Ternary Conjugates of Guanosine Monophosphate as Initiator Nucleotides for the Enzymatic Synthesis of 5′-Modified RNAs

Burckhard Seelig and Andres Jäschke*

Institut für Biochemie, Freie Universität Berlin, Thielallee 63, D-14195 Berlin. Received July 23, 1998; Revised Manuscript Received October 26, 1998

We give a detailed account on the enzymatic synthesis of RNA conjugates by T7 RNA polymerase using modified initiator nucleotides during transcription. Following two different routes, ternary conjugates of guanosine-5′-monophosphate, poly(ethylene glycol), and anthracene were synthesized via phosphoramidite intermediates and characterized by a variety of spectroscopic techniques. Up to a degree of polymerization n_{PEG} of about 17, these conjugates were efficiently incorporated into RNA by T7 RNA polymerase at the 5′-termini, thereby giving access to RNA conjugates required for biochemical studies as well as for the exploration of the catalytic potential of ribonucleic acids. The resulting conjugates are intact and functional.

INTRODUCTION

Oligonucleotide conjugates have found many uses in biochemical research and medical diagnostics, and a large number of conjugate groups have been used (Agrawal, 1994; Beaucage and Iyer, 1993; Goodchild, 1990). The most common strategies for site-specific conjugation of oligonucleotides are (i) transformation of the conjugate group into a phosphoramidite and direct incorporation during automated solid-phase synthesis of oligonucleotides and (ii) incorporation of a reactive linker during oligonucleotide synthesis and postsynthetic attachment of the conjugate group to this linker.

While these conjugation strategies work well with short oligonucleotides accessible by chemical synthesis, the possibilities to conjugate enzymatically synthesized long nucleic acid sequences are very limited [e.g., Oh and Pace (1994) and Tong et al. (1993)]. This is especially problematic with ribonucleic acids, where chemical synthesis is normally limited to a chain lengths of about 50 nucleotides. Most RNAs of biological interest are much longer, and for biochemical studies they are either isolated from biological sources or prepared by enzymatic transcription from DNA templates using viral RNA polymerases (Milligan et al., 1987). To study RNA processing, translocation, or ribozyme reaction mechanisms, it is highly desirable to have simple and reliable methods available that allow the site-specific incorporation of conjugate groups (Bevilacqua et al., 1994; Igloi, 1996; Moore and Sharp, 1992).

Recently, ternary RNA conjugates have successfully been used for the in vitro selection of new catalytic RNA species (Tarasow et al., 1997; Wiegand et al., 1997; Seelig and Jäschke, 1999). A key feature of these strategies is the use of synthetic RNA conjugate libraries in which a small organic residue as a potential reactant is attached to each individual sequence of a combinatorial RNA pool via a flexible polymeric tether. These RNA conjugates are then incubated with a second reactant carrying a biotin tag. If an RNA molecule catalyzes the reaction of the attached reactant with the biotinylated free reactant, the reaction product would also carry the biotin tag and could be isolated by affinity chromatography. The RNA part of the isolated conjugate is then enzymatically amplified. The cycle of conjugation, reaction, selection, and amplification is repeated until the active species are sufficiently enriched from the ancestral RNA pool. This approach was successfully applied to the selection of RNA Diels–Alderases and RNA amide synthases (Tarasow et al., 1997; Wiegand et al., 1997; Seelig and Jäschke, 1999).

Toward the same end, we have described the synthesis of multifunctional RNA conjugates in which a small organic molecule is site-specifically attached to the 3′-terminal hydroxyl group of the RNA via a long flexible poly(ethylene glycol) tether harboring a photocleavage site (Hausch and Jäschke, 1997). In that case, we made use of an enzymatic two-step procedure involving preparation of the unmodified RNA molecule by enzymatic transcription and subsequent addition of a conjugated dinucleotide by T4 RNA ligase.

In a recent short communication, we have described an enzymatic one-step procedure which permits an easy access to RNA 5′-conjugates (Seelig and Jäschke, 1997). This procedure is based on the known tolerance of T7 RNA polymerase toward certain chemical modifications in the initiation step (Pitulle et al., 1992). The conjugate group is added at the 5′-end during transcription by T7 RNA polymerase, which utilizes ternary conjugates of guanosine monophosphate, poly(ethylene glycol), and anthracene (as a potential organic reactant) exclusively during the initiation, but not during the elongation steps. While a number of reports have been published on the use of different initiator nucleotides, a systematic investigation of this method has not been carried out so far. Here, we give a detailed account on the chemical synthesis of ternary initiator nucleotides with varying lengths of the poly(ethylene glycol) linker, an investiga-

tion of their enzymatic incorporation, and a detailed characterization of the enzymatically synthesized conjugates.

MATERIALS AND METHODS

General. Poly(ethylene glycol) was purchased from Fluka; all other chemicals, buffers, solvents and reagents were obtained as the highest commercial grade available and used without further purification. Reactions were carried out at room temperature unless stated otherwise. Silica gel (0.063−0.200 mm) for column chromatography was obtained from J. T. Baker. HPLC purification was performed on a Beckman System Gold chromatograph using an Ultrasphere ODS reversed-phase column (4.6 × 250 mm, flow 1 mL/min). NMR spectra were recorded using a Bruker A250 (^{13}C) and a Bruker AMX500 (^{1}H, ^{31}P). ESI mass spectra were recorded on a Finnigan MAT 7M spectrometer, and MALDI TOF mass spectra were obtained using a Bruker Reflex spectrometer. UV spectra were recorded with a Shimadzu UV-160A.

Mono-[9-(methyl)anthracene]-PEG 600 Conjugate and Mono-[9-(methyl)anthracene]-PEG 1500 Conjugate 1. PEG 600 (3.6 g, 6 mmol) or PEG 1500 (9 g, 6 mmol) was dried in vacuo (P_4O_{10}) and dissolved in dry benzene (30 mL). *n*-Butyllithium (2.5 mL, 6.2 mmol, 2.5 M solution in hexane) was added dropwise under vigorous stirring. After further stirring for 2 h, benzene was removed by rotary evaporation, and the product was redissolved in dry *N*,*N*-dimethylformamide (45 mL). 9-(Chloromethyl)anthracene (1.36 g, 6 mmol) was added, and the mixture was stirred for 2 h at room temperature. The solvent was removed under reduced pressure, and the resulting oil subjected to silica gel chromatography (CH_2Cl_2/MeOH 96:4 v/v for PEG 600 conjugate and CH_2Cl_2/MeOH 9:1 v/v for PEG 1500 conjugate). Concentration in vacuo afforded mono-[9-(methyl)anthracene]-PEG 600 **1** with a yield of 39% [mono-[9-(methyl)anthracene]-PEG 1500 with a yield of 48%], referred to PEG. ^{1}H NMR (250 MHz, [D$_1$]CHCl$_3$, 25 °C): δ = 3.5−3.8 (m, 56 H; CH_2−O for n = 14), 5.6 (s, 2H; CH_2−Ar), 7.48 (m, 4H; H-2/H-3/H-6/H-7), 8.0 (d, 2H; H-1/H-8), 8.4 (d, 2H; H-4/H-5), 8.42-(s, 1H; H-10). ^{13}C NMR (63 MHz, [D$_1$]CHCl$_3$, 25 °C): δ = 131.2, 130.8, 128.8, 128.6, 128.1, 125.9, 124.7, 124.3. ESI$^+$-MS: calculated for $C_{43}H_{68}O_{15}$ (n = 14) [MH$^+$] = 825.0, found 825.

Mono-[9-(methyl)anthracene]-PEG 600-(2-cyanoethyl-*N*,*N*-diisopropyl)-phosphoramidite 2. Mono-[9-(methyl)anthracene]-PEG 600 **1** (260 mg, 325 μmol) was coevaporated twice from CH_2Cl_2/pyridine (9:1 v/v) and dried in vacuo overnight (P_4O_{10}). *N*,*N*-Diisopropylethylamine (585 μL, 3.25 mmol) and dichloromethane (1 mL, refluxed with CaH_2 and distilled in the dark immediately before use) were added under argon. (2-Cyanoethyl-*N*,*N*-diisopropyl)chlorophosphoramidite (73 μL, 325 μmol) was added dropwise, and the mixture was stirred for 30 min in the dark. A total of 50 μL of anhydrous methanol was added, and the reaction mixture was diluted with CH_2Cl_2 to 30 mL. After extraction with saturated $NaHCO_3$ solution and with water, the organic phase was dried over Na_2SO_4 and solvent was removed under reduced pressure to yield 190 mg (58%) of phosphoramidite **2**, which was used for coupling without further purification.

^{31}P NMR (202 MHz, [D$_1$]CHCl$_3$, 20 °C): δ = 146.05 ppm.

2′-O,3′-O,*N*^{2}-Triisobutyrylguanosine 3. N^2-Isobutyryl-5′-*O*-(4,4′-dimethoxytrityl)guanosine (3.28 g, 5 mmol) was added to a solution of isobutyric anhydride (8.33 mL, 50 mmol) in pyridine (50 mL) and stirred for 20 h. Pyridine was distilled off, and the residue was dissolved in water (50 mL) and extracted with dichloromethane (200 mL). After extraction with saturated $NaHCO_3$ solution, saturated NaCl solution and water, the organic phase was dried over Na_2SO_4 and solvent was removed under reduced pressure. The residue was subjected to silica gel chromatography (CH_2Cl_2/MeOH/triethylamine 96:4:0.25 v/v). The pooled fractions were evaporated to dryness and detritylated with trichloroacetic acid (3%) in dichloromethane for 2 min. The solution was extracted with saturated $NaHCO_3$ solution, saturated NaCl solution, and water. After evaporation, the final purification by silica gel chromatography (CH_2Cl_2/MeOH 98:2 v/v) gave 775 mg (31%) of 2′-O,3′-O,N^2-triisobutyrylguanosine **3**. ^{1}H NMR (500 MHz, [D$_1$]CHCl$_3$, 20 °C): δ 1.0−1.23 (m, 18 H; 6 × CH_3-Ibu), 2.4, 2.6 (2 × septet, 2 × 1H; CH-2′,3′-Ibu), 2.78 (septet, 1H; CH-N^2-Ibu), 3.74 (dd, 1H; H-5′), 3.92 (dd, 1H; H-5′), 4.2 (q, 1H; H-4′), 5.63 (dd, 1H; H-3′), 5.86 (d, 1H; H-1′), 5.91 (t, 1H; H-2′), 7.8 (s, 1H; H-8). ^{13}C NMR (63 MHz, [D$_1$]CHCl$_3$, 25 °C): δ = 18.5-18.8 (9 × CH_3), 33.5, 33.7 (CH-2′,3′-Ibu), 36.1 (CH-N^2-Ibu), 61.7 (C-5′),71.1 (C-4′), 72.3 (C-2′), 84.4 (C-1′), 87.4 (C-3′), 122.1 (C-5), 138.9 (C-8), 147.6 (C-4), 148 (C-6), 155.3 (C-2), 175.3 (C=O, 2′-Ibu), 175.8 (C=O, 3′-Ibu), 179.4 (C=O, N^2-Ibu). ESI$^+$-MS calculated for $C_{22}H_{31}O_8N_5$ [M$^+$]: 493. Found: 493.

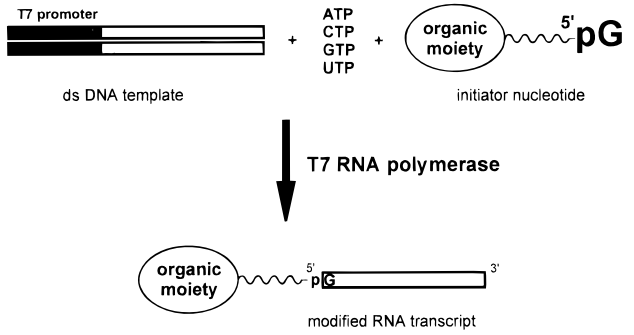
2′-O,3′-O,*N*^{2}-Triisobutyrylguanosine-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite 4. 2′-O, 3′-O, N^2-Triisobutyrylguanosine **3** (493 mg, 1 mmol) was dried in vacuo overnight (P_4O_{10}) and dissolved in dichloromethane (4 mL, refluxed with CaH_2 and distilled in the dark immediately before use) under argon. *N*,*N*-Diisopropylethylamine (1.22 mL, 7 mmol) was added, and (2-cyanoethyl-*N*,*N*-diisopropyl)chlorophosphoramidite (340 μL, 1.5 mmol) was added dropwise and the mixture was stirred for 30 min in the dark. A total of 100 μL of anhydrous methanol was added, and the reaction mixture was diluted with CH_2Cl_2 to 30 mL. After extraction with saturated $NaHCO_3$ solution and with water, the organic phase was dried over Na_2SO_4 and solvent was removed under reduced pressure. The yielded phosphoramidite **4** was used for coupling without further purification. TLC in $CHCl_2$/MeOH/triethylamine (90:10:0.25 v/v) showed the product spot (R_f = 0.68) and the pale spot of the starting material (R_f = 0.48), indicating almost complete conversion.

Initiator Nucleotide 6. Route 1: 2′-O,3′-O,N^2-Triisobutyrylguanosine **3** (30 mg, 60 μmol) and 1.5 equiv of mono-[9-(methyl)anthracene]-PEG 600-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite **2** (90 mg, 90 μmol) was coevaporated twice from pyridine and dried in vacuo overnight (P_4O_{10}). The two components were dissolved in anhydrous acetonitrile (5 mL), and a solution of tetrazole in acetonitrile (510 μL/0.47 M, 240 μmol) was added under argon. The mixture was stirred for 15 min, and iodine (450 μL/0.1 M in tetrahydrofurane/collidine/water 2:2:1 v/v, 45 μmol) was added. After 5 min, the mixture was diluted with an aqueous solution of sodium thiosulfate (5 mL/1 M, 5 mmol), and the product was extracted with dichloromethane (50 mL). The organic phase was extracted with saturated $NaHCO_3$ solution and water and dried over Na_2SO_4. The solvent was removed under reduced pressure, and the residue was subjected to silica gel chromatography (CH_2Cl_2/MeOH 85/15). The fractions **5** with the typical additive anthracene/guanosine UV spectrum were pooled and deprotected with aqueous ammonia (4 mL, 33%) at 55 °C overnight. After evaporation to dryness, product **6** was finally purified and fractionated according to the degree of polymerization of PEG by isocratic HPLC using 38% acetonitrile in 100 mM

triethylammonium acetate (TEAA), pH 7.0. The fractions were lyophilized.

Route 2: Mono-[9-(methyl)anthracene]-PEG 600 **1** (1.2 g, 1.5 mmol) or mono-[9-(methyl)anthracene]-PEG 1500 (2.25 g, 1.5 mmol) and 0.67 equiv of 2′-O,3′-O,N^2-triisobutyrylguanosine-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite **4** (1 mmol) and were coevaporated twice from pyridine and dried in vacuo overnight (P_4O_{10}). The two components were dissolved in anhydrous acetonitrile (10 mL) and a solution of tetrazole in acetonitrile (8.5 mL/0.47 M, 4 mmol) was added under argon. The mixture was stirred for 15 min and iodine (12 mL/0.1 M in tetrahydrofurane/collidine/water 2:2:1 v/v, 1.2 mmol) was added. After 5 min, the mixture was diluted with an aqueous solution of sodium thiosulfate (1 M) until the brown color of iodine disappeared. The product was extracted with dichloromethane (70 mL). The organic phase was extracted with saturated $NaHCO_3$ solution and with water and dried over Na_2SO_4. The solvent was removed under reduced pressure and the product **5** was chromatographically purified, deprotected, and finally HPLC-purified exactly as described for route 1.

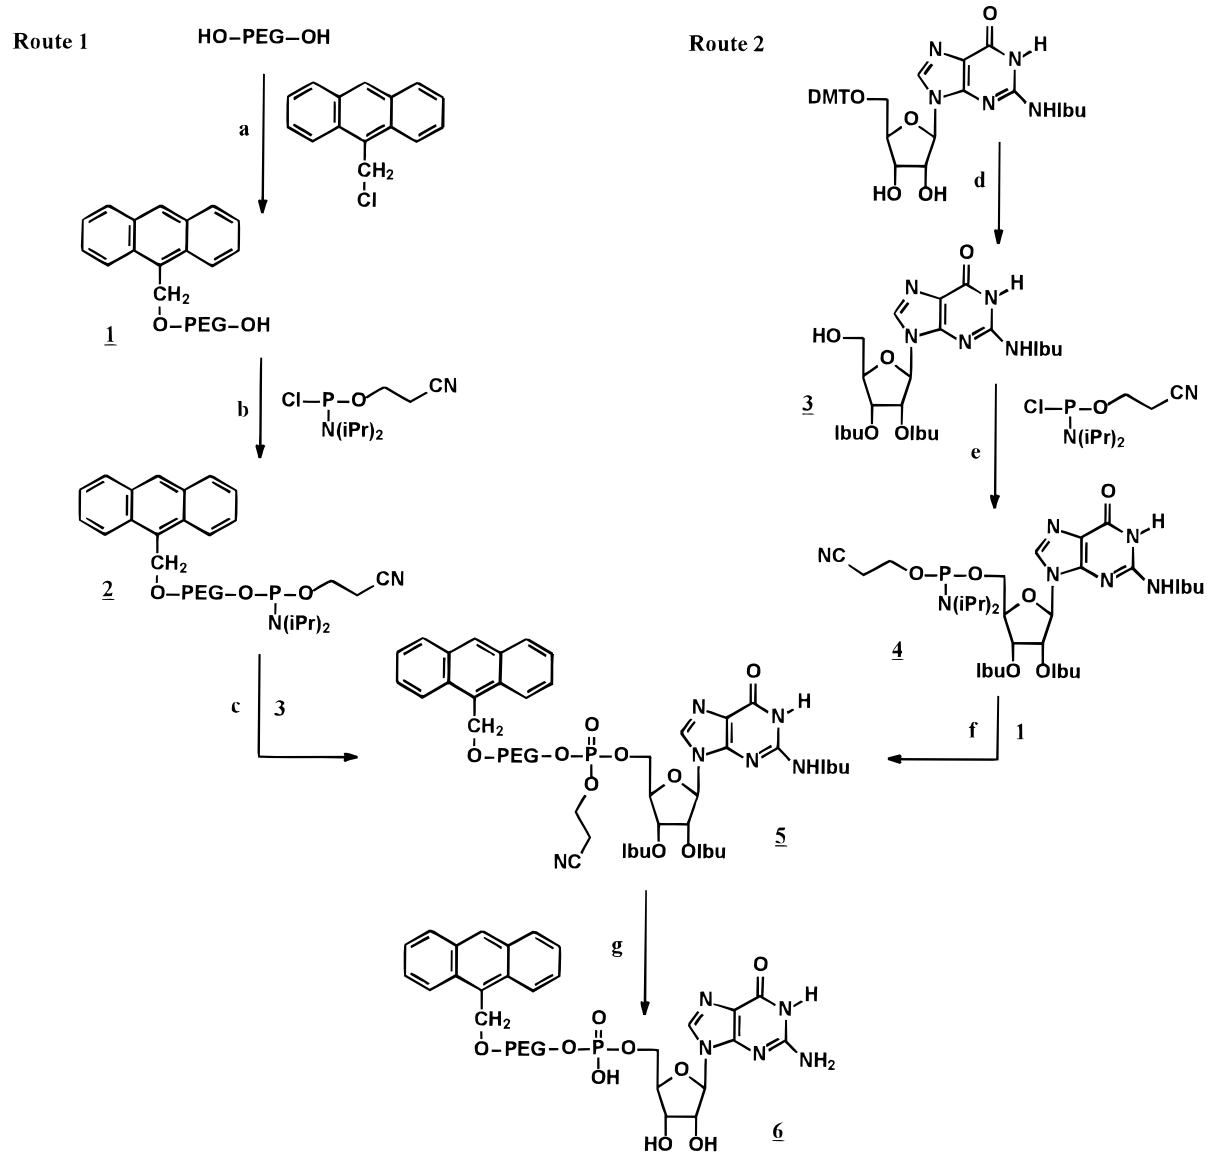
MALDI$^+$-MS calcd for $C_{45}H_{65}O_{18}N_5P$ ($n = 10$) [MH^+]: 994.4. Found: 994. Calcd for $C_{93}H_{159}O_{42}N_5P$ ($n = 34$) [MH^+]: 2050.27. Found: 2049.6. UV (H_2O): λ_{max}= 254.5, 348, 365, 385, 277 nm (shoulder). Fluorescence spectrophotometry (H_2O): emission at $\lambda = 419$ nm upon exitation at $\lambda = 254$ nm (Figure 1).



T7 Transcriptions. T7 transcriptions were performed essentially as described (Milligan et al., 1987). DNA templates for T7 transcription were synthesized by standard phosphoramidite chemistry and purified by reversed-phase HPLC (C18) using a gradient from 8 to 32% acetonitrile in 100 mM triethylammonium acetate, pH 7.0, in 30 min. The DNA template for the 25 nt transcript was a duplex of a 44-mer (3′-AG ATT ATG CTG AGT GAT ATC CTC GAG TCG GAA GTG ACG AGG TGG-5′) and a 38-mer (5′-TC TAA TAC GAC TCA CTA TAG GAG CTC AGC CTT CAC TGC-3′), prepared by heating a mixture of the two DNA strands to 95 °C for 3 min and then cooling to room temperature in 1 h. The DNA templates for the randomized 113 and 159 nt transcripts were prepared essentially as described (Hausch and Jäschke, 1997) with completely randomized regions of 74 and 120 nt, respectively, flanked by constant sequences at the termini.

The transcription reactions were run in 80 mM HEPES (pH 7.5), 1 mM spermidine, 22 mM $MgCl_2$, 10 mM dithiothreitol, 120 μg/mL bovine serum albumin, 4 mM NTPs (except GTP), 3 μM [α-^{32}P]CTP (0.2 μCi/μL from Amersham Buchler), 1 μM dsDNA template, 0.5 units/μL ribonuclease inhibitor (MBI Fermentas), and 1 unit/μL T7 RNA polymerase (Stratagene). The concentrations of GTP and initiator nucleotide **6** were varied as indicated in each experiment. The reaction mixtures were incubated at 37 °C for 3 h. After transcription, the RNA was heated in loading buffer containing 50% formamide at 95 °C for 2 min immediately prior to loading on an analytical 15% (25 nt transcript) or 10% (113/159 nt transcript) denaturing polyacrylamide gel. Products were separated on a 24 cm vertical gel apparatus, and the band was located by autoradiography, cut out, and Cerenkov counted in a Beckman LS 6000 SC liquid scintillation counter to determine yields.

RESULTS AND DISCUSSION



Design, Synthesis, and Characterization of the Initiator Nucleotides. The most common method to synthesize RNA in the laboratory is in vitro transcription. The DNA-dependent RNA polymerase of bacteriophage T7 recognizes and binds to specific double-stranded DNA promotor sequences and starts transcription right behind the promotor by using ribonucleotide-5′-triphosphates according to the sense strand of the DNA duplex. Synthesis stops at the end of the DNA template (runoff transcription). The first incorporated nucleotide is always GTP. The polymerase has been shown to be rather tolerant toward certain modifications at the 5′-position of this first guanosine in the initiation step (Martin and Coleman, 1989). Therefore, the use of 5′-modified guanosines as "initiator nucleotides" has been described for the incorporation of cap-analogues, nucleoside monophosphates, or thiophosphates as well as short oligonucleotides and fluorescence-labeled nucleotides at 5′-terminal positions of RNA transcripts (Burgin and Pace, 1990; Darzynkiewicz et al., 1988; Logsdon et al., 1992; Pitulle et al., 1992). These initiator nucleotides cannot be incorporated during elongation, since they are lacking the essential 5′-triphosphate.

Scheme 1. General Scheme for 5′-Conjugation by Runoff Transcription Using Ternary Initiator Nucleotides

To develop a generally applicable method to attach labels, fluorophores, cross-linkers or reactive groups to long RNA molecules without interfering with the overall RNA structure, we chose to investigate ternary conjugates in which the organic moiety is attached to the 5′-position of guanosine via a polymeric tether (Scheme 1). As the organic moiety, we chose anthracene primarily for use of the resulting conjugates in selection experiments similar to those described by Tarasow et al. (1997), i.e., for the selection of RNA molecules catalyzing Diels−Alder reactions from combinatorial libraries (Seelig and Jäschke, 1999). Additionally, anthracene turned out to be a convenient molecule to study because (i) it is a highly sensitive fluorophore and can thus be easily detected, (ii) attachment of anthracene to an RNA molecule causes significant shifts in reversed-phase HPLC, and (iii) the specific reactivity of anthracene provides an additional means to study the properties of the conjugates. We used poly(ethylene glycol) as a tether because it is highly flexible, water soluble, and its chemical properties are known to be compatible with RNA chemistry (Jäschke, 1997; Jäschke et al., 1996). To select catalysts from libraries without prior structural knowledge, the use of polydisperse PEG was thought to be beneficial because a range of different tether lengths would allow the system to find the optimum tether length itself. We designed initiator nucleotide **6**, consisting of guanosine monophosphate, esterified with the terminal PEG hydroxyl group, while the other end of the PEG chain was connected to the anthracene ring system via an ether linkage (Scheme 2).

Scheme 2. Synthesis of Initiator Nucleotides[a]

[a] (a) benzene, *n*-butyllithium; DMF; (b) CH_2Cl_2, *N*,*N*-diisopropylethylamine; (c) acetonitrile, tetrazole; iodine; (d) pyridine, isobutyric acid; CH_2Cl_2, trichloroacetic acid (e) CH_2Cl_2, *N*,*N*-diisopropylethylamine; (f) acetonitrile, tetrazole; iodine; (g) 33% aqueous ammonia.

Initiator nucleotides **6** were synthesized by two different ways (Scheme 2). In the first route, PEG 600 was converted into the alcoholate and reacted with 9-chloromethylanthracene. The resulting mixture was chromatographically fractionated, and monoanthracene-PEG **1** was reacted with (2-cyanoethyl-*N*,*N*-diisopropyl)chlorophosphoramidite to give phosphoramidite **2**. 2′-O,3′-O,N^2-Triisobutyrylguanosine **3** was prepared from 5′-*O*-dimethoxytrityl-N^2-isobutyrylguanosine and reacted with **2** in the presence of tetrazole. After coupling, the reaction mixture was oxidized and purified by column chromatography on silica gel. **5** was deprotected using aqueous ammonia giving initiator nucleotide **6**, which was fractionated by reversed-phase HPLC according to the number of ethylene glycol units into 12 product peaks.

Alternatively, 2′-O,3′-O,N^2-triisobutyrylguanosine **3** was reacted with (2-cyanoethyl-*N*,*N*-diisopropyl)chlorophosphoramidite to give a protected guanosine-5′-phosphoramidite **4** which allowed an easier chromatographic purification, compared to polydisperse **2**. After reaction with **1** and tetrazole, oxidation, deprotection, and purification, **6** was obtained. Total yields were generally higher with route 2, which was also used for the synthesis of derivatives with higher n_{PEG}, starting from PEG 1500.

As observed with oligonucleotide−PEG conjugates (Jäschke et al., 1993, 1994, 1996), the degree of polymerization (number of CH_2CH_2O units) of the coupled PEG influences the molecular properties of the conjugates. For initiator nucleotides **6**, single degrees of polymerization were eluted sequentially in reversed-phase HPLC, giving a characteristic elution pattern. Figure 1a shows the chromatogram of initiator nucleotides derived from PEG 1500. For PEG 600, similar chromatograms were observed at lower acetonitrile concentrations (Seelig and Jäschke, 1997). The UV spectra of the conjugates show the typical features of both anthracene (absorbance maximum at 254.5 nm, "fingers" at 348, 365, and 385 nm) and guanosine (shoulder at 277 nm, see Figure 1b), and no influence of n_{PEG} on the spectroscopic properties was observed. Upon UV excitation at 254 nm, the initiator nucleotides show a typical blue anthracene fluorescence with an emission maximum at 419 nm (Figure 1c). The correct composition was corroborated by MALDI mass spectrometry (Figure 1d), and the mea-

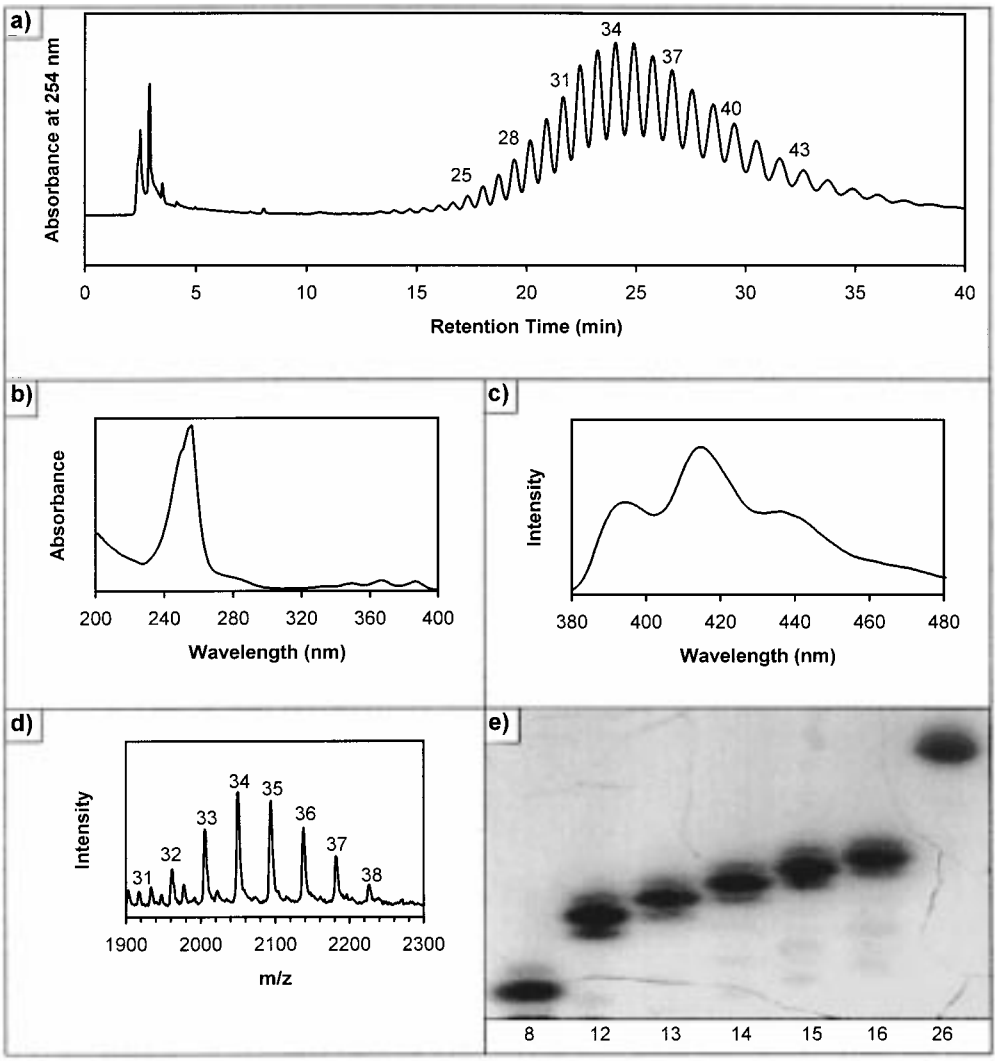


Figure 1. (a) Reversed-phase HPLC of initiator nucleotides **6** (PEG 1500). Eluent: 38% acetonitrile in 100 mM triethylammonium acetate, pH 7.0. The figures at the peaks indicate the respective degree of polymerization. (b) UV spectrum of the peak eluted at 13.2 min. (c) Fluorescence spectrum measured on excitation at 254 nm at a concentration of 1 μM. (d) MALDI mass spectrum of polydisperse **6** (PEG 1500). (e) Electrophoretic analysis of **6** with varying n_{PEG}. Two A_{260} units each of HPLC-purified **6** (n_{PEG} = 8−35) were loaded in 50% formamide and ran on a 15% denaturing polyacrylamide gel. Bands were visualized by epiillumination at 254 nm and photographed.

sured *m*/*z* values were in good agreement with the calculations (typically ±0.5 Da). The molecular masses of neighboring peaks differ by 44 Da, i.e., by the size of one CH_2CH_2O unit. Electrophoretic mobility decreases with increasing size of the PEG chain (Figure 1e). Generally, the electrophoretic mobility is rather low, due to the low charge-to-mass ratio. On a 15% denaturing polyacrylamide gel, **6** with n_{PEG} = 8 has about the mobility of an 32-mer oligonucleotide.

Enzymatic Synthesis and Characterization of Ternary RNA Conjugates. To investigate whether T7 RNA polymerase incorporates the synthesized initiator nucleotides, HPLC-purified monodisperse **6** with n_{PEG} = 10 was added to standard transcription reactions from a short synthetic DNA template, while the concentration of GTP was reduced accordingly (Figure 2). Since T7 RNA polymerase always generates a mixture of correct transcripts and molecules with an additional nucleotide appended to the 3′-end, RNA transcripts of 25 (*n*-mer, band 5) and 26 nucleotides (*n*+1-mer, band 4), respectively, were generated. With increasing concentration of **6,** two new bands with lower electrophoretic mobility (1 and 2) appeared in the autoradiogram (Figure 2a). Upon excitation with 254 nm UV light, these bands showed the typical blue anthracene fluorescence. (Figure 2b). The third fluorescent band found on the photograph (band 3) does not contain RNA and is a decomposition product arising from **6** during incubation. Transcription reactions using polydisperse initiator nucleotides give complex mixtures of varying electrophoretic mobility with the longer oligomers moving slower than the shorter ones. The percentage of RNA molecules being coupled to anthracene is a function of the ratio of **6** to GTP, while the overall transcription yield drops with decreasing GTP concentration (Figure 2c). Bands were excised from the gel, eluted, and analyzed by MALDI mass spectrometry. The *n*-mer conjugate band 2 was found to have a molecular weight of 8623.3 (calculated 8623.7 for $[MH^+]$), indicating that no other modifications had taken place. A typical mass spectrum for a mixture of *n*+1-mers is shown in Figure 2d (n_{PEG} = 15), and three signals were found at *m*/*z* =9104.6, 9126.9, and 9145.3, while the calculated values with the arbitrarily appended "*n*+1"-nucleotide were 9106 (for N=C), 9107 (U), 9130 (A), and 9146 (G).

To investigate whether T7 RNA polymerase could also be used to fuse even larger molecules to RNA, we then systematically studied the dependence of the enzymatic

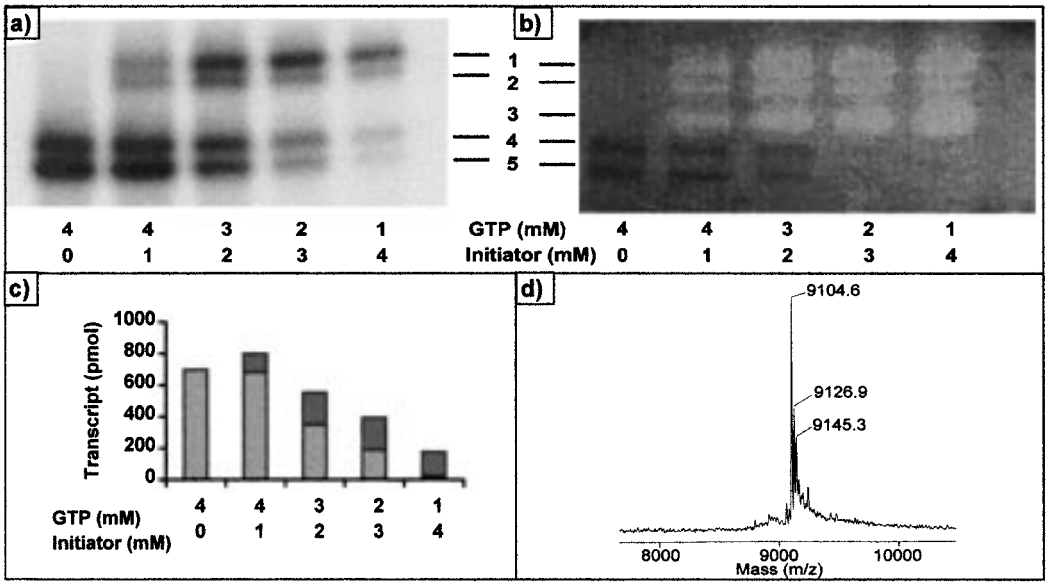

Figure 2. T7 transcriptions using initiator nucleotides **6** (n_{PEG} = 10). (a) Transcription by T7 RNA polymerase of a short DNA oligonucleotide duplex (see Materials and Methods). Autoradiogram of a 15% denaturing polyacrylamide gel. Nucleotide sequence of transcripts (bands 1,2,4,5), 5′(anthracene-PEG-)G GAG CUC AGC CUU CAC UGC UCC ACC (N)3′ (N = A, C, G or U); band 5, unmodified *n*-mer transcript; band 4, *n*+1-mer; band 2, anthracene-PEG-conjugate, *n*-mer; band 1, anthracene-PEG-conjugate; *n*+1-mer. (b) Fluorescence photograph of the same gel upon epiillumination at 254 nm. (c) Dependence of transcription yields on the composition of the transcription mixture. Light gray, unmodified RNA; dark filling, RNA conjugates. (d) MALDI mass spectrum of *n*+1-mer conjugates (equivalent to band 1 in Figure 2a) with n_{PEG} = 15. Bands were excised from the gel and eluted.

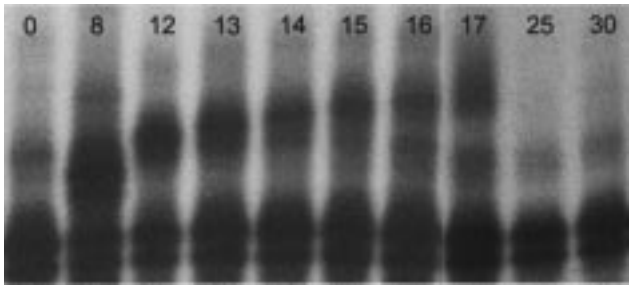

Figure 3. Electrophoretic analysis of transcripts prepared using **6** with varying n_{PEG}. Templates and conditions were identical to Figure 2. c_{GTP} was 4 mM, and $c_{Initiator}$ was 1 mM. HPLC-purified initiator nucleotide fractions were used. Bands were visualized by autoradiography.

incorporation on the length of the PEG tether. Transcription mixtures were prepared from individual HPLC fractions of initiator nucleotides derived from PEG 600 and PEG 1500, respectively. These fractions contained each at least 80% of one single degree of polymerization. To ensure sufficient yield of total transcript, GTP was kept at 4 mM, while initiators **6** were used at 1 mM. Figure 3 shows the autoradiograms of 15% denaturing polyacrylamide gels with n_{PEG} varying from 8 to 30. Up to n = 13, the initiators **6** are efficiently incorporated giving transcripts with the electrophoretic mobility decreasing with increasing n_{PEG}. From n = 14, a decline in the yield of conjugate occurs, while no significant effect on the yield of unmodified transcript is observed. From n = 25, no incorporation at all can be detected. These results demonstrate that initiator nucleotides **6** of this type can be used to introduce a poly(ethylene glycol) spacer of up to 50 atoms, while longer spacers are not incorporated.

Longer RNA transcripts up to 159 base pairs containing regions of randomized sequence for in vitro selection experiments were efficiently transcribed and conjugated

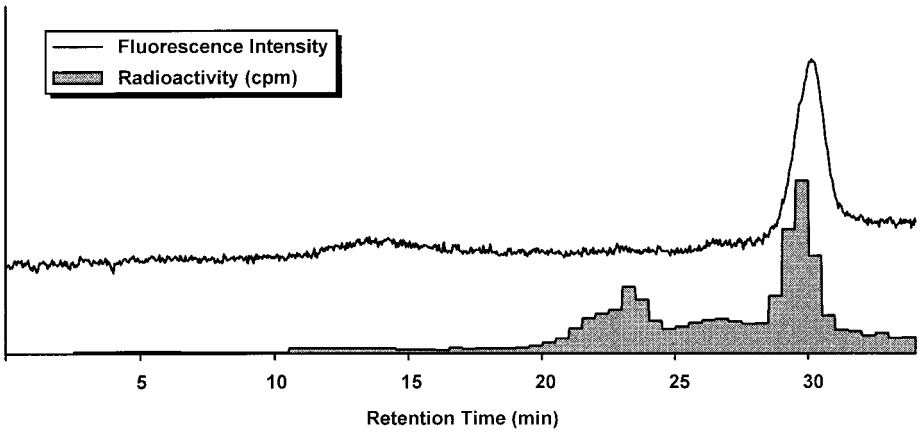

Figure 4. Reversed-phase HPLC analysis of a transcription reaction from a randomized ds DNA pool in the presence of polydisperse **6**. Nominal length of transcripts: 159 nucleotides. Separation was carried out on a C_4 column using a linear gradient of 1 to 32% acetonitrile in 40 min at a flow rate of 1 mL/min. Fluorescence detection was carried out with a Shimadzu RF 535 HPLC fluorescence detector using an excitation wavelength of 254 nm and an emission wavelength of 419 nm. Fractions of 500 μL were collected and analyzed by Cerenkov counting.

in the presence of initiator nucleotides **6** and using appropriate double-stranded DNA template molecules. A ratio of 3 mM GTP/2 mM **6** gave an average of 57% of the transcripts conjugated at their 5′-ends with only marginally lower total yield, compared with transcription in the absence of **6**. Quantitative separation, however, was not achieved under standard electrophoresis conditions due to the fact that the mass difference caused by coupling of anthracene−PEG is smaller than the mass dispersion caused by randomization of large parts of the molecules. Reversed-phase HPLC of transcript mixtures using a C4 column with fluorescence detection and Cerenkov counting of collected fractions turned out to be suitable for purification and quantification of incorporation (Figure 4). As expected, anthracene caused a significantly increased retention, and two peaks were detected containing radioactivity, with only the second showing anthracene fluorescence.

RNA-linker−anthracene conjugate libraries prepared by this method have successfully been used in selection experiments toward RNA Diels−Alderases. In short, these experiments involve incubation of the conjugate library with biotin maleimide, and biotinylated RNA species are isolated by affinity chromatography on immobilized streptavidin. These RNAs are then efficiently reverse transcribed and PCR amplified, demonstrating that conjugation does not interfere with recognition of RNA by polymerases. Repetitive rounds of conjugation, selection, and amplification were carried out, leading to the enrichment of highly active Diels−Alder catalysts (Seelig and Jäschke, 1999).

CONCLUSION

Methods for the site-specific incorporation of nonnucleotide moieties into RNA are valuable tools in RNA biochemistry and for the expansion of RNA catalysis beyond self-modification. The approach described here for coupling of anthracene−PEG derivatives allows the incorporation of a single conjugate group at the 5′-position of a transcript with high efficiency in a single step. The guanosine part of the initiator nucleotides represents the minimum substrate for T7 RNA polymerase (Martin and Coleman, 1989), and up to about $n_{PEG} = 13$, the poly(ethylene glycol) linker does not interfere with the transcription reaction. Combined with data from other publications (Martin and Coleman, 1989; Pitulle et al., 1992), the results indicate that a poly(ethylene glycol) linker attached to the 5′-phosphate of GMP could be used to incorporate various other molecules into RNA, too. The chemical synthesis of the described initiator nucleotides **6** is straightforward and can be easily carried out on a multigramm scale, thereby allowing the production of quantities sufficient for numerous preparative transcription reactions.

Using polydisperse poly(ethylene glycols), libraries of initiator nucleotides were synthesized differing only in the number of ethylene glycol units, thereby spanning a distance from about 20 to 60 Å from the 5′-end of the RNA to the attached moiety. This could be useful for finding the optimum length of the linker for applications were distances are critical (Cload et al., 1993) or as a mobility modifier for coding purposes (Baron et al., 1996; Grossman et al., 1994).

Finally, terminal coupling of PEG has been reported to increase the resistance of oligonucleotides to degradation in biological media and also to alter the pharmacokinetic properties, so enzymatic PEGylation strategies might provide an elegant alternative to the chemical methods described (Jäschke et al., 1994; Kawaguchi et al., 1995; Manoharan et al., 1995).

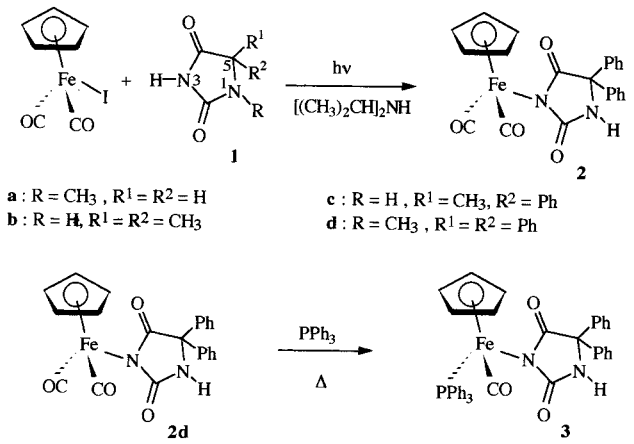
Received July 29, 1998; Revised Manuscript Received December 3, 1998

As part of our ongoing development of the CMIA nonisotopic immunoassay method, in which the tracers are metal carbonyl complexes and detection is by Fourier transform infrared spectroscopy, we examined the potential use as tracers of the complexes $CpFe(CO)_2$(5,5-diphenylhydantoin) **2d** and CpFe(CO)(PPh_3)(5,5-diphenylhydantoin) **3**. The present study involved the synthesis of a series of hydantoin complexes (**2a**−**2d**), in particular that of the derivative of 5,5-diphenylhydantoin **2d**. The structure of **2d** was confirmed by X-ray crystallography. The infrared analysis, establishing the position and intensity of the characteristic metal−carbonyl peaks of complexes **2d** and **3** in the 1850−2200 cm^{-1} region, shows that measurement of the absorbance values of these characteristic peaks will permit quantitative analysis in the picomole range, the norm for routine use in immunoassay and thus suitable for use as CMIA tracers. Cross-reaction rates of these tracers with anti-DPH specific antibodies show that **2d** and **3** are both recognized by anti-DPH antibodies (cross-reaction rates 43 and 20%, respectively). In developing a CMIA of DPH with these tracers, it was found that **3**, with a single, intense band at 1977 cm^{-1}, had very promising IR characteristics for use in multiassay CMIA, but probably owing to its relatively weak affinity for the antibodies, it was not possible to develop a CMIA for DPH using this tracer. Complex **2d**, however, showed better recognition by the antibodies, and using this complex as a tracer, it was possible to develop a particularly sensitive monoassay of DPH by the CMIA method.

INTRODUCTION



We recently developed a new type of nonisotopic immunoassay termed carbonyl metallo immuno assay (CMIA)[1], using metal carbonyl complexes as tracers and Fourier transform infrared spectroscopy (FT-IR) as the detection method. The feasibility of the method was first shown in the case of the monoimmunoassay of three antiepileptic drugs, phenobarbital (*1*), diphenylhydantoin (DPH) (*2*), carbamazepine (*3*) and of a circulating hormone, cortisol (*4*). These experiments allowed us to establish the strengths of this new assay method, which include the absence of nonspecific signals (due to the entirely exogenous nature of the metal carbonyl tracers), and the fact that a metal carbonyl tracer can be synthesized for any given hapten. Clearly the greatest strength of the CMIA method, however, is the potential it affords to perform multiimmunoassays of two (*5*) or three (*6*) analytes simultaneously. Although the development of nonisotopic immunoassays has received considerable attention over the past few years, there have been few breakthroughs in the area of the simultaneous multiassay, owing to the difficulty of finding tracers that give simultaneously analyzable signals. Such analyses would however meet a number of clearly defined needs (thyroid checks, allergen studies, testing of patients on multiple medications, emergency toxicology), and some authors have suggested that this is one of the major challenges in the area of immunoassay development today (*7*, *8*). It is interesting to note, for example, that the radioactive tracers that led to the first immunoassays and the enzymatic tracers that are in most frequent use today cannot be used for more than a double immunoassay. The only promising routes at present appear to be those offered by fluorescent lanthanides (*9*) and metal carbonyl tracers. In simultaneous analysis by CMIA, the starting point is the search for new metal carbonyl complexes possessing $\nu_{(CO)}$ vibration peaks that can be individualized and simultaneously analyzed by infrared in a mixture containing the other tracers that have already been developed. The characteristics of a good tracer are the following: it must be stable in biological media (pH buffer 7.4) and possess intense $\nu_{(CO)}$ vibration peaks in the 1850−2200 cm^{-1} region, thus permitting quantitative analysis in the picomole range. We have previously tested the following complexes: (η^6-C_6H_5-R)$Cr(CO)_3$, (R-C≡C-R′)$Co_2(CO)_6$, (η^5-C_5H_4-R)$Mn(CO)_3$. To extend the range of available tracers, we felt it would be of interest to examine the potential for use in CMIA of $CpFe(CO)_2$ and

$CpFe(CO)(PPh_3)$ moieties, which permit the formation of novel complexes of DPH in which the drug is directly bonded to the metal atom. The full development of the CMIA of DPH, a drug widely used in the treatment of epilepsy, using **2d** and **3** as tracers, will permit a clearer assessment of the individual potential of these complexes for the purpose.

RESULTS AND DISCUSSION

(I) Synthesis of the Tracers. Synthesis of $CpFe(CO)_2^-$ Complexes of Hydantoin Anions. We recently studied the photochemical substitution reaction of the iodide ligand in cyclopentadienyl iron dicarbonyl iodide [$CpFe(CO)_2I$] by an anion derived from an acidic NH group. Our study included pyrroles, indoles, imides, and uracils (*10*), and we attempted to extend this study to the hydantoins, in particular 5,5-diphenylhydantoin (DPH), with the aim of using the resulting complex as a tracer in the CMIA of DPH.

We have found that illumination with visible light of $CpFe(CO)_2I$ in the presence of hydantoins **1a**, **1b**, and **1d** in benzene leads to the formation in high yield of a single, yellow product **2a**, **2b**, and **2d**, respectively (Scheme 1).

The structures of these products were confirmed by elemental analyses and by IR and NMR data. The IR spectra of the hydantoin starting material in chloroform solutions display two bands in the region of carbonyl stretching vibrations: a weak band at ~1750−1770 cm^{-1} and a strong band at ~1720−1730 cm^{-1}. In the spectra of their $CpFe(CO)_2$ complexes, **2**, these two bands are shifted toward lower wavenumbers: 1715−1730 (weak) and 1650−1660 (strong). The same phenomenon was observed on going from phthalimide to $CpFe(CO)_2$-(η^1-*N*-phthalimidato) (*10c*). The ^{13}C NMR spectrum of hydantoin **1a** in $CDCl_3$ solution shows two carbonyl resonances at 170.2 and 156.6 ppm. The corresponding $CpFe(CO)_2$ complex **2a** displays two carbonyl resonances of the hydantoin ligand at 182.8 and 168.0 ppm, i.e., shifted downfield 11.4−12.6 ppm. These downfield shifts are very close to those observed on going from phthalimide to $CpFe(CO)_2$(η^1-*N*-phthalimidato), (13.5 ppm) (*10c*), which is in keeping with the coordination of the $CpFe(CO)_2$ moiety to the nitrogen bound to two carbonyls, i.e., to N(3). Conclusive evidence for this type of coordination is provided by the X-ray structure of **2d** (see below).

In the case of hydantoin **1c**, the same treatment gave a mixture of yellow and orange products. We were able to obtain the yellow product in a pure form by column chromatography. Its IR spectrum was very similar to those of **2a**, **2b**, and **2d**, which together with the NMR data, suggested the structure **2c**. Our attempts to isolate the orange product in the pure form by column chromatography met with failure. It was always contaminated with variable amounts of **2c**. The IR spectra of this material showed three distinct bands in the region of 1800−1600 cm^{-1}, namely at 1735, 1660, and 1615 cm^{-1} (all bands with comparable intensity). We have suggested that this material could be the isomeric complex **2c′** having the $CpFe(CO)_2$ moiety bound to deprotonated N(1) contaminated with **2c**, as indicated by the presence of the characteristic IR band at 1660 cm^{-1} and by TLC. It is likely that this product is kinetically labile and undergoes isomerization to **2c** during the separation procedure.

Synthesis of $CpFe(CO)(PPh_3)$(5,5-diphenylhydantoin) 3. **3** was prepared by the standard method (*10b*), by refluxing **2d** in benzene in the presence of triphenylphosphine (Scheme 1).

(II) X-ray Crystal Structure of 2d. The crystal structure of **2d** provides unambiguous evidence that the $CpFe(CO)_2$ moiety binds to deprotonated N(3) of the DPH molecule. A perspective view of **2d** is presented in Figure 1, and this also includes the atomic numbering scheme. Crystal data and structure refinement details are listed in Table 1, final atomic coordinates in Table 2, and selected bond lengths and angles in Table 3.

In the crystals of **2d**, the monomers are held together by two intermolecular (symmetry dependent) hydrogen bonds N(2)−H(2)···O(1) to effectively become dimeric molecules. The N(2)−O(1) distance of 2.84 Å is typical for strong hydrogen bonds. As found in similar structures, the coordination around the iron atom is pseudo-octahedral (three-legged piano-stool geometry). The two CO ligands and N(1) atom occupy three *fac* positions, and the cyclopentadienyl ring acting in a tridentate mode occupies the three remaining positions. In accord with this description, the angles C(31)FeN(1) and C(31)FeC(41) are close to 90° [93.3(2)−94.3(2)°]. The cyclopentadienyl ring is planar [maximum deviation from the best plane being 0.004(9) Å]. All the carbon atoms of this ring have high displacement parameters (>0.1 $Å^2$). The Fe−N(1) distance of 1.949(3) Å is similar to that found in $CpFe(CO)_2$(*N*-phthalimidato), 1.956(3) Å, and substantially shorter than that observed in the analogous florafur [5-fluoro-2(2-tetrahydrofuryl)uracil] complex, 1.991(4) Å.

(III) FT-IR Spectroscopy Study of the Organometallic Complexes 2d and 3. **2d** and **3** constitute potential tracers for an immunoassay of DPH by CMIA. The preliminary step in this assay is FT-IR quantification of the metal carbonyl entities by measurement of the absorbance values of the characteristic $\nu_{(CO)}$ vibration bands that appear in the 1800−2200 cm^{-1} region. These bands offer the dual advantage of possessing intensities 7−10 times higher than all the other bands of the spectrum and of occurring in a region which is normally devoid of other bands. The 1800−2200 cm^{-1} sections of the IR spectra of these complexes are shown in Figure 2. In this region, **2d** shows two narrow and intense peaks at 2010 and 2054 cm^{-1}, and **3** a single peak at 1977 cm^{-1}.

For the CMIA of DPH, we chose to work in the presence of 50 pmol of one of the tracers **2d** and **3**. The quantitative analysis of these tracers was performed using a light-pipe cell with an optical path length of 2 cm for an internal volume of only 30 μL (*12*). We have shown that this cell permits quantitative analysis of organometallic complexes in the picomole or even femtomole range (*13*). In the case of **2d** and **3** the absorbance values of the peaks at 2054 and 2010 cm^{-1} (**2d**) and 1977

cm^{-1} (**3**) are closely proportional to the quantity of tracer, in the range of 0−50 pmol (Table 4) which is an appropriate range for immunoassay. For quantification of **2d** later in this study, the peak at 2054 cm^{-1} (analytical peak) will be used.

With a view to the possible utilization of these complexes as tracers in a simultaneous multiimmunoassay by CMIA, the number, position, and intensities of the $\nu_{(CO)}$ bands of **2d** and **3** were compared with those of the tracers already available. These values are shown in Table 4. It should be noted first that the peaks of **2d** do not overlap at all with those of the chromium carbonyl tracer, which would permit the simultaneous quantification of the two markers $Cr(CO)_3$ and $CpFe(CO)_2$ and consequently a double immunoassay. Also, the ϵ values of the analytical peaks of these moieties are closely comparable (1096−1542), which would allow the same analytical sensitivity for the two tracers. Complex **3** in particular possesses only a single CO ligand and thus only one $\nu_{(CO)}$ vibrational peak at 1977 cm^{-1}, which has no overlap with the characteristic peaks of the tracers

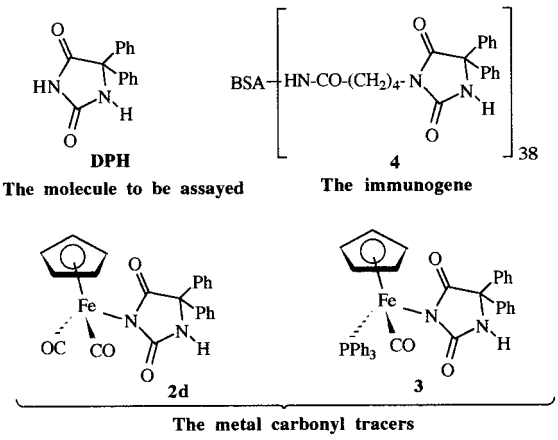
for dicobalt hexacarbonyl, **6**, and manganese tricarbonyl, **5**, which we already have available. In addition, this peak has a high ϵ value (1238). The characteristics of this tracer in infrared spectroscopy thus appear highly favorable for a multiimmunoassay by CMIA.

(IV) Biochemical Study. The components for an immunoassay by CMIA are three in number: the analyte (i.e., the substance to be assayed, here DPH), the tracer, which is a derivative of the analyte onto which a marker has been attached to permit quantification at low quantities, here $CpFe(CO)_2$ or $CpFe(CO)(PPh_3)$, and the specific antibodies of the substance to be assayed (Scheme 2).



Preparation and Specificity of anti-DPH Antibodies. DPH is a hapten, i.e., a molecule of low molecular weight with no antigenic properties. For this reason, anti-DPH antibodies can only be obtained after coupling this molecule to a vector protein such as bovine serum albumin (BSA). In the case of DPH, we chose to synthesize the immunogen DPH-3-valerate-BSA, **4** (Scheme 2). It is obtained by coupling DPH-valeric acid to BSA, using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC).

Table 4. Infrared Characteristics of the Metal Carbonyl Complexes in the ν(CO) Region

Metal carbonyl complexes	ν(CO), cm^{-1}	$\epsilon^{a)}$
2d	2054[c] 2010	1096 1157

 **4**[b]	1971[c] 1898	1542[d]
 **5**[e]	2032[c] 1955	1212[d]
 **6**[f]	2094 2056[c] 2027	3355[d]

[a] Molar extinction coefficient (cm^{-1} M^{-1}) measured in a light-pipe cell, 20 mm path length, filled volume, 30 μL as described in ref *13* with a Bomen MB100 equipped with a InSb detector. Measurements are done in CCl_4 except for **5** where it is done in $CHCl_3$. [b] Prepared as described in ref *2*. [c] Analytical band of the complex, i.e., the band used to performed quantitative analysis. [d] ϵ value for the analytical band of the complex. [e] Prepared as described in ref *5*. [f] Prepared as described in ref *3*.

Scheme 2. Molecules Involved in the Carbonyl Metallo Immunoassay (CMIA) of DPH

Injection of rabbits with this immunogen gives anti-DPH specific antibodies (*2*).

Measurement by Radioimmunoassay (RIA) of the Cross-Reaction Rates of Tracers 2d and 3 to anti-DPH Specific Antibodies. In order for the organometallic complexes **2d** and **3** to be useful as tracers in a CMIA assay, they must be recognized by the available anti-DPH specific antibodies. To ascertain this, an RIA test was performed to determine cross-reaction rate (CR%) of the complexes relative to the anti-DPH specific antibodies. **2d** and **3** showed a CR% of 43 and 20%, respectively, showing that the two complexes are recognized by anti-DPH antibodies and are thus candidates for use as tracers in CMIA. However, **2d** has much better

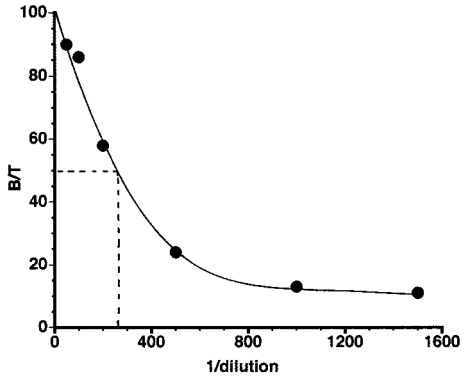

Figure 3. Antiserum dilution curve of anti-DPH antibodies by CMIA (50 pmol of **2d**, quantification of the free fraction of the tracer by FT-IR spectroscopy).

recognition than **3**, probably owing to the high level of steric crowding of the PPh_3 ligand.

CMIA Determination of the Titer Value of anti-DPH Antibodies Using 2d or 3 as Tracer. Once tracers and specific antibodies for the substance to be assayed have been obtained, the immunoassay itself can be started, beginning with a titration curve. These curves are obtained by incubating a fixed quantity of tracer (50 pmol) in the presence of increasing dilutions of anti-DPH antibodies. At the end of the incubation period (2 h at room temperature), the free and bound fractions of the tracer are separated by extraction using isopropyl ether. The organic fraction containing the free fraction is recovered and evaporated on a Speed-Vac. The FT-IR spectrum of each fraction is obtained after redissolving the residue in CCl_4 and quantification of the tracer is performed by measuring the absorbance of the analytical peak of each tracer (2054 cm^{-1} for **2d** and 1977 cm^{-1} for **3**). The starting point for a titration curve by CMIA is thus a series of IR spectra corresponding to the quantity of free tracer (**2d** or **3**) present in each fraction. When **2d** is used as the tracer, the curve shown in Figure 3 is obtained. The titer value of the antibody tested, which by definition is the inverse value of the dilution corresponding to $B/T = 50\%$, is 250 in this case. This value is entirely satisfactory and permits the further development of the immunoassay of DPH by CMIA.

In the case of **3**, the binding rate of the tracer to the anti-DPH antibody is low, in fact with 50 pmol of tracer, only 35% is bound for the first point of the curve (antibody dilution 1/50; data not shown). By extrapolation, a titer value of 25 is obtained, which is insufficient to permit further development of the immunoassay with the combination anti-DPH antibody/tracer **3**.

Acquisition of a Standard Assay Curve of DPH by CMIA Using 2d as Tracer. The titer value is an indication of the quantity of antibodies present in the antisera under study and of their affinity for the tracer. However, it does not give any indication of the feasibility of the assay itself, in particular regarding the capacity of the antibody−tracer complex to displace the analyte. This must be established by acquisition of a standard curve to allow quantitative assay of the analyte. This curve is obtained by incubating a fixed quantity of tracer (50 pmol of **2d**) in the presence of a fixed dilution of antibody (equal to the titer value, i.e., 1/250) and increasing quantities of DPH, between 10 and 200 pmol. After incubation, separation of the free and bound fractions and quantification of the tracer by FT-IR, a curve is obtained as shown in Figure 4. This curve has the classic appearance of the curves obtained by other types of immunoassay, such as radioimmunoassay, and is an indication of the feasibility of performing a monoimmunoassay of DPH by CMIA using **2d** as tracer. Several comments are suggested by this particular curve. First, it is noteworthy that the B/B_0 value goes as low as approximately 9%, indicating a low nonspecific binding rate of the tracer with the antibody. This can be explained by the fact that the chemical structure of the tracer, with a direct bond between the drug and the organometallic moiety, is completely different from the structure of the immunogen, where a spacer connects DPH to BSA. This eliminates the possibility of binding of **2d** to anti-spacer antibodies and a concomitant rise in the nonspecific binding rate.

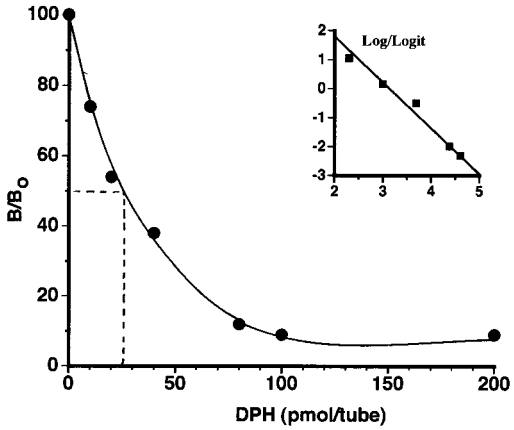

Figure 4. Standard cure of DPH by CMIA (50 pmol of **2d**, quantification of the free fraction of the tracer by FT-IR spectroscopy). (Inset) Log/Logit transformation of the curve.

Another interesting result is the quantity of DPH needed to reach a B/B_0 value of 50%. This value is calculated by linearization of the standard curve shown in Figure 4 by the log/logit function (Figure 4, inset). The value found is 23 pmol, signifying that the highest sensitivity of the assay will be obtained around this value, i.e., for quantities of DPH between 10 and 50 pmol. This is of particularly high sensitivity. This result may be explained by the cross-reaction rate of 43% obtained for **2d**. This rate is high enough to permit binding of the tracer and antibody, but not too high to allow its later displacement by small quantities of DPH. The compromise between these parameters is particularly advantageous in this case. Taking into account the range of measurement for serum concentrations, which is between 2.5 and 40 μg/mL, the assay can be performed with less than a microliter of serum.

Conclusion and Future Perspectives. We have synthesized a series of novel metal carbonyl complexes of phenytoins, in particular the complexes $CpFe(CO)_2$-DPH, **2d**, and $CpFe(CO)(PPh_3)$-DPH, **3**. The study described here demonstrates the feasibility of a monoassay of DPH by CMIA, using the metal carbonyl tracer **2d**, thus adding a new type of metal carbonyl moiety to the list of those suitable for use with this assay method. On the other hand, the affinity of **3** for the anti-DPH antibodies we obtained is too low to permit immunoassay using the antibody/tracer combination we currently have. The interest of **3** for multiimmunoassay is clear, however, because the metal carbonyl entity $CpFe(CO)(PPh_3)^-$ shows in IR a single, high-intensity $\nu_{(CO)}$ peak at 1977 cm^{-1}, which is a region where the dicobalt hexacarbonyl and manganese tricarbonyl tracers do not absorb. The very high steric crowding of the PPh_3 ligand is no doubt the reason for the greatly reduced affinity of the tracer **3** for the antibodies. Replacement of the triphenylphos-

phine by less bulky P-ligands is expected to produce a tracer with better antibody affinity.

EXPERIMENTAL PROCEDURES

Materials. All syntheses were carried out under argon. Solvents were dried using standard procedures. Chromatographic separations were carried out on silica gel 60 (Merck, 230−400 mesh ASTM). $CpFe(CO)_2I$ was prepared according to King (*11*). 5,5-Diphenylhydantoin (DPH), bovine serum albumine (BSA), 1-ethyl-3-[3-(dimethylaminopropyl)]carbodiimide (EDAC), Freund's complete and incomplete adjuvant, charcoal (Norit A) and dextran T70, were purchased from Sigma. [4-^{14}C]DPH (specific activity, 107 GBq/mmol) was supplied by DuPont, NEN Products (Boston MA). Other compounds were commercally available (Aldrich, Fluka) and were used as received. NMR spectra were run on a Varian Gemini 200 BB spectrometer (200 MHz for ^{1}H) in $CDCl_3$ solutions and referenced toward internal Me_4Si. Mass spectra were determined on an LKB 2001 spectrometer. Elemental analyses were done by the Analytical Services of the CBMiM PAN (Łodz).

X-ray Structure Determination for 2d. Crystals of **2d** were grown from layered dichloromethane-hexane for 2 days. Crystal data and details of the data collection and refinement are listed in Table 1. The intensities were corrected for Lorenz and polarization effects. No absorption correction was applied. The structure was solved by Patterson method and refined by the full-matrix least-squares method using the SHELXS programs (*14*). All non-hydrogen atoms were refined anisotropically. H atoms for the Cp ring were refined isotropically by the "riding mode". The remaining H atoms were located in the difference map and refined isotropically.

General Procedure for the Synthesis of the $CpFe(CO)_2$-Hydantoins (2a−2d). $CpFe(CO)_2I$ (455 mg, 1.5 mmol), hydantoin (1.0 mmol), benzene (15 mL), and diisopropylamine (1 mL) were introduced to a glass tube, saturated with argon, and photolyzed with visible light (4 × 150 W domestic tungsten lamps). The photolyzed mixture was magnetically stirred and externally cooled by immersion in a water−ice bath. During the photolysis, the initial black coloration of the photolyte turned yellow. After 3 h of photolysis, the solid, diisopropylamine hydroiodide, formed and was filtered off and washed with a small volume of benzene. The filtrate was evaporated to dryness, and the residue dissolved in chloroform and chromatographed on Kieselgel 60 (6 g) using chloroform as eluent. The yellow band which followed the black band of the unreacted $CpFe(CO)_2I$ was collected and evaporated to dryness. The products were crystallized from dichloromethane-hexane. In the case of **1c,** the chromatography yields two overlapping bands (yellow and orange). These bands can be separated on a longer column to give pure yellow **2c** and orange **2c′**, presumably the N1 addition product contaminated with **2c**.

Yields (%): **2a**, 96; **2b**, 85; **2c**, 76; **2d**, 94. Melting Points. (**2a**) 94−96 °C; (**2b**) 159−162 °C (decomp.); (**2c**) decomp. 169 °C; (**2d**) decomp. 182 °C.

Synthesis of $CpFe(CO)(PPh_3)$-5,5-diphenylhydantoin 3. **2d** (221 mg, 0.51 mmol) and triphenylphosphine (186 mg, 0.71 mmol) were refluxed in benzene (8 mL) for 3.5 h. After evaporation to dryness, the residue was dissolved in chloroform and chromatographed. The brown-red band was collected to give **3** as a brown-red solid, crystallized form dichloromethane-hexane. Yield: 58.6%. Melting point.: 130 °C (decomp.). Elemental analysis (calcd/found): $C_{39}H_{31}N_2O_3PFe$ C (70.71/70.83); H (4.72/4.92) N (4.23/4.32). ^{1}H NMR ($CDCl_3$): 7.1−7.25 (m, 25H, Ph), 6.85 (bs 1H, NH), 4.58 (s 5H, Cp). IR ($CHCl_3$): 1980 ($\nu_{C\equiv O}$), 1710 (w), 1625 (s) ($\nu_{C=O}$).

FT-IR Spectroscopy. Infrared spectra for characterization of the products were recorded in $CHCl_3$ on a Specord 75 IR spectrometer. Infrared spectra for quantitative analyses were recorded on a benchtop Bomem, MB-100 FT-spectrometer equipped with a liquid nitrogen-cooled, 1.00 mm^2 InSb (indium antimonide) detector and a microbeam attachment which reduced the 6.00 mm incident IR beam to a 1.00 mm diameter focal beam by means of a 90°, off-axis, 100 mm focal length, gold-coated parabolic mirror. The spectral data were manipulated on an NEC APC IV microcomputer. Routinely, 20 scans were coadded (data collection time: 1.1 min). The absorbance values were baseline corrected and determined using the program "Trend Line Analysis" contained in the Bomem software. With this spectrometer configuration, the samples have to be handled manually. A more detailed description is given in a previous paper (*13*). The IR solution cell used was an ultralow volume, gold light-pipe cell with a fill volume of 30 μL and an optical path length of 20 mm (*12*).

Preparation of Rabbit anti-DPH Antibodies. Polyclonal antisera were produced in "fauves de Bourgogne" rabbits, by subcuteneous administration of [(DPH-VA)-BSA] immunogen prepared as described in ref *2*. Each rabbit received 1 mL of an initial emulsion consisting of 250 μg of the immunogen (lyophilized fraction) in 25% water and 75% Freund's complete adjuvant (*15*). Boosters injections identical in composition and amount to the intitial injection (excepted that Freund's incomplete adjuvant was used) were given monthly 4 weeks after the primary for up to 60 weeks. Blood (5−10 mL) was taken 10−15 days after each booster, kept at room-temperature one night, then centrifuged. Sera were then separated in 150 μL fractions and stored at −20 °C.

Study of Cross-Reactions by RIA. Fractions of 500 μL containing 50 μL of antibody (final dilution 1/250), 50 μL (30 pmol) of [^{14}C]DPH, and increasing amounts of

2d or **3** in 500 μL of RIA buffer (Na_2HPO_4, 30 mM; NaH_2PO_4, 30 mM; NaCl, 160 mM; gelatine, 1 g/L; and sodium azide, 30 mM; pH 7.4) were incubated for 2 h at 0 °C. At the end of the incubation period, the free and bound fractions were separated by DCC treatment (1.25% charcoal, 0.125% dextran; final concentration). The supernatant liquids were transferred into vials, and the radioactivity was counted on an LKB Rackbeta counter. The cross-reactivity (CR%) is equal to the quantity (pmol) of **2d** or **3** displacing 50% of [^{14}C]DPH/quantity (pmol) of DPH displacing 50% of [^{14}C]DPH.

Titration Curves by CMIA. Fractions of 500 μL containing 50 pmol of **2d** or **3**, 50 μL of anti-DPH antibody (1/30 to 1/3000) in CMIA buffer (Na_2HPO_4, 30 mM; NaCl, 160 mM; sodium azide, 30 mM; and glycerol, 10% v/v) were incubated at 0 °C for 2 h. At the end of the incubation period, the free and bound fractions of the tracer were separated by selective solvent extraction of the free fraction with isopropyl ether in the following manner: 1.0 mL of the organic solvent saturated in buffer was added to each tube, the mixtures were vortexed for 1 min, and then 750 μL of the organic phase which contained the free tracer were withdrawn and transferred immediatly to 1.5 mL Eppendorf tubes. The solutions were quickly evaporated to dryness on a Speed Vac (Savant) concentrator. Samples for IR analysis were obtained by dissolving the dry residues in 30 μL of CCl_4. The FT-IR spectra were immediately recorded on a Bomem Michelson 100 FT spectrometer using the gold light-pipe cell described previously (*12*). The absorbance of the 2054 cm^{-1} (for **2d**) or 1977 cm^{-1} (for **3**) peak was proportional to the free fractions of the tracer (F = free). The absorbance of the total quantity of tracer (T) present in the incubation buffer was obtained following extraction of a 500 μL fraction containing an identical quantity of tracer but no antibodies. The bound fraction (*B*) was calculated from the difference $T - F$. Titration curves were then constructed by plotting the B/T ratio for each sample versus the inverse of the dilution of the antibodies. The linearization of this curve is obtained by plotting ln(amount of DPH in the tube) versus logit Y, with $Y = \ln[B/B_0/100 - (B/B_0)]$.

Standard Curves by CMIA. Fractions of 500 μL containing a dilution of the anti-DPH antibody equal to the titer value, 50 pmol of **2d**, 50 μL of various quantities of DPH, and 350 μL of CMIA buffer were incubated at room temperature for 1 h. Separation of the free and bound fractions was performed by solvent extraction with isopropyl ether, and determination of the bound fractions was performed as described for the titration curves by CMIA. B_o is the B value obtained in the absence of DPH. Standard curves were then obtained by plotting the B/B_o ratios against the amounts of DPH added.

ACKNOWLEDGMENT

We wish to thank Professor Pierre Brossier (Université de Dijon, France) for providing anti-DPH antibodies, Michèle Salmain for helpful discussion, Annie Cordaville for technicial assistance and Barbara McGlinchey for her assistance in translating the manuscript.

Received September 9, 1998; Revised Manuscript Received February 8, 1999

Hydrazino nicotinate (HYNIC) has been shown to produce technetium-99m (^{99m}Tc)-labeled proteins and peptides of high stability with high specific activities. However, persistent localization of radioactivity was observed in nontarget tissues such as the liver and kidney after administration of [^{99m}Tc]HYNIC-labeled proteins and peptides, which compromises the diagnostic accuracy of the radiopharmaceuticals. Since lysosomes are the principal sites of intracellular catabolism of proteins and peptides, ^{99m}Tc−HYNIC-labeled galactosyl-neoglycoalbumin (NGA) was prepared using tricine as a co-ligand to investigate the fate of the radiolabel after lysosomal proteolysis in hepatocytes. When injected into mice, over 90% of the injected radioactivity was accumulated in the liver after 10 min injection. At 24 h postinjection, ca. 40% of the injected radioactivity still remained in liver lysosomes. Size-exclusion HPLC analyses of liver homogenates at 24 h postinjection showed a broad radioactivity peak ranging from molecular masses of 0.5−50 kDa. RP-HPLC analyses of liver homogenates suggested the presence of multiple radiolabeled species. However, most of the radioactivity migrated to lower molecular weight fractions on size-exclusion HPLC after treatment of the liver homogenates with sodium triphenylphosphine-3-monosulfonate (TPPMS). The TPPMS-treated liver homogenates showed a major peak at a retention time similar to that of [[^{99m}Tc](HYNIC−lysine)(tricine)(TPPMS)] on RP-HPLC. Similar results were obtained with urine and fecal samples. These findings suggested that the chemical bonding between ^{99m}Tc and HYNIC remains stable in the lysosomes and following excretion from the body. The persistent localization of radioactivity in the liver could be attributed to the slow elimination rate of the final radiometabolite, [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$], from lysosomes, and subsequent dissociation of one of the tricine co-ligands in the low pH environment of the lysosomes in the absence of excess co-ligands, followed by binding proteins present in the organelles. The findings in this study also suggested that the development of appropriate co-ligands capable of preserving stable bonding with the Tc center is essential to reduce the residence time of radioactivity in nontarget tissues after administration of [^{99m}Tc]HYNIC-labeled proteins and peptides.

INTRODUCTION

Radiopharmaceuticals derived from low molecular weight peptides and antibody fragments have been used for visualization of the sites of tumors, infections, and thromboses at early postinjection times (*1*−*3*). The pharmacokinetics of these molecules are well matched with the physical half-life of ^{99m}Tc, the most widely used and the least expensive radionuclide for external imaging. Some peptides contain the N_4 tetraamide (Gly-Gly-Gly), N_3S triamidethiol (Gly-Gly-Cys), or N_2S_2 diamidedithiol (Cys-Gly-Cys) tripeptide sequence (*4*−*7*), which form stable ^{99m}Tc complexes with the $[Tc{=}O]^{3+}$ core. However, the radiolabeling of these tripeptide sequences may require harsh conditions such as high pH and high temperatures. In addition, ^{99m}Tc labeling may lead to the loss of receptor-binding affinity if the tripeptide sequence constitutes part of the receptor-binding motif. Furthermore, some peptides and proteins do not possess such endogenous binding sites to form ^{99m}Tc chelate with high stability. Thus, attachment of appropriate chelating agents to proteins or peptides constitutes a major strategy for labeling of these molecules with ^{99m}Tc for in vivo applications.

Hydrazino nicotinate (HYNIC) is one of the most attractive bifunctional coupling agents for labeling of peptides and proteins with ^{99m}Tc. Indeed, HYNIC provides ^{99m}Tc-labeled nonspecific human IgG, human serum albumin, Fab fragment, chemotactic peptides, and RGD peptides with high specific radioactivities and high radiochemical yields (*8*−*13*). Previous studies indicated that HYNIC acts as a monodentate or bidentate ligand to form a mixed ligand ^{99m}Tc complex in the presence of appropriate co-ligands such as glucoheptonate or tricine (*8*, *14*). Both Tc−hydrazido and Tc−diazenido bonds have been reported and characterized by X-ray crystallography (*15*−*19*). A recent study also suggested that HYNIC

requires two tricine ligands to complete the coordination sphere regardless of whichever type of bond ^{99m}Tc and HYNIC may form (*12*).

When administered in vivo, [^{99m}Tc]HYNIC-labeled proteins and peptides show localization of radioactivity in target tissues. However, high and persistent radioactivity levels were also observed in the liver and kidney where catabolism of the parent proteins and peptides occurs, which compromises the diagnostic accuracy of these radiopharmaceuticals (*8*, *20*−*22*). Since indium-111 (^{111}In)-labeled proteins and peptides also show persistent localization of radioactivity in tissues in which they are catabolized due to the slow elimination rates of the final radiometabolites generated after lysosomal proteolysis in these tissues (*23*−*27*), similar mechanisms may be responsible for the long residence times of the radioactivity derived from [^{99m}Tc]HYNIC-labeled proteins and peptides in these tissues. Decomposition or exchange reactions of the [^{99m}Tc]HYNIC−tricine mixed ligand complex may also account for the long residence times of the radioactivity in the lysosomal compartment where the complexes are present at very low ligand concentrations in the low pH environment. Indeed, decomposition of a [^{99m}Tc]HYNIC-conjugated peptide was indicated in a dilute solution (*12*). However, little is known regarding the retention of radioactivity at the sites of catabolism after administration of [^{99m}Tc]HYNIC-labeled proteins and peptides (*22*). Since HYNIC allows preparation of a variety of ^{99m}Tc-labeled proteins and peptides, the chemical design of HYNIC-based chelating agents that circumvent such undesirable localization of radioactivity is required. Thus, understanding of the fate of ^{99m}Tc after metabolism of [^{99m}Tc]HYNIC-labeled proteins and peptides is essential.

Since lysosomes are the principal sites of intracellular catabolism of proteins and peptides (*28*), metabolic analysis of [^{99m}Tc]HYNIC-labeled proteins in the lysosomal compartment of the liver or kidney would provide insight into the mechanisms responsible for the prolonged radioactivity levels in these organs. Galactosyl-neoglycoalbumin (NGA) is incorporated by hepatic parenchymal cells via receptor-mediated endocytosis immediately after administration (*29*). Use of NGA as a carrier protein provides explicit information regarding the fate of radioactivity after lysosomal proteolysis in hepatocytes without being affected by transchelation of radiolabels in plasma or redistribution of radiometabolites generated elsewhere in the body to the liver (*24*, *30*). In addition, a recent study indicated that an [^{111}In]DTPA-adduct of lysine was generated as the final radiometabolite in the liver and kidney when ^{111}In-labeled NGA and antibodies using cyclic DTPA dianhydride (cDTPA) as the bifunctional chelating agent (BCA) were administered into animals (*31*).

In the present study, NGA was used as a model protein, and biodistribution and subcellular localization of the radioactivity in the murine liver was investigated after administration of [^{99m}Tc]HYNIC-labeled NGA using tricine as the co-ligand. Radiometabolites retained in the liver and excreted from the body were analyzed to determine the fate of the radiolabel, ^{99m}Tc, after lysosomal proteolysis in hepatocytes. Factors affecting the long residence time of radioactivity in nontarget tissues after administration of [^{99m}Tc]HYNIC-labeled proteins and peptides will be discussed. Since HYNIC generates ^{99m}Tc-labeled proteins and peptides in the presence of two tricine co-ligands (*12*, *14*, *32*), ^{99m}Tc-labeled HYNIC−NGA and HYNIC−lysine are abbreviated as [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] and [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$], respectively.

MATERIALS AND METHODS

Reagents and Chemicals. [^{99m}Tc]Pertechnetate ($^{99m}TcO_4^-$) was eluted in saline solution on a daily basis from Daiichi Radioisotope Laboratory generators (Chiba, Japan). Reversed-phase high-performance liquid chromatography (RP-HPLC) was performed with a Cosmosil 5 C_{18}-MS column (4.6 × 150 mm, Nacalai Tesque, Kyoto) at a flow rate of 1 mL/min with a gradient mobile phase starting from 100% A (0.1% aqueous trifluoroacetic acid) to 100% B (acetonitrile with 0.1% trifluoroacetic acid) in 30 min (solvent system 1). RP-HPLC was also performed with a gradient mobile phase starting from 10% acetonitrile in 0.05 M phosphate buffer (pH 7.0) to 90% acetonitrile in the same buffer in 20 min and the final solvent composition was maintained for a further 10 min (solvent system 2). Size-exclusion HPLC was performed using a 5 Diol-300 column (7.5 × 600 mm, Nacalai Tesque) connected to a 5 Diol-300 guard column (7.5 × 50 mm, Nacalai Tesque), eluted with 0.1 M phosphate buffer (pH 6.8) at a flow rate of 1 mL/min. The eluent was collected with a fraction collector (RediFrac; Pharmacia Biotech, Tokyo) at 30 s intervals, and the radioactivity levels in each fraction (500 μL) were determined with an auto well counter (ARC-2000; Aloka, Tokyo). TLC analyses were performed with silica plates (Merck Art 5553) with a mixture of 10% aqueous ammonium chloride-methanol (1:1) or saline as developing solvents. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Bruker AC-200 spectrometer, and the chemical shifts are reported in parts per million downfield from an internal tetramethylsilane standard. Fast atom bombardment mass spectra (FAB-MS) were obtained with a JMS-HX/HX 110 A model (JEOL Ltd., Tokyo). Sodium triphenylphosphine-3-monosulfonate (TPPMS) was purchased from Tokyo Kasei Kogyo Co. Ltd. (Tokyo), and other reagents were of reagent grade and used as received. To facilitate collection of urine and feces after administration of radiolabeled NGA, mice were housed in metabolic cages (Metabolica, MM type; Sugiyama-Gen Iriki Co. Ltd., Tokyo). Succinimidyl 6-hydrazinopyridine-3-carboxylate hydrochloride (SHNH) was synthesized according to the procedure of Abrams et al. (*8*).

Synthesis of Galactosyl-Neoglycoalbumin (NGA). Cyanomethyl-2,3,4,6-tetra-*O*-acetyl-1-β-galactopyranoside, synthesized according to the procedure of Lee et al. (*33*), was conjugated with human serum albumin (HSA, A-3782; Sigma Co., St. Louis, MO), according to the procedure of Stowell et al. (*34*). The phenol-sulfuric acid reaction (*35*) indicated that 43 galactose units were attached to each HSA molecule.

Synthesis of HYNIC−Lysine. Boc-protected SHNH (500 mg, 1.43 mmol), prepared by the method of Abrams et al. (*8*), in 15 mL of dry acetonitrile was added to a solution of α-Boc-L-lysine (352 mg, 1.43 mmol) in saturated $NaHCO_3$ (5 mL) at 0 °C. The reaction mixture was stirred at room temperature for 6 h. After filtration to remove white precipitates, the filtrate was cooled to 0 °C, and the solution was acidified to pH 2−3 with concentrated H_2SO_4 before extraction with ethyl acetate (20 mL × 4). The organic layers were combined and dried over anhydrous calcium sulfate. After removing the solvent in vacuo, the oily residue was chromatographed on silica gel using a mixture of chloroform-methanol-acetic acid (10:1:0.1) as the eluent to produce Boc-HYNIC-

α-Boc-L-lysine as white crystals (532 mg, 75.9%). ^{1}H NMR (CD_3OD): δ 1.26−1.81 [6H, m, $(CH_2)_3$], 1.43 (9H, s, Boc), 1.46 (9H, s, Boc), 3.39 (2H, t, NCH_2), 4.23 (1H, q, CH), 6.46 (1H, d, pyridine), 7.82 (1H, dd, pyridine), 8.10 (1H, d, pyridine). Anal. calcd for $C_{22}H_{35}O_7N_5 \cdot CH_3COOH$: C, 53.23; H, 7.21; N, 12.94. Found: C, 53.06; H, 7.04; N, 12.88. FAB-MS calcd for $C_{22}H_{36}O_7N_5$ (MH^+): *m/z* 482. Found: *m/z* 482.

Boc-HYNIC-α-Boc-L-lysine dissolved in 2 mL of dry ethyl acetate was added to a solution of 4 N HCl prepared in 2 mL of dry ethyl acetate. The reaction mixture was stirred at room temperature for 1 h. The HCl salt of HYNIC−lysine precipitated as white crystals (160 mg, 91.4%). ^{1}H NMR (DMSO-d_6): δ 1.36−1.87 [6H, m, $(CH_2)_3$], 3.24 (2H, t, NCH_2), 3.86 (1H, q, CH), 6.93 (1H, d, pyridine), 8.16 (1H, dd, pyridine), 8.67 (1H, d, pyridine). Anal. calcd for $C_{12}H_{21}O_3N_5Cl_2 \cdot 1/3\ C_4H_{10}O \cdot 3H_2O$: C, 37.66; H, 6.60; N, 16.47. Found: C, 37.65; H, 6.88; N, 16.35. FAB-MS calcd for $C_{12}H_{20}O_3N_5$ (MH^+): *m/z* 282. Found: *m/z* 282.

Preparation of HYNIC−NGA Conjugate. The conjugation reaction of HYNIC with NGA was performed according to the procedure of Abrams et al. (*8*) with slight modifications as follows: Briefly, 10 μL of SHNH (8.3 mg/100 μL) in dimethyl sulfoxide (DMSO) was added dropwise to a 1 mL of stirred NGA solution (20 mg/mL) in 0.15 M borate buffer (pH 8.5). The solution was stirred gently for 2 h at room temperature protected from the light. The HYNIC−NGA conjugate was purified by Sephadex G-50 (Pharmacia Biotech Co. Ltd., Tokyo) column chromatography (1.8 × 40 cm) equilibrated and eluted with 10 mM citrate buffer (pH 5.2). The protein fractions were subsequently concentrated to 5 mg/mL by ultrafiltration (8 MC model, Amicon Grace, Tokyo). The number of HYNIC groups attached per molecule of NGA was determined by measuring the hydrazino groups with *p*-nitrobenzaldehyde, according to the method of King et al. (*36*).

^{99m}Tc Labeling of HYNIC−NGA and HYNIC−Lysine. To a solution of HYNIC−NGA (100 μL; 5.0 mg/mL) in 10 mM citrate buffer (pH 5.2) was added an equal volume of [^{99m}Tc]tricine$_2$ prepared by the method of Larsen et al. (*14*), and the mixture was incubated for 1 h at room temperature. [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] was purified by the centrifuged column procedure using a Sephadex G-50 column equilibrated and eluted with 0.1 M phosphate buffer (pH 7.0) (*37*). Radiochemical yields of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] were determined by size-exclusion HPLC and TLC developed with saline. In a control study, unmodified NGA was labeled with [^{99m}Tc]tricine$_2$, according to the procedures described above.

A solution of [^{99m}Tc]tricine$_2$ (100 μL) was added to a 100 μL of HYNIC−lysine solution (2 mg/mL) in 10 mM citrate buffer (pH 5.2), and the reaction mixture was incubated for 1 h at 37 °C. Radiochemical yields were assessed by size-exclusion HPLC, RP-HPLC, and TLC developed with a mixture of 10% aqueous ammonium chloride-methanol (1:1).

[[^{99m}Tc](HYNIC−Lysine)(Tricine)(TPPMS)] Ternary Mixed Ligand Complex. A solution of [[^{99m}Tc]-(HYNIC−lysine)(tricine)$_2$] (100 μL) prepared as described above was mixed with 100 μL of TPPMS solution (5 mg/mL) in 0.1 M acetate buffer (pH 3.0). The solution was acidified to pH 3 with 0.1 N HCl and incubated at 37 °C for 1 h. The reaction mixture was analyzed by RP-HPLC, size-exclusion HPLC and TLC developed with a mixture of 10% aqueous ammonium chloride-methanol (1:1).

Plasma Stability of [[^{99m}Tc](HYNIC−NGA)(Tricine)$_2$]. [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] was diluted 20-fold with freshly prepared murine plasma, and the solution was incubated at 37 °C for 24 h. After 1 and 24 h of incubation, 50 μL aliquots of the samples were drawn, and the radioactivity was analyzed by size-exclusion HPLC and TLC developed with saline.

In Vivo Studies. The protein concentration of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] was adjusted to 90 μg/mL with saline. Biodistribution studies were performed by the intravenous administration of [[^{99m}Tc](HYNIC−NGA)-(tricine)$_2$] to 6-week-old male ddY mice (27−30 g) (*38*). Groups of five mice each were administered 9 μg (37−56 KBq) of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] prior to sacrificing the animals at 10 and 30 min and 1, 3, 6, and 24 h postinjection by decapitation. Previous studies indicated that under these conditions radiolabeled NGAs are incorporated by parenchymal cells of murine liver via receptor-mediated endocytosis (*24*, *30*). Tissues of interest were removed, weighed and the radioactivity counts were determined with an auto well γ counter (ARC 2000). To determine the amounts and routes of excretion of radioactivity from the body, mice were housed in metabolic cages for 24 h after administration of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$], and urine and feces were collected and the radioactivity was determined.

The subcellular distribution of radioactivity in the murine liver was investigated by perfusing the organ in situ with cold 0.25 M sucrose buffered with 10 mM phosphate buffer (pH 7.4) at 1 and 24 h postinjection of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$]. The liver was treated according to the procedure described previously (*24*, *30*). Briefly, the isolated organ was minced with scissors, suspended in 4 vol of the same buffer prior to homogenization by hand with a Dounce homogenizer (20 strokes). This was followed by two final strokes in an ice-cooled Potter-Elvehjem homogenizer with a Teflon pestle rotated at 800 rpm. The resulting homogenate was centrifuged twice for 5 min at 340 *g* at 4 °C. The isolated supernatant was then layered on top of iso-osmic (0.25 M sucrose) 37.5% Percoll (9 mL, Pharmacia Biotech Co. Ltd.) at a density of 1.08 g/mL. After centrifugation at 20000*g* (RP 30 rotor; Hitachi Co. Ltd., Tokyo) for 90 min at 4 °C, the gradients were collected in 14 fractions. β-Galactosidase was used as a marker enzyme for lysosomes (*39*, *40*) and its activity in each fraction was determined using *p*-nitrophenyl β-galactopyranoside as the substrate (*41*). The density and radioactivity counts of the respective fraction were also determined.

The radiolabeled species remaining in the liver at 1 and 24 h postinjection and excreted in the urine and feces by 24 h postinjection of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] (133−266 KBq) were analyzed according to the procedure described previously (*24*, *30*). Briefly, the murine liver was perfused in situ with cold 0.1 M Tris-citrate buffer (pH 6.5) containing 0.15 M NaCl, 0.02% sodium azide, 1 TIU/mL aprotinin, 2 mM benzamidine-HCl, 2 mM iodoacetamide, 1 mM phenylmethanesulfonyl fluoride, and 5 mM diisopropyl fluorophosphate before the hepatic samples (1 g each) were isolated. Each tissue sample was placed in a test tube and subjected to three cycles of freezing (dry ice-acetone bath) and thawing. After addition of 5 vol of the same buffer containing an additional 35 mM β-octyl-glucoside, the samples were homogenized with a Polytron homogenizer (PT 10-35, Kinematica GmbH, Littau, Switzerland) set at full speed with three consecutive 30 s bursts prior to centrifugation at 48000*g* for 20 min at 4 °C (Himac CS-120 Centrifuge; Hitachi

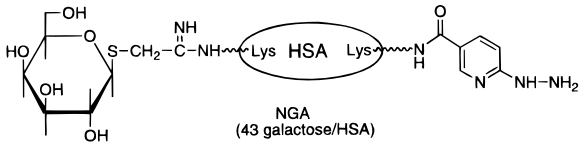

Figure 1. Chemical structure of HYNIC−NGA.

Co. Ltd., Tokyo). The supernatant was separated from the pellet, and the radioactivity was counted. In a procedure similar to that used for liver tissue, fecal samples were homogenized in the presence of 0.1 M phosphate buffer (pH 6.0) before centrifugation at 10000*g* for 20 min at 4 °C. The liver, feces, and urine samples were analyzed immediately by size-exclusion HPLC and TLC after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm (Nacalai Tesque). Each sample was also analyzed immediately by RP-HPLC after ultrafiltration with a 10 kDa cutoff membrane (Microcon-10, Amicon).

Since TPPMS forms a ternary mixed ligand complex with [[^{99m}Tc](HYNIC−peptide)(tricine)$_2$] (*32*), the liver homogenates were reacted with TPPMS and the reaction products were analyzed to further characterize the radiometabolites retained in the liver. The supernatants of the liver homogenates (100 μL) were mixed with a 100 μL solution of TPPMS (5 mg/mL) in 0.1 M acetate buffer (pH 3.0) after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm. After acidification to pH 3 with 0.1 N HCl, the reaction mixture was incubated at 37 °C for 1 h. The reaction mixture was analyzed by size-exclusion HPLC and TLC after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm. Each sample was also analyzed by RP-HPLC after filtration through a 10 kDa cutoff ultrafiltration membrane. The fecal homogenates and urine samples obtained at 24 h postinjection of [[^{99m}Tc](HYNIC−NGA)-(tricine)$_2$] were also reacted with TPPMS by similar procedures, and the radioactivity in the reaction mixture was analyzed.

RESULTS

In Vitro Studies. HYNIC−NGA conjugate (Figure 1) was prepared by reaction of the active esters of SHNH with ϵ-amine residues of the NGA. Three HYNIC groups were attached per molecule of NGA as determined by measuring the hydrazine groups. After purification by the centrifuged column procedure, [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] was obtained with radiochemical yields over 95% as determined by size-exclusion HPLC and TLC. The reaction of [^{99m}Tc]tricine$_2$ with unmodified NGA resulted in only 5.4% of the radioactivity associated with protein. Figure 2 shows size-exclusion radiochromatograms of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] before and after incubation in freshly prepared murine plasma for 24 h. The radioactivity associated with NGA fractions was unchanged before (98.7%) and after 24 h incubation (97.6%). Similar results were obtained by TLC analyses.

In Vivo Studies. The biodistribution of radioactivity after intravenous administration of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] is summarized in Table 1. At 10 min postinjection, more than 92% of the injected radioactivity was accumulated in the liver. The radioactivity was gradually eliminated from the liver by hepatobiliary excretion as the major excretion route. At 24 h postinjection, over 38% of the injected radioactivity was still retained in the liver. During the same postinjection period, 38 and 14% of the injected radioactivity was excreted in the feces and urine, respectively.

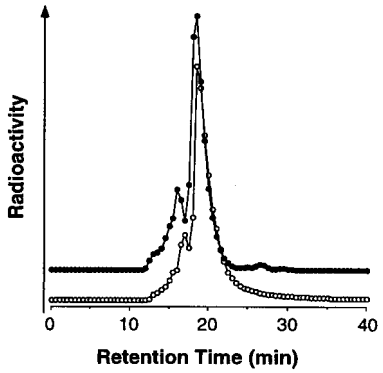

Figure 2. Size-exclusion radiochromatograms of [[^{99m}Tc]-(HYNIC−NGA)(tricine)$_2$] before (○) and after (●) incubation in freshly prepared murine plasma at 37 °C for 24 h.

[a] Expressed as % injected dose. Each value represents the mean (s.d.) for five animals at each interval. [b] Time after administration. [c] Expressed as percent dose per gram.

The Percoll density gradient centrifugation profiles of radioactivity in the liver at 1 and 24 h postinjection of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] are illustrated in Figure 3. Each liver homogenate showed a major radioactivity peak at a density of ca. 1.10 g/mL, which correlated well with the β-galactosidase activity profiles.

The supernatants of the liver homogenates were obtained with radiochemical efficiencies of over 90%. After filtration of the liver supernatant at 1 and 24 h postinjection through the polycarbonate membrane, the radioactivity was recovered in the filtrates with 86.1 and 92.3% efficiencies, respectively. When analyzed by size-exclusion HPLC, while the liver supernatant at 1 h depicted a major radioactivity peak at a retention time close to that of [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] (Figure 4C), radioactivity was also detected in fractions over 10 kDa (Figure 4A). A significant increase in radioactive fractions over 10 kDa was observed with the liver supernatant at 24 h postinjection (Figure 4B). Under these conditions, the parental [[^{99m}Tc](HYNIC−NGA)-(tricine)$_2$] had a retention time of 18 min (Figure 4, panels A and B). On TLC analyses, the liver homogenates had radioactivity at the origin with a broad peak at R_f values of 0.5−0.65. The liver supernatant at 1 h postinjection was recovered in the filtrate with 76.3% efficiency after filtration through a 10 kDa cutoff ultrafiltration membrane, whereas the radioactivity recovered in the filtrate decreased to 54.3% after filtration of the liver supernatant at 24 h postinjection. RP-HPLC radiochromatograms

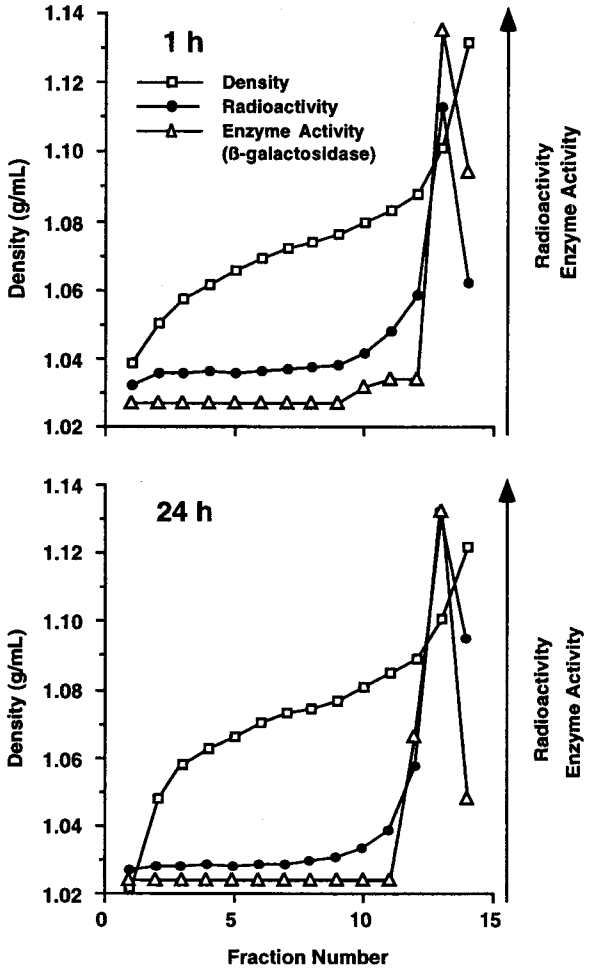

Figure 3. Percoll density gradient centrifugation profiles of liver homogenate at 1 and 24 h postinjection of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$]. In both preparations, a single radioactivity peak (●) that coincided with β-galactosidase activity (△) was detected at a density (□) of ca. 1.10 g/mL.

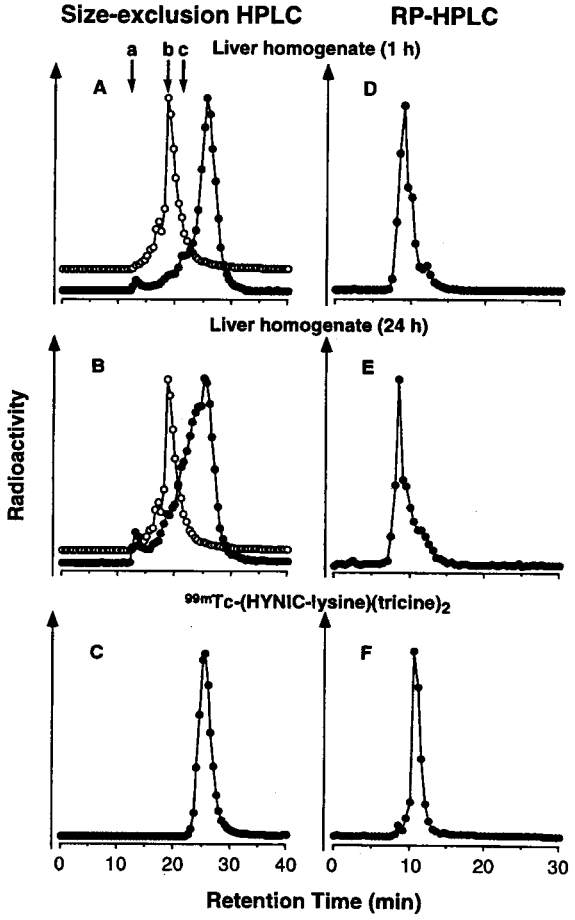

Figure 4. Analyses of liver homogenates (●) at 1 and 24 h postinjection of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] (○) by size-exclusion HPLC (A and B) and RP-HPLC using solvent system 1 (D and E). Radiochromatograms of [[^{99m}Tc](HYNIC−lysine)-(tricine)$_2$] when analyzed by size-exclusion HPLC (C) and RP-HPLC (F). Under these conditions, thyroglobulin (a; 670 kDa), bovine serum albumin (b; 68 kDa) and cytochrome C (c; 13 kDa) had retention times of 13, 18, and 21 min, respectively, on size-exclusion HPLC.

of the liver supernatant at 1 and 24 h postinjection using the solvent system 1 are shown in Figure 4, panels D and E. Both supernatants showed similar radiochromatograms with a major radioactivity peak at a retention time of 8−9 min and a shoulder at a retention time of 11 min. Under these conditions, [[^{99m}Tc](HYNIC−lysine)-(tricine)$_2$] showed a radioactivity peak at a retention time of 11 min (Figure 4F). RP-HPLC analyses of the liver homogenates using solvent system 2 showed a radioactivity peak at a retention time of 4 min (Figure 6, panels A and B).

The radiochromatograms of the TPPMS-treated liver homogenates are illustrated in Figures 5 and 6. The radioactivity recovered in the filtrates was 91.1 and 88.6% after filtration of the TPPMS-homogenates obtained at 1 and 24 h postinjection through a polycarbonate membrane, respectively. On size-exclusion HPLC, a significant decrease in the radioactive fractions over 10 kDa was observed with TPPMS-treated liver homogenate at 24 h postinjection. The reaction product of [[^{99m}Tc]-(HYNIC−lysine)(tricine)$_2$] and TPPMS showed a single radioactivity peak at a retention time of 26 min on size-exclusion HPLC (Figure 5C). The radioactivity recovered in the filtrates increased to 89.2 and 91.1% for the TPPMS-treated liver homogenates obtained at 1 and 24 h postinjection after filtration through a 10 kDa cutoff ultrafiltration membrane. On RP-HPLC using solvent system 1, the TPPMS-treated liver homogenates showed a sharp radioactivity peak at a retention time of 17 min for both preparations, which was identical to that of the reaction product of [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] and TPPMS (Figure 5F). This was confirmed by co-chromatographic analyses (data not shown). Under these conditions, the reaction products of [^{99m}Tc]tricine$_2$ and TPPMS showed a radioactivity peak at a retention time of 13 min on RP-HPLC. Similar results were obtained on RP-HPLC analyses of the liver homogenates using solvent system 2, where both TPPMS-treated liver homogenates and [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] showed a single radioactivity peak at a retention time of 8.5 min, as shown in Figure 6. On TLC analyses, both TPPMS-treated liver homogenates and the reaction product of [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] and TPPMS showed a radioactivity peak at an R_f value of 0.7.

Figure 7 shows radiochromatograms of fecal and urine samples analyzed by size-exclusion HPLC and RP-HPLC using solvent system 1. Supernatants of feces were obtained with an efficiency of 54.6%. The recovered radioactivities in the filtrates after filtration though the polycarbonate membrane and the ultrafiltration membrane were 66.7 and 82.5% for feces and 96.9 and 98.3% for urine samples, respectively. Both fecal and urine samples showed a single radioactivity peak on size-exclusion HPLC at a retention time of 26 min (Figure 7, panels A and B). On RP-HPLC, a broad radioactivity

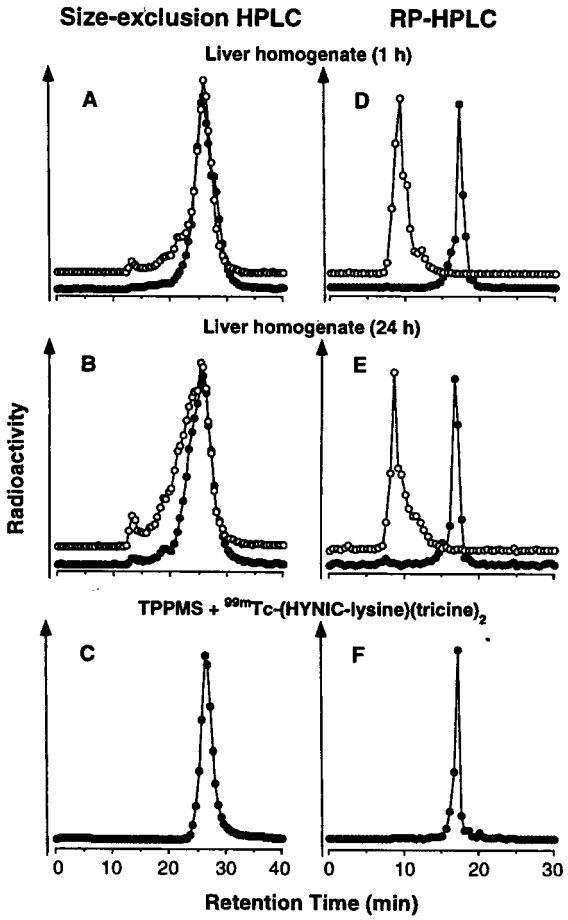

Figure 5. Radiochromatograms of liver homogenates at 1 and 24 h postinjection before (○) and after (●) TPPMS treatment by size-exclusion HPLC (A and B) and RP-HPLC using solvent system 1 (D and E). The reaction product of [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] with TPPMS was analyzed by size-exclusion HPLC (C) and RP-HPLC (F).

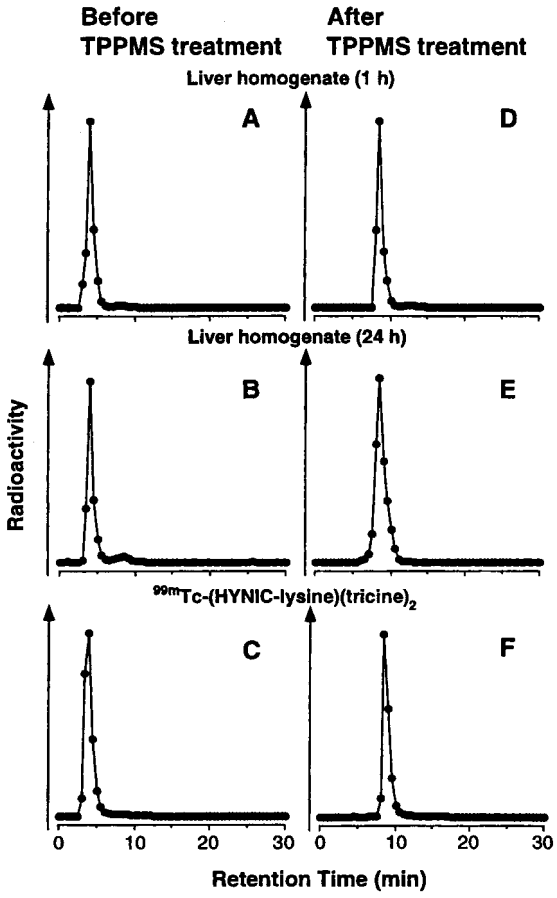

Figure 6. RP-HPLC radiochromatograms of liver homogenates at 1 and 24 h postinjection before and after treatment with TPPMS using solvent system 2. RP-HPLC radiochromatograms of [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] are also shown before and after treatment with TPPMS under similar conditions (C and F).

profile at a retention time of around 9 min was observed with both preparations using solvent system 1 (Figure 7, panels C and D). After TPPMS treatment, both feces and urine preparations showed migration of the radioactivity peaks to a retention time of 17 min, which was identical to that of the reaction product between [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] and TPPMS (Figure 7, panels E and F). Similar results were obtained by TLC analyses, where both preparations showed a radioactivity peak at an R_f value of 0.7 after TPPMS treatment.

DISCUSSION

Selective complexation of ^{99m}Tc to the HYNIC moiety was indicated by the exchange reaction of [^{99m}Tc]tricine$_2$ with HYNIC−NGA as shown by the small amounts of ^{99m}Tc attached to unmodified NGA. Unchanged size-exclusion HPLC radiochromatograms before and after incubation for 24 h in murine plasma reinforced the stable chemical bonding between ^{99m}Tc and HYNIC (Figure 2). In biodistribution studies, persistent localization of the radioactivity was observed in the murine liver in which catabolism of NGA occurs following the administration of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] (Table 1). These findings using NGA as a model protein were in good agreement with those of previous studies using [^{99m}Tc]HYNIC-labeled proteins in experimental animals (*8*, *42*, *43*).

Radioactivity in the liver homogenates was copurified with lysosomes at 1 and 24 h postinjection of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] (Figure 3), as observed in previous studies using ^{111}In-labeled NGAs with cDTPA or 1-(4-isothio,cyanatobenzyl)ethylenediaminetetraacetic acid (SCN−Bz-EDTA) as the BCAs (*24*, *26*, *31*, *44*, *45*). Previous studies also showed that both ^{111}In-labeled NGAs generated lysine-adducts ([^{111}In]DTPA-lysine and [^{111}In]SCN−Bz-EDTA-lysine) as the major final radiometabolites in murine hepatocytes and the slow elimination rates of the radiometabolites from the lysosomal compartment of hepatocytes are responsible for the persistent localization of the radioactivity in the liver. Since HYNIC was also conjugated to the ϵ-amine residues of NGA, lysine-adduct of HYNIC was prepared and radiolabeled with [^{99m}Tc]tricine$_2$ as a standard compound for subsequent analyses of the radioactivity retained in the liver and excreted in the urine and feces.

On size-exclusion HPLC analyses, the liver homogenates registered a radioactivity peak at a retention time representative of low molecular weight compounds such as [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] (Figure 4), as observed with ^{111}In-labeled NGAs. In contrast to ^{111}In-labeled NGAs, radiolabeled species were also registered in higher molecular weight fractions and the proportion of the fractions increased with postinjection interval. This was reflected in the decreased recovery of radioactivity in the filtrates of liver homogenates at 24 h postinjection using 10 kDa cutoff ultrafiltration membranes. Since generation of the final radiometabolites of ^{111}In-labeled NGAs was complete within 1 h postinjection (*24*, *30*), the time-dependent increase in high molecular weight frac-

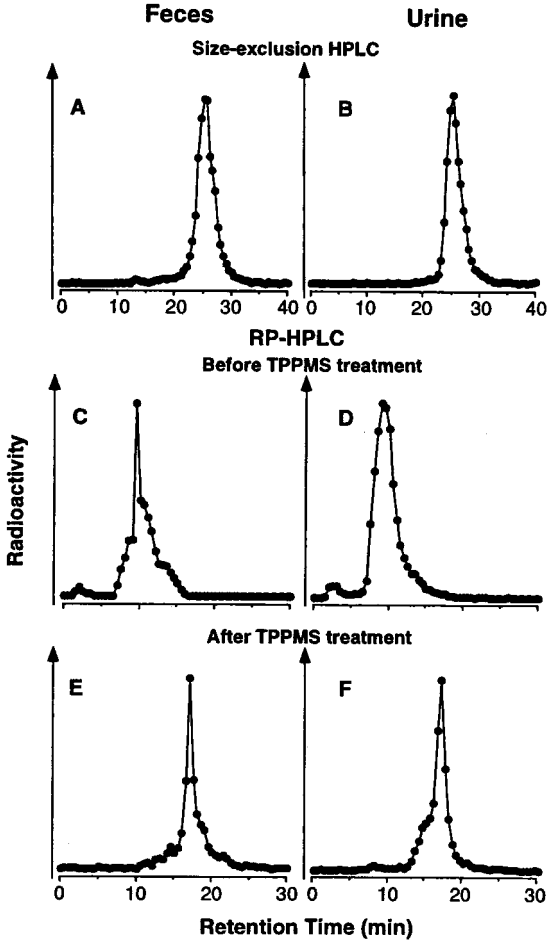

Figure 7. Analyses of feces and urine samples obtained at 24 h postinjection of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] by size-exclusion HPLC (A and B) and RP-HPLC (C and D) using solvent system 1. After reacting with TPPMS, both preparations were analyzed by RP-HPLC (E and F).

tions suggested binding of radiometabolites derived from [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] with proteins present in the lysosomes, which would constitute a major reason for the long residence time of radioactivity in the liver.

To further understand the persistent localization of the radioactivity in the liver after administration of [[^{99m}Tc]-(HYNIC−NGA)(tricine)$_2$], radiolabeled species retained in the liver at the two postinjection intervals were analyzed. Both liver homogenates showed a broad radioactivity peaked at a retention time close to that of [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] (Figure 4), suggesting that multiple radiolabeled species derived from [[^{99m}Tc]-(HYNIC−lysine)(tricine)$_2$] would be present in the liver homogenates. Since [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] showed no change in RP-HPLC radiochromatograms after removing excess ligands (data not shown), the broad radioactivity of the liver homogenates suggested the formation of new mixed ligand ^{99m}Tc complexes. On the other hand, the reaction mixture of the liver homogenates with TPPMS showed RP-HPLC radiochromatograms similar to that of the reaction product of [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] and TPPMS (Figures 5 and 6). A recent study of [^{99m}Tc]HYNIC-labeled peptides showed that [[^{99m}Tc](HYNIC−peptide)(tricine)$_2$] reacts with TPPMS to provide a new ternary mixed ligand complex [[^{99m}Tc]-(HYNIC−peptide)(tricine)(TPPMS)], in which one tricine co-ligand was replaced with one TPPMS molecule (*32*). It has also been reported that [[^{99m}Tc](HYNIC−peptide)-(tricine)$_2$] gradually decomposed to hydrophilic ^{99m}Tc species in a dilute solution (*12*). Furthermore, the binding of [^{99m}Tc]HYNIC-labeled antibodies and DNA with serum proteins was observed (*11*, *46*). Thus, the findings in this study, together with those results of previous studies, suggested that [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] would be generated as the final radiometabolite after lysosomal proteolysis of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] in the murine liver. However, one of the two tricine co-ligands of the metabolite would be replaced with amino acids to generate new mixed ligand ^{99m}Tc complexes of high protein binding ability or with amine residues of proteins present in the organelles, facilitated by a low pH environment in the absence of excess co-ligand.

The radiolabeled species excreted in the urine and feces were present as multiple low molecular weight compounds (Figure 7). However, since the TPPMS-treatment of urine samples and fecal extracts showed migration of the radioactivity with a retention time similar to that of [[^{99m}Tc](HYNIC−lysine)(tricine)(TPPMS)] on RP-HPLC, the radiolabeled species excreted from the body appeared to still retain the [[^{99m}Tc]HYNIC−tricine] bond in the absence of excess co-ligands. The multiple peaks in urine and feces determined by RP-HPLC also suggested the participation of amino acids in the mixed ligand [^{99m}Tc]-HYNIC complexes generated in the lysosomes of the liver.

In conclusion, the findings in this study implied that the bonding between ^{99m}Tc and HYNIC is extremely stable at low pH in the absence of excess co-ligands. The persistent localization of radioactivity in the liver after administration of [[^{99m}Tc](HYNIC−NGA)(tricine)$_2$] was attributed to the slow elimination rate of the final radiometabolite, [[^{99m}Tc](HYNIC−lysine)(tricine)$_2$] from the lysosomes, and subsequent replacement of one of the tricine co-ligands with amino acids to generate new ternary mixed ligand complexes of high protein binding ability or with amine residues of proteins in the lysosomes, presumably due to the low pH environment of the organelles and the absence of excess co-ligands. These findings also suggested that the development of appropriate co-ligands that form stable [^{99m}Tc]HYNIC−[co-ligand] mixed complexes at low pH in the absence of excess co-ligands is essential to reduce localization of radioactivity in nontarget tissues after administration of ^{99m}Tc-labeled proteins using HYNIC.

The many laboratory and diagnostic applications utilizing streptavidin as a molecular adaptor rely on its high affinity and essentially irreversible interaction with biotin. However, there are many situations where recovery of the biotinylated molecules is desirable. We have previously shown that poly(*N*-isopropylacrylamide) (PNIPAAm), a temperature-sensitive polymer, can reversibly block biotin association as the polymer's conformation changes at its lower critical solution temperature (LCST). Here, we have constructed a streptavidin−PNIPAAm conjugate which is able to bind biotin at room temperature or lower and release bound biotin at 37 °C. The conjugate can repeatedly bind and release biotin as temperature is cycled through the LCST. A genetically engineered streptavidin mutant, E116C, which has only one cysteine residue, was conjugated site specifically via the sulfhydryl groups with a PNIPAAm that has pendent sulfhydryl-reactive vinyl sulfone groups. The conjugation site is near the tryptophan 120 residue, which forms a van der Waals contact with biotin that is important in generating the large binding free energy. The temperature-induced conformational change of the polymer at position 116 may lead to structural changes in the region of tryptophan 120 that are responsible for the reversible binding between biotin and the conjugated streptavidin.

INTRODUCTION

Diverse and widespread applications utilizing streptavidin as a molecular adaptor have been developed that utilize the tight binding of biotin to the protein (ca. 10^{13-15} M^{-1}) (*1*). Streptavidin can be detected and quantitated with high sensitivity in such complexes by labeling it with enzymes, fluorescent, chemiluminescent, or radioactive agents, and metals. Labeled streptavidin has been used to detect proteins on a cell surface (*2*), to visualize and quantitate blots (*3*−*7*), and to perform an enzyme-linked immunosorbent assay ELISA (*8*−*12*). Streptavidin can also be readily immobilized at surfaces to capture biotinylated molecules or cells. These surfaces are used to detect and separate molecules or cells of interest from complex mixtures (*13*, *14*). Isolation of polymerase chain reaction (PCR) products is simplified by employing streptavidin-immobilized magnetic microbeads (*15*−*17*). Streptavidin has also been investigated for targeted delivery of drugs or immunotoxins (*18*).

These applications rely on the essentially irreversible binding of biotin and streptavidin. However, there are many cases in which dissociation of bound biotin is desired to recover biotinylated molecules or cells, or to release therapeutic reagents at targeted sites. Currently, harsh denaturing conditions are used to dissociate biotin from streptavidin (*19*). These denaturing conditions are undesirable especially to bioseparations. Thus, it is an important goal to effect the capture and release of biotinylated molecules and cells under mild conditions. We have developed a streptavidin−temperature sensitive polymer conjugate in which the polymer is covalently and site specifically linked to the outer edge of the biotin-binding site (*20*). The biotin-binding sites of the conjugate can be blocked by a small change of temperature. The collapse of the polymer did not release bound biotin, however. Morag et al. (*21*) have derivatized the tyrosine residues within the binding sites of avidin or streptavidin with tetranitromethane. The nitro-avidin is able to bind biotin at low pH and release bound biotin at high pH.

Our approach to developing a reversible biotin-binding system is to site specifically conjugate a stimuli-sensitive polymer to streptavidin. Control of biotin-binding is achieved by manipulating the conformation of the polymer, which can be specifically designed to respond sharply to changes in temperature, pH, and even light. For example, we have previously conjugated PNIPAAm to an N49C mutant of streptavidin to reversibly block biotin binding. PNIPAAm is a temperature-sensitive polymer that exhibits lower critical solution temperature (LCST) behavior, in which the polymer changes from a water-soluble coil to a water-insoluble collapsed (dehydrated) globule as temperature increases through the LCST. PNIPAAm and other stimuli-sensitive polymers have been used for enzyme recovery (*22*−*24*), affinity separation (*25*), immunoassay (*26*), and drug delivery (*27*, *28*). In this paper, we present our investigation of a new streptavidin conjugation site, that was designed near an important binding site residue. By changing the location of the mutation site of streptavidin and the structure of the polymer, we are now able both to block biotin binding and to release the bound biotin by changing temperature.

zation from *n*-hexane. Methanol was used to recrystallize 2,2′-azoisobutyronitrile (AIBN) (J. T. Baker, Phillipsburg, NJ). To purify 2-hydroxyethyl methylacrylate (Aldrich, Milwaukee, WI), distillation under reduced pressure was employed. Divinyl sulfone (DVS) and d-biotin were purchased from Aldrich (Milwaukee, WI) and used without treatment. d-[8,9-^{3}H]Biotin is a product of Amersham Life Science (Buckinghamshire England). Trypsin, type III from bovine pancreas, was purchased from Sigma (Sigma, St. Louis, MO). Dehydrated dimethylformamide (Sigma, St. Louis, MO) was used without further treatment. Tris-(2-carboxyethyl) phosphine (HCl) (TCEP) (Pierce, Rockford, IL) was used as received. Tosyl-activated magnetic microbeads (DYNABEADS M-280, Dynal, Inc. Lake Success, NY) (TMB) were used. All other reagents were of analytical grade. *Msc*I and *Mlu*I restriction enzymes and T4 DNA Ligase were purchased from New England Biolabs (Beverly, MA). Qiaex II kit for extracting DNA was purchased from Qiagen (Santa Clarita, CA). pET21a vector was obtained from Novagen (Madison, WI).

Preparation and Activation poly(NIPAAm). A copolymer of (NIPAAm-*co*-HEMA) was prepared by free-radical polymerization using AIBN as an initiator, as shown in Figure 1. NIPAAm (11.3 g), HEMA (0.503 mL), and AIBN (0.164 g) were added to 50 mL of dehydrated DMF. The solution was degassed by freezing, evacuating, and thawing three times and then sealed. Polymerization was carried out at 60 °C for 20 min. The conversion of monomers was controlled within 20% in order to obtain relatively homogeneous composition of copolymer. The copolymer was collected by precipitation in diethyl ether and dried in a vacuum oven. For further purification, the dried copolymer was redissolved in 40 mL of dichloromethane and precipitated in diethyl ether. The molecular weight of the copolymer was determined by vapor pressure osmometry (VPO, model OSV111 from Knauer, German). Proton NMR spectroscopy was performed with a Bruker 200 MHz instrument to evaluate the composition of the copolymer. ^{1}H NMR (dimethyl sulfoxide-d_6): 5.05 ppm (1H, −OH) and 7.25 ppm (1H, −NH).

The hydroxyl groups of HEMA in the copolymer were further reacted with DVS in alkaline conditions, as shown in Figure 1. The copolymer and DVS were dissolved in dichloromethane. The solution was purged with nitrogen at room temperature for 30 min before addition of 0.03 g of potassium tert-butoxide. The reaction was carried out at room temperature for 16 h under protection of nitrogen. The derivatized copolymer was isolated by precipitation in diethyl ether. The derivatized copolymer was submitted to NMR analysis and Ellman's reagent analysis (*29*, *30*) for determination of VS content. ^{1}H NMR (dimethyl sulfoxide-d_6): 6.21 ppm (2H, $=CH_2$), 6.97 ppm (1H, $-SO_2CH=$), and 7.20 ppm (1H, −NH). In the Ellman's assay, the polymer was reacted with excess of cystamine followed by titrating the remaining cystamine with Ellman's reagent. Since the copolymer has pendant reactive groups, the VS groups, the copolymer is denoted as PNIPAAm-pP. Thermal responsiveness of PNIPAAm-pP was determined spectroscopically using 0.23 wt % of copolymer solution.

Genetic Engineering of Streptavidin. The streptavidin mutant E116C was constructed by site-directed, cassette mutagenesis, using a synthetic "core" streptavidin gene previously designed and constructed for protein expression in *Escherichia coli* (*31*). Oligonucleotides were designed to substitute glutamic acid at position 116 with cysteine. The following sense and anti-sense oligonucleotides were obtained from Integrated DNA Technologies (Coralville, IA) (the bold-face type indicates amino acid change): 5′CCAGTACGTTGGTGGTGCTGAAGCTCGTATCAACACCCAGTGGTTGTTGACCTCCGGCACCACC**TGC**GCTAA-3′ and 3′GGTCATGCAACCACCACGACTTCGAGCATAGTTGTGGGTCACCAACAACTGGAGGCCGTGGTGG**ACG**CGATTGCGC-5′.

The streptavidin gene in pUC18 was digested with *Msc*I and *Mlu*I restriction enzymes, isolated on a 1.2% agarose gel, extracted, and purified using Qiaex II kit. The synthetic oligonucleotides, designed with *Msc*I and *Mlu*I ends, were annealed then ligated into the pUC18/StAv vector using T4 DNA Ligase. The DNA sequence of the mutant gene was confirmed using automated dyedeoxy sequencing (PE Applied Biosystems, Foster City, CA). The streptavidin mutant (StAv/E116C) gene was subsequently subcloned into pET21a for expression in *E. coli* strain BL21(DE3). The protein was expressed and refolded using established protocols. Analysis of the E116C streptavidin mutant included SDS−PAGE, mass spectrometry, and biotin-binding studies.

Conjugation of Polymer to Protein. Conjugation between E116C and PNIPAAm-pP was carried out in 100 mM sodium tetraborate buffer, pH 8.5, containing 50 mM sodium chloride and 5 mM EDTA at 4 °C for 16 h. Cysteine residues of E116C form disulfide bonds during storage. To reduce disulfide bonds to sulfhydryl groups, TCEP at 50-fold molar excess to E116C was used. PNIPAAm-pP in 50-fold molar excess to E116C was used in order to obtain high conjugation efficiency. The conjugate, denoted as E116C-pP, was separated from unconjugated E116C by thermal-induced precipitation, i.e., centrifuging the mixture at 15 000 rpm (31000*g*) for 15 min at 37 °C. The unconjugated E116C was retained in the supernatant. The thermal-induced precipitation was repeated twice for further purification.

Immobilization of Conjugates. Tosyl-activated magnetic beads were used to immobilize the conjugate, E116C, and trypsin-pP. E116C-pP conjugate dissolved in 100 mM sodium tetraborate buffer, pH 9.5 (concentration = 100 μg/mL) was mixed with TMB in a ratio of E116C-pP:TMB = 100 μg:1 mg. The mixture was rotated head-over-end at 37 °C for 16 h. The E116C-pP immobilized beads (E116C-pP-TMB) were washed with and redispersed in 100 mM sodium phosphate buffer, pH 7.4 (PB). The efficiency of immobilization was determined by mass balance determination of protein loss from solution, which was quantified by the absorbance at λ = 280 nm. A trypsin-pP immobilized magnetic bead surface was used as a control.

Biotin-Binding Assay. [^{3}H]Biotin was employed to quantitate biotin binding. To eliminate unconjugated

biotin-binding sites from interfering with biotin-binding assay, the E116C-pP-TMB was presaturated with cold biotin at 37 °C. To do so, $10^{-9}-10^{-10}$ mol of E116C-pP-TMB was incubated at 37 °C for 1 h followed by mixing with 10-fold excess unlabeled biotin at 37 °C. The mixture was incubated at 37 °C for 1 h to allow complete biotin binding to the unconjugated sites. Unbound biotin was removed by washing the beads with PB at 37 °C five times. [^{3}H]Biotin was then added to the presaturated E116C-pP-TMB at 37 °C. One hour incubation was allowed to reach an equilibrium. An aliquot was taken from the supernatant to determine the [^{3}H]biotin concentration in the supernatant using a β-counter (LS7000 Liquid scintillation system, Beckman Instruments, Inc. Fullerton, CA). The bead suspension was then incubated at 4 °C for 1 h to reach a biotin-binding equilibrium before the biotin concentration of the supernatant was measured. Temperature cycling continued three times. [^{3}H]Biotin concentration of supernatant after incubation at each temperature was determined by a β-counter. Bound biotin was quantitated by the following formula:

$$Q_T = Q_0 - Q_{S/N,T}$$

where Q_T is the bound biotin (mol) at temperature T (°C), Q_0 is the total amount of [^{3}H]biotin (mol) added to the E116C-pP-TMB suspension, and $Q_{S/N,T}$ is the quantity of [^{3}H]biotin (mol) remaining in the supernatant after incubation at temperature T (°C)

The blocking or releasing efficiency was represented by following formula:

$$B\ (\%) = (Q_{4°C} - Q_{37°C}) \times 100/Q_{4°C}$$

Measurement of Cumulative Release of Bound Biotin. Immobilized E116C or E116C-pP-TMB, which was presaturated with cold biotin at 37 °C, was mixed with [^{3}H]biotin at 4 °C for 1 h to allow biotin binding. The mixtures were then incubated at 37 °C for 1 h. To collect the released biotin, the supernatant was removed from the mixture after incubation at 37 °C. The beads were washed with prewarmed (37 °C) PB and then redispersed in the same volume of PB for the next cycle. [^{3}H]Biotin concentration in the supernatant was measured to quantify the cumulative release of [^{3}H]biotin.

RESULTS AND DISCUSSION

P(NIPAAm-*co*-HEMA) and PNIPAAm-pP were characterized by VPO, ^{1}H NMR, and Ellman's reagent. VPO analysis showed that the P(NIPAAm-*co*-HEMA) had a number average molecular weight (Mn) of 7500. ^{1}H NMR analysis demonstrated that all of the hydroxyl groups in the copolymer were converted to vinyl sulfone groups in the derivatization step. Analysis using Ellman's Reagent showed that the vinyl sulfone group content in the copolymer was 4.5 mol %, indicating that every copolymer chain had an average of three vinyl sulfone groups. Figure 2 shows the thermal-responsive properties of P(NIPAAm-*co*-HEMA) and PNIPAAm-pP. It is interesting that the LCST of P(NIPAAm-*co*-HEMA) (32.1 °C) is similar to that of a NIPAAm homopolymer (32−33 °C). Vinyl sulfone derivatization makes polymer more hydrophobic because the LCST of PNIPAAm-pP (27.5 °C) is lower than that of P(NIPAAm-*co*-HEMA). The LCST of PNIPAAm-pP in PB (20.2 °C) is much lower than that in water (27.5 °C). Hence, the salt has a strong effect on the thermal-responsiveness of PNIPAAm-pP.

Studies have shown that the tryptophan-120 plays an important role in generating a large binding free energy

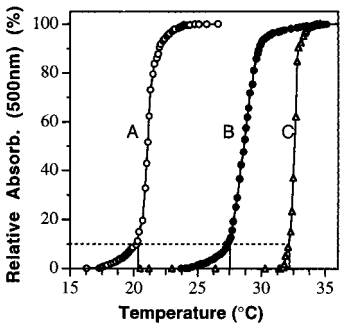

Figure 2. The LCSTs of PNIPAAm-pP in sodium phosphate buffer (A), in deionized and distilled water (B), and that of poly(NIPAAm-*co*-HEMA) in deionized and distilled water (C). Polymer concentration was 0.20 wt %. The LCST is defined as the temperature at which the polymer solution is of 10% of maximum turbidity.

by forming van der Waals contact with biotin (*31*). Conformational change at this site may affect the binding properties significantly. Hence, we desinged a conjugation site near the tryptophan-120. Site-directed mutagenesis techniques were used to replace the native glutamate at position 116 with cysteine. As shown in Figure 3, this cysteine is near tryptophan-120, located on the same loop that contributes to the binding site from an adjacent subunit. Conjugation of the polymer to the E116C mutant was achieved by reacting the vinyl sulfone groups of the PNIPAAm-pP with the genetically engineered sulfhydryl groups (*29*), as shown in Figure 4. Since every monomer of E116C mutant has only one cysteine, the conjugation is site specific. To avoid possible reaction between the vinyl sulfone and primary amines of the protein, which becomes significant only at higher pH (*32*), we used pH 8.5 for the conjugation to minimize this side reaction. The conjugation reaction is quite efficient. A typical conjugate yield is 70%. The conjugate was subsequently immobilized on magnetic microbeads. A commonly used method to immobilize streptavidin on a surface is to use biotinylated solid substrates. However, such biotin-immobilized streptavidin may release from the surface due to the exchange of immobilized biotin with free biotin. Therefore, covalent linkage was used to immobilize streptavidin onto magnetic microbeads, as shown in Figure 4. The efficiency of immobilization, or the percentage of protein which is immobilized, ranged from 30 to 80%.

To maximize the sensitivity of analysis of the temperature responsiveness of the conjugate, the E116C-pP-TMB system was presaturated with biotin at 37 °C. Our studies have indicated that not all of the biotin-binding sites of an E116C molecule are conjugated with copolymer. The biotin-binding properties of the polymer-conjugated sites should show temperature dependence while the unconjugated sites should not show a significant effect of temperature on binding or release of biotin. Presaturating the unconjugated sites with unlabeled biotin reduces the signal from unconjugated binding sites.

Figure 5 shows the changes in the biotin-binding capacity of the E116C-pP-TMB as a function of temperature. The first temperature cycle shows that the polymer at position 116 can block the association of biotin at 37 °C while leaving the binding site open to biotin at 4 °C. In the second cycle, when the temperature was increased from 4 to 37 °C, where the polymer collapsed, a significant fraction of the bound biotin was released. When the temperature was decreased from 37 to 4 °C, the unoccupied polymer-conjugated sites were able to rebind biotin. Therefore, biotin can be bound to and released

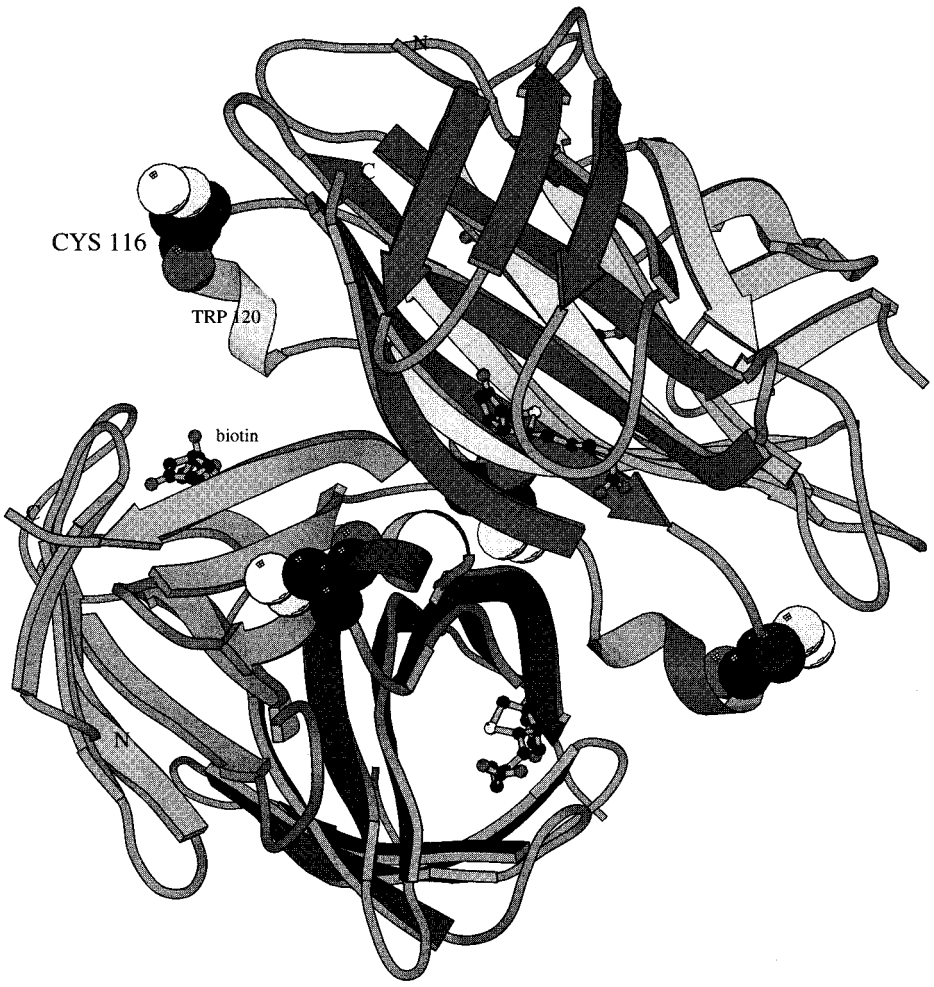

Figure 3. Computer model of the E116C mutant binding site.

from the conjugate by changing the temperature from below to above the polymer's LCST.

The biotin-binding properties of the unconjugated E116C streptavidin are shown in Figure 6 which demonstrates that the immobilized E116C mutant does not display a significant temperature-dependent change of % biotin bound over one cycle. Furthermore, Figure 7 shows that neither a control trypsin-PNIPAAm immobilized conjugate nor the unreacted magnetic bead surface adsorbs or traps biotin at 37 or 4 °C. These controls support the conclusion that the temperature responsiveness of biotin binding shown in Figure 5 is due to the unique site-specific conjugation of E116C with the thermally sensitive PNIPAAm.

To further investigate the release of bound biotin from polymer-conjugated sites, we have conducted cumulative release experiments. Figure 8 shows that all of the bound biotin to the polymer-conjugated sites is released after four washing cycles. It is also shown that repeatedly changing the temperature is necessary to release all of the bound biotin. It should be noted that the complete release of bound biotin is not a consequence of protein denaturation because the conjugate is able to bind biotin after the washes. Figure 8 also shows that about 17% of bound biotin is released from immobilized E116C streptavidin with four washes. Streptavidin has an off-rate of 3.24×10^{-5} (s^{-1}) at 37 °C and 1.03×10^{-7} (s^{-1}) at 4 °C (*33*). It has also been shown that biotin-binding activity decreases when streptavidin is immobilized on a solid surface (*34*). In the cumulative release experiments, the biotin concentration of supernatant was very low because the supernatant was replaced with fresh buffer in every cycles. All these facts may contribute to the release of small amounts of bound biotin from the E116C. However, the biotin release from E116C is significantly less than that from the conjugate.

While the precise mechanism by which polymer collapse causes release of biotin cannot be determined experimentally, it is likely that the polymer conformational change alters the conformation of the tryptophan 120 loop. The radius of the PNIPAAm molecules reduces to half of its original radius upon collapse (*35*, *36*). This conformational change is transmitted to the biotin-binding site, as demonstrated by the change in biotin affinity that leads to biotin release. Because one PNIPAAm-pP chain contains three vinyl sulfone groups on average, it is possible that one copolymer chain is conjugated to more than one site on the protein. We observed such multiple-point conjugation, as indicated by formation of insoluble gel when conjugation was performed at high concentrations of protein and the polymer. The multiple-point conjugation may transmit the conformational change from the polymer to the protein more efficiently.

CONCLUSIONS

We have prepared a new site-specific conjugate of streptavidin with a temperature-sensitive polymer. When this conjugate is thermally stimulated, it is able to reversibly bind and release biotin because of the unique combination of specific conjugation sites on a genetically engineered protein and a stimuli-responsive copolymer. The conjugate binds biotin at 4 °C where the polymer is hydrated and releases a significant fraction of bound biotin at 37 °C where the polymer is collapsed. By combining temperature cycling between 4 and 37 °C with washing at 37 °C, all of the bound biotin can be released. The conjugate is immobilized on magnetic microbeads and can be used to capture and to recover biotin. This system is potentially useful for separation and recovery of biotinylated substances without the need for harsh elution conditions.

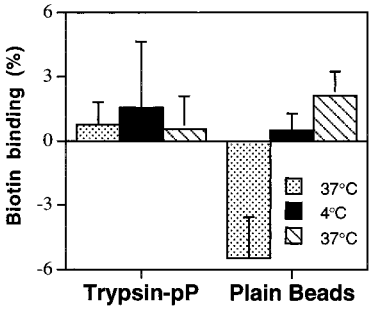

Figure 7. Nonspecific adsorption of biotin to various surfaces. The data presented are an average of triplicate determinations. Magnetic beads (Dynal M-280) immobilized with 1.0×10^{-9} mol of trypsin-pP were used for the assay. Sodium phosphate buffer, pH 7.4, 100 mM was used as the medium.

Hemolytic Activity of pH-Responsive Polymer-Streptavidin Bioconjugates†

Chantal A. Lackey,‡ Niren Murthy,‡ Oliver W. Press,§ David A. Tirrell,|| Allan S. Hoffman,*,⊥ and Patrick S. Stayton*,#

Department of Bioengineering and Department of Medicine, University of Washington, Seattle, WA 98195, and Department of Chemical Eng'g, Calif. Institute of Technology, Pasadena CA. Received September 11, 1998; Revised Manuscript Received March 11, 1999

Drug delivery systems that increase the rate and/or quantity of drug release to the cytoplasm are needed to enhance cytosolic delivery and to circumvent nonproductive cell trafficking routes. We have previously demonstrated that poly(2-ethylacrylic acid) (PEAAc) has pH-dependent hemolytic properties, and more recently, we have found that poly(2-propylacrylic acid) (PPAAc) displays even greater pH-responsive hemolytic activity than PEAAc at the acidic pHs of the early endosome. Thus, these polymers could potentially serve as endosomal releasing agents in immunotoxin therapies. In this paper, we have investigated whether the pH-dependent membrane disruptive activity of PPAAc is retained after binding to a protein. We did this by measuring the hemolytic activity of PPAAc−streptavidin model complexes with different protein to polymer stoichiometries. Biotin was conjugated to amine-terminated PPAAc, which was subsequently bound to streptavidin by biotin complexation. The ability of these samples to disrupt red blood cell membranes was investigated for a range of polymer concentrations, a range of pH values, and two polymer-to-streptavidin ratios of 3:1 and 1:1. The results demonstrate that (a) the PPAAc−streptavidin complex retains the ability to lyse the RBC lipid bilayers at low pHs, such as those existing in endosomes, and (b) the hemolytic ability of the PPAAc−streptavidin complex is similar to that of the free PPAAc.

INTRODUCTION

There are now many biomolecular drugs in development for the treatment of a wide variety of medical ailments. These therapeutics include DNA for gene therapies, oligonucleotides for antisense therapies, and protein or peptide drugs and toxins for disease (e.g., cancer) therapies. A significant problem with the development of many DNA and protein therapies is the delivery of the biomolecule to the proper intracellular site. The efficacy of DNA and protein therapeutics is often limited by cellular trafficking processes that shunt the agents to undesirable compartments or recycle them out of the cell (*1*). Both DNA and protein therapeutics rely on complicated trafficking routes initiated with receptor-mediated endocytosis followed by transport through endosomal, endoplasmic reticulum, and/or trans-Golgi compartments. The efficiency of delivery across these compartments to the cytosol, a necessary step in gene therapy and many protein therapies, is often the limiting factor in treatment efficacy.

When drugs and their complexes or conjugates with carriers are endocytosed, they are often rapidly trafficked from early endosomes to late endosomes, and eventually to lysosomes where they are degraded (*2*). Internalized drugs are not normally released into the cytoplasm of the cell. An important example is the Immunotoxin family, which exploits the specificity of monoclonal antibodies for delivery of toxins to specific cellular and tissue targets. The most commonly utilized toxins are ricin, a plant toxin from the seeds of *Ricinus communis*, and the bacterial toxins *Diphtheria* toxin and *Pseudomonas* exotoxin A (*3*). The efficacy of immunotoxins has been shown to be dependent on the specific monoclonal antibody used (*3*). Antibodies internalized by endocytosis are often trafficked to lysosomes where they are degraded (*4*), unlike the native toxin which is translocated into the cytosol (*5*). Previous attempts to circumnavigate this trafficking limitation include the modification of ricin A chain by the addition of endoplasmic reticulum and Golgi retention sequences (*6*), the use of endosome-destabilizing peptides (*7*), and pH-triggered bispecific antibodies (*8*, *9*).

We have been investigating pH-sensitive or "intelligent" polymers that are capable of lysing red blood cells at pH values observed in endosomes, while being non-disruptive at a physiologic pH of 7.4. These are based on α-alkyl acrylic acids. One example is poly(2-ethylacrylic acid) (PEAAc),[1] which has been shown to have pH-dependent membrane-disruptive properties in liposomes (*10*). A pH-triggered conformational change occurs at pH

6.3 and below (*11*, *12*). At these lower pH conditions, PEAAc appears to permeabilize phosphatidylcholine (PC) membranes, disrupt the lamellar structure of lipid bilayers, and form mixed micelles composed of polymer and lipid. This process has a high efficiency, and the disruption of PC membranes in liposomes is general, as PEAAc disrupts distearoyl, dipalmitoyl, dimyristoyl, dilauroyl, and dioleoyl PC at low pH (*10*). These observations suggested that these polymers may be useful as a new class of drug delivery formulation components that enhance delivery of biomolecules to the cytoplasm.

We have recently shown that PEAAc and PPAAc efficiently induce red blood cell (RBC) hemolysis at lower pHs, such as those existing in endosomes (*13*, *14*). To be effective in assisting endosomal release of therapeutics, PEAAc and PPAAc must retain their hemolytic activity when conjugated to a protein. In this paper, we have prepared complexes of PPAAc and streptavidin at stoichiometries of 1:1 and 3:1 polymer to protein. This serves as a model to test the ability of the membrane−disruptive polymer when linked to a protein to disrupt the lipid bilayers of RBC membranes at the pHs existing in endosomes.

EXPERIMENTAL PROCEDURES

Polymer Preparation. Amine-terminated PPAAc (PPAAc−NH_2) was synthesized using established chain-transfer free-radical polymerization techniques. The propyl acrylic acid monomer was mixed with 1 mol % initiator (azobisisobutyronitrile) and 4 mol % chain-transfer agent (cysteamine). The mixture was degassed by first freezing in liquid nitrogen, and subsequently placed under vacuum and thawed. This was repeated three times. Polymerization was carried out at 60 °C. Two different PPAAc preparations were used in subsequent experiments. The product of the first PPAAc polymerization reaction was fractionated by preparative gel permeation chromatography (GPC), while ether precipitation was used to remove small polymer chains from the second PPAAc polymerization products.

Biotinylation of PPAAc. PPAAc−NH_2 was biotinylated using sulfosuccinimidyl-6-(biotinamido)-6-hexanoate (EZ-Link sulfo-NHS-LC−biotin, Pierce). PPAAc−NH_2 was dissolved in 0.1 M sodium phosphate and 0.15 M NaCl, pH 7.4. The NHS-LC-biotin was dissolved in water at a concentration of 20 mg/mL and added to each of the polymers at a 20 times molar excess. This was reacted for 2 h at room temperature. The biotinylation was repeated using a 15 times molar excess of biotin to maximize the yield of biotinylated polymer molecules. The samples were purified using a PD-10 desalting column (Pharmacia) in order to ensure that all the free biotin was removed. Absorbance at 220 nm was used to detect which fractions contained polymer, and these fractions were subsequently pooled.

Determination of Concentration of PPAAc−Biotin. To determine the concentration of the biotinylated PPAAc (PPAAc−biotin), the neutravidin-HABA dye assay was used. A total of 1.5 mg of neutravidin (Molecular Probes) was dissolved in 3 mL of 0.1 M sodium phosphate and 0.15 M NaCl, pH 7.4. 4′-Hydroxyazobenzene-2-carboxylic acid (HABA) (Sigma) was dissolved in 10 mM NaOH at a concentration of 2.42 mg/mL (10 mM), and 75 μL was added to the protein. D-Biotin (Sigma) was dissolved in 0.1 M sodium phosphate and 0.15 M NaCl, pH 7.4, at a concentration of 0.5 mM. This solution was added in 10 μL aliquots to the protein−HABA complex, while the absorbance at 500 nm was measured after each addition. By plotting the absorbance at 500 nm versus the amount of biotin added, the calibration curve was constructed. In parallel, incremental amounts of PPAAc−biotin were added to the neutravidin and HABA solution, and the absorbance at 500 nm was measured. The slope of the curve generated was compared to the calibration curve in order to determine the concentration.

Hemolysis Assay. The pH-dependent membrane-disruptive activity of the PPAAc was measured using a red blood cell (RBC) hemolysis assay. RBCs were harvested by centrifuging whole blood for 4 min. They were washed three times with 100 mM dibasic sodium phosphate at the desired pH, and resuspended in the same buffer to yield the initial volume. They were diluted 10 times in the same buffer, and 200 μL of this suspension was used for each tube. This yields 10^8 RBCs per tube. Each tube contained 800 μL of buffer, 200 μL of the RBC suspension, and the polymer. Each sample was done in triplicate, and was then repeated to verify reproducibility. The tubes were incubated for an hour and a half in a 37 °C incubator. They were spun for 5 min at full speed in the microcentifuge. Lysis was determined by measuring the absorbance of the supernatant at 541 nm, reflecting the amount of hemoglobin which had been released into the supernatant. Percent hemolysis was calculated assuming 100% lysis to be measured by the hemoglobin released by the red blood cells in water; controls of RBCs in buffer with no polymer or in buffer with added streptavidin were also run.

RESULTS

Polymer Preparation and Properties. To investigate the importance of polymer polydispersity, the PPAAc was fractionated by preparative GPC. The resulting polymer mixture displayed an average molecular mass that is equivalent to a PEG standard of 20 kDa. We found that the hemolytic activity of the polymer was not strongly dependent on the degree of polydispersity, as ether-precipitated PPAAc with higher polydispersities demonstrated the same hemolytic activity as fractionated PPAAc.

Biotinylation of PPAAc. The neutravidin-HABA assay was used to determine the fraction of PPAAc that was biotinylated. The results demonstrate that no detectable quantity of the polymer remains unbiotinylated. In addition, if unbiotinylated PPAAc remained in the mixture, we would expect that the concentration dependence of the hemolysis assay (below) would be shifted to reflect the higher concentration added by the nonderivatized polymer. The biotinylation of PPAAc was also verified with an SDS−PAGE gel shift assay (Figure 2). Samples of streptavidin alone, a physical mixture of streptavidin and PPAAc−NH_2, and a complex of streptavidin and PPAAc−biotin were analyzed. The biotin−streptavidin affinity was exploited to create the streptavidin−biotinylated polymer complex as diagrammed in Figure 3. Because the polymer is negatively charged at neutral pH, the streptavidin−biotinylated PPAAc complex migrates further in the gel. The physical mixture of streptavidin and PPAAc−NH_2 does not display a shift in electrophoretic mobility, indicating that the interaction between streptavidin and PPAAc is specifically mediated by biotin.

Hemolysis Assay. The abilities of five different samples to hydrolyze RBCs were compared. Test samples included amine-terminated PPAAc; biotinylated PPAAc; a physical mixture of streptavidin + amine-terminated PPAAc; a streptavidin−biotinylated PPAAc complex; streptavidin alone; and RBCs alone. The abilities of these samples to

disrupt RBC membranes was investigated for a range of polymer concentrations, a range of pH values, and for two polymer-to-streptavidin ratios of 3:1 and 1:1. Figure 4 shows the effect of concentration of PPAAc on hemolysis

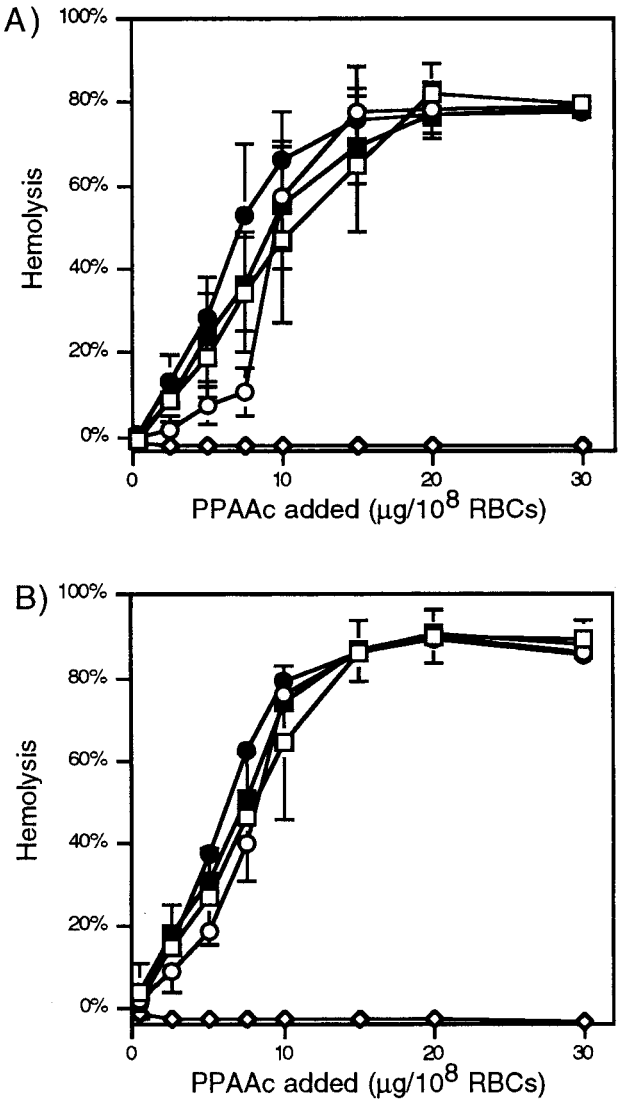

Figure 4. Concentration dependence of hemolytic activity for PPAAc−NH_2 (open squares), PPAAc-biotin (open circles), streptavidin + PPAAc−NH_2 physical mixture (closed squares), streptavidin/PPAAc-biotin complex (closed circles), and streptavidin alone (diamonds), with a polymer:protein stoichiometry of 3:1 (A) and 1:1 (B).

at pH 5 for a polymer-to-protein ratio of 3:1 (Figure 4A) and 1:1 (Figure 4B). All the samples containing PPAAc display equivalent hemolytic activity, as illustrated by the superimposable curves of all derivatives of PPAAc, which are normalized to the weight of PPAAc in each sample. The maximum hemolytic capability is reached at roughly 15 μg of PPAAc per 10^8 RBCs. Figure 5 displays the % hemolysis versus pH for PPAAc at a concentration of 15 μg of polymer per 10^8 RBCs. Results for polymer-to-protein ratios of 3:1 and 1:1 are presented in Figure 5. A sharp dependence on pH is demonstrated, with no significant hemolytic activity at pH 7.4 and a maximum achieved by pH 6.3.

