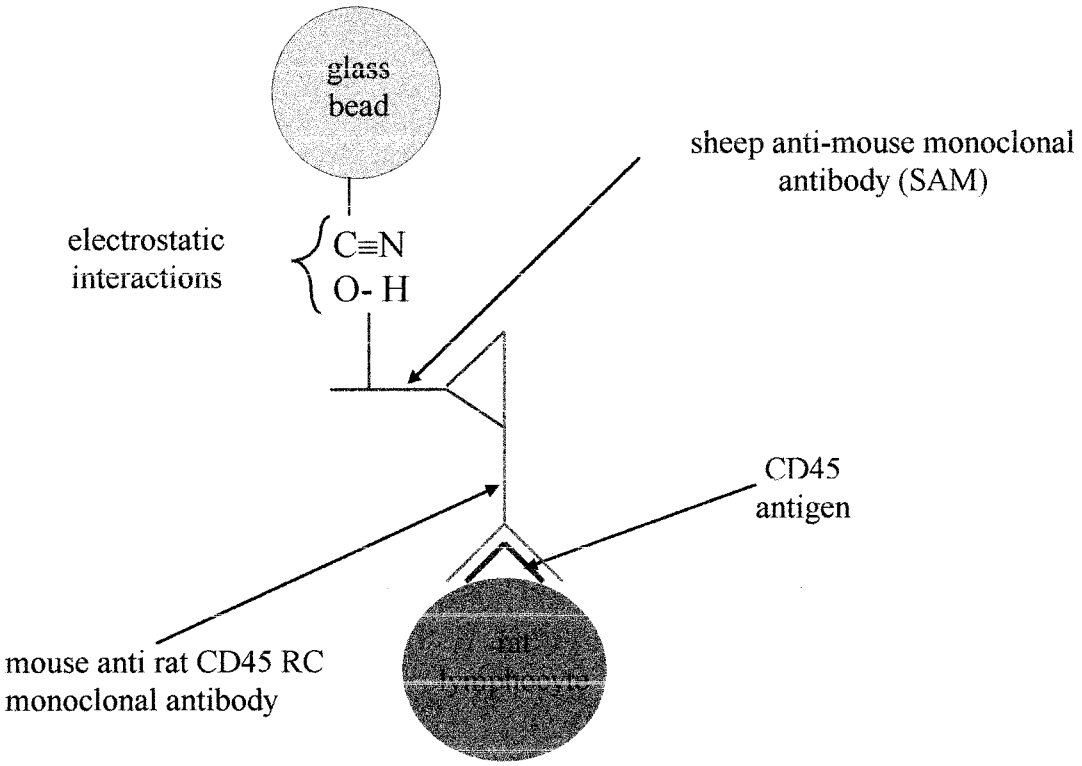

Figure 10. Rat cell immobilization by silane-activated glass beads with SAM Ab.

of a great number of hydroxyl groups on the surface which are required for the silanization process (Figure 4). Great care must be taken with cleaned samples, as organic molecules can readily be adsorbed on these reactive surfaces, inducing an increase of the contact angle within a few minutes. Because of this, as soon as the treatment is finished, the samples are placed under vacuum.

After silanization, contact angles increase up to around 71.5 ± 1.8° proving the presence of silane. This surface treatment induces a more homogeneous surface (low standard deviation).

To be sure that no contamination takes place, a sample treated by this process but without the silanization step was tested. In this condition, the value of the contact angle increased up to 40.6°: lower than the value obtained with the silane, but higher than that obtained after sulfochromic treatment.

AFM technique was used to characterize the molecular organization of silane on glass slides. Substrate modifications after reaction were checked by measuring surface roughness variations.

Table 2 shows the evolution of this surface roughness parameter (rms).

The roughness of the silanized surface was found to be higher than the untreated one (rms = 0.7 nm compared to 0.3 nm), values which could be compared to those obtained by Perrin et al. (*14*) who used the same chain length for the silane reagent.

Figure 5 obtained in tapping mode (1 μm × 1 μm) shows that the silane layer was dense and relatively homogeneous, except for a small number of pinhole defects. Thanks to these defects, the thickness of one layer was evaluated at 0.58 nm, as shown in Figure 5. This figure also shows a thicker area, proving that in some cases aggregates can be formed. It is noteworthy that by using silane molecules with long alkyl chains [Si−$(CH_2)_{17}CH_3$, for example], a monolayer with almost no defects was observed (*15*). Such aggregates are known (*16*) to be induced by nonuniform reactions on the surface which lead to the formation of at least two different distributions of attached ligands: the expected siloxane bonds and hydrogen bonds between cyano groups and free surface silanols. Although nonuniform reactions take place, the architecture of the film obtained thus appears quite similar for various tested samples. In addition, these interactions are strong enough to resist several washing processes.

The presence of silane on treated microbeads was confirmed by the diffuse reflection infrared spectroscopy method.

Figure 6 shows the presence of nitrile and alkyl functions at the surface of the microbeads, whereas no peaks were obtained with untreated microbeads.

According to the infrared analysis conditions used and taking into account the sensitivity of the apparatus, if only one monolayer was present on the surface, no peak would be visible. In our case, the presence of nitrile and alkyl peaks confirmed that the silanization process had occurred, forming a few aggregates.

In this context, silanization effects would appear to similar for both substrates.

Immobilization of Immunological Species. Figure 7 shows an AFM profile taken in tapping mode in air from antibodies deposited onto cyanosilane. The profile showed aggregates which were about 5 nm high. These aggregates suggest that lateral interactions occur between the adjacent IgG molecules. It was not surprising to find such lateral interactions, as this protein has some self-aggregating properties.

The height of these molecules roughly matched the known size of one IgG molecule (5 × 15 nm) (*4*) set horizontally confirming the orientation of the antibodies and thus the nature of the link (electrostatic interactions between OH groups of the glycosylated regions on the Fc fragment of antibodies and CN functions of the silane).

Optimization of Antibody Fixation: ELISA Assay. The ELISA assay was done with mouse anti-rat CD45RC

in concentrations ranging from a few nanograms per milliliters to several micrograms per milliliter in different buffers: PBS, PBS/BSA (1%), and carbonate/bicarbonate. This assay was used to determine the optimum mouse anti-rat CD45RC level coupled to well-defined surfaces of glass slides activated with the cyanosilane by varying the antibody concentration and the incubation buffer.

The antibody surface density was given as a function of initial antibody concentration in solution for three buffers.

Results are shown in Figure 8. Concerning the nonspecific binding, measurements carried out on unsilanized slides lead to an adsorption rate which never exceeds 3%.

These results showed the validity of the cyanosilane coupling agent for the immobilization of antibodies onto glass or silica surfaces.

The most suitable buffer was found to be the carbonate buffer with a pH of 9.4.

Cell Binding. Table 3 compares cell immobilization behavior in various fixation modes. The fixation control was carried out by a camera coupled to an optical microscope, and results were expressed as + for subsequent immobilization (a mean number of at least one cell fixed to bead after centrifuging at 450−500*g*), ± for weak immobilization (some beads fix no cells), and − for no immobilization of cells on the substrate.

This table shows that only activated microbeads with SAM Ab incubated with sensitized cells subsequently immobilize cells (in the table, the fifth substrate and fixation mode). In this case, microbeads grafted with SAM Ab, which acts as a spacer, allow cells sensitized with CD45 Ab to approach the microbeads better, which is in good agreement with the literature (*17*). Figure 9 shows photographs of cell aggregation around microbeads. The architecture of the biochemical link between cells and microbeads is given in Figure 10. Moreover, by fixing SAM Ab, which is able to recognize mouse species on lymphocytes, to substrates, unexpected antibody fixation to or removal from substrates could be minimized.

The experimental procedure was validated by producing blanks to confirm that no fixation occurs when microbeads were not silanized and also that SAM Ab does not recognize CD45 molecules expressed on lymphocytes.

CONCLUSION

By applying a specific functionalization process, activated hollow silica microbeads were shown to be able to fix rat cells strongly and selectively. Efficient fixation of antibodies was obtained with a reproducible silane layer, through electrostatic interactions between the OH groups of the glycosylated regions on the Fc fragments and CN groups of the silane. The recognizing capabilities of the Fab groups are preserved when this type of fixation method is used. A further step could be the destruction of the cells as the microbeads could be destroyed under ultrasonic power. Such a process could be used successfully to separate different strains of cells.

Recognition of Novel Amphiphiles with Many Pendent Mannose Residues by Con A†

Koji Tagawa, Naoko Sendai, Kohji Ohno, Tomoaki Kawaguchi, and Hiromi Kitano*

Department of Chemical and Biochemical Engineering, Toyama University, Toyama 930-8555, Japan

Takayuki Matsunaga

Toyama Prefectural Institute of Pharmaceutical Science, Kosugi, Toyama 939-0363, Japan. Received July 15, 1998; Revised Manuscript Received November 19, 1998

Novel amphiphiles which carry many mannose residues as side chains were prepared by telomerization of *N*-methacryloylaminopropyl D-mannopyranoside (α:*β* = 20:1), *N*-methacryloylaminohexyl D-mannopyranoside (α:*β* = 20:1), or 3-(2-methacryloylaminoethylthio)propyl D-mannopyranoside (α:*β* = 4:1) using a lipophilic radical initiator. The mannose-carrying amphiphiles incorporated in liposomes were recognized by a lectin from *Canavalia ensiformis* (Con A), which was proven by the increase in turbidity of the liposome suspension after mixing with Con A. The interaction between sugar residues on the liposome surface and the lectin was largely affected by the degree of polymerization (DP) and the surface density of the amphiphile in the liposomes. The distance between the sugar residues and the polymer main chain did not affect the specific recognition by the lectin significantly in the liposome system, whereas it appreciably affected the recognition in the water-soluble polymer system. The association constants (K_a) of the amphiphiles (DP ≃ 18) with Con A ($0.3-2.2 \times 10^6$ M^{-1} at 25 °C) were much larger than that of α-methyl D-mannopyranoside (8.2×10^3 M^{-1}) due to the "*cluster effect* ". The positive entropy change (20−52 J/mol K) for the binding of Con A to mannose residues on the liposome surface showed that the recognition in the liposome system was largely promoted by the release of water molecules from both the sugar residues on the liposome surface and the binding site of Con A.

INTRODUCTION

Sugar chains in glycolipids and glycoproteins on cell membranes are, in general, made of limited kinds of monosaccharides such as glucose, galactose, mannose, fucose, *N*-acetylgalactosamine, and sialic acids (*N*-acetyl neuraminic acid) (*1*). However, oligosaccharides are able to have a larger number of structures compared with oligopeptides and oligonucleotides that are composed of an equivalent number of residues. Because of this diversity of sugar derivatives, sugar chains are essential moieties to take charge of various information in living bodies. For example, sugar chains are closely related to recognition phenomena *in vivo* (e.g., cell−cell recognition and adhesion, bacteria or viruses' infection, and immunological protection system). Since the specific receptors for sugars have been found to locate on various cell surfaces, targeting devices utilizing the recognition of sugar chains have been frequently investigated in recent years. For example, there are many studies on drug targeting using the galactose-receptor on the surface of parenchymal hepatocytes (*2*), the mannose-receptor on Kupffer cells (*3*) or various macrophages (*4*). Furthermore, some sugars above cell walls or around biopolymers can be used even for evasion from the uptake by the cells in reticuloendothelial systems (RES)[1] (*5*).

Meanwhile, we previously prepared liposome-forming amphiphiles having pH or temperature responsiveness by polymerization of acrylic acid or *N*-isopropylacrylamide, respectively, with a lipophilic radical initiator (*6*) or lipophilic chain-transfer reagent (*7*). Sugar-carrying amphiphiles were also prepared using a lipophilic radical initiator and sugar-carrying vinyl monomers (*8*−*11*). These hybrid amphiphiles with many monomer residues in their head region would be strong candidates as a component in drug delivery systems (DDS).