DISCUSSION

The results show that PPAAc hemolyzes red blood cells with the same efficiency whether as a free polymer or complexed via biotin to the protein streptavidin. The hemolysis versus concentration profile is virtually identical for all samples containing PPAAc, indicating that the hemolytic activity of PPAAc is not affected by its linkage to a protein. Hemolysis by PPAAc reaches its maximum

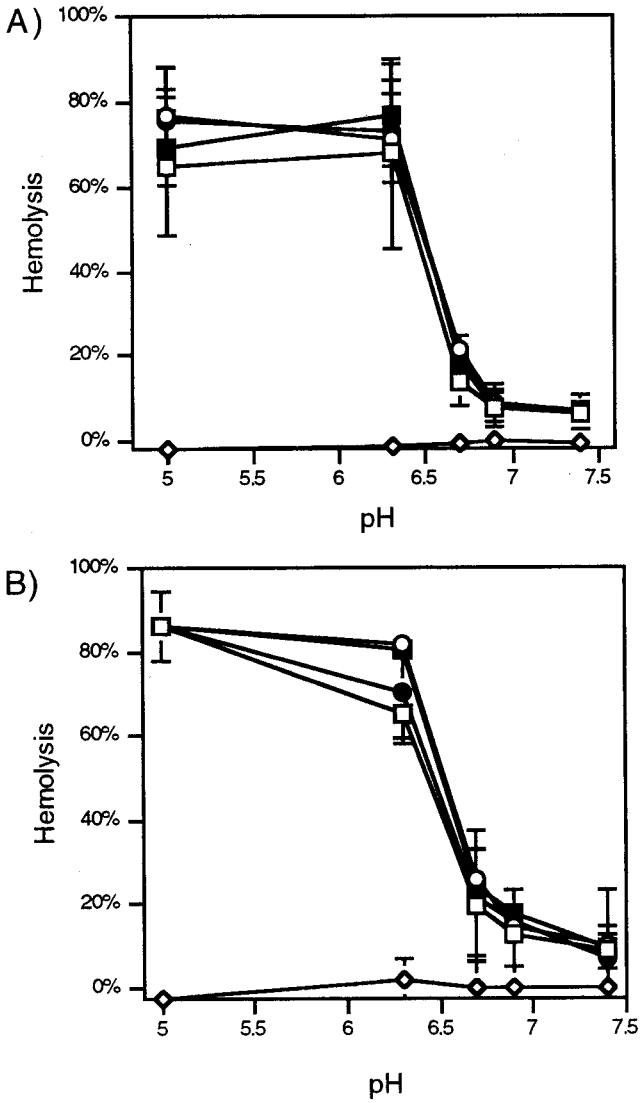

Figure 5. pH dependence of hemolytic activity for PPAAc−NH_2 (open squares), PPAAc-biotin (open circles), streptavidin + PPAAc−NH_2 physical mixture (closed squares), streptavidin/PPAAc-biotin complex (closed circles), and streptavidin alone (diamonds), with a polymer:protein stoichiometry of 3:1 (A) and 1:1 (B). All samples with polymer contained 15 μg of PPAAc.

at ca. 15 μg of polymer/10^8 red blood cells, which corresponds to ca. 4.5×10^6 molecules of PPAAc/red blood cell. Since polymer-to-protein ratios of 3:1 and 1:1 displayed equivalent activity, we can conclude that it is unnecessary to have more than one polymer chain complexed per protein molecule to achieve a highly efficient membrane lytic activity. The hemolysis versus pH curves were also identical for the free PPAAc and for the PPAAc−protein conjugates at both PPAAc:protein ratios. The hemolysis is strongly pH dependent, with the transition from negligible lysis to maximum lysis occurring as the pH decreases over a narrow range from pH 6.9 to 6.3. Thus, linkage of PPAAc to the protein does not affect the pH-dependent conformational and physical change of the polymer and its ability to disrupt the RBC membrane.

We have not investigated the mechanism of this action, but Tirrell and co-workers have studied the disruption of liposomes by PEAAc (*15*). Their surface tensiometry results were consistent with a micellization process driven by hydrophobic interactions of the polymer and the lipid bilayer. Such a mechanism is similar to that seen for amphiphilic, α-helix-based polypeptides, but the polymer is unlikely to adopt a secondary structure, implying that the hydrophobic-to-hydrophilic ratio is the most important factor in liposome micellization (*15*). They also found that the rate of micellization was determined by the rate and extent of PEAAc absorption, which in turn was determined by the lateral compressibility of the membrane (*16*). In comparison, melittin, the most membrane disruptive peptide known, was less effective on a molar basis (*17*).

The ability of the PPAAc−streptavidin complexes to disrupt RBC membranes at lowered pHs, such as those present in endosomes, suggests that these unusual pH-responsive polymers represent a new avenue to facilitate endosomal release and to improve the intracellular delivery of protein or DNA therapeutics.

Efficient Gene Transfer by Histidylated Polylysine/pDNA Complexes

Patrick Midoux* and Michel Monsigny

Centre de Biophysique Moléculaire, Glycobiologie CNRS UPR4301 and University of Orléans, rue Charles-Sadron, F-45071 Orléans Cedex 02, France. Received September 14, 1998; Revised Manuscript Received December 22, 1998

Plasmid/polylysine complexes, which are used to transfect mammalian cells, increase the uptake of DNA, but plasmid molecules are sequestered into vesicles where they cannot escape to reach the nuclear machinery. However, the transfection efficiency increases when membrane-disrupting reagents such as chloroquine or fusogenic peptides, are used to disrupt endosomal membranes and to favor the delivery of plasmid into the cytosol. We designed a cationic polymer that forms complexes with a plasmid DNA (pDNA) and mediates the transfection of various cell lines in the absence of chloroquine or fusogenic peptides. This polymer is a polylysine (average degree of polymerization of 190) partially substituted with histidyl residues which become cationic upon protonation of the imidazole groups at pH below 6.0. The transfection efficiency was optimal with a polylysine having 38 ± 5% of the ϵ-amino groups substituted with histidyl residues; it was not significantly impaired in the presence of serum in the culture medium. The transfection was drastically inhibited in the presence of bafilomycin A_1, indicating that the protonation of the imidazole groups in the endosome lumen might favor the delivery of pDNA into the cytosol.

INTRODUCTION

Poly-L-lysine, which strongly interacts with DNA, may be used to compact plasmid DNA (pDNA) in order to increase the uptake of foreign genes in mammalian cells with the aim to transfect them. The resulting polyplexes—a polyplex is a cationic polymer/DNA complex (*1*)—are taken up by the cells via either a nonspecific endocytosis or a receptor-mediated endocytosis after polylysine substitution with a recognition signal (for reviews, see refs *2*−*5*). However, one of the main limiting factors for the transfection is the inefficacy of the delivery of plasmids into the cytosol from the endocytotic vesicles. Indeed, upon internalization, most of the plasmid molecules are sequestered for several hours into vesicles from where very few plasmid molecules can escape to reach the nuclear machinery. Polyfection—polyfection is a polyplex-mediated transfection—was shown to be much more efficient when cells were incubated in the presence of membrane-disrupting agents such as chloroquine (*6*−*8*), glycerol (*9*), or fusogenic peptides which destabilize the membrane of acidic vesicles containing polyplexes (*7*, *10*−*17*). Therefore, the designing of cationic polymers inducing pDNA compaction and membrane disruption in a slightly acidic medium will be good candidates to help the pDNA to enter the cells and to escape the endocytotic pathway leading to the delivery to lysosomes. Knowing that (i) the imidazole group of histidine has a p*K* around 6.0 and thus becomes cationic in a slightly acidic medium and (ii) poly-L-histidine mediates an acid-dependent fusion and leakage of negative charged liposomes (*18*, *19*), we planned to use a histidylated cationic polymer as a vector for transfecting cells. Because poly-L-histidine is not charged at pH 7.4 and does not form complexes with pDNA at neutral pH, polylysine was partially substituted with histidyl residues.

In the present work, we show that (i) histidylated poly-L-lysine was suitable to make complexes with pDNA and to efficiently transfect various cell lines in the absence of chloroquine or fusogenic peptides; (ii) the highest gene transfer efficiency was obtained with a polylysine (average degree of polymerization of 190) having 38 ± 5% of the ϵ-amino groups substituted with histidyl residues; (iii) the transfection was rather insensitive to the presence of serum in the culture medium; and (iv) the transfection efficiency depended on the protonation of the imidazole groups in the acid lumen of intracellular vesicles.

MATERIALS AND METHODS

Preparation of Partially Histidylated Polylysine (His-pLK). Poly-L-lysine and HBr 30000−50000 (pLK,[1] DP = 190) (Bachem Feinchemikalien, Bubendorf, Switzerland) (1 g in 200 mL H_2O) were passed through an anion-exchange column (Dowex 2 × 8, $^-$OH form, 20−50 mesh) in order to remove bromide ions (*20*). The eluate was neutralized with a 10% *p*-toluenesulfonic acid solution in water and freezed-dried. pLK *p*-toluenesulfonate salt (50 mg; 0.86 μmol) in 3 mL of dimethyl sulfoxide (Aldrich, Strasbourg, France) in the presence of diisopropylethylamine (42 μL; 288 μmol) (Aldrich) was reacted for 24 h at 20 °C with (Boc)His(Boc)-OH (32 mg; 96 μmol) (Novabiochem, Bad Soden, Germany) in the presence of benzotriazol-1-yl-oxy-tris-(dimethylamino) phosphonium hexafluorophosphate (Richelieu Biotechnologies, Saint Hyacinthe, Canada) (43 mg; 97 μmol). The N-protecting Boc groups were removed by acidic treatment by adding 20 mL of H_2O/trifluoroacetic acid mixture (1:1; v/v) for 24 h at 20 °C. Water and trifluoroacetic acid were removed under reduced pressure. The polymer was precipitated by adding 10 vol of 2-propanol and spun down by centrifugation (1800*g* for 15 min). The pellet was washed with 2-propanol, collected by centrifugation (1800*g* for 15 min), solubilized in distilled water, and freeze-dried. The average number of His molecules bound

per pLK molecule was determined by ^{1}H NMR spectroscopy at 300 MHz in D_2O according to $x = 6(h_{8.7}/h_{Lys})$DP, where $h_{8.7}$ was the value of the integration of the signal at 8.7 ppm corresponding to the proton (1H C_{12}) of His (Figure 1), h_{Lys} was in the range 1.3−1.9 ppm corresponding to the 6 methylene protons (C_3, C_4 and C_5) of lysine residues (Figure 1), and DP was the degree of polymerization of pLK. The number of His residues bound per pLK molecule was 70. Histidylated polylysine was fluoresceinylated by using fluoresceinyl isothiocyanate (FITC isomer I, Molecular Probe, La Jolla, CA) as previously described (*7*).

Cells and Cell Culture. COS-7 (SV40 transformed kidney cells of African green monkey, ATCC CRL 1651, ATCC, Rockville, MA), 293-T7 (human embryonic kidney producing T7 RNA polymerase) (*21*), and Rb1 (rabbit smooth muscle cells) (*22*) cells were cultured in DMEM (Gibco, Renfrewshire, U.K.) supplemented with 10% heat inactivated fetal bovine serum (FBS, Gibco); HeLa cells (ATCC CCL 2.1) in DMEM with 5% FBS; B16 cells (murine melanoma cells, ATCC CRL 6322) in DMEM with 10% heat-inactivated new borne calf serum (Gibco); HepG2 (human hepatoma cells, ATCC HB 8065), MCF-7 cells (human breast adenocarcinoma cells, ATCC HTB22), and HOS cells (human osteosarcoma cells, ATCC CRL 1543) in MEM (Gibco) with 10% heat inactivated FBS; 16HBE cells (human airway epithelial cells) in DMEM with 10% heat-inactivated FBS in fibronectin-coated culture plates; A549 cells (human nonsmall cell lung carcinoma cells, ATCC CCL 185) in RPMI with 10% heat-inactivated FBS. All culture media were supplemented with 2 mM L-glutamine (Merck, Darmstadt, Germany) and antibiotics (100 units/mL penicillin and 100 μg/mL streptomycin, Eurobio, France). Cells were grown at 37 °C in a humidified atmosphere containing 5% CO_2 and 95% air. Cells were harvested by treatment with PET [PBS with 0.02% (w/v) EDTA and 2.5 μg/mL trypsin] at 37 °C for 5 min. Cells were mycoplasma free as evidenced by bisbenzimidazole (Hoechst 33258) (*23*).

Plasmids. pSV2*LUC* plasmid (5 kb) was an expression vector encoding the firefly luciferase gene under the control of the SV40 T large antigen promoter (*24*). pUT650 plasmid (5.15 kb) (CAYLA, Toulouse, France) was an expression vector encoding the firefly luciferase gene under the control of the human cytomegalovirus promoter. Supercoiled DNA plasmids were isolated by a standard alkaline lysis method followed by CsCl gradient centrifugation in the presence of ethidium bromide, extensive extraction with *n*-butanol, and precipitation with ethanol.

Polyfection. Polyplexes (histidylated polylysine or polylysine/pDNA complexes) were prepared by adding, under agitation, polymers in 0.3 mL of serum-free DMEM, pH 7.4 to 5 μg (1.5 pmol) of plasmid in 0.7 mL of serum-free DMEM. The mixed solution was kept for 30 min at 20 °C before use. Adherent cell lines [(2−4) × 10^5 cells] were plated (day 0) into 4 cm^2 culture dishes (12-well culture plates). On day 1, the medium was removed and 1 mL of a solution containing a polyplex supplemented with 1% FBS, unless otherwise specified, was added into each well. After 4 h of incubation at 37 °C in a humidified atmosphere (95% air, 5% CO_2), the medium was removed and cells were further incubated at 37 °C in 2 mL of the relevant complete culture medium in a humidified atmosphere (95% air, 5% CO_2). When used, chloroquine (100 μM) was added to the transfection solution, which was immediately supplemented with 1% FBS and put into each well. When used, the fusogenic peptide (E5CA, GLFEAIAEFIGGWEGLIEGCA) (*7*) (10 μM) was added and the transfection solution was immediately supplemented with 1% FBS and put into each well.

Polyethylenimine (PEI 25 kDa from Aldrich) (4.5 mg) was dissolved in 10 mL of H_2O, neutralized with HCl, and sterilized by filtration. Polyplexes were prepared by mixing 10 μL of PEI in 50 μL of 0.15 M NaCl with 5 μg (1.5 pmol) plasmid in 50 μL 0.15 M NaCl. The mixed solution was kept for 30 min at 20 °C. Then, the solution supplemented with 1 mL of DMEM containing 10% FBS was added into each well. After 4 h of incubation at 37 °C in a humidified atmosphere (95% air, 5% CO_2), the medium was removed and cells were further incubated at 37 °C in 2 mL of the relevant complete culture medium in a humidified atmosphere (95% air, 5% CO_2).

Luciferase Assay. Luciferase gene expression was measured by monitoring its luminescence activity according to De Wet et al. (*25*). The medium was discarded, and the cells were washed three times with PBS. The homogenization buffer (200 μL of 8 mM $MgCl_2$, 1 mM DTT, 1 mM EDTA, 1% Triton X100, 15% glycerol, 25 mM Tris-phosphate buffer, pH 7.8) was poured into each well, and the tissue culture plates were kept for 15 min at 20 °C. The solution was recovered and further spun down (5 min at 800*g*). A total of 95 μL of a 2 mM ATP solution in the homogenization buffer without Triton X100 was added to 60 μL of supernatant, and the solution was shaken with a vortex. The luminescence was recorded for 4 s in a Lumat LB 9501 luminometer (Berthold, Wildbach, Germany) upon addition of 150 μL of a 167 mM luciferin solution in water. Measurements were done in duplicate. The data shown correspond to the number of relative light units (RLU) from 10^6 cells. The number of RLU of 1 pg/mL of luciferase was 2000 under these assay conditions.

ζ Potential Measurement. Polyplexes were prepared in 10 mM NaCl, 1 mM MOPS, and 0.1 mM EDTA, at pH 7.2 to a pDNA final concentration of 10 μg/mL. ζ potential was measured by using a ZetaSizer 3000 (Malvern Instruments, Orsay, France) with the following parameters: viscosity, 1.014 cP; dielectric constant, 79; temp, 25 °C; *F*(Ka), 1.50 (Smoluchowsky); current, 10 mA.

RESULTS

Polyfection by Using Histidylated Polylysine. Histidylated polylysine containing 84 histidyl residues (His_{84}-pLK) (Figure 1) was complexed in 1 mL of serum-free DMEM at pH 7.4 with pUT650 plasmid encoding the luciferase gene, and the polyplexes were used to transfect HepG2 cells. The luciferase activity in the cell lysates was compared to that obtained after polyfection with pLK/pUT650 complexes in the absence and in the presence of either chloroquine or E5CA, a fusogenic peptide. Regarding to the luciferase activity, the polyfection was very efficient with His_{84}-pLK/pDNA complexes and very inefficient with pLK/pDNA complexes. The luciferase activity was 4.5 orders of magnitude (10^7

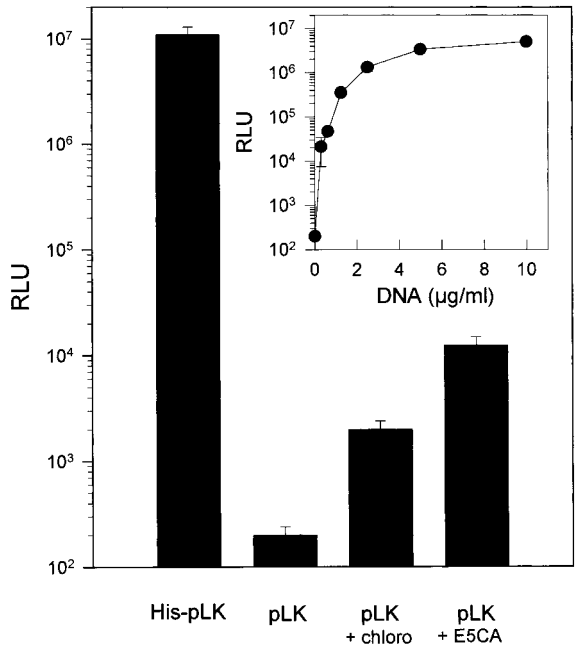

Figure 2. Histidylated polylysine mediated polyfection. Polyplexes were prepared by mixing either His_{84}-pLK (40 μg) or pLK (5 μg) in 0.3 mL of serum-free DMEM with 10 μg (3 pmol) of pUT650 plasmid in 0.7 mL of serum-free DMEM. The solution was kept for 30 min at 20 °C. When it is relevant the solution was made 100 μM in chloroquine or 10 μM in E5CA. HepG2 cells (3×10^5 cells plated in a 4 cm^2 well) were incubated for 4 h at 37 °C with polyplexes in the presence of 5% FBS. Then cells were washed and incubated in complete culture medium containing 10% FBS. The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells. (Inset) Concentration dependence of polyfection with His_{84}-pLK/pDNA complexes.

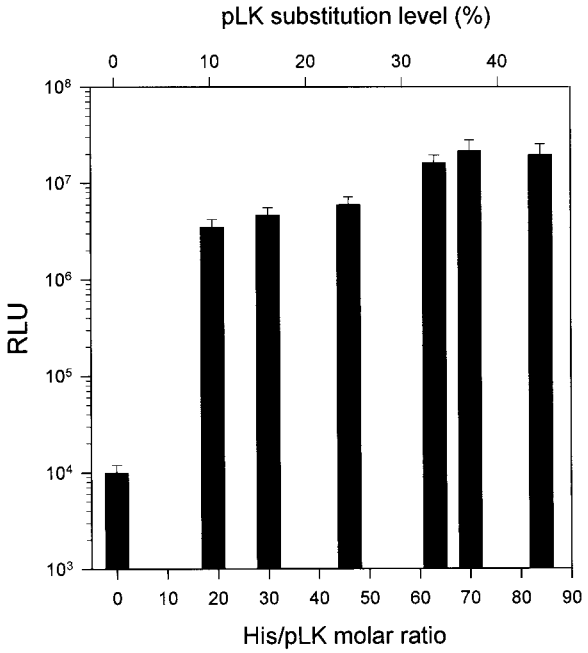

Figure 3. Histidylated polylysine mediated polyfection:influence of the His/pLK ratio. Polyplexes were prepared by mixing pLK substituted with histidyl residues in 0.3 mL of serum-free DMEM with 10 μg (3 pmol) of pUT650 plasmid in 0.7 mL of serum-free DMEM. The solution was kept for 30 min at 20 °C. HepG2 cells (3×10^5 cells plated in a 4 cm^2 well) were incubated for 4 h at 37 °C with polyplexes in the presence of 1% FBS. Then, cells were washed and incubated in complete culture medium containing 10% FBS. The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells.

RLU/10^6 cells) higher than with pLK/pDNA complexes (200 RLU/10^6 cells); it was 3.5 (2×10^7 RLU/10^6 cells) and 3 (10^7 RLU/10^6 cells) orders of magnitude higher than with pLK/pDNA complexes in the presence of chloroquine and the fusogenic peptide, respectively (Figure 2). The luciferase activity was maximal when the cells were incubated for about 3−4 h in the presence of His_{84}-pLK/pDNA complexes (data not shown); increasing the incubation period (up to 24 h) did not increase the luciferase activity. It is noteworthy to emphasize that no cytoxicity was observed whatever the incubation duration (from 4 to 24 h) in the presence of the polyplexes. The amount of plasmid was varied between 0.05 and 10 μg, keeping constant the histidylated polylysine/pDNA ratio equal to 4:1 (weight by weight), the number of cells per well [(2−3) $\times 10^5$ cells in a 4 cm^2 well] and the volume (1 mL) of the solution containing the polyplexes. The polyfection was maximal in the presence of 5 μg of plasmid. Increasing the amount of plasmid did not increase the luciferase activity (Figure 2 inset). Increasing the number of cells per well did not increase the luciferase activity.

Optimal Number of Histidyl Residues on One Polylysine Molecule. HepG2 cells were transfected by using polyplexes made with pUT650 and polylysine substituted with different number of histidyl residues. The luciferase activity in cell lysates was maximal with polylysine substituted with 72 ± 9 histidyl residues/pLK molecule corresponding to 38 ± 5% substitution of the polylysine ϵ-amino groups (Figure 3). When polyfection was performed with pLK containing 20 histidyl residues, the luciferase activity was 10-fold lower than with pLK substituted with 70 histidyl residues.

Influence of the Histidylated Polylysine/pDNA Molar Ratio. The luciferase activity was maximal with polyplexes made by complexing 10 μg of plasmid with 30 (polymer/pDNA molar ratio of 183) to 40 μg (polymer/pDNA molar ratio of 244) of His_{84}-pLK (Figure 4). Increasing the molar ratio did not increase the luciferase activity. The efficiency decreased 10-fold when the molar ratio was down to 122 (20 μg of His_{84}-pLK) and was completely inefficient when the molar ratio was lower than 60 (10 μg of His_{84}-pLK). Under conditions optimal for transfection, polyplexes were positively charged with a ζ potential of +24 mV (Figure 4).

Influence of the Serum Concentration. Polyfection with His_{70}-pLK was not impaired in the presence of serum. The luciferase activity was 2-fold greater in the presence of 5 and 10% FBS than in the presence of 1% FBS, and it was as large in the presence of 20% FBS as in the presence of 1% FBS (Figure 5).

Gene Transfer into Various Cell Lines. The transfection of different mammalian cell lines including human hepatoma cells (HepG2), human breast adenocarcinoma cells (MCF-7), human epidermoid carcinoma cells (HeLa), human osteosarcoma cells (HOS), human airway epithelial cells (16HBE), murine melanoma cells (B16), and simian kidney cells (COS) was assessed by using His_{70}-pLK/pUT650 complexes and rabbit smooth muscle cells (Rb-1) by using His_{70}-pLK/pSV2*LUC* complexes. All the cell lines (except COS cells) were efficiently transfected with luciferase activity ranging from 2×10^6 to 10^7 RLU/10^6 cells (Figure 6). The transfection was compared with that obtained with PEI/pDNA complexes (Table 1). Depending on the cell line, the transfection by His-pLK/pDNA complexes was as effective or less effective (up to 20-fold) than with PEI/pDNA complexes.

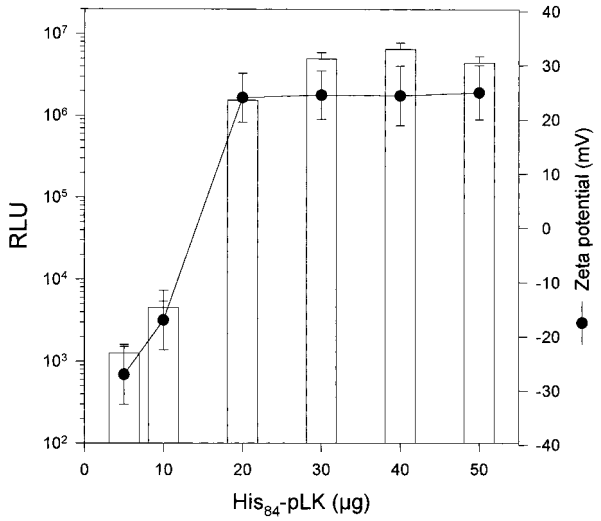

Figure 4. Histidylated polylysine mediated polyfection:influence of the polymer/pDNA ratio and ζ potentials of polyplexes. Polyplexes were prepared by mixing 10 μg (3 pmol) of pUT650 plasmid in 0.7 mL of serum-free DMEM with different amounts of histidylated polylysine (His_{84}-pLK) in 0.3 mL of serum-free DMEM. The solution was kept for 30 min at 20 °C. HOS cells (2×10^5 cells/4 cm^2) were incubated for 4 h at 37 °C with polyplexes in the presence of 5% FBS. Then cells were washed and incubated in complete culture medium containing 10% FBS. The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells.

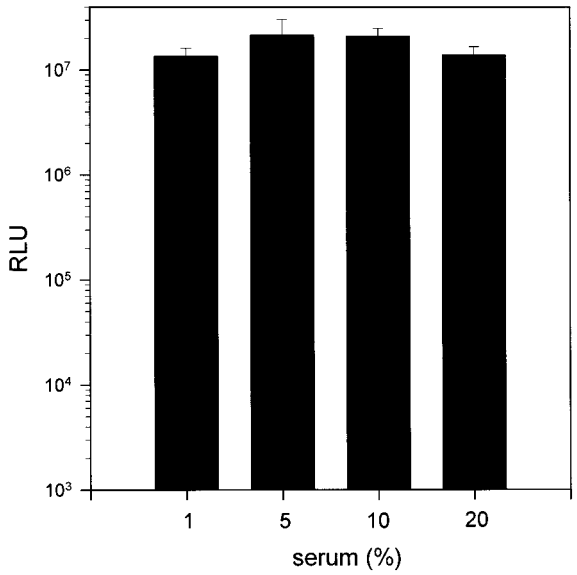

Figure 5. Histidylated polylysine mediated polyfection:influence of the serum. HepG2 cells (3×10^5 cells/4 cm^2 well) were incubated for 4 h at 37 °C with 5 μg/mL of the polyplexes (His_{70}-pLK/pUT650) in the presence of various amount of FBS. Then, cells were washed and incubated in complete culture medium containing 10% FBS. The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells.

Influence of the Endosomal pH. Histidylated polylysine is supposed to increase the delivery of pDNA into the cytosol via membrane destabilization of acidic endocytotic vesicles containing His_{70}-pLK/pDNA complexes following the protonation of the imidazole groups. This was assessed by transfecting cells in the absence or in the presence of bafilomycin A_1, an inhibitor of vacuolar ATPase endosomal proton pump (*26*). When the polyfection of Rb-1 cells by His_{70}-pLK/pSV2*LUC* complexes was performed in the presence of 200 nM bafilomycin A_1, the luciferase activity into cells was about 3 order of magnitude lower than in the absence of bafilomycin A_1 (Figure 7). A flow cytometry analysis showed that, in the absence of bafilomycin A_1 , the polyplexes were in acidic compartment as evidenced by a 1.8-fold increase of the cell fluorescence intensity after a postincubation in the presence of monensin (*27*, *28*); conversely, the fluorescence intensity of cells incubated in the presence of bafilomycin A_1 did not increase upon a postincubation in the presence of monensin (data not shown). Therefore, the decrease of the transfection efficiency of histidylated polylysine/pDNA complexes in the presence of bafilomycin A_1 , indicated that the protonation of the imidazole groups in acidic medium was involved in the polyfection process.

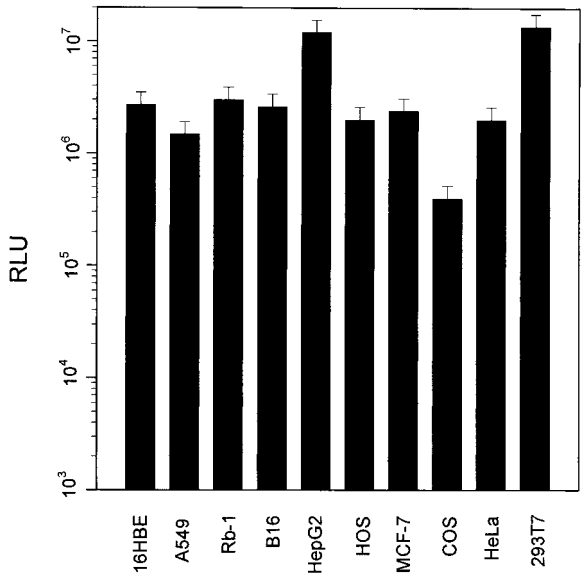

Figure 6. Histidylated polylysine mediated polyfection of various cell lines. Polyplexes were prepared by mixing His_{70}-pLK (30 μg) in 0.3 mL serum-free DMEM with 10 μg (3 pmol) of plasmid (pUT650 or pSV2*LUC* for Rb-1 cells) in 0.7 mL of serum-free DMEM. The mixed solution was kept for 30 min at 20 °C. Cell lines [$(2-3) \times 10^5$ cells/4 cm^2 well] were incubated for 4 h at 37 °C with polyplexes in the presence of 10% FBS. Then, cells were washed and incubated in complete culture medium containing 10% FBS. The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells.

Table 1. Comparison of the Transfection Efficiency by Using Either Histidylated Polylysine or Polyethylenimine as DNA Carriers[a]

cells	PEI/His-pLK	cells	PEI/His-pLK
B16	5.8	A549	21
293	0.6	Rb-1	17

[a] Cells (2×10^5 cells/4 cm^2 well) were transfected for 4 h at 37 °C with 5 μg/mL (pUT650 or pSV2*LUC* for Rb-1 cells) complexed with either His-pLK or PEI in the presence of 10% FBS. Then, cells were washed and incubated in complete culture medium containing 10% FBS. The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. PEI/His-pLK represents the ratio of the luciferase activity into cells transfected by PEI polyplexes to the luciferase activity into cells transfected by His-pLK polyplexes.

DISCUSSION

The introduction in mammalian cells of a foreign gene as a plasmid DNA by nonviral vectors requires the entry of the plasmid into the cell and then into the nucleus.

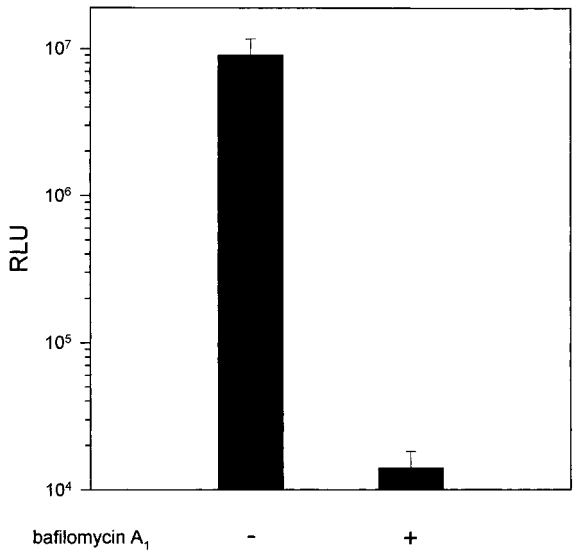

Figure 7. Influence of bafilomycin A1 on the polyfection efficiency. Rb-1 cells (2×10^5 cells/4 cm^2 well) were incubated at 37 °C in the presence of 1 mL His_{70}-pLK/pSV2*LUC* complexes (5 μg of pDNA) and in the absence or in the presence of 200 nM bafilomycin A_1. After 4 h, the cells were washed and incubated in complete culture medium containing 10%. The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells.

The compaction of a pDNA in the presence of polylysine increases its uptake by the cells via making the endocytotic process more easy. Once complexed and taken up by cells, plasmids are sequestered for several hours in vesicular compartments from where they cannot escape to reach the nucleus. The delivery of the pDNA into the cytosol should be obtained from early acidic vesicles formed during polyplex uptake under the condition that the endosomal membrane is disrupted by devices bound to the plasmid-associated carrier working at a weakly acidic medium. In this study, we show that partial substitution of poly-L-lysine with histidyl residues results in a cationic polymer that forms complexes with a plasmid DNA at pH 7.4. These complexes actively transfect cells in culture in the absence of any helper compounds such as chloroquine or a fusogenic peptide. Optimal conditions for transfection were found when polylysine was substituted with 72 ± 9 histidyl residues, corresponding to a polylysine substitution level of $38 \pm 5\%$; the efficiency was 10-fold lower when polylysine substitution was down to 10%. The polyfection was efficient when the global charge of the polyplexes was slightly positive (ζ potential = +24 mV), which likely increased their binding on the cell surface and facilitated their uptake by the cells.

The polyplexes are internalized by the cells in acidic compartments. The mechanism of polyfection mediated by histidylated polyplexes is not yet known, but it is supposed that a subsequent delivery of pDNA into the cytosol occurs by the membrane destabilization of acidic vesicles containing polyplexes, upon the protonation of imidazole groups. Although, there is no evidence that the DNA leaves endocytotic vesicles, this statement is supported by (i) the fact that poly-L-histidine induces fusion of lipid bilayers (*18*, *19*) and (ii) the fact that bafilomycin A_1 which is known to impair the acidification of the lumen of the endosomes, made polyfection inefficient. Poly-L-histidine destabilizes lipid bilayers in a slightly acidic medium and induces fusion upon protonation of the imidazole groups by increasing interactions between this polymeric polycation and the membrane phospholipids (*18*). In acidic medium, poly-L-histidine is more fusogenic than polylysine: efficient fusion of negatively charged liposomes (phosphatidylserine liposomes) occurs at a ratio of the positive charge of poly-L-histidine to the negative charge of the liposomes equal to 0.2 while it occurs at a ratio equal to 1 in the case polylysine. Recently, we have reported that the amphipatic peptide H5WYG (GLFHAIAHFIHGGWHGLIHGWYG) containing five histidyl residues, which does not adopt a helical structure in acidic medium, permeabilizes cell membranes in such an acidic medium (pH 6.4) (*17*). In addition, this peptide increased the expression efficiency when a gene is transferred into cells as glycosylated polylysine/pDNA complexes; the transfection was also inhibited in the presence of bafilomycin A_1 (*17*). These results suggest that the generation of cationic charges via the protonation of several imidazole groups bound to pDNA inside the endosomes consecutively to the acidification of their lumen is a suitable approach to modify the intracellular routing of pDNA, especially its delivery into cytosol. Therefore, the mechanism involved for polyfection with histidylated polylysine could be different from that of polyethylenimine which is supposed to act as a buffer, preventing acidification of the endosomal lumen and inducing the swelling of these vesicles, leading to a membrane destabilization (*29*).

The transfection efficiency by using histidylated polylysine/pDNA complexes was greater than by using polylysine/pDNA complexes in the presence of either chloroquine or the fusogenic peptide E5CA. Chloroquine concentrates in the acidic compartments and prevents the delivery of the endosomal content to lysosomes; it induces the formation of large endosome-derived vacuoles. In addition, it allows the dissociation of pDNA/polylysine conjugate complexes (*8*). Anionic permeabilizing peptides, adopting an α-helical structure at pH <5.5, may destabilize the membrane of weakly acidic vesicles containing the polyplexes leading to the delivery of pDNA into the cytosol. Histidylated polyplexes were efficient for all cell types tested while the efficiency of anionic peptides such as E5CA depends on several parameters in relation with the cell type. These parameters include the number of vesicles containing both polylysine/pDNA complexes and peptides separately taken up, the peptide concentration, and the luminal pH of the vesicles. In addition, histidylated polylysine may destabilize membranes as well as H5WYG peptide at a pH less acidic than E5CA peptide and thus may be effective in early endosomes at pH around 6.4; at this pH, anionic peptides were inefficient.

Chloroquine and fusogenic peptides cannot be used in vivo. Indeed, (i) they are small molecules which are cleared soon after their injection; (ii) chloroquine must concentrate in acidic vesicles and reach a high concentration before being able to induce an efficient transfection (*8*); (iii) polyplex solution to be injected cannot contain a high concentration of chloroquine, because above 1 mM chloroquine, polyplexes start to dissociate (*8*); (iv) the effect of anionic peptides bearing negative charges at neutral pH is inhibited in the presence of serum probably because they bind to serum proteins, and in addition, the effect is diminished when they are chemically linked to polyplexes. With histidylated polylysine, the membrane-disrupting device is bound to the plasmid and the transfection efficiency was not significantly reduced in the presence of serum up to 20%.

In conclusion, histidylated polylysine, a synthetic compound, easy to prepare and to purify, is a good

nonviral vector for gene transfer into mammalian cells. Histidylated polylysine gives polyplex formulation suitable for transferring gene in vivo. In addition, histidylated polylysine may be substituted with recognition signal molecules in order to deliver the gene into cells which specifically express a related receptor; this aspect is currently under development in our laboratory.

ACKNOWLEDGMENT

We express our gratitude to Dr. A. B. Brasier (Massachusetts General Hospital, Boston, MA) for pSV2*LUC* plasmid, Dr. D. C. Gruenert (Gene Therapy Core Center, University of California, San Francisco), Dr. M. Nachtigal (University of South Carolina, Columbia, SC), and Dr. L. Huang (University of Pittsburgh, Pittburgh, PA) for 16HBE, Rb-1, and 293-T7 cells, respectively. We thank Mahajoub Bello-Roufaï for ζ potential measurements and Sophie Fauvin and Suzanne Nuques for their skillful technical helps in cell culture and transfections. We thank Françoise Fargette for the preparation of plasmids and Henri Labbé for his skillfull assistance in NMR spectroscopy. Temperature Sensitization of Liposomes Using Copolymers of *N*-Isopropylacrylamide

Hiroshi Hayashi,[†] Kenji Kono,*[,‡] and Toru Takagishi[‡]

Shiga Central Research Laboratories, Noevir, Co., Ltd., Yokaichi, Shiga 527-8588, Japan, and Department of Applied Materials Science, College of Engineering, and Department of Applied Bioscience, Research Institute for Advanced Science and Technology, Osaka Prefecture University, Sakai, Osaka 599-8531, Japan.
Received September 15, 1998; Revised Manuscript Received December 30, 1998

To obtain liposomes which release the contents in response to ambient temperature, liposomes modified with copolymers of *N*-isopropylacrylamide with varying lower critical solution temperatures have been designed. Poly(*N*-isopropylacrylamide-*co*-acrylamide)s with various compositions were synthesized by free-radical copolymerization. The lower critical solution temperature of the polymer increased with increasing acrylamide content in the polymer. Poly(*N*-isopropylacrylamide-*co*-acrylamide-*co*-*N*,*N*-didodecylacrylamide)s were also prepared via the same method as the thermosensitive polymers having anchor groups to the liposome membrane. Calcein-loaded dioleoylphosphatidylethanolamine/egg yolk phosphatidylcholine (6:4, w/w) liposomes were coated with these polymers by incubating the liposomes with aqueous solutions of the polymers. The liposomes hardly released the contents below the lower critical solution temperature of the polymer, but the release was greatly enhanced above that temperature. The liposomes were also made from a mixture of the same lipids and the polymer. The liposome revealed a more drastic release property than the liposomes prepared by the incubation with the polymer solution, because the polymer chains were bound on both surfaces of the membrane. The close relationship between lower critical solution temperatures of the polymers and temperature regions where enhancement of the release from the polymer-fixed liposomes demonstrates that the release was triggered by alteration of the polymers from a hydrophilic state to a hydrophobic state occurring at their lower critical solution temperatures.

INTRODUCTION

Since liposomes made from naturally occurring lipids are biocompatible, their application to drug delivery systems has been extensively attempted (*1*). To elevate their usefulness, a number of liposomes with various functionalities have been designed. While several approaches to the production of functional liposomes have been employed, one of the most effective methods is modification of liposomes with functional polymers (*2*, *3*). For example, pH sensitization of liposomes using poly(2-ethylacrylic acid) has been reported by Tirrell and coworkers (*4*). They have shown that release of the contents from the polymer-modified liposomes is triggered under weakly acidic conditions. Also, Kitano et al. have prepared pH-responsive liposomes by using amphiphiles having acrylic acid oligomer moieties (*5*).

Recently, temperature sensitization of liposomes has been attempted using poly(*N*-isopropylacrylamide) [poly(NIPAM)][1] (*6*−*9*). It is well-known that poly(NIPAM) shows a lower critical solution temperature (LCST) at 30−35 °C (*10*, *11*). The polymer is hydrophilic and soluble in water below the LCST, but becomes hydrophobic and forms an insoluble aggregate above that temperature due to hydrophobic interactions and hydrogen bondings (*11*, *12*). Therefore, if the polymer chains are fixed on the liposome membrane, release of the contents from the liposomes is expected to be controlled by the interaction between the polymer and liposome membrane in a temperature-dependent fashion. In a previous study, we have demonstrated that liposomes bearing poly(NIPAM) release the contents above its LCST (*7*, *13*). In addition, aggregation and fusion of poly(NIPAM)-coated liposomes were induced above the LCST, indicating that surface property of the liposome is also made temperature sensitive by modification of liposomes with poly(NIPAM) (*14*).

Because temperature sensitivity of the liposome is considered to be given by alteration of the polymer chain from the hydrophilic state to the hydrophobic state in response to the ambient temperature, it is expected that liposomes which reveal the response at a desired temperature are obtained by the modification with polymers having LCST at that temperature. It is known that LCST of poly(NIPAM) can be controlled by copolymerization of NIPAM with comonomers with varying hydrophobicity or hydrophilicity (*15*−*17*).

The object of this study is to examine the possibility of temperature sensitization of liposomes using thermosensitive polymers which exhibit LCST at varying temperatures. We prepared phosphatidylcholine-phosphatidylethanolamine (4:6, w/w) liposomes modified with poly(NIPAM-*co*-acrylamide) with varying NIPAM/acryl-

amide (AAM) ratios and found that release of entrapped calcein from the copolymer-modified liposomes was greatly promoted above the LCST of the polymers. A close relationship between the temperature region where enhancement of the release was observed and the LCST of the polymer is reported.

EXPERIMENTAL SECTION

Materials. L-α-Dioleoylphosphatidylethanolamine (DOPE), egg yolk phosphatidylcholine (EYPC), and calcein were purchased from Sigma (St. Louis, MO). *N*-Isopropylacrylamide (NIPAM) was obtained from Tokyo Kasei (Tokyo, Japan). Azobis(isobutyronitrile) (AIBN), tris(hydroxymethyl)aminomethane (Tris), *N*,*N*-dimethylformamide, and ethylenediaminetetraacetic acid (EDTA) were supplied from Kishida Chemical (Osaka, Japan). *N*,*N*-Didodecylacrylamide (NDDAM) was prepared as described elsewhere (*18*). NIPAM and AIBN were purified by recrystallization from benzene-*n*-hexane and methanol, respectively.

Polymer Synthesis. Poly(NIPAM) and three kinds of poly(NIPAM-*co*-AAM)s were prepared by free-radical polymerization using AIBN as the initiator. NIPAM and AAM in the ratio of 10/0, 9/1, 8/2, or 7/3 (total 10 mmol) and AIBN (0.03 mmol) were dissolved in freshly distilled tetrahydrofuran (10 mL), and then the solution was heated to 60 °C for 6 h in N_2 atmosphere. The polymer was recovered by precipitation with diethyl ether and dried under vacuum. The polymer was dissolved in water, dialyzed against water for 4 days, and then recovered by lyophilization. Four kinds of poly(NIPAM-*co*-AAm-*co*-NDDAM)s were obtained by the same procedure except that NIPAM, AAM, and NDDAM in the ratios of 99/0/1, 89.1/9.9/1, 79.2/19.8/1, and 69.3/29.7/1 (total 10 mmol) were used as the monomers. Composition of polymers was estimated by elemental analysis and ^{1}H NMR.

Cloud Point Determination. Optical density of aqueous copolymer solutions (5 mg/mL) in 140 mM NaCl and 10 mM Tris-HCl-buffered solution (pH 7.4) at 500 nm was monitored using a spectrophotometer (Jasco V-520) with a water-jacketed cell holder coupled with a circulating bath. Temperature was raised at 0.3 °C/min. Cloud points were taken as the initial break points in the resulting transmittance versus temperature curves.

Liposome Preparation. Two types of polymer-fixed liposomes, namely liposomes having polymer chains on the outer surface of the membrane (Figure 1A) and liposomes having polymer chains on both sides of the membrane (Figure 1B), were prepared. Liposomes having polymer chains on the outer surface were obtained as follows. To a dry, thin membrane consisting of a mixture of DOPE (6 mg) and EYPC (4 mg), 1.5 mL of aqueous calcein solution (63 mM, pH 7.4) was added and sonicated for 15 min under an N_2 atmosphere using a probe-type sonicator (Tomy Seiko, UD-201). A given volume of polymer solution (10 mg/mL) containing 63 mM calcein (pH 7.4) was added to liposome suspension and kept at 5 °C for 12 h. Liposomes having polymer chains on both surfaces of the membrane were made by vortexing polymer/lipid mixed membranes in an aqueous 63 mM calcein solution and subsequent extrusion through a polycarbonate membrane filter with a pore size of 100 nm in an ice-cooled water bath. Free calcein and free polymer were removed by gel permeation chromatography on a Sephacryl-400 column at 4 °C using 10 mM Tris-HCl-buffered solution containing 140 mM NaCl and 0.1 mM EDTA at pH 7.4 as an eluent.

Calcein Release from Liposome. The release measurements were performed according to the method previously reported (*7*, *13*). An aliquot of dispersion of liposomes encapsulating 63 mM calcein was added to 2 mL of 10 mM Tris-HCl, 140 mM NaCl, and 0.1 mM EDTA solution (pH 7.4) in a quartz cell (final concentration of the lipids 5.0 μM) at a given temperature and the fluorescence intensity of the solution was monitored using a spectrophotofluorimeter (Hitachi, F-3010). The excitation and monitoring wavelengths were 490 and 520 nm, respectively. The percent release of calcein from liposome was defined as

$$\% \text{ release} = (F^t - F^i)/(F^f - F^i) \times 100$$

where F^i and F^t mean the initial and intermediary fluorescence intensities of the liposome suspension, respectively. F^f is the fluorescence intensity of the liposome suspension after the addition of Triton X-100 (final concentration, 0.15%). Since release of calcein was very fast above LCST of the copolymer, it was impossible to determine F^i. In contrast, release was slow below the LCST, and liposome hardly released calcein at 10 °C. Therefore, we used initial fluorescence intensity of the liposome suspension at 10 °C for F^i. Change in fluorescence intensity depending on temperature was corrected although the change was not significant under the experimental conditions.

Other Methods. The amount of polymer bound onto liposome was estimated by HPLC on an Asahipak GF-310HQ column using methanol as an eluent, according to the method previously reported (*14*). NMR spectra were taken with a JEOL JNM-GX 270 MHz instrument. Differential scanning calorimetry (DSC) was performed with a Seiko Electronics DSC 120 microcalorimeter. Size of liposome was evaluated by dynamic light scattering (Otsuka Electronics, LPA3100S). The weight average molecular weight (Mw) and the number average molecular weight (Mn) of polymers were estimated by GPC on a Shodex KD-803 columns (Showa Denko) using *N*,*N*-dimethylformamide as an eluent and poly(ethylene glycol) as the standard.

RESULTS AND DISCUSSION

Characterization of Thermosensitive Polymers. As thermosensitive polymers with varying LCSTs, we prepared three kinds of poly(NIPAM-*co*-AAM)s with different NIPAM/AAM ratios as well as homopolymer of NIPAM. Also, we synthesized three kinds of poly(NIPAM-*co*-NDDAM-*co*-AAM)s and poly(NIPAM-*co*-NDDAM) which correspond to analogues of these poly(NIPAM-*co*-AAM)s and poly(NIPAM) with anchor groups to the liposome membrane. Already, many studies have shown that poly(NIPAM) having hydrophobic groups can be fixed on liposome membranes through hydrophobic interactions between the hydrophobic groups and lipid membranes

Table 1. Composition and Molecular Weight of Thermosensitive Polymers

polymer	composition: NIPAM/AAM/NDDAM (mol/mol/mol)	Mw	Mw/Mn
poly(NIPAM)	100/0/0	8900	2.2
poly(NIPAM-AAM10)	89.6/10.4/0	8500	2.2
poly(NIPAM-AAM20)	76.8/23.2/0	8200	2.2
poly(NIPAM-AAM30)	65.3/34.7/0	14 000	2.5
poly(NIPAM-NDDAM)	98.9/0/1.1	10 000	2.1
poly(NIPAM-NDDAM-AAM10)	86.7/12.3/1.0	9300	2.2
poly(NIPAM-NDDAM-AAM20)	73.5/25.5/1.0	10 700	2.3
poly(NIPAM-NDDAM-AAM30)	63.0/35.9/1.1	12 000	2.3

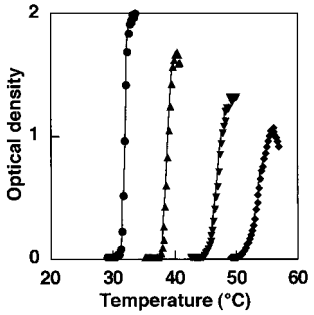

Figure 2. Cloud point curves for solutions of poly(NIPAM) (●), poly(NIPAM-*co*-AAM10) (▲), poly(NIPAM-*co*-AAM20) (▼), and poly(NIPAM-*co*-AAM30) (◆) in 10 mM Tris-HCl buffered solution containing 140 mM NaCl at pH 7.4.

(*7*, *13*, *14*, *19*). Composition, weight average molecular weight, and polydispersity index (Mw/Mn) of these polymers are listed in Table 1.

To determine the LCSTs of these polymers in the Tris-HCl-buffered solution, cloud point and DSC measurements were performed. Figure 2 illustrates typical cloud point curves for solutions of poly(NIPAM) and poly(NIPAM-*co*-AAM)s in the Tris-HCl-buffered solution. The solutions of poly(NIPAM) and poly(NIPAM-*co*-AAM10) exhibited sharp increases in optical density at 32 and 39 °C, respectively. Similarly, aqueous solutions of poly(NIPAM-*co*-AAM20) and poly(NIPAM-*co*-AAM30) displayed increases in optical density around 48 and 54 °C, respectively, although the optical density rose and reached a maximum in relatively broader temperature regions, compared with the cases of poly(NIPAM) and poly(NIPAM-*co*-AAM10). However, the cloud point measurement showed that LCST of poly(NIPAM-*co*-AAM) is elevated with increasing amount of the AAM content. Incorporation of AAM to the polymer chain increases hydrophilicity of the polymer chain, resulting in the increased LCST.

Figure 3 represents typical DSC curves of these polymer solutions. Each polymer solution exhibited an endotherm near the cloud point of the polymer. For example, the solution of poly(NIPAM) revealed an endotherm centered at 32 °C, which is the same to the LCST estimated from the cloud point measurement. However, the endotherm was seen between 27 and 37 °C. Since the endotherm is mainly related to the destruction of water around the hydrophobic N-isopropyl groups by hydrophobic interactions between the hydrophobic groups (*17*), this result suggests that hydrophobicity of the polymer chain was changing in this temperature region. In the case of poly(NIPAM-*co*-AAM), an endotherm appeared at a higher temperature region depending on the AAM content, which is consistent with the result of cloud point measurement. As is apparent in Figure 3, ΔH of the phase separation of the polymer solution decreased with increasing AAM content of the polymer. Feil et al. have reported that ΔH of the phase separation of NIPAM copolymer solutions is directly

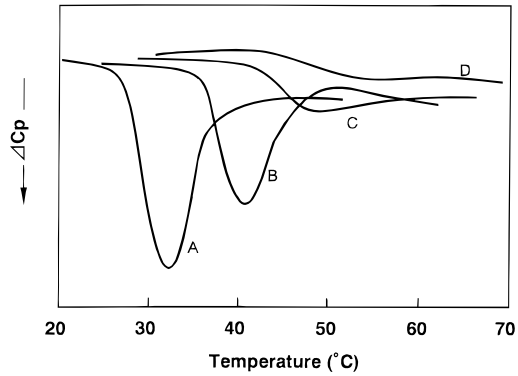

Figure 3. Microcalorimetric endotherms for poly(NIPAM) (A), poly(NIPAM-*co*-AAM10) (B), poly(NIPAM-*co*-AAM20) (C), and poly(NIPAM-*co*-AAM30) (D) in 10 mM Tris-HCl-buffered solution containing 140 mM NaCl at pH 7.4. The samples (100 mg/ml, 50 μL) were heated at 0.5 °C/min.

Table 2. LCST of Polymers

polymer	cloud point (°C)	T_{max}[a] (°C)	ΔH (cal/g of NIPAM unit)
poly(NIPAM)	32.0	32.2	5.6
poly(NIPAM-AAM10)	39.0	40.3	4.6
poly(NIPAM-AAM20)	47.2	48.0	2.0
poly(NIPAM-AAM30)	53.2	55.0	0.8
poly(NIPAM-NDDAM)	28.0	28.1	5.3
poly(NIPAM-NDDAM-AAM10)	33.8	35.5	3.5
poly(NIPAM-NDDAM-AAM20)	39.6	45.0	0.8
poly(NIPAM-NDDAM-AAM30)	46.2	n.d.[b]	

[a] Temperature of peak maximum of calorimetric endotherm. [b] Not detected.

related to its phase separation temperature and a higher LCST leads to a reduced ΔH, because an increase in temperature leads to a reduction in the structuring of water around the N-isopropyl groups (*17*). Since poly(NIPAM-*co*-AAM) with a higher AAM content has a higher LCST, it reveals a smaller ΔH of the phase separation.

Cloud point temperatures, DSC endothermic peaks, and ΔH for solutions of poly(NIPAM), poly(NIPAM-*co*-AAM)s, poly(NIPAM-*co*-NDDAM), and poly(NIPAM-*co*-AAM-*co*-NDDAM)s prepared in this study are summarized in Table 2. LCSTs of poly(NIPAM-*co*-AAM)s and poly(NIPAM-*co*-AAM-*co*-NDDAM)s as a function of AAM content are shown in Figure 4. As is seen in Figure 4, LCSTs of these polymers are linear functions of the AAM content. Also, incorporation of ca. 1 mol % of NDDAM unit caused a decrease in LCST by about 6−7 °C.

Release Property of Thermosensitive Polymer-Fixed Liposomes. As a lipid for liposome preparation, phosphatidylcholines are used most frequently. However, in a previous study, we have shown that interaction of poly(NIPAM) with phosphatidylcholine membranes is not strong enough to destroy the membranes (*7*). Recently, we have found that incorporation of phosphatidyletha-

Table 3. Preparation of Liposomes[a]

[a] Liposome-8(E) and liposome-9(E) were prepared by vortexing and subsequent extrusion. Other liposomes were prepared by sonication and subsequent incubation with polymers.

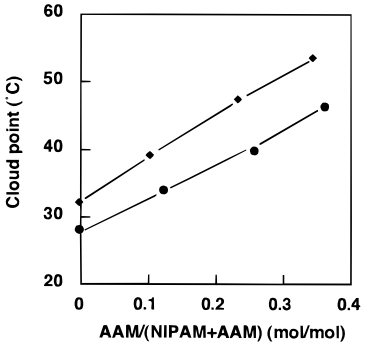

Figure 4. Lower critical solution temperature of poly(NIPAM-*co*-AAM) (◆) and poly(NIPAM-*co*-NDDAM-*co*-AAM) (●) as a function of AAM content.

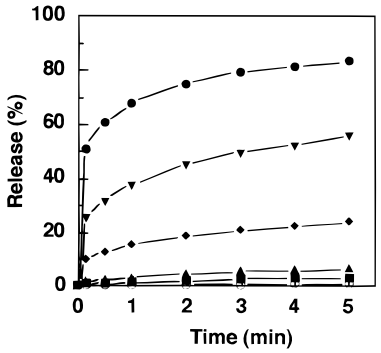

Figure 5. Release profiles of calcein from poly(NIPAM-*co*-NDDAM-*co*-AAM10)-fixed liposome in 10 mM Tris-HCl-buffered solution containing 140 mM NaCl and 0.1 mM EDTA at 20 (○), 30 (■), 35 (▲), 40 (◆), 45 (▼), and 50 °C (●). The liposome-4 was used.

nolamine enhances the polymer−membrane interaction, possibly because phosphatidylethanolamine possesses ability to form hydrogen bondings with the polymer (*18*). Therefore, in this study, we used EYPC/DOPE (4/6, w/w) as liposome lipids. While DOPE liposomes cannot be obtained under neutral conditions due to its strong tendency to take on a hexagonal (H_{II}) phase, liposomes were readily obtained from a mixture of EYPC and DOPE (4/6,w/w) at pH 7.4.

EYPC/DOPE liposomes were prepared by sonication and were coated with poly(NIPAM-*co*-NDDAM) or poly(NIPAM-*co*-AAM-*co*-NDDAM) by incubating the liposome with the polymer. The liposomes obtained by this procedure are considered to have the polymer chains only on the outer surface of the membrane as shown in Figure 1A. The amounts of the polymer added and adsorbed on the liposomes and diameter of the liposome are listed in Table 3. When the EYPC/DOPE liposomes were incubated with poly(NIPAM-*co*-NDDAM-*co*-AAM10) in the ratio of 0.1:1 (polymer/lipid, w/w), 0.04 mg of the polymer was adsorbed onto 1 mg of the liposomal lipid. By increasing the polymer/lipid ratio to 0.5:1 (w/w) during the incubation, amount of the polymer adsorbed onto the liposome increased to 0.11 mg/mg lipid. However, further increase in polymer/lipid ratio to 1:1 (w/w) during the incubation resulted in almost the same amount of the adsorbed polymer. When 0.5 mg of each polymer was added per 1 mg of liposomal lipid, 0.09−0.12 mg of the polymer was adsorbed onto 1 mg of the liposomal lipid. Diameters of the polymer-fixed liposomes were 110−118 nm and approximately the same to the diameter of the bare liposome, indicating that aggregation or fusion of the liposomes did not occur during the incubation of the liposomes with these polymers.

Figure 5 shows typical profiles of calcein release from poly(NIPAM-*co*-NDDAM-*co*-AAM10)-fixed liposome at various temperatures. The liposome hardly released calcein below 35 °C. However, the release was promoted remarkably with rising temperature above 35 °C. Since long alkyl chains on NDDAM units are considered to be inserted into membranes (*19*), these groups might not affect the transition of the polymer chains of NIPAM and AAM units existing in the aqueous environment. Thus, it is likely that the polymer chain of poly(NIPAM-*co*-NDDAM-*co*-AAM10) undergoes the hydrated coil-dehydrated globule transition at the LCST of poly(NIPAM-AAM) with the same AAM/NIPAM ratio, which is estimated to be ca. 40 °C from Figure 4. Therefore, the enhancement of calcein release observed around 40 °C is considered to be triggered by the transition of the polymer chain attached on the liposome surface.

As is seen in Figure 5, calcein release became more significant with raising temperature above 40 °C. While phase separation of the aqueous poly(NIPAM-AAM10) solution occurred in a very narrow temperature region (Figure 2), the DSC measurement indicated that dehydration of the polymer chain still proceeded above the phase transition temperature (Figure 3). In the case of poly(NIPAM-AAM10), an endotherm of the phase separation was seen between 36 and 50 °C. Thus, it is likely that the polymer chains becoming more hydrophobic with rising temperature above 40 °C destabilized the liposome membrane more strongly.

Figure 6 shows an effect of the amount of the polymer fixed on the liposome on its release property. While fixation of the polymer did not affect the release property of the liposome at 35 °C, which is lower than the polymer's LCST, extent of the release increased with increasing amount of the polymer at 45 and 50 °C, which are higher than the LCST. Thus, the liposomes having a larger amount of the polymer revealed a more significant temperature response. While extent of the release was elevated with increasing amount of the polymer above the LCST, further improvement of temperature response

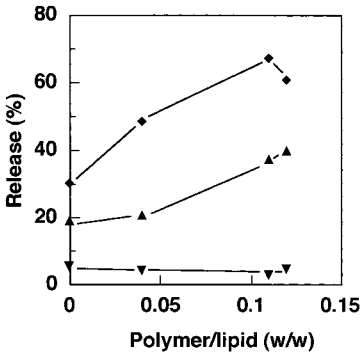

Figure 6. Effect of amount of polymer fixed on liposome on release property at 35 (▼), 45 (▲), and 50 °C (◆). Poly(NIPAM-*co*-NDDAM-*co*-AAM10) was used. Percent release after 1 min incubation is shown.

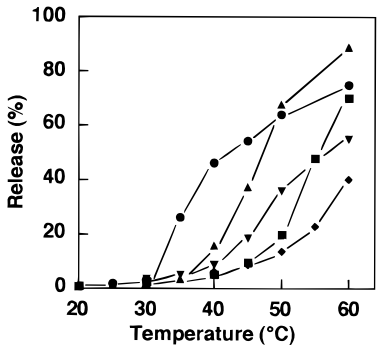

Figure 7. Percent release of calcein from liposomes modified with poly(NIPAM-*co*-NDDAM) (●), poly(NIPAM-*co*-NDDAM-*co*-AAM10) (▲), poly(NIPAM-*co*-NDDAM-*co*-AAM20) (■), and poly-(NIPAM-*co*-NDDAM-*co*-AAM30) (◆) and unmodified liposome (▼) in 10 mM Tris-HCl-buffered solution containing 140 mM NaCl and 0.1 mM EDTA at pH 7.4. Percent release after 1 min incubation is shown. The liposomes-1, 2, 4, 6, and 7 were used.

seems not to be achieved by fixation of more than 0.11 mg of the polymer/1 mg of liposomal lipid.

If release of calcein is triggered by alteration of the polymer chain from a hydrophilic state to hydrophobic state, the critical temperature for the onset of release should be controlled by using polymers with a LCST of a desired temperature. To examine if the calcein release is really triggered by the hydrophilic-to-hydrophobic change of the polymer chains, release properties of various poly(NIPAM-*co*-NDDAM-*co*-AAM)-fixed liposomes were investigated.

Figure 7 depicts percent release of calcein from these liposomes as a function of temperature. These liposomes revealed an enhanced release at different temperatures. For the poly(NIPAM-*co*-NDDAM)-coated liposome, enhancement of the release started between 30 and 35 °C, which corresponds to the LCST of poly(NIPAM). Similarly, poly(NIPAM-*co*-NDDAM-*co*-AAM10)-fixed, poly-(NIPAM-*co*-NDDAM-*co*-AAM20)-fixed, and poly(NIPAM-*co*-NDDAM-*co*-AAM30)-fixed liposomes promoted the contents release from around 40, 50, and 50−55 °C, respectively, which are very close to LCSTs of poly-(NIPAM-*co*-AAM) with same NIPAM/AAM ratios, which are estimated from the result of Figure 4 to be ca. 40, 49, and 55 °C, respectively. This result clearly indicates that the contents release was triggered by the hydrophilic−hydrophobic change of the polymer fixed on the liposome.

A remarkable release was also observed for the unmodified liposome above 45 °C. Because DOPE has a tendency to take on a hexagonal phase and this tendency should increase with temperature, it is possible that DOPE molecules formed the nonbilayer structure in the liposome membrane and caused destabilization of the membrane above that temperature. We examined the occurrence of the bilayer−nonbilayer phase transition in the unmodified liposome membrane by a fluorometric analysis using a fluorescent lipid, dioleoyl-*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)phosphatidylethanolamine (*13*, *22*). The result suggested that the transition takes place between 40 and 45 °C, which is the temperature region where the contents release from the unmodified liposome was promoted (result not shown).

As is seen in Figure 7, calcein release from poly-(NIPAM-*co*-NDDAM-*co*-AAM20)- and poly(NIPAM-*co*-NDDAM-*co*-AAM30)-fixed liposomes was still on a low level around 45−55 °C. This fact suggests that the hydrated polymer chains increased stability of the liposome. It has been reported that, in order for bilayer-to-hexagonal transitions to occur in phosphatidylethanolamine membranes, the membranes have to come into a close contact (*20*, *21*); under nonaggregating conditions such as dilute suspensions of unilamellar liposomes, the phase transition of phosphatidylethanolamine membrane does not take place even above its phase transition temperature (*23*). We have already shown that hydrated poly(NIPAM) chains stabilize DOPE liposomes and suppress occurrence of the bilayer-to-hexagonal transition in the liposome membrane, probably by preventing the bilayer contact between liposomes (*13*). However, under a condition where the polymer chains are dehydrated, the polymer chains interact with the liposome membrane through hydrophobic interactions and hydrogen bondings (*18*). This interaction should promote formation of the nonbilayer structure in the membrane and induce destabilization and/or rupture of the liposome. In fact, it is known that nonpolar molecules such as alkanes promote the formation of the hexagonal phases (*24*). Thus, it may be considered that the primary role of the polymer is the control of the transition to the nonbilayer phase in the liposome membrane. Several stimuli-sensitive liposomes have been prepared using bilayer-to-nonbilayer transitions of phosphatidylethanolamine membranes. Among them are photosensitive liposomes reported by O'Brien and co-workers (*25*, *26*) and target-sensitive liposomes by Huang and his colleagues (*27*).

It is expected that liposomes having the polymer chains on both surfaces of the membrane (Figure 1B) exhibit a more drastic temperature response than liposomes having the polymer chains only on the outer surface (Figure 1A). Thus, two kinds of liposomes of the former type, liposome-8(E) and liposome-9(E), were prepared from the polymer−lipid mixtures. The diameter of the liposome and the amount of the polymer fixed on the liposome are shown in Table 3. Since the liposome-9(E) has 0.18 mg of the polymer/1 mg of the liposomal lipid, density of the polymer chain on the liposome surface may be considered to be roughly the same to that on the outer surface of the liposome-4, which is calculated to have ca. 0.2 mg of the polymer/1 mg of the liposomal lipid. Figure 8 illustrates typical examples of release profiles of calcein from the liposome-9(E). While only a limited extent of release was seen below 35 °C, an intensive and fast release occurred above 45 °C. In comparison with the case of liposome-4 (Figure 5), the release from the liposome-9(E) above the LCST of the polymer is apparently more drastic.

Temperature dependence of the release from these liposomes is shown in Figure 9. Whether the liposome has the polymer chains on the outer surface or on both

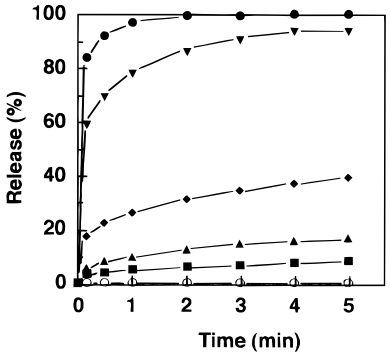

Figure 8. Release profiles of calcein from liposome having polymer on both surfaces of membrane in 10 mM Tris-HCl-buffered solution containing 140 mM NaCl and 0.1 mM EDTA at 20 (○), 30 (■), 35 (▲), 40 (◆), 45 (▼), and 50 °C (●). The liposome-9(E) was used.

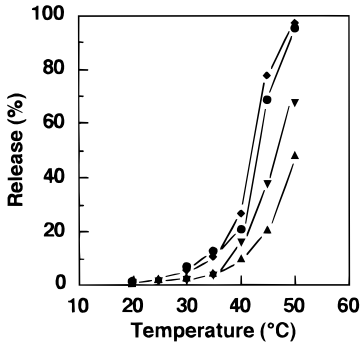

Figure 9. Comparison of release property of liposomes having poly(NIPAM-*co*-NDDAM-*co*-AAM10) on outer surface (▲, ▼) and on both surfaces (●, ◆) of membrane. Percent release of calcein from liposome-3 (▲), liposome-4 (▼), liposome-8(E) (●), and liposome-9(E) (◆) after 1 min incubation is shown as a function of temperature.

surfaces, the release was enhanced remarkably above ca. 40 °C. Although the liposome-8(E) has a lower amount of polymer than the liposome-4, the former revealed a more drastic release. About 70% of the contents was released in 1 min from the liposome-8(E) at 45 °C, whereas only 38% was released from the liposome-4 in the same period. The liposome-9(E) exhibited slightly more drastic release than the liposome-8(E). These results indicate that temperature-sensitive release property of the liposome can be improved by fixing the polymer on both surfaces of the liposome membrane.

Recently, we have found that poly(NIPAM) chain hardly influences fluidity of the hydrophobic region of phospholipid membranes but decreases fluidity of the surface region of membrane above its LCST, suggesting that the hydrophobic polymer chain interacts mainly with the surface region of liposome membrane (*18*). Therefore, in the case of liposome having polymer chains only on the outer surface, the polymer might disturb mainly the outer leaflet of the membrane. Since the inner leaflet of the liposome membrane acts as a barrier to the permeation of calcein, release from the liposome was relatively low. In contrast, for the liposome having the polymer chains on both surfaces of the membrane, the polymer chains destabilize both leaflets of the membrane, and hence, a more intensive release was induced above the LCST. As is seen in Figure 9, the liposome-9(E) might release only less than 15% of the contents at 37 °C, which is the physiological temperature, but about 80% of the contents was released in 1 min at 45 °C. Therefore, this liposome may be useful as a temperature-sensitive drug delivery system.

In conclusion, calcein-loaded EYPC/DOPE liposomes modified with the NIPAM copolymers with varying LCSTs were prepared. It was found that the polymer-fixed liposome hardly released the contents below its LCST, whereas the release was strongly promoted above the LCST. A close relationship between temperature region where the release was enhanced and LCST of the polymer was observed. The results obtained in this study indicate that liposomes which reveal the response at a desired temperature region can be made by modification of liposomes with a NIPAM copolymer, which exhibits a LCST at that temperature. Also, it was shown that temperature response of the liposome can be improved by fixing the polymer on both surfaces of the membrane. Some liposomes prepared in this study exhibited the response around the physiological temperature. Release of the contents from these liposomes might be triggered by the heating of a region of the body. Thus, these liposomes may have potential usefulness as a site-specific drug carrier with temperature sensitivity.

Electrostatic Interactions of Redox Cations with Surface-Immobilized and Solution DNA

Adam B. Steel,*,† Tonya M. Herne, and Michael J. Tarlov*

Process Sensing Group, NIST, Gaithersburg, Maryland 20899. Received September 18, 1998; Revised Manuscript Received January 5, 1999

Association constants for ruthenium(III) hexaamine and cobalt(III) tris(2,2′-bipyridine) with solution and surface-immobilized DNA were determined. The interaction of the cationic redox molecules with calf thymus DNA was monitored via normal pulse voltammetry with analysis of the mass-transfer limited current assuming a discrete binding-site model. Single-stranded DNA was immobilized on gold via self-assembly of a 5′ hexanethiol linker. Double-stranded surface-immobilized DNA was produced by hybridization of a complementary target to surface-immobilized single strands. The interaction between the metal complexes and surface-immobilized DNA was determined using chronocoulometry to construct adsorption isotherms. The measured binding constants for the cationic redox molecules with solution, surface-immobilized single-stranded, and double-stranded DNA are well-correlated, even as a function of ionic strength. The agreement between the determined association constants for the surface-immobilized and solution DNA indicates the potential utility of DNA-derivatized electrodes for examination of small molecule interactions with nucleic acids.

INTRODUCTION

Heterogeneous DNA hybridization, the association of a solution-phase single strand with its immobilized complementary strand at a solid surface, has received considerable attention as an alternative to current DNA diagnostic methods because it is more labor, time, and material efficient (*1*). While biosensors based on heterogeneous hybridization at arrays are now being commercially developed, the physical characteristics of the surface-immobilized DNA are at present poorly understood (*2*). Of particular interest is the influence of surface immobilization on small molecule binding to DNA. In this report, we compare the electrostatic binding of small redox molecules to DNA in solution and immobilized on alkanethiol-modified gold surfaces.

Small molecule binding to DNA has been researched in great detail due to its importance in strand scission mediation, as a structural probe, and as a model for protein−nucleic acid interactions (*3*). Binding modes include covalent attachment, electrostatic attraction, and intercalation into the hydrophobic regions of the DNA. The interaction between a molecule and DNA is often an interplay of the available binding modes. Studies of the binding of electrochemically active small molecules to solution-phase DNA have provided association constants for a wide range of organic and metal chelate compounds (*3*, *4*). The binding constants can be subsequently decomposed into contributions for each type of interaction to provide a more detailed picture of the bound complex.

DNA biosensors have been developed based on an electrochemical signal change for the interaction of small molecules with oligonucleotides immobilized on an electrode surface (*1*, *5*). We recently reported an electrochemical method to determine DNA immobilized on gold based on the electrostatic accumulation of electroactive metal complexes with the nucleotide phosphate backbone (*6*). The quantitative validity of this method rests heavily on using molecules that interact with DNA predominately through electrostatic attraction. As such, small, highly charged redox cations such as ruthenium hexaamine (RuHex) and cobalt trisbipyridyl (CoBPY) were selected as electrochemical markers. In this paper, we report the binding constants for RuHex and CoBPY with solution and surface-immobilized DNA.

EXPERIMENTAL SECTION

Materials. All reagents were obtained from Aldrich Chemical, unless otherwise noted. All solutions were made with deionized water (18 MΩ cm resistivity) from a Barnstead NANOpure system (*7*). Calf thymus DNA was obtained from Sigma Chemical Co. (St. Louis, MO) and was used as received. Concentrated DNA solutions (3−6 mM in nucleotide phosphate) were prepared by dissolving the solid sodium salt of DNA in the measurement electrolyte. Synthetic DNA oligonucleotide probes were purchased from Research Genetics (Huntsville, AL). The probe oligonucleotide contained a 6-mercaptohexyl linker at the 5′ end and 25 bases with the sequence 5′-$HS(CH_2)_6$-CAC GAC GTT GTA AAA CGA CGG CCA G-3′. The complementary single-stranded target was a 25mer with the sequence 5′-CTG GCC GTC GTT TTA CAA CGT CGT G-3′. 6-Mercapto-1-hexanol (MCH) and 2-mercapto-1-ethanol (MCE) were purified using flash chromatography (silica, chloroform). Hexaammineruthenium(III) chloride (99%) (Strem Chemical, Newburyport, MA) was used as received. Tris(2,2′-bipyridyl) cobalt(III) perchlorate was prepared using the procedure of Dollimore and Gillard and recrystallized twice from water prior to use (*8*).

Electrode Preparation. Gold electrodes were prepared by rf sputter deposition of ca. 20 nm of a chromium adhesion layer followed by ca. 200 nm of gold (each 99.99% purity) onto glass microscope slides. Electrodes were cleaned by exposure to warm piranha solution [70% concentrated sulfuric acid, 30% peroxide solution (30%); **WARNING**: piranha reacts violently with organic sol-

vents] for 12 min. The electrodes were rinsed thoroughly with deionized water and placed in monolayer deposition solutions while wet.

MCE- and MCH-modified surfaces were prepared from 1 mM aqueous solutions. DNA-modified surfaces were prepared using our previously described procedure (*9*). Briefly, mixed monolayer surfaces containing thiolated probe DNA (ss-DNA) and MCH were prepared by immersing the clean gold substrate in a 1.0 μM solution of probe oligonucleotide in 1.0 M potassium phosphate buffer, pH 7, for 15 min, rinsing with 10 mM NaCl, 5 mM Tris buffer, pH 7.4 (R-BFR) for 5 s, immersing in a 1.0 mM MCH solution in deionized water for 1 h, and finally rinsing with R-BFR for 5 s and drying under a stream of nitrogen. Surface-immobilized double-stranded DNA (ds-DNA) was obtained by hybridization of the immobilized ss-DNA to the complementary target at 35 °C for 60 min in 1.0 M NaCl, 10 mM Tris buffer, and 1 mM EDTA, pH 7.4. The concentration of complementary target was 1.0 μM. Upon removal from the hybridization reaction solution, the electrodes were rinsed with R-BFR for 5 s and dried under a stream of nitrogen prior to electrochemical characterization.

Instrumentation. Cyclic voltammetry (CV), normal pulse voltammetry (NPV), and chronocoulometry (CC) were performed with a CH Instruments (Cordova, TN) model 660 electrochemical analyzer (*7*). The following parameters were employed: CV, sweep rate = 100 mV/s; NPV, pulse duration = 100 ms, pulse frequency = 1 s^{-1}, step increment = 4 mV; CC, pulse period = 500 ms, pulse width = 500 mV. Ultraviolet-visible spectra were obtained on a Perkin-Elmer Lambda Bio 20 spectrophotometer (*7*).

Procedures. All electrochemical characterizations were performed in a single-compartment cell with a 10 mL volume. The working electrodes were prepared as described above. A saturated calomel electrode (SCE) and platinum wire gauze served as the reference and counter electrodes, respectively. Supporting electrolyte, 10 mM Tris buffer, pH 7.4 (E-BFR), was deoxygenated via purging with nitrogen gas for 10 min prior to measurements, and the cell was blanketed with nitrogen for the experiment duration. All experiments were carried out at laboratory ambient temperature (21−24 °C).

Binding constants for redox cations with calf thymus DNA in solution were calculated following the DNA titration strategies of the Bard (*3e*) and Thorp (*3h*) groups. Aliquots of solution containing 50 μM redox cation and 3.0 mM nucleotide phosphate were added to a solution containing 50 μM redox cation in 10 mM Tris buffer. For competitive binding studies, NaCl was added to the Tris buffer. Normal pulse voltammograms were collected for each nucleotide phosphate concentration at a MCE-modified electrode. MCE-modified electrodes were used in place of a bare gold electrode because the self-assembled monolayer blocks nonspecific adsorption of the redox molecule and DNA without affecting the reaction kinetics (*10*).

Binding constants for redox cations with surface-immobilized ss- and ds-DNA were calculated from adsorption isotherms. The amount of redox cation accumulated at the electrode surface due to the presence of nucleotide phosphate was determined via chronocoulometry as previously described (*6*). In brief, double layer charge determinations were made in the electrolyte buffer without redox cation. When a redox cation is added to the low ionic strength electrolyte, the redox cation exchanges with the native charge compensation cation, accumulating at that interface. The amount of accumulated redox cation can then be measured using chronocoulometry, a current integration technique, under equilibrium conditions. The number of redox cations at the electrode surface is determined from the difference in chronocoulometric intercepts for the identical potential step experiment in the presence and absence of redox cation. Accumulation of the redox cation at the electrode surface does not significantly alter the double layer charge for the electrode based on experiments using an equivalent potential step magnitude but over a region where the redox cation is not electroactive. Adsorption isotherms were constructed by adding aliquots of a redox cation solution to 10 mL of electrolyte buffer, stirring the solution, and waiting 1 min prior to recording the chronocoulometric trace. Variable waiting periods were used to ensure that the system had reached equilibrium; 30 s of equilibration time was found to be sufficient.

RESULTS AND DISCUSSION

Solution-Phase DNA Interactions. Association constants for electrostatic binding of RuHex and CoBPY to DNA were determined following the method of the Bard and Thorp groups (*3e,h*). High-affinity binding to DNA, as is the case for the redox molecules under consideration here, is best described by a discrete site model. Free small molecule and DNA-binding sites, of a fixed size *s* in base pairs, are in equilibrium with the bound species. An expression for the bound fraction as a function of the association constant, *K*, and the binding site size, *s*, can be derived from the equilibrium constant expression

$$X_b = \frac{b - \left(b^2 - \frac{2K^2[M][NP]}{s}\right)^{1/2}}{2K[M]} \quad (1a)$$

$$b = 1 + K[M] + \frac{K[NP]}{2s} \quad (1b)$$

where X_b is the bound mole fraction, [M] is the total metal ion concentration, and [NP] is the nucleotide phosphate concentration. Equation 1 is valid for noncooperative, nonspecific binding to a unique binding site on DNA. Values for the binding constant, *K*, and the binding site size, *s*, are determined by nonlinear regression analysis of bound fraction versus nucleotide phosphate profiles.

The bound fraction of redox molecule was determined from the plateau current in normal pulse voltammograms obtained during the titration of redox molecule with calf thymus DNA (*3h*). The plateau current diminishes upon the addition of DNA because the effective diffusion coefficient of the redox molecule is lowered by binding to DNA. The bound mole fraction, assuming rapid exchange between free and bound states on the voltammetric time scale, is given by a ratio of squared current differences

$$X_b = \frac{i^2 - i_o^2}{i_{sat}^2 - i_o^2} \quad (2)$$

where i_o is the plateau current in the absence of DNA and i_{sat} is the current at complete saturation.

Because we are interested in promoting electrostatic attraction between the redox cations and nucleotide phosphate backbone, DNA titrations were performed in the absence of excess electrolyte cation. Titration data are given in Figure 1 for both RuHex and CoBPY with the associated nonlinear regression best-fits to eqs 1a and 1b. The regression analysis results are summarized in Table 1. The association constant for the smaller, harder RuHex is an order of magnitude larger than that for

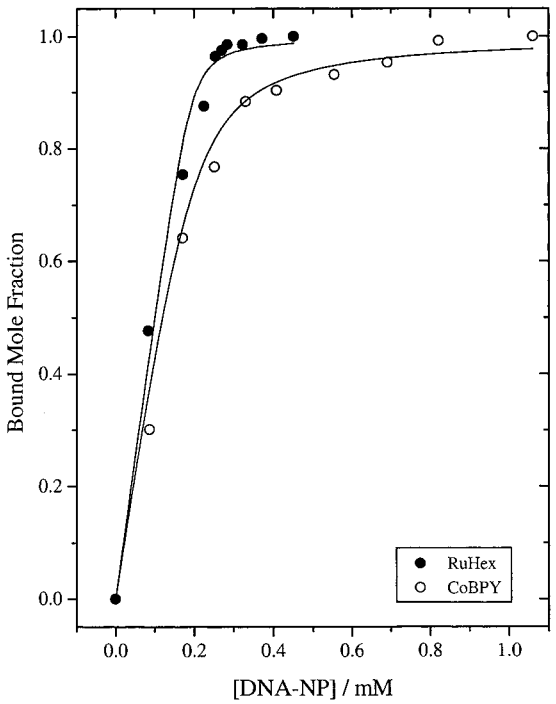

Figure 1. Plot of the bound mole fraction of 50 μM metal complex upon titration with calf thymus DNA in 10 mM Tris buffer, pH 7.4, no excess Na^+, and associated nonlinear least-squares fits to eq 1. Binding titrations are given for ruthenium(III) hexaamine (RuHex, closed circles) and cobalt(III) trisbipyridal (CoBPY, open circles).

Table 1. Binding Constants of RuHex and CoBPY to Calf Thymus DNA in Solution

complex	excess [Na^+] (mM)	K^a (M^{-1})	s^a (bp)
RuHex	0	1.2×10^6	2.0
	10	5.0×10^5	2.5
	100	6.0×10^4	4.0
CoBPY	0	2.0×10^5	2.0
	10	4.5×10^4	3.0
	15[b]	5.8×10^4	3.0

[a] The binding constant, *K*, and binding site size, *s*, were calculated from linear regression analysis of titration data in electrolytes with increasing excess sodium ion concentration. [b] Reference *3h*.

CoBPY. The binding site sizes obtained for RuHex and CoBPY in the absence of excess electrolyte cation are the same, within the experimental uncertainty. Furthermore, the binding site size of 2.0 base pairs approaches the theoretical saturated binding site size of 1.5 base pairs for complete charge compensation of the nucleotide phosphate by trivalent redox cation. We note that the sodium ion concentration in these experiments is equivalent to the nucleotide phosphate concentration, roughly 1 mM, so that a significant amount of sodium cation is available in solution to compete with the redox cation for the anionic phosphate-binding sites. It is not surprising then that the theoretical saturated binding site size of 1.5 base pairs/trivalent redox cation is not achieved.

The influence of a competing cation, e.g., sodium, was studied further by measuring the binding constant, *K*, and site size, *s*, in solutions with increasing ionic strength. Binding isotherms for RuHex are given in Figure 2 with the accompanying nonlinear regression analysis fits. The data are summarized in Table 1. As would be expected, the binding constant decreases and the effective binding site size increases with increasing ionic strength. Our results are in good agreement with those reported by Welch et al. (*3h*).

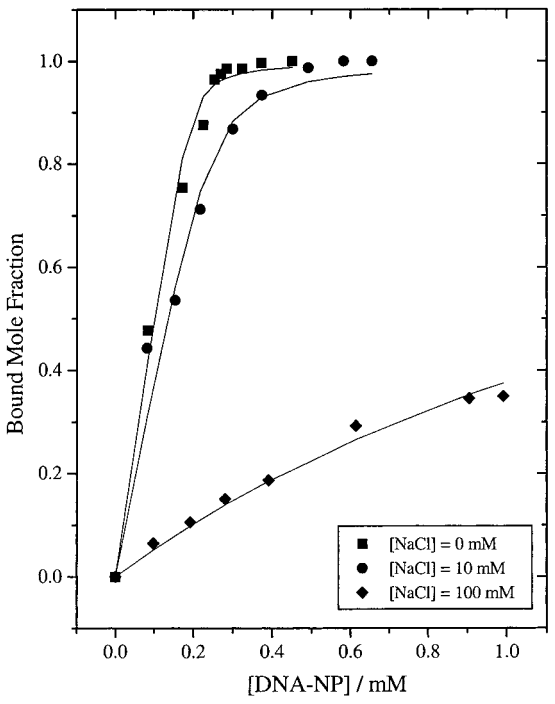

Figure 2. Plot of the bound mole fraction of 50 μM RuHex upon titration with calf thymus DNA in 10 mM Tris buffer, pH 7.4 with increasing excess Na^+ and associated nonlinear least-squares fits to eq 1. Binding titrations were performed with excess sodium concentrations of 0 (squares), 10 (circles), and 100 (diamonds) mM.

Surface-Immobilized DNA. Study of the interactions of small molecules with surface-immobilized oligonucleotides is important for the developing field of DNA diagnostics. Of particular interest here is the interaction of electrostatically bound molecules to DNA immobilized on gold. Attachment of DNA to an electrode surface provides a convenient means to probe the interactions of redox molecules and DNA, as shown by Kelley et al. (*1a*). Surfaces modified with ss-DNA and ds-DNA were prepared to determine if molecule binding affinity is a function of DNA structure (i.e., single-strand vs duplex DNA).

Cationic RuHex interacts strongly with the polyanionic backbone of surface-immobilized DNA. The strong interaction is manifested in cyclic voltammograms as a post-wave shoulder attributable to surface-confined species (*11*). Five consecutive voltammograms for a ss-DNA-modified electrode in 50 μM RuHex are given in Figure 3. The overlap of all of the voltammograms is evidence that equilibrium has been established in the system. Also shown in Figure 3 is a series of voltammograms taken after exposing the electrode to 50 μM RuHex solution, then transferring the electrode to a redox-free buffer for measurement. Removal of the electrode from the redox-containing solution allows us to ascribe the peak at -272 mV to surface-confined redox molecules. Further confirmation that the peak at -272 mV is due to a surface-confined species is determined from scan rate dependence studies. The peak currents at -168 mV (diffusion-limited) and -272 mV (surface-confined) are plotted as a function of scan rate in Figure 4. The peak current at -272 mV is linear with scan rate, indicating a surface-confined reaction, while the peak current data for -168 mV is indicative of the mass-transfer limited reaction.

The voltammetry of CoBPY at DNA-modified electrodes does not exhibit a post-wave, as was observed for RuHex, reflecting the difference in the relative strength

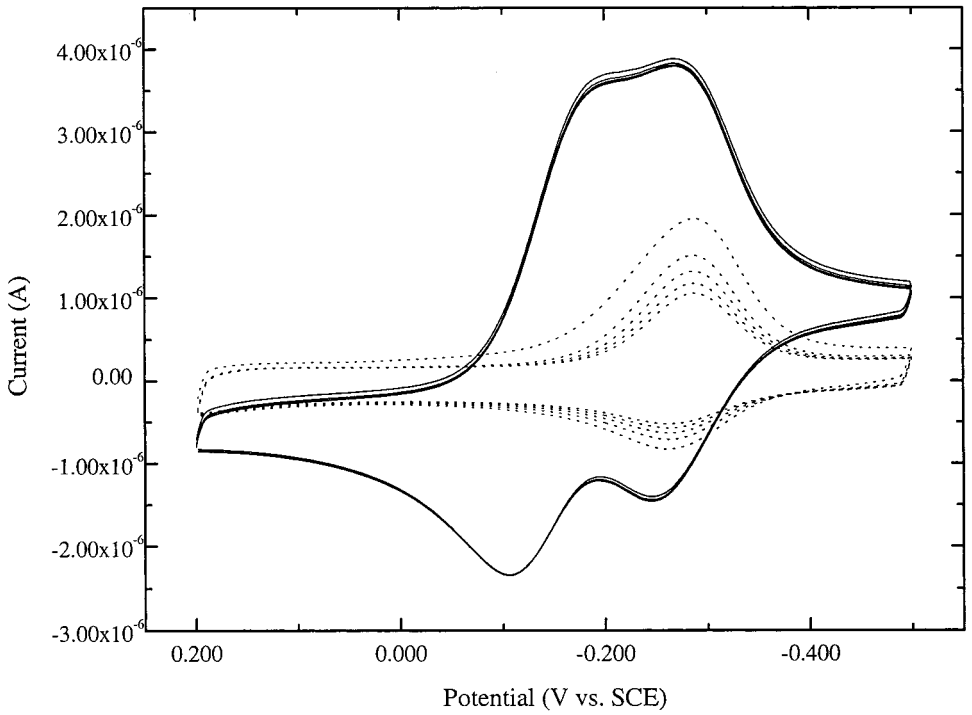

Figure 3. Cyclic voltammetry of RuHex at ss-DNA modified electrode. The first five cycles, $v = 100$ mV/s, for an electrode in 50 μM RuHex, 10 mM Tris, pH 7.4 (solid line), and an electrode that was incubated in same solution for 1 min, washed, and transferred to 10 mM Tris, pH 7.4, for measurement (dotted line).

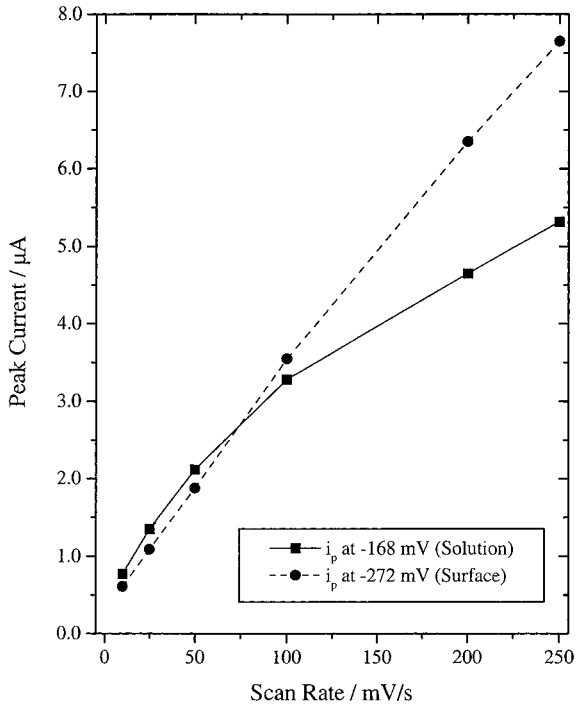

Figure 4. Plot of the peak currents at −168 (squares) and −272 mV (circles) versus scan rate for a ss-DNA modified electrode in 50 μM RuHex, 10 mM Tris, pH 7.4. The lines are given as a guide to the eye only.

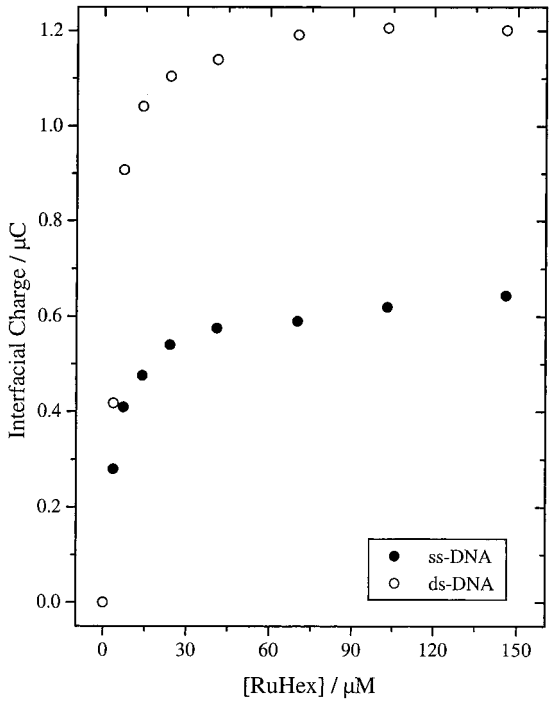

Figure 5. Adsorption isotherms of RuHex at ss-DNA (closed circles) and ds-DNA (open circles) modified electrodes. The interfacial charge due to adsorbed RuHex was determined from the increase in chronocoulometric intercept with increasing metal complex concentration.

of the redox cation/DNA interaction (*11*). Loading experiments, such as those included for RuHex in Figure 3, show that CoBPY does accumulate at the electrode surface.

Determination of Redox Molecule Affinities for Surface-Immobilized DNA. The binding constants of redox molecules with ss- and ds-DNA were determined from adsorption isotherms. The amount of surface-confined redox molecule was measured using chronocoulometry. Binding isotherms for RuHex at ss- and ds-DNA modified electrodes in E-BFR are given in Figure 5. An association constant, K, was calculated from the isotherm data using the Langmuir adsorption isotherm model. The Langmuir model assumes that the every binding site is equivalent and that the ability of a molecule to bind is independent of occupation of nearby sites. A linearized form of the Langmuir isotherm in terms of the solution

Table 2. Binding Constants of RuHex and CoBPY to ss- and ds-DNA Immobilized on an Electrode Surface

complex	excess [Na^+] (mM)	K/ss-DNA[a] (M^{-1})	K/ds-DNA[a] (M^{-1})
RuHex	0	$(2.2 \pm 0.9) \times 10^6$	$(1.3 \pm 0.4) \times 10^6$
	10	$(3.7 \pm 2.2) \times 10^5$	$(3.0 \pm 0.6) \times 10^5$
	100	$(2.7 \pm 1.6) \times 10^4$	$(4.1 \pm 0.8) \times 10^4$
CoBPY	0	$(2.7 \pm 0.5) \times 10^5$	$(1.6 \pm 0.3) \times 10^5$
	10	$(6.9 \pm 0.3) \times 10^4$	$(5.6 \pm 0.4) \times 10^4$

[a] The binding constants, K, were determined from Langmuir analysis of adsorption isotherm data in electrolytes containing the listed excess sodium ion concentrations. The average and standard deviation on at least three measurements per entry are given.

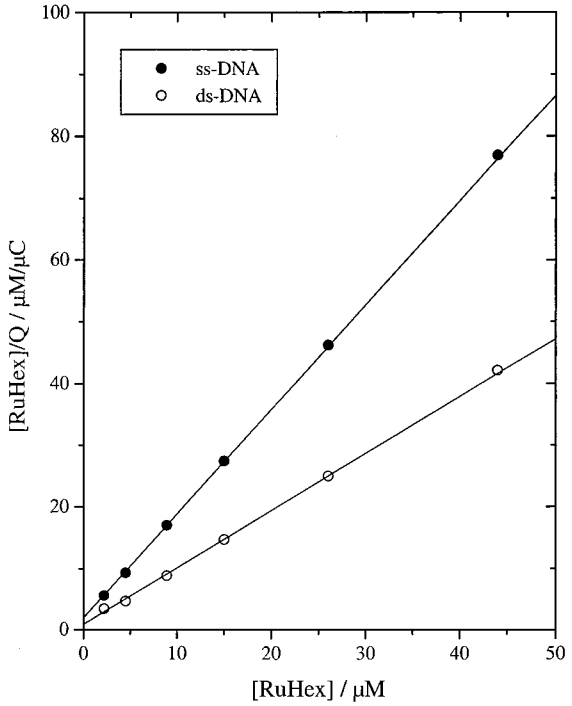

Figure 6. Linearized Langmuir isotherm. The adsorption isotherm data for RuHex at ss-DNA (closed circles) and ds-DNA (open circles) modified electrodes in accordance with eq 3. The lines are the least-squares best-fit to the data used to calculate the binding constants given in Table 2.

redox cation concentration, [M], the accumulated charge at the electrode surface, Q, and the saturated charge, Q_{sat}, is given by eq 3.

$$\frac{[M]}{Q} = \frac{[M]}{Q_{sat}} + \frac{1}{KQ_{sat}} \quad (3)$$

Results of Langmuir analysis of isotherm data are given in Table 2. The binding isotherm data for RuHex at ss- and ds-DNA modified electrodes in E-BFR (no added NaCl) are plotted in the linearized Langmuir plot in Figure 6. The saturation coverages of RuHex are 0.6 and 1.2 μC/cm^2 for ss- and ds-DNA modified surfaces, respectively. Binding constants calculated from the plots in Figure 6 are 2.1×10^6 and 1.1×10^6 M^{-1} for ss- and ds-DNA, respectively.

The doubling of the redox molecule coverage in going from ss- to ds-DNA is particularly satisfying because it indicates that all of the ss-DNA is hybridized when we form our ds-DNA samples. The doubling of saturated redox molecule coverage is a result of our probe and target having the same length so that forming the hybrid doubles the number of binding sites (nucleotide phosphates) at the electrode surface. We have previously shown that the interaction of RuHex with surface-immobilized DNA can be used as a means to quantitate the surface density of DNA when the length of the probe and target are known (*6*). The DNA surface densities calculated from the saturated RuHex coverages in Figure 6 are 3.2×10^{12} probes/cm^2 and hybrids/cm^2.

Comparison of the binding constants in Table 2 shows that these cations interact equivalently with ss- and ds-DNA over the range of ionic strengths studied. The correspondence of these binding constants indicates that electrostatic attraction is the predominant contributor to the overall metal chelate−DNA interaction. Comparison of the association constants in Tables 1 and 2 shows that binding affinity is not affected by end-tethering DNA to a surface.

CONCLUSION

We have shown that electrostatic binding of select cationic molecules to DNA is not affected by immobilization of the nucleic acid to a surface. Thus, DNA-derivatized electrodes provide a convenient and potentially powerful means to study the interactions of small molecules with nucleic acids. We intend to explore the utility of the techniques outlined herein for the investigation of other small molecule−DNA interactions.

Received September 29, 1998; Revised Manuscript Received February 25, 1999

A novel, highly specific protein modification approach is described. By using conventional molecular cloning techniques, a protein can be constructed and expressed such that the N-terminal residue is replaced by cysteine. Its 1,2-aminothiol structure reacts very specifically with a glyoxylyl group at pH 7 or below, forming a relatively stable thiazolidine bridge. Therefore, a glyoxylyl-based labeling agent (e.g., radioactive tags, fluorescent probes, biotin) can be used to specifically modify a protein at its N-terminus. To highlight this novel approach, a recombinant anti-insulin single chain antibody (scFv) was specifically biotinylated at its N-terminus even in the presence of other proteins in the total cell lysate. The glyoxylyl-biotinylated scFv retained binding activity similar to unmodified scFv.

INTRODUCTION

One of the major efforts in bioconjugate chemistry research is to develop methods for the derivatization of macromolecules in a site-specific manner (*1*). Commonly, peptides and proteins are modified either on the side chains of lysine residues by using amine-reactive reagents or on the side chains of cysteine residues by using thiol-reactive reagents. Less popular methods include derivatization at the tyrosine residue side chains (*2*) and the enzyme-catalyzed reverse proteolytic reactions at the C-terminal carboxylate group (*3*). Among all these methods, only the enzyme-catalyzed reverse proteolytic reaction is truly site specific. Amine-reactive reagents, which include reagents based on active esters (e.g., N-hydroxysuccinimide ester), isothiocyanides, aldehydes, and sulfonyl halides, etc., react predominately with ϵ-amino functional groups and to a lesser extent α-amino functional groups. Despite the mild conditions under which these reagents are used, heterogeneity of the modified products arises because of the high abundance of lysine residues in proteins and many peptides. Thiol-reactive reagents, such as the maleimide-based reagents and the haloacetic-based reagents, are somewhat more selective because of the lower abundance of cysteine residues in peptides and proteins. In cases where all thiol groups are involved in disulfide bond formation, one can introduce a single surface-accessible thiol into the target protein by site-directed mutagenesis (*4*). Although thiol-reactive reagents are more specific than the amine-reactive reagents, reactions with other nonthiol nucleophiles are possible, especially when the modification is forced by use of excess maleimide-based reagents resulting in modification of the side chains of histidine, lysine, α-amino groups of peptides (*5*).

An interesting approach to label only the N-termini was developed by Geoghegan et al. (*6*) and Gaertuer et al. (*7*). This approach takes advantage of the special reactivity of IO_4^- toward vicinal $-OH$ and $-NH_2$ groups which exist in N-terminal serine or threonine. The 2-amino alcohol group can be easily oxidized by periodate at pH 7, generating a glyoxylyl group which specifically reacts with either a hydrazide group (*6*) or an aminooxy group (*8*). This approach has been used for specific labeling of interleukin-8 at the N-terminus with aminooxy-functionalized fluorescent probes (*9*) and poly(ethylene glycol) polymers (*8*). Later, Zhang and Tam (*10*) extended this approach by using a 1,2-aminothiol-based biotinylation agent which specifically react with the N-terminal glyoxylyl group forming a stable thiazolidine ring.

To avoid potential oxidation of peptides and proteins by periodate, we developed an alternative approach which utilizes a glyoxylyl-based labeling agent to specifically label a synthetic peptide by reacting with either an N-terminal cysteine or a side-chain-attached cysteine resulting in a thiazolidine ring bridge (*11*). We also proposed that this approach could also be used to label a protein at its N-terminus where the original residue can easily be changed to cysteine using site-directed mutagenesis (*11*). In this paper, we report the cloning and expression of a recombinant protein with cysteine added to its N-terminus and the procedure of using a glyoxylyl-based modification reagent to label this protein at the N-terminus either before or after its purification. To highlight this novel approach, we chose to modify a recombinant anti-insulin antibody, designated HB125 scFv[1] (*12*), and a glyoxylyl-functionalized biotin as the modification agent. The conjugate products were then analyzed by Western blot in conjunction with streptavidin-alkaline phosphatase. A flexible and hydrophilic linker molecule was also synthesized and used in the synthesis of labeling agents in order to limit any unwanted structural perturbations of the protein being modified.

dium(0), and sodium periodate were purchased from Aldrich (Milwaukee, WI); Fmoc-Lys(Aloc)-OH was from SNPE (Princeton, NJ); Boc-Ser(t-but)-OH and Fmoc-Osu were purchased from Advanced ChemTech (Louisville, KY). All other reagents and solvents were purchased from commercial sources and used without purification. ISMS and FABMS were acquired at the Mass Spectoscopy Facility, College of Pharmacy, University of Arizona. HRFABMS was acquired at the Mass Spectroscopy Facility, Department of Chemistry, University of Arizona. HPLC was carried out on an ISCO two-solvent system (Lincoln, NE). For analytical work, a column 250 × 4 mm i.d. (vydac) was used at a flow rate of 10 mL/min. Solvent A was prepared by adding 2 mL of TFA to 4 L of water. Solvent B was prepared by adding 1.7 mL of TFA to 500 mL of water and making up to 4 L with acetonitrile.

Synthesis of Fmoc-Protected 4,7,10-Trioxa-1,13-tridecanediamine Succinimic Acid (Fmoc-Ttds), (Scheme 1). 4,7,10-Trioxa-1,13-tridecanediamine (2.22 g, 10 mmol) was dissolved in 50 mL of CH_3CN and placed in a 250 mL flask with magnetic stirring. Succinic anhydride (1 g, 10 mmol) in 25 mL of CH_3CN was added dropwise over an hour. The reaction was allowed to proceed for an additional 3 h at room temperature. After the waxy product settled, organic solvent was decanted and discarded. The product was rediluted in 100 mL of 50% aqueous CH_3CN and chilled in an ice bath for 30 min before Fmoc-OSu (4.4 g, 13 mmol) in 25 mL of CH_3CN was added. Enough diisopropylethylamine was then added to maintain pH 8−9 throughout the reaction. After stirring for 10 h at room temperature, the solvents were removed in vacuo. The resultant product was dissolved in 100 mL of 5% $NaHCO_3$ and washed with EtOAc. The aqueous phase was then acidified with 1 N HCl to pH 2 and extracted 3 times with 50 mL of EtOAc. The combined organic phase was washed with distilled H_2O and dried over anhydrous Na_2SO_4. The evaporation of organic solvent gave 4 g of product (75% yield). Molecular weight calculated for this compound: 543.5. Found: 543.2 by ion spray mass spectroscopy (ISMS).

Scheme 2. Sythesis of Glyoxylyl-Functionalized Biotin

[a] (i) AA, DIC, HOBt (AA = Fmoc-Lys(Aloc)-OH, Fmoc-Ttds-OH, Boc-Ser(t-But)-OH; (ii) 20% piperidine in DMF; (iii) tetrakis(triphenylphosphine) palladium(0); (iv) biotin, HTBU, HOBt, DIEA; v, 10% TFA in DCM; (vi) $NaIO_4$ (0.02 M NaAc, 0.02 M EDTA, pH 4.2).

Synthesis of Glyoxylyl Functionalized Biotin (Glyoxylyl-Biotin). Synthesis of the glyoxylyl functionalized biotin (glyoxylyl-biotin) is outlined in Scheme 2. Briefly, protected tripeptide, Boc-Ser-Ttds-Lys(aloc)-resin, was synthesized with Fmoc solid-phase chemistry (*13*). Deprotection of lysine side chain, Lys(Aloc), was carried out by Loffexís procedure (*14*) with tetrakis (triphenyl phosphine) palladium(0) as the reducing agent. The on-bead biotinylation was performed by using HBTU and HOBt as the coupling agents. Enough (40−50%) diisopropylethylamine (DIEA) was added to dissolve biotin which is not soluble in pure DMF. The biotinylated tripeptide was then cleaved from the Rink resin with 95% TFA−5% H_2O, and purified on preparative HPLC (ISCO, Lincoln, NE) using a linear gradient of 0 to 50% (by vol) B over 30 min. The product, Ser-Ttds-Lys(biotin)-NH_2, has the expected molecular weight as determined by HRFABMS (M + H calculated for $C_{33}H_{61}O_{10}S$ 761.4231, found 761.4241). The biotinylated tripeptide was quantitatively oxidized following a published procedure (*6*). The resulting glyoxylyl functionalized biotin (glyoxylyl-biotin) was purified by preparative HPLC. After loading the filtered reaction solution onto the column, the inorganic salts were eluted for 10 min with solvent A. The product was then eluted off with a linear gradient of 0 to 100% (by vol) B over 15 min. The molecular weight was determined by FabMS (M + H, 730.3, observed 729.7, and M + H + H_2O, 748.3, observed 747.6). However, the signal was too small for a high-resolution MS analysis, probably because no ionizable group was present in the molecule. A similar result was also observed by Rose et al. (*15*).

Construction of N-Terminal Cysteine Anti-Insulin scFv (NCscFv). Wild-type anti-insulin scFv(WTscFv) constructed from murine anti-insulin IgG1 (HB125) hybridoma, obtained from ATCC, was molecularly cloned into pET21d expression vector as previously reported (*12*). WTscFv was amplified from this vector using a 5′ primer which has a cysteine codon at the 5′ end (5′-

[1] Abbreviations: HBTU, *O*-benzotriazol-*N*,*N*,*N*′*N*′-tetramethyl-uronium-hexafluorophosphate; HOBt, *N*-hydroxybenzotriazol; DIEA, diisopropylethylamine; TFA, trifluoroacetic acid; ISMS, ion spray mass spectroscopy; FABMS, fast-atom bombardment mass spectroscopy; HRFABMS, high-resolutioin fast-atom bombardment spectroscopy; scFv, single-chain Fv; NCscFv, N-terminal cysteine-containing scFv; WTscFv, wild-type scFv; IPTG, isopropylthio-β-galactoside; NHS-LC-biotin, sulfosuccinimidyl-6-(biotinamido) hexanoate; BCIP, 5-bromo-4-chloro-3-indolyl phosphate; NBT, nitroblue tetrazolium; IMAC, immobilized metal affinity chromatography; Ttds, 4,7,10-trioxa-1,13-tridecanediamine succinimic acid.

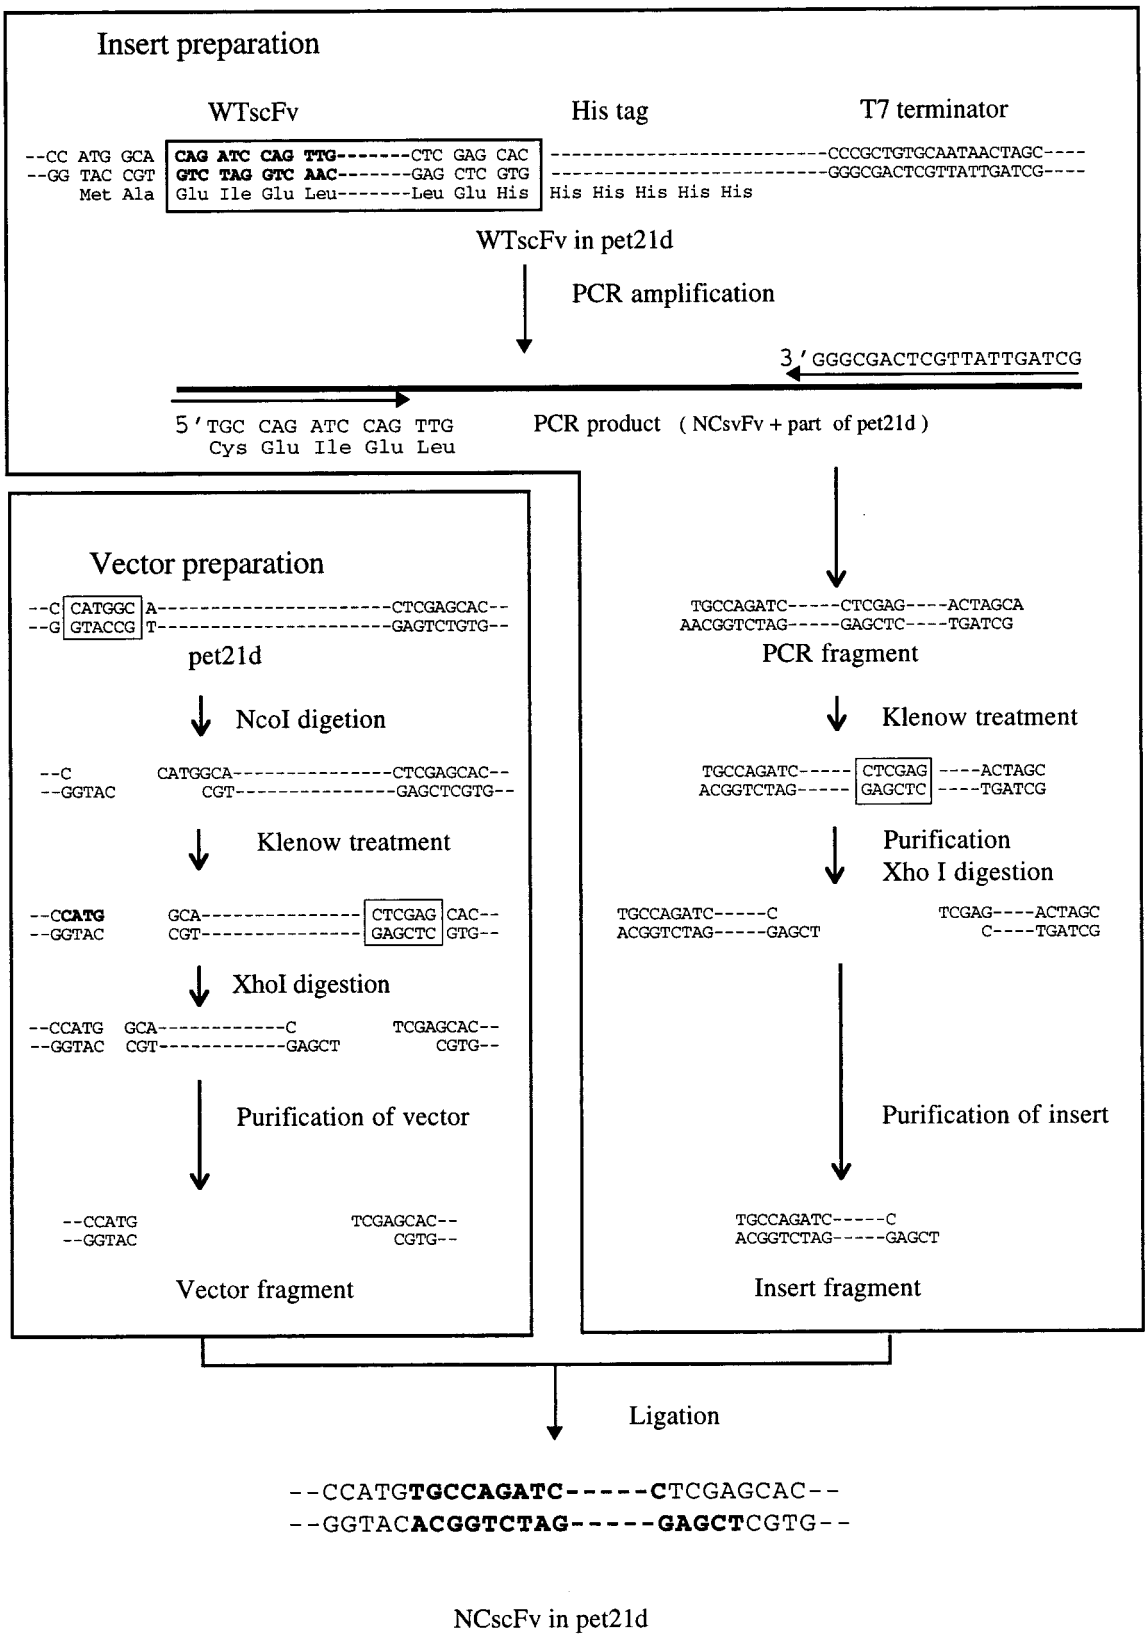

Figure 1. Construction of N-terminal cysteine-containing scFv Vector preparation. Pet21d vector was digested with *Nco*I, followed by Klenow treatment to make blunt ends. After digestion with *Xho*I, the vector was purified. Insert preparation. WTscFv in pet21d was amplified with a 5′ primer hybridizing to the WTscFv with an N-terminal cysteine codon "TGC" and 3′ T7 terminator primer hybridizing to the vector. The resultant NCscFv was blunt ended with Klenow enzyme and purified. The NCscFv insert was digested with *Xho*I and purified. Vector and insert fragments were ligated together. The new NCscFv was then sequenced to ensure correct reading frame. Dotted lines represent nucleotide sequences.

TGCCAGATCCAGTTG) and a 3′ end T7 terminator primer (5′-GCTAGTTATTGCTCAGCGG) as shown in Figure 1. Briefly, the PCR product was blunt-ended with Klenow enzyme for 30 min at 37 °C, electrophoresed on a 1% agarose gel, and purified using a Qiagen Gel Extraction Kit II. The N-terminal cysteine scFv (NCscFv)

insert was then digested with *Xho*I and purified. To prepare the vector for cloning, pET21d was digested with *Nco*I followed by Klenow treatment which resulted in blunt ends. After Klenow enzyme inactivation, pET21d was digested with *Xho*I. Finally, pET21d and the NCscFv insert were ligated overnight by T4 ligase. The ligation mixture was used to transform Novablue cells on an LB plate containing 50 μg/mL ampicillin. All molecular techniques were carried out according to Ausubel et al. (*16*). Fifty colonies were picked and grown in LB overnight after which minipreps were performed using a standard alkaline lysis procedure. Inserts were identified by PCR screening with 5′ T7 promotor and 3′ T7 terminator primers. Dideoxynucleotide DNA sequencing (*17*) was performed on selected clones to ensure correct position of the N-terminal cysteine codon at the 5′ end of the scFv.

Expression and Preparation of Cell Lysates of NCscFv and WTscFv in *Esherichia coli*. BL21 (DE3) bacterial cells were transformed with pET21d containing either NCscFv or WTscFv genes. One colony of each transformed bacterial cells was grown separately in 50 mL of terrific broth (TB) at 37 °C, 200 rpm to OD = 0.8. IPTG was then added to a final concentration of 1 mM, and the cells were grown for two more hours. Cells were harvested by centrifugation for 5 min in JA 17 rotor at 8000 rpm and resuspended in lysis buffer (50 mM Tris-Cl, pH 8, 1 mM EDTA, and 100 mM NaCl) containing 5 mg of lysozyme. After 1 h incubation at room temperature, the cells were sonicated three times for 15 s, then subjected to centrifugation at 8000 rpm for 5 min. The pellets of lysates were resuspended with 50 mM Tris-Cl, pH 8, and centrifugated. After resuspension in 8 M urea, 5 mM Tris-Cl, pH 8, lysates were sonicated again three times for 30 s each and incubated for 1 h on ice. Urea-solubilized cell lysates were collected after centrifugation. The supernatant was filtered through 0.45 μm membrane filter and saved for purification or direct cell lysate assay.

Purification of NCscFv and WTscFv. The recombinant proteins were purified from the cell lysates on a nickel-sepharose column using previously reported methods (*12*). Fractions were collected and analyzed by SDS−PAGE to determine which fraction contained desired proteins. Further purification of NCscFv for the purpose of protein sequencing was carried out by continuous elution SDS−PAGE gel electrophoresis using model 491 Prep Cell (Bio-Rad). Purified NCscFv was dialyzed against 25 mM triethylamine overnight, lyophilized, and resuspended in 100 μL of distilled water. NCscFv was precipitated at −70 °C overnight after the addition of 900 μL of acetone. The protein pellet was obtained by centrifugation at 13 000 rpm for 30 min and air-dried. The N-terminal cysteine residue of the purified NCscFv was derivatized with 4-vinylpyridine according to the protocol in the Applied Biosystems User Bulletin (no. 28, 1987), and the amino acid sequence was determined by an Applied Biosystems model 470A gas-phase sequencer equipped with a model 120 A path analyzer.

Biotinylation of NCscFv and WTscFv in Cell Lysates. The prepared cell lysates were adjusted to pH 6 with 5× phosphate buffer (0.4 M NaOH, 0.2 M H_3PO_4, and 0.2 M boric acid). One microliter of glyoxylyl-biotin (0.4 mg/ml) or 1 μL of sulfo NHS-LC-biotin (0.4 mg/ml, Pierce, Rockford, IL) was added to 10 μL of cell lysates and incubated at room temperature for 30 min. The glyoxylyl-biotinylation reaction was stopped by adding 1 μL of L-cysteine (0.4 mg/mL) while the NHS-LC-biotin reaction was stopped by adding 1 μL of 150 mM Tris-HCl buffer (pH 7.9).

Biotinylation of Purified WTscFv, NCscFv, and Insulin. Purified protein was refolded using the same methods published before (*12*). WTscFv and NCscFv were finally dialyzed against carbonate buffer (15 mM Na_2CO_3 and 35 mM $NaHCO_3$, pH 8). Sulfo NHS-LC biotin or glyoxylyl-biotin was added to WTscFv or NCscFv solution and incubated for 30 min at RT. The reaction was stopped by Tris HCl (1 M, pH 7.9) or free cysteine (1 mg/mL) for 2 h at RT. Further removal of free reagents from scFv solutions was done by dialyzing against carbonate buffer. Porcine insulin (Sigma, MO) was resuspended in PBS (pH 8.0) according to the manufacturer's instruction and labeled with Sulfo NHS-LC biotin as described above. The insulin solution was dialyzed against PBS (pH 7.3) to remove free reagents.

SDS−PAGE and Western Blotting. Biotinylated cell lysates and purified scFvs were mixed with 2× SDS sample buffer and loaded onto a 9% reducing SDS−PAGE gel. After electrophoresis, the gel was cut in half. One-half of the gel was stained with Coomassie Blue while the proteins on the other half of the gel were transferred to nitrocellulose paper in transfer buffer (25 mM Tris-base, 192 mM glycine, 20% methanol, and 1% SDS, pH 8.3). Transblotting was carried out at 30 V, 4 °C overnight using Trans Blot (Bio-Rad). Nonspecific binding to the nitrocellulose membranes was blocked by phosphate-buffered saline containing 0.1% porcine gelatin and 0.05% Tween-20 (blocking buffer) for 2 h at room temperature. Streptavidin-alkaline phosphatase (Pierce, rockford, IL) diluted in blocking buffer (1:5000 dilution) was incubated with the membranes for 1 h at room temperature. After washing with PBS-0.1% Tween, the membranes were developed by incubating with 5-bromo-4-chloro-3-indolyl phosphate (BCIP)/nitroblue tetrazolium (NBT), both obtained from Amresco (Solon, OH) in alkaline phosphatase buffer, pH 9.4 (1.5% diethanolamine, 0.5% NaN_3, and 1 mM $MgCl_2$)

Insulin-Binding ELISA. A 96 well plate was coated with anti-insulin antibody HB125 (1 μg/mL) for 1 h at 37° and blocked with 3% BSA in phosphate-buffered saline (137 mM NaCl, 2.7 mM KCl, 4.3 mM NaH_2PO_4, and 1.4 mM KH_2PO_4, pH 7.3). Biotinylated insulin (10 nM) was preincubated with various concentrations of competitors such as WTscFv, NCscFv, or glyoxylyl-biotinylated NCscFv for 1 h at RT. After HB125 coated plates were washed with washing buffer (0.05% Tween20 in PBS), preincubated biotinylated insulin and scFv mixtures were then added to HB125 IgG coated plate and incubated for another hour at RT. Unbound insulin, scFv and insulin bound scFv were washed out with washing buffer. Streptavidin-horseradish peroxidase (SA-HRP, Pierce,IL) was added and incubated for 1 h at RT to detect biotinylated insulin bound to HB125. 3,3′5,5′-Tetramethylbenzidine base (TMB, Gibco BRL, MD) was added. Color development was stopped with 0.5 N H_2SO_4 and optical densities (OD) were measured at 450 nm.

RESULTS AND DISCUSSION

Synthesis of Glyoxylyl Functionalized Biotin Reagent (Glyoxylyl-Biotin). One major concern for the synthesis of functionalized biotin (glyoxylyl-biotin) was whether the biotin group, which contains a thioether bond, remained unchanged when subjected to periodate oxidation. Fortunately, our results show that this is not a problem under the reaction conditions. Conventional cross-linking reagents contain a lengthy and flexible linker, but many of them are hydrophobic such as the hexanyl linker in NHS-LC-biotin. In this study we

Table 1. Comparison between the Ligation Methods

	this paper	Georghegan et al., Gaertuer et al., and Tam et al. (*6, 7, 10*)
site of derivatization	*N*-terminal cysteine	N-terminal threonine glyoxylyl group
protein oxidation with sodium periodate	no	yes (convert N-terminal threonine or serine to glyoxylyl group)
derivatizing reagent	glyoxylyl compound	hydrazide or aminooxy compound
specific derivatization without protein purification	yes	to be proven

decided to use a lengthy, flexible, and hydrophilic molecule as the linker in order to minimize any unwanted structural perturbation of the target protein. For this purpose a poly(ethylene glycol) (PEG) linker would be ideal, but the commercially available PEGs usually consist of a mixture of PEG molecules with different molecular weights, thus causing problems in purification and characterization. Therefore, we chose a molecule which is similar to triethylene glycol and derivatized it into a special amino acid, so it can be used in standard Fmoc solid-phase peptide synthesis. As a result, the new biotin reagent shows excellent solubility in both aqueous and polar aprotic solvents. Our experiments also show that the glyoxylyl-based biotin reagent is very stable in both acidic and basic conditions (data not shown). This is clearly an advantage over other common NHS-based or maleimide-based biotinylating reagents. We are currently developing a solution-phase synthesis procedure, so that this glyoxylyl-based reagent can be made in bulk quantities.

Site-Directed Mutagenesis and Expression of Anti-Insulin ScFv Containing N-Terminal Cysteine. As described in Materials and Methods, the codon for N-terminal cysteine was added by PCR-based site-directed mutagenesis of WTscFv creating NCscFv. The NCscFv gene was then cloned into pET21d expression vector. Figure 1 shows the initial DNA sequences of the mutated fragments which contain codons corresponding to formyl-Met-Cys. Then pET21d vector containing NCscFv was used to transform BL21 (DE3) *E. coli* host cells for expression. Since the immunoglobulin fragments produced from the pET21d transformed cells contained a carboxyl $(His)_6$, they were purified on a nickel-agarose column using immobilized metal affinity chromatography (IMAC) (*18*). Distinct bands at approximately 31 kDa can be seen in lanes 2 and 4 of Figure 2, corresponding to the wild-type scFv (WTscFv) and the N-terminal cysteine containing scFv (NCscFv), respectively. Purified anti-insulin NCscFv was subjected to protein microsequencing as described in Materials and Methods. Both DNA and protein sequencing analysis showed that a cysteine residue was successfully added to the N-terminus 5′ of glutamine, which was the first residue of WTscFv (data not shown).

In our bacterial protein expression system, a methionine residue is incorporated at the N-termimus as a part of the universal translation-initiation signal used by prokaryotes as well as eukaryotes. In prokaryotes, the methionyl moiety carried by the initiator tRNA is N-formylated prior to its incorporation. For a significant fraction of intracellular proteins, the amino-terminal methionine is also removed enzymatically by a methionine-specific aminopeptidase after the initiation of translation (*19*, *20*). We took advantage of these N-formyl methionine cleavage mechanisms as demonstrated by our ability to selectively label an N-terminal cysteine. Interestingly, methionine aminopeptidase has been reported to be particularly effective when cysteine is at the penultimate position (*21*).

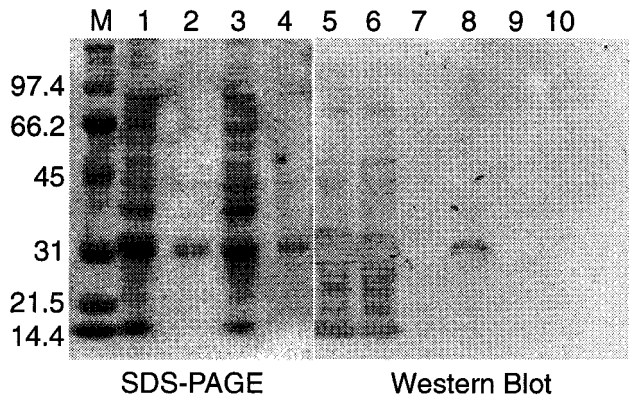

Figure 2. SDS-PAGE and Western blot Analysis of Derivatized proteins. Coomassie Blue stain of SDS/PAGE gel (lane M, 1−4) and Western blot of biotinylated and untreated lysates (lanes 5−10). Bands in lanes 5−10 were detected with streptavidin-alkaline phosphatase using BCIP/NBT as substrates. Lane M, molecular weight marker; lane 1, WTscFv cell lysate; lane 2, purified WTscFv; lane 3, NCscFv cell lysate; lane 4, purified NCscFv; lane 5, sulfo NHS-LC biotin labeled WTscFv cell lysate; lane 6, sulfo NHS-LC biotin labeled NCscFv cell lysate; lane 7, glyoxylyl-biotin labeled WTscFv cell lysate; lane 8, glyoxylyl-biotin labeled NCscFv cell lysate; lane 9, untreated WTscFv cell lysate; lane 10, untreated NCscFv cell lysate.

Biotinylation of Anti-Insulin ScFv in Total Cell Lysates. Total cell lysates that contained either WTscFv or NCscFv were biotinylated with (i) the conventional sulfo NHS-LC-biotin or (ii) our newly developed glyoxylyl-biotin. The streptavidin-alkaline phosphatase system coupled with a colorimetric detection system (BCIP/NBT) was used to detect biotinylated products in the western blot (Figure 2). Biotinylation by sulfo NHS-LC-biotin was essentially identical for both WTscFv lysates (lane 5) and NCscFv lysates (lane 6). This is not suprising since NHS-based reagents label predominantly lysine side chains which are abundant in most proteins. Thus, the western blot pattern of lanes 5 and 6 resembled that of the Coomassie Blue stain as all proteins were labeled (compare lanes 5 and 6 with lanes 1 and 3). When glyoxylyl-biotin was used to biotinylate total lysates, only one predominant band with a molecular mass of approximately 31 kDa in the NCscFv lysate was biotinylated (lane 8). This corresponds to the purified scFv shown in lanes 2 and 4. In contrast, only minor background was detected when the total WTscFv lysate was biotinylated with glyoxylyl-biotin under identical conditions (lane 7). As a negative control, no biotinylation or non-specific binding to streptavidin was detected for the untreated cell lysates (lanes 9 and 10). The above result clearly demonstrates that the glyoxylyl-biotin reagent is highly specific, that it can specifically label the N-terminal cysteine even in the presence of a large number of other proteins, and that glyoxylyl-biotin also works in the presence of 8 M urea under reducing conditions where many other free sulfhydryl groups of other proteins are exposed.

Site-Specific Modification Does Not Significantly Alter the Binding Affinity of Anti-Insulin ScFv.

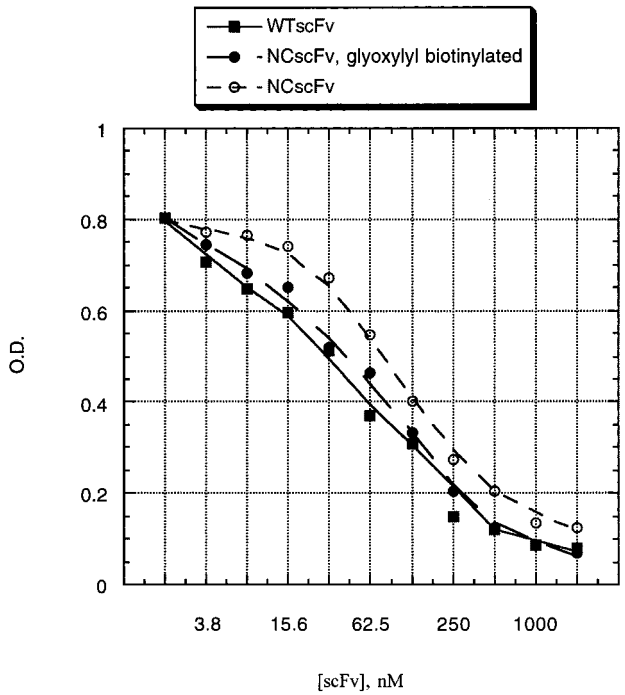

Figure 3. Insulin binding ELISA. A 96 well plate was coated with purified murin anti-insulin antibody (HB125) and blocked. Biotinylated porcine insulin was preincubated with serial dilutions of WTscFv, NCscFv, or glyoxylyl-biotinylated NCscFv, and was then place in HB125 coated 98 well plate. ScFvs and scFv0porcine insulin complex were removed by washing and biotinylated insulin captured by HB125 on plate was detected with SA-HRP and TMB [(■) WTscFv, (○) NCscFv, (●) glyoxylyl-biotinylated NCscFv].

Purified anti-insulin WTscFv and NCscFv were refolded as described (*12*). To investigate the changes in binding affinities of N-terminally mutated anti-insulin scFv to insulin, an insulin binding ELISA was performed with WTscFv, NCscFv, and glyoxylyl-biotinylated NCscFv. First, a 96 well plate was coated with purified parent anti-insulin IgG antibody (HB125). Sulfo NHS-LC biotin-labeled insulin was preincubated with serial dilutions of WTscFv, NCscFv, or glyoxylyl-biotinylated NCscFv prior to adding to HB125-coated plate. During this preincubation step, scFvs bound biotinylated insulin. Since insulin has only one antigenic determinant recognized by parent HB125 anti-insulin antibody, insulin prebound to HB125 scFvs will no longer bind to plate-coated HB125 parent antibody. Thus, only free insulin will be captured by HB125 antibody while scFv−insulin complexes will remain in solution and washed away. Captured insulin was detected with SA-HRP and TMB substrate. The stronger the scFv binds to the insulin, the lesser amount of insulin will be captured by plate bound HB125 antibody, which in turn will lead to a lower OD 450 measurement. Using this assay, the relative reactivities of the three scFvs were assessed (Figure 3). All scFvs, NCscFv, WTscFv, and NCscFv-glyoxyl-biotin, inhibited insulin from binding the parent HB125 IgG in a concentration-dependent manner. WTscFv and glyoxylyl-biotinylated NCscFv similarly inhibit insulin from binding to the parent antibody, whereas the reactivity between insulin and underivatized NCscFv is slightly weaker than the other two in this competition assay. The above study indicates that site-specific modification does not significantly alter the binding affinity of scFv.

Site-Specific Modification. There are several approaches available for site-specific protein modification (*3*, *6*−*8*, *22*, *23*). Among them are the ones developed by Geoghegan (*6*), Gaertuer (*7*), and Tam (*10*). Their approaches are novel and easy to perform compared to other protein-labeling strategies. The strategy we present in this paper is partially inspired by their efforts and, therefore, shares some similarity with their approaches. For example, our method as well as the methods by Geoghegan et al. (*6*), Gaertuer et al. (*7*), or Tam (*10*) use glyoxylyl-based chemistry and both methods result in derivatization at the N-terminus of a protein.

However, there are significant differences between our method and theirs (Table 1). For example, in our method, an N-terminal cysteine is incorporated into the protein using conventional site-directed mutagenesis. Then, the N-terminal cysteine, having a 1,2-aminothiol group, reacts specifically with glyoxylyl reagent forming a thiazolidine ring (*11*). Therefore, the protein itself is not modified after expression in the *E. coli* system. In contrast, the other methods require incorporation of N-terminal threonine or serine into the protein (by site-directed mutagenesis) followed by oxidation with periodate, a condition that potentially can damage the protein. The second difference between the methods is that we introduced a glyoxylyl group into the derivatizing reagent whereas the other methods uses hydrazide, aminooxy, or 1,2-aminothiol groups. Finally, in our approach, the modification reaction can be performed in total cell lysates before proteins fold into their native forms, making this approach attractive for protein purification as well as detection. The reaction between glyoxylyl groups and N-terminal cysteines is extremely selective so that only the target protein is modified at its N-terminal cysteine, even in the presence of many other proteins and biological molecules (Figure 2). It is also important to note that the cell lysates are produced in bacterial cells in reduced form so that in the presence of >6 M urea, the N-terminal cysteine is free from forming disulfide bonds with other cysteine residues. Therefore, the presence of a 1,2-aminothiol structure is assured for the glyoxylyl-based ligation. Under the same conditions, other nonterminal cysteine residues are present in reduced form but are not modified by the glyoxylyl group as observed in our experiments. We believe this approach can be used as a general method to site-specifically label the N-terminus of any recombinant protein. One obvious application is to produce well-defined radioimmunoconjugates for radioimmunotherapy of cancer. Other applications include the selective labeling of sensitive proteins such as enzymes that could be inactivated by oxidation or over modification of free thiol or amino groups.

Preparation, ^{99m}Tc-Labeling, and in Vitro Characterization of HYNIC and N_3S Modified RC-160 and [Tyr^3]Octreotide

Clemens Decristoforo and Stephen J. Mather*

Nuclear Medicine Research Laboratory, St. Bartholomews hospital, West Smithfield, London EC1 7BE, U.K.
Received October 5, 1998; Revised Manuscript Received February 1, 1999

The synthesis of conjugates of two somatostatin analogues, RC-160 and [Tyr^3]octreotide with different bifunctional chelators for labeling with Tc-99m, is described. Conjugates with hydrazinonicotinamide (HYNIC) and two N_3S compounds (benzoyl MAG3 and a N_3S adipate derivative) were prepared on a small scale with high purity allowing evaluation of different bifunctional chelators on the same peptide without extensive peptide synthesis. High in vitro stability and retained binding affinity was found for all conjugates except for the N_3S adipate. Peptide conjugates could be labeled at high specific activities (>1 Ci/μmol) with ^{99m}Tc, and different coligands were explored for the HYNIC conjugates. The resulting radiolabeled complexes were highly stable and showed binding affinity to somatostatin receptors in the nanomolar range. Varying labeling yield, stability, lipophilicity, and isomerism were found for different coligands used for labeling HYNIC conjugates, with lower lipophilicity, higher stability, and fewer coordination isomers for EDDA and tricine/nicotinic acid as ternary coligand compared to tricine. In particular, HYNIC complexes showed promising results for further in vivo evaluation.

INTRODUCTION

The radiolabeled somatostatin analogue ^{111}In-DTPA-D-Phe^1-octreotide (Octreoscan) has found a wide clinical application for imaging a range of tumors, including neuroendocrine cancer, carcinoid, and lymphoma (*1*−*4*) but one of the, at least, theoretical disadvantages of this compound is its restricted reactivity to receptor-subtypes SSR2 and SSR5. Recently, it has been demonstrated that another somatostatin analogue (RC-160 or vapreotide) has affinity for a different set of somatostatin receptor subtypes which may increase its usefulness for targeting more common tumors such as those of breast, ovary, exocrine pancreas, prostate, and colon (*5*−*7*). In further contrast to octreotide, RC-160 can also pass the blood-brain barrier and might therefore be used for imaging brain tumors (*8*). RC-160 has previously been radiolabeled with ^{123}I (*9*), ^{111}In (*10*), and recently ^{188}Re (*11*), and high affinity to somatostatin receptors in vivo has been proven.

Although the radiolabel of choice for tumor imaging would be technetium-99m, experience with suitable labeling methods is not yet as great as for other radionuclides [for review, see Liu et al. (*12*)]. The most widely used method for labeling such small highly specific peptides is by conjugation of bifunctional chelators (BFCs) to the peptide. The number of BFCs suitable for labeling with technetium-99m at the high specific activities necessary to permit the use of pharmacologically highly potent peptides in nontoxic doses is limited, but, in recent years, attempts have been made to label various somatostatin analogues with ^{99m}Tc using a number of different BFCs including diamidedithiols, triamidemonothiols and triaminemonothiols (*13*), propyleneamine oxime (*14*), tetramine (*15*), and hydrazinonicotinamide (HYNIC) (*16*). Such methods are generally considered more appropriate than the alternative approach of direct labeling following reduction of the disulfide bridge (*17*, *18*), which forms ^{99m}Tc complexes of uncertain structure and raises concerns with regard to the retention of specific binding to somatostatin receptors.

The aim of this study was to perform a comparison of some of the BFCs previously described, in order that some recommendations can be made on the most suitable system for technetium labeling of these small peptides. This report describes the small-scale preparation of conjugates of RC-160 and [Tyr^3]octreotide (TOC) with different BFCs, based on the triamidemonothiol and HYNIC cores. Results from ^{99m}Tc-labeling experiments using different coligand systems and in vitro evaluations of the resulting ^{99m}Tc complexes are reported and provide data for direct comparison of different BFCs.

EXPERIMENTAL PROCEDURES

Materials. Reagents were purchased from Aldrich-Sigma Chemical Co. except where otherwise stated and used as they were received.

6-BOC-hydrazinopyridine-3-carboxylic acid (BOC-HYNIC) was synthesized and characterized according to Abrams et al. (*19*).

2,3,5,6,-Tetrafluorothiophenyl-*S*-(1-ethoxyethyl)mercaptoacetamidoadipoylglycylglycine [N_3S-adipate (*20*)] was a gift from Alan R. Fritzberg (NeoRx Corporation, Seattle, WA).

N-Hydroxysuccinimide-*S*-acetyl-mercaptoacetyltriglycin [S-acetyl-NHS-MAG3 (*21*)] was a gift from Donald J. Hnatowich (University of Massachusetts, Worcester, MA).

S-Benzoyl-mercaptoacetyltriglycine (S-benzoyl-MAG3) was a gift from Ole K. Hjelstuen (Isopharma Radiopharmaceuticals, Oslo, Norway).

[Lys^5-BOC]RC-160, RC-160, [Tyr^3, Lys^5-BOC]octreotide, and [Tyr^3]octreotide (TOC) were synthesized by Bachem UK Ltd.

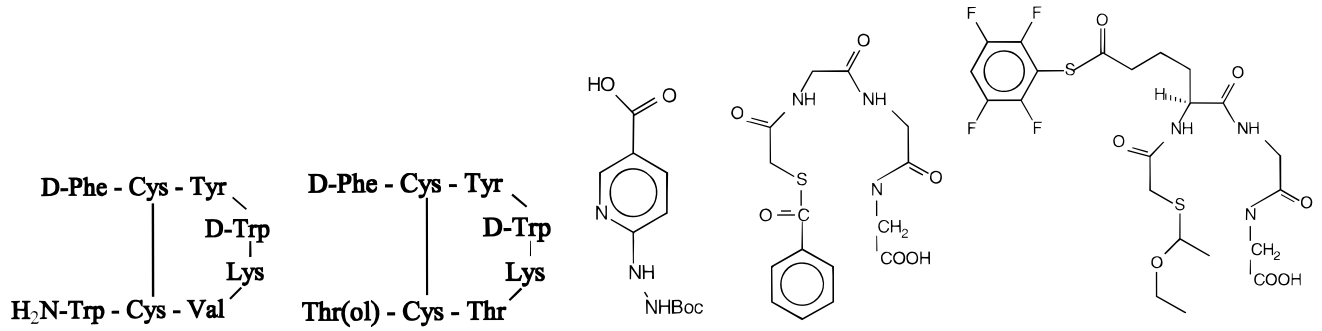

Figure 1. Structures of peptides and BFCs used. From left to right: RC-160, [Tyr^3]octreotide BOC-HYNIC, benzoyl-MAG3, N_3S-adipate.

(3-[^{125}I]iodotyrosyl^{11})Somatostatin-14 ([^{125}I]SST14) was purchased from Amersham Life Science Ltd. (Amersham, U.K.).

$Na^{99m}TcO_4^-$ was obtained from commercial $^{99}Mo/^{99m}Tc$ generator (Nycomed Amersham). Deionized water was obtained from a ELGA Elgastat UHP Water System and was of >18 MΩ quality.

INSTRUMENTS AND METHODS

HPLC. A Beckman solvent module 125 with Beckman UV detector 166NM and radiometric detection was used for reversed-phase HPLC analysis and preparation. A Beckman Ultrasphere ODS 5 μm, 4.6 × 250 mm column, flow rates of 1 mL/min, and UV detection at 220 nm were employed together with the following solvent systems. Method 1: acetonitrile/0.1%TFA/water. Gradient: 0−3 min 0% ACN; 3−13 min 0 to 50% ACN; 13−23 min 50% ACN, 23−26 min 50 to 70% ACN, 26−27 min 70 to 0% ACN. Method 2: acetonitrile/0.01 N phosphate buffer, pH 6.2. Gradient as in method 1. Method 3: acetonitrile/0.1% TFA/water; 0−3 min 0% ACN; 3−10 min 0 to 40% ACN; 10−20 min 40% ACN; 20−23 min 40 to 70% ACN; 26−27 min 70 to 0% ACN. Method 4: acetonitrile/0.01 N phosphate buffer, pH 6.2; 0−3 min 0% ACN; 3−10 min 0 to 25% ACN; 10−20 min 25% ACN; 20−23 min 25 to 70% ACN; 26−27 min 70 to 0% ACN.

Methods 1 and 2 were used for analyses of RC-160 conjugates, methods 3 and 4 for TOC conjugates.

TLC. Instant thin-layer chromatography on silica gel (ITLC-SG, Gelman Sciences) was performed using different mobile phases. 2-Butanone was used to determine the amount of free $^{99m}TcO_4^-$ ($R_f = 1$), and the PBS buffer was used to determine non-peptide-bound ^{99m}Tc coligand and $^{99m}TcO_4^-$ ($R_f = 1$), 50% acetonitrile/water for ^{99m}Tc colloid ($R_f = 0$).

SPE Purification. For purification of the radiolabeled peptide for stability studies, a solid-phase extraction (SPE) method was used. The radiolabeling mixture was passed through a C18-SEPPAK-Mini cartridge (Waters, Milford, MA). The cartridge was washed with 5 mL of water, the radiolabeled peptide eluted with 80% acetonitrile, and the organic solvent evaporated under vacuum. This method efficiently removed all hydrophilic impurities ($^{99m}TcO_4^-$, ^{99m}Tc coligand) and ^{99m}Tc colloid to a concentration of less than 2% when tested by HPLC or TLC.

Synthesis of Peptide Conjugates. Structures of RC-160, [Tyr^3]octreotide (TOC), and the BFC used are shown in Figure 1.

Synthesis of HYNIC-RC-160. A total of 0.3 mg of BOC-HYNIC, 2.0 mg of *O*-(7-azabenzotriazolyl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU), and 5 mg of diisopropyethylamine (DEA) in 300 μL of DMF were reacted for 15 min. A total of 60 μL of this solution was added to 1.0 mg of Lys-BOC-RC-160 in 20 μL of DMF/5 μL of water and allowed to react for 1 h. To stop the reaction, 1 mL of water was added, and the resulting solution was passed through a C18 SEPPAK cartridge (Waters, Milford, MA) washed with additional 5 mL of water and finally eluted with 1 mL of 100% acetonitrile. The acetonitrile solution was reduced under vacuum to a volume of 100 μL. A total of 300 μL of TFA and 10 μL of thioanisole were added and reacted for 10 min. The solution was evaporated to dryness, and the residue dissolved in 200 μL of 50% ethanol and purified on HPLC using method 1. The peak of HYNIC-RC-160 was collected and stored in the HPLC eluent at −20 °C under nitrogen. Further characterization was performed by HPLC analysis and matrix assisted laser desorption ionization MS on a Lasermat 2000 (Finnigan Mat).

Synthesis of S-Acetyl-MAG3-RC-160. A total of 0.3 mg of Lys-BOC RC-160, 1.0 mg of S-acetyl-NHS-MAG3, and 1 mg of DEA were reacted for up to 3 h. SEPPAK purification and deprotection was carried out as described for HYNIC-RC-160.

Synthesis of S-Benzoyl-MAG3-RC-160. A total of 2.2 mg of S-benzoyl-MAG3, 1.0 mg of HATU, and 1 mg of DEA in 170 μL of DMF were reacted for 15 min. A total of 40 μL of this solution was added to 0.4 mg of Lys-BOC-RC-160 in 20 μL of DMF/5 μL of water and allowed to react for 1 h. SEPPAK purification and deprotection was carried out as described for HYNIC-RC-160.

Synthesis of N_3S-RC-160. A total of 0.4 mg of N_3S adipate, 0.67 mg of Lys-BOC-RC-160, and 0.3 mg of DEA in 150 μL of DMF were incubated for 80 min. SEPPAK purification and deprotection was carried out as described for HYNIC-RC-160.

Synthesis of S-Benzoyl-MAG3- and HYNIC-TOC. Conjugates were prepared in the same way as the RC-160 conjugates corrected for molecular weight, purified and analyzed by HPLC method 3.

^{99m}Tc Labeling. *[^{99m}Tc]HYNIC conjugate.* Tricine as coligand: in a rubber sealed vial, 10 μg of HYNIC conjugate was incubated with 0.5 mL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), 0.5 mL of $^{99m}TcO_4^-$ solution (100−1000 MBq), and 25 μL of tin(II) solution (10 mg of $SnCl_2 \cdot 2H_2O$ in 10 mL of nitrogen purged 0.1 N HCl) for 30 min at room temperature.

Ethylendiaminediacetic acid (EDDA) as coligand: 10 μg of HYNIC-RC-160 was incubated with 0.5 mL of solution of EDDA (10 mg/mL, pH 7.0), 0.5 mL of $^{99m}TcO_4^-$ solution (100−1000 MBq), and 5−10 μL of tin(II) solution (10 mg of $SnCl_2 \cdot 2H_2O$ in 10 mL of nitrogen purged 0.1 N HCl) for 60 min at room temperature.

Nicotinic acid/tricine as coligands: 10 μg of HYNIC-RC-160, 0.4 mL of tricine solution (100 mg/mL in 25 mM

succinate buffer, pH 5.0), 0.1 mL of nicotinic acid (NA) (20 mg/mL in 25 mM succinate buffer pH 5.0), 0.5 mL of $^{99m}TcO_4^-$ solution (100−500 MBq), and 25 μL of tin(II) solution (10 mg of $SnCl_2 \cdot 2H_2O$ in 10 mL of nitrogen purged 0.1 N HCl) were heated at 100 °C for 15 min.

[^{99m}Tc]MAG3 Conjugate. A total of 10 μg of S-benzoyl-MAG3 conjugate was heated with 0.5 mL of sodium tartrate (100 mg/mL in 0.1 M phosphate buffer, pH 7.2), 1.5 mL of $^{99m}TcO_4^-$ solution (100−1000 MBq), and 40 μL of tin(II) solution (10 mg of $SnCl_2 \cdot 2H_2O$ in 10 mL of nitrogen purged 0.1 N HCl) at 100 °C for 15 min.

[^{99m}Tc]N_3S-RC-160. A total of 10 μg of N_3S-RC-160, 1.0 mL of glucoheptonate solution (40 mg/mL pH 2.5), 0.5 mL of $^{99m}TcO_4^-$ solution (100−1000 MBq), and 20 μL of tin(II) solution (10 mg of $SnCl_2 \cdot 2H_2O$ in 10 mL of nitrogen purged 0.1 N HCl) were heated at 80 °C for 20 min.

In Vitro Characterization of Radiolabeled Peptides. *Stability*. The stability of the radiolabeled peptides in aqueous solution was tested by incubation of the SPE purified peptide in 0.1 M phosphate buffer and in a solution containing 1000-fold excess cysteine over the peptide at pH 7.4 at room temperature up to 24 h. Cysteine, naturally occurring and a strong chelating compound for technetium, is thought to be responsible for in vivo degradation of ^{99m}Tc complexes and is frequently used for in vitro stability studies (*22*). As a control, the stability of [^{99m}Tc]tetraglycine, a technetium complex with a low complex stability (*23*), was tested in parallel. Stability in fresh human plasma was also measured at 37 °C for up to 4 h followed by precipitation of plasma protein with acetonitrile. Degradation of the ^{99m}Tc complex was assessed by TLC and HPLC.

Somatostatin Receptor Binding. The binding affinity of peptide conjugates was tested in a competition assay against [^{125}I]SST14 as described elsewhere (*24*). Mouse pituitary [AtT20 cells, expressing SST receptors subtype 2 and 5 (*25*)] and rat pancreatic [AR42J cells, expressing SST receptors subtype2 (*26*)] tumor cell membranes were used as a source for somatostatin receptors and were separated from free radioligand by filtration through glass fiber filters (Whatman GF/C), and IC_{50} values were calculated following nonlinear regression with Origin software (Microcal Origin 5.0, Northampton MA). The specific binding of the ^{99m}Tc-labeled peptides was determined by competition against unmodified RC-160 in a similar assay. K_d values of ^{99m}Tc-labeled peptide conjugates were determined in radioligand saturation assays using AR42J cell membranes as receptor source.

RESULTS

Synthesis of Peptide Conjugates. HPLC analysis of reaction mixtures of different RC-160 conjugates is shown in Figure 2, preparation of TOC conjugates gave similar results. Quantitative peptide coupling of BOC-HYNIC (Figure 2C, peak 3) and S-benzoyl-MAG3, using HATU, as well as of the N_3S adipate active STFP ester was achieved within 1 h. For the *N*-hydroxysuccinimide-activated S-acetyl-MAG3, no quantitative reaction could be achieved in DMF even at high molar excess of the activated ester over the peptide. Deprotection of the peptide conjugates with TFA resulted in one major HPLC-peak for HYNIC-RC-160 (Figure 2D, peak 4) and S-benzoyl-MAG3 (Figure 2F, peak 5). Overall yields were >50% for both these BFCs. In the case of S-acetyl-MAG3, multiple peaks were observed, indicating instability of the conjugate under acidic conditions (Figure 2E) and no pure peptide conjugate could be isolated. The N_3S-RC-160 deprotection solution also showed several byproducts

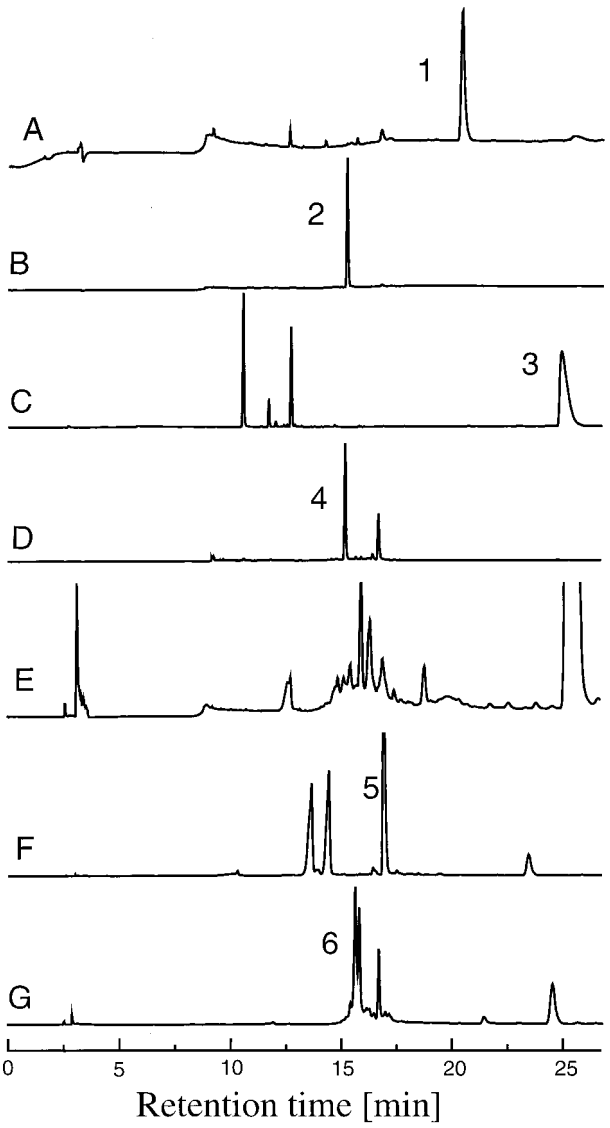

Figure 2. HPLC traces (UV 220 nm, method 1) from the synthesis of RC-160 conjugates. (A) Lys-BOC-RC-160 standard, (B) RC-160 standard, (C) reaction solution of BOC-HYNIC-RC-160 before deprotection, (D) deprotection solution of HYNIC-RC-160, (E) deprotection solution of S-acetyl-MAG3-RC-160, (F) deprotection solution of S-benzoyl-MAG3-RC-160, (G) deprotection solution of N_3S-RC-160. Peaks marked with numbers: 1, Lys-BOC-RC-160; 2, RC-160; 3, BOC-protected-HYNIC-RC-160; 4, HYNIC-RC-160 (deprotected); 5, S-benzoyl-MAG3-RC-160; 6, N_3S-RC-160.