In this report, we prepared novel amphiphilic compounds with many pendent mannose residues in their hydrophilic headgroup by telomerization of mannose-carrying vinyl monomers using a lipophilic radical initiator. Recognition of the mannose-carrying amphiphilic compounds by a lectin from *Canavalia ensiformis* (Concanavalin A, Con A) was investigated in the liposome

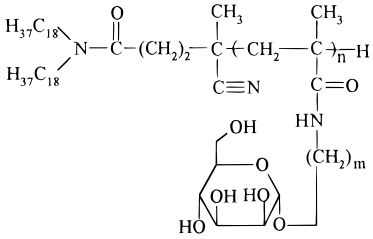
system. The association constants for Con A to mannose-carrying amphiphiles incorporated in liposomes were also estimated.

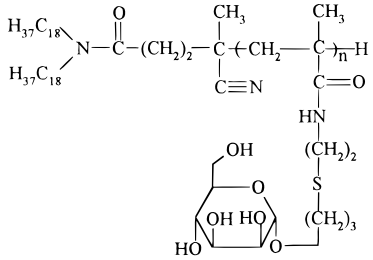
EXPERIMENTAL PROCEDURES

Materials. A lipophilic radical initiator (DODA-501, Scheme 1A) was prepared from dioctadecylamine (DODA, Fluka, Switzerland) and 4,4′-azobis(cyanovaleric acid) (V-501, Wako Pure Chemicals, Osaka, Japan) as previously reported (*6*). Succinimidyl methacrylate was prepared as described before (*11*). 1,3-Di-*O*-hexadecylglycerol was synthesized by the reaction of epichlorohydrin and 1-hexadecanol in the presence of sodium hydride at 80 °C overnight (*13*). A lectin, concanavalin A (Con A) from *Canavalia ensiformis*, was purchased from Sigma. Bis(*trans*,*trans*-2,4-dioctadecadienoyl)phosphatidylcholine (DDPC) was kindly donated from the Japan Fat & Oil Co, Tokyo, Japan. 2,2′-Azobis(2-amidinopropane)dihydrochloride (V-50) was kindly donated from Wako Pure Chemicals. Other reagents were commercially available. A Milli-Q grade water was used for preparation of sample solutions.



Preparation of 3-(2-Methacryloylaminoethylthio)-propyl D-Mannopyranoside (MEPMan, Scheme 1C). 3-(2-Aminoethylthio)propyl D-mannopyranoside (2.40 g, 8.1 mmol), which was prepared by the method reported by Lee and Lee (*14*), was coupled with an equivalent amount of succinimidyl methacrylate (1.48 g, 8.1 mmol) and dry triethylamine (0.80 g, 7.9 mmol) in the presence of (dimethylamino)pyridine (100 mg) and hydroquinone (30 mg) in dry DMF (20 mL) for 24 h. The solution mixture was condensed by evaporation and purified by a silica gel column chromatography two times [eluting solutions; methanol (first purification) and ethyl acetate: *n*-hexane: methanol = 1:1:6) (second)] (MEPMan, 1.87 g, 63% yield). ^{1}H NMR (400 MHz, D_2O): δ 5.56 (s, 1H, CH_2=C<, Z-form H), 5.32 (s, 1H, CH_2=C<, E-form H), 4.71 (d, 1H, J = 1.6 Hz, H_1), 4.51 (d, 1H, H_1), 3.44 (t, 2H, −SCH_2CH_2N−), 3.33 (t, 2H, −CH_2CH_2CH_2S−), 2.52 (m, 2H, >CH_2) and 1.79 (s, 3H, −CH_3). The anomeric ratio of MEPMan was estimated as α:β = 4:1 by ^{1}H NMR [δ 4.71 (α) and 4.51 (β)]. IR (KBr): O−H stretching of mannose 3316 cm^{-1}, C=O stretching of secondary amide 1616 cm^{-1}, N−H deformation of secondary amide 1541 cm^{-1}, CH_2 ν_{as} 2924 cm^{-1}, CH_2 ν_s 2853 cm^{-1}, C=C stretching 1654 cm^{-1}. Anal. calcd for $C_{15}H_{26}O_7NS\cdot 2H_2O$: C, 47.88; H, 8.05; N, 3.72. Found: C, 47.04; H, 7.37; N, 3.56.

Preparation of *N*-Methacryloylaminopropyl D-Mannopyranoside (MPMan, Scheme 1D). *N*-Methacryloylaminopropyl alcohol was prepared by the coupling of 3-amino-1-propanol (6.15 g, 82 mmol) with succinimidyl methacrylate (10 g, 55 mmol) and 4-(dimethylamino)pyridine (100 mg) in dry chloroform (100 mL). The solution mixture was condensed by evaporation and purified by a silica gel column chromatography (ethyl acetate: *n*-hexane: methanol = 6:3:1). Tetra-*O*-acetyl D-mannopyranoside (1.5 g, 4.3 mmol), which was prepared by the method described before (*15*), was reacted with trichloroacetonitrile (1.6 g, 11 mmol) in the presence of anhydrous cesium carbonate (0.50 g, 1.5 mmol), and afterward, with *N*-methacryloylaminopropanol (0.68 g, 4.7 mmol) in the presence of trimethylsilyl trifluoromethanesulfonate (0.85 g, 3.8 mmol). The oily product was deacetylated with a 28% methanol solution of sodium methoxide (200 μL) as a catalyst and purified by a silica gel chromatography (methanol:chloroform = 1:2). (MPMan, 0.48 g, 50% yield). ^{1}H NMR (400 MHz, D_2O): δ 5.61 (s, 1H, CH_2=C<, Z-form H), 5.37 (s, 1H, CH_2=C<, E-form H), 4.77 (d, 1H, J = 1.6 Hz, H_1), 4.58 (d, 1H, H_1), 3.87−3.28 (11H, others), 1.86 (s, 3H, −CH_3), and 1.17 (m, 6H, >CH_2). The anomeric ratio of MPMan was estimated as α:β = 20:1 by ^{1}H NMR [δ 4.77 (α) and 4.58 (β)]. IR (KBr) O−H stretching of mannose 3435 cm^{-1}, C=O stretching of secondary amide 1620 cm^{-1}, N−H deformation of secondary amide 1561 cm^{-1}, CH_2 ν_{as} 2930 cm^{-1}, CH_2 ν_s 2877 cm^{-1}, C=C stretching 1655 cm^{-1}. Anal. calcd for $C_{13}H_{23}O_7N\cdot 1.5H_2O$: C, 46.98; H, 7.88; N, 4.21. Found: C, 46.30; H, 7.17; N, 3.89. By the similar procedure, *N*-methacryloylaminohexyl D-mannopyranoside was prepared (MHMan, α:β = 20:1, Scheme 1D).



Preparation of Mannose Lipid (DHDG-Man, Scheme 1B). Following the method of Minamikawa et al. (*15*), 1,3-di-*O*-hexadecyl-2-*O*-(2,3,4,6-tetra-*O*-acetyl α-mannosyl)glycerol was prepared by the coupling of 1,3-di-*O*-hexadecylglycerol (820 mg, 1.5 mmol) and 2,3,4,6-tetra-*O*-acetylmannosyl 1-α-trichloroacetimidate (500 mg, 1.0 mmol) in the presence of trimethylsilyl trifluoromethanesulfonate (270 mg, 1.2 mmol) in dry chloroform [20 mL, molecular sieves 4A (1 g) were added] for 6 h at 0 °C. After purification, the residual oil was mixed with a 28% methanol solution of sodium methoxide (100 μL) for deacetylation. The solution mixture was condensed by evaporation and purified by a silica gel column chromatography (methanol:chloroform = 1:7). (DHDG-Man, 290 mg, 46% yield). ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.09 (d, 1H, J = 2.0 Hz, H_1), 3.96−3.14 (m, 19H, others), 1.4−1.1 (m, 52H, CH_2 of hexadecyl chains) and 0.88 (t, 6H, CH_3 of hexadecyl chains). IR (KBr): O−H stretching of mannose 3449−3294 cm^{-1}, CH_2 ν_{as} 2918 cm^{-1}, CH_2 ν_s 2850 cm^{-1}, C−O−C stretching of glycerol moiety 1140−1061 cm^{-1}. Anal. calcd for $C_{43}H_{86}O_9$: C, 70.02; H, 11.78. Found: C, 69.96; H, 11.92.

Preparation of Mannose-Carrying Homopolymer. MPMan (180 mg, 570 mmol), V-50 (1.6 mg, 5.7 mmol) as initiator, and cystamine hydrochloride (3.3 mg, 29 mmol) as chain-transfer reagent were dissolved in water (10 mL). After a N_2 gas was passed through the solution for 5 min, the mixture was tightly sealed and incubated for 24 h at 70 °C. The solution mixture was repeatedly ultrafiltrated with water (Amicon Model 8010; membrane, YM-1; exclusion limit, 1000) to remove small impurities. The viscous solution retained above the

membrane was lyophilized (91 mg, PMPMan, 59% yield). The degree of polymerization (DP) of the homopolymer was determined as 17 by the conductometric titration of amino group at the end of the polymer. IR (KBr) O−H stretching of mannose 3394 cm^{-1}, CH_2 ν_{as} 2939 cm^{-1}, CH_2 ν_s 2863 cm^{-1}, C═O stretching of secondary amide 1641 cm^{-1}, N−H deformation of secondary amide 1532 cm^{-1}, C−O−C stretching of glycerol moiety 1132−1045 cm^{-1}. Anal. calcd for C_2H_8NSCl $(C_{13}H_{23}O_7N)_{17}$·$18H_2O$: C, 46.92; H, 7.00; N, 4.48. Found: C, 46.90; H, 7.53; N, 4.34. By the similar procedure, PMHMan (DP = 16) was prepared (120 mg, 35% yield).

Preparation of Mannose-Carrying Amphiphiles by Polymerization. DODA-501 (31 mg, 23 μmol) in THF (5 mL) and MPMan (290 mg, 940 μmol) in methanol (5 mL) were mixed in a small round-bottomed flask. After passing a N_2 gas through the solution for 5 min, the reaction mixture was tightly sealed and incubated for 24 h at 70 °C. After evaporation of the solvent, the mannose-carrying amphiphile was purified by washing with *n*-hexane (to remove unreacted initiator) and subsequently with cold water (to remove polymers without lipophilic end group). The amphiphile, which had been dispersed in water by a vortex mixer and subsequently by an ultrasonifier (Astrason W-385, Heat Systems-Ultrasonics, Inc., NY) at 50 °C for 3 min, was further purified by passing through a GPC column (2 × 20 cm, Sephacryl S-200; mobile phase, water) and lyophilized (126 mg, DODA-PMPMan, 42% yield, Scheme 2A). IR (KBr) O−H stretching of mannose 3370 cm^{-1}, C≡N stretching 2245 cm^{-1}, C═O stretching of secondary amide 1616 cm^{-1}, C═O stretching of tertiary amide 1654 cm^{-1}, N−H deformation of secondary amide 1529 cm^{-1}, CH_2 ν_{as} 2923 cm^{-1}, CH_2 ν_s 2853 cm^{-1}. The DP value of the amphiphiles was determined as 18 by elemental analyses and NMR. Anal. calcd for $C_{42}H_{82}ON_2$ $(C_{13}H_{23}O_7N)_{18}$·$36H_2O$: C, 48.92; H, 8.44; N, 4.13. Found: C, 48.49; H, 7.66; N, 4.06.

Using the similar method, dioctadecylamine−poly(*N*-methacryloylaminohexyl D-mannopyranoside) conjugate (DODA-PMHMan, DP = 9, 18, 23 and 25, Scheme 2A) and dioctadecylamine−poly[3-(2-methacryloylaminoethylthio)propyl D-mannopyranoside] conjugate (DODA-PMEPMan, DP = 17, Scheme 2B) were prepared (Table 1). Because of the difficulty to purify amphiphilic compounds, the yields of mannose-carrying amphiphiles were in general very low (Table 1).

Table 1. Preparation of Mannose-Carrying Amphiphiles

Preparation of Liposome. DDPC was dissolved in chloroform (1 mL) in a small round-bottomed flask, and the solvent was evaporated. The thin lipid membrane formed was dispersed in a Hepes buffer (pH 8.2, 10 mM) in which the mannose-carrying amphiphile had been dispersed beforehand using a vortex mixer at 50 °C. The dispersion was further sonicated by the ultrasonifier for 3 min while a N_2 gas was passed through the dispersion. The liposome (small uni-lamellar vesicle, SUV) dispersion was passed through a syringe filter (Millipore Millex-GV; pore size, 0.22 μm) and finally irradiated in a quartz cell by a UV lamp (UI-5010, Ushio, Tokyo, Japan) at room temperature for 4 h to polymerize the dienoyl groups of DDPC. The progress of polymerization was followed by the decrease in absorbance at 258 nm by using a UV−vis spectrometer (Ubest-35, Japan Spectroscopic Co., Tokyo, Japan).

Dynamic Light Scattering Method. Hydrodynamic diameter of SUV liposomes composed of mannose-carrying amphiphile, and DDPC was determined by the dynamic light scattering (DLS) method (DLS-7000, Otsuka Electronics, Hirakata, Japan. light source, He−Ne laser 632.8 nm).

Turbidity Measurements. The lectin-induced agglutination of liposomes was followed by the increase in decadic absorbance at 350 nm by using a stopped flow spectrophotometer (RA-401, Otsuka Electronics, Hirakata, Japan). The observation cell was thermostated by a water bath (Neslab RTE−8, Neslab Instruments, Inc., Portsmouth, NH). To get reliable data, the measurements were carried out 5 or 6 times at various lectin concentrations. The uncertainties of the rate of turbidity change were within 10%.

Association Constants for Con A to Mannose-Carrying Liposomes. The association constant, K_a, between Con A, L, and the mannose-carrying amphiphile, S, (eq 1) was determined by the Scatchard plot.

$$L + S \overset{K_a}{\rightleftharpoons} L{\cdot}S \qquad (1)$$

The ratio of the concentration of free Con A to that of the complex with Con A is given by the eq 2.

$$[L{\cdot}S]/[L] = K_a(n[S]_o - [L{\cdot}S]) \qquad (2)$$

where [L·S] and [L] refer to the concentration of bound Con A and that of free Con A, respectively, and $[S]_o$ refers to the total concentration of mannose-carrying am-

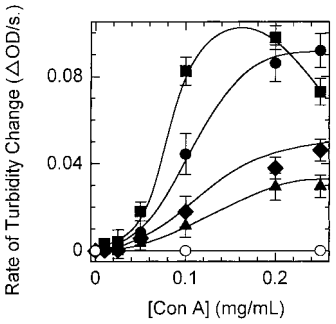

Figure 1. Effect of concentration of Con A on the turbidity change after the addition of Con A to the liposome suspension at 25 °C. Wavelength = 350 nm. Content of mannose-carrying lipid = 20 wt %. [Liposome] = 50 μg of lipid/mL. 10 mM HEPES buffer (pH 8.2) containing 0.1 mM $CaCl_2$ and 0.1 mM $MnCl_2$. (○) DHDG-Man; (▲) DODA-PMHMan DP = 9, (◆) DP = 18, (●) DP = 23, and (■) DP = 25.

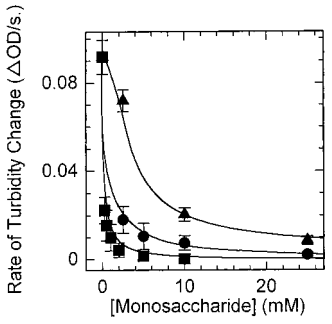

Figure 2. Inhibitory effects of monosaccharides on the rate of turbidity change in the aggregation of mannose-carrying liposomes by Con A at 25 °C. Wavelength = 350 nm. Content of DODA-PMHMan (DP = 23) = 20 wt %. [Liposome] = 50 μg of lipid/mL. [Con A] = 0.25 mg/mL. (▲) Glucose; (●) mannose; (■) α-methyl D-mannopyranoside.

phiphiles. A plot of [L·S]/[L] versus [L·S] should ideally give a straight line with a slope $-K_a$. The association constant obtained from the plot was expressed in inverse molarity, assuming a molecular weight of 26 500 for four subunits in Con A (*16*).

The mannose-carrying liposome suspension in a test tube (1 mL) was incubated with various concentrations of Con A (1 mL) at 25 °C for 1.5 h. The Con A bound to the liposome (actually the aggregates of liposomes cross-linked by Con A molecules) was removed with a syringe filter (Millipore Millex-GV; pore size, 0.22 μm), and the absorbance of the filtrate at 280 nm was measured. Although the filter of low protein binding was used to remove the liposome−Con A aggregates, free Con A was observed to adsorb to the filter a little. Therefore, we at first estimated the relationship between the absorption of filtrate (2 mL) at 280 nm vs the concentration of free Con A before the filtration, and the amount of Con A bound to the liposome was calculated with the help of this calibration curve.

Estimation of Contents of Phospholipids and Sugar Residues in Liposomes. The contents of phospholipids and sugar residue in the liposomes were estimated by the Bartlett method (*17*) and phenol-sulfuric acid method (*18*), respectively.

RESULTS AND DISCUSSION

A. Recognition of Pendent Mannose Residues on Liposomes by Con A. The physically stabilized liposomes could be easily prepared by the photoirradiation of liposomes composed of glycolipids and the polymerizable phospholipid (DDPC) (*19*). The liposomes prepared here probably bring about the phase separation of the mannose-carrying amphiphiles in the liposomes by two-dimensional photopolymerization of DDPC molecules (*20*). Using the DLS method, diameters of the liposomes (SUV) composed of polymerized DDPC and DODA-PMPMan, DODA-PMHMan, or DODA-PMEPMan were estimated to be 1300−1400 Å on average, respectively, and the diameters of the liposomes did not change for at least 1 month (data were not shown).

Turbidity of mannose-carrying liposome suspension at 350 nm was rapidly increased by the addition of Con A (Figure 1). The initial slope of the turbidity change increased both with the concentration of Con A and the degree of polymerization of mannose-carrying amphiphiles incorporated in the liposome. The latter is because a steric hindrance for the lectin to approach mannose residues on the liposome surface decreased with the DP value. When the mannose-carrying liposome consisted of 1,3-di-*O*-hexadecyl-2-*O*-(α-mannosyl)glycerol (DHDG-Man), and polymerized DDPC was incubated with the Con A solution, the turbidity did not increase at all, because the mannose residues were too close to the liposome surface.

Next, the effects of various monosaccharides on the Con A-induced turbidity change of mannose-carrying liposome dispersions were examined (Figure 2). It was previously reported that the inhibition activity of α-methyl D-mannopyranoside (α-MeMan) was much higher than any other monosaccharide (*21*). The tendency observed in Figure 2 is consistent with the data reported previously. Furthermore, the subsequent addition of monosaccharides to the dispersion of mannose-carrying liposome−Con A aggregates induced the prompt reduction of turbidity (data not shown). These results strongly support that the turbidity change is due to the specific recognition of mannose residues on the liposomes by Con A, and subsequent aggregation of liposomes mediated by the tetrameric lectin molecules.

It should be mentioned here that the sugar-carrying amphiphiles prepared here were stably incorporated in the liposome membrane. For example, after passing a gel permeation chromatography (GPC) column (Sephacryl S-200, 2 × 20 cm), the contents of phospholipid and manno-lipid in the DODA-PMPMan (DP = 18) − polymerized DDPC liposome estimated by the Bartlett method and phenol-sulfuric acid method, respectively, were the same as those without the GPC treatment (91% of the manno-lipid was retained in the liposome after the GPC). Furthermore, after the GPC, the DODA-PMPMan-polymerized DDPC liposome mixed with the Con A solution showed a quite similar turbidity change to the liposome of the same concentration without the GPC treatment.

B. Effect of the Distance between the Polymer Chain and Mannose Residues on the Recognition by Con A. Figure 3a shows that the rate of turbidity change was not dependent on the distance between the polymer main chain and mannose residues as for the amphiphiles with the same DP value [DODA-PMPMan (DP = 18) and DODA-PMHMan (DP = 18)]. We had expected that the rate of turbidity change of DODA-PMHMan (the distance between the polymer main chain and mannose residue, about 14 Å) would be larger than that of DODA-PMPMan (about 9 Å).

The results obtained here suggest the following situation: In the liposome system, the steric hindrance of the gigantic carrier liposome for Con A molecule to approach the mannose residues was dominant, and Con A could limitedly bind the end mannose residues in the

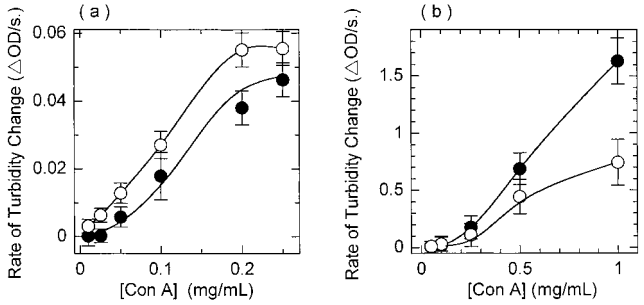

Figure 3. Effect of concentration of Con A on the rate of turbidity change after the addition of Con A at 25 °C. Wavelength = 350 nm. (a) Liposome suspension. Content of mannose-carrying amphiphile = 20 wt %. [Liposome] = 50 μg of lipid/mL. (○) DODA-PMPMan (DP = 18); (●) DODA-PMHMan (DP = 18). (b) Solution of mannose-carrying polymer. [Polymer] = 50 μg/mL. (○) PMPMan (DP = 17); (●) PMHMan (DP = 16).

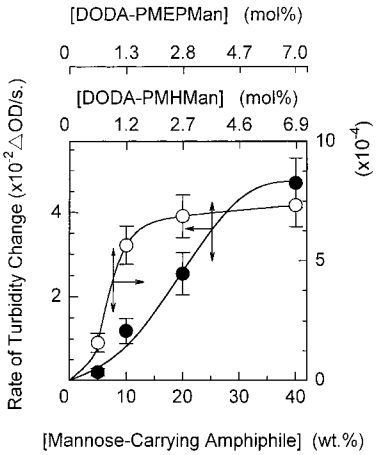

Figure 4. Effect of mannose-carrying amphiphile content in the liposome on the rate of turbidity change after the addition of Con A into the liposome suspension at 25 °C. Wavelength = 350 nm. [Liposome] = 50 μg of lipid/mL. [Con A] = 0.1 mg/mL. (○) DODA-PMEPMan (DP = 17) (α:β = 4:1); (●) DODA-PMHMan (DP = 18) (α:β = 20:1).

polymer chain. Consequently, the effect of spacer length in the liposome systems on the recognition did not clearly appear.

In the water-soluble polymer system, on the contrary, the length of spacer (Figure 3b) appreciably affected the turbidity change. In the absence of the gigantic carrier liposome, Con A can make a multidirectional approach to the mannose residues in the polymer. The difference in the distances between the mannose residue and polymer main chain, therefore, became effective in the recognition of the mannose residue by Con A molecule.

C. Effect of the Content of Mannose-Carrying Amphiphile on the Recognition by Con A. Figure 4 shows the effect of mol percent of mannose-carrying amphiphile (DODA-PMEPMan and DODA-PMHMan) on the turbidity change. The distances between mannose residues and polymer chain in these amphiphiles were comparable (about 14 Å). It is very clear that there was a steep increase in the rate of turbidity change at a low content of mannose-carrying amphiphile in both systems. The presence of threshold value in 5 mol % of lactosylceramide in liposomes at the lectin-induced aggregation was previously reported (*22*). In the present liposome systems, however, the turbidity increased with time at the very small mole percent of mannose-carrying amphiphile, probably because many mannose residues are present in a polar head region of one lipid molecule, which makes it unnecessary for the lectin to bind to

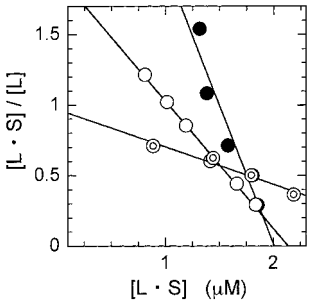

Figure 5. Scatchard plots for the binding of mannose-carrying liposomes to Con A at 25 °C. (○) DODA-PMPMan (DP = 18); (●) DODA-PMHMan (DP = 18); (◎) DODA-PMEPMan (DP = 17).