Table 1. Molecular Weight of Peptide Conjugates Determined by Laser Desorption MS Compared with the Theoretical Value

mass	calculated	found
HYNIC-RC-160	1264.5	1265.0
S-benzoyl-MAG3-RC-160	1479.6	1479.4
N_3S-RC-160	1533.6	1462.4
HYNIC-TOC	1170.5	1170.0
S-benzoyl-MAG3-TOC	1383.5	1383.4

(Figure 2G), and the overall yield was <20%. Mass spectrometry data are summarized in Table 1. For HYNIC-RC-160 and S-benzoyl-MAG3, as well as for the TOC conjugates, the calculated MW matched well with the experimental value and the conjugates were stable for several months. N_3S-RC-160 showed a significantly lower MW than calculated, its difference matching the S-ethylethoxy protection group, indicating a cleavage during the deprotection reaction. The stability of this

Tyr octreo	HYNIC-tricine/NA	2.11
Tyr octreo	HYNIC-EDDA	2.65
Tyr octreo	MAG3	1.11

conjugate was considerably lower, and degradation was seen already after 1 week of storage at −20 °C. Nevertheless the conjugate continued to produce stable and reproducible labeling results and was therefore considered for further evaluation, but no conjugate of TOC was prepared.

^{99m}Tc Labeling. Labeling yields of RC-160 and TOC conjugates at specific activities of approximately 1 Ci/μmol are listed in Table 2, and radiochromatograms for RC-160 conjugates are shown in Figure 3. Almost quantitative labeling (>90%) was achieved for most conjugates and coligand systems. Lipophilic impurities in varying amounts were found in the MAG3 conjugate-labeling mixture (Figure 3D). Labeling HYNIC-RC-160 with EDDA as coligand at room-temperature resulted in an average yield of 69% (Figure 3C), for HYNIC-TOC 63.9%. Labeling yield for the EDDA compounds was independent of pH between 4 and 7.2, and no significant increase was observed by heating the labeling mixture. The optimal EDDA concentration was found to be 5 mg/mL, but the labeling yield was mainly influenced by the concentration of stannous ions in the labeling solution. A rapid decline in labeling yields for HYNIC-RC-160 with increasing amounts of stannous ions was observed (Figure 4) when EDDA was used as coligand. Using pyridine/tricine as ternary ligands, labeling of the peptide conjugate was quantitative, but residues of the binary tricine complex were found when labeling was performed at room temperature. Quantitative labeling to the ternary ligand was only achieved by heating at 100 °C for 15 min.

^{99m}Tc-labeled TOC conjugates showed considerably lower retention times on HPLC compared to their RC-160 counterparts, indicating the considerably lower lipophilicity of this peptide. HPLC profiles were dependent on the pH of the aqueous solvent employed. When water/0.1% TFA HPLC systems were used, retention times were very similar for all ^{99m}Tc-labeled conjugates of the same peptide (see Figure 3, left columns). Using a phosphate buffer at pH 6.2, a better distinction between different labeled peptide conjugates was achieved (see Figure 3, right column). Retention times were in the following order: EDDA-HYNIC < tricine/NA-HYNIC < N_3S < MAG3 < tricine-HYNIC (main peaks) for both RC-160 and TOC conjugates. Multiple peaks were found for tricine as coligands (Figure 3A) and two main peaks for tricine/NA as ternary coligands for HYNIC conjugates (Figure 3B). Except for the N_3S conjugate, this HPLC method allowed efficient separation of the ^{99m}Tc complex from the cold conjugate to yield carrier free Tc complexes that could be used for radioligand binding assays.

Stability of ^{99m}Tc-labeled Peptide Conjugates. ^{99m}Tc-labeled peptide conjugates were stable in aqueous solutions for 24 h, except for tricine-HYNIC conjugates, which, when excess tricine was removed by SEPPAK purification, showed a radiochemical purity of less than 80% after 24 h. Challenge experiments with 1000-fold molar excess of cysteine showed no significant degree of transchelation for N_3S and HYNIC conjugates while, for the MAG3 conjugates, 20% transchelation after 24 h was observed. Results of cysteine challenge experiments are shown for RC-160 in Figure 5, the decrease in the radiochemical purity over time can be related to the transchelation to cysteine. All compounds were stable to 4 h incubation in human plasma, although varying amounts of labeled peptide were protein bound and were precipitated with plasma proteins by acetonitrile, higher amounts for RC-160 compared to TOC.

Receptor Binding. The cold peptide conjugates all showed a high binding affinity on AtT20 and AR42J cell membranes. Competition curves for RC-160 conjugates against [^{125}I]SST14 are shown in Figure 6. For the RC-160 itself, an IC_{50} value of 0.38 nM was calculated while, for S-benzoyl-MAG3-RC-160, binding affinity was almost identical with an IC_{50} of 0.36 nM. HYNIC-RC-160 and N_3S-RC-160 showed a slightly lower binding affinity with IC_{50} values of 1.51 and 1.73 nM, respectively (Figure 6). HYNIC-TOC showed an IC_{50} value of 1.55 nM and S-benzoyl-MAG3-RC-160 of 0.15 nM compared to 0.39 nM for unmodified TOC.

All ^{99m}Tc-labeled conjugates tested showed high specific binding to somatostatin receptors, with calculated K_d values in the nanomolar range, varying from 0.93 to 2.65 nM. Binding affinities were similar for RC-160 and TOC derivatives. K_d values determined on AR42J cell membranes are listed in Table 3. Saturation curves for the ^{99m}Tc-labeled EDDA-HYNIC peptide conjugates are shown as examples in Figure 7.

DISCUSSION

Preparation of Conjugates. RC-160 and [Tyr^3]-octreotide not only have potential clinical utility in their own right but they also represent model compounds which make them ideal for comparison of conjugation and radiolabeling strategies. Both are small octapeptides cyclized through a disulfide bridge and both contain a critical lysine residue, which is essential to preserve in order to retain receptor affinity. The use of a BFC approach for preparation of conjugates for ^{99m}Tc labeling thus requires protection of the lysine-epsilon amino group with a cleavable group like BOC, and conjugation and labeling conditions must be chosen which do not put the disulfide at risk. In addition, many BFCs additionally contain thiols for chelating ^{99m}Tc that also require protection. In this case, the number of protection strategies is very limited. The thiol-protecting group needs to be stable against the slightly alkaline conditions used in the conjugation reaction and also strong acidic conditions during the cleavage of the BOC-amino protection. At the same time, however, the thiol-protecting group must be readily cleaved during the labeling reaction in order to bind ^{99m}Tc. We tested three N_3S-BFCs with different

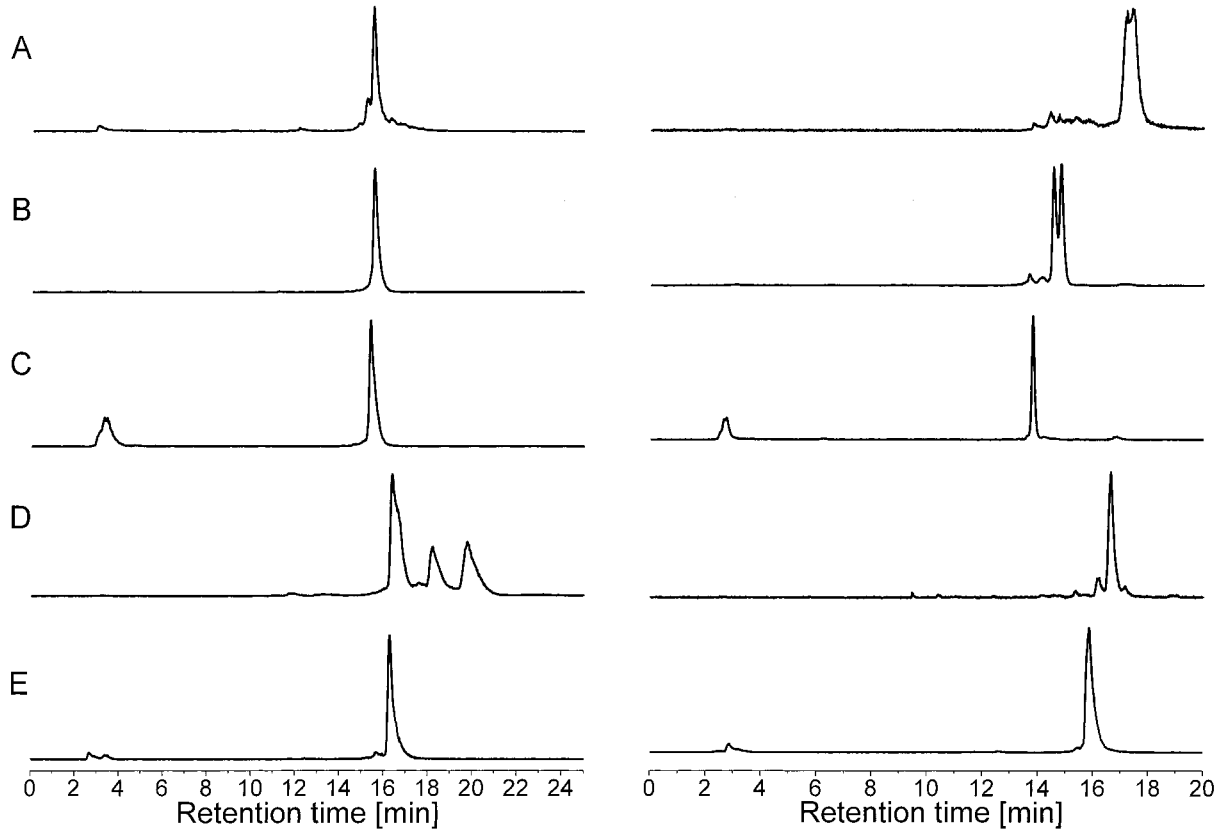

Figure 3. Radiochromatograms of labeling mixtures of different radiolabeled RC-160 conjugates, analyzed by HPLC method 1 (left column) and method 2 (right column). (A) Tricine-HYNIC-RC-160, (B) tricine/NA-HYNIC-RC-160, (C) EDDA-HYNIC-RC-160, (D) MAG3-RC-160, (E) N_3S-RC-160.

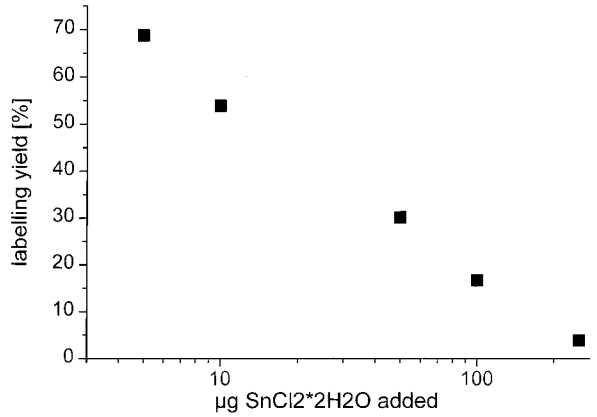

Figure 4. Dependence of labeling yields for EDDA-HYNIC-RC-160 on stannous ion concentration. Conditions for labeling: 10 μg of peptide, 100 MBq ^{99m}Tc.

protection groups on the thiol (benzoyl-MAG3, acetyl-NHS-MAG3, and ethylethoxy-N_3S adipate). Only the benzoyl group remained stable during the coupling reaction, and both acetyl and ethylethoxy groups were cleaved, mainly during the TFA deprotection reaction.

Using HATU for in situ activation of the free carboxylic acid in the BFC molecule, quantitative coupling yields of the BFC to the peptide and high overall yields on a very small scale (less than 1 mg of peptide) were achieved. Surprisingly, with the N-hydroxysuccinimide-activated ester (NHS-MAG3), which is a widely used system for activating the BFC, even at a high excess of BFC over the peptide, residues of the uncoupled peptide remained which would be likely to cause a problem in the preparation of high-specific activity preparations.

^{99m}Tc Labeling and Stability. Since radiolabeling with technetium requires the use of a reductant, in this case stannous ion, labeling was performed at room temperature, whenever possible, to limit the possibility of a reduction of the disulfide bridge. Although our principle aim was not to achieve the quantitative levels of labeling required for clinical use, sufficiently high labeling efficiencies for in vitro and in vivo evaluations of all the prepared ^{99m}Tc-labeled peptide conjugates were achieved. High specific activity labeling, greater than 1 Ci/mmol could be achieved in all cases. Radiolabeling of HYNIC conjugates requires the use of additional coligands to complete the technetium coordination sphere and our results of labeling using aminocarboxylates as coligands was basically in concordance with the findings

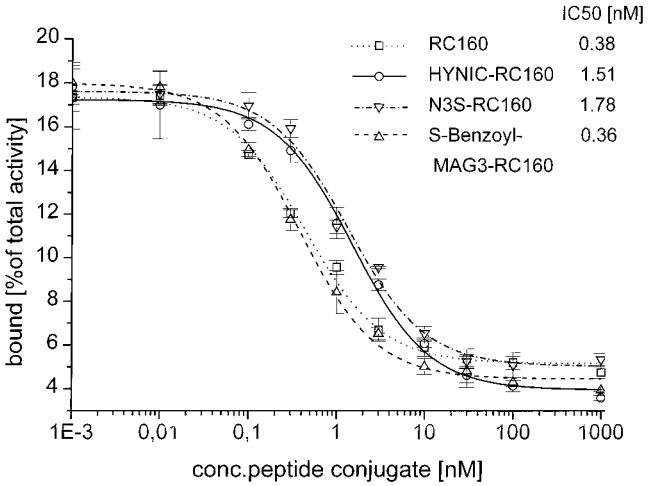

Figure 6. Competition curves of different RC-160 conjugates and calculated IC_{50} values, determined on AtT20-cell membranes, radioligand: [^{125}I]SST14 (data points: bound ± sd).

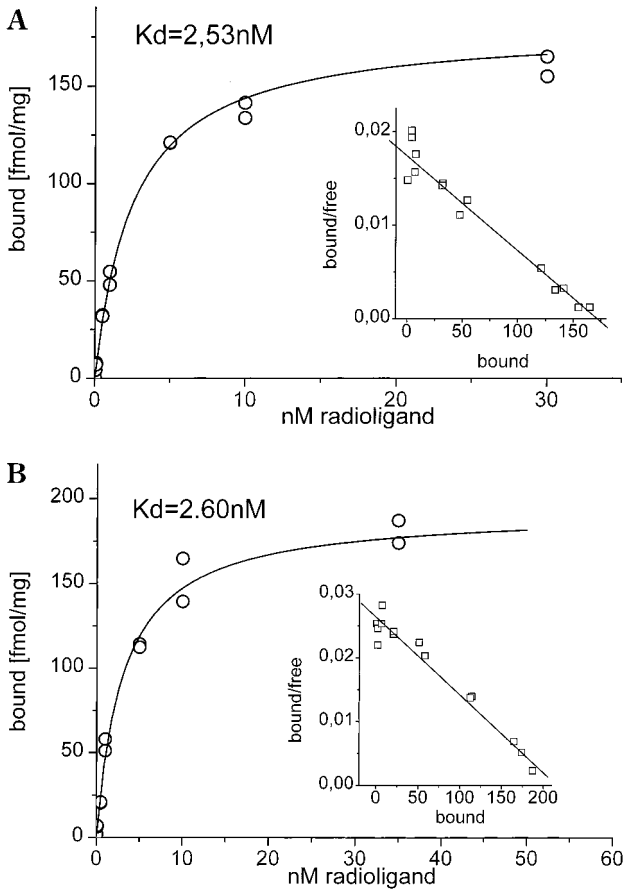

Figure 7. Saturation assays of ^{99m}Tc-labeled EDDA-HYNIC conjugates with respective Scatchard plot, left RC-160 (A), right [Tyr^3]octreotide (B).

of Liu et al. (*27*), who also addressed the problem of specific activity in more detail. Labeled HYNIC conjugates with varying coligands could better be distinguished on HPLC using a phosphate buffer, pH 6.2, gradient than with TFA. For tricine as coligand, a lower in vitro stability (with degradation of the complex especially after removal of excess tricine) and a greater number of isomers were found compared to EDDA. EDDA gave consistently lower labeling yields, but interestingly, we found that the yields were mainly dependent on the amount of stannous ions added and less on the EDDA concentration, pH, or temperature. Although not explored, this presumably relates to differences in the oxidation state of the technetium in the EDDA complex at different stannous ion concentrations.

The high number of isomers and the relatively low stability of ^{99m}Tc-labeled HYNIC modified peptides with tricine as coligand can be overcome by adding a ternary ligand to the labeling solution. We preferred not to use the well characterized triphenylphosphines as described by Edwards et al. (*28*) since their strong reducing properties might affect the disulfide bond. We therefore chose pyridines such as nicotinic acid which were recently described as possible ternary ligands for the tricine-HYNIC system (*29*). Nicotinic acid was compared with other pyridines such as pyridinesulfonic acid or pyridineacetic acid but did not show significantly different properties. To achieve quantitative labeling, heating at 100 °C for 15 min was necessary as ternary ligand complexes were not quantitatively obtained at room temperature. These complexes had a higher stability and lower retention time on HPLC, indicating lower lipophilicity. The number of isomers also was reduced to two compared to more than seven for the tricine binary complex.

^{99m}Tc labeling of the benzoyl-MAG3 conjugates at room temperature failed to achieve complexation, even at high pH [as previously described for MAG3 labeling (*30*)]. Efficient labeling required heating at 100 ˚C to remove the protection group, but even these conditions resulted in the presence of lipophilic impurities possibly due to insufficient deprotection and/or degradation of the peptide conjugate yielding mixed complexes as described for MAG3 itself (*30*−*32*). There was also concern that boiling the peptides in the presence of stannous ion might reduce the disulfide bridge. However, radioligand binding assays showed that the [^{99m}Tc]MAG3 conjugates retain high binding affinity despite this treatment and no difference in retention times or conjugate stability was observed. Studies on tricine/NA ternary ligand systems comparing ternary complexes obtained at room temperature and after heating at 100 °C also showed no difference in the binding affinity of both complexes. These studies prove the stability of the disulfide bridge against reduction by stannous ions even at elevated temperature.

Receptor Binding and Tumor Targeting Properties. In general, all the conjugates prepared and their technetium complexes showed high-affinity specific binding to somatostatin receptors with no relevant differences in binding constants (IC_{50}, K_d values) so far as their likely utility for imaging tumors is concerned. Binding constants of the ^{99m}Tc complexes were in the low nanomolar range, which can be considered sufficiently high for imaging SST-receptors in vivo.

The compounds thus show promise for future tumor-targeting studies initially in animal models and subsequently in patients. Further experiments also have to show the differences of the two investigated peptides described in this study concerning their imaging properties. However, recent publications on ^{111}In-DTPA-RC-160 in comparison with octreotide have shown no advantages of RC-160 in humans (*33*) also no relevant brain uptake was found for the investigated RC-160 derivative (*10*). Whether this holds true for the described ^{99m}Tc-labeled compounds and whether the difference in receptor specificity might offer advantages for RC-160 derivatives remains to be answered.

CONCLUSION

This paper describes the preparation of peptide conjugates using a variety of bifunctional chelate systems suitable for ^{99m}Tc labeling on a small scale using two model peptides. The methods described can be used to evaluate different labeling techniques without extensive and expensive peptide synthesis. Stable HYNIC binary and tertiary complexes in particular could be prepared easily and in high yield. All ^{99m}Tc complexes showed retained binding affinity to somatostatin receptors and further evaluation in vivo will explore their potential for imaging tumors using nuclear medicine techniques.

ACKNOWLEDGMENT

The study described was supported by a EC-"Marie Curie Research Training Grant", proposal E B4001GT9-63891 and the IAEA Coordinated Research Program "^{99m}Tc Labeled Peptides for Imaging of Peripheral Receptors". Special thanks go to H. R. Maecke and M. Behe for their help in the peptide preparation and for sharing their experience in HYNIC labeling. In addition we would like to thank A. R. Fritzberg, D. J. Hnatowich, and O. K. Hjelstuen for the supply of bifunctional chelators.

Recognition of Hairpin-Containing Single-Stranded DNA by Oligonucleotides Containing Internal Acridine Derivatives

Jean-Christophe François* and Claude Hélène

Laboratoire de Biophysique, Muséum National d'Histoire Naturelle, INSERM Unité 201- CNRS UA 481, 43 rue Cuvier, 75231 Paris Cedex 05, France . Received October 7, 1998; Revised Manuscript Received January 27, 1999

Oligodeoxynucleotides with an internal intercalating agent have been targeted to single-stranded sequences containing hairpin structures. The oligonucleotide binds to nonadjacent single-stranded sequences on both sides of the hairpin structure in such a way as to form a three-way junction. The acridine derivative is inserted at a position that allows it to interact with the three-way junction. The melting temperature (T_m) of complexes formed between the hairpin-containing target and oligonucleotides containing one internal acridine derivative was higher than that obtained with the same target and an unmodified oligonucleotide ($\Delta T_m = +13$ °C). The internal acridine provided the oligonucleotide with a higher affinity than covalent attachment to the 5′ end. Oligonucleotides could also be designed to recognize a hairpin-containing single-stranded nucleic acid by formation of Watson−Crick hydrogen bonds with a single-stranded part and Hoogsteen hydrogen bonds with the stem of the hairpin. An internal acridine derivative was introduced at the junction between the two domains, the double helix domain with Watson−Crick base pairs and the triple helix domain involving Hoogsteen base triplets in the major groove of the hairpin stem. Oligonucleotides with an internal acridine or an acridine at their 5′ end have similar binding affinities for the stem-loop-containing target. The bis-modified oligonucleotide containing two acridines, one at the 5′ end and one at an internal site, did not exhibit a higher affinity than the oligonucleotides with only one intercalating agent. The design of oligonucleotides with an internal intercalating agent might be of interest to control gene expression through recognition of secondary structures in single-stranded targets.

INTRODUCTION

Hairpin structures frequently occur in RNA secondary structures and also in DNA sequences that are found near functional loci and therefore seem to play a critical role in gene regulation (*1*). In the antisense strategy where the antisense oligonucleotides are targeted to single-stranded messenger RNAs, it was shown that stem-loop structures can compete with intermolecular hybridization of the oligonucleotides to the complementary sequences (*2*). Nevertheless, hairpin structures could also be exploited in the design of the recognition elements of an oligonucleotide aimed at inhibiting mRNA translation (*3*, *4*) or probing RNA structures (*5*).

We have previously shown that hairpin-containing nucleic acids could bind oligodeoxynucleotides complementary to nonadjacent single-stranded sequences on both sides of the stem-loop sequence (*6*). Oligonucleotides can also bind to hairpin-containing single-stranded nucleic acids (DNA or RNA) by using both triple helix and double helix formation (*3*, *7*−*15*).

In the present paper, we have investigated the effect of introducing an intercalating agent, an acridine derivative, in an oligonucleotide designed to recognize two single-stranded sequences separated by a hairpin structure. We demonstrate that when the acridine is inserted at an internal position close to the bases of the stem loop structure, the resulting complexes are more stable than when it is linked to the 5′ end of the oligonucleotide, suggesting a preferential site of interaction for the acridine ring near the center of the three-way structure.

The formation of triple helices is of interest in both the antisense and the antigene strategies (*16*). Clamp oligonucleotides can bind to an oligopurine sequence in a single-stranded nucleic acid by forming both Watson−Crick and Hoogsteen hydrogen bonds (*17*−*19*). Circular oligonucleotides can also be designed to bind via both double and triple helix formation (*20*, *21*). Recently, it was shown that the incorporation of an acridine derivative at an internal site of an oligonucleotide stabilizes triplexes with an interruption in the oligopurine target sequence and therefore opens new possibilities to extend the range of DNA sequences recognized by triplex-forming oligonucleotides (*22*, *23*). Triplex-specific intercalating agents such as benzopyridoindole and benzopyridoquinoxaline derivative could also be introduced into triplex-forming oligonucleotides to increase binding affinity to the DNA double helices (*24*, *25*).

We have previously demonstrated that antisense oligonucleotides could bind to hairpin-containing single-stranded nucleic acids by using both triple helix and double helix formation (*9*). These oligonucleotides interact with one of the two single-stranded sequences flanking the hairpin via Watson−Crick base pair formation and with the double-stranded stem sequence of the hairpin via Hoogsteen base triplet formation. These newly designed antisense oligonucleotides were called Watson−Crick/Hoogsteen oligonucleotides (abbreviated as WC/H). We have now synthesized WC/H oligonucleotides with an internally incorporated acridine in such a way that the acridine ring is located at the junction between the

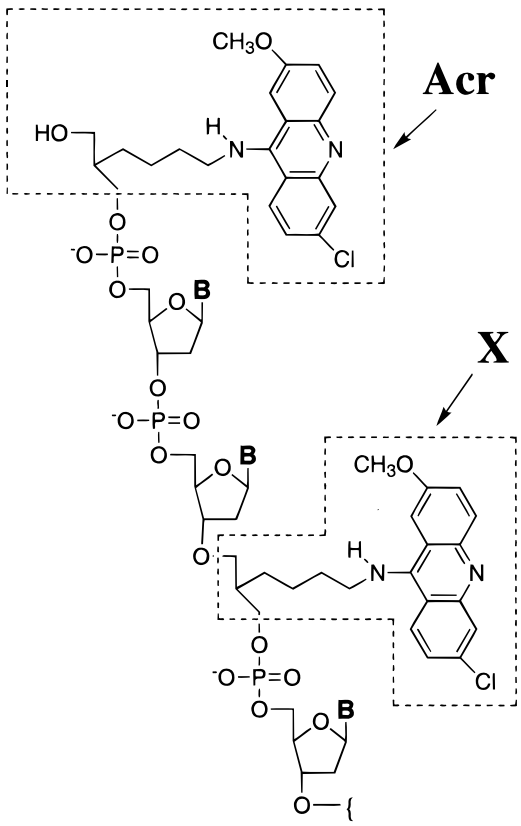

Figure 1. Chemical structures of the internally incorporated acridine within an oligonucleotide and the acridine linked at the 5′ end of an oligonucleotide. Note that the acridine ring covalently linked to the 5′ end was noted in the text as Acr and that the internal acridine derivative was referred to as X. B represents a base.

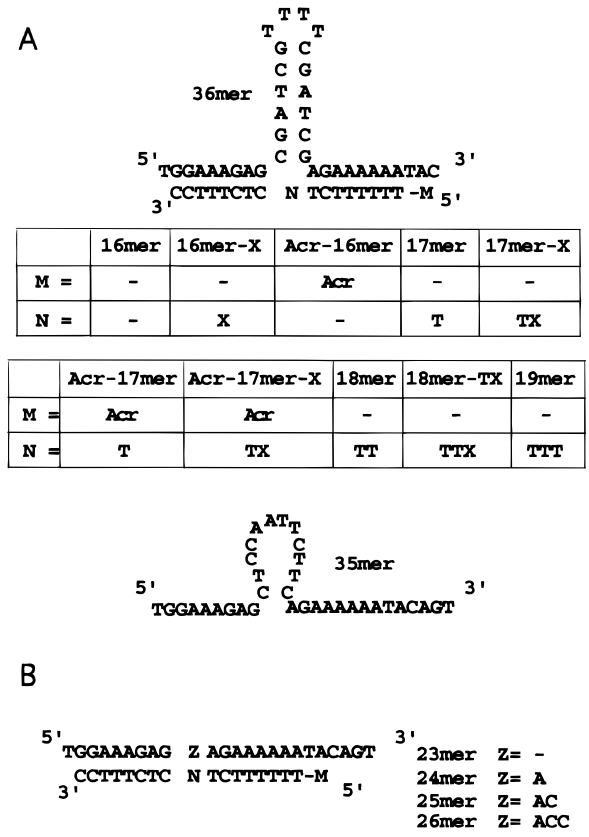
duplex and triplex portions of the complex. These WC/H oligonucleotides with an internal acridine form more stable complexes with their target than the unmodified oligonucleotides. The binding affinity of the WC/H oligonucleotide with an internal acridine is similar to the binding affinity of the oligonucleotide with an acridine linked to its 5′ end.

MATERIALS AND METHODS

Oligonucleotides. Oligonucleotides and acridine-containing oligonucleotides were synthesized by Eurogentec (Belgium). Acridine phosphoramidite (Glen Research) was either internally incorporated into oligonucleotides in the course of the synthesis or incorporated at the end of synthesis for 5′-linked oligonucleotides. Note that the natural three carbon internucleotidic phosphate distance is maintained in the oligonucleotide containing an internal acridine (Figure 1). The acridine ring was tethered to the backbone via five atoms. The 5′-linked acridine was tethered to the 5′-phosphate group via a seven atom containing linker. A bis-modified oligonucleotide with two acridines, one internal and one linked to the 5′ end, was obtained by the same procedure.



Before utilization, the acridine-oligonucleotide conjugates were purified by gel-filtration on G25 sephadex minicolumns (Boehringer Mannheim) in order to eliminate uncoupled acridine. The quality of acridine-oligonucleotide conjugates was then checked by denaturing gel electrophoresis (20% polyacrylamide/7 M urea). For detection, we used both the UV shadow effect of the oligonucleotide with irradiation at 254 nm on a chromatography paper containing a fluorescent-indicator, (TLC plastic sheets silica gel 60 F254, Merck), and the fluorescence of the incorporated acridine (obtained after excitation at 320 nm). Dark bands at 254 nm (corresponding to absorption of the bases of the oligomers) comigrated with yellow bands at 320 nm (corresponding to the fluorescence of the acridine). With this control assay, all acridine-containing oligonucleotides exhibited only one band that migrated more slowly than the dark band of the unmodified oligonucleotides. The length of 5′ end-labeled unmodified oligonucleotides has also been checked by gel electrophoresis.

The concentration of oligonucleotides and acridine-containing oligonucleotides was determined using the extinction coefficient for acridine at 424 nm, 8500 M^{-1} cm^{-1} or calculated by nearest-neighbor method (*26*) assuming an extinction coefficient for acridine of 85 000 M^{-1} cm^{-1} at 260 nm. The concentration of the oligonucleotide containing two acridine rings was estimated at 260 nm. With this oligonucleotide, calculations using the extinction coefficient at 424 nm gave an underestimated concentration, probably due to the existence of interactions involving the two acridine rings.

Melting Experiments. Absorption spectra were recorded on an UVIKON 940 spectrophotometer with cell holders thermoregulated by a circulating liquid (80% water, 20% ethylene glycol). Sample temperature was decreased from 90 to 5 °C and increased back to 90 °C at a rate of 0.25 °C/min with absorption readings at 260 and 540 nm taken every 5 min. Melting curves were obtained by subtracting the absorbance recorded at 540 nm where none of the constituents absorbed light from that recorded at 260 nm. Under all the experimental conditions described in the figures, all melting profiles were reversible. The melting temperature T_m (±1 °C) was determined as the maximum of the first derivative of melting curves. All the T_m experiments presented in this study were performed with 2 μM hairpin-containing target and 2 μM oligonucleotide ligand, therefore, enabling direct comparison of T_m values. It should be noted that these T_m values depend on the concentration of oligonucleotides. For acridine-containing oligonucleotides, identical melting temperatures were obtained from absorbance measurements at 260 or 425 nm (where acridine absorbs).

RESULTS AND DISCUSSION

Design of Hairpin-Containing Targets and Acridine-Containing Oligonucleotides. In the first DNA model, a single-stranded nucleic acid fragment, 36 nucleotides (nt) in length (36mer) was used as a target for 16mer oligonucleotides linked to an acridine derivative (Figure 2A). The structure of the acridine conjugates is shown in Figure 1. The 36mer can form a hairpin structure with four G·C and two A·T base pairs in the stem and four thymines in the loop. The sequence of the control 35mer was identical to that of the 36mer except that the sequence in the stem-loop $^{5'}$CGATCGTTTTCGATCG$^{3'}$ was changed to $^{5'}$CTCCAATTCTTC$^{3'}$, preventing the formation of a hairpin structure in the 35mer. Three additional nucleotides (AGT) were present at the 3′ end of the 35mer [referred in a previous paper as 35mer-(AAT) (*6*)]. The 16mer oligonucleotides were designed to bind to both sides of the hairpin-containing 36mer forming two mini double helices separated by the stem-loop region (Figure 2A). For comparison with targets containing intervening sequences, oligonucleotides and acridine-oligonucleotide conjugates were targeted to the 23mer, a single-stranded DNA target with no hairpin structure (Figure 2B).

Figure 2. (A) Sequences of the hairpin-containing oligonucleotide 36mer and of the 35mer with no hairpin structure. The unmodified ligands, 16mer, 17mer, 18mer, and 19mer together with the sequences of the acridine-modified oligonucleotides are shown. X corresponds to the internal acridine and Acr to the 5′-linked acridine (see Figure 1). (B) Sequences of the 23mer, 24mer, 25mer, and 26mer targets that exhibited no hairpin structure. Sequences of their unmodified or modified oligonucleotide ligands, 16mer, 16mer-X, and Acr-16mer are shown in Figure 2A.

In the second DNA model, the target 46merWC→H has two different domains, a double-stranded stem and a single-stranded sequence, allowing both triple helix and double helix formation with acridine-containing 17mer oligonucleotide ligands (Figure 3). Only one possibility for designing the WC/H targets was studied [see previous paper for details (*9*)]. The single-stranded purine-rich region of the 46mer was chosen to be on the 5′ side of the hairpin and was referred to as the Watson−Crick-toward-Hoogsteen orientation, 46merWC→H in ref *9*. The 17mer oligonucleotides were designed to bind to both single-stranded and double-stranded regions of the hairpin-containing 46merWC→H. The stem sequence in 46merWC→H was chosen to be long enough to give rise to two distinct melting transitions corresponding to oligonucleotide dissociation and stem disruption. It should be noted that the 46merWC→H had a short (5 nt) single-stranded sequence added to the 3′ end of the stem.

Acridine derivatives were either attached to the 5′ end of the oligonucleotides (Acr-16mer and Acr-17mer) or incorporated in the center of the oligonucleotide sequence (for 16mer-X, 17mer-X, and 18mer-X). The acridine of the oligonucleotide ligand was located in the complex formed with the DNA targets, either between the two single-stranded parts of the 36mer (Figure 2) or at the junction between the single-stranded and the double-stranded domains of 46merWC→H (Figure 3). Additional thymines were introduced in replacement of the acridine derivative

Figure 3. Sequences of the hairpin-containing oligonucleotide 46merWC→H and its ligands: unmodified 17mer, 18mer, 19mer, and 16mer; acridine-containing ligands: 17mer-X, 18mer-TX, 18mer-XT, 16mer-X, and Acr-17mer. Note that single-stranded sequences are present on both the 5′ and 3′ sides of the hairpin of the 46mer WC→H. The mutated oligonucleotide 17mer-Mut $^{5'}$dTTCACTCTTCTCTTTCC$^{3'}$ is identical to the 17mer sequence except for three nucleotides located in the 5′ part of the oligonucleotide (underlined on the ligand sequence). The 16mer and 16mer-X $^{5'}$dTTTTTTCTCTCTTTCC$^{3'}$ lack an internal thymine when compared to the 17mer and 17mer-X, respectively.

or near the acridine derivative to obtain 17mers, 18mers, 19mers, 18mer-TX, and 18mer XT (Figures 2 and 3). A bis-modified oligonucleotide, Acr-17mer-X, with two acridines (one at an internal position and one at the 5′ end of the oligonucleotide) was also targeted to the 36mer (Figure 2A).

Recognition of Two Nonadjacent Sequences by Acridine-Oligonucleotide Conjugates: Model 1. As shown on the melting profile presented in Figure 4A, the melting transitions corresponding to oligonucleotide dissociation and stem fusion of the 36mer were well separated. Melting temperature (T_m) of the stem-loop structure of the 36mer was estimated from the first derivative of melting curves as shown in Figure 4B. The T_m of the $^{5'}$CGATCGTTTTCGATCG$^{3'}$ stem loop in the 36mer was 65 ± 1 °C in the incubation conditions of Figure 4A (0.1 M NaCl). Previous melting experiments have shown that the $^{5'}$CGATCGTTTTCGATCG$^{3'}$ oligonucleotide formed a hairpin structure with a T_m of 70 °C in 0.1 M NaCl (*27*). These results suggested that the addition of flanking sequences to the hairpin-forming sequence $^{5'}$CGATC-GTTTTCGATCG$^{3'}$ decreased by 5 °C the stability of the hairpin in the 36mer.

The unmodified 16mer oligonucleotide binds to the 36mer with a T_m of 25 ± 1 °C at 2 μM concentration in a pH 7.02 buffer containing 50 mM cacodylate and 0.1 M sodium chloride (Figure 4). The addition of an acridine at the 5′ end of the 16mer in Acr-16mer increased the T_m value by 8 °C (Figure 5). This stabilization was already demonstrated for oligonucleotide-acridine conjugates targeted to single-stranded DNA sequences without any secondary structure (*28*, *29*). The 16mer-X with an internal acridine in the center of the 16mer sequence had a higher T_m value (38 ± 1 °C) as compared to the Acr-16mer (T_m = 33 °C) and 16mer (T_m = 25 °C) (Figure

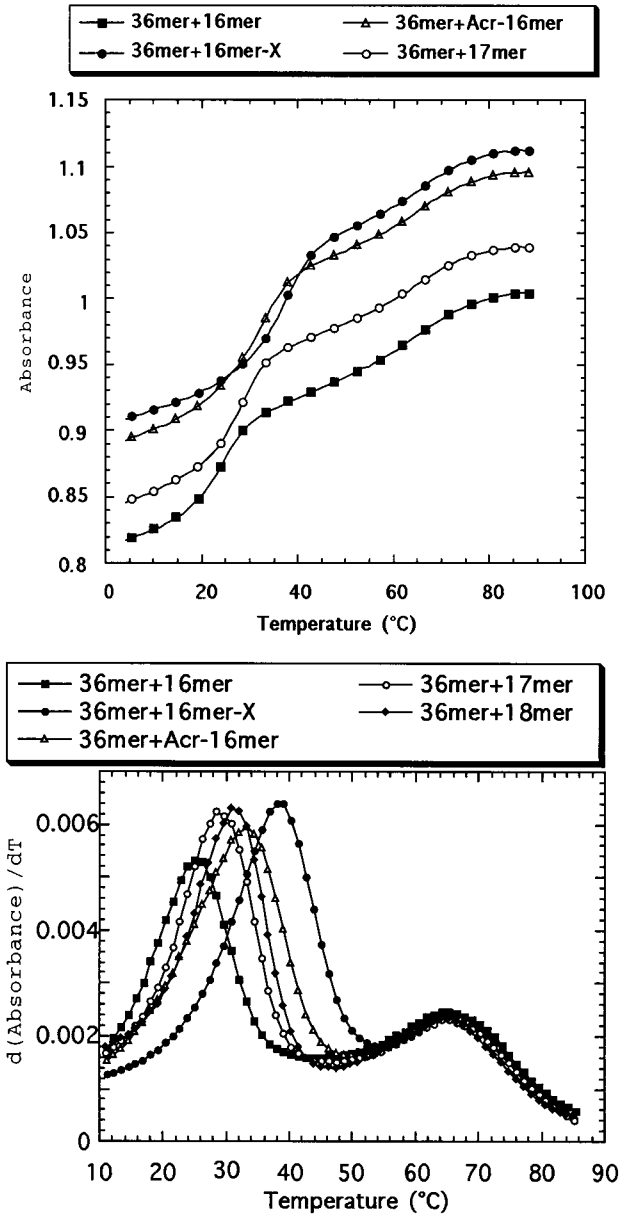

Figure 4. (A) Melting curves measured at 260 nm for 2 μM 36mer bound to 2 μM of 16mer (■), 16mer-X (●), Acr-16mer (△), and 17mer (○) in 50 mM cacodylate buffer, pH 7.02, containing 0.1 M NaCl. The melting temperature corresponding to stem fusion is 65 ± 1 °C. (B) First derivative of the melting curves shown in Figure 4A. Legend symbols are the same as in Figure 4A. In addition the derivative of the melting curve of the 36mer/18mer complex is also shown (◆).

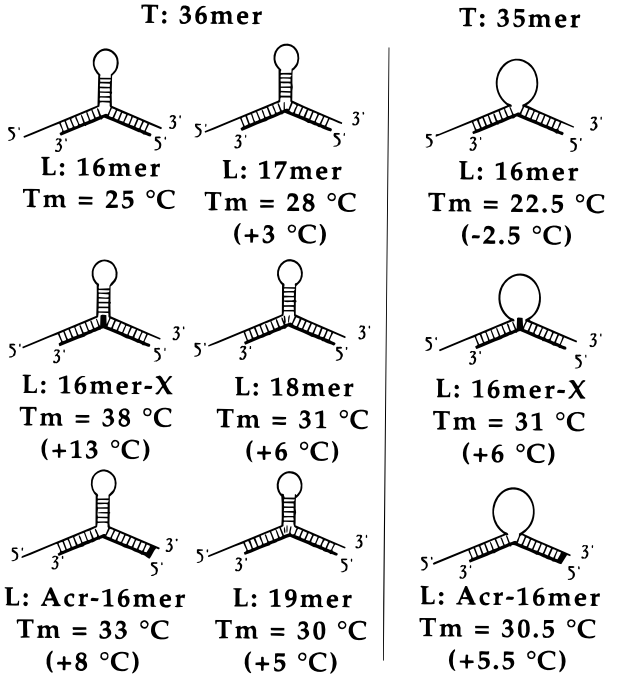

Figure 5. Schematic representations of the complexes formed by acridine-containing and unmodified oligonucleotide ligands (L) with the hairpin-containing 36mer or the 35mer target containing no hairpin structure (T), 36mer and 35mer. Melting temperatures indicated below each complex were obtained with 2 μM/2 μM T/L in the same buffer used in Figure 4. The T_m of the 16mer/36mer (T_m = 25 °C) was taken as reference for the ΔT_m calculations.

5). These results suggested that the location of the acridine in the 16mer-X/36mer complex, near the branch-point of the three-way structure, was likely a preferential site for intercalation of acridine.

The replacement of acridine by one internal thymine (17mer/36mer complex) at the junction between the two single-stranded domains of the 36mer strongly decreased the T_m value from 38 to 28 °C. The 17mer/36mer complex was only slightly stabilized (ΔT_m = +3 °C) as compared to that for the 16mer/36mer complex (Figure 5). The 18mer with two additional thymines had a T_m increased by 6 °C (T_m = 31 °C) (Figure 5), indicating that the introduction of thymines in such structures improved the binding affinity likely via stacking interactions at the branch point as previously described for DNA three-arm junctions (*30*−*33*). No additional increase of stability was observed with the introduction of a third thymine (T_m = 30 °C for the 19mer).

The 17mer-X oligonucleotide with an acridine and a thymine both located at the junction of the three-way structure has a higher melting temperature than the unmodified 17mer [$\Delta T_{m\ (17mer-X/17mer)}$ = +9 °C], but has a melting temperature similar to that of Acr-17mer. The T_m values for complexes with 17mer-X and Acr-17mer are, respectively, 37 and 36.5 °C (data not shown). This result indicated that the addition of acridine either internally or at the 5′ end of the oligonucleotide ligand stabilized to the same extent as the complexes containing one unbound internal thymine (17mer). It should be noted that the replacement of the central thymine in the 17mer by an acridine ring (to obtain the 16mer-X) strongly increased binding affinities as shown by the ΔT_m between the complexes formed by 17mer and 16mer-X [$\Delta T_{m\ (16mer-X/17mer)}$ = +10 °C] (Figure 5). This result indicated that the tricyclic acridine ring interacted as an intercalating agent much better than an additional thymine. The charge of the acridine molecule (assuming that at neutral pH, the ring is still positively charged) may also participate in stabilization of complexes. Nevertheless, this electrostatic stabilization may occur with internal acridine and with acridine linked to the 5′-end of the oligonucleotide ligand. The addition of one thymine in 17mer-X/36mer or two thymines in 18mer-TX/36mer did not give more stable complexes than that formed by 16mer-X/36mer [$T_{m\ (17mer-X/36mer)}$ = 37 °C and $T_{m\ (18mer-TX/36mer)}$ = 38 °C].

In an attempt to increase the binding affinity of 17mer-X ligand to its 36mer target, we have synthesized Acr-17mer-X, an oligonucleotide with two acridine derivatives, one inserted at a internal site and the second one at the 5′ end (Figure 2). Surprisingly, no additional stabilization was observed when compared to the oligo-

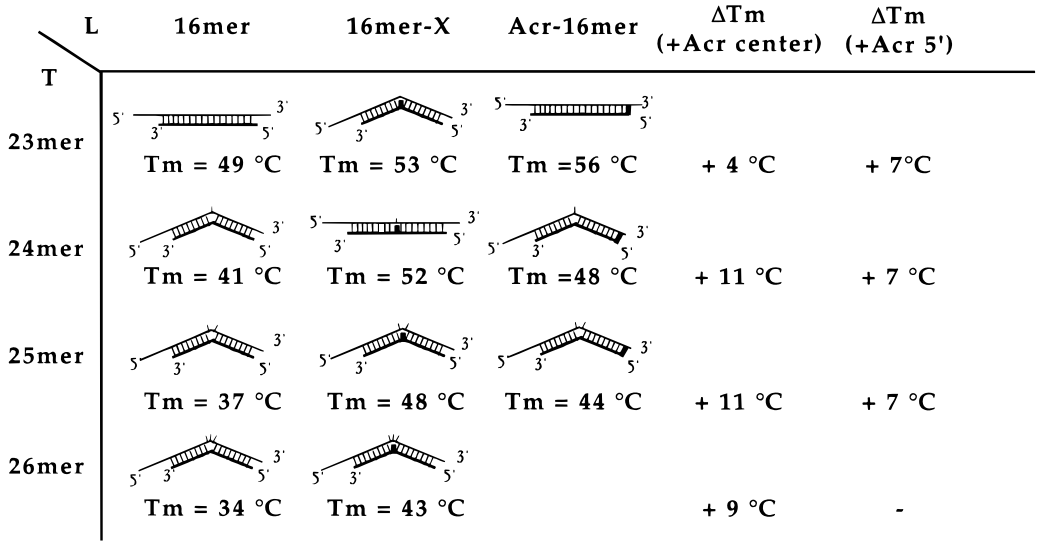

Figure 6. Schematic representations of the complexes formed by acridine-containing and unmodified oligonucleotide ligands (L) with the targets that contains no secondary structures (T), 23mer, 24mer, 25mer and 26mer. Experimental conditions were the same as in Figures 4 and 5. The two columns (to the right of the figure) represent the ΔT_m values with and without acridine attached in the center or at the 5′-end of the ligand for each of the target.

nucleotides with only one acridine, 17mer-X and Acr-17mer [$T_{m\ (Acr-17mer-X/36mer)} = 36$ °C]. The Acr-17mer-X did not give a melting transition when heated alone at 5 μM in the conditions described in Figure 4A (data not shown). However, this does not exclude a stacking interaction between the two acridine rings. 2-Methoxy-6-chloro-9-amino acridine derivatives are known to self-associate in aqueous solutions with a dimerization constant around 10^3 M^{-1} (*34*). In the oligonucleotide, this process becomes intramolecular and can compete with binding of the bis-substituted oligonucleotide to its target sequence.

To determine if the presence of the hairpin structure was necessary for the increase in binding stability of oligonucleotides with an internal acridine, the 35mer which has no hairpin structure but contains the target sequences for each half of the 16mers was synthesized. As shown in Figure 5, the absence of hairpin structure in the 16mer/35mer complexes slightly decreased T_m values, but the addition of acridine either at the 5′ end or internally increased melting temperatures to the same extent [$\Delta T_{m(16mer-X/16mer)} = +8.5$ °C and $\Delta T_{m(Acr-16mer/16mer)} = +8$ °C]. As compared to the hairpin-containing structure [$\Delta T_{m(16mer-X/16mer)} = +13$ °C and $\Delta T_{m(Acr16mer/16mer)} = +8$ °C], there is clearly an increased binding energy of the internal acridine with the hairpin-containing target reflecting the strongest interaction of the acridine with the three-way junction.

Double Helices Formed by Acridine-Oligonucleotide Conjugates and Target Oligonucleotides without Any Secondary Structure. Oligonucleotides and acridine-oligonucleotide conjugates were targeted to the 23mer, a single-stranded DNA target with no secondary structure and no interruption of the complementary sequence of the 16mer and to longer oligomers, 24−26 nt in length, with one, two, or three additional bases at the position where the hairpin sequence of the 36mer was inserted (Figure 2B). All melting temperatures described in Figure 6 were higher than those obtained with targets containing hairpin structures (Figure 5), emphazing the destabilizing role of the hairpin structure in complexes with 36mer. As shown in Figure 6, when the 16mer was targeted successively to the 23mer, 24mer, 25mer, and 26mer, a decrease of T_m values was observed, demonstrating the destabilizing effect of introducing bulges, i.e., nonmatched additional bases (*35*, *36*). Incorporation of an internal acridine in the 16mer sequence (16mer-X) resulted in an increase in binding affinity but to a lesser extent ($\Delta T_{m(16mer-X/23mer)} = +4$ °C, see Figure 6) than that obtained with the 36mer ($\Delta T_{m(16merX/36mer)} = +13$ °C, see Figure 5). Similar results were obtained with oligonucleotides containing an internal acridine ring that were targeted to a target containing an abasic, an apyrimidinic or an apurinic site (*37*, *38*).

In contrast to what was observed with the 16mer/36mer complexes (Figure 5), the Acr-16mer oligonucleotide had a higher T_m value than the 16mer-X when bound to the 23mer ($\Delta T_m = +7$ °C). It should be noted that the stabilization obtained when the acridine was attached to the 5′ end of the 16mer (Acr-16mer) was the same for all targets: 23mer, 24mer, 25mer, and 26mer (Figure 6). For all targets in Figure 6, $\Delta T_{m(Acr-16mer/16mer)}$ was +7 °C. For the 36mer and the 35mer, addition of acridine at the 5′ end resulted in an increase of T_m of +8 °C (Figure 5). These results demonstrated that the intercalating acridine exhibited a similar behavior concerning the stabilization of duplex DNA even if this DNA contained bulged nucleotides or hairpins located 8 nucleotides away from the 5′ end of the oligonucleotide ligand.

The addition of an acridine ring in the center of the 16mer sequence (16mer-X) increased T_m values by +4, +11, and +9 °C for the 16mer-X/23mer, 16mer-X/24 or 25mer, and 16mer-X/26mer, respectively (Figure 6). A stabilization of +8.5 °C was obtained with 16mer-X bound to the 35mer target [($\Delta T_{m(16mer-X/16mer)} = +8.5$ °C, see Figure 5], suggesting that the additional stabilization afforded by an internally attached acridine does not depend on the number of looped-out bases above three bases. The stabilization observed when the 16mer-X binds to the hairpin-containing 36mer ($\Delta T_m = +13$ °C) indicates that the hairpin is formed when the oligonucleotide is bound and that the acridine has a preferential site of interaction at the branch point of the three-way junction.

Recognition of Hairpin-Containing Structures by Acridine-Oligonucleotide Conjugates via Both Watson−Crick and Hoogsteen Hydrogen Bonding: Model 2. We previously demonstrated that the 17mer

Table 1: Melting Temperatures (T_m) for the Dissociation of Oligonucleotide Ligands (L) from a Hairpin-Containing Target (T), 46Mer WC→H[a]

oligonucleotide ligands	T_m (S+) (°C)	ΔT_m (S+)	T_m (°C)	ΔT_m

18mer-TX	50	+16	34	+20
19mer	39	+5	19	+5
17mer-Mut	26.5	−7.5	12.5	− 1.5

[a] See sequences in Figure 3. Concentration of both the oligonucleotide ligand and the target were 2 μM. Samples were incubated in a 50 mM cacodylate buffer containing 0.1 M NaCl at pH 7.02 in the absence (right columns) or in the presence of 0.2 mM spermine (S+) (left columns). T_m values were determined as described in Materials and Methods and were rounded off to the nearest 0.5 °C and error is estimated at ± 1 °C. Melting temperatures of the stem sequence of the 46mer WC→H are respectively 64 °C and 70 °C in absence and in the presence of 0.2 mM spermine. ΔT_m represents the increase in T_m upon addition of thymines or acridine derivatives for each incubation conditions. The reference is the 17mer complex.

shown in Figure 3 binds to the 46mer WC→H by forming both Watson−Crick and Hoogsteen hydrogen bond interactions (*9*). The difference in stability between the 17mer and the 17mer-Mut complex (ΔT_m = −7.5 °C, Table 1) demonstrated that the 5′ end of the 17mer was bound to the stem sequence of the 46merWC→H via triple helix formation as previously described (*9*).

In the 18mer/46merWC→H complex, the addition of a thymine at the junction of the two domains increased the T_m by +8 °C (Figure 7A and Table 1). As previously reported (*9*), the addition of one nucleotide increases the binding affinity when it is located at the junction of a WC→H complex, but decreased the affinity when it was located at the junction of a H→WC complex (*9*). The addition of two thymines at the junction of 19mer/46merWC→H complex increased T_m by only +5 °C with respect to the 17mer/46merWC→H. The presence of one additional thymine in the 19mer/46merWC→H complex might slightly distort the structure of the 18mer/46merWC→H complex (Table 1).

The introduction of an acridine derivative at the junction between the triple helix and the double helix domains of the 17mer/46merWC→H complex increased the binding affinity by +16 °C (Table 1). The T_m of the 17mer/46merWC→H and 17mer-X/46merWC→H complexes are, respectively, 34 and 50 °C in the presence of 0.2 mM spermine (Figure 7A). It should be noted that the acridine at the junction (in 17mer-X/46merWC→H complex) increases the binding affinity much more than one or two thymines at the junction (in 18mer/46merWC→H and 19mer/46merWC→H complex), demonstrating an important stabilizing role of the intercalating agent at the junction of WC→H structures.

We have also measured the effect of covalent attachment of the acridine derivative to the 5′ end of the 17mer ligand. Acr-17mer binds to the WC→H complex forming a double helix with the 5′ sequence and a triple helix with the stem of the 46merWC→H (Figure 7). The acridine can intercalate in the stem sequence at the junction between the triple helical and the double helical domains as previously demonstrated for triplex-forming acridine-oligopyrimidine conjugates (*39*). The presence of the intercalating agent at the 5′ end of the 17mer (Acr-17mer) increased the T_m by +15 °C (Figure 7 and Table 1), a value close to that obtained with the acridine attached

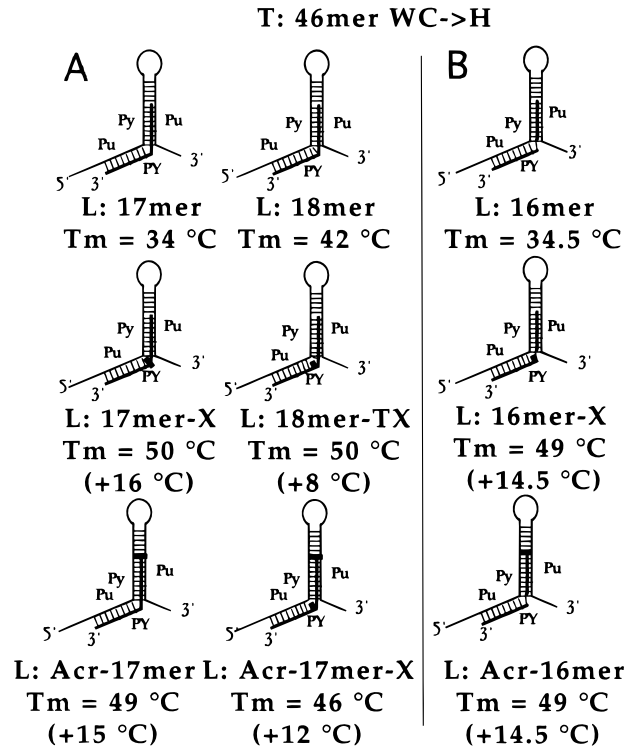

Figure 7. Schematic representations of the complexes formed by the hairpin containing targets (T) 46mer WC→H with the acridine-containing or unmodified oligonucleotide ligands (L). Melting temperatures indicated below each complex were obtained with 2 μM/2 μM T/L in a pH 7.02 cacodylate buffer (50 mM) containing 0.1 M NaCl and either 0.2 mM (A) or 1 mM spermine (B). ΔT_m values are calculated as the difference between the T_m values of the acridine-containing and the corresponding unmodified oligonucleotide.

to the internal site. Surprisingly, the bis-modified oligonucleotide Acr-17mer-X did not exhibit a better affinity for the target 46merWC→H than the acridine-containing oligonucleotides, 17mer-X and Acr-17mer, a similar result to that obtained in the first model of a hairpin target described in this paper (model 1).

To obtain more information on the type of interactions engaged by the internally located acridine, an additional thymine was inserted either between the duplex-forming sequence and the acridine (18mer-XT) or between the acridine and the triplex-forming sequence (18mer-TX). In both cases, the T_m (50 °C) was identical to that of the 17mer-X/46merWC→H complex (only 18mer-TX is shown in Figure 7 and Table 1). As compared to the 18mer, which contains the additional thymine but no acridine, the stabilization afforded by the acridine is only +8 °C as compared to +16 °C for the 17mer. These results demonstrates that two elements contribute to the acridine-induced stabilization: an increased flexibility at the junction between the two domains of the 17mer and a specific interaction of the acridine ring at the junction of the duplex and triplex structures.

Spermine is known to stabilize triple helices (*40*, *39*). When the spermine concentration was raised from 0.2 to 1 mM, the T_m of the 17mer was increased by 3 °C (from 34 to 37 °C). Under these conditions, the lack of a thymine in the triplex-forming sequence of the 16mer decreased the T_m value by 2.5 °C (Figure 7B). Introduction of the intercalating agent in 16mer-X stabilized the interaction with the 46merWC→H target [$\Delta T_{m(16mer-X/16mer)}$ = +14.5 °C] (Figure 7B). A similar stabilization was observed with the 5′-substituted Acr-16mer.

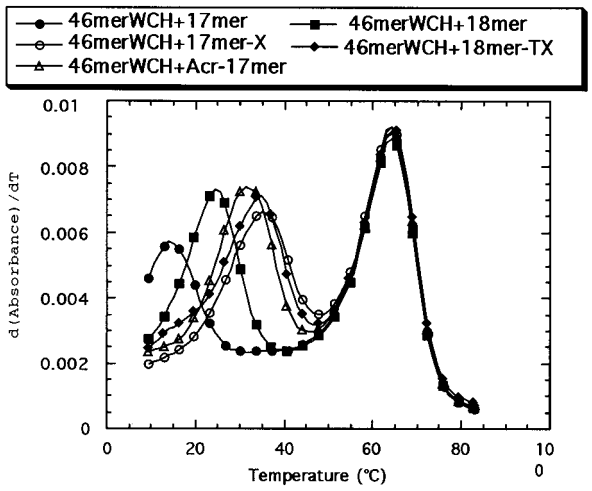

Figure 8. First derivative profiles of the melting curves obtained at 260 nm for 2 μM 46merWC→H bound to 2 μM of 17mer (●), 17mer-X (○), Acr-17mer (△), 18mer (■), and 18mer-TX (◆) in 50 mM cacodylate buffer, pH 7.02, containing 0.1 M NaCl.

Melting experiments with oligonucleotide ligands and the 46merWC→H target were also performed in the absence of spermine. Melting profiles obtained in the absence of spermine with 17mer, 17mer-X, and Acr-17mer bound to the 46merWC→H (Figure 8) demonstrated that the acridine ring better stabilized the complexes when it was located at the internal position than at the 5′ end of the 17mer oligonucleotide [$\Delta T_{m(17mer-X/17mer)} = +21$ °C, $\Delta T_{m(Acr-17mer/17mer)} = +17.5$ °C]. A similar behavior was observed with the 18mer and 18mer-TX (Table 1).

In the 17mer/46merWC→H complex in the absence of spermine, the triplex-forming portion of the 17mer (the 5′ sequence) was not expected to form a stable triple helix with the stem sequence of the 46merWC→H. As a matter of fact, mutations introduced in this part of the 17mer sequence (as in 17mer-Mut) did not markedly change the T_m value of the complex ($\Delta T_m = -1.5$ °C). For the Acr-17mer oligonucleotide, it is likely that a triplex is formed between the 5′ sequence of the 17mer and the stem sequence of the 46mer WC→H with the acridine intercalated at the junction of triplex and duplex domains (*39*). The increase in T_m value obtained when the 17mer is 5′-substituted with acridine (Acr-17mer, $\Delta T_m = +17.5$ °C) and when it is internally substituted (17mer-X, $\Delta T_m = +21$ °C) strongly suggests that 17mer-X also forms a complex involving the triplex portion even in the absence of spermine. The internal acridine could be either intercalated at the junction or located at a preferential binding site within the branch point of the WC→H structure leading to a high stabilization of complexes.

CONCLUSION

In the present study, we demonstrated that an acridine incorporated at an internal site within an oligonucleotide is able to stabilize the binding of this oligonucleotide to a hairpin-containing target sequence when the acridine ring is located at the base of the stem-loop region (model 1). The internal acridine leads to a better stabilization of complexes ($\Delta T_m = +13$ °C) than an acridine covalently linked to the 5′-end of the oligonucleotide ($\Delta T_m = +8$ °C), suggesting the existence of a preferential site of interaction/intercalation for the acridine ring at the three-way junction. The binding of oligonucleotides to hairpin-containing nucleic acids could also be stabilized by insertion of modified bases such as a 5-methyl-N^4-(1-pyrenylmethyl)cytidine or a 2′-deoxy-5-methyl-N^4-(4-phenoxyphenyl)cytidine instead of an acridine ring (*41*−*43*).

Acridine-containing oligonucleotides have also been targeted to hairpin-containing targets in such a way as to form both Watson−Crick base pairs and Hoogsteen base pairs (WC→H recognition, model 2). In the presence of spermine, no differences in stabilization of WC→H complexes were observed between an internal acridine and an acridine linked to the 5′ extremity of the oligonucleotide. Melting temperatures of DNA complexes were increased by +15−16 °C. In the absence of spermine, the oligonucleotide with an internal acridine bound to the hairpin-containing target exhibited a higher stability than the 5′ acridine-oligonucleotide conjugate ($\Delta T_m = +21$ °C compared to +17.5 °C).

What has emerged from our study is that acridine incorporated into an oligonucleotide could be used to recognize hairpin-containing nucleic acids with higher affinity than the unmodified oligonucleotides either by formation of a three-way structure or by a combination of double and triple helix formation. These oligonucleotide-intercalator conjugates are easily synthesized with existing building blocks and provide a new approach to selectively recognize secondary structures in nucleic acids. Their potential applications in the antisense strategy should be evaluated in future investigations.

Received October 26, 1998; Revised Manuscript Received February 4, 1999

The anti-Tac disulfide-bonded variable region fragment (dsFv) is a genetically engineered, 25 kDa, murine monoclonal antibody fragment that recognizes the α subunit of the interleukin-2 receptor (IL-2Rα). The dsFv radiolabeled with the tetrafluorophenyl ester (TFP) of [^{99m}Tc]mercaptoacetyltriglycine ([^{99m}Tc]MAG3-TFP) showed rapid tumor uptake and fast blood clearance in mice, resulting in high tumor-to-nontumor background ratios. However, its high renal uptake was a problem. In this study, we tested the effect of lowering the isoelectric point (pI) of dsFv to <9.3 on renal and tumor uptake. To lower the pI, dsFv was acylated simultaneously with both [^{99m}Tc]MAG3-TFP and TFP-glycolate. The acylation of dsFv decreased its pI and its immunoreactivity inversely proportional to the molar ratio of TFP-glycolate to dsFv, whereas the conjugation of [^{99m}Tc]MAG3-TFP alone did not. When biodistribution studies were performed in nude mice, the effect of the lowered pI was reflected primarily in decreased kidney uptake and whole-body retention, with its highest effect seen at the earliest time point (15 min) after injection. In tumor-bearing nude mice, glycolated [^{99m}Tc]MAG3-dsFv with a pI range of 4.9 to 6.5 accumulated selectively into IL-2 receptor-positive SP2/Tac tumor similar to that of the control [^{125}I]dsFv labeled by the Iodo-Gen method, whereas its renal uptake was 25% of [^{125}I]dsFv at 15 min. At 90 min, the ratios of tumor to receptor-negative SP2/0 tumor, liver, kidney, stomach, and blood had peaked at 10.9, 8.5, 0.3, 5.0, and 6.2, respectively, for the glycolated [^{99m}Tc]MAG3-dsFv. The corresponding ratios for [^{125}I]dsFv were 3.7, 5.0, 0.1, 1.5, and 2.1, respectively.

INTRODUCTION

Anti-Tac monoclonal antibody (anti-Tac MoAb) recognizes the α subunit of IL-2 receptor (IL-2Rα),[1] which is overexpressed on activated T-cells (*1*−*3*), and various malignant lymphomas and leukemias (*4*−*7*). Disulfide-stabilized, variable-region fragments (dsFv) of anti-Tac MoAb were recently produced by recombinant DNA technology (*8*). Amino acid residues in conserved framework regions of both light (V_L) and heavy (V_H) chain variable domains of the anti-Tac antibody were mutated into cysteines at positions compatible with the formation of an interdomain disulfide linkage (i.e., V_H-44gly and V_L-99ser). These mutant V_H and V_L chains were produced in separate *Escherichia coli* cultures from the plasmids pYR43 and pKW50, respectively. The V_H and V_L chains were then combined in equimolar amounts to form an interchain disulfide bridge of the disulfide-bonded Fv molecule. This dsFv bound to IL-2Rα with an affinity identical to that of humanized anti-Tac IgG (K_d = 3 nM) and the corresponding single chain Fv (scFv) (*8*). This dsFv was found to be substantially more stable to denaturation by heat or urea treatment than the scFv.

Anti-Tac dsFv has previously been radiolabeled with ^{125}I (*9*, *10*), ^{18}F (*10*), ^{99m}Tc (*11*), and ^{67}Ga (*12*). Compared to ^{125}I-labeled intact anti-Tac MoAb, these labeled dsFv fragments show improved tumor targeting with faster penetration into tumors due to their small size (25 kDa) (*8*). They also clear faster from blood and most organs, thereby resulting in high tumor-to-nontumor ratios (*9*−*12*). However, these radiolabeled dsFv fragments showed high renal uptake, thus resulting in high renal radiation doses and potentially decreasing imaging sensitivity in the abdomen. High renal accumulation is a common problem for low molecular weight proteins (LMWPs) (*13*). The mechanism of renal uptake and retention of LMWPs is believed to involve glomerular filtration and subsequent reabsorption and catabolism in the proximal tubular cells (*14*). Several investigators have lowered the renal uptake of various LMWPs by infusing basic amino acids such as L-lysine and arginine (*13*, *15*−*19*). These basic amino acids are believed to block the tubular absorption of LMWPs by masking the negatively charged phospholipid bilayers of the tubular cells. We showed previously that the renal uptake of ^{99m}Tc- and ^{125}I-labeled dsFv could be blocked by L-lysine co-injection, in a dose- and time-dependent manner (*20*).

In this study, we lowered the isoelectric point (pI) of dsFv by acylating its amino groups with different concentrations of glycolate molecules. We report the effects of this lowered pI on renal and tumor uptake of ^{99m}Tc-labeled dsFv in nude mice and nude mice xenografted

with IL-2α-receptor-positive SP2/Tac and receptor-negative SP2/0 cells. The preliminary portion of this work has been previously reported in abstract form (*21*).

MATERIALS AND METHODS

Synthesis. Tetrafluorophenyl (TFP)-glycolate was synthesized as follows. Briefly, 2,3,5,6-tetrafluorophenol (TFP, 100 mmol) and glycolic acid (10 mmol) were reacted in 10 mL of acetonitrile, with dicyclohexylcarbodiimide (12 mmol) used as a coupling agent, for 4 h at room temperature. The ester derivative was purified by normal-phase HPLC equipped with a μPorasil PrepPak cartridge (Waters, Milford, MA, hexane:ethyl acetate:acetic acid = 150:50:1, 5 mL/min). The yield of TFP-glycolate was 56.9%, The melting point of the product was 90.8−91.2 °C, as measured on an electrothermal digital melting point apparatus (Electrothermal, Southend, England), and reported without calibration. ^{1}H NMR ($CDCl_3$): δ 7.12 (m, 1 aromatic *H*), 4.59 (s, 2 CH_2), 3.49 (s, 1 *OH*). Anal. ($C_8H_4O_3F_4$) C, H, F.

Acylation and Radiolabeling with ^{99m}Tc and ^{125}I. Benzoyl (Bz)-MAG3 was synthesized according to the method of Fritzberg et al. (*22*). Bz-MAG3 was radiolabeled with ^{99m}Tc, activated to the TFP ester of ^{99m}Tc MAG3 using the methods of Visser et al. (*23*) and Yoo et al. (*11*), and purified by a Sep-Pak C_{18} column. The purified [^{99m}Tc]MAG3-TFP in acetonitrile was dried with a stream of nitrogen gas and was allowed to react with dsFv (100 μg/100 μL, 4 × 10^{-5} M) in 0.1 M sodium bicarbonate-sodium carbonate buffer (pH 9.5) for 30 min at 4 °C. To acylate the dsFv, we added TFP-glycolate at several different concentrations [TFP-glycolate-to-dsFv molar ratios of 36, 73, and 110 prepared in dimethylformamide (DMF)] to the reaction mixture immediately after we added the dsFv solution to [^{99m}Tc]MAG3-TFP. The amount of DMF added to the reaction mixture was less than 10% of the total volume to prevent the potential deactivation of dsFv by the organic solvent. The conjugation reactions at the molar ratios of 36, 73, and 110 produced glycolated [^{99m}Tc]MAG3-dsFv with pI ranges of 6.6−9.3 (product I), 4.9−6.5 (product II), and 4.4−6.1 (product III). These products were purified on a size-exclusion PD-10 column (Pharmacia Biotech AB, Uppsala, Sweden) with 0.02 M sodium phosphate in saline (PBS). The total reaction scheme is shown in Figure 1. To use as a control for the biodistribution studies, the dsFv was radioiodinated with ^{125}I by the Iodo-Gen method as described previously (*11*). The purity of the radiolabeled dsFv preparations was confirmed with ITLC, paper chromatography and size-exclusion HPLC with a TSK G2000SW column (TosoHass, Philadelphia, PA; 0.067 M sodium PBS−0.1 M KCl, pH 6.8; 1 mL/min).

Isoelectric Focusing and Autoradiography. The radiolabeled dsFv (0.3−1.0 μg) and standard markers with pI values ranging 3.5−9.3 were electrofocused on gels (PhastGel IEF 3-9, Pharmacia Biotech AB, Uppsala, Sweden) using PhastSystem (Pharmacia Biotech AB, Uppsala, Sweden). These gels were then stained with Coomassie Blue R 350 to reveal protein bands and were autoradiographed to reveal radioactive bands using Bioimaging Analyzer BAS-1500 (Fuji Medical Systems, Inc., Stamford, CT). The pI values of the dsFv products were determined by comparing their bands to the standard bands with known pIs.

Immunoreactivity. Immunoreactivity was determined by a modified cell-binding assay of Lindmo et al. (*24*). Aliquots of the radiolabeled dsFvs (0.7−1.0 ng/100 μL) were incubated for 2 h at 4 °C with 1.1 × 10^4 to 4.0 × 10^7 SP2/0 and SP2/Tac cells. Nonspecific binding to the cells was examined under conditions of antibody excess (25 μg of nonradiolabeled anti-Tac IgG antibody). The maximum cell-bound counts, corrected for the nonspecific binding and expressed as a percentage of the total counts, were taken to be the immunoreactivity.

Biodistribution Studies in Nontumor Bearing Mice. Animal studies were performed under an approved Institutional Animal Care and Use Committee protocol. Groups of five female nude mice (NCI, Frederick, MD, 4−7 weeks old, 16−23 g) were used. The mice were injected via the tail vein with either ^{99m}Tc-labeled dsFv or glycolated ^{99m}Tc-labeled dsFv (1.5−6.0 μCi/0.5−1.0 μg), plus [^{125}I]dsFv (0.6−1.6 μCi/0.1−1.0 μg) in 0.2 mL of PBS solution containing 1% BSA. The total dose of dsFv injected was 1.5−2.2 μg. The animals were euthanized

with CO_2 at 15, 45, 90, and 180 min and exsanguinated by cardiac puncture before dissection. Tumors, major organs, blood, and injected-dose standards were weighed, and the radioactivity was counted in a γ counter (Packard Auto-Gamma, Meriden, CT). The percentage of the injected dose per gram (% ID/g) of tissue or blood was calculated and normalized to a 20 g mouse. The whole-body retention was determined by adding the counts in organs, blood and carcasses and dividing by the counts in the injected dose.

Biodistribution Studies in Tumor-Bearing Mice. Tumor xenografts were established by subcutaneous (s.c.) inoculations of 3.5×10^6 SP2/0 cells in the left flanks and same amount SP2/Tac cells in the right flanks of female athymic nude mice ($n = 5$). Biodistribution studies were performed approximately 10 days later, when SP2/Tac tumors weighed a mean of 155 mg (20−477 mg) and SP2/0 tumors a mean of 101 mg (41−172 mg). The mice were injected via the tail vein with a mixture of glycolated ^{99m}Tc-labeled dsFv (product II, 1.7 μCi/1.4 μg) and [^{125}I]-dsFv (1.0 μCi/0.1 μg). Biodistribution was determined as described above for the nontumor-bearing mice.

RESULTS

Radiolabeling and Immunoreactivity. The preformed chelate approach to radiolabel the dsFv involved three steps. Bz-MAG3 was first radiolabeled with ^{99m}Tc producing a quantitative yield of [^{99m}Tc]MAG3 and then activated to TFP ester of [^{99m}Tc]MAG3. The recovery yield of the purified [^{99m}Tc]MAG3-TFP was 70−75%. However, the final conjugation yield of [^{99m}Tc]MAG3-TFP to dsFv was low, 24 ± 8.0% ($n = 8$) because only a low concentration of dsFv (4×10^{-5} M) was used due to a limited amount available and also the very mild reaction conditions (30 min at 4 °C) were selected to minimize potential deactivation of immunoreactivity. The specific activities of the radiolabeled dsFvs ranged from 1.7 to 7.8 μCi/μg. The immunoreactivity of [^{99m}Tc]MAG3-dsFv was similar to that of [^{125}I]dsFv (75%), indicating that the conjugation of a tracer amount of [^{99m}Tc]MAG3 to dsFv did not alter its immunoreactivity. However, the immunoreactivity of glycolated [^{99m}Tc]MAG3-dsFvs was decreased inversely proportional to the TFP-glycolate-to-dsFv molar ratio. The immunoreactivity was decreased by 20% for product II from the TFP-glycolate-to-dsFv molar ratio of 73 and by 35% for product III from the ratio of 110 when compared to [^{125}I]dsFv (75%).

Isoelectric Focusing. The isoelectric focusing experiments showed that the protein bands obtained with Coomassie Blue staining were superimposable on the radioactivity bands, indicating that the ^{99m}Tc labeling reflected the glycolate conjugation (Figure 2). The conjugation of a tracer amount of [^{99m}Tc]MAG3 to dsFv did not change the pI (9.3) of dsFv. However, glycolation decreased the pI of dsFv as the TFP-glycolate to dsFv reaction molar ratio was increased. At molar ratios of 36, 73, and 110, the pI of the glycolated ^{99m}Tc-labeled dsFv decreased to 6.6−9.3 (product I), 4.9−6.5 (product II), and 4.4−6.1 (product III), respectively (Table 1).

Biodistribution Studies. The biodistribution studies of the nonglycolated and the three glycolated products were performed first in nude mice (female, 20 g, $n = 5$) without tumors. For each biodistribution study, [^{125}I]anti-Tac dsFv radiolabeled using the Iodo-Gen method was co-injected as a control to estimate run-to-run variations. Since the run-to-run variations were not significantly large, we used data from all biodistribution experiments to calculate the means and standard deviations for [^{125}I]-anti-Tac dsFv (Table 2). These labeled dsFvs were taken up rapidly by the kidneys such that the amount of radioactivity accumulated in blood and other organs such as liver, spleen, stomach, and intestine was small, generally less than 5% ID/g for a 3 h period. The biodistribution of [^{99m}Tc]MAG3-dsFv differed from that of the glycolated [^{99m}Tc]MAG3-dsFvs; renal uptake, especially at 15 min, was decreased proportionally with the lowering of the pI (Figure 3). Likewise, the whole-body retention of the glycolated products was also much lower, especially at 15 min, proportional to the lowering of the pI (Figure 4). These results appear to indicate that the glycolated [^{99m}Tc]MAG3-dsFv with a lower pI is excreted via the kidneys faster than nonglycolated [^{99m}Tc]MAG3-dsFv. The biodistribution in blood and other organs

[c] $P < 0.05$ compared with [^{125}I]dsFv.

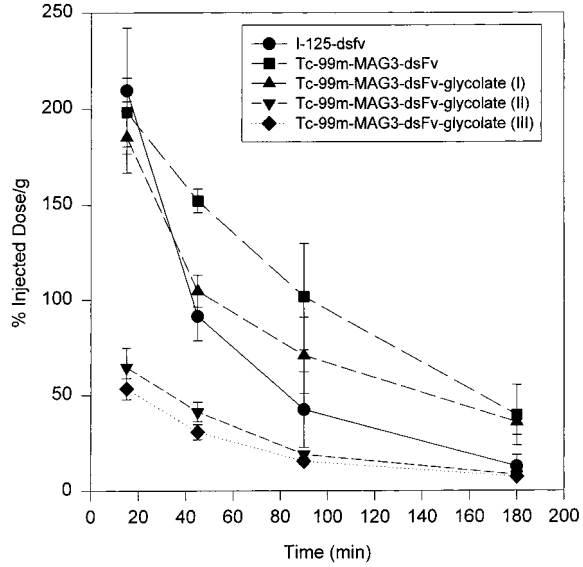

Figure 3. Kidney clearance in nontumor-bearing nude mice ($n = 5$). I, II, and III represent the conjugates from the reaction at the TFP-glycolate-to-dsFv molar ratios of 36, 73, and 110, respectively. The % ID/g of tissue with standard deviation (bar) was plotted against time.

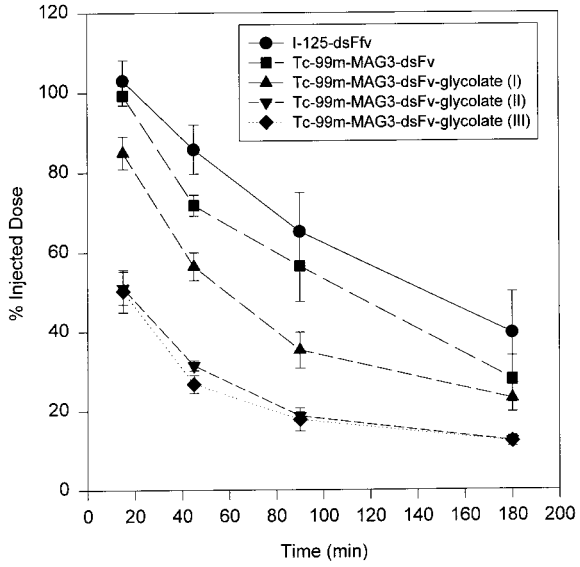

Figure 4. Whole-body clearance in nontumor-bearing nude mice ($n = 5$). I, II, and III represent the conjugates from the reaction at the TFP-glycolate-to-dsFv molar ratios of 36, 73, and 110, respectively. The % ID with standard deviation (bar) was plotted against time.

including liver was very similar between nonglycolated and the three glycolated dsFvs. Compared to [^{99m}Tc]-MAG3-dsFv, [^{125}I]dsFv showed higher blood and stomach accumulation, whereas it cleared faster from kidneys. These results are consistent with our previous findings that showed that [^{125}I]dsFv catabolizes rapidly in kidney and that the radiocatabolite reenters the circulation (*10*, *11*, *20*).

To test the effect of the acylation on tumor targeting, nude mice bearing IL-2 receptor-positive SP2/Tac and receptor-negative SP2/0 tumors were injected intravenously (i.v.) with a total 1.5 μg of product II and [^{125}I]-dsFv. We injected this amount of dsFv because we have previously observed that SP2/Tac tumors shed a small amount of soluble IL-2Rα receptors in the circulation and that the binding of dsFv to the soluble receptors could retain the labeled dsFv longer in the blood when the amount of dsFv was not in a large excess to the soluble receptors (*25*). This biodistribution study in the tumor-bearing mice showed the blood concentrations of the ^{99m}Tc and ^{125}I labels comparable to those in nontumor mice, indicating that a dose of 1.5 μg of dsFv was in gross excess to the soluble receptors. Similar to the biodistribution shown in the nontumor mice, II in the tumor-bearing mice showed a lower uptake in blood and organs including kidney and stomach than the control [^{125}I]dsFv. It is especially interesting to notice that product II showed a drastically reduced renal uptake that was only 25% of that seen in the control [^{125}I]dsFv at 15 min (Figures 5 and 6). However, the renal uptake of product II and [^{125}I]dsFv in the tumor-bearing mice were higher ($p < 0.05$) than those in the nontumor mice at the later time points; at 180 min the renal uptake of product II was 16% ID/g in the tumor-bearing mice vs 8% ID/g in

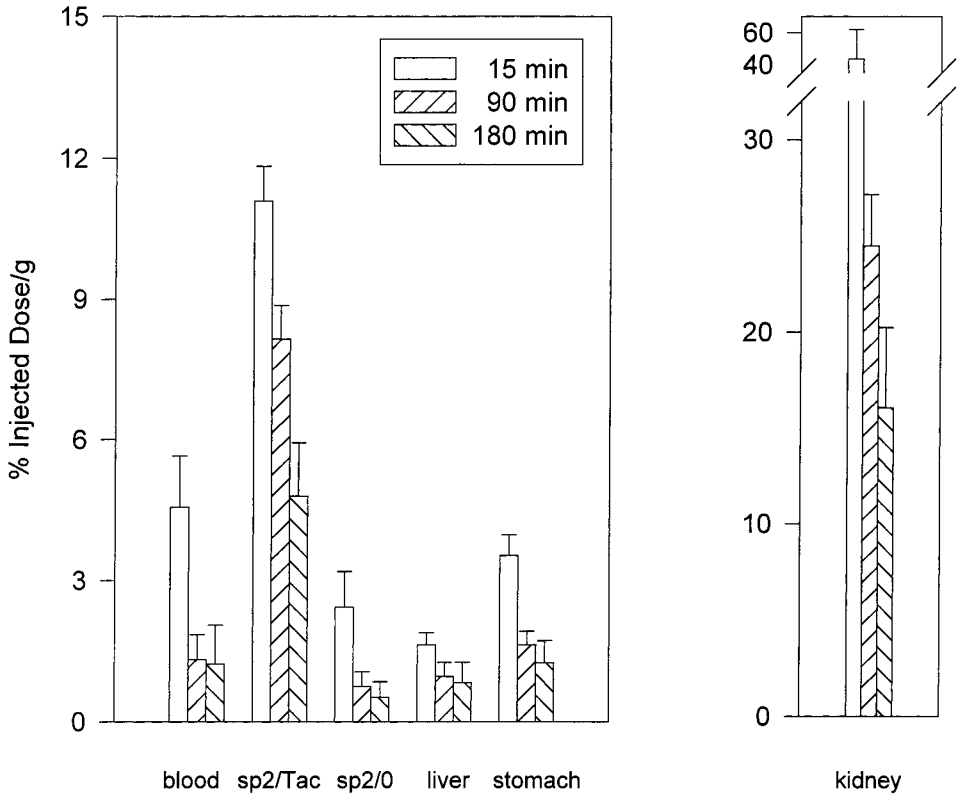

Figure 5. Biodistribution of glycolated [^{99m}Tc]MAG3-dsFv (II) in tumor-bearing nude mice ($n = 5$). The II represents the glycolated [^{99m}Tc]MAG3-dsFv from the reaction at a TFP-glycolate-to-dsFv molar ratio of 73. The % ID/g of tissue with standard deviation (bar) was plotted.

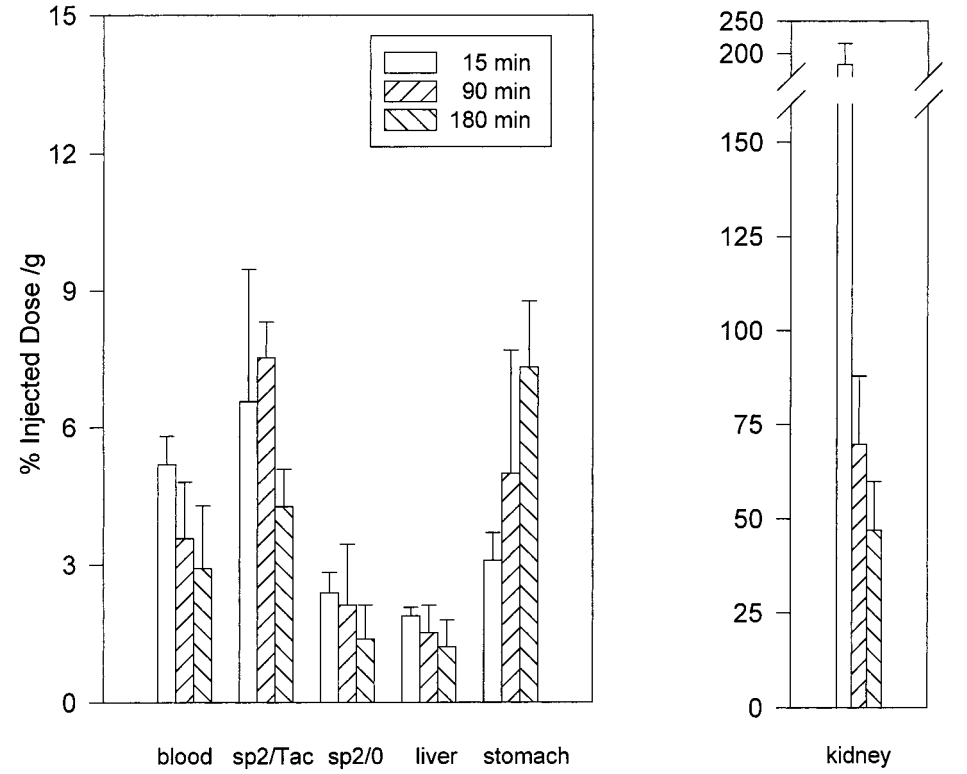

Figure 6. Biodistribution of [^{125}I]dsFv in tumor-bearing nude mice ($n = 5$). The % ID/g of tissue with standard deviation (bar) was plotted.

the nontumor mice. The cause of this higher renal uptake is not known, but it is possible that this higher renal accumulation might be caused by the receptor-bound radioactivity. Product II accumulated selectively into SP2/Tac, similar to that of the control [^{125}I]dsFv at 90 and 180 min (Figures 5 and 6). Since the glycolated [^{99m}Tc]MAG3-dsFv cleared from blood and organs rapidly, whereas it accumulated rapidly in the receptor-positive tumor, high receptor-positive tumor-to-nontumor tissue radioactivity ratios were obtained within 90 min. At 90

min, the ratios of receptor-positive to receptor-negative tumor, liver, kidney, stomach, and blood were 10.9, 8.5, 0.3, 5.0, and 6.2, respectively, for the glycolated [^{99m}Tc]-MAG3-dsFv, whereas the ratios were 3.7, 5.0, 0.1, 1.5, and 2.1, respectively for the control [^{125}I]dsFv. The tumor to nontumor ratios for the glycolated [^{99m}Tc]MAG3-dsFv were higher ($p < 0.05$) than those for the control throughout the 3 h observation.

DISCUSSION

Anti-Tac dsFv is a disulfide-stabilized variable-region fragment with a molecular mass of 25 kDa and a pI of >9.3, thus highly positively charged at physiological pH. The radiolabeled dsFv, due to its small size, is believed to be filtered readily through the glomerulus, but is absorbed by proximal tubular cells via an electrostatic attraction between the positive charge of dsFv and the negative charge of phospholipid bilayers of parenchymal cells of the tubules, resulting in the high renal concentration of radiolabeled dsFv. In this study, we lowered the pI of dsFv by chemical modifications to test whether this lowered pI decreased its renal uptake. The pI of dsFv can be lowered chemically either by the acylation of the ϵ amino group of lysine residues or by the addition of acidic amino acids to the carboxy terminus. We chose the acylation reaction because dsFv has 12 lysine residues whose ϵ amino group is readily acylated.

The acylation of amino groups to the corresponding amides is a common method of neutralizing the positive charges on the proteins (*26*). We used TFP-glycolate as an acylating agent because it is a small molecule with a polar hydroxy group that is expected to cause only a small perturbation to the tertiary structure of dsFv. The conversion of an amino group to an amide by acylation with one glycolate molecule reduces one positive charge from the native dsFv, adds one hydroxyl group, and increases the molecular weight by 58. Thus, the maximum glycolation of all 12 lysine residues would increase the molecular weight of the 25 kDa dsFv by 696, only 2.8% increase in the molecular weight. This study demonstrates that the acylation of the amino groups of dsFv with glycolate molecules lowers its pI inversely proportional to the molar ratio of glycolate-TFP to dsFv (Table 1), and that this lowering of the pI decreases the renal uptake (Figure 3) and the whole-body retention (Figure 4). The effect was especially pronounced at 15 min. At this time, the renal uptake of the labeled, glycolated dsFv with a pI range below 7 was reduced to about 50% ID/g, or 25% of the renal uptake of nonglycolated [^{99m}Tc]MAG3-dsFv, and the whole-body retention of the glycolated dsFv was decreased to 50% ID. These results suggest that one-half of the injected dose was excreted via the kidneys within 15 min for the glycolated dsFv conjugate. These results are consistent with our observation that the [^{99m}Tc]99m activity excreted in urine was all bound to dsFv up to 15 min for the [^{99m}Tc]99m MAG3-dsFv-glycolate prepared at a molar ratio of 73 (data not shown). Since lowering the pI of dsFv reduced renal uptake without altering the blood activity, it is likely that the glomerular filtration was unaffected and that it is the tubular reabsorption that was blocked by the lowering of the pI.

The effect of the lowered pI on the biodistribution of dsFv was somewhat different from that on the biodistribution of ^{111}In-labeled Fab′ (50 kDa), especially in blood concentrations. Tarburton et al. (*27*) reported that the acetylation with acetic anhydride lowered the pI of ^{111}In-labeled Fab′ and that the acetylated [^{111}In]Fab′ showed lower kidney and higher blood concentrations than the nonacetylated [^{111}In]Fab′. A similar result was also reported by Fagnani et al. (*28*) for the [^{111}In]Fab′ that had its pI reduced by conjugation with low-molecular-mass dextran (6000 ± 500 Da). We recently demonstrated that ^{125}I-labeled Fab of anti-Tac monoclonal antibody increased blood concentration, but reduced renal uptake when its pI was lowered by acylation with TFP-glycolate (*29*).

The effect of pI on tumor uptake was investigated with [^{99m}Tc]MAG3-dsFv-glycolate prepared at a TFP-glycolate-to-dsFv reaction molar ratio of 73 because this reaction ratio produced a glycolated dsFv with a pI range below 7 at the expense of only 20% deactivation of immunoreactivity. This glycolated [^{99m}Tc]MAG3-dsFv accumulated selectively into the receptor-positive SP2/Tac tumor with the tumor uptake similar to that of [^{125}I]dsFv at 90 and 180 min. In contrast, the kidney accumulation of the glycolated conjugate was decreased to only 25% of the control [^{125}I]dsFv at 15 min, due to its rapid excretion into urine (Figures 5 and 6), as reflected by a low whole-body retention, with 60% ID remaining at 15 min, compared to 97% ID remaining with [^{125}I]dsFv. In conclusion, this study demonstrated that TFP-glycolate is an efficient acylating agent for lowering the pI of dsFv. This new approach holds promise for enhancing the renal clearance of radiolabeled variable region fragments without altering their tumor uptake.

ACKNOWLEDGMENT

The authors thank Dr. Thomas A. Waldmann for providing SP2/Tac and SP/0 cell lines, David S. Paik for his computational and editorial assistance, and Sue Kendall for her editorial assistance.

NMR Studies of the Metal-Loading Kinetics and Acid−Base Chemistry of DOTA and Butylamide-DOTA

David A. Keire* and Mitsuo Kobayashi

Received October 30, 1998; Revised Manuscript Received January 19, 1999

The conjugation of a chelating agent to a protein via a covalent linkage has been previously reported to change the metal-binding characteristics of the chelator. A fundamental understanding of these binding changes would enable design of a new generation of metal-chelating agents for biological applications. To assess the effect of conjugation on the commonly used chelating agent 1 4,7,10-tetraaazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraaacetic acid (DOTA), we synthesized a model protein conjugate, 1,4,7-tris(carboxymethyl)-10-(butylaminocarboxymethyl)-1,4,7,10-tetraaazacyclododecane (BD) and explored the metal-binding characteristics via NMR. The extent of ionization of the carboxylic acid groups and the two protonated macrocycle nitrogens of DOTA and BD were determined as a function of pH by chemical shift changes in proximal carbon-bonded protons. In addition to the expected sensitivity of the chemical shifts to titration of proximate acidic groups, BD resonances from carbon-bonded protons 10−17 bonds distant from the deprotonation site also shifted significantly, indicating the presence of conformational changes. Furthermore, increased shielding of the amide and alkyl proton signals upon deprotonation of the carboxylic acid groups indicates the presence of pH-dependent hydrogen-bonded BD isoforms. On the basis of these NMR data, we propose new structures for the doubly protonated forms of DOTA and BD. To measure metal loading, the yttrium-loading rates (type I to type II) of DOTA and BD were determined by following the intensity of type I and type II proton signals as a function of time. The yttrium-loading rates of BD are approximately one-half those of DOTA at pHs between 4.6 and 6.5 and 37 °C. The loading rates measured as a function of pH indicate that while both the doubly protonated and singly protonated forms of DOTA are reactive to metal loading, only the singly protonated form of BD is reactive.

INTRODUCTION

The conjugation of metals to proteins via a chelating agent is of fundamental interest in the design of proteins with modified properties. Introduction of a metal center may be used to add radioactive, paramagnetic, or redox character to proteins that lack these properties. For example, radiometals attached to antibodies via a chelating agent have been used for the delivery of therapeutic radiation directly to tumor sites and in the development of new contrast reagents for magnetic resonance imaging [for review, see Alexander (1995)]. However, the conjugation of a chelating agent to protein surface amino groups alters the metal-binding characteristics of the chelating agent, and although a number of applications would benefit from greater understanding of how the metal-binding parameters are modified, very little data exist describing the nature of the changes that occur.

To begin to address this lack of information, we compared the acid−base chemistry and the yttrium metal loading kinetics of 1,4,7,10-tetraazacyclododecane-*N*,*N*′,-*N*″,*N*‴-tetraacetic acid, DOTA,[1] to those of a model protein conjugate, butylamide-DOTA (or BD) by NMR methods. The alkylamide-substituted BD compound is clinically relevant because it mimics the lysine-side-chain protein-conjugate form of the chelating agent. Significant differences in pK_as, kinetics, and structure are observed between the two compounds, and the importance of this to protein conjugate design is discussed.

We chose DOTA for study because it is well-known to form very stable complexes with a wide variety of divalent and trivalent metal ions (Figure 1) (Loncin et al., 1986; Cacheris et al., 1987; Kumar et al., 1989; Broan et al., 1991; Clarke and Martell, 1991a,b). For example, DOTA binds Ca^{2+} and Y^{3+} with stability constants (log K_{LM} = [ML]/[M][L] at 25 °C) of 16.5 and 24.9 M^{-1}, respectively (Alexander, 1995). The tetraaza macrocycle contains a rigid preorganized-binding pocket that allows the formation of highly stable metal chelates. However, at the same time, this rigid pocket leads to a rate of metal incorporation slower than more flexible (and less stable) macrocycles. For example, Gd^{3+} is incorporated into DOTA at a rate 100 times slower than it is into 1,4,7,-10,13,16-hexaazacyclooctadecane-*N*,*N*′,*N*″,*N*‴,*N*⁗,*N*⁗′-hexaacetic acid (Kodama et al., 1991).

The effective ionic radius of the metal is also important to the rate of metal incorporation into DOTA. Larger ionic radii metals such as gadolinium (1.06 Å) and yttrium (1.02 Å) load slowly into DOTA because the binding requires a reorganization of the binding pocket. The metal−DOTA complex formation with these larger radii metals is a two-step process (Kasprzyk and Wilkins, 1982; Wang et al., 1992). Initially, a reversible type I

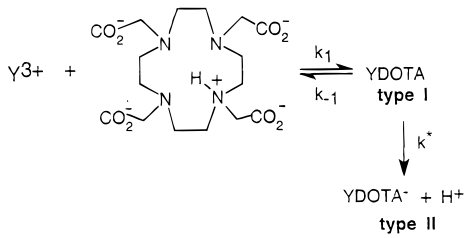

Figure 1. The reaction scheme of the $HDOTA^{3-}$ with Y^{3+}.

adduct forms (ca. $k_1 = 50\ M^{-1}\ s^{-1}$ for Gd^{3+}), followed by a relatively slow forming type II complex (ca. $k^* = 10^{-3}\ s^{-1}$ for Gd^{3+}) that has the metal fully coordinated (Figure 1).

The formation of the fully coordinated metal DOTA complex is highly pH dependent. The singly protonated form of DOTA (LH^{3-}) is the most reactive species, and the doubly protonated LH_2^{2-} form is 4 orders of magnitude less reactive (Wang et al., 1992). Desreux proposed that the slow kinetics of metal−DOTA complex formation is caused, in part, by the dynamics of conversion between isomers of metal−DOTA compounds (Desreux, 1980). Thus, the rate of metal−DOTA complexation is much higher at elevated temperature or with more flexible macrocycles because the rate of conformational change between isomers is more rapid (Desreux, 1980; Kodama et al., 1991).

Despite a relatively slow metal complexation rate, DOTA has been actively studied for use as a metal chelator in biological systems due to its serum stability (Desphande et al., 1990; Li and Meares, 1993; Lewis et al., 1994). The metal-loading yield of free polyaza macrocycles normally exceeds 95% at room temperature in about an hour [e.g., Stimmel et al. (1995)], but it has been observed that upon conjugation to an antibody much lower metal-loading yields are realized. For example, Meares and co-workers incubated $^{88}Y^{3+}$ with an antibody-DOTA conjugate containing a flexible linker for 3 h at room temperature and obtained a 26% radiolabeling yield (Li and Meares, 1993). More recently, two studies have shown that elevated temperature (>40 °C) and optimized pH and the buffer used can greatly improve the yttrium metal incorperation into DOTA-antibody conjugates (Lewis et al., 1994; Govindan et al., 1998). These studies suggest that the chelation properties of free DOTA are altered in protein-chelating agent conjugates and that these changes affect metal-loading efficiency.

Currently, no accepted model explains the observed change in the metal-loading efficiency of DOTA upon conjugation to a protein. A number of possible factors have been proposed to explain the altered metal-loading rates, including the alkyl amide modification of DOTA in the conjugation reaction, competition from other protein metal binding sites, and steric hindrance caused by the conformation of the chelating agent at the protein surface. In this work, a butylamide-DOTA conjugate has been synthesized to explore the effects of an alkyl amide modification on DOTA metal loading kinetics and pK_as.

EXPERIMENTAL PROCEDURES

General. The trisodium salt of DOTA was purchased from Parish Chemical Co. (Orem, UT), and the sulfo-NHS and EDC were purchased from Pierce (Rockford, IL). The butylamine for the conjugation reaction and the yttrium chloride hexahydrate for the metal-loading experiments were procured from Aldrich (Milwaukee, WI). All glassware was acid washed and liberally rinsed with distilled deionized water (Thiers, 1957).

Synthesis and Purification of BD. Synthesis of BD began with the addition of a solution of 60 mg (128 μmol) of DOTA and 56 mg (256 μmol) of sulfo-NHS in 2 mL of H_2O to 0.982 mL (256 μmol) of a freshly prepared solution of EDC (50 mg/mL)[1]. This reaction mixture gave a theoretical concentration of the active ester of 12.7 mM. After 30 min, 25 μL (18.7 mg, 256 μmol) of neat butylamine was added to the reaction mixture, the pH adjusted to 8 with 220 μL of 1 M NaOH, and the solution left overnight. The next morning, the reaction was quenched by lowering the pH of the reaction mixture to 2 with the addition of 670 μL of 1 N HCl. The final mixture contained both doubly and singly modified forms of BD and unmodified DOTA that were separated by reversed-phase HPLC.

The products of the reaction were purified using a Biocad Sprint chromatography system (Perseptive Biosystems, Farmingham, MA), equipped with a 4.6 mm × 10 cm POROS R2 stationary phase column (equivalent to a C18 column) and UV detection at 214 nm. The purification method used a flow rate of 1 mL/min for the wash step and a 4 mL/min flow rate for the linear gradient from 0 to 100% solvent B over 5 min (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH_3CN), beginning 7 min after injection. This method yielded three peaks upon injection of the reaction mixture. The first peak contained unreacted DOTA and other starting material (eluted in the wash step), the second peak contained singly modified BD (also eluted in the wash step, baseline resolved from the first peak), and the third peak contained the doubly conjugated product (eluted in the gradient portion of the method).

The peaks were collected, lyophilized, and identified by their mass-to-charge ratio (vida MALDITOF[1]). The mass-to-charge ratio of the peaks from the HPLC purification were measured on a Kratos Kompact MALDI III spectrometer, using α-cyano-4-hydroxycinnamic acid as the matrix. The spectra were collected in low-mass mode and calibrated with an external standard. A saturated solution of matrix was made in acetone and spotted on the MALDI stage in two 0.5 μL aliquots. The HPLC fraction of each of the peaks was mixed one-to-one with a 70% H_2O/30% CH_3CN/0.1% TFA solution, spotted on the MALDI stage in 1 μL aliquots, and air-dried. Mass-to-charge ratios (MH+) were observed for DOTA, BD, and doubly modified DOTA (2BD) of 406, 460, and 516 amu, respectively.

NMR Measurements. NMR experiments were performed on a Varian Unity Plus 500 MHz spectrometer (Varian Instruments, Palo Alto, CA) with the probe air temperature regulated at 25−37 °C. NMR studies on DOTA and BD in solution were performed at 1−2 mM concentrations in 90% H_2O/10% D_2O solutions with the pH adjusted by addition of HCl or NaOH. All pH measurements were performed with an Orion model 601 pH meter equipped with a combination electrode for 5 mm NMR tubes (Ingold Electrodes, Wilmington, MA). Standard aqueous buffers were used for electrode calibration at pH 4 and 7. All chemical shifts were referenced to the methyl proton signal of sodium-2,2-dimethyl-2-silapentane-5-sulfonate (DSS, at 0 ppm), which was added to the samples.

The assignment of the pH-dependent chemical shifts for BD protons was aided by the observed magnitude of the chemical shift changes during the titration of proximate acidic groups. Those carbon-bonded protons closest to the deprotonation site generally have the largest increase in shielding and, concomitantly, the largest chemical shift changes to lower ppm values. The assign-

ments were confirmed by total correlation spectroscopy [TOCSY (Braunschweiler and Ernst, 1983)] spectra connectivities at selected pHs. Typically, the TOCSYs were performed with 2K points collected in t_2 (32−48 transients/increment), and 256 complex points in t_1 (States et al., 1982). The transmitter channel was used for excitation and observation of the 6000 Hz proton frequency range as well as presaturation of the H_2O signal. Data were processed with zero filling to 2K points in F_1 and shifted sine-bell apodization functions in both F_1 and F_2.

The DOTA and BD type I to type II rate constants (k*) were determined as a function of pH by measuring the intensity of the type I and type II forms as a function of time after the addition of excess yttrium. Typically, 700 μL of a 1 mM BD or DOTA solution was made in 90% H_2O/10% D_2O, the pH adjusted to the desired value with 1 M KOH and 1 N HCl, and a 1D spectrum acquired. Subsequently, 50 μL of a 120 mM yttrium chloride stock solution was added to the NMR tube (ca. 5 mM), and a series of spectra acquired as a function of time over 10 to 14 h. The peak heights of the signals from the acetate methylene group protons in the type I and type II forms were measured from each time-course data set and plotted.

Acid-Dissociation Constants. Acid dissociation constants were determined by fitting NMR chemical shift titration data to monoprotic and diprotic acid models by nonlinear least-squares (Jardetzky and Roberts, 1981; Keire et al., 1992). For a monoprotic acid system, the observed chemical shift is given by the eq 1

$$\delta_{obs} = f_{HA}\delta_{HA} + f_A\delta_A \quad (1)$$

where f_{HA} and f_A represent the mole fractions, and δ_{HA} and δ_A the chemical shifts of the acid in its protonated and deprotonated states. The model equation for a monoprotic acid is obtained by expressing f_{HA} and f_A in terms of the acid dissociation constant, K.

$$\delta_{obs} = \frac{[H^+]\,\delta_{HA} + K\delta_A}{[H^+] + K} \quad (2)$$

The following model equation for the diprotic acid is derived in the same way.

$$\delta_{obs} = \frac{[H^+]^2\delta_{H_2A} + [H^+]K_1\delta_{HA} + K_1K_2\delta_A}{[H^+]^2 + [H^+]K_1 + K_1K_2} \quad (3)$$

The criteria used to select a model were the number of observed inflection points and comparison of the χ^2 values obtained from fitting the data to monoprotic and diprotic models. The DOTA and BD k*s for yttrium were determined by the method of initial rates. Peak intensities were fit to a straight line to determine the initial rate. The fitting of the acid dissociation and rate constants was performed with Mathematica 3.0 (Wolfram Research, Champaign, IL).

RESULTS

Synthesis of BD. The *N*-hydroxysulfo-OSSu active ester of the DOTA carboxylic acids was prepared by a water-soluble method commonly used in peptide synthesis and protein modification (Yamada et al., 1981; Staros et al., 1986; Gilles et al., 1990). A mole ratio of DOTA to sulfo-NHS to EDC of 1:2:2 was used in order to minimize the number of multiply activated DOTA carboxyl groups. The active ester form of DOTA reacts with the primary amine group of the butylamine to form an amide bond in the conjugation reaction. The reaction produced two main products, BD and doubly modified BD (2BD), that were separated by reversed-phase HPLC and identified by their mass-to-charge ratios. The yield of the reaction after purification (based on the DOTA as the limiting reactant) was 38% BD (22.1 mg) and 14% 2BD (9.4 mg).

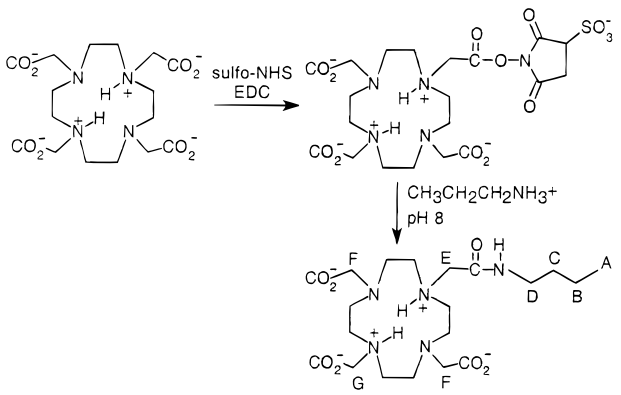

Figure 2. The synthesis of butylamide-DOTA (BD)

NMR pH Titration of DOTA. DOTA and BD have multiple sites with Brønsted acid−base properties in aqueous solution. For DOTA, these are the four carboxylic acid groups and two protonated macrocycle nitrogen protons. Over the range pH 0−13 these groups undergo protonation/deprotonation reactions, and the chemical shifts of the carbon-bonded protons near sites of protonation or deprotonation are expected to change due to through-bond electrostatic effects (Jardetzky and Roberts, 1981). Thus, acid dissociation constants were determined for these groups from the dependence of the chemical shifts of the carbon-bonded protons on pH.

The NMR spectrum of DOTA in aqueous solution consists of two signals, one for the acetate methylene group protons and the other for the macrocycle ethylene protons (Desreux et al., 1981). The signal for the protons on the macrocycle nitrogens are not observable because of exchange broadening (Brucher et al., 1991). Instead, the presence of nitrogen-bound protons in the macrocycle are inferred by the pH dependence of the chemical shifts of other nearby carbon-bonded proton signals at basic pHs. An abrupt change in the chemical shifts is observed at pH 11 is due to K^+ complexation by the fully deprotonated form of DOTA (Clarke and Martell, 1991a).

Macroscopic acid dissociation constants were determined for the various groups by fitting the NMR pH titration data to monoprotic and diprotic models (eqs 1−3). The criteria used to select a model were the number of observed inflection points and the fit of the data based on the χ^2 value. For example, the chemical shifts of the DOTA ethylene proton signal over the range pH 0−7 was fit to a monoprotic model and the acetate chemical shifts were fit to a diprotic model (data not shown). Both the acetate methylene and the macrocycle ethylene signals were fit with a monoprotic model for the amine deprotonation over the range pH 7−11. The chemical shift values of the fully deprotonated and fully protonated forms of DOTA titratable groups (and the intermediate value in the diprotic model) are also obtained from the fits of the NMR pH titration data. The values obtained for the DOTA pK_as and the titration shifts for the acetate and methylene protons are listed in Table 1.

The measured macroscopic pK_as are assigned to protonation of two trans amine nitrogens (designated G amines, 10.26), the two carboxyl groups near the non-

Table 1. Acid Dissociation Constants and Titration Shifts for DOTA in 0.1 M KCl at 25 °C

[a] Calculated titration constants from the relationship between macroscopic and microscopic pK_as [see Edsall and Wyman (1958)] and the average of the measured pK_as. [b] Desreux et al. (1981). [c] Clarke and Martell (1991a). [d] Stetter and Frank (1976). [e] Delgado and Fausto Da Silva (1982).

protonated amines (designated F carboxylates, 4.57), and the remaining two carboxylic acid groups near the protonated amines (designated G carboxylates, 1.54). The individual pK_as of the six DOTA protons were calculated using the relationship between macroscopic and microscopic protonation constants (Edsall and Wyman, 1958). The agreement among protonation constants determined for DOTA in Table 1 is reasonably good compared to those measured in other studies by potentiometric and NMR methods (Stetter and Frank, 1976; Desreux et al., 1981; Delgado and Da Silva, 1982; Clarke and Martell, 1991a). The value of the most basic amine pK_a reported in Table 1 is lower than the other measured values presumably because of the effect of the K^+ complexation with the $DOTA^{4-}$ form at pHs above 11.

NMR pH Titration of BD. The conjugation of butylamine with DOTA active ester to form BD greatly increases the number of NMR signals present, whereas only two signals were observed in DOTA spectra (Figure 3). For example, in the conjugate, separate NMR peaks are observed for the acetate and ethylene signals directly adjacent and opposite to the site of the modification because the molecule is no longer symmetric; in symmetrical DOTA, these signals overlap. The separate signals allow the measurement of the microscopic protonation constants of the three carboxylic acid groups and the two macrocyle amines via fits of the pH-dependent chemical shifts of proximal carbon-bonded protons.

These proton signals shift as a function of pH and the protonation state of BD. The 1D 1H NMR spectra of BD as a function of pH for the acetate signals is shown in Figure 3 (similar shifts were observed for the ethylene proton signals). The resonances were individually assigned by comparison with DOTA chemical shifts, their pattern of chemical shift changes with pH, relative intensities, and TOCSY spectra that indicated connectivities between connected ethylene protons or adjacent butylamide proton signals. For example, the methylene protons of the DOTA acetate arm that is involved in the conjugation to butylamine (Figure 4, E protons) exhibits the smallest chemical shift change with titration of the unconjugated carboxylic acids. Similarly, the methylene groups on the carboxylic acids not attached to a protonated nitrogen (Figure 4F) show the smallest perturbation with titration of the two macrocycle nitrogen protons.

In another example, the BD F and G acetate methylene protons give rise to separate signals at low pH (Figure 3). Because the BD G protons are the most DOTA-like acetate methylene protons in BD, they were assigned based on the similarity in chemical shift with the DOTA G proton signal at low pHs (at pH 0.8 BD and DOTA G protons have chemical shifts of 3.935 and 3.992, respectively). In addition, the BD F proton signal can be differentiated from the G signal because it is larger (it arises from four identical protons versus 2 G protons).

To follow the titration shifts of the ethylene signal chemical over the 0−13 pH range, TOCSY spectra were collected at pH 1.24, 2.92, 3.14, 5.70, 7.0, and 9.60. In these experiments, TOCSY connectivities are observed in BD between the G′ and F″ proton signals and the E′ and F′ proton signals. These connectivities, in combination with the pH-dependent shifts were used to assign the macrocycle ethylene proton resonances.

The acetate methylene proton signals (labeled E, F, and G) shift and change shape as a function of the protonation state of BD (Figure 3). For example, the F and G acetate methylene signals at pH 1 are broad and have separate signals. Upon deprotonation of the G carboxylate, these signals move together and overlap, become sharp, and shift to lower chemical shift values. The F and G signals become nonequivalent again upon deprotonation of the F carboxylic acid groups.

The increased shielding (shift to lower chemical shift value) of the methylene signals is expected due to the increased electron density in the adjacent deprotonated carboxylic acid group. Typically, in the absence of structural alterations, the closer that the carbon-bonded proton is to the site of the deprotonation, the greater the magnitude of the chemical shift change. By contrast, deprotonation events that lead to deshielding (movement to higher chemical shift values) for carbon-bonded protons more than 3−5 bonds distant from the site of deprotonation indicate the presence of conformation-dependent through-space interactions.

In particular, the formation of hydrogen bonds between amines and carboxylate groups can be identified from observation of deshielding chemical shift changes as a function of pH (Bundi and Wuthrich, 1979). The chemical shifts change because the N−H bond becomes strongly polarized when the amine or amide proton forms a hydrogen bond, the proton is deshielded and its resonance shifted to higher chemical shift values. Furthermore, the deshielding tends to occur upon titration of carboxylic acid groups because a deprotonated carboxylate forms a stronger hydrogen bond than the protonated form.

Deshielding chemical shift changes attributed to the formation of hydrogen bonds and conformational changes are evident in the NMR pH titration data of BD (Table 2). For example, the E acetate methylene signal is a broad singlet at low pH and upon titration of the G carboxylic acid group shifts to a higher (deshielded) chemical shift value. This signal also sharpens to an AB pattern as the two geminal protons become magnetically nonequivalent (at pH 3.3 $^2J_{AB}$ is −14.2 Hz and $\Delta\nu(\nu_a - \nu_b)$ is 0.033 ppm). With the titration of the F carboxylate groups, the E acetate methylene proton signal is slightly shielded and the AB pattern is altered (at pH 5.5, $\Delta\nu$ is 0.101 ppm).

Simultaneously, the amide, D, and C proton signal chemical shifts decrease upon G deprotonation and increase upon F carboxylate deprotonation (Figure 5). Because the E acetate methylene and butylamide protons (A, B, C, D, and the NH) are 10−17 bonds distant from the site of the G carboxylate deprotonation and 7−12 bonds distant from the site of F carboxylate deprotona-

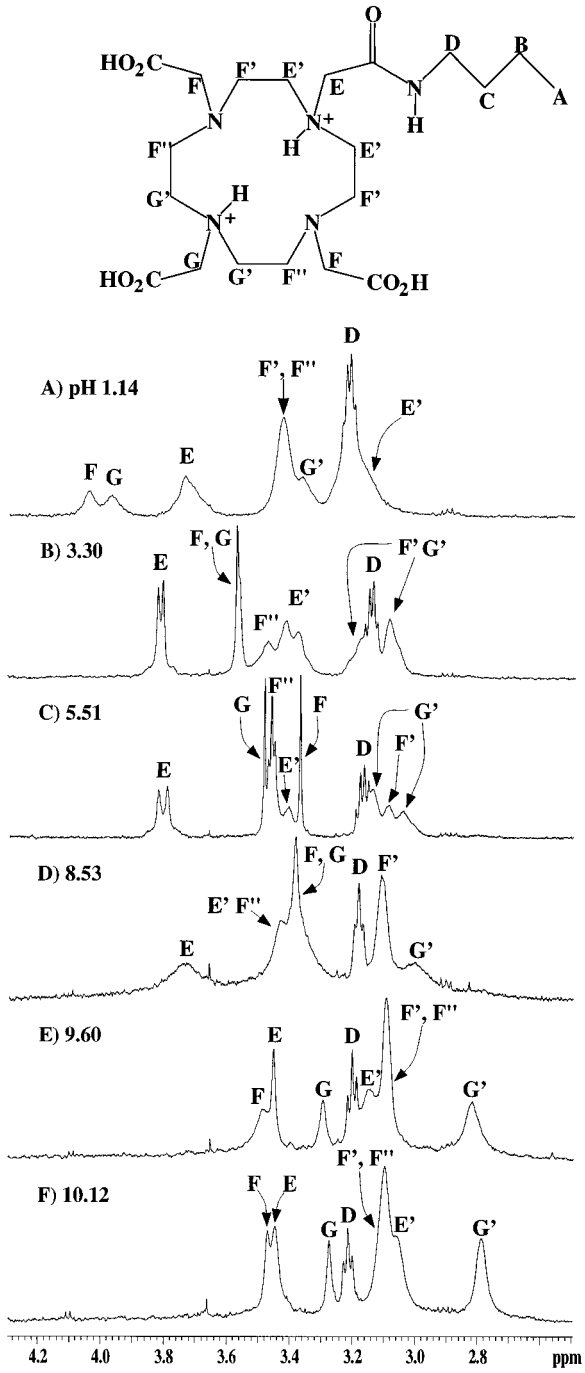

Figure 3. The 2.5−4.3 ppm region of the 500 MHz ^{1}H NMR spectra of 1 mM BD in 90% H_2O/10% D_2O at pH (A) 1.14, (B) 3.30, (C) 5.51, (D) 8.53, (E) 9.60, and (G)10.12. The signals from the various BD protons are labeled in the accompanying structure and the spectra.

tion, these shifts indicate that BD undergoes conformational changes and that these changes are dependent on the protonation state of the molecule. The effects of these structural alterations are evident in the NMR pH titration spectra (the observed chemical shifts, line shapes, and coupling constants are weighted averages of these parameters in the different isomers present at a particular pH).

The BD acetate methylene and macrocycle methylene titration shift data were fit to monoprotic or diprotic models to determine the pK_as of the various functional groups and titration shifts (Table 2). Of note, the fit of pH shifts resulting from titration of the F carboxylate protons revealed two values, 3.52 (±0.12) (three of the

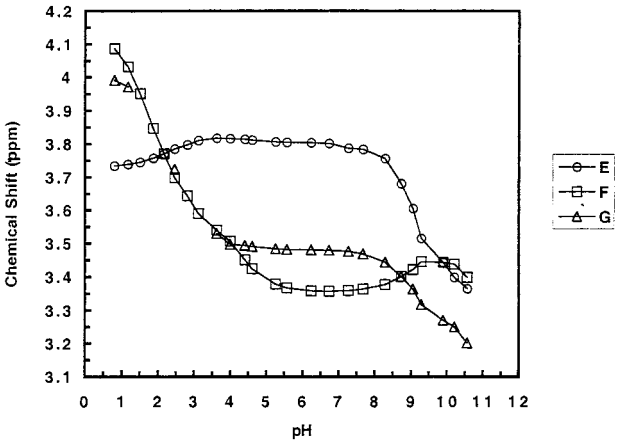

Figure 4. A plot of the chemical shifts of the BD E, F, and G acetate methylene proton signals as a function of pH.

eight values) and 4.53 (±0.24) (five of the eight values). In addition, the formation of a possible hydrogen bond with the pendant arm amide proton is indicated by its deshielding chemical shift change which occurs with the deprotonation of the second F carboxylate group (Table 2).

Yttrium Metal Loading Rates in DOTA. The yttrium metal loading into DOTA over time was monitored by proton NMR (as shown in Figure 6). The rate of the formation of type I complexes is such that by the time the first NMR spectrum is collected after adding excess metal, most of the chelator is in the type I and type II forms. In the presence of the metal, the NMR signals broaden and shift, and, over a period of hours, several of the broad signals disappear. This reflects the transition from the type I to type II complex (Figure 6).

The resonances in the yttrium−DOTA complex previously have been assigned and show that the DOTA protons become magnetically nonequivalent because of the rigid structure induced by metal binding (Broan et al., 1991). The signals labeled F,G in Figure 6A are the methylene protons of the F and G acetate groups of $YDOTA^-$ (an AB pattern with $^2J_{AB}$ of 16 Hz). Three multiplets, J, I, and K, are also observed with a signal intensity ratio of 4:8:4, respectively. Signal *J* is from the ring protons closest to the carboxyl group in the structure induced by metal complexation. The signals in Figure 6A are from the fully metal-loaded form of DOTA (type II complex) and the spectrum in Figure 6B represents a mixture of signals from the type I and type II forms.

With the identity of the type II complex signals established, the broad signals observed in 1H NMR spectra (Figure 6B) of Y−DOTA complexes (that do not correspond to signals in Figure 6A) are assigned to the intermediate type I complex. These type I signals decrease as a function of time after mixing and as the type II signals increase. These data reveal the rate of transition from the type I to type II complex. To determine the initial rates, the intensity of the I and K resonances (at 2.74 and 2.42 ppm, respectively) was plotted as a function of time after adding metal. Table 3 shows the initial rates of yttrium metal loading over the pH range 4.5−6.5 at 37 °C.

Yttrium Metal Loading Rates in BD. The 1H NMR spectrum of the fully metal-loaded (type II) complex of yttrium and BD (Y−BD) has a similar pattern of signals as Y−DOTA (Figure 7A). The resonances of the E, F, and G acetate and the J, I, and K methylene protons of Y−BD appear in the same order as the F, G, J, I, and K signals in Y−DOTA (compare spectra in Figures 6 and 7A).

[a] The pK_as were calculated from fits to monoprotic and diprotic models of the NMR pH titration data. [b] The titration shifts were calculated from the chemical shift values obtained in the pK_a fits ($\delta_{HA} - \delta_A$).

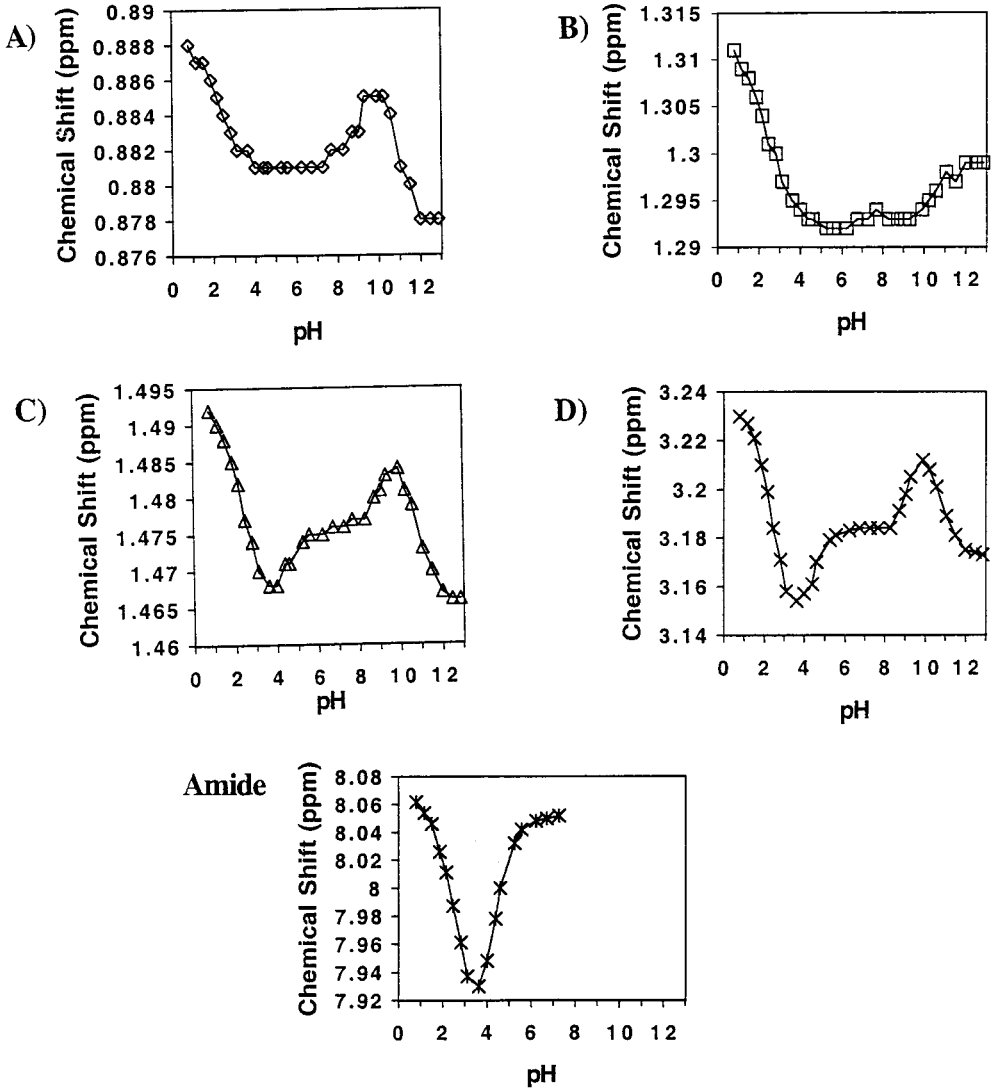

Figure 5. Plots of the chemical shifts of the A, B, C, D, and amide protons of the butylamide portion of BD as a function of pH. The labels are the same as in Figure 1.

However, the E, F, and G acetate methylene protons in Y−BD are split into AB patterns and have different chemical shifts (E being the most deshielded) because of the butylamide substitution. A similar pattern is observed for the macrocycle ring K protons, in which separate signals are observed for the proton next to the E methylene [K(E)], and the F and G methylenes [K(F,G)]. Also, the butylamide D methylene signal is split into a multiplet (vida TOCSY).

The formation of the multiplet patterns in Y−BD for the methylene protons is indicative of the formation of a rigid structure that causes the geminal proton pairs to become magnetically nonequivalent. For example, the splitting of the E and D methylene proton resonances into

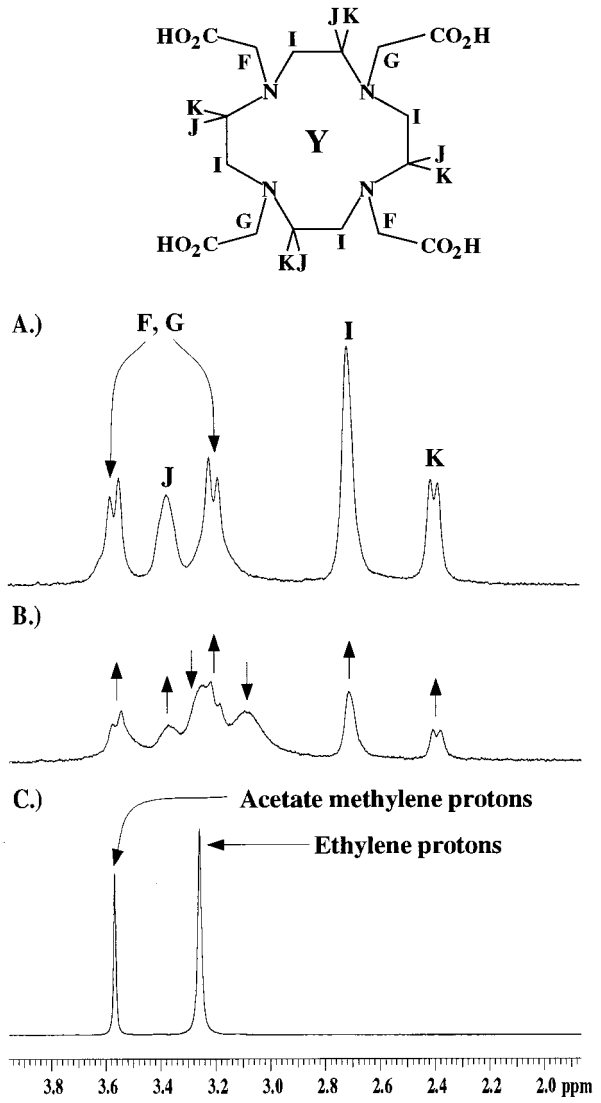

Figure 6. The 1.5−3.9 ppm region of the 500 MHz ^{1}H NMR spectra of (C) a 2 mM solution of DOTA at pH 5, (B) the same solution as in C6 6 min after adding 27 mM Y^{3+}, and (A) the same solution as in panel B acquired 5 h after adding metal. All solutions were 90% H_2O/10% D_2O and the probe air temperature was regulated at 25 °C. Spectra B and C were acquired and displayed with the same parameters and A is labeled as in the accompanying structure. The up and down arrows of spectrum B indicate signals from the type II and type I Y−DOTA complex, respectively, that increase and decrease as a function of time.

Table 3. Rate Constants for Yttrium Metal Loading (Type I to Type II) in DOTA and BD as a Function of pH at 37 °C

pH	*n*	DOTA, k_1 (s^{-1})	BD, k_1 (s^{-1})
4.6	8	0.84 (±0.07) × 10^{-3}	
4.6	4		0.45 (±0.02) × 10^{-3}
5.7	4	1.68 (±0.12) × 10^{-3}	
5.6	4		0.63 (±0.10) × 10^{-3}
6.7	4	2.35 (±0.28) × 10^{-3}	
6.5	3		1.07 (±0.06) × 10^{-3}

AB patterns suggests that metal coordination occurs with the butylamide carbonyl group, fixing the geometry of this portion of BD. At the same time, the A, B, and C proton signals are mostly unchanged, indicating that their environment is not significantly altered by metal binding (although the B proton signal is broadened in the type II complex).

As with Y−DOTA, to determine the BD type I to type II metal loading rate constants, the intensity of three BD proton signals were measured as a function of time after addition of excess yttrium (Table 3). In Figure 7B, the increase in the F,G multiplet pattern at 3.6 ppm and the K(F,G) multiplet at 2.43 ppm and the decrease in the E proton AB pattern doublet at 3.95 ppm peak height as a function of time were plotted and the initial rates determined. The initial rates of yttrium metal loading (type I to type II) into BD as a function of pH at 37 °C are shown in Table 3 and are approximately one-half the rates for DOTA at the same pH.

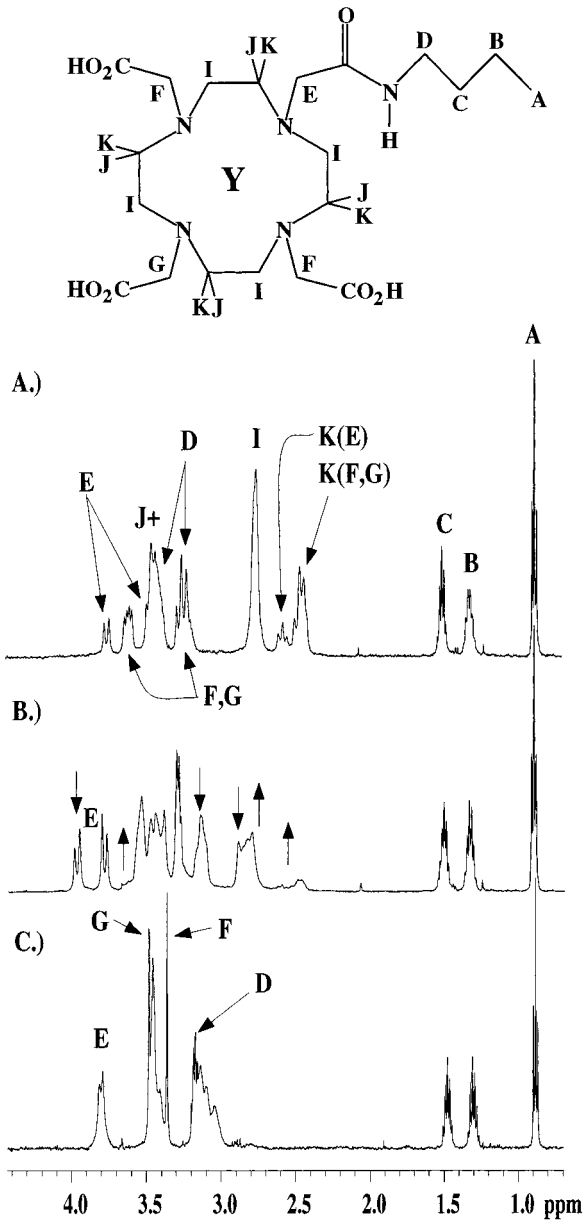

Figure 7. The 0.7−4.4 ppm region of the 500 MHz ^{1}H NMR spectra of (C) a 1 mM solution of BD at pH 7.1, (B) the same solution as in C 6 min after adding 5 mM Y^{3+}, and (A) the same solution as in panel B acquired ca. 24 h after adding metal. All solutions were 90% H_2O/10% D_2O and the probe air temperature was regulated at 37 °C. Spectra B and C were acquired and displayed with the same parameters, and A is labeled as in the accompanying structure. The up and down arrows of spectrum B indicate signals from the type II and type I Y−BD complex, respectively, that increase and decrease as a function of time.

Metal-Loading Forms of DOTA and BD. Examining of the combination of the pK_a and rate data reveals that although both the doubly and singly protonated species of DOTA are reactive to metal loading, only the

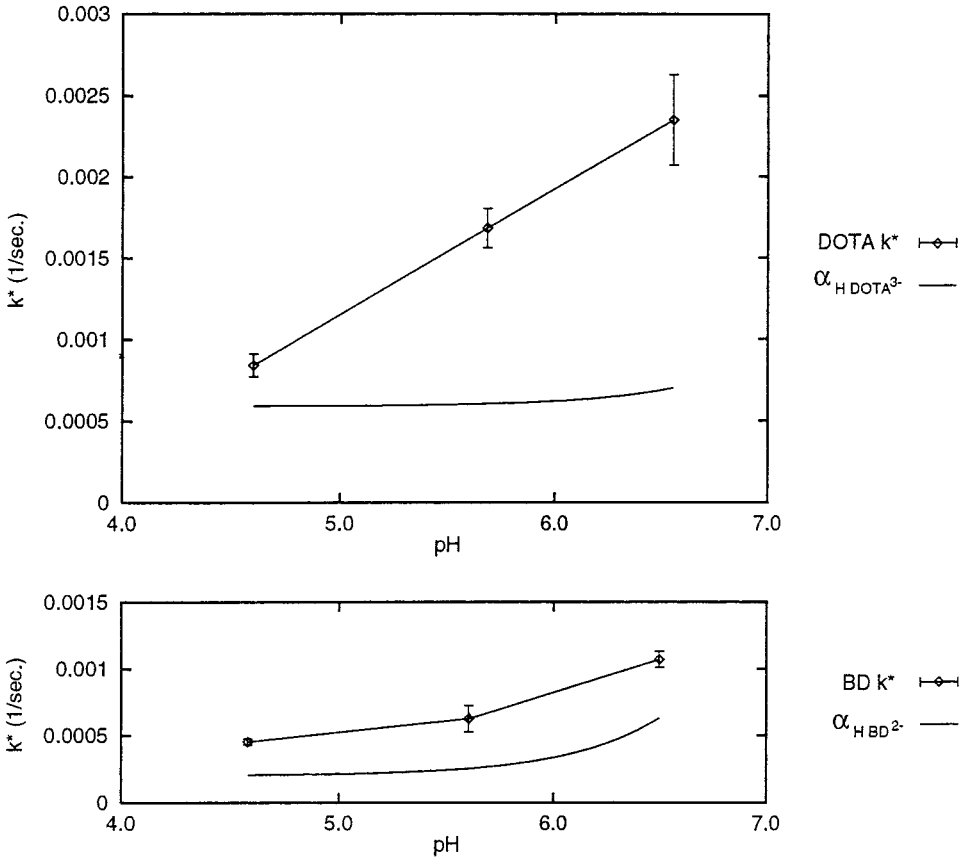

Figure 8. Combined plots of the type I to type II metal loading rate (k*) and the fraction in the singly protonated form of (top) DOTA and (bottom) BD.

singly protonated form of BD is reactive (Figure 8). For DOTA, over the 4.6−6.5 pH range, the change in k* increases more rapidly with pH than the fraction of the chelator in the singly protonated form ($HDOTA^{3-}$) (Figure 8, top). This increase in k* is best explained by metal loading into both the H_2DOTA^{2-} and $HDOTA^{3-}$ forms (the singly protonated form is orders of magnitude more reactive but much less abundant then the doubly protonated form). In contrast, for BD, the change in k* is best fit solely by the increase in the fraction of the singly protonated form (Figure 8 bottom).

DISCUSSION

The modification of a single pendant arm of DOTA to create BD significantly alters the structure and characteristics of the chelator. For example, the NMR pH titration on BD shows a 0.6 pK_a unit decrease in one of the amine nitrogens relative to DOTA. The decrease in the pK_a of the macrocycle amine is important because the singly protonated form is the most reactive to metal loading in both DOTA and BD. The decrease in the pK_a value leads to an increase in the population of the singly protonated form of BD compared to DOTA (at pH 7 the $HDOTA^{3-}$ is 0.002% and HBD^{2-} is 0.009%). Thus, if the macrocycle amine pK_as were the only determinant in the metal-loading rate of BD, BD would metal-load more rapidly than DOTA.

Because the yttrium metal loading rates of BD are approximately one-half the rates measured for DOTA at the same pH and temperature, other factors (e.g., the proton-transfer ability of the pendant arm groups) must be involved in the type I to type II transition. Evidence for the proton-transfer mechanism is observed in ab initio calculations on $Y-H_2DOTA^{2-}$ that show that the pendant carboxylate groups are near enough in space to form hydrogen bonds with the protonated nitrogens of the macrocycle and may act to facilitate the deprotonation of these nitrogens that occurs with metal loading [Jang and Goddard (1999) *J. Am. Chem. Soc.* (Manuscript submitted for publication)].

Consistent with the pendant group proton-transfer mechanism are the observations of Takenouchi et al. (1993a,b) who reported carboxymethyl-substituted derivatives of 6-(4-nitrobenzyl)-1,4,8,11-tetraazacyclotridecane-N,N',N'',N'''-tetraacetic acid (p-NO_2-Bz-TRTA) that showed a distance dependent rate enhancement for Y metal loading. p-NO_2-Bz-TRTA derivatives that contained a (carboxymethyl)amino group appended with a methylene or ethylene spacer increased the Y-metal loading rate by a factor of 2 or had no effect, respectively. Thus, the longer spacer arm may not allow effective proton transfer from the macrocycle nitrogens.

The type I to type II rate constants of DOTA metal loading measured in this work (Table 3) differ from the rate constants measured previously under different conditions. Kodama et al. (1991) reported a $DOTA-Y^{3+}$ metal loading rate of 7.7×10^{-5} s^{-1} (pH 7.8, 25 °C, I = 0.1 from $NaClO_4$ and 25 mM HEPES buffer) compared to value obtained in this work of 2.35×10^{-3} s^{-1} at pH 6.7 and 37 °C (Table 3). Wang et al. (1992) and Wu and Horrocks (1995) measured the pH dependent kinetics of $DOTA-Gd^{3+}$ (pH 3.8−5.8, 25 °C, I = 1 from NaCl and buffer) and $DOTA-Eu^{3+}$ (pH 4.5−5.7, 25 °C, I = 0.1 from KCl and 20 mM buffer) complexation, respectively, and showed rate constants 4−28 times faster (at similar pHs) than the rates measured in this work at 37 °C. These differences are attributed to the sensitivity of DOTA

metal loading rates to pH, ionic strength, temperature, buffer, and the effective ionic radii of the metal used.

DOTA Structure. The structure of DOTA in solution may also influence the kinetics of metal loading. Protonation-state dependent H-bonded forms of DOTA have been proposed to explain the low basicity of two of the macrocycle amine nitrogens (Micheloni et al., 1978; Desreux et al., 1981). Micheloni et al. (1978) first proposed that the two trans protonated macrocycle nitrogens formed intracation H-bonds with the unprotonated macrocycle nitrogens. Later, Desreux (1981) proposed a structure for H_4DOTA that had H-bonds between the two deprotonated G carboxylate groups and the macrocycle G amine protons (a five-membered ring).

For type II complex formation, the possible structures of the H_2DOTA^{2-} and $HDOTA^{3-}$ are the most important because they are reactive to metal loading. Ab initio calculations indicate that in H_2DOTA^{2-} H-bonds between the F carboxylate and G amine groups (an eight-membered ring) are more energetically favorable than H-bonds between the G carboxylate and G amine (Jang and Goddard, unpublished results). The NMR data on DOTA indicates that the H-bonded isoforms must be in fast exchange because only two singlets (from carbon-bonded protons) are observed in the proton NMR spectra. Furthermore, the two macrocycle amine protons may not be observed because of exchange among the possible H-bonded forms between the amines, solvent water, and the macrocycle carboxylates. The exchange mechanism between $-NH$, $-CO^{2-}$, and H_3O^+ or OH^- could also serve as a means to remove protons from the macrocycle ring when metal loading in the type I to type II metal complex forms of DOTA.

Structures of the Various Protonated States of BD. The observed deshielding titration shifts in the BD signals are attributed to the formation of hydrogen-bonded isomers of BD that are protonation-state dependent. The NMR shift data indicates the presence of several pH-dependent hydrogen-bonded structures. The H-bond formation is accompanied by structural changes that affect the chemical shifts of the butylamide portion of BD (Figure 4). Further evidence for the structural alterations is seen in the change in the coupling patterns and line shapes of the E, F, and G protons (Figure 3).

Deriving structure from the titration shift data is complicated by the simultaneous presence of multiple protonated forms of BD. The NMR titration shifts of BD represent a mixture of the effects of the structural changes and the redistribution of electron density caused by titration of proximate groups. These changes can only be interpreted based on a series of structures for each of the protonation states of BD. The BD signals in the NMR spectra represent a population-weighted average of the chemical shifts and line widths of the protonation-state dependent structures present at a particular pH.

The NMR spectra at basic pHs show the macrocycle amine protons exist predominantly in the E−G configuration because of the large titration shift (0.4 ppm, Table 2) of the E acetate methylene proton upon deprotonation of the first macrocycle amine. The BD pK_as have been calculated based on the assumption that the E−G isomer is also favored in the higher protonation states. Thus, the G carboxylate is deprotonated first because it is adjacent to the positively charged protonated macrocycle nitrogen (as in DOTA).

However, the macrocycle amine protons can exist in two different trans isomers (E−G and F−F pairs) that have similar energy in the fully protonated form (Jang and Goddard, unpublished results). If the F−F isomer is present in appreciable amounts (in the fully protonated BD), the assignment of the first deprotonated carboxylate would be one of the two F groups. Further experiments are necessary to clarify the location of the macrocycle amine protons in different protonation states of BD.

For BD, the protonated forms that are most relevant to metal loading are the H_2BD^- and HBD^{2-}. The titration shift data show the amide proton is deshielded (−0.148 ppm, Table 2) upon deprotonation of the second F carboxylate group. This shift indicates the formation of a H-bond involving the amide proton (Bundi and Wuthrich, 1979). For H_2BD^-, we propose that two H-bonds are present, one between the F carboxylate and the butylamide amide (F−HN) and the other between the second F carboxylate and the G amine proton (F−G). The H_2BD^- form may metal-load more slowly than H_2DOTA^{2-} because the BD amide carbonyl is not as facile a proton-transfer mediator as the carboxylate groups of DOTA.

CONCLUSIONS

The ideal chelating agent for biological applications would metal-load rapidly (<1 h) under mild conditions (pH 7 and 25 °C) thereby avoiding protein aggregation and denaturation problems. However, little is known about the effects of conjugation on the metal binding of most chelating agents. This paper provides detailed information regarding the effects of modification of the commonly used chelator DOTA on its pK_as and type I to type II metal loading rates. This information can be used to predict pendant arm modifications that could improve the metal-loading rates of this chelator for biological applications. The DOTA analogue selected for this study mimics the lysine side-chain-conjugated form of DOTA used in radioimmunotherapy of cancer.

The present work shows that the substitution of a single pendant arm of DOTA significantly perturbs the properties of the chelator. The data suggests that DOTA modifications which lower the pK_as of the macrocycle ring amine protons (in the absence of other effects) should increase the rate of type I to type II metal loading reactions at acidic pHs because these DOTA analogues will have a greater population of the reactive singly protonated form. In general, the greater that the electronegativity is of the pendant groups, the greater the acidity of the attached amine. Thus, more electronegative pendant groups than the carboxylates or butylamide could be chosen to decrease the amine pK_as and increase k*. The H-bonding ability of pendant groups may also be important to the deprotonation of the macrocycle for metal loading. Pendant arms that are better proton-transfer mediators may also increase the rate of the metal-loading reaction.

As noted in the Introduction, several possible factors have been proposed to explain the decrease in the metal-loading rates of DOTA when conjugated to a protein. This study shows the modification of the one of the pendant side-chain groups of DOTA to create a model protein conjugated form can be in part responsible for the observed decrease in the rate. In addition, the competition for metal binding by other protein sites and the steric hindrance of the protein to chelate metal loading may further decrease the rate of metal loading. Further studies on the role of these factors on DOTA−protein conjugate metal loading are in progress.

A Synthetic Cysteine Oxidase Based on a Ferrocene-Cyclodextrin Conjugate

Suzanne K. Schreyer and Susan R. Mikkelsen*

Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1. Received November 5, 1998; Revised Manuscript Received January 22, 1999

We report a novel synthetic cysteine oxidase consisting of a ferrocene-β-cyclodextrin conjugate in which the ferrocene moiety is bound to the secondary hydroxyl side of the cyclodextrin cavity through an ethylenediamine linker. Cysteine oxidation occurs after the ferrocene group is electrochemically oxidized to the ferricinium form, and this generates a voltammetric electrocatalytic wave, the magnitude of which is related to the rate constant for cysteine oxidation. Comparison of cysteine oxidation rates for the primary and secondary β-cyclodextrin derivatives (105 and 1470 M^{-1} s^{-1}, respectively) shows that the secondary derivatives are more effective synthetic enzymes. Substrate selectivity of the secondary derivative is demonstrated by comparison of oxidation rates for cysteine (1470 M^{-1} s^{-1}) and glutathione (260 M^{-1} s^{-1}) at pH 7.0. The rate constant for cysteine oxidation was 3-fold higher at pH 8.0. With a constant synthetic enzyme concentration, electrocatalytic limiting currents increased linearly with increasing cysteine concentration to a maximum at 6 mM cysteine; above this concentration, the current decreased significantly. These and other results suggest that product inhibition of the catalytic cycle occurs as a result of cystine binding more strongly to the cyclodextrin than cysteine.

INTRODUCTION

Synthetic enzymes have been interesting to chemists and biochemists for several decades. Fundamentally, they are relatively simple models of more complicated biochemical catalysts, possessing both selectivity and enhanced reaction rates in structurally well-defined and relatively small molecules. Their potential applications have encouraged research, since they are expected to be stable under conditions of temperature, pH, and solvent composition that would denature or inactivate natural, protein-based biocatalysts.

In essence, an enzyme may be thought of as a selective substrate-binding site attached rigidly or flexibly to a nearby catalytic site. This simple definition has been realized by various researchers in molecules that selectively catalyze hydrolyses (*1*, *2*), isomerizations (*3*−*5*), addition (*6*), and decarboxylation (*7*). Examples of synthetic oxidoreductases that use cyclodextrins or selective substrate recognition have used attached inorganic catalytic groups [iron−sulfur complexes (*8*), an oxodiperoxomolybdenum complex (*9*), polyamine complexes of various divalent metal ions (*10*), and ferrocene (*11*)] or organic catalysts [porphyrins (*12*, *13*) and flavin analogues (*14*−*18*)] to mimic biological redox processes.

The first synthetic flavoenzyme was reported by Tabushi and Kodera and consisted of riboflavin bound to one of the primary β-cyclodextrin hydroxyl groups (*14*). They reported a 240-fold rate enhancement for the oxidation of *n*-hexyldihydronicotinamide by the primary flavocyclodextrin in comparison with free riboflavin possessing an equivalent but inert substituent.

Ye et al. have reported several studies of β-cyclodextrin derivatized with isoalloxazines (the redox-active part of riboflavin) on either the primary or secondary hydroxyl side of the cavity (*16*, *17*). In this work, the catalysts were compared with free riboflavin for their abilities to oxidize nicotinamides and substituted benzyl acohols (*16*) and to oxidize alcohols or thiols and reduce aldehydes (*17*). Early results showed that *p-tert*-butylbenzyl alcohol was oxidized to its corresponding aldehyde by the secondary flavocyclodextrin 650 times faster than by riboflavin (16a). Subsequent studies with the same flavocyclodextrin revealed that thiol oxidation was effectively catalyzed, and the authors concluded that although the secondary cyclodextrin derivative had a dissociation constant for phenylmethanethiol binding similar to the primary derivative (1.89 mM vs 2.38 mM, respectively), its overall rate (as k_{cat}/K_{diss}) was twice as fast as the primary derivative (0.587 vs 0.246 M s^{-1}) because orientation and alignment of the reacting atoms produced a higher k_{cat} value in the secondary derivative.

Suzuki et al. reported catalytic alcohol oxidation to aldehydes by a primary β-cyclodextrin derivative of ferrocenecarboxylic acid (*11*). In this 1:1 ferrocene:cyclodextrin derivative, all of the remaining hydroxyl groups (14 secondary and six primary hydroxyls) are acetylated, and this results in a lipophilic catalyst. The reactive ferricinium form was generated electrochemically during controlled-potential coulometry experiments using acetonitrile as a solvent. Although kinetic constants are not reported, the authors showed that after 12 h, each catalyst molecule had converted an average of 22 benzyl alcohol molecules and 59 1-naphthalenemethanol molecules to their corresponding aldehyde products; these values are more than 10-fold higher than those obtained after 24 h using methylferrocenecarboxylate, a model catalyst in which substrate binding could not occur. The authors propose a catalytic cycle in which the attached ferrocene, initially bound through the narrower primary opening to the cyclodextrin cavity, is excluded from the

cavity upon oxidation, allowing substrate binding. Upon substrate oxidation, the attached ferrocene reassociates with the cavity while the oxidation product is excluded.

In this paper, we report the synthesis and preliminary kinetic characterization of two new ferrocene-β-cyclodextrin derivatives. For both, ferrocenemonocarboxaldehyde was reacted with ethylenediamine under reducing conditions prior to reaction with the primary or secondary *p*-toluenesulfonyl derivative of β-cyclodextrin to produce a $-CH_2NHCH_2CH_2NH-$ spacer linking one of the cyclopentadienyl rings of the ferrocene moiety with the cyclodextrin. UV−vis spectrophotometry and electrospray mass spectrometry were used to confirm product structures, and voltammetric experiments were performed to kinetically characterize the two species as synthetic thiol oxidases.

EXPERIMENTAL SECTION

Materials. β-Cyclodextrin hydrate (β-CD), ferrocene carboxaldehyde, dimethylaminomethyl ferrocene, sodium hydride (67% dispersion in mineral oil), *p*-toluenesulfonyl chloride, reduced glutathione, L-cysteine hydrochloride hydrate, sodium formate, *N*,*N*-dimethylformamide, 4A molecular seives, anhydrous pyridine, sodium cyanoborohydride, and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) were purchased from Aldrich. Oxidized glutathione, L-cystine dihydrochloride, sodium acetate, dibasic sodium phosphate, and ethylenediamine were purchased from Sigma. Glacial acetic acid, dimethyl sulfoxide, acetone, and HPLC-grade acetonitrile were obtained from Baker. Potassium hexacyanoferrate(II) and monobasic sodium phosphate were obtained from Fisher. Chemicals were of the highest available grade and were used as received. All solutions were made using distilled, deionized water from a Barnstead Nanopure ion-exchange system.

Instrumentation. A Cary 1 double-beam UV-vis spectrophotometer was used to obtain absorbance spectra, with 1 cm quartz cuvettes and blank 0.1 M phosphate buffer, pH 7.0 reference solutions. Purification of β-CD derivatives was done using an HPLC system consisting of a reciprocating pump (Waters model 510), a Rheodyne 2500 injector with a 100 μL sample loop, a 150 × 4.6 mm C18 column (Phenomenex ODP-50 4D) and a refractive index detector (Waters model 410). Electrochemical experiments were performed in nitrogen-deaerated solutions at 25 °C using a BAS 100A potentiostat (Bioanalytical Systems) with glassy carbon or carbon paste working and silver/silver chloride reference electrodes (Bioanalytical Systems) and a coiled NiChrome wire auxiliary electrode. Mass spectra were obtained using an SSQ 700 electrospray mass spectrometer (Finnegan MAT) in the positive ion mode.

Methods. **Preparation of Cyclodextrin Derivatives**. β-CD was initially converted to either the primary or secondary tosylate according to selective literature procedures (*19*, *20*). Briefly, the primary tosylate was formed by combining 2.04 g (1.8 mmol) β-CD with an excess (8.22 g, 43 mmol) of *p*-toluenesulfonyl chloride in 400 mL of pyridine. After 48 h at room temperature, the solution was vacuum distilled to give a viscous yellow liquid. The secondary tosylate was prepared by combining 1.1 g of β-CD with 60 mg of 60% sodium hydride dispersion in 40 mL of DMF (dried over 4A molecular sieves) and stirred at room temperature under dry conditions for 12 h. *p*-Toluenesulfonyl chloride (0.68 g) dissolved in 5 mL of dry DMF was then added, and stirring was continued for 1 h. Water (30 mL) was then added dropwise, and the solution was combined with 500 mL of acetone. The product was collected by filtration as a white precipitate.

Ferrocenecarboxaldehyde (2.14 g, 10.0 mmol) was dissolved in 100 mL of 0.1 M HEPES buffer, 0.60 g (10.0 mmol) of ethylenediamine was added, and the pH was adjusted to 7.5. Sodium cyanoborohydride (6.28 g) was then added, and the solution was stirred at room temperature for 12 h. A 1:1 molar ratio of either the primary or secondary β-CD tosylate was then added to the filtered solution, and the reaction proceeded with stirring at room temperature for 5 days.

Products were purified by reversed-phase HPLC, using a mobile phase consisting of 10% aqueous acetonitrile. Peaks were identified by injecting standard solutions of the starting materials and intermediate product mixtures. The primary ferrocene-β-CD reaction product exhibited a unique redox-active component that eluted at 5.5 min, in comparison with the primary tosylate (13.6 min) and the ferrocenylmethylethylenediamine product mixture (2.3 and 19.5 min). The secondary ferrocene-β-CD product showed two unique components under these conditions (5.9 and 9.8 min), one of which was redox-active with a formal potential of +220 mV vs Ag/AgCl (9.8 min); the component that eluted at 5.9 min is probably a secondary ethylenediamine-β-CD conjugate with no ferrocene attached. The secondary β-CD tosylate eluted at 12.1 min under these conditions. Electrochemical studies by Matsue et al. have shown that noncovalent ferrocene-cyclodextrin association products associate and dissociate so rapidly that the resulting voltammograms display averaged features (*22*); thus, only covalently bound ferrocene-β-CD species would elute under our slower chromatographic conditions.

Purified samples of the primary and secondary β-CD tosylates as well as their ferrocenylmethylethylenediamine-β-CD products (1°-Fc-β-CD and 2°-Fc-β-CD, respectively) were collected for mass spectrometric analysis. Larger quantities of the two ferrocene derivatives were purified and concentrated with a rotary evaporator for electrochemical experiments.

Electrochemical Studies. Glassy carbon working electrodes (0.071 cm^2) were polished prior to each voltammogram using a slurry of 1 μm alumina (Buehler) in water on a polishing cloth (Bioanalytical Systems), and were sonicated in and rinsed with water prior to use. Unless otherwise stated, voltammograms were recorded from 0.0 to 0.7 V (vs Ag/AgCl) at a scan rate of 2 mV/s.

At glassy carbon electrodes, thiol oxidation is kinetically slow, but is facilitated by an EC′ or electrocatalytic reaction mechanism in which an electrocatalyst, such as a ferrocene derivative or hexacyanoferrate (II), is readily oxidized at the electrode and subsequently oxidizes the thiol to the thiyl radical as it is reduced (eqs 1−3):

$$\text{ferrocene} \rightarrow \text{ferricinium} + e^- \quad (1)$$

$$\text{ferricinium} + R{-}SH \xrightarrow{k} \text{ferrocene} + R{-}S\cdot + H^+ \quad (2)$$

$$2R{-}S\cdot \rightarrow R{-}S{-}S{-}R \quad (3)$$

In this scheme, eqs 1 and 3 are expected to proceed rapidly, while the measured *k* values apply to eq 2 as the rate-determining step.