Table 2. Association Constants (K_a) for the Complexation of Con A with Mannose-Carrying Amphiphiles and Sugar Derivatives at 25 °C

amphiphiles	K_a ($\times 10^6$ M^{-1})[a]
DODA-PMHMan (DP = 18)	2.2 ± 0.1
DODA-PMPMan (DP = 18)	0.9 ± 0.1
DODA-PMEPMan (DP = 17)	0.3 ± 0.03
sugar derivatives	**K_a (M^{-1})[b]**
α-methyl D-glucopyranoside	2.0×10^3
α-methyl D-mannopyranoside	8.2×10^3
oligosaccharide[c]	1.4×10^6

[a] In the 10 mM Hepes buffer (pH 8.2) containing 0.1 mM $CaCl_2$ and 0.1 mM $MnCl_2$. [b] Ref *23*. [c] (GlcNAc(β1,2)−Man)$_2$−(α1,6, α1,3)Man−OH.

plural number of mannose-carrying amphiphiles on each liposome to bring about the significant aggregation, and consequently, the agglutinability of the lectin at the very small mol percent of mannose-carrying amphiphile was observed. A similar tendency was observed in the lectin-induced aggregation of liposomes that contained glucose- or galactose-carrying amphiphiles prepared with the lipophilic radical initiator (*8*, *9*).

It should be noted here that the scales of ordinate in the figure are different for two kinds of mannose-carrying amphiphiles. Con A possesses about 30 times the binding ability to α-derivatives compared with that to β-derivatives (*21*). Therefore, it is understandable that DODA-PMHMan (α:β = 20:1) which contained many α-form mannose residues in one lipid molecule was much more easily recognized than DODA-PMEPMan (α:β = 4:1).

D. Association Constants for Con A to Mannose-Carrying Amphiphiles. The association constants for Con A to various mannose-carrying liposomes obtained by the Scatchard plot (exemplified in Figure 5) are shown in Table 2. The K_a values were much lager than those of α-MeMan and α-MeGlc (*23*) and similar to the value of a branched penta-saccharide shown in the footnote c of the table. These results show that sugar residues incorporated in polymer chain as pendent groups enhance appreciably the affinity for Con A compared with monosaccharides. This is called the "*cluster effect* " which enhances the apparent affinity of cluster glycosides toward lectins without significantly changing the sugar concentration (*2a*, *24*). Previously we examined catalytic behavior of galactose oxidase at lipid bilayer−liquid interfaces (*10*, *11*), and observed that the affinity of galactose oxidase for the amphiphiles that carried many pendent galactose residues was much higher (10^4 times at the most) than those for various galactose derivatives with low molecular weight.

α-methyl D-mannopyranoside	−22.3	−34.3	−41
oligosaccharide[d]	−35.1	−44.3	−31

[a] In the 10 mM HEPES buffer (pH 8.2) containing 0.1 mM $CaCl_2$ and 0.1 mM $MnCl_2$. [b] Calculated from the data by Mandal et al. (*23*). [c] Temp at 25 °C. [d] (GlcNAc(β1,2)−Man)$_2$−(α1,6 α1,3)Man−OH.

parameters for the K_a values of Con A−mannose-carrying amphiphiles were estimated by the van't Hoff plot (Table 3). The enthalpy change has been interpreted in terms of differences in the interactions between the solvent and lectin and between the ligand and lectin (*25*). These interactions involve hydrogen bonding and electrostatic and van der Waals interactions (*26*). On the other hand, the increase in entropy change is associated with the release of water from the binding site of the lectin and the sugar residue into bulk solvent (*25*).

The absolute value of enthalpy change for the DODA-PMHMan system was larger than that for the DODA-PMPMan system. This difference might be due to the strength of hydrophobic interaction between the spacer part and the binding site of the lectin, because the DODA-PMHMan has three more methylene groups in its spacer part than the DODA-PMPMan. It was reported that the binding of 4-methylumbelliferyl α-D-galactopyranoside with L-14 lectin was about 50-fold larger than that of D-galactose due to the presence of large nonpolar aglycon (*27*). In the DODA-PMEPMan system, on the contrary, the presence of thioether group in the spacer part might reduce the hydrophobic interaction with the lectin, resulting in the smallest absolute value of enthalpy change.

The entropy change for the binding of Con A to mannose residues on the liposome surface was positive in all the mannose-carrying amphiphiles examined here, which is in contrast with the negative value for various sugar derivatives with low molecular weight (*23*). Therefore, the binding process between the pendent mannose-carrying liposomes and Con A were entropically driven by the dehydration effect rather than enthalpically driven.

It is indispensable for the safe usage and effective action of medicine to selectively deliver the medicine to the target parts. This is a final goal of pharmacology. For the achievement of the goal, a lot of attempts to modify medicine itself or to incorporate the medicine in the microparticles have been carried out. Liposomes, unnecessary to say, are quite attractive material as drug carrier to achieve the targeting. Meanwhile, the activated macrophages play an important role in the host defense against neoplasias (*28*). In this case, after being activated by the uptake of the liposomes which incorporate biological response modifiers, the macrophages arrive at the tumoricidal state and destroy the tumorigenic cells. Taking account of the previous reports that mannosylated liposomes were easily taken up by Kupffer cells (*3*) or macrophages (*4*) in greater amounts than the nontargeted liposomes, the mannose-carrying amphiphilic compounds prepared here have a possibility to be used as a tool not only for the DDS to target cells with sugar receptors, such as Kupffer cells or other macrophages, but also for the activation of these cells to join the self-defense system against neoplasias.

ACKNOWLEDGMENT

We are grateful to Wako Pure Chemicals for their kind donation of V-501 and V-50. This work was supported by the Grant-in-Aid for Scientific Research on Priority Areas (08246222, 09232223, 09240213, and 10126221) from the Ministry of Education, Science, Sports and Culture.

We have synthesized and evaluated five series of polymeric gadolinium chelates which are of interest as potential MRI blood pool contrast agents. The polymers were designed so that important physical properties including molecular weight, relaxivity, metal content, viscosity, and chelate stability could be varied. We have shown that, by selecting polymers of the appropriate MW, extended blood pool retention can be achieved. In addition, relaxivity can be manipulated by changing the polymer rigidity, metal content affected by monomer selection, viscosity by polymer shape, and chelate stability by chelator selection.

INTRODUCTION

The use of paramagnetic gadolinium chelates to enchance magnetic resonance imaging (MRI) examinations has become increasingly important (Hohenschuh and Watson, 1997). The gadolinium-containing contrast agents that are currently approved for human use (Omniscan, Magnevist, Prohance, and Dotarem) are all low molecular weight chelates. When administered parenterally, these agents rapidly extravasate out of the circulation into the interstitial space. For some imaging applications (Brasch, 1992), it would be desirable to have an agent that was largely retained within the intravascular space during the time frame of an MRI examination, a so-called "blood pool" agent. Several approaches have been explored in the quest for MR blood pool agents including: (1) low MW Gd-chelates that bind to serum proteins (Lauffer et al., 1996; Wallace et al., 1998), (2) iron oxide particles (Engelbrecht et al., 1998), (3) Gd-liposomes (Unger et al., 1990), and (4) polymeric Gd-chelates. While others have prepared polymeric Gd-chelates by grafting chelators onto preformed polymers such as albumin (Schmiedl et al., 1987), polylysine (Schuhmann-Giampieri et al., 1991), dextran (Rebizak et al., 1998; Casali et al., 1998), and dendrimers (Schwickert et al., 1995), we have focused our efforts to obtain MR blood pool agents primarily on wholly synthetic polymers.

As contrast agents for MRI, the potential advantages of macromolecular complexes in comparison to the currently available monomeric low molecular weight complexes are well recognized (Brasch, 1991). An increased lifetime of the contrast agent in the blood pool has been identified as an important feature in both blood pool and dynamical tumor imaging (Brasch, 1991; Desser et al., 1994a). However, increasing the lifetime in the blood pool is a necessary, but not sufficient, criteria for attaining a useful contrast agent. The agent must also fulfill additional safety related criteria. The ideal Gd-based MR blood pool contrast agent will reside in the blood pool long enough to allow for convenient MR imaging, then clear from the blood pool rapidly after completion of the MR imaging procedure. For dynamical tumor imaging, the situation is even more complicated (Desser et al., 1994a; Roberts et al., 1997). The uptake and clearance from tumors depends on many factors, including the size and structure of the contrast agent (Roberts et al., 1997). Whatever the application, the agent should be a benign, low-volume parenteral that is completely eliminated from the body within a reasonable time. However, except for possibly the dendrimer-based gadolinium chelates, little attention has been given to the design of macromolecular complexes which have a basic structure that can easily be altered to control the resulting physical properties and size. Such a structure that can easily be altered is important, because it allows optimization of the contrast agent with respect to blood pool lifetime or tumor uptake and clearance. Within the basic structure of these complexes, the molecular weight, as well as other important physical properties including relaxivity, metal content, viscosity, and chelate stability, can be optimized. This report describes the design rationale that we employed and the results that were obtained with five series of polymeric gadolinium chelates. Since the polymers described herein are prototypical, not all of the above parameters were optimized, or even measured, for each polymer. Indeed, optimization of all of the parameters for a given agent is probably not feasible due to the interrelationship of the parameters studied, which necesitates the need to make compromises when designing a new agent. Thus, for each series, one or more features were chosen to be modified to illustrate the effect on a given parameter and to demonstrate the feasibility of modifying the key attributes of an MR blood pool polymer.

EXPERIMENTAL PROCEDURES

General Procedures. The identity of all intermediates was confirmed by ^{1}H NMR spectroscopy; purity was assessed by silica gel TLC. Molecular weight, polydispersity, and purity of polymers were determined by size-exclusion-HPLC.

Molecular Weight Determinations. Molecular weights and molecular weight distributions were obtained by size exclusion-HPLC comparing the polymers to a set of PEG standards obtained from American Polymer Standards Corp. A Perkin-Elmer series 200 analytical HPLC fitted with a series of three Supelco 30 cm × 7.8 mm size-exclusion columns comprised of a Progel-TSK G2000 SWXL, a Progel-TSK G3000 SWXL, and a Progel-TSK G4000 SWXL were employed. Detection was with a refractive index detector. The method involved 20 μL injections of 1 mg/mL solutions of the polymer samples, a mobile phase comprised of 30% acetonitrile:70% pH 6.8 phosphate buffer, a flow rate of 0.6 mL/min, and a 60 min isocratic program. Turbochrome software was used to control the program and Turbogel software to do the MW analysis.

Rabbit Blood Pool Retention Measurements. Formulations of polymers in isotonic saline were injected into the lateral ear vein of New Zealand white rabbits via a 21-gauge Butterfly needle at doses of 0.06 or 0.10 mmol of Gd/Kg. Arterial blood samples for relaxivity measurement were obtained via a catheter placed percutaneously into the lateral ear artery. Blood samples were withdrawn and collected into heparin tubes at 0, 5, 15, 30, 60, 120, 360, 600, and 1440 min following the injection (note: in some experiments every time point was not collected). T_1 measurements were made on the blood samples using a Bruker Mini-Spec operating at 20 MHz and 40 °C.

^{153}Gd Labeling of Polymers. Unmetalated polymers were dissolved in 0.1 M, pH 5.0, sodium acetate buffer and treated with ^{153}Gd by addition of $^{157}GdCl_3$ containing approximately 0.1% (w/w) $^{153}GdCl_3$ (Amersham, Arlington Heights, IL). The DTPA polymers were reacted for 15 min at room temperature, and the DOTA polymers were reacted for 2 h at 50 °C. The radiolabeling efficiencies as determined by instant thin-layer chromatography (ITLC) and HPLC were found to be >99%. The labeled polymers were purified by preparative SEC-HPLC, and the test article was diluted in 0.9% sterile saline, pH 6.5, to a final concentration of approximately 30 mM Gd.

Rat Blood Pool Retention Measurements. Six rats (0.35−0.45 Kg) previously prepared with polyurethane catheters were injected intravenously with 0.08 mmol of Gd/Kg (approximately 0.5 mL containing 1 mCi) of test article. Blood samples (100 mL) were withdrawn at 0.042, 0.08, 0.17, 0.33, 0.5, 0.75, 1, 1.25, 1.5, 2, 4, 6, 24, 48, and 168 h and the radioactivity quantitated using a γ counter.

Viscosity Measurements. The viscosities were measured in water with a Brookfield viscometer (model LVCP DVII-plus) equipped with a cone and plate spindle and a jacketed sample cell for temperature control. The temperature was controlled with a LAUDA RM6 circulating water bath. The viscometer was calibrated using Brookfield viscosity standards that ranged from 5 to 100 cP.

Relaxation Rate Measurements. The proton longitudinal relaxation rate ($1/T_1$) for aqueous solutions of the polymers was measured by the inversion−recovery method using a Bruker Minispec PC 120/125/10 Vts NMR Process Analyzer operating at 0.47 T and 40 °C. The relaxivity of a given polymer was calculated by subtracting the $1/T_1$ of pure water from the $1/T_1$ measured for the polymer-containing solution and dividing this quantity by the concentration of gadolinium as determined by ICP. The relaxivities were found to be independent of gadolinium concentration.

Polyoxyethylene Bis(chloride) (3). To a solution of poly(ethylene glycol) [**2**, average MW, 1.45K] (1000 g, 0.69 mol) in 1.5 L of toluene (60−80 °C) were added $SOCl_2$ (200 mL, 2.76 mol) and DMF (10 mL) dropwise over 10 min. The reaction mixture was heated on a steam bath for 1 h. An analysis by TLC (CH_2Cl_2:MeOH; 6:1) indicated that a very small amount of starting material still remained. An additional 20 mL of $SOCl_2$ was added to the reaction, and it was heated on the steam bath for another 20 min to drive the reaction to completion. After cooling the reaction to 0 °C with an ice bath, 1 N NaOH (2.5 L) was carefully introduced to neutralize the solution and the layers were separated. The aqueous layer was washed with CH_2Cl_2 (3 × 1 L), and the combined CH_2Cl_2 layers were washed with water (2 × 1 L) and dried with $MgSO_4$. It was filtered and concentrated under reduced pressure to give a light yellow oil. The product was precipitated by adding TBME (2 L) to the residue with cooling and stirring. The filtered product was dried in the oven under vacuum overnight to yield 941 g (94%) of the titled compound as a white solid. An analysis by HPLC indicated that the purity of the product was 99.86% with no oligomer present. Anal. calcd for $C_{64}H_{128}O_{31}Cl_2$: C, 52.49; H, 8.81; Cl, 4.84. Found: C, 51.94; H, 8.43; Cl, 5.00.

Polyoxyethylene Bis(azide) (4). To a suspension of polyoxyethylene bis(chloride) (**3**, 500 g, 0.336 mol) and KI (139 g, 0.841 mol) in 1500 mL of DMF was added NaN_3 (109 g, 1.68 mol). The suspension was heated on a steam bath at 70 °C for 12 h to give a yellow solution. After cooling the reaction to room temperature, 2.5 L of water was added and the solution was extracted with CH_2Cl_2 (3 × 1 L). The combined CH_2Cl_2 layers were washed with water (3 × 1 L), dried over $MgSO_4$, filtered, and concentrated under reduced pressure to give a light yellow oil. The product was precipitated out by adding TBME (1 L) to the residue with cooling and stirring. The filtered product was dried in the oven under vacuum overnight at room temperature to yield 452 g (90%) of the PEG diazide as a white solid. An analysis by HPLC indicated that the purity of the product was 99.2% with no oligomers present. Anal. calcd for $C_{64}H_{128}O_{31}N_6$: C, 52.09; H, 8.73; N, 5.69. Found: C, 52.50; H, 8.58; N, 5.11.

Polyoxyethylene Bis(amine) (5). To a solution of polyoxyethylene bis(azide) (**4**, 176 g, 0.117 mol) in 1 L of 1 N HCl was added Pd/C (17.6 g). The suspension was hydrogenated at 45 psi for 15 h. An aliquot withdrawn from the reaction indicated no more starting material by TLC (CH_2Cl_2:MeOH; 4:1), and the catalyst was removed by carefully filtering through a short plug of Celite. The filtrate was neutralized with 10% NaOH to pH 5−6 and extracted with CH_2Cl_2 (3 × 600 mL) to remove the impurities. The aqueous solution was neutralized with 35% NaOH to pH >10 and extracted with CH_2Cl_2 (2 × 500 mL). The CH_2Cl_2 layer was washed with water (500 mL), brine (500 mL), and dried over $MgSO_4$. The filtrate was concentrated under reduced pressure to give a light yellow oil. The product was precipitated by adding TBME (1 L) to the residue with cooling and stirring. The filtered product was dried in the oven under vacuum at room-temperature overnight to give 138 g (81% yield) of the titled compound as a white solid. Analysis by HPLC indicated that the purity of the product was 96.9% with no oligomer detected by gel chromatography. Anal. calcd

for $C_{64}H_{132}O_{31}N_2$: C, 53.92; H, 9.33; N, 1.96. Found: C, 53.24; H, 9.35; N, 1.66.

Preparation of Polymer NC 66368 (1a). [Note: WFI (water for injection) is used for this entire process.] To a solution of polyoxyethylene bis(amine) (**5**, 550 g, 0.380 mol) in 5500 mL of water was added triethylamine (159 mL, 1.14 mol) and DTPA-dianhydride (**6**, 149 g, 0.418 mol). The suspension was stirred at room temperature and gave a clear solution after 10 min. The reaction was stirred for an additional 50 min, and a solution of $GdCl_3 \cdot 6H_2O$ (156 g, 0.418 mol) in 2000 mL of water was added. The reaction mixture was checked with PAR reagent to be sure only a slightly excess of $GdCl_3 \cdot 6H_2O$ was added. The complexed solution (pH 2) was neutralized to pH ~5 with 10% NaOH and then diafiltered using a Pellicon diafiltration unit with a 10K cutoff filter for 10 turnovers: A 10% NaCl (USP grade) solution (filtered through a 0.22 μ filter) was used for the first four turnovers and water was used for the remaining six turnovers. At the end of the diafiltration, the solution was concentrated to half of its original volume (pH 7), filtered through a 0.22 μ filter and then lyophilized for 3 days leaving (532 g, 80%) a sponge-like product. MW = 20 200; $p = 1.63$. Total Gd = 7.09% w/w. KF moisture = 2.55%. Elemental analysis; anal. calcd for $[C_{80}H_{152}GdN_5O_{40}]_x$: C, 48.50; H, 7.73; N, 3.53. Found (corrected for H_2O): C, 48.14; H, 7.91; N, 3.29.

Preparation of Polymer NC 22181 (10a). (Note: WFI is used for this entire process). To a solution of hexamethylenediamine (**8**, 200 g, 1.72 mol) in 4 L of DMSO was added triethylamine (810 mL, 5.52 mol) and DTPA-dianhydride (**6**, 664 g, 1.84 mol). The suspension was stirred at room temperature for 45 h, and a light yellow solution was obtained. Four liters of EtOAc was added to the solution, and product (**9**) was precipitated as an oil. Solvent was decanted, and the oil product was further washed with EtOAc (2 × 2 L). After the oil product was dried under vacuum for 1 h, it was dissolved in 4 L of water and $GdCl_3 \cdot 6H_2O$ (312 g) was added (PAR reagent was used to ensure that no excess Gd^{3+} was added). The solution was neutralized to pH ~5 with NaOH and filtered through a 0.45 μ filter. The filtered solution was diafiltered using a Pellicon diafiltration unit with a 10K cutoff filter for 10 turnovers: A 10% NaCl (USP grade) solution (filtered through a 0.22 μ filter) was used for the first five turnovers and water was used for the remaining five turnovers. At the end of the diafiltration, the solution was concentrated to half of its original volume (pH 7), filtered through a 0.22 μ filter and then lyophilized for 3 days leaving (203 g) a sponge-like product (**10a**). MW = 18 900; $p = 1.51$. Total Gd = 22.00% w/w. KF moisture = 10.68%. Elemental analysis; anal. calcd for $[C_{20}H_{32}GdN_5O_8]_x$ (corrected for H_2O and NaCl): C, 33.54; H, 5.70; N, 9.78. Found: C, 33.44; H, 5.77; N, 9.63; Na, 0.69; Cl, 0.98.

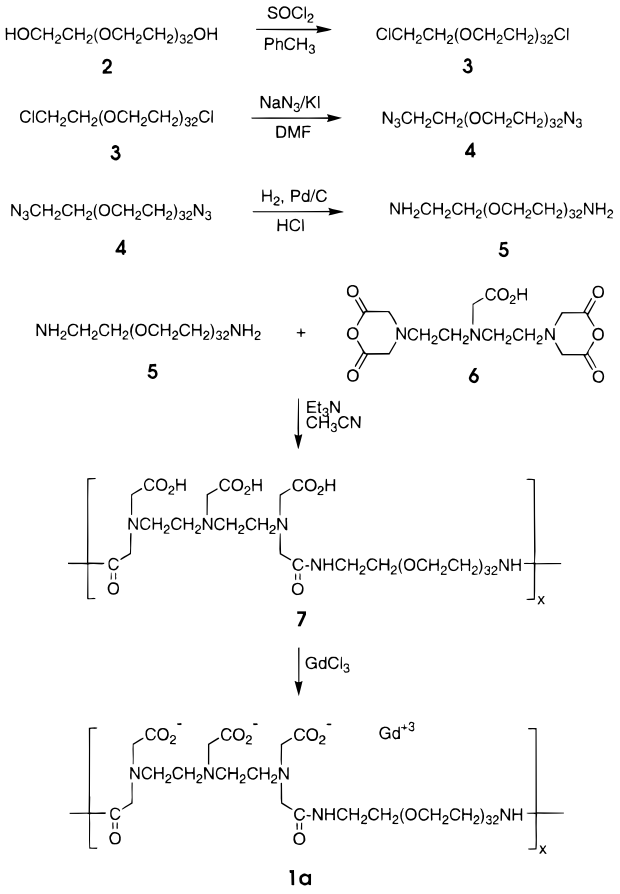
In a similar manner polymers **10a** of different MWs were prepared using the following conditions:

expt	mmol of **8**	mmol of **6**	base/mmol	DMSO (mL)	reaction time (h)	molecular mass (kDa)/ polydispersity
1	5.1	5.5	NaOH/16.5	18	50	8.8/1.50
2	51.0	55.0	Et_3N/159.	206	18	14.2/1.54
3	645.	678.	Et_3N/2030.	2500	168	18.1/1.34
4	129.1	135.5	Et_3N/406.6	250	24	21.0/1.39

In experiment 3, intermediate **9** was precipitated with ether prior to complexation with $GdCl_3 \cdot 6H_2O$; in experiments 1, 2, and 4, the reaction mixtures were diluted with water and then complexed with $GdCl_3 \cdot 6H_2O$.

Preparation of Polymer NC 22177 (16a). A solution of methoxy-PEG of average MW 550 (**11**, 66.67 g, 0.1212 mol; Sigma Chemical Co.) in 1000 mL of toluene was refluxed with azeotropic removal of water for several hours. The cooled toluene solution was treated with triethylamine (55.75 mL, 0.4 mol), 4-(dimethylamino)-pyridine (2.96 g, 0.0242 mol) and tosyl chloride (69.33 g, 0.3636 mol) and heated in an oil bath at 60 °C for 48 h. The reaction mixture was then cooled and filtered. The filtrate was extracted three times with water. The combined aqueous extracts were washed three times with ether, then extracted three times with chloroform. The chloroform extracts were dried over anhydrous $MgSO_4$ and concentrated to yield 47.58 g (56%) of product **12**. A solution of 14.96 g (21.25 mmol) of **12** in 150 mL of absolute EtOH was treated with 31.8 mL (213 mmol) of tris(2-aminoethyl)amine (**13**). The reaction mixture was heated in a stainless steel bomb at 160 °C for 16 h. The solvent was removed by evaporation and the residue dissolved in 257 mL of water and made basic with 42.5 mL of 1 N NaOH. The basic solution was washed twice with ether, then extracted twice with chloroform. The chloroform extracts were dried over anhydrous $MgSO_4$; solvent evaporation followed by heating at 90 °C under vacuum (1 mm) to remove residual tris(2-aminoethyl)-amine (**13**) yielded 12.14 g (84%) of **14** as a viscous tan oil. A solution of 4.23 g (6.24 mmol) of **14** in 42 mL of acetonitrile was treated with triethylamine (2.61 mL, 18.7 mmol) and diethylenetriaminepentaacetic acid dianhydride (**6**) (3.34 g, 9.36 mmol). After 1.0 h at room temperature, 168 mL of water was added and the solution was stirred for 30 min. The solution of crude polymer **15** was treated with gadolinium(III) chloride hexahydrate (3.65 g, 9.83 mmol) then diafiltered against water in a diafiltration cell equipped with a 10 000 MW cutoff membrane. The pH of the solution was adjusted to 7 with NaOH, then the solution was filtered through a 0.2 mm nylon filter. Lyophilization yielded 4.15 g of product (**16a**) of average molecular mass 13 600 Da ($p = 1.36$) as determined by SEC-HPLC using PEG molecular mass standards; 15.6% gadolinium by weight.