Rate constants for thiol oxidation by electrocatalysts were determined using dilution experiments, with a 10:1 molar ratio of thiol to ferrocene-cyclodextrin conjugate. Under these conditions, the limiting electrocatalytic

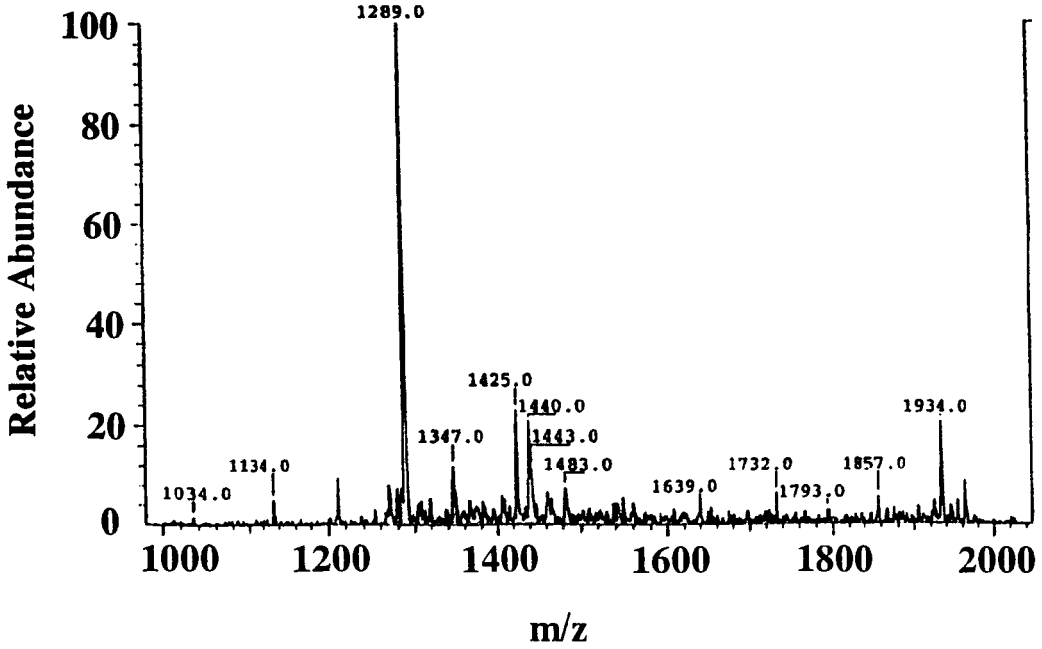

Figure 1. Electrospray mass spectrum of primary tosylate of β-CD dissolved in 10 mM sodium formate. Spectrum has been corrected by subtraction of the atomic weight of sodium.

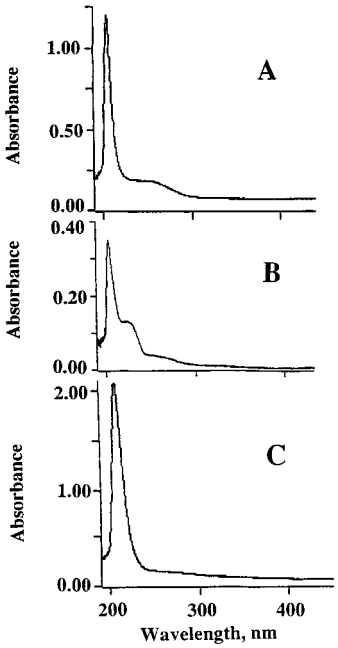

Figure 2. UV−vise spectra of (A) 42 μM dimethylaminomethylferrocene, (B) primary ferrocenylmethylethylenediamine-β-CD, and (C) secondary ferrocenylmethylethylenediamine-β-CD. All species were dissolved in 10 mM phosphate buffer, pH 7.0.

current is described by eq 4, below (*21*):

$$i_{\text{lim}} = nFAC(Dk[\text{thiol}])^{1/2} \quad (4)$$

where i_{lim} is the limiting electrocatalytic oxidation current, n is the number of electrons in the electrochemical reaction, F is Faraday's constant, A is the electrode area, C is the concentration of the electrocatalyst, D is the diffusion coefficient of the electrocatalyst, and k is the rate constant for thiol oxidation, shown in eq 2. Thus, a plot of limiting current against $C[\text{thiol}]^{1/2}$ will have a slope equal to $nFA(Dk)^{1/2}$. Using diffusion coefficients obtained by Matsue et al. of 6.4×10^{-6} and 2.6×10^{-6} cm^2/s for free and CD-bound ferrocenecarboxylic acid at 27 °C (*22*) and 6.50×10^{-6} cm^2/s for hexacyanoferrate(II) (*23*), rate constants are readily calculated.

RESULTS AND DISCUSSION

Structural Characterization of CD Derivatives. Electrospray mass spectrometry was used to characterize the products of the primary and secondary CD tosylation reactions in 0.1 M sodium acetate buffer, pH 4.0, as described by Tinke et al. (*24*) and Lamcharfi et al. (*25*). Under these conditions, a positive ion is generated by the association of sodium ion with the CD. Figure 1 shows the sodium-corrected mass spectrum obtained for the primary tosylation reaction product, where a strong signal can be seen at the expected *m/z* value of 1289, which corresponds to singly tosylated β-CD. Smaller signals at 1134 and 1443 indicate the presence of small quantities of the starting CD and the ditosylated product, respectively. Similar results were observed for the secondary tosylation reaction product: prominent peaks were observed at *m/z* 1134, 1289, and 1443, with the *m/z* 1289 peak being about 5-fold more intense than the *m/z* 1443 peak.

HPLC-purified primary and secondary ferrocenylmethylethylenediamine-β-CD were examined in 0.1 M phosphate buffer, pH 7.0, by UV-vis spectrophotometry and compared with a standard solution of dimethylaminomethylferrocene. The spectra, shown in Figure 2, all possess strong maxima near 205 nm. The molar absorptivity of dimethylaminomethylferrocene at 204 nm (2.71×10^4 M^{-1} cm^{-1}) was used to determine the concentrations of the CD derivatives in subsequent electrochemical experiments.

Electrospray mass spectrometry as described above was used to examine the ferrocene-CD conjugates. Under these conditions, no molecular ion peak was observed at the expected *m/z* value of 1561, but prominent peaks were observed at the much smaller *m/z* values of 403, 457, and 487 for both the primary and secondary conjugates, as shown in Figure 3. Varying the buffer and cone voltage conditions did not result in the expected molecular ion peaks.

The most prominent peaks in the spectra shown in Figure 3, at *m/z* 403.2, can be attributed to the fragmen-

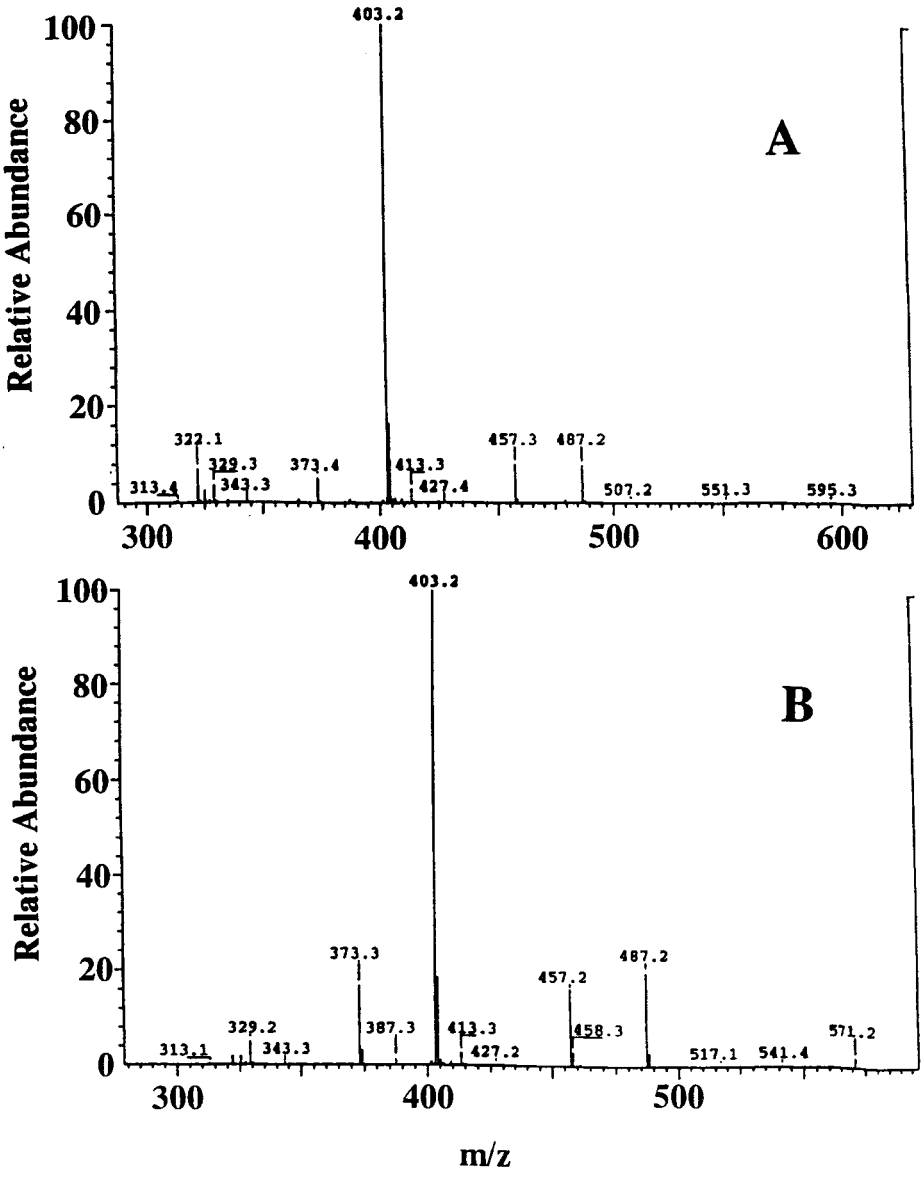

Figure 3. Electrospray mass spectrum of (A) primary ferrocenylmethylethylenediamine-β-CD, and (B) secondary ferrocenylmethylethylenediamine-β-CD, after purification by reversed-phase HPLC. CD derivatives were dissolved in 10 mM aqueous sodium formate. Spectra were not corrected for sodium.

tation products shown in Figure 4, in which the ferrocenylmethylethylenediamine moiety is bound to a single glucose residue through either a primary (Figure 4A) or secondary (Figure 4B) hydroxyl site. This is consistent with recent electrospray ion trap mass spectrometry fragmentation patterns for oligosaccharides observed by Sheeley and Reinhold (*26*).

Electrocatalysis of Thiol Oxidation. Preliminary electrochemical studies were done with simple electrocatalyst species such as ferrocyanide, ferrocenecarboxaldehyde, and dimethylaminomethylferrocene to determine the thiol oxidation rates for their ferricyanide and ferricinium forms by electrocatalytic voltammetry as described in the Experimental Section. Table 1 shows the rates obtained for cysteine and glutathione oxidation in 0.10 M phosphate buffer, pH 7.0, in the presence and absence of free 10 mM β-CD.

Thiol oxidation by ferricyanide has been studied by absorption spectrophotometry, where rate constants of 4.3 and 30 M^{-1} s^{-1} were obtained for the oxidation of mercaptoacetic acid at pH 1.4 and 1.9, respectively (*27*), and a value of 61 M^{-1} s^{-1} was obtained for the oxidation

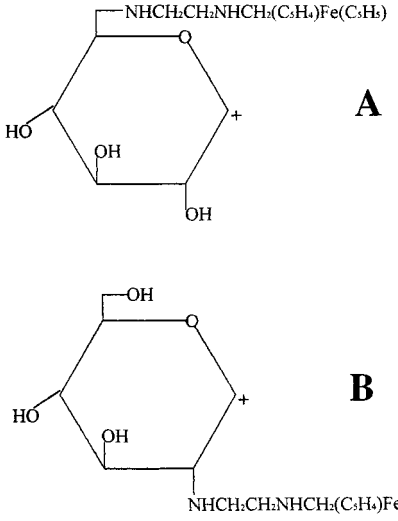

Figure 4. Proposed fragments of (A) primary ferrocenylmethylethylenediamine-β-CD, and (B) secondary ferrocenylmethylethylenediamine-β-CD, each having a mass of 403.2 amu.

Table 1. Rate Constants for the Oxidation of Thiols by Electrocatalysts[a]

electrocatalyst	thiol	[β-CD] (mM)	pH	k (M^{-1} s^{-1})
ferricyanide	GSH	0	7.0	48
		10	7.0	38
	Cys	0	7.0	90
		10	7.0	38
ferriciniumcarbox-aldehyde	GSH	0	7.0	2.1
		10	7.0	21
dimethylaminomethyl-ferricinium	GSH	0	7.0	103
		10	7.0	134
	Cys	0	8.0	30
		10	8.0	23
1°-Fc-β-CD	GSH	0	7.0	143
	Cys	0	7.0	105
2°-Fc-β-CD	GSH	0	7.0	260
	Cys	0	7.0	1470
		0	8.0	4120

[a] Measured by linear-sweep voltammetry (2 mV/s) at glassy carbon electrodes in solutions containing a 10-fold excess of thiol and 10 mM phosphate. Abbreviations: GSH, glutathione; Cys, cysteine; 1°-Fc-β-CD, primary ferrocenylmethylethylenediamine-β-CD; 2°-Fc-β-CD, secondary ferrocenylmethylethylenediamine-β-CD. RSD values were less than 7%.

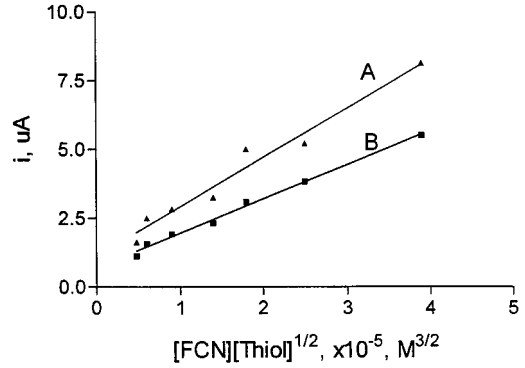

Figure 5. Limiting electrocatalytic current vs [ferricyanide]-[thiol]$^{1/2}$, for (A) cysteine and (B) glutathione oxidation. Data were recorded at 500 mV vs Ag/AgCl following linear-sweep voltammetry at 2 mV/s at a glassy carbon working electrode in 0.10 M phosphate, pH 7.0.

of mercaptopropionic acid at pH 3.8 (*28*). This trend toward increased rates at higher pH values is continued in the values observed in this work. Figure 5 shows plots of limiting electrocatalytic current against [ferricyanide]-[thiol]$^{1/2}$ for the determination of cysteine and glutathione oxidation rate constants. The rate constants compiled in Table 1 indicate not only that the rates of cysteine and glutathione oxidation by ferricyanide (90 and 48 M^{-1} s^{-1}, respectively) are of the same order of magnitude as those reported earlier, but also that the rates are significantly lower when 10 mM β-CD is present. This indicates that both cysteine and glutathione bind β-CD while ferricyanide does not, so that the effective thiol concentration is lower in the presence of the CD.

Results obtained for the two ferrocene derivatives, on the other hand, show increased thiol oxidation rates in the presence of 10 mM β-CD. Dimethylaminomethylferricinium oxidizes glutathione at a 1.3-fold higher rate, while ferriciniumcarboxaldehyde oxidizes glutathione at a 10-fold faster rate in the presence of 10 mM β-CD. These unexpected results are attributed to the simultaneous association of glutathione and ferricinium derivative with free CD. The formation of ternary complexes of CDs with two guest species has been observed previously by stopped-flow kinetic measurements, where association constants for complex formation were determined from CD-catalyzed ester hydrolysis rates that increased in the presence of the second guest species (*29*).

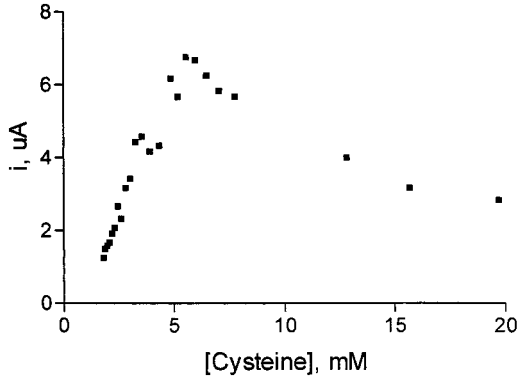

Figure 6. Limiting electrocatalytic current vs cysteine concentration, with [2°-Fc-β-CD] held constant at 0.80 mM. Data were recorded at 500 mV vs Ag/AgCl following linear−sweep voltammetry at 2 mV/s at a glassy carbon working electrode in 0.10 M phosphate, pH 7.0.

Table 1 also shows thiol oxidation rates obtained for the primary and secondary ferrocene derivatives of β-CD. Clearly, the primary derivative does not facilitate thiol oxidation, since rates obtained with this species are not much different than those seen with dimethylaminomethylferrocene; thus, in this derivative, the ferrocene/ferricicinium couple behaves as if it had no CD attached, as long as its lower diffusion coefficient is taken into account. However, the secondary derivative is a much better catalyst of thiol oxidation, especially with cysteine as a substrate: rate constants of 260 and 1470 M^{-1} s^{-1} were observed for glutathione and cysteine oxidation, respectively. Furthermore, if the pH is increased to 8.0 in 0.10 M phosphate, the rate of cysteine oxidation increases to 4120 M^{-1} s^{-1}, while free dimethylaminomethylferrocene shows a rate of 30 M^{-1} s^{-1}. These results suggest that sulfhydryl deprotonation is important during some stage of the reaction, since the pK_a is 8.15 for the cysteine sulfhydryl (*30*). Possibly, the relatively low oxidation rate observed for free dimethylaminomethylferrocene at higher pH is due to the known instability of ferricinium toward nucleophiles (*31*). However, the 140-fold acceleration factor due to covalently bound β-CD is of a similar magnitude to the 650-fold acceleration of *p-tert*-butylbenzyl alcohol oxidation by the secondary flavocyclodextrin derivative reported by Ye et al. (*16a*).

Calibration curves of limiting current against cysteine concentration were obtained while holding the total concentration of secondary ferrocene-β-CD constant. A typical plot, obtained using a glassy carbon working electrode, is shown in Figure 6. A similar curve was observed using a carbon paste working electrode. A linear region can be seen in Figure 6 below 6 mM cysteine, while higher cysteine concentrations yield decreased electrocatalytic wave heights. The shape of this curve suggests product inhibition, in that tighter binding of the disulfide product to the β-CD cavity would effectively reduce the available catalyst concentration; this phenomenon has been documented extensively for enzymatic reactions (*32*). Electrochemical dilution experiments provided confirmation of this type of inhibition. Rate constants observed at pH 7.0 for the oxidation of glutathione by 2°-Fc-β-CD decreased 10-fold when the bulk solution initially contained oxidized glutathione (GS−SG) at half the glutathione concentration. Similarly, when cystine was initially present in the bulk solution at only 4% of the cysteine concentration (this was limited by cystine solubility), the observed rate constant for cysteine oxida-

tion by 2°-Fc-β-CD decreased to less than 10% of the value observed in the absence of cystine. Thus, the disulfide oxidation products appear to associate with the CD cavity more strongly than the sulfhydryl substrates. Despite this, at cysteine concentrations below 6 mM (see Figure 6), 2°-Fc-β-CD appears to be a very effective synthetic cysteine oxidase.

An N_2S_2 Bifunctional Chelator for Technetium-99m and Rhenium: Complexation, Conjugation, and Epimerization to a Single Isomer

Leonard G. Luyt, Hilary A. Jenkins,† and Duncan H. Hunter*

Department of Chemistry, University of Western Ontario, London, Ontario, Canada N6A 5B7. Received November 6, 1998; Revised Manuscript Received January 18, 1999

A bifunctional chelator **6** was prepared bearing an N_2S_2 core for binding rhenium or technetium and a carboxylic acid group for conjugation to amino groups of biomolecules. Complexation of **6** with rhenium(V) resulted in two kinetic isomers, anti-**7** and syn-**7**, being formed in approximately equal amounts. Epimerization with 0.5 M NaOH yields a single isomer anti-**7**, as determined by NMR spectroscopy and single-crystal X-ray analysis. The ^{99m}Tc complex was prepared at the tracer level by reaction of the ligand with $^{99m}TcO_4^-$, tin(II) chloride and sodium gluconate giving a mixture of two isomers, but showing a preference for the anti isomer. Chelation in the presence of 1 M NaOH results in anti-**8** being formed as the sole product. The bifunctional ability of the ligand was explored by amide formation with (*S*)-α-phenethylamine, either by direct DCC coupling or through the N-hydroxy succinimidyl ester **9** intermediate. The deprotected bioconjugate **11** was complexed with rhenium, yielding similar amounts of two isomeric rhenium complexes, anti-**12** and syn-**12**, which were isolated and characterized by NMR spectroscopy. Treatment of the kinetic mixture of anti-**12** and syn-**12** with 1 M NaOH resulted in quantitative conversion to a single rhenium complex anti-**12**. With technetium-99m in 0.1 M sodium acetate, bioconjugate **11** yielded both technetium-99m complexes anti-**13** and syn-**13**, in a 2:1 ratio, respectively. In contrast, complexation in the presence of 1 M NaOH gave only one technetium-99m complex, assigned the structure anti-**13**.

INTRODUCTION

Single photon emission computed tomography (SPECT) imaging with ^{99m}Tc is the most commonly utilized method for routine diagnostic nuclear medicine procedures. ^{99m}Tc is preferred as a radionuclide for its favorable nuclear characteristics, availability, and low cost. A wide variety of ^{99m}Tc-containing radiopharmaceuticals are used (*1*), but only a few receptor-specific small-molecule ^{99m}Tc radiopharmaceuticals have been designed that are directed to bind at specific receptor sites (*2*). Receptor-binding radiotracers allow for the study of changes in receptor concentrations that often accompany disease states or for the imaging of tissues rich in a specific receptor.

One approach to the production of a target-directed ^{99m}Tc radiopharmaceutical is to attach a bifunctional chelator to a biospecific molecule, followed by radiolabeling with ^{99m}Tc. Target-directed radiopharmaceuticals are of importance for diagnostic imaging purposes when ^{99m}Tc is utilized, but also allow for radiotherapy using the chemically analogous ^{186}Re/^{188}Re species (*3*–*5*). For chelating purposes, the amide thiolate ligands (N_2S_2 agents) were attractive since they have been shown to form stable complexes with technetium and rhenium (*6*, *7*). For attachment to a biomolecule, the carboxyl group was selected since many biomolecules contain amino groups available for amide formation.

A number of modifications to the original (*6*, *7*) ethylene/propylene framework of amide thiolate N_2S_2 agents have been made, and analogues bearing carboxyl groups have already been studied as chelating agents (*8*, *9*). However, substituents can introduce stereochemical problems. This is illustrated in Figure 1 for *N*,*N*′-bis(mercaptoacetyl)-2,3-diaminopropanoate (CO_2DADS), where, for R = OH, four stereoisomers are known since each of the anti and syn diastereomers can exist as enantiomers (*10*). All four stereoisomers of these CO_2DADS complexes have been synthesized and differences in biodistribution characteristics were observed (*11*, *12*).

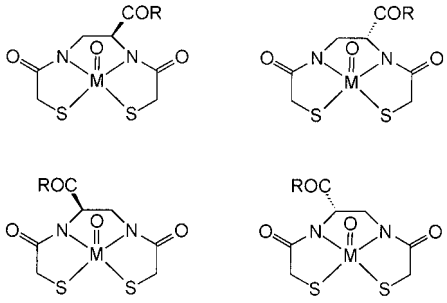

Figure 1. The four anionic stereoisomers formed from chelation of *N*,*N*′-bis(mercaptoacetyl)-2,3-diaminopropanoate (CO_2-DADS) with rhenium or technetium. For R = OH, two sets of enantiomers are formed; for R = chiral biomolecule, four diastereomers are formed.

If the CO_2DADS chelator shown in Figure 1 is attached to a chiral biomolecule (R = chiral molecule), then four different diastereomers will be produced. This could have serious consequences on yields, characterization, and isolation of individual species (*13*), each of which could have differing biological activities. In the case of the dopamine transporter imaging agent [^{99m}Tc]TRODAT-1, the two separated isomers displayed different binding affinities in a SPECT imaging study (*14*).

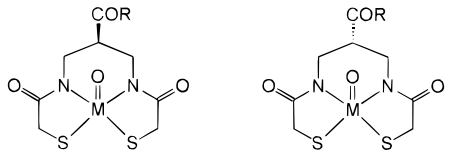

Figure 2. The two anionic isomers formed upon chelation of **6** with rhenium or technetium. For R = OH or R = chiral biomolecule, only two isomers are formed.

In an attempt to minimize the chemical and biological complications of generating multiple stereoisomers, the carboxylic acid linker was placed at the apex of an eventual six membered ring. This is illustrated in Figure 2, which shows that only two stereoisomers (anti and syn) would result with or without attachment to a chiral biomolecule. We have endeavored to keep the chelator as small in size as possible to help minimize disruption on the receptor-binding affinity. The anticipated formal negative charge on the chelate may limit its general applicability as a radiolabel.

EXPERIMENTAL SECTION

Chemicals were purchased from commercial sources as reagent grade and used as received. 2-Triphenylmethylmercaptoacetic acid and dioxobisethylenediaminerhenium(V) chloride were prepared according to literature procedures (*15*, *16)*. ^{1}H NMR spectra were collected on a Varian Gemini-300 or Varian Gemini-200 spectrometer with TMS as an internal reference. ^{13}C NMR and two-dimensional spectra were obtained on a Varian Gemini-300 or Varian 300-XL spectrometer with the ^{13}C acquisition at 75 MHz. ^{1}H spin−spin decoupling NMR spectra were obtained on a Varian Gemini-300 spectrometer. Infrared spectra were recorded in the range 4000−600 cm^{-1} on either a Bruker IFS 5500 FT-IR with a Spectra-Tech diffuse reflectance accessory (DRIFT) or on a Perkin-Elmer 2000 FT-IR utilizing a solution cell or thin film NaCl plate. Routine mass spectra (MS) and negative ion fast-atom bombardment mass spectra (FABMS) were measured on a Finnigan MAT 8200 spectrometer. Melting points were taken on a Gallenkamp or a Fisher−Johns melting point apparatus and are uncorrected. HPLC was performed using either a Varian 5500 or a Dionex DX 300 HPLC under the column and eluent conditions noted in the Experimental Section. Elemental analyses were performed by Guelph Chemical Laboratories Ltd. (Guelph, Ontario). $Na^{99m}TcO_4$ was obtained from a commercial ^{99}Mo/^{99m}Tc generator as supplied by DuPont.

3,3-Dicyano-propionic Acid Ethyl Ester (1). Sodium hydride dispersion (7.89 g of 60% w/w, 0.197 mol) was placed in a three-necked flask with attached dropping funnel, condensor, vacuum inlet, and argon bubbler. The glassware was assembled hot, then twice evacuated and filled with argon. Freshly distilled THF (400 mL distilled from sodium/benzophenone) was added via glass syringe, and the mixture was cooled to 0 °C. Malononitrile (26.1 g, 0.395 mol) was dissolved in 100 mL of distilled THF and added dropwise. After the reaction mixture was warmed to room temperature, ethyl chloroacetate (23.3 g, 0.190 mol) was added, and the mixture was brought to reflux for 2 h. After cooling to room temperature, the THF was removed using a rotary evaporator. The solids were taken up in 250 mL of $CHCl_3$ and washed with two portions of 0.5 M HCl. The organic layer was dried over $MgSO_4$, and the solvent removed by a rotary evaporator. A ^{1}H NMR spectrum of the crude product indicated 63% **1** and 37% 3,3-dicyano-pentanedioic acid diethyl ester byproduct. Using fractional reduced pressure distillation, the desired product was collected over 86−92 °C at 0.2 mmHg, then cooled to allow crystallization. The resulting solid was recrystallized from diethyl ether/petroleum ether to give shiny colorless plates (17.1 g, 59% yield). A sample was further purified by sublimation: mp 70−71 °C. ^{1}H NMR ($CDCl_3$): δ 1.30 (t, 3H, CH_3), 3.04 (d, 2H, CH_2), 4.16 (t, 1H, CH), 4.26 (q, 2H, CH_2O); ^{13}C NMR ($CDCl_3$) δ 13.59 (CH_3), 18.39 (CH), 34.48 (CH_2CO), 62.26 (CH_2O), 111.31 (CN x2), 166.33 (CO). FT-IR (thin film) cm^{-1}: 2263, 1727. HRMS (CI) *m/z*: calcd for $C_7H_8N_2O_2$ $(M + H)^+$ 153.0664. Found: 153.0667. Anal. ($C_7H_8N_2O_2$): C, H, N, O.

4-Amino-3-aminomethyl-butyric Acid Ethyl Ester Dihydrochloride (2). A Parr glass flask was charged with **1** (1.53 g, 10.1 mmol), 50 mL of ethanol (0.2% H_2O as determined by Karl Fischer titration), PtO_2 (148 mg), and 1.73 mL of concentrated HCl (20.8 mmol). The flask was attached to a Parr hydrogenator, twice evacuated and filled with H_2, then filled with H_2 to a pressure of 53 psig. The hydrogenation proceeded at room temperature for 18 h with continuous shaking. The black catalyst was filtered, the solution was transferred to a round-bottom flask, and the ethanol was removed using a rotary evaporator. The product was dried at room temperature under 0.3 mmHg vacuum for 3 h yielding 2.39 g of fluffy white crystals (quantitative yield). This material was used without further purification. ^{1}H NMR (D_2O): δ 1.08 (t, 3H, CH_3), 2.41 (m, 1H, CH), 2.52 (d, 2H, CH_2CO), 2.98 (dd, 4H, NCH_2), 4.01 (q, 2H, CH_2).

***N*-Hydroxysuccinimidyl 2-Triphenylmethylmercaptoacetate (3)**. 2-Triphenylmethylmercaptoacetic acid (4.76 g, 14.2 mmol) and 1.64 g (14.3 mmol) *N*-hydroxysuccinimide (NHS) were added to 25 mL of acetonitrile. The reaction mixture was cooled to 0 °C followed by the addition of 3.01 g (15.7 mmol) 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) and 2,4,6-trimethylpyridine (2.1 mL) with subsequent warming to room temperature. The mixture was stirred under argon at room temperature for 3 h and then cooled to 0 °C. The resulting precipitate was removed by filteration and washed with cold acetonitrile to give 5.31 g (yield 86%) of colorless crystals: mp 178.0−179.0 °C. ^{1}H NMR ($CDCl_3$): δ 2.76 (s, 4H, CH_2 succinimidyl), 3.17 (s, 2H, CH_2S), 7.22 to 7.42 (m, 15H, ar). ^{13}C NMR ($CDCl_3$): δ 25.49 (CH_2), 31.38 (CH_2S), 67.98 (CPh_3), 127.09 (ar), 128.19 (ar), 129.43 (ar), 143.48 (ar), 164.99 (CO), 168.54 (CO).

3,3-Bis(triphenylmethylthio-acetidomethyl)propanoic Acid Ethyl Ester (4). A two-necked flask with an attached argon bubbler was charged with 100 mL of CH_2Cl_2, **2** (1.46 g, 6.28 mmol), **3** (5.23 g, 12.1 mmol), and 2.2 mL (12.6 mmol) of *N*,*N*-diisopropylethylamine (DIPEA). The reaction mixture was stirred at room temperature under a flow of argon for 20 h, then transferred to a separatory funnel, washed with saturated $NaHCO_3$ (2 × 75 mL), 0.5 M HCl (2 × 70 mL), and saturated NaCl. The organic layer was dried over $MgSO_4$ and filtered, and the solvent was removed by a rotary evaporator and placed under high vacuum to give 5.05 g of a yellow crystalline solid. Recrystallization from ethyl acetate/hexanes afforded 3.27 g of fine colorless crystals (68% yield): mp 193−194 °C. ^{1}H NMR ($CDCl_3$): δ 1.19 (t, 3H, CH_3), 1.86 (m, 1H, CH), 2.01 (d, 2H, CH_2CO), 2.78 (m, 4H, CH_2N), 3.01 (s, 4H, CH_2−S), 4.06 (q, 2H, CH_2 Et), 6.47 (t, 2H, NH), 7.22 to 7.37 (m, 30H, ar). ^{13}C NMR ($CDCl_3$) δ 14.17 (CH_3), 34.71 (CH_2CO), 35.92 (CH), 36.04 (CH_2S), 39.96 (CH_2N), 60.61 (CH_2O), 67.74 (CPh_3), 126.96 (ar), 128.10 (ar), 129.45 (ar), 143.94 (ar), 168.88 (CO),

172.08 (CO). FT-IR ($CHCl_3$ solution cell): cm^{-1} 3382, 1728, 1664. Anal. ($C_{49}H_{48}N_2O_4S_2$): C, H, N, O, S.

3,3-Bis(triphenylmethylthio-acetamidomethyl)-propanoic Acid (5). To a solution of 25 mL of THF and 25 mL of 1 M NaOH was added **4** (1.00 g, 1.27 mmol). The mixture was stirred at room temperature under argon for 18 h with the reaction progress being monitored by TLC (Silica 60, ethyl acetate). The reaction mixture was acidified by the addition of 25 mL of 1 M HCl. The THF was removed by rotary evaporator and the product extracted with three portions of CH_2Cl_2, which was washed with saturated NaCl and dried over $MgSO_4$. After filtering, the solvent was removed by a rotary evaporator, leaving the crude product as fine colorless crystals (0.93 g). Recrystallization from CH_2Cl_2/hexanes gave the propanoic acid (0.88 g, 0.91 mmol, 91% yield): mp 214−215 °C. ^{1}H NMR ($CDCl_3$): δ 1.72 (m, 1H, CH), 1.93 (d, 2H, CH_2CO), 2.53 (ddd, 2H, CHN x2), 3.00 (ddd, 2H, CHN x2), 3.09 (s, 4H, CH_2S), 6.71 (m, 2H, NH), 7.17 to 7.41 (m, 20H, ar). ^{13}C NMR (d_6-DMSO): δ 33.94 (CH_2CO), 35.21 (CH), 36.02 (CH_2S), 39.96 (CH_2N), 66.10 (CPh_3), 126.81 (ar), 128.08 (ar), 129.10 (ar), 144.06 (ar), 167.65 (CO), 173.38 (CO). FT-IR (thin film) cm^{-1}: 3326, 1718, 1647. Anal. ($C_{47}H_{44}N_2O_4S_2$): C, H, N, O, S.

3,3-Bis(thio-acetamidomethyl)propanoic Acid Oxorhenium(V) (7). A solution of **5** (261 mg, 0.341 mmol) in 14 mL CH_2Cl_2 was cooled to 0 °C with an ice bath. To this were added 8 mL (0.1 mol) of cold trifluoroacetic acid (TFA) and triethylsilane (115 μL, 0.720 mmol). The mixture was stirred at 0 °C for 25 min then warmed to room temperature and transferred to a separatory funnel with additional CH_2Cl_2. Water was added, and the triphenylmethane was extracted with three CH_2Cl_2 extractions.

The aqueous layer containing **6** [3,3-bis(thioacetamidomethylene)propanoic acid] was transferred to a 100 mL flask, and solid sodium acetate was added until the solution tested basic. Dioxobis(ethylenediamine)rhenium-(V) (139 mg, 0.342 mmol) was added and the solution turned a clear yellow color. The mixture was heated to reflux for 45 min with the color turning to red. After cooling to room temperature, tetraphenylarsonium chloride was added (286 mg, 0.682 mmol) with an immediate precipitate formation. The rhenium complex was filtered to give a pale rose powder that was recrystallized from methanol/water, dried under 0.025 mmHg vacuum to give 148 mg of **7** (51% yield) as a mixture of two isomers. ^{1}H NMR (d_6-DMSO): δ 2.17 (m, 1H, CH syn), 2.35 (m, 1H, CH anti), 2.41 (d, 2H, J = 6.5 Hz, CH_2CO_2H anti), 2.44 (d, 2H, J = 6.8 Hz, CH_2CO_2H syn), 2.63 (dd, 2H, J = 13.2, 10.8 Hz, CHN x2 anti), 3.31 (dd, 2H, J = 13.6, 6.6, CHN x2 syn), 3.48/3.79 (AB, 4H, J = 17.2 Hz, CH_2S syn), 3.57/3.64 (AB, 4H, J = 17.1 Hz, CH_2S anti), 3.78 (dd, 2H, J = 13.2, 2.3 Hz, CHN x2 anti), 3.88 (dd, 2H, J = 13.6, 3.1, CHN x2 syn), 7.76−7.90 (40 H, ar). IR (diffuse reflectance): 1712, 1606, 974 (ReO). HRMS, FAB (negative ion) m/z calcd: $C_9H_{12}N_2O_5S_2{}^{187}Re$ 478.9745. Found: 478.9738. HPLC (Dionex IonPac AS9-SC 4.0 × 250 mm; eluent 1.0 mL/min of 20% CH_3CN/80% 0.1 M NaCl, 1.8 mM Na_2CO_3, 1.7 mM $NaHCO_3$ solution; UV detector at 260 nm): product retention times of 10.69 (45%) and 11.65 min (55%).

Epimerization to anti-7. A sample of the epimers **7** (48 mg) was dissolved in 5 mL of methanol with slight warming to assist in the dissolution. To this solution was added 5 mL of 0.5 M sodium hydroxide solution, and the mixture was stirred at room temperature for 30 min. Acidification was carried out by the addition of 1 M HCl until the pH was slightly acidic. The methanol was then removed by a rotary evaporator resulting in a rose-colored powder precipitating from the aqueous solution. The solid was filtered, washed with water, and dried under vacuum, leaving 46 mg (96%) of a single isomer: mp 278−279 °C. ^{1}H NMR (d_6-DMSO): δ 2.35 (m, 1H, CH), 2.41 (d, 2H, J = 6.5 Hz, CH_2CO_2H), 2.63 (dd, 2H, J = 13.2, 10.8 Hz, CHN x2), 3.57/3.64 (AB, 4H, J = 17.1 Hz, CH_2S), 3.78 (dd, 2H, J = 13.2, 2.3 Hz, CHN x2), 7.77−7.90 (20 H, ar). ^{13}C NMR (d_6-DMSO, assignments based on HETCOR): δ 36.86 (CH_2CO_2H), 36.95 (CH_2S), 40.48 (CH), 54.63 (CH_2N), 121.02 (ar), 130.89 (ar), 133.17 (ar), 134.27 (ar), 173.27(CO), 194.25 (CO). HPLC (Dionex IonPac AS9−SC 4.0 × 250 mm; eluent 1.0 mL/min of 20% CH_3CN/80% 0.1 M NaCl, 1.8 mM Na_2CO_3, 1.7 mM $NaHCO_3$ solution; UV detector at 260 nm): product retention time, 11.58 min.

3,3-Bis(thio-acetamidomethyl)propanoic Acid Oxotechnetium(V) (8): **General Method**. A 3 mL vial was charged with 10 μL of aqueous base solution (0.1 M NaOAc or 1.8 mM Na_2CO_3/1.7 mM $NaHCO_3$ or 1 M NaOH), 10 μL of sodium gluconate (10 mM aqueous solution), 50−150 μCi $Na^{99m}TcO_4^-$ in saline, 10 μL of **6** (0.5 mM aqueous solution), and 0.02 mg of $SnCl_2$. The mixture was heated at 70 °C for 40−120 min. The reaction mixture was injected onto a HPLC with an anion-exchange column (Dionex IonPac AS9-SC 4.0 × 250 mm; eluent 1.0 mL/min of 20% CH_3CN/80% 0.1 M NaCl, 1.8 mM Na_2CO_3, 1.7 mM $NaHCO_3$ solution; radiometric γ detector) with resulting product retention times for the two epimers of 11.1 and 12.3 min. The eluent from the HPLC was collected for the period of 11−13 min, thereby allowing for the collection of both isomers of **7**. The collected eluent was counted in a dose calibrator giving a radiochemical yield of 67−88%.

3,3-Bis(triphenylmethylthio-acetamidomethyl)-propanoic Acid *N*-Hydroxysuccinimidyl Ester (9). The acid **5** (407 mg, 0.532 mmol), *N*-hydroxysuccinimide (69 mg, 0.60 mmol) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (118 mg, 0.62 mmol) were placed in a flask with 25 mL of CH_2Cl_2. To this was added 77 μL of 2,4,6-trimethylpyridine (0.58 mmol), and the mixture was stirred at room temperature under argon for 18 h. The reaction mixture was placed in a separatory funnel, washed twice with 0.1 M HCl, water, and saturated NaCl solution. The organic layer was dried over $MgSO_4$ and filtered, and the solvent was removed by a rotary evaporator leaving a clear colorless oil (382 mg, 83%). The product which crystallized when triturated with hexanes was then recrystallized from $CHCl_3$/hexanes and dried under vacuum at room temperature: mp 87 °C (dec). ^{1}H NMR ($CDCl_3$): δ 1.97 (m, 1H, CH), 2.33 (d, 2H, CH_2CO), 2.77 (s, 4H, CH_2 NHS), 2.75−2.99 (m, 4H, CH_2N), 3.05 (d, 4H, CH_2S), 6.61 (t, 2H, NH), 7.17−7.42 (m, 30H, ar). ^{13}C NMR ($CDCl_3$): δ 25.54 (CH_2 NHS), 31.73 (CH_2CO), 35.95 (CH_2S), 36.44 (CH), 39.63 (CH_2N), 67.70 (CPh_3), 126.96 (ar), 128.11 (ar), 129.45 (ar), 143.93 (ar), 167.34 (CO), 168.93 (CO), 169.21 (CO).

***N*-[(*S*)-1-Phenylethyl]-3,3-bis(triphenylmethylthio-acetamidomethyl)propanamide (10)**: **Method A**. The N_2S_2 acid **5** (823 mg, 1.08 mmol), 1-hydroxybenzotriazole (1-HOBT, 184 mg, 1.20 mmol), and dicyclohexylcarbodiimide (DCC, 244 mg, 1.18 mmol) were added to 30 mL of CH_2Cl_2. To this was added (*S*)-1-phenethylamine (137 mg, 1.13 mmol) and 2,4,6-trimethylpyridine (156 μL, 1.18 mmol). The reaction mixture was stirred at room temperature under a constant argon flow for 3 days. The dicyclohexylurea byproduct was removed by filtration. The reaction mixture was placed in a separatory funnel and washed with saturated $NaHCO_3$ (x2), 0.5 N HCl (x2),

and saturated NaCl. The organic layer was then dried over $MgSO_4$, the solvent was removed by a rotary evaporator, followed by drying at room temperature under vacuum to give 1.01 g of a beige solid. This solid was triturated with EtOAc and recrystallized from $CHCl_3$/hexanes to give 821 mg of colorless fine crystals (yield 88%): mp 187−189 °C. ^{1}H NMR ($CDCl_3$): δ 1.43 (d, 3H, CH_3), 1.65 (m, 1H, CH), 1.78 (d, 2H, CH_2), 2.42 (ddd, 1H, CH_2N), 2.54 (ddd, 1H, CH_2N), 2.98 (m, 2H, CH_2NH), 3.03 (s, 4H, CH_2S), 5.02 (quintet, 1H, CHPh), 6.70 (m, 2H, NH x2), 7.16 to 7.42 (m, 35H, ar), 7.81 (d, 1H, NH). ^{13}C NMR ($CDCl_3$): δ 22.42 (CH_3), 36.09 (CH_2S), 36.59 (CH_2), 37.95 (CH), 39.86 (CH_2N), 40.01 (CH_2N), 49.01 (CHPh), 67.75 (CPh_3), 126.17 (Ph), 126.95 (Trt), 128.10 (Trt), 128.45 (Ph), 129.45 (Trt), 143.91 (Trt), 143.95 (Ph), 169.57 (CO), 169.66 (CO). 170.29 (CO). MS (CI, isobutane): *m/z* 867 (M+), 624 (M − trityl), 382 [M − (trityl)$_2$]. HRMS (EI, dprobe): *m/z* calcd: $C_{17}H_{23}N_3O_3S_2$ (detritylated), 381.1181. Found: 381.1169. Anal. ($C_{55}H_{53}N_3O_3S_2$): C, H, N, O, S.

Method B. The succinimidyl ester **9** (155 mg, 0.180 mmol), (*S*)-phenylethylamine (27 mg, 0.220 mmol), and *N,N*-diisopropylethylamine (31 μL, 0.180 mmol) were added to 15 mL of CH_2Cl_2. The reaction contents were stirred at room temperature under argon for 18 h, then transferred to a separatory funnel and washed with 0.1 M HCl, saturated $NaHCO_3$, and saturated NaCl. The organic layer was dried over $MgSO_4$ and filtered, and the solvent was removed by a rotary evaporator and dried under vacuum leaving fine white crystals. Recrystallization from $CHCl_3$/hexanes gave 124 mg of fine white crystals (79%) with characterization consistent to that reported for method A.

***N*-[(*S*)-1-Phenylethyl]-3,3-bis(thio-acetamidomethyl)propanamide (11)**. A two-necked flask containing 10 mL of CH_2Cl_2 was charged with **10** (301 mg, 0.346 mmol). The flask was cooled to 0 °C with an ice bath while under a continuous flow of argon. Trifluoroacetic acid (6 mL, 78 mmol) and triethylsilane (122 μL, 0.762 mmol), both at 0 °C, were added. The reaction mixture was stirred for 30 min with the initially clear and yellow solution turning to clear and colorless. Additional CH_2Cl_2 was added, and the mixture was placed in a separatory funnel then washed twice with water. The organic layer was transferred into a flask, the solvent was removed by a rotary evaporator, and the resulting solid was vacuum-dried at room temperature. The colorless solid was repeatedly triturated with hexane to remove the majority of the triphenylmethane. The crude dithiol product **11** was used without further purification (132 mg). ^{1}H NMR ($CDCl_3$): δ 1.49 (d, 3H, CH_3), 1.98 (t, 2H, SH), 2.08 (m, 3H, CH and CH_2), 2.97 (m, 2H, CH_2N, H_a), 3.22 (d, 4H, CH_2S), 3.40 (m, 2H, CH_2N, H_b), 5.02 (quintet, 1H, NCH), 7.08−7.32 (m, 5H, ar), 7.82 (br.t, 2H, NH), 8.33 (d, 1H, NH).

***N*-[(*S*)-1-Phenylethyl]-3,3-bis(thio-acetamidomethyl)propanamide Oxorhenium(V) (12)**. The crude dithiol **11** (0.346 mmol) was placed in a three-necked flask to which was added trichlorooxobis(triphenylphosphine)-rhenium (288 mg, 0.346 mmol). The flask was evacuated and filled with argon, followed by the addition of 15 mL of 1 M sodium acetate in methanol (degassed for 1 h with bubbling argon). The reaction mixture was brought to reflux, stirred under argon at reflux for 5 h, and then cooled to room temperature. The methanol was removed using a rotary evaporator, and water was added to give a clear solution with a fine brown precipitate. The precipitate was filtered using a sintered glass filter. To the clear brown filtrate was added tetraphenylarsoniumchloride hydrate (162 mg, 0.387 mmol), resulting in the immediate precipitation of pale orange crystals. The crystals were removed by filtration and dried at room temperature under 0.025 mmHg vacuum to give 210 mg (63% for two steps) of a mixture of two isomers. IR (diffuse reflectance): 971 (ReO). HRMS FAB (negative ion) *m/z* calcd: $C_{17}H_{21}N_3O_4S_2187Re$, 582.0531. Found: 582.0567. HPLC using a reversed-phase column indicates that two products are present with retention times of 9.6 (54%) and 11.5 (46%) min under the conditions noted: C_{18} reversed-phase Waters μBondpak 3.9 × 300 mm; eluent 1.0 mL/min of 15% CH_3CN/85% 10 mM KH_2PO_4 solution ramped over 10 min to 30% CH_3CN/70% 10 mM KH_2PO_4 solution, and maintained at that solvent ratio; UV detector at 220 nm.

Epimerization to *anti*-*N*-[(*S*)-1-Phenylethyl)]-3,3-bis(thio-acetamidomethyl)propanamide Oxorhenium(V) (anti-12). The mixture of the two isomers **12** (185.6 mg, 0.192 mmol) was dissolved in 30 mL of methanol followed by the addition of 15 mL of 1 M NaOH. After stirring at room temperature for 30 min, an aliquot was taken and checked by HPLC, indicating 98.8% of a single isomer. Water was added to the flask, and the methanol removed by a rotary evaporator. The rose-colored crystals that formed were filtered and dried under vacuum, yielding 164.4 mg (89%): mp 127−130 °C. ^{1}H NMR ($CDCl_3$): δ 1.48 (d, 3H, CH_3), 2.27 (d, 2H, CH_2CO), 2.56 (m, 1H, CH), 2.87 (m, 2H, CHN x2), 3.59/3.74 or 3.76 (AB, 2H, CHS x2, $|J| = 17.1$ Hz), 3.62/3.74 or 3.76 (AB, 2H, CHS x2, $|J| = 17.1$ Hz), 3.92 (m, 2H, CHN x2), 5.06 (quintet, 1H, CHPh), 5.98 (d, 1H, NH), 7.2−7.8 (ar, 25H). ^{13}C NMR ($CDCl_3$): δ 21.94 (CH_3), 38.61 (CH_2S), 39.99 (CH_2CO), 40.96 (CH), 48.90 (CHPh), 54.90 (CH_2N), 55.04 (CH_2N), 170.4 (NHCO), 195.9 (CO), 196.0 (CO). HPLC of the product was performed under identical conditions as used for compound **12**. The UV chromatogram indicated a single product eluting with a retention time of 9.6 min: C_{18} reversed-phase Waters μBondpak 3.9 × 300 mm; eluent 1.0 mL/min of 15% CH_3CN/85% 10 mM KH_2PO_4 solution ramped over 10 min to 30% CH_3CN/70% 10 mM KH_2PO_4 solution and maintained at that solvent ratio; UV detector at 220 nm.

HPLC Separation of *syn*-*N*-[(*S*)-1-phenylethyl]-3,3-bis(thio-acetamidomethyl)propanamide Oxorhenium(V) (syn-12). A concentrated solution of a mixture of the two isomers (**12**) was prepared in acetonitrile. Semipreparative HPLC was performed on a Varian Vista 5500, with a Varian MicroPak MCH-10 (30 cm × 8 mm) C_{18} reversed-phase column and a UV detector set at 220 nm. The eluent was a gradient from 20% CH_3CN/80% 10 mM KH_2PO_4 solution to 30% CH_3CN/70% 10 mM KH_2PO_4 over 15 min. A flow rate of 2.0 mL/min allowed for the complete separation of the two isomers with retention times of 12.7 and 15.1 min. Two fractions were collected and combined from a total of four HPLC runs. Each was placed in a flask, and the CH_3CN was removed by a rotary evaporator followed by the addition of Ph_4AsCl. The precipitate that formed was collected by filtration and dried under vacuum leaving approximately 2 mg of each isomer. The product eluting at 12.7 min was found to be the anti isomer as shown by ^{1}H NMR spectroscopy. The material eluting at 15.1 min was syn-**12** and was characterized. ^{1}H NMR ($CDCl_3$): δ 1.40 (d, 3H, $J = 6.9$ Hz, CH_3), 2.63 (dd, 2H, CH_2CO), 2.80 (m, 1H, CH), 3.42 (m, 2H, CHN x2), 3.76/3.84 (AB, 2H, CHS x2, $|J| = 17.2$ Hz), 3.86 (m, 2H, CHN x2), 4.04/4.09 (AB, 2H, CHS x2, $|J| = 17.4$ Hz), 5.06 (quintet, 1H, CHPh), 6.13 (d, 1H, NH), 7.2 to 7.9 (ar, 25H). HPLC (conditions

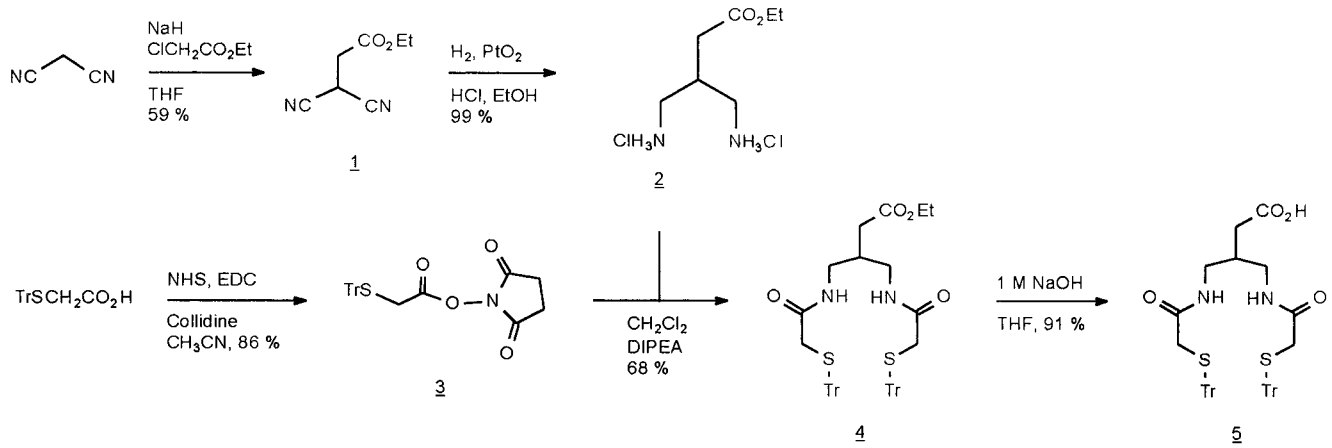
as listed for the semipreparative column): product retention time, 14.9 min.

***N*-[(*S*)-1-Phenylethyl]-3,3-bis(thio-acetamidomethyl)propanamide Oxotechnetium-99m(V) (13)**. A 3 mL vial was charged with 10 μL of 0.1 M sodium acetate, 10 μL of sodium gluconate (10 mM aqueous solution), 100.4 μCi $Na^{99m}TcO_4^-$ in 30 μL of saline, 20 μL of 0.42 mM **11**, and 0.02 mg of $SnCl_2$ in 10 μL of water. The mixture was heated at 60−65 °C for 80 min. From the vial, 47.1 μCi of the reaction mixture was injected onto the HPLC. The eluent at 10−12 min was collected and counted as 34.2 μCi to give a radiochemical yield of 73%. HPLC (C_{18} reversed-phase Waters μBondpak 3.9 × 300 mm; eluent 1.0 mL/min of 15% CH_3CN/85% 10 mM KH_2PO_4 solution ramped over 10 min to 30% CH_3CN/70% 10 mM KH_2PO_4 solution and maintained at that solvent ratio; radiometric γ detector): product retention times, 10.3 and 11.7 min.

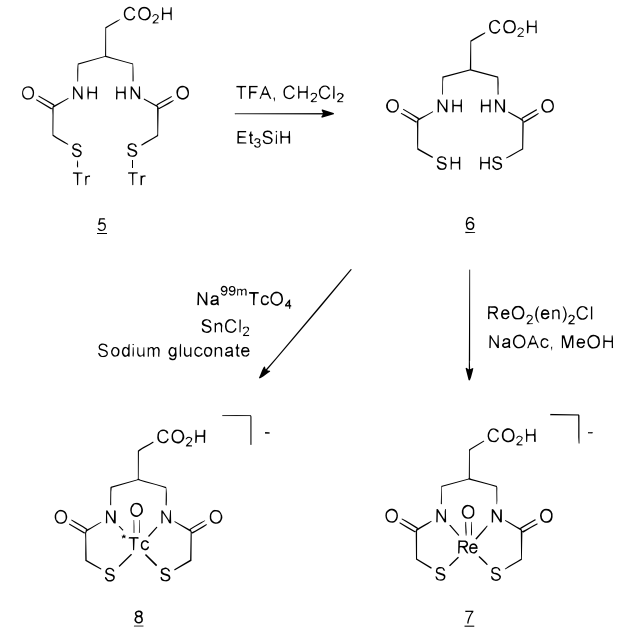
Crystal Structure of anti-7. Crystals of anti-**7** were grown from a saturated solution in methanol. A crystal suitable for X-ray analysis was selected and cut to appropriate size and mounted on a glass fiber. Crystal data and refinement parameters for anti-**7** are listed in Table 1, and selected interatomic distances and angles are listed in Table 2. Data were collected on a Nonius Kappa-CCD system at room temperature. Unit cell parameters were calculated from reflections obtained from 10 consecutive data images collected at φ intervals of 1°. One full hemisphere of data was collected by incremental φ scans of 1° followed by 1° ω scans to capture cusp data. Systematic absences and intensity data indicated the space group $P2_12_12_1$. Data were scaled, and empirical absorption corrections were applied using redundant data and XPREP (Shelxtl 5.03). Full-matrix least-squares refinement on F^2 was performed after solving using Patterson methods and the solution package SHELXTL 5.03 (Sheldrick, G. M., Madison, WI). Anisotropic thermal parameters were applied to all nonhydrogen atoms; C6, O4, and O5 were disordered over two positions and refined with site occupancy factors of 0.65 and 0.35. Hydrogen atoms were placed in idealized positions and updated with each least-squares refinement. The absolute structure parameter was −0.017(6). The largest residual peak was found in the lattice and was associated with O4 (0.567 eÅ^{-3}). In the final stages of refinement, $R_1 = 2.46\%$ and $R_{w2} = 5.58\%$.

RESULTS AND DISCUSSION



This section presents the synthetic pathway followed for the preparation of the target N_2S_2 chelator bearing a carboxylic acid group. The chelating ability of **6** was demonstrated by complexation of the ligand to both rhenium and technetium-99m. In both cases, the reaction yielded two kinetic isomers, anti and syn, which can be completely converted to the thermodynamically favored anti isomer. Single-crystal X-ray analysis and NMR spectroscopy were used to characterize the rhenium complexes. Finally, the protected chelator **5** was conjugated to (*S*)-α-phenethylamine yielding compound **10**, which after deprotection was also complexed to both rhenium and technetium-99m. Again two kinetic isomers were formed, but only one thermodynamic bioconjugate product resulted. The rhenium isomers were separated and characterized by NMR spectroscopy.

The preparation of the thiol protected N_2S_2 ligand **5** follows a five-step procedure as shown in Scheme 1. The scheme parallels a previously reported pathway for the syntheses of mercaptoamides by using a diamine and two equivalents of a thioglycolate (*17*). The dicyano ester **1** was prepared by alkylation of malononitrile with ethyl chloroacetate. Dialkylation is a significant side reaction in this step as has been noted for various malononitrile alkylations (*18*, *19*). The optimum yield of **1** was obtained with a 2-fold excess of malononitrile over ethyl chloroacetate. The excess malononitrile was removed by extraction followed by fractional vacuum distillation to give **1** in an overall 59% yield. Compound **1** was readily reduced to the 1,3-diamino derivative **2** by catalytic hydrogenation and was isolated as the dihydrochloride in approximately quantitative yield. Attempts to purify this gummy solid by recrystallization or ion-exchange chromatography met with limited success. Instead, **2** was used immediately without further purification.



Mercaptoacetic acid was protected using triphenylmethanol (*20*). The procedure for conversion to the N-hydroxy succinimidyl ester **3** was modified from a literature procedure (*21*), using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDC) as the coupling reagent to give **3** in 86% yield. Compound **4** was synthesized via a conventional amide coupling reaction using the diamine **2** and 2 equiv of the ester **3** in 68% yield. The final step involved the room-temperature saponification to the N_2S_2 carboxylic acid **5**.

As shown in Scheme 2, complex formation with either rhenium or technetium was a two-step process. In the first step, the thiol groups were deprotected using trifluoroacetic acid and triethylsilane or triisopropylsilane as a cation scavenger (*20*). The dithiol intermediate **6** was not purified in order to avoid possible oxidation. Chelation with rhenium was accomplished using a ligand-exchange reaction with $ReO_2(en)_2Cl$ in the presence of sodium acetate. The resultant rhenium complex **7** was precipitated from solution as the tetraphenylarsonium

Scheme 1

Scheme 2

salt. HPLC and ^{1}H NMR spectroscopy ascertained that the reaction product consisted of a mixture of two isomers in an approximate 1:1 ratio. These two epimers were determined to be the anti and syn isomers with respect to the rhenium oxo and carboxylic acid groups. As shown in Figure 3, room-temperature isomerization using a 0.5 M sodium hydroxide solution in water/methanol allowed for the complete conversion of the mixture of epimers to a single isomer. Characterization of this product by ^{1}H NMR spectroscopy and X-ray crystallography indicated that the configuration is anti. In contrast, exposure of the mixture of epimers to 1 M HCl had no effect on the ratio of the two epimers.

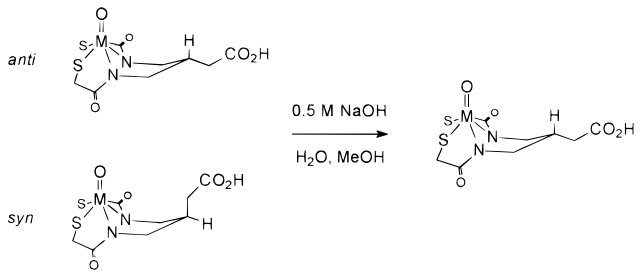


Figure 3. Isomerization at room-temperature results in complete conversion of the mixture of isomers to the anti isomer.

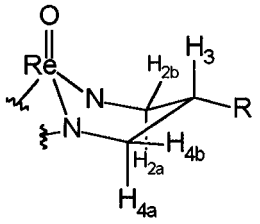

While compounds **7** and **8** are not the first examples of rhenium(V) and technetium(V) N_2S_2 complexes that undergo base-catalyzed isomerization, to our knowledge they are unique in that they form a single stable isomer. It is interesting to note that, in an oxygen-exchange reaction study of N_2S_2 rhenium(V) and technetium(V) DADS complexes (*22*), oxygen exchange was found to be base catalyzed and that no exchange occurred under the acidic conditions employed. In another study, an N_3S peptide chelator for rhenium(V) and technetium(V) was demonstrated to undergo conversion between anti and syn isomers (*23*). This conversion was sufficiently slow that the isomers could be separated by HPLC but sufficiently rapid at room temperature that it prevented isolation of the individual, separated isomers. The structurally related CO_2-DADS rhenium complexes (Figure 1) containing a five-membered ring were not observed to convert from one epimer to another in the pH range of 1−11 (*9*).

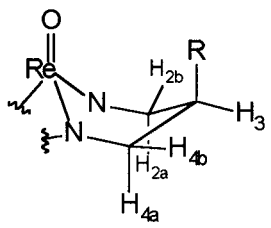

Table 3 shows the ^{1}H NMR analysis which allowed for the determination of the six-membered ring configuration of compounds **7**. Measurement of the coupling constants for the axial (H_{2a}, H_{4a}) and equatorial (H_{2b}, H_{4b}) protons adjacent to the nitrogen atoms allowed for the determination of their spatial relationship to H_3. For anti-**7**, the axial protons next to the nitrogen have two large coupling constants ($|J|$ = 13.2 Hz, $|J|$ = 10.8 Hz) implying a geminal and an axial−axial interaction. Spin−spin decoupling experiments with irradiation at 2.63 ppm converts the doublet of doublets at 3.78 ppm into a broad singlet, and irradiation at 3.78 ppm converts the doublet of doublets at 2.63 ppm into a doublet ($|J|$ = 10.8 Hz). This confirmed that the orientation of H_3 is axial, and therefore, the pendant carboxylic acid group is equatorial.

Since the syn isomer was not isolated, a ^{1}H NMR spectrum could not be acquired. Instead the ^{1}H NMR spectrum was deduced by subtraction of the anti-**7** spectrum from the spectrum of the isomeric mixture of **7**. The doublet of doublets at 3.31 ppm is assigned to the axial protons H_{2a} and H_{4a}, with coupling constants of $|J|$ = 13.6 Hz and $|J|$ = 6.6 Hz, indicating a geminal coupling and an axial−equatorial coupling respectively, consistent with the syn configuration shown in Table 3.

The infrared spectrum (DRIFT) showed a rhenium-oxo stretch at 974 cm^{-1}, in the expected range for a $Re{=}O^{3+}$ core (*9*, *24*). Fast-atom bombardment mass spectroscopy (FABMS) in the negative ion mode confirmed the presence of the rhenium complex with the parent ion peaks at *m*/*z* 479 and 477 with the expected intensity for ^{187}Re/^{185}Re (63:37).

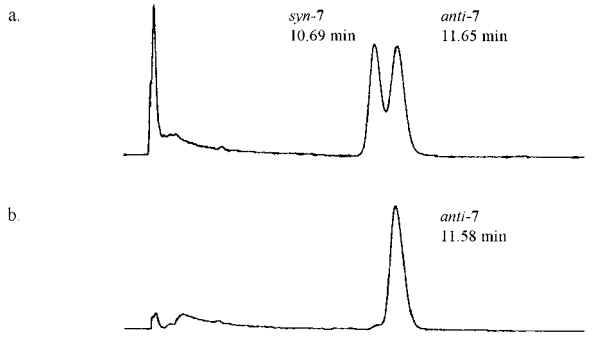

Figure 4. HPLC chromatograms (UV detector) of complex **7** on an anion-exchange column (see Experimental Section for conditions). (a) syn and anti-**7**; (b) anti-**7** after the mixture is exposed to 0.5 M NaOH (water/methanol) at room temperature.

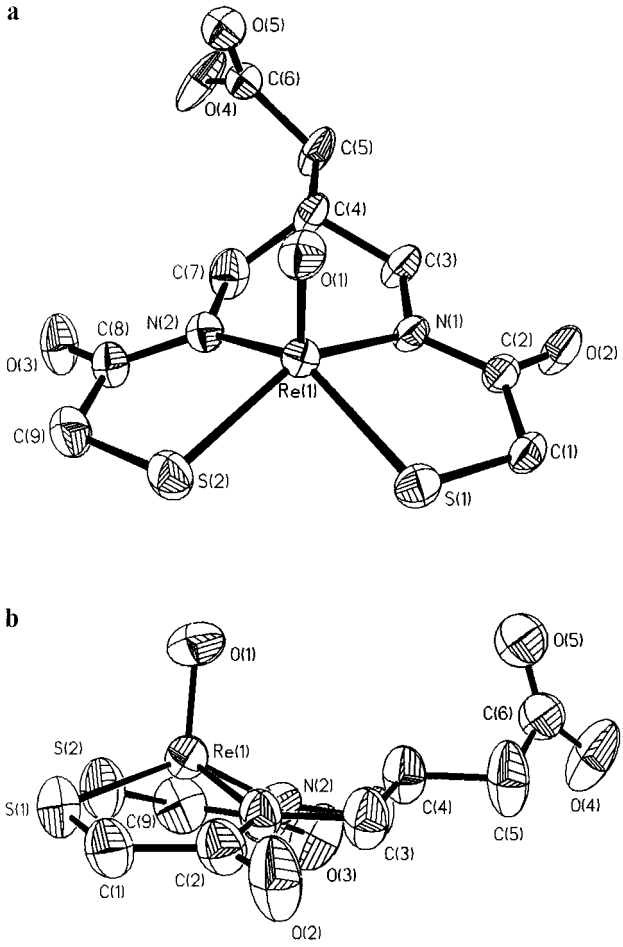
HPLC of Re and ^{99m}Tc Complexes. An anion-exchange column was utilized for the HPLC analysis of the carboxylic acid rhenium complexes **7** and technetium complexes **8**. With rhenium, as can be seen in Figure 4a, the complex formed initially was a 45:55 mixture of two isomers having retention times of 10.7 and 11.7 min (see Experimental Section for conditions). Figure 4b shows the result of an HPLC analysis after treatment of this mixture with 0.5 M NaOH at room temperature for 30 min. Conversion to a single isomer has occurred with the exclusive and later-eluting compound being anti-**7** as established by ^{1}H NMR analysis and X-ray structure determination.

Labeling of the ligand with 99m-pertechnetate was successful using tin(II) chloride, sodium gluconate, and the dithiol ligand **6** in excess. Similar to chelation with rhenium, two isomers of **8** were observed by HPLC. Co-injection of this mixture of technetium-99m isomers along with the mixture of syn and anti isomers of **7** onto an ion-exchange HPLC column allowed for comparison of the retention times of the technetium-99m and rhenium chelates. Elution of the technetium-99m isomers (syn-**8** then anti-**8**) was monitored by a radiometric γ detector (placed in series after the UV detector) with retention times of 11.5 and 12.3 min while the rhenium complexes monitored by a UV detector eluted at 10.7 and 11.7 min. Under the ^{99m}Tc-labeling conditions used, a preference for the later-eluting anti isomer was observed, with radiochemical yields of 67−88%. Labeling of **6** in the presence of 1 M NaOH resulted in only the anti-**8** product being formed. This is consistent with the anti-configuration being thermodynamically preferred for both the rhenium and technetium complexes of **6**. From a practical point of view, this means that labeling of **6** with technetium-99m can result in but one isomer being produced.

Crystal Structure. Crystals of anti-**7** suitable for X-ray diffraction crystallography were grown from a saturated methanol solution. Perspective views of the complex are shown in Figure 5, with crystal data in Table 1 and selected bond lengths and angles in Table 2. The rhenium atom is situated in a square pyramidal geometry with the rhenium atom located 0.6849 Å above the square plane formed by the two nitrogen and two sulfur atoms. The deviation from planarity for the four ligand atoms is 0.0303 Å. The rhenium−oxo bond length is 1.675 Å, within the expected range of 1.66−1.68 Å as noted for similar N_2S_2 chelators (*22*). The molecules pack by intermolecular hydrogen bonding between the carboxylic acid of one molecule and an amide carbonyl of another molecule. HPLC and mixed melting point analysis confirmed that the crystals selected for X-ray analysis consisted solely of the anti isomer. As mentioned earlier, the crystal structure establishes that the later-eluting isomer in Figure 4 is the anti epimer as assigned. It also shows that in the crystalline form the carboxylic acid is situated in an equatorial position. Therefore, the conformation of anti-**7** is the same in both the crystalline form, determined by the crystal structure and, in solution, as determined by ^{1}H NMR spectroscopy.

Bioconjugation. The bifunctional ability of **6** was explored using (*S*)-α-phenethylamine to act as a model of chiral, amine containing pharmaceuticals. As illustrated in Scheme 3, amide formation was accomplished in two ways: by either direct DCC coupling in 88% yield or by first forming a N-hydroxysuccinimidyl (NHS) ester of **6** and subsequent coupling of **9** to the amine in a 66% two-step yield. Direct DCC coupling would be appropriate for compounds bearing available amino groups but not carboxylic acid groups while the NHS ester is appropriate for the technetium-99m labeling of peptides and analogous compounds.

As illustrated in Scheme 4, the complex **11** was chelated with rhenium in a ligand-exchange reaction using either $ReOCl_3(PPh_3)_2$ or $ReO_2(en)_2Cl$ in the presence of sodium acetate. As with **7**, the rhenium chelation product **12** is formed as a mixture of two isomers in a nearly 1:1 ratio. The separation of the two epimers was



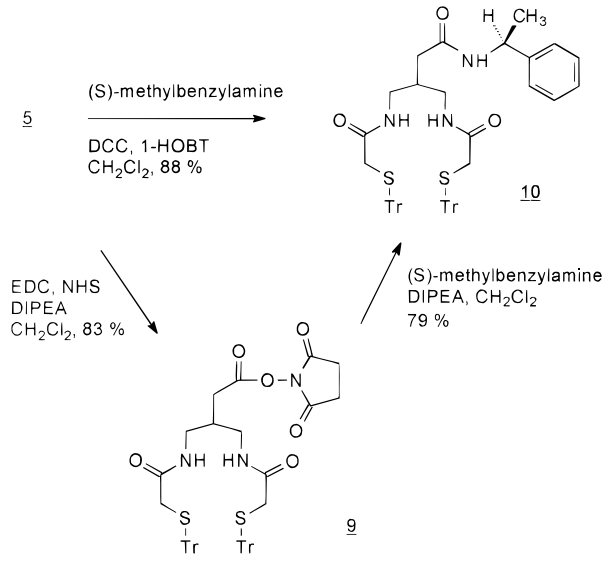


Figure 5. Perspective views of the anion anti-**7**. Thermal ellipsoids are drawn at the 50% probability level. Side view (**b**) indicates the anti arrangement of the rhenium oxo and pendant carboxylic acid functionality.

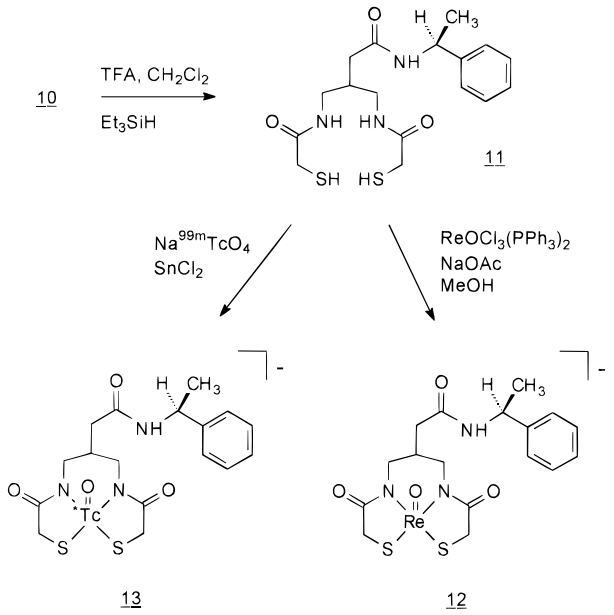

Scheme 3

accomplished using HPLC (C_{18} reversed-phase), with the two isomers having retention times of 9.6 and 11.5 min under the conditions noted in the Experimental Section.

As with **7**, epimerization of this mixture of isomers was accomplished by treating the complexes with 1 M NaOH for 30 min at room temperature. HPLC analysis indicated 98.8% of a single isomer which is the earlier-eluting

Scheme 4

isomer under these HPLC conditions. As described below, identification of the earlier eluting isomer was carried out by ^{1}H NMR spectroscopy resulting in its characterization as anti-**12**. While the anti isomer was readily prepared by epimerization of the mixture of isomers, the syn isomer was isolated by semipreparative HPLC.

The proton NMR spectra for **12** is complicated by the presence of five nonequivalent protons on the six-membered ring ($H_{2a,b}$, H_3, and $H_{4a,b}$). Through COSY and decoupling experiments, the chemical shifts and coupling constants for all five protons were established and are presented in Table 4. The conformation of the six-membered ring was elucidated from the coupling constants of the axial and equatorial protons on H_2 and H_4 as coupled to H_3. For the anti isomer, $|J_{gem}|$ for $H_{2a}-H_{2b}$ and $H_{4a}-H_{4b}$ is 13.1 and 13.6 Hz, respectively. The coupling constant for either axial proton (H_{2a} or H_{4a}) with H_3 is 11.4 Hz, indicating an axial−axial relationship, while the coupling constant for either equatorial proton (H_{2b} or H_{4b}) with H_3 is 2.3 Hz, consistent with a gauche relationship expected for the anti isomer with an equatorial substituent. Spin−spin decoupling ^{1}H NMR experiments verified this assignment and allowed for the chemical shift assignment of the four protons (H_{2a}, H_{2b}, $H_{4a,}$ and H_{4b}).

For the syn isomer, $|J_{gem}|$ for $H_{2a}-H_{2b}$ and $H_{4a}-H_{4b}$ was found to be 14.2 and 14.3 Hz, respectively. The vicinal coupling constants ($J_{2a,3} = J_{4a,3} = 3.5$ Hz and $J_{2b,3} = J_{4b,3} = 3.1$ Hz) were consistent with a gauche relationship as expected for the syn isomer with an axial substituent as illustrated in Table 4.

The infrared spectra (DRIFT) showed the Re=O stretch at 971 cm^{-1}. FABMS in the negative ion mode confirmed the presence of the rhenium complex by exhibiting the characteristic 2:1 rhenium isotopic ratio, with the parent ion peaks at *m*/*z* 582 and 580.

Labeling of **11** with technetium-99m was accomplished with $Na^{99m}TcO_4$ using $SnCl_2$ as the reducing agent and D-gluconate for ligand exchange. Under mild basic conditions (0.1 M NaOAc), the radiochemical yield for **13** was 73%, with a 2:1 ratio between the anti/syn isomers as shown in Figure 6a. When the technetium-99m chelation was carried out in the presence of 1 M NaOH, only the earlier-eluting anti-**13** was formed as indicated by the

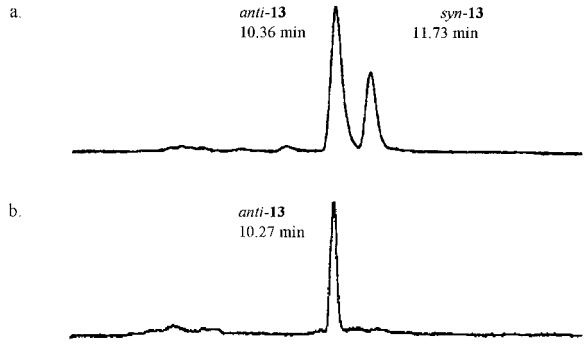

Figure 6. HPLC chromatograms (radiometric γ detector) of complex **13** on a C_{18} reversed-phase column (see Experimental Section for conditions). (a) anti and syn-**13** from chelation in the presence of 0.1 M NaOAc; (b) anti-**13** from chelation in the presence of 1 M NaOH.

HPLC radiometric trace shown in Figure 6b. Co-injection of the rhenium complexes **12** and the technetium-99m complexes **13** was used to compare retention times. Using a C_{18} reversed-phase column, the HPLC eluent was monitored by a UV detector followed in series by a radiometric γ detector. The rhenium epimers **12** had retention times of 9.6 and 11.5 min, while the ^{99m}Tc epimers **13** eluted at 10.3 and 11.7 min. A slight deviation in retention time is expected since the detectors are arranged in series, with the radiometric detector situated after the UV detector.

CONCLUSIONS

An achiral ligand **6** has been prepared in six steps. Chelation of this ligand with rhenium or technetium-99m results in the formation of two isomers as the kinetic products. Equilibration with 0.5 M NaOH yielded a single isomer. This thermodynamically favored epimer is the anti isomer, and this product was fully characterized by NMR spectroscopy and X-ray crystallography.

The bifunctional ability of the ligand was investigated using (*S*)-α-phenethylamine as a model amine, and the resulting complex was chelated with rhenium and technetium-99m. Again, the kinetic products were a mixture of two isomers which was epimerized quantitatively to the anti isomer. This shows that coupling with either NHS or DCC yields amides in good yield and that single isomer bioconjugates can be produced. This will be of value in the preparation and purification of single isomer radiopharmaceuticals and consequently simplify interpretation of potentially complex biodistributions.

ACKNOWLEDGMENT

This work is supported by NSERC (National Science and Engineering Research Council of Canada) and Merck-Frosst. The authors acknowledge the assistance of the Nuclear Medicine Department of the London Health Sciences Centre, University Campus and Surface Science Western. We wish to thank Doug Hairsine for running mass spectra.

An N_2S_2 Bifunctional Chelator for Technetium-99m and Rhenium: Complexation, Conjugation and Epimerization to a Single Isomer

Leonard G. Luyt, Hilary A. Jenkins[†] and Duncan H. Hunter[*].

Supporting Information

Analytical Data (weight percent composition by element)

3,3-Dicyano-propionic acid ethyl ester (**1**):

	Carbon	Hydrogen	Nitrogen	Oxygen
Calculated	55.26	5.30	18.41	21.03
Observed	55.42	5.14	18.35	21.23

3,3-Bis(triphenylmethylthio-acetidomethyl)propanoic acid ethyl ester (**4**):

	Carbon	Hydrogen	Nitrogen	Oxygen	Sulphur
Calculated	74.21	6.10	3.53	8.07	8.09
Observed	74.23	5.83	3.68	8.15	7.94

3,3-Bis(triphenylmethylthio-acetamidomethyl)propanoic acid (**5**):

	Carbon	Hydrogen	Nitrogen	Oxygen	Sulphur
Calculated	73.79	5.80	3.66	8.37	8.38
Observed	73.44	5.81	3.55	8.33	8.48

N-((S)-1-Phenylethyl)-3,3-bis(triphenylmethylthio-acetamidomethyl)propanamide (**10**):

	Carbon	Hydrogen	Nitrogen	Oxygen	Sulphur
Calculated	76.09	6.15	4.84	5.53	7.39
Observed	76.24	6.11	4.80	5.80	7.36

Supplementary X-ray Data

Table 1. Crystal data and structure refinement for *anti*-7.

Identification code	*anti*-7	
Empirical formula	$C_{33}\ H_{33}\ As\ N_2\ O_5\ Re\ S_2$	
Formula weight	862.85	
Temperature	294(2) K	
Wavelength	0.71073 Å	
Crystal system	Orthorhombic	
Space group	P2(1)2(1)2(1)	
Unit cell dimensions	a = 9.4435(3) Å b = 14.3439(4) Å c = 24.1591(5) Å	alpha = 90 deg. beta = 90 deg. gamma = 90 deg.
Volume, Z	3272.5(2) $Å^3$, 4	
Density (calculated)	1.751 Mg/m^3	
Absorption coefficient	4.887 mm^{-1}	
F(000)	1700	
Crystal size	0.30 x 0.20 x 0.20 mm	
Theta range for data collection	1.65 to 25.00 deg.	
Limiting indices	-12<=h<=12, -19<=k<=20, -28<=l<=30	
Reflections collected	22399	
Independent reflections	5752 [R(int) = 0.0452]	
Absorption correction	Semi-empirical	

Max. and min. transmission	0.3158 and 0.2131
Refinement method	Full-matrix least-squares on F^2
Data / restraints / parameters	5749 / 0 / 405
Goodness-of-fit on F^2	0.988
Final R indices [I>2sigma(I)]	R1 = 0.0246, wR2 = 0.0558
R indices (all data)	R1 = 0.0302, wR2 = 0.0693
Absolute structure parameter	-0.017(6)
Extinction coefficient	0.00022(10)
Largest diff. peak and hole	0.567 and -0.649 e.Å^{-3}

Table 2. Atomic coordinates (x 10^4) and equivalent isotropic displacement parameters (Å^2 x 10^3) for *anti*-7. U(eq) is defined as one third of the trace of the orthogonalized Uij tensor.

Multivalent Thioether−Peptide Conjugates: B Cell Tolerance of an Anti-Peptide Immune Response

David S. Jones,* Stephen M. Coutts, Christina A. Gamino, G. Michael Iverson, Matthew D. Linnik, Martina E. Randow, Huong-Thu Ton-Nu, and Edward J. Victoria

La Jolla Pharmaceutical Company, 6455 Nancy Ridge Drive, San Diego, California 92121.
Received November 17, 1998; Revised Manuscript Received February 19, 1999

Antibodies which bind β_2-glycoprotein I (β_2GPI) are associated with antiphospholipid syndrome. Synthetic peptide mimotopes have been discovered which compete with β_2GPI for binding to selected anti-β_2GPI. A thiol-containing linker was attached to the N-terminus of two cyclic thioether peptide mimotopes, peptides **1a** and **1b**. The resulting peptides, with linker attached, were reacted with two different haloacetylated platforms to prepare four tetravalent peptide-platform conjugates to be tested as B cell toleragens. The linker-containing peptides were reacted with maleimide-derivatized keyhole limpet hemocyanin (KLH) to provide peptide−KLH conjugates. Peptides **1a** and **1b** were also modified by acylation with 3-(4′-hydroxyphenyl)propionic acid *N*-hydroxysuccinimidyl ester. The resulting hydroxyphenyl peptides were radioiodinated and used to measure anti-peptide antibody levels. The KLH conjugates were used to immunize mice to generate an anti-peptide immune response. The immunized mice were treated with the conjugates or saline solution and boosted with the appropriate peptide−KLH conjugate. Three of the four conjugates suppressed the formation of anti-peptide antibody. The stabilities of the conjugates in mouse serum were measured, and the relative stabilities did not correlate with ability to suppress antibody formation.

INTRODUCTION

Multiple copies of a hapten attached covalently to a nonimmunogenic polymeric backbone or platform can tolerize those B lymphocytes producing antibodies that bind the hapten, rendering them nonresponsive to haptenated immunogens (*1*, *2*). The result is a decrease in the amount of antibody produced against the hapten. Molecules such as these, which suppress antibody production by B cells, are called toleragens. For example, 2,4-dinitrophenyl (DNP) groups attached to the D-lysines in polymers consisting of D-amino acids can suppress IgG production in animals which have been immunized with DNP-derivatized proteins. Such findings suggested a therapeutic approach for treatment of autoimmune disorders by specifically tolerizing antigen-specific B cells.

B cell tolerance is the reduction of the ability of a specific B cell to produce antibody. B cell tolerance in vivo can be accomplished by treatment with a toleragen, a molecule bearing multiple copies of hapten. Tolerization of mice, which were immunized with synthetic double stranded oligonucleotides, has been accomplished with a "platform conjugate" consisting of four double-stranded oligonucleotides on a PEG based platform (*3*). This concept was further refined into LJP 394, a molecule designed to treat lupus nephritis (*4*). LJP 394 consists of four double-stranded oligonucleotides connected to a defined platform.

The prospect of developing treatments for other autoimmune diseases has led us to search for peptide mimotopes of naturally occurring antigens. β_2-glycoprotein I (β_2GPI) has been implicated as the natural antigen of what have been historically referred to as anticardiolipin antibodies (ACA), which are associated with arterial and venous thrombosis, recurrent fetal loss, and thrombocytopenia (*5*, *6*). A number of ACA-binding peptides have been discovered by screening random-peptide phage libraries (*7*). Most of these phage-derived ACA-binding peptides are cyclic due to an intramolecular disulfide bond in each. Two analogues of these cyclic peptides have been synthesized as thioether peptide analogues in which the disulfide (S−S) is replaced with a thioether (CH_2−S) (*8*, *9*). Both thioether peptide analogues compete with β_2GPI for ACA which was affinity purified from serum from a single recurrent stroke patient.

The goal of these studies was to develop a method for attaching cyclic thioether peptide analogues to multivalent platforms and test their ability to tolerize an immune response. Thioether peptide analogues were attractive for several reasons. First, a thiol linker can be conveniently used to attach molecules of interest to haloacetylated platforms. A cyclic peptide thioether bond is stable in the presence of a thiol linker, whereas a disulfide bond may be reactive with a thiol linker. Thiol exchange between a thiol and a disulfide can be a rapid reaction leading to mixtures of products (*10*). Second, a thioether bond may be less rapidly metabolized than a disulfide bond (*11*), addressing a major concern with peptide-based drugs.

EXPERIMENTAL PROCEDURES

All chemicals were used as purchased unless otherwise specified. Ethyldiazoacetate, 2-[2-(2-chloroethoxy)ethoxy]-ethanol, BF_3·Et_2O, thiobenzoic acid, 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU), triphenylmethyl chloride, *p*-nitrophenol, dicyclohexylcarbodiimide (DCC), di-*tert*-butyldicarbonate, 3,5-diaminobenzoic acid, *N*-hydroxysuccinimide (NHS), ethylenediamine, triethyleneglycol bischloroformate, and iodoacetic anhydride were purchased from Aldrich Chemical Co. Maleimidyl-activated KLH

was purchased from Pierce (catalog no. 77105). 3-(4′-Hydroxyphenyl)propionic acid *N*-hydroxysuccinimidyl ester (Taggit) was purchased from Novabiochem. Silica gel chromatography was performed on silica gel (230−400 Mesh ASTM) purchased from Baxter. TLC was performed on silica gel TLC plates (5554) manufactured by EM Separations. Phosphate-buffered saline (PBS) was prepared by dissolving 175 g of NaCl, 6.5 g of $NaH_2PO_4 \cdot H_2O$, and 40.9 g of $Na_2HPO_4 \cdot H_2O$ in H_2O and diluting to a final volume of 20 L. Tris-buffered saline (TBS) was prepared by dissolving 219.9 g of NaCl and 151.4 g of tris(hydroxymethyl)aminomethane in H_2O, adjusting the pH to 8.0, at a final volume of 25 L, with HCl.

Melting points are reported uncorrected. NMR spectra were recorded on a Bruker AC-300 spectrometer with broad band probe. Elemental analyses were performed by Desert Analytics of Tucson, Arizona. Mass spectra were recorded on a Finnigan LC-Q electrospray mass spectrometer or obtained from the Mass Spectroscopy Lab at the Scripps Research Institute, San Diego, CA.

Bis-*N*-(tert-butyloxycarbonyl)diaminobenzoic acid, compound 4. A solution of 7.18 g (32.9 mmol) of di-*tert*-butyldicarbonate in 5.5 mL of MeOH was slowly added to a solution of 2.5 g (16.4 mmol) of 3,5-diaminobenzoic acid and 2.76 g (32.9 mmol) of $NaHCO_3$ in 44.5 mL of H_2O and 22.5 mL of MeOH, and the mixture was stirred at room temperature for 24 h. The mixture was cooled to 0 °C, and 6.53 g of citric acid was added. The mixture was extracted with EtOAc, and the combined EtOAc layers were dried ($MgSO_4$), filtered, and concentrated. The residue was dissolved in 40 mL of Et_2O, and the solution was filtered through Celite. The Et_2O layer was extracted with two 40 mL portions of HCl. The Et_2O layer was dried ($MgSO_4$), filtered, and concentrated to give 3.81 g (66%) of **4** as a foamy pink solid; mp 199 °C. ^{1}H NMR ($CDCl_3$): δ 1.55 (s, 18H), 6.80 (brd, 2H), 7.74 (s, 2H), 7.95 (s, 1H) ^{13}C NMR ($CDCl_3$): δ 28.3, 81.4, 113.1, 115.2, 131.1, 139.6, 153.4, 170.7. MS (ESI): $(M + Na)^+$ 375.2. Anal. ($C_{17}H_{24}N_2O_6$) C, H, N (Table 1).

***N*-Hydroxysuccinimidyl Ester of Compound 4, Compound 5**. Dicyclohexylcarbodiimide (3.34 g, 16.2 mmol) was added to a solution of 3.8 g (10.8 mmol) of compound **4** and 1.24 g (10.8 mmol) of *N*-hydroxysuccinimide in 55 mL of EtOAc which had been cooled to 0 °C, and the resulting mixture was stirred for 18 h allowing to come to room temperature. Acetic acid (0.55 mL) was added to the mixture, and the mixture was stirred for 30 min and placed in the freezer at −20 °C for 2 h. The mixture was filtered to remove solids, and the filtrate was concentrated to give 5.80 g of pink foamy solid. Purification by silica gel chromatography (60/40/1 hexane/EtOAc/HOAc) gave 4.30 g (89%) of compound **5** as a slightly pink solid; mp 133−137 °C. ^{1}H NMR ($CDCl_3$): δ 1.55 (s, 18H), 2.94 (s, 4H), 6.81 (s, 2H), 7.79 (s, 2H), 7.96, (s, 1H). ^{13}C NMR ($CDCl_3$): δ 25.6, 28.2, 81.2, 113.9, 114.3, 126.3, 139.8, 152.3, 161.4, 169.0. MS (ESI): $(M + Na^+)$ 472.2. Anal. ($C_{21}H_{27}N_3O_8$) C, H, N.

Mono-*N*-(tert-butyloxycarbonyl)ethylenediamine, Compound 6. This compound was prepared in a manner similar to that described by Huang (*12*), A solution of 1.5 g (25.0 mmol) of ethylenediamine in 15 mL of CH_2Cl_2 was cooled to 0 °C, and a solution of 1.82 g (8.33 mmol) of di-*tert*-butyldicarbonate was added slowly to the mixture. The mixture was stirred at room temperature for 18 h and filtered, and the filtrate was concentrated. Purification by silica gel chromatography (90/10/1 CH_2Cl_2/MeOH/HOAc) gave 0.98 g (67%) of compound **6** as an oil.

Bis-[N_1-(N_2-(*tert*-butyloxycarbonyl)-2-aminoethyl)-carbamoyl]triethylene Glycol, Compound 7. To a solution of 750 mg (4.25 mmol) of compound **6** and 345 μL (337 mg, 4.25 mmol) of pyridine in 6 mL of CH_2Cl_2 was added 445 μL (559 mg, 2.02 mmol) of triethyleneglycol bis-chloroformate. The mixture was stirred for 3.5 h, and partitioned between 35 mL of CH_2Cl_2 and 35 mL of 1 N HCl. The CH_2Cl_2 layer was washed with H_2O, dried (Na_2SO_4), filtered, and concentrated to give 1.14 g of compound **7** as a white solid; mp 105−110 °C. ^{1}H NMR ($CDCl_3$): δ 1.46 (s, 18H), 3.30 (brd s, 8H), 3.68 (s, 4H), 3.72, (s, 4H), 4.24 (s, 4H), 5.16 (brd s, 2H), 5.56 (brd s, 2H). ^{13}C NMR ($CDCl_3$): δ 28.4, 40.5, 41.2, 64.1, 69.6, 70.6, 79.4, 156.3, 156.9. MS (ESI): $(M + Na^+)$ 545.3. Anal. ($C_{22}H_{42}N_4O_{10}$) C, H, N.

Compound 8. Compound **7** (300 mg, 0.57 mmol) was dissolved in 3.5 mL of CH_2Cl_2, and 3.5 mL of trifluoroacetic acid was added. The mixture was stirred for 3 h at room temperature, and the solution was concentrated to give 398 mg of residue. The residue was dissolved in 1.5 mL of H_2O, and to the resulting solution was added 193 mg (2.30 mmol) of $NaHCO_3$ followed by a solution of 567 mg (1.26 mmol) of compound **5** in 6 mL of dioxane. The mixture was stirred for 3 h, acidified with 1 N HCl, and partitioned between 20 mL of 1 N HCl and 30 mL of EtOAc. The aqueous layer was washed with 2 × 20 mL portions of EtOAc. The combined EtOAc layers were washed with saturated $NaHCO_3$ solution, dried ($MgSO_4$), filtered, and concentrated to give 490 mg (86%) of crude compound **8** as a white foamy solid. Purification by silica

gel chromatography (EtOAc) gave 276 mg (48%) of compound **8** as a white foamy solid; mp 138−140 °C. ^{1}H NMR ($CDCl_3$): δ 1.55 (s, 36H), 3.38 (m, 4H), 3.51 (m, 4H), 3.65 (m, 8H), 4.21 (m, 4H), 5.99 (t, 2H), 7.11 (t, 2H), 7.24 (s, 4H), 7.44 (s, 4H), 7.89 (s, 2H). ^{13}C NMR ($CDCl_3$): δ 28.5, 40.6, 41.0, 64.3, 69.8, 70.8, 80.8, 111.6, 112.0, 135.8, 139.7, 153.1, 157.6, 168.4. Anal. ($C_{46}H_{70}N_8O_{16}$) C, H, N.

Compound 3. Compound **8**, (100 mg, 0.1 mmol) was dissolved in 1 mL of 1/1 TFA/CH_2Cl_2, and the mixture was stirred for 1 h at room temperature. Et_2O was added to the mixture to precipitate the resulting tetraamine salt which was dried under vacuum to give a white crystalline solid. The solid was dissolved in 1 mL of H_2O together with 168 mg (2.0 mmol) of $NaHCO_3$, and the resulting mixture was cooled to 0 °C. To the cooled solution was added a solution of 212 mg (0.6 mmol) of iodoacetic anhydride in 2 mL of dioxane. The mixture was stirred at 0 °C for 15 min, acidified to pH 4 with 1 N H_2SO_4, and partitioned between 10 mL of H_2O and 6 × 10 mL portions of 8/2 CH_2Cl_2/MeOH. The combined organic layers were dried ($MgSO_4$), filtered, and concentrated to give 202 mg of yellow oily solid. Purification by silica gel chromatography (9/1 CH_2Cl_2/MeOH) yielded 57 mg (45%) of compound **3** as a white solid; mp 126−140 °C dec.; ^{1}H NMR (1/1 $CDCl_3$/CD_3OD): δ 3.32 (m, 4H), 3.50 (m, 4H), 3.59 (s, 4H), 3.68 (m, 4H), 3.88 (s, 8H), 4.18 (m, 4H), 7.73 (s, 4H), 7.99 (s, 2H), 8.48 (m, amide protons partially exchanged), 10.41 (s, anilide protons partially exhanged). MS (ESI): *m/z* $(M + H)^+$ 1263, $(M + Na)^+$ 1285. Anal. ($C_{34}H_{42}N_8O_{12}I_4$) C, H, N.

Ethyl-11-chloro-3,6,9-trioxaundecanoate, 9. This compound was prepared as described by Boumrah (*13*). A 0 °C solution of ethyldiazoacetate (11.56 mL; 10.704 g; 110 mmol) in 100 mL of CH_2Cl_2 was added dropwise over 30 min to a solution of 2-[2-(2-chloroethoxy)ethoxy]-ethanol (14.54 mL, 16.86 g, 100 mmol) and BF_3·Et_2O (1.23 mL, 1.066 g, 10 mmol) in 150 mL of CH_2Cl_2, under a nitrogen atmosphere, at 0 °C. The solution was stirred for 30 min at 0 °C, and 100 mL of H_2O was added to the reaction mixture. The mixture was transferred to a separatory funnel and shaken vigorously. The CH_2Cl_2 layer was washed twice with 100 mL of H_2O, dried ($MgSO_4$), filtered, and concentrated. The concentrate was distilled under vacuum to give 14.47 g (57%) of **9** as an oil (bp 94−140 °C, 0.25 mmHg). ^{1}H NMR ($CDCl_3$): δ 1.29 (t, 3H), 3.60−3.81 (m, 12H), 4.16 (s, 2H), 4.22 (q, 2H). ^{13}C NMR ($CDCl_3$): δ 14.1, 42.8, 61.0, 68.9, 70.4, 70.4, 70.5, 70.7, 71.2, 170.6.

Ethyl *S*-Benzoyl-11-mercapto-3,6,9-trioxaundecanoate, 10. A solution of 6.51 g (47.1 mmol) of thiobenzoic acid in 25 mL of dry DMF was added to a 0 °C solution of 10.0 g (39.3 mmol) of **9** in 80 mL of dry DMF. To the mixture was added 10.85 g (78.5 mmol) of DBU in 45 mL of dry DMF. The mixture was stirred at 0 °C for 10 min and heated to 70 °C for 16 h. The mixture was concentrated, and the concentrate was partitioned between 200 mL of CH_2Cl_2 and 2 × 200 mL of 1 N HCl. The CH_2Cl_2 layer was washed with saturated $NaHCO_3$, dried ($MgSO_4$), filtered, and concentrated to give 13.2 g of crude product. Purification by silica gel chromatography (7:3 hexane/ethyl acetate) gave 9.49 g (68%) of **10** as a light yellow oil. ^{1}H NMR ($CDCl_3$): δ 1.30 (t, 3H), 3.31 (t, 2H), 3.69−3.78 (m, 10H), 4.18 (s, 2H), 4.23 (q, 2H), 7.48 (m, 2H), 7.59 (m, 1H), 8.00 (d, 2H). ^{13}C NMR ($CDCl_3$): δ 14.4, 28.7, 60.5, 68.4, 70.1, 70.2, 70.4, 70.6, 127.5, 129.0, 133.5, 137.0, 170.5, 191.5. HRMS (FAB) *m/z* cald for $C_{17}H_{24}O_6SNa$: (M + Na) 379.1191. Found: 379.1203.

Ethyl *S*-Triphenylmethyl-11-mercapto-3,6,9-trioxaundecanoate, 11. A 2.27 M solution of sodium ethoxide in ethanol (10.5 mL, 28.1 mmol) was added under N_2 to a 0 °C solution of 5.0 g (14.0 mmol) of **10** in 15 mL of ethanol, and the mixture was stirred at 0 °C for 30 min. The reaction was acidified to approximately a pH of 2 with 5 N HCl, and the mixture was concentrated. The concentrate was partitioned between 2 × 200 mL of ethyl acetate and 200 mL of 1 N HCl. The combined ethyl acetate layers were dried ($MgSO_4$), filtered, and concentrated. The resulting orange oil was dissolved in 15 mL of CH_2Cl_2, the resulting solution was cooled to 0 °C, and 5.67 mL (5.55 g, 70.15 mmol) of pyridine and 4.30 g (15.43 mmol) of triphenylmethyl chloride was added. The mixture was stirred for 2 h at room temperature and concentrated. The concentrate was partitioned between 3 × 200 mL of ethyl acetate and 200 mL of 1 N HCl. The ethyl acetate layer was dried ($MgSO_4$), filtered, and concentrated. Purification by silica gel chromatography (7:3 hexane/ethyl acetate) gave 4.18 g (60%) of **11** as a viscous oil. ^{1}H NMR ($CDCl_3$): δ 1.28 (t, 3H), 2.46 (t, 2H), 3.32 (t, 2H), 3.47 (m, 2H), 3.60 (m, 2H), 3.69 (m, 2H), 3.73 (m, 2H), 4.14 (s, 2H), 4.21 (q, 2H), 7.20−7.33 (m, 9H), 7.43 (m, 6H). ^{13}C NMR ($CDCl_3$): δ 14.3, 31.9, 61.2, 66.5, 68.7, 69.6, 70.1, 70.3, 70.6, 70.8, 127.1, 128.1, 129.9, 145.0, 170.6. HRMS (FAB) *m/z* calcd for $C_{29}H_{35}O_5S$: (M + H) 495.2205. Found: 495.2216.

***S*-Triphenylmethyl-11-mercapto-3,6,9-trioxaundecanoic acid, 12**. To a solution of 2 g (4.04 mmol) of **11** in 12.2 mL of ethanol was added 1.6 mL (0.648 g; 16.16 mmol) of 10 M NaOH, and the mixture was stirred for 90 min. The mixture was acidified with 1 N HCl to a pH of 2 and partitioned between 200 mL of EtOAc and 200 mL of 1 N HCl. The aqueous layer was washed with two 200 mL portions of EtOAc. The combined EtOAc layers were dried ($MgSO_4$), filtered, and concentrated to give 1.84 g (97%) of **12** as a viscous oil which solidified on standing to give a white solid; mp 59−60 °C. ^{1}H NMR ($CDCl_3$): δ 2.46 (t, 2H), 3.32 (t, 2H), 3.48 (m, 2H), 3.65 (m, 2H), 3.70 (m, 2H), 3.75 (m, 2H), 4.14 (s, 2H), 7.22−7.34 (m, 9H), 7.44 (m, 6H). ^{13}C NMR ($CDCl_3$): δ 31.9, 66.8, 69.6, 69.8, 70.2, 70.4, 71.3, 126.6, 127.8, 129.6, 145.0, 173.2. HRMS (ESI) *m/z* calcd for $C_{27}H_{30}O_5SNa$: (M + Na) 489.1712. Found: 489.1723. Anal. ($C_{27}H_{30}O_5S$) C, H.

4′-Nitrophenyl-*S*-triphenylmethyl-11-mercapto-3,6,9-trioxaundecanoate, 13. To a solution of 1.5 g (3.21 mmol) of **12** in 15 mL of CH_2Cl_2 cooled to 0 °C were added 0.447 g (3.21 mmol) of *p*-nitrophenol and 0.93 g (4.48 mmol) of DCC, and the mixture was stirred at room temperature for 18 h. To the mixture was added 105 μL (0.108 g; 1.79 mmol) of acetic acid, and stirring was continued at room temperature for 1 h. The mixture was placed in the freezer for 30 min and filtered. The filtrate was concentrated, and the residue was purified by silica gel chromatography (70/30/1 hexane/EtOAc/HOAc) to give 1.65 g (87%) of **13** as white crystals; mp 73−74 °C. ^{1}H NMR ($CDCl_3$): δ 2.47 (t, 2H), 3.35 (t, 2H), 3.48 (m, 2H), 3.62 (m, 2H), 3.75 (m, 2H), 3.85 (m, 2H), 4.47 (s, 2H), 7.20−7.35 (m, 11H), 7.42 (m, 6H), 8.29 (d, 2H). ^{13}C NMR ($CDCl_3$): δ 32.0, 66.6, 68.5, 69.6, 70.1, 70.4, 70.8, 71.2, 122.2, 125.2, 126.7, 127.9, 129.6, 145.0, 155.0, 168.5. HRMS (FAB) *m/z* calcd for $C_{33}H_{33}O_7SNa$: (M + Na) 610.1875. Found: 610.1904. Anal. ($C_{33}H_{33}NO_7S$) C, H, N.

Attachment of Linker 13 to 1a, Synthesis of Compound 15a. To 15 mg (0.013 mmol) of compound **1a** were added 160 μL of a solution of 29.5 mg of compound **13** and 17.5 μL of diisopropylethylamine in 0.5 mL of DMF. The mixture was stirred for 2 h and

[a] Five mice per group were immunized with peptide−KLH conjugate **19a** or **19b**. Three weeks later, the mice were treated with tetravalent peptide conjugate. Five days later, the mice were boosted with peptide−KLH conjugate. Seven days later, the mice were bled. [b] Antigen-binding capacity (ABC) (see refs *15* and *16*). [c] ABC significantly lower than control (experiment 1, $p = 0.0157$; experiment 2, $p = 0.0015$; experiment 4, $p = 0.0015$).

precipitated by addition of Et_2O. The precipitate, compound **14a**, was dried under vacuum and dissolved in 650 μL of a solution of 1/1/0.056/0.040 TFA/CH_2Cl_2/thiophenol/Me_2S, and the solution was allowed to stand for 1 h. Precipitation by addition of Et_2O gave crude compound **15a** which was purified by HPLC (C18, 15−45% CH_3CN/H_2O 0.1% TFA). Fractions containing pure product were lyophilized to give 8.6 mg (48%) of **15a** as a white solid; MS (ESI): *m/z* (M + H) 1357.

Attachment of Linker 13 to 1b, Synthesis of Compound 15b. To 100 mg (0.084 mmol) of compound **1b** was added 1.05 mL of a solution of 88.5 mg of compound **13** and 52.5 μL of diisopropylethylamine in 1.5 mL of DMF. The mixture was stirred for 16 h and precipitated by addition of Et_2O. The precipitate, compound **14b**, was dried under vacuum and dissolved in 3.35 mL of a solution of 1/1/0.056/0.040 TFA/CH_2Cl_2/thiophenol/Me_2S, and the solution was allowed to stand for 2 h. Precipitation by addition of Et_2O gave crude compound **15b** which was purified by HPLC (C18, 15−45% CH_3CN/H_2O 0.1% TFA). Fractions containing pure product were lyophilized to give 60 mg (51%) of **15b** as a white solid; MS (ESI): *m/z* (M + H) 1402.

Conjugate 16a. To a solution of 45 mg (33.2×10^{-6} mol) of **15a** in 3.32 mL of He-sparged pH 8.5, 200 mM borate buffer was added 1.02 mL of a 8.2 mg/mL solution of **3** in MeOH. The mixture was stirred for 16 h and 12 mL of 10% HOAc/H_2O solution was added. The mixture was purified by HPLC (C18, gradient 30−45% CH_3CN/H_2O 0.1% TFA) to give 9.0 mg of **16a**; MS (ESI) *m/z* calcd for $C_{270}H_{443}N_{68}O_{80}S_8$: (M + H) 6178. Found: 6179.

Conjugate 16b. To a solution of 33.1 mg (23.6×10^{-6} mol) of **15b** in 2.8 mL of He-sparged pH 8.5, 100 mM borate buffer was added 707 μL of a 8.4 mg/mL solution of **3** in MeOH. After 2 h, another 6.6 mg of **15b** was added. The mixture was stirred for 3 h and 0.5 mL of 10% HOAc/H_2O solution was added. The mixture was purified by HPLC (C18, gradient 30 to 40% CH_3CN/H_2O 0.1% TFA) to give 23.0 mg of **16b** MS (ESI) *m/z* calcd for $C_{270}H_{455}N_{80}O_{80}S_8$: (M + H) 6359. Found: 6361.

Conjugate 17a. To a solution of 8.6 mg (6.3×10^{-6} mol) of **15a** in 630 μL of He-sparged, pH 8.5, 200 mM borate buffer was added 40 μL of a 40 mg/mL solution of **2** in 9/1 MeOH/H_2O. The mixture was stirred for 24 h, and 1 mL of 10% HOAc/H_2O solution was added. The mixture was purified by HPLC (C18, gradient 25 to 55% CH_3CN/H_2O 0.1% TFA) to give 8.3 mg of **17a**. MS (ESI) *m/z* calcd for $C_{284}H_{485}N_{70}O_{82}S_8$: (M + H) 6449. Found: 6449.

Conjugate 17b. To a solution of 38.0 mg (27.1×10^{-6} mol) of **15b** in 2.7 mL of He-sparged, pH 8.5, 100 mM borate buffer was added 452 μL of a 13.5 mg/mL solution of **2** in MeOH. The mixture was stirred for 2 h and 0.5 mL of 10% HOAc/H_2O solution was added. The mixture was purified by HPLC (C18, gradient 15 to 35% CH_3CN/H_2O 0.1% TFA) to give 20.0 mg of **17b**; MS (ESI) *m/z* calcd for $C_{284}H_{497}N_{82}O_{82}S_8$: (M + H) 6629. Found: 6629.

Preparation of KLH Conjugate, 19a. Compound **15a** (2.5 mg, 1.8 μmol) was dissolved in 0.43 mL of PBS containing 1 mM EDTA, and to the resulting solution was added 0.43 mL of a 10 mg/mL solution of maleimidyl-activated KLH (Pierce Chemical catalog no. 77105) in water. The mixture was tumbled slowly for 2h at room temperature and was exhaustively dialyzed against PBS at 4 °C. The presence of conjugated peptide was demonstrated by the binding of relevant ACA to microplates coated with KLH−peptide conjugate (*14*).

Preparation of KLH Conjugate, 19b. The preparation of **19b** was done essentially similarly to the preparation of **19a** using **15b** instead of **15a**.

Preparation of HOP Peptide, 20a. Compound **20a** was prepared essentially similarly to the preparation of **20b**, using **1a** instead of **1b**, to provide **20a** as a white solid. MS (ESI): *m/z* $(M + H)^+$ 1299.

Preparation of HOP Peptide, 20b. To a solution of 10 mg (8.4 μmol) of peptide **1b** in 840 μL of pH 8.5 200 mM sodium borate buffer was added 110 μL (41.8 μmol) of a solution of a 100 mg/mL solution of 3-(4′-hydroxyphenyl)propionic acid *N*-hydroxysuccinimidyl ester in DMSO. After 2 h, 10 mL of 8/1/1 H_2O/CH_3CN/HOAc was added, and the resulting solution was loaded onto a preparative HPLC column and purified by HPLC (C_{18}, 12 mL/min, gradient 8/2/0.1 H_2O/CH_3CN/TFA to 6/4/0.1 H_2O/CH_3CN/TFA over 40 min, 210 nm, retention time 26−30 min) to provide 6 mg of **20b** as a white solid after lyophilization. MS (ESI): *m/z* $(M + H)^+$ 1343.

In Vivo Biology. Mice (C57Bl/6, five mice per group) were immunized with **19a** or **19b**, a conjugate of the peptide covalently attached to KLH. The immunizations were accomplished by intraperitoneal (IP) injection of 0.5 mL of a solution containing 10 μg of the conjugate (**19a** or **19b**) precipitated on 2 mg of alum and 2×10^9 *Bordetella pertussis* organisms as an adjuvant (*15*). Three weeks after immunization, the mice were injected, IP, with the test toleragens **16a**, **16b**, **17a**, or **17b** at the doses indicated in Table 2. Mice immunized with **19a** were injected with **16a** or **17a**, while mice immunized with **19b** were injected with **16b** or **17b**. A control group was injected with 0.5 mL of saline instead of the toleragen. Five days later, mice in both groups were boosted with the peptide−KLH conjugate in saline solution. Seven days later, all of the mice were bled, and serum was harvested. The anti-peptide antibody levels of the serum, reported as antigen-binding capacity (ABC), was determined by a Farr assay where the radioactive antigen **20a** or **20b** was present at 10^{-8} M (*15*, *16*).

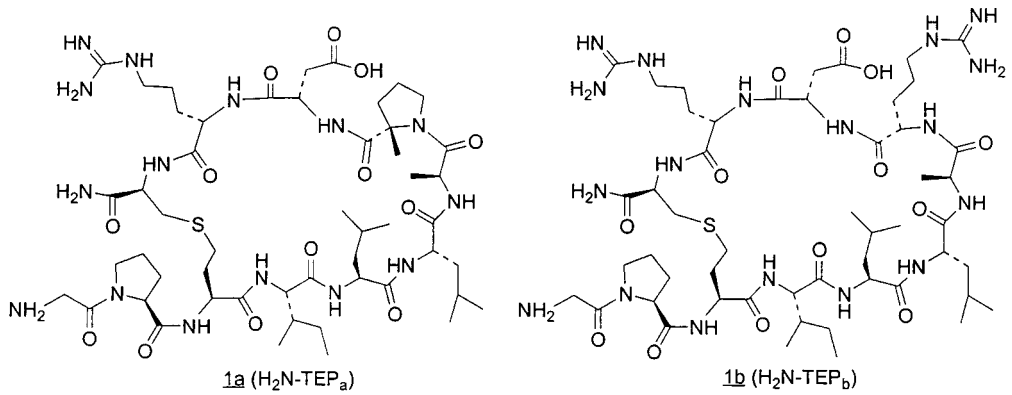

Figure 1.

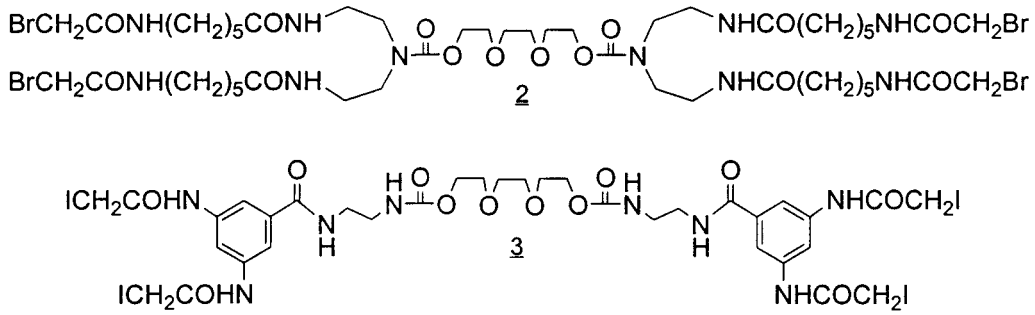

Figure 2.

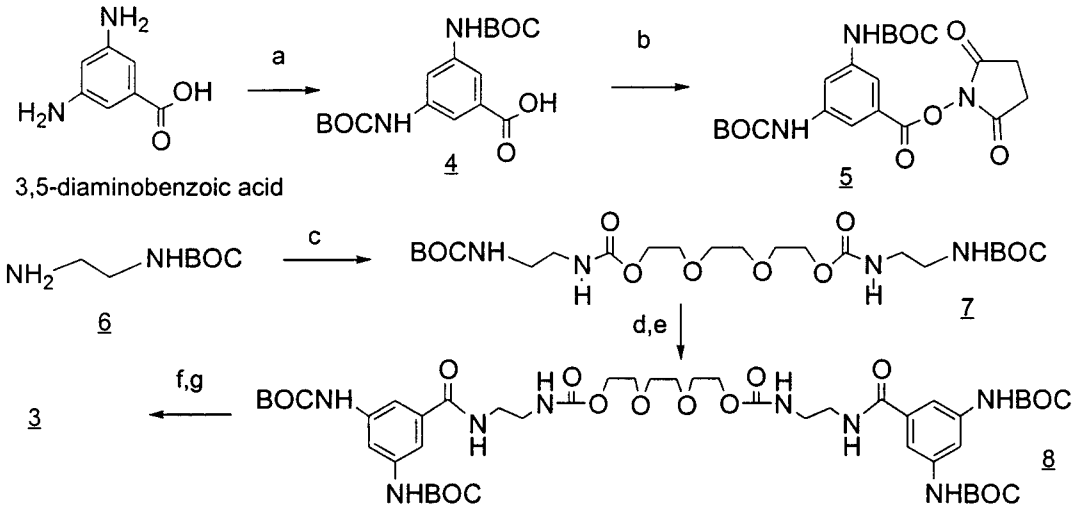
Determination of Serum Levels of Anti-Peptide Antibodies Using the Farr Assay. Hydroxyphenylated peptide, **20a** or **20b**, was trace radiolabeled as follows. To 50 μg of hydroxyphenylated peptide in 50 μL of, pH 7.5, 100 mM phosphate buffer (PB) was added 1 mCi of ^{125}I (New England Nuclear, NE2−033H) followed by 25 μL of a solution of 2 mg/mL of chloramine T in PB. After 1.5 min, a solution of 25 μL of a solution of 2 mg/mL of sodium metabisulfite in PB was added. The mixture was loaded onto a Sep-pak C_{18} cartridge (Waters part no. 020515), which had been washed with CH_3CN followed of H_2O. The column was eluted with H_2O to wash away salts, then with 50/50 CH_3CN/H_2O to elute peptide. Radiolabeled peptide fractions were pooled and used as radioactive antigen in the Farr assay (*15*). Serum samples from the mice were diluted by factors of 6, 36, and 216 with 10% normal rabbit serum in 0.1 M, pH 8.6, borate buffer, and the radiolabeled peptide was added to the mixture to give a peptide concentration of 10^{-8} M. The IgG was precipitated by addition of an equal volume of saturated ammonium sulfate solution, and the counts in the precipitate were measured to determine the percentage of counts bound to the IgG. The values are reported in Table 2 as antigen-binding capacity (ABC) (*16*).

Serum Stability Studies. To 720 μL of mouse serum (Sigma) was added 80 μL of a 10 mg/mL solution of conjugate (**16a**, **16b**, **17a**, or **17b**) in water, and the mixture was incubated at 37 °C. For each time point, 100 μL of the mixture was added to 900 μL of a cocktail which contained **1b** as an internal standard (80 μL of a 10 mg/mL solution of **1b** in water added to 7.12 mL of a 1 M solution of guanidine HCl in 99/1 water/TFA). The resulting solution was loaded onto a C_{18} Extract Clean column (Alltech Associates Inc., part no. 205 000, 100 mg/1.0 mL) which had been washed with 2 mL of MeOH and 4 mL of water. The peptide conjugate and internal standard were eluted with 1 mL of MeOH, and the eluate was filtered and analyzed by HPLC (C_{18}, gradient 15/85/0.1 CH_3CN/H_2O/TFA to 30/70/0.1 CH_3CN/H_2O/TFA, 0 to 10 min, then 30/70/0.1 CH_3CN/H_2O/TFA to 35/65/0.1 CH_3CN/H_2O/TFA, 10 to 20 min).

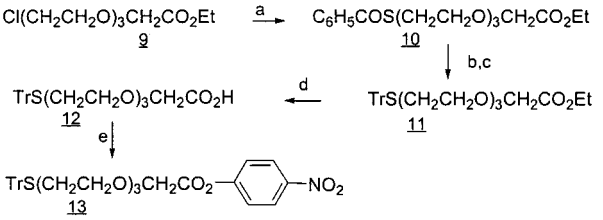
DISCUSSION AND RESULTS



To test the ability of cyclic thioether peptides **1a** and **1b** to effect tolerance when presented on a multivalent platform, chemistry was developed to prepare both tolerageneic and immunogenic conjugates.

Peptides have been conjugated to a variety of substances including other peptides, proteins, and carrier molecules. Some examples of the various methods used are mentioned below. Each method has its own advantages and disadvantages, and the best method for a particular application depends on a number of factors such as what functional groups are present on each partner in the coupling reaction and the solvent compatibility of the partners.

Condensation of protected peptide fragments with amino poly(ethylene glycol) (amino-PEG) has provided PEG−peptide conjugates (*17*). Carboxy-terminal cysteines have been used to link peptides to PEG via disulfide bonds (*18*). Peptide segments have been ligated to provide native proteins by taking advantage of the ability of an N-terminal cysteine on one peptide to react with C-terminal thioesters on another peptide to give a thioester which can rearrange to a natural amide bond (*19*). Ligation via thiazolidine formation between a C-terminal aldehyde and an N-terminal cysteine is another method of connecting two unprotected peptides (*20*). For a review of protein synthesis by chemical ligation see Walker (*21*).



Bromoacetylated peptides have been attached to antibodies (*22*) or ligated to a second cysteine-containing peptide (*23*) via thioether bonds. Peptides with cysteine sulfhydryl groups have been attached to DNA using thioether bonds (*24*). Another method of attaching peptides to other biomolecules is oxime formation between aminooxy peptides and aldehyde or ketone groups (*25*).

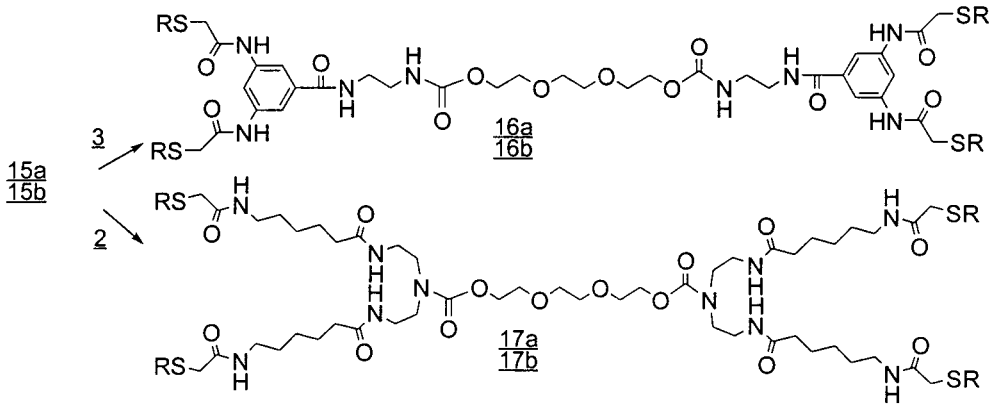
Reductive amination of peptide amino groups with oxidized dextran has been used to immobilize peptides on ELISA plates (*26*).

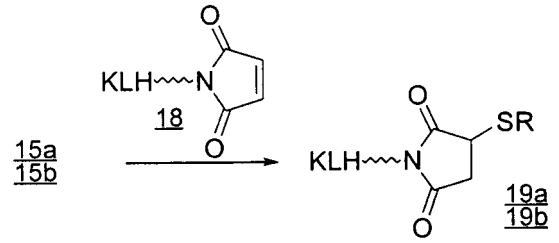
In this report, multivalent thioether peptide conjugates were prepared by first attaching a thiol-containing linker to the thioether peptides, then using the thiol to form a thioether bond with a multivalent haloacetyl platform molecule. This provides a tetravalent conjugate consisting of four identical cyclic thioether peptides attached to a common nonimmunogenic carrier platform. The objective of preparing such conjugates was to test their ability to tolerize an anti-peptide immune response in a model in which mice were immunized with peptide attached to keyhole limpet hemocyanin (KLH).



Cyclic thioether peptide analogues **1a** (H_2N-TEP_a) and **1b** (H_2N-TEP_b), which compete with β_2GPI for selected ACA are shown in Figure 1. The sequences of these peptides were derived from phage libraries which contained two fixed cysteines with seven variable amino acids between the cysteines (*27*). Phage which bound ACA were sequenced, and the sequences were used to prepare peptides which bound ACA when oxidized to cyclic disulfides. Peptides **1a** and **1b** are analogues of the primary sequences in which the disulfide bond is replaced with a thioether bridge. In addition peptide **1a** contains an α-methyl proline replacement of a sequence which originally contained a proline at that position. Incorporation of α-methyl proline resulted in tighter binding to ACA and is expected to confer protease resistance.

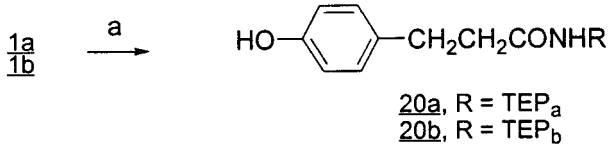
Peptides **1a** and **1b** were prepared by two different methods for preparing cyclic thioether analogues of cyclic disulfide peptides. Compound **1a** was prepared, as previously described, using a presynthesized thioether intermediate, which was incorporated in solid-phase synthesis (*8*). This method used an amide bond formation to affect cyclization. Compound **1b** was prepared by an alternate method which involved cyclization of a cysteine sulfhydryl with a 4-chloro-2-amino-butyric acid residue which was incorporated in solid-phase synthesis (*9*). The only difference between **1a** and **1b**, is in the fourth amino acid from the C-terminus. Compound **1a** has an (*S*)-α-methylproline at that position, whereas compound **1b** has an arginine at that position. The α-methylproline analogue was included in this study, because it was anticipated that it would have greater metabolic stability. Both analogues have similar ACA binding properties. The relative molar concentrations for 50% inhibition (IC_{50}) of binding of ACA to β_2GPI for **1a** and **1b** are 1.32×10^{-4} M and 2.17×10^{-4} M (*28*).

Tetravalent conjugates of both cyclic thioether peptide analogues, **1a** and **1b**, were prepared using two platforms, compounds **2** and **3**, which are shown in Figure 2. Compound **2** was available from previous studies (*4*). Compound **3** was designed as a hybrid of **2** and a poly(ethylene glycol)-based platform (*3*) which had been previously used successfully in earlier tolerance studies with melittin peptides (*29*).



The synthesis of compound **3** is described in Scheme 1. The amino groups of 3,5-diaminobenzoic acid were protected with *tert*-butyloxycarbonyl (BOC) groups to provide compound **4**. Treatment of **4** with *N*-hydroxysuccinimide in the presence of DCC gave the NHS ester, **5**. Mono-BOC-protected ethylenediamine, **6**, (*12*) was condensed with triethylene glycol bis-chloroformate to provide **7**. The BOC groups were removed, and the resulting

Scheme 4[a]



[a] a, R = $(CH_2CH_2O)_3CH_2CONH\text{-}TEP_a$; b, R = $(CH_2CH_2O)_3CH_2CONH\text{-}TEP_b$.

Scheme 5[a]

[a] a, R = $(CH_2CH_2O)_3CH_2CONH\text{-}TEP_a$; b, R = $(CH_2CH_2O)_3CH_2CONH\text{-}TEP_b$.

Scheme 6[a]

[a] (a) 3-(4′-Hydroxyphenyl)propionic acid *N*-hydroxy succinimidyl ester, DMSO, pH 8.5, borate.

diamine was condensed with **5** to provide **8**. Finally, the BOC groups were removed and the resulting amines were acylated with iodoacetic anhydride to provide **3**.

A trityl protected thiol linker, compound **13**, was developed which could be attached to the N-terminus of **1a** or **1b** via acylation. This linker was designed to provide some distance between the platform and the peptide, and to provide water solubility. The synthesis of **13** is diagramed in Scheme 2. Chlorotriethylene glycol was converted to compound **9** by a modification of an existing procedure (*13*). Treatment of **9** with thiobenzoic acid provided the thioester **10**. The thioester was removed by treatment with sodium ethoxide, and the resulting thiol was protected by tritylation to give trityl-thioether **11**. The ester was saponified with sodium hydroxide to provide the acid **12**, which was esterified with DCC and *p*-nitrophenol to provide **13**.

The linker was attached to thioether peptides **1a** ($H_2N\text{-}TEP_a$) and **1b** ($H_2N\text{-}TEP_b$) by acylation at the N-terminus by reaction with **13** as shown in Scheme 3. The resulting peptide products with linker attached, **14a** and **14b**, were treated with trifluoroacetic acid in the presence of scavengers to remove the trityl group and provide **15a** and **15b**, the peptides with the free thiol linker.

Tetravalent conjugates were prepared as described in Scheme 4. Compound **15a** was reacted with platform **3** in pH 8.5 aqueous sodium borate to provide **16a**. Reaction of **15a** with **2** in the same buffer gave conjugate **17a**. Compound **15b** reacted with **3** to give **16b** and with **2** to give **17b**. The reaction mixtures, containing crude conjugates, were loaded directly onto a preparative HPLC column for purification by preparative HPLC.

KLH conjugates **19a** and **19b** were prepared for the purpose of immunizing and boosting mice with peptide. The KLH conjugates were prepared as follows and as described in Scheme 5. A solution of **15a** or **15b** in PBS was added to an aqueous solution of KLH which was modified with maleimide groups on lysine ϵ-amines (compound **18**, Pierce Chemical Co.) resulting in the formation of putative KLH peptide conjugates **19a** and **19b**. These conjugates were not chemically characterized, since KLH itself is an ill-defined multisubunit-containing protein; however, they were characterized by their ability to bind ACA when coated on ELISA plates. The conjugates were also characterized functionally by their ability to elicit an anti-peptide immune response in mice.

Hydroxyphenylated peptides, **21a** and **21b**, were prepared as follows for use in the Farr assay, a solution phase assay for determining antigen binding capacity (ABC) (*15*). Thus, peptides **1a** and **1b** were hydroxyphenylated by adding a solution of 3-(4′-hydroxyphenyl)-propionic acid N-hydroxysuccinimidyl ester (Taggit, Novabiochem) in DMSO to a solution of peptide in pH 8.5 borate buffer to provide **20a** and **20b** as described in Scheme 6.

The Farr assay is a radioimmunoprecipitation assay which measures the amount of radiolabled antigen found in immunoglubulin which has been precipitated in the presence of antigen. The Farr assay is our method of choice for measuring antibody levels when the unbound antigen does not precipitate under the antibody-precipitating conditions. It is our method of choice because it is a relatively simple assay to run, it is reproducible, and it gives a numerical result, the antigen-binding capacity (ABC), which is independent of the dilution at which the assay is run.

An immunization protocol was designed to specifically produce antibodies against the peptide. These anti-peptide antibodies would not exist in the absence of the immunization, because the peptide is totally synthetic. Thus, the ability of compounds **16a**, **16b**, **17a**, and **17b** to tolerate an anti-peptide immune response was tested in mice which were immunized with the relevant peptides conjugated to KLH, conjugates **19a** and **19b**. Three weeks later the mice were treated with one of the tetravalent peptide conjugates, **16a**, **16b**, **17a**, or **17b**. Five days after treatment with the tetravalent peptide conjugates, the mice were boosted with a second administration of the relevant peptide conjugated to KLH (**19a** or **19b**). Seven days after boosting, the ABC of treated and control mice

Table 3. Degradation of Conjugates 16a, 16b, 17a, and 17b in Mouse Serum

compd	time to 50% degradation (h)
16a	10.7
16b	3.6
17a	13.3
17b	3.0

were measured using a Farr assay at dilutions of 1/6, 1/36, and 1/216 (*15*). These data are summarized in Table 2. The specificity of the treatments was demonstrated with measurements of both anti-peptide antibody titers using the Farr assay, and anti-carrier (KLH) antibodies using an ELISA assay (*30*). Three of the conjugates, **16a**, **16b**, and **17b**, resulted in a significant reduction in the anti-peptide antibody levels, whereas, there were no reductions in the anti-KLH antibody levels in any of the experiments (data not shown). Thus, these toleragens were specific for downregulating the anti-peptide response without affecting the response to the protein carrier, KLH. Conjugate **17a** did not reduce the anti-peptide response at the doses used, perhaps due to differences in the distribution, clearance, or metabolic properties of **17a** from the other conjugates. The stabilities of the conjugates in serum were studied to determine if ability to tolerize correlated to metabolic stability. The results, shown in Table 3, indicate that compound **17a** is actually the most stable conjugate of the four conjugates tested in normal mouse serum, so its lack of tolerance activity cannot be explained by the issue of susceptibility to serum proteases.

These studies show that cyclic thioether peptide antigen mimotopes, when presented as a tetravalent conjugate, can cause downregulation of an anti-peptide antibody response. The downregulation is specific to the antibodies against the immunizing peptide as evidenced by no downregulation of antibodies against the carrier protein, KLH, which was used in the immunization. The downregulation is evidence of B cell tolerance, since the tetravalent conjugate is administered 5 days before the boost, at which time little or no toleragen would be present.

(14) The direct binding ELISA was carried out as follows. Immulon II 96-well microplates (Dynatech laboratories, Inc.) were treated with 100 μL/well of dilutions of KLH−peptide conjugate at concentrations of 0−4 μg/mL in an aqueous solution consisting of 15 mM Na_2CO_3 and 35 mM $NaHCO_3$ for 2 h. The liquid was removed, and each well was treated with 200 μL of 0.5% (w/v) bovine serum albumin (BSA, Sigma Chemical catalog no. A7638) in TBS for 2 h. Each well was washed 5 times with TBS and treated with 100 μL of ACA-6501 serum or normal AB serum diluted in 0.5% BSA/TBS for 1 h with gentle agitation, then washed 5 times with TBS. Each well was treated with goat anti-human IgG alkaline phosphatase conjugate (Zymed, catalog 15, no. 62-8422) diluted 1:1000 in 0.5% BSA-TBS (100 μL) for 1 h, washed 5 times with TBS and developed by adding 100 μL of PPMP solution (7.8 g of phenolphthalein monophosphate and 69.5 g of 2-amino-2-methyl-1-propanol in 100 mL of water and diluted 1:26 with water immediately before use). Color development was stopped by adding 50 μL of 0.2 M Na_2HPO_4 solution to each well. Absorbance at 550 nm was read and plotted vs amount of KLH−peptide added.

(16) The percentage of antigen bound multiplied by the dilution factor is the same as the antigen binding capacity (ABC) up to 35% bound, because the percentage of antigen bound is directly proportional to dilution in that range. For bindings greater than 35%, the log of ABC is proportional to the log of the percentage bound and is calculated by the following formula [ABC = [2 × 1/10 antilog(% bound/35 × log 3.5)] × dilution factor]. Values of ABC reported are the average of ABC values calculated from percentage of antigen bound in the range 10−70% (*15*).

(28) ACA ELISA data were obtained as follows. Polystyrene microtitration plates were coated with cardiolipin (50 μg/well) in ethanol. After evaporation of solvent, wells were blocked (5% fish gelatin/PBS, pH 7.2), washed (TBS, pH 7.4), and coated with β_2GPI (2.3% IgG-depleted normal human serum). Wells were incubated with a mixture of peptide and ACA serum, diluted 1:400 with 3% fish gelatin in 1:1 TBS/PBS, then washed (TBS) and treated with goat anti-human IgG alkaline phosphatase conjugate. After washing with TBS, the wells were treated with colorimetric substrate to determine the amount of ACA bound. The IC_{50} is the concentration of peptide that inhibited ACA binding by 50%.

External imaging of energy production activity of living cells with ^{99m}Tc-labeled compounds is a challenging task requiring good design of ^{99m}Tc-radiopharmaceuticals. On the basis of our recent findings that ^{11}C- and ^{123}I-labeled medium-chain fatty acids are useful for measuring β-oxidation activity of hepatocytes, we focused on development of ^{99m}Tc-labeled medium-chain fatty acid analogues that reflect β-oxidation activity of the liver. In the present study, monoamine−monoamide dithiol (MAMA) ligand and triamido thiol (MAG) ligand were chosen as chelating groups because of the stability and size of their complexes with ^{99m}Tc and their ease of synthesis. Each ligand was attached to the ω-position of hexanoic acid (MAMA-HA and MAG-HA, respectively). In biodistribution studies, [^{99m}Tc]MAMA-HA showed high initial accumulation in the liver followed by clearance of the radioactivity in the urine. Analysis of the urine revealed [^{99m}Tc]MAMA-BA as the sole radiometabolite. Furthermore, when [^{99m}Tc]MAMA-HA was incubated with living liver slices, generation of [^{99m}Tc]-MAMA-BA was observed. However, [^{99m}Tc]MAMA-HA remained intact when the compound was incubated with liver slices in the presence of 2-bromooctanoate, an inhibitor of β-oxidation. The findings in this study indicated that [^{99m}Tc]MAMA-HA was metabolized by β-oxidation after incorporation into the liver. On the other hand, poor hepatic accumulation was observed after administration of [^{99m}Tc]-MAG-HA.

INTRODUCTION

In the liver, the parenchymal cells are responsible for the metabolism of many substances, and parenchymal cell function is also related to the reserve capacity of the liver (*1*−*3*). Therefore, the development of radiopharmaceuticals which reflect viability of hepatocytes might provide us useful information for predicting prognosis after surgery or determining the efficacy of the treatment.

The β-oxidation of fatty acids is an important pathway for the production of energy for activity of hepatocytes (*4*, *5*). In addition to β-oxidation, however, long-chain fatty acids are esterified and retained in the liver to a fairly large extent. On the other hand, medium-chain fatty acids such as octanoate and hexanoate are recognized only as substrates for β-oxidation and are not esterified in the hepatocytes (*6*−*8*). Indeed, [1-^{11}C]octanoate was metabolized rapidly to $^{11}CO_2$ by β-oxidation and cleared quickly from the liver. In addition, the hepatic elimination rate of the radioactivity was significantly delayed in animal models of hepatitis (*9*). Such characteristics render [1-^{11}C]octanoate useful as a radiopharmaceutical for measuring the viability of hepatocytes by positron emission tomography (PET) imaging.

Medium-chain fatty acid analogues labeled with single photon emitters are more desirable for routine clinical studies to estimate the viability of hepatocytes. We recently found that *p*-[^{123}I]iodophenylenanthic acid ([^{123}I]-IPEA) was taken up by the liver following administration and elimination rate of the final radiometabolite, *p*-iodohippuric acid, from the liver reflected β-oxidation activities of the hepatocytes. A significant delay in elimination of the radioactivity from the liver was observed in hepatitis models (*10*). These findings prompted us to further examine the use of ^{99m}Tc-labeled medium-chain fatty acid analogues for hepatic studies since ^{99m}Tc possesses ideal characteristics for a radiopharmaceutical such as optimal γ-ray energy (141 keV), short half-life (6 h), low-cost, and widespread availability of the ^{99}Mo/^{99m}Tc generator.

Introduction of a chelating group is necessary for labeling of fatty acids with ^{99m}Tc based on the idea of bifunctional chelating agent. A variety of chelating groups have been developed for such purposes. Among these groups, two ^{99m}Tc chelating groups were chosen as candidates in the present study because of the stability and molecular size of their complexes with ^{99m}Tc and ease of synthesis, and each chelating group was attached to the ω-position of hexanoic acid. One was a recently reported monoamine−monoamide dithiol (MAMA) ligand, which forms a stable, neutral, and slightly lipophilic mononuclear ^{99m}Tc complex with pentavalent $^{99m}TcO^{3+}$ (*11*−*13*). The amino nitrogen was the site of attachment to hexanoic acid (MAMA-HA). The other chelating group was a triamide thiol group (N_3S) which has been used clinically as a ^{99m}Tc complex of mercaptoacetylglycylglycylglycine (MAG_3) (*14*−*16*). It forms a negatively charged mononuclear ^{99m}Tc complex with pentavalent $^{99m}TcO^{3+}$. The terminal glycine of MAG_3 was altered to 6-amino-

hexanoic acid (MAG-HA). The biodistribution and metabolism of the two ^{99m}Tc-labeled medium-chain fatty acid analogues were investigated in rats to estimate the molecular design for measuring the viability of hepatocytes.

MATERIALS AND METHODS

Materials. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Bruker AC-200 spectrometer, and the chemical shifts are reported in parts per million (ppm) downfield from an internal tetramethylsilane standard. Fast-atom bombardment mass spectra (FABMS) were obtained with a JMS-HX/HX 110 A (JEOL Ltd. Tokyo). Imaging studies were performed using a SPECT2000H-40 (Hitachi Medical Co., Tokyo). [^{99m}Tc]-Pertechnetate ($^{99m}TcO_4^-$) was eluted in saline solution on a daily basis from Daiichi Radioisotopes Labs generator (Chiba, Japan). Reversed-phase high performance liquid chromatography (RP-HPLC) was performed using a Cosmosil 5C_{18}-AR 300 column (150 × 4.6 mm; Nacalai Tesque Co., Ltd., Kyoto). TLC analysis was performed with silica plates (Merck Art 5553). All chemicals were of reagent grade and were used as received.

Synthesis of Tr-MAMA-HA and Its Analogues. *N-[[[2-[(Triphenylmethyl)thio]ethyl]amino]acetyl]-S-(triphenylmethyl)-2-aminoethanethiol (Tr-MAMA) (**3**).* Trityl chloride (27.3 g, 97.9 mmol) and compound **1** (11.1 g, 97.7 mmol) were dissolved in 150 mL of *N*,*N*-dimethylformamide (DMF), and the reaction mixture was stirred for 48 h at room temperature. The solvent was removed in vacuo, and the residue was dissolved in ethyl acetate. After cooling the solution on ice, a saturated solution of $NaHCO_3$ was gradually added. The precipitated white crystals were collected and washed with distilled water to afford compound **2** as the crude product. Crude **2** (9.97 g, 28 mmol) in chloroform (ca. 50 mL) was mixed with triethylamine (14 mL), and the mixture was gradually added to a solution of bromoacetyl bromide (2.84 g, 14 mmol) in 40 mL of chloroform at −78 °C. The reaction mixture was stirred at the same temperature for 30 min and warmed to room temperature over a period of 1 h. After stirring at room temperature for 24 h, the mixture was washed with diluted H_2SO_4 (pH 3), saturated $NaHCO_3$, and brine. The organic layer was dried over anhydrous $CaSO_4$, and the solvent was removed in vacuo. The crude product of compound **3** was obtained after silica gel column chromatography of the oil residue eluted with chloroform. Further purification was performed by silica gel chromatography using ethyl acetate−hexane (60:40) as the eluent to produce 3 (0.95 g, 10.0% from **2**) as a pale yellow oil. ^{1}H NMR ($CDCl_3$): ***δ*** 7.44−7.15 (overlapped m, 30H), 3.07 (td, 2H), 3.02 (s, 2H), 2.45 (t, 2H), 2.38−2.31 (overlapped m, 4H). FABMS calcd for $C_{44}H_{42}N_2OS_2$ ($M + H^+$): m/z 679. Found: 679.

*N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-6-aminohexanoic Acid Methyl Ester (**5**).* Methyl 6-bromohexanoate (**4**) (160 mg, 0.77 mmol) in 8 mL of acetonitrile was gradually added to a mixed solution of Tr-MAMA (400 mg, 0.59 mmol) and diisopropylethylamine (120 mg, 1.84 mmol) in 2 mL of acetonitrile. After stirring the reaction mixture at room temperature for 48 h, the solvent was removed in vacuo. The oily residue was purified by silica gel chromatography using ethyl acetate−hexane (95:5) as the eluent to provide compound **5** (117 mg, 24.6%) as a yellow oil. ^{1}H NMR ($CDCl_3$): *δ* 7.43−7.15 (overlapped m, 30H), 3.64 (s, 3H), 3.01 (td, 2H), 2.82 (s, 2H), 2.40−2.33 (overlapped m, 4H), 2.28−2.20 (overlapped m, 6H), 1.59−1.48 (m, 2H), 1.37−1.19 (overlapped m, 4H). FABMS calcd for $C_{51}H_{54}N_2O_3S_2$ ($M + H^+$): *m/z* 807. Found: 807.

*N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-6-aminohexanoic Acid (Tr-MAMA-HA) (**6**).* Compound **6** was obtained quantitatively as a viscous yellow oil by hydrolysis of the methyl ester of **5** in 5% NaOH. ^{1}H NMR ($CDCl_3$): *δ* 7.40−7.14 (overlapped m, 30H), 2.99 (td, 2H), 2.87 (s, 2H), 2.40−2.33 (overlapped m, 4H), 2.28−2.20 (overlapped m, 6H), 1.59−1.48 (m, 2H), 1.32−1.21 (overlapped m, 4H). FABMS calcd for $C_{50}H_{52}N_2O_3S_2$ ($M + H^+$): *m/z* 793. Found: 793.

N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-4-aminobutyric Acid (Tr-MAMA-BA). *N*-[[[[2-[(Triphenylmethyl)-thio]ethyl]amino]carbonyl]methyl]-*N*-[2-[(triphenylmethyl)thio]ethyl]-4-aminobutyric acid ethyl ester was synthesized by reaction of Tr-MAMA and ethyl bromobutyrate according to the procedure described above with 3.25% yield. ^{1}H NMR ($CDCl_3$): *δ* 7.45−7.15 (overlapped m, 30H), 4.06 (q, 2H), 3.01 (td, 2H), 2.84 (s, 2H), 2.38−2.32 (overlapped m, 4H), 2.29−2.18 (overlapped m, 6H), 1.68−1.26 (m, 2H), 1.20 (t, 3H). After hydrolysis of the ester bond, Tr-MAMA-BA was obtained. ^{1}H NMR ($CDCl_3$): *δ* 7.40−7.17 (overlapped m, 30H), 2.99 (td, 2H), 2.87 (s, 2H), 2.36−2.33 (overlapped m, 4H), 2.30−2.23 (overlapped m, 6H), 1.65−1.62 (m, 2H). FABMS calcd for $C_{48}H_{48}N_2O_3S_2$ ($M + Na^+$): *m/z* 787. Found: 787.

N-[[[[2-[(Triphenylmethyl)thio]ethyl]amino]carbonyl]-methyl]-N-[2-[(triphenylmethyl)thio]ethyl]-2-aminoacetic Acid (Tr-MAMA-AA). This compound was synthesized using Tr-MAMA and methyl bromoacetate according to the procedure described above with 17.5% yield. After hydrolysis, *N*-[[[[2-[(triphenylmethyl)thio]ethyl]amino]-carbonyl]methyl]-*N*-2-[(triphenylmethyl)thio]ethyl]-2-aminoacetic acid (Tr-MAMA-AA) was obtained (72.5%). ^{1}H NMR ($CDCl_3$): *δ* 7.39−7.14 (overlapped m, 30H), 3.10 (s, 2H), 2.99 (s, 2H), 2.98 (td, 2H), 2.50 (t, 2H), 2.34 (t, 2H), 2.24 (t, 2H). FABMS calcd for $C_{46}H_{44}N_2O_3S_2$ ($M + Na^+$): *m/z* 759. Found: 759.

Synthesis of MAG-HA. *S-Acetylthioglycolic Acid N-Hydroxysuccinimide Ester (SATA) (**10**).* *S*-Acetylmercaptoacetic acid (**9**) was synthesized from mercaptoacetic acid (**8**) according to the published procedure (*17*). Compound **9** (5.15 g, 38.5 mmol) and *N*-hydroxysuccinimide (NHS) (4.45 g, 38.5 mmol) were dissolved in 50 mL of anhydrous tetrahydrofurane (THF), and the reaction mixture was stirred at room temperature for 10 min. After cooling on ice, dicyclohexylcarbodiimide (DCC) (7.95 g, 38.5 mmol) in 5 mL of THF was added and the reaction mixture was stirred overnight. The precipitated dicyclohexylurea was removed by filtration, and the solvent was evaporated to dryness in vacuo (*18*). The residue was washed with hexane several times to afford compound **10** as white crystals (7.69 g, 86.3%). ^{1}H NMR ($CDCl_3$): *δ* 3.99 (s, 2H), 2.85 (s, 4H), 2.43 (s, 3H).

*S-Acetylmercaptoglycylglycylaminohexanoic Acid (S-acetyl MAG-HA) (**13**).* *N*-Succinimide ester of Boc-glycylglycine (compound **11**) was prepared by the reaction of Boc-glycylglycine with NHS in the presence of DCC. Compound **11** (2.37 g, 7.2 mmol) in 30 mL of acetonitrile was slowly added to a solution of 6-aminohexanoic acid (0.79 g, 6 mmol) in 0.2 M NaOH at 50−60 °C, and the reaction mixture was refluxed for 2 h. After cooling, the reaction solution on ice, the pH of the solution was brought to ca. 3 with diluted H_2SO_4, followed by extraction with ethyl acetate (20 mL × 3). The organic layers were combined and dried over anhydrous $CaSO_4$. Compound **12** (1.41 g, 56.7% from **11**) was obtained as a

viscous oil after removing the solvent in vacuo. Crude **12** (1.3 g, 3.8 mmol) was then treated with 5% anisol in trifluoroacetic acid (TFA) to deprotect the Boc group. After removing TFA in vacuo, the residue was dissolved in 20 mL of water and the solution was neutralized with 1 M NaOH. This solution was then added dropwise to a solution of SATA (1.04 g, 4.5 mmol) in 20 mL of DMF. After stirring the reaction mixture at room temperature for 2 h, the solvent was removed in vacuo to precipitate compound **13** as white crystals (396 mg, 29.1% from **12**). ^{1}H NMR ($CDCl_3$): δ 8.42 (t, 1H), 8.13 (t, 1H), 7.70 (t, 1H), 3.72 (d, 2H), 3.66 (s, 2H), 3.65 (d, 2H), 3.03 (td, 2H), 2.36 (s, 3H), 2.19 (t, 2H), 1.54−1.21 (overlapped m, 6H). FABMS calcd for $C_{14}H_{23}N_3O_6S$ ($M+H^+$): *m*/*z* 362. Found: 362.

Radiolabeling. ^{99m}Tc complexes of each ligand were prepared by ligand-exchange reaction with $^{99m}TcO_4^-$ reduced with Sn(II) glucoheptonate (GH). A solution of $^{99m}TcO_4^-$ eluted from the generator every morning was added to stock freeze-dried powder of Sn(II) GH (made from 4 g of GH and 1.2 mg of $SnCl_2$ in 50 mL of aqueous solution pH 8.6) to produce a final GH concentration of 3−5 mg/mL. After standing for 10 min, the formation of [^{99m}Tc]GH was ascertained by TLC developed with acetone.

The bistritylated compound **6** (1 mg) was treated with TFA under cation trapping conditions (5% triethylsilane) (*19*). After removing the solvent under a stream of N_2, the residue was neutralized with 1 M NaOH and 0.4 mL of phosphate buffer (0.1 M, pH 8.0). [^{99m}Tc]GH (0.4 mL) was then added to the bisthiol compound, and the reaction mixture was left for 1 h at room temperature. [^{99m}Tc]MAMA-HA was purified by RP-HPLC eluted with a gradient mobile phase starting from 10% acetonitrile in 0.05 M phosphate buffer (pH 7.0) to 100% acetonitrile in 60 min at a flow rate of 1 mL/min at 30 °C (R_t, 14 min for [^{99m}Tc]MAMA-HA, 3 min for [^{99m}Tc]GH). ^{99m}Tc complexes of MAMA-BA and MAMA-AA were prepared by procedures similar to those described above.

^{99m}Tc complex of MAG-HA was also prepared by reaction of [^{99m}Tc]GH with *S*-acetyl MAG-HA as follows. A solution of *S*-acetyl MAG-HA (3 mg) in 1 mL of phosphate buffer (0.1 M, pH 8.0) was mixed with the same volume of [^{99m}Tc]GH, and the reaction mixture was heated at 90−95 °C for 30 min. After cooling, [^{99m}Tc]-MAG-HA was purified by RP-HPLC eluted with a gradient mobile phase starting from 10% methanol in 0.05 M phosphate buffer (pH 7.0) to 50% methanol in 30 min at a flow rate of 1 mL/min at 30 °C (R_t, 20 min for [^{99m}Tc]-MAMA-HA, 3 min for [^{99m}Tc]GH).

The radiochemical yield and purity of ^{99m}Tc-labeled fatty acid analogues were determined by RP-HPLC under the conditions described above and TLC developed with acetone.

Partition Coefficient Determination. The partition coefficients of [^{99m}Tc]MAMA-HA and [^{99m}Tc]MAG-HA were measured by mixing 10 μL of each ^{99m}Tc-labeled compound with 3 g each of 1-octanol and phosphate buffer (0.1 M, pH 7.4) in a test tube. After vortexing for 1 min × 3 times, the solution was left to stand at room temperature for 20 min. Each tube was then centrifuged at 1000 × g for 5 min. Two weighed samples from the 1-octanol and buffer layers were counted in a γ counter. The partition coefficient was determined by calculating the ratio of counts per minute per gram (cpm/g) of octanol to that of buffer.

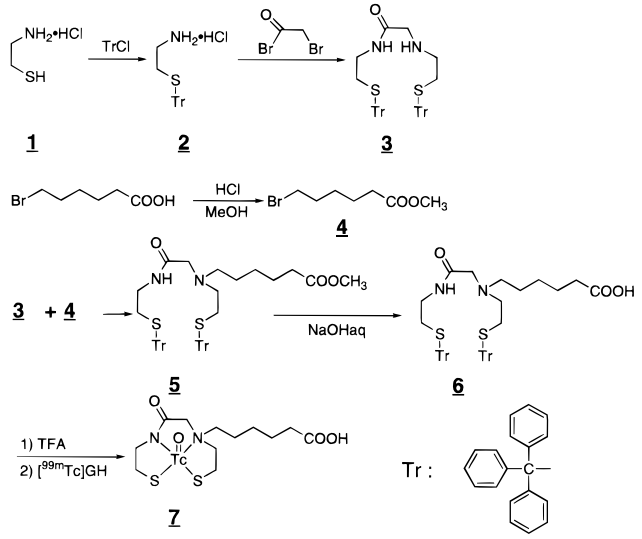
Cysteine Challenge Assay. To compare the stability of [^{99m}Tc]MAMA-HA and [^{99m}Tc]MAG-HA, a cysteine challenge assay was performed. Both ^{99m}Tc-labeled fatty acid analogues were incubated with 10 μM cysteine, which is the concentration in blood, in phosphate buffer (0.05 M, pH 7.0) at 37 °C. At 5 or 60 min after incubation, the integrity of each was analyzed by RP-HPLC under the conditions used for purification.

Animal Studies. Male Wistar rats (200−250 g) were housed for 1 week under a 12 h light/12 h dark cycle and had free access to food and water for subsequent metabolite analyses in vitro, imaging and biodistribution studies.

Planar imaging studies of ^{99m}Tc-labeled fatty acid analogues were performed as follows. Normal rats were anesthetized with pentobarbital (50 mg/kg i.p.). Dynamic planar scanning (20 s × 30 frames, 1 min × 10 frames, 2 min × 20 frames) was initiated immediately after administration of ^{99m}Tc-labeled compounds (15 MBq/0.5 mL) via the tail vein.

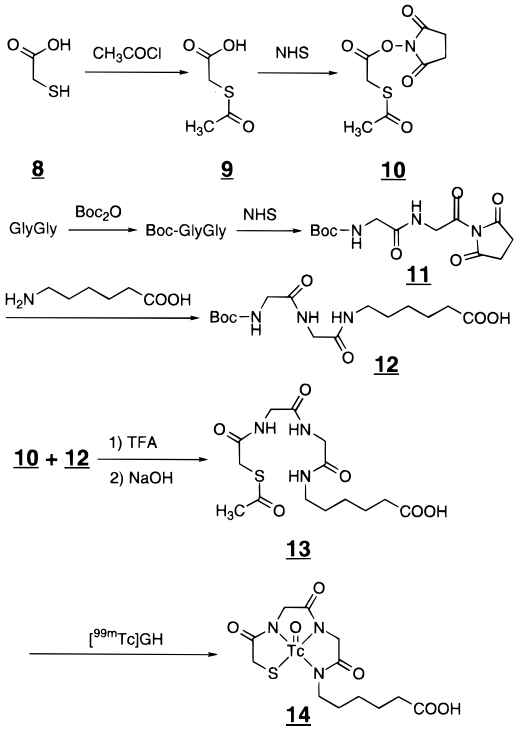
For biodistribution studies, [^{99m}Tc]MAMA-HA (37 kBq in 0.1 mL saline) was administered to normal rats via the tail vein. At appropriate time points after administration, rats were sacrificed by decapitation. Samples of blood and the organs of interest were excised and weighed, and the radioactivity was quantified using a NaI (Tl) γ scintillation counter (Packard Auto-Gamma 500, Packard Inst. Co.). The results are expressed as percent injected dose per gram of blood or organs after decay correction.

Determination of Radiometabolites in Vivo. At 60 min postinjection of [^{99m}Tc]MAMA-HA, urine samples were obtained from the bladder. After filtration of the urine samples through a 10 kDa cutoff ultrafiltration membrane (Molcut II LGC; NIHON MILLIPORE Co, Yonezawa, Japan), the filtrate was analyzed by RP-HPLC eluted with a gradient mobile phase starting from 10% methanol in 0.05 M phosphate buffer (pH 7.0) to 100% methanol in 60 min at a flow rate of 1 mL/min at 30 °C.