Preparation of Polymer NC 100203 (24a). A solution of 5.00 g of **19** (hydrobromide salt; WO 93/02045), methyl bromoacetate (0.795 mL), tetramethylguanidine (14.0 mL), and 100 mL of acetonitrile was refluxed for 3 h. The reaction mixture was then concentrated and the residual oil taken up in toluene and washed three times with water. The toluene solution was dried over anhydrous magnesium sulfate and concentrated to 4.46 g of product **20**. A solution of 4.10 g of **20** in 82 mL of methanol was treated with 41 mL of tris(2-aminoethyl)amine and stirred for 3 days at room temperature under N_2. The solution was concentrated under reduced pressure (1 mm) at 60 °C then taken up in $CHCl_3$ and washed four times with water, dried over anhydrous $MgSO_4$, and concentrated to 4.56 g of **21**.



A solution of 3.989 g of **17** (Shearwater Polymers, Inc.) in 26.8 mL of CH_2Cl_2 was treated with 270.5 mg of *N*-hydroxysuccinimide and 2.579 mL of a 1 M solution of dicyclohexylcarbodiimide in CH_2Cl_2 for 2 h.

The above reaction mixture of **18** was treated with a solution of 0.776 g of **21** in 23 mL of CH_2Cl_2 for 1 h, filtered, and concentrated to give 3.81 g of **22**. The tri-*tert*-butyl ester **22** (4.78 g) was treated with 48 mL of CH_2Cl_2 and 5 mL of TFA for 16 h, a second 5 mL portion of TFA was added, and the reaction continued for 16 h; a third 5 mL portion of TFA was added, and the reaction

continued for another 16 h, after which NMR indicated incomplete reaction. A fourth 5 mL portion of TFA was added, and after 4 days, the reaction was concentrated to dryness; NMR still indicated incomplete reaction. The crude product was treated with 25 mL of neat TFA for 16 h, after which NMR indicated complete reaction. The reaction mixture was then concentrated and taken up in 100 mL of water, and the pH was raised to 7.0 with 2 N KOH. The solution was then diafiltered vs water in a stirred cell with a YM-3 membrane (Amicon, Inc., Beverly, MA) and lyophilized to give 3.56 g of **23**. A 1.55 g sample of **23** in 31 mL of water was treated with 0.185 g of $GdCl_3 \cdot 6H_2O$; the pH was maintained at 4.5 with 1 N NaOH for 16 h. The pH was lowered to 3.0 with 1 N HCl, and then the solution was diafiltered vs water in a stirred cell with a YM-3 membrane (Amicon, Inc., Beverly, MA). The pH was adjusted to 7.0, and the solution lyophilized to give to give 1.41 g of **24a** of average molecular mass 16 200 Da ($p = 1.36$) as determined by SEC-HPLC using PEG molecular mass standards; 2.51% Gd by weight determined by ICP. The R_1 relaxivity was determined to be 6.6 mM^{-1} s^{-1} using a Bruker Mini-Spec operating at 20 MHz and 40 °C.

Preparation of Polymer NC 100372 (34). To a solution of 24.6 g (0.062 mol) of 6-aminocaproic acid benzylester *p*-toluenesulfonic acid salt and 20 g (0.19 mol) of sodium carbonate in 460 mL of 50% water in methylene chloride was added dropwise over 45 min a solution of 10 mL (0.13 mol) of chloroacetyl chloride in 230 mL of methylene chloride. Stirring was continued at room temperature under a nitrogen atmosphere for 2 h. The organic phase was separated and dried over anhydrous magnesium sulfate. Evaporation of the solvent left 18.4 g of crude product **28** which was further purified by flash chromatography on silica gel eluting with CH_2Cl_2. A solution of 0.676 g (1.14 mmol) of **19**, 0.338 g (1.14 mmol) of **28,** and 0.43 mL (3.4 mmol) of 1,1,3,3-tetramethylguanidine in 14 mL of acetonitrile was stirred at room temperature under a nitrogen atmosphere for 18 h. Volatiles were removed under reduced pressure, and the residue was partitioned with a mixture of toluene and water.The toluene phase was separated and washed with water, then dried over anhydrous magnesium sulfate, filtered from the drying agent, and concentrated to yield 0.79 g of product **29**. A solution of 5.0 g (6.4 mmol) **29** in 200 mL of methanol was treated with 0.5 g of 10% palladium on carbon and hydrogenated on a PARR shaker for 17 h. After the uptake of hydrogen had ceased, the catalyst was removed by careful filtration through a bed of Celite. The volatiles were removed from the filtrate using reduced pressure, and the residue obtained was triturated well with dry ethyl ether. The ether phase was decanted and concentrated under reduced pressure to yield 2.3 g of the product **30** as a white glass. Another 1.4 g of less pure product remained after the ether trituration. To a stirring solution of 2.25 g (3.30 mmol) of **30** (previously dried via azeotropic distillation from methylene chloride) and 0.43 g (3.6 mmol) of dry *N*-hydroxysuccinimide in 45 mL of methylene chloride at room temperature and under a nitrogen atmosphere was added dropwise, in 5 min, a solution of 7.4 mL (3.7 mmol) of 0.5 M *N*,*N*-dicyclohexylcarbodiimide in methylene chloride. After the addition was complete, stirring was continued at room temperature under nitrogen for about 17 h. The reaction slurry was filtered, and the volatiles were removed from the filtrate under reduced pressure to yield 2.7 g of the product **31** as a white glass. A solution of 0.437 g (0.076 mmol) of third generation PAMAM dendrimer (Meltzer et al., 1992) and 2.6 g (2.7 mmol) of **31** in 20 mL of

Scheme 1

anhydrous dimethyl sulfoxide was stirred at room temperature under a nitrogen atmosphere for 3 days. Most of the solvent was removed under reduced pressure at 60 °C, and the viscous residue was triturated with absolute ethyl ether three times, decanting each time, leaving a residue which was dried under high vacuum yielding 1.6 g of product **32**. The average number of unreacted amines on the PAMAM dendrimer moiety of compound **32** was determined to be approximately four by a ninhydrin assay (Curotto and Aros, 1993).

Elemental analysis calcd for $C_{905}H_{1,573}N_{191}O_{225}$, corrected for water of hydration: C, 51.14%; H, 7.46%; N, 12.6%. Found: C, 51.44%; H, 7.66%; N, 12.18%.

Treatment of 1 g (0.5 mmol) of **32** with 50 mL of a 25% trifluoroacetic acid solution in methylene chloride at 0 °C under a nitrogen atmosphere was followed by allowing the stirring reaction mixture to warm to ambient temperature during 1 h after which the volatiles were removed under reduced pressure. The residue was triturated with absolute ethyl ether, the ether decanted, and the residue dried under vacuum. The reaction was repeated with 50% trifluoroacetic acid for overnight reaction time. The volatiles were removed under reduced pressure, and the resulting residue stirred with absolute ethyl ether for 2 h, then filtered, washed with ether, and dried in a vacuum oven at 50 °C to give 0.9 g. The 0.9 g was dissolved in 10 mL of deionized water and filtered, and the pH of the filtrate was raised to 8 with 2 N potassium hydroxide solution. This solution was then diafiltered in an Amicon stirred cell against water using a 5000 Da cutoff membrane for 30 turnovers totaling 300 mL. The purified solution was filtered through a 0.2 μ filter and lyophilized yielding a tan foam which was dried under high vacuum and 40 °C to afford 0.4 g of **33**

RESULTS AND DISCUSSION

Initially, we prepared (Desser et al., 1994a) a series of copolymers of diethylenetriaminepentaacetic acid (DTPA) and poly(ethylene glycol) (PEG) diamines chelated to gadolinium (**1**, Gd-DTPA-PEGs) ranging in MW from 10.8 to 83.4 kDa as shown in Scheme 1. PEG-diamine (**5**) was prepared in two steps from poly(ethylene glycol) (**2**) and polymerized with the dianhydride of DTPA (**6**) and the resultant polymer (**7**) chelated with gadolinium to produce the Gd-DTPA-PEG polymer (**1a**). DTPA was selected as the chelator based upon its successful use in the marketed agents Omniscan and Magnevist; poly(ethylene glycol) diamines were chosen based upon the well-established biocompatability, hydrophilicity, and synthetic accessibility of PEG derivatives (Zalipsky, 1995). The Gd-DTPA-PEG polymers were evaluated (Desser et al., 1994a) in a rabbit model to (1) identify the molecular weight above which Gd-DTPA-PEG polymers behave as blood pool agents and (2) to analyze the tumor enhancement dynamics as a function of polymer molecular weight in a rabbit tumor model. This study showed that linear Gd-DTPA-PEG polymers with a molecular mass of 20 kDa and higher exhibited significant blood pool retention over a 60 min time frame. Therefore, we focused upon a Gd-DTPA-PEG polymer (**1a**, NC 66368) with a molecular mass of ~20 kDa prepared from polyethene glycol of MW 1450 (Scheme 1) as our initial lead structure.

While NC 66368 proved to be efficacious in the rabbit tumor model (Desser et al., 1994a) and a model demonstrating time-of-flight magnetic resonance angiography (TOF-MRA) (Desser et al., 1994b), it possessed some shortcomings. The low R_1 relaxivity (6.0) combined with the low gadolinium content (7.1%) made it necessary to administer large amounts of polymer in order to achieve adequate doses of gadolinium to produce the required t_1 shortening. In addition, as the formulation concentration of NC 66368 was increased to minimize the injection volume, the solution viscosity became unacceptably high (56.1 cP for a 100 mM Gd formulation, see Table 1).

One approach to addressing the shortcoming of NC 66368 was to design an analogous series of copolymers (**10**) of diethylenetriaminepentaacetic acid with short-chain alkyldiamines in place of the longer chain poly(ethylene glycol) diamines (Scheme 2). While these polymers had the expected increase in gadolinium content, from 7.1% for **1a** to 22.0% for **10a**, they also exhibited (Kellar et al., 1997) unexpected increases in R_1 relaxivity, from 6.0 for **1a** to 9.5 for **10a**. A subset of this series, analogues of **10** in which the spacer length (n) was

Scheme 2

varied, was found to have relaxivities up to 20.7 (Kellar et al., 1997). This combination of increased gadolinium content and increased relaxivity resulted in significant decreases in the amount of polymer required for imaging studies. From this series of polymers, NC 22181 (**10a**) was identified as a significantly improved lead. Like NC 66368, NC 22181 has been shown to be an effective contrast agent for MRA imaging in rabbits (T. Desser and D. L. Rubin, unpublished data) and an effective agent for MR urography in pigs (Nolte-Ernsting et al., 1997). While blood pool retention is known to be affected by polymer MW, size, shape, and charge (Petrak and Goddard, 1989), within a given series in which MW and consequently size is the only variable, it would be expected that blood pool retention would be determined by MW. However, this relationship would not necessarily hold up comparing polymers across series as more than one variable could be changing. Therefore, the results from the Gd-DTPA-PEG polymer series could not be used to confidently predict the minimal MW required for NC 22181 to act as a blood pool agent, and thus polymers ranging in molecular mass from 9 to 21 kDa were prepared and evaluated in the rabbit model. The results of this study are summarized in Figures 2 and 3. The data shows that NC 22181 of molecular mass 14 kDa and above has a prolonged blood pool phase reflected in significantly increased blood half-lives and decreased volumes of distribution and thus would qualify as a candidate MR blood pool imaging agent.