In Vitro Metabolite Studies. Male Wistar rats were anesthetized with pentobarbital (50 mg/kg i.p.), and the rat liver was perfused via the portal vein with O_2/CO_2 (95/5)-saturated cold 20 mM Tris-HCl buffer (pH 7.4) containing 100 mM KCl, 5 mM $MgCl_2$, and 5 mM KH_2PO_4. The rat liver was immediately excised and sliced at a thickness of 300 μm. After weighing, the slices were incubated for 5 min at 37 °C in the presence or absence of 100 μM 2-bromooctanoate which inhibits β-oxidation of long and medium-chain fatty acids (*20*, *21*). Then, [^{99m}Tc]MAMA-HA (3.7 MBq) was added, and the solution was shaken 60 times/min under bubbling O_2/CO_2 (95/5) at 37 °C for 60 min. After addition of 5 mL of acetonitrile, the solution was homogenized and centrifuged at 1000*g* for 20 min to precipitate protein. After removing the organic solvent in vacuo, the residue was filtered through polycarbonate membrane with a pore diameter of 0.22 μm (Hospital/pharmacy Milles GV, Millipore), and the filtrate was analyzed by RP-HPLC as described above. The integrity of the hepatocytes in the slices was determined by measuring lactate dehydrogenase (LDH) activity leaked into the buffer at the end of the incubation. There was no significant difference in LDH activity in the presence or absence of 2-bromooctanoate (3285 ± 367 IU/L vs 3175 ± 478 IU/L, respectively).

Statistical Analyses. Data were analyzed using unpaired two-tailed alternate Welch *t*-tests. A value of $p < 0.05$ was considered significant.



RESULTS

Synthesis of Fatty Acid Analogues. The bistritylated derivative of MAMA-HA (**6**) was synthesized ac-

Scheme 1

Scheme 2

cording to the procedure outlined in Scheme 1. After protecting the thiol group of cysteamine chloride with trityl chloride, the resulting compound **2** was reacted with bromoacetyl bromide to prepare **3**. The amine group of **3** was then alkylated with 6-bromohexanoate to produce **5**. After hydrolysis of the ester group, **6** was obtained as a yellow oil with an overall yield of 2.26%.

The synthetic procedure for *S*-acetyl MAG-HA (**13**) is outlined in Scheme 2. The active ester of **11** was reacted with the amine group of 6-aminohexanoic acid to provide **12**. *S*-Acetyl MAG-HA was obtained as white crystals by the reaction of SATA (**10**) with **12** after deprotecting the Boc group of **12**. The overall yield was 3.70%.

Radiolabeling. [^{99m}Tc]MAMA-HA and [^{99m}Tc]MAG-HA were obtained in radiochemical yields of 77% and 87%, respectively. After RP-HPLC purification, both ^{99m}Tc-labeled fatty acid analogues showed radiochemical purities of over 99% as determined with RP-HPLC and

[a] Values are means (range) as % dose/gram tissue for three rats.

TLC. No changes were observed in the radiochemical purities with the two ^{99m}Tc-labeled fatty acids after standing for 24 h at room temperature. On the other hand, the derivatives prepared for metabolite analysis, [^{99m}Tc]MAMA-BA and [^{99m}Tc]MAMA-AA, were obtained in radiochemical yields of 37.4 and 59.7%, respectively; both radiochemical purities were also over 99% after RP-HPLC purification.

Partition Coefficient. Table 1 shows partition coefficients of [^{99m}Tc]MAMA-HA and [^{99m}Tc]MAG-HA at pH 7.4. [^{99m}Tc]MAMA-HA showed a slightly but significantly higher partition coefficient than [^{99m}Tc]MAG-HA.

Cysteine Challenge Assay. Table 2 shows the stability of [^{99m}Tc]MAMA-HA and [^{99m}Tc]MAG-HA. After 60 min of incubation, 88% of [^{99m}Tc]MAMA-HA and 80% of [^{99m}Tc]MAG-HA remained intact, indicating that [^{99m}Tc]-MAMA-HA was more stable than [^{99m}Tc]MAG-HA.

In Vivo Studies. [^{99m}Tc]MAMA-HA showed rapid accumulation of the radioactivity in the liver immediately after administration (Figure 1A). At 60 min postinjection, most of the radioactivity was observed in the kidney and bladder due to its rapid elimination from the liver (Figure 1B). On the other hand, the majority of radioactivity was immediately excreted from the kidney to the bladder after administration of [^{99m}Tc]MAG-HA (Figure 1, panels C and D). Similarly, [^{99m}Tc]MAMA-BA showed rapid excretion of the radioactivity from the kidney into the urine with little radioactivity in the liver (Figure 1E). At 60

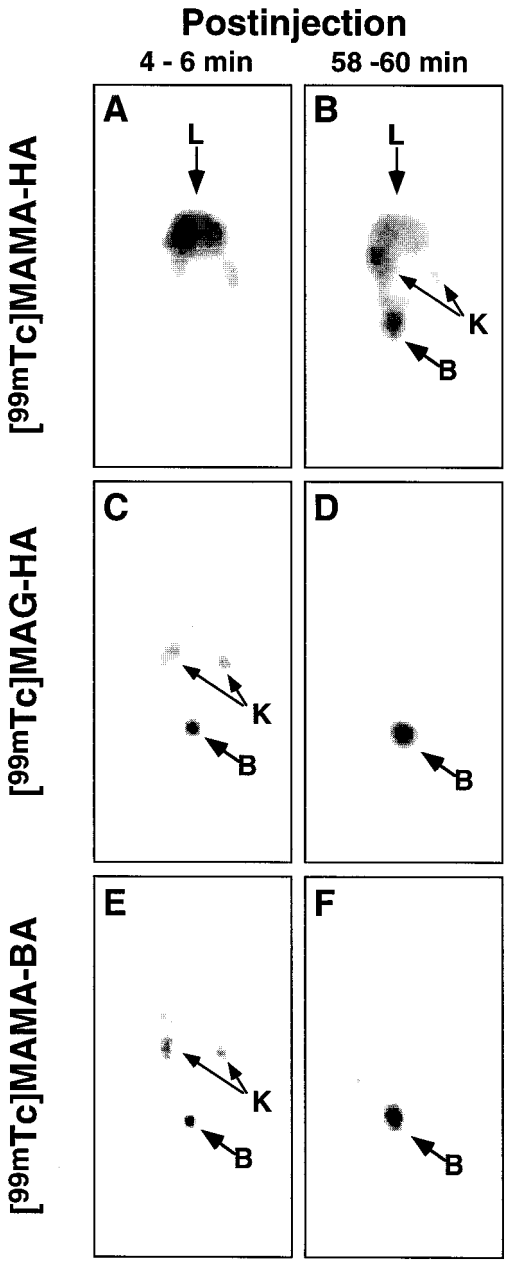

Figure 1. Planar images of ^{99m}Tc-labeled fatty acid analogues. ^{99m}Tc-labeled compounds (15 MBq each) were administered to normal rats via the tail vein. Dynamic scanning was initiated immediately after administration of ^{99m}Tc-labeled compounds. (A) [^{99m}Tc]MAMA-HA, 4−6 min, (B) [^{99m}Tc]MAMA-HA, 58−60 min, (C) [^{99m}Tc]MAG-HA, 4−6 min, (D) [^{99m}Tc]MAG-HA, 58−60 min, (E) [^{99m}Tc]MAMA-BA, 4−6 min, (F) [^{99m}Tc]MAMA-BA, 58−60 min. L, K, and B represent liver, kidney, and bladder, respectively.

min postinjection, radioactivity was observed in the bladder (Figure 1F).

Table 3 summarizes the biodistribution of the radioactivity after administration of [^{99m}Tc]MAMA-HA to normal rats. [^{99m}Tc]MAMA-HA in the liver showed high initial uptake of radioactivity (10.59 % dose/g at 5 min after injection) with low radioactivity levels in the blood for imaging diagnosis. With time, the radioactivity in the liver decreased with only a slight increase in that in the intestine. On the other hand, although the highest radioactivity level was observed in the kidney at 5 min postinjection, high radioactivity levels were still observed at 20 and 60 min postinjection.

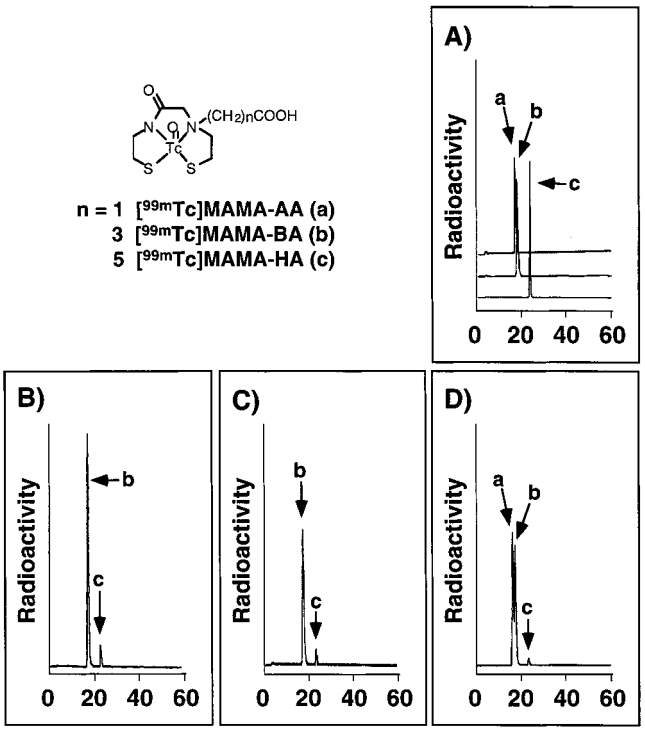

Figure 2. Metabolite analysis of urine samples after administration of [^{99m}Tc]MAMA-HA in rats. Proposed structures of a series of [^{99m}Tc]MAMA derivatives are shown. The parental [^{99m}Tc]MAMA-HA (c) and analytical controls, [^{99m}Tc]MAMA-BA (b) and [^{99m}Tc]MAMA-AA (a), were eluted at retention times of 23, 17, and 16 min, respectively (A). Urine samples showed two radioactivity peaks with a major peak eluted at a retention time of 17 min (B). RP-HPLC analysis of the urine samples coinjected with [^{99m}Tc]MAMA-BA showed a single radioactivity peak at a retention time of 17 min in addition to the peak of [^{99m}Tc]MAMA-HA (C). Cochromatographic analysis of the urine samples with [^{99m}Tc]MAMA-AA showed two peaks well-separated in addition to the peak of [^{99m}Tc]MAMA-HA (D).

The proposed structures of the mother compound [^{99m}Tc]MAMA-HA and its expected radiometabolites, [^{99m}Tc]MAMA-BA and [^{99m}Tc]MAMA-AA, are shown in Figure 2. Figure 2A shows typical radiochromatograms of [^{99m}Tc]MAMA-HA, [^{99m}Tc]MAMA-BA, and [^{99m}Tc]-MAMA-AA. The urine samples showed two well-separated radioactivity peaks at retention times of 17 and 23 min with the former peak representing 82.9 ± 9.0% of the radioactivity in the urine (Figure 2B). Cochromatographic analysis of the urine samples with [^{99m}Tc]MAMA-BA indicated two radioactivity peaks at retention times of 17 and 23 min on RP-HPLC (Figure 2C). However, three radioactivity peaks were detected on RP-HPLC at retention times of 16, 17, and 23 min when the urine sample were cochromatographed with [^{99m}Tc]MAMA-AA (Figure 2D).

In Vitro Metabolite Studies. More than 90% of the radioactivity in the liver homogenate was extracted with acetonitrile. RP-HPLC analysis of the acetonitrile-extracted fraction depicted two radioactivity peaks at retention times of 17 and 23 min when the slices were incubated with [^{99m}Tc]MAMA-HA in the absence of 2-bromooctanoate (Figure 3A) with the former fraction representing 21.2 ± 3.0% of the radioactivity in the supernatant. However, the supernatant showed a single radioactivity peak at a retention time of 23 min (Figure 3B) when incubated with [^{99m}Tc]MAMA-HA in the presence of 2-bromooctanote.

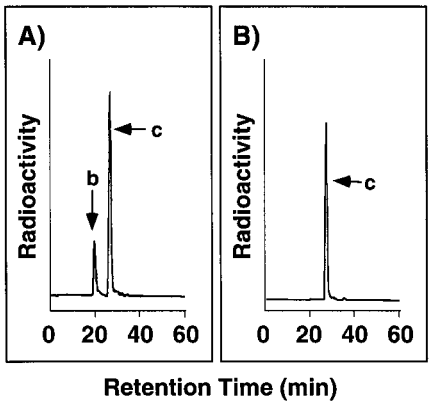

Figure 3. Metabolite analysis of [^{99m}Tc]MAMA-HA in liver slices. The liver slices were incubated with [^{99m}Tc]MAMA-HA for 60 min at 37 °C. Two radioactivity peaks were observed, the former of which had a retention time similar to that of [^{99m}Tc]-MAMA-BA (A). However, RP-HPLC showed a single radioactivity peak with a retention time similar to that of parental [^{99m}Tc]MAMA-HA in the presence of 2-bromooctanoate which inhibits 3-ketothiolase, the last enzyme of the fatty acid oxidation pathway (B).

DISCUSSION

External imaging of energy production levels of living cells with ^{99m}Tc-labeled compounds is a challenging task for the development of ^{99m}Tc-radiopharmaceuticals. Indeed, efforts have been made to develop ^{99m}Tc-labeled long-chain fatty acid analogues for myocardial imaging studies. However, their application has been hampered by poor accumulation in the heart, and it seemed that these ^{99m}Tc-labeled fatty acid analogues were not recognized as substrates for β-oxidation (*22*, *23*).

β-Oxidation is the main pathway providing energy in the liver. On the basis of our recent findings that ^{11}C- and ^{123}I-labeled medium-chain fatty acids were useful for measuring β-oxidation activity of hepatocytes (*9*, *10*), we designed two ^{99m}Tc-labeled medium-chain fatty acid analogues as prototype compounds and evaluated their potential as substrates for β-oxidation in the liver.

In biodistribution studies in rats, [^{99m}Tc]MAMA-HA showed rapid accumulation in the liver following injection. [^{99m}Tc]MAMA-HA also exhibited rapid elimination of the radioactivity from the liver into urine. RP-HPLC analysis of urine samples obtained at 60 min postinjection showed that the major radioactivity peak had a retention time identical to that of [^{99m}Tc]MAMA-BA. This was supported by cochromatographic analyses of the urine samples with [^{99m}Tc]MAMA-BA or [^{99m}Tc]MAMA-AA. In addition, [^{99m}Tc]MAMA-BA showed rapid excretion of the radioactivity into urine via the kidney with little accumulation in the liver, indicating that redistribution of [^{99m}Tc]MAMA-BA generated in the body to the liver was negligible. These findings suggested that [^{99m}Tc]-MAMA-HA would be metabolized to [^{99m}Tc]MAMA-BA in the liver via β-oxidation, and the radiometabolite was excreted from the liver into the urine.

The metabolism of [^{99m}Tc]MAMA-HA to [^{99m}Tc]MAMA-BA by β-oxidation in the liver was also indicated by in vitro studies using living slices of rat liver. [^{99m}Tc]MAMA-BA was observed as the sole radiometabolite after incubation (Figure 3). However, generation of [^{99m}Tc]-MAMA-BA was completely inhibited when [^{99m}Tc]MAMA-HA was incubated with the liver slices in the presence of 2-bromooctanote, an inhibitor of 3-ketothiolase, the last enzyme involved in long- and medium-chain fatty acid oxidation in the mitochondria. These findings implied that after uptake by the liver, [^{99m}Tc]MAMA-HA was recognized as a substrate for β-oxidation and metabolized to [^{99m}Tc]MAMA-BA.

The final radiometabolite of [^{99m}Tc]MAMA-HA was not [^{99m}Tc]MAMA-AA but [^{99m}Tc]MAMA-BA as demonstrated by cochromatographic analyses. Since [^{99m}Tc]MAMA-HA possesses a 6-carbon chain, [^{99m}Tc]MAMA-AA was expected to be the final radiometabolite after β-oxidation. Indeed, our recent study indicated that the radioiodinated medium-chain fatty acid analogue [^{123}I]IPEA was metabolized to iodohippuric acid via iodobenzoate. This suggested that, unlike iodobenzene, the presence of [^{99m}Tc]MAMA chelate might have hindered further recognition of [^{99m}Tc]MAMA-BA by the enzymes that are involved in β-oxidation.

In contrast to [^{99m}Tc]MAMA-HA, [^{99m}Tc]MAG-HA showed little accumulation in the liver after administration. Although [^{99m}Tc]MAG-HA was less stable than [^{99m}Tc]MAMA-HA, about 80% of [^{99m}Tc]MAG-HA was intact even after 60 min of incubation. Since the radioactivity in rats following [^{99m}Tc]MAG-HA injection was rapidly eliminate from blood to urine as shown in Figure 1, panels C and D, the instability of [^{99m}Tc]MAG-HA in the blood was considered not to be a major factor responsible for poor liver uptake. On the other hand, [^{99m}Tc]MAG-HA showed a lower partition coefficient than [^{99m}Tc]MAMA-HA. [^{99m}Tc]MAG-HA had a retention time similar to that of [^{99m}Tc]MAMA-BA, a radiometabolite of [^{99m}Tc]MAMA-HA, on RP-HPLC under the same conditions. Moreover, [^{99m}Tc]MAMA-BA and [^{99m}Tc]MAG-HA showed similar biodistributions. These findings suggested that the low lipophilicity of [^{99m}Tc]MAG-HA was responsible for its poor hepatic accumulation although negatively charged ^{99m}Tc-MAG chelate may also be involved.

In conclusion, [^{99m}Tc]MAMA-HA was metabolized by β-oxidation to [^{99m}Tc]MAMA-BA after uptake into the liver. Thus, [^{99m}Tc]MAMA-HA is the first ^{99m}Tc-labeled compound recognized as a substrate for energy production in living cells. Appropriate lipophilicity of [^{99m}Tc]-MAMA chelate would be useful to facilitate rapid elimination of the final radiometabolite, [^{99m}Tc]MAMA-BA, from the liver into urine without being retained in the hepatocytes. Since the procedure for synthesis of MAMA-HA was applicable to fatty acids with different chain lengths, further derivation of this compound may lead to development of ^{99m}Tc-radiopharmaceuticals more appropriate for visualization of energy production levels in the liver.

Purified Protein Derivative (PPD) as an Immunogen Carrier Elicits High Antigen Specificity to Haptens

Binodh S. De Silva,† Kamal L. Egodage,‡ and George S. Wilson*

Department of Chemistry, Malott Hall, University of Kansas, Lawrence, Kansas 66045. Received June 23, 1998; Revised Manuscript Received February 12, 1999

The effectiveness of the carrier protein in eliciting antigen-specific antibodies was investigated. The effect of the carrier protein was independent of the conjugation chemistry involved. Keyhole limpet hemocyanin (KLH), purified protein derivative (PPD), and ovalbumin (OVA) were used as carrier proteins in the immunization of mice. Three antigens were studied: LY170881 (a small drug molecule), 4-[1′-cyanobenz(*f*)isoindolyl]butyric acid (CBI-butyric acid), and a seven residue peptide GPGRGPG (KLE1). The serum antibody response to the antigen or antigen:BSA conjugate was superior in the case where the PPD:antigen conjugates were used as the immunogen when compared to KLH and OVA. The specificity of the antibodies to the respective antigens vs cross-reactivity with the carrier protein was investigated. PPD-coupled antigen immunized mice generated a higher percentage of antigen-specific hybridomas compared to the other carrier proteins. These findings confirmed PPD as the best carrier molecule for the production of both polyclonal and monoclonal antibodies.

INTRODUCTION

With the advent of monoclonal antibodies (Köhler and Milstein, 1975), many analytical and clinical applications have relied on the highly specific antigen antibody interaction made possible by this methodology. In theory, antibodies could be made to any synthetic molecule, protein, nucleic acid, carbohydrate, or lipoprotein. With the extensive understanding about processes involving the immune system, it has now become possible to characterize the physical requirements of an antigen which result in improved production of antibodies (Eshhar, 1985).

Antigens in general can be classified into two major groups; those that are intrinsically immunogenic and those that have to be conjugated to a carrier to elicit an immune response. There is considerable interest in producing monoclonal antibodies to such small molecules including, for example, drugs, pesticides, and peptides. Typically, an antigen possesses an epitope that can be recognized by surface immunoglobulins on B-cells. However, this is not sufficient to elicit an antibody response. In addition to the B-cell epitope, the antigen has to possess a class II MHC T-cell receptor site that enables the cascade of events resulting in the production of antibodies to a particular antigen of interest. Haptens in classical immunology lack this T-cell epitope. Landsteiner (1936) showed that the T-cell epitope can be introduced by conjugating to a carrier protein, using what he called the "artificial conjugated antigens". Since then, many approaches have attempted to improve the methodology for producing anti-hapten and anti-peptide antibodies. Some of the strategies used are incorporation of T-cell epitopes (Francis et al., 1987; Good et al., 1987), preparation of immunostimulating complexes (Morein et al., 1987), use of a variety of adjuvants and liposomes to enhance the longevity of the antigen of interest in the body (Kawamura and Berzofsky, 1986), and cross-linking of the antigen with antibodies against surface receptors on B-cells, T helper cells or other antigen presenting cells to target the antigen to the cells involved in the immune system (Snider et al., 1987; Hendrickson et al., 1994). Multiple antigen peptide (MAP) where both the B-cell and T-cell epitopes are incorporated into one peptide antigen and synthesized as a single molecule (Tam, 1989) has been successfully used to elicit immune response. This latter approach eliminates the conjugation of peptides to proteins and uses solid-phase peptide synthesis to prepare the immunogen.

Even with the advancement of methodology for the preparation of monoclonal and polyclonal antibodies, the use of the hapten−protein conjugates or peptide−protein conjugates as immunogens still remains the most common method of choice. The simplicity of these techniques, which do not require sophisticated equipment, and the flexibility of choosing a conjugation method applicable to the analyte of interest (use of NH_2, COOH, and SH groups for coupling) favors this mode of immunogen preparation. However, such preparations must strive to preserve the integrity of the antigen structure, since many applications involving these antibodies require the discrimination of analogues with very small conformational differences. There are number of important characteristics to consider when preparing these conjugates. For example, the specificity of the assay, the metabolites of interest, the characteristic site of the antigen that is important for the specificity of the assay, the carrier molecule, epitope density, the method of conjugation, and the chemistry of the linking group between the hapten and the carrier will determine the properties of the resulting antibody.

An important unit of the conjugate is the carrier molecule which provides the T-cell epitope for the production of a successful immune response. Common car-

rier proteins such as serum albumin (bovine, human) hemocyanin, ovalbumin, g-globulins of various species, thyroglobulin, tetanus toxoid, peptide antigens, and synthetic carriers such as poly-L-lysine have been used extensively (Plaue et al., 1990). The protein carrier chosen must come from a species different from the animal to be immunized (Walker et al., 1973). The proteins to be used as carriers must possess functional groups that can easily be substituted (such as amines or sulfhydryls). The molar ratio of the hapten:protein will greatly influence the immune response and this depends on the coupling method used. Generally a hapten:protein molar ratio of 10:1 is maintained in our laboratory (Tijssen, 1985).

The hapten−protein conjugate once administered to an animal will elicit antibodies that have a specificity to the haptenic group as well as the carrier. While the carrier-specific antibodies could be removed by affinity purification using a column with immobilized carrier protein, antibodies that bind part of the hapten or peptide and the carrier protein will also be removed. More critical, however, is the impact of carrier-specific antibodies on the hybridoma screening process. In the preparation of monoclonal antibodies, the hybridoma supernatants are typically screened first against a hapten−protein conjugate, where the protein is different to that used in the immunization. These supernatants were subsequently screened against the carrier protein used in the immunogen to estimate the number of hybridomas specific to the carrier. If a positive response is obtained, then the well will likely be discarded even if it also may contain antigen-specific antibodies. Since carrier-specific antibodies can correspond to a significant fraction of the antibodies produced, their elimination will greatly simplify identification of the desired antibodies, thus resulting in significantly higher yields of specific antibody hybridoma cell lines.

Keyhole limpet hemocyanin (KLH), ovalbumin (OVA), and bovine serum albumin (BSA) are typical carriers used in the preparation of hapten−protein conjugates. However, purified protein derivative (PPD), currently used in the measurement of T-cell reactivity in persons exposed to tuberculosis or vaccinated with Bacillus Calmette-Guérin (BCG), has been suggested as an ideal carrier candidate (Lachmann et al., 1986).Their studies indicate the advantages of PPD as a carrier molecule and as an adjuvant in vaccine preparations. The present study deals with the properties of PPD as a carrier for the preparation of anti-hapten antibodies. These studies were carried out using two haptens (small organic molecules) and a peptide. The antigens used were LY170881 (a small drug molecule), 4-[1′-cyanobenz(*f*)-isoindolyl]butyric acid (CBI-butyric acid) (Figure 1) and a seven residue peptide, GPGRGPG (KLE1).

EXPERIMENTAL SECTION

Materials and Methods. LY170881 and its conjugates with BSA, PPD, OVA, and KLH were provided by Lilly Laboratories (Indianapolis, IN). The seven residue peptide (GPGRGPG) (KLE1) was synthesized by Coast Scientific Products (La Jolla, CA). 4-[1′-Cyanobenz(*f*)-isoindolyl]butyric acid (CBI-butyric acid) was synthesized at the University of Kansas (Orosz and Carlson, 1990). All buffer components used were of analytical grade and purchased from Fisher Scientific, Fairlawn, NJ. BSA, and KLH were purchased from Sigma Chemical Co. (St. Louis, MO). PPD was provided by Lederle Laboratories, NY.

CBI-butyric acid-PPD	carbodiimide	30
CBI-butyric acid-KLH	carbodiimide	10
KLE1-PPD	carbodiimide	25
KLE1-KLH	carbodiimide	25

Preparation of the Immunogens. KLH and PPD were used as the protein carriers in the conjugation of the peptide and CBI-butyric acid used for immunizations.The CBI-butyric acid and the KLE1 peptide were coupled through the −COOH group by first activating it with water-soluble 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDAC, Pierce, IL) according to the enhanced carbodiimide coupling method of Staros et al. (1986), using sulfo *N*-hydroxysuccinimide (Sulfo-NHS, Pierce, IL) as the enhancer. The molar ratio of KLH: antigen was 1:100. One milligram of antigen was dissolved in 1 mL of 0.01 M phosphate buffer (PB), pH 7.4, containing no azide. EDAC was added to a final concentration of 0.1 M. After stirring for a few minutes, sulfo-NHS was added dropwise (1.25 times antigen concentration). Finally, 1 mg of KLH was added and the solution was made up to 2 mL. The reaction was allowed to proceed for 24 h at room temperature. The order of the addition of the reagents is critical to obtaining a successful conjugate. The PPD-antigen and the BSA−antigen conjugates were prepared in a similar manner using a molar ratio of protein:antigen of 1:10. All conjugates that contained the LY170881 antigen were prepared by the Lilly Laboratories using the mixed anhydride method (Bowsher et al., 1994).

Immunization Schedule. Immunogens were administered to 4−6 week old female BALB/c mice. The immunogens used and their respective dosages are given in Table 1. One week prior to the first immunization with the respective PPD conjugates, the mice were sensitized with 50 μg of Bacillus Calmette-Guérin (BCG; RIBI Immunochemical Research Inc., MT) via the intramuscular (i.m.) route in 50 μL of sterile saline. The rest of the immunization protocol was as follows: the first immunization was intraperitoneal (i.p.) at four sites with 100 μL/site in complete Freund's adjuvant (CFA; Gibco Laboratories, NY) at a 3:1 v/v (adjuvant:conjugate) ratio. The second immunization was intravenous (i.v.) in sterile saline at a ratio of 2:1 v/v (saline:conjugate) after 2 weeks. Biweekly i.p. immunizations (four sites with 100 μL/site)

in incomplete Freund's adjuvant (IFA; Gibco Laboratories, NY) were administered until a desired circulating antibody concentration (1:1000 dilution) specific to each immunogen was attained in the serum. A v/v ratio of 3:1 (IFA:conjugate) was maintained. The conjugates prepared with KLH and OVA as the carriers were employed in mouse immunization in a manner similar to that described above but without the BCG sensitization.

Fusion. Four days after the final immunization, the spleen of the hyperimmunized mouse was fused with the myeloma cell line Sp2/0−Ag-14 (ATCC CRL 1581; American Type Culture Collection, Rockville, MD) according to Galfré and Milstein (1981). A spleen cell: myeloma cell ratio of 10:1 was used and poly(ethylene glycol), molecular weight 3350 (Sigma, St. Louis, MO), was used as the fusogen. Typically, the cell pellet of fused cells is diluted in a large volume (almost 40−50 mL) of growth medium to ensure a reasonable dilution and seeded on 10−12 plates on average, at 50 μL/well. After 2 weeks, the supernatants were screened for specific antibody production using enzyme linked immunosorbent assays (ELISA) as described below.

Screening Procedures. All ELISA procedures were designed to screen for antibodies that reacted with the antigen of interest and the carrier used in the immunizations. Two general ELISA procedures are reported in this manuscript because the antigens used in this work were used for different analytical purposes. The ELISA methods have to be designed in such a way as to get the best antibodies that recognize the antigen of interest and not the carrier protein. Therefore, the following ELISA methods will be described in detail for each antigen.

ELISA Method 1. This ELISA method will allow the selection of antibodies that would recognize the antigen−protein conjugate. The carrier protein used in the ELISA procedure is different from the one that was used in the immunization. This eliminates the selection of antibodies to the carrier protein used in the immunizations. The hybridoma clones that secrete antibodies recognizing the antigen and/or the linking group can be selected using this procedure. This ELISA method was used to screen against BSA−CBI butyric acid and BSA−LY170881 antigen conjugates. The ELISA method used was a modification of Bahr et al. (1980). The ELISA plates (Corning, NY) were coated with 100 μL of antigen−BSA conjugate or the respective carrier proteins (BSA/PPD/KLH/ovalbumin) (10 μg/mL in 0.1 M carbonate buffer, pH 9.35) (plate coating buffer) overnight at 4 °C. The plates were washed four times with 0.01 M PBS containing 0.05% Tween 20 (Sigma, St. Louis, MO) (wash buffer) and patted dry on a stack of paper towels. Wash buffer containing 0.2% BSA (150 μL/well) (ELISA diluent buffer) was added and incubated for 1 h at 37 °C to block the remaining active sites on the plastic surface. The plates were washed four times with wash buffer and patted dry. Serum (1:100 dilution) or culture supernatant (50 μL/well) was added and incubated for 1 h at 37°C. The plates were washed four times with wash buffer and patted dry. Horseradish peroxidase (HRP) labeled goat-anti-mouse (goat anti-Mo−HRP, Organon Teknika Corp., Durham, NC) immunoglobulin (100 μL, 1:10,000 dilution) was added and incubated at 37 °C for an additional hour. The plates were washed four times with Nanopure water (Barnstead, Nanopure II Sybron, Barnstead, MA) and patted dry. A total of 100 μL of HRP substrate (tetramethyl benzidine (TMB) and hydrogen peroxide, KP Laboratories, MD) was added, and after 20 min, the enzyme reaction was quenched with 1 M HCl. The optical density was read at 450 nm using a 96 well plate reader. (V_{max}, Molecular Devices, CA). The screening procedures for LY170881 used the wash buffer and the ELISA diluent buffer recommended by the Lilly Laboratories. In ELISA experiments, using supernatant, serum from an immunized mouse served as the positive control and serum from an unimmunized mouse was used as the negative control.

ELISA Method 2. The primary purpose in preparing antibodies to the peptide, KLE1, was to select antibodies that recognized the native structure of the parent protein. Therefore, during the selection process, it was necessary to identify antibodies that recognized the component peptide only. The following ELISA method was used to fulfill this purpose: 100 μL of the KLE1 peptide antigen (20 μg/mL) was coated on ELISA plates in 0.1 M plate coating buffer and incubated overnight at 4 °C. The plates were washed four times with wash buffer and blocked with 100 μL of 0.2% gelatin in wash buffer to block the remaining active sites on the plates. The plates were incubated at 37 °C for 1 h. The plates were washed four times with wash buffer and patted dry. Serum (1:100 dilution) or culture supernatant (50 μL/well) was added and incubated for 1 h at 37 °C. The plates were washed four times with wash buffer and patted dry. A total of 100 μL of goat anti-Mo−HRP conjugate was added (1:15000 dilution in wash buffer containing 0.2% gelatin) to each well and incubated at 37 °C for an additional hour. The plates were washed four times with Nanopure water and patted dry. A total of 100 μL of HRP substrate was added, and after 20 min, the enzyme reaction was quenched with 1 M HCl. The optical density was read at 450 nm using the 96 well plate reader.

Data Analysis. The statistical analysis of the results was done using the Minitab statistical program (version 8.21, State College, PA).

RESULTS

Serum Response to Antigens. The two ELISA procedures described above were specifically aimed at evaluating the antibody responses to suit the particular analytical method under development. Figures 2 and 3 show the antibody titers in serum for the respective antigens/antigen-BSA and carriers used. At least two mice were immunized with each antigen. The optical density data were statistically analyzed using the Minitab program, and the results for the different animals were pooled where the data showed no significant difference at a 95% confidence level as shown by a one way ANOVA. Figure 2 compares the antibody titers to the peptide, CBI-butyric acid-BSA conjugate, and their respective carrier proteins. When KLH was used as the carrier, the immune response to KLH was far superior to that for the antigen/antigen-BSA of interest. The immune response to PPD on the other hand was significantly lower compared to that for the respective antigens. These results agree with the fact that PPD is a T cell antigen and does not elicit a favorable immune response (Lachman et al., 1986).

Figure 3 shows the serum titers to the LY170881−BSA conjugate and the respective carrier proteins used in the immunization procedures. The antibody responses to the BSA−LY170881 conjugate are comparable to that of the carriers in the case where PPD and OVA were used. The serum titer for PPD is around 51 200 and to OVA is 25 600. The KLH response is far superior to the BSA−LY170881 response.

Fusion. A minimum of two fusions were performed from each category. The hybridoma supernatants were

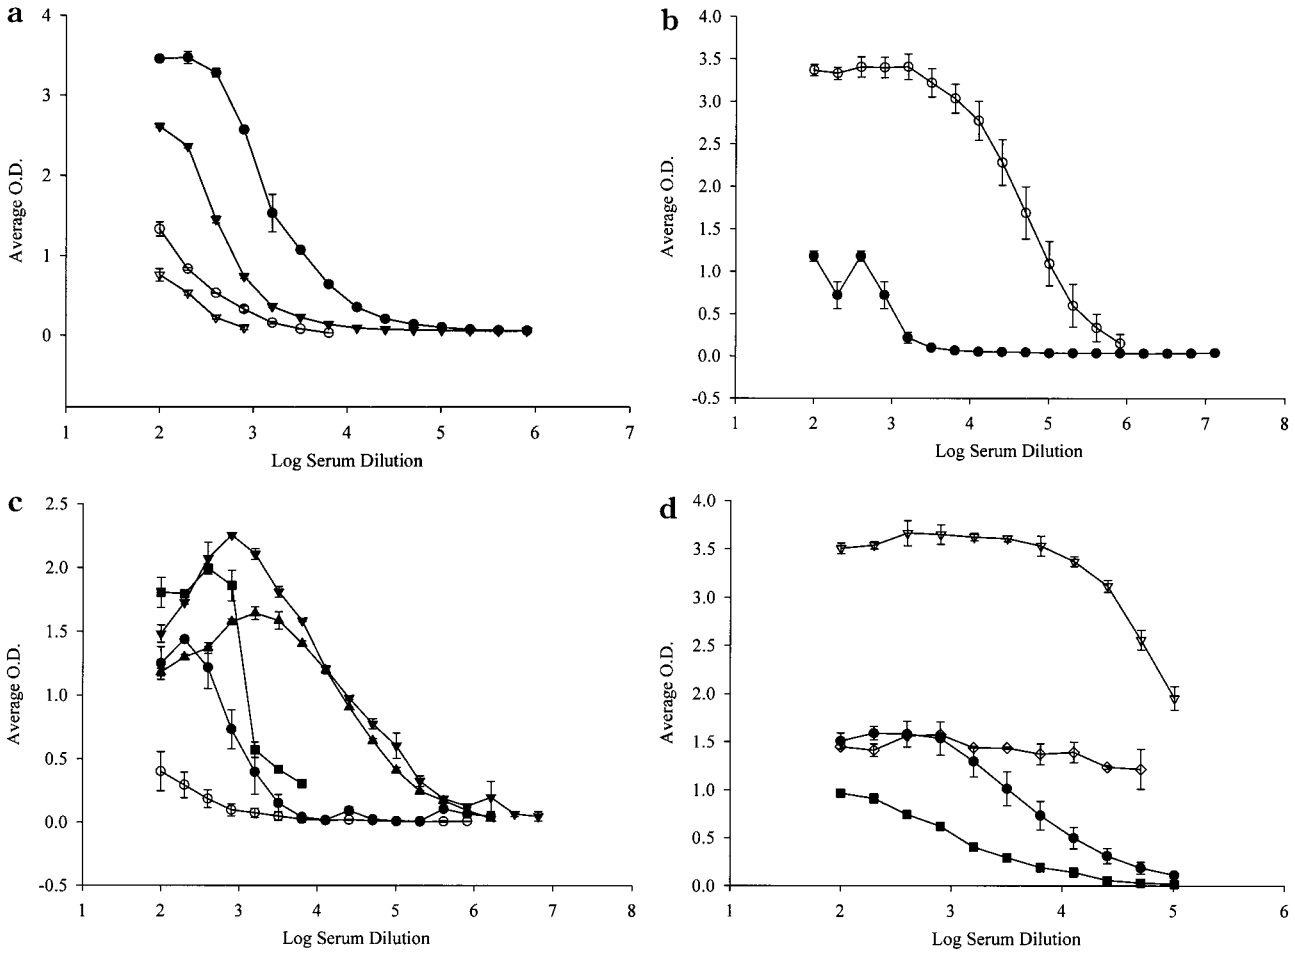

Figure 2. Serum dilution curves for the antigens and their respective carriers used in the immunizations. The solid symbols indicate the response to the antigen or the peptide, and the open symbols indicate the serum response to each carrier molecule. (a) KLE1-PPD [(●, ▼) antigen response for two mice, (○, ▽) carrier for two mice], (b) KLE1-KLH [(●) average antigen response for two mice, (○) average carrier response for two mice], (c) CBI-butyric acid-PPD [(●, ■, ▲, ▼) antigen response for four mice, (○) average carrier response for four mice], (d) CBI-butyric acid-KLH [(●) average antigen response for two mice, (■) antigen response for one mouse, (▽) average carrier response for two mice, (◇) carrier response for one mouse].

tested for the production of antibodies against the BSA-conjugated CBI butyric acid, BSA-conjugated LY170881, KLE1 peptide, and the respective carriers. The results are summarized in Table 2. The percent of specific wells were calculated as follows:

$$\%\ \text{specific wells} = (\text{number of wells positive toward the antigen/carrier})/(\text{total number of growing wells}) \times 100$$

These results clearly indicate that PPD does elicit a superior antigen-specific immune response compared to that of KLH. The percentage of antigen-specific hybridoma wells (Table 2) is about four times higher for PPD than for KLH. The higher percentage of antigen-specific hybridomas makes available a larger number of cell lines from which to choose the appropriate monoclonal antibodies for the specific application. The percentage of specific wells to KLH and OVA was not calculated for the LY170881 antigen, since over 90% of the supernatants screened showed cross reactivity between the carrier and the antigen of interest.

DISCUSSION

This study evaluates the effectiveness of different protein molecules as carriers used in the production of antibodies against haptens and small peptides irrespective of the conjugation process. The primary goal of this project was to enhance the production of anti-hapten/anti-peptide antibodies in systems which are not intrinsically very immunogenic. The ELISA procedures described in the previous section served two purposes: the selection of antigen specific antibodies and the elimination of carrier-specific antibodies. These screening procedures were carefully designed in order to select antigen-specific antibodies which are useful in the analytical procedures that were envisioned for these antibodies. The serum and the fusion results clearly indicate a dramatically reduced carrier response of PPD over KLH and OVA. It has been reported that the efficacy of each carrier protein and the immune response it elicits are difficult to compare since they vary depending on the individual and the species (Pratt, 1978). These variations were taken into consideration during these experiments, and the conditions were kept as comparable as practically possible in designing the immunogens. Furthermore, the animals used were of similar age and belonged to the same species.

The serum titer results we have obtained show great promise when preparing polyclonal antibodies (Figure 2 and Figure 3) and were measured in the serum after the immunization. The low/no titers shown for PPD response is a clear indication of the exceptional effect of PPD in eliciting a specific antibody response to the antigen of

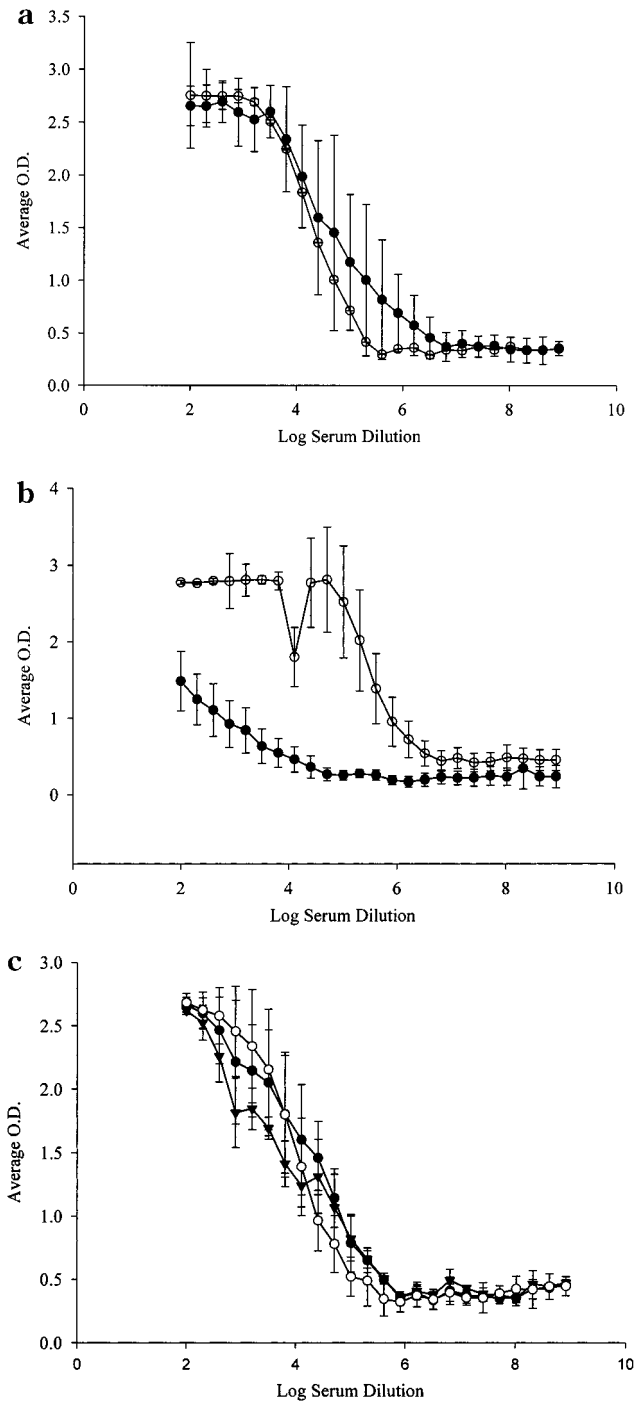

Figure 3. Serum dilution curves for LY170881−BSA conjugate and the carrier proteins used in the immunization. (a) LY170881−PPD [(●) average antigen response for two mice, (○) average carrier response for two mice], (b) LY170881−KLH [(●) average antigen response for two mice, (○) average carrier response for two mice], (c) LY170881−OVA [(●) average antigen response for two mice, (▼) antigen response for one mouse, (○) average carrier response for all three mice].

interest without itself eliciting and immune response. When both KLH and OVA were used, the majority of the time the serum antibody response to the carrier obscured that of the antigen of interest. This poses a great difficulty when purifying the serum to obtain polyclonal antibodies, which are antigen specific, due to the high concentration of antibodies to carrier molecules. The strong carrier response has the effect of reducing the antigen-specific antibody concentration in the IgG fraction.

Table 2. Fusion Results

immunogen	% antigen specificity (a)	% carrier specificity (b)		$[(a)/(a+b)] \times 100$
		PPD	KLH

CBI-butyric acid-KLH	29	na	95	23
LY170881-PPD	4.1	2	na	68

[a] na, not applicable.

The major advantage of producing antigen-specific antibodies lies in the preparation of monoclonal antibodies. When the specificity toward the antigen is greater than that of the carrier, the selection of optimal antibodies for a particular assay becomes trivial. The high percentage of antigen-specific hybridomas (Table 2) in PPD immunized mice confirm the reduction of carrier-specific hybridomas by using PPD as a carrier molecule. In the case of KLE1 peptide, when PPD was used as a carrier molecule 61% of the wells screened for carrier and antigen were antigen specific as opposed to 15% for KLH. The 4-fold increase in the antigen-specific hybridomas will increase the probability of selecting the optimal cell line for the subsequent analytical procedure.

The serum antibody response may or may not be a true predictor of the number of specific hybridoma cells that are produced during a fusion. However, the number of hybridoma wells that cross-reacted with KLH in both the peptide and the CBI-butyric acid was greater than those for PPD (Table 2). The specificity to the antigen is almost 12 times greater when PPD was used as the carrier in CBI-butyric acid. It could be argued that the antigen was not exposed to the surface (epitopic suppression) in KLH due to the large molecular weight of this protein. However, this should be not the case since the molar ratios in each situation were comparable. These results strongly support the fact that PPD is indeed a T-cell antigen.

The KLE1 peptide specificity results are also very encouraging. The fusion results were much superior when the PPD conjugates were used as the immunogen when compared to KLH (Table 2). The results show no advantage to using KLH in obtaining peptide-specific antibodies. Peptides typically have low antigenicity, particularly if they are naturally occurring. To increase the antigenicity, the most common approach has been to use KLH whose immunogenicity KLH masks the production of peptide-specific antibodies, a major disadvantage when preparing peptide-specific antibodies. The role of PPD therefore is to act as a T-cell activation leaving the B-cells to respond to the peptide (Lachmann et al., 1986).

PPD has not been extensively used in the preparation of protein−hapten conjugates. The principal practical use of PPD for the last half century has been as an in vivo diagnostic test for previous encounters with *Mycobacterium tuberculosis* (Lachmann, 1988). However, its potential in the "heterogenization" of tumor cells and the results of these studies in the production of antibodies against tumor antigens has been very encouraging (Lachmann et al., 1981; Sia et al., 1984). PPD has being used by Lachmann et al. (1986) in the preparation of peptide conjugates that were used in the production of anti-peptide antibodies. Antibodies against PPD cannot be precipitated in the Farr assay (Lachmann, 1988), but there has been an ELISA method developed to detect PPD-specific antibodies in the detection of tuberculosis in children (Barrera et al., 1989). Our results do show a

weak antibody response to PPD compared to the other carriers used. On the basis of the Farr assay, Lachmann (1988) defines PPD as a poor B-cell antigen. However, the antibodies that are present in our experiments could be against the impurities present in the protein preparations since it is not clear that the PPD used in most of the clinical testing is of 100% purity (Lachmann et al., 1986). KLH, BSA, and OVA are excellent carrier proteins commonly used in the preparation of hapten−protein conjugates.

We have clearly described the exceptional ability of PPD as a carrier in the production of hapten-specific antibodies. Although this unique characteristic of PPD as a carrier protein is not completely understood, it is assumed that the denatured structure of PPD could be responsible for the activation of T-cell receptors. It is conceivable that as the T-cells recognize processed antigenic epitopes, the heat-denatured PPD could be a potential target for their activation. The activity of PPD is enhanced only in animals previously exposed to *Mycobacterium tuberculosis* or immunized with BCG. These animals show a delayed-type hypersensitivity (DTH) when challenged with PPD. This, on the other hand, may cause a retention of the antigen for a prolonged period of time at the site of the injection, thus giving rise to an adjuvant effect. This has invoked an interest in using PPD in vaccine preparations. Thus PPD has demonstrated its usefulness as a carrier molecule in the preparation of hapten−protein/peptide−protein conjugates and its potential in vaccine preparation as an adjuvant.

ACKNOWLEDGMENT

This work was supported in part by the Center for BioAnalytical Research at University of Kansas, the Procter and Gamble Company, and Eli Lilly Laboratories. We thank Lederle Laboratories for the generous donation of the PPD.

Epidermal Growth Factor Radiopharmaceuticals: ^{111}In Chelation, Conjugation to a Blood-Brain Barrier Delivery Vector via a Biotin-Polyethylene Linker, Pharacokinetics, and in Vivo Imaging of Experimental Brain Tumors

Atsushi Kurihara, Yoshiharu Deguchi, and William M. Pardridge*

Department of Medicine, UCLA School of Medicine, Los Angeles, California 90095-1682. Received October 9, 1998; Revised Manuscript Received December 29, 1998

Epidermal growth factor (EGF) is a potential peptide radiopharmaceutical for detection of brain tumors, because many human gliomas overexpress the EGF receptor (EGFR). The transport of EGF to the brain, however, is restricted by the blood-brain barrier (BBB). The purpose of the present study was to develop a vector-mediated brain delivery system for radiolabeled EGF. Human EGF was monobiotinylated with NHS-PEG^{3400}-biotin, where NHS is *N*-hydroxysuccinimide and PEG^{3400} is poly(ethylene glycol) of 3400 Da molecular mass. EGF-PEG^{3400}-biotin was radiolabeled with either ^{125}I or ^{111}In through the metal chelator, diethylenetriaminepentaacetic acid (DTPA). The radiolabeled EGF was then conjugated to a BBB delivery vector comprised of a complex of the OX26 monoclonal antibody (MAb) to the rat transferrin receptor, which was coupled to streptavidin (SA). Following intravenous injection in rats, the ^{125}I conjugate was rapidly degraded in vivo, while the ^{111}In conjugate was metabolically stable. The brain delivery of [^{111}In]DTPA-EGF-PEG^{3400}-biotin was enabled by conjugation with OX26/SA and was optimized by co-injection of unlabeled EGF to saturate EGF receptors in the liver. The specific binding of the [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to OX26/SA to the EGF receptor was confirmed in C6 rat glioma cells, which had been transfected with a gene encoding for the human EGF receptor under the regulation of a dexamethasone-inducible promoter. In vivo studies of C6-EGFR experimental tumors in Fischer 344 rats demonstrated successful brain imaging only when the peptide radiopharmaceutical was conjugated to the BBB delivery system, although the C6-EGFR tumors did not express EGFR in vivo. In conclusion, these studies describe the molecular formulation of a peptide radiopharmaceutical that can be used for imaging brain tumors behind the BBB.

INTRODUCTION

Primary human brain tumors frequently overexpress the receptor for epidermal growth factor (EGF) (*1*−*3*), and EGF peptide radiopharmaceuticals are potential imaging agents for the diagnosis of human brain gliomas (*4*). However, like most other neuropeptides, EGF does not cross the brain capillary endothelial wall (*5*), which makes up the blood-brain barrier (BBB) in vivo. Since the BBB is intact (*6*), until the end stage of most human brain tumors, it may be necessary to conjugate EGF to BBB transport vectors in order to use this peptide as a radiopharmaceutical for imaging human brain tumors. BBB transport vectors include the OX26 monoclonal antibody (MAb), which targets the rat transferrin receptor (*7*), or the anti-human insulin receptor MAb (HIRMAb), which is a BBB delivery vector active in humans or Old World primates such as Rhesus monkeys (*8*). Peptide radiopharmaceuticals may be conjugated to BBB transport vectors using avidin-biotin technology (*7*).

Previous studies describe the biotinylation of human EGF at surface ϵ-amino moieties of lysine residues using a 14 atom bis(aminohexanoyl) spacer arm (-XX-) between the EGF and the biotin (*9*). However, when the EGF-XX-biotin was bound to a conjugate of the OX26 MAb and streptavidin (SA), which is designated OX26/SA, the EGF no longer bound to the EGF receptor on C6 rat glioma cells (*9*). These C6 cells had been transfected with a gene encoding the human EGF receptor under the influence of a dexamethasone-inducible promoter and designated C6EGFRp cells (*10*). Conversely, when the -XX- linker was replaced with a >200 atom linker comprised of poly(ethylene glycol) of 3400 Da molecular mass, designated PEG^{3400}, the binding of the peptide to the EGF receptor was restored despite conjugation to the OX26/SA BBB delivery system (*9*). The radionuclide used in previous studies was ^{125}I, which was added to surface tyrosine residues on EGF.

The present investigations extend these previous studies (*9*) and examine the pharmacokinetics and in vivo metabolic stability of the [^{125}I]EGF-PEG^{3400}-biotin conjugated to OX26/SA. However, the initial studies with the EGF peptide radiopharmaceutical formulated with the ^{125}I radionuclide demonstrated a marked metabolic instability in vivo. Therefore, the present study also describes the preparation of a human EGF peptide radiopharmaceutical that is conjugated with both diethylenetriaminepentaacetic acid (DTPA), to enable chelation with the ^{111}In radionuclide, and monobiotinylation using NHS-PEG^{3400}-biotin, where NHS = *N*-hydroxysuccinimide. The monobiotinylated form of EGF was purified by gel filtration fast-protein liquid chromatography (FPLC) using two columns in series and characterized using

matrix-assisted laser desorption ionization mass spectrometry (MALDI) and sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and Western blotting. The metabolic stability of the EGF conjugate formulated with the ^{111}In radionuclide was demonstrated with FPLC analysis of rat serum taken 60 min after an intravenous (i.v.) injection. The affinity of the EGF peptide radiopharmaceutical conjugated to the BBB delivery system for the human EGF receptor was examined using the C6EGFR cells both in tissue culture and in vivo, wherein experimental brain tumors were formed by implanting the C6EGFR cells into the caudate-putamen nucleus of Fischer 344 rats. Following initial pharmacokinetic analysis, the EGF peptide radiopharmaceutical conjugated to the BBB delivery system and formulated with the ^{111}In radionuclide was used for neuroimaging of experimental brain tumors.

EXPERIMENTAL PROCEDURES

Materials. [^{125}I]Na was supplied by Amersham (Arlington Heights, IL). [^{111}In]Cl_3 was supplied by NEN Life Science Product Inc. (Boston, MA). NHS-PEG^{3400}-biotin was obtained from Shearwater Polymers (Huntsville, AL), where NHS = *N*-hydroxysuccinimide and PEG^{3400} = poly(ethylene glycol) of 3400 Da molecular mass. Diethylenetriaminepentaacetic (DTPA) dianhydride was obtained from Aldrich Chemical Co., Inc. (Milwaukee, WI). Chloramine-T was purchased from MCB Reagents (Cincinnati, OH). Recombinant streptavidin (SA), recombinant human epidermal growth factor (EGF), and all other reagents were obtained from Sigma Chemical Company (St. Louis, MO). Superose 12 HR 10/30 FPLC columns and High-Trap copper affinity columns (1.0 mL) were obtained from Pharmacia Biotech (Piscataway, NJ). C6 rat glioma cells transfected with the gene for the human EGF receptor were kindly provided by Dr. Robert Fenstermaker of the Roswell Park Cancer Institute (Buffalo, NY), and these cells are designated C6EGFRp (*10*). The mouse hybridoma line producing the 528 MAb to human EGFR was obtained from the American Type Culture Collection (Rockville, MD). The anti-human EGFR mouse MAb was purchased from Upstate Biotechnology (Lake Placid, NY), catalog no. 05-101. The ABC-Elite immunocytochemistry kit was obtained from Vector Labs (Burlingame, CA). Mouse IgG1 and IgG2a isotype controls were obtained from Cappel Pharmaceuticals (Aurora, OH).

Preparation of [^{125}I]EGF-PEG^{3400}-biotin. NHS-PEG^{3400}-biotin (65 nmol in 100 μL of 0.05 M $NaHCO_3$) was added in an 8:1 molar ratio to 50 μg of EGF (8.0 nmol in 100 μL of 0.05 M $NaHCO_3$, pH 8.3) followed by incubation at room temperature for 60 min. Of this mixture, 20 μL was added to 20 μL of 0.3 M NaH_2PO_4 (pH 7.0) followed by the addition of 2 mCi of ^{125}I and 10 μL (0.8 μg) of chloramine-T. After a 60 s incubation, an additional 10 μL (0.8 μg) of chloramine-T was added, and 60 s later, the reaction was terminated by the addition of 50 μL (65 nmol) of sodium metabisulfite. Buffer A (0.05 M NaH_2PO_4/0.5 M NaCl/pH 7.0) was added to a volume of 1.0 mL, and the mixture was then applied to a 1.0 mL High-Trap copper affinity column to remove unreacted NHS-PEG^{3400}-biotin, as described previously (*11*). The column was initially washed with 5.0 mL of water and charged with 0.5 mL of 0.1 M $CuSO_4$ followed by washing with 5.0 mL of water, followed by application of the sample. The column was washed with 10 mL of buffer A, and the [^{125}I]EGF-PEG^{3400}-biotin was eluted with 5.0 mL of 50 mM imidazole in buffer A. One milliliter of this eluate (250 μCi) was added to a Centricon-3 microconcentrator (Amicon, Inc., Beverly, MA), and the volume was reduced to 200 μL by centrifugation at 7500 rpm (7500*g*) for 40 min at room temperature. Then [^{125}I]EGF-PEG^{3400}-biotin was purified by size-exclusion chromatography using a TSK-gel G2000$_{SWXL}$ column (TosoHaas, Montgomery, PA) with an elution buffer of 0.01 M NaH_2PO_4/0.15 M NaCl/pH 7.4/0.05% Tween-20 at a flow rate of 0.5 mL/min.

Preparation of [^{111}In]DTPA-EGF-PEG^{3400}-biotin. NHS-PEG^{3400}-biotin (80 nmol in 50 μL of 0.05 M $NaHCO_3$) was added in a 5:1 molar ratio to EGF (16 nmol in 200 μL of 0.05 M $NaHCO_3$) followed by incubation at room temperature for 60 min. To this mixture, 50 μL of 0.43 M $NaHCO_3$ and 850 nmol of DTPA dianhydride (17 μL of a dimethyl sulfoxide solution) were added, followed by incubation at room temperature for 60 min. The entire mixture was then applied to two Superose 12 HR 10/30 FPLC columns in series, followed by the elution in 0.01 M NaH_2PO_4/0.15 M NaCl/pH 7.4 at a flow rate of 0.5 mL/min for 90 min. EGF, containing a single DTPA group and a single PEG^{3400}-biotin moiety and designated DTPA-EGF-PEG^{3400}-biotin, eluted at 52 min from the column, as demonstrated by MALDI (below). Two millicurie of ^{111}In was added to the DTPA-EGF-PEG^{3400}-biotin. After 30 min at room temperature, unreacted free ^{111}In was removed by Sephadex G25 size-exclusion chromatography with an elution buffer of 0.01 M NaH_2PO_4/0.15 M NaCl/pH 7.4 containing 0.05% Tween-20.

Conjugation of [^{125}I]EGF-PEG^{3400}-biotin or [^{111}In]-DTPA-EGF-PEG^{3400}-biotin to OX26/SA. The conjugate of the OX26 MAb and recombinant streptavidin (SA) was prepared with a thiol-ether linkage as described previously (*12*). Briefly, 17 mg of OX26 MAb was thiolated with a 10:1 molar ratio of 2-iminothiolane; 7 mg of recombinant SA was activated with a 20:1 molar ratio of *m*-maleimidobenzoyl *N*-hydroxysuccinimide ester (MBS). The activated SA and the thiolated OX26 were then mixed and incubated at room temperature for 3 h. The OX26/SA conjugate was labeled with 2.5 μCi of [^{3}H]biotin and was purified on a 2.6 × 92 cm column of Sephacryl S300HR (Pharmacia) followed by elution in 0.01 M NaH_2PO_4/0.15 M NaCl/pH 7.4/0.05% Tween-20 at 30 mL/h, and 3 mL fractions were collected. The conjugate peak was separated from either aggregates, unconjugated OX26 MAb, or unconjugated SA. The number of biotin binding sites per OX26/SA conjugate was 3.3 ± 0.3, as determined with the [^{3}H]biotin binding assay (*12*).

The conjugate of [^{125}I]EGF-PEG^{3400}-biotin and OX26/SA was prepared by mixing 1 mL of the imidazole eluate from the High-Trap column containing [^{125}I]EGF-PEG^{3400}-biotin (0.6 nmol) and 400 μg (0.2 nmol) of OX26/SA (*9*). After reduction of the volume to 0.2 mL with a Centricon-30 microconcentrater, [^{125}I]EGF-PEG^{3400}-biotin conjugated to OX26/SA was separated from either [^{125}I]-EGF or unreacted [^{125}I]EGF-PEG^{3400}-biotin by size-exclusion chromatography using a TSK-gel G2000$_{SWXL}$ with an elution buffer of 0.01 M NaH_2PO_4/0.15 M NaCl/pH 7.4/0.05% Tween-20 at a flow rate of 0.5 mL/min.

The conjugate of [^{111}In]DTPA-EGF-PEG^{3400}-biotin and OX26/SA was prepared by mixing [^{111}In]DTPA-EGF-PEG^{3400}-biotin (5 nmol) eluted from Sephadex G25 column with OX26/SA (8 nmol).

Matrix-Assisted Laser Desorption Ionization Mass Spectrometry (MALDI). Mass spectra of DTPA-EGF-PEG^{3400}-biotin eluted from the two Superose 12HR 10/30 FPLC columns in series were recorded with a reflector time-of-flight instrument (PerSeptive Biosystems Voyager RP) used in the linear mode with stainless steel targets. An aliquot of sample solution (0.5 μL) or sample

solution plus internal standard (myoglobin 5 pmol in 0.5 μL of water) was overlaid on top of an aliquot matrix (sinapinic acid), and after drying, the target was inserted into the mass spectrometer, and time/intensity data from 50 to 100 scans was averaged and converted to mass/intensity data using external calibration from myoglobin.

SDS−PAGE and Western Blotting. The change in molecular weight of EGF following conjugation with NHS-PEG^{3400}-biotin was confirmed by SDS−PAGE. The reaction mixture of EGF and varying concentrations of NHS-PEG^{3400}-biotin was applied to a 16.5% SDS−PAGE minigel (Bio-Rad, Rhichmond, CA), and electrophoresis was performed at constant voltage (100 V) for 2 h at room temperature. The gel slab was stained for protein content with Coomassie Blue G250. The incorporation of biotin at the tip of PEG strand was confirmed by Western blotting. Following SDS−PAGE, the gel slab was blotted to a nylon membrane without methanol (100 V, 60 min, 4 °C) and the membrane was subsequently stained for biotin content with the ABC kit (Vector Labs, Burlingame, CA) using avidin and biotinylated peroxidase and diaminobenzidine as chromagen (13). SDS−PAGE molecular weight standards were obtained from Bio-Rad (Richmond, CA).

C6EGFRp Radioreceptor Assay. C6EGFRp cells were grown in Dulbecco's modified Eagle medium (DMEM) with 4.5 g/L D-glucose, 4 mM glutamine, 10% fetal bovine serum, and 250 μg/mL G418, used as a selection agent, in 24-well cluster dishes. For the dexamethasone stimulation condition, the medium was changed to DMEM with 4.5 g/L D-glucose, 4 mM glutamine, 1% fetal bovine serum, and 1 μM dexamethasone 24 h prior to performing radioreceptor assays (*10*). Cells were washed with 0.01 M HEPES/0.15 M NaCl/pH 7.4/0.1% BSA (HBSB buffer), followed by 15 min to 120 min incubation at 37 °C with 200 μL of HBSB buffer containing 1.0 μCi/mL (0.2 nM) of [^{111}In]DTPA-EGF-PEG^{3400}-biotin with and without OX26/SA in the presence and absence of 1 μM unlabeled EGF. After incubation, supernatants were aspirated and the cells were washed two times with cold 0.01 M HEPES/0.15 M NaCl/pH 7.4, and solubilized by the addition of 0.5 mL of 1 N NaOH and incubation at 37 °C for 4 h. ^{111}In radioactivity was counted by γ counter and protein content of the cells was measured with the bicinchoninic acid (BCA) protein assay (Pierce Chemical Co., Rockford, IL). Cell-associated binding (surface-binding and intracellular accumulation) was expressed as percent of medium radioactivity bound per milligram of cell protein.

Pharmacokinetics and Brain Drug Delivery. Male Sprague−Dawley rats weighing 280−350 g were anesthetized with 100 mg/kg ketamine and 2 mg/kg xylazine intraperitoneally (ip). The femoral vein was cannulated with a PE50 cannula and injected with either 5 μCi of [^{125}I]EGF-PEG^{3400}-biotin or 5 uCi of [^{111}In]DTPA-EGF-PEG^{3400}-biotin, with or without conjugation to OX26/SA and either 0 or 16 nmol of unlabeled human EGF. Blood samples (0.25 mL) were collected via a PE50 cannula implanted in the femoral artery at 0.25, 1, 2, 5, 15, 30 and 60 min after the injection of the isotope solution. The blood volume was replaced with an equal volume of saline. After 60 min, the animals were decapitated for removal of the brain, liver, kidney, heart, and lung. The radioactivity in the plasma and organ samples were counted using a γ counter (Beckman Instruments, Inc., Fullerton, CA).

Pharmacokinetic parameters were calculated by fitting the plasma radioactivity data to a biexponential equation (*14*):

$$A(t) = A_1 e^{-k_1 t} + A_2 e^{-k_2 t}$$

where $A(t)$ = % ID/mL plasma and ID = injected dose. For [^{125}I]EGF-PEG^{3400}-biotin, TCA-precipitable radioactivity data was used. The biexponential equation was fit to plasma data by a derivative-free nonlinear regression analysis (PARBMDP, Biomedical Computer P-Series, developed at UCLA Health Science Computing Facilities). The area under the plasma concentration−time curve (AUC), the steady-state volume of distribution (Vss), total plasma clearance (Cl), and the mean residence time (MRT) were calculated from A_1, A_2, k_1, k_2, and the body weight (kg) of the rat as described by Gibaldi and Perrier (*15*). The organ permeability−surface area (PS) product was calculated as

$$\mathrm{PS} = [V_d - V_0]\mathrm{Cp(60min)/AUC(0-60min)}$$

where Cp(60min) is the terminal plasma concentration (dpm/μL) at 60 min after injection, V_d is the tissue volume of distribution determined from the ratio of disintegrations per minute per gram of the tissue to Cp(60min), and V_0 is the organ plasma volume, which has been measured previously (*14*). The organ delivery of the EGF conjugate was determined as

$$\%\ \mathrm{ID/g} = \mathrm{PS} \times \mathrm{AUC(0-60min)}$$

where % ID/g is the percent injected dose taken up per gram of organ.

The metabolic stability in plasma of the [^{125}I]EGF-PEG^{3400}-biotin was determined by trichloroacetic acid (TCA) precipitation of 50 μL aliquots of the plasma sample removed at each time point. The metabolic stability in plasma of the [^{111}In]DTPA-EGF-PEG^{3400}-biotin bound to the OX26/SA conjugate was also examined by elution of plasma through a single Superose 12 HR 10/30 FPLC column. In this study, blood was removed at 60 min following intravenous injection of 60 μCi of [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to OX26/SA and 16 nmol of unlabeled EGF. Fifty microliters of serum sample was applied to the FPLC column, followed by the elution in 0.01 M NaH_2PO_4/0.15 M NaCl/0.05% Tween-20/pH 7.4 at a flow rate of 0.5 mL/min for 50 min. Column fractions (0.5 mL) were assayed for ^{111}In radioactivity.

Intracerebral Tumor Implantation and in Vivo Autoradiography. Male CD Fischer 344 rats weighing 170−180 g were implanted with C6EGFRp cells (*4*, *10*). The rats were anaesthetized with a mixture of ketamine (100 mg/kg) and xylazine (2 mg/kg) ip and fixed in a stereotactic frame. A burr hole was drilled 3 mm to the right of midline, 1 mm posterior to bregma. C6EGFRp cells were suspended in serum-free DMEM containing 1.2% methylcellulose. Five microliters of cell suspension (1×10^5 cells) was injected into the right caudate nucleus at a depth of 4 mm over 10 s, using a 10 μL Hamilton syringe with fixed needle. At the end of the procedure, the viability of the remaining cells was determined by means of the trypan blue exclusion method. To allow for the implanted glioma cells to produce a tumor of a adequate size (~5 mm), in vivo autoradiography studies were carried out 4 weeks following tumor cell implantation (*4*). Tumor-bearing rats were intravenously injected with either [^{111}In]DTPA-EGF-PEG^{3400}-biotin (100 μCi) with OX26/SA and 16 nmol of unlabeled EGF or [^{111}In]-DTPA-EGF-PEG^{3400}-biotin (100 μCi) alone. Sixty minutes after isotope injection, rats were decapitated and the brain was rapidly removed from the cranium and sec-

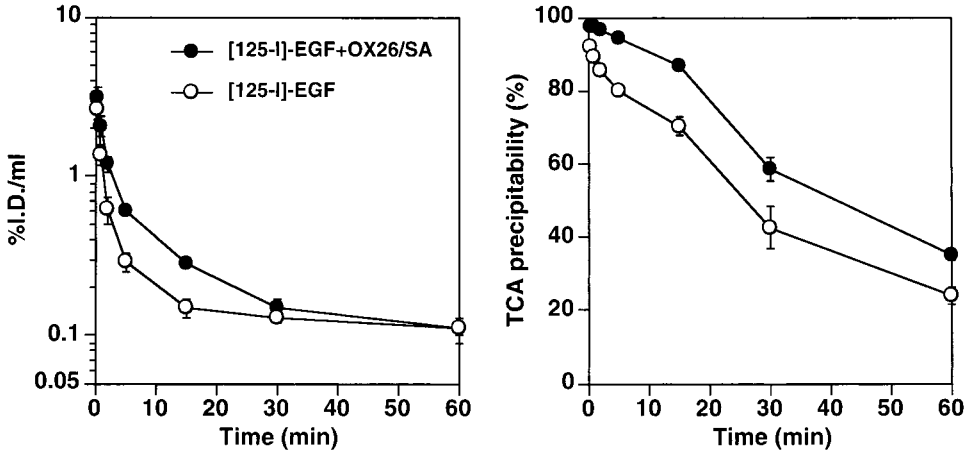

Figure 1. (Right panel) Profile of the TCA-precipitable plasma radioactivity of either unconjugated [^{125}I]EGF-PEG^{3400}-biotin (open circle) or the [^{125}I]EGF-PEG^{3400}-biotin conjugated to the OX26/SA vector (closed circle) after an i.v. injection of 5 μCi/rat. (Left panel) Time course of the percent of plasma radioactivity that is precipitable with TCA after the i.v. injection. Each point represents the mean ±SE of three rats.

tioned into 3 mm slabs. The slabs were plunged into powdered dry ice for rapid freezing over 30 min. Frozen sections of 15 μm were cut and thaw-mounted on glass cover slips. After drying, these cover slips were placed in apposition to Kodak Biomax MS X-ray film and exposed for 4 days at −70 °C with intensifying screen. The film was scanned with a Hewlett-Packard ScanJet IIcx/T flatbed scanner and transferred to Adobe Photoshop on a Power Macintosh 7100/66 microcomputer, followed by colorization with NIH image software, and prints were generated with a Kodak printer.

Immunocytochemistry. The expression of the EGF receptor in the C6EGFRp glioma cells that had been transplanted into the caudate-putamen nucleus of Fischer 344 rats was investigated with immunochemistry at 4 weeks after the implantation of 1×10^5 C6EGFRp cells. Rats were sacrificed and the brain was rapidly removed and frozen in pulverized dry ice. The frozen brain was then embedded in tissue OCT (Tissue Tek II, Miles, Elkhart, IN) and 15 μ frozen sections were obtained with a Bright cryostat. Sections were mounted to glass slides and then fixed in either 100% acetone at −20 °C for 20 min or fixed by drying in an oven at 60 °C for 30 min. Endogenous peroxidase activity was inactivated with 1% H_2O_2 for 5 min at room temperature, and the slides were blocked with 3% horse serum for 30 min at room temperature. Two different primary antibodies were used. The 528 mouse MAb to the human epidermal growth factor receptor was generated from conditioned medium produced from 528 hybridoma cells. The 528 antibody has been demonstrated in previous studies to illuminate the human EGF receptor in experimental brain tumors with immunocytochemistry (*16*). A second primary antibody that was used in these studies was the anti-human EGF receptor mouse monoclonal antibody from Upstate Biotechnology (Lake Placcid, NY). The monoclonal antibodies were used at a concentration of 3 and 10 μg/mL and mouse IgG1 or mouse IgG2$_a$ isotype controls were employed in parallel. Following reaction with a biotinylated horse anti-mouse antibody that had been preabsorbed with rat immunoglobulin (Vector Laboratories, Burlingame, CA, catalog no. BA-2001), the slides were exposed to avidin and biotinylated peroxidase using the vector ABC method (Vector Labs, Burlingame, CA). These slides were lightly counterstained with hematoxylin and mounted. As a control, human glioblastoma multiforme U87 cells, which express the human EGF receptor (*16*), were obtained from the American Type Culture Collection and examined in parallel. These cells formed tumors in the brains of nude rats and the U87 cells, both in cell culture and in vivo as brain tumors, highly expressed immunoreactive human EGF receptor.

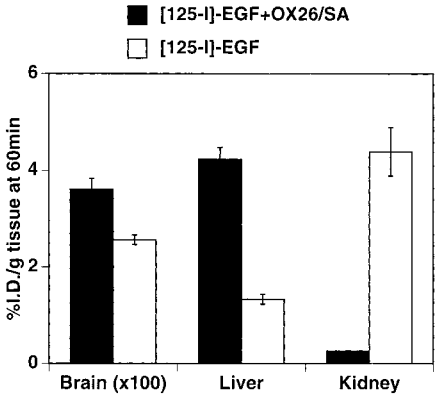

Figure 2. Tissue uptake of unconjugated [^{125}I]EGF-PEG^{3400}-biotin (open column) or the [^{125}I]EGF-PEG^{3400}-biotin conjugated to the OX26/SA vector (closed column) 60 min after the i.v. injection of 5 μCi/rat. Data are mean ±SE (n = 3 rats).

RESULTS

Pharmacokinetics and Brain Uptake of [^{125}I]EGF Conjugate. The [^{125}I]EGF-PEG^{3400}-biotin was prepared and injected intravenously into anesthetized rats with or without conjugation to OX26/SA and the plasma radioactivity profile is shown in Figure 1 (left panel). The EGF radiolabeled with ^{125}I radionuclide was rapidly removed from the plasma compartment despite conjugation to OX26/SA and exhibited reduced metabolic stability based on measurement of plasma radioactivity that was precipitable with trichloroacetic acid (TCA), as demonstrated in Figure 1 (right panel). Analysis of distribution of the EGF conjugate into organs (brain, liver, and kidney) demonstrated the expected redirection of the EGF radiopharmaceutical from kidney to liver following conjugation to the anti-transferrin receptor MAb (Figure 2). However, the brain uptake of the EGF radiopharmaceutical formulated with a ^{125}I radionuclide was low with or without conjugation to OX26/SA (Figure 2). As noted in previous studies (*13*), it is difficult to achieve effective brain uptake of drugs, despite conjugation to BBB delivery systems, when the peptide is inherently metabolically labile. These results indicated

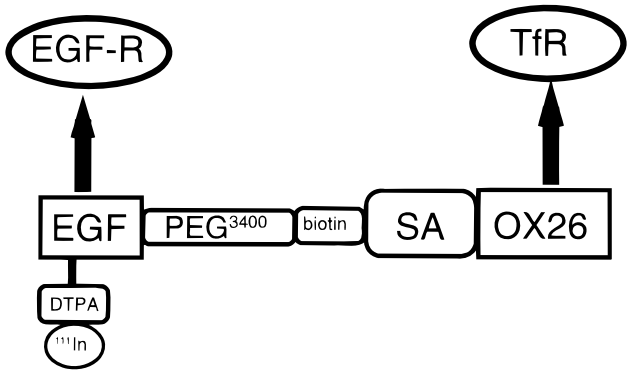

Figure 3. Delivery of radiolabeled EGF through the blood-brain barrier and binding to EGF receptor (EGF-R) overexpressed in glioma cells. The delivery system is comprised of three domains: (i) a glioma binding domain consisting of EGF radiolabeled stably with ^{111}In through the metal chelator, diethylenetriaminepentaacetic acid (DTPA); (ii) a linker domain consisting of *single* strand of PEG^{3400} spacer arm attached to EGF and the biotin moiety, which is in turn bound to streptavidin (SA); (iii) and a BBB transport domain consisting of the OX26 anti-rat transferrin receptor (TfR) monoclonal antibody (MAb), which is conjugated to SA through stable thioether linkage. The OX26 MAb undergoes receptor-mediated transcytosis through the blood-brain barrier via the brain capillary endothelial TfR (*21*). The EGF moiety binds to EGF-R positive glioma cells. The PEG^{3400} linker releases steric hindrance of the OX26 MAb on binding of the EGF to its cognate receptor (*9*). The radioligand ^{111}In is suitable for imaging and confers metabolic stability of the radionuclide moiety compared to ^{125}I.

the necessity of reformulating the EGF peptide radiopharmaceutical with a radionuclide that provided a greater degree of metabolic stability.

Synthesis and Characterization of [^{111}In]EGF Conjugate. The structure of the EGF peptide radiopharmaceutical conjugated to the BBB delivery system and formulated with ^{111}In radionuclide though a DTPA chelator moiety is shown in Figure 3. The placement of a >200 atom linker comprised of PEG^{3400} reduces any steric hindrance between the two components of the conjugate (*9*). The extended linker allows for maintenance of bifunctionality of the conjugate with binding to both the EGF receptor, for imaging brain tumors, and to the transferrin receptor, to enable receptor-mediated transyctosis through the BBB in vivo. Following reaction of DTPA dianhydride with NHS-PEG^{3400}-biotin, the human EGF was eluted through two Superose 12HR gel filtration FPLC columns in series and the elution profile is shown in Figure 4. The identity of the various peaks was determined by either MALDI (Experimental Procedures), or by parallel injection of standards. The EGF peak that contained a single DTPA residue and a single PEG^{3400}-biotin residue was found in peak C, and the measured molecular mass, 10 193 Da, was the expected size, which is approximately 10 200 Da (inset, Figure 4). Following reaction with NHS-PEG^{3400}-biotin, the EGF was also examined with SDS−PAGE, shown in Figure 5. The Coomassie blue stain of the SDS−PAGE gel (Figure 5A) shows the molecular weight of the unconjugated EGF at 6200 Da, and a second band is formed on the gel when NHS-PEG^{3400}-biotin is added, and this band is seen in lanes 1−4 of Figure 5A and migrates at a molecular size of 10 000 Da, which approximates the expected molecular weight, 9900 Da, of EGF with a single PEG^{3400}-biotin residue attached. At the higher molar ratios of NHS-PEG^{3400}-biotin:EGF, an additional band is detected which migrates at 16 000 Da and approximates the expected molecular weight (14 000 Da) of EGF with 2 PEG^{3400}-biotin moieties attached. The attachment of the

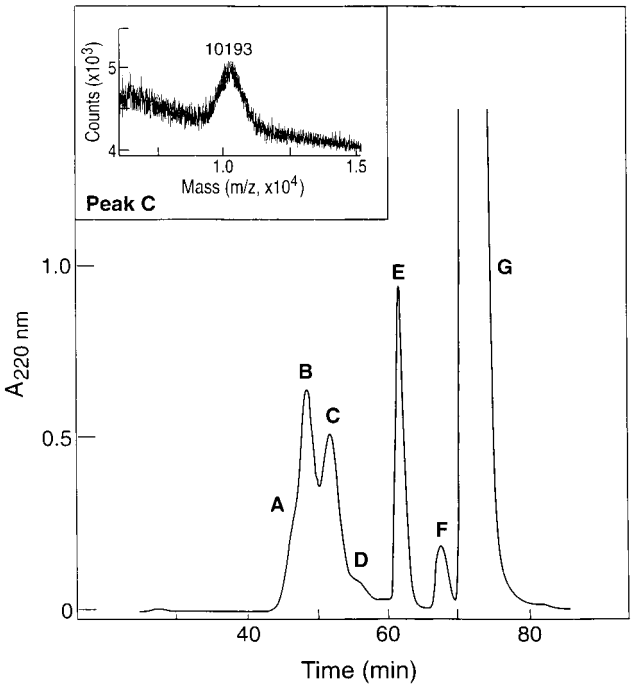

Figure 4. Purification of monobiotinylated DTPA-EGF-PEG^{3400}-biotin by FPLC. Reaction mixture of EGF, NHS-PEG^{3400}-biotin, and DTPA dianhydride was applied to two Superose 12 HR 10/30 FPLC column in series, followed by the elution in 0.01 M NaH_2PO_4/0.15 M NaCl/pH 7.4 at a flow rate of 0.5 mL/min for 90 min. Peak A, EGF-(PEG^{3400}-biotin)$_3$; peak B, DTPA-EGF-(PEG^{3400}-biotin)$_2$; peak C, DTPA-EGF-PEG^{3400}-biotin; peak D, DTPA-EGF; peak E, DTPA; peak F, NHS-PEG^{3400}-biotin; peak G, solvent peak. (Insert) MALDI mass spectra shows mean molecular mass of 10 193 Da for peak C (DTPA-EGF-PEG^{3400}-biotin, theoretical MW, 10 240). Peak A, EGF-(PEG^{3400}-biotin)$_3$ and peak B, DTPA-EGF-(PEG^{3400}-biotin)$_2$ showed molecular masses of 17 500 Da (theoretical 17 542 Da) and 13 801 Da (theoretical 13 891 Da), respectively, with the MALDI analysis. The (PEG^{3400}-biotin)$_n$ nomenclature, where n = 1, 2, or 3, refers to the number of PEG^{3400} strands conjugated to the EGF.

biotin residue was confirmed by Western blotting as shown in Figure 5B. No signal is detected in lanes 5 or 6, which represent reactions that contained either no NHS-PEG^{3400}-biotin or no EGF, respectively. The reaction with a 1:1 molar ratio of NHS-PEG^{3400}-biotin:EGF yields a single prominent band of 9200 Da, and this corresponds to the approximate molecular mass of EGF with a single PEG^{3400}-biotin residue attached. At the higher molar ratios (lanes 1−3) of NHS-PEG^{3400}-biotin:EGF, a second higher molecular weight band is detected of 14 600 Da (Figure 5B), and this approximates the molecular mass of EGF with 2 PEG^{3400}-biotin moieties attached.

Radioreceptor Assays with [^{111}In]EGF Conjugate and C6 Glioma Cells in Tissue Culture. The EGF-PEG^{3400}-biotin formulated with ^{111}In and DTPA radionuclide still actively bound to the EGF receptor on the C6EGFRp cells with or without conjugation to OX26/SA, as shown in Figure 6. Radioreceptor assays performed with the C6EGFRp cells pretreated with 1 μM dexamethasone for 24 h are shown in the right-hand panel of Figure 6, and radioreceptor assays performed with these cells without dexamethasone pretreatment are shown in the left-hand panel of Figure 6. In the absence of dexamethasone pretreatment, there is little induction of the EGF receptor in these cells, which explains the minimal binding of unconjugated [^{111}In]EGF (Figure 6, left-hand panel). However, there was significant binding, even in the C6EGFRp cells that were not pretreated with

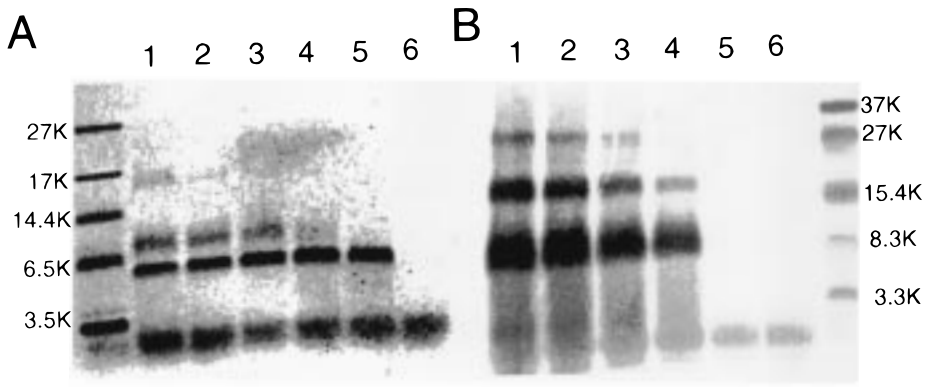

Figure 5. SDS-polyacrylamide gel electrophoresis (A) and Western blotting (B) of EGF-PEG^{3400}-biotin. Reaction mixture of EGF and varying concentration of NHS-PEG^{3400}-biotin was applied to a 16.5% SDS−PAGE minigel. Gel slab was either stained with Coomassie Blue G250 for protein content (panel A), or blotted to a nylon membrane followed by staining with avidin and biotinylated peroxidase to visualize the attachment of PEG^{3400}-biotin to the EGF molecule (panel B). Molar ratio of NHS-PEG^{3400}-biotin: EGF in the reaction mixture was 5:1 (lane 1), 4:1 (lane 2), 2:1 (lane 3), 1:1 (lane 4), 0:1 (lane 5), and 5:0 (lane 6).

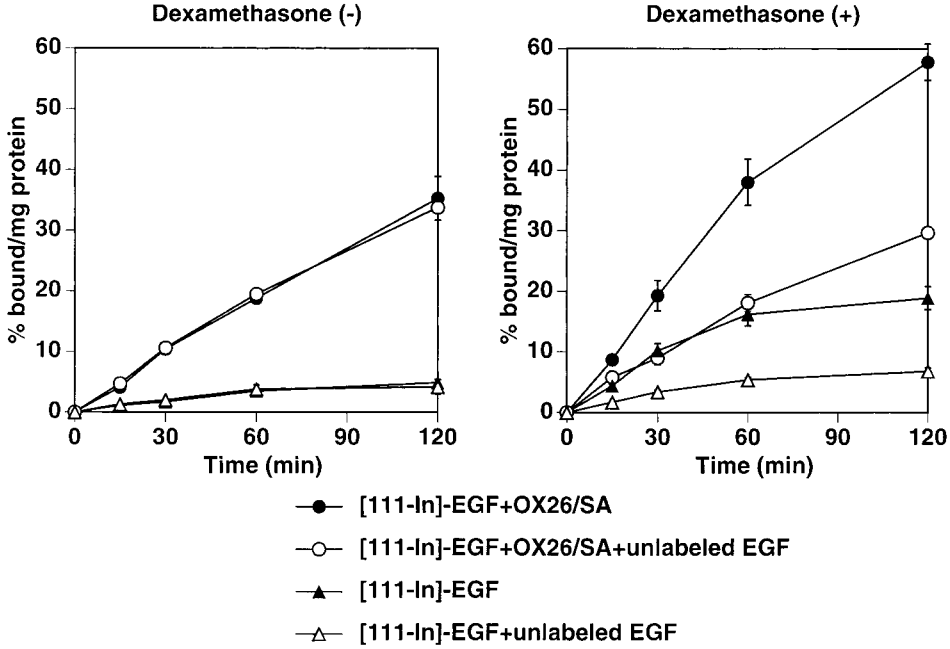

Figure 6. Radioreceptor assay showing time course of binding of either [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to OX26/SA (circles) or binding of [^{111}In]DTPA-EGF-PEG^{3400}-biotin (triangles) to C6 rat glioma cells transfected with the human EGF receptor gene. Assays were performed in the presence (right panel) or absence (left panel) of prior dexamethasone (1 μM) stimulation and in the presence (open symbols) or absence (closed symbols) of 1 μM unlabeled EGF. Each point represents the mean ±SE of three wells.

dexamethasone, of the [^{111}In]EGF-PEG^{3400}-biotin following conjugation to OX26/SA, owing to the expression of transferrin receptor on these cells. The conjugate bound to both transferrin receptor and EGF receptor on the cells, when the EGF receptor was induced by dexamethasone pretreatment (Figure 6, right-hand panel). A saturation analysis demonstrated that the ED_{50} of EGF competition of the binding of [^{111}In]EGF-PEG^{3400}-biotin conjugated to OX26/SA was approximately 1 nM.

Pharmacokinetics and Brain Uptake of [^{111}In]-EGF Conjugate. The pharmacokinetic analysis showed that unconjugated [^{111}In]EGF- PEG^{3400}-biotin was rapidly removed from the bloodstream (Figure 7), similar to the rapid removal of [^{125}I]EGF- PEG^{3400}-biotin from the circulation (Figure 1). For example, the % ID/mL of plasma was approximately 0.1% ID/mL at 10 min for either form of the EGF, indicating that >90% of the peptide had been removed from the circulation within the first 10 min after injection. Following conjugation of [^{111}In]EGF- PEG^{3400}-biotin to OX26/SA, there was some improvement in the plasma AUC (Table 1), but the EGF-PEG^{3400}-biotin conjugated to OX26/SA and formulated with DTPA/^{111}In was still relatively rapidly removed from the bloodstream (Figure 7). Since human EGF is avidly removed from the circulation by the hepatic rat EGF receptor (*17*, *18*), we co-administered a loading dose of unlabeled human recombinant EGF in parallel with the intravenous injection of the EGF-PEG^{3400}-biotin conjugated to OX26/SA and radiolabeled with ^{111}In (Figure 7). The co-injection of the unlabeled EGF resulted in a >4-fold increase in the plasma AUC (Table 1), and the EGF loading also optimized the brain uptake of the conjugate, as shown in Figure 8. In the presence of the unlabeled EGF, the brain uptake of the [^{111}In]EGF-PEG^{3400}-biotin conjugated to OX26/SA was increased more than 10-fold compared to the brain uptake of [^{111}In]EGF-PEG^{3400}-biotin without attachment to the BBB delivery system (Figure 8).

The metabolic stability of the EGF-PEG^{3400}-biotin conjugated to OX26/SA and formulated with DTPA/^{111}In was confirmed by gel filtration FPLC analysis of rat serum taken 60 min after an intravenous injection of the

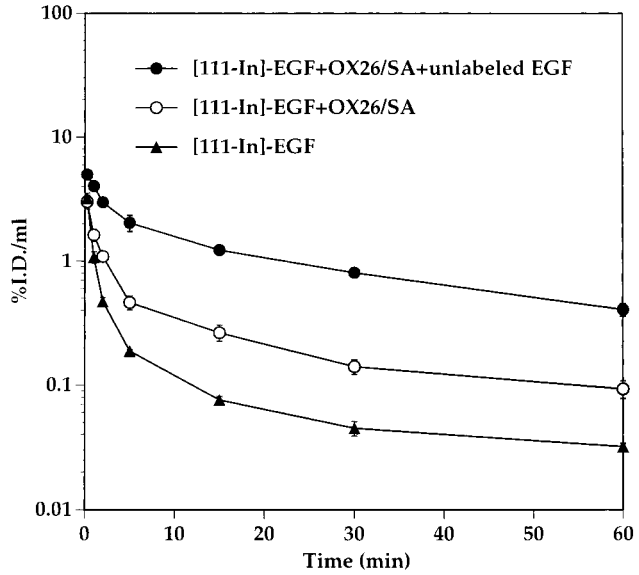

Figure 7. Profile of plasma radioactivity of either unconjugated [^{111}In]DTPA-EGF-PEG^{3400}-biotin (closed triangle), the [^{111}In]-DTPA-EGF-PEG^{3400}-biotin conjugated to the OX26/SA vector (open circle) or [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to the OX26/SA vector and co-injected with 16 nmol of unlabeled EGF (closed circle) after an i.v. injection of 5 μCi/rat. Each point represents the mean ±SE of three rats.

Table 1. Pharmacokinetic Parameters[a]

parameter	[^{111}In]EGF	[^{111}In]EGF + OX26/SA	[^{111}In]EGF + OX26/SA + unlabeled EGF
A_1 (% ID/mL)	3.3 ± 0.7	2.6 ± 0.2	3.5 ± 0.3
A_2 (% ID/mL)	0.11 ± 0.02	0.31 ± 0.03	1.7 ± 0.1
k_1 (min^{-1})	1.1 ± 0.2	0.60 ± 0.11	0.43 ± 0.06
k_2 (min^{-1})	0.044 ± 0.016	0.021 ± 0.001	0.024 ± 0.002
$t_{1/2}^1$ (min)	0.71 ± 0.14	1.2 ± 0.2	1.7 ± 0.2
$t_{1/2}^2$ (min)	33 ± 8	33 ± 2	29 ± 2
AUC(0−60) (% ID min/mL)	6.6 ± 0.6	15 ± 1	63 ± 4
AUC(0−∞) (% ID min/mL)	8.0 ± 0.4	19 ± 1	79 ± 6
Vss (mL/kg)	1297 ± 376	636 ± 7	155 ± 7
Cl (mL/min/kg)	44 ± 3	18 ± 2	4.2 ± 0.3
MRT (min)	30 ± 9	38 ± 5	37 ± 3

[a] Computed from the plasma data in Figure 7. In all cases, the [^{111}In]EGF represents [^{111}In]EGF-PEG^{3400}-biotin.

conjugate (Figure 9). No free EGF was detected, and no significant transfer of the ^{111}In radionuclide to circulating transferrin was detected (peak 4 and 3, respectively, Figure 9). Although there were some transfer of radioactivity to high molecular weight fraction in serum that comigrated with lipoproteins, the principal peak remaining in serum 60 min after intravenous injection was the intact conjugate (peak 2, Figure 9).

In Vivo C6 Glioma Tumor Imaging with [^{111}In]-EGF Conjugate. The quantitative autoradiography (QAR) and tumor imaging using an EGF peptide radiopharmaceutical that is radiolabeled with ^{111}In and administered either with or without the OX26/SA BBB delivery system is shown in Figure 10. The brain images obtained following the intravenous injection of [^{111}In]-EGF-PEG^{3400}-biotin without attachment to the OX26/SA BBB delivery system are shown in the bottom panels (E−H) of Figure 10 and indicate that there is no measurable BBB transport of the peptide radiopharmaceutical into either normal brain or the brain tumor. When the [^{111}In]EGF-PEG^{3400}-biotin is conjugated to OX26/SA and injected intravenously into C6EGFR tumor-bearing rats,

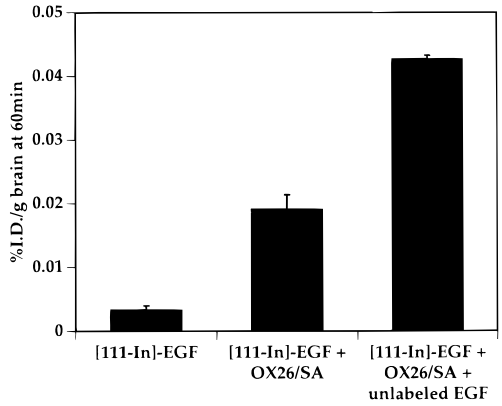

Figure 8. Brain uptake of unconjugated [^{111}In]DTPA-EGF-PEG^{3400}-biotin, [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to the OX26/SA vector, or [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to the OX26/SA vector and co-injected with 16 nmol of unlabeled EGF 60 min after the i.v. injection of 5 μCi/rat. Data are mean ±SE (n = 3 rats).

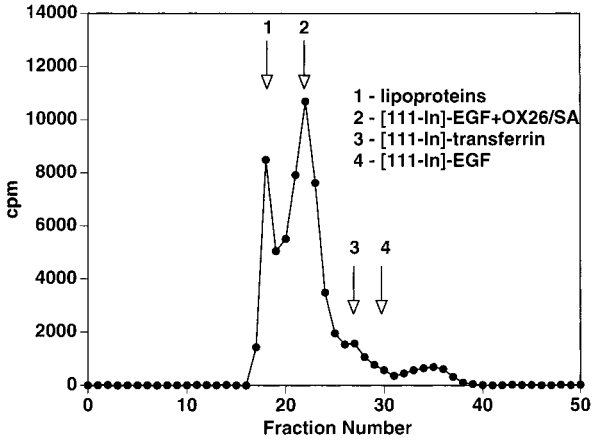

Figure 9. Elution from single Superose 12 HR 10/30 FPLC column of rat serum obtained 60 min after an i.v. injection of 60 μCi of [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to the OX26/SA vector with 16 nmol of unlabeled EGF. Fifty microliters of pooled serum was applied to the FPLC column, followed by the elution in 0.01 M NaH_2PO_4/0.15 M NaCl/0.05% Tween-20/pH 7.4 at a flow rate of 0.5 mL/min for 50 min. Column fractions (0.5 mL) were assayed for [^{111}In]radioactivity. Arrows 1, 2, 3, and 4 indicate elution time of lipoproteins, [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to the OX26/SA, [^{111}In]transferrin, and [^{111}In]DTPA-EGF-PEG^{3400}-biotin, respectively. The result shows that [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to OX26/SA is stable in the circulation at 60 min after i.v. injection in rats.

there is a marked increase in the generalized brain uptake of the peptide radiopharmaceutical owing to transport through the BBB as shown in the top panels (A−D) of Figure 10. The regions of the tumor are clearly demarcated owing to the reduced radionuclide signal emanating from the tumor region. This reduced signal suggested that the C6EGFRp cells, which produce the EGF receptor under the influence of a dexamethasone inducible promoter (*10*), do not express the human EGF receptor in vivo. This was confirmed by immunocytochemistry using two different monoclonal antibodies to the human EGF receptor. Immunocytochemistry of frozen sections of the C6EGFRp tumor showed no visible immunoreactive EGF receptor in the tumor cells in vivo. The positive control cells, U87 human glioma cells, demonstrated high expression of immunoreactive human EGF receptor using either of the monoclonal antibodies (Experimental Procedures).

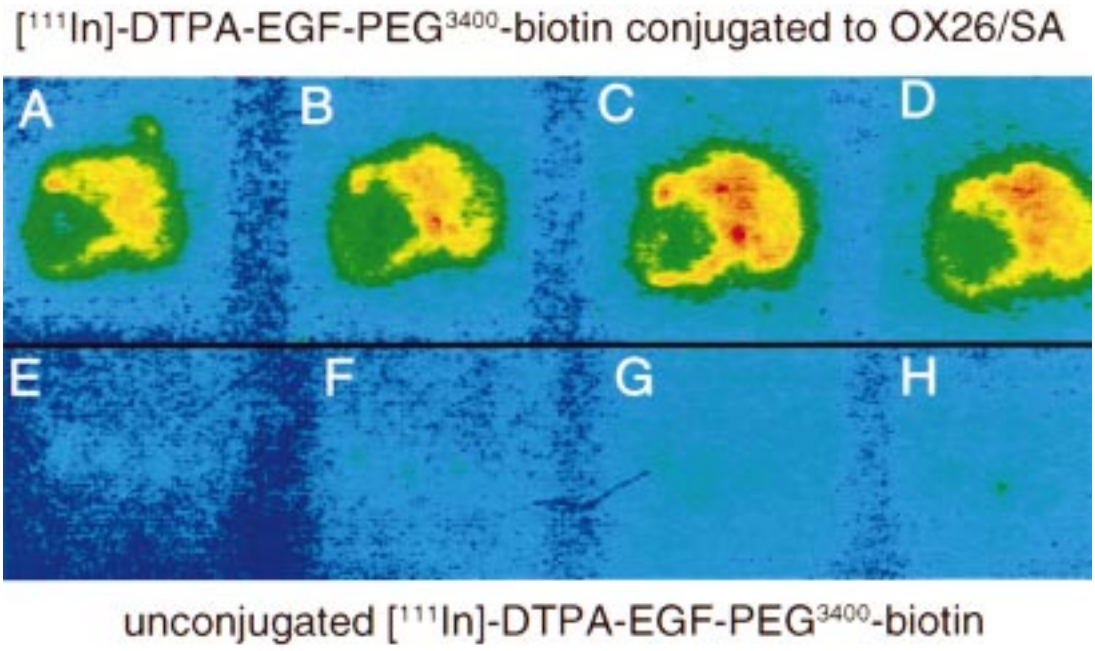

Figure 10. Film autoradiography of brain sections obtained from C6EGFRp tumor-bearing rats injected i.v. with 100 μCi of either [^{111}In]DTPA-EGF-PEG^{3400}-biotin with OX26/SA and 16 nmol of unlabeled EGF (panels A−D) or [^{111}In]DTPA-EGF-PEG^{3400}-biotin alone (panels E−H). The C6EGFRp rat glioma cells (1×10^5 cells/rat) were implanted into the brains of CD Fischer 344 rats and grown for 4 weeks prior to brain distribution experiments. Brains were removed 60 min after the isotope injection. Biomax MS X-ray films were exposed for 4 days at −70 °C with intensifying screen.

DISCUSSION

The results of the present investigation are consistent with the following conclusions. First, formulation of the EGF conjugate with the ^{125}I radionuclide yields a radiopharmaceutical that is metabolically unstable (Figure 1). Second, biotinylation of EGF with NHS-PEG^{3400}-biotin yields a mixture of mono- and dibiotinylated peptide, even at a 1:1 molar ratio of EGF:NHS-PEG^{3400}-biotin, as demonstrated by either SDS−PAGE (Figure 5) or gel filtration FPLC (Figure 4); the EGF construct with a single DTPA residue and a single PEG^{3400}-biotin moiety, such as that depicted in Figure 3, can be purified using two Superose 12HR gel filtration FPLC columns in series (Figure 4). Third, the [^{111}In]EGF-PEG^{3400}-biotin conjugated to OX26/SA binds to both transferrin receptor and EGF receptor in the C6EGFRp cells under the influence of 1 μM dexamethasone, but no specific EGF receptor activity is detected in the cells that are not exposed to dexamethasone (Figure 6). Fourth, the EGF-PEG^{3400}-biotin conjugated to OX26/SA and formulated with the ^{111}In radionuclide shows a high degree of metabolic stability, as low molecular weight ^{111}In-labeled metabolites are not detected in plasma (Figure 9). In contrast, there is a rapid appearance of TCA-soluble low molecular weight ^{125}I metabolites formed in plasma when the ^{125}I radionuclide is used to label the EGF (Figure 1, right panel). Fifth, the [^{111}In]DTPA- EGF-PEG^{3400}-biotin conjugated to OX26/SA is rapidly removed from plasma (Figure 7), and this rapid uptake by peripheral tissues is greatly reduced by co-injection of 16 nmol/rat (100 μg/rat) of unlabeled EGF (Figure 7, Table 1). Sixth, imaging of brain with radiolabeled forms of EGF is not possible when the peptide is not coupled to a BBB drug delivery system (Figure 10, panels E−H), but brain structures and tumors can be imaged with radiolabeled EGF that is conjugated to a BBB drug delivery system using a PEG^{3400} linker (Figure 10, panels A−D).

The plasma AUC and whole body Vss values are comparable for EGF conjugates when either the ^{125}I or the ^{111}In radionuclide is used. For example, the plasma $AUC|_0^\infty$ for [^{125}I]EGF-PEG^{3400}-biotin conjugated to OX26/SA or [^{111}In]DTPA-EGF-PEG^{3400}-biotin conjugated to OX26/SA are 23 ± 2% ID min/mL (data not shown) and 19 ± 1% ID min/mL (Table 1), respectively. When the EGF is conjugated to OX26/SA and co-injected with unlabeled EGF, the plasma $AUC|_0^\infty$ for the ^{125}I and the ^{111}In formulations are 61 ± 8% ID min/mL (data not shown) and 79 ± 6% ID min/mL (Table 1), respectively. However, after uptake by peripheral tissues (e.g., liver and kidney), the ^{125}I radionuclide is rapidly exported to the plasma in the form of low molecular weight TCA soluble metabolites (Figure 1, right panel), but there is no export to plasma of low molecular weight ^{111}In metabolites (Figure 9). These low molecular weight metabolites may include either radiolabeled iodide or amino acids such as iodotyrosine, which are capable of transport through the BBB via carrier-mediated transport and give artifactually high basal uptakes of brain radioactivity (*11*, *19*). Such artifacts are seen in the present study; the basal brain uptake of [^{125}I]EGF-PEG^{3400}-biotin, 0.026 ± 0.001% ID/g (Figure 2), is 10-fold greater than the basal brain uptake of [^{111}In]DTPA-EGF-PEG^{3400}-biotin (Figure 8). The brain uptake of these low molecular weight ^{125}I metabolites would make brain imaging very difficult as it would reduce the signal/noise ratio of the image. Conversely, the brain uptake of radioactivity is negligible when the EGF is administered in the form of the ^{111}In radionuclide, and EGF is not conjugated to a BBB drug delivery system such as OX26/SA (Figure 10, panels E−H). These considerations are further evidence that the measurement of brain uptake of ^{125}I-labeled peptides following peripheral administration is driven principally by the artifactual uptake of low molecular weight metabolites rapidly generated by the degradation of the peptide in noncerebral tissues (*11*).

The synthetic scheme for [^{125}I]EGF-PEG^{3400}-biotin yields a mixture of mono- and dibiotinylated peptide

Table 2. PS Values (μL/min/g)[a]

organ	[^{111}In]EGF	[^{111}In]EGF + OX26/SA	[^{111}In]EGF + OX26/SA + unlabeled EGF
heart	6.3 ± 0.4	2.9 ± 0.7	0.17 ± 0.11
lung	8.9 ± 2.8	11.1 ± 1.9	4.0 ± 0.5
liver	635 ± 33	390 ± 12	74 ± 4
kidney	1006 ± 32	145 ± 13	76 ± 6

[a] Determined at 60 min after intravenous injection. Mean ± S. E. (n = 3 rats). Computed from the plasma data in Figure 7. In all cases, the [^{111}In]EGF represents [^{111}In]EGF-PEG^{3400} biotin.

(Experimental Procedures). Owing to the multivalency of streptavidin binding of biotin, there is a potential for aggregates to form when the ligand is multibiotinylated and bound to OX26/SA. However, in the present studies of the ^{125}I radionuclide formulation, significant aggregates are minimized, as the molar ratio of the [^{125}I]EGF-(PEG^{3400}-biotin)$_2$ and the OX26/SA was approximately 1:1 (Experimental Procedures). Moreover, when the monobiotinylated form of EGF-PEG^{3400}-biotin was purified by two Superose 12HR gel filtration FPLC columns in series (Figure 4) and then radiolabeled with ^{125}I and chloramine T (*9*), there were no significant differences in the plasma radioactivity profiles (unpublished observations).

The conjugation of EGF-PEG^{3400}-biotin to OX26/SA resulted in a redirection of the EGF peptide from kidney to liver (Figure 2, Table 2). The molecular mass of EGF-PEG^{3400}-biotin is approximately 10 000 Da, and the molecular mass of OX26/SA is 200 000 Da. Therefore, following conjugation to OX26/SA, the effective molecular mass of the EGF increases from 10 000 Da to 210 000 Da, and this explains the marked reduction in renal clearance of the EGF conjugate. However, the EGF is still rapidly removed from plasma despite conjugation to OX26/SA (Figure 7). Previous studies have shown that human recombinant EGF is rapidly taken up by the rat EGF receptor in liver in vivo (*17*, *18*). Therefore, we considered that co-injection of unlabeled EGF (100μg/rat) would saturate hepatic uptake of the EGF construct, prolong the circulation time of the imaging agent, and have a beneficial pharmacokinetic effect. This was observed as the plasma AUC$|_0^\infty$ was increased 4-fold from 19 ± 1 to 79 ± 6% ID min/mL following EGF loading (Table 1). The systemic volume of distribution (Vss) was also decreased 4-fold from 637 ± 7 to 157 ± 7 mL/kg following EGF loading (Table 1). The plasma AUC$|_0^\infty$ of [^{111}In]DTPA-EGF-PEG^{3400}-biotin, 8.0 ± 0.4% ID min/mL, is comparable to the plasma AUC for [^{125}I]EGF, 6.8% ID min/mL, which is calculated from the data of Kim et al. (*18*). The principal effect of EGF loading is a 5-fold reduction in the organ clearance by liver, although EGF clearance by heart, lung, and kidney is also decreased by EGF loading (Table 2).

The pharmacokinetic data for [^{111}In]DTPA-EGF-PEG^{3400}-biotin in Tables 1 and 2 allow for comparison with similar data reported previously for [^{125}I]EGF (*17*, *18*). The fact that the plasma clearance for the two formulations of EGF are comparable means that placement of a *single* PEG moiety on a peptide such as EGF does not significantly reduce the rate of plasma clearance of the peptide. Pegylation of proteins is well-known to delay plasma clearance, but this requires the placement of *multiple* PEG moieties on the surface of the protein (*11*).

The EGF peptide radiopharmaceutical depicted in Figure 3 and used for the brain imaging studies shown in Figure 10 embodies three aspects of the formulation that allow for optimization of the brain imaging signal. First, a >200 atom PEG^{3400} linker is placed between the EGF and the biotin to release any steric hindrance caused by binding to streptavidin (*9*). This long flexible arm allows for free binding of the construct to either the EGF receptor or the BBB transferrin receptor. Second, the radionuclide moiety is ^{111}In rather than the ^{125}I used in previous studies (*9*). The use of the ^{111}In radionuclide confers a greater degree of metabolic stability (Figure 9) and a very low basal uptake of the unconjugated peptide (Figure 10). Third, the co-injection of unlabeled EGF inhibits hepatic uptake of the conjugate approximately 5-fold (Table 2), and this optimizes the plasma pharmacokinetics (Table 1, Figure 7) and results in a proportionate increase in brain uptake (Figure 8).

The brain imaging studies in Figure 10 allow for the following conclusions. First, [^{111}In]DTPA-EGF-PEG^{3400}-biotin does not cross either the BBB in normal brain or the blood-tumor barrier (BTB) in the brain tumor (Figure 10, panels E−H). The uptake of the [^{111}In]EGF-PEG^{3400}-biotin in brain is 0.0033 ± 0.0007% ID/g (Figure 8), and this approximates the brain uptake of sucrose (*7*). The failure of EGF to cross the BBB in normal brain is expected based on previous studies (*5*). Although the BTB is more permeable than the normal BBB to small molecules (*20*), the BTB in the C6 glioma is clearly not permeable to the unconjugated EGF peptide radiopharmaceutical, which has a molecular mass of approximately 10 000 Da, as shown in the bottom panels (E−H) of Figure 10. Second, the [^{111}In]DTPA-EGF-PEG^{3400}-biotin does cross the BBB and enter brain following conjugation to OX26/SA. The in vivo QAR studies (Figure 10, panels A− D) show increased brain uptake of the EGF peptide radiopharmaceutical that is attached to the OX26 MAb BBB delivery system. The transcytosis of the OX26 MAb through the BBB has been demonstrated previously at the electron microscopic level with conjugates of OX26 and 5 nm gold (*21*) and at the light microscopic level using autoradiography (*22*). Third, the EGF peptide pharmaceutical conjugated to OX26/SA also crosses the BTB, although the signal in the tumor brain is reduced compared to normal brain (Figure 10, panels A−D). This reduced signal suggested that the human EGF receptor was not expressed by the C6EGFRp cells following implantation in brain and growth as a brain tumor. The absence of EGF receptor in these cells in vivo was confirmed by immunocytochemistry (Results) and is consistent with the tissue culture experiments (Figure 6) showing minimal binding to the EGF receptor in the C6EGFRp cells that were not exposed to 1 μM dexamethasone for 24 h. The expression of the human EGF receptor in the C6EGFRp cells is driven by the dexamethasone-inducible mouse mammary tumor virus long terminal repeat (MMTV-LTR) promoter (*10*). We administered 1 mg/rat of dexamethasone 24 h prior to sacrifice but still could not detect any immunoreactive EGF receptor in these brain tumors in vivo (unpublished observations). Another reason the signal in the brain tumor region is decreased compared to normal brain most likely arises from the decreased vascular density in the brain tumor compared to normal brain. In previous studies with peptide radiopharmaceuticals that were enabled to undergo transport through the BBB by attachment to BBB drug delivery systems, there was a marked increase in the image in gray matter versus white matter in the primate brain in vivo (*8*). This arose from the 3-fold greater vascular density in gray matter versus white matter and, accordingly, the 3-fold greater vascular density of BBB receptor being targeted by the delivery system. The vascular density in the C6 glioma

is probably comparable to the vascular density in white matter, since the rate of cerebral blood flow (CBF) in the C6 glioma approximates white matter CBF, which is only 44% of the CBF in gray matter (*23*).

The present studies show that the C6EGFRp cells express undetectable levels of human EGF receptor when the cells form experimental brain tumors in vivo based on both the in vivo imaging (Figure 10) and the EGFR immunocytochemistry (Results). Experimental tumors such as the U87 human glioblastoma multiforme, which grows as experimental brain tumors in immuno-compromised rodents (*16*), may prove to be a more suitable model for imaging the human EGF receptor in experimental brain tumors in vivo. Factors that will affect the tumor imaging using EGF peptide radiopharmaceuticals that are enabled to cross the BTB include (i) the vascular density and local concentration of transferrin receptor at the BTB and (ii) the local expression of the EGF receptor in the tumor cells and the rate of endocytosis of the EGF into the tumor cells. These receptor systems may be investigated in future imaging of brain tumors using peptide radiopharmaceuticals such as that depicted in Figure 3. The present studies demonstrate that peptide radiopharmaceuticals such as EGF may undergo special molecular formulation to enable both metabolic stability of the radionuclide and transport of the peptide radiopharmaceutical through the BBB in vivo.

ACKNOWLEDGMENT

Margarita Tayag provided expert technical assistance and the manuscript was skillfully prepared by David Kim and Daniel Jeong. This work was supported by a grant from the U.S. Department of Energy. Dr. Kym Faull performed the MALDI analyses. Dr. Dafang Wu asisted with the brain tumor implants.

Transcriptional regulation in human immunodeficiency virus type 1 (HIV-1) requires specific interactions of Tat protein with the trans-activation responsive region (TAR) RNA, a 59-base stem-loop structure located at the 5′-ends of all HIV-1 mRNAs. We have used a site-specific cross-linking method based on 4-thio-uracil (4-thioU) photochemistry to determine the interactions of a Tat peptide, Tat(38−72), with the loop region of TAR RNA under physiological conditions. A TAR RNA construct with a single 4-thioU residue at positions U31 in the loop sequence was synthesized by chemical methods. Upon UV irradiation, 4-thioU at U31 formed a covalent cross-link with the Tat peptide. We did not observe any RNA−RNA cross-link formation. Competition experiments revealed that a specific RNA−protein complex formation was necessary for the RNA−protein cross-linking reaction. Our results demonstrate that, during RNA−protein recognition, the Tat peptide is located in close proximity to O^4 of U31 in the TAR RNA loop sequence.

INTRODUCTION

The human immunodeficiency virus type 1 (HIV-1)[1] encodes a transcriptional transactivator protein called Tat, which is expressed early in the viral life cycle and is absolutely required for viral replication and progression of disease (*1*−*3*). In the absence of Tat, most of the viral transcripts terminate prematurely producing short RNA molecules ranging in size from 60 to 80 nucleotides. The Tat protein is a small, cysteine-rich nuclear protein containing 86 amino acids and an arginine-rich RNA-binding region (amino acids 49−57) located in the carboxy-terminal half of the molecule (*1*, *4*). HIV-1 Tat protein acts by binding to the TAR (trans-activation responsive) RNA element, a 59-base stem-loop structure located at the 5′-end of all nascent HIV-1 transcripts (*5*). RNA−protein interaction between TAR and Tat converts RNA polymerase II into its processive form and causes a substantial increase in the production of full-length viral transcripts (*6*−*13*).

TAR RNA was originally localized to nucleotides +1 to +80 within the viral long terminal repeat (LTR) (*14*). Subsequent deletion studies have established that the region from +19 to +42 incorporates the minimal domain which is both necessary and sufficient for Tat responsiveness in vivo (*15*−*17*). TAR RNA contains a six-nucleotide loop and a three-nucleotide pyrimidine bulge which separates two helical stem regions (*5*, *14*, *15*, *18*). The trinucleotide bulge is essential for high affinity and specific binding of the Tat protein (*19*, *20*). Tat protein binds TAR RNA in vitro with high affinity. Due to difficulties in Tat purification, small Tat peptides that specifically bind TAR RNA with high affinity have been used in many Tat−TAR studies (*21*−*27*). In our Tat−TAR photo-cross-linking studies, we used ADP-1, a Tat fragment (37−72), which binds TAR RNA with high specificity and includes the basic and part of the core regions of Tat (*24*). To avoid oxidation problems, we deleted the N-terminal cysteine residue from the ADP-1 sequence (*26*−*28*).

RNA molecules can fold into extensive structures containing regions of double-stranded duplex, hairpins, internal loops, bulged bases and pseudoknotted structures (*29*, *30*). Due to the complexity of RNA structure, the rules governing sequence-specific RNA−protein recognition are not well understood. RNA−protein interactions are vital for many regulatory processes, especially gene regulation where proteins specifically interact with binding sites found within RNA transcripts. Understanding the principles of Tat−TAR interactions is a crucial step for drug design. Although high-resolution NMR information is limited to the TAR RNA component, a structure of the RNA−protein complex is still missing. Therefore, new methods are needed to determine the topology of RNA−protein complexes under physiological conditions. Recently, we have applied photo-cross-linking and affinity cleaving methods to probe RNA folding and RNA−protein interactions under physiological conditions (*26*−*28*, *31*−*34*).

Chemical synthesis of long oligoribonucleotides containing modified nucleosides, such as 29-bases TAR RNA, is still not very efficient. To circumvent this problem, two short oligoribonucleotides were synthesized and annealed together to form a duplex RNA that contained the trinucleotide bulge to create a structure similar to the Tat binding site in TAR RNA (*35*−*37*). Chemically synthesized duplex TAR RNAs without loop residues have been used to study the role of various functional groups in Tat recognition (*35*−*37*). Recently, we and others have performed RNA−protein cross-linking studies on synthetic TAR RNA duplex structures containing Tat-binding bulge sequences (*26*, *38*). Here, we synthe-

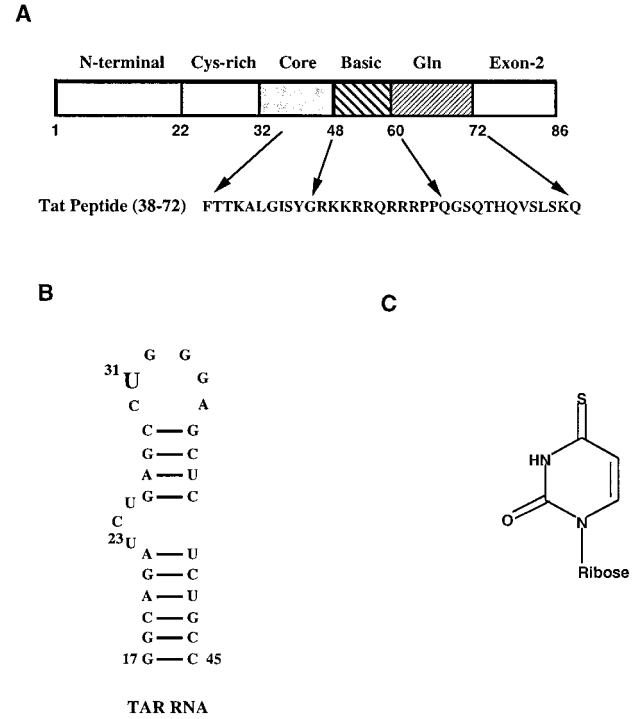

Figure 1. (A) Regions of the HIV-1 Tat protein and sequence of the Tat(38−72) peptide. (B) Secondary structure of TAR RNA used in this study. TAR RNA spans the minimal sequences that are required for Tat responsiveness in vivo (*15*) and for in vitro binding of Tat-derived peptides (*43*). Wild-type TAR contains two non-wild-type base pairs to increase transcription by T7 RNA polymerase. Site of 4-thioU incorporation, U31, is highlighted in the TAR RNA. Numbering of nucleotides in the RNA corrsponds to their positions in wild-type TAR RNA. Incorporation of 4-thioU at position 31 was accomplished by chemical synthesis of RNA (*31, 34*). (C) Structure of 4-thiouridine.

sized a TAR RNA construct (Figure 1) with a single 4-thiouridine (4-thioU) residue at position 31 in the loop sequence. 4-thioU is a very useful photoactivatable probe which has been widely used to study RNA structure (for a review, see ref *39*). This is the first example of chemical synthesis of functional TAR RNA containing loop-residues and a photoactivatible nucleoside. Upon UV irradiation, this 4-thioU labeled RNA formed a covalent cross-link with Tat(38−72) peptide. No RNA−RNA cross-link formation was observed. Competition experiments revealed that a specific RNA−protein complex formation was necessary for the RNA−protein cross-linking reaction. Our results indicate that, during RNA−protein recognition, the Tat peptide is located in close proximity to O^4 of U31 in the TAR RNA loop sequence.

MATERIALS AND METHODS

Buffers. All buffer pH values refer to measurements at room temperature. TK buffer: 50 mM Tris-HCI (pH 7.4), 20 mM KCI, and 0.1% Triton X-100. Transcription buffer: 40 mM Tris-HCI (pH 8.1), 1 mM spermidine, 0.01% Triton X-100, and 5 mM DTT. TBE buffer: 45 mM Tris-borate, pH, 8.0, and 1 mM EDTA. Sample loading buffer: 9 M urea, 1 mM EDTA, and 0.1% bromophenol blue in 1× TBE buffer. Binding buffer: 25 mM Tris-HCI (pH 7.5), 100 mM NaCI, 1 mM $MgCI_2$, and 0.1% Triton X-100. Hydrolysis buffer: 50 mM $Na_2CO_3/NaHCO_3$, pH 9.2. Elution buffer: 1× TBE and 10% sodium acetate (3M), pH 5.5.

RNA Synthesis. RNAs were synthesized by chemical and enzymatic methods. Chemical syntheses were performed on ABI synthesizer model 392 using standard protocols. All the monomers of (2-cyanoethyl)phosphoramidites were obtained from Glen Research (Sterling, VA). Site-specific incorporation of 4-thioU at position 31 in TAR RNA was carried out by chemical synthesis of RNA using triazoloU phosphoramidite as a precursor of 4-thioU (*31*). Synthesis of RNA, deprotection, characterization, and purification were performed as described earlier (*31, 34*). Briefly, incorporation of 4-thioU in the TAR RNA sequence was confirmed by enzymatic digestion. Enzymatic digestion was carried out by incubating 0.2 A_{260} unit of purified oligonucleotide at 37 °C overnight with 6 μL (12 μg) of snake venom phosphodiesterase and 2 μL (2 units) of alkaline phosphatase in a total volume of 78.2 μL of 32 mM Tris, pH 7.5, and 15 mM $MgCl_2$. Nucleosides were recovered by adding 10 μL of 3 M NaOAc, pH 5.2, and 234 μL of 95% ethanol, mixing and chilling to −80 °C for 30 min. After centrifugation at 13 000 rpm for 20 min at 4 °C, the supernatant was taken and dried in Speedvac (Savant) and redissolved in 200 μL of water for HPLC analysis. HPLC analysis of nucleosides was performed as described previously (*31, 33*).

All other RNAs were prepared by in vitro transcription (*40*). The template strand of DNA was annealed to an equimolar amount of top strand DNA, and transcriptions were carried out in transcription buffer and 4.0 mM NTPs at 37 °C for 2−4 h (*41*). For reactions (20 μL) containing 8.0 pmol of template DNA, 40−60 units of T7 polymerase (Promega) was used. Transcription reactions were stopped by adding an equal volume of sample loading buffer. RNA was purified on 20% acrylamide 8 M-urea denaturing gels (*41*). RNAs were stored in DEPC water at −20 °C.

RNAs were 5′-dephosphorylated by incubation with calf intestinal alkaline phophatase (Promega) for 1 h at 37 °C in 50 mM Tris-Cl, pH 9.0, 1 mM $MgCl_2$, 0.1 mM $ZnCl_2$, and 1 mM spermidine. The RNAs were purified by multiple extractions with Tris-saturated phenol and one extraction with 24:1 chloroform:isoamyl alcohol followed by ethanol precipitation. The RNAs were 5′-end-labeled with 0.5 μM [γ-^{32}P]ATP (6000 Ci/mmol) (ICN) per 100 pmol of RNA by incubating with 16 units of T4 polynucleotide kinase (New England Biolabs) in 70 mM Tris-HCl, pH 7.5, 10 mM $MgCl_2$, and 5 mM DTT. RNAs were gel purified on a denaturing gel, visualized by autoradiography, and recovered from gels as described earlier (*41*).

Peptide Synthesis. All Fmoc-amino acids, piperidine, 4-(dimethylamino)pyridine, dichloromethane, *N*,*N*-dimethylforamide, 1-hydroxybenzotriazole (HOBT), 2-(1H-benzotriazo-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), diisopropylethylamine, and HMP-linked polystyrene resin were obtained from Applied Biosystems Division, Perkin-Elmer. Trifluoroacetic acid, 1,2-ethanedithiol, phenol, and thioanisol were from Sigma. Tat-derived peptide (from amino acids 38 to 72) was synthesized on an Applied Biosystems 431A peptide synthesizer using standard FastMoc protocols. Cleavage and deprotection of the peptide was carried out in 2 mL of Reagent K for 6 h at room temperature. Reagent K contained 1.75 mL of TFA, 100 μL of thioanisole, 100μL of water, and 50 μL of ethanedithiol (*42*). After cleavage from the resin, peptide was purified by HPLC on a Zorbax 300 SB-C_8 column. The mass of fully deprotected and purified peptides were confirmed by FAB mass spectrometry; calculated mass for Tat(38−72) $C_{175}H_{298}N_{64}O_{43}$ = 4082.7, found = 4083.7 (M + H).

Gel Retardation Assays. RNA−protein binding reactions (20 μL) contained 0.05 μM wild-type, modified TAR, or wild-type TAR RNA and 0−1 μM Tat(38−72) in TK

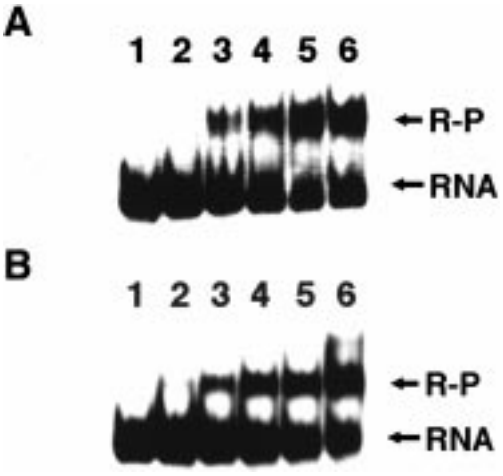

Figure 2. Binding of Tat(38−72) peptide to TAR RNA (A) or 4-thioU-31-modified TAR RNA (B). Binding reactions contained 0.05 μM of 5′-^{32}P-end-labeled RNA and increasing concentration of Tat peptide. Lane 1 was a control lane without the peptide. Complex formation was performed in the TK buffer and incubation at room temperature for 1 h. Complexes were separated from unbound RNA by electrophoresis in nondenaturing 8% polyacrylamide gels containing 0.1% Triton X-100. Gels were run in cold room at 300 V for 2 h. The relative amounts of free and bound RNA were determined by phosphor imaging. RNA−peptide complexes are shown as R-P.

buffer. After 15 min of incubation at room temperature, the complexes were resolved on a nondenaturing 8% acrylamide gels and quantified as described earlier (*26*).

Site-Specific Photo-Cross-Linking Reactions. Typically, 5 pmol of TAR RNA (5′-end labeled with ^{32}P) was mixed with 6 pmol of Tat (38−72) in TK buffer, incubated at room temperature for 10 min, and UV irradiated (360 nm) for 5 min on ice in a Rayonet Photochemical Reactor (RPR-100). After irradiation, 2 μL of Yeast tRNA (20 μg/μL) and 12 μL of sample loading buffer were added to each sample and electrophoresed on 8 M urea-20% acrylamide gels. Efficiencies of cross-linking were determined by a Phosphor Image analysis (Molecular Dynamics).

RNA Sequencing. Alkaline hydrolysis of RNAs was carried out in hydrolysis buffer for 8−12 min at 85 °C. RNAs were incubated with 0.1 units RNAse from *Bacillus cereus* (Pharmacia) per pmol of RNA for 4 min at 55 °C in 16 mM sodium citrate, pH 5.0, 0.8 mM EDTA, 0.5 mg/mL yeast tRNA (Gibco-BRL). This enzyme yields U and C specific cleavage of RNA. Sequencing products were resolved on 20% denaturing gels and visualized by phosphor image analysis.

RESULTS AND DISCUSSION

Tat Binding To Modified TAR RNA. To characterize and evaluate the Tat binding capabilities of 4-thioU containing TAR RNA, we determined the dissociation constants of modified TAR−Tat complexes. Equilibrium dissociation constants of the Tat:TAR complexes were measured using direct electrophoretic mobility assays (*24*, *27*, *33*). A Tat fragment, Tat(38−72), was used in these measurements. A typical gel of these experiments is shown in Figure 2. These results showed that Tat(38−72) binds the 4-thioU-31 modified TAR RNA with a K_D of 0.22 ± 0.05 μM. To compare the Tat-binding affinities of the modified RNA to wild-type RNA, we synthesized an unmodified RNA (Figure 1). Dissociation constants of the unmodified TAR:Tat complexes were determined under the same conditions used for 4-thioU31-TAR:Tat(38−72) complexes. These experiments showed that

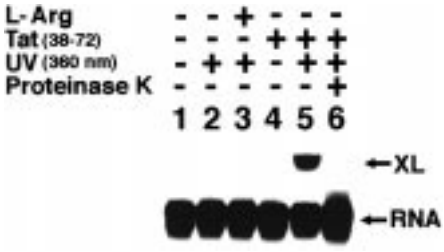

Figure 3. Cross-linking reactions of TAR RNA labeled with 4-thioU at position 31. TAR RNA was labeled with ^{32}P at the 5′-end and UV irradiated at 360 nm. Cross-linked products were resolved on a 20% acrylamide-8 M urea gel and visualized by autoradiography. Lane 1: RNA without irradiation. Lane 2: RNA with irradiation. Lane 3: RNA irradiated with 1 mM L-argininamide. Lane 4: RNA with Tat(38−72) and no irradiation. Lane 5: RNA irradiated in the presence of Tat(38−72). Lane 6: RNA irradiated in the presence of Tat(38−72) and the sample was treated with Proteinase K for 15 min at 55 °C. RNA−protein cross-links are indicated as XL.

the unmodified TAR duplex binds Tat with a K_D of 0.13 ± 0.08 μM (Figure 2). A relative dissociation constant (K_{rel}) can be determined by measuring the ratios of the modified TAR to wild-type TAR dissociation constants (K_D) for Tat(38−72). Our results demonstrate that the calculated value for K_{rel} was 1.7. These results indicate that incorporation of 4-thioU in the TAR loop sequence did not significantly alter the structure of the RNA, thus preserving the Tat-binding affinities of the RNA.

TAR RNA Labeled with 4-thioU at U31 Forms Cross-Link with a Tat Fragment. Specific RNA−protein complexes were formed by adding the approximately equimolar amounts of TAR RNA and the Tat peptide. Under these conditions, electrophoretic mobility-shift assays revealed only one slow-migrating RNA−peptide complex, indicating the absence of other nonspecific RNA−peptide complex formation (*24*, *32*). TAR RNA labeled at its 5′-end with ^{32}P was incubated with the Tat peptide for 10 min in TK buffer and UV irradiated with 360 nm light (see Materials and Methods). Products of the photoreaction were analyzed by denaturing 8 M urea PAGE (Figure 3). Irradiation of the RNA−peptide complex yields band with electrophoretic mobility less than that of RNA (Figure 3, lane 5). Both the peptide and UV irradiation are required for the formation of this cross-linked RNA−protein complex because this cross-linked product is observed only when RNA is irradiated in the presence of Tat peptide (lane 5), and no cross-link is formed with peptide in dark without UV irradiation (lane 4). The formal possibility that the new mobility is due to an alternative RNA−RNA cross-link was ruled out by perfroming proteinase K digestion of the RNA−protein cross-link. RNA−protein cross-link products are degraded by proteinase K enzyme while RNA−RNA cross-link species are stable under these conditions (*26*, *28*). Proteinase K digestion of the RNA−protein cross-link resulted in a loss of RNA−protein cross-link and a gain in free RNA as observed by band intensities on the gel (Figure 3, lane 6). The products of irradiation were also analyzed on a denaturing SDS−15% polyacrylamide gel. Again, a photoproduct with electrophoretic mobility less than that of TAR RNA was observed, which was dependent on the presence of RNA and peptide (data not shown). The photoproduct yields were ∼37% as determined by a Phosphor Image analysis. Since the cross-linked RNA−peptide complex is stable to alkaline pH (9.2), high temperature (85 °C), and denaturing conditions (8 M urea, 2% SDS), we conclude that a covalent bond is

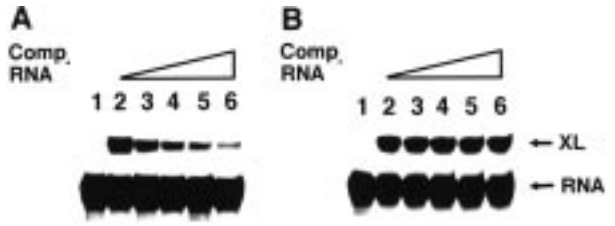

Figure 4. Specificity of the Tat−TAR cross-linking reaction determined by competition assays. RNA−protein complexes were formed between 0.25 μM ^{32}P-5′-end labeled TAR RNA modified with 4-thioU at position 31 and 0.5 μM of Tat(38−72) in the presence of unlabeled wild-type TAR RNA (A) or bulge mutant TAR RNA (B). Concentrations of the competitor RNA in lanes 2, 3, 4, 5, and 6 were 0, 0.5, 0.75, 1.0, and 1.25 μM, respectively. Lane 1 was a control RNA−peptide complex without UV irradiation. RNA−protein cross-link is shown as XL.

formed between TAR RNA and the peptide during the cross-linking reaction.

Specificity of the RNA−Protein Cross-Link Formation. Specificity of the cross-linking reaction was established by competition experiments (*28*). Cross-linking reactions were performed in a 10 μL volume containing 0.25 μM of 5′-^{32}P-labeled 4-thio-U31 modified TAR RNA, 0.5 μM Tat peptide, 25 mM Tris.HCl (pH 7.4), 100 mM NaCl, and up to 1.25 μM unlabeled competitor RNA. Cross-linked products were separated by 8 M urea-20% polyacrylamide gels and visualized by phosphor image analysis. Figure 4 shows that cross-linking was inhibited by the addition of unlabeled wild-type TAR RNA and not by a bulge mutant TAR RNA. Therefore, we conclude that formation of a specific RNA−protein complex between 4-thioU modified TAR RNA and Tat is necessary for photo-cross-linking.

4-Thio-Uridine 31 in TAR RNA Cross-Links to Tat(38−72). Mapping of the cross-link site on TAR RNA to single nucleotide resolution was carried out by partial RNAse digestion and alkaline hydrolysis of the gel-purified RNA−protein cross-link. Fragment sizes are determined by comparison with RNA oligonucleotides of defined sequence and length generated by digesting RNA with RNases T_1 and *B. cereus*. Alkaline hydrolysis of RNA and cross-linked RNA−peptide complex generates a ladder of RNA-degradation products. Bands of cross-linked RNA−peptide complexes migrate slower than corresponding free RNA (lane 3 in Figure 5). Base hydrolysis of the 5′-end-labeled cross-linked complex (lane 3 in Figure 5) results in an RNA ladder in which all fragments up to C30 are resolved. There is an obvious gap in the hydrolysis ladder after C30, indicating that the fragments above C30 from the 5′-end are linked to the Tat peptide (Figure 5, lane 3) that is not seen with the un-cross-linked RNA (lane 2). On the basis of these results, we conclude that 4-thio-U31 of TAR RNA is indeed the site in RNA sequence at which cross-linking occurs.

The basic regions of tat proteins are directly involved in RNA binding. Short basic peptide mimics of this region bind TAR RNA in the bulge region (*21, 23−25, 43*). A number of studies determined the sequence requirements within the basic region of Tat for RNA binding. In vivo experiments using full-length Tat and in vitro studies with synthetic peptides indicate that conservation of overall positive charge including several arginines is essential for TAR RNA recognition. For example, Tat−TAR interactions are not affected by interchanging the basic region sequences of Tat and Rev (*44*). Amino acid substitutions that recreate the consensus sequence of the

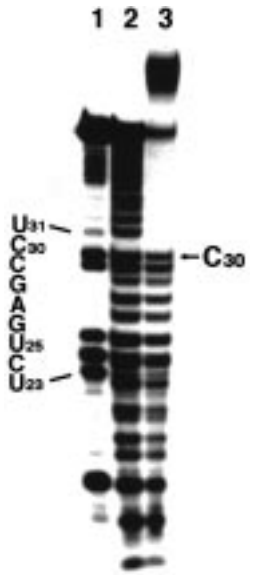

Figure 5. Mapping of cross-linked base in the RNA−protein cross-links by alkaline hydrolysis. Analysis of the RNA−protein cross-link containing 5′-end labeled TAR RNA: *B. cereus* ladder of TAR RNA (lane 1); hydrolysis ladder of TAR RNA (lane 2); hydrolysis ladder of the RNA−peptide cross-link (lane 3). Sequence of the TAR RNA from U23 to U31 is labeled, and a gap in the sequence is obvious after C30 residue indicating that indeed U31 is the cross-linked base.

RNA-binding region (R/KXXRRXRR, where R is arginine, K is lysine, and X is any amino acid) reconstitute a functional Tat protein. These results are in agreement with in vitro peptide studies showing that high-affinity TAR RNA binding requires three of four arginines within the RRXRR stretch, although any one arginine can be substituted, suggesting some redundancy (25). These studies raised the possibility that several amino acids from the RNA-binding region of Tat could be cross-linked to 4-thioU31 in TAR RNA. Although a discrete band for the RNA−protein cross-link was observed in our experiments (Figures 3−5), it is possible that more than one cross-link product is present in the band. To determine the homogeneity of the cross-link products, we analyzed the products by reversed-phase HPLC. Our chromatography data showed that the RNA−protein cross-link products eluted in a single sharp peak from the HPLC column under various solvent systems and gradients (data not shown). These results indicate that homogeneous RNA−protein cross-link products were formed during photo-cross-linking reactions.

Models for Tat−TAR Recognition. Tat protein recognizes the trinucleotide bulge in TAR RNA. Key elements required for TAR recognition by Tat have been defined by extensive mutagenesis, chemical probing, and peptide binding studies (*21−24, 36, 37, 43, 45−48*). Tat interacts with U23, and two other bulge residues, C24 and U25, act as spacers because they can be replaced by other nucleotides or linkers (*24, 35*). Previous studies suggest that Tat protein contacts TAR RNA in a widened major groove (*21, 26, 41*). A rhodium complex, Rh(phen)$_2$phi^{3+}, was used to probe the effect of bulge bases on the major groove width in TAR RNA (*41*). This study showed two important results for Tat−TAR recognition: (i) there is a correlation between major groove opening and Tat binding. At least a two base bulge is required for major groove widening and other conformational changes to facilitate Tat binding. This cannot be accomplished by a single-base bulge. (ii) A Tat peptide occupies the major groove of TAR RNA and abolishes

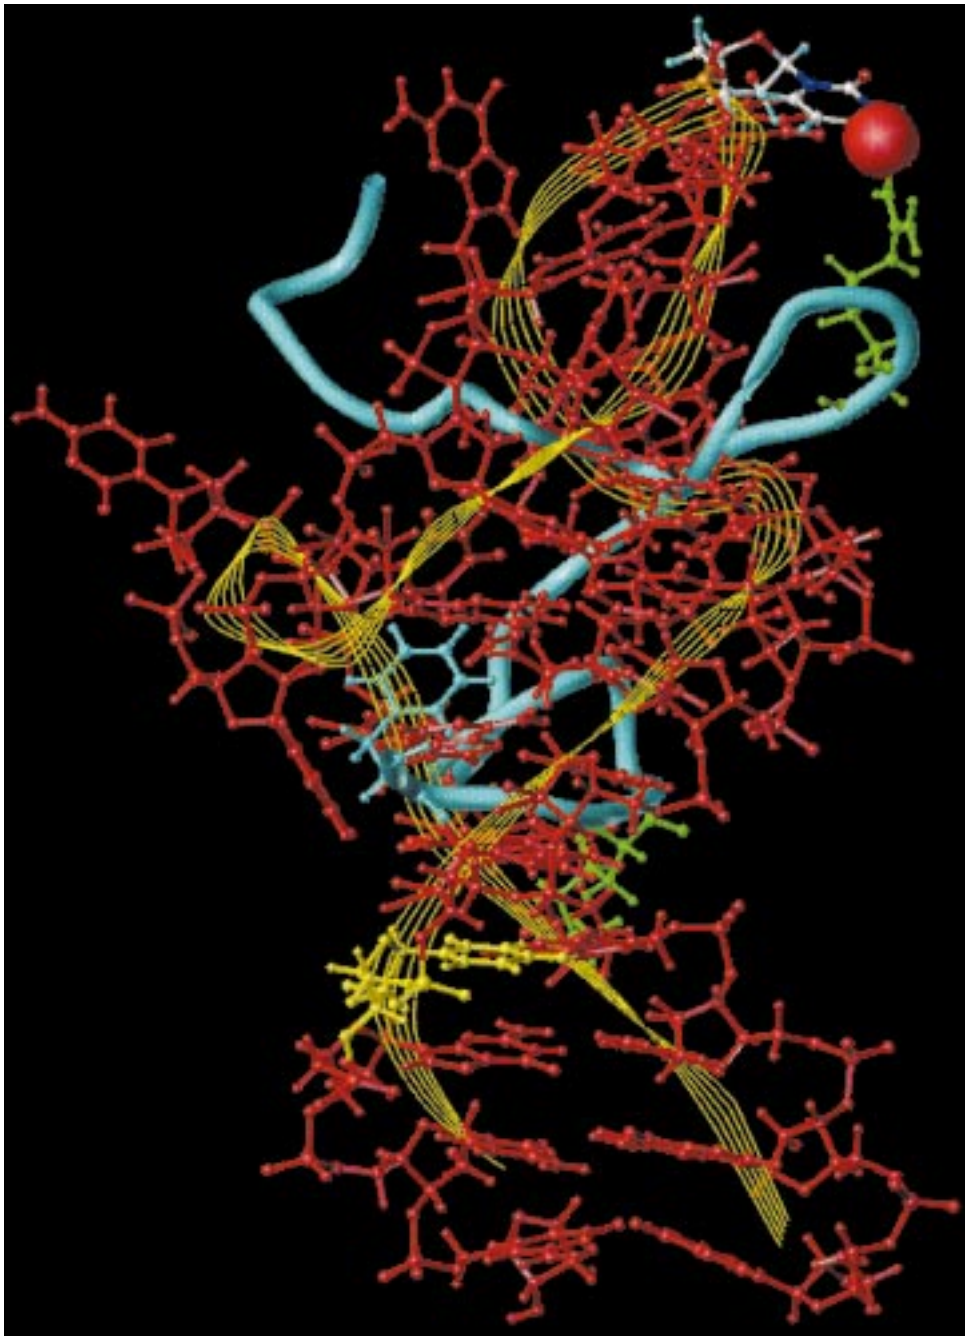

Figure 6. Proposed model for Tat peptide-TAR interactions showing protein orientation and the proximity of U31 to the peptide in the RNA−protein complex. Ribbon structure of TAR RNA is shown in yellow lines and nucleotides in red (*52*). Ribbon structure of the Tat peptide (ribbon/tube) and the amino terminal Phe38 are shown in cyan color. Ribbon structure of the Tat peptide is drawn from Tat protein structure (*53*). Orientation of the Tat peptide is based on previous photo-cross-linking results indicating that Lys41 and Arg57 are close to U42 and U31, respectively (*28, 32*). Lys41 and Arg57 side chains are shown in green. U42 is shown in yellow and U31 in atom-by-type colors. It is evident that O^4 (red spacefill sphere) of U31 is close to Arg57 side chain of the Tat peptide. Structures of RNA and protein were visualized using Insight II software on an IRIS workstation.

access of the rhodium complex (*41*). In addition to the trinucleotide bulge region, two base pairs above and below the bulge also contribute significantly to Tat binding (*21*, *24*). Phosphate contacts below the bulge at positions 22, 23, and 40 are critical for Tat interactions (*23*, *24*, *36*). In a chemical cross-linking study, Gait and co-workers showed that a TAR duplex containing a trisubstituted pyrophosphate replacing the phosphate at 38−39 reacted specifically with Lys51 in the basic region of Tat(37−72) peptide (*38*). We carried out 4-thiouracil-mediated photo-cross-linking studies on Tat−TAR complex and showed that Tat interacts with U23, U38, and U40 in the major groove of TAR RNA (*26*). Our recent cross-linking experiments using 6-thioG-modified TAR RNA demonstrated that Tat interaction with G21 and G26 also takes place in the major groove of RNA (*49*). Taken together, these studies establish that Tat binds TAR RNA at the trinucleotide bulge region and interacts with two base pairs above and below the bulge in the major groove of RNA.

The orientation of a Tat peptide in the Tat−TAR complex was determined by a new method based on psoralen photochemistry (*32*). A psoralen was chemically attached at the amino terminus of a Tat(42−72) peptide. Upon near-ultraviolet irradiation (360 nm), this synthetic psoralen-peptide cross-linked to a single site in TAR RNA

sequence. The RNA−protein complex was purified, and the cross-link site on TAR RNA was determined by chemical and primer extension analyses. These results showed that the amino terminus of Tat(42−72) contacts, or is close to, uridine 42 in the lower stem of TAR RNA (*32*). To define the relative orientation of the C-terminal part of the arginine-rich domain of Tat, we synthesized Tat(38−72) and replaced Arg57 with Cys to introduce a unique thiol group (−SH) in the peptide (*26*). A psoralen derivative which can react with thiol groups was synthesized and used for specific chemical modification of Cys57−Tat(38−72). We used this psoralen−Tat conjugate [psoralen−Cys57−Tat(38−72)] to form a specific complex with TAR RNA. Photo-cross-linking and RNA sequencing results revealed that Cys57 of Tat(38−72) is close to U31 of TAR RNA (*26*).

In a recent report from our laboratory, we applied a site-directed RNA-cleaving strategy to determine the neighborhood of the core domain of a Tat fragment in Tat−TAR complex (*27*). We attached an EDTA analogue to the amino terminus of Tat(38−72) by standard peptide synthesis methods and used this EDTA−Tat conjugate to form a specific complex with TAR RNA. This sequence-specific RNA-binding peptide was converted into a sequence-specific RNA-cleaving peptide by the addition of Fe(II) salt, ascorbate, and H_2O_2. Hydroxyl radicals generated from the tethered Fe(II) cleaved TAR RNA backbone in two localized regions. Site-specific cleavage of TAR RNA was observed at the bulge residues (U23, C24, and U25), in the loop region (G34 and A35), and at the strand opposite the bulge (U40 and C41). These results demonstrate that in the three-dimensional structure of Tat−TAR complex, the Phe38 of Tat(38−72) is located in the proximity of the bulge region and two nucleotides from the loop sequence (*27*).

Here we show that 4-thioU at position 31 cross-links to the Tat peptide. Results from the above studies are summarized in a model for Tat−TAR complex showing the protein orientation, location of N-terminus of the peptide, and U31 functional groups (Figure 6). Our attempts to locate the cross-linked amino acid in the Tat peptide by protein sequencing were not successful. This is not an unexpected result due to the length of the fragment and relatively harsh conditions of peptide sequencing which could result in the destruction of the cross-link between the peptide and RNA (*50*). Previously, we used 4-thioU modified TAR RNA to form Tat−TAR cross-links and we were unable to locate the cross-linked amino acid by Edman protein sequencing (*26*). Recently, Farrow et al. (*51*) applied MALDI-TOF mass spectrometric analysis to locate the cross-link sites in the basic region of a Tat peptide to chemically modified TAR RNA. Farrow et al. (*51*) used a model duplex TAR RNA, and the RNA−protein cross-linked products contained 14−17 nucleotide long RNAs. We followed the methods of Farrow et al. (*51*), and prepared RNA−protein cross-linked products on a large scale and subjected to the MALDI-TOF MS analysis. Due to the larger size of our RNA−protein cross-linked complex, we were unable to analyze it by MALDI-TOF MS. Since our previous findings showed that a psoralen attached to Arg57 formed a cross-link with U31 (*28*), Arg57 is displayed as a potential side chain located in proximity to U31 of TAR RNA. It is important to note that, in previous studies, psoralen was attached to cysteine 57 by a linker of ∼10 Å and psoralen could have preferably photoreacted with uridines in RNA (*28*). Although psoralen photo-cross-linking provides useful information about protein orientation in the Tat−TAR complex, direct interactions and close proximity between the RNA and protein have not been established. Experiments presented in this report show that 4-thioU31 directly contacts Tat peptide. A refined model for Tat−TAR interactions is presented in Figure 6 showing protein orientation and close proximity of U31 to an Arg residue. The RNA structure is derived from ref *52*, and the ribbon structure of Tat(38−72) peptide is based on Tat protein structure (*53*). The Tat peptide is positioned in the major groove of TAR RNA and the RNA is folded to bring O^4 of U31 within 5 Å of Arg57 side chain. All other structural constraints are based on previous photo-cross-linking and affinity cleaving experiments (*26*−*28*, *32*). Due to technical difficulties, we were unable to determine which amino acid formed the cross-link with U31. However, Arg57 is the only amino acid which can be placed in close proximity of U31 in order to generate a structure which is consistent with previous cross-linking and affinity cleaving results.

Mutational analyses have shown that sequences in the loop of TAR RNA are required for trans-activation (*54*, *55*) and not for Tat binding (*35*, *36*, *43*). Tat binds duplex TAR RNA sequences with approximately half the affinity for wild-type TAR RNA (*36*). Duplex TAR RNA sequences have been used previously to study RNA folding and RNA−protein interactions (*26*, *38*, *56*). Recently, Jones and co-workers have identified a novel CDK9-associated C-type cyclin, cyclin T1, which interacts with Tat and increases its affinity and specificity for TAR RNA (*57*). Formation of a specific and high-affinity ternary complexes (Tat:TAR:Cyclin T1) requires sequences in the loop of TAR RNA (*57*). Whether Tat protein or cyclin T1 forms a cross-link with 4-thioU31-modified TAR or not, remains to be determined.

ACKNOWLEDGMENT

We wish to thank Drs. Michael Gait and Thomas Barlow for MALDI-TOF MS analysis and helpful discussions. This work was supported in part by the National Institutes of Health Grants AI 41404 and TW00702 and a Research Career Development Awrad to T.M.R.

Accelerated Clearance of Polyethylene Glycol-Modified Proteins by Anti-Polyethylene Glycol IgM

Tian-Lu Cheng,[†,‡] Pin-Yi Wu,[‡] Ming-Fang Wu,[§] Ji-Wang Chern,[∥] and Steve R. Roffler*[,‡]

Institute of Biomedical Sciences, Academia Sinica; Graduate Institute of Life Sciences, National Defense Medical Center; College of Medicine, National Taiwan University; School of Pharmacy, National Taiwan University, Taipei, Taiwan. Received December 2, 1998; Revised Manuscript Received March 3, 1999

Tumor therapy by the preferential activation of a prodrug at tumor cells targeted with an antibody−enzyme conjugate may allow improved treatment efficacy with reduced side effects. We examined antibody-mediated clearance of poly(ethylene glycol)-modified β-glucuronidase (βG−sPEG) as a method to reduce serum concentrations of enzyme and minimize systemic prodrug activation. Enzyme-linked immunosorbent assay and immunoblot analysis of two monoclonal antibodies generated by immunization of BALB/c mice with an antibody−βG−sPEG conjugate showed that mAb 1E8 (IgG1) bound βG and βG−sPEG whereas mAb AGP3 (IgM) bound poly(ethylene glycol). Neither antibody affected the βG activity. mAb 1E8 and AGP3 were modified with 36 and 208 galactose residues (1E8−36G and AGP3−208G) with retention of 72 and 48% antigen-binding activity, respectively, to target immune complexes to the asialoglycoprotein receptor on liver cells. mAb 1E8 and AGP3 cleared βG−PEG from the circulation of mice as effectively as 1E8−36G and AGP3−208G, respectively. mAb AGP3, however, cleared βG−sPEG more completely and rapidly than 1E8, reducing the serum concentration of βG−sPEG by 38-fold in 8 h. AGP3 also reduced the concentration of an antibody−βG−sPEG conjugate in blood by 280-fold in 2 h and 940-fold in 24 h. AGP3-mediated clearance did not produce obvious damage to liver, spleen, or kidney tissues. In addition, AGP3 clearance of βG−sPEG before administration of BHAMG, a glucuronide prodrug of *p*-hydroxyaniline mustard, prevented toxicity associated with systemic activation of the prodrug based on mouse weight and blood cell numbers. AGP3 should be generally useful for accelerating the clearance of PEG-modified proteins as well as for improving the tumor/blood ratios of antibody−βG−PEG conjugates for glucuronide prodrug therapy of cancer.

INTRODUCTION

Drugs, toxins, and isotopes can be selectively delivered to tumors by creating conjugates with monoclonal antibodies (mAb)[1] that preferentially bind tumor-associated antigens. While high serum concentrations of immunoconjugates can increase accumulation and provide more uniform distribution in tumors (Thomas et al., 1989; Fujimori et al., 1990), low serum concentrations of cytotoxic conjugates are preferable to minimize systemic toxicity. High tumor/blood ratios are also desirable for noncytotoxic immunoconjugates such as antibody−enzyme conjugates employed for prodrug activation to minimize systemic prodrug activation.

Tumor/blood ratios of immunoconjugates can be increased by employing an agent that preferentially clears conjugate from the circulation. Avidin has been used to accelerate the clearance of biotinylated antibodies (Klibanov et al., 1988; Stella et al., 1994; Kobayashi et al., 1995) and improve the localization in tumors (Yao et al., 1995; Zhang et al., 1997). Clearance of biotinylated immunoconjugates, however, can be adversely impacted by the high concentrations of endogenous biotin present in serum (Guilarte, 1985) as well as by cleavage of biotin by biotinidase in serum (Wolf et al., 1990). Alternatively, antibodies against primary antibodies (Goldenberg et al. 1987; Sharkey et al., 19984) and antibody−enzyme conjugates (Kerr et al., 1993; Wallace et al., 1994) have also been employed to promote the clearance and tumor localization of immunoconjugates.

In the present study, we were interested in developing a clearance system for PEG-modified conjugates for use in cancer therapy by antibody-directed enzyme activation of glucuronide prodrugs. β-Glucuronidase targeted to tumor cells can activate the glucuronide prodrug (BHAMG) of *p*-hydroxy aniline mustard (pHAM) in vitro (Wang et al., 1992) and cure advanced hepatoma ascites in a rat model (Chen et al., 1997). Antibody−βG conjugates injected intravenously, however, are rapidly cleared from

the circulation before significant tumor accumulation can occur (Cheng et al., 1997). Modification of βG with PEG can extend the half-life of antibody−βG conjugates, decrease normal tissue uptake, and increase the localization of conjugate at solid tumors in nude mice (Cheng et al., 1997). Although the extended half-life of PEG-modified βG conjugates is desirable for improved tumor uptake, at least 5 days were required for the serum concentration of conjugate to reach safe levels before prodrug could be administered (Cheng et al., 1997). Accelerated clearance of conjugates from the circulation may allow earlier prodrug administration when the greatest amount of conjugate is present at tumor cells. In the present study, we generated mAbs against βG and PEG and examined their effect on the clearance of βG−sPEG conjugates. The effect of incorporating galactose residues in the antibodies on the clearance of βG−sPEG conjugates was also examined because galactose can accelerate the removal of proteins from the circulation (Thornburg et al., 1980) by the hepatic asialoglycoprotein receptor (Ong et al., 1991). Rapid clearance of an antibody−carboxypeptidase G2 conjugate by a galactose-modified antibody (Sharma et al., 1990, 1994) allowed earlier administration of a prodrug with reduced toxicity (Rogers et al., 1995). In addition, galactose-modified mAb has also been employed in a clinical trial to remove residual antibody−carboxypeptidase G2 conjugate from the circulation before prodrug administration (Martin et al., 1997). We show that an IgM antibody against PEG can rapidly clear PEG-containing conjugates from the circulation without toxicity and that galactose modification of the IgM is unnecessary.