A third approach to designing blood pool agents was aimed primarily at addressing the relaxivity and viscosity

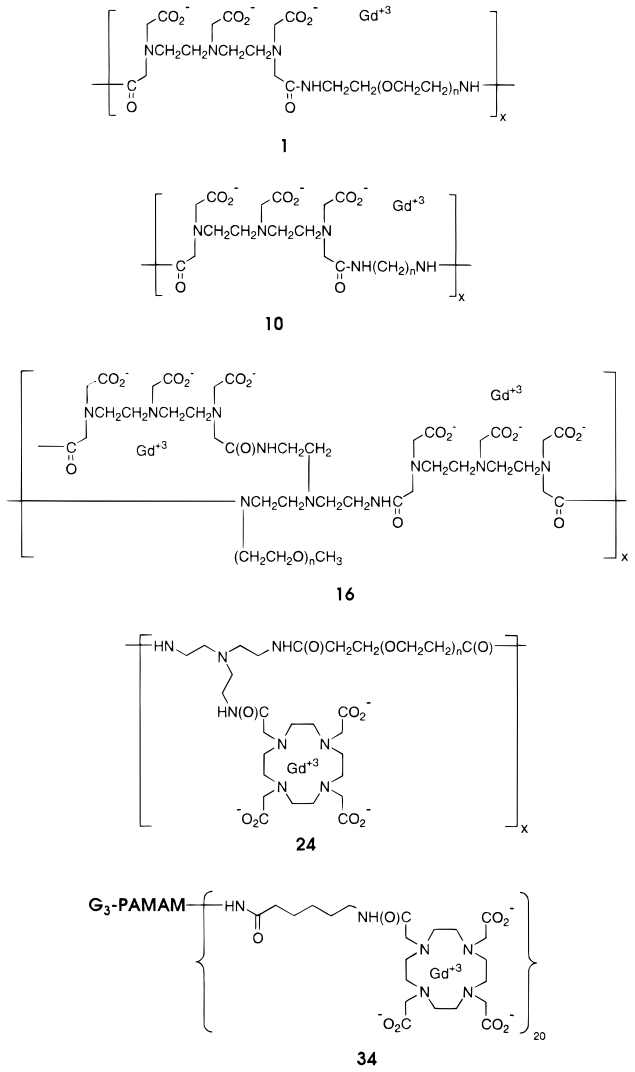

Figure 1. Polymeric gadolinium chelates.

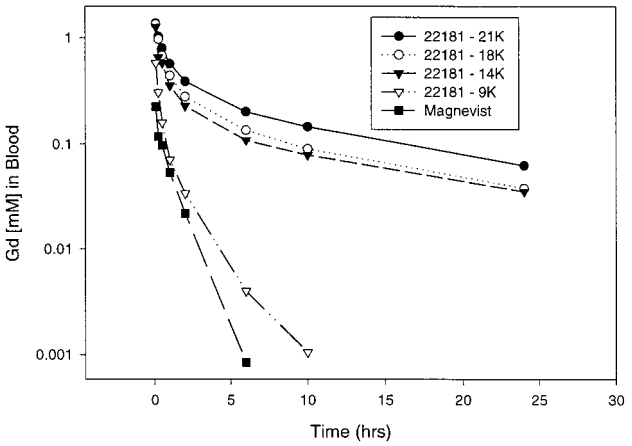

Figure 2. Blood retention vs time for NC 22181 of four different molecular weights and Magnevist.

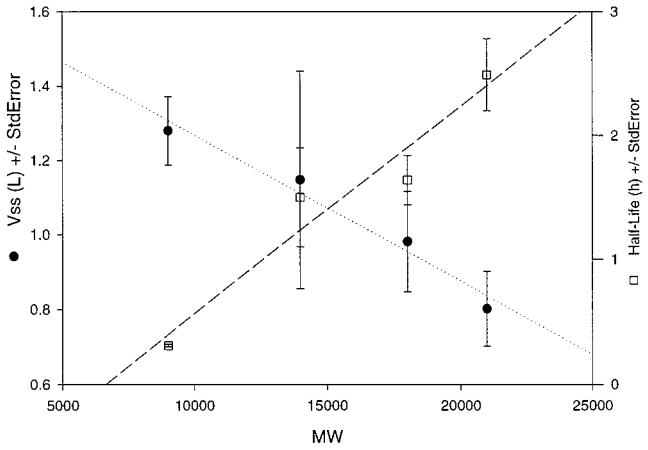
issues. A series was designed (Ladd, 1996) to produce polymers with a more globular shape than the above two linear polymers. The nonlinear shape was achieved by appending poly(ethylene glycol) chains to the polymer backbone [vs incorporation of poly(ethylene glycol) chains into the polymer backbones of **1** and **10**] and incorporating interchain cross-links through the DTPA moieties (Scheme 3). Methoxy-PEG-triamine (**14**) was prepared from the methoxy-PEG-tosylate (**12**), polymerized with



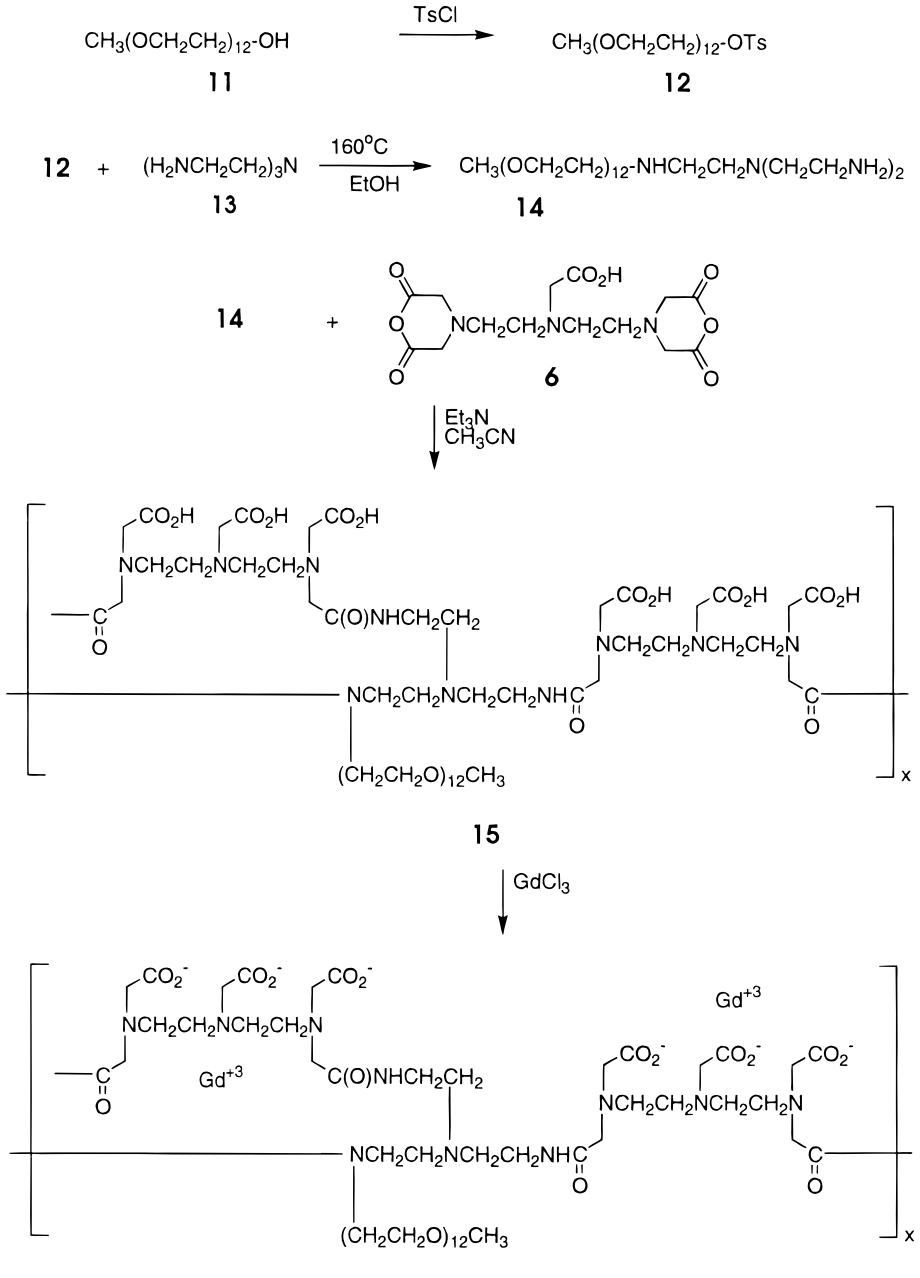


Figure 3. Volume of distribution and overall blood clearance half-life vs molecular weight for NC 22181 of four different molecular weights.

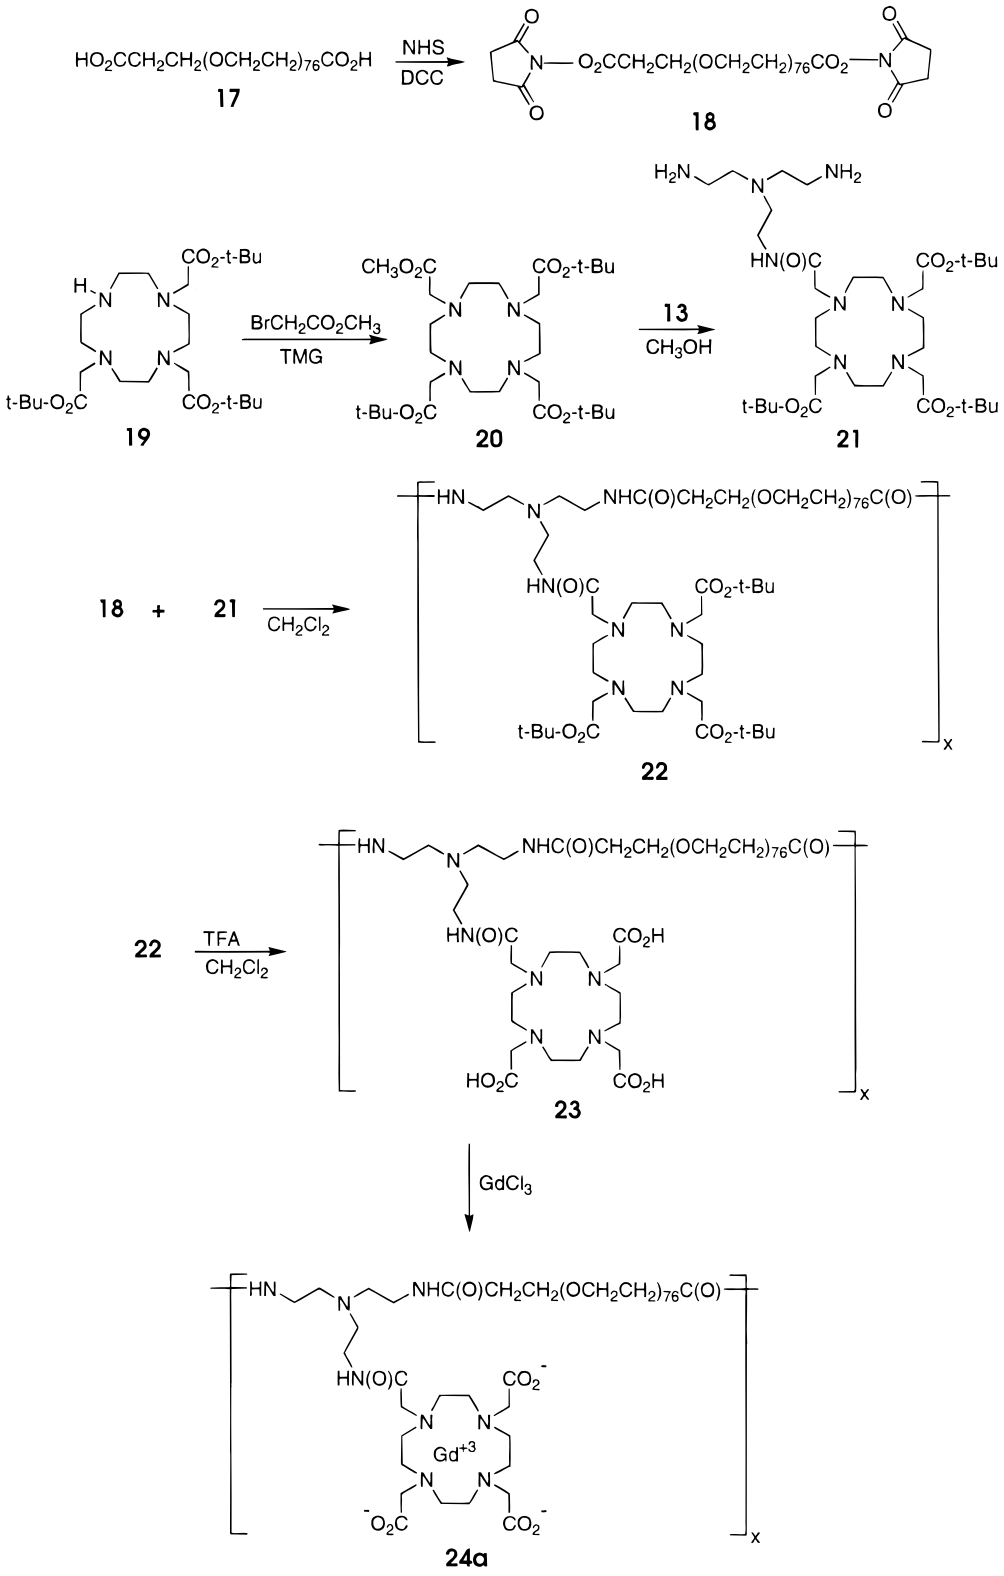
1.5 equiv of DTPA dianhydride and chelated with gadolinium to give **16a**. It was expected that the more globular shape of **16a** would result in lower viscosity solutions and that the increased rigidity resulting from cross-linking would result in higher relaxivities. This was indeed found to be the case. Solutions of **16a** had considerably lower viscosities than solutions of **1a** when compared on the basis of similar gadolinium concentration or polymer concentration (see Table 1). The relaxivity of **16a** (10.1) was found to be 68% higher than for the linear, non-cross-linked polymer **1a**.