EXPERIMENTAL PROCEDURES

BSA (Fraction V), sPEG, tPEG, cyanomethyl-2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-galactopyranoside, trinitrobenzenesulfonic acid, fluorescamine, and *p*-nitrophenyl β-D-glucuronide were purchased from Sigma (St. Louis, MO). Sepharose S-200 HR, Sepharose S-300 HR and Sephadex G-25 gels were from Pharmacia Biotech Asia Pacific Ltd. (Taiwan). pHAM and BHAMG were synthesized as described (Roffler et al., 1991). SMCC was from Pierce Chemical Company, Rockford, IL. Second antibodies were purchased from Organon (Durham, NC). FO myeloma cells were purchased from ATCC, Manassas, VA. BALB/c mice were obtained from the animal room of the Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

PEG-Modification of βG. Recombinant βG was produced and purified as described (Cheng et al., 1997). Twenty milligrams of sPEG per milligram of βG (2 mg/mL) was mixed in coupling buffer (deoxygenated PBS containing 1 mM EDTA, pH 8.0) at room temperature for 2 h before one-tenth the volume of a saturated solution of glycine in coupling buffer was added to stop the reaction. Unreacted PEG was removed by extensive dialysis against PBS or by gel filtration on a 2.5 × 100 cm Sepharose S-200 HR column eluted with PBS at 15 mL/h. Relevant fractions were pooled and concentrated by ultrafiltration to 1.5−2.0 mg/mL for storage at −80 °C. BSA was modified with sPEG in a similar manner. Protein concentrations were determined by the bicinchoninic acid assay (Pierce, Rockford, IL) with BSA employed as the reference protein. The BCA assay was not affected by covalently coupled PEG after removal of free PEG. In some experiments, βG in coupling buffer was modified with 2 mg of sPEG or with 2 or 20 mg of tPEG/mg of βG.

Conjugation of antibodies to βG−sPEG. mAb RH1 (Roffler et al., 1994) and 5A8 (Maloney et al., 1985) were passed through a 2.6 × 30 cm Sephadex G-25 column equilibrated with coupling buffer and concentrated by ultrafiltration to 3 mg/mL. A 4-fold molar excess of SMCC (1 mg/mL in dioxane) was slowly added to the antibodies and allowed to react at room temperature for 50 min. Unreacted SMCC was removed by gel filtration on a 2.6 × 30 cm Sephadex G-25 column equilibrated with coupling buffer. The average number of maleimido groups introduced into antibodies (1−1.5) was assessed as described (Ishikawa et al., 1987). βG−sPEG, prepared as described above, was partially reduced by adding dithiothreitol to a final concentration of 20 mM for 1 h at 37 °C. βG−sPEG was then desalted on a 2.6 × 30 cm Sephadex G-50 column equilibrated with coupling buffer and concentrated to 2 mg/mL. Freshly derivatized antibody and βG−sPEG were immediately mixed at equal molar ratios, concentrated to 2 mg/mL by ultrafiltration and incubated at room temperature for 2 h. Cysteine was added to a final concentration of 2 mM to stop the reaction and the mixture was concentrated by ultrafiltration to about 5 mg/mL. Conjugates were purified by gel filtration on a 2.6 × 100 cm Sepharose S-300 HR column equilibrated with PBS at a flow rate of 15 mL/h. Fractions containing conjugate monomers (antibody/enzyme = 1:1) were pooled and concentrated by ultrafiltration to 1.5−2.0 mg/mL for storage at −80 °C. The yield of conjugates averaged around 35% based on the weight of purified conjugate divided by the total starting weights of antibody and enzyme.

Generation of Monoclonal Antibodies against βG and βG−PEG. Female BALB/c mice were i.v. injected with 200 μg of RH1−βG−PEG in PBS on day 1 and i.p. injected with 100 μg of RH1−βG−PEG on days 7, 14, 21, and 28. Mice received a final i.v. injection of 200 μg of RH1−βG−PEG on day 54. Hybridomas were generated by fusing spleen cells with FO myeloma cells 3 days later (Yeh et al., 1979). Hybridomas were screened by ELISA in 96-well microtiter plates coated with 1 μg/well βG or βG−PEG. Selected hybridomas were cloned 3 times by limiting dilution in 96-well microtiter plates containing thymocyte feeder cells in HT medium supplemented with 15% fetal calf serum. The isotypes and subclasses of mAbs were determined with the Mouse MonoAb-ID kit according to the manufacturer's instructions (Zymed laboratories, South San Francisco, CA). The apparent affinity constants (avidity) of antibodies for βG and βG−sPEG were measured as described (Beatty et al., 1987).

Antibody ELISA. Microtiter plates were coated with 1 μg/well βG, βG−sPEG, BSA, or BSA−sPEG in PBS and blocked with 2% skim milk. Serial dilutions of 1E8 and AGP3 were added to the plates for 1 h at 37 °C. The plates were washed 3 times with PBS-T and 3 times with PBS before horseradish peroxidase conjugated second antibody was added for 1 h at 37 °C. Plates were washed and bound peroxidase activity was measured by adding 100 μL/well ABTS solution [0.4 mg/mL 2,2′-azino-di(3-ethylbenzthiazoline-6-sulfonic acid), 0.003% H_2O_2, 100 mM phosphate-citrate, pH 4.0] for 15 min at room temperature. Absorbance (405 nm) of wells was measured in a microplate reader (Molecular Device, Menlo Park, CA).

Immunoblotting of PEG-Modified Proteins. Samples were electrophoresed in sodium-dodecyl polyacrylamide gels under reducing conditions before overnight transfer to nitrocellulose paper by passive diffusion in blotting buffer (50 mM NaCl, 2 mM EDTA, 0.5 mM 2-mercaptoethanol, and 10 mM Tris-HCl, pH 7.5). Blots were blocked with 5% skim milk and incubated for 1 h at 37 °C with 1E8 or AGP3 ascites diluted 1:2000 in PBS containing

0.05% BSA. Blots were washed 3 times with PBS-T and twice with PBS before incubation with horseradish peroxidase conjugated second antibody for 30 min at 37 °C. Blots were washed and bands were visualized by ECL detection according to the manufacturer's instructions (Pierce, Rockford, IL).

Galactose-modification of antibodies. Cyanomethyl-2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-galactopyranoside was reacted with 0.1 M sodium methoxide in dry methanol for 48 h (Marshall et al., 1995). The methanol was removed by evaporation under vacuum and antibodies (5 mg/mL in pH 8.5 borate buffer) were directly added and allowed to react for 2 h. Different amounts of galactose were incorporated into antibodies by varying the ratio of the reactants. The number of galactose groups introduced into antibodies was estimated by the reduction of trinitrobenzesulfonic acid reactive amine groups after galactose modification (Habeeb, 1966) using a molar extinction coefficient (ϵ^{335}) of 1.31×10^4 for 1E8 and 1.38×10^4 for AGP3. Galactose groups were also estimated by measuring amine groups before and after galactose modification with fluorescamine (Stocks et al., 1986).

Serum Half-Lives of Antibodies. BALB/c mice were i.v. injected with 200 μg of unmodified or galactose-modified antibody. Serum was isolated from blood samples that were periodically removed from the tail vein of mice. The concentrations of 1E8 or AGP3 were determined in duplicate samples by ELISA in microtiter plates coated with βG or βG−sPEG, respectively, by comparison to standard curves generated with known concentrations of the corresponding unmodified or galactose-modified antibody.

Clearance of βG−PEG and 5A8-βG−PEG from Serum. Groups of 3 BALB/c mice were i.v. injected with βG−sPEG or 5A8−βG−PEG at time zero. Blood samples were periodically removed before i.v. injection of unmodified or galactose-modified 1E8 or AGP3 at 24 h. Additional blood samples were taken at subsequent times and the βG activity in duplicate samples was measured using *p*-nitrophenol β-D-glucuronide as substrate (Wang et al., 1992). Sample concentrations were calculated by comparison of absorbance values with a standard curve constructed from known concentrations of βG−sPEG or 5A8−βG−sPEG. For meaningful comparison of clearance results, the measured concentrations of βG−sPEG in mice injected with clearing antibodies were normalized to the mean concentration of βG−sPEG in control (uncleared) mice just before clearance by

$$N_j = (C_{\mathrm{mi}}/C_{\mathrm{i}})C_j$$

where N_j is the normalized serum concentration of βG−sPEG in an experimental mouse at time j, C_{mi} is the mean serum concentration of βG−sPEG in the control group of mice at the last time point before clearance, C_{i} is the serum concentration of βG−sPEG in an experimental mouse at the last time point before clearance, and C_j is the serum concentration of βG−sPEG in an experimental mouse at time j.

Toxicity of Clearance. The number of WBC, RBC, and PLT in groups of 6 BALB/c mice were measured as described (Chen et al., 1997) 1 day before i.v. injection of 50 μg of βG−PEG or PBS. Mice were i.v. injected 24 h later with 300 μg of AGP3 or AGP3−208G or two fractionated 150 μg doses of AGP3−208G separated by 4 h. After allowing 6 h for clearance, mice were i.v. injected with two 7.5 mg/kg doses of BHAMG in PBS. On day 8, the number of WBC, RBC, and PLT in serum samples were determined. On days 3 and 10, the spleen, liver, and kidney were removed from one mouse in each group and fixed in 10% formalin. Ethanol dehydrated samples were embedded in paraffin and cut into 3 μm sections. Sections were then dewaxed with xylene, stained with hematoxylin/eosin, and dehydrated before observation under a light microscope. The weight of mice was followed for 18 days.

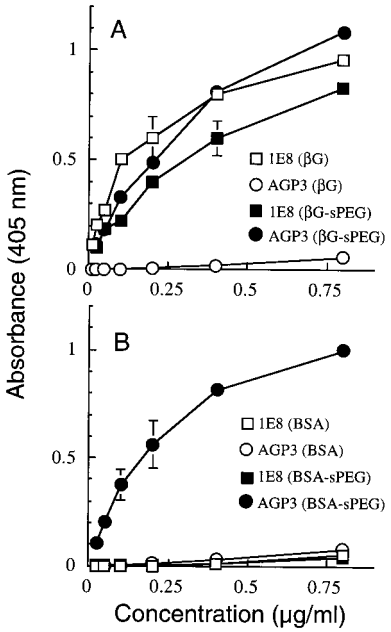

Figure 1. Binding specificity of 1E8 and AGP3. (A) 1E8 or AGP3 antibodies were incubated in microtiter plates coated with βG or βG−sPEG. (B) 1E8 or AGP3 were incubated in microtiter plates coated with BSA or BSA−sPEG. Binding of antibodies was detected by measuring the absorbance of wells at 405 nm as described in the Experimental Procedures. The mean absorbance values of triplicate determinations are shown. Bars, SE.

pH Dependence of βG Activity. Fifteen microliters of βG (4 μg/mL) was mixed in microtiter plates with 200 μl of βG buffer (Wang et al., 1992) with pH values ranging 3−10. Twenty-five microliters of *p*-nitrophenol β-D-glucuronide (32 mM) was added to the wells at 37 °C for 15 min, excess 1 N NaOH was added to adjust the pH to greater than 10, and absorbance was read at 405 nm in a microplate reader. To test the pH stability of βG, enzyme was incubated in βG buffer adjusted to pH values ranging 3−11 for 4 h at 37 °C before neutralization to pH 7.0 and assay of enzymatic activity.

Data Analysis. Statistical significance of differences between mean values was estimated with the shareware program Schoolstat (White Ant Occasional Publishing, West Melbourne, Australia) using the independent *t*-test for unequal variances.

RESULTS

Antibodies against βG−PEG. Monoclonal antibodies against βG−sPEG were generated from spleen cells of mice that had received multiple injections of RH1−βG−PEG. mAb 1E8 (IgG1) and AGP3 (IgM) were selected for further characterization based on preliminary screening by ELISA. 1E8 bound to βG and, to a lesser extent, βG−sPEG (Figure 1A). The apparent affinity constants of 1E8 for βG and βG−sPEG were 0.83 and 1.8 nM, respectively (data not shown). In contrast, AGP3 bound βG−sPEG with an apparent affinity constant of 0.79 nM but did not bind βG (Figure 1A), suggesting that this antibody recognizes PEG chains present on βG−sPEG. AGP3 specificity for PEG was supported by the finding that it

[a] The amount of activated galactose added per milligram of antibody. [b] Determined by the fluorescamine method as described by Stocks et al. (1986). [c] Determine by the trinitrobenzesulfonic acid method as described in the Experimental Procedures. [d] Antigen-binding activity determined by ELISA.

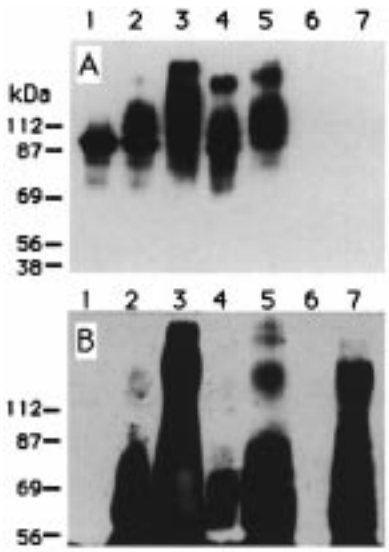

Figure 2. Immunoblot analysis of 1E8 and AGP3 binding. Proteins were electrophoresed in a 3−12.5% gradient reduced SDS−PAGE, transferred to nitrocellulose paper, and probed with 1E8 (A) or AGP3 (B) as described in the Experimental Procedures. Lane 1, βG; lane 2, βG−sPEG (2 mg of sPEG/mg of βG); lane 3, βG−sPEG (20 mg of sPEG/mg of βG); lane 4, βG-tPEG (2 mg of tPEG/mg of βG); lane 5, βG-tPEG (20 mg of tPEG/mg of βG); lane 6, BSA; lane 7, BSA−sPEG (20 mg of sPEG/mg of BSA). kDa, molecular mass in thousands.

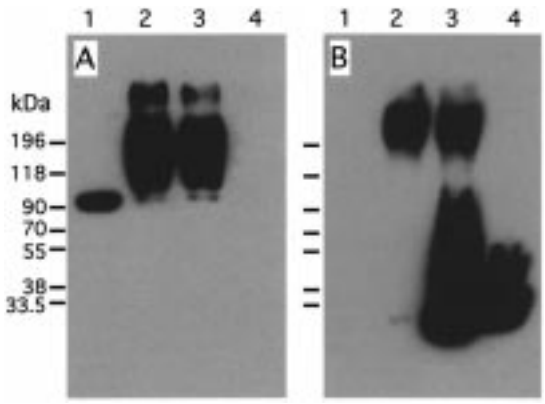

Figure 3. Immunoblot of different βG−PEG preparations. Samples were electrophoresed on a 8% reduced SDS−PAGE, transferred to nitrocellulose paper, and probed with 1E8 (A) or AGP3 (B) as described in the Experimental Procedures. Lane 1, βG; lane 2, βG−sPEG purified by gel filtration; lane 3, βG−sPEG purified by dialysis; lane 4, sPEG neutralized with excess glycine. kDa, molecular mass in thousands.

also bound BSA−sPEG but not BSA (Figure 1B). As expected, 1E8 bound neither BSA nor BSA−sPEG (Figure 1B). Neither mAb affected the activity of βG (results not shown).

The specificity of mAb binding was further examined by immunoblotting. Figure 2A shows that 1E8 detected βG and PEG-modified βG (lanes 1−5), but not BSA or BSA−sPEG (lanes 6 and 7). Figure 2B shows that AGP3, in contrast, did not bind βG (lane 1) or BSA (lane 6) but detected all proteins that incorporated PEG (βG−sPEG, βG−tPEG, and BSA−sPEG). The ability of AGP3 to bind either sPEG or tPEG-modified proteins demonstrates that this antibody binds to poly(ethylene glycol) rather than the linker between PEG and proteins.

Substantial amounts of PEG were present in βG−sPEG preparations purified by dialysis (Figure 3B, lane 3). AGP3 immunoblotting of sPEG after neutralization with glycine (Figure 3B, lane 4) produced a similar smeared band, indicating that the low molecular weight material in βG−sPEG corresponded to free PEG rather than degraded βG−sPEG fragments. Purification of βG−PEG by gel filtration on Sepharose S-200 HR resulted in the removal of free PEG (Figure 3B, lane 2). This βG−sPEG conjugate (Figure 3B, lane 2), containing 9.2 ± 0.3 sPEG groups/βG subunit and possessing 69% of original enzymatic activity, was employed in all subsequent experiments.

Galactose-Modification of Antibodies. 1E8 and AGP3 were modified with galactose to target their uptake by the asialoglycoprotein receptor on hepatocytes. Modification of 1E8 with increasing amounts of activated galactose resulted in the incorporation of up to 47 galactose residues/antibody (Table 1). Introduction of up to 20 galactose residues did not affect the binding of 1E8 to βG whereas greater incorporation of galactose decreased 1E8 activity by about 35%. A maximum of 290 galactose residues could be introduced into AGP3 (Table 1). The greater number of galactose residues incorporated into AGP3 primarily reflects the larger size of the IgM molecule; galactose incorporation for both 1E8 and AGP3 corresponded to 0.3 galactose moieties/kDa of antibody. AGP3 was more sensitive to galactose modification with a 2.4-fold decrease in antigen-binding activity at the highest levels of galactose incorporation.

The half-lives of galactose-modified antibodies were determined in BALB/c mice. Figure 4A shows that 1E8 was eliminated from serum with a half-life of 22 h. Introduction of increasing numbers of galactose residues into 1E8 resulted in progressively faster initial clearance rates. Even at the highest galactose incorporation, however, residual concentrations of 1−4 μg/mL 1E8−46G were present in the serum after 5 h. Unmodified AGP3 cleared from serum with a half-life of 13 h but in contrast to galactose-modified 1E8, almost no residual antibody could be detected in the circulation within 5 h after administration of AGP3 modified with greater than 130 galactose moieties (Figure 4B). On the basis of the elimination kinetics of the antibodies, 1E8−36G and AGP3−208G were selected for further study.

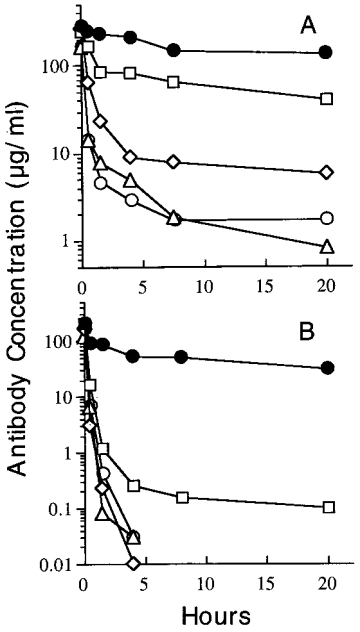

Figure 4. Elimination of galactose-modified antibodies from serum. Single BALB/c mice were i.v. injected with 200 μg of 1E8 (●), 1E8−9G (□), 1E8−19G (◇), 1E8−36G (△), or 1E8−46 (○) (A) or 200 μg of AGP3 (●), AGP3−64G (□), AGP3−130G (◇), AGP3−208G (△), or AGP3−285G (○) (B). The concentrations of antibodies in serum samples taken at the indicated times were measured as described in the Experimental Procedures.

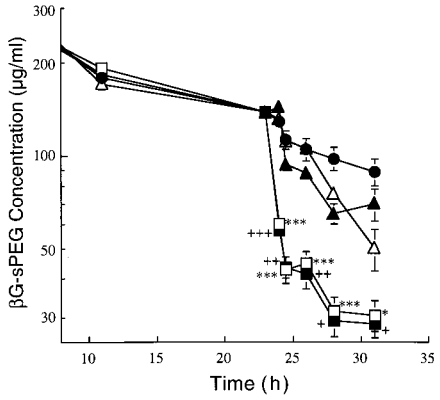

Figure 5. Clearance of βG−PEG by antibodies. Mice injected with 200 μg of βG−sPEG at time 0 were i.v. injected 23 h later with PBS (●) or 250 μg of 1E8 (△), 1E8−36G (▲), AGP3 (□), or AGP3−208G (■). The concentration of βG−sPEG in serum samples was measured and normalized as described in the Experimental Procedures. Mean concentrations from three mice are shown. Significant differences between AGP3 and 1E8 clearance are indicated: (*) $p \leq 0.05$; (**) $p \leq 0.005$; (***) $p \leq 0.0005$. Significant differences between AGP3−208G and 1E8−36G clearance are indicated: (+) $p \leq 0.05$; (++) p ≤ 0.005; (+++) $p \leq 0.0005$. Bars, SE.

In Vivo Clearance of βG−PEG. The ability of antibodies to clear βG−sPEG from the circulation was examined by i.v. injecting mice with 200 μg of βG−sPEG followed 24 h later with 250 μg of unmodified or galactose-modified antibody. Figure 5 shows that both 1E8 and AGP3 accelerated the clearance of βG−sPEG from the circulation. 1E8−36G cleared significantly more βG−sPEG than 1E8 at early times but by 8 h after antibody administration there was no significant difference between these antibodies. AGP3 and AGP3−208G cleared significantly more βG−sPEG than either 1E8 or 1E8−36G at all times examined. βG−sPEG was cleared equally well by AGP3 and AGP3−208G under these experimental conditions.

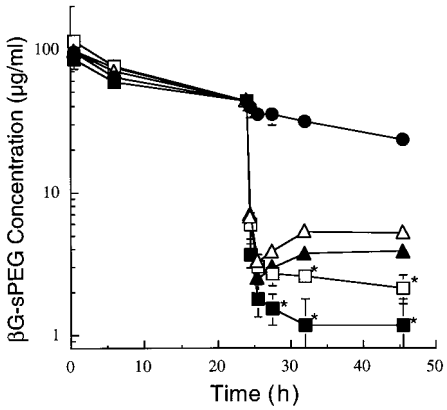

Figure 6. Dose dependence of AGP3 clearance of βG−PEG. Groups of three mice were injected at time 0 with 50 μg of βG−sPEG followed 24 h later by PBS (●), 150 μg of AGP3 (□), 150 μg of AGP3−208G (△), 300 μg of AGP3 (■), or 300 μg of AGP3−208G (▲). The concentration of βG−PEG in serum samples was measured and normalized as described in the Experimental Procedures. Mean concentrations from three mice are shown. Significant differences between AGP3 and AGP3−208G groups are indicated; (*) $p \leq 0.05$. Bars, SE.

Table 2. Clearance of 5A8-βG−PEG by AGP3[a]

		AGP3 clearance	
time (h)	no clearance (μg/mL)	(μg/mL)	reduction[b](fold)
24	24 ± 2.1	37 ± 1.5	1.0
26	18 ± 3.5	0.10 ± 0.001	280
48	6.1 ± 0.7	0.01 ± 0	940

[a] Groups of 3 mice were i.v. injected with 175 μg of 5A8-βG−PEG. At 24 and 25 h, mice were injected with PBS (no clearance) or 300 μg of AGP3. The concentration of 5A8-βG−PEG in serum was determined by measuring βG activity. [b] The ratio of 5A8-βG−PEG concentration in serum without clearance to the concentration with clearance, normalized for the difference in conjugate concentrations at 24 h.

We examined whether increasing the ratio of AGP3 to βG−sPEG would improve clearance. Figure 6 shows that i.v. injection of 150 or 300 μg of AGP3 or AGP3−208G 24 h after i.v. injection of 50 μg of βG−sPEG resulted in rapid removal of 90−95% of the enzyme within 1.5 h. The concentration of βG−sPEG in the circulation, however, rebounded from a minimum of about 2 μg/mL to 4−5 μg/mL 8 h after injection of AGP3−208G. In contrast, the concentration of βG−sPEG decreased to 1.0 μg/mL 8 h after injection of 300 μg of AGP3. Although a dose of 300 μg of AGP3 appeared to more completely clear βG−sPEG compared to 150 μg of AGP3, the difference was only significant ($p \leq 0.05$) 1.5 h after antibody administration. In contrast, clearance of βG−sPEG with both 150 and 300 μg of AGP3 was significantly ($p \leq 0.05$) better than clearance with either dose of AGP3−208G at all times. AGP3 also efficiently cleared 5A8−βG−PEG, reducing the serum concentration of conjugate by 280-fold within 2 h (Table 2).

Prodrug Toxicity After Clearance of βG−sPEG. Clearance of circulating βG−sPEG should reduce systemic activation of the glucuronide prodrug BHAMG, thereby reducing toxicity. Accumulation of cleared immune complexes in organs, however, could result in tissue damage. Organ tissue sections from mice that were injected with PBS or βG−sPEG followed 24 h later by AGP3 and then BHAMG were therefor examined after 3 or 10 days. Figure 7 shows that injection of AGP3 and BHAMG as well as clearance of βG−sPEG with AGP3 before BHAMG administration did not cause obvious

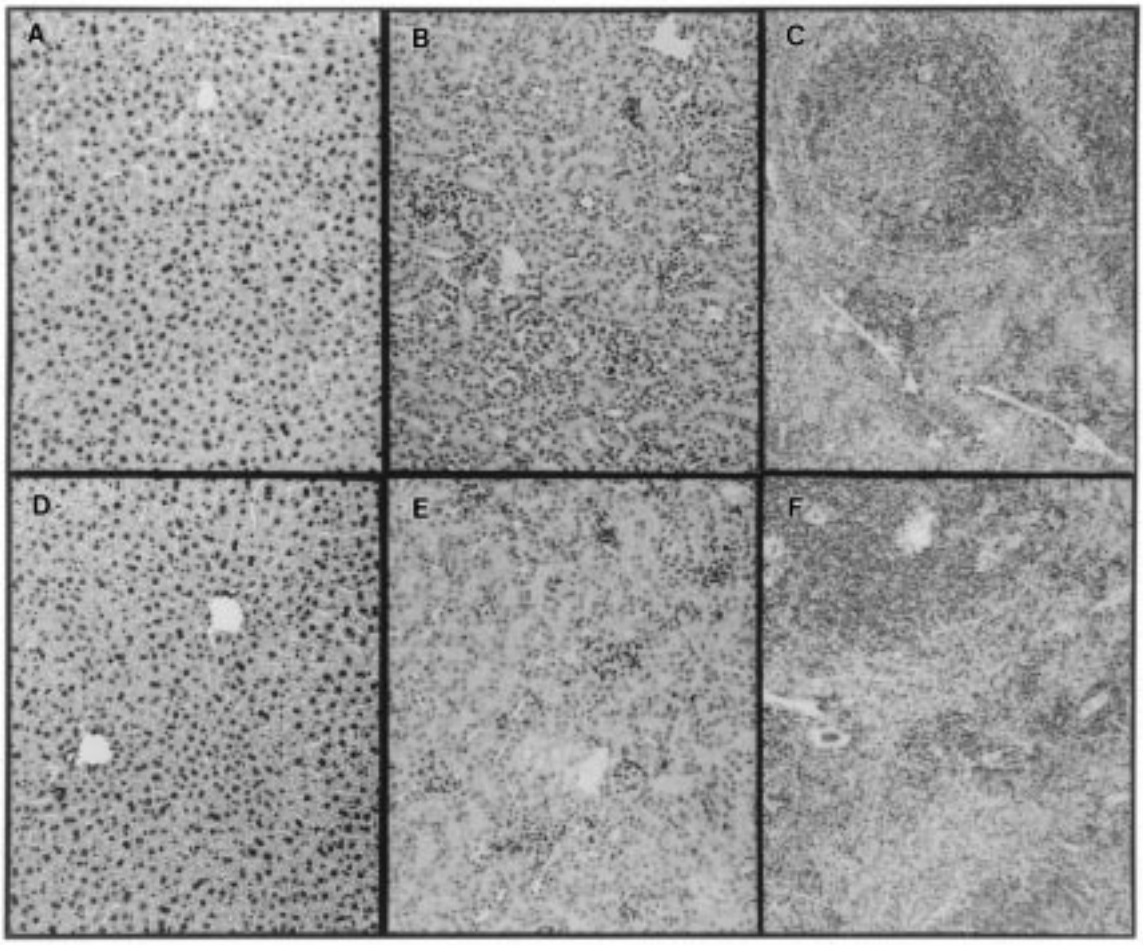

Figure 7. BHAMG-induced organ pathology after βG−PEG clearance. Mice were injected with PBS (A−C) or βG−sPEG (D−F) on day 1. Mice were i.v. injected with AGP3 and BHAMG 24 and 30 h later, respectively. Tissue sections of liver (A, D), kidney (B, E), and spleen (C, F) recovered 10 days later were stained with hematoxylin and eosin.

damage to the liver, spleen, or kidney 10 days after BHAMG administration. Similarly, no tissue damage was observed 3 days after prodrug administration (results not shown).

The toxicity associated with clearance and prodrug administration was also assessed by measuring the weight and blood cells of mice. Administration of AGP3 and 15 mg/kg BHAMG (control group) produced only a small transient decrease in the weight of mice (Figure 8A). In contrast, injection of 50 μg of βG−sPEG 24 h before administration of BHAMG caused significant weight loss and resulted in the death of 1 of 4 mice. Clearance of βG−sPEG with 300 μg of AGP3 or 2 injection of 150 μg of AGP3−208G before prodrug administration prevented significant weight loss compared to the control group. Mice that were cleared with one 300 μg dose of AGP3−208G before injection of BHAMG lost significantly more weight than control mice after day 8, but the loss was much less than in the uncleared mice. Figure 8B shows that the numbers of RBC, PLT, and RBC were significantly reduced in mice injected with βG−sPEG and BHAMG compared to mice injected with AGP3 and BHAMG (control mice). In contrast, the numbers of RBC, WBC, and PLT in mice in which βG−sPEG was cleared with 300 μg of AGP3 before BHAMG administration were not significantly different from control mice. Clearance of βG−sPEG with AGP3−208G before injection of prodrug reduced but did not eliminate hematological toxicity.

AGP3/βG−PEG immune complexes may be routed to the acidic environment of lysosomes after clearance. The effect of pH on βG activity was examined by incubating βG at various pH values for 4 h before neutralization and assay of activity at pH 7.0. βG was irreversibly deactivated at pH values less than 5.0 or greater than 9.0 (Figure 9).

DISCUSSION

We have previously shown that PEG modification of βG increases the tumor localization of antibody−βG conjugates for targeted activation of glucuronide prodrugs (Cheng et al., 1997). PEG-modified βG conjugates, however, are slowly eliminated from the circulation, resulting in low tumor-to-blood ratios. We therefore generated mAbs against βG and PEG and investigated whether these antibodies could accelerate the clearance of βG−sPEG from blood.

mAb 1E8 and AGP3 were modified with galactose to direct uptake of immune complexes by asialoglycoprotein receptors on liver cells (Thornburg et al., 1980; Mattes, 1987). Binding of circulating βG−sPEG by 1E8−36G or AGP3−208G was expected to result in rapid endocytosis, routing to lysosomes and catabolism of enzyme (Ciechanover et al., 1983; Geuze et al., 1983), thereby preventing systemic activation of glucuronide prodrugs. In agreement with previous studies (Mattes, 1987; Sharma et al., 1990), extensive galactose modification of 1E8 and AGP3 (up to 47 and 290 residues, respectively) did not dramati-

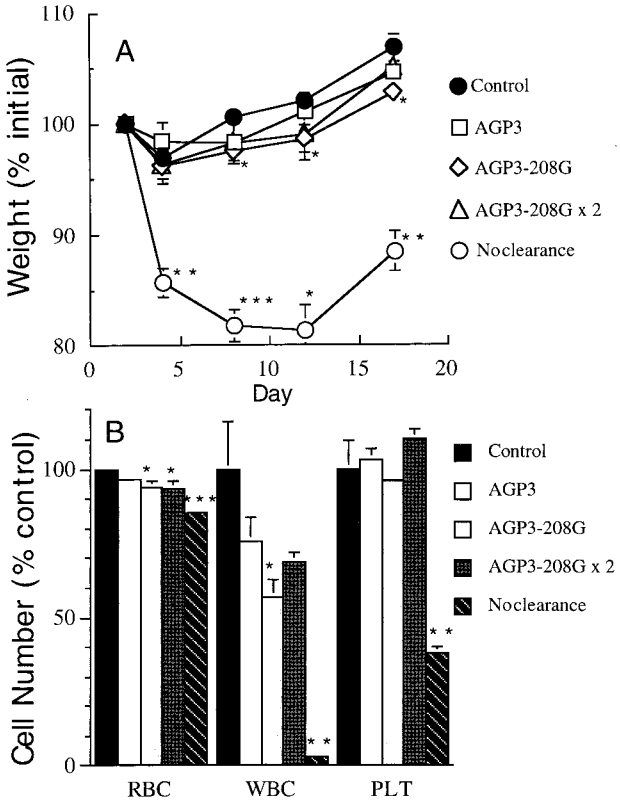

Figure 8. Weight and hematological toxicity of BHAMG after clearance of βG−PEG. Groups of 4 mice were i.v. injected at time zero with PBS (control) or βG−sPEG. Twenty-four hours later, mice received i.v. injections of 300 μg of AGP3 (control and AGP3 groups), 300 μg of AGP3−208G, 150 μg of AGP3−208G (×2, 4 h delay), or PBS (no clearance). Six hours later, all mice were i.v. injected with BHAMG. (A) The time course of mouse weight (% of initial weight) and (B) mean numbers of WBC, RBC, and platelets on day 8 are shown. Significant differences between the control and experimental groups are indicated: (*) $p \leq 0.05$; (**) $p \leq 0.005$; (***) $p \leq 0.0005$. Bars, SE.

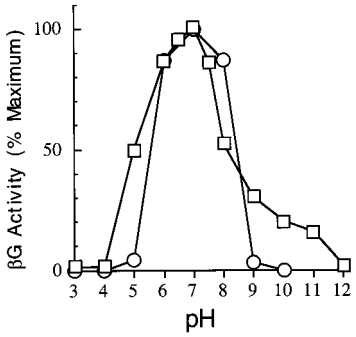

Figure 9. pH sensitivity of βG. βG was assayed for enzymatic activity at various pH values (□) or incubated at the indicated pH for 4 h before neutralization and assay at pH 7.0 (○). Results represent percentage of maximum activity.

cally alter the antigen-binding activity of the antibodies. Increasing the level of galactose residues per antibody did not greatly affect the initial rate of clearance, but did increase the total amount of antibody that was removed from the circulation. For example, the concentrations of 1E8−9G, 1E8−19G, and 1E8−36G in serum were 45, 5.3, and 1.2% of 1E8 levels after 8 h (Figure 4). The galactose-modified antibodies that were not removed from the circulation within the first 5 h exhibited similar elimination kinetics as unmodified 1E8, indicating that a critical number of galactose residues was required for efficient uptake by the asialoglycoprotein receptor, similar to the results found for galactosylated BSA and superoxide dismutase (Nishikawa et al., 1995). The more efficient uptake of galactosylated AGP3 (=99.5% by 4 h for ϵ 130 galactose moieties) compared to galactose-modified 1E8 was unlikely due to differences in the surface density of galactose groups since galactose incorporation was similar based on the molecular weights of 1E8 and AGP3. The asialoglycoprotein receptor is a hetero-oligomer composed of two types of polypeptide chains (Lodish, 1991). High-affinity binding of ligands involves the interaction of three galactose residues in ligands with sites in both polypeptide chains (Rice et al., 1990). Specific orientation of the galactose residues is required for high-affinity receptor binding (Lee et al., 1983; Townsend et al., 1986), suggesting that the orientation of incorporated galactose groups in the pentameric structure of IgM may promote high-affinity binding to the asialoglycoprotein receptor.

AGP3 cleared βG−sPEG more rapidly and completely than 1E8. Hindered binding of 1E8 by PEG chains on βG−sPEG may have contributed to the high residual serum concentrations of βG−sPEG after 1E8 administration. The pentameric structure of AGP3 combined with the presence of multiple PEG chains on each βG tetramer may have promoted the formation of large immune complexes, which are cleared more rapidly than small immune complexes (Roitt et al., 1989). AGP3 appears to produce more rapid and complete clearance than other antibodies previously employed for clearance, which have been limited to IgG fractions of polyclonal antiserum (Bradwell et al., 1983; Sharkey et al., 1984; Pedley et al., 1989; Begent et al., 1989) or monoclonal IgG antibodies (Sharma et al., 1990; Kerr et al., 1993; Haisma et al., 1995; Wallace et al., 1994). Polyclonal IgG antibodies reduced radioimmunoconjugate levels in serum from around 10-fold (Bradwell et al., 1983; Sharkey et al., 1984; Begent et al., 1989) to 130-fold (Pedley et al., 1989) in 24 h whereas monoclonal IgG antibodies reduced the serum levels of antibody−enzyme conjugates from 3−10-fold in a few hours (Sharma et al., 1990; Haisma et al., 1995) to 40−60-fold in 24 h (Kerr et al., 1993; Wallace et al., 1994). In comparison, AGP3 reduced the serum concentration of 5A8−βG−PEG by 280-fold in 2 h and 940-fold in 24 h. Although it is difficult to directly compare clearance results employing different immunoconjugates and experimental conditions, these results suggest that IgM may clear immunoconjugates from blood more rapidly and completely than IgG.

Comparison of AGP3 and AGP3−208G clearance demonstrated that both antibodies initially cleared βG−sPEG with similar rapid kinetics, but that AGP3 removed significantly more βG−sPEG from the circulation than AGP3−208G. The better clearance of unmodified AGP3 can be attributed to the prolonged half-life of AGP3 ($\tau_{1/2}$=13 h) compared to AGP3−208G ($\tau_{1/2}$ < 1 h). βG−sPEG released from normal tissues after rapid removal from blood could be bound and cleared by free AGP3 remaining in the blood pool whereas the rapid endocytosis of both free and complexed AGP3−208G prevented further formation of complexes with βG−sPEG. This behavior is clearly evident in Figure 6 where the concentration of βG−sPEG in the circulation rebounded after an initial period of rapid clearance by AGP3−208G.

One concern of employing IgM to clear proteins is that the immune complexes could be deposited in organs and cause tissue damage. In addition, deposition of βG−PEG on the surface of cells could result in prodrug activation and tissue toxicity. Tissue damage, however, was not

observed after clearance of βG−sPEG with AGP3 and subsequent administration of BHAMG. In addition, clearance of βG−sPEG with AGP3 prevented weight loss and hematological toxicity associated with systemic activation of BHAMG by βG−PEG in the circulation. Soluble IgM immune complexes are primarily removed from the circulation and catabolized by the mononuclear phagocyte system in the liver, spleen, and lungs (Roitt et al., 1989), possibly by receptor-mediated binding of high mannose oligosaccharides exposed upon conformational changes in IgM after binding to antigen (Day et al., 1980). The low toxicity of BHAMG after clearance of βG−sPEG with AGP3 indicates that immune complexes formed between AGP3 and βG−sPEG are rapidly internalized where βG is inactivated, degraded or inaccessible to prodrug. Routing of βG−sPEG to lysosomes is expected to result in loss of enzymatic activity because βG is irreversibly inactivated at pH values lower than 5.0. Deactivation of βG in lysosomes may prevent accumulation of active enzyme and prodrug activation in the liver as observed after antibody-mediated clearance of carboxypeptidase G2 conjugates (Rogers et al., 1995).

PEG modification is a useful technique to improve the stability, prolong serum half-life and decrease the antigenicity and immunogenicity of proteins (Delgado et al., 1992). Because AGP3 binding to PEG is protein independent, this antibody should be generally applicable to the clearance of PEG-modified immunoconjugates. Clearance of immunoconjugates from the circulation can also result in decreased tumor accumulation (Pedley et al., 1989; Sharkey et al., 1992; Kerr et al., 1993), likely due to the generation of a concentration gradient of conjugate from tumor to blood, allowing immunoconjugates that dissociate from tumor antigen to be released into the blood. The large size of IgM may retard passage into the tumor interstitial space, minimizing interactions between localized immunoconjugate and clearing antibody. In addition, the rapid clearance achieved with AGP3 may allow administration of prodrug or other targeting moieties before significant immunoconjugate is released from the tumor. The application of AGP3 for clearing B72.3−βG−PEG conjugates for glucuronide prodrug therapy of colorectal cancer is currently under investigation.

Received December 14, 1998

The DNA targets may be labeled and simultaneously amplified in the polymerase chain reaction (PCR) using a pair of respective primers after elongation with nucleoside-5′-triphosphates carrying photoreactive groups. The amplified DNA may be subsequently photoactivated by irradiation above 300 nm, resulting in photo-cross-linking of the strands. For this goal 5-[3-(*E*)-(4-azido-2,3,5,6-tetrafluorobenzamido)propenyl-1]-, 5-{*N*-[*N*′-(4-azido-2,3,5,6-tetrafluorobenzoyl)-3-aminopropionyl]aminomethyl}-, and 5-{*N*-[*N*′-(2-nitro-5-azidobenzoyl)-3-aminopropionyl]aminomethyl}-2′-deoxyuridine-5′-triphosphate (**VII**, **VIa**, and **VIb**) derivatives have been synthesized. It was found that **VII** is capable of efficiently elongating DNA primers with both Klenow fragment DNA polymerase I and *Thermus aquaticus* DNA polymerase. Thereto, it turned out to provide quantitative incorporation in DNA as revealed by the formation of the full-length amplificate by PCR in the presence of this photoreactive analogue without any dilution with natural dTTP. On the contrary, it was found, that incorporation of **VIa** and **VIb** do not permit further DNA replication.

INTRODUCTION

Nucleoside-5′-triphosphate derivatives carrying a photoreactive aryl azido residue attached to heterocyclic moiety were proposed a few years ago as substrates of the nucleic acid polymerases for the preparation of photoreactive oligonucleotides. UTP and CTP analogues were used for preparation photoreactive transcript, which can be used for affinity labeling of *Escherichia coli* RNA polymerase (*1*, *2*). The dCTP derivative carrying a *p*-perfluoroazido benzoyl residue bound to exocyclic NH_2 group via a $-CH_2CH_2NH-$ spacer was prepared and used for primer extension by a DNA polymerase α-primase complex from human placenta. The duplex obtained was demonstrated to carry out affinity modification of a number of the subunits of the complex (*3*). The same derivative as well as another one, carrying *p*-perfluoroazido benzoyl residue attached to 5-C of dCTP via the spacer $-CH{=}CH-CH_2-NH_2$, was found to be a substrate of the HIV-1 reverse transcriptase, and it was shown that specific modification of DNA template in the complex with the enzyme was carried out (*4*). The primer extension products obtained with 37-meric DNA and M13 DNA templates were found to photo-cross-link with both the enzyme and template DNA (*4*, *5*). Thus, the approach turned out to be promising for the specific labeling of both polymerases and DNA templates. To expand the possibilities of the approach a number of dTTP, dCTP and dATP analogues were prepared as the tools for investigation of nucleic acid—nucleic acid and protein—nucleic acid interactions (*6*).

Recently, we proposed to use this approach to elaborate a new version of the fluorescent DNA probes localization on chromosomes and chromatin (*7*). This version is based upon the elongation of the hybridized probe in the presence of DNA polymerase and a mixture of deoxynucleoside-5′-triphosphate containing a photoreactive analogue of one of the substrates. This procedure permits the subsequent photo-cross-linking of the elongated probe with chromatin, thus making possible the following extensive washing to remove nonspecific signals and, consequently, to achieve higher contrast of the specific one. In our first work, we used a dTTP analogue with 2-nitro-5-azidobenzoyl residue attached to 5-C atom of deoxyuridine-5′-triphosphate via a $-CH_2NHC(O)(CH_2)_2-NH-$ spacer.

Obviously, the efficient incorporation of photoreactive dNTP[1] in the product of DNA replication is one of essential prerequisites for the subsequent efficient cross-linking. The main goal of this work was to prepare the photoreactive nucleoside-5′-triphosphate derivative, which can be efficiently incorporated into DNA primers by DNA polymerases with subsequent cross-linking with the template DNA under irradiation. Since it was shown earlier that, among aryl azides investigated, the *p*-azido perfluorobenzoyl residue is the most reactive toward complementary oligonucleotide chain (*8*, *9*), we have

prepared new dNTP analogues, carrying this group connected with pyrimidine heterocycle via two different spacers. One of them, 5-[3-(*E*)-(4-azido-2,3,5,6-tetrafluorobenzamido)propenyl-1]-2′-deoxyuridine-5′-triphosphate, turned out to provide quantitative incorporation in DNA as revealed by the formation of the full-length amplificate in the presence of this dU*TP analogue without any dilution with natural dTTP. The amplified DNA subsequently may be photoactivated by irradiation above 300 nm, leading to the photo-cross-linking of the strands. These results indicate that new photoreactive analogue **VII** can be used for in vitro incorporation into DNA probes to label genetic targets on human metaphase chromosome spreads and interphase nuclei after the formation of covalent links between the photoanchoring probes and template DNA.

EXPERIMENTAL PROCEDURES

Materials. *N*,*N*-Dimethylformamide, acetone, acetonitrile, pyridine, and triethylamine were purified and dried according to standard procedures. Triethyl phosphate, *β*-alanine, DCC, *N*-hydroxysuccinimide, and bis-(tri-*n*-butylammonium)pyrophosphate were purchased from Merck (Germany). Phosphoroxychloride, 2′-deoxyuridine, and 2′-deoxyuridine-5′-triphosphate were purchased from Fluka (Switzerland). Dowex 50W X2 was purchased from Serva (Germany). DEAE-cellulose DE-32 was purchased from Whatman (England). Polynucleotide kinase and dNTP were purchased from NIKTI BAV (Russia). DNA polymerase *Thermus aquaticus* was from Biopol (Russia). [^{32}P]-*o*-phosphate was purchased from "Nuclid Trans" (Moscow, Russia). Other reagents were of analytical grade.

General Methods. ^{1}H NMR spectra were recorded on a Bruker WP-200 SY (200 MHz) and on a Bruker AC-200 (200.132 MHz) spectrometers. All ^{1}H chemical shifts are reported relative to TMS as an internal standard. ^{31}P NMR spectra were recorded on a Bruker AC-200 (81.015 MHz) spectrometer, the ^{31}P chemical shifts are reported using an external standard of 85% H_3PO_4. Infrared spectra were recorded on a Specord M80 (Karl Zeiss, Yena). UV absorption spectra were recorded on a Specord M40 (Karl Zeiss, Yena).

Analytical TLC was carried out on silica gel plates (Merck, DC-Alufolien Kieselgel 60 F_{254}) in ethanol/NH_4-OH, 4:1(v/v), (system A); in dioxane/NH_4OH/water, 6:1:4 (v/v), (system B); and in $CHCl_3$/ethanol, 4:1 (v/v), (system C). The compounds containing amino groups were visualized by the ninhydrin reaction (1% ninhydrin, 2% acetic acid in methanol).

Isolation and purification of the dU*TP derivatives were performed by reversed-phase high-performance liquid chromatography using a LiChrosorb RP-18, 10 μm (Merck, FRG), 4.6 × 250 mm column, a Waters 600E chromatograph, and Waters 484 tunable absorbance detector. A linear gradient (2 mL/min) from 0 to 30% of acetonitrile in 0.05 M TEAB (pH 7.5) was used. Analytical anion-exchange microcolumn chromatography was performed on the Milichrom chromatograph (Russia) using a Polisil-SA, 15 μm (Vector, Russia), 2.5 × 30 mm column. A linear gradient (flow rate 50 μL/min) from 0 to 1 M of NaCl in 7 M urea and 0.01 M Na_2HPO_4 (pH 9) was employed.

The oligodeoxyribonucleotides pd(GACCTGCCACTTTG-GCTGAA) and pd(CACAATGCTGCCTTTTCCAA) were prepared by Dr. Galiya A. Maksakova as described (*10*). The oligonucleotide pd(CACAATGCTGCCTTTTCCAA) was 5′-end labeled using T4-polynucleotide kinase, [γ-^{32}P]-ATP (>3000 Ci/mmol). After purification on 20% polyacrylamide gel under denaturing conditions (8 M urea, 89 mM Tris-H_3BO_3, ~40 °C), oligonucleotide [^{32}P]d-(CACAATGCTGCCTTTTCCAA) was used as a primer in PCR experiments.

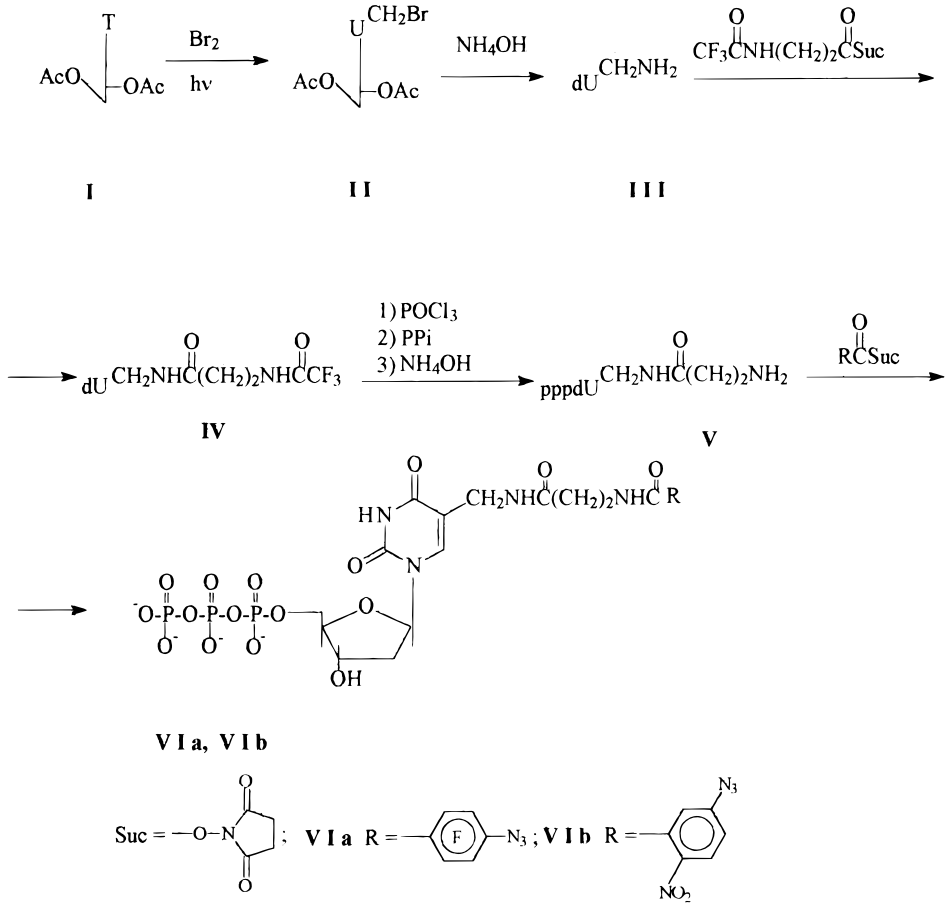
The amplification of DNA was performed on a DNA Thermal Cycler Manual (Bis, Russia).

thermal cycling profile	
inital denaturation (25−30 cycles)	95 °C, 3 min
denaturation step	95 °C, 36 s
annealing step	55 °C, 60 s
elongation step	70 °C, 2 min

A 50 μL PCR Mastermix contained 1 μg of each primer, 0.01 μg of DNA template (pTBE−51.1 plasmid), 1.5 mM $MgCl_2$, 67 mM Tris-HCl (pH 8.9), 16 mM $(NH_4)_2SO_4$, 0.05% Tween 20, 0.5 mM solution of dATP, dCTP, dGTP, and either dTTP, the photoreactive 2′-deoxyuridine-5′-triphosphate derivative, or mixture of definite amount of both photoreactive dU*TP and dTTP and 0.5 units of *Taq* DNA-polymerase. The reaction products were separated by agarose gel (2%) electrophoresis. The gels were visualized by ethidium bromide staining or autoradiography.

After synthesis of DNA by PCR in the presence of photoreactive dU*TP analogue **VII**, the PCR products were separated in 10% nondenaturating PAAG in the dark. The amplified DNA was extracted from the gel by electroelution and precipitated by addition of 2% $LiClO_4$ in acetone. The precipitate was carefully washed with acetone (2 × 1.2 mL). UV (H_2O) $\lambda_{max,}$ 268 nm; IR (0.02 mm CaF_2 cuvette) $\nu_{max,}$ 2100 ($-N_3$) cm^{-1}.

The M13mp10 phage DNA was isolated from the culture fluid of a recipient K12 x L1 *E. coli* strain. The primer pd(CCCAGTCACGACGT) was labeled at the 5′-position by [γ-^{32}P]ATP with a specific activity of 1500 Ci/mmol (Radioisotop, Russia) using T4-polynucleotide kinase and annealed with the template at the ratio 1:1 under standard conditions [60 °C, 10 min, in 10 mM Tris-HCl buffer (pH 7.9), 5 mM $MgCl_2$, and 1 mM dithiothreitol]. The primer−template complex was purified by gel filtration on a Bio-Gel A (1.5 mesh) microcolumn, prewashed by 10 mM Tris-HCl (pH 7.6) and 1 mM EDTA.



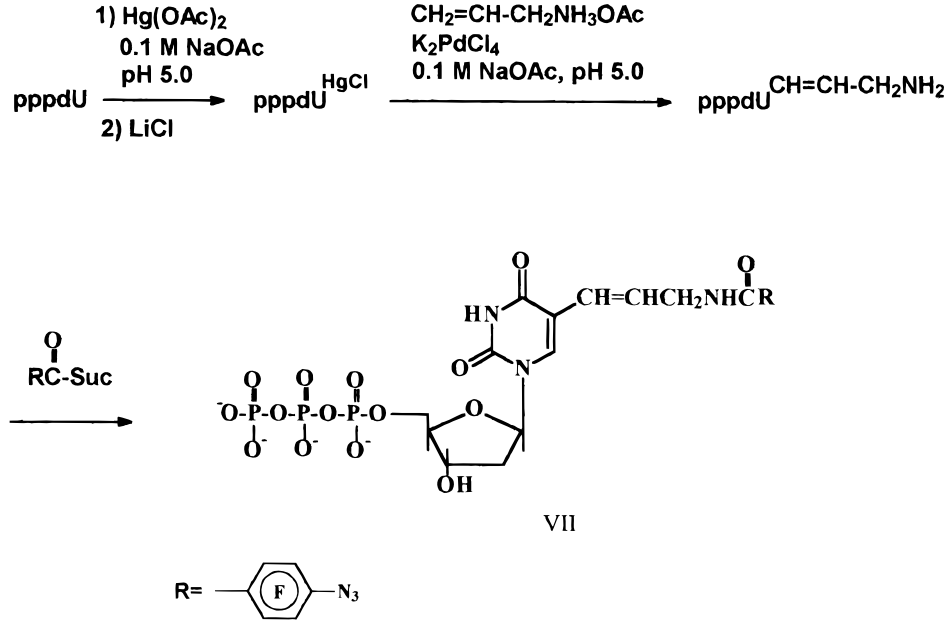
DNA polymerase assays were carried out as described (*11*). The reaction mixture (6 μL) containing 0.2 units of DNA polymerase I Klenow fragment (Promega) or *Taq* DNA polymerase (Biopol, Russia), 10 nM of the primer−template complex, natural substrates (dTTP, dGTP), or the testing compound **VII** was incubated during 15 min at 20 °C for Klenow fragment and 15 min at 72 °C for *Taq* DNA polymerase. The reaction was stopped by addition of 3 μL of formamide containing 0.1% of xylenecyanol, 0.1% of bromophenol blue, and 20 mM EDTA, pH 8.0. The reaction products were separated by electrophoresis in a 20% PAAG under denaturing conditions. The gels were visualized by autoradiography.

N-Hydroxysuccinimide esters of 2-nitro-5-azidobenzoic and 4-azido-2,3,5,6-tetrafluorobenzoic acids were synthesized as described (*12*).

Thymidine monophosphate kinase was isolated from *E. coli* MRE-600 according to the described method (*13*).

Synthesis of 5-{*N*-[3-(trifluoroacetylamino)propionyl]aminomethyl}-2′-deoxyuridine derivative (IV). Compound **IV** was obtained from thymidine in four steps with 68% yield (see Scheme 1) using the method described earlier (*14*): R_f = 0.78 in the system A; UV (H_2O, pH 9) $\lambda_{max,}$ 267 nm (ϵ = 8 800); λ_{min}, 235 nm (ϵ = 3 500). ^{1}H NMR (D_2O): δ 2.35 (m, H2′, 2H), 2.50 (t, J =

Scheme 1



6.0 Hz, H8, 2H), 3.58 (m, H9, 2H), 3.79 (m, H5′, 2H), 4.04 (m, H7, H4′, 3H), 4.45 (m, H3′, 1H), 6.26 (t, J = 6.0 Hz, H1′, 1H), 7.54 (s, H6, 1H).

Synthesis of 5-[*N*-(3-aminopropionyl)aminomethyl]-2′-deoxyuridine-5′-triphosphate derivatives (triethylammonium salt) (V). Compound **V** was obtained from **IV** using the method described earlier for the ATP (*15*). A total of 21 μL (300 μmol) of $POCl_3$ was added to an ice-cooled suspension of **IV** 41.4 mg (100 μmol) in 300 μL of triethyl phosphate. After 16 h at 4 °C, the reaction mixture was treated with a freshly prepared solution of 500 μL of 1 M bis(tri-*n*-butylammonium) pyrophosphate and 100 μL of tri-*n*-butylamine. When the phosphorylation was complete (about 1 min), 10 μL of 1 M triethylammonium bicarbonate was added. After 1 h at room temperature, the reaction mixture was pooled on a rotary evaporator and treated with 10 mL of concentrated aqueous ammonia during 3 h to remove the trifluoroacetic protecting group. The solution was evaporated and diluted with 15 mL of water, and the product was isolated by ion-exchange chromatography on DEAE-cellulose DE-32 (1 × 15 cm) using a gradient of triethylammonium bicarbonate (0.00−0.35 M, pH 7.5). The fraction containing **V** was evaporated and dried in vacuo to give 30 μmol (30%) of **V**: R_f = 0.11 in the system B; UV (H_2O) $\lambda_{max,}$ 268 nm (ϵ = 8800); λ_{min}, 235 nm (ϵ = 3700). ^{31}P NMR (D_2O): δ −21.49 (t, J = 20 Hz, P_β, 1P), −11,16 (d, J = 20 Hz, P_α, 1P), −6.0 (d, J = 20 Hz, P_γ, 1P).

Synthesis of 5-{*N*-[*N*′-(4-azido-2,3,5,6-tetrafluorobenzoyl)-3-aminopropionyl]aminomethyl}-2′-deoxyuridine-5′-triphosphate (lithium salt) (VIa). *N*-Hydroxysuccinimide ester of 4-azido-2,3,5,6-tetrafluorobenzoic acid 4.88 mg (16 μmol) was added to a solution of **V** (4 μmol) in a mixture of DMF (60 μL) and TEA (10 μL). The reaction mixture was kept at room temperature for 4 h and then loaded directly onto a column of DEAE-cellulose DE-32 (1 × 20 cm). A linear gradient (flow rate 0.5 mL/min) from 0.05 to 0.3 M TEAB (pH 7.5) was employed. Fractions containing photoreactive nucleoside-5′-triphosphate were pooled and subjected to reversed-phase HPLC. The product **VIa** was precipitated by addition of 2% $LiClO_4$ in acetone and dried in vacuo. The yield of **VIa** was 87%. The isolated compound was homogeneous as shown by thin-layer and anion-exchange chromatography. R_f = 0.54 in the system B; UV (H_2O) $\lambda_{max,}$ 259 nm (ϵ = 33 900); λ_{min}, 232 nm (ϵ = 10 900). ^{31}P NMR (D_2O): δ −20.9 (t, J = 20 Hz, P_β, 1P), −11.08 (d, J = 20 Hz, P_α, 1P), −5.72 (d, J = 20 Hz, P_γ, 1P). ^{1}H NMR (D_2O): δ 2.43 (dd, J = 6 Hz, J = 2 Hz, H2′, 2H), 2.70 (t, J = 6 Hz, H8, 2H), 3.71 (m, H4′, H9, 3H), 4.30 (m, H3′, H5′, H7, 5H), 6.30 (t, J = 7 Hz, H1′, 1H), 7.90 (s, H6, 1H).

Synthesis of 5-{*N*-[*N*′-(2-nitro-5-azidobenzoyl)-3-aminopropionyl]aminomethyl}-2′-deoxyuridine-5′-triphosphate (lithium salt) (VIb). Compound **VIb** was synthesized from derivative **V** by treatment with *N*-hydroxysuccinimide ester of 2-nitro-5-azidobenzoic acid according to the method described above for the synthesis of **VIa**. The yield of **VIb** was 82%. The isolated compound was homogeneous by thin-layer and anion-exchange chromatography. R_f = 0.55 in the system B; UV (H_2O) λ_{max}, 269 nm (ϵ = 9000), 321 nm (ϵ = 8800); λ_{min}, 245 nm (ϵ = 7900). ^{31}P NMR (D_2O): δ −20.33 (t, J = 20 Hz, P_β, 1P), −10.95 (d, J = 20 Hz, P_α, 1P), −5.10 (d, J = 20 Hz, P_γ, 1P). ^{1}H NMR (D_2O): δ 2.23 (m, H2′, 2H), 2.65 (t, J = 5.2 Hz, H8, 2H), 3.65−3.75 (m, H4′, H9, 3H), 4.16 (m, H3′, H5′, H7, 5H), 6.25 (t, J = 6.5 Hz, H1′, 1H), 7.15 (d, J = 2.3 Hz, H10, 1H), 7.37 (dd, J = 8.9 and 2.3 Hz, H11, 1H), 7.71 (s, H6, 1H), 8.25 (d, H12, 1H).

Scheme 2

Synthesis of 5-[3-(*E*)-(4-Azido-2,3,5,6-tetrafluorobenzamido)-propenyl-1]-2′-deoxyuridine-5′-triphosphate (lithium salt) (VII). Compound **VII** was obtained according to the method of Wlassoff et al. (*6*), described for synthesis of 5-[3-[(*E*)-(2-nitro-5-azidobenzamido)propenyl-1]-2′-deoxyuridine-5′-triphosphate with the use of *N*-hydroxysuccinimide ester of 4-azido-2,3,5,6-tetrafluorobenzoic acid (see Scheme 2). The yield of **VII** (mixture of isomers) was 90%. The separation of isomers was carried out by reversed-phase HPLC. The yield of **VII** (E) was 60%. The isolated compound was homogeneous by thin-layer and anion-exchange chromatography. $R_f = 0.70$ in the system B; UV (H_2O) λ_{max}, 255 nm (ϵ = 32 600); λ_{min}, 218 nm (ϵ = 17 900). IR (KBr) ν_{max}, 2205 ($-N_3$), 1630 ($-C{=}O_{amid}$) cm^{-1}. ^{31}P NMR (D_2O): δ −21.4 (t, J = 20 Hz, P_β, 1P), −10.7 (d, J = 20 Hz, P_α, 1P), −7.8 (d, J = 20 Hz, P_γ, 1P). ^1H NMR (D_2O): δ 2.37 (t, J = 5.5 Hz, H2′, 2H), 4.03 (m, H3′, H4′, H5′, 4H), 4.10 (d, J = 5.0 Hz, H9, 2H), 6.2−6.4 (m, H1′, H7, H8, 3H), 7.9 (s, H6, 1H).

Synthesis of 5-{*N*-[*N*′-(2-nitro-5-azidobenzoyl)-3-aminopropionyl]aminomethyl}-2′-deoxyuridine-[α-^{32}P]-5′-triphosphate (lithium salt) (VI*b). 5-(Trifluoroacetylaminomethyl)-2′-deoxyuridine was synthesized from derivative **III** (0.1 mmol) by treatment with 1 mmol of ethyl trifluoracetate (120 μL) in methanol (1 mL) in the presence of 1.5 mmol of TEA (207 μL). After stirring for 15 h at 20 °C, the solution was evaporated under reduced pressure. The yellow liquid residue was dissolved in 3 mL of water and applied on a Dowex 50W X2 column (1.5 × 20 cm). 5-(Trifluoroacetylaminomethyl)-2′-deoxyuridine was eluted by water, and fractions were evaporated under reduced pressure. The yield was 94%: R_f = 0.73 in system A.

The obtained deoxyuridine analogue was converted to the 5′-*O*-dimethoxytrityl derivative by conventional procedure (*16*) and subjected to phosphorylation with $POCl_3$ using the known method (*15*). Compound **VIII** was obtained by deprotection by incubation in 0.1 N HCl in methanol (0.5 h) followed by treatment with 10 mL of concentrated aqueous ammonia for 3 h. The solution was evaporated, diluted with 15 mL of water and the product was isolated by ion-exchange chromatography on DEAE-cellulose DE-32 (1 × 20 cm) using a gradient of thriethylammonium bicarbonate (0.00−0.2 M, pH 7.5). The fraction containing **VIII** was evaporated and dried in vacuo. The yield of **VIII** was 53%: R_f = 0.76 in system B; UV (H_2O) λ_{max}, 269 nm (ϵ = 8800).

The overall procedure relies on modification of the method of Walseth and Johnson (*17*) for the enzymatic preparation of [α-^{32}P]nucleoside-5′-triphosphates from 5-(aminomethyl)-2′-deoxyuridine-3′-monophosphate and [γ-^{32}P]ATP.

The [α-^{32}P]photoreactive nucleoside-5′-triphosphate derivative **VI*b** was obtained by succesive acylation of NH_2-group of **X** with trifluoroacetyl-β-alanine *N*-hydroxysuccinimide, and benzoylation of deprotected NH_2-group of the β-alanine with 2-nitro-5-azidobenzoic acid *N*-hydroxysuccinimide as described above for compound **VIa**. The yield of **VI*b** was 83%: R_f = 0.30 in system B.

Studies of the Thermolytic Stability of Azido Group of Photoreactive Nucleoside-5′-triphosphate Derivative VII. The thermolytic stability of azido groups of new compouds under the conditions of PCR was studied using the compound **VII**. A 0.5 mM aqueous solution (100 μL) of photoreagent **VII** was subjected to the thermal regime of the amplification procedure. The dU*TP was precipitated by addition of 2% $LiClO_4$ in acetone. The precipitate was carefully washed with acetone (2 × 1.2 mL). IR (KBr) ν_{max}, 2205 ($-N_3$), 1630 ($-C{=}O_{amid}$) cm^{-1}.

Photochemical Behavior of Photoreactive Amplified DNA. A 10^{-7} M solution (20 μL) of photoreactive amplified [^{32}P]DNA in 0.15 M NaCl, 0.1 mM EDTA, and 0.02 M Na_2HPO_4 (pH 9) was pipetted into a 96-well polystyrene plate at 4 °C. Irradiation was carried out by exposing the plate for 18 min to filtered light (300−365 nm) emitted by a high-pressure mercury lamp with an intensity 10^{15} quanta × cm^{-2} × s^{-1}. The irradiated mixture was subjected to electrophoresis in 10% denaturing PAAG and vizualized by radioautography. Quantitative treatment of radioautographs was carried out using Ultrascan laser densitometer (LKB).

RESULTS AND CONCLUSIONS

Synthesis and Characterization of Photoanalogues dU*TP. Synthesis of new dUTP derivatives

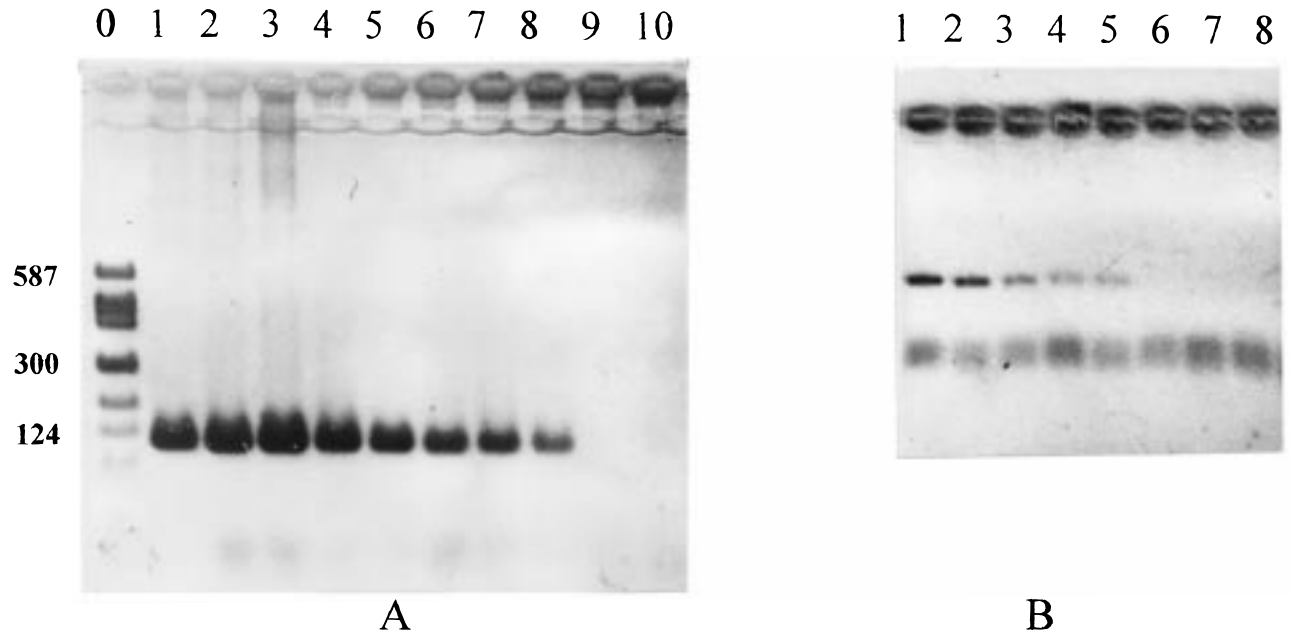


Figure 1. The product of the PCR in the presence of different amount of dU*TP analogue **VIa** (A); analogue **VIb** (B). (A) Lane 1, dTTP only; 2, 10% **VIa**; 3, 20% **VIa**; 4, 50% **VIa**; 5. 60% **VIa**; 6, 70% **VI**a; 7, 80% **VIa**; 8, 85% **VIa**; 9, 90% **VIa**; 10, 100% **VIa**. (B) Lane 1, dTTP only; 2, 10% **VIb**; 3, 20% **VI**; 4, 50% **VIb**; 5, 60% **VIb**; 6, 70% **VIb**; 7, 80% **VIb**; 8, 100% **VIb**; 4 μL from a 50 μL PCR product was analyzed by 2% agarose gel electrophoresis and visualized by ethidium bromide staining. (dU*TP), carrying photoreactive groups, which are highly reactive toward both DNA and proteins were carried out as shown in Schemes 1 and 2.

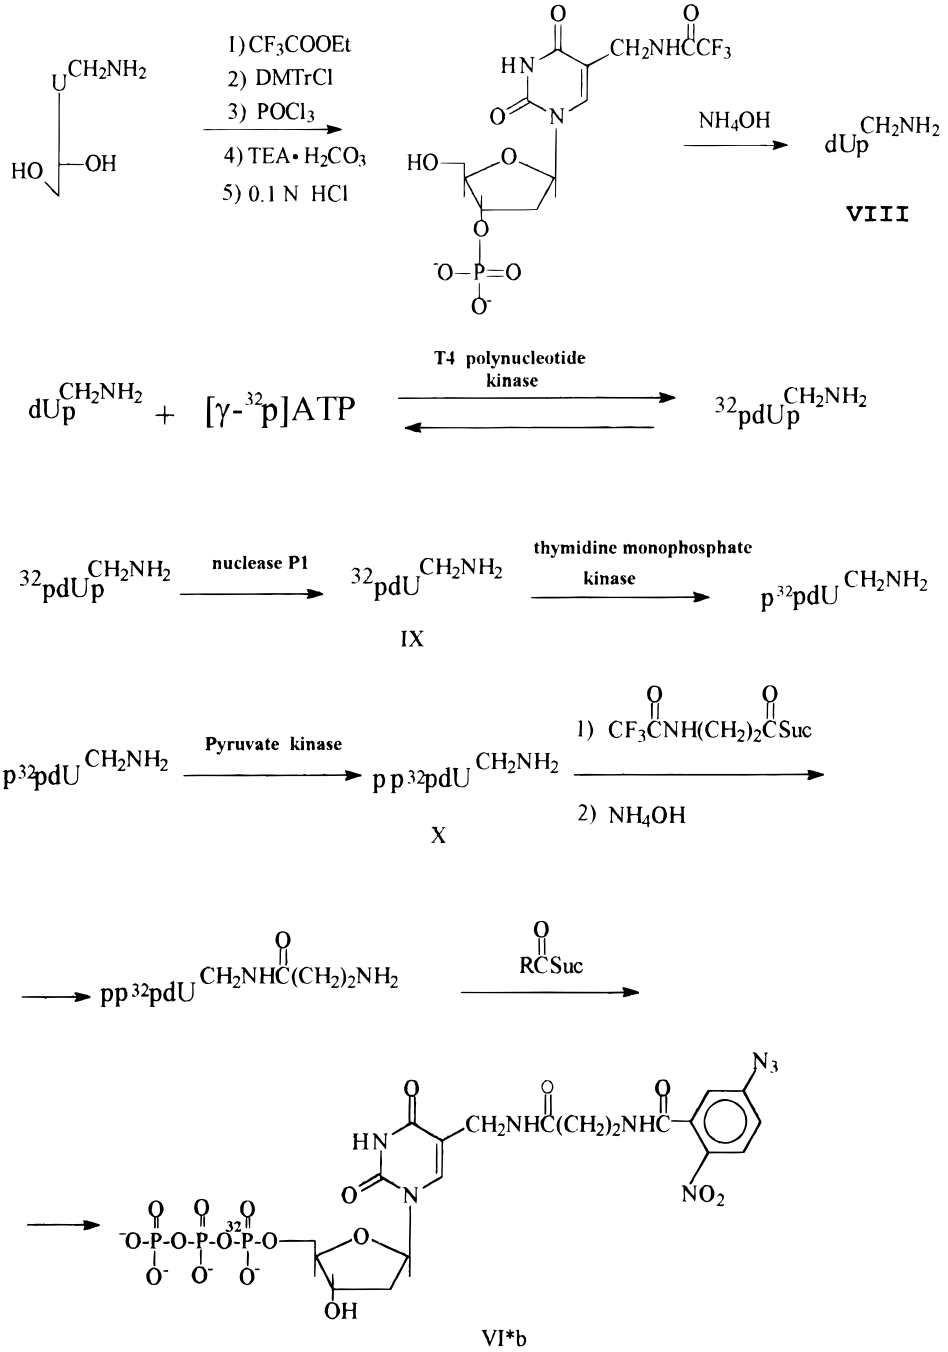
It is known that the introduction of CH═CH−CH_2−NH_2 spacer to 5-C of 2′-deoxyuridine is accompanied by the formation of isomers with the trans propenyl configuration being the major product (*6*, *18*). We have isolated three isomers of compound **VII** by reversed-phase HPLC. We have proposed that they are E and Z isomers and 5-[3-(4-azido-2,3,5,6-tetrafluorobenzamido)propenyl-2]-2′-deoxyuridine-5′-triphosphate—the product of arylation of allylamine in C2 position, on the basis of ref *18*.

Compounds **I**−**IV** were obtained using the known method (*14*). Reaction of **IV** with $POCl_3$ resulted in the formation of a mixed anhydride, which produced nucleoside-5′-triphosphate **V** under interaction with bis(tri-*n*-butylammonium)pyrophosphate and the following treatment of the reaction mixture with concentrated aqueous ammonia, permitted to remove CF_3CO residue quantitatively off the β-alanyl NH_2-group. Photoreactive derivatives **VIa**,**b** were obtained by benzoylation of aliphatic amino group of **V** with *N*-hydroxysuccinimide esters of 4-azido-2,3,5,6-tetrafluorobenzoic or 2-nitro-5-azidobenzoic acids. The use of the triethylammonium salt of **V** permitted to carry out the reaction in DMF in the presence of triethylamine, thus opening the possibility to achieve higher yields (near 90%) with lower excesses of *N*-hydroxysuccinimide esters.

The structure of photoreactive dU*TP derivatives **VIa**,**b** and **VII** (E) was verified by ^{1}H NMR. The data of anion-exchange chromatography and ^{31}P NMR spectroscopy [the presence of the resonance at δ −21.4 ppm (t, J = 20 Hz, P_β, 1P), −10.7 (d, J = 20 Hz, P_α, 1P), −7.8 (d, J = 20 Hz, P_γ, 1P), for one example, the compound **VII**] proved the presence of the 5′-triphosphate moieties. IR spectra of the compounds obtained revealed the presence of the band at 2205 cm^{-1} (KBr) characteristic of the azido group.

Each photoreactive dU*TP analogue was examined to answer the following questions. Is the dU*TP derivative a substrate for DNA polymerases? Is the newly synthesized DNA containing photoreactive groups a template for the following DNA replication? Is it able to efficiently cross-link with template DNA under irradiation?

Consequently, we have carried out the polymerase chain reaction (PCR) using DNA polymerase *Thermus aquaticus* assays and offering our photoreactive nucleoside-5′-triphosphates as substrates both in the presence and in the absence of dTTP. The amplification of DNA was performed using a pair of oligodeoxyribonucleotide primers which flank a 110 bp region in the gene of the envelope protein E of the tick-borne encephalitis virus. Optimal conditions of PCR for this system with natural nucleoside-5′-triphosphates were elucidated earlier (*19*).



Since azides are known to undergo thermolytic decomposition, the stability of photoreactive nucleoside-5′-triphosphates was preliminary investigated. The thermolytic stability of azido groups of new compounds under the conditions of PCR was studied using the compound **VII**. A 0.5 mM aqueous solution (50 μL) of photoreagent **VII** was subjected to the terminal regime of the amplification procedure. The dU*TP was precipitated by addition of 2% $LiClO_4$ in acetone. The presence of an azido group in the product was proved by IR spectroscopy (the presence of distinct band at 2205 cm^{-1}). The ratio of intensities ν_{2205}/ν_{1630} did not change after treatment in the thermal PCR regime.

When the reaction mixture for PCR with photoanalogues **VIa**,**b** were used in the absence of dTTP, no traces of the full-length primer extension product was observed (Figure 1). The amplified DNA appeared only in the case of simultaneous presence of certain amount of both photoreactive dU*TP and dTTP.

To establish if dU*TP can be used by the DNA polymerase as the substrate, the incorporation of [α-^{32}P]-dU*TP analogue **VIb** in the amplified product was estimated.

Synthesis of the photoreactive [α-^{32}P]dU*TP was fulfilled according to the Scheme 3. Deoxyuridine analogue **III** was converted to 5′-*O*-dimethoxytrityl derivative by

Scheme 3

a conventional procedure and subjected to phosphorylation with $POCl_3$ with subsequent hydrolysis by triethylammonium bicarbonate and deprotection of 5′-OH group by incubation in 0.1 N HCl. The 2′-deoxyuridine-3′-monophosphate analogue **VIII** obtained was enzymatically converted to [5′-^{32}P]2′- deoxyuridine-3′,5′-diphosphate using [γ-^{32}P]ATP and T4 polynucleotide kinase. Then 3′-phosphate was removed by nuclease P1. [5′-^{32}P]-dU*MP (**IX)** was further phosphorylated to dU*DP with nonradioactive ATP using thymidine monophosphate kinase from *E. coli* MRE-600 and to dU*TP (**X**) with phosphoenolpyruvate using pyruvate kinase. Interestingly, despite its high specificity, dTMP kinase turned out to be able to catalyze phosphorylation of **IX**, albeit at lower efficiency as compared with dTMP. The same results were obtained for the analogue with protecting trifluoroacetyl residue on aliphatic amino group.

The [α-^{32}P]photoreactive nucleoside-5′-triphosphate derivative **VI*b** was obtained by succesive acylation of NH_2-group of the compound **X** with trifluoroacetyl-β-alanine *N*-hydroxysuccinimide, removal of trifluoroacetyl residue, and benzoylation of deprotected NH_2-group of the β-alanine with *N*-hydroxysuccinimide ester of 2-nitro-5-azidobenzoic acid as described above for **VIa**.

The product was separated from reaction mixture by ion-exchange and reversed-phase chromatography and analyzed by thin-layer chromatography (TLC). The radiolabeled dU*TP (**VI*b**) had $R_f = 0.3$ on DC-Alufolien Kieselgel TLC plates in the system (B), which is identical with that for nonradioactive photoreactive dU*TP derivative **VIb**.

When the polymerase chain reaction was carried out using the mixture of 50% of photoreactive [α-^{32}P]2′-deoxyuridine-5′-triphosphate derivative **VI*b** and the

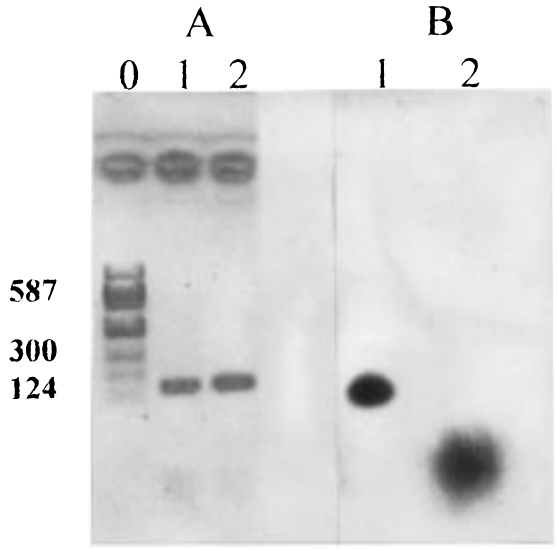


Figure 2. The product of the PCR carried out with 100% dTTP and ^{32}P-foward primer (lane 1); with 50% compound **VI*b** and 50% dTTP (lane 2); lane 0, the molecular size marker as Figure 1. A total of 4 μL from a 50 μL PCR product was analyzed by 2% agarose gel electrophoresis and visualized by ethidium bromide staining (A), autoradiography (B).

dTTP (50%), the formation of full-length amplificate band was observed, as revealed by ethidium bromide staining of the gel (Figure 2A). However, the respective band did not contain any radioactivity (Figure 2B). The radioactive label was observed only in shorter fragments. This indicates that incorporation of the analogue does not permit further elongation. On the contrary, it was found that **VII** (E) replaced dTTP during synthesis of DNA by PCR as revealed by the formation of the full-length amplificate in the presence of this dU*TP analogue without any dilution with natural dTTP (Figure 3). In the same time, we did not obtain full-length amplificate using compounds **VII** (Z) and 5-[3-(4-azido-2,3,5,6-tetrafluorobenzamido)propenyl-2]-2′-deoxyuridine-5′-triphosphate.

The PCR mixture was subjected to electrophoresis in 10% PAAG. The amplified DNA was extracted from the gel by electroelution and inspected by UV and IR spectroscopy. The UV absorption spectra of the product (2×10^{-4} M, H_2O) showed λ_{max} 260 nm characteristic of the oligonucleotide component. IR spectroscopy (2×10^{-4} M, H_2O, 0.02 mm CaF_2 cuvette) proved that analogue **VII** (E) was included into the DNA by PCR (the presence of the characteristic band of the azido group at 2100 cm $^{-1}$).

The photolytic behavior of photoreactive amplified DNA was investigated. The solution of amplified [^{32}P]-DNA (10^{-7} M) in 0.15 M NaCl and 0.02 M Na_2HPO_4 (pH 9) was subjected to photolysis for 18 min and analyzed by denaturing gel electrophoresis. The irradiation time was chosen to be 10-fold greater than the half-life of photolysis. The kinetics of photolysis was studied by recording the IR spectra (2000−3000 cm^{-1}) of the samples irradiated for definite time intervals. As shown in Figure 4, irradiation of the full-length amplificate resulted in the appearance of the cross-linked amplification product (peak 2).

To prove additionally the ability of **VII** (E) to serve a substrate of DNA polymerases, we studied its incorporation into the system: 3′-GGGTCAGTGCTGCAACATTTT-GCTGC... (as a template) and [^{32}P]CCCAGTCACGACGT (as a primer).

It can be seen in Figure 5 that the compond **VII** (E) is incorporated into the DNA chain by the Klenow fragment

Figure 3. The product of the PCR carried out with 100% compound **VII** (E) (lane 1); with 100% dTTP (lane 2). A total of 4 μL from a 50 μL PCR product was analyzed by 2% agarose gel electrophoresis and visualized by ethidium bromide staining.

of DNA polymerase I (lanes 4−9) and *Taq* DNA polymerase (lanes 13−15). In the control assays, tetradecanucleotide was extended by one residue in the presence of dTTP (lanes 2 and 11) and by three residues in the presence of dTTP and dGTP (lanes 3 and 12) giving

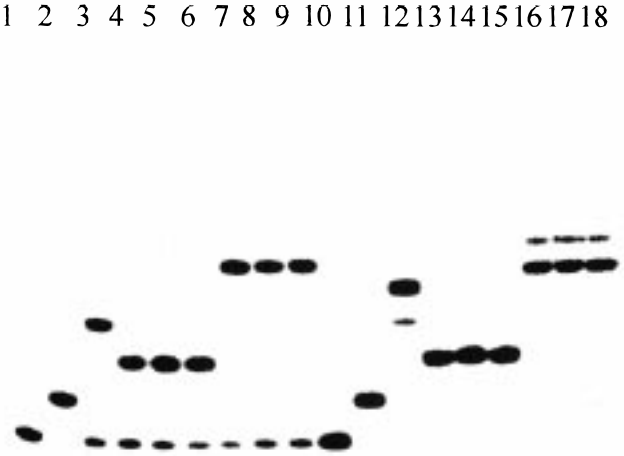

Figure 5. Primer extension catalyzed by Klenow fragment of DNA polymerase I (lanes 1−9) and *Taq* DNA polymerase (lanes 10−18). lanes 1 and 10, enzyme + primer-template 3′GGGTCAGTGCTGCAACATTTTGCTGC (the M13mp10 phage DNA) [^{32}p]CCCAGTCACGACGT (the primer); lanes 2 and 11, as in lanes 1 and 10 + 2 μM dTTP; lanes 3 and 12, as in lanes 2 and 11 + 2 μM dGTP+; lanes 4−6 and 13−15, as in lane 1 + 0.5 μM, 2 μM, and 8 μM compound **VII** (E); lanes 7−9 and 16−18, as in lanes 4−6 and 13−15 + 2 μM dGTP. The reaction products were separated by electrophoresis in the denaturing 20% PAAG.

15-mer and 17-mer, respectivelly. Additionally, there is an 18-mer band most probably due to misincorporation of dGMP residue with formation of mismatched T:G pair, which is most stable among noncanonic pairs (*20*). In the case of the Klenow fragment of *E. coli* DNA polymerase I, displaying 3′-5′ exonuclease activity, which is absent in *Taq* DNA polymerase, low level of a mismatched incomplete nucleotide at the 3′-end was observed. This has been noticed many times before in the systems with a reduced set of substrates (*21*, *22*). Incorporation of one residue of **VII** (E) into a nascent DNA chain would result in formation of a hydrophobic 15-mer of lower electrophoretic mobility (lanes 4−6) as compared with its natural counterpart (lane 2). After addition of dGTP to the assay containing **VII,** one can see the elongation of 15-mer band by two nucleotides (17-mer band) according to the template context (lanes 7−9). The position of 17-mer band corresponds to the mobility of oligonucleotide with two hydrophobic residues. So, we can state that Klenow fragment of *E. coli* DNA polymerase I and *Taq* DNA polymerase are able to incorporate the modified deoxyuridine-5′-phosphate residue with large hydrophobic photoreactive substituents at the 5-position into the 3′-end of the DNA chain keeping the ability of further elongation. Thus, it was shown that the use of modified substrate did not lead to the loss of the specificity of template synthesis.

The unique property of dU*TP analogue **VII** (E) made it possible to use it for direct incorporation in the course of elongation of DNA probes at the template DNA in chromosomes and in interphase chromatin with subsequent cross-linking of the elongated probes with matrixed DNA. This ability might provide a possibility of localization of short probes. We have used this approach for localization of nucleotide sequences on human metaphase chromosomes and interphase nuclei. These results presented in a separate communication (*23*).

ACKNOWLEDGMENT

The authors are grateful E. Yu. Dobrikova for the preparation pTBE-51.1-plasmid DNA, to Dr. V. N. Silnikov for the registration of IR spectra, to V.V. Kandaurova for the registration of NMR spectra, and to Prof. D. G. Knorre for the helpful discussions. This work was supported in part by the grant of the Russian States Program "Human Genome", by the grant of the Russian Fund of Fundamental Investigations, and by the Grant CDA-NIS.

TECHNICAL NOTES

Direct Observation of Fibrinogen−Heparinoid Complexes Formation Using Surface Plasmon Resonance

Nobuyuki Sakamoto, Tomoko Shioya, Takeshi Serizawa, and Mitsuru Akashi*

Department of Applied Chemistry and Chemical Engineering, Faculty of Engineering, Kagoshima University, 1-21-40 Korimoto, Kagoshima 890-0065, Japan. Received December 26, 1997; Revised Manuscript Received December 8, 1998

We analyzed the binding of heparinoid or heparin with fibrinogen by real-time measurement using surface plasmon resonance technology. Poly(glucosyloxyethyl methacrylate) sulfate [poly(GEMA) sulfate] and dextran sulfate were used as heparinoids. The binding ability of each sulfated polymer was estimated by having each polymer-containing buffer interact with the sensor chip surfaces that had immobilized fibrinogen. Dextran sulfate and poly(GEMA) sulfate showed high affinity to the fibrinogen in this experiment, while the heparin did not. All of the dextran sulfates were desorbed from its surface, while about 30% of the poly(GEMA) sulfate remained on the immobilized fibrinogen upon the addition of NaCl to the buffer which was done in order to analyze the desorption of poly(GEMA) sulfate or dextran sulfate from the surface of the fibrinogen. These data show that the type of binding between fibrinogen−poly(GEMA) sulfate was different from that of dextran sulfate, indicating that the interaction between fibrinogen and poly(GEMA) sulfate was caused not only by an electrostatic but also by a hydrophobic force. These results suggest that the interaction mechanism of heparinoids with fibrinogen was different from that of heparin.

INTRODUCTION

Extensive research has been done about the interaction of blood plasma protein with polysaccharide sulfuric acid esters (*1*). Fibrinogen (which is blood clotting factor I), forms a soluble complex with polyanion [sulfate, polyvinyl sulfate, and polyisoprene sulfonate (*2*−*6*)], although fibrinogen contains an overall negative charge in a neutral buffer solution. The distribution of charges on a fibrinogen surface should be heterogeneous. This is a reasonable assumption based on the recently elucidated first-order structure and higher order structures of human fibrinogen (*7*, *8*). In our previous study on glycoside polymer, we found that sulfated poly(glucosyloxyethyl methacrylate) [poly(GEMA) sulfate], which bears sulfated D-(+)-glucose, exhibited anticoagulant activity (*9*), and we studied their anticoagulant mechanism by evaluating various in vitro clotting tests (*10*, *11*). Next, we found that poly(GEMA) sulfate and dextran sulfate formed insoluble complexes with bovine plasma fibrinogen by the turbidity measurement of each complex that contained PBS by using an UV−vis spectroscopy. In our experiment, the amount of poly(GEMA) sulfate−fibrinogen insoluble complex increased with an increase in the amount of poly(GEMA) sulfate. On the other hand, the amount of dextran sulfate−fibrinogen insoluble complex showed a maximum (0.01 mg of dextran sulfate to 4.5 mg of fibrinogen in 1 mL of PBS) when dextran sulfate was added to fibrinogen PBS solution. However, these tendencies were not shown upon the addition of heparin, although heparin has a relatively high charge density (1.5−2.0/pyranose ring). The effects of the inhibition of fibrinogen polymerization by sulfated polymers act on both stages when A and B chains are split by thrombin and on the polymerization of fibrin monomers (*3*). Therefore, we concluded that poly(GEMA) sulfate or dextran sulfate formed insoluble complexes with fibrinogen and then these sulfated polymers appeared to have anticoagulant activity.

Thus far, researchers have clarified the complex formation between fibrinogen and sulfated polymers by precipitation measurements, transmittance measurements using UV−vis spectroscopy, circular dichroism measurements, and electrophoretic mobility measurements with a Tiselius apparatus (*2*, *3*, *5*, *12*). However, there have been few studies about kinetic measurements of these complex formations because it is very difficult to use the radio-labeling and fluorescence-labeling techniques (*13*) for either fibrinogen or sulfated polymers. Moreover, there has been no research about association and dissociation rate constant measurement of interaction between fibrinogen and sulfated polymer in situ. Therefore, a kinetic study on heparinoid−plasma protein interaction would provide significant data in regards to its anticoagulant activity.

In this paper, we analyzed the interactions between plasma fibrinogen and each sulfated polymer at physiological pH values in detail using surface plasmon resonance (SPR) technology (*14*, *15*). The BIAcore system (*16*−*18*) used in this study was produced by Pharmacia Biosensor AB (Uppsala, Sweden). BIAcore is a new type of technology that is designed to analyze label-free

macromolecular interactions in real-time. The interactions between an immobilized molecule on a sensor chip and ligand is monitored by surface plasmon resonance, which detects changes in mass. We also studied the interactions of fibrinogen or albumin with some sulfated polymers for comparative process. The addition of salt to the buffer for desorption of each sulfated polymer from the immobilized fibrinogen gave insights into the mechanistic aspects of the interactions between each sulfated polymer and fibrinogen.

MATERIALS AND METHODS

Materials. Poly(GEMA) sulfate was obtained by the sulfation of poly(GEMA) (*9*). We estimated the degree of sulfation of the poly(GEMA) sulfate by elemental analysis (which is the number of substituted hydroxyl groups in a glucose unit) to be 3.8. Heparin sodium salt (LotM2E) was purchased from Nacalai Tesque (Kyoto, Japan) and had an anticoagulant activity of 187.5 IU mg^{-1} solid. Dextran sulfate was also purchased from Nacalai Tesque and the degree of sulfation was 2.1. The structures of these sulfated polymers are shown in Figure 1. Bovine plasma fibrinogen and bovine serum albumin were purchased from Sigma (St. Louis, MO). A BIAcore, Sensor Chip CM5 (a carboxymethylated dextran that is coupled to a gold-coated glass surface according to procedures described elsewhere) and an Amine Coupling Kit containing EDC, NHS, and a solution of 1 M ethanol amine hydrochloride that was adjusted to a pH of 8.5 with sodium hydroxide were obtained from Pharmacia Diagnostics AB. All other reagents used were of analytical grade. In addition, MilliQ-grade water was used.

SPR Apparatus. SPR phenomenon was first developed by Otto (*14*) and Kretschmann and Raether (*15*). A laser beam is directed onto the underside of a glass prism, which is an index that is matched to a metal-coated microscope slide and undergoes the total internal reflection at the glass/metal interface. A specific angle of incident beam and surface plasmon at the metal/air interface causes the surface plasmon to be excited and a leads to a subsequent reduction in the intensity of the internally the reflected light. The angle at which this excitation occurs (the SPR angle) is dependent upon the dielectric properties of the layers above the gold surface; therefore, SPR can be used to detect the adsorption of molecules at this interface. In an automatic instrument, BIAcore 2000, the sensor device is composed of three parts: a sensor chip that is a thin film of gold covered with carboxymethylated dextran, a prism which is placed on the opposite glass surface of the chip, and a microfluidices cartridge that can provide proper reaction fluid onto the surface of the sensor chip. As molecules adsorb to the sensor surface, the change in the SPR angle is recorded as a function of time in order to observe the adsorption process onto the sensor surface in real time.

Immobilization of Fibrinogen and Albumin. The immobilization of fibrinogen or albumin on Sensor Chip CM5 in BIAcore was done as follows (*19*, *20*). Separate vials that contained 200 μL of 0.1 M NHS, 0.4 M EDC, and a 1 M ethanolamine hydrochloride solution and a vial for mixing EDC and NHS were placed in an autosampler together with a solution of fibrinogen or albumin that was to be immobilized. A continuous flow pump was filled with PBS buffer (pH 7.4). After Sensor chip CM5 had been conditioned with PBS for a few minutes, an automated immobilization cycle was performed at a flow rate of 5 μL min^{-1}. Eighty microliters of EDC and NHS mix (1/1) was transferred to the mixing vial, and forty microliters of the mixed solution was injected on the surface. Fibrinogen and albumin were dissolved in a 10 mM acetate buffer (pH 5.0) at a concentration of 250 and 400 μg mL^{-1}, respectively. Eighty microliters of each protein solution were then injected, followed by 35 μL of ethanolamine hydrochloride solution. Approximately 1.6×10^4 resonance units (RU) of fibrinogen and 1.2×10^4 RU of albumin were immobilized on the sensor chip. These corresponded to 4.7×10^{-5} nmol mm^{-2} and 17.8×10^{-5} nmol mm^{-2}, respectively, based on the relationship in which 1000 RU equals 1 ng mm^{-2} bound protein (refractive index in protein = 1.6).

Interaction of Sulfated Polymers with Fibrinogen Surface. We estimated the binding of each sulfated polymer to the immobilized fibrinogen as follows: a sensor chip (CM5) with immobilized fibrinogen was brought into contact with the PBS buffer. The flow rate of the buffer solution was kept at a high level (10 μL min^{-1}) in order to prevent mass transport limitation at the sensor surface/solution interface. After reaching a stable baseline (80 s), we injected 40 μL of PBS buffer which contained every sulfated polymer (0.3, 1.5, 3, and 30 μg mL^{-1}), through the fibrinogen surfaces in order to observe the association rate constant (80−320 s). Next, we injected 40 μL of PBS buffer for the purpose of observing the dissociation rate constant (320−560 s). We monitored the changes in the resonance angle consecutively with time intervals of 1 s. This was done for 15−20 min.

Desorptions of Sulfated Polymers from Fibrinogen Surface. We estimated the degree of dissociation of poly(GEMA) sulfates or dextran sulfates from the fibrinogen surface by the addition of NaCl (0.03−3.0 M) in the PBS buffer. After performing the dissociation cycle (560 s, the resonance unit of this point is approximately

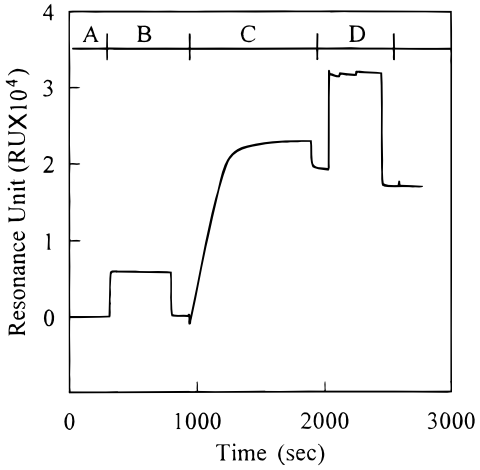

Figure 2. The sensorgram showing the procedure and response of the immobilization of fibrinogen to the sensorchip surface. The letters A, B, C, and D indicate time intervals during which the sensor was in contact with different solutions (A, PBS buffer; B, EDC/NHS; C, acetate buffer with fibrinogen 250 μg mL^{-1}; D, ethanolamine hydrochloride).

constant), we injected NaCl-containing buffer (10 μL) into each of the heparinoid−fibrinogen complex surfaces and the remaining heparinoid on the fibrinogen surface (which was represented by a resonance unit) was estimated as a $\Delta RU_{560s}/\Delta RU_{930s}$ ratio (Figure 6a).

RESULTS AND DISCUSSION

Interactions of Sulfated Polymers with Protein Surface. Figure 2 shows a sensorgram that was recorded during the immobilization of fibrinogen onto the carboxymethylated dextran that covered the sensorchip of a plasmon resonance sensor. The SPR angle is represented as a resonance unit (RU) in BIAcore (0.1° = 1000 RU). During the time interval when the sensor was in contact with the fibrinogen solution, we observed an increase in the resonance unit (RU), which indicates the adsorption of fibrinogen onto the surface. The shape of the response curve (C) indicates that the saturation of the surface with fibrinogen is slow. The RU (after the immobilization of the fibrinogen) was normalized to D as the baseline.

If sulfated polymers are injected, we can monitor the time course of the binding as a change in RU. The sensorgram gives data about the association of the complex that can be followed; the equilibrium or the steady state is readily displaced by the analyte sulfated polymer flow. When the analyte is replaced by a buffer flow, the dissociation of the complex is also monitored. In this study, bovine plasma fibrinogen was covalently coupled to the carboxymethylated dextran surface of the sensorchip as a ligand and sulfated polymer (analyte) buffer solution was flowed. This is because we detect nonspecific adsorbed albumin and fibrinogen on the carboxymethylated dextran surface and we did not detect any adsorbed all sulfated polymers on its surface in the control experiments.

The overlay sensorgrams for the interaction of each sulfated polymer with fibrinogen are shown in Figure 3. We collected binding curves from different batches of proteins because fibrinogen was an unstable protein and tended to denature in the regeneration process. We observed an increase in RU during its contact with a continuous flow (10 μL min^{-1}) of the PBS buffer that contained poly(GEMA) sulfate or dextran sulfate at a concentration of 0.3−30 μg mL^{-1}, indicating a net adsorption of each heparinoid to the immobilized fibrinogen. During subsequent contact with the PBS buffer, the RU decreased slightly, indicating a net desorption of each heparinoid from the fibrinogen (Figure 3, panels a and b). On the other hand, its adsorption of heparin was slightly observed as a refractive index shift (Figure 3c), which indicates its lower affinity for heparin. These results clarified that poly(GEMA) sulfate and dextran sulfate directly formed complexes with fibrinogen; heparin, however, did not. These results are also consistent with our previous research (*10*).

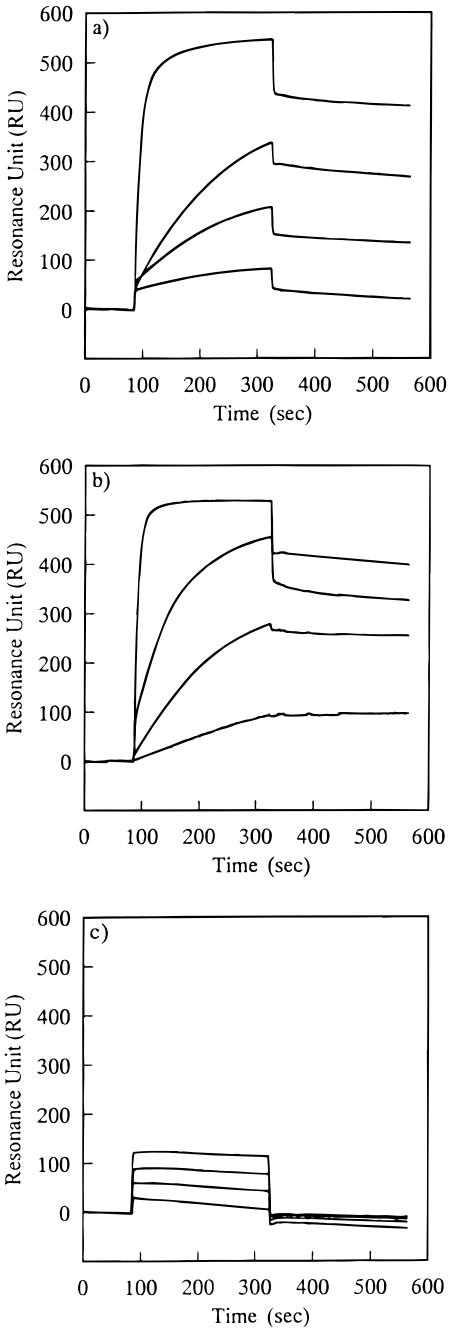

Figure 3. Adsorption of poly(GEMA) sulfate (a), dextran sulfate (b), and heparin (c) to immobilized fibrinogen. Each sulfated polymer concentration is 0.3, 1.5, 3, and 30 μg mL^{-1}. PBS buffer, pH 7.4.

Using the sensorgrams for the binding of poly(GEMA) sulfates and dextran sulfates with fibrinogen (Figure 3, panels a and b) we were able to obtain the maximum binding RU (ΔRU_{max}) of each heparinoid on the fibrinogen surface at a suitable concentration as a function of each

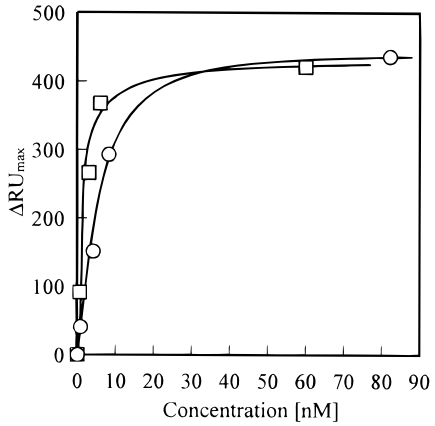

Figure 4. Adsorption isotherms for poly(GEMA) sulfate-binding (○) and dextran sulfate-binding (□) to fibrinogen surfaces. PBS buffer, pH 7.4.

heparinoid concentration (Figure 4). The ΔRU_{max} curves for poly(GEMA) sulfate and dextran sulfate on fibrinogen reached plateaus at a high concentration of heparinoid (30 μg mL^{-1}), indicating that the adsorption behavior of each heparinoid on the fibrinogen was Langmuirian. This suggests that there was neither multilayer aggregation nor heterogeneous adsorption on the fibrinogen surface.

The SPR method can directly evaluate the time-dependent interaction between heparinoid and fibrinogen; the turbidity measurement of the heparinoid−fibrinogen complex, however, cannot. Therefore, association and dissociation processes can be monitored by the SPR method, providing a base for kinetic studies. The time needed to reach an equilibrium state for the binding of each heparinoid (30 μg mL^{-1}) to the fibrinogen surface was about 5 min (Figure 3, panels a and b). In our previous study (*10*), we evaluated the turbidity of the heparinoid−fibrinogen mixture solution in a PBS buffer by allowing a heparinoid−fibrinogen mixture solution to stand for 10 min. The SPR results described above show that the turbidity measurements were done in an equilibrium state. However, another advantage of SPR measurements in regard to analyzing the direct affinity between heparinoid and fibrinogen is because turbidity measurements can only detect large aggregated structures, although the latter is much easier to measure than the former.

We calculated the dissociation constant (K_D) from sensorgrams for the binding of each heparinoid to fibrinogen (Figure 3, panels a and b) by following pseudo-first-order kinetics (BIAcore system manual). We obtained very high correlation coefficients in the determination of K_D for the binding of both heparinoids (~0.99), and a K_D (6.2×10^{-10} M) for the binding of dextran sulfate to fibrinogen was lower than that (3.1×10^{-8} M) for poly(GEMA) sulfate. This might be due to differences in electrostatic force between dextran sulfate and poly(GEMA) sulfate. In this study, we did not confirm the presence of a stoichiometrical complex because the refractive index of poly(GEMA) sulfate and dextran sulfate have not been obtained by anyone yet. If refractive indices of heparinoids are obtained, the interaction mechanism between each heparinoid and fibrinogen can be analyzed in more detail.

The overlay sensorgrams for the interaction of each sulfated polymer with albumin are also shown in Figure 5. We observed lower nonspecific adsorption of all sulfated polymers to the immobilized albumin as a slight refractive index shift. These results indicate the lower

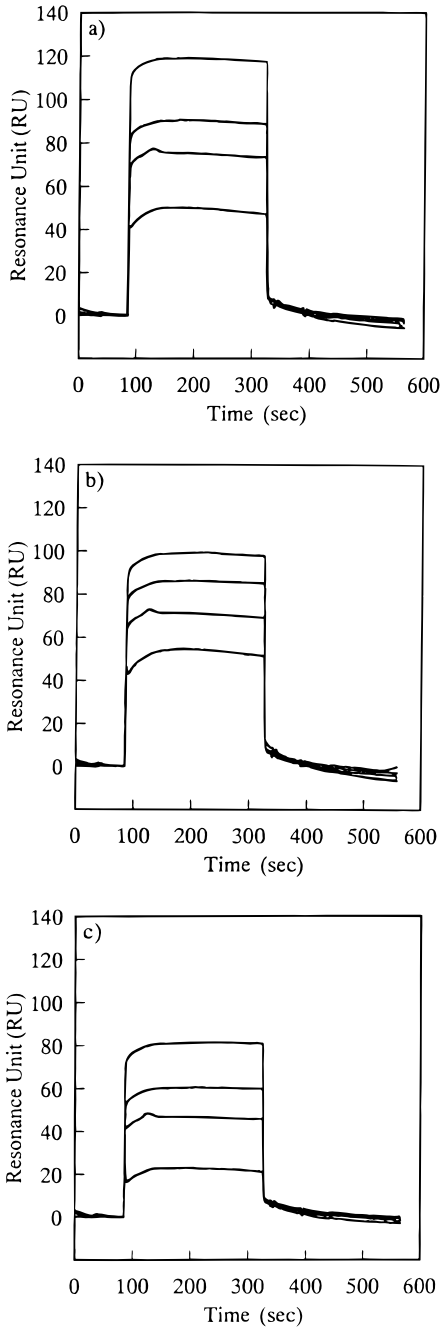

Figure 5. Adsorption of poly(GEMA) sulfate (a), dextran sulfate (b), and heparin (c) to immobilized albumin. PBS buffer, pH 7.4.

affinity of all sulfated polymers for the albumin. However, it seems that the BIAcore system is not able to detect the binding profiles of a lower association constant ($K_D < 10^4$ M). In addition, each sulfated polymer may be prevented from penetrating the albumin-immobilized matrix by steric factors.

Poly(GEMA) sulfate and dextran sulfate showed a high affinity with fibrinogen in this study, while heparin had little or no affinity. The binding amount was dependent on the heparinoid. These results suggest that the interaction mechanism of heparinoid with fibrinogen was different from that of heparin. It is well-known that the aggregation of plasma fibrinogen at physiological pH values is caused by the addition of dextran sulfate, although no aggregations have been observed upon addition of heparin, because of the limited number of

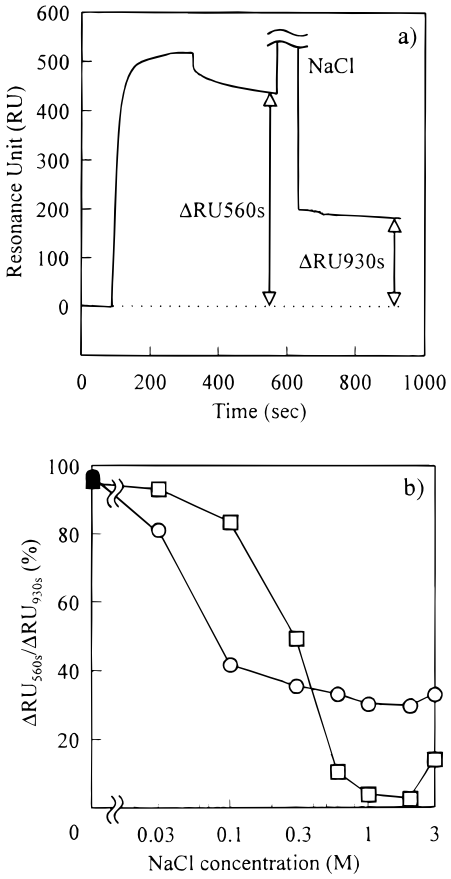

Figure 6. (a) The sensorgram showing the effect of the addition of the 1.0 M NaCl on desorption of poly(GEMA) sulfate from immobilized fibrinogen. (b) Decrease of $\Delta RU_{560s}/\Delta RU_{930s}$ by the desorption of poly(GEMA) sulfate (○) and dextran sulfate (□) from the fibrinogen surface with the addition of NaCl containing PBS buffer.

association constants between heparin and fibrinogen. Therefore, these results are consistent with the above.

Desorption of Sulfated Polymer from Fibrinogen Surface. To obtain data on the binding mechanism of poly(GEMA) sulfate or dextran sulfate to fibrinogen, we examined the degree of dissociation of a sulfated polymer from immobilized fibrinogen in the presence of a NaCl-containing PBS buffer. In general, the interaction of protein with other molecules is believed to be due to (i) ion−ion interaction, (ii) ion−dipole and dipole−dipole interaction, (iii) solvophobic interaction, and (iv) dispersion or van der Waals forces. Our experiment will show if an insoluble complex formation will only lead to an electrostatic interaction between heparinoid and fibrinogen. A sensorgram of the poly(GEMA) sulfate desorption from immobilized fibrinogen with a PBS buffer that contains 1.0 M NaCl is shown in Figure 6a. ΔRU_{560s} indicates the amount of binded heparinoid to the fibrinogen surface after 560 s from the starting point of the experiment. ΔRU_{930s} (RU_{930s} can be seen as a stable baseline because dissociation curve in Figure 6a represents very slow kinetics) indicates the amount of remaining heparinoid on the sensor chips after the injection of NaCl containing buffer (0.03−3.0 M) for 330s to the heparinoid−fibrinogen complexes. We compared the $\Delta RU_{560s}/\Delta RU_{930s}$ values for poly(GEMA) sulfate against NaCl concentration with those for dextran sulfate (Figure 6b). The amount of adsorbed heparinoid to fibrinogen surface decreased with an increase in the ionic strength of the NaCl-containing buffer. Upon the addition of a 1.0 M NaCl containing buffer, all of the dextran sulfates were

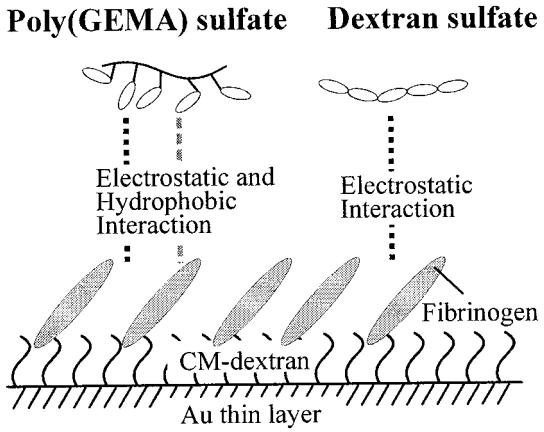

Figure 7. Schematic representation of interaction between each heparinoid and fibrinogen.

desorbed from it, while the poly(GEMA) sulfates were incompletely desorbed, about 30% of poly(GEMA) sulfate remained on the fibrinogen surface despite the presence of a 2.0 M NaCl containing buffer injection. Above concentrations of 2.0 M, we also observed the higher adsorption of both heparinoids to fibrinogen. A consideration of above result can be explained by the denaturing of immobilized fibrinogen. These data show that the binding behavior of poly(GEMA) sulfate with fibrinogen was different from that of dextran sulfate, indicating that the interaction between fibrinogen and poly(GEMA) sulfate was not only caused by electrostatic but also by hydrophobic force (Figure 7). This is because the poly(methacrylate) backbone of poly(GEMA) sulfate is the most hydrophobic part in the polymer. In our previous study, we noted that the interaction mechanism of poly(GEMA) sulfate to fibrinogen was differed from that for dextran sulfate (*10*). This is consistent with our previous research. In further research, we will clarify the formation mechanism of heparinoid−fibrinogen complexes in detail by using different kinds of salt, i.e., by using a lyotropic series that is a defined as the salting-out effects on ions on protein as well as the effects of ions on the surface tension of water (*21*).

The interactions between fibrinogen and sulfated polymers could be observed using the SPR technique in real-time. This is consistent with our turbidity measurement study (*10*). The kinetic constants between heparinoid−fibrinogen can also be obtained. We clarified the differences in the interaction mechanism of poly(GEMA) sulfate to fibrinogen and that of dextran sulfate by using a NaCl-containing buffer. In general, SPR methodology is used for the kinetic determination of the interaction of macromolecules. In this study, we showed that these SPR methods and experimental procedures can be used to obtain data on mechanistic interactions between various sulfated polymers and various plasma proteins by using a salt-containing buffer. This methodology cannot only obtain the kinetic constants between antigen−antibody but also gives us new and valuable insights into physiological mechanistic aspects such as the interactions between body components (proteins, phospholipids, DNAs, and cells) and biomaterials (natural occurring polymers, synthetic polymers, and inorganic materials).

ACKNOWLEDGMENT

This study was financially supported in part by the project entitled “High and Ecological Utilization of Regional Carbohydrates”, through Special Coordination Funds for Promoting Science and Technology (Leading

Research Utilizing Potential of Regional Science and Technology) of the Science and Technology Agency of the Japanese Government, 1997, and this study also was financially supported in part by a Grant-in-Aid for Scientific Research in Priority Areas of "Super-Biosystem Constructed by Cognitive Multidimensional Glyco-molecules" (no. 285/09240105) from the Ministry of Education, Science, Sports and Culture, Japan. The authors thank Dr. Akio Kishida of Kagoshima University for their experimental supports and helpful discussions.

Chemoenzymatic Synthesis of 3′-*O*-(Carboxyalkyl)fluorescein Labels

Maciej Adamczyk,* Jonathan Grote, and Jeffrey A. Moore

Department of Chemistry (D9NM), Abbott Laboratories, Building AP 20, 100 Abbott Park Road, Abbott Park, Illinois, 60064-6016. Received January 23, 1999

A general and versatile method is described for the synthesis of fluorescent labels. Coupling of the 3′-phenol of fluorescein methyl ester with hydroxyalkyl benzyl esters, followed by benzyl ester hydrolysis, provided a series of fluorescein carboxyalkyl ethers. Use of the Mitsunobu reaction allowed for the introduction of linkers of different lengths onto the 3′-phenol of fluorescein. Chemoenzymatic benzyl ester hydrolysis was achieved with LPL-80 lipase, providing pH-independent labels useful for the preparation of fluorescent conjugates.

INTRODUCTION

Fluorescent labels play an important role in a variety of biological and biotechnological applications including fluorescence microscopy, flow cytometry, immunoassay development, and various spectrofluorometic methodologies (*1*−*5*). As the utilization of these fluorescent-dependent applications increases, so does the need for the development of new fluorogenic labels. This need for new fluorogenic labels is particularly true for studying the interactions of fluorescent conjugates with their respective binding proteins or receptors, as the choice of the fluorescent conjugate can be crucial for optimal conjugate performance and cannot usually be made a priori. The factors that affect performance can include the particular fluorescent chromophore utilized in preparation of the conjugate and the location and length of the linker arm employed (*6*−*8*).

The most commonly used fluorescein derivatives include the carboxyfluoresceins, the aminofluoresceins, the fluorescein isothiocyanates, and the aminomethylfluoresceins (*9*). These derivatives allow for conjugation of ligands through the 5- or 6- position of the phenyl ring of fluorescein. Additionally, 4′-(aminomethyl)fluorescein has been utilized for the preparation of tracers used in commercially available immunoassays (*10*, *11*). This fluorescein derivative allows for conjugation through the xanthinyl ring of fluorescein. A series of carboxyalkyl ethers linked through the 3′-phenol of fluorescein would thus represent a significant addition to the repertoire of labels available for conjugation. We describe here the preparation of a series of fluorogenic labels containing linkers of different lengths which permit conjugation through the xanthinyl ring of fluorescein.

EXPERIMENTAL PROCEDURES

All reagents used in syntheses were purchased from Aldrich Chemical Co. (Milwaukee, WI) and utilized without further purification, except lipase LPL-80 (*Pseudomonas sp*.) which was purchased from Amano (Lombard, IL). Solvents (HPLC grade) and silica gel were obtained from E. Merck Science (Gibbstown, NJ) and used without further purification. Hydroxyalkyl benzyl esters were prepared from commercially available hydroxyalkyl acids and benzyl bromide by the method of Ono et al. (*12*). ^{1}H and ^{13}C NMR spectra were recorded at 300 and 75 MHz, respectively, on a Varian Gemini 300 spectrometer (Palo Alto, CA) with TMS as internal standard. Electrospray ionzation mass spectrometry (ESI-MS) was carried out on a Perkin-Elmer (Norwalk, CT) Sciex API 100 benchtop system employing the Turbo IonSpray ion source. Analytical HPLC was performed on a Waters (Millford, MA) RCM C18 (8 × 100 mm) reversed-phase μBondapak column eluting at 2 mL/min with aqueous acetonitrile (v:v, CH_3CN/H_2O) containing 0.05% trifluoroacetic acid as noted. Elution profiles were recorded at 220 nm. Preparative HPLC purification was performed on a Waters RCM C18 (40 × 100 mm) reversed-phase μBondapak column eluting at 40 mL/min with aqueous acetonitrile (v:v, CH_3CN/H_2O) containing 0.05% trifluoroacetic acid as noted, followed by lyophilization. Absorbance spectra were obtained on a Beckman DU 640 spectrophotometer (Fullerton, CA). Fluorescence emission spectra were obtained on an ISS PC1 spectrofluorometer (Champaign, IL).

Fluorescein Methyl Ester (*2*). Fluorescein methyl ester was prepared by an improvement of the method described by Feuerstein (*13*). Briefly, concentrated sulfuric acid (7.5 mL) was added dropwise to a suspension of fluorescein (**1**, 10 g, 30 mmol) in methanol (30 mL). The resulting suspension was refluxed for 14 h with an addition funnel packed with oven dried 3 Å molecular sieves between the pot and condenser to continuously dry the cooled methanol. The mixture was then cooled, and ice (10 g) was added, followed by sodium bicarbonate (30 g). The suspension was filtered and washed with water. The resulting red solid was suspended in 2% aqueous sodium bicarbonate (200 mL), filtered, and washed with water. The washing process was repeated four additional times, the solid was resuspended in 1% HOAc, filtered, and finally washed with water. Drying at 110 °C for 1 h yielded a red solid (10.2 g, 95%). ^{1}H NMR (DMSO-d_6): δ 8.25 (d, 1H, J = 7.4 Hz), 7.90 (td, 1H, J = 7.2, 1.4 Hz), 7.82 (td, 1H, J = 7.4, 1.4 Hz), 7.51 (d, 1H, J = 7.6 Hz), 7.09 (d, 2H, J = 9.2 Hz), 7.00 (d, 2H, J = 1.5 Hz), 6.76 (dd, 2H, J = 9.2, 2.0 Hz), 3.56 (s, 3H). ^{13}C NMR (DMSO-d_6): δ 172.4, 165.1, 158.8, 157.3, 133.5, 133.2, 131.3, 130.8, 130.5, 130.4, 129.3, 121.1, 115.4, 102.8, 52.4. ESI-MS m/z: 347.2 $(M + H)^+$.

zyl)carboxyalkyl]fluorescein Methyl Esters (*3a*−*e*). To a suspension of fluorescein methyl ester (**2**, 200 mg, 0.58 mmol), triphenylphosphine (227 mg, 0.87 mmol), and a hydroxyalkyl benzyl ester (0.70 mmol) in 50% THF/CH_3CN (4 mL) was added diethyl azodicarboxylate (0.12 mL, 0.64 mmol) (*14*). The mixture was stirred for 1 h, concentrated in vacuo, and filtered through a pad of silica gel. The silica gel was washed with 20% *tert*-BuOMe/CH_2Cl_2, and the filtrate was concentrated in vacuo to a thick oil. Purification by preparative HPLC provided compounds **3a**−**e** as thick red oils.

Compound **3a** was obtained from compound **2** and benzyl glycolate (238 mg, 94%). Preparative HPLC (53:47). Analytical HPLC (60:40): retention time, 5.2 min, >98%. ^{1}H NMR ($CDCl_3$): δ 8.38 (d, 1H, J = 7.2 Hz), 7.84 (m, 2H), 7.37 (m, 12H), 5.29 (s, 2H), 4.95 (s, 2H), 3.65 (s, 3H). ^{13}C NMR ($CDCl_3$): δ 167.3, 166.8, 165.2, 160.3, 157.8, 134.6, 133.3, 133.0, 132.4, 131.6, 129.7, 129.0, 128.8, 123.3, 119.2, 117.4, 117.0, 103.5, 100.9, 67.9, 65.8, 52.7. ESI-MS m/z: 495.5 $(M + H)^+$.

Compound **3b** was obtained from compound **2** and benzyl 4-hydroxybutyrate (212 mg, 72%). Preparative HPLC (56:44). Analytical HPLC (60:40): retention time, 6.0 min, >98%. ^{1}H NMR ($CDCl_3$): δ 8.28 (d, 1H, J = 7.6 Hz), 7.76 (td, 1H, J = 7.3, 1.5 Hz), 7.70 (td, 1H, J = 7.7, 1.5 Hz), 7.35 (m, 6H), 6.96 (m, 3H), 6.76 (m, 3H), 5.14 (s, 2H), 4.15 (t, 2H, J = 6.2 Hz), 3.63 (s, 3H), 2.59 (t, 2H, J = 6.3 Hz), 2.20 (quintet, 2H, J = 6.2 Hz). ^{13}C NMR ($CDCl_3$): δ 172.8, 169.2, 165.2, 160.0, 159.5, 134.4, 132.9, 131.3, 130.8, 130.0, 129.4, 128.7, 128.4, 117.4, 114.9, 105.2, 100.8, 67.8, 66.5, 52.4, 30.4, 24.1. ESI-MS m/z: 523.5 $(M + H)^+$.

Compound **3c** was obtained from compound **2** and benzyl 6-hydroxycaproate (259 mg, 79%). Preparative HPLC (59:41). Analytical HPLC (70:30): retention time, 5.3 min, >98%. ^{1}H NMR ($CDCl_3$): δ 8.34 (d, 1H, J = 7.2 Hz), 7.82 (m, 2H), 7.46 (s, 1H), 7.34 (m, 10H), 7.06 (d, 1H, J = 9.1 Hz), 5.12 (s, 2H), 4.21 (t, 2H, J = 6.1 Hz), 3.63 (s, 3H), 2.39 (d, 2H, J = 7.4 Hz), 1.89 (m, 2H), 1.70 (m, 2H), 1.48 (m, 4H). ^{13}C NMR ($CDCl_3$): δ 173.6, 168.4, 165.3, 160.1, 157.9, 136.1, 133.4, 133.2, 132.0, 131.5, 130.8, 129.9, 129.8, 128.6, 128.2, 123.9, 119.0, 116.8, 116.1, 103.6, 100.3, 70.0, 66.1, 52.6, 34.0, 28.5, 28.3, 25.4, 24.6. ESI-MS m/z: 565.3 $(M + H)^+$.

Compound **3d** was obtained from compound **2** and benzyl 10-hydroxydecanoate (325 mg, 92%). Preparative HPLC (74:26). Analytical HPLC (70:30): retention time, 7.8 min, >99%. ^{1}H NMR ($CDCl_3$): δ 8.36 (d, 1H, J = 7.3 Hz), 7.84 (m, 2H), 7.52 (s, 1H), 7.34 (m, 10H), 7.11 (dd, 1H, J = 9.4, 2.2 Hz), 5.10 (s, 2H), 4.24 (t, 2H, J = 6.4 Hz), 3.64 (s, 3H), 2.36 (t, 2H, J = 7.6 Hz), 1.91 (m, 2H), 1.64 (m, 2H), 1.32 (m, 10H). ^{13}C NMR ($CDCl_3$): δ 173.8, 169.1, 165.2, 160.0, 158.3, 136.1, 133.2, 131.5, 131.1, 129.8, 128.6, 128.2, 123.0, 119.5, 116.4, 103.4, 100.3, 66.2, 52.6, 34.1, 32.2, 29.1, 29.0, 28.9, 28.5, 25.6, 24.7. ESI-MS m/z: 607.4 $(M + H)^+$.

Compound **3e** was obtained from compound **2** and benzyl 12-hydroxydodecanoate (351 mg, 95%). Preparative HPLC (81:19). Analytical HPLC (70:30): retention time, 10.5 min, >99%. ^{1}H NMR ($CDCl_3$): δ 8.37 (d, 1H, J = 7.3 Hz), 7.84 (m, 2H), 7.60 (d, 1H, J = 2.0 Hz), 7.35 (m, 10H), 7.13 (dd, 1H, J = 9.2, 2.3 Hz), 5.11 (s, 2H), 4.27 (t, 2H, J = 6.6 Hz), 3.64 (s, 3H), 2.36 (t, 2H, J = 7.6 Hz), 1.91 (t, 2H, J = 7.6 Hz), 1.64 (t, 2H, J = 6.2 Hz), 1.28 (m, 14 H). ^{13}C NMR ($CDCl_3$): δ 174.2, 169.6, 165.2, 160.0, 158.7, 133.2, 132.1, 131.6, 131.2, 131.0, 129.8, 128.6, 128.2, 122.6, 120.1, 117.0, 116.6, 103.5, 100.3, 66.2, 52.7, 34.3, 29.3, 29.2, 29.1, 29.0, 28.5, 25.7, 24.8. ESI-MS m/z: 635.4 $(M + H)^+$.

General Procedure for Preparation of 3′-*O*-(Carboxyalkyl)fluorescein Methyl Esters (*4a*−*e*). LPL-80 lipase (*Pseudomonas sp*., 100 mg) was added to solutions of 3′-*O*-[(benzyl)carboxyalkyl]fluorescein methyl esters (**3a**−**e**, 0.25 mmol) in CH_3CN/50 mM phosphate buffer (1:1, 10 mL, pH 8), and the reaction mixtures were stirred at ambient temperature for 72−96 h. The reaction mixtures were then transferred to test tubes and additional CH_3CN was added until two distinct layers were present. The resulting clear orange organic phases were separated from the lipase containing aqueous phases and purified directly by preparative HPLC providing acids **4a**−**e** as orange solids.

Compound **4a** was obtained from compound **3a** (92 mg, 91%). Preparative HPLC (40:60). Analytical HPLC (35:65): retention time, 5.5 min, >98%. ^{1}H NMR (CD_3CN): δ 8.27 (dd, 1H, J = 7.8, 1.2 Hz), 7.85 (td, 1H, J = 7.6, 1.6 Hz), 7.79 (td, 1H, J = 7.6, 1.6 Hz), 7.30 (dd, 1H, J = 7.6, 1.2 Hz), 7.17 (d, 1H, J = 2.5 Hz), 7.06 (t, 2H, J = 9.3 Hz), 6.94 (dd, 1H, J = 9.0, 1.6 Hz), 6.59 (dd, 1H, J = 9.6, 2.0 Hz), 6.53 (d, 1H, J = 2.0 Hz), 4.84 (s, 2H), 3.60 (s, 3H). ^{13}C NMR (CD_3CN): δ 174.7, 168.8, 165.4, 156.3, 150.9, 134.2, 133.3, 130.8, 129.7, 125.6, 117.4, 114.8, 103.4, 100.9, 52.3. ESI-MS m/z: 405.2 $(M + H)^+$.

Compound **4b** was obtained from compound **3b** (96 mg, 89%). Preparative HPLC (40:60). Analytical HPLC (50:50): retention time, 3.7 min, >98%. ^{1}H NMR ($CDCl_3$): δ 8.34 (dd, 1H, J = 1.6 Hz), 7.81 (m, 2H), 7.34 (m, 3H), 7.23 (dd, 2H, J = 9.2, 1.4 Hz), 7.13 (dd, 1H, J = 9.3, 2.2 Hz), 7.03 (dd, 1H, J = 9.2, 2.3 Hz), 4.30 (t, 2H, J = 6.3 Hz), 3.64 (s, 3H), 2.59 (t, 2H, J = 6.9 Hz), 2.21 (m, 2H). ^{13}C NMR ($CDCl_3$): δ 179.0, 167.1, 165.1, 159.9, 156.9, 133.4, 132.9, 131.7, 130.6, 130.4, 129.8, 129.7, 124.8, 117.7, 116.7, 116.4, 115.7, 103.6, 100.5, 68.4, 52.4, 29.5, 23.6. ESI-MS m/z: 433.5 $(M + H)^+$.

Compound **4c** was obtained from compound **3c** (99 mg, 83%). Preparative HPLC (48:52). Analytical HPLC (50:50): retention time, 5.5 min, >99%. ^{1}H NMR ($CDCl_3$): δ 8.35 (d, 1H, J = 7.0 Hz), 7.83 (m, 2H), 7.57 (s, 1H), 7.28 (m, 5H), 7.08 (d, 1H, J = 2.0 Hz), 4.25 (t, 2H, J = 6.5 Hz), 3.64 (s, 3H), 2.38 (t, 2H, J = 7.2 Hz), 1.92 (m, 2H), 1.68 (m, 2H), 1.49 (m, 4H). ^{13}C NMR ($CDCl_3$): δ 175.9, 168.9, 165.3, 160.1, 158.3, 133.3, 133.2, 131.5, 131.1, 129.9, 123.4, 119.5, 116.9, 116.3, 103.6, 100.4, 70.1, 52.7, 33.6, 28.3, 28.2, 25.2, 24.3. ESI-MS m/z: 475.3 $(M + H)^+$.

Compound **4d** was obtained from compound **3d** (112 mg, 87%). Preparative HPLC (57:43). Analytical HPLC (60:40): retention time, 5.7 min, >99%. ^{1}H NMR ($CDCl_3$): δ 8.35 (d, 1H, J = 7.8 Hz), 7.82 (m, 2H), 7.53 (d, 1H, J = 2.1 Hz), 7.36−7.20 (m, 5H), 7.10 (dd, 1H, J = 9.2, 2.3 Hz), 4.24 (t, 2H, J = 6.4 Hz), 3.64 (s, 3H), 2.34 (t, 2H, J = 7.6 Hz), 1.90 (t, 2H, J = 6.7 Hz), 1.62 (m, 2H), 1.33 (m, 10H). ^{13}C NMR ($CDCl_3$): δ 176.1, 168.7, 165.2, 160.1, 158.2, 133.2, 132.0, 131.5, 131.1, 130.8, 129.9, 123.6, 119.4, 116.9, 116.3, 103.6, 100.4, 70.3, 52.7, 33.8, 29.0, 28.9, 28.8, 28.4, 25.6, 24.5. 4e	11	23,417	0.21 ± 0.04
Fluorescein	-	25,427	0.92[c]

[a] Values reported are the average of duplicate determinations. [b] Values reported are the average of triplicate determinations. [c] Obtained from refs *15* and *16*.

Photophysical Studies. All absorbance and fluorescence spectra of 3′-*O*-(carboxyalkyl)fluorescein methyl ester labels (**4a**−**e**) were obtained in 40 mM sodium phosphate, 20% MeOH, pH 7.4. Absorbance and fluorescence spectra of fluorescein were obtained in 10 mM aqueous NaOH. Absorbance spectra were obtained at final concentrations of 2−47 μM (entries 4a and 4e), 2−58 μM (entry 4b), 2−52 μM (entry 4c), 0.3−10 μM (entry 4d), and 1−31 μM (fluorescein). Fluorescence emission spectra were obtained for 50 nM samples with an excitation wavelength of 456 nm and excitation and emission slits of 8 nm. The quantum yield of each label was determined using the expression

$$\frac{Q_{F(sample)}}{Q_{F(fluorescein)}} = \frac{I_{(sample)}}{I_{(fluorescein)}} \frac{\epsilon_{(fluorescein)}}{\epsilon_{(sample)}}$$

where Q_F = quantum yield ($Q_{F(fluorescein)} = 0.92$) (*15*, *16*), I is the total fluorescence emission intensity over all wavelengths, and ϵ is the molar extinction coefficient determined at 456 nm.

RESULTS AND DISCUSSION

The general synthesis of 3′-*O*-(carboxyalkyl)fluorescein methyl esters (**4a**−**e**) is depicted in Scheme 1. Fluorescein (**1**) was esterified in refluxing acidic methanol by the method of Feuerstein (*13*), except that 3 Å molecular sieves were used to absorb water, providing fluorescein methyl ester (**2**) in nearly quantitative yield. Coupling the 3′-phenol of fluorescein methyl ester (**2**) with hydroxyalkyl benzyl esters under Mitsunobu conditions afforded the benzyl protected 3′-*O*-(carboxyalkyl)fluorescein methyl esters (**3a**−**e**) in 72−95% yield (*17*). The syntheses were completed by selective hydrolysis of the benzyl esters of **3a**−**e** by LPL-80 lipase (*Pseudomonas sp*.) providing the desired 3′-*O*-(carboxyalkyl)fluorescein methyl ester labels (**4a**−**e**) in 80−91% yield (*18*, *19*).

Alkylation of the 3′-phenol of fluorescein esters has been reported twice in the literature (*20*, *21*). Lohse et al. synthesized the ethyl ester analogue of **4a** by coupling *tert*-butyl bromoacetate to fluorescein ethyl ester in the presence of diisopropylethylamine (78% yield) (*20*). Likewise, Shubert et al. prepared selected 3′-*O*-(hydroxyalkyl)-fluorescein methyl esters in low to moderate yield (33% for the single yield reported) by coupling dimethoxytrityl protected hydroxyalkyl chlorides to fluorescein methyl ester under basic conditions (*21*). Such O-alkylations are usually efficient using activated alkylhalides, but less effective using long-chain alkylhalides (cf. refs *20*−*22*). On the other hand, an alkylation performed under Mitsunobu conditions is relatively insensitive to alkyl chain length. Such a novel alkylation of the 3′-phenol of fluorescein methyl ester with hydroxyalkyl esters under Mitsunobu conditions is advantageous, since it provides an efficient method for the incorporation of linkers of different lengths.

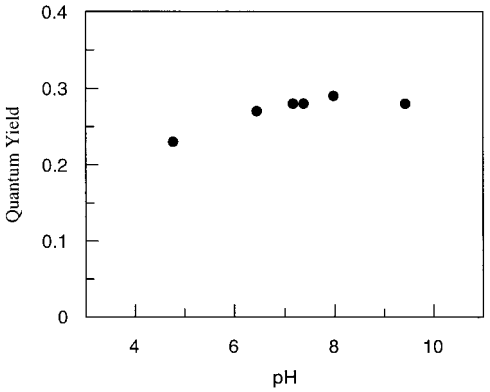

Figure 1. A representative plot of fluorescence quantum yield vs pH (labels **4a**−**e**). Data shown is for compound **4c**.

The choice to use *benzyl* esters in the Mitsunobu coupling was critical. Benzyl esters can be formed selectively in the presence of a terminal hydroxyl functionality (*12*), and are stable to the Mitsunobu coupling conditions. Most importantly, the benzyl ester functionality of the resulting fluorescein intermediates (**3a**−**e**) can be selectively cleaved with LPL-80 lipase without methyl ester cleavage (*18*, *19*).

The spectral properties of labels **4a**−**e** were evaluated and shown to be uniform and comparable to the spectral properties of reported fluorescein mixed ether/esters (*20*, *21*). The UV−visible absorbance spectra of labels **4a**−**e** exhibit absorption maxima at 456 and 481 nm with molar extinction coefficients determined at 456 nm ranging $(2.1-3.5) \times 10^4$ M^{-1} cm^{-1} (Table 1). The fluorescence emission spectra of labels **4a**−**e** are broadened and red-shifted ($\lambda_{max} = 532$ nm) relative to that of fluorescein ($\lambda_{max} = 513$ nm). The fluorescence quantum yields determined for the labels ranged 0.18−0.31 (Table 1). These quantum yield values are consistent with the value reported by Lohse et al. for a pentapeptide conjugate containing the ethyl ester analogue of compound **4a** ($Q_F = 0.18 \pm 0.02$). Furthermore, the quantum yields determined for labels **4a**−**e** are pH independent (pH 4.8−9.4, Figure 1) as the derivatives are locked into a fluorescent quinoid form by virtue of the methyl ester functionality. The pH independence exhibited by labels **4a**−**e** is desirable in situations mandating direct quantification of the fluorophore in different environments (*21*).

In summary, 3′-*O*-(carboxyalkyl)fluorescein methyl esters (**4a**−**e**) were prepared by esterification of fluorescein, Mitsunobu coupling of fluorescein methyl ester with hydroxyalkyl benzyl esters, and selective lipase catalyzed benzyl ester hydrolysis. The Mitsunobu coupling provides an efficient method for incorporation of linkers of different lengths, while utilization of benzyl esters provides a functionality which is both stable to the Mitsunobu reaction and subsequently removable by lipase mediated hydrolysis. This series of pH independent fluorescein labels allows for conjugation through the xanthinyl ring of fluorescein with linkers of different lengths.

Synthesis of Novel Cationic Poly(Ethylene Glycol) Containing Lipids

Uwe Schulze,[†] Hans-Werner Schmidt,*[,‡] and C. R. Safinya*[,†]

Materials Department, Physics Department, and Biochemistry and Molecular Biology Program, University of California, Santa Barbara, California 93106, and Makromolekulare Chemie I und Bayreuther Institut für Makromolekülforschung (BIMF) Universität Bayreuth, 95440 Bayreuth, Germany. Received September 14, 1998; Revised Manuscript Received December 4, 1998

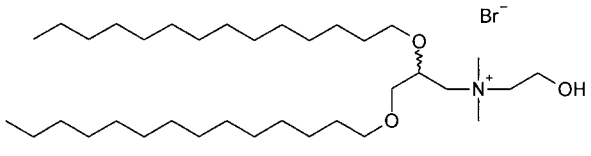
°In this paper, the synthesis of novel divalent cationic lipids with poly(ethylene glycol) segments is described. The lipids consist of an unsaturated double-chain hydrophobic moiety based on 3,4-dihydroxy benzoic acid, attached to a hydrophilic poly(ethylene glycol) spacer which contains a divalent cationic end group. As poly(ethylene glycol) spacers monodisperse triethylene glycol and telechelic poly(ethylene glycol)s with an average degree of polymerization of 9, 23, and 45 were used. The divalent cationic end group was attached by coupling a protected dibasic amino acid to the PEG spacer and following cleavage of the protecting groups. These novel class of cationic lipids is of particular interest for nonviral gene delivery applications.

INTRODUCTION

In the past few years, a very large research effort has been devoted in developing new compounds which are carriers of DNA[1] into human cells. Especially complexes of DNA and cationic liposomes, which are mixtures of neutral and cationic lipids, so-called CL−DNA complexes, seem to be very promising vectors for nonviral gene therapy applications (*1*−*6*). The advantages of these complexes compared to viral methods are lower toxicity, simpler preparation, the lack of immune response from the body and their ability to carry large pieces of DNA.

There are two major arguments for the utilization of lipids with cationic headgroups as DNA carriers. First, the ionic interactions between the positively charged headgroup of the lipid and the negatively charged phosphate groups of the DNA molecule lead to efficient complexation and compaction of DNA mimicking highly compact viral DNA particles. In fact, it has been found that CL−DNA complexes are comprised of highly ordered self-assembled structures, either of the lamellar type (*7*−*10*), or of the inverted hexagonal type (*11*). Second, a positively charged CL−DNA complex is able to interact with the negatively charged cell membrane. This enhances the chances for the complex to enter the cytoplasm of the cell by endocytosis or fusion (*11, 12*). Liposomes for gene therapy applications normally consist of mixtures of neutral lipids and cationic lipids. This enables the independent variation of two important parameters: the charge density of lipid membrane at different neutral lipid/cationic lipid ratios and the overall charge of the CL−DNA complex at different total lipid/DNA ratios (*7, 8, 11*). Commonly used neutral lipids are 1,2-dioleyl-*sn*-glycero-3-phosphocholine (DOPC) and 1,2-dioleyl-*sn*-glycero-3-phosphoethanolamine (DOPE). Scheme 1 shows three of the most commonly used cationic lipids in gene therapy applications (*13*).

In contrast to the cationic lipids shown above, our research goal was to develop a new class of cationic lipids which have a hydrophilic flexible spacer between the hydrophobic alkyl chains and the cationic headgroup. We decided to use poly(ethylene glycol) as spacer unit. PEG is a nonionic water soluble polymer of extremely low immunogenicity which has been studied and applied in a broad range of scientifically and technologically important problems in colloidal science, complex fluids (*14*), drug delivery, and gene therapy (*15*) as well as in biology and biotechnology (*16*−*18*). PEG-containing lipids have also been used in Stealth liposomes (*19*−*22*) as in vivo drug carrier systems. These liposomes consist of closed bilayer shells of phospholipids covered with PEG-based lipids anchored to the membrane. The concept of a poly(ethylene glycol) containing spacer between hydrophobic lipid segments and biologically relevant ligands such as peptides or oligosaccharide-linked glycoproteines is described in studies of Zalipsky et al. (*23, 24*) and Frisch et al. (*25*). Zalipsky reported also on long circulating liposomes containing a monovalent cationic amino-PEG-phosphatidylethanolamine with an average degree of polymerization of the PEG chain of 45 (*26*).



The properties of cationic lipids and their applications in the area of gene therapy may potentially be strongly influenced by the variation of the chain length of the poly(ethylene glycol) spacer and the number of positive charges on the headgroup. To fully explore and elucidate the role of the cationic lipid, we synthesized new types of multivalent cationic lipids. In these lipids, the PEG spacer increases the area per charged lipid. This allows us to directly vary the electrostatic interaction by significantly changing the lipid membrane charge density. In addition, an outer shell of poly(ethylene glycol) seg-

ments protects the complexes from the immune response of the body (*19*−*22*). This paper describes the synthesis of divalent cationic lipids with poly(ethylene glycol) spacers. The lipids consist of an unsaturated double-chain hydrophobic moiety based on 3,4-dihydroxy benzoic acid, attached to a hydrophilic poly(ethylene glycol) spacer which contains a divalent cationic end group. As poly(ethylene glycol) spacers monodisperse triethylene glycol and telechelic poly(ethylene glycol)s with an average degree of polymerization of 9, 23, and 45 were used. Scheme 2 shows the chemical structure of the cationic lipids presented in this paper.

EXPERIMENTAL PROCEDURES

Materials and Reagents. Oleyl bromide, 3,4-dihydroxy benzoic acid ethyl ester (protocatechuic acid ethyl ester), L-ornithine hydrochloride, di-*tert*-butyl pyrocarbonate, and *N*,*N*′-dicyclohexyl carbodiimide (DCC) were purchased from Sigma. 4-Dimethylamino pyridine (DMAP), *p*-toluenesulfonyl chloride (TsCl), tetrabutylammonium hydrogensulfate (TBAH), acrylonitrile, triethylene glycol (TEG), and poly(ethylene glycol)s (PEG) were obtained from Aldrich. Triethylene glycol and poly(ethylene glycol)s were dried in a vacuum prior to use. All other reagents and solvents were at least analytical grade and used as received.

General Methods. Infrared spectra were recorded on a Perkin-Elmer 1605 FTIR spectrophotometer calibrated using polystyrene film. ^{1}H and ^{13}C NMR spectroscopies were carried out on a Bruker Avance 200 MHz spectrometer. Molecular weight distributions were determined on a gel permeation chromatography system equipped with an Acuflow Series II pump (eluent, THF; flow rate, 1 mL/min), four Phenomenex Phenogel 5 columns (10^5, 10^4, 10^3, and 500 Å pore size), and a VDS Optilab RI-detector. The GPC was calibrated with polystyrene standards. Elemental analysis was carried out on a Control Equipment Corp. organic elemental analyzer model CEC 440HA.

3,4-Di(oleyloxy) Benzoic Acid (1). A total of 5.0 g (15.0 mmol) of oleyl bromide, 1.24 g (6.8 mmol) of protocatechuic acid ethyl ester, 2.8 g (20.4 mmol) of potassium carbonate, and 0.13 g (0.8 mmol) of potassium iodide were suspended in 40 mL of cyclohexanone and stirred at 100 °C for 18 h under nitrogen. Because of the light sensitivity of oleyl bromide, the flask was covered with aluminum foil. The hot reaction mixture was filtered and the solvent was removed in a vacuum. The residue was dissolved in 30 mL of ethanol containing 1.14 g (20 mmol) potassium hydroxide and refluxed for 4 h. The hot reaction mixture was added to 80 mL of water. Acidifying with concentrated hydrochloric acid to pH 1 resulted in the precipitation of a white solid. The solid was filtered off and washed several times with water. The crude acid was recrystallized from 20 mL of ethanol and dried in a vacuum.

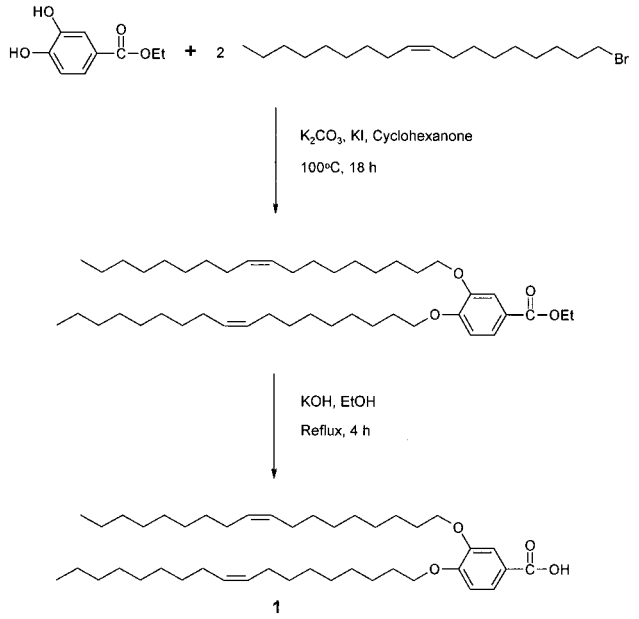
Yield: 3.2 g (72%). mp: 60.5 °C. TLC (silica gel) chloroform/methanol (9:1): R_f 0.42. ^{1}H NMR ($CDCl_3$): δ 0.88 (t, 6H), 1.20−1.58 (m, 44H), 1.78−1.96 (m, 4H), 1.96−2.12 (dt, 8H), 4.08 (t, 4H), 5.37 (t, 4H), 6.90 (d, 1H), 7.60 (d, 1H), 7.74 (dd, 1H) ppm.

C18-PEG-OH (2a−d): General Procedure. A total of 1.30 g (2.0 mmol) of 3,4-di(oleyloxy) benzoic acid (**1**), 20 mmol of poly(ethylene glycol), 0.39 g (2.1 mmol) of *p*-toluenesulfonyl chloride, 0.13 g (1.1 mmol) of 4-dimethylamino pyridine, 0.13 g (0.5 mmol) of tetrabutylammonium hydrogensulfate, and 1.9 g (13.6 mmol) of potassium carbonate were suspended in 60 mL of tetrahydrofuran. The reaction mixture was stirred for 24 h

at 45 °C. After cooling to room temperature, the mixture was poured into 700 mL of water and 100 mL of methylene chloride were added. The solution was slowly acidified with dilute hydrochloric acid till pH 1 was reached. The organic layer was separated, washed four times with 400 mL of water and dried over magnesium sulfate. The solvent was removed in a vacuum and the residue dissolved in 40 mL of ethanol. The colorless solution was kept overnight at 4 °C, which resulted in the formation of a white precipitate. After removal of the precipitate by filtration, the solvent was removed in a vacuum. Traces of byproducts could be removed by filtration over an aluminum oxide (basic) containing column (extraction with ethyl acetate and ethanol). The product was dried in a vacuum.

Yield: 60−80%. GPC (THF): M_w/M_n 1.01−1.03. ^{1}H NMR ($CDCl_3$): δ 0.88 (t, 6H), 1.20−1.58 (m, 44H), 1.78−1.96 (m, 4H), 1.96−2.12 (dt, 8H), 3.56−3.90 (m, 4n-2H), 4.08 (t, 4H), 4.45 (t, 2H), 5.37 (t, 4H), 6.90 (d, 1H), 7.60 (d, 1H), 7.74 (dd, 1H) ppm.

Di-*tert*-butyloxycarbonyl-L-ornithine (3). A total of 2.53 g (15 mmol) L-ornithine hydrochloride were dissolved in 12 mL of 2 N sodium hydroxide solution and cooled with an ice−water bath. Within 1 h, 9.8 g (45 mmol) of di-*tert*-butyl pyrocarbonate dissolved in a small amount of tetrahydrofuran and 19 mL of 4 N sodium hydroxide was added in portions to the reaction mixture. The colorless solution was stirred overnight. The solution was acidified with dilute hydrochloric acid and the product extracted twice with 200 mL of ether. The combined ether phases were washed several times with water and dried over magnesium sulfate. The solvent was removed in a vacuum and the product dried in high vacuum at room temperature.



Yield: 4.8 g (97%). ^{1}H NMR ($CDCl_3$): δ 1.45 (s, 18H), 1.65−2.05 (m, 4H), 3.05−3.25 (m, 2H), 4.32 (m, 1H), 4.80 (b, 1H), 5.28 (b, 1H) ppm.

C18-PEG-Orn(BOC) (4a−d): General Procedure. A total of 1.4 mmol of C18-PEG-OH (**2a**−**d**), 0.51 g (1.6 mmol) of di-*tert*-butyloxy-L-ornithine (**3**), and 42 mg (0.35 mmol) of 4-dimethylamino pyridine were dissolved in 40 mL of methylene chloride. A total of 0.35 g (1.7 mmol) of *N,N′*-dicyclohexyl carbodiimide was dissolved in a minimal amount of methylene chloride and added to the reaction mixture. The solution was stirred for 3 h at room temperature. The dicyclohexyl urea was filtered off, and the solvent was removed in a vacuum. The crude product was dissolved in 30 mL of acetone and kept at 4 °C overnight. Dicyclohexyl urea was filtered off again, and the solvent was removed in a vacuum. Traces of unreacted di-*tert*-butyloxy-L-ornithine could be removed by filtration over an aluminum oxide (basic) containing column (elution with acetone). The product was dried in a vacuum.

Yield: 50−95%. GPC (THF): M_w/M_n 1.02−1.05. ^{1}H NMR ($CDCl_3$): δ 0.85 (t, 6H), 1.20−1.58 (m, 44H), 1.40 (s, 18H), 1.65−1.92 (m, 8H), 1.92−2.12 (dt, 8H), 3.02−3.22 (m, 2H), 3.56−3.88 (m, 4n−4H), 4.02 (t, 4H), 4.15 (m, 1H), 4.29 (t, 2H), 4.42 (t, 2H), 5.35 (t, 4H), 6.83 (d, 1H), 7.50 (d, 1H), 7.63 (dd, 1H) ppm.

C18-PEG-Orn (5a−d). General Procedure. A total of 1.0 mmol of C18-PEG-Orn(BOC) (**4a**−**d**) was dissolved in 5 mL of trifluoroacetic acid and cooled with an ice−water bath. After complete dissolution, the solution was stirred for additional 5 min. Longer reaction times may result in an increase of byproducts. The solvent was removed in a vacuum and the residue was dried in high vacuum. The crude product was purified by column chromatography on silica gel and elution with chloroform/methanol (4:1).

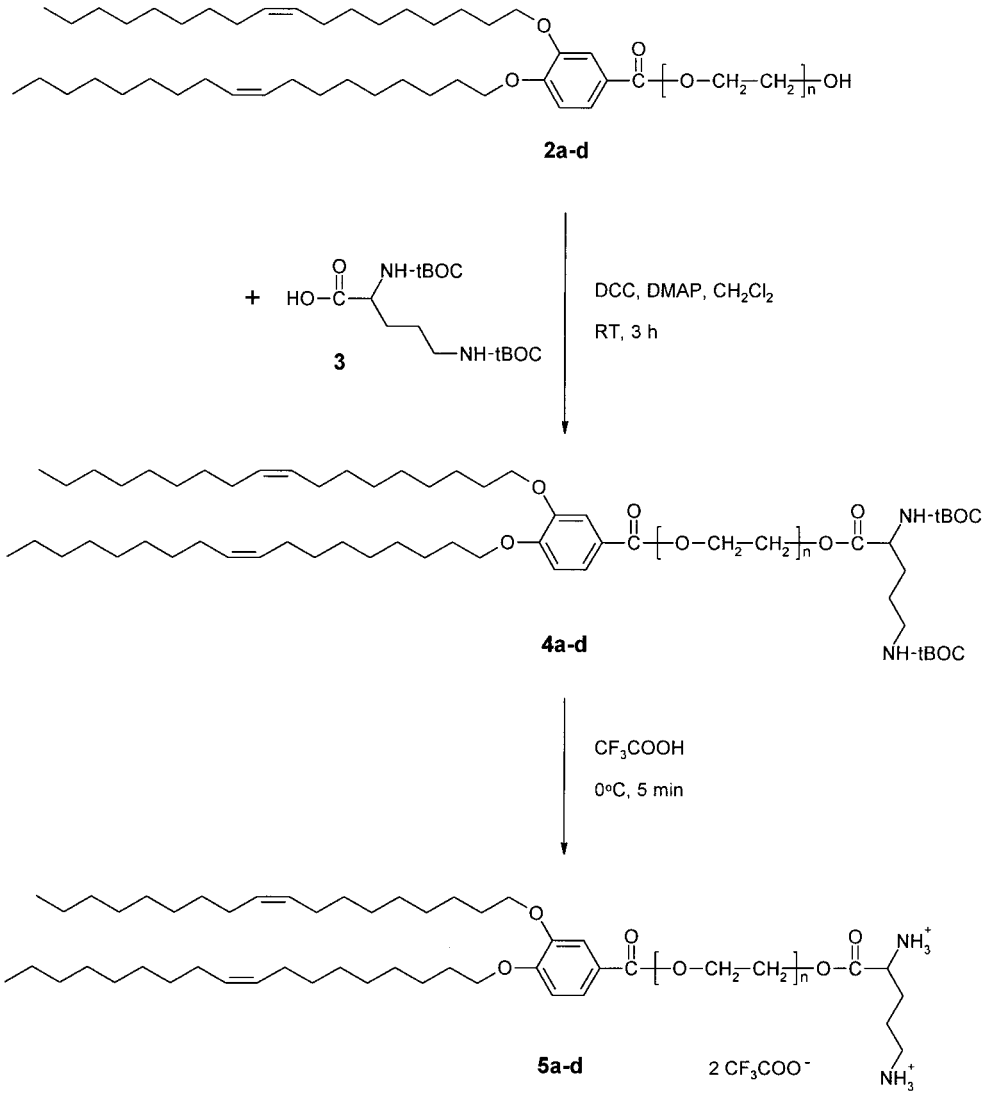
RESULTS AND DISCUSSION

The cationic PEG-containing lipids were synthesized following a route which consists of three main stages: (a) synthesis of the hydrophobic moiety of the lipid; (b) coupling of the hydrophilic PEG spacer segment; (c) attachment of the cationic headgroup to the lipid.

For the synthesis of the hydrophobic moiety of the lipid, we used a dihydroxy- and monocarboxy-substituted benzene ring as a central unit. This substitution pattern enables working with different linkage groups for the aliphatic alkyl chains (ether linkage) and the poly(ethylene glycol) segment (ester linkage). In this paper, we focus on the use of 3,4-dihydroxy benzoic acid which leads to two-chain lipids. Two-chain lipids are also the ones which are commonly found in natural membranes. Altough the benzene ring is an unusual unit in natural lipids there should be pointed out that ether and ester derivatives of the 3,4-dihydroxy benzoic acid (protocatechuic acid) are found in many fruits (*27*). As alkyl chains unsaturated C18 chains were used which will provide strong anchoring of the lipid in the bilayer membrane and chain flexibility due to the cis-double bond. 3,4-Di(oleyloxy) benzoic acid (**1**) was synthesized by etherification of 3,4-dihydroxy benzoic acid ethyl ester with oleyl bromide and following cleavage of the ethyl ester with potassium hydroxide (Scheme 3) (*28*−*30*).



The next synthetic stage is the coupling reaction of 3,4-di(oleyloxy) benzoic acid (**1**) with α,ω-dihydroxy poly(ethylene glycol) (Scheme 4) based on a procedure of

Percec et al. (*31*). Poly(ethylene glycol) was used in a 10-fold excess to avoid esterification of both hydroxyl groups. After reaction was completed, the excess PEG was removed by extraction with water followed by filtration of the product over an aluminum oxide (basic) containing column. The absence of traces of excess PEG was checked by gel permeation chromatography. The resulting hydroxy functionalized PEG containing lipids (**2a**−**d**) are useful intermediates for the attachment of a variety of biologically relevant end groups.

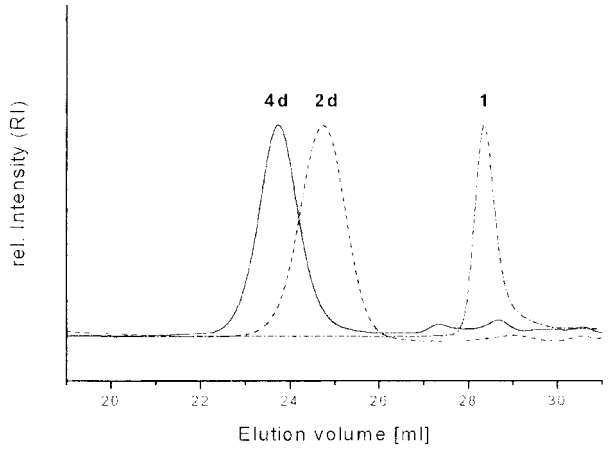

Figure 1. GPC elution diagrams of 3,4-di(oleyloxy) benzoic acid (**1**), the hydroxy functionalized PEG containing lipid (**2d**), and the corresponding PEG containing lipid with the tBOC protected end group (**4d**); eluent, THF; flow rate, 1 mL/min.

The carriers of the positive charge in cationic lipids are amino groups. In this work, we attached a *tert*-butyloxycarbonyl (tBOC) protected dibasic amino acid (L-ornithine) to the free hydroxyl group of the PEG segment (Scheme 5). The use of dicyclohexyl carbodiimide as esterification reagent allows us to run the reaction under mild conditions at room temperature (*32*). The use of a small excess of the protected L-ornithine ensures the complete conversion of the hydroxy functionalized PEG containing lipid. Excess L-ornithine could be removed by filtration over an aluminum oxide (basic) containing column. The purity of the product was checked by GPC and NMR spectroscopy. Figure 1 compares the GPC curves of 3,4-di(oleyloxy) benzoic acid (**1**), the hydroxy functionalized PEG containing lipid (**2d**), and the corresponding PEG containing lipid with the tBOC-protected end group (**4d**). The shift to higher molecular weight (lower elution volume) between the different coupling stages can be clearly observed. In addition, all peaks possess a monomodal distribution.

Cleavage of the *tert*-butyloxycarbonyl protecting groups with trifluoroacetic acid and purification of the crude product by column chromatography on silica gel lead to the cationic polymer lipids (**5a**−**d**) (Scheme 5). The structure was verified by ^{1}H NMR, ^{13}C NMR, COSY-NMR spectroscopy, and elemental analysis.

In conclusion, the successful synthesis of cationic PEG-containing lipids was demonstrated. These lipids have structural advantages compared to other cationic lipids. The divalent cationic headgroup of the lipid may potentially condense neighboring DNA strands, which further compacts DNA inside the complex. These compact structures are thought to enhance the transport of DNA into cells. Of particular interest in this series is the variability of the length of the poly(ethylene glycol) spacer. This spacer is expected to make the DNA strand−strand complexation more efficient and to avoid the immune response from the body by using the Stealth effect.

Enzymatic Cleavage of Peptide-Linked Radiolabels from Immunoconjugates

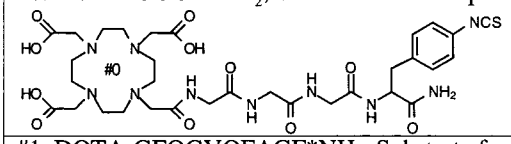
James J. Peterson and Claude F. Meares*

Department of Chemistry, University of California, One Shields Avenue, Davis, California 95616-5295. Received January 25, 1999

We have incorporated peptides selected by combinatorial library [Peterson, J. J., and Meares, C. F. (1998) *Bioconjugate Chem. 9*, 618−626) into peptide-linked radiolabeled immunoconjugates of the form DOTA-peptide-antibody. Decapeptide linkers -GFQGVQFAGF- and -GFGSVQFAGF-, selected for cleavage by human liver cathepsin B, were rapidly digested in vitro when compared to the simple model tetrapeptide motif of the prototype -GGGF− [Li, M., and Meares, C. F. (1993) *Bioconjugate Chem. 4*, 275−283]. Cleavage properties of these library-selected substrates for cathepsin B compared favorably with decapeptide linkers -GLVGGAGAGF- and -GGFLGLGAGF-, which incorporate two of the most labile extended cathepsin B substrates from the literature. The decapeptide linker -GFGSTFFAGF-, selected from the library for cleavage by human liver cathepsin D, was rapidly digested by cathepsin D while the others were not.

INTRODUCTION

Radioimmunotherapy and imaging use cancer-selective radiolabeled monoclonal antibodies (mAbs) to deliver therapeutic or imaging doses of radiation to the site of disease (*1*−*3*). Undesired accumulation of radioactivity in healthy tissues continues to be an impediment to this approach (*4*−*8*). One possible source of radiation in nontarget organs could be radiometal that has transchelated to proteins such as transferrin (*9*) or albumin (*10*), but this problem has been practically overcome through the use of reagents with high metal-chelate stability (*11*−*14*).



Elimination of radioactivity from the liver, for example, is a complex process involving both enzymatic liberation of low molecular weight radioactive fragments from the targeting molecule (usually an antibody or antibody fragment) and intracellular processing of these fragments (*15*−*18*). One strategy for improved clearance is to insert a metabolizable linker between the tumor-targeting moiety and the radiolabel. Linkers may be designed to mimic natural substrates for enzymes endogenous to the cells of interest, and may include features designed to take advantage of appropriate intracellular pathways of elimination of the resulting low molecular weight fragments (*19*−*21*). The exact conditions in vivo where either cleavage or subsequent metabolite processing will become rate limiting are still unclear, partly because potential linkers are subject to multiple lysosomal enzymes (*22*−*25*) and metabolic pathways (*26, 27*)—all of which are sensitive to variations in linker structure (*8, 16, 17*). Exploration of multiple structures with oligomeric linkers

of readily modified sequence offers a natural approach to further understanding the problem.

Metabolizable linkers explored for reducing radiation in healthy organs during radioimmunotherapy include esters, thioethers, disulfides, amides, and even hydrocarbon chains (*16*, *17*, *20*, *21*, *28*). Although ester linkers exhibit rapid cleavage in the liver, peptide linkers are preferred for their relative stability in circulation (*20*, *21*). It has been demonstrated in vitro that simple tetrapeptides can serve as cleavable linkers for radioimmunotherapy, where cleavage by endoproteases can occur over a period of hours at levels of enzyme expected to be present in vivo (*29*, *30*). The great differences in susceptibility of different peptides to enzymatic cleavage, and the range of possible metabolites resulting from cleavage of polypeptides by different enzymes, afford an opportunity to improve the rate at which radioactive metabolites are eliminated.

Previously, we selected peptide linkers from a combinatorial library using cleavage by specific lysosomal enzymes implicated in hepatic protein turnover: human liver cathepsins B and D (*31*). We have chosen for further study two substrates for cathepsin B and one for cathepsin D, which matched the consensus sequences deduced in that work. Using a convenient solid-phase procedure for the N-terminal functionalization of peptides with the DOTA[1] macrocycle (*32*), we prepared and conjugated peptide-linked chelators to Lym-1, a murine IgG_{2a} mAb used in cancer therapy (*6*). These conjugates were radiolabeled and treated with endoproteases to explore their cleavage properties in vitro compared to the simple prototype DOTA-tetrapeptide-Lym-1 (*30*). In addition, we inserted labile peptide substrates from literature sources (*33*, *34*) into the DOTA-peptide-Lym-1 format for comparison with conjugates derived from our combinatorial selection.

RESULTS AND DISCUSSION

Table 1 gives the formula for each substrate studied. Methods of preparation and comjugation are described in detail in Supporting Information. Thin layer chro-

[1] Abbreviations: DOTA, 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid.

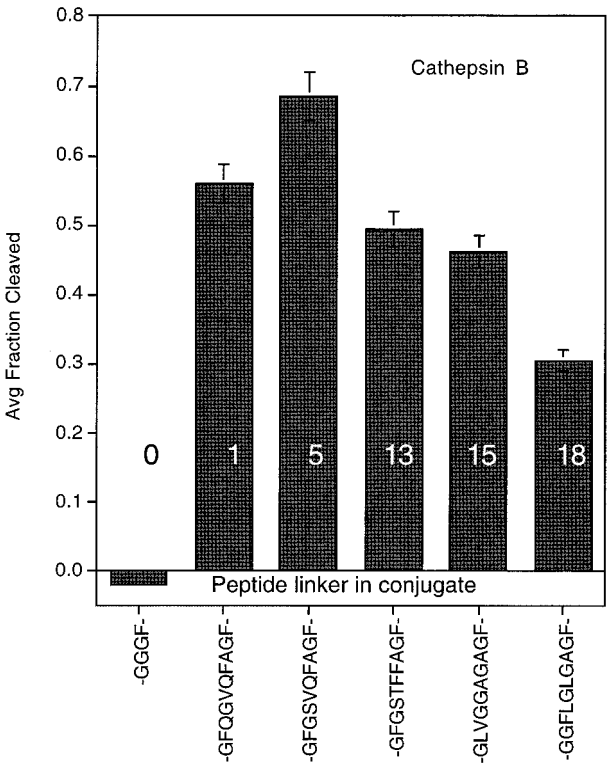

Figure 1. Digestions of ^{90}Y-DOTA-peptide-Lym-1 conjugates with human liver cathepsin B at 37 °C, 0.11 units/mL, 37 min. Experiments were performed in triplicate; error bars represent 1 standard deviation.

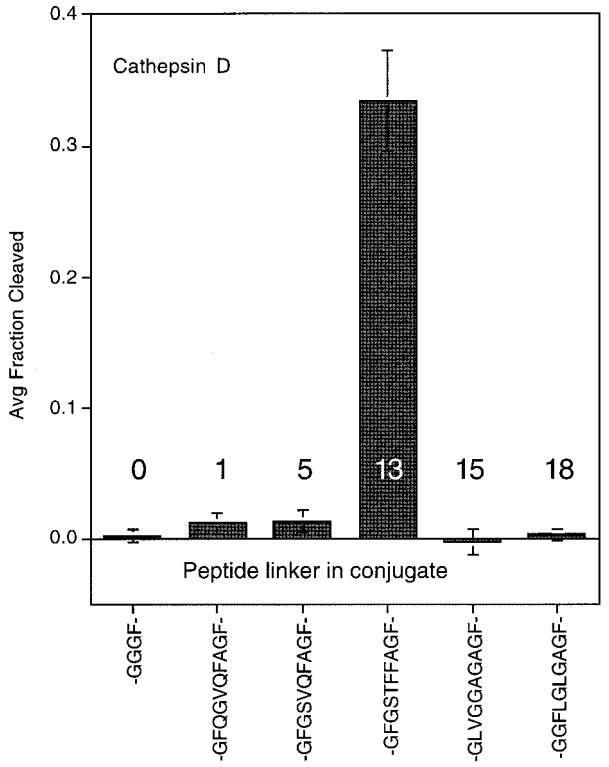

Figure 2. Digestions of ^{90}Y-DOTA-peptide-Lym-1 conjugates with human liver cathepsin D at 37 °C, 0.22 units/mL, 65 min. Experiments were performed in triplicate; error bars represent 1 standard deviation.

matograms showed that the stability of the unconjugated nitro form of each DOTA-peptide-^{90}Y complex was not adversely affected by the enzymatic cleavage buffer. All peptide linkages were stable in cleavage buffer lacking enzyme. Under these conditions [ca. 10-fold lower in enzyme concentration than those previously used (*30*)], no significant cleavage of the prototype DOTA-peptide#0-Lym-1 occurred, while substantial cleavage of all literature and library-based decapeptide conjugates was observed for cathepsin B (Figure 1). The conjugate most labile to cathepsin B (no. 5) was derived from our combinatorial library (*31*). The lability of conjugate 1, also derived from the library for cleavage by cathepsin B, compared favorably with literature-based conjugate 15 (*34*). All decapeptide conjugates were cleaved to a greater extent than conjugate no. 18. Surprisingly, even conjugate 13, selected from the combinatorial library for cleavage by cathepsin *D*, was substantially cleaved during treatment with cathepsin B.

Cathepsin D was able to significantly cleave conjugate 13, while none of the other conjugates were significantly cleaved by this enzyme under these conditions (Figure 2). In our attempts to prepare a literature-based substrate for cathepsin D (*35*), the product was not sufficiently soluble at the DOTA-peptide stage to be readily isolated.

Linkers for radioimmunotherapy that consist of unnatural amide bonds have been referred to as "peptidyl" in the sense that the backbone of the folded antibody flanking each modified lysine may serve as a set of arbitrary peptidyl enzyme substrates (*36*, *37*). It has been found that the potential cleavage sites on Lym-1 provide relatively poor substrates for lysosomal endoproteases when compared to short—or even arbitrary—peptide linkers attached to ϵ-amines on Lym-1 (*29*, *30*). Until very recently (*21*), ester-based linkers (despite their relative lack of stability in plasma) have continued to find favor when compared to simple mono- or diamide linkages, due to their superior elimination properties in healthy tissues (*19*, *20*, *36*−*39*). However, it is unlikely that lysosomal endoproteases are able to participate in catabolic processes involving unnatural amide-based linkers.

Cathepsin D, for example, requires an extended substrate (>5 amino acid residues) for cleavage (*40*, *41*). The cathepsin D results in Figure 2 emphasize the importance of fine structural detail. We and others have found cathepsin D to be a more selective enzyme than cathepsin B (*31*, *42*−*44*).

It is clear from the results in Figure 1 that all conjugates derived from specific substrates for cathepsin B were efficiently cleaved by this enzyme in their bioconjugate form. The effect of linker length on cathepsin B cleavage is still unclear, although the activity of this enzyme may be expected to be hindered by the proximity of the intended substrate to the targeting macromolecule (*31*). Conjugates derived from our combinatorial library were cleaved more quickly than extended cathepsin B substrates from literature that might be considered appropriate candidates for cleavable linkers.

The sensitivity of conjugate 13 (a library substrate selected for cleavage by cathepsin D) to cathepsin B is notable. Our stock of cathepsin B was assayed by the supplier to be over 92% pure by SDS−PAGE, and the method used for its purification was designed to remove cathepsin D (*35*). However, we did not include any specific inhibitors of cathepsin D during cathepsin B cleavage experiments; thus, we cannot rule out the possibility that our stock of cathepsin B was contaminated with traces of cathepsin D.

In conclusion, highly labile cathepsin substrates were derived from a combinatorial library which tapped only

a modest fraction of the potential of this approach (having only four variable positions and nine variable amino acids, or $9^4 = 6561$ unique peptide sequences). It should be possible to make use of a much larger set of amino acid side chains, to incorporate features that may expedite elimination of the fragments as well (*21*, *27*). Subsequent experiments by others have confirmed that the reagents studied here are able to stably link ^{90}Y to Lym-1 for extended periods in human plasma under physiological conditions (David Kukis, personal communication).

FOOTNOTES

1. Abbreviations used: BCA, bifunctional chelating agent; DMF, N,N-dimethylformamide; DMSO, methylsulfoxide; DOTA, 1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid; DTPA, diethylenetriamine pentaacetic acid; ESIMS, electrospray ionization mass spectrometry; ITC, isothiocyanate.
2. Radioimmunoconjugates remain fixed at the origin, while low molecular weight impurities such as unreacted radiolabeled BCA or chelate liberated by proteolysis migrate up the plate.
3. The concentration of Lym-1 was determined by measuring its absorbance at 280nm after an appropriate dilution in 0.1M sodium phosphate pH7. ($E^{1\%}_{280}$ = 1.35 (9))

EXPERIMENTAL PROCEDURES

Reagents. Fluorescamine, Pd on activated carbon, CCl_4, $CSCl_2$, were purchased from Aldrich Chemical Co. Methanol, NaOH, HCl (aq.), biotechnical grade CF_3COOH, and HPLC grade CH_3CN, and Fuji X-ray film were purchased from Fisher. HPLC grade DMSO was purchased from Fluka. Aqueous 25% tetramethylammonium hydroxide was purchased from Acros Organics. H_2 gas was purchased from Matheson. All buffers were made using 18MΩ•cm water. DOTA-peptides were synthesized as described (2). Human liver cathepsin D was purchased from Calbiochem-Novabiochem Corp. Human liver cathepsin B and Sephadex G-50 was purchased from Sigma. Lym-1 monoclonal antibody was purchased from Techniclone. $^{111}InCl_3$ was kindly provided by the laboratory of Dr David Goodwin. $^{90}YCl_3$ was purchased from Pacific Northwest National Laboratory. Plastic backed thin layer silica gel plates (Kieselgel 60) were purchased from EM Science.

Mass Spectrometry, IR and UV Spectroscopy. Electrospray mass spectrometry was performed on a Fisons Instruments VG Quattro triple quadrupole spectrometer using an eluent of 0.1% HCOOH, 49.95% H_2O, 49.95% CH_3CN at a flow rate of 5μL/min. Cone voltage was set to 50V. Source temperature was set to 80°. Samples collected during HPLC were lyophilized and rewetted at least twice on a Savant model SVC-100H speed-vac lyophilizer before analysis. Calibration of the mass scale was performed using a solution of PEG 300, PEG 600, and PEG 1000 as calibration standard. Infrared spectra were recorded on a Mattson Galaxy Series FTIR 300. UV spectroscopy was performed on a Hewlett-Packard model 8450 UV/vis spectrophotometer.

HPLC. For analytical HPLC a Dynamax microsorb 100 Å 5μm 4.6mm × 250mm C-18 column was used at a flow rate of 1mL/min. For semi-preparative HPLC, a Phenomenex Magellan 100Å 5μm 10 × 250mm C-18 column was used at a flow rate of 3mL/min.

© 1999 American Chemical Society, Bioconjugate Chem., Peterson bc990010t Supporting Info Page 3

HPLC buffers were: Buffer system A=0.068 N NH_4Oac, pH 4.8, vs CH_3CN. Buffer system B=0.1% CF_3COOH in H_2O vs 0.1% CF_3COOH in CH_3CN. Eluting peaks were detected at 280nm unless otherwise indicated.

Gradient 1=Hold 0% CH_3CN for 5 min and linear gradient to 50% by 35min.

Gradient 2=Hold 20% CH_3CN for 5 min and linear gradient to 50% by 23min.

Gradient 3=Hold 25% CH_3CN for 5 min and linear gradient to 50% by 25min.

Thin Layer Chromatography and Imaging. Silica gel thin layer chromatograms were developed on multiple 0.9 × 7.0 cm lanes using a 50:50 mixture of CH_3OH and 10% aqueous NaOAc as the eluent. Chromatograms were first imaged using both X-ray film and an AMBIS radioanalytical imaging system. Fractions of each lane were then cut out using the X-ray image as a template and placed >4 cm apart on AMBIS plates, which were again imaged and quantified using the AMBIS software.

Bifunctional Chelator Synthesis. Several DOTA-peptides containing C–terminal nitrophenylalanine amide were synthesized as described (2). The conversion of DOTA-peptide#18-Lym-1 from the nitro to the isothiocyanato form described below is representative (Scheme S1).

DOTA-peptide #18-L-p-aminophenylalanine amide (2). DOTA-peptide#18-L-p-nitrophenylalanine amide **1** (24mg, 18μmol) was dissolved in 3.0mL water and 1mL CH_3OH in a 25mL pear bottom flask. The pH was adjusted to 10.5 with 0.1N NaOH and 17mg Pd/C was added. The flask was fitted with a vented rubber septum, purged for 5min with argon through a 20-gauge syringe needle, purged 15min with H_2, and charged with H_2 at 5psig. The mixture was vigorously stirred for 15h at room temperature, filtered via 0.45μm syringe filter, and adjusted with 0.1N HCl to pH 5. A small sample was removed for HPLC analysis (gradient #1, buffer system A). A single peak eluting at 27 min was collected and thoroughly lyophilized. The product tested positive for free amine by fluorescamine test (3). Reaction solvent was evaporated to give

© 1999 American Chemical Society, Bioconjugate Chem., Peterson bc990010t Supporting Info Page 4

the sodium salt of **2** (31 mg) in near quantitative yield. ESIMS calc *m/z* $(M+H+Na)^{++}$ for $C_{59}H_{90}N_{16}O_{17}$ = 658.8 *m/z* $(M+H+Na)^{++}$ found = 658.3.

DOTA-peptide#18-p-isothiocyanatophenylalanine amide (3). Compound **2** (30mg) was taken up in 2mL 0.1M HCl, 300mL CCl_4, and 1.7mL $CSCl_2$ and stirred vigorously for 3h. A small aliquot of the aqueous layer was neutralized with NaOH and tested negative for free amines by fluorescamine test. The organic layer was removed, and the aqueous solution was washed 4 × 2mL CH_2Cl_2. After evaporation, crude **3** was dissolved in 2mL HPLC grade DMSO and analyzed by HPLC using gradient 1 buffer system B. The peak eluting at 34min (89% of the total integrated area) using gradient 1 was purified on Magellan C-18 using gradient 3, buffer system B. HPLC solvents were evaporated to yield **3** (20mg, 14.9mmol) after lyophilization. Overall yield of **3** from compound **1**: 83%. IR (KBr) 2102 cm^{-1} (ν N=C=S) ESIMS calc *m/z* $(M+H)^+$ for $C_{59}H_{90}N_{16}O_{17}$ = 1337.7 $(M+H)^+$ found = 1335.3 $(M+2H)^{++}$ found = 668.6. Table S1 shows analytical and yield data for all 5 peptides. All isothiocyanates were stored at 50mM in DMSO at –70°C.

Preparation of DOTA-peptide-Lym-1 conjugates (4). Conjugations were performed in parallel for all bifunctional chelators. Two general procedures were performed. In method 1, isothiocyanate chelators were first labeled with radiometal and then conjugated to Lym-1. In method 2, the isothiocyanates were first conjugated to Lym-1, then radiolabeled.

Method 1. Dilute 5mM solutions of 8μL DOTA-peptide-ITC #0, #1, #5, #13, #15, or #18 (Table S1) in DMSO were buffered with 6μL 0.26M tetramethylammonium acetate pH 5.5, and $^{90}YCl_3$ (2μL; 600μCi) was added to each BCA. For controls, radiometal was incubated with buffer alone and with DTPA alone. The labeling reaction was allowed to proceed for 2h at 40°. An aliquot of each reaction (1μL) was applied to TLC, and 2μL of 0.2M DTPA pH 5.5 was added to the remaining mixture to sequester any unchelated metal. The solution was allowed to react at room temperature for 1.5 h, and

© 1999 American Chemical Society, Bioconjugate Chem., Peterson bc990010t Supporting Info Page 5

another 1μL was removed and analyzed by TLC. Radiolabeled BCA and radiolabeled DTPA migrated at R_f 0.25-0.35 and 0.6, respectively. Lym-1 mAb (9.17mg/mL)[3] was transferred from pH 7 storage buffer to conjugation buffer (0.1M tetramethylammonium phosphate, pH 9) using Sephadex G-50 gel filtration media (4) and 100μL (0.92mg; 5.9nmol) Lym-1 was added to each BCA. Conjugation was allowed to proceed for 3h at 37°C, and the conjugates were purified and buffer exchanged on G-50 gel filtration media into 0.1M tetramethylammonium acetate, pH 4.8. Samples of each conjugate applied to TLC before and after gel filtration confirmed the removal of low molecular weight impurities.[2] Similar labelings were performed with $^{111}InCl_3$.

Method 2. Freshly thawed DOTA-peptide-ITC #0, #1, #5, #13, #15, or #18 (10μL; 50nmol) in DMSO was added to Lym-1 mAb (100μL; 1.67mg; 10.8nmol) in 0.1M tetramethylammonium acetate, pH 8.95. Conjugation was allowed to proceed for 3h at 37°C. Unreacted BCA was removed by gel filtration and the buffer exchanged with 0.4M NH_4OAc, pH 7.0. Conjugate concentration was measured (typically 15mg/mL)[3] and $^{90}YCl_3$ (4μL; 400μCi) was added. The chelation reaction was allowed to proceed for 2.3h at 40°C for every reaction. Reaction mixture aliquots were applied to TLC, and a challenge chelate solution was added (12μL 0.1M DTPA/ 0.5M ammonium citrate, pH 6.5). After 1.5h at 37°C, 1μL aliquots were removed for TLC and the conjugates were purified by gel filtration into 0.1M tetramethylammonium acetate, pH 4.8. Analysis of the TLC plates before and after challenge confirmed removal of unchelated metal by DTPA. TLC analysis before and after final gel filtration confirmed removal of any radiolabeled DTPA or citrate.

***In vitro* Enzymatic Digestions of Protein Conjugates.** Radiolabeled conjugates from method 2 were diluted to 8.5mg/mL in cathepsin cleavage buffer (0.1M tetramethylammonium acetate, pH 4.8) and portioned into 3 × 25μL aliquots for triplicate digestions with cathepsin B, 3 × 25μL aliquots for triplicate digestions with cathepsin D, and 1 × 50μL aliquots for buffer-only controls. Human liver cathepsin B (50μL @ 1.53 units/mL (5)) stored in 50mM NaOAc/ 1mM EDTA, pH 5 was preactivated for 30min with

© 1999 American Chemical Society, Bioconjugate Chem., Peterson bc990010t Supporting Info Page 6

4μL 1M DTT and 2μL of this preactivated enzyme solution was added to three separate 25μL reaction vials for each conjugate at 37°C. Samples were taken at several times during the incubation, and reaction products analyzed by TLC. The object was to find an early time point before all the peptides had been cleaved, at which the differences in substrate properties of the peptides would be readily apparent.

Cathepsin D (2.5μL @ 2.40units/mL (6,7)) was added to another set of three aliquots of each conjugate at 37°C, and reaction aliquots were analyzed as described above for cathepsin B.

Final enzyme concentrations for cathepsin B and D reactions were 0.11units/mL and 0.22 units/mL respectively. For control experiments, each conjugate was exposed to cleavage buffer containing no enzyme, and (separately) the nitro form of DOTA-peptide#0 (2.5mM) was labeled with ^{90}Y and incubated in labeling and cleavage buffers. Proteolytic cleavage was quantified as described above.

RESULTS

Synthesis of Bifunctional Chelating Agents and DOTA-peptide-Lym–1 Conjugates. The preparation of bifunctional chelating agent DOTA-peptide#18-ITC is representative of all five BCAs synthesized (Scheme S1). Conversion of the nitro function to isothiocyanato was modified to accommodate far more hydrophobic peptides and to avoid hydrolysis of the C-terminal amide reported previously (1). For example, during reduction CH_3OH was added to prevent aggregation. To prevent loss of the C-terminal amide, a lower concentration of acid was used in the aqueous phase in the conversion of the aromatic amine to isothiocyanate (8). Despite this precaution, we cannot rule out co-purification of a small amount of C-terminal acid, due to the structural complexity of these high molecular weight BCAs. Hydrolysis of the C-terminal amide would result in a *m/z* one mass unit higher than that calculated for the amide. Although none of the masses in Table S1 are consistent with hydrolysis, our measurements do not

© 1999 American Chemical Society, Bioconjugate Chem., Peterson bc990010t Supporting Info Page 7

have sufficient accuracy to dismiss it. Distinctive IR stretches confirm the presence of the isothiocyanate. Standard size-exclusion and TLC analysis (4) confirmed covalent modification of Lym-1 and stable chelation of either ^{111}In or ^{90}Y in the presence of the challenge chelate, DTPA.

DOTA-peptides #1, #5, #13, and #18 were less soluble in water than DOTA-peptides #0 and #15, whose conjugation consistently resulted in more extensively radiolabeled antibody.

Size Reduction of Galactosylated PEI/DNA Complexes Improves Lectin-Mediated Gene Transfer into Hepatocytes

Thierry Bettinger, Jean-Serge Remy,* and Patrick Erbacher

Laboratoire de Chimie Génétique, Faculté de Pharmacie, CNRS (UMR 7514) et Université Louis Pasteur de Strasbourg, BP 24, F-67401 Illkirch Cedex, France. Received January 13, 1999

Hepatocytes are interesting targets for gene therapy applications. Several hepatocyte-directed gene delivery vectors have been described. For example, simple galactosyl residues coupled to polyethylenimine (PEI) gave an efficient vector which selectively transfected hepatocytes via the asialoglycoprotein receptor-mediated endocytosis [Zanta, M. A., et al. (1997) *Bioconjugate Chem*. *8*, 839−844]. However, the large size of these galactosylated PEI/DNA complexes prevented their use in vivo. We have investigated the role of the saccharide length on the size of glycosylated-PEI/DNA particles. When 5% of the PEI nitrogens were grafted with a linear tetragalactose structure (*l*Gal4), small and stable particles were formed upon complexation with plasmid DNA. These particles were essentially toroids having a size of 50−80 nm and a ζ-potential close to neutrality. Moreover, these slightly charged PEI−*l*Gal4/DNA complexes were as selective as the previously described galactosylated−PEI vector to transfect hepatocytes, but in addition, they were more efficient. It is expected that the properties of the PEI−*l*Gal4/DNA complexes may increase their diffusion into the liver and their efficiency to transfect hepatocytes.

In the nonviral gene delivery field, the cationic polyethylenimine and its derivatives are efficient gene transfer vectors, both in vitro and in vivo (*1*−*5*). Recently, a hepatocyte-directed vector has been developed, consisting of a 5% galactose-bearing polyethylenimine (PEI−Gal)[1] (*6*). The PEI−Gal conjugate was prepared by reductive amination between PEI and lactose in the presence of sodium cyanoborohydride. This vector possesses a DNA-binding domain, an intrinsic endosomal-disrupting activity ("proton sponge" effect), and a galactose specific lectin-binding moiety. The transfection of hepatocytes expressing a galactose-specific membrane lectin was selective and highly efficient. Unfortunately, transmission electron microscopy pictures showed aggregated PEI−Gal/DNA complexes in physiological saline conditions. So, we have investigated the size and the morphology of glycosylated-PEI/DNA complexes (*7*), in relation with the length of the osidyl structure (1−9 units) and the glycosylation extent of the polymer (2.5−25% of grafted nitrogens). Only when 5% of the PEI nitrogens were modified with a linear tetragalactose structure (*l*Gal4), small and stable particles were formed with plasmid DNA.

The 25 kDa PEI (branched polymer, Aldrich) was glycosylated by the reductive amination procedure. Linear tetragalactose (Gal α3 Gal β4 Gal α3 Gal, *l*Gal4, Dextra Laboratories Ltd.) or tetraglucose (Glc α4 Glc α4 Glc α6 Glc, *l*Glc4, Sigma) (5 μmol) and sodium cyanoborohydride (25 μmol, Aldrich) were added to PEI (100 μmol of monomer, 100 μL of a 1 M, pH 7.0, stock solution) in 0.9 mL of borate buffer 0.2 M, pH 8.2, and left for 96 h at rt under continuous stirring. Low molecular weight compounds were removed by gel filtration on a Sephadex G-25 fine column (12.5 × 450 mm, Fluka) in 0.15 M NaCl. The grafting extent of the *l*Gal4 motif per PEI molecule, expressed as a percentage of glycosyl structures per nitrogen, was determined by using the resorcinol/sulfuric acid micromethod (*8*) and was 5%. The polymer amine concentration was determined by the TNBS assay (*9*). PEI−Gal (Figure 1A) and PEI-Glc (data not shown) were prepared as previously described (*6*), except that PEI conjugates were purified by gel filtration (see above). The monosaccharide was unable to prevent particle aggregation in physiological saline conditions (Figure 1A) at PEI nitrogen to DNA phosphate ratios (*N*/*P*) of 3 and 5. Increasing the length of the grafted saccharide to 4 units (*l*Gal4 or *l*Glc4) led to the formation of smaller particles (Figure 1A), which were only slightly charged, as shown by ζ-potential measurements (Figure 1B). In these conditions, the particles were stable, indicating that the linear tetraglycosyl structure (*l*Gal4 or *l*Glc4) was able to prevent aggregation and masked the surface charge (Figure 1, panels A and B). This phenomenon occurred even at high *N*/*P* ratios (≥10). The *N*/*P* ratio slightly influenced the size of tetraglycosyl-PEI/DNA complexes in physiological saline conditions, in contrast to the size of DNA complexed with unmodified PEI, PEI−Gal or other PEI derivatives bearing peptides or proteins (*5*, *10*). The size and morphology of the PEI−*l*Gal4/DNA complexes were determined by negative staining transmission electron microscopy. A homogeneous population of essentially toroidal particles, with a size of 50−80 nm, was observed for *N*/*P* of 5 and 10 (Figure 1C).

We have shown that the terminal galactosyl residues on the PEI−*l*Gal4/DNA complexes were easily accessible and recognized by using a galactose-binding RCA_{120} lectin-mediated agglutination (Figure 2). The recognition

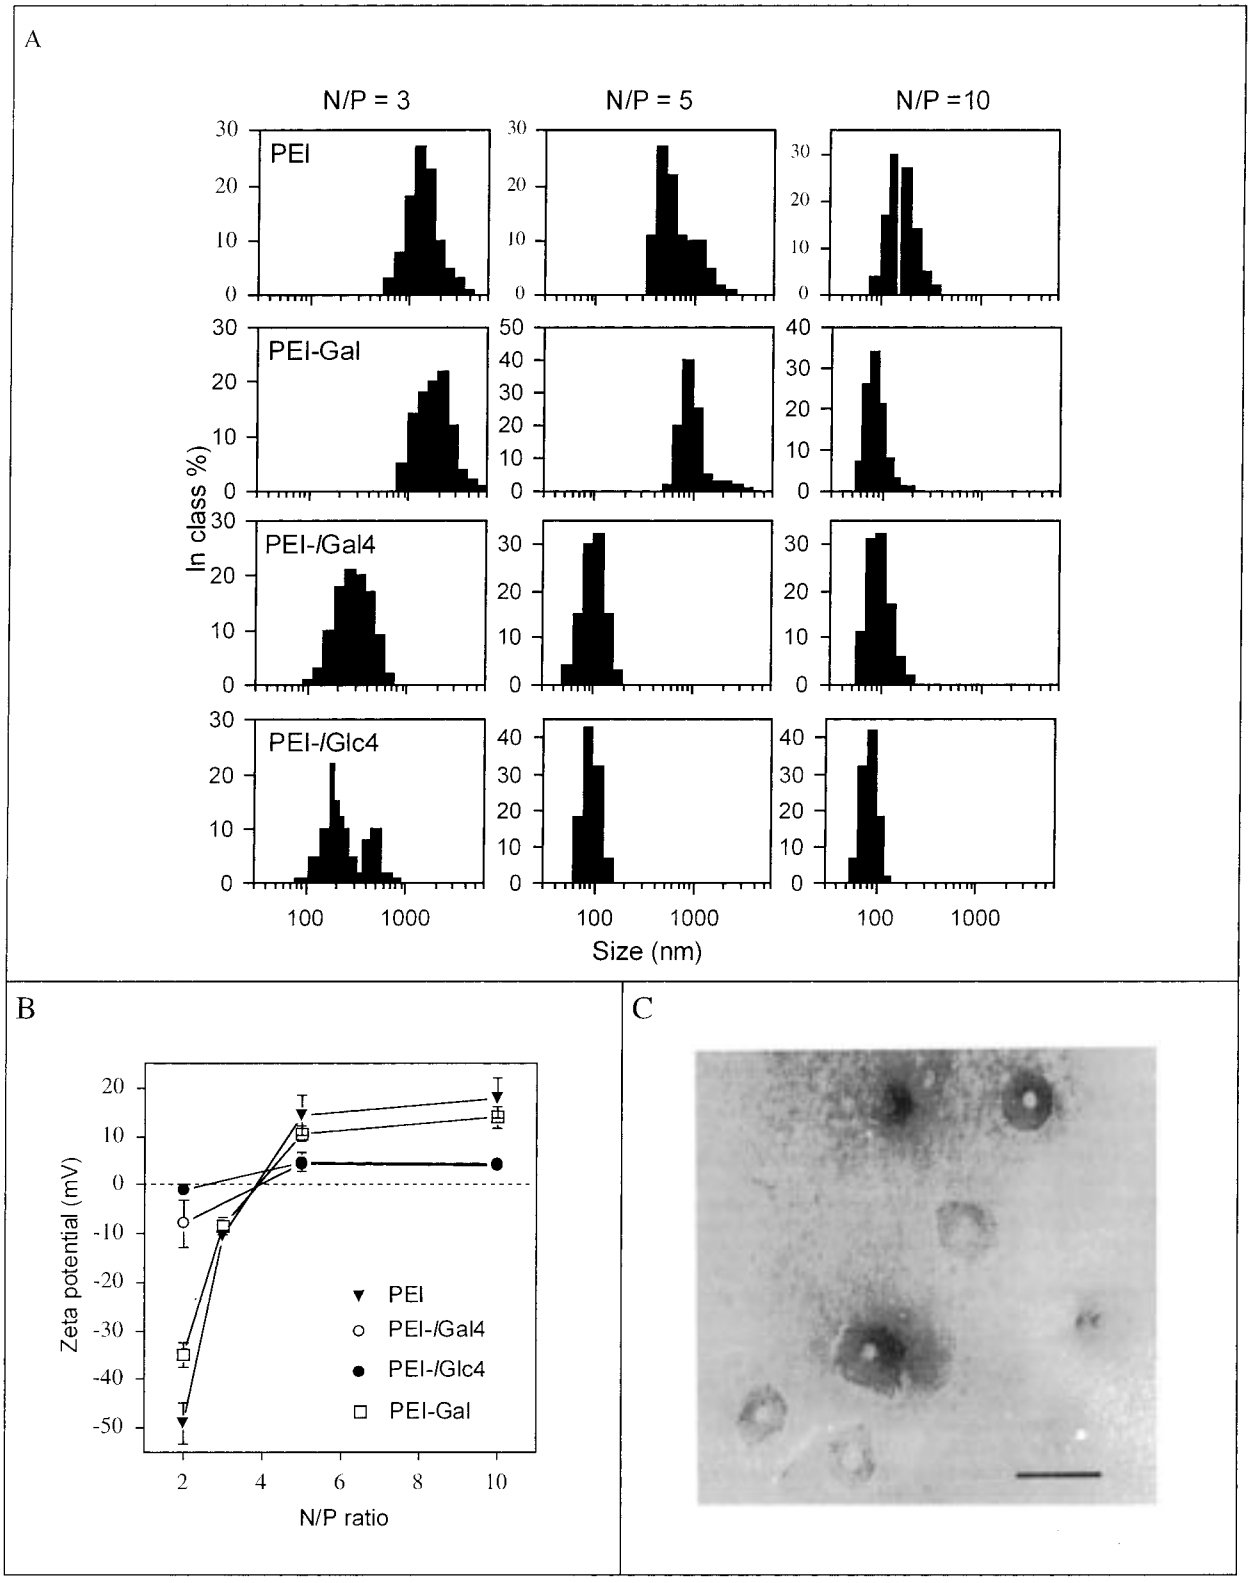

Figure 1. Particle size (A, C) and ζ-potential (B) measurements. DNA (40 μg of pCMVLuc) and the desired amount of glycosylated PEI or unmodified PEI were each diluted separately in 500 μL of a 150 mM NaCl solution. After 10 min, solutions were mixed, homogenized, and left for 10 min. Particle size (A) was determined by dynamic laser light scattering using a Zetamaster 3000 (Malvern Instrument, Orsay, France). ζ-Potential was measured electrophoretically using the same apparatus (B), as previously described (*15*). For transmission electron microscopy (C), a drop (5 μL) of a solution containing the PEI−*l*Gal4/DNA complexes ($N/P = 10$) was added to a carbon-covered grid and left for 1 min. Complexes were negatively stained with 30 μL of an aqueous uranyl acetate solution (1%, w/w), for 20 s. Observations were done at 80 kV on a Philips EM 410 transmission electron microscope, bar is 100 nm.

and agglutination of the PEI−*l*Gal4/DNA complexes by the RCA_{120} lectin were totally reversible after the addition of a 1000-fold molar excess of galactose. Moreover, a nonspecific agglutination mediated by electrostatic interactions was unlikely, as shown by the results obtained with the PEI and PEI−*l*Glc4/DNA complexes, at $N/P = 10$ (Figure 2). These biophysical and recognition properties of PEI−*l*Gal4/DNA complexes confirmed that the

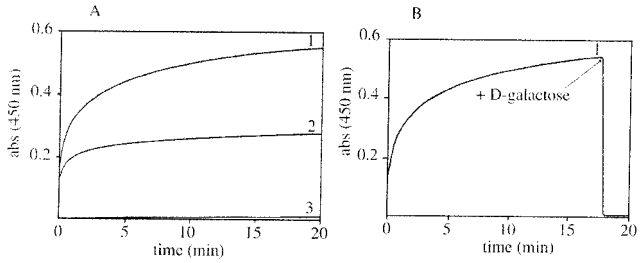

Figure 2. Accessibility of the galactosyl residues at the surface of the complexes. (A) PEI or PEI conjugates/pCMVLuc complexes (20 μg/mL DNA, protocol described in the legend of Figure 1) were incubated in the presence of *Ricinus communis* RCA_{120} lectin (90 μg/mL, Sigma) in 300 μL (total volume) of 10 mM phosphate buffer pH 7, 150 mM NaCl. Agglutination was monitored by following the turbidity at 450 nm, during 20 min. (1) PEI−*l*Gal4/DNA complexes at $N/P = 10$, (2) PEI−*l*Gal4/DNA complexes at $N/P = 5$, and (3) PEI or PEI−*l*Glc4/DNA complexes at $N/P = 10$. (B) The RCA-mediated agglutination of PEI−*l*Gal4/DNA complexes ($N/P = 10$) was reversible when D-galactose was added to a final concentration of 1 M.

glycosyl structures controlled the particle behavior and were exposed at their surface.

Transfections were performed in the presence of 10% serum and without the plate centrifugation step that generally leads to higher efficacies (*6*, *11*). Gene transfer efficiencies were evaluated on the BNL CL.2 murine hepatocyte cell line which expresses a galactose specific membrane lectin (*12*, *13*) and on the HeLa human epitheloid carcinoma cell line which does not express a galactose specific receptor (*14*). In both cases, unmodified PEI-mediated transfection efficiency increased with the *N*/*P* ratio (Figure 3), according to the ionic cell binding mechanism. The PEI−*l*Gal4/DNA complexes showed improved efficiency over PEI−Gal and PEI-mediated gene transfer on BNL CL.2 cells (receptor +), at all *N*/*P* ratios. When *l*Gal4 was replaced by *l*Glc4 motif, transfection efficiencies were comparable to those obtained with the unmodified PEI. On HeLa cells (receptor −), none of the vectors showed any evidence of a selective gene delivery (Figure 3). The differences in expression levels are probably related to differences in the size of particles and to a lesser extent to their surface charge, both important parameters for cellular uptake. At the optimal *N*/*P* ratio, competition experiments with an excess of asialofetuin (20-fold molar excess over galactose), the natural ligand of the asialoglycoprotein receptor, decreased the transfection efficiency of the PEI−*l*Gal4/DNA complexes by 1 order of magnitude on BNL CL.2 cells. In contrast, the transfection of BNL CL.2 cells with PEI or PEI−*l*Glc4/DNA complexes was (only) affected by 2.5 or 5-fold in the presence of asialofetuin or albumin, respectively. The involvement of the asialoglycoprotein receptor was clearly demonstrated by both comparative and competitive experiments showing that transfection of hepatocytes with small and slightly charged PEI−*l*Gal4/DNA complexes was selective and efficient.

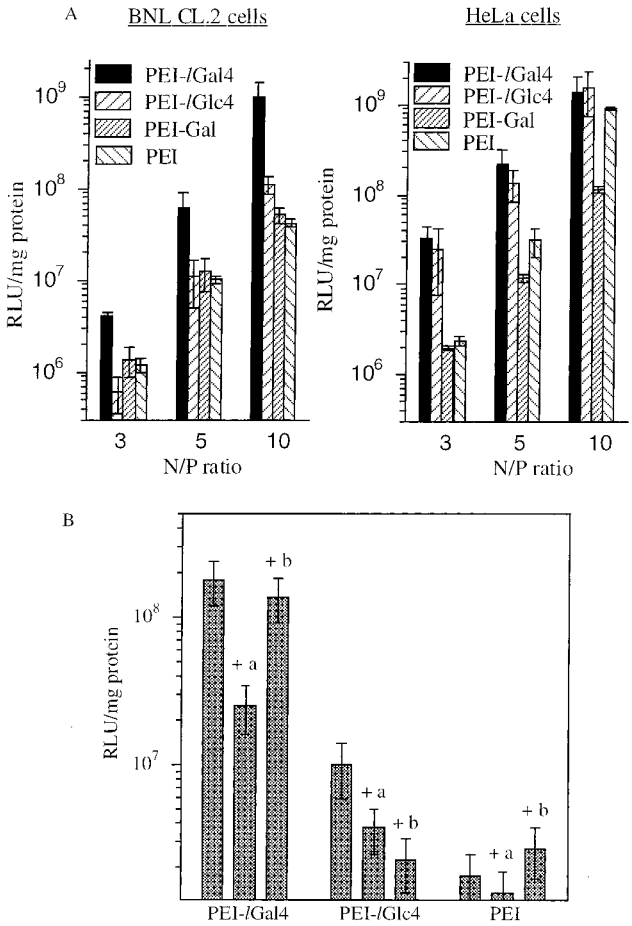

Figure 3. Transfection efficiency of the glycosylated PEI/DNA complexes on the BNL CL.2 murine hepatocyte and HeLa human epitheloid carcinoma cell lines. A day prior to transfection, (5−6) × 10^4 cells/well were seeded in 24 well tissue culture plates and were incubated at 37 °C in a 5% CO_2 humidified atmosphere. Before transfection, cells were supplemented with 1 mL of fresh complete medium containing 10% FCS (DMEM with high glucose (4.5 g/L) for BNL CL.2 and MEM with Earle's salt for HeLa cells). DNA (6 μg of pCMVLuc, for a triplicate experiment) and the desired amount of PEI or PEI conjugates were diluted separately in 150 μL of 0.15 M NaCl. After 10 min, the polycation was added to the DNA, the solution was homogenized and left for 10 min. The polycation/DNA complexes (100 μL/well) were added onto the cells. For the competition experiments, BNL CL.2 cells were transfected with pCMVLuc (1 μg) complexed with PEI−*l*Gal4, PEI−*l*Glc4 or PEI at $N/P = 10$. Before the addition of the polycation/DNA complexes onto the cells, 1 mg of asialofetuin (+a) or bovin serum albumin (+b) was added per well. After 24 h of incubation, cells were lyzed and luciferase gene expression was quantitated using a commercial kit (Promega) and a luminometer (Biolumat LB 9500, Berthold). Results were expressed as light units integrated over 10 s, per mg of cell protein using the BCA assay (Pierce). Values are the mean ± sd of three independent experiments made in triplicate.

ACKNOWLEDGMENT

We thank Jean-Paul Behr for his great interest in this work. T.B. and P.E. are recipient of a doctoral fellowship from the 'Ministère de l'Enseignement Supérieur, de la Recherche et des Technologies' (MESRT) and a postdoctoral fellowship from the 'Association pour la Recherche sur le Cancer' (ARC), respectively.

ARTICLES

Grafting Protein Ligand Monolayers onto the Surface of Microparticles for Probing the Accessibility of Cell Surface Receptors

Andreas Frey,* Barbara Meckelein, and M. Alexander Schmidt

Institut für Infektiologie, Zentrum für Molekularbiologie der Entzündung (ZMBE), Westfälische Wilhelms-Universität Münster, von-Esmarch-Strasse 56, D-48129 Münster, Germany. Received October 16, 1998; Revised Manuscript Received April 28, 1999

Coupling of a specific ligand to vaccines or drugs can be a powerful aid to route these compounds to a certain target cell population. However, if the targeted receptor is buried in a glycocalyx, binding of the ligand may be sterically hindered or even abolished, especially when the ligand is attached to bulky payloads. The antigen-transporting M cells that cover the gut-associated lymphoid tissue have a less pronounced glycocalyx than neighboring enterocytes. Such architectural differences might provide a possibility for targeting micro- or nanoparticulate vaccines to the mucosal immune system. To investigate the influence of the glycocalyx on the accessibility of cell surface receptors, we developed a system where a monolayer of ligand molecules is coupled in spatially aligned manner onto the surface of microparticles. On the basis of fluorescent carboxylate-modified particles of 1 μm diameter, different synthetic strategies were tested. Particles were first modified to display aldehyde functions on their surface, then protein ligands were coupled via Schiff base formation. The performance of the particles was tested on cultured mouse fibroblasts using the B subunit of cholera toxin as ligand and the plasma membrane glycolipid ganglioside G_{M1} as receptor. Cholera toxin B subunit-coated microparticles generated by one of our synthetic pathways exhibited specific binding to fibroblasts which could be blocked with soluble cholera toxin B subunit. As particles as small as 50 nm and any proteinaceous ligand may be used, this system provides a versatile means for monitoring receptor accessibilities in vitro and in vivo.

INTRODUCTION

Ligands which specifically bind to certain cell types are deemed proverbial "magic bullets" for delivering pharmaceuticals to their desired site of action. The concept of targeting a compound to a given cell type is of particular interest for the development of mucosal vaccines. The chief task of a mucosal vaccine is to induce a secretory immunoglobulin A response at the mucosal surfaces and thus intercept microbial pathogens in the run-up of infection (Kraehenbuhl and Neutra, 1992). Such a secretory immunoglobulin A response is induced only when the antigen is delivered to the mucosal immune system via the organized mucosa-associated lymphoid tissue, such as the Peyer's patches in the small intestine, the tonsils, and adenoids in the nasopharyngeal area or the appendix (Neutra et al., 1996b). At these sites, the antigen is taken up by M cells, a specialized epithelial cell type which is able to endocytose particulate antigens of up to 10 μm in diameter (Eldridge et al., 1989; Ermak et al., 1995) and translocate them to the underlying lymphoid tissue where an immune response is mounted (Kraehenbuhl and Neutra, 1992; Neutra et al., 1996b). M cells are therefore prime candidates for the targeted delivery of vaccines to the mucosal immune system. A major obstacle along that line, however, is the apparent lack of specific receptors on the apical M cell surface. No universal M-cell specific surface molecule has been identified as yet, and only a few cytoplasmic M cell markers have been described so far (Jepson et al., 1992; Gebert et al., 1994; Rautenberg et al., 1996). Nonetheless, M cells differ from the neighboring epithelial lining cells. For example, M cells lack an organized brush border and, in the gut, they display a less pronounced glycocalyx than the adjacent enterocytes (Kato, 1990; Gebert and Bartels, 1995; Frey et al., 1996; Neutra et al., 1996a). Consequently, plasma membrane receptors may be more accessible on M cells than on enterocytes. This opens up the possibility to target a ubiquitous receptor selectively on M cells simply because it may be shielded by the glycocalyx on neighboring enterocytes. We provided the proof of principle for this concept in a previous study in which we could demonstrate that binding of the B

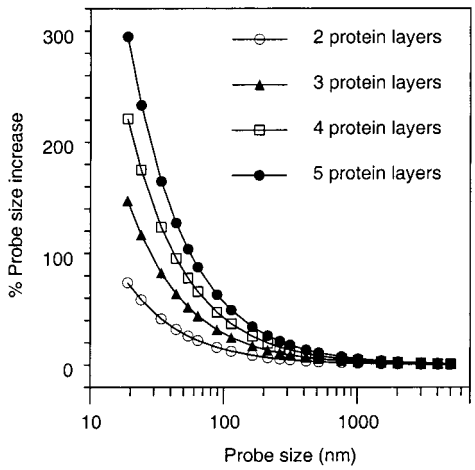

Figure 1. Influence of protein multilayers on probe size. Relative increase in total hydrodynamic diameter of a nano- or microparticulate probe caused by multilayers of an average protein (hydrodynamic diameter 7 nm) when compared to the hydrodynamic diameter of the same probe carrying a protein monolayer only.

subunit of cholera toxin (CTB)[1] to the plasma membrane glycolipid G_{M1} in the small intestine becomes M-cell specific when CTB is offered as a particulate probe of approximately 30 nm diameter (Frey et al., 1996). Soluble CTB of 7 nm hydrodynamic diameter bound ubiquitously, and CTB-coated particles exceeding 1 μm in diameter did not bind at all to the small intestinal epithelium. Consequently, there must be a size window in which selective ligand-mediated targeting of intestinal M cells is possible without the need for a specific receptor on the M-cell surface.

To define the exact size of this window, we were in demand of easy-to-detect, preferably fluorescent nanoparticulate probes on which a monolayer of proteinaceous ligands can be coupled covalently. The formation of a single ligand layer on the probe core is essential because the final probe size will be affected strongly by ligand multilayers or spikes consisting of ligand molecules which are coupled to each other (Figure 1).

Currently, there are only few companies who offer derivatizable fluorescent nanoparticles of a well-defined size. Most of these products carry carboxylate groups on their surface intended for attaching proteins via their amino functions by use of carbodiimides (Molday et al., 1975; Illum and Jones, 1985). A direct coupling of protein ligands to carboxylate-modified microparticles in the presence of carbodiimide cross-linker, however, also enables protein molecules to react with each other, thereby generating the undesired multilayers. We were therefore seeking alternative strategies in which the particles are preactivated such that they will react with ligand molecules without the need for additional cross-linkers.

In this report, we describe a system where a monolayer of proteinaceous ligands is coupled in a spatially aligned manner onto the surface of fluorescent microparticles. The resulting probes were shown to be versatile tools for assessing the accessibility of receptor molecules in complex biological settings.

MATERIALS AND METHODS

Materials and Cell Lines. Red and green fluorescent, carboxylate-modified microparticles of 1.0 μm nominal diameter (FluoSpheres) were from Molecular Probes Europe (Leiden, The Netherlands). These microparticles consist of a polystyrene core grafted with poly(acrylic acid) and acrylic acid. They possess a specific surface load of 0.1286 mequiv of carboxylate/g (corresponding to 7.76×10^{-14} mequiv of carboxylate/particle).

Cholera toxin B subunit (CTB) (low salt) was purchased from List Biological Laboratories (Campbell, CA; via Quadratech, Epsom, U.K.), avidin ($\geq$13.5 Units/mg) from Molecular Probes and chicken egg white ovalbumin (OVA) from Calbiochem-Novabiochem (Bad Soden, FRG). Biotinyl-3,6,9-trioxaundecanediamine (TEG-biotin) was obtained from Molecular Biosciences (Boulder, CO).

The BALB/c 3T3 fibroblast cell line clone A 31 was obtained from the American Type Culture Collection (Rockville, MD). Defined bovine calf serum (iron-supplemented) was from Hyclone (Logan, UT), Dulbecco's modified Eagle's medium (DMEM), glutamine, penicillin/streptomycin, and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (Hepes) were from PAA Laboratories (Linz, Austria). Round glass coverslips (13 mm diameter) were obtained from Bellco Glass (Vineland, NJ; via Dunn Labortechnik, Asbach, FRG).

Poly(vinyl formal) (Formvar 15/95) and 150 square mesh copper grids were purchased from Polysciences Europe (Eppelheim, FRG). Mowiol 4-88 was from Calbiochem-Novabiochem. FilterCount scintillation liquid was obtained from Canberra Packard (Dreieich, FRG), [^{14}C]ethanolamine was from Moravek Biochemicals (Brea, CA; via Hartmann Analytic, Braunschweig, FRG), and [^{14}C]biotin from Amersham Buchler (Braunschweig, FRG). Nitrocellulose filter membranes were from Schleicher & Schuell (Dassel, FRG). Micro BCA Protein Assay Reagent was from Pierce (Rockland, IL; via KMF, Sankt Augustin, FRG). Purpald and aminoacetaldehyde dimethylacetal were purchased from Aldrich (Deisenhofen, FRG). All other chemicals and solvents were from various sources in the highest quality commercially available.

Activation of Carboxylate-Modified Microparticles (1). A total of 1.29×10^9 carboxylate-modified microparticles (corresponding to 0.1 μmol of carboxylate groups according to the specific surface load given by the supplier) were washed twice by suspending in 1.8 mL of H_2O followed by two times 20 min centrifugation at 10000*g* and removal of the supernatant to less than 20 μL. The microparticles were suspended in 65 μL of H_2O before 100 μL of 10 mM 4-morpholinoethanesulfonic acid (MES)−NaOH, pH 6.0, 15 μL of 0.1 M *N*-hydroxysulfonylsuccinimide (S-NHS) (Staros et al., 1986), and 20 μL of 0.1 M 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) were added. The suspension was sonicated for 30 s in a Sonorex RK 510S sonifier (Bandelin Electronic, Berlin, FRG) and allowed to react for 20 min at room temperature (RT). The activated microparticles (**1**) were immediately used for the subsequent derivatization reactions without further purification.

Synthesis of Aldehyde-Derivatized Microparticles (2, 3). *Method A: via Aminoacetaldehyde Dimethylacetal*. To the suspension of activated microparticles (**1**) were added 200 μL of H_2O, 500 μL of 0.1 M Hepes−NaOH, pH 7.4, and 100 μL of 1 M aminoacetaldehyde dimethylacetal. The suspension was incubated for 16 h at RT in the dark on an end-over-end mixer rotating with 15 rpm. The particles (**2a**) were washed four times with 1.8 mL of H_2O each and resuspended in 1 mL of 1 M HCl. In some experiments, 0.1 M citric acid or 3.25 M TFA was used instead of 1 M HCl. The suspension was incubated for 4 h under rotation as described above, with 2×30 s sonication every 30 min. The aldehyde-deriva-

tized particles (**2**) were washed three times with 1.8 mL of H_2O and once with 1.8 mL of 50 mM Hepes−NaOH, pH 7.4.

Method B: via Ethylenediamine-Glutaraldehyde Bridge. To the suspension of activated microparticles (**1**) were added 200 μL of H_2O, 500 μL of 0.1 M Hepes−NaOH, pH 7.4, and 100 μL of 1 M ethylenediamine−HCl, pH 8. The suspension was incubated for 16 h under continuous rotation as described above. The particles (**3a**) were washed four times with 1.8 mL of H_2O each, suspended in 1 mL of 50 mM Hepes−NaOH, pH 7.4, and 0.1 M glutaraldehyde, sonicated 2 × 30 s, and rotated as described above for 4 h. The aldehyde-derivatized particles (**3**) were washed four times with 1.8 mL of H_2O and used immediately for subsequent coupling reactions.

Synthesis of Biotin-Derivatized Microparticles (4). To the suspension of activated microparticles (**1**) were added 275 μL of H_2O, 500 μL of 0.1 M Hepes−NaOH, pH 7.4, and 25 μL of 20 mM TEG-biotin. The suspension was incubated for 16 h under continuous rotation, and the biotinylated particles (**4**) were washed four times with 1.8 mL of H_2O as described above.

Protein Coupling to Aldehyde-Derivatized Microparticles. For the protein coupling reaction, 1.29×10^9 aldehyde-derivatized microparticles (**2** or **3**) were suspended in 500 μL of 0.1 M Hepes−NaOH, pH 7.4, and, in case of avidin coupling reactions, 100 μL of 5 M NaCl. To this suspension, 176 μL of 0.5 mg/mL (8.6 μM) CTB (1.51 nmol) or 88 μL of 1 mg/mL (22.2 μM) OVA (1.96 nmol) or 116 μL of 1 mg/mL (14.7 μM) avidin (1.70 nmol) were added, and the volume was adjusted to 1 mL with H_2O. The suspension was rotated at 4 °C for 1 h, then 50 μL of 1 M $NaCNBH_3$ was added, and the incubation was continued for 36 h under continuous rotation at 4 °C. The particles were washed three times with 1.8 mL of 10 mM Hepes−NaOH, pH 7.4, 0.2 M NaCl (avidin-derivatized particles: once with 10 mM Hepes−NaOH, pH 7.4, 0.2 M NaCl, twice with 250 mM sodium carbonate, pH 9.5, 0.5 M NaCl), with at least 30 min rotation at 4 °C for each washing step. For blocking of the remaining free aldehyde functions, the particles were suspended in 1 mL of 50 mM Hepes−NaOH, pH 7.4, containing 0.1 M ethanolamine (or 0.1 M glycine) and 50 mM $NaCNBH_3$, before they were incubated under continuous rotation at 4 °C for 16 h, washed three times with 1.8 mL of 10 mM Hepes−NaOH, pH 7.4, and stored in this buffer at 4 °C in the dark.

Determination of Maximum Ligand Load. The maximum number of protein molecules that can be bound to one individual microparticle in a monolayer was estimated with a model which assumes tight packing of globular protein molecules on the surface of a spherical core (Frey et al., 1996). The maximum ligand load in a protein monolayer is then given by eq 1:

$$n_{\text{molecules}} = \frac{2\pi}{\sqrt{3}}\left(\frac{d_{\text{particle}}}{d_{\text{protein}}} + 1\right)^2 \qquad (1)$$

where d_{particle} is the diameter of the microparticle and d_{protein} is the hydrodynamic diameter of the ligand. To determine the hydrodynamic diameters of CTB, avidin, and OVA, the respective diffusion coefficients were measured by dynamic light scattering as described before (Frey et al., 1996) and the hydrodynamic diameters d_h were calculated with the Stokes−Einstein eq 2:

$$d_h = \frac{2kT}{6\pi\eta D} \qquad (2)$$

Table 1. Maximum Protein Load of 1 μm Microparticle

protein	diffusion coefficient[a] (10^{-13} m^2/s)	diameter[b] (nm)	load[c] (molecules/particle)
CTB	634 ± 22	7.4	71 000
avidin	662 ± 17	7.0	80 000
ovalbumin	679 ± 6	6.4	92 000

[a] Diffusion coefficient at 24 °C in PBS as determined by dynamic light scattering. Data represent mean ± standard deviation of at least six independent experiments. [b] Hydrodynamic diameters were calculated from the mean diffusion coefficients using the Stokes−Einstein equation (see text). [c] The maximum number of protein molecules in a monolayer on the surface of one individual microparticle (diameter = 1030 nm) was calculated using eq 1 (see text).

where k is the Boltzmann constant, T is the absolute temperature, η is the viscosity of water, and D the diffusion coefficient. The diameter of the microparticles (1030 nm ± 2.3%) was provided by the manufacturer. The maximum ligand load for the proteins on the microparticles used in this study is given in Table 1.

Analytical Procedures. *Electron Micoscopy.* Carboxylate-modified microparticles were washed three times, suspended in H_2O to a concentration of 5×10^4 particles/μL, and sonicated for 30 s. Of these suspensions, 20 μL was placed on a Formvar-coated copper grid and allowed to settle for 90 min. Particles were contrasted with 4% (w/v) $U(OAc)_2$ for 2 min and photographed at 38000× and 69000× magnification in a Philips 401 transmisson electron microscope (Philips Electron Optics, Eindhoven, The Netherlands).

Determination of Coupling Yields. To determine the maximum number of derivatizable functional groups, 1.29×10^9 carboxylate-modified microparticles were activated with EDC and S-NHS to yield the active ester (**1**) as described above and incubated in 1 mL 50 mM Hepes−NaOH, pH 7.4, containing 2 mM/0.8 μCi/mL [^{14}C]-ethanolamine for 16 h at RT under continuous rotation. For quantitation of the product (**5**), aliquots of the reaction suspension were filtered through a glass frit equipped with a BA 85 nitrocellulose filter membrane (0.1 μm pore size) and washed extensively with 0.2 M NaCl under continuous suction. The filter membranes were air-dried, transferred into scintillation vials, and counted in a Beckman LS 6000 scintillation counter (Beckman, Fullerton, CA) 2 h after addition of 5 mL of FilterCount scintillation liquid.

The yields of acetal-derivatized (**2a**) and biotin-derivatized (**4**) particles were determined indirectly by coupling [^{14}C]ethanolamine to residual unreacted carboxylate groups in the presence of EDC and S-NHS as described above.

To determine the yield of aldehyde functionalization, the particles (**2**, **3**) were incubated at RT under continuous rotation in 1 mL of 50 mM Hepes−NaOH, pH 7.4, containing 2 mM/0.8 μCi/mL [^{14}C]ethanolamine. After 1 h of incubation, 2 μmol of $NaCNBH_3$ was added, and the incubation was continued for 16 h under rotation. The amount of radiolabel bound to the particles was determined as described above.

Determination of Protein Derivatization Yields. To determine the protein derivatization of microparticles in analytical assays, 1.29×10^9 microparticles either activated with EDC and S-NHS (**1**), or after aldehyde (**2**, **3**) or biotin derivatization (**4**) were incubated in 1 mL of 50 mM Hepes−NaOH, pH 7.4, 0.5 M NaCl, and 5 μM (5 nmol) avidin for 36 h at 4 °C under rotation. The particles were washed once with 10 mM Hepes−NaOH, pH 7.4,

0.2 M NaCl, and twice with 250 mM sodium carbonate, pH 9.5, 0.5 M NaCl. The avidin-derivatized particles (**6**, **7**, **8**, or **9**) were suspended in 1 mL of 50 mM Hepes−NaOH, pH 7.4, 5 μM/0.27 μCi/mL [^{14}C]biotin and incubated, processed, and counted as described above.

The protein load of particles derivatized with CTB, OVA, and avidin was also determined with the Micro BCA Protein Assay. The assay protocol provided by the supplier was modified to allow for determination of protein bound covalently to a particulate carrier (Stich, 1990). Suspensions of 1×10^9 particles in 500 μL of 10 mM Hepes−NaOH, pH 7.4, were mixed with 500 μL of Micro BCA working solution and incubated at 50 °C under continuous rotation (180 rpm) for 60 min. The suspensions were quickly cooled to 4 °C and centrifuged at this temperature for 10 min at 14000*g*. The supernatants were removed and their optical density at 562 nm was determined immediately. Protein solutions of known concentration were treated identically to the samples and used as standards.

Acetaldehyde Dimethylacetal Cleavage and Purpald Assay. Acetaldehyde dimethylacetal (final concentration 2 mM) was incubated for 2 h at RT in the following solutions: 3.25 M TFA (pH <0), 1 M HCl (pH 0); 0.1 M oxalic acid (pH 1.4); 0.1 M citric acid (pH 2.1); 0.1 M citric acid-NaOH (pH 2.5; pH 3.0; pH 3.5; pH 4.0; pH 5.0); 0.1 M MES−NaOH (pH 6.5); 0.1 M sodium phosphate (pH 7.0; pH 8.3). The amount of aldehyde released was determined spectrophotometrically (Watanabe et al., 1978) using acetaldehyde as standard. To 100 μL of the standard or the acetal reaction mixture were added 200 μL of 5 N NaOH and 150 μL of 5 mg/mL 4-amino-3-hydrazino-5-mercapto-1,2,4-triazole (Purpald) in 0.5 N HCl. The mixture was incubated for 20 min at RT, 150 μL of 7.5 mg/mL KIO_4 was added under vigorous shaking, and the absorbance at 550 nm was determined immediately.

Binding of Microparticles to BALB/c 3T3 Fibroblasts. BALB/c 3T3 fibroblasts were grown in high glucose (25 mM) DMEM supplemented with 10% (v/v) calf serum, 2 mM glutamine, 100 units/mL penicillin/100 μg/mL streptomycin, 25 mM Hepes, and 3.7 g/L $NaHCO_3$ at 37 °C in a humidified atmosphere containing 10% (v/v) CO_2. For particle-binding studies, the cells were seeded onto round glass cover slips in 24-well tissue culture plates and used on days 20−22 (=14−16 days post confluence). The cells were washed gently four times with 2 mL of prewarmed (37 °C) phosphate-buffered saline (PBS) containing 0.9 mM $CaCl_2$ and 0.5 mM $MgCl_2$, before 500 μL of DMEM containing a 1:1 mixture of 2.5×10^7 particles/mL each of CTB particles (or avidin particles) and OVA particles (in different color) were added. For competition with soluble CTB, cells were preincubated with 250 μL of 20 μg/mL CTB in DMEM for 15 min at 37 °C before 250 μL of a 1:1 mixture of 5×10^7 particles/mL each of CTB particles and OVA particles were added. After incubation for 60 min at 37 °C, the cells were washed again as above and fixed in 1 mL of 3% (w/v) *p*-formaldehyde in PBS for 90 min at RT in the dark. The coverslips were washed three times in PBS and once in H_2O and mounted on glass slides with Mowiol containing 2.5% (w/v) 1,4-diazabicyclo-[2.2.2]octane. Cell layers were examined and photographed en face with a Zeiss Axiophot microscope equipped for epifluorescence (Zeiss, Jena, FRG).

Data Collection and Statistical Analysis. For quantitative analysis of microparticle binding to the fibroblast monolayers, four randomly selected nonoverlapping regions of each coverslip were photographed with the Zeiss Axiophot microscope connected to an Intas Seescan Color LC 100C low light camera system (Intas, Göttingen, FRG) consisting of a Sony XC-003P Color Video Camera Module and a Seescan LC 100C control unit. Photographic documentation of microparticle binding was done with Kodak T-Max 400 film. Digitalized images were processed on a Power Macintosh G3 (Apple, Cupertino, CA) using Adobe Photoshop 4.0 (Adobe Systems, San Jose, CA) and Claris Draw 1.0v4 (Apple) software, printed on a HP Laserjet 4000 TN (Hewlett-Packard, Palo Alto, CA) and counted manually. Statistical analysis of particle binding and coupling yields was carried out with the StatView 4.5 program package (Abacus Concepts, Berkeley, CA). Mixed probes of test and control particles were considered paired samples, and the results of independent experiments were treated as unpaired samples. Results were considered significant only if $p < 0.05$.

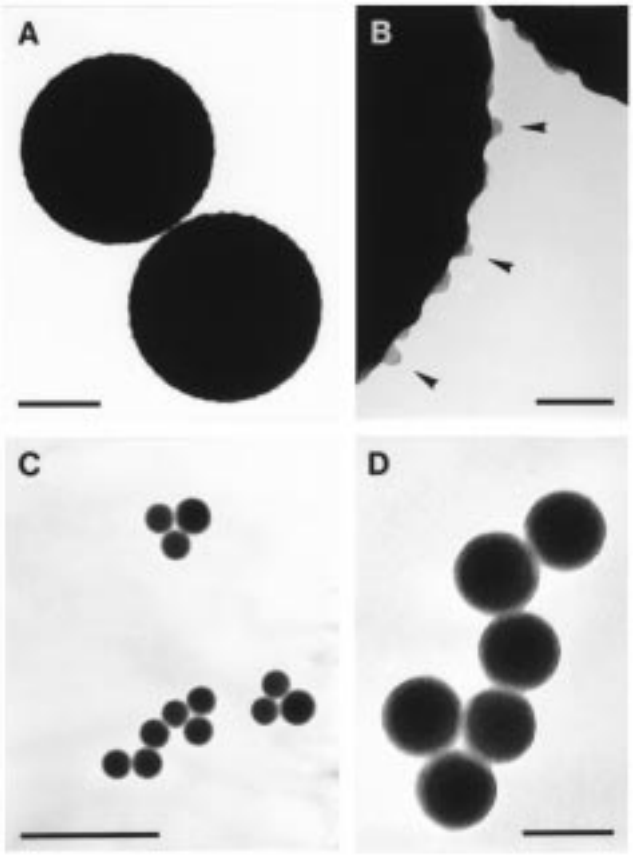

Figure 2. Electron microscopic analysis of carboxylate-modified particles. Particles of 1 μm (A, B) and 100 nm (C, D) nominal diameter were analyzed by transmission electron microscopy. While the majority of all 1 μm particles analyzed had small protrusions on their surface (B, arrowheads), 100 nm particles displayed a smooth surface texture (D). Bar, 400 nm (A, C), 100 nm (B, D).

RESULTS

Analysis of the Shape and Surface Texture of Carboxylate-Modified Microparticles. A uniform population of the core particles is a prerequisite for obtaining ligand-coated probes of well-defined size. For that reason, the red- and green-fluorescent carboxylate-modified microparticles were analyzed by transmission electron microscopy (Figure 2). The 1 μm particles were highly spherical in shape, but consisted of two subpopulations with respect to their surface texture. Approximately 20% of all red-fluorescent and 5−10% of all green-fluorescent

[a] Carboxylate-modified polystyrene microparticles (diameter 1030 nm) were incubated with different chemicals for indicated times and analyzed visually (under the fluorescent microscope) for their integrity. [b] Particles tend to coagulate at acidic pH, but become again fully dispersed after neutralization and sonication. [c] Analyzed with Purpald.

particles analyzed by electron microscopy exhibited a smooth surface. The majority of all particles showed tiny, bell-shaped protrusions extending up to 20 nm from the spherical particle core (Figure 2, panels A and B). These protrusions clearly do not have any significant impact on the diameter of the 1 μm particles and, hence, the final probe size, but their presence must be taken into account when the particle surface is considered.

However, protrusions of this size would greatly influence the overall probe size of nanoparticles (see Figure 1). We therefore examined fluorescent, carboxylate-derivatized particles of 100 and 200 nm nominal diameter provided by the same supplier. Transmission electron microscopy at 38000× and 69000× magnification did not reveal any protrusions on the surface of the 200 nm and 100 nm particles (Figure 2, panels C and D). Thus, all particles examined in this study were suited for the development of size-defined ligand-coated fluorescent probes.

Derivatization of Fluorescent, Carboxylate-Modified Microparticles with Protein Monolayers. The demand for a ligand monolayer on the particle surface ruled out the use of carbodiimide-type cross-linkers in a one-pot reaction as proteinaceous ligand molecules may also get linked to each other. To overcome this problem, the particles had to be activated such that they displayed protein-reactive groups on their surface and then reacted with an excess of ligand molecules.

The polystyrene nature of the microparticle core precluded a synthetic procedure in organic solvents, even in lower alcohols (Table 2). Hence, reaction conditions were evaluated, which allowed particle activation and protein coupling in an aqueous system. Initial attempts to isolate N-hydroxysuccinimide or N-hydroxybenzotriazole esters of the particles before reacting them with a ligand resulted in very low yields (<2%) when tested with ^{14}C-labeled ethanolamine. Furthermore, satisfactory separation of the 1 μm particles from reactants was achieved only after several centrifugation steps consuming at least 40 min. Analogous procedures with smaller particles are anticipated to be even more time consuming and hence to lead to a substantial loss of the active ester by hydrolysis. This approach was therefore not pursued further. Subsequent experiments to generate an aldehyde derivative by oxidative fission of aminopropanediol that was coupled onto the particles failed as well because periodate caused damage to the particles, liberating some Purpald-reactive substance from the parent particles already.

Thus, alternative approaches to introduce aldehyde functions onto the particle surface were developed (Scheme 1). Activated carboxylate groups (**1**) were reacted in situ either with aminoacetaldehyde dimethylacetal followed by acidic cleavage of the protection group yielding **2**, or with ethylenediamine and glutaraldehyde resulting in **3**. Proteins were then reacted with the aldehyde functions under reducing conditions (**7**, **8**). In a completely different approach, a strategy via a biotin−avidin bridge was pursued (Scheme 1). First TEG-biotin was coupled to activated carboxylate groups yielding **4**, followed by binding of avidin to the biotin-derivatized microparticles (**9**). The resulting avidin-monolayer may serve as an anchor for any biotinylated ligand molecule. For comparison, direct coupling of avidin to carboxylate-modified microparticles in the presence of a carbodiimide cross-linker was also performed (**6**).

The efficacy of the individual pathways was evaluated by reacting [^{14}C]ethanolamine with each of the active intermediate compounds. Direct coupling to the active ester **1** showed that only approximately 14% of all carboxylate functions could be derivatized under these conditions (Table 3). After biotin derivatization, this value was reduced to 1.96 ± 0.22%, indicating that TEG-biotin had reacted with the majority of all accessible carboxylate groups. Derivatization of the carboxylate-modified microparticles with acetaldehyde dimethylacetal and subsequent determination of unreacted carboxylate functions gave a comparable result. After acidic cleavage of the acetal protection group, however, binding of ethanolamine to the aldehyde-modified microparticles occurred only with very low yields (Table 3). We therefore tried to optimize the reaction for the acetal cleavage of compound **2a** by assaying the aldehyde release from acetaldehyde dimethylacetal in the presence of different acids and at various pHs (Figure 3). Under all conditions applied in our synthesis (0.1 M citric acid, 1 M HCl, and 3.25 M TFA), aldehyde was released completely from the acetal in solution. In the heterogeneous reaction system involving the microparticles, however, yields could not be increased further even if incubation was prolonged (>12 h) or elevated temperatures (55 °C) or intense ultrasound treatment (2 × 30 min) were applied.

Nevertheless, the relatively low yield of aldehyde groups generated via both pathways was considered to be sufficient for the coupling of proteins, since a protein monolayer on the surface of 1 μm particles consists of only 70000−90000 protein molecules/microparticle, corresponding to 0.15−0.2 nmol of protein/0.1 μmol of

Scheme 1. Conjugation of Protein Monolayers onto Carboxylate-Modified Microparticles

conjugate	cleavage of aldehyde protective groups	% carboxylate functions activated
1	na	14.1 ± 2.7[b]
2	0.1 M citric acid	<2 (~0.0)
2	1 M HCl	<2 (~1.1 ± 0.4)
2	3.25 M TFA	2.4 ± 0.2[b]
3	na	<2 (~1.1 ± 0.3)
4	na	12.1 ± 2.7[b,c]

[a] Results refer to experiments with red-fluorescent carboxylate-modified microparticles (diameter 1030 nm). Each experiment was carried out at least in triplicate. Results are given as means ± standard deviation. [b] Yields differ significantly from nonspecific background binding ($p < 0.02$, two-tailed Student's unpaired *t*-test). [c] Yield determined indirectly; for details see text. na: not applicable.

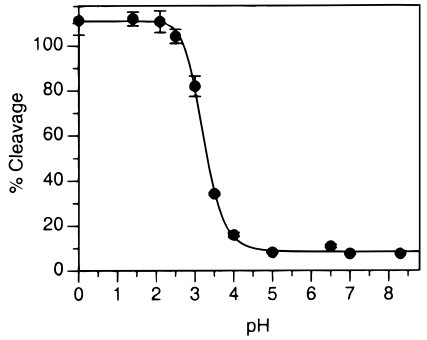

Figure 3. pH Dependence of acetal cleavage. Acetaldehyde dimethylacetal was incubated at different pH values, and the relative amount of aldehyde released was determined by Purpald assay. Data represent mean ± standard deviation of two independent experiments.

carboxylate functions (Table 1). For analytical purposes, the S-NHS/EDC/particle reaction mixture (**1**) and aldehydes **2** and **3**, as well as the biotinylated particles **4** were reacted with a 30-fold molar excess of avidin (relative to the protein amount sufficient to fill a complete monolayer) and coupling yields were determined by binding of [^{14}C]biotin (Table 4). A virtually complete avidin monolayer could be obtained with the aldehyde-derivatized particles generated either via aminoacetaldehyde dimethylacetal coupling followed by HCl cleavage or by an ethylendiamine−glutaraldehyde bridge. The binding of avidin via the TEG-biotin bridge was less efficient. As expected, direct coupling of avidin in the presence of EDC and S-NHS lead to the generation of multiple protein layers and/or multimeric avidin chains on the surface of the carboxylate-modified microparticles.

For the preparation of protein-coated microparticles, aldehyde-derivatized particles **2** (generated via HCl cleavage) and **3** were reacted with a 10-fold molar excess of CTB, OVA, or avidin. To reduce nonspecific reactions of remaining free aldehyde functions, the particles were finally incubated under reducing conditions with excess

Table 4. Avidin Binding to Surface-functionalized Carboxylate-Modified microparticles[a]

conjugate	cleavage of aldehyde protective groups	nmol of [^{14}C]biotin per 100 nmol carboxylate groups[b]	nmol of avidin[b,c] per 100 nmol carboxylate groups	% avidin monolayer formed[d]

[a] Results refer to experiments with red-fluorescent carboxylate-modified microparticles (diameter 1030 nm). Each experiment was carried out at least in triplicate. Results are given as means ± standard deviation. [b] Corrected for nonspecific background binding. Nonspecific adherence of avidin to nonactivated carboxylate-modified particles resulted in binding of 0.096 ± 0.017 nmol [^{14}C]biotin corresponding to 0.024 ± 0.004 nmol of avidin/100 nmol of carboxylate groups. [c] Assuming three accessible biotin binding sites per avidin molecule on compound 9 particles, four accessible biotin binding sites per avidin molecule on all other particles. [d] Calculated by using eq 1. [e] Significantly different from nonspecific background binding ($p < 0.005$, two-tailed Student's unpaired *t*-test). na, not applicable.

ethanolamine, introducing a hydrophilic function in addition to the secondary amine, or with excess glycine, which results in a zwitterionic blocking group.

To compare the protein coupling efficiency in the preparative reactions with the previous analytical setups, the protein load of various microparticle preparations was analyzed using the Micro BCA Protein Assay in a suspension reaction. Avidin coupling to red-fluorescent, aldehyde-derivatized particles in the preparative set up lead to the formation of a 89 ± 20% filled monolayer which is not statistically different from the value obtained in the analytical coupling procedure (94 ± 1%, as determined by [^{14}C]biotin binding). Coupling of CTB to red- and green-fluorescent microparticles by the same procedure resulted in a 93 ± 9% filled monolayer, while ovalbumin yielded a 33 ± 17% filled monolayer.

Binding of Protein-Coated Microparticles to Cultured BALB/c 3T3 Fibroblasts. To assess the biological functionality of our ligand-coated particles, we used fluorescent CTB-coated 1 μm particles to probe the accessibility of the plasma membrane receptor ganglioside G_{M1} on cultured BALB/c 3T3 fibroblasts, a cell line known to express ample amounts of receptor (Critchley et al., 1982) and to display a rudimentary glycocalyx only (Bailey and Gingell, 1988). In all experiments, confluent live 3T3 cell monolayers grown on glass coverslips were exposed to a 1:1 mixture of 2.5×10^7 particles for 1 h at 37 °C. CTB particles of two colors (red and green) generated via both synthetic pathways (via aldehyde **2** or **3**) and blocked with different aliphatic amines (ethanolamine and glycine) were examined in separate experiments. OVA particles of the respective other color served as internal background binding control (Figure 4, panels A−C). To verify the specificity of the binding, CTB particle binding was competed with 10 μg/mL soluble CTB (Figure 4, panels D−F).

Ethanolamine-quenched CTB particles generated via aminoacetaldehyde dimethylacetal coupling and HCl cleavage bound in a significantly higher number to the fibroblasts than did the respective OVA particles (Student's paired *t*-test, $p < 0.0001$) (Figure 5A). A total of 3.2 times (green particles) to 4.9 times (red particles) more CTB particles than OVA particles adhered to the confluent cell layers. By competition with soluble CTB, binding of red CTB particles could be reduced to 1.7 times that of the green OVA particles, while binding of green CTB particles did no longer differ from binding of red OVA particles (Figure 5A). Particles which had been synthesized by the same procedure but quenched with glycine showed similar binding characteristics (Figure 5A).

We also studied the binding behavior of avidin particles synthesized via the acetal route. Those particles exhibited

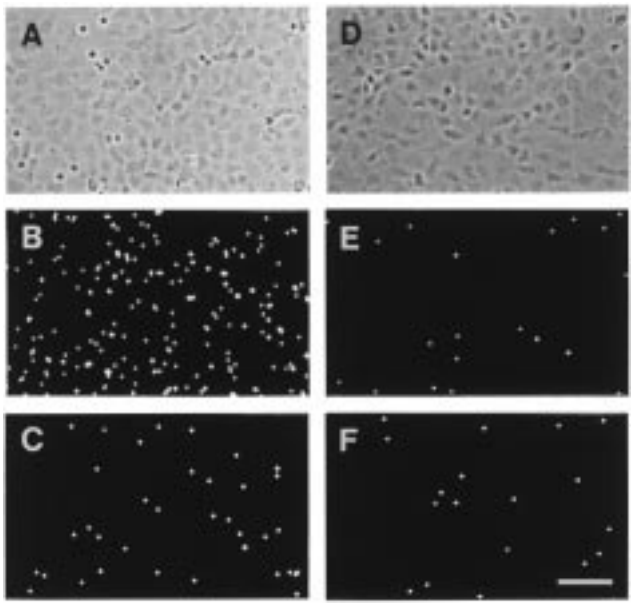

Figure 4. Binding of CTB particles to BALB/c 3T3 fibroblasts. Carboxylate-modified 1 μm particles were derivatized via aminoacetaldehyde dimethylacetal coupling and HCl cleavage and reacted with either CTB or OVA. Remaining aldehyde groups were quenched with ethanolamine/$NaCNBH_3$. BALB/c 3T3 fibroblasts grown on glass coverslips were incubated with 2.5×10^7 particles/mL each of red-fluorescent CTB particles and green-fluorescent OVA particles in the absence (A−C) or presence (D−F) of soluble CTB. Identical fields of the cell layers were photographed en face under phase contrast (A, D), under red fluorescence to visualize adherent CTB particles (B, E) and under green fluorescence to visualize adherent OVA particles (C, F). Bar, 100 μm.

a very strong binding to 3T3 fibroblasts, with 4.8−6.9 times more avidin than OVA particles bound (Figure 5B).

The binding of microparticles derivatized via the glutaraldehyde route was analyzed as well. Regardless of their protein load, all particles of this type showed a very high unspecific binding to 3T3 fibroblasts. Here, OVA particles bound approximately to the same extent as CTB particles (Figure 5B) which in turn bound as well (green particles) or even better (red particles) than those generated via the acetal pathway. Moreover, binding of CTB particles could not be reduced by competition with soluble CTB.

We also investigated whether the binding of the protein-coated microparticles (generated via the acetal pathway) was influenced by fluorophor color. Differences between the binding of red and green particles were detectable only when particle binding was low (less than 500 particles/mm^2). Significantly less green OVA particles

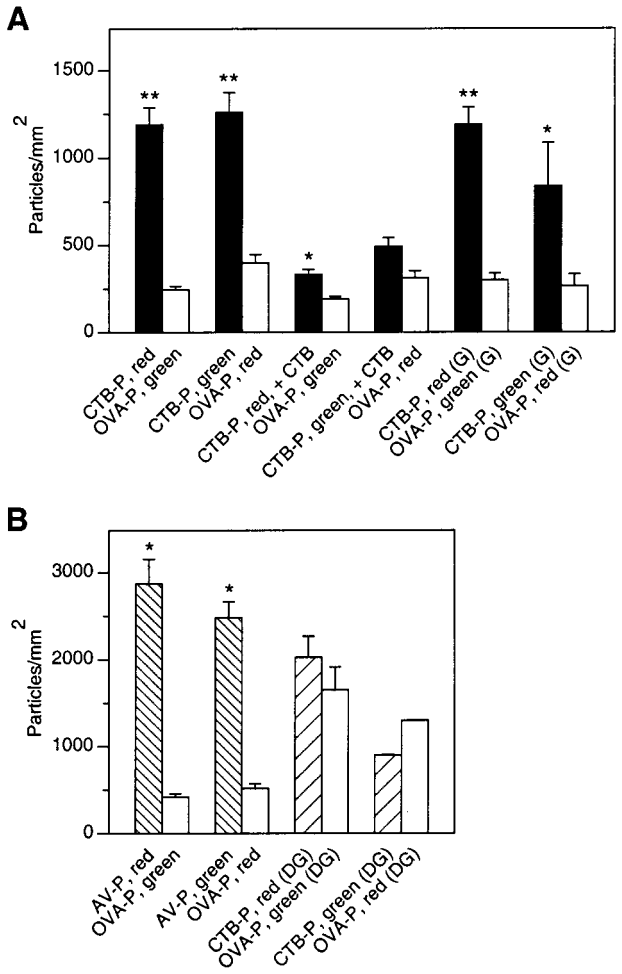

Figure 5. Quantitative analysis of microparticle binding to BALB/c 3T3 fibroblasts. BALB/c 3T3 fibroblasts grown on glass coverslips were incubated with 2.5×10^7 particles/mL each of CTB particles (CTB-P) (or avidin particles, AV-P) and OVA particles (OVA-P). Competition was done by addition of 10 μg/mL soluble CTB (+CTB). Bound particles were quantitated as described in Materials and Methods. Each bar represents the mean value and standard error of at least 3 independent experiments. (DG) Aldehyde particles synthesized via ethylenediamine and glutaraldehyde coupling, quenched with ethanolamine; (G) aldehyde particles synthesized via aminoacetaldehyde dimethylacetal coupling and HCl cleavage, quenched with glycine; (all others) aldehyde particles synthesized via aminoacetaldehyde dimethylacetal coupling and HCl cleavage, quenched with ethanolamine. (Asterisks) Binding significantly higher than that of the respective OVA particles [Student's paired *t*-test, $p < 0.001$ (two asterisks) or $p < 0.05$ (one asterisk)].

bound to the fibroblasts than red OVA particles, while in competition experiments with soluble CTB, less red CTB particles bound than green CTB particles (Student's unpaired *t*-test, $p < 0.02$). These differences became unsignificant for the binding of CTB particles (in the absence of competing soluble CTB) and of avidin particles, where high binding rates to fibroblasts were observed (more than 1000 particles/mm^2).

Taken together, we could demonstrate that carboxylate-modified microparticles which were aldehyde-derivatized by aminoacetaldehyde dimethylacetal-coupling and acid-deprotection bind protein ligands in a way that preserves their biological function. In addition, these probes show a low nonspecific binding which makes them useful tools to analyze the accessibility of cell surface receptors.

DISCUSSION

Affinity and specificity of ligand−receptor interactions are analyzed for the most part in biochemical or histological assays which assume a sterically unhindered contact, with affinities and specificities being solely due to endogenous features of the reaction partners themselves. However, the mere capacity to interact is a necessary but not always sufficient requirement for successful binding. In living systems, cell surface molecules were shown to modulate cell−cell binding by shielding certain receptor molecules (Manjunath et al., 1993; Wesseling et al., 1996) while other molecules evolved into rigid spikes which are purposely exposed to facilitate a certain type of interaction (Patel et al., 1995). The totality of the carbohydrate-rich cell surface molecules which form a continuous coat that covers the cell membrane, collectively termed glycocalyx, extends from 5 nm on erythrocytes (Linss et al., 1991) up to 1000 nm on intestinal epithelial lining cells (Frey et al., 1996; Neutra et al., 1996a). In a recent study, we could demonstrate that it might be possible to utilize such differences in the glycocalyx structure for targeting mucosal vaccines to Peyer's patch M cells (Frey et al., 1996). Plasma membrane ganglioside G_{M1}-specific CTB-probes of 30 nm diameter bound selectively to M cells, while soluble CTB of 7 nm diameter exhibited ubiquitous binding to the epithelium, and CTB probes of 1 μm diameter did not bind at all. To further define the size window for this M-cell tropism, we now have developed a conjugation procedure which enables us to synthesize CTB probes of a well-defined size range on the basis of commercially available fluorescent carboxylate-modified micro- and nanoparticles as a tool to probe the pore size and nanoarchitecture of the glycocalyx.

The key feature of this method is the controlled grafting of no more than one layer of ligand molecules onto the particle surface. Most current protocols for coupling proteins on microparticles are set up as one-pot reactions in which the protein is conjugated onto the particle by use of carbodiimides (Molday et al., 1975; Illum and Jones, 1985), conditions under which we observed the formation of protein multilayers. The main problem with those multilayers is that they are sterically undefined. Some areas of the particle may display the desired monolayer while in other regions multiple ligand molecules may be linked to each other forming thicker coats or even spike-like structures extending from the surface. Such an irregular, hairy surface will result in an increase of the hydrodynamic diameter of the probe and thus may reduce its advance to the cell membrane. On the other hand, long, thin spikes might be able to penetrate the glycocalyx which in fact may enhance access and binding to the plasma membrane receptor.

The three coupling procedures devised in this study overcome these problems by modifying the particulate probe core in such a way that chemically or biologically reactive functions are displayed on its surface. These functional groups are then able to react with respective counterparts of a ligand molecule without the need for an additional cross-linker. Our experiments started with fluorescent microparticles which carry a dense cage of carboxylate groups on their surface. Such microparticles are commercially available in different colors and in sizes ranging from 10 nm to several micrometers. For the sake of convenience, only 1 μm particles in two different colors were used to test and validate our coupling chemistry as those could be washed and separated from solute reactants simply by repeated centrifugation steps.

The most obvious approach to obtain protein-reactive particles was the conversion of the surface carboxylates into active esters followed by the removal of the unreacted activating agents and subsequent coupling of protein ligands via their amino functions. The lability of the carboxylate-modified polystyrene particles in organic solvents, however, necessitated the activation, washing, and final coupling steps to be performed in an aqueous environment. The coupling yields obtained following this approach were poor, probably due to the short half-life of active esters in aqueous solution (Jarret, 1987).

We therefore decided to introduce hydrolysis-resistant amine-reactive aldehyde functions or avidin-binding biotinyl groups onto the particle surface. In the latter case, an avidin or streptavidin bridge would be used to eventually attach a biotinylated ligand. Both strategies were evaluated in parallel. In all cases, the initial step was the reaction of the surface carboxylates with an excess of aliphatic amine in the presence of carbodiimide and *N*-hydroxysulfonylsuccinimide. The yield of these reactions was determined to be approximately 14% based on the number of carboxylate functions. Surprisingly, this yield could not be increased further by any means, such as longer reaction times, elevated temperatures, use of different buffers, higher excess of reactants, or sonication. We assume that this result represents the highest coupling rate achievable with these specific particles since their extremely high surface density of carboxylate functions (7 $Å^2$/charge group) may prevent complete derivatization by sterical hindrance.

The use of a water-soluble amino-biotin lead directly to the desired biotinylated particles. The formation of surface aldehyde groups required additional reaction steps. In case of the acetal-derivatized particles (**2a**), the protective groups had to be cleaved off in an acidic environment. Again, low reaction yields were obtained with dilute organic and mineral acids ($\leq$17% deprotection yield). In contrast to that, soluble acetaldehyde dimethylacetal performed as expected and was deprotected completely at pH $\leq$2. The meager reactivity of the immobilized acetal groups was paralleled in the second reaction step of the alternative pathway, where glutaraldehyde was coupled to the ethylenediamine-derivatized particles (**3a**) with a reaction yield of $\leq$8%. Yet, these moderate yields turned out to be ample for coupling proteinaceous ligands onto the particle surface. Both types of aldehyde-derivatized particles (**2**, **3**) bound a complete monolayer of avidin onto their surface, while avidin binding to the biotinylated particles fell short with only 16% surface coverage. Hence, we focused on the aldehyde-functionalized particles in the subsequent biological assays.

For these experiments, the B subunit of cholera toxin was chosen as ligand. CTB binds exclusively to the plasma membrane glycolipid ganglioside G_{M1}, a receptor that was shown to be accessible to 1 μm probes on BALB/c 3T3 fibroblasts (Frey et al., 1996). Ovalbumin and avidin served as control ligands. When using the particles prepared via the acetal route, the probes displayed a specific binding to fibroblast monolayers when coated with CTB and a low nonspecific background binding when covered with OVA. In contrast, protein-coated probes generated via the glutaraldehyde approach exhibited a high nonspecific background binding. The reasons for this behavior remain to be elucidated. It seems unlikely that the background binding was caused by aldehyde groups residing on the particle surface, since unreacted aldehyde functions were blocked with a more than 1000-fold excess of aliphatic amines in the presence of cyanoborohydride. Moreover, glutaraldehyde should not be able to span the protein layer. We rather attribute this phenomenon to the extra positive charges which we introduced along with the glutaraldehyde cross-linker after reduction of the Schiff bases. The impact of positive charges on the nonspecific binding was emphasized in experiments with avidin particles which had been prepared via the acetal route. The switch from OVA to avidin dramatically increased the nonspecific binding, most likely because of the high positive charge of avidin under assay conditions [pI_{Avidin} 10.5 (Green, 1975)]. OVA and CTB, on the other hand, have pIs of 4.9 (Salaman and Williamson, 1971) and 7.8 (Spangler, 1992) and are therefore less prone to interact with negatively charged cell surfaces at physiological pH. However, a negative charge on the particle surface does not necessarily preclude nonspecific background binding. In our hands, the carboxylate-modified parent particles showed a nonspecific binding similar to that of avidin-coated probes (data not shown).

Thus, an ideal probe core would consist of a fluorophor-loaded seed particle which is covered by a shell of uncharged hydrophilic molecules bearing terminal acetal functions that can be converted into aldehydes upon demand by acid deprotection. An aldehyde content of 1×10^{-7} mequiv/cm^2 should be sufficient for most applications. In a very recent publication, Búcsi et al. (1998) described the synthesis of poly(ethylene oxide)-coated latex nanoparticles with acetal functions terminating the poly(ethylene oxide) chains, an approach almost meeting the above demands. Unfortunately, the authors did not test their particles in biological settings, and shortcomings such as holes in the poly(ethylene oxide) shell were reported. If those problems can be fixed and an easily detectable label, such as a fluorophor, can be incorporated, these particles may provide an interesting alternative to the aldehyde-derivatized carboxylate-modified particles described in this report.

ACKNOWLEDGMENT

The authors thank Ms. Liselotte Greune for expert technical assistance with the electron microscopy and Dr. Winfried Weissenhorn for his help in the dynamic light scattering experiments. This work was supported by a personal grant from the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie and research grant FR 958/2-1 from the Deutsche Forschungsgemeinschaft to A.F.

A Psoralen-Conjugated Triplex-Forming Oligodeoxyribonucleotide Containing Alternating Methylphosphonate−Phosphodiester Linkages: Synthesis and Interactions with DNA

Paul S. Miller,* Sarah A. Kipp, and Cory McGill†

Department of Biochemistry, School of Public Health, Johns Hopkins University, 615 North Wolfe Street, Baltimore, Maryland 21205 . Received November 18, 1998; Revised Manuscript Received March 2, 1999

A psoralen-conjugated oligodeoxyribopyrimidine (1443), PS-pTTTT*C*TTTT*C*TT*C*TT, where PS is trimethylpsoralen and *C* is 5-methyl-2′-deoxycytidine, that contains alternating methylphosphonate-phosphodiester internucleotide linkages was synthesized. The ability of 1443 to form triple-stranded complexes with a purine tract in a synthetic DNA duplex was studied. Irradiation of solutions containing the DNA target and 10 μM 1443 or 0.25 μM of a similar psoralen-conjugated oligodeoxyribonucleotide that contained all phosphodiester linkages, (1193), with long-wavelength UV light resulted in approximately 80% formation of interstrand cross-links at pH 7.0, 37 °C, in the presence of 20 mM magnesium chloride. The extent of triplex formation as monitored by photo-cross-linking decreased over the pH range 5.5−8.0, and the apparent p*K* of the 5-methylcytosines (*C*) in 1443 was approximately one-half of a pH unit less than that of the 5-methylcytosines in 1193. Oligomer 1443 formed triplexes in the absence of magnesium, and maximum triplex formation was observed in solutions containing 2.5 mM magnesium, whereas maximal triplex formation by the fully charged 1193 was not observed until the magnesium concentration was 10 mM or higher. Unlike the all-phosphodiester backbone of 1193, the alternating methylphosphonate-phosphodiester backbone of 1193 is resistant to hydrolysis by exonucleases in fetal calf serum. The nuclease resistance of 1443 and its ability to form triplexes at very low magnesium concentrations suggests that triplex-forming oligomers with alternating methylphosphonate-phosphodiester backbones may be good candidates for use as antigene reagents in cell culture.

INTRODUCTION

Short oligonucleotides can bind to double-stranded DNA to form triple-stranded complexes. These triplex forming oligomers or TFOs[1] interact with homopurine tracts in DNA through the formation of Hoogsteen or reversed Hoogsteen hydrogen bonds. This observation has generated considerable interest in developing TFOs to suppress or manipulate gene expression (for reviews, see refs *1* and *2* and references therein). Most of the current studies on triplex formation have employed oligodeoxyribonucleotides. While certain oligodeoxyribonucleotides can form stable triplexes under physiological conditions, the phosphodiester linkages of these oligonucleotides are susceptible to nuclease hydrolysis, a property that can potentially limit their use in cell culture and in vivo.

This problem can be circumvented in principle by using nuclease-resistant oligonucleotide analogues. A number of nuclease-resistant oligonucleotide analogues have been shown to form triplexes with double-stranded DNA. These include oligodeoxyribonucleotide phosphorothioates (*3*−*6*), α-anomeric oligonucleotides (*7*−*9*), peptide nucleic acids (PNAs) (*10*, *11*), oligonucleotides with riboacetal internucleotide linkages (*12*), and oligonucleotides with methylphosphonate (*13*) or (aminoalkyl)-phosphonate internucleotide linkages (*14*, *15*).

Previous studies showed that a pyrimidine-containing oligodeoxyribonucleotide with methylphosphonate linkages could form a stable triplex, but only at low pH (*13*). In an effort to increase triplex stability while maintaining nuclease resistance, we have recently begun to explore triplex formation by chimeric oligodeoxyribonucleotides that contain alternating methylphosphonate-phosphodiester internucleotide linkages, d-AOMPs. In this paper, we describe the interaction of a psoralen-conjugated d-AOMP with double-stranded DNA.

MATERIALS AND METHODS

Nucleoside-derivatized controlled pore glass supports, protected deoxyribonucleoside-3′-*O*-(β-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidites, and 2-[4′-(hydroxymethyl)-4,5′,8-trimethylpsoralen]hexyl-1-*O*-[β-cyanoethyl-(*N*,*N*-diisopropyl)]phosphoramidite were purchased from Glen Research, Inc, Sterling, VA. Protected deoxyribonucleoside-3′-*O*-(*N*,*N*-diisopropyl)methylphosphonamidites were obtained from JBL Scientific, San Luis Obispo, CA. All chemicals were of reagent grade or better. Phosphoramidite and phosphonamidite solutions were prepared using HPLC-grade acetonitrile stored over calcium hydride. Polyacrylamide gel electrophoresis was carried out on 20 × 20 × 0.75 cm gels containing 20% acrylamide and 7 M urea. The running buffer was TBE, which contained 89 mM Tris, 89 mM boric acid, and 0.2 mM

ethylenediaminetetraacetate buffered at pH 8. The gel loading buffer contained 90% formamide, 0.05% xylene cyanol, and 0.05% bromophenol blue.

Syntheses of Oligodeoxyribonucleotides. Oligodeoxyribonucleotides 1196, 1197, psoralen derivatized oligodeoxyribonucleotide 1193, and psorlen-derivatized alternating methylphosphonate-phosphodiester oligonucleotide 1443 whose sequences are shown in Figure 1 were synthesized on nucleoside-derivatized controlled pore glass supports using an Applied Biosystems model 392 DNA/RNA synthesizer. The concentrations of the phosphoramidites or methylphosphonamidites were 0.15 M in anhydrous acetonitrile and the coupling time was 90 s. Tetrazole in acetonitrile was used as the activating agent. The coupling step was followed by a capping step, then iodine oxidation followed by a second capping step. Capping reagent B consisted of a solution of 2.54 g of (dimethylamino)pyridine in 50 mL of anhydrous pyridine. The synthesizer was programmed to remove the last dimethoxytrityl group from oligomers 1196 and 1197. Oligomers 1193 and 1443 were derivatized with psoralen using the psoralen phosphoramidite reagent.

Oligomers 1193, 1196, and 1197 were deprotected by treatment with solution of 50% concentrated ammonium hydroxide in pyridine at 55 °C for 6 h. Oligomer 1443 was deprotected by sequential treatment with ammonium hydroxide and ethylenediamine (*16*). Following deprotection, oligomers 1196 and 1197 were purified by strong anion-exchange HPLC. A 20 OD_{260} sample of each oligomer was injected onto the column, and the column was eluted with 18 mL of a linear gradient of 0 to 0.8 M ammonium sulfate in 20% acetonitrile buffered with 1 mM ammonium acetate at pH 6.2. The flow rate was 0.6 mL/min and the column was monitored at 290 nm. Psoralen-conjugated oligomers 1193 and 1443 were purified by reversed-phase HPLC on a C-18 column using a 20 mL gradient of 2 to 40% acetonitrile in 50 mM sodium phosphate buffered at pH 5.8. The flow rate was 1.0 mL/min, and the column was monitored at 290 nm. The oligomers were then desalted on SEP PAK C-18 cartridges.

Oligomer 1193 was completely degraded to pT and p−d*C* in the expected ratios when incubated with 2 μg of snake venom phosphodiesterase in 10 mM Tris, pH 8.1, and 2 mM magnesium chloride at 37 °C for 16 h. Similar treatment of oligomer 1443 produced d-pT*p*T, d−p*Cp*T, d-pT*pC* and pT, where *C* is 5-methyldeoxycytidine and *p* is methylphosphonate. The products of these enzyme digestions were analyzed by C-18 reversed-phase HPLC using a 20 mL gradient of 2 to 40% acetonitrile in 50 mM sodium phosphate buffered at pH 5.8. The extinction coefficients of the oligomers were determined by comparing the absorbances of a given amount of oligomer before and after digestion by snake venom phosphodiesterase as previously described (*17*). The ϵ_{260} values obtained were oligomer 1196, 225 000; oligomer 1197, 253 000; oligomer 1193, 107 000; and oligomer 1443, 96 500.

Triplex Formation and Photo-Cross-Linking Experiments The 5′-hydroxyl groups of oligomers 1196 and

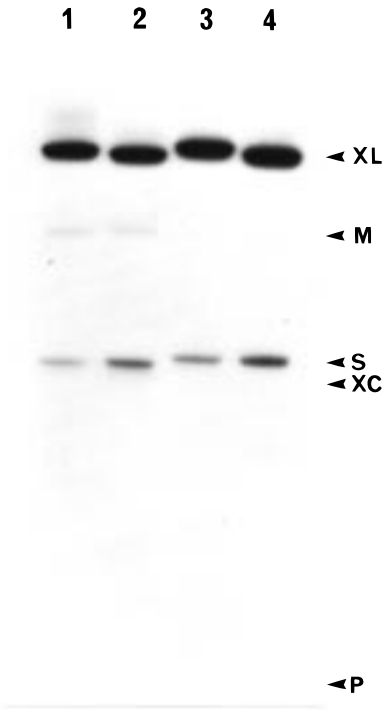
1197 were each phosphorylated by polynucleotide kinase using γ-[^{32}P]ATP (specific activity 50−200 Ci/mmole). The labeled oligomers were purified on MicroSpin Sephadex G-25 columns (Amersham Pharmacia Biotech Inc). Duplexes were formed by mixing 1 equiv of labeled strand with 1.2 equiv of complementary unlabeled strand in a triplex buffer system containing 100 mM sodium chloride, 0−20 mM magnesium chloride, and 50 mM Mops buffered at the specified pH. The solution was heated at 65 °C for 2 min and then allowed to cool to room temperature.

Photo-cross-linking experiments were carried out as follows. Equal volumes of duplex solution and a solution of the triplex forming oligomer in triplex buffer were mixed, and the solution was incubated at a given temperature for 3−16 h. Ten microliter aliquots of the solution were then irradiated with 365 nm UV light for 10 min at 2 °C in borosilicate glass test tubes as previously described (*18*). The solvents were evaporated in a Speed Vac concentrator, and the residue was dissolved in 5−10 μL of gel loading buffer. The samples were electrophoresed on a 20% polyacrylamide gel run under denaturing conditions. Gels were run at 800 or 1000 V at room temperature until the bromophenol blue dye had migrated ∼15 cm on the gel. The wet gel was wrapped in Saran Wrap and imaged by autoradiography or by a FujiX BAS 1000 phosphorimager. Phosphorimages were quantitated using the Fuji software package to determine the amount of cross-linking. Control experiments showed that the same percentage of photoadduct formation was obtained regardless of whether the samples were irradiated at the temperature of incubation or at 2 °C. Thus, for example, when 0.1 μM 1193 was incubated with duplex 1196/1197 for 16 h at 22 °C and then irradiated for 10 min, 91% cross-linking was observed when irradiation was carried out at 2 °C and 91% cross-linking was observed when irradiation was carried out at 22 °C. Similarly, incubation of 2.5 μM 1443 and 1196/1197 for 16 h at 22 °C followed by irradiation gave 86% cross-linking when irradiation was carried out at 2 °C and 86% cross-linking when irradiation was carried out at 22 °C. The lower irradiation temperature was used in the experiments described here to minimize the possibility of evaporation and thus changes in concentration during irradiation.

RESULTS AND DISCUSSION

Synthesis and Stability of the Psoralen-Conjugated d-AOMP Oligomer 1443 whose general structure is shown in Figure 1, consists of thymidine and 5-methyldeoxycytidine linked by alternating methylphosphonate-phosphodiester internucleotide bonds. The oligomer is conjugated with trimethylpsoralen through a six carbon linker attached to the 5′-terminal phosphate group. The oligomer was prepared on a controlled pore glass using commercially available protected nucleoside β-cyanoethyl-*N*,*N*-(diisopropyl)phosphoramidites and protected nucleoside *N*,*N*-(diisopropyl)methylphosphonamidites. The amino group of 5-methyldeoxycytidine was protected with an isobutryl protecting group. The psoralen group was introduced as the phosphoramidite during the last coupling reaction. A control oligomer, 1193, that contains contiguous phosphodiester linkages was synthesized in a similar manner.

Protected oligomer 1443 was first treated with ammonium hydroxide for 30 min at room temperature. This treatment removes the isobutryl protecting groups from the 5-methyldeoxycytidines, partially removes the β-cyanoethyl groups, and partially cleaves the oligomer from the support. These conditions do not result in hydrolysis of the methylphosphonate linkages. The oligomer was then treated with 50% ethylenediamine for 6 h at room temperature to complete removal of the β-cyanoethyl groups and to completely cleave the oligomer from the support. This sequential deprotection scheme avoids transamination of the 5-methyldeoxycytidines by ethylenediamine (*16*).



Previous studies have shown that the phosphodiester linkages of oligothymidine d-AOMPs can be hydrolyzed by an endonuclease activity found in snake venom phosphodiesterase (*19*). Similar results were observed for oligomer 1443. Thus, 1443 was incubated with snake venom phosphodiesterase for 18 h at 37 °C, and the products of the reaction analyzed by C-18 reversed-phase HPLC. In addition to the pT, which results from hydrolysis of the 3′-terminal phosphodiester linkage, three dimers, pT*p*T, p*Cp* T, and pT*pC* were observed. As expected, the methylphosphonate linkages of the oligomer were not hydrolyzed.

The stability of 1443 in cell culture medium containing 10% fetal calf serum was also studied. Because it was not possible to introduce a radioactive label into the oligomer, the fate of the oligomer was followed by C-18 reversed-phase HPLC. In contrast to the behavior observed with snake venom phosphodiesterase, the internal phosphodiester linkages of 1443 appear to be resistant to the 3′-exonuclease activity that is commonly found in most mammalian sera (*20*). Thus, only the 3′-terminal thymidine was hydrolyzed when 1443 was incubated with culture medium containing 10% fetal calf serum whereas similar incubation of the all phosphodiester oligomer 1193 resulted in approximately 40% hydrolysis of the oligomer after 1 h and complete hydrolysis after 4 h.

Interaction with Double-Stranded DNA. The interaction of 1443 and 1193 with double-stranded DNA was studied using the target system show in Figure 1. The target duplex, 1196/1197, which consists of 27 base pairs, contains a 15 nucleotide homopurine tract. The sugar−phosphate backbones of 1443 and 1193 have the same polarity as this purine tract, and both oligomers would be expected to interact with this tract via Hoogsteen hydrogen bonds with the formation of T·A−T and C^+·G−C triads (*21*). 5-Methyl-2′-deoxycytidine, *C*, was used instead of 2′-deoxycytidine because it has a higher apparent p*K* than dC and thus enables triplex formation to occur at higher pH. The 5′−T−A/5′−T−A sequence at the duplex/triplex junction would be expected to serve as a binding site for the psoralen group conjugated to the 5′-ends of either 1443 or 1193 (*22*−*24*).

The interaction of phosphodiester oligomer 1193 and duplex 1196/1197 could be detected by conventional melting experiments. Thus, a melting transition due to the dissociation of 1193 from the triplex was readily observable at pH 8.0 (T_m 24 °C) and a single melting transition (T_m 65 °C) due to dissociation of the triplex was observed at pH 6.2 (data not shown). The T_m of the duplex 1196/1197 was 65 °C at both pH 8.0 and 6.2. Similar melting experiments were carried out with methylphosphonate oligomer 1443 and duplex 1196/1197. In contrast to the results obtained with 1193, very broad transitions with small hypochromicity changes were observed for 1443. The midpoints of these transitions appeared to be approximately 45 °C at pH 6.2 and 16 °C at pH 8.0, although the breath the transitions precluded an accurate determination of the melting temperatures.

Triplex formation between 1443 or 1193 and duplex 1196/1197 was observed indirectly by irradiation of

Oligomer	% Cross-Link *p1197/1196	*p1196/1197
1443	80	82
1193	89	87

Figure 2. Triplex-mediated photoadduct formation. Solutions containing 0.7 μM 1193 (lane 1) or 2.5 μM 1443 (lane 2) and 100 nM *p1197/1196, or 0.7 μM 1193 (lane 3) or 2.5 μM 1443 (lane 4) and 100 nM *p1196/1197 in 100 mM sodium chloride, 20 mM magnesium chloride, 50 mM Mops, pH 7.0 were incubated for 16 h at 22 °C and then irradiated with 365 nm UV light at 2 °C for 10 min. The products of the reaction were analyzed by PAGE on a 20% gel. The mobilities of the labeled duplex strand (S), interstrand cross-linked products (XL), the monoadduct (M), xylene cyanol (XC) and bromophenol blue (P) are indicated at the side of the gel. The products were quantitated by phosphorimaging.

solutions containing the oligomer and [^{32}P]-labeled duplex with long wavelength (365 nm) UV light followed by analysis of the photoproducts by denaturing polyacrylamide gel electrophoresis. Under these conditions, photoproducts can arise only as a consequence of triplex formation between the oligomer and the duplex and only covalent adducts can give rise to mobility shifts on the gel.

Figure 2 is an autoradiogram of a gel from such an experiment. The experiment was carried out at 22 °C in the presence of 2.5 μM 1443 or 0.7 μM 1193 with a duplex whose upper, purine-rich strand or lower, pyrimidine-rich strand carried a 5′-terminal [^{32}P]phosphate. Both oligomers form triplexes as signaled by the presence of bands on the gel whose mobilities are less than those of single strands, *p1196 or *p1197. The bands of lowest mobility represent complexes formed by interstrand cross-links between the psoralen-conjugated oligomer and the duplex. The observation that essentially the same percentage of photoadduct is observed when either the upper or lower strand of the duplex is labeled is consistent with this interpretation. These interstrand cross-links most likely result from formation of photoadducts between the two thymidines at the 5′−T−A/5′−T−A duplex triplex junction and the furan and pyrone rings of the tethered psoralen (*24*). The bands of intermediate mobility result from monoadduct formation between the psoralen and the labeled strand of the duplex and represent less than 2% of the total photoadduct formation. The results of this experiment demonstrate that the alternating methylphosphonate-phosphodiester backbone is compatible with the formation of triple-stranded complexes.

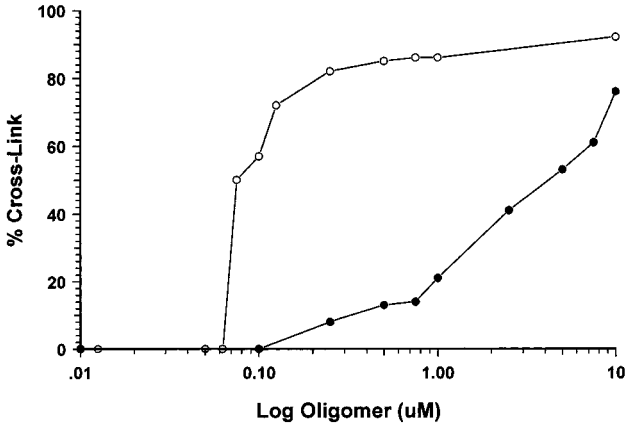


Figure 3. Effect of oligomer concentration on triplex formation. Solutions Mops containing 10 nM to 10 μM 1193 (○) or 1443 (●) and 2.5 nM *p1196/1197 in 100 mM sodium chloride, 20 mM magnesium chloride, 50 mM Mops, pH 7.0, were incubated at 37 °C for 3 h and then irradiated at 2 °C for 10 min and the products analyzed by gel electrophoresis. The percentage of interstrand cross-linked product was determined by phosphorimaging.

Effect of Oligomer Concentration on Triplex Formation. The dependence of triplex formation on oligomer concentration is shown in Figure 3. These experiments were carried out at pH 7.0 and 37 °C over a oligomer concentration range of 10 nM to 10 μM. Both oligomers undergo extensive triplex formation at 37 °C as monitored by photoadduct formation. However, an approximately seven times higher concentration of 1443 is required to achieve cross-linking comparable to that of 1193 under these conditions.

Photoadduct formation by 1193 is observed at nanomolar concentrations and the transition from no photoadduct formation to maximal photoadduct formation occurs over a relatively narrow concentration range. Thus, maximal photoadduct formation is observed by 0.25 μM oligomer and less than 1% photoadduct formation is seen below 0.07 μM 1193. Reduced photoadduct formation by 0.7 μM 1193 is observed at 37 °C (50%) as compared to that observed at 22 °C (88%, see Figure 2). This reduction most likely reflects the reduced stability of the triplex at the higher temperature.

The transition from no photoadduct formation to maximal photoadduct formation by 1443 is observed over a much broader concentration range, from 0.1 to 10 μM. Again, a lower percentage of photoadduct is observed at 37 °C (42%) than at 22 °C (81%) in the presence of 2.5 μM 1443.

The differences in the amounts of photoadduct formed by oligomers 1193 and 1443 most likely reflect differences in the stability of the triplexes formed by these two oligomers. Oligomer 1443 contains seven methylphosphonate linkages and thus consists of a mixture of 128 diastereoisomers. Molecular modeling experiments suggest that the Rp methylphosphonate linkage should not interfere with triplex formation (*25*). Preliminary results with a triplex forming oligomer that contains a single

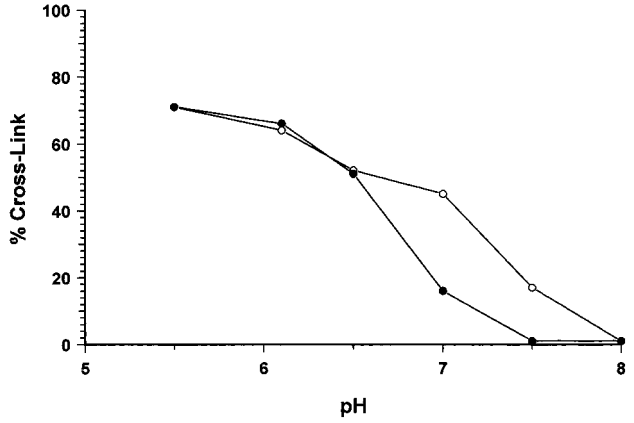

Figure 4. Effect of pH on triplex formation. Solutions containing 0.1 μM 1193 (○) or 2.5 μM 1443 (●) and 20 nM *p1196/1197 in 100 mM sodium chloride, 20 mM magnesium chloride and 50 mM Mops buffered at pH 5.5, 6.1, 6.5, 7.0, 7.5, or 8.0 were incubated at 37 °C for 3 h and then irradiated at 2 °C for 10 min and the products analyzed by gel electrophoresis. The percentage of interstrand cross-linked product was determined by phosphorimaging.

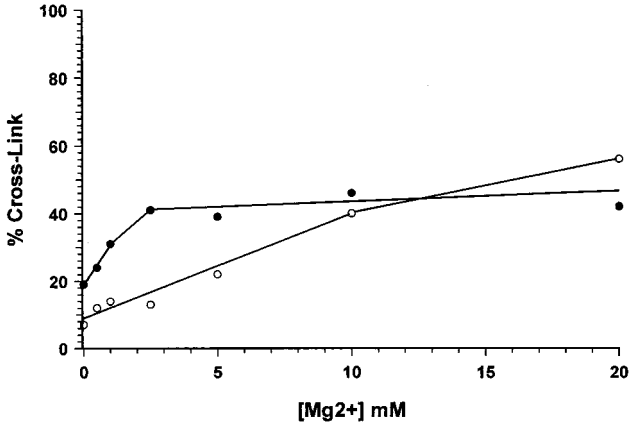

Figure 5. Effect of magnesium ion concentration on triplex formation. Solutions containing 0.1 μM 1193 (○) or 2.5 μM 1443 (●) and 20 nM *p1197/1196 in 100 mM sodium chloride, 50 mM Mops buffered at pH 7.0, and 0, 0,5, 1.0, 2.5, 5.0 10, or 20 mM magnesium chloride were incubated at 22 °C for 3 h and then irradiated at 2 °C for 10 min and the products analyzed by gel electrophoresis. The percentage of interstrand cross-linked product was determined by phosphorimaging.

methylphosphonate linkage suggest that the oligomer with an Rp methylphosphonate linkage forms a more stable triplex than does the oligomer with an Sp methylphosphonate linkage. Thus, the relatively higher concentrations of 1443 required for photoadduct formation may simply reflect the presence of diastereoisomers with high percentages of lower binding Sp methylphosphonate linkages.

Effect of pH on Triplex Formation. Formation of Hoogsteen bonded C^+·G−C triads requires protonation of 5-methylcytosine. Thus triplex formation and stability by oligomers that contain this base increases as pH decreases. The effects of pH on triplex formation by 1443 and 1193 were compared as shown in Figure 4. This experiment was carried out at 37 °C using oligomer concentrations which gave comparable levels of photoadduct formation at low pH. Both oligomers formed the same amount of photoadduct over the pH range 5.5−6.5. Above pH 6.5, photoadduct formation dropped off more rapidly for the triplex formed by 1443 and essentially no photoadduct formation was observed at pH 7.5 or higher under these conditions. In contrast, 1193 continued to form photoadducts at pH 7.5 with no photoadduct formation at pH 8.0.

Protonation of the three 5-methylcytosines of 1443 or 1193 introduces multiple positive charges into the oligomer. The resulting charge repulsion between the protonated 5-methylcytosines is probably compensated to some extent by the negatively charged phosphodiester groups in the oligomer backbone. The results of the experiment in Figure 4 suggest that the apparent p*K* of the 5-methylcytosines in oligomer 1443 is approximately a half pH unit less than the apparent p*K* of the 5-methylcytosines in oligomer 1193. This decrease in apparent p*K* is most likely the consequence of the decreased net negative charge of the alternating methylphosphonate backbone of 1443 versus that of the all phosphodiester backbone of 1193. This decreased net charge would therefore make it more difficult to protonate the 5-methylcytosines of 1443, resulting in reduced triplex stability as the pH of the medium is increased. Consistent with this explanation is the observation that apparent p*K* of cytosine bases in the all methylphosphonate oligomer d$(CT)_8$ is approximately 1.2 pH units less than that of the corresponding all phosphodiester oligomer when these oligomers form 2:1 d$(CT)_8$:d$(AG)_8$ triplexes (*13*).

Effect of Magnesium Concentration on Triplex Formation. Triplex stability is sensitive to ionic strength and is stabilized by divalent metal ions such as magnesium. The effect of magnesium ion concentration on photoadduct formation by 1443 and 1193 was examined as shown in Figure 5. These experiments were carried out at concentrations of 1443 and 1193 that gave comparable amounts of photoadduct in the presence of 20 mM magnesium ion. As shown in Figure 5, 1443 formed an appreciable amount of photoadduct even in the absence of magnesium. Maximal photoadduct formation was observed once the magnesium concentration reached 2.5 mM. In contrast to this behavior, very little photoadduct formation was observed for 1193 in the absence of magnesium and maximal photoadduct formation was not observed until the magnesium concentration reached 10 mM.

The differences in the dependence of triplex formation on magnesium concentration between the two oligomers can most reasonably be explained by the reduced number of phosphodiester linkages in the backbone of 1443. Because the sugar phosphate backbones of the triplex forming oligomer and the purine strand of the target are in close proximity, triplex formation would be expected to entail considerable charge repulsion between these two strands. This charge repulsion can be reduced by the presence of divalent metal ions or polycations such as spermine. Oligomer 1443 contains 7 negatively charged phosphodiester groups as opposed to the 14 negative charges in the backbone of oligomer 1193. Thus, charge repulsion between the backbone of 1443 and the purine strand of 1196/1197 would be expected to be considerably less than that in the triplex formed by 1193 and consequently the dependence of triplex stability on magnesium concentration is reduced.

CONCLUSION

The results of the experiments described above show that an oligopyrimidine with an alternating methylphosphonate-phosphodiester backbone can form stable triplexes with a duplex DNA target under physiological conditions of ionic strength and temperature. Triplex forming oligomers with this type of backbone may have distinct advantages over triplex forming oligodeoxyribonucleotides. Because the backbone of the d-AOMP is

resistant to nuclease hydrolysis, this type of oligomer may be particularly useful in cell culture experiments. The reduced dependence of triplex formation by this type of oligomer on divalent metal ion concentration may also promote triplex formation in the intracellular environment.

A potential drawback of pyrimidine containing TFOs is their pH dependence of triplex formation. This problem becomes more serious as the number of 5-methylcytosines in the oligomer increases and is particularly serious for oligomers that contain multiple contiguous 5-methylcytosines. The problem appears to be more serious for the partially charged d-AOMPs than fully charged oligodeoxyribonucleotides. This problem can in theory be circumvented by use of base analogues which do not require protonation or by employing other triplex motifs such as the antiparallel purine motif to form triplexes. Experiments to test these possibilities are currently in progress.

Synthesis and Application of Novel Bifunctional Spin Labels

Ralf M. Lösel,[†,‡] Reinhard Philipp,[†] Tamás Kálai,[§] Kálmán Hideg,[§] and Wolfgang E. Trommer*[,†]

Fachbereich Chemie, Universität Kaiserslautern, P.O. Box 3049, D-67653 Kaiserslautern, Germany, and Institute of Organic and Medicinal Chemistry, University of Pécs, H-7643 Pécs, P.O. Box 99, Hungary. Received November 18, 1998; Revised Manuscript Received February 22, 1999

The synthesis of new bifunctional spin-labeled cross-linking reagents is described. Covalent attachment to papain was achieved via a thiol-specific thiosulfonate residue and, for the second anchor point, via a nonspecific photoreactive azido function. The thiosulfonate formed a reversible disulfide linkage, which could be cleaved again reductively by dithiothreitol. The spin label, a pyrroline-1-oxyl radical, was highly immobilized after attachment to papain by both functional groups and showed little if any relative motion with respect to the protein.

INTRODUCTION

Spin labeling has widely been used for studies of structure−function relationships in proteins. ESR investigations using spin labels may yield information about local polarities, segmental mobilities, and the conformational changes correlated with these parameters (*1, 2*). Moreover, precise intramolecular distances have been obtained in special cases (*3*−*5*). Interpretation of the data may, however, be hampered due to relative mobility of the spin label with respect to the macromolecule to which it is attached. In case of distance measurements, the error increases from several tenths of an angstrom by more than an order of magnitude (*6, 7*). This problem pertains even more to motional studies of the protein. Relative motion of the spin label with respect the macromolecule can be minimized by the use of bifunctional probes which allow for cross-links within, e.g., the protein. Such compounds have first been described by Wenzel et al. (*8*), but they contain a rather long spacer between the nitroxide and the reactive groups which are also of low specificity with respect to protein side chains.

Intramolecular cross-linking of proteins with chemical reagents has become a well-established technique to give information on the proximity of amino acid residues. The reagents used for such purposes contain, separated by a spacer of defined length, two functional groups that may exhibit either equal (homobifunctional) or different (heterobifunctional) selectivity toward amino acid residues. Photoreactive groups are often favored as they remain silent, i.e., unreactive unless irradiated. Among the amino acids containing reactive side chains, amino and thiol (sulfhydryl) groups are most suitable for chemical derivatization as reactions usually take place under mild conditions. Whereas amino groups of lysines are quite abundant in most proteins, thiol-containing cysteines are usually present in small numbers, only. For this reason, the selective chemical modification of cysteines usually allows for rather precise determination of the site of attachment. There are, however, few reagents that are truly specific for thiols, as the commonly applied haloacetamides or maleimides may also react with other functional groups, particularly with amino groups of lysines. Among the specific sulfhydryl reagents are those forming disulfide bonds with the protein. This may be accomplished by disulfide exchange or by a substitution reaction with thiosulfonates (*9*). Cross-linking reagents with sulfhydryl-specific functionalities and additional photoreactive groups have been described (*10*−*13*).

A thiol-specific, reversible methanethiosulfonate spin label has been described earlier (*14*−*16*). On the basis of this compound (**1**), we have synthesized several derivatives containing a photoreactive moiety and applied them to the test system papain. The latter is a thiol protease consisting of 212 amino acids with a molecular weight of 23 406 (*17*). Its essential thiol located at Cys 25 is very reactive and easily modified. In the following, we demonstrate the application of the new compounds for spin labeling of papain under stepwise intramolecular cross-linking as shown in Figure 1.

EXPERIMENTAL PROCEDURES

Papain, twice crystallized (Sigma Lot no. 100H8075), was reductively activated at a concentration of 40 mg/mL by incubation with 50 mM dithiothreitol (DTT) in 0.1 M acetate, pH 4.5, for 1 h. There was no difference in final enzyme activity compared to longer incubation periods (up to 12 h). Activation did not cause significant autolytic degradation of papain as judged from SDS−PAGE (*18*). Activity measurements were done by photometric determination of liberated 4-nitroaniline from the substrate N_α-benzoyl-L-arginine-*p*-nitroanilide [L-BAPA (*19*), commercially available from Merck]. Briefly, the assay mixture contained 0.1 M Tris, 0.2 M KCl, 1 mM EDTA, pH 7.0, supplemented with 1 mM L-BAPA. Nitroaniline formation was followed at 410 nm ($\epsilon = 8800$ M^{-1} cm^{-1}) for 2 min using a Beckman DU 640 UV spectrometer operating in the kinetics mode. Protein concentration was estimated by the Bradford procedure (*20*) using defatted bovine serum albumin as a standard rather than by A_{280} determination, as the aromatic moiety of incorporated spin-labels interfered at this wavelength.

Photolysis was carried out by irradiating samples with 366 nm UV-light using a CAMAG source (254 or 366 nm, 4 W) or a Rayonet photoreactor (350 nm, 750 W).

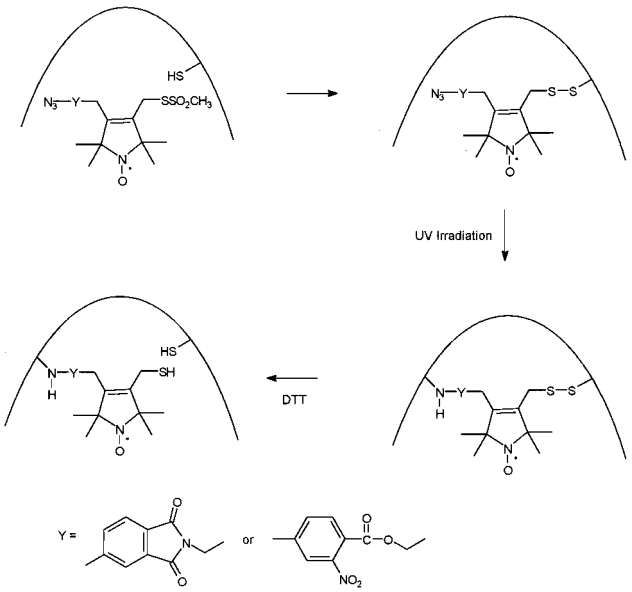

Figure 1. Principle of the method. After selective reaction of the reagent with the thiol group of the protein under disulfide formation, irradiation effects covalent binding via decomposition of the azide group (at the other terminus). Finally, the disulfide may be cleaved reductively. At each step, ESR spectra may be recorded.

ESR spectra were recorded at 25 °C on a BRUKER ESP 300E ESR spectrometer operating in the X-band mode and employing a 100 kHz modulation of 1 G amplitude.

To modify the enzyme, reductively activated aliquots (100 μL) were passed through centrifuge columns filled with Sephadex G25 (*21*) and equilibrated with the buffer used for activity measurements (0.1 M Tris, 0.2 M KCl, and 1 mM EDTA, pH 7.0). Some protein precipitated due to the different pH, but readily dissolved upon addition of an equal volume of buffer. To 100 μL of enzyme solution, 5 μL of the reagent stock solution (50 mM in dimethyl formamide) was added and thoroughly mixed. Reagents **2**, **3**, and **4** were not completely soluble under these conditions and formed turbid solutions. Samples were incubated for 1 h under exclusion of light and then separated from unbound reagent by column centrifugation over Sephadex G25 (*21*). Except for the thiosulfonate reagent **1**, this procedure was insufficient to completely remove unspecifically bound spin-label, as indicated by an intense ESR signal of freely mobile label. Therefore, microdialysis against the same buffer (16 h at room temperature) was used in addition.

Molecular modeling was performed using the QUANTA program running on a Silicon Graphics INDY. The structure data file used was 1pop found in the Protein Data Bank. Minimization was done in the CHARMm force field.

Synthesis of 1-Oxyl-3-[(*N*-phthalimido)ethyl]-4-methanethiosulfonylmethyl-2,5-dihydro-2,2,5,5-tetramethyl-1*H*-pyrrole (3). 1-Oxyl-3-[(*N*-phthalimido)-ethyl]-4-bromomethyl-2,5-dihydro-2,2,5,5-tetramethyl-1*H*-pyrrole (102 mg, 0.25 mmol), prepared analogously as described by Kálai et al. (*22*) for the 4-azido-*N*-phthalimido derivative, and $NaSSO_2CH_3$ (67 mg, 0.5 mmol) were dissolved in a mixture of dioxane (10 mL) and water (3 mL) and were refluxed for 30 min. Then the mixture was concentrated in vacuo, and the residue was dissolved in chloroform (20 mL), washed with brine (10 mL), dried over $MgSO_4$, filtered, evaporated and, purified by preparative TLC on a silica gel plate (hexane−ethyl acetate, 2:1). Yield 61 mg (56%); R_f 0.40 ($CHCl_3$-Et_2O 1:1); mp 128−129 °C. Anal. calcd for $C_{20}H_{25}N_2O_5S_2$ (437.54): C, 54.90; H, 5.76; N, 6.40; S, 14.65. Found: C, 54.73; H, 5.77; N, 6.27; S, 14.32 (Heraeus Micro U/E, sulfur titrimetrically by Schöniger's method). IR: 1700 cm^{-1} (C═O), 1610 cm^{-1} (C═C). MS *m/z* (rel int.%): 437 (M^+, 68), 407(36), 310(66), 160(100), carried out on a VG Trio 2 instrument, EI mode 70 eV, direct inlet.

C, 45.58; H, 5.00; N, 14.12; S, 12.50. MS: *m*/*z* (rel int.%) 498 (M^+, 6), 468 (7), 442 (8), 196 (21), 165 (29), 134 (40), 65 (100). Compounds **1** and **2** were synthesized according to published procedures (*14*, *22*).

RESULTS

Papain was labeled at cysteine-25 with methanethiosulfonate spin label **1** under loss of activity and exhibited an ESR spectrum very similar to the one obtained by Berliner et al. (*14*) with the same reagent (data not shown). Likewise, the new spin-labeled reagents **2**, **3**, and **4** (structures shown in Figure 2) efficiently modified the active-site cysteine under complete inactivation of the enzyme.

The spectrum of the phthalimide **2** (Figure 3), when bound to the protein but before irradiation, however, was strikingly different from that of the simple thiosulfonate **1**. Whereas with **1**, a $2A_{zz}$ value of 52 G typical of weakly immobilized nitroxide radicals was observed, **2** exhibited a value of 67 G. Such large values are seen in highly immobilized radicals and are close to the rigid powder limit in a hydrophobic environment. Irradiation in a photoreactor at 350 nm for 10 min did not alter the spectrum, although **2** can be photolyzed readily in solution upon irradiation at 366 nm with a simple hand-held UV lamp (CAMAG) as demonstrated by concomitant changes in the UV spectrum (complete loss of absorbance at 261 and 344 nm within 15 min; isosbestic points at 231 and 375 nm). The almost identical, but not photoreactive label **3** after reaction with papain gave a spectrum that is indistinguishable from the one obtained with **2** (data not shown).

ESR spectra obtained with the azidonitrophenyl compound **4,** on the other hand, showed a significantly lower immobilization of the label ($2A_{zz} = 64.8 \pm 0.1$ G, Figure 4a) as compared to phthalimides **2** and **3**. After irradiation in a Rayonet photoreactor for 10 min, the maximum separation observed had increased to 67.1 ± 0.1 G (Figure 4b), thus, clearly indicating that an additional immobilization had occurred due to a second covalent linkage to the protein via the nitrene generated by photolysis. Upon addition of 3 mM DTT, the signal from freely tumbling radical increased, reaching equilibrium after about 30 min when *N*-ethyl maleimide in a final concentration of 20 mM was added to stop the disulfide

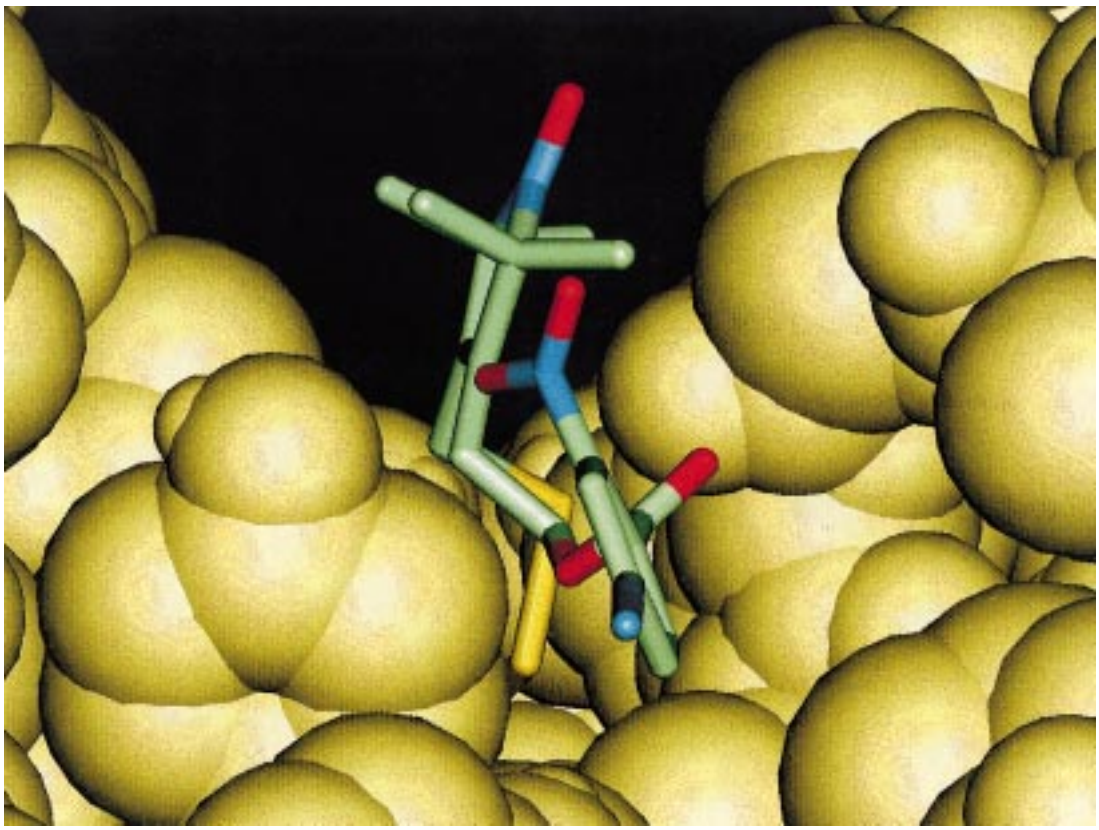

Figure 5. Molecular model of reagent **4** (liquorice model, colored by elements) bound in the substrate-binding cleft of papain (space-filling model, yellowish) as obtained from the CHARMm calculations.

reduction by DDT. At this point, the solution of modified protein was divided into two parts. One part was kept at room temperature without further treatment, while the other was dialyzed for 4 h against dialysis buffer as described in the Experimental Procedures. After this time, $2A_{zz}$ was 65.5 ± 0.2 G in the dialyzed sample (Figure 4c), whereas the spectrum of the reference sample had remained unchanged. The residual bound signal in several experiments accounted for at least 50% cross-linking. For comparison, in a control sample modified with thiosulfonate **1**, the reaction was complete in only 5 min, leaving no residual signal of immobilized radical.

Molecular modeling using the protein structure and the azidophenyl compound **4** with subsequent energy minimization in a force field by the program CHARMm gave an excellent fit for location of the aromatic group of **4** in the S_2 subsite of the protease (*23*) with the nitroxide moiety pointing outward, while the pyrroline ring to which the latter is attached is bound in the substrate-binding cleft (Figure 5).

DISCUSSION

The heterobifunctional spin label **4** was shown to react in a stepwise manner with papain under formation of a cross-link between the essential cysteine residue 25 and an amino acid located in the S_2 subsite. Modification of the thiol group of Cys-25 was accompanied by the loss of enzymic activity. That cross-linking (at least 50%) had indeed occurred upon irradiation was seen clearly by the increase in the $2A_{zz}$ value of the ESR spectrum of **4**. Subsequent reduction with DTT of the disulfide linkage lead again to a smaller $2A_{zz}$ value, indicating higher relative mobility. Upon double attachment, the label shows little if any relative motion with respect to papain ($2A_{zz} = 67.1$ G). According to Stoke's eq 1 and a radius of papain of about 25 Å the rotational correlation time τ_r at 25 °C is 1.41×10^{-8} s (eq 1). On the basis of the $2A'_{zz}$ value of **4** of 74 G in frozen solution at −25 °C (data not shown) a τ_r of 1.36×10^{-8} s can be calculated according to eq 2 for Brownian diffusion (*24*). Hence, **4** is well suited for motional studies of the protein by ESR and potentially, ST-ESR spectroscopy. The degree of cross-linking, however, is likely to vary from protein to protein.

$$\tau_r = 4\pi\eta r^3/3kT \quad (1)$$

$$\tau_r = 5.4 \times 10^{-10}\,(1 - A'_{zz}/A_{zz})^{-1.36} \quad (2)$$

Both reagents **2** and **3** exhibited highly immobilized ESR spectra after reaction with Cys-25 independent of subsequent irradiation. Apparently, the hydrophobic interaction of the aromatic moieties of these reagents with the S_2 subsite sufficiently immobilizes these compounds even without a second covalent linkage. Although the azido function in **2** can be converted to a reactive nitrene by irradiation as shown by UV spectroscopy, it did not form a stable bond with any of the amino acids in its vicinity as shown by almost complete release of the label upon reduction of the disulfide linkage by DTT. However, **2** should prove as useful for a stepwise and double attachment to appropriate proteins as was shown for reagent **4** in this study. Due to the strong hydrophobic interaction of the aromatic moieties in **2** and **3** with papain, motional studies, e.g. by means of ST-ESR, can be caried out even without the second attachment.

ACKNOWLEDGMENT

The authors express their gratitude to Anke Constantz and Elke Litmianski for excellent technical assistance. This work was supported by grants from the Hungarian National Research foundation (T017842) to K.H. and Fonds der Chemischen Industrie to W.E.T.

Molecular Modeling of Hapten Structure and Relevance to Broad Specificity Immunoassay of Sulfonamide Antibiotics

C. A. Spinks,* G. M. Wyatt, H. A. Lee, and M. R. A. Morgan

Department of Biochemistry, Institute of Food Research, Norwich Research Park, Colney, Norwich, NR4 7UA, U.K. Received May 26, 1998; Revised Manuscript Received February 22, 1999

Molecular modeling of hapten structure was used to predict and influence, through appropriate synthetic work, the outcome of an immunization program. Examination of the structures of sulfonamide antibiotics led to the development of a hypothesis and the consequent synthesis of a sulfacetamide–protein immunogen aimed at the generation of broad specificity anti-sulfonamide antibodies. The antisera generated, alongside anti-sulfachlorpyradizine antisera generated at the same time, were characterized for cross-reactions against a range of sulfonamide drugs, and were found to exhibit good but not the desired broad specificity. Discussion is presented as to the reasons for the failure of the hypothesis. Further hypotheses are developed and speculation is made as to the future of molecular modeling in immunochemical research.

INTRODUCTION

Compounds of molecular masses less than about 1000–10000 Da are usually not intrinsically immunogenic. To generate antibodies to such compounds, it is required that they are covalently linked to a carrier of high molecular weight (almost always a protein) that is itself capable of stimulating the immune system. Of the many antibodies so produced, some are capable of recognizing the hapten molecule alone. On this basis, immunoassays have been established for many low molecular weight analytes, including mycotoxins (Wilkinson et al., 1992), pesticides (Van Emon et al., 1989) and vitamins (Finglas and Morgan, 1994). These reviews give an indication of the diversity and convenience of immunoassays for small molecules.

It has long been recognized that the manner of the linking of hapten to carrier protein for immunogen synthesis is critical in determining the nature of the antibody response; thus, antibody specificity is maximal for those sites distal to the point of conjugation (Landsteiner, 1945). With this knowledge, it has been possible to generate antibodies of very high specificities, capable of distinguishing very closely related structures. For example, high specificity has been particularly important in circumstances where close structural relationships do not reflect similar bioactivities. Wie and Hammock (1984) devised novel routes of synthesis in order to obtain maximum specificity for benzoylphenylurea insecticides.

However, it is sometimes also necessary to analyze a group of compounds of similar structure. This aim can often be achieved by judicious synthesis of the hapten–protein immunogen to expose maximally common features while minimizing the presentation of structural differences to the immune system. An example of this approach would be the immunoassay developed for quantification of the potato glycoalkaloids (Morgan et al., 1983). A further possibility is provided by monoclonal antibody technology, whereby low-frequency antibodies from the polyclonal population can be selected via the cloning and screening process. Accordingly, Ward et al. (1990) have described a surprisingly diverse population of anti-aflatoxin antibodies obtained through use of one immunogen.

In past years, the development of high specificity antibodies has been a paramount consideration in the acceptance of immunoassay technology. However, the importance of broad specificity analysis is increasing, particularly in circumstances where a high proportion of samples will be negative, since economic and regulatory factors dictate that more resources are required for positive samples. Given their robustness, simplicity, high sample through-put, and low cost per sample, the immunoassays should be as well-suited to application in screening assays as they are in specific determinations. The limiting factor is the development of suitable antibodies.

The sulfonamide antibiotic drugs are analytes for which there is considerable demand for a broad specificity assay, detecting all members of the group and allowing the high proportion of negative samples to be rejected. The sulfonamides (used in pigs, cattle, and poultry, for example) seem to be particularly resistant to attempts to produce broad specificity antibodies. This is rather surprising since at first glance the general structure of the sulfonamides (Figure 1) with the comparatively large common aromatic ring moiety at one end of the molecule looks eminently suitable for broad specificity antibody generation. Indeed, Sheth and Sporns (1991) have described the production of antibodies using a sulfathiazole derivative linked through the variable R-group and exposing the common ring. The resultant antibodies were not as broadly specific as would be liked. Other groups of antibiotic drugs have proved easier to deal with (Kitagawa et al., 1983; Stanker et al., 1993; Brandon et al., 1994), but sulfonamide–protein immunogens have invariably generated antibodies of high specificity (Singh, et al., 1989; McCaughey, et al., 1990; Sheth and Sporns, 1990; Hoffmeister, et al., 1991; Martlbauer, et al., 1992; Garden and Sporns, 1994; Thomson and Sporns, 1995).

Molecular modeling of hapten structure has recently been used with some success in developing insight as to the reasons for the cross-reaction characteristics of

particular antibodies. There are clear advantages to looking at three-dimensional representations of structure, even without the further possibilities of investigating hydrophobic and electrostatic properties. Carlin et al. (1994) modeled the diuretic furosemide and related compounds and were able to explain the observed cross-reactions of a monoclonal anti-furosemide antibody. Elissalde et al. (1995) modeled the mycotoxin fumonisin and revealed unexpected folding within the structure with high significance for anyone interested in immunochemical studies on this compound.

Such studies and others have been carried out after the antibodies have been produced. In the present report, we describe the results of efforts to use molecular modeling in a predictive manner in order to enhance the possibility of developing a broad specificity anti-sulfonamide antibody.

MATERIALS AND METHODS

Chemicals. All starting materials for hapten synthesis and conjugation were obtained from Sigma Chemical Co. (Dorset, U.K.). All reagents were of the highest quality available.

Molecular Modeling. Modeling studies were carried out on a Silicon Graphics Workstation (Mountain View, CA) running QUANTA software (Molecular Simulations Inc., Burlington, MA). Twenty-two different sulfonamides were modeled. Minimum energy conformations of the compounds were calculated using the CHARMm force field. (CHARMm uses empirical energy functions to describe the forces on atoms in molecules, calculating conformational energies, local minima, barriers to rotation, energy surfaces, and time-dependent dynamic behavior).

Conformational searches were carried out by rotating all rotatable bonds through 360° in 30° increments and the lowest energy conformation computed. Electrostatic potentials were mapped across the surface of the structures by tumbling a positively charged particle over the surface of the molecule and calculating the energy for repulsion. Accordingly, high-energy regions correspond to a negative charge distribution within the molecule.

Synthesis of Drug–Protein Conjugates for Immunization. (i) Sulfacetamide Immunogen (SAM-BTG). Sulfacetamide (SAM) was reduced by sodium borohydride in a manner similar to the method described for triadimefon by Newsome (1986). SAM (400 mg) was dissolved in ethanol (20 mL) and mixed with sodium borohydride (700 mg in 12 mL ethanol). Frothing was observed, and the mixture was left overnight, after which concentrated HCl (4 mL) was added and the ethanol removed by rotary evaporation.

The SAM derivative (110 mg) was dissolved in pyridine (5 mL), to which succinic anhydride (500 mg) was added and left stirring gently for 3 days at room temperature. Pyridine was removed by rotary evaporation, and the residue dissolved in dichloromethane (6 mL). After washing with 1 M HCl (2 mL) followed by water (4 mL), the sample was again dried and the hemisuccinate product (52 mg) dissolved in dioxan (3 mL). The mixed anhydride method for conjugation to protein was then carried out (Erlanger et al., 1959) where isobutylchloroformate (4 μL)

and tributylamine (8 μL) was added to the SAM hemisuccinate solution and stirred for 30 min, ensuring that the temperature did not rise above 5 °C. In the meantime, bovine thyroglobulin (BTG; 45 mg) was dissolved in water (2 mL). Dioxan (2 mL) was added and mixed with half of the solution containing the activated SAM hemisuccinate, maintaining the pH at 9.0 with 1 M NaOH. After exhaustive dialysis against water, the conjugate was lyophilized.

(ii) Sulfachlorpyridazine (SCP) Immunogen (SCP−BTG). On the basis of the method described by Schlaeppi et al. (1989), SCP was derivatized by replacing the terminal chlorine atom with a hydroxyl group. SCP (0.5 g) was dissolved in 6 M HCl (10 mL) and stirred at room temperature for 4 h. The mixture was dried by rotary evaporation to give a brown syrup, half of which was dissolved in pyridine (4 mL). 2-Fluoro-1-methylpyridinium *p*-toluenesulfonate (FMP; 100 mg) was added and then stirred gently at room temperature for 1 h, after which BTG (86 mg) in carbonate buffer (pH 9.6; 10 mL) was added. After exhaustive dialysis against water, the conjugate was lyophilized.

Synthesis of Drug−Protein Conjugates for Coating Microtitration Plates. (i) SCP−BSA Conjugate. As with the immunogen, SCP was derivatized to produce a hydroxyl group. Succinic anhydride (500 mg) in pyridine (5 mL) was added to the derivative and gently stirred for 3 days at room temperature. The pyridine was removed by rotary evaporation, and half of the product was taken and added to 0.2 M phosphate buffer (pH 7.3; 1 mL) containing EDC (100 mg). After 30 min, BSA (75 mg) dissolved in 0.2 M phosphate buffer (pH 7.3; 2 mL) was added, and gently stirred for 1 h. After dialysis against water, the conjugate was lyophilized and stored at −20 °C.

(ii) SAM-BSA Conjugate. The SAM derivative (190 mg), used for the immunogen, was dissolved in pyridine (5 mL). Pyridine is necessary both as a solvent and scavenger. FMP (200 mg) was added to the solution and left for 30 min at room temperature. The solution turned dark red in color. Bovine serum albumin (BSA; 140 mg) was dissolved in 0.2 M carbonate buffer (pH 9.6; 5 mL), and this solution was added to the SAM derivative to cause fizzing and a change to a yellow/brown color. The whole mixture was stirred gently overnight, and then dialyzed exhaustively against water and lyophilized.