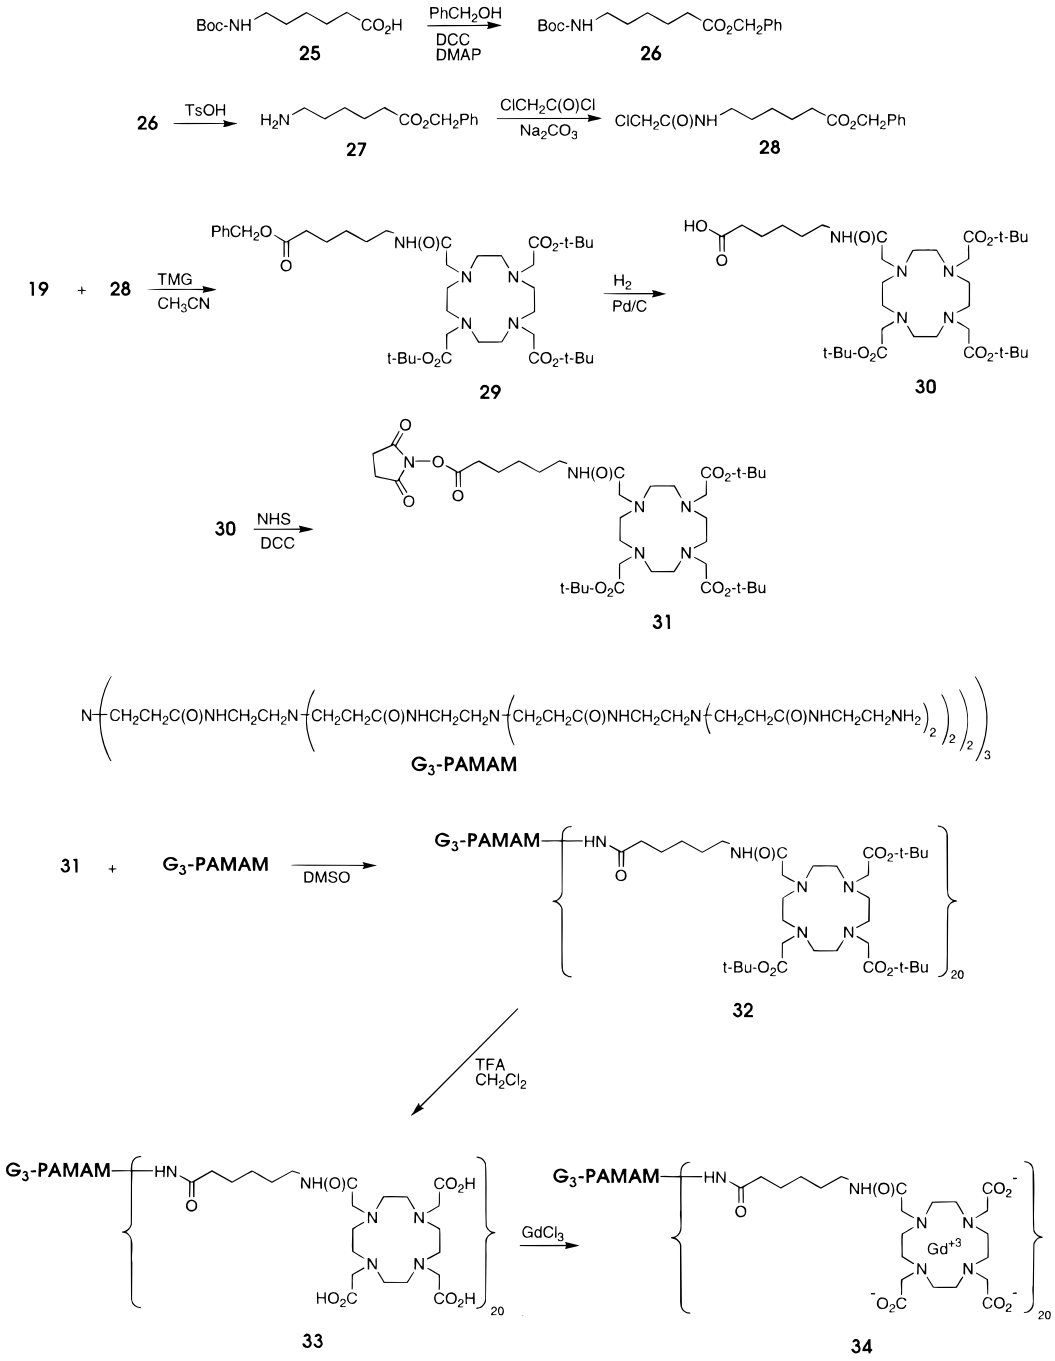
Since blood pool gadolinium polymers, by design, reside in the body for extended periods of time, there is an increased opportunity for in vivo metal dissociation (Cacheris et al., 1990; Wedeking et al., 1992; Duncan et al., 1994; Deal et al., 1996; Corot et al., 1998). This is illustrated by the percentage of the injected dose recovered in the bone at 7 days (Table 1). For example, Magnevist with a short half-life has bone gadolinium retention of 0.21% of the injected dose (% ID), while the two DTPA based polymers (**1a** and **10a**) showed higher levels of retention at 7 days, 3.50 and 4.91%ID, respectively. Only bone data at 7 days is reported in Table 1 as no other major organs retained significant amounts of metal and bone retention is generally considered to be a good measure of long term gadolinium retention. Traditionally, reduction of metal retention has been addressed by the choice of chelator. Therefore, in response to the concern of long term metal retention, a series of polymers was designed which employ the macrocyclic chelator DOTA in place of the linear chelator DTPA. Macrocyclic Gd-DOTA chelates which are found in the marketed agents Prohance and Dotarem are known (Wedeking et al., 1992) to be more thermodynamically and kinetically stable than linear Gd-DTPA chelates. Scheme 4 shows the synthesis of a DOTA polymer (**24a**). The PEG-bis-NHS ester (**18**) was polymerized with the tri-*tert*-butyl ester-DOTA-diamine (**21**), and the resultant polymer (**22**) deprotected with TFA and chelated with gadolinium. The requirement that the DOTA nucleus maintains at least three carboxylates to maintain the desired tight metal binding necessitated trade offs that resulted in a polymer with less than optimal properties. Appending the chelator to the polymer backbone through a single amide bond resulted in a nonrigid structure and consequently a relatively low R_1 relaxivity of 6.6. Because the polymerization of **21** with PEG-bis-NHS esters was not a very efficient process, a high molecular mass PEG monomer



Scheme 3

(**18**, molecular mass = 3.4 kDa) was needed to form a polymer with the requisite MW for blood pool retention resulting in a low metal content for the polymer (2.5%). As anticipated, the 7 day bone retention for **24a** (0.76% ID) was significantly lower than for the two DTPA based polymers (**1a** and **10a**). While it is recognized that **24a** is structurally dissimilar to **1a** and **10a**, its significant blood half-life in rats qualifies it as a blood pool agent and therefore the reduced bone retention is meaningful.

An additional example of a polymeric Gd-DOTA (**34**) was prepared (Scheme 5) by grafting DOTAs onto the surface of a dendrimer. While various linkers and chemistries have been employed (Lewis et al., 1994; Li et al., 1994; McCall et al., 1990; Kline et al., 1991; Brasch et al., 1994; Kubomura et al., 1993; Schmitt-Willich et al., 1992) to graft DOTA macrocycles onto a variety of macromolecules, we chose to use the novel intermediate **31**. DOTA-tris(*tert*-butyl ester) activated ester (**31**) was designed to couple DOTA to the dendrimer via conversion of one of the four DOTA carboxylates to an amide of aminocaproic acid, thus placing the chelators at a reasonable distance from the surface of the dendrimer. Intermediate **28** was prepared from amino-ester **27** (Goodacre et al., 1977), which was prepared (Callahan et al., 1988) from **25** (Sigma). When activated ester **31** was reacted with a third generation PAMAM dendrimer, approximately 20 of the 24 surface amino groups on the dendrimer were derivatized to form the DOTA grafted dendrimer **32**. Deprotection of **32** with TFA followed by metalation with gadolinium chloride produced the chelated polymer **34**. Like **24a**, **34** was found to have less 7 day bone retention (0.62% ID) than the DTPA-based polymers **1a** and **10a**. While the blood half-life of globular polymer **34** was determined to be longer than Magnevist, it was considerably shorter than the linear DOTA polymer **24a** which likely is a reflection of the influence of shape on polymer retention.



Scheme 4

CONCLUSION

We have shown that polymeric gadolinium chelates with extended blood pool retention can be obtained by selecting polymers of the appropriate MW. For example, with linear copolymers of DTPA and PEG-diamines (**1**), it was found that polymers of 20 kDa and higher are blood pool agents as are linear copolymers of DTPA and alkyldiamines (**10**) of 14 kDa and higher. For polymer **10a** (NC 22181), linear relationships were found for both overall blood clearance half-lives and volumes of distribution vs MW within the range of MWs studied (Figure 3). In addition, with copolymers **10** a significant decrease in dose was realized as a consequence of these polymer's increased metal contents and higher relaxivities. It has also been shown that additional features which are important to achieve a pharmaceutically acceptable contrast agent can be controlled by the design of the polymer. Changing the shape of the polymer from linear as are

Scheme 5

series **1** and **10** to the more globular series **16** resulted in decreased viscosity as well as increased relaxivity. Potential in vivo metal dissociation was addressed by designing a polymer series (**24**) which employs the DOTA chelator which is known to form gadolinium chelates that are both kinetically and thermodynamically more stable than DTPA gadolinium chelates. Finally, we designed a polymer (**34**) that conceptually incorporates most of the above desirable features. The DOTA-dendrimer construct is globular with tight binding gadolinium chelators capable of incorporating a high percentage of metal. In summary, we have demonstrated that the principal characteristics of polymeric gadolinium chelates including blood retention, metal content, viscosity, chelate stability, and relaxivity can be manipulated by the choice of features incorporated into the polymer.

To the best of our knowledge, this report is the first study that addresses the rational design of polymeric MR blood pool contrast agents. The purpose of this study was not to evaluate every parameter for each class of polymer, but to emphasize the relative importance of each parameter. We hope that this paper serves as the basis for further work to develop agents to satisfy an important unmet medical need.