(iii) Diazo Conjugates. Several drug−protein conjugates were synthesized by the diazotization method and used as solid phases of the ELISA. This method links the drug to the protein via the para-amino benzene group of the common moiety. Essentially, the drug was dissolved in 1 M HCl (10 mL) with 0.1 M $NaNO_2$ added dropwise until a positive starch test was obtained. The solution was added to 0.1 M sodium borate buffer (10 mL) containing the protein carrier. The pH of the total mixture was maintained at pH 9.0 with 1 M NaOH and left gently stirring for 1 h at room temperature. The conjugation mixture was subsequently dialyzed against water and lyophilized. Amounts of drug and protein, respectively, used in diazo conjugate synthesis were for sulfachlorpyridazine, 23 mg and 100 mg of BSA; sulfaquinoxaline, 44 mg and 100 mg of keyhole limpet haemocyanin (KLH); sulfamethazine, 25 mg and 75 mg of KLH; sulfanilamide, 18 mg and 80 mg of BSA; 4-aminodibenzene-sulfonamide, 25 mg and 50 mg of KLH; 4-aminophenyl-4-methyl benzenesulfonamide, 25 mg and 50 mg of KLH.

(iv) Sulfabenzamide (SBA) Conjugate. Sulfabenzamide (SBA, 0.38 g) was dissolved in ethanol (15 mL) and mixed with sodium borohydride (0.2 g) in ethanol (15 mL). The mixture effervesced and a white precipitate formed. The ethanol was removed by rotary evaporation and the solid refluxed for 5 h with succinic anhydride (570 mg) in pyridine (10 mL). FMP (225 mg) was added, and the mixture left at room temperature for 30 min. KLH (75 mg) in carbonate buffer (pH 9.6, 15 mL) was added and left overnight at room temperature. The conjugation mixture was exhaustively dialyzed against water and then lyophilized.

Immunization of Rabbits. For each immunogen, two New Zealand White rabbits were immunized with 100 μg/animal of SCP−BTG or SAM−BTG conjugate emulsified in 1 mL of complete Freund's adjuvant and sterile physiological saline, 1:1 (v:v). The animals were immunized subcutaneously in multiple sites on the back. Subsequent monthly immunizations were carried out as above, except that incomplete Freund's adjuvant was used.

Blood (10 mL) was taken from the marginal ear vein of each animal 10 and 14 days after immunization. The blood was collected in heparinized tubes and centrifuged at 2500 rpm for 10 min. The supernatant was collected and stored frozen, with aliquots at 4 °C for use in ELISA.

Determination of Antibody Response. In 0.05 M sodium bicarbonate/carbonate buffer, pH 9.6, 96-well microtitration plates were coated with 1 μg mL^{-1} of the appropriate drug−protein conjugate. All wells were filled with 300 μL of the coating solution and incubated overnight at 2 °C, at which point they were washed 3 times with water using a Denley Wellwash 5000 microtitration plate washer (Denley Instruments Limited, Sussex, England). Plates were stored dry at room temperature until required for use.

A Beckman BioMek 1000 robotic pipetting workstation and side loader was programmed using BioMek software version 2.11 to carry out the liquid handling stages of the ELISAs. Each rabbit antiserum was diluted 1:1000 (v:v) in PBST and 200 μL added in triplicate to coated plates. A 10-fold serial dilution was carried out four times and the plates were incubated at 37 °C for 2 h. After washing and aspirating the plates five times with PBST, anti-rabbit IgG-HRP conjugate diluted 1:1000 (v:v; 200 μL) in PBST was added to each well and incubated for 1 h at 37 °C. After a further washing with PBST, to each well was added 200 μL of tetramethylbenzidine (TMB)-based substrate (Vetoquinol, Bicester, U.K.). After 10 min, the reaction was stopped using 50 μL/well of 2 M H_2SO_4. The absorbance of each well was measured at 450 nm using a Titertek Multiskan MCC plate reader.

Competitive ELISA. Since it was necessary to screen the antibodies raised against as many of the drugs as possible, the Beckman BioMek 1000 robotic system was programmed to perform all the liquid handling stages of the competitive ELISAs. The basic format of the assay involved the addition (in triplicate) of 100 mL of each standard at each concentration in PBST to drug−protein coated plate, followed by 100 mL of antiserum diluted in PBST to a concentration previously determined by ELISA. The concentrations of drug standards used were 1 mg mL^{-1}, 100 ng mL^{-1}, 1 ng mL^{-1}, and zero. The plates were incubated for 2 h at 37 °C, washed five times with PBST, and then 200 mL/well of anti-rabbit IgG-HRP diluted 1:1000 (v:v) in PBST was added to all wells. After a further incubation of 2 h at 37 °C the plates were washed and TMB substrate added (200 mL/well). After 10 min. the reaction was stopped with 2 M H_2SO_4 and absorbances of each well determined at 450 nm.

RESULTS AND DISCUSSION

The initial modeling studies carried out after performing a search rotating all torsions and energy minimizing for a number of different sulfonamides (Figure 2 shows only SCP and SAM) revealed that the drugs each had a characteristic "bend" around the tetrahedral $-SO_2-$ grouping. The bend varied considerably, being of least angle in SMZ (with the two halves of the drug almost folded back on each other) and of greatest angle in SP (where the drug is almost planar). The angles recorded are given in Table 1. Given the nature of the general structure of the sulfonamides, the differences are clearly due to the influence of the R-group alone.

Our initial hypothesis was based on the idea that maximal exposure of the common moiety was compromised in those drugs where the bend was of smallest angle. Consequently, recognition of the common moiety would be maximal in those drugs where the bend was of greatest angle. We synthesized two immunogens, the SAM−BTG and SCP−BTG conjugates, with the former being a more planar structure, the latter having a greater bend. Reasonable titers were obtained with both immunogens, and subsequent characterization was carried out by determining the ability of the antibodies to recognize different drug conjugates immobilized by passive adsorption to the wells of microtitration plates. Primary antiserum dilution was always 1:1,000 (v:v) for both anti-SAM and anti-SCP antisera. The results are summarized in Table 2. (The anti-SCP antiserum has been applied to the specific determination of the drug in food materials; Spinks et al., unpublished data).

Table 2. Summary of Antisera Binding to Different Hapten Conjugates[a]

coating conjugate based on:	immunogen based on: sulfachlor-pyridazine	sulf-acetamide
sulfachlorpyridazine (R-group linkage)	+++	++++
sulfamethazine (R-group linkage)	+++	++
sulfacetamide	+++	++++
acetyl sulfanilyl chloride	++	+++
sulfabenzamide	++	+++
sulfachlorpyridazine (common group linkage)	++++	−
4-aminodibenzene-sulfonamide	−	nt
4-aminophenyl-4-methyl benzenesulfonamide	+++	+++
sulfamethazine (common group linkage)	++++	++++
sulfaquinoxaline	−	−
sulfanilamide	+++	++++
sulfanillic acid	+++	+++
sulfasalazine	++	−

[a] Absorbance values obtained in ELISA of antiserum diluted 1:1000 v:v (++++ = >2.0; +++ = 1.5−2.0; ++ = 1.0−1.5; − = <0.5; nt = not tested).

Despite some recognition of the different immobilized sulfonamides, neither antisera showed useful broad specificity recognition of unconjugated sulfonamides by competitive ELISA (data not shown). Where recognition does occur (for example with the anti-SCP antiserum cross-reacting with SEZ and SMP), there are close structural similarities in the R-group. SEZ, SMP, and SCP all have an N−N structure within the R-group, and all have significant cross-reaction (1.9, 10.4, and 100%, respectively) as determined in the competitive ELISA. No cross-reactions were observed in the competitive ELISA for the anti-SAM antiserum.

Since the hypothesis based on maximal exposure of the common moiety by use of sulfonamide haptens with minimal bend was disproved, how can new hypotheses

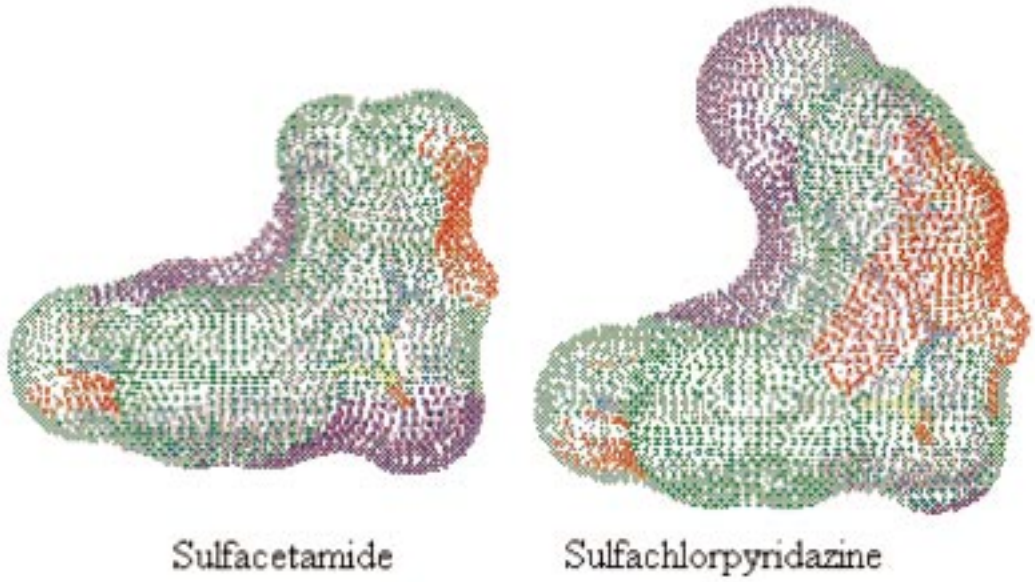

Figure 3. Electronic charge distribution across the surface of sulfacetamide and sulfachlorpyridazine. Blue = negatively charged; red = positively charged; green = relatively neutral.

be developed? It seems that there might be two possibilities. The first is that the $-SO_2-$ function provides a dominant recognition point for antibodies generated in vivo. Consequently, the antibody-binding sites would include some, if not all, of the variable R-group, and would always have a comparatively high degree of specificity. To overcome this problem, it might be possible to generate antibodies against "minimal" haptens such as sulfanilic acid, which does not contain the equivalent of an "R-group". However, antibodies generated against sulfanilic acid (data not presented) did not show any recognition of intact sulfonamides, again suggesting that the $-SO_2-$ moiety might be exerting disproportionate influence.

A second, and in our view more likely, explanation, lies in an examination of the charge distribution across the sulfonamide structures (Figure 3). We had anticipated that the R-group would not exert a significant effect on the charge distribution across the common group. However, it can be seen that this was not the case. Drugs such as SCP and SAM appear to be very different across the whole structure. Since so little is known about the molecular detail of recognition by antibodies of haptens, only speculation on the relative roles of different molecular attributes such as charge distribution or shape or hydrophobicity is possible. If charge distribution were the dominant force, then it would have to be the case that true broad specificity antibodies against sulfonamides would be impossible to generate in vivo.

In vitro generation of antibodies might offer hope of success, either through the use of artificial libraries of antibody genes (Hoogenboom and Winter, 1992), containing rare antibody functionalities not normally seen in nature or through the manipulation of antibody binding properties using the tools of molecular biology (Sharon et al., 1993). It is clear that recombinant antibodies offer considerable opportunities for future research (Nissim et al., 1994), though this has yet to be realized in terms of new applications. Molecular modeling of antibody-binding sites will be more widely utilized as rational manipulation of the binding site properties becomes an achievable goal for immunochemists. Part of this process will inevitably involve greater understanding of hapten structure at an earlier stage in proceedings than is currently the case. A limiting factor in the process will be the poor understanding of hapten-antibody interactions relative to protein-antibody interactions. It must also be remembered that interaction of antibodies with haptens is, if not an aberration, then at the extreme of a normal in vivo response. Given that the size of an amino acid side chain may be bigger than some haptens, then the degree of subtlety involved in bestowing specificity may be beyond current comprehension (and computing power). The involvement of antibody framework regions in the specificity of an anti-hapten response has previously been described (Kreissig et al., 1995). Mutations carried out on genes coding for those amino acids of the framework regions close to the complementarity-determining regions can have effects on antibody−antigen interactions since they may affect the conformation or stability of the binding site. Studies using anti-idiotype antibodies (Spinks et al. 1993) also suggest that framework regions may have some role in binding specificity.

In conclusion, molecular modeling of potential hapten structures has revealed an unexpected layer of complexity among a family of related structures, the sulfonamide drugs. While molecular modeling was, in this instance, unable to solve the problem of producing broad specificity antibodies, it has suggested new routes of experimentation. This, together with previous reports where molecular modeling was used to understand more about the interaction of antibody with target, suggests that modeling will become an increasingly used tool for the immunochemist.

ACKNOWLEDGMENT

The financial support of the Ministry of Agriculture, Fisheries and Food is gratefully acknowledged. We thank Dr. Steve Dixon (MAFF) for helpful discussion during the course of the research.

Structure−Activity Relationships of Water-Soluble Cationic Methacrylate/Methacrylamide Polymers for Nonviral Gene Delivery

Petra van de Wetering,[†] Ed E. Moret,[‡] Nancy M. E. Schuurmans-Nieuwenbroek,[†] Mies J. van Steenbergen,[†] and Wim E. Hennink*[,†]

Department of Pharmaceutics, Department of Medicinal Chemistry, Utrecht Institute for Pharmaceutical Sciences (UIPS), Faculty of Pharmacy, Utrecht University, Utrecht, The Netherlands. Received December 12, 1998; Revised Manuscript Received March 31, 1999

A number of water-soluble cationic carriers was evaluated as transfectant. Almost all studied cationic methacrylate/methacrylamide polymers were able to condense the structure of plasmid DNA, yielding polymer/plasmid complexes (polyplexes) with a size of 0.1−0.3 μm and a slightly positive ζ-potential, which can be taken up by cells, e.g., via endocytosis. However, the transfection efficiency and the cytotoxicity of the polymers differed widely: the highest transfection efficiency and cytotoxicity were observed for poly[2-(dimethylamino)ethyl methacrylate], p(DMAEMA). Assuming that polyplexes enter cells via endocytosis, p(DMAEMA) apparently has advantageous properties to escape the endosome. A possible explanation is that, due to its average pK_a value of 7.5, p(DMAEMA) is partially protonated at physiological pH and might behave as a proton sponge. This might cause a disruption of the endosome, which results in the release of both the polyplexes and cytotoxic endosomal/lysosomal enzymes into the cytosol. On the other hand, the analogues of p(DMAEMA) studied here have a higher average pK_a value and have, consequently, a higher degree of protonation and a lower buffering capacity. This might be associated with a lower tendency to destabilize the endosome, resulting in both a lower transfection efficiency and a lower cytotoxicity. Furthermore, molecular modeling showed that, of all studied polymers, p(DMAEMA) has the lowest number of interactions with DNA. We therefore hypothesized that the superior transfection efficiency of p(DMAEMA) containing polyplexes can be ascribed to an intrinsic property of p(DMAEMA) to destabilize endosomes combined with an easy dissociation of the polyplex once present in the cytosol and/or the nucleus.

INTRODUCTION

In previous studies, it has been shown that poly(2-(dimethylamino)ethyl methacrylate), p(DMAEMA), is able to bind plasmid DNA, yielding polymer/plasmid complexes (also called polyplexes) (*1*). The size and ζ-potential of the polyplexes were dependent on the polymer/plasmid ratio. We demonstrated that polyplexes with a slightly positive ζ-potential (25−30 mV) and a size around 0.2 μm possessed the highest transfection potential (*2*, *3*). However, as observed for many other polycationic compounds (*4*, *5*), e.g., the frequently used transfectant poly(l-lysine) (*6*), p(DMAEMA) is cytotoxic (*3*). We also reported, upon the synthesis and characterization of random copolymers of DMAEMA with hydrophilic, noncharged comonomers. These copolymers showed a better efficacy/cytotoxicity ratio as compared to p(DMAEMA) of comparable molecular mass (*7*).

In this study, the transfection capability of other water-soluble cationic polymers with structures closely related to p(DMAEMA) is evaluated to obtain insight into the relationship between their structure and activity. For cationic lipids, peptides, and cationic amphiphiles, a number of studies has been published concerning the relationship between structure and their transfection characteristics. For lipids, the effects of the nature of the lipid headgroup (*8*, *9*), the length of the hydrophobic tail (*10*), and the length of the head−tail linker (*11*) on their transfection characteristics have been studied. The influence of structural modifications in peptoids (*12*), peptides (*13*−*15*), and cationic facial amphiphiles (*16*) on transfection efficiency has been investigated. For synthetic cationic polymers, no systematic studies have been reported so far, to our knowledge.

The polymers in this study were evaluated on their ability to bind plasmid DNA using dynamic light scattering (DLS), and the resulting polyplexes were characterized by ζ-potential measurements. The transfection efficiency and the cytotoxicity of the polyplexes were studied in vitro in OVCAR-3 cells. Furthermore, molecular modeling was used to obtain insight into the characteristics of possible DNA−polymer interactions.

Polymer Selection. The structure of p(DMAEMA) is shown in Figure 1a. The effect of a propyl side chain instead of an ethyl side chain is studied with poly[3-(dimethylamino)propyl methacrylate] [p(DMAPMA), Figure 1b]. Substitution of the ester group in p(DMAEMA) by an amide group is evaluated with poly[2-(dimethylamino)ethyl methacrylamide] [p(DMAEMAm), Figure 1c]. The effect of both a longer side chain and an amide group is studied with poly[3-(dimethylamino)propyl methacrylamide] [p(DMAPMAm), Figure 1d]. P(DMAEMA) contains tertiary amino groups, with an average pK_a of 7.5, implying that around 50% of the side groups is positively charged at physiological pH. Poly[2-(trimethy-

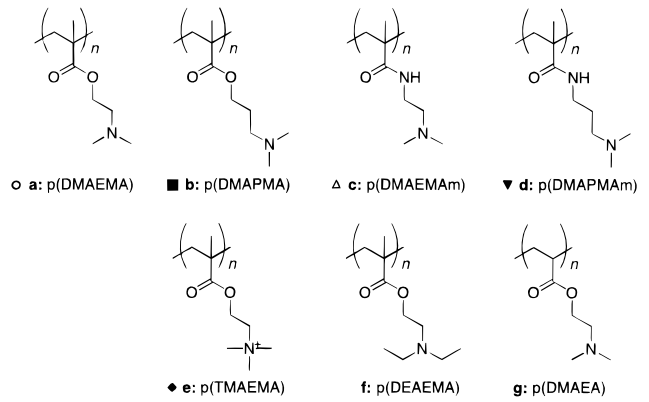

Figure 1. Chemical structure of (a) poly(2-(dimethylamino)-ethyl methacrylate), p(DMAEMA); (b) poly(3-(dimethylamino)-propyl methacrylate), p(DMAPMA); (c) poly(2-(dimethylamino)-ethyl methacrylamide), p(DMAEMAm); (d) poly(3-(dimethylamino)propyl methacrylamide), p(DMAPMAm); (e) poly(2-(trimethylamino)ethyl methacrylate chloride), p(TMAEMA); (f) poly(2-(diethylamino)ethyl methacrylate), p(DEAEMA); and (g) poly(2-(dimethylamino)ethyl acrylate), p(DMAEA).

lamino)ethyl methacrylate chloride] [p(TMAEMA), Figure 1e] is used to study the effect of structurally almost identical polymers with permanently positively charged side chains. Another modification of the amino group is studied with poly[2-(diethylamino)ethyl methacrylate] [p(DEAEMA), Figure 1f]. This polymer contains diethylamino groups instead of dimethylamino groups. Finally, the effect of a more hydrophilic, and probably more flexible, polymer backbone is investigated with poly[2-(dimethylamino)ethyl acrylate] [p(DMAEA), Figure 1g].

MATERIALS AND METHODS

Materials. The following compounds were used as received: 2-(dimethylamino)ethyl methacrylamide (DMAEMAm, Polysciences), 3-(dimethylamino)propyl methacrylamide (DMAPMAm, Aldrich, Bornem, Belgium), 2-(trimethylamino)ethyl methacrylate chloride (TMAEMA, Aldrich), 2-(dimethylamino)ethyl acrylate (DMAEA, Aldrich), 2,2′-azobisisobutyronitrile (AIBN, Fluka, Bornem, Belgium), and ammonium peroxodisulfate (APS, Fluka). All other chemicals were of analytical grade. Water purified by reversed osmosis was applied throughout the study.

2-(Dimethylamino)ethyl methacrylate (DMAEMA, Fluka) and 2-(diethylamino)ethyl methacrylate (DEAEMA, Aldrich) were purified by distillation under reduced pressure before use. 3-(Dimethylamino)propyl methacrylate (DMAPMA) was synthesized from methacryloyl chloride and 3-(dimethylamino)propanol as described elsewhere (*17*).

Cell culture flasks and microtiter plates were obtained from Falcon (Micronic, Lelystad, The Netherlands). Dulbecco's Modified Eagle's Medium (DMEM) and RPMI 1640 medium were from Gibco (Life technologies, Breda, The Netherlands). Fetal calf serum (FCS) was from Integro (Zaandam, The Netherlands). Biotinylated, methoxypsoralen inactivated adenovirus dl1014 (*18*, *19*) (stock solution 1.9×10^{11} particles/mL) was kindly provided by Dr. E. Wagner (Bender, Austria).

Hepes-buffered saline (HBS) was composed of 150 mM NaCl, 20 mM Hepes, pH 7.4. The plasmid pCMVLacZ containing a bacterial *LacZ* gene preceded by a nuclear localization signal under control of a CMV promoter was amplified and purified as reported before (*2*).

Synthesis and Characterization of Polymers. The polymers were synthesized by radical polymerization of the corresponding monomers essentially as described in detail previously for the synthesis of p(DMAEMA) (*3*). Polymers of DMAEMA, DMAEA, and DEAEMA were synthesized in toluene (20% w/v) using AIBN as initiator (M/I 100−250, mol/mol). After 22 h at 60 °C the polymers were isolated by precipitation in a 5−10-fold excess cold petroleum ether and dried in vacuo. The polymers were dissolved in water, dialyzed against water, and isolated by lyophilization. Polymers of DMAEMAm, DMAPMA·HCl, DMAPMAm·HCl, and TMAEMA were synthesized in aqueous hydrochloric acid (20% w/v) using APS as initiator (M/I 100−500, mol/mol). Polymerizations were stopped after 22 h at 60 °C, by transferring the reaction mixture into dialysis tubes. After extensive dialysis against water at 4 °C, the polymers were obtained by lyophilization.

The weight and number average molecular masses of the polymers were determined by gel permeation chromatography (GPC). The GPC measurements were performed with two thermostated (35 °C) columns in series (Shodex OHpak KB-802 and KB-80M, Showa Denko, Japan) equipped with a refractive index detector. The eluent was an aqueous solution of 0.7 M $NaNO_3$, 0.1 M Tris (pH 7.2), and the flow rate was 1 mL/min. The columns were calibrated using dextran standards of known molecular masses (Fluka).

pK_a Measurements. The pK_a values of monomers and polymers were determined by titration with a Metrohm combi-titrator, equipped with a 614 pulsomat. The compounds were dissolved in 0.9 w/v % NaCl solutions (to a final concentration of 0.2−0.3 w/v %), acidified with 0.1 M HCl and titrated with 0.25 M NaOH.

Particle Size and ζ-Potential Measurements. For dynamic light scattering (DLS) measurements, the stock solutions of the polymers (2 mg/mL in HBS) were diluted with "fake" RPMI medium (RPMI 1640 medium without phenol red and vitamins) to 2.4−78 μg/mL. The plasmid pCMV*LacZ* was diluted to 25 μg/mL in fake RPMI. Polymer solution (400 μL) was added to 100 μL of plasmid solution, resulting in 0.39/1 to 12.5/1 (w/w) polymer/plasmid ratio. After 30−45 min complex formation time, *Z*-average particle size and polydispersity index (PI) of the polyplexes were determined by dynamic light scattering (DLS) at 25 °C with a Malvern 4700 system using an argon-ion laser (488 nm) operating at 10.4 mW (Uniphase). The PCS (photon correlation spectrometry) software for Windows (version 1.34, Malvern, U.K.) was used. For the data analysis, the viscosity and refractive index of pure water at 25 °C were used. The instrument was checked with a polystyrene dispersion containing particles of 100 nm.

For the ζ-potential measurements, the polymer stock solutions were diluted with 20 mM Hepes. Next, 680 μL of polymer solution was added to 170 μL of plasmid solution (75 μg/mL in 20 mM Hepes), resulting in 0.39/1 to 12.5/1 (w/w) polymer/plasmid ratio. After 30−45 min of complex formation time, the ζ-potential was measured at a temperature of 25 °C in an aqueous DTS5001 cell with a Zetasizer 2000 (Malvern, U.K.) and PCS software for Windows (version 1.34, Malvern, U.K.). The instrument was checked using a polystyrene dispersion with a known ζ-potential.

Molecular Modeling. Molecular modeling was performed with Insight II 97.0 (*20*) on a Silicon Graphics workstation. Eight adenine-thymine (AT) basepairs were built in canonical B-conformation with Insight II. To choose a starting orientation of the flexible polymer backbone, either in the major or in the minor groove of octa(DNA), a Monte Carlo simulated annealing docking

was used. Therefore, the backbone of octa(DMAEMA) was docked flexibly five times to DNA with AutoDock 2.2 (*21*). The results were clustered and the best cluster was used as a starting conformation for building syndiotactic octa(DMAEMA). This was also done for the other polymers. The number of protonated side groups in the octamers was varied. To mimic the situation at pH 7.4, the fraction of protonated groups was calculated from the average pK_a values of the polymers. To exclude end effects, the outer groups of the octamers were protonated preferentially.

Minimization of the structure was performed with the CVFF force field and conjugate gradients in Discover 2.98. Minimization was stopped after 10^5 iterations or when the maximum derivative of the potential energy was less than 0.001 kcal/Å. Throughout the minimization and molecular dynamics, the DNA was held fixed, and the nonbonded energy (representing the hydrogen bonds) was computed within a cutoff radius of 12.5 Å at a default dielectric constant of 1. The minimized structure was subjected to 500 ps of molecular dynamics at 300 K with 1 fs steps. The number of hydrogen bonds formed during the simulation were counted every ps and used as a measure of binding. All simulations were performed at least twice.

Cell Culture. The human ovarian cancer cell line NIH:OVCAR-3 originated from Dr. Hamilton (National Cancer Institute, Bethesda, MD) (*22*). OVCAR-3 cells were cultured in DMEM supplemented with 10% (v/v) FCS, l-glutamine (2 mM), l-glucose (4.5 g/L), penicillin (100 IU/mL), streptomycin (100 μg/mL), and amphotericin B (0.25 μg/mL). Before performing a transfection experiment, the cells were grown to 60−80% confluency at 37 °C in a humidified atmosphere containing 5% CO_2.

Preparation of Polymer/Plasmid Complexes for Transfection Experiments. The stock solutions of the polymers (2 mg/mL in HBS) were diluted to 2.4−(6×10^{2}) μg/mL with plain RPMI medium. The plasmid pCMV-*LacZ* was diluted to 25 μg/mL in RPMI. Complexes of polymer and plasmid were prepared by adding 400 μL of polymer solution to 100 μL of plasmid solution, resulting in 0.39/1 to 100/1 (w/w) polymer/plasmid ratio. After 30−60 min complexation time, the complexes were added to the cells.

Transfection Studies. Transfection experiments were performed with OVCAR-3 cells using the plasmid pCMV*LacZ* as reporter gene essentially as described before (*2*, *3*, *7*). In brief, cells were seeded at a concentration of 3×10^4/cm^2 in 96-well plates 24 h before transfection. At the day of transfection, cells were rinsed and incubated for 1 h with 200 μL of polyplexes/well.

Transfection experiments in the presence of adenovirus were performed essentially as described above and analogous to Cotten et al. (*23*). Polyplexes were prepared by adding 5 μL (9.4×10^8 particles) of adenovirus and 50 μL of polymer solution (78 and 156 μg/mL) to 50 μL of plasmid solution (50 μg/mL). After 30 min, 400 μL of RPMI was added and the complexes were applied to the cells.

All transfection experiments were performed in two identical series in separate 96-well plates. After removal of the transfection complexes, 100 μL of fresh culture medium was added, and the cells were further cultured for about 48 h. Then, one series was tested for reporter gene expression (β-galactosidase) by histochemical staining with X-Gal (*24*). To determine the cytotoxic effect of polyplexes, the number of viable cells was measured using a XTT colorimetric assay (*25*).

RESULTS

Polymer Characterization. The different (meth)acrylate/methacrylamide polymers (Figure 1) were synthesized by radical polymerization of the corresponding monomers. Since the transfection efficiency of p(DMAEMA) depended on the molecular mass (*3*), the aim was to synthesize high molecular mass polymers, which are also able to condense DNA to particles with a size of about 0.1−0.3 μm. Table 1 shows the molecular masses of the synthesized polymers. Except for p(DMAEA), polymers with a weight average molecular mass of ≥90 kDa were obtained. Further, Table 1 shows that the average pK_a (which is defined as the pH at which 50% of the amino groups in the polymers are protonated) is 0.1−1.3 pH units below the pK_a of the monomers. A likely explanation is that the presence of protonated side chains reduced the protonability of the remaining di(m)ethylamino groups; a phenomenon that has been reported before for other polymers (*26*).

Particle Size and ζ-Potential Measurements. The characteristics of the polyplexes in terms of particle size and ζ-potential were studied as a function of polymer/plasmid ratio. As reference polymer, p(DMAEMA) with good condensing properties (M_w 550 kDa) was used.

Like p(DMAEMA), polymers of DMAEMAm, DMAPMA, DMAPMAm, and TMAEMA were able to condense plasmid to particles with a size of 0.1−0.3 μm at a polymer/plasmid ratio of 1.5−3/1 (w/w) (Figure 2). P(DMAEA) (Figure 1g) was not able to condense plasmid to

p(TMAEMA)	30 ± 2	21 ± 2	45 ± 2

small particles; a heterogeneous mixture (particle size 1−2 μm) with a high polydispersity was formed. This might be explained by the low molecular mass of this polymer (Table 1). At room temperature, only large aggregates were formed by incubation of p(DEAEMA) (Figure 1f) and plasmid. Particles with a relatively smaller size were obtained by incubation of p(DEAEMA) and plasmid at 4 °C (polymer/plasmid 6/1, particle size 0.6−0.7 μm). However, when the dispersion was brought at ambient temperature, aggregates of about 2 μm were formed within 5 min. The relatively low molecular mass of p(DEAEMA) combined with the low solubility of this polymer around pH 7 (*27*) could be the reason for the inability to form small complexes with DNA.

It was shown that at a polymer/plasmid ratio of ≥2/1 (w/w), the ζ-potential of the polyplexes composed of p(DMAEMAm), p(DMAPMA), p(DMAPMAm), or p(TMAEMA) and plasmid was 26−30 mV, which is comparable with the ζ-potential of polyplexes composed of p(DMAEMA) and plasmid (Table 3) and comparable with other systems [poly(l-lysine) (*28*), liposomes (*9*, *29*, *30*)].

Modeling. With molecular dynamics, the hydrogen bonding between octamers of all polymers [octa(repeating unit)] and a DNA octamer was studied. The octamers were built in a syndiotactic form, which is the preferred configuration for p(DMAEMA) prepared by radical polymerization (*31*). As an example, Figure 3 shows that the docking of octa(DMAEMA) to a DNA octamer resulted in a stable orientation in the major groove. Minimization and molecular dynamics performed on the complex showed that octa(DMAEMA) remained in the major groove, which was also observed for poly(N-vinyl pyrrolidone), PVP, by Mumper et al. (*32*). PVP was placed in a minimized conformation near a DNA oligomer. In their study, two kinds of interactions could be distinguished. The vinyl backbone of PVP provided a hydrophobic surface on DNA and hydrogen bonding was observed between the hydrophilic pyrrolidone groups and the base pairs of DNA.

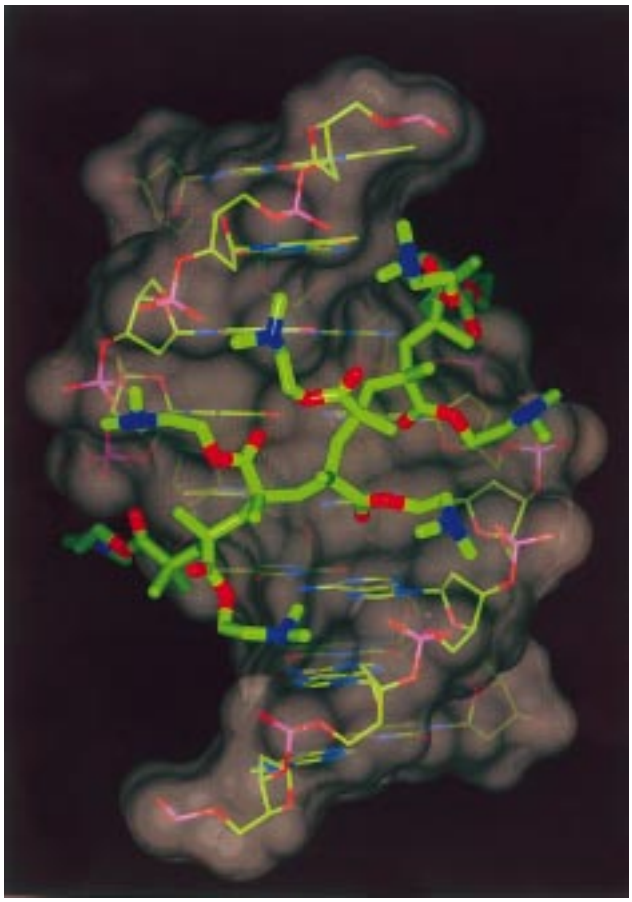

Figure 3. Octa(DMAEMA) docked into the major groove of octa(DNA).

In our study, using molecular dynamics, three (Figure 4) and four (Figure 5) types of interactions were observed between DNA and the methacrylate octamers and methacrylamide octamers, respectively. First, interaction occurred between the positively charged amino groups and the negatively charged phosphate groups in DNA: $(PO_4^-)_{DNA}$-$(amino)_{poly}$ interaction. Second, interaction between a NH of adenine and the C═O group of the polymers was observed ($(NH)_{DNA}$-$(C{=}O)_{poly}$, see Figure 6). Third, interaction between the positively charged amino

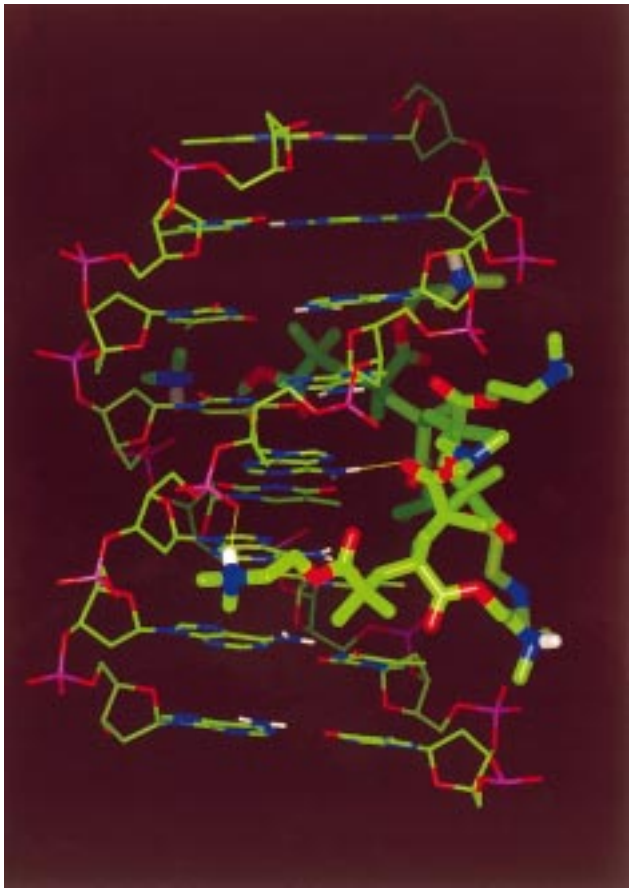

Figure 4. Interactions between a DNA octamer and octa(DMAEMA) $(PO_4^-)_{DNA}$-$(amino)_{poly}$ and $(NH)_{DNA}$-$(C{=}O)_{poly}$.

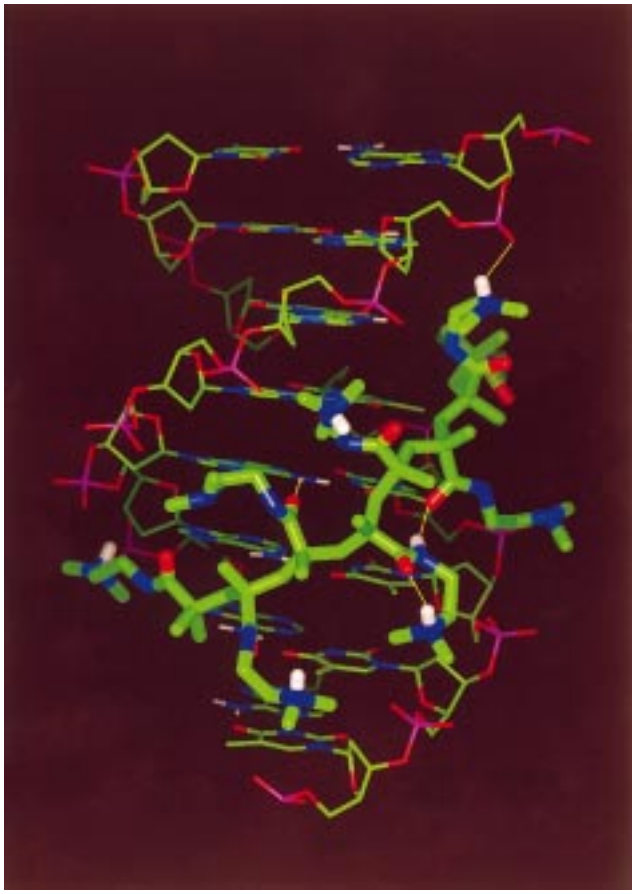

Figure 5. Interactions between a DNA octamer and octa(DMAEMAm) $(PO_4^-)_{DNA}$-$(amino)_{poly}$, $(NH)_{DNA}$-$(C{=}O)_{poly}$, $(amino)_{poly}$-$(C{=}O)_{poly}$, and $(amide)_{poly}$-$(C{=}O)_{poly}$.

group and the carbonyl group within a polymer chain occurred [intrapolymeric interaction: $(amino)_{poly}$-$(C{=}O)_{poly}$]. The fourth type of interaction could only occur between methacrylamide compounds, because it involved the interaction of the amide proton with the carbonyl: $(amide)_{poly}$-$(C{=}O)_{poly}$ interaction.

First, the effect of the degree of protonation of amino groups on the interaction with DNA was studied for octa(DMAEMA) (Figure 4). Table 2 shows that, with an increasing degree of protonation, the total number of $(PO_4^-)_{DNA}$-$(amino)_{poly}$ interactions increased. However, the number of these interactions per protonated group slightly decreased with an increasing degree of protonation. Besides $(PO_4^-)_{DNA}$-$(amino)_{poly}$ interactions, also $(NH)_{DNA}$-$(C{=}O)_{poly}$ interactions were observed. With exception of octa(DMAEMA) bearing five protonated groups, octa(DMAEMA)$^{5+}$, the number of interactions between the $(NH)_{DNA}$ and $(C{=}O)_{poly}$ increased with the degree of protonation. Taking both types of interactions together, it can be concluded that, with an increasing degree of protonation, the octamer comes into a more fixed position in the major groove of DNA.

Next, the number and types of interactions between the different fully protonated octamers and octa(DNA) were compared. Table 2 shows that replacement of the ester group in octa(DMAEMA)$^{8+}$ by an amide group, i.e. octa(DMAEMAm)$^{8+}$, had no significant effect on the number of interactions between $(PO_4^-)_{DNA}$ and $(amino)_{poly}$. Due to the presence of the amide group, octa(DMAEMAm)$^{8+}$ showed additional $(amide)_{poly}$-$(C{=}O)_{poly}$ interactions as well as an increased number of $(amino)_{poly}$-$(C{=}O)_{poly}$ interactions (Figure 5). In contrast, the number of interactions between $(C{=}O)_{poly}$ and $(NH)_{DNA}$ was lower in comparison with octa(DMAEMA)$^{8+}$, which might be due to the large increase in the number of $(amino)_{poly}$-$(C{=}O)_{poly}$ interactions. When the behavior of octa(DMAEMA)$^{8+}$ is compared with octa(DMAPMA)$^{8+}$, the number of interactions between $(PO_4^-)_{DNA}$ and $(amino)_{poly}$ was higher for octa(DMAPMA)$^{8+}$, whereas $(NH)_{DNA}$-$(C{=}O)_{poly}$ interactions were absent. As was observed for octa(DMAEMA)$^{8+}$, the number of intrapolymeric interactions within octa(DMAPMA)$^{8+}$ were marginal. Replacing the ester group in octa(DMAPMA)$^{8+}$ with an amide group, i.e. octa(DMAPMAm)$^{8+}$, resulted in an increase of $(PO_4^-)_{DNA}$-$(amino)_{poly}$ interactions while the number of $(NH)_{DNA}$-$(C{=}O)_{poly}$ and intrapolymer interactions remained very low. Similar as observed for octa(DMAEMAm)$^{8+}$, octa(DMAPMAm)$^{8+}$ also showed additional $(amide)_{poly}$-$(C{=}O)_{poly}$ interactions. However, in contrast to the ethyl compound octa(DMAEMAm)$^{8+}$, octa(DMAP-

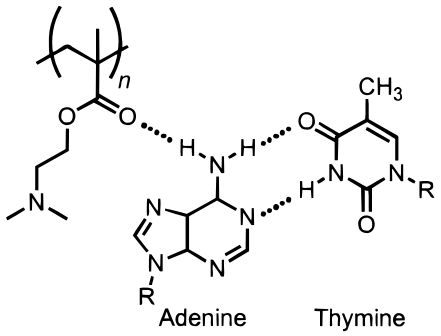

Figure 6. Interaction between an adenine-thymine base pair (R = sugar/phosphate backbone) and adenine and (the carbonyl group of) the polymer.

MAm)$^{8+}$ had no intrapolymeric $(amino)_{poly}$-$(C{=}O)_{poly}$ interactions.

Finally, we compared the types and the number of interactions at pH 7.4. For each octamer, the fraction protonated with amino groups was calculated from the average pK_a of the polymers (Table 2). Comparison of the interactions of the different octamers with DNA at pH 7.4 shows similar trends, as were observed for fully protonated octamers. However, the only observed difference is that for p(DMAEMA)$^{4-5+}$, the number of $(PO_4\text{-})_{DNA}$ and $(amino)_{poly}$ interactions, was 1.5, 2.8−3.5, and 4−5 times lower in comparison with octa(DMAEMAm)$^{6+}$, octa(DMAPMA)$^{7+}$, and octa(DMAPMAm)$^{8+}$, respectively.

For octa(TMAEMA), which permanently bears positively charged amino groups, interaction with DNA is expected. Because the $(PO_4\text{-})_{DNA}$-$(amino)_{poly}$ interaction does not involve hydrogen bonds, it was not possible to quantify the number of interactions between octa(DNA) and octa(TMAEMA). However, due to its permanent positive charge, relatively strong electrostatic interactions between octa(TMAEMA) and DNA can be expected.

Although complexing problems prevented evaluation in transfection, octa(DMAEA) and octa(DEAEMA) could be studied in terms of interaction with DNA. As can be seen in Table 2, for octa(DMAEA) and octa(DEAEMA), similar numbers of DNA−octamer interactions were observed. However, in comparison with the results of octa(DMAEMA), the number of $(PO_4^-)_{DNA}$-$(amino)_{poly}$ interactions was higher than the number of interactions found for octa(DMAEMA).

Transfection Efficiency and Influence on Cell Viability. The influence of the polymer concentration on the cell viability was evaluated in cell culture for the different polymers. From Figure 7a, which shows the effect of the polymer concentration on the cell viability, the IC_{50} values [defined as the concentration resulting in 50% inhibitory activity (cell-death)], which give an indication about the cytotoxicity, were determined (Table 3). Both Figure 7a and Table 3 show that all evaluated polymers had a lower cytotoxicity than p(DMAEMA). P(DMAEMAm) was about 3-fold less toxic than p(DMAEMA). The analogue with a propyl instead of an ethyl side chain, p(DMAPMA), was almost 9-fold less toxic than p(DMAEMA). Combination of both structural differences (amide and propylene side chain) in p(DMAPMAm) did not result in a synergistic reduction of the cytotoxicity: p(DMAPMAm) was only 3-fold less toxic than p(DMAEMA). Finally, the permanently positively charged p(TMAEMA) had about a 5-fold lower toxicity as compared to p(DMAEMA).

Next, the influence of the polymer/plasmid ratio on the cell viability and transfection efficiency was evaluated for the different polymers. Figure 7b shows the relation between the polymer/plasmid ratio and the cell viability. The same trend as found for the free polymers was observed (Figure 7a). The IC_{50} values, calculated from Figure 7b, give an indication about the cytotoxicity of the transfection mixture, consisting of polyplexes and free polymer which is likely present above a certain polymer/plasmid ratio. Comparison of the IC_{50} values of the polymers with the IC_{50} values of the polyplexes shows that the presence of plasmid masked part of the cytotoxic effect of the polymer. This phenomenon has also been reported for, e.g., α-helical peptides (*14*) and liposomes (*33*).

For p(DMAEMA), a bell-shaped relation between polymer/plasmid ratio and transfection efficiency was found (Figure 7c). At low polymer/plasmid ratios (<2/1, w/w), the polyplexes consisted of large aggregated particles (size around 1 μm), which obviously could not enter the cell easily. At a polymer/plasmid ratio 2−3/1 (w/w), the DNA was condensed by the polymer into small complexes (size 0.1−0.2 μm) with a positive ζ-potential. Here, about 10−20% of the cells was transfected. When the polymer/plasmid ratio was increased, the particles still had the

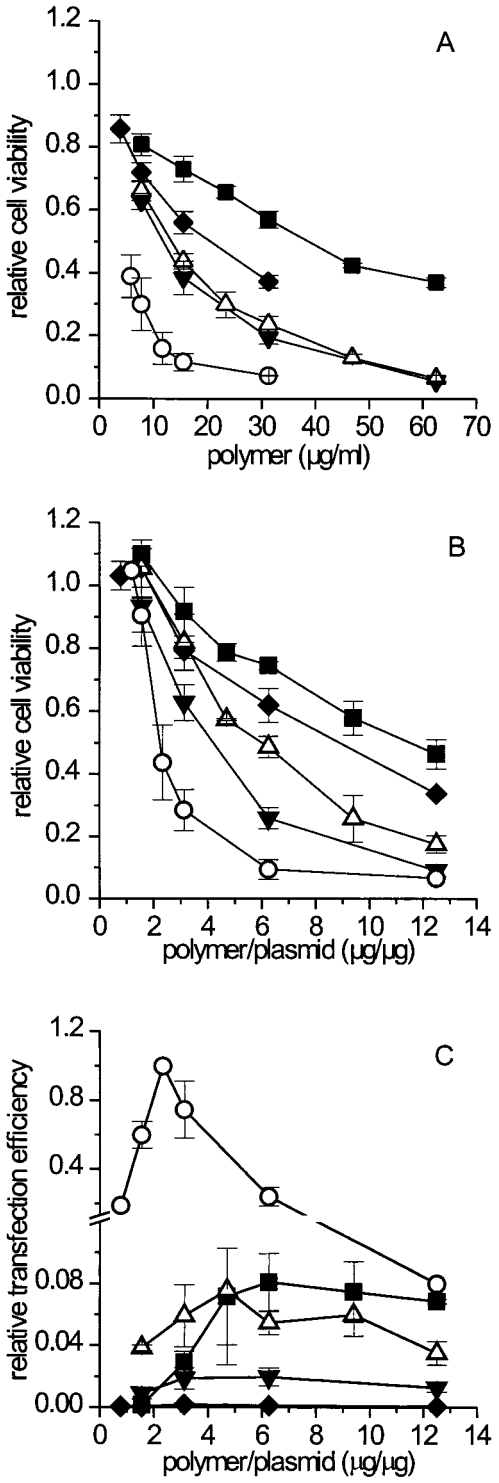

Figure 7. Effect of polymer concentration on the relative cell viability (a), effect of polymer/plasmid ratio on the relative cell viability (b), and transfection efficiency (c). The plasmid concentration was 5 μg/mL, the transfection time (incubation time of the complexes with OVCAR-3 cells) was 1 h. Transfection values are normalized to the maximum number of transfected cells after incubation with plasmid complexed to p(DMAEMA). The results are shown as mean values (±SEM) of three experiments. Symbols as in Figure 2.

Table 4. Relative Transfection Efficiency, Particle Size and Polydispersity (PI) of Polyplexes, Prepared at Two Different Polymer/Plasmid Ratios

	polymer/plasmid 3/1 (mg/mg)			polymer/plasmid 6/1 (mg/mg)		
polymer	relative transfection[a] (%)	particle size (mm)	PI	relative transfection[a] (%)	particle size (mm)	PI

p(TMAEMA)	0.19 ± 0.10	0.16 ± 0.02	0.1	0.12 ± 0.05	0.14 ± 0.01	0.2

[a] Transfection values are normalized to the maximum number of transfected cells obtained with p(DMAEMA)/plasmid complexes (resulting in an absolute transfection efficiency of 5−20%).

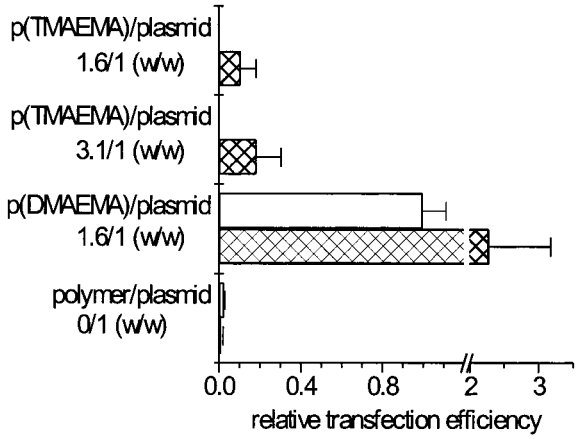

Figure 8. Influence of the presence of adenovirus during transfection on the relative transfection efficiency. Cells were incubated with polyplexes in the absence (open bars) or the presence (filled bars) of 1.9×10^9 adenovirus particles/mL. Transfection values are normalized to the maximum number of transfected cells after incubation with p(DMAEMA)/plasmid 1.6/1 (w/w) in absence of adenovirus. The plasmid concentration was 5 μg/mL. The results are shown as mean values (±SEM) of three experiments.

same physicochemical characteristics as observed at polymer/plasmid ratio 2−3/1 (w/w). However, at this high polymer/plasmid ratio, the transfection formulation contained besides polyplexes probably also free polymer. Due to the presence of an increasing amount of free polymer with an increasing polymer/plasmid ratio, the cell viability decreased resulting in a reduction of the transfection efficiency (*3*).

For the studied analogues of p(DMAEMA), the transfection efficiency was 5−400-fold lower than observed for p(DMAEMA). Moreover, the bell-shaped curve was less pronounced. Table 4 summarizes for two polymer/plasmid ratios, the particle size, the polydispersity index (PI) of the polyplexes and the relative transfection efficiency. Again, it can be seen that despite the fact that polyplexes with the same physicochemical characteristics are formed, the transfection efficiency of these polyplexes differed widely: p(DMAEMA) is far superior as transfectant in comparison with the other polymers investigated.

Figure 8 shows the effect of the presence of adenovirus during transfection with p(DMAEMA)/plasmid and p(TMAEMA)/plasmid complexes. In agreement with the results obtained with poly(l-lysine) (*23*), the transfection efficiency of p(DMAEMA)/plasmid complexes was enhanced in the presence of adenovirus. More interestingly, complexes of p(TMAEMA) and plasmid were also able to transfect at polymer/plasmid (w/w) ratios of 1.6/1 and 3.1/1, respectively, while in the absence of adenovirus, practically no cells were transfected. The cell viability was not significantly influenced by the presence of adenovirus.

DISCUSSION

To transfect cells, the polymer has to condense DNA to a particle of about 0.1−0.3 μm. After cellular entry via, e.g., endocytosis the plasmid has to be transported into the nucleus, which requires endosomal escape and dissociation of the polymer/plasmid complex. This study shows that relatively small changes in the structure of p(DMAEMA) do not have a large effect on the condensing properties of the polymer (Figure 2, Tables 3 and 4), while the effect on the cytotoxicity and transfection capability is substantial. For example, the presence of an amide group instead of an ester group in p(DMAEMAm) or a side chain with an extra methylene group in p(DMAPMA) resulted in a decrease in transfection capacity of the polymer (Table 4, Figure 7c). Since the polyplexes have comparable physicochemical characteristics, the reduced transfection efficiency cannot be ascribed to the formation of large complexes (*3*, *34*) or differences in ζ-potential (*9*) as was observed before.

The highest transfection efficiency was obtained with polyplexes containing p(DMAEMA). This superior transfection efficiency cannot be ascribed to the relatively high molecular mass of p(DMAEMA) as compared to the other polymers studied (Table 1) since we have demonstrated that both the DNA condensing properties and the transfection potential were independent of molecular mass of p(DMAEMA) above M_w 100−200 kDa (*3*, *7*). Assuming that all studied polymers are endocytosed in a comparable way, polyplexes containing p(DMAEMA) are apparently able to escape the endosome, and/or facilitate transport into the nucleus most efficiently. The more efficient endosomal escape of p(DMAEMA)-containing polyplexes might be explained by its (low) pK_a value. Due to a pK_a value of 7.5, p(DMAEMA) is only partially protonated at physiological pH, like poly(ethyleneimine) (PEI) (*35*) and poly(amidoamine) cascade polymers (*36*). Analogous to PEI and poly(amidoamine), p(DMAEMA) might also buffer the acidification in the endosomal/lysosomal vesicle and act as a so-called proton sponge, resulting in osmotic swelling and destabilization of the endosomal/lysosomal vesicle (*35*). This hypothesis is further supported by the observation that the presence of an endosome-disruptive agent (adenovirus) during the transfection resulted in a 2-fold increased transfection efficiency with p(DMAEMA)/plasmid complexes and in a substantially increased transfection efficiency with p(TMAEMA)/plasmid complexes. Although p(DEAEMA) and p(DMAEMAm) also have buffering capacity at physiological pH (pK_a 7.5 and 7.8, respectively (Table 1), the transfection efficiency was not evaluated for the p(DEAEMA)-containing complexes (because of severe aggregation) and was low for the p(DMAEMAm)-based polyplexes. The latter observation might be due to the lower buffering capacity of p(DMAEMAm) (Table 1), the greater size of the polyplexes (Table 4), and the higher

number of DNA-polymer interactions (Table 2) as compared to p(DMAEMA).

The relatively high cytotoxicity of p(DMAEMA) as compared to the other polymers (Table 3) might also be ascribed to its ability to destabilize endosomes. Disruption of endosomes is associated with the release of endosomal and/or lysosomal enzymes into the cytosol, which might exert a toxic effect to the cellular functions.

Once released from the endosome, the plasmid has to reach the nucleus. Therefore the polyplex has to dissociate, either in the cytosol or in the nucleus. Molecular modeling was used to obtain more insight into the interactions between polymer and plasmid DNA. Molecular modeling showed that elongation of the side group of octa(DMAEMA) resulted in an increase of the interactions between the cation and the DNA, due to a better fit of the propyl chain of octa(DMAPMA) into the major groove of octa(DNA). This also explains the high number of interactions between $(PO_4^-)_{DNA}$ and $(amino)_{poly}$ for the other propyl containing compound, octa(DMAPMAm). Furthermore, while the fit of the ethyl group in the major groove of DNA is similar for octa(DMAEMAm) and octa(DMAEMA), the presence of the amide group in octa(DMAEMAm) caused an increase in the number of intrapolymeric interactions, which can strengthen the conformation of the cation resulting in a more stable positioning in the major groove. An indication that a combination of a better fit and a rigid conformation could indeed result in an increase in the number of interactions with DNA was shown by octa(DMAPMAm). The higher number of interactions between DNA and the analogues of p(DMAEMA) can also explain the adequate condensing properties of p(DMAEMAm) with a relatively low molecular mass (120 kDa) in comparison with low molecular mass p(DMAEMA) (*3*). Molecular modeling suggests that p(DMAEMA) has the lowest number of interactions with DNA. This might be the reason for an easy dissociation of the polyplex, which is a prerequisite for the synthesis of the protein the plasmid encodes for. In a recent study using surface plasmon resonance (SPR) spectroscopy, the reversibility of p(DMAEMA)/plasmid interactions was indeed demonstrated (*37*).

Summarizing, we have shown that a combination of physicochemical, biological, and modeling techniques can shed light onto the factors determining the efficiency of polymeric transfectants.

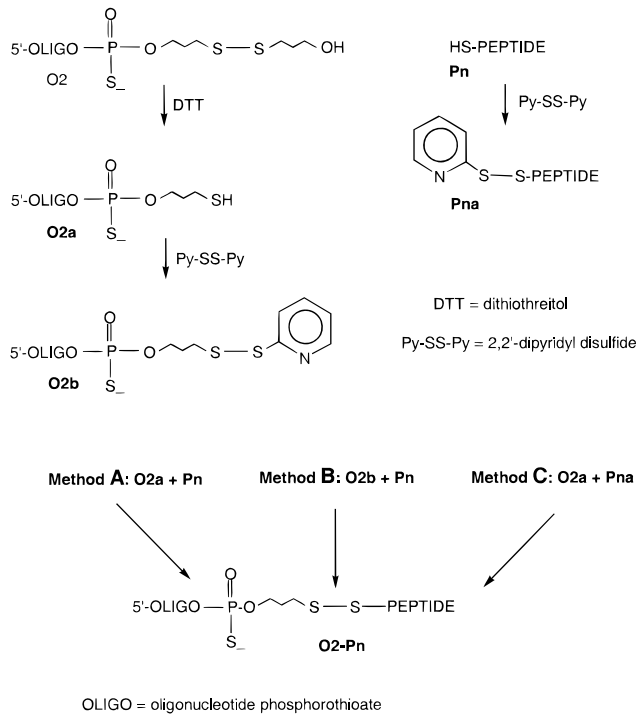
Eighteen peptide−oligonucleotide phosphorothioate conjugates were prepared in good yield and thoroughly characterized with electrospray ionization mass spectra. When applied to the living cells, conjugates exhibiting membrane translocation and nuclear localization properties displayed efficient intracellular penetration but failed to show any serious antisense effect. Studies on the intracellular distribution of the fluorescein-labeled conjugates revealed their trapping in endosomes.

INTRODUCTION

Synthetic peptides having membrane translocation properties and those possessing additionally nuclear localization properties have been found to be useful vectors for efficient internalization of oligonucleotides into living cells. These peptides and their polylysine derivatives have been shown to complex with oligonucleotides and hence serve as carriers for cytoplasmic or nuclear delivery (*1, 2*). Covalent oligonucleotide−peptide conjugates have also received considerable attention as new potential antisense agents exhibiting potentially enhanced cellular uptake (*3*−*17*). The preparation of such conjugates has been accomplished by various methodologies, based either on postsynthetic conjugation of oligonucleotides and peptides, both bearing appropriate reactive groups (*3*−*8*, *10*, *11*, *13*, *14*, *16*, *17*) or on solid-phase assembly (9, *12*, *15*). Most of these methods concern the synthesis of conjugates of natural phosphodiester oligonucleotides, and only few papers describe the preparation of oligonucleotide phosphorothioates linked to peptides. Lebleu and co-workers have synthesized a 25-mer peptide-oligo-dC phosphorothioate conjugate in a 53% coupling yield, assessed from the HPLC trace (*8*), However, neither the yield of the isolated product nor characterization of this conjugate were reported. Heitz et al. have recently reported on successful use of a carrier peptide−oligonucleotide phosphorothioate conjugate (POPC) in transfer of an antisense sequence into living cells (*17*). Unfortunately, no experimental details concerning the synthesis, isolation, and characterization of this interesting compound were given. Since most peptides used as carriers for oligonucleotides possess relatively long hydrophobic sequences, the properties of their conjugates (e.g. solubility, chromatographic behavior, etc.) appear to differ considerably from those of oligonucleotide phosphorothioates, which, in turn, possess some restrictions to the methods that may be applied to synthesis of POPCs. We believe that appropriate synthetic procedures to obtain well-characterized POPCs are of considerable importance.

The present paper describes the synthesis of 18 POPCs. In these, the 3′-terminus of the oligonucleotide phosphorothioate is linked by a disulfide bond to the N- or C-terminus of either a 17-mer membrane permeable motif (MPM)—the hydrophobic region of signal peptide sequence of the Kaposi fibroblast growth factor, known to interact with lipid bilayers, or a 27-mer peptide (MPM-NLS), containing in addition to the above-mentioned MPM motiff a nuclear localization sequence (NLS) of the transcription nuclear factor *k*B (*18*). Furthermore, the cellular uptake and intracellular localization of fluorescein-labeled conjugates have been examined and inhibition of the luciferase gene expression in a cell-free model transcription-translation system and in living cells has been attempted.

EXPERIMENTAL PROCEDURES



Peptide Synthesis. Fmoc-L-amino acids for peptide synthesis were purchased from Bachem and Novabiochem. Peptides **P1** and **P2** were synthesized on Fmoc-rink amide PEGA resin, peptide **P3** on Fmoc-Cys(Trt)-NovaSynPA500 resin, and peptide **P4** on Fmoc-Pro-NovaSynPA500 (Scheme 2), all from Novabiochem. The pyridinium salt of 3-tritylthiopropionic acid was obtained by the standard tritylation procedure and finally crystallized (ether/hexane); mp 175−177 °C. ^{1}H NMR ($CDCl_3$): δ 7.43−7.19 (m, 15H, arom.), 2.45 (t, 2H, J = 7.4 Hz, $-CH_2-$), 2.33 (t, 2H, J = 7.4 Hz, $-CH_2-$). The synthesis of all peptides was performed by a solid-phase method on a Milligen 9050 synthesizer. Standard protocols based on Fmoc/HBTU/TEA chemistry were used. 3-Tritylthiopropionic acid was introduced to the N-terminus of two peptides (**P2**, **P4**) directly on a synthesizer (HBTU/TEA condensation).

Oligonucleotide Synthesis. The oligonucleotide phosphorothioates were prepared on a solid support, bearing a disulfide linker (*19*). 2′-Deoxyribonucleoside 3′-phosphoramidites, fast-sulfurizing reagent, and fluorescein phosphoramidite were products of Glen Research. The solid-phase synthesis was performed on a PE Applied Biosystems 392 DNA synthesizer on a 1 μM scale.

Cationic Lipid Formulations. Formulations with Cytofectin GS (Glen Research) were prepared following the manufacturer's procedure.

HPLC Techniques. The peptides and their 2-pyridylsulfide derivatives were analyzed and isolated by reversed-phase chromatography (RP) (column, Genesis C4, 300 Å, 4 μm, 4.0 × 150 mm, Jones Ltd.; buffer A, 0.05 M triethylammonium acetate; buffer B, 0.05 M triethylammonium acetate in 80% MeCN; flow rate, 1.0 mL min^{-1}; a linear gradient from 40 to 100% B in 30 min was applied). The oligonucleotides containing disulfide tethers were analyzed and isolated by ion-exchange chromatography (IE) (column, PolyWax LP 300 Å, 4 μm, 4.6 × 100 mm, buffer A, 0.05 M KH_2PO_4 in 50% aqueous formamide, pH 6.7; buffer B, A + 1,5 M NaBr; flow rate, 1.0 mL min^{-1}; a linear gradient from 0 to 70% B in 30 min was applied) and RP [column, Genesis C18, 300 Å, 4 μm, 4.0 × 150 mm, Jones Ltd.; buffer A, 0.05 M triethylammonium acetate (TEAA); buffer B, 0.05 M TEAA in 80% MeCN; flow rate, 1.0 mL min^{-1}; a linear gradient from 0 to 50% B in 30 min was applied]. The conjugates were analyzed by IE as described for oligonucleotides. The final isolation and analysis of the conjugates were performed by RP HPLC similar to that described for oligonucleotides (a linear gradient from 0 to 100% B in 30 min was applied in this case).

Methods to Synthesize Disulfide Cross-Linked Conjugates. *Oligonucleotide **O2a***. A 5% triethylamine (TEA) in ethanol (40 μL) was added to a solution of oligonucleotide **O2** (20 OD) in 0.05 M TEAA buffer (1.5 mL). Dithiothreitol (3 mg) was then added, and the mixture was left for 3 h at rt and finally concentrated to a volume of 0.5 mL. The oligonucleotide bearing a free mercapto group was isolated by RP HPLC and used immediately.

*Oligonucleotide **O2b***. Oligomer **O2a** (20 OD) in 0.05 M TEAA buffer (1.5 mL) was diluted with an equal volume of ethanol. 2,2′-Bis(dipyridyl)disulfide (3 mg) was then added, and the mixture was left to stand for 1 h at rt. The corresponding 2-pyridyl sulfide derivative **O2b** was then concentrated to a volume of 0.5 mL and separated from the excess of 2,2′-bis(dipyridyl)disulfide and other byproducts with RP.

*Peptide **P2a***. Peptide (**P2**, 3 mg) was dissolved in a mixture of ethanol and formamide (1:1, 1 mL). 2,2′-Bis-(dipyridyl)disulfide (5 mg) was then added to a solution and the mixture was left for 1 h at rt. The pyridyl sulfide derivative was purified by RP HPLC. The appropriate peak (1.5 mL) was collected and diluted with formamide to a volume of 30 mL, followed by addition of 5% TEA in ethanol (300 μL).

Method A. Oligomer **O2a** (2 OD) in 0.05 M TEAA buffer (0.15 mL) was added to a solution of peptide **P2** (0.3 mg) in formamide-TEA (100:1, 3.03 mL) immediately after its separation. The mixture was kept overnight at rt and applied onto a DEAE-Toyopearl 650M column (10 × 80 mm, Br^-), equilibrated with 50% formamide. The column was washed with 50% formamide (50 mL), and the conjugate was eluted with 1 M NaBr and 0.05 M potassium phosphate buffer in 50% formamide (pH 6.5). Crude conjugate was finally analyzed, purified by RP HPLC, and desalted.

Method B. Oligomer **O2b** (2 OD) in 0.05 M TEAA buffer (0.15 mL) was added to a solution of peptide **P2** (0.3 mg) in formamide-TEA (100:1, 3.03 mL). The mixture was kept overnight at rt and the crude conjugate was analyzed and purified as in method A.

Method C. Oligomer **O2a** (2 OD) in 0.05 M TEAA buffer (0.15 mL) was added to a solution of peptide **P2a** (0.3 mg) in formamide-TEA (100:1, 3.03 mL). The mixture was kept overnight at rt and the crude conjugate was analyzed and purified as in method A.

Peptide–Oligonucleotide Phosphorothioate Conjugates. Each conjugate was synthesized according to method C, starting from 20 OD of initial oligonucleotide.

Electrospray Ionization Mass Spectrometry. Mass spectra were acquired using an LCQ quadrupole ion trap mass spectrometer equipped with an electrospray ionization source (Finnigan MAT, San Jose, CA). The spray needle was set to −3 kV. The nitrogen sheath gas flow rate was set to 70. The stainless steel inlet capillary was heated to 200 °C, and the capillary voltage was −39 V. The number of negative charges was maximized by calibrating the tube lens offset with a 15-mer oligonucleotide (data not shown). The value chosen was −10 V. The spectra were measured using 200 ms for collection of the ions in the trap, and 5−12 microscans were summed. The eluent consisted of 80% acetonitrile containing 25 mM TEA. The eluent flow rate was set to 10 μL/min, and 5 μL samples containing 1−20 pmol of conjugates were injected to the system. Positive ion mass spectra of the peptides were acquired by using 50% methanol as the eluent. The sample concentration was 10 μg/mL, and 5 μL was injected. The spray needle potential was set to 5 kV, capillary voltage 20 V, and tube lens 10 V. Other conditions were as in negative ion mode. The molecular weights of the compounds were calculated using computer program Gretas Carbos, created by Hines and Gibson (UCSF).

^{32}P-Labeling of Phosphorothioate Oligonucleotides and Oligonucleotide−Peptide Conjugates and Their Gel Electrophoresis. Oligonucleotides and conjugates were 5′-^{32}P-labeled with T4 polynucleotide kinase (Pharmacia), purified on the OPS cartridge (PE-Applied Biosystems). A 15% PAGE was employed to analyze the oligonucleotides and conjugates.

Development of Stable Cell Lines Expressing Luciferase Activity. CHO-AA8-Luc cells expressing luciferase activity were purchased from Clontech Inc. (Palo Alto, CA). Stable cell lines expressing tetracycline-regulated luciferase mRNA and activity were developed by the method of Gossen and Bujard (*20*) according to the instructions and plasmids from Clontech Inc (Palo Alto, CA). Briefly, monkey kidney fibroblast CV1-P and human retinal pigmented epithelium D407 cell lines were transfected with pTet-Off with calcium phosphate transfection (*21*), and cells with stably integrated plasmid DNA were selected in the presence of 0.4 mg/mL G418 (Calbiochem, La Jolla, CA) and tested for the expression of tetracycline-sensitive regulator by transient transfection of pTRE-luc and pCMV-beta-galactosidase plasmids, culturing in the presence or absence of 2 mg/L tetracycline and luciferase assays. Those cell lines displaying tetracycline-repressible luciferase activity were expanded and transfected with pTRE-luc plus pTK-hyg plasmids. Cells with stably integrated luciferase cDNA were selected in the presence of both 0.4 mg/mL G418 and 0.1 mg/mL hygromycin B (Calbiochem) and screened again for tetracycline-repressible luciferase activity. This procedure yielded derivatives indistinguishable from their parent CV1-P and D407 with respect to cell morphology and growth characteristics. The CV1-P derivatives CV-11 and CV-19 and D407 derivative 6-2 were used in this study.

Uptake of ^{32}P-Labeled Oligonucleotides and Conjugates. CV1-P cells were plated in Dulbecco's modified Eagle's medium (DMEM, Gibco) with 10% fetal bovine serum (FBS, Gibco) in 96-well plates, 2×10^5 cells/well, and grown for 24 h in a humidified cell incubator with 5% CO_2 at 37 °C. After washing the cells, medium was replaced with 180 μL of the serum-free medium containing a mixture of 5′-labeled (3.5×10^4 - 1.75×10^6 cpm) and unlabeled oligonucleotide or conjugate (0.1−5 μM). After 4 h of incubation at 37 °C, cells were washed several times with medium, phosphate buffer saline (PBS, Gibco), high salt-low pH buffer solution (0.4 M NaOAc, 1 M NaCl, pH 3.3), and finally with PBS (*22*, *23*). The cells were solubilized in 1% sodium dodecyl sulfate (SDS, Sigma) solution and the radioactivity was measured in the same plates with Micro Beta counter (Wallac). Aliquots of 20 μL from each well were taken for protein measurement. Background estimation experiments were conducted in parallel in separate plates without cells, where the corresponding amounts of cold and labeled oligonucleotides or conjugates were added. Both protein content data and background estimation experiments were taken into consideration while presenting the results of cellular uptake experiments. The stability of the oligonucleotides and conjugates in the cellular uptake experiments was controlled by PAGE electrophoresis which did not reveal any substantial degradation of the compounds.

Antisense Activity of the Oligonucleotides and Oligonucleotide−Peptide Conjugates. The luciferase-expressing cells were plated in 24-well plates at a density of $(4-5) \times 10^4$ cells/well and grown for 24 h to approximately 60−80% confluence. CV1-P cells were grown in DMEM with 10% of FBS, D 407 cells in DMEM with 5% of FBS, and CHO cells in α-modified Eagle's medium (α-MEM, Gibco) with 10% of FBS and medium before transfection was replaced by serum-free medium containing oligonucleotides, conjugates, or their Cytofectin GC formulation and incubated for 4 h. Cells were then grown in the normal medium for 12−20 h, washed with PBS, lysed, and tested for the luciferase activity as described earlier (*24*).

Luciferase Expression Assay. The influence of the compounds on the luciferase expression in vitro in the cell-free system was studied using TNT Coupled Wheat Germ Extract Systems kit (Promega) as described earlier (*24*).

RNase H Cleavage Experiments. Synthetic RNA fragment 5′-UACUGUUGGUAAAAUGGAAGACGCCA-AAAACAUA-3′ (**M**) was 5′ labeled with ^{32}P using T4 polynucleotide kinase (Pharmacia). One picomole of labeled matrix was annealed to 1 pmol of oligonucleotides or conjugates by heating to 70 °C and slowly decreasing the temperature to 25 °C overt 2 h. Annealed complexes were incubated with 1 unit of RNase H (USB−Amersham Pharmacia Biotech) in 20 mM Tris-HCl buffer, pH 7.5; containing 20 mM KCl, 10 mM $MgCl_2$, 0.1 mM EDTA, and 0.1 mM cystamine for 30 min at 37 °C. Products of the reaction were analyzed by 15% PAGE and subsequent autoradiography.

Confocal Fluorescence Microscopy. Luciferase-expressing cells were plated in glass Lab Tek 8-chamber slides (NUNC Inc.) at a density of $(6-10) \times 10^4$ cells/well and cultured for 36 h. The culture medium was discarded and after washing replaced by the serum-free medium containing fluorescein-labeled oligonucleotides, oligonucleotide−peptide conjugates, or their Cytofectin GC formulation. Cells were incubated for 4 h and washed twice with the serum-free medium and three times with PBS. After washing, cells were fixed with 0.1% glutaric dialdehyde in PBS for 5 min, washed with PBS, and mounted in 90% glycerol in PBS. Cells were examined under the confocal laser scanning microscope (Leica).

RESULTS AND DISCUSSION

Comparison of Methods To Synthesize Disulfide Cross-Linked Peptide-Oligonucleotide Phosphorothioate Conjugates. It is obvious that the yield of any reaction leading to the disulfide cross-linked POPC strongly depends on the spatial structures of the peptide

and the oligonucleotide in question. To develop a method of cross-linking that is as independent as possible of the structures of the molecules to be linked together, the composition of the solvent mixture and concentrations of the reacting components were first optimized. A large number of preliminary experiments demonstrated that the best yields were obtained when the resulting conjugation mixture contained about 90% of a chaotropic solvent, formamide, the concentration of peptides being about 0.09 mg/mL and that of oligonucleotides about 0.6 OD/mL. In principle, there are at least three straightforward routes to generate a disulfide bond between an oligonucleotide phosphorothioate tethered with a linker, bearing a mercapto group, and a synthetic peptide also having a mercapto function. This function may reside either in peptide's C-terminal cysteine or in a mercaptopropionic acid residue, attached to the N-terminus. We have investigated the applicability of these possible alternative procedures by binding peptides **P1**−**P4** to oligonucleotide **O2**: method A, the reaction of a thiol containing peptide with an oligonucleotide bearing mercaptoalkyl group [analogous to the approach mentioned in the literature (*17*)]; method B, the reaction of a thiol containing peptide with an oligonucleotide possessing a pyridyl disulfide function, similar to procedure reported by Lebleu et al (*8*); and, finally, method C, the reaction of a pyridyl disulfide containing peptide with an oligonucleotide having a mercaptoalkyl group (Scheme 1).

The results of these experiments have demonstrated that the yield of isolated conjugate strongly depends on the method of coupling and the peptide's structure. Method A gave yields ranging from 0.4 to 23%. Testing of method B has also revealed relatively low yields from 7 to 24%. Method C, however, have demonstrated the highest yields, ranging from 36 to 88%.

An additional experiment, employing method C, was carried out in order to demonstrate the absence of coupling between the peptide, activated by a pyridyl disulfide function and the phosphorothioate groups of the oligonucleotide. In this experiment, a control oligonucleotide phosphorothioate had the same sequence as **O1**, but contained no 3′-mercaptoalkyl function. After 12 h at rt, IE HPLC has revealed no formation of any conjugated structure. Oligonucleotide phosphorothioate appeared to be intact. RP HPLC, in turn, has demonstrated the formation of only 3% of peptide dimer, with the rest of the activated peptide remaining stable in the reaction mixture.

Thus, method C appears to be the procedure of choice for preparation of the disulfide cross-linked peptide−oligonucleotide phosphorothioate conjugates.

Synthesis and Characterization of Peptide−Oligonucleotide Phosphorothioate Conjugates. Method C was employed to synthesize 18 POPCs (Scheme 2). In all of these conjugates, the oligonucleotide moiety is a 15-mer (**O1**−**O4**) or 25-mer (**O5**) phosphorothioate. The peptide moiety is either a modified 17-mer hydrophobic MPM (**P1**, **P2**) or a modified 27-mer sequence, containing the above-mentioned 17-mer sequence and a the basic 10-mer NLS (**P3**, **P4**). The disulfide bridge was formed between the 3′-ends of **O1**−**O5** oligonucleotides and either the C-termini (**P1**, **P3**) or N-termini (**P2**, **P4**) of peptides. The yields of conjugates synthesized were 35−60%, and purity, as assessed from RP HPLC was higher than 95%. The 15% denaturing PAGE (data not shown) revealed good purity for all conjugates synthesized. The migration rate of the conjugates of peptides **P1** and **P2** was about 0.73−0.75 times, and that of peptides **P3** and **P4** conjugates 0.63−0.65 times that of the parent oligonucleotides. The final characterization of POPCs was achieved by electrospray ionization mass spectrometry (ESI-MS), which has proven to be a powerful method for the characterization of oligonucleotides (*25, 26*) as well as their peptide conjugates (*27*). In our study, the negative ion ESI mass spectra of the conjugates displayed a series of deprotonated molecules $(M - nH)^{n-}$ as major peaks, the charge states ranging from 4 to 9. Figure 1 demonstrates a typical ESI mass spectrum obtained after injection of 5 μL of conjugate **O4**−**P3**. Mass deconvulation program can be used for reconstruction of the molecular weight of the conjugate using the *m*/*z* values of the multiply deprotonated molecules (Figure 2). The measured and theoretically calculated average molecular weights of compounds reported here were in excellent agreement. The difference between the calculated and measured molecular masses was always less than 3.1 mass units (0.05%).

Attempted Inhibition of Luciferase Gene Expression in Vivo in Living Cells by Peptide−Oligonucleotide Phosphorothioate Conjugates. The peptide moiety of conjugates reported here contains membrane translocation and nuclear localization motives which are supposed to assist the oligonucleotide in passing through the cell membrane and reaching the nucleus. The oligonucleotide moiety is expected to display its antisense effect in the cytoplasm and nucleus, inhibiting the target gene expression (*28*).

We have attempted to influence the luciferase gene expression in stably transfected CV1-P, CHO-AA8-Luc, or D-407 luciferase producing cells with our conjugates. As in **O1**, the oligonucleotide sequence in the tested conjugates **O1**−**Pn** was complementary to the initiation codon region of firefly luciferase mRNA and was reported earlier to work as an effective antisense compound (*29*). The rest of the conjugates were used as controls containing either a reversed (**O2**−**Pn**) or a sense (**O3**−**Pn**) stretches. More than 10 identical experiments were performed in which the influence of these compounds on the reporter gene expression was compared to the inhibition of expression by the cationic lipid formulation of **O1** or **O1**−**P3** with the Cytofectin GC. These experiments have demonstrated the inability of the conjugate **O1**−**P3** alone to display any serious antisense effect. We have obtained more or less similar results for conjugates **O1**−**P1**, **O1**−**P2**, and **O1**−**P4** and conjugates **O5**−**P3** and **O5**−**P4**, which contain a longer antisense oligonucleotide sequence **O5** in comparison to **O1**. It is noteworthy that a substantial inhibition of luciferase expression was observed in all experiments with the Cytofectin formulation of **O1** or **O1**−**P3**. It appears that unlike the case where cationic lipid formulation was used, our conjugates alone fail to display reproducible antisense action.

Nevertheless, it was still interesting to find out which part of these conjugates (oligonucleotide or peptide) failed to play the desired role.

Cellular Uptake Studies with 5′-[^{32}P]-Oligonucleotide Phosphorothioates and Peptide−5′-[^{32}P]-Oligonucleotide Phosphorothioate Conjugates. Our unsuccessful attempt to inhibit the luciferase gene expression in cells raised some points of substance. First, it was necessary to verify if any of our conjugates were taken up by these cells. If some conjugates entered living cells, then it would be interesting to find out whether they remain intact throughout our experiment. Figure 3 demonstrates a typical result of cellular uptake experiments. One can see a relatively strong association of conjugate **O2**−**P3** with CV1-P cells in comparison to conjugates **O2**−**P1** and **O2**−**P2** and oligonucleotide **O2**.

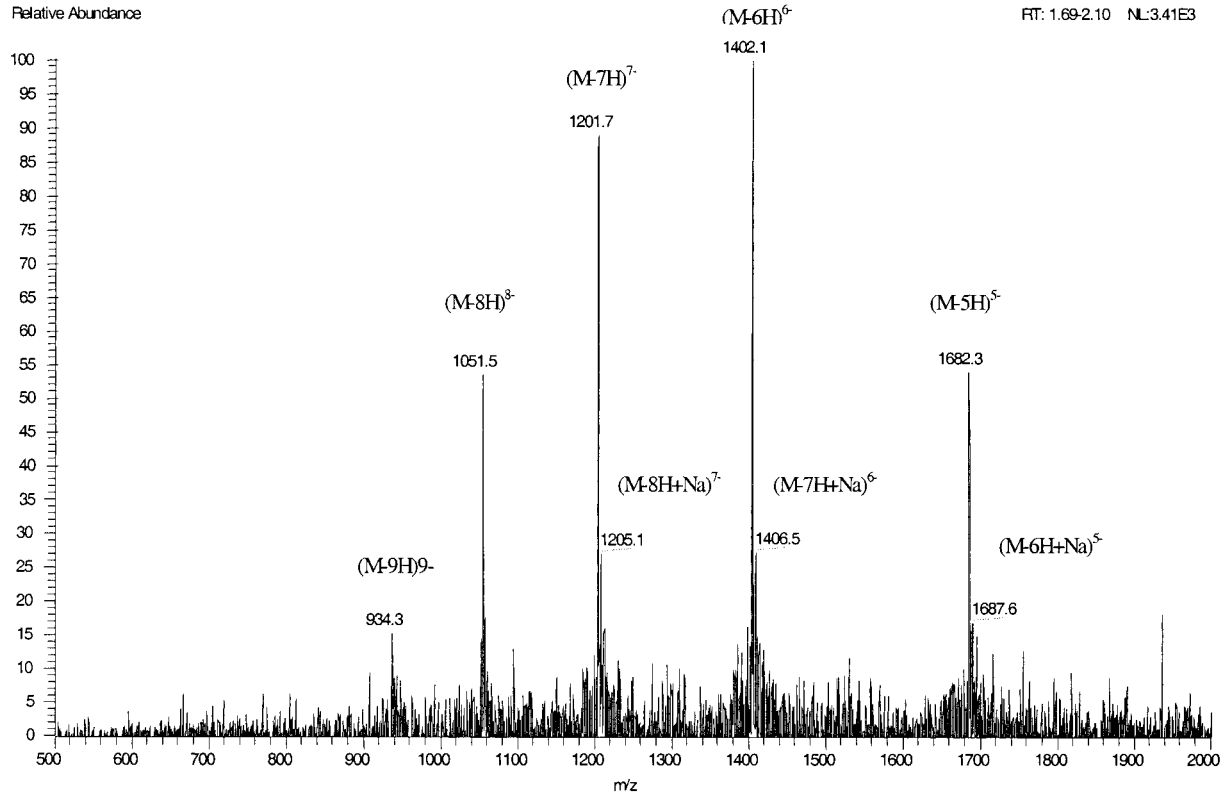

Figure 1. Negative ion ESI mass spectrum of conjugate **O4**−**P3**. The major multiply charged ions represent negative charge states from 5 to 9. Sample: 5 μL of conjugate **O4**−**P3**. Eluent: 10 μL/min of 80% acetonitrile with 25 mM triethylamine.

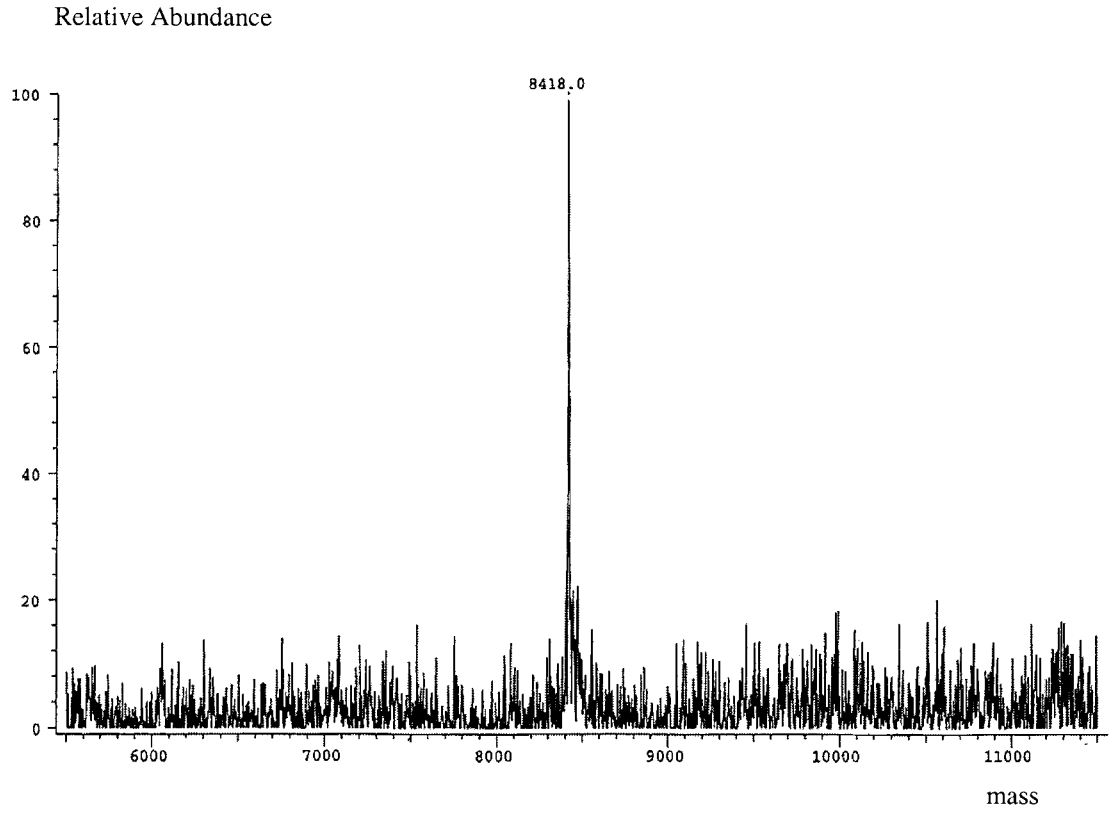

Figure 2. Reconstructed molecular weight spectrum of conjugate **O4**−**P3** (calculated mass 8418.1).

It is clear that the presence of the long 27-mer peptide with both membrane translocation and nuclear localization properties (**O2**−**P3**) is somehow responsible for this strong association, while the presence of mere membrane permeable motif (**O2**−**P1** and **O2**−**P2**) for some reason retards association even as compared to oligonucleotide **O2**. This conclusion received additional support from the stability test. Figure 4 shows the autoradiography of PAGE of cell lysates after incubation with ^{32}P-labeled conjugates and careful washing—standard procedure,

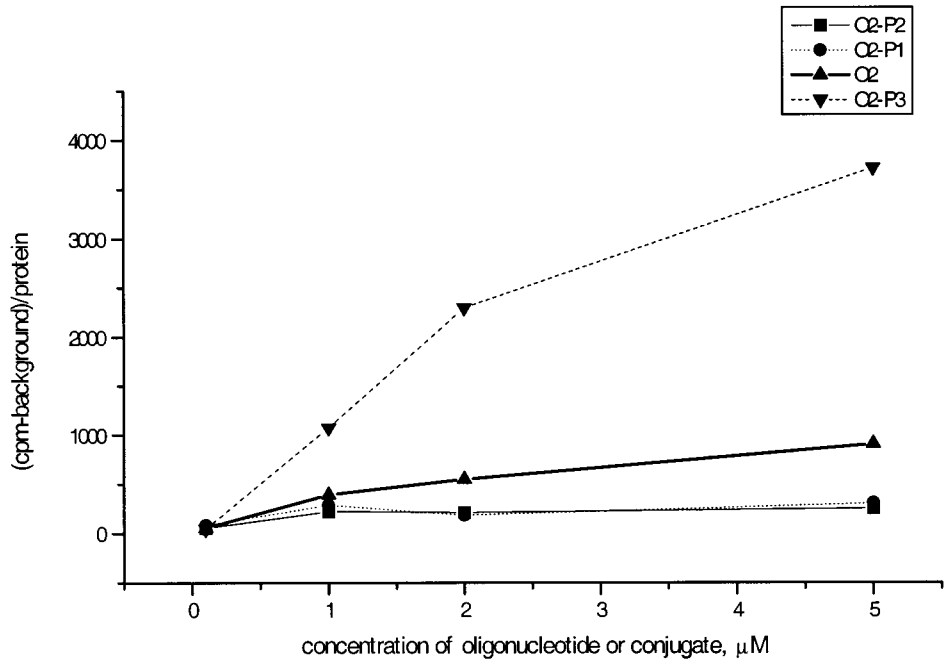

Figure 3. Uptake of the ^{32}P-labeled oligonucleotide and oligonucleotide–peptide conjugates by CV1-P cells. Dependence of cell associated radioactivity on the concentration of ^{32}P-labeled oligonucleotides and oligonucleotide–peptide conjugates in the incubation mixture. Cells were incubated with control substances for 4 h, washed and lysed as described in Experimental Procedures.

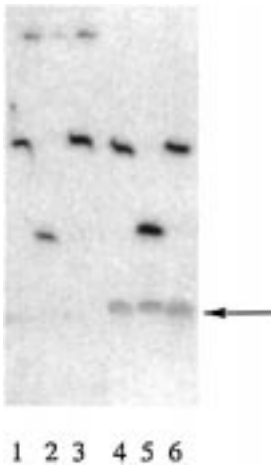

Figure 4. Stability of the oligonucleotide–peptide conjugates in the cells**.** Autoradiogram of 15% PAAG electrophoresis of the cell lysates and control ^{32}P-labeled conjugates: lines 1–3—cells incubated with mixtures of 5 μM unlabeled and 1.75×10^6 cpm of ^{32}P-labeled **O1**–**P3**, **O1**–**P1**, or **O2**–**P3** respectively; lines 4–6—^{32}P-labeled **O1**–**P3**, **O1**–**P1**, or **O2**–**P3**. The migration position of **O1** is indicated with arrow.

removing the noninternalized conjugates and dead cells, capable of accumulating labled compounds (*22*, *23*). Very little if any degradation was detected, demonstrating sufficient stability of the peptide–oligonucleotide phosphorothioate conjugates throughout our experiments with cells.

RNase H Mediated Cleavage of Synthetic RNA-Conjugate Complexes and Inhibition of Luciferase Gene Expression in an in Vitro Transcription-Translation System. The next question was whether our conjugates were capable of triggering the RNase H mediated cleavage of the target RNA. The answer to this question appears to be of significant importance since this type of mRNA degradation is believed to be the most common mechanism of the antisense action (*30*). To investigate this subject, we synthesized a 34-mer oligoribonucleotide (**M**), corresponding to the −13 to +21 fragment of the luciferase mRNA. This RNA fragment was 5′-^{32}P-labeled and subjected to the action of RNase H in the presence of oligonucleotide **O1** and conjugate **O1**–**P3** or **O1**–**P4**, all containing the 15-mer complementary sequence. Conjugates **O3**–**P3** and **O3**–**P4** containing the sense sequences were used as controls. The autoradiography of PAGE referring to these experiments is shown in Figure 5. One can see that while conjugates **O1**–**P3** or **O1**–**P4**, as well as oligonucleotide **O1**, clearly triggered the RNase H activity (Figure 5, lines 1, 2, and 5), control conjugates O3–P3 and O3–P4 were unable to recruit the enzyme for the RNA fragment digestion (Figure 5, lines 3 and 4). The observed effect of **O1**–**P3**

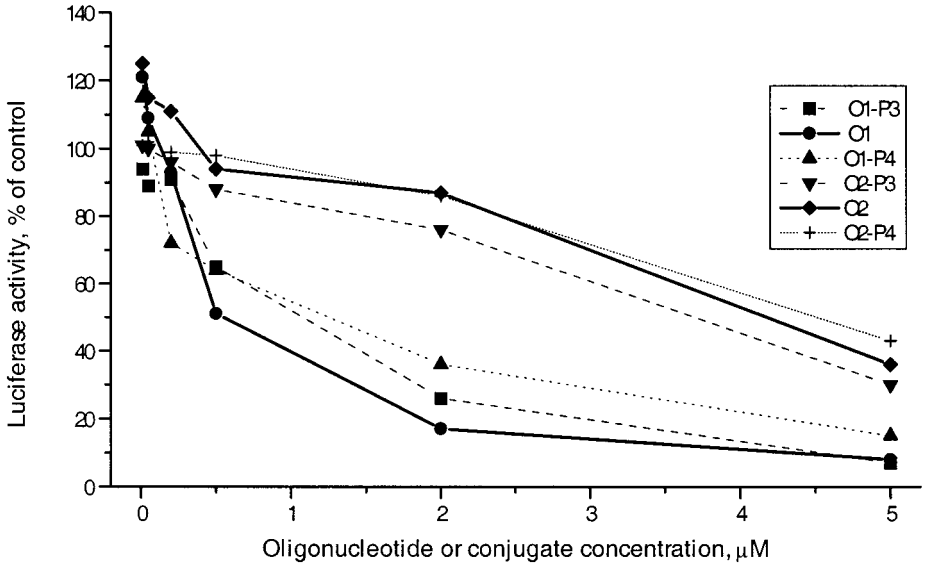

Figure 6. Influence of the antisense and control oligonucleotides and/or oligonucleotide−peptide conjugates on the luciferase reporter gene expression in cell-free system.

and **O1**−**P4** was noticably smaller than that of **O1**. This fact may be attributed to the reduced binding affinity of oligonucleotide part of conjugates to the target RNA, when compared to that of oligonucleotide phosphorothioate **O1**.

As indicated above, our conjugates contained sequences complementary to the initiation codon region of the firefly luciferase mRNA, and therefore, it was reasonable to probe their antisense properties in a cell-free luciferase gene expression system which proved to be a rather useful tool in our previous studies (*24*). In fact, this type of experiment would mimic the testing with living cells better than the enzymatic assay with RNase H, and it would hence better elucidate the potency of our conjugates as antisense agents. Figure 6 shows that conjugates **O1**−**P3** or **O1**−**P4**, as well as oligonucleotide **O1**, all containing the antisense sequence, were able to decrease the luciferase activity by 60−80% at 2 μM concentration, while the control conjugates **O2**−**P3**, **O2**−**P4**, and control oligonucleotide **O2**, all containing reversed sequence, showed inhibition of only 10−20% under the same conditions. Hence, it became obvious that our conjugates are taken up by the cells and they are in principle capable of showing the antisense properties. Their failure to demonstrate these features in the experiments with cells should be attributed to their "incorrect" intracellular distribution, i.e., absence from the cytoplasm and/or nucleus, where they have to be present in order to display antisense properties.

Cellular Localization of Peptide−Oligonucleotide Phosphorothioate Conjugate. To gain insight into localization of our conjugates in cells, we treated CV1-P cells with 5′-fluorescein-labeled oligonucleotide **O4**, conjugate **O4**−**P3**, and finally with **O4**−**P3** as a cationic lipid formulation with the Cytofectin GC, and examined the cells with confocal microscopy. Figure 7A demonstrates that while most of the conjugate **O4**−**P3** associated with cells is localized in endosomes, there is only faint fluorescence in cytoplasm and nucleus. Even lower level of nuclear fluorescence was detected when CV1-P cells were incubated with oligonucleotide **O4** (Figure 7B) alone. The cytoplasmic fluorescence detected in this case was much weaker than with conjugate **O4**−**P3**, and it may in all likelihood be attributed to very low level of oligonucleotide phosphorothioate internalization. In contrast to that, when the conjugate **O4**−**P3** was employed as a cationic lipid formulation, a very strong fluorescence was found within the nucleus (Figure 7C), indicating a different type of intracellular distribution as compared to results with pure conjugate (Figure 7A). Taken together, the microscopy results clearly show that although our conjugates as such indeed possess a clear affinity to cells they are trapped in the endosomes unlike the liposomal formulation. Therefore, the access of POPCs to their target in cytoplasm and nucleus is limited.

CONCLUSION

We have optimized the preparation of disulfide cross-linked POPCs. According to our results, the most efficient procedure makes use of a disulfide exchange reaction between an oligonucleotide phosphorothioate tethered with a mercaptoalkyl group and a peptide bearing a pyridyl disulfide function in 90% formamide. Eighteen compounds were prepared in a yield of 35−60% and thoroughly characterized by electrospray ionization mass spectroscopy.

The present work demonstrates that our POPCs are capable of inhibiting the luciferase gene expression in a cell-free model transcription-translation system. When applied to the living cells, some of conjugates with MPM-NLS peptide display the efficient intracellular penetration properties but fail to show any serious antisense effect. Studies on the intracellular distribution of the fluorescein-labeled conjugates have revealed their endosomal localization, thus indicating a failure to reach the cytoplasm and/or nucleus and hence to produce the antisense effect. On the contrary, when used as a cationic lipid formulation with the Cytofectin GC, our conjugates achieved effective and selective antisense inhibition of the reporter gene expression. All these data taken together brings over the conclusion that the structure of the conjugates of oligonucleotide phosphorothioates with peptides, exhibiting membrane translocation and nuclear localization properties, yet has to contain some additional feature to avoid endosomal trapping. It appears that mere conjugation of antisense oligonucleotides and peptides possessing membrane penetration and nuclear localization properties does not necessarily result in a reliable delivery system which works well with a number of cell types. However, the chemical methodology devel-

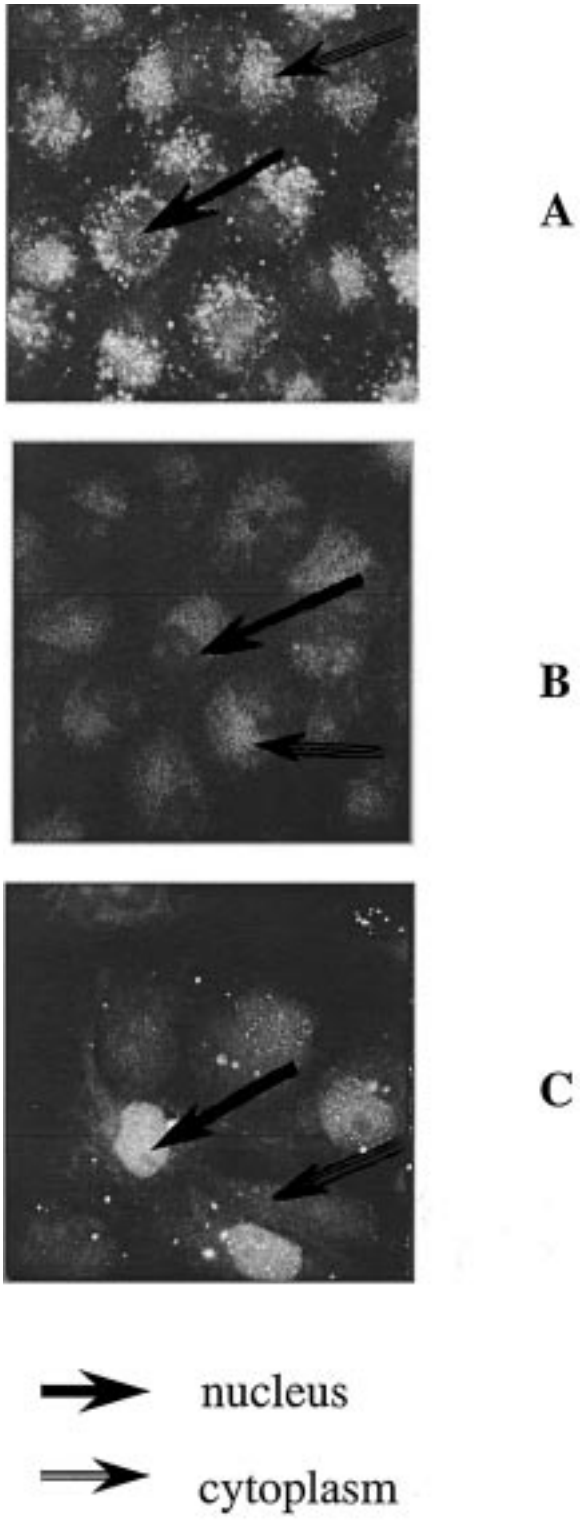

Figure 7. Confocal microscopy pictures of CV1-P cells after 4 h incubation with the fluoresceine-labeled antisense oligonucleotide and antisense oligonucleotide–peptide conjugate. Use of Heavy-Metal Clusters in the Design of N-Succinimidyl Ester Acylation Reagents for Side-Chain-Specific Labeling of Proteins

Domenico Osella,*,† Paola Pollone,† Mauro Ravera,† Michèle Salmain,‡ and Gérard Jaouen*,‡

Dipartimento di Scienze e Tecnologie Avanzate, Università del Piemonte Orientale "Amedeo Avogadro", Corso T. Borsalino, 54, I-15100 Alessandria, Italy, and Ecole Nationale Supérieure de Chimie de Paris, Laboratoire de Chimie Organométallique, UMR CNRS 7576, 11, rue Pierre et Marie Curie, F-75231 Paris Cedex 05, France . Received November 19, 1998; Revised Manuscript Received March 10, 1999

New heavy transition metal carbonyl markers for protein labeling, containing an "$M_n(CO)_{11}$" (M = Ru, Os, $n = 3$; M = Ir, $n = 4$) moiety, were prepared by reaction of "lightly stabilized" clusters with an N-succinimidyl ester functionalized phosphine, namely N-succinimidyl 3-diphenylphosphinepropionate (DPPS). The reaction of $Os_3(CO)_{11}$(DPPS) with the model amino acid β-alanine was performed and led to the expected amide. From the reaction of $M_n(CO)_{11}$(DPPS) with bovine serum albumin (BSA) in mixed organic/aqueous medium, conjugates bearing a fairly high number of metal carbonyl fragments were obtained, thus demonstrating the usefulness of this class of reagents for the selective and covalent graft of heavy metal clusters to side chain of proteins.

INTRODUCTION

Amine-reactive compounds are widely used in protein chemistry for probing protein structure and/or function or to introduce radioactive or cold reporter groups (Wong, 1991). Some examples of application of the resulting bioconjugates are immunoanalysis and immunohistochemistry. In these applications, the stability of the chemical bond between the marker and the biomolecule is particularly important.

The most widely used amine-reactive probes are reagents that form carboxamide, sulfonamide, urea, or thiourea bonds upon reaction with proteins amino groups (Means and Feeney, 1990). In particular, N-succinimidyl esters are able to acylate amines and lead to the formation of a peptide bond (Anderson et al., 1964). This family of reagents displays a high reactivity with protein amino groups (Brinkley, 1992). This is particularly interesting because virtually all proteins have lysine residues and, owing to their hydrophilic nature, most of them are located at the surface of proteins, readily accessible to reagents. Moreover, they have a very low reactivity toward tyrosine, serine, histidine, and cysteine residues (Anjaneyulu and Staros, 1987). Water-soluble N-sulfosuccinimidyl esters have also been described (Staros, 1982).

The prototypical compound of this category is the Bolton−Hunter reagent, *N*-succinimidyl 3-(4-hydroxy-5-iodophenyl)propionate (Bolton and Hunter, 1973), commercially available as labeled with ^{125}I. Proteins and peptides radiolabeled via the Bolton−Hunter reagent often exhibit a lower degree of deiodination compared with directly radioiodinated proteins and higher conjugation efficiencies are reached (Bolton et al., 1976; Vaidyanathan and Zalutsky, 1990).

Although radioisotopic labeling is a very sensitive method, owing to legal and technical problems associated with radioactivity, the implementation of "cold" labeling procedures has been an important goal (Gosling, 1990). Application of organotransition metal complexes containing biologically relevant ligands have attracted considerable attention in this field in recent years (*bioorganometallic chemistry*) (Severin et al., 1998). In this area, Jaouen et al. (1993) developed the so-called *carbonyl-metallo-immunoassay* (CMIA),[1] where biomolecules are labeled with metal carbonyl fragments and conjugates detected by FT-IR spectroscopy in the carbonyl ligands stretching vibration modes region (2150−1800 cm^{-1}), where proteins do not absorb. Transition metal carbonyl complexes containing an N-succinimidyl ester function (Varenne et al., 1993; Salmain et al., 1994; Gorfti et al., 1996), a pyrylium group (Salmain et al., 1994; Malisza et al., 1995), or an isothiocyanate (Kazimierczak et al., 1997), all reacting at the N-terminal position and/or the lysine residues of proteins, have been developed for this purpose.

In the same context, we covalently linked a third-row transition metal cluster fragment, namely "$Os_3(CO)_{10}$", to a model amine (i.e., benzylamine), to model amino acids (i.e., β-alanine and Nα-protected lysine), and finally to bovine serum albumin (BSA) by using *N*-succinimidyl-4-pentynoate as the linker. The average coupling ratio (CR) between the Os_3-marker and BSA was fairly high, i.e., around 20 (Osella et al., 1996). This was the first example of a marker containing a metal carbonyl cluster of predefinite nuclearity.

To make the Bolton−Hunter-like procedure more widely applicable to polymetallic carbonyl compounds, we have designed a new phosphine linker functionalized by an N-succinimidyl ester, namely *N*-succinimidyl 3-diphe-

nylphosphine propionate (DPPS), **1**. In this paper, we report the synthesis of three polymetallic carbonyl complexes containing the DPPS ligand, namely $Ru_3(CO)_{11}$(DPPS), **5**, $Os_3(CO)_{11}$(DPPS), **6**, and $Ir_4(CO)_{11}$(DPPS), **7**, and their reactivity toward β-alanine and BSA.

Our goal is to label proteins with metal carbonyl clusters that we expect to be useful in scanning transmission electron microscopy (STEM) studies, owing to their electron-dense cores. In contrast to colloidal gold, derivatives **5**−**7** are not adsorbed but covalently linked to the target biomolecules, avoiding nonspecific interactions. An interesting precedent is the use of the rigid dimer $[Ir_4(CO)_{11}][Ph_2POC_6H_4{-}C_6H_4OPPh_2]$, which showed paired spots (ca. 6 Å in diameter) in STEM micrograph. The average separation between paired spots allowed the dimensions of molecular electronics structures to be established (Furuya et al., 1988).

Moreover, compounds **5**−**7** could be useful for the production of isomorphous heavy metal derivatives for protein X-ray crystallographic structure determination (Weinstein et al., 1989). Derivatization with heavy atom compounds at a unique lattice site is frequently used to obtain phase information and enable X-ray structure resolution of proteins (Branden and Tooze, 1991). This project may substantially contribute to the better understanding of the structure and role of proteins and other biomolecules.

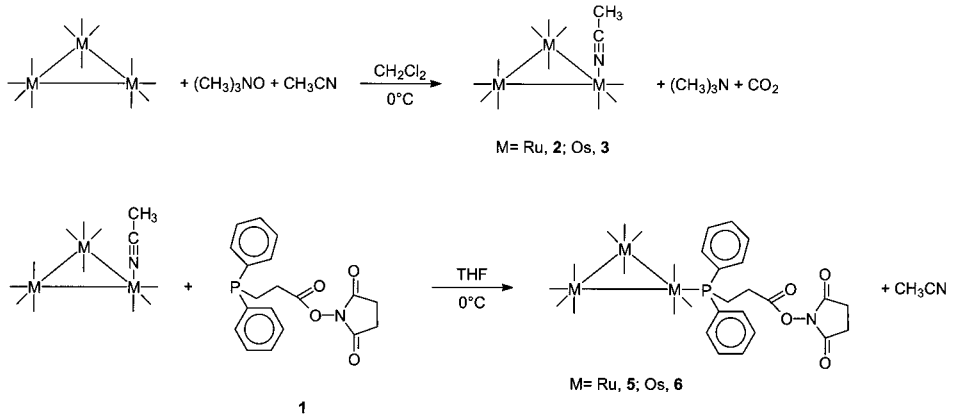
EXPERIMENTAL PROCEDURES

Materials and Methods. Reactions were carried out under nitrogen using dried and prepurified solvents. Chromatographic separations were performed using microcrystalline cellulose (Merck Avicel). Routine FT-IR and FT-NMR spectra were recorded on a Bruker Equinox 55 and on a JEOL-EX 400 spectrometer, respectively. NMR chemical shifts are referenced to the internal standard tetramethylsilane (TMS) and 85% H_3PO_4 for ^1H and ^{31}P spectra, respectively. UV−vis spectra were recorded on a Safas UV/mc^2 spectrometer. DCI-MS spectra were recorded on a Finnigan-MAT 95Q instrument with magnetic and electrostatic analyzers. Isobutane was used as the reagent gas at 0.5 mbar pressure. The ion source temperature was kept at 50 °C, the electron emission current at 0.2 mA, and the electron energy at 200 eV. Positive ion spectra were collected. A computer program provided a digital readout of peak intensities and their comparison with the simulated isotopic pattern. The fit was satisfactory for all compounds under investigation. Quantitative FT-IR analyses were performed by depositing 10 mL samples on 9 mm diameter nitrocellulose membranes (Alltech), and recording spectra on a Bomem MB100 FT-spectrometer equipped with a liquid nitrogen-cooled MCT detector as described (Salmain et al., 1993).

N-Succinimidyl 3-diphenylphosphinepropionate, **1**, (DPPS) (Santimaria et al., 1995), lightly activated clusters **2** and **3** (Drake and Khattar, 1988), and **4** (Chini et al., 1978) were synthesized according to the literature methods and their purity checked by spectroscopic techniques.

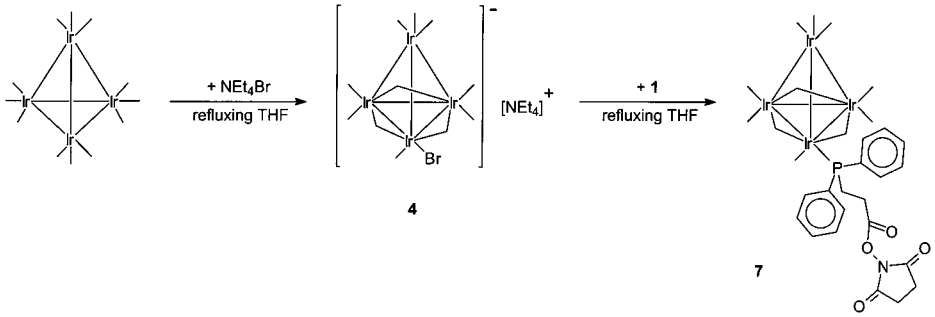
Synthesis of $M_3(CO)_{11}$(DPPS) (M = Ru, 5, and Os, 6). Solid $M_3(CO)_{11}(NCCH_3)$ (M = Ru, **2**, and Os, **3**) (**2** 200 mg, 0.31 mmol; **3** 100 mg, ca. 0.11 mmol) was added to a freshly distilled THF solution (ca. 10 mL) of DPPS (1:1 ratio) at 0 °C in a Schlenk tube equipped with a magnetic stirring bar and an inlet arm for purging the solution with nitrogen. The color turned from yellow to orange. The mixture was allowed to reach room temperature and chromatographed on a cellulose column. Petroleum ether first eluted adventitious $M_3(CO)_{12}$, then mixtures containing petroleum ether and increasing amounts of CH_2Cl_2 eluted the monosubstituted compound (**5** or **6**) and then the higher substituted compounds. The polysubstituted compounds $M_3(CO)_{12-n}(DPPS)_n$ (n = 2, 3) were identified by comparison of their IR spectra with those of original samples (Bruce, 1987). The desired compounds were crystallized in petroleum ether/CH_2Cl_2 (1:1 v/v) at −10 °C, giving yellow or orange microcrystals.

Analytical Data for 5. IR (CH_2Cl_2): ν_{CO} 2097m, 2047vs, 2027sh, 2014vs, 1990sh, 1817w, 1790w, 1745ms cm^{-1}. UV−vis (absolute ethanol): λ_{max} 419 nm (ϵ = 5100). ^1H NMR (400 MHz, $CDCl_3$): δ 7.51 (m, 10H, Ph), ca. 2.9 (partially overlapped to the following signal, 2H, P−CH_2−CH_2), 2.83 (s, 4H, N-succinimidyl cycle), 2.50 (q, 2H, P−CH_2−CH_2-). ^{31}P NMR (161.9 MHz, $CDCl_3$): δ 27.6. MS (DCI, isobutane): $[M + H]^+ = 969$ m/z. Anal. Calcd. for $C_{30}H_{18}NO_{15}PRu_3$: C, 37.28; H, 1.88. Found: C, 37.06; H, 1.98.



Analytical Data for 6. IR (CH_2Cl_2): ν_{CO} 2108m, 2055s, 2033ms, 2018vs, 2000ms, 1989ms, 1818w, 1789w, 1745ms cm^{-1}. UV−vis (absolute ethanol): λ_{max} 407 (ϵ = 4600), 345 (ϵ = 12000) nm. ^1H NMR (400 MHz, $CDCl_3$): δ 7.51 (m, 10H, Ph), 3.03 (q, 2H, P−CH_2−CH_2-), 2.83 (d?, 4H, N-succinimidyl cycle), 2.47 (q, 2H, P−CH_2−CH_2-). ^{31}P NMR (161.9 MHz, $CDCl_3$): δ −9.21. MS (DCI, isobutane): $[M + H]^+ = 1236$ m/z. Anal. Calcd for $C_{30}H_{18}NO_{15}POs_3$: C, 29.20; H, 1.47. Found: C, 29.01; H, 1.62.

Synthesis of $Ir_4(CO)_{11}$(DPPS), 7. $Ir_4(CO)_{12}$ (100 mg, 0.09 mmol) was added to a freshly distilled THF solution (ca. 20 mL) of $(C_2H_5)_4NBr$ (25 mg, 0.12 mmol) in a three-necked flask equipped with a magnetic stirring bar and an inlet arm for purging the solution with nitrogen. The solution was refluxed for 4 h, then DPPS (25 mg, 0.12 mmol) was added and refluxed for 1 h. The mixture was chromatographed on a cellulose column. Mixtures of petroleum ether and 10% CH_2Cl_2 first eluted **7**, then pure CH_2Cl_2 eluted the disubstituted compound $Ir_4(CO)_{10}$(DPPS)$_2$ in trace amounts. **7** was crystallized in dichloromethane/petroleum ether (1:1 v/v) at −10 °C, giving yellow microcrystals. The disubstituted compound $Ir_4(CO)_{10}(DPPS)_2$ was identified by comparison of its IR spectrum with that of an original sample of $Ir_4(CO)_{10}(PPh_3)_2$ (Darensbourg and Baldwin-Zuschke, 1982).



Analytical Data for 7. IR (CH_2Cl_2): ν_{CO} 2089m, 2057vs, 2020s, 1843m, 1819m, 1791w, 1745s cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ 7.50 (m, 10H, Ph), 2.83 (s, 4H, N-succinimidyl cycle), 2.73 (q, 2H, P−CH_2−CH_2−), 2.60 (q, 2H, P−CH_2−CH_2−). ^{31}P NMR (161.9 MHz, $CDCl_3$): δ −15.5. MS (DCI, isobutane): $[M + H]^+ = 1434$ m/z. Anal. Calcd. for $C_{30}H_{18}NO_{15}PIr_4$: C, 25.16; H, 1.27. Found: C, 24.80; H, 1.52.

Reaction of 6 with β-Alanine Ethyl Ester. β-Alanine ethyl ester hydrochloride, dissolved in CH_2Cl_2, was neutralized with a slight excess of triethylamine, then solid **6** was added in a 1:1 molecular ratio. The mixture was stirred overnight at room temperature, and chromatographed on a silica gel column. CH_2Cl_2 removed side-products, then acetone eluted the desired product $Os_3(CO)_{11}(Ph_2P(CH_2)_2C(O)NH(CH_2)_2COOEt)$, **8**, in 80% yield. IR (CH_2Cl_2): ν_{CO} 2107m, 2054s, 2033sh, 2017vs, 1999ms, 1990sh, 1730w, 1679w, 1607m, 1518w cm^{-1}. ^1H NMR (400 MHz, CD_2Cl_2): δ 7.61 (m, 10H, Ph), 6.07 (t, br, 1H, NH), 4.27 (m, 2H, −CH_2CH$_3$), 3.57 (m, 2H, −NH−CH_2CH$_2$−), 3.18 [m, 2H, −P−(CH_2)$_2$−], 2.62 (t, 2H, −NH−CH$_2$CH_2−), 2.17 [m, 2H, −P−(CH_2)$_2$−], 1.41 (t, 3H, −COOCH$_2$CH_3). ^{31}P NMR (161.9 MHz, $CDCl_3$): δ −9.01.

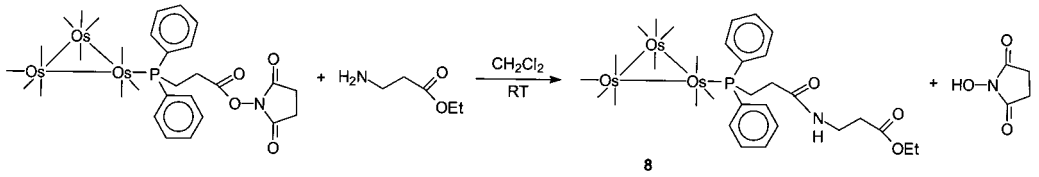
Labeling of BSA with 5−7. Two stock solutions were prepared, the first being 10 μM in BSA (crystallized, Serva), dissolved in borate buffer (0.1 M pH 9.0 prepared from demineralized water), the second being 4 mM in **5**−**7** dissolved in DMF (**5** and **6**), or 2-propanol (**7**). To 0.45 mL of protein solution was added 0.05 mL of marker solution (the resulting solutions have a 10% v/v organic solvent content and a 45:1 marker-protein molar ratio). The solutions were stirred 5 h at room temperature, filtered on 0.2 μm porosity PVDF membranes, and chromatographed on a prepacked gel filtration column (Kwiksep 5 mL, Pierce) using NH_4HCO_3 10 mM as eluent. Twelve 0.5 mL fractions were collected and analyzed as described below.



Analysis of the Conjugates. Protein concentration [P] was determined by the Coomassie blue method (Bradford, 1976) while marker concentration [M] was measured by UV−vis spectroscopy for **5** and **6** (**5** at $\lambda =$ 419 nm, $\epsilon = 5100$; **6** at $\lambda = 407$ nm, $\epsilon = 4600$) or by FT-IR spectroscopy of the ν_{CO} band at 2058 cm^{-1} ($k = 85$) for **7**, following a technique previously described (Salmain et al., 1993). The combination of these data provided the final ratio between marker and protein concentrations, namely the so-called coupling ratio CR = [M]/[P], and the coupling yield CY defined as $\{([M]/[P])_{final}/([M]/[P])_{initial}\} \times 100$. Reversed-phase HPLC of the conjugates was perfomed on a 4.6 × 150 mm Si-C4 column (Vydac 214 TP). Species were eluted by applying a linear gradient from 20 to 60% of 0.1% TFA-CH_3CN in 0.1% TFA-H_2O in 30 min (flow rate = 1 mL min^{-1}) and were detected at 280 nm.

RESULTS AND DISCUSSION

Synthesis and Characterization of Markers. Since the parent clusters $Ru_3(CO)_{12}$, $Os_3(CO)_{12}$, and $Ir_4(CO)_{12}$ are quite inert toward CO substitution, activated derivatives should be used. The "activated" $M_3(CO)_{11}(NCMe)$ (M = Ru, **2**, and Os, **3**) and $Ir_4(CO)_{11}Br$, **4**, have been prepared from the reaction of the parent clusters with trimethylamine-N-oxyde, $(CH_3)_3NO$ (Drake and Khattar, 1988) (Scheme 1), and tetraethylammonium bromide, $(C_2H_5)_4NBr$ (Chini et al., 1978) (Scheme 2), respectively. These intermediates are very convenient precursors in the preparation of the corresponding derivatives with a variety of phosphines in mild experimental conditions (Foulds et al., 1985; Ros et al. 1986). Hence, compounds **2**−**4** underwent fast reaction with **1** in THF giving $M_3(CO)_{11}(DPPS)$ (M = Ru, **5**, and Os, **6**) and $Ir_4(CO)_{11}(DPPS)$ (**7**) in excellent yields for Os and Ir (ca. 80%) (Schemes 1 and 2). Unfortunately, **5** was always obtained in low yield (ca. 15%) due to further substitution of CO ligands with DPPS, yielding the higher substituted $Ru_3(CO)_{10}(DPPS)_2$, and $Ru_3(CO)_9(DPPS)_3$, even when a low stoichiometric ratio between ligand and activated cluster was employed. Thermal reaction of $Ru_3(CO)_{12}$ with a wide variety of phosphines (L) led directly to the formation of trisubstituted $Ru_3(CO)_9(L)_3$, suggesting that replacement of carbonyl ligands by phosphorus ligands accelerates the rate of further substitution. This rate enhancement has been confirmed by a number of kinetic investigations (Muetterties et al., 1982). Alternative synthetic strategies have been attempted employing benzophenone ketyl (BPK) (Bruce, 1987) or [PPN^+] salts (PPN^+ = bis(triphenylphosphine)iminium) as catalysts (Lavigne and Kaesz, 1984). In both cases, the major product was again the disubstituted derivative.

Compounds **5**−**7** were characterized by elemental analysis, IR, ^1H and ^{13}C NMR spectroscopy, and DCI-MS (see Experimental Procedures). Noteworthy, compounds **5**−**7**, which have fairly high molecular weights and moderate to low polarity, were much more effectively characterized by the DCI technique than both electron impact (EI, ionizing energy = 70 eV) or fast-atom

Scheme 3. Coupling Reaction of 6 with β-Alanine Ethyl Ester

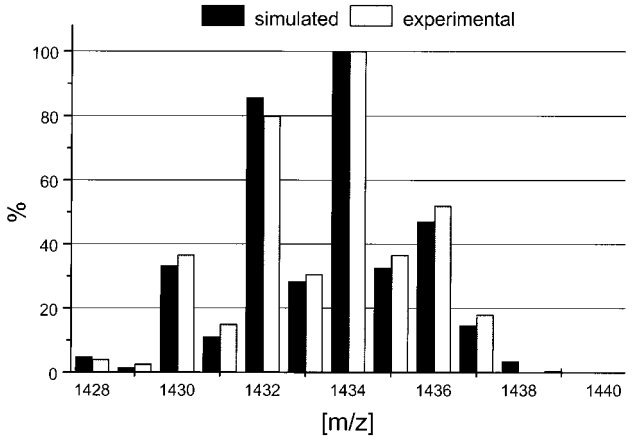


Figure 1. Experimental and simulated DCI mass spectra of **7** in the region corresponding to the $[M + H]^+$ peak. The two isotopic patterns have been compared by setting at 100% intensity the most abundant peaks at *m/z* 1434 in each spectrum.

bombardment (FAB, glycerol matrix) ionization methods. Among these techniques, only DCI-MS provided clean spectra, good sensitivity and well-defined isotopic patterns for the parent ions $[M + H]^+$ (Figure 1).

Coupling Reaction of 6 with β-Alanine Ethyl Ester. Once the synthesis and characterization of derivatives **5**−**7** was completed, it was still necessary to check that the coordination by metal fragments had not altered the acylating property of **1.** It was done by testing its reactivity with a model amino acid in dichloromethane. The reaction of **6** with β-alanine ethyl ester proceeded smoothly and completely within 24 h at ambient temperature giving the expected amide $Os_3(CO)_{11}[Ph_2P-(CH_2)_2C(O)N(H)(CH_2)_2C(O)OEt]$, **8**, in good yield (Scheme 3).

As already reported (Osella et al., 1996), the IR, in the ν_{CO} region, and UV−vis spectra of **6** and **8** are quite similar, representing good fingerprints for the presence of metallic markers in the conjugate.

Labeling Tests of BSA. Bovine serum albumin (BSA) is a very convenient and inexpensive model to test the binding capacity of newly developed amine reactive compounds. In particular, its contents in lysines is of 59 (i.e., a total of 60 amino groups), but in nondenaturating conditions (low temperature and low amount of organic cosolvent), 30−40 lysines are believed to be accessible to reagents (Erlanger, 1980).

Solutions of BSA at pH 9.0 were allowed to react with compounds **5**−**7** dissolved in DMF (**5** and **6**) or 2-propanol (**7**), so that the percentage of organic cosolvent was 10% and the initial reagent to protein molar ratio was 45. Reaction proceeded at room temperature for 5 h, and samples were submitted to gel filtration chromatography after filtration. The protein-containing fractions were analyzed by several spectroscopic methods in order to calculate the coupling ratio CR, corresponding to the final number of organometallic clusters bound per protein molecule. Results are reported in Table 1.

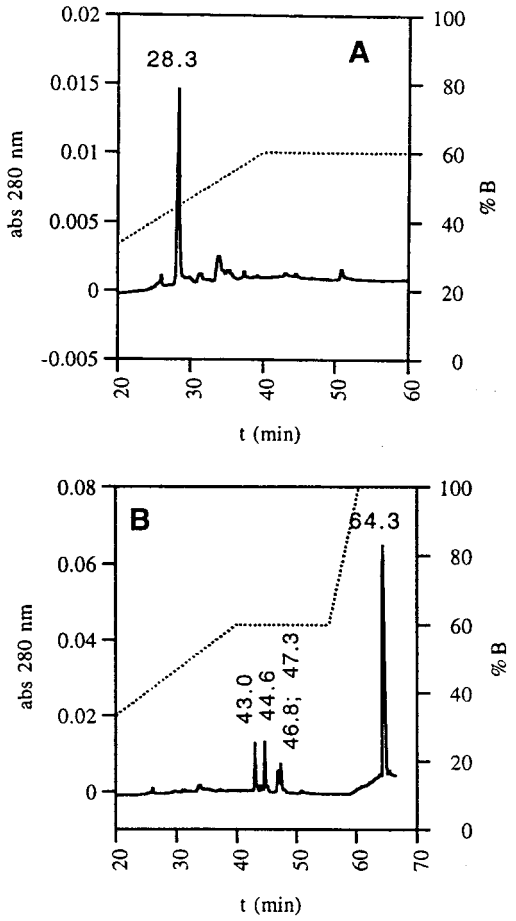

Figure 2. RP-HPLC of BSA (A) and BSA-**6** conjugate (B). For elution conditions, see the Experimental Procedures.

Table 1. Labeling of BSA with Compounds 5−7 (10% organic solvent in borate buffer pH 9.0, initial reagent to protein molar ratio = 45)

reagent	$[M]_{final}$ (M)	$[P]_{final}$ (M)	coupling ratio CR[a]	coupling yield CY[b]
5	48×10^{-6} [c]	4.2×10^{-6}	11.4	25%
6	88×10^{-6} [d]	6.5×10^{-6}	13.2	30%
7	59×10^{-6} [e]	6.1×10^{-6}	9.7	22%

[a] Coupling ratio CR = $[M]_{final}/[P]_{final}$. [b] Coupling yield CY = $[([M]/[P])_{final}/([M]/[P])_{initial}] \times 100$ = CR/45. [c] Measured by UV−vis spectroscopy at 419 nm. [d] Measured by UV−vis spectroscopy at 407 nm. [e] Measured by FT-IR spectroscopy at 2058 cm^{-1}.

Because of the high molecular weight of the reagents and their hydrophobic nature, we encountered some hurdles during the purification of the conjugates. Dialysis was unable to remove excess reagents (some part precipitated). Gel filtration chromatography of the reagents incubated in the same conditions without protein showed that some of them eluted in the same tubes as the protein while the rest precipitated in the column. We conclude that this means of purification is likely to lead to conjugates contaminated with noncovalently bound cluster.

The ultimate evidence of covalent binding of clusters **5**−**7** to BSA was brought by RP-HPLC. Chromatograms of BSA and BSA-**6** conjugates are displayed Figure 2. In the elution conditions chosen, BSA had a retention time of 28.3 min while BSA-**6** gave 4 major peaks at higher retention times ($43 < t_r < 47.3$ min), in agreement with the conjugation of several hydrophobic clusters to the protein. The presence of unbound cluster was detected by elution with 100% CH_3CN.

In summary, we observed a similar behavior of compounds **5**−**7** toward BSA; in particular, compound **6**, namely $Os_3(CO)_{11}$(DPPS), represents the best compromise between the moderate propensity toward hydrolysis showed by the isostructural compound **5** and the bulky hydrophobic character exhibited by the tetranuclear cluster **7**, so giving the highest CR and CY values.

CONCLUSIONS

Coordination of the ligand *N*-succinimidyl 3-diphenylphosphine propionate to activated triruthenium, triosmium, and tetrairidium clusters was achieved and the resulting complexes were shown to label BSA with yields in the range 22−30%. Within the Bolton−Hunter-like protocol for obtaining metallic-labeled acylating reagents for proteins, this phosphine ligand appears as a more widely applicable linker than the previously employed *N*-succinimidyl 4-pentynoate, since almost all metal carbonyl clusters react with phosphorus ligands and maintain their geometry. On the contrary, the coordination of the triple bond to clusters is not straightforward and often causes structural rearrangements (Osella and Raithby, 1989). By a similar strategy, it should also be possible to prepare derivatives targetted toward thiols (by introducing a maleimide function in place of the N-hydroxysuccinimide ester) or water-soluble compounds by exchanging some of the remaining CO ligands with water-soluble phosphines.

ACKNOWLEDGMENT

We thank Johnson Matthey for a generous loan of precious metals, European Union (EU) and MURST (COFIN 98) for financial support, and Dr. M. Vincenti (Department of Analytical Chemistry, University of Torino) for recording DCI-M.S. spectra. We are indebted with the two reviewers for valuable and constructive suggestions.

Conjugation, Immunoreactivity, and Immunogenicity of Calix[4]arenes; Model Study to Potential Calix[4]arene-Based Ac^{3+} Chelators

Marcel H. B. Grote Gansey,[†] Annemarie S. de Haan,[‡] Ebo S. Bos,[‡] Willem Verboom,[†] and David N. Reinhoudt*,[†]

Department of Supramolecular Chemistry and Technology, MESA+ Research Institute, University of Twente, P.O. Box 217, 7500 AE Enschede, The Netherlands, and Department of Analytical Chemistry for Research, N. V. Organon, P.O. Box 20, 5340 BH Oss, The Netherlands. Received December 10, 1998; Revised Manuscript Received April 9, 1999

For the development of calix[4]arene-based radiotherapeutic agents, the conjugation to biomolecules and immunogenicity in mice of potential $^{225}Ac^{3+}$-chelating calix[4]arenes were studied. A calix[4]arene triethyl ester isothiocyanate and a bis(calix[4]arene) hexacarboxylic acid, containing a masked thiol functionality, were used in conjugation experiments to a mouse monoclonal antibody and serum albumins. All characterization techniques indicate that only the calix[4]arene carboxylic acid is successfully conjugated to the biomolecules. The immunoreactivity of the conjugates is not impaired when up to 6 equiv of calixarene are bound to the monoclonal antibody. Animal tests indicated that the immunogenicity toward the calix[4]arene is strongly influenced by the nature of the carrier, the dosage, and the injection method. No immune response occurred when a homologous carrier was used or when a heterologous carrier was applied at a dosage of 10 μg per immunization via intravenous injection. Under all other conditions, the presence of antibodies directed against the calix[4]arene was demonstrated. Thus, for the application in radioimmunotherapy, the conjugation of a calix[4]-arene to a humanized antibody will probably not lead to an immune response, and the immunoreactivity will not be disturbed.

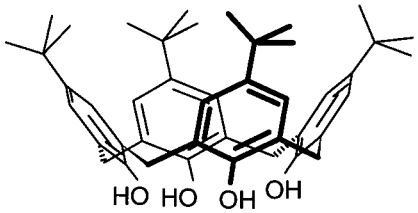
INTRODUCTION

Ionizing radiation is effective in the treatment of cancer. Radiolabeled agents that are selectively taken up by cancer cells confine the radiation specifically in the tumor, thereby minimizing damage to normal cells. For this purpose, tumor-selective mAbs or organ specific proteins are used (*1*−*7*). Crucial for the success of this approach are bifunctional ligands that can be attached to a protein and can bind a radioactive metal cation rapidly and selectively. The complex formed has to be kinetically inert with respect to dissociation either by acid or (serum) cation promoted pathways.

Calix[4]arene **1** is a cyclophane consisting of four phenolic units linked by methylene groups. It is widely used in supramolecular chemistry, e.g., in ionophores for cations and anions (*8*, *9*). We are interested in complexes of calix[4]arenes with cations in biological systems and have developed water-soluble derivatives (*10*) capable of sequestering luminescent trivalent lanthanide cations (*11*, *12*) as potential fluoroimmunoassays. This requires coupling of the ligand to biomolecules, such as mAbs and organ specific peptides. Kinetically inert ^{81}Rb complexes of calix[4]arene **2** were used to measure the renal blood flow (*13*, *14*).

Our ultimate goal is a calix[4]arene-based ionophore that irreversibly binds $^{225}Ac^{3+}$ (*15*), an α-emitting isotope with a half-life of 10 days and an attractive candidate for radiotherapy (*16*, *17*). Such a calix[4]arene should be conjugated to a mAb in order to convey the radiation source to the target. Very recently, Chen et al. (*18*) demonstrated the potential of calixarenes by performing extraction of $^{225}Ac^{3+}$ from an aqueous into an organic phase with a tetracarboxylic acid calix[4]arene.

The best position to connect a ligand to an antibody is at the Fc part, because it is positioned relatively distant from the variable region of the antibody, which is used for the recognition of and binding to the antigen. This is crucial for labeling antibodies in order to maintain a high degree of specific binding to target sites. Furthermore, the calix[4]arene−antibody conjugate should not elicit an immune response to the chelator, as this precludes repetitive administration of the therapeutic agent as has been described for DOTA[1] (*19*) and DTPA (*20*).



To the best of our knowledge, this paper describes the first study toward bioconjugation of calix[4]arenes that

are potential chelators for $^{225}Ac^{3+}$. We will discuss the characterization of the conjugates and the important questions of whether the conjugation of calix[4]arenes alters the immunoreactivity of the antibody and whether it leads to an immune response reaction in mice.

MATERIALS AND METHODS

Melting points were determined with a Reichert melting point apparatus and are uncorrected. ^{1}H NMR (250 MHz) and ^{13}C NMR (62.9 MHz) spectra were recorded with a Bruker AC250F spectrometer in the absence of an internal standard. FAB mass spectra were obtained with a Finnigan MAT90 mass spectrometer using NBA as a matrix. The presence of solvent in the analytical samples was confirmed by ^{1}H NMR spectroscopy. CH_2Cl_2 was distilled from $CaCl_2$ and stored over molecular sieves (4 Å), EtOAc was distilled from K_2CO_3 and stored over molecular sieves (4 Å), THF was distilled over sodium benzophenone ketyl prior to use. All other solvents and chemicals were of reagent grade and were used without purification. Silica gel (particle size 0.040−0.063 mm, 230−400 mesh) was obtained from Merck, Darmstadt, Germany. All reactions were carried out under an argon atmosphere. For reasons of clarity and in order to reduce space, the name calix[4]arene was used instead of the original IUPAC name: pentacyclo-[19.3.1.1^{3,7}.1^{9,13}.1^{15,19}]octacosa-1(25),3,5,7(28),9,11,13(27),-15,17,19(26),21,23-dodecaene. HSA (M_w = 68 000 g/mol), MSA (M_w = 65 000 g/mol), and OVA (M_w = 46 000 g/mol) were purchased from Sigma, St. Louis, MO. MAb 506-A (M_w = 160 000 g/mol), directed against hCG, was prepared by standard hybridoma technology. PD-10 columns (purchased from Pharmacia Biotech) are prepackaged, disposable columns (bed volume 9.1 mL, bed height 5 cm) containing Sephadex G-25 M swollen in distilled water containing 0.15% Kathon CG/ICP Biocide (trademark of Röhm and Haas) as preservative.

Synthesis of Bifunctional Ligands. **25-[(Hydroxycarbonyl)methoxy]-26,27,28-tris[(ethoxycarbonyl)-methoxy]calix[4]arene (4)**. To a solution of calix[4]-arene **3** (*21*) (2.50 g, 3.25 mmol) in CH_2Cl_2 (75 mL) were added 100% HOAc (5.0 mL) and 65% HNO_3 (8.3 mL). The mixture was stirred at room temperature for 45 min and subsequently poured into a mixture of CH_2Cl_2 (125 mL) and water (750 mL). The organic layer was washed with water (2 × 750 mL). Evaporation of the solvent yielded pure **4** as a white solid. Yield 95%; mp 141−143 °C; ^{1}H NMR ($CDCl_3$) δ 7.1−6.9 (m, 6 H, ArH), 6.6−6.5 (m, 6 H, ArH), 4.99 (part of ABq, 2 H, J = 13.0 Hz, $ArCH_2Ar$), 4.92 [s, 2 H, $OCH_2C(O)$], 4.89 [d, 2 H, J = 15.0 Hz, $OCH_2C(O)$ proximal to carboxylic acid], 4.69 (part of ABq, 2 H, J = 13.3 Hz, $ArCH_2Ar$), 4.69 [s, 2 H, $OCH_2C(O)$], 4.41 [d, 2 H, J = 15.8 Hz, $OCH_2C(O)$ proximal to carboxylic acid], 4.3−4.2 (m, 6 H, OCH_2Me), 3.32 (part of ABq, 2 H, J = 13.3 Hz, $ArCH_2Ar$), 3.29 (part of ABq, 2 H, J = 13.3 Hz, $ArCH_2Ar$), 1.31 (t, 9 H, J = 7.1 Hz, CH_3); ^{13}C NMR ($CDCl_3$) δ 170.7, 170.0, and 169.5 (s, C=O), 157.0, 154.5, and 153.8 (s, ArC−O), 135.7, 135.3, 133.3, and 133.1 (s, Ar*C*-CH_2), 129.4, 129.2, 128.9, 128.5, 124.7, 124.0, and 123.7 (d, ArC−H), 73.0, 72.5 and 71.4 [t, O*C*H_2C(O)], 61.2 and 60.7 (t, OCH_2Me), 31.0 and 30.9 (t, $ArCH_2Ar$), 14.2 (q, CH_3); FAB-MS m/z 741.0 ([M + H]$^+$, calcd 741.3); Anal. ($C_{42}H_{44}O_{12}$) C, H.

25,26,27-Tris[(ethoxycarbonyl)methoxy]-28-[(4-nitrobenzylcarbamoyl)methoxy]calix[4]arene (5). Calix[4]arene monocarboxylic acid triethyl ester **4** (2.37 g, 3.20 mmol) was dissolved in oxalyl chloride (10 mL), and the solution was refluxed for 1 h. After evaporation of the excess of oxalyl chloride, the residue was dissolved in CH_2Cl_2 (50 mL) and slowly added to an ice-cooled solution of *p*-nitrobenzylamine hydrochloride (0.72 g, 3.84 mmol) and DBU (1.46 g, 9.60 mmol) in CH_2Cl_2 (25 mL). The mixture was stirred overnight at room temperature, CH_2Cl_2 (50 mL) was added, and the solution was washed with 0.2 N HCl (2 × 100 mL) and H_2O (100 mL). After evaporation of the solvent, the crude product was purified via column chromatography (SiO_2, CH_2Cl_2:EtOAc 9:1, R_f 0.4) to give pure **5** as a slightly yellow solid. Yield 73%; mp 63−65 °C; ^{1}H NMR ($CDCl_3$) δ 8.98 (t, 1 H, J = 6.3 Hz, NH), 8.11 (d, 2 H, J = 8.7 Hz, O_2N−ArH), 7.49 (d, 2 H, J = 8.7 Hz, O_2N−ArH), 6.85−6.7 (m, 6 H, ArH), 6.45−6.2 (m, 6 H, ArH), 4.87 (part of ABq, 2 H, J = 16.4 Hz, $ArCH_2Ar$), 4.7−4.4 [m, 12 H, $ArCH_2Ar$, $OCH_2C(O)$, and NCH_2Ar], 4.16 (q, 2 H, J = 7.2 Hz, OCH_2Me opposite of amide bond), 3.85−4.0 (m, 4 H, OCH_2Me next to amide bond), 3.21 (part of ABq, 2 H, J = 14.0 Hz, $ArCH_2Ar$), 3.19 (part of ABq, 2 H, J = 13.9 Hz, $ArCH_2Ar$), 1.22 (t, 3 H, J = 7.2 Hz, CH_3 opposite of amide bond), 1.08 (t, 6 H, J = 7.1 Hz, CH_3 next to amide bond); ^{13}C NMR ($CDCl_3$) δ 170.7, 170.1, and 169.5 (s, C=O), 156.6, 155.0, and 154.8 (s, ArC−O), 147.0 and 146.9 (s, O_2N−ArC), 135.2, 135.0, 133.5, and 133.3 (s, Ar*C*-CH_2), 132.7, 129.4, 129.2, 128.4, 127.8, 127.6, 123.7, 123.4, and 123.0 (d, ArC−H), 73.9, 71.5, and 71.3 [t, O*C*H_2C(O)], 60.9 and 60.7 (t, OCH_2Me), 42.3 (t, NCH_2Ar), 31.5 and 30.9 (t, $ArCH_2Ar$),

14.2 and 14.1 (q, CH_3); FAB-MS *m/z* 897.5 ($[M + Na]^+$, calcd 897.3); Anal. ($C_{49}H_{50}N_2O_{13}\cdot 0.3H_2O$) C, H, N.

Reduction of Nitrocalix[4]arene 5 to Aminocalix-[4]arene 6. Calix[4]arene monoamide **5** (0.53 g, 0.60 mmol) was dissolved in a mixture of EtOH (20 mL) and THF (5 mL) in a 250 mL pressure barrel. A catalytic amount of palladium on charcoal (10%) was added, and the mixture was stirred at room temperature for 3 h under a H_2 atmosphere. The mixture was filtered over Hyflo filter aid and the filter was rinsed with CH_2Cl_2 (100 mL). The solvent was evaporated, and the crude product (0.47 g) was immediately used in the reaction with thiophosgene. ^{1}H NMR spectroscopy of a crude sample shows a complete disappearance of the signals of the phenyl group bearing the nitro moiety, but also indicates that aminocalix[4]arene **6** has a tendency to oligomerize.

25,26,27-Tris[(ethoxycarbonyl)methoxy]-28-[(4-isothiocyanatobenzylcarbamoyl)methoxy]calix[4]-arene (7). To a solution of crude **6** (0.47 g) in CH_2Cl_2 (10 mL) was added 1 mL of a 0.61 M solution of thiophosgene in CH_2Cl_2. Subsequently, 1 mL of a 0.61 M solution of triethylamine in CH_2Cl_2 was added, and the mixture was stirred at room temperature for 4 h. After evaporation of the solvents, the crude product was taken up in CH_2Cl_2 (50 mL) and washed with H_2O (50 mL). The organic phase was evaporated and the crude product was purified with column chromatography (SiO_2, CH_2Cl_2:EtOAc 9:1, $R_f = 0.4$) to give pure **7** as a white solid. Yield 55% (based on nitro compound **5**); mp 58−60 °C; ^{1}H NMR ($CDCl_3$) δ 8.83 (t, 1 H, $J = 6.3$ Hz, NH), 7.30 (d, 2 H, $J = 8.4$ Hz, SCN−ArH), 7.10 (d, 2 H, $J = 8.4$ Hz, SCN−ArH), 6.8−6.7 (m, 6 H, ArH), 6.5−6.2 (m, 6 H, ArH), 4.83 (part of ABq, 2 H, $J = 16.4$ Hz, $ArCH_2$-Ar), 4.7−4.4 [m, 12 H, part of AB system of $ArCH_2Ar$, $OCH_2C(O)$, and NCH_2Ar], 4.16 (q, 2 H, $J = 7.2$ Hz, OCH_2-Me opposite of amide bond), 4.0−3.9 (m, 4 H, OCH_2Me next to amide bond), 3.19 (part of ABq, 2 H, $J = 14.0$ Hz, $ArCH_2Ar$), 3.18 (part of ABq, 2 H, $J = 13.9$ Hz, $ArCH_2$-Ar), 1.22 (t, 3 H, $J = 7.1$ Hz, CH_3 opposite of amide bond), 1.10 (t, 6 H, $J = 7.2$ Hz, CH_3 next to amide bond); ^{13}C NMR ($CDCl_3$) δ 170.6, 169.9, and 169.5 (s, C═O), 156.6 (s, ArC−O), 138.7(s, ArC), 135.2, 135.0, 133.6, and 133.3 (s, Ar*C*-CH_2), 129.8 (s, ArC), 129.3, 129.2, 128.4, 128.2, 125.7, 123.4, 123.3, and 123.0 (d, ArC−H), 74.0, 71.4, and 71.3 [t, O*C*H_2C(O)], 60.9 and 60.7 (t, OCH_2Me), 42.2 (t, NCH_2Ar), 31.5 and 30.9 (t, $ArCH_2Ar$), 14.2 and 14.1 (q, CH_3); FAB-MS *m/z* 887.2 ($[M + H]^+$, calcd 887.3); IR (KBr) ν 2099 (NCS), 1757 (C═O ester), 1680 (C═O amide) cm^{-1}; Anal. ($C_{50}H_{50}N_2O_{11}S\cdot 0.5H_2O$) C, H, N.

Bis[25,26,27-tris[(ethoxycarbonyl)methoxy]-28-[4-[(2-thioethyl-thioureido)benzylcarbamoyl]methoxy]-calix[4]arene] (8). To a solution of calix[4]arene isothiocyanate **7** (0.275 g, 0.325 mmol) in CH_2Cl_2 (10 mL) was added cystamine dihydrochloric acid salt (0.0366 g, 0.163 mmol) and triethylamine (45 μL, 0.325 mmol). The mixture was stirred at room temperature for 4 h and subsequently washed with water. After evaporation of the solvent, the crude product was purified with preparative thin-layer chromatography (SiO_2, CH_2Cl_2:EtOAc 1:1). Yield 73%; mp 101−103 °C; ^{1}H NMR ($CDCl_3$) δ 8.91 [t, 2 H, $J = 6.3$ Hz, C(O)NH], 8.03 (s, 2 H, ArNH), 7.34 (d, 4 H, $J = 8.3$ Hz, N−ArH), 7.15 (d, 4 H, $J = 8.3$ Hz, N−ArH), 6.8−6.65 [m, 14 H, CH_2−N*H*-C(S) and ArH], 6.5−6.2 (m, 12 H, ArH), 4.86 (d, 4 H, $J = 16.5$ Hz, $ArCH_2$-Ar), 4.7−4.4 [m, 24 H, $ArCH_2Ar$, $OCH_2C(O)$, and $ArCH_2N$], 4.2−3.8 (m, 16 H, OCH_2Me and NCH_2CH_2), 3.20 (d, 4 H, $J = 14.1$ Hz, $ArCH_2Ar$), 3.18 (d, 4 H, $J = 13.9$ Hz, $ArCH_2$-Ar), 2.82 (t, 4 H, $J = 6.2$ Hz, S−CH_2), 1.25−1.05 (m, 18 H, CH_3); ^{13}C NMR ($CDCl_3$) δ 181.0 (s, C═S), 170.7, 170.1, and 169.6 (s, C═O), 156.5, 155.1, and 155.0 (s, ArC−O), 137.9, 135.4, 135.1, 134.9, 133.7, and 133.3 (s, ArC), 129.3, 129.1, 128.4, 125.3, 123.3, and 123.0 (d, ArC−H), 74.0, 71.4, and 71.3 [t, O*C*H_2C(O)], 60.9 and 60.8 (t, OCH_2Me), 43.9 (t, $ArCH_2N$), 42.3 (t, NCH_2CH_2S), 37.2 (t, NCH_2CH_2S), 31.5 and 31.0 (t, $ArCH_2Ar$), 14.2 and 14.1 (q, CH_3); FAB-MS *m/z* 1948.5 ($[M + Na]^+$, calcd for $C_{104}H_{112}N_6O_{22}S_4$, 1948.6), 962.5 ($[1/2M + H]^+$, calcd for $C_{52}H_{56}N_3O_{11}S_2$, 962.3).

Bis[25,26,27-tris[(hydroxycarbonyl)methoxy]-28-[4-[(2-thioethyl-thioureido)benzylcarbamoyl]-methoxy]calix[4]arene] (9). A solution of K_2CO_3 (0.15 g, 1.09 mmol) in water (2 mL) was added to a refluxing solution of calix[4]arene **8** (0.107 g, 0.058 mmol) in MeOH (10 mL). After the mixture was refluxed for 30 min, it was poured into water (150 mL), after which the pH was adjusted to about 2 with 1 N HCl. The product was extracted with CH_2Cl_2 (3 × 50 mL) to give, after evaporation of the solvent, pure **9** as a white solid. Yield 92%; mp 169−171 °C; ^{1}H NMR[2] (THF-d_8) δ 9.07 (s, 2 H, ArNH), 8.57 [br t, 2 H, C(O)NH], 7.47 (d, 4 H, $J = 8.2$ Hz, N−ArH), 7.38 [s, 2 H, ArNHC(S)], 7.30 (d, 4 H, $J = 8.2$ Hz, N−ArH), 6.85−6.55 [m, 26 H, ArH and CH_2N*H*C-(S)], 5.0−4.6 [m, 28 H, $ArCH_2Ar$, $OCH_2C(O)$, and $ArCH_2N$], 3.92 (br q, 4 H, $NHCH_2CH_2$), 3.30 (d, 4 H, $J = 13.5$ Hz, $ArCH_2Ar$), 3.29 (d, 4 H, $J = 13.5$ Hz, $ArCH_2Ar$), 3.03 (t, 4 H, $J = 6.0$ Hz, CH_2S); FAB-MS *m/z* 1757.6 ($[M + H]^+$, calcd, 1757.5), 880.3 ($[1/2M + H]^+$, calcd, 879.3), 846.6 ($[1/2M - S]^+$, calcd, 846.3); Anal. ($C_{92}H_{88}N_6O_{22}S_4\cdot 4H_2O$) C, H, N.

Conjugation Experiments. *Conjugation of Calix[4]-arene Isothiocyanate **7** to mAb 506-A and HSA*. A 4.48 mM (3.97 mg/mL) stock solution of calix[4]arene isothiocyanate **7** in DMF was made. A 14.7 μM (1.00 mg/mL) stock solution of HSA in PBS was prepared, as was a 6.25 μM (1.00 mg/mL) stock solution of mAb 506-A in PBS. To a volume containing 1 mg of biomolecule were added different amounts of calix[4]arene **7**. Table 1 summarizes the performed experiments. After mixing the two volumes, the pH of the mixture was adjusted to approximately 9.0 with 0.1 M triethylamine in doubly distilled water and incubated at 37 °C for 2 h. In experiments 3, 4, 7, and 8, some additional DMF was added (up to 86 μL), because the mixtures became turbid. This did not result in improved clarity. Subsequently, the mixture was chromatographed on PD-10 columns equilibrated in PBS according to the manufacturers descriptions.

*Conjugation of Calix[4]arene Disulfide **9** to mAb 506-A, HSA, and MSA*. Two buffer solutions were prepared;

[2] Several signals in the ^{1}H NMR spectrum of bis-calixarene **9** are double, probably caused by hydrogen bonding of the thiourea hydrogen atoms to the oxygen atoms of carboxylic acid moieties.

Table 2. Conjugation Experiments with Calix[4]arene Disulfide 9

expt	vol of calix[4]arene solution (μL)	vol of HSA-GMBS solution (μL)	vol of MoAb-GMBS solution (μL)	molar ratio calix[4]arene: biomolecule

16	115		4400	50:1

buffer A consisted of Na_2HPO_4 (50 mM) and EDTA (disodium salt, 1 mM) in milli Q water. The pH was adjusted to 7.5 with H_3PO_4. Buffer B consisted of Na_2HPO_4 (50 mM), EDTA (1 mM), and NaCl (100 mM) in milli Q water. The pH was adjusted to 6.0 with H_3PO_4. Nitrogen was bubbled through the solution in order to remove oxygen. PD-10 columns were equilibrated with buffer A. A solution of the biomolecule in PBS (1.0 mL of a 10 mg/mL HSA solution, 2 × 2.5 mL of a 2.7 mg/mL mAb 506-A solution) was chromatographed according to the manufacturers descriptions. The concentrations were determined by measuring the absorbance at 280 nm (3.9 mg/mL for HSA, 1.1 mg/mL for mAb 506-A). A 7.1 mM (2 mg/mL) stock solution of GMBS in DMF was freshly prepared. To 1.54 mL of the HSA solution (6.0 mg HSA) in buffer A was added 495 μL of the GMBS stock solution (molar ratio HSA:GMBS = 1:40). To 5.45 mL of the mAb 506-A solution (6.0 mg mAb 506-A) was added 79 μL of the GMBS stock solution (molar ratio mAb 506-A:GMBS = 1:15). The solutions were incubated at ambient temperature for 1 h in the dark. Subsequently, the solutions were chromatographed on PD-10 columns that were equilibrated with buffer B. The concentrations were determined spectrophotometrically (0.57 mg/mL for HSA, 0.23 mg/mL for mAb 506-A). A 1.42 mM (2.5 mg/mL) stock solution of calix[4]arene disulfide **9** in DMF was freshly prepared. Under a nitrogen atmosphere, 10 μL of tributylphosphine was diluted with 990 μL of 1-propanol to give a 36 mM solution of which 39.5 μL was added to 1 mL of the calix[4]arene **9** stock solution (molar ratio calix[4]arene **9**:PBu_3 = 1:1). The mixture was incubated at ambient temperature for 15 min. To a volume containing 1 mg of biomolecule were added different amounts of reduced calix[4]arene. Table 2 summarizes the performed experiments.

After incubation in the dark overnight at ambient temperature, to the HSA and mAb experiments were added 90 μL and 40 μL (24 equiv), respectively, of a 0.46 mg/mL cysteamine solution in water. Subsequently, the mixtures were chromatographed on PD-10 columns equilibrated with PBS.

The procedure for the MSA conjugates was comparable to the HSA conjugates.

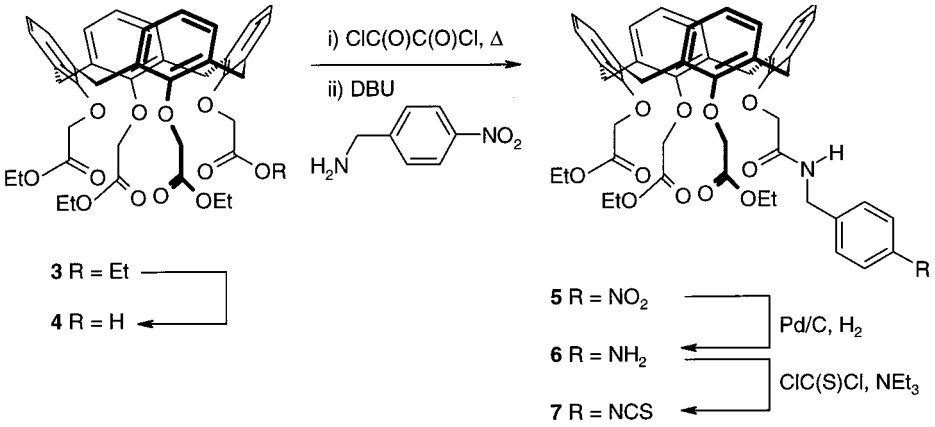
Conjugation Characterization. *MALDI-ToF MS.* MALDI-ToF MS was carried out using a PerSeptive Biosystems Voyager-DE-RP MALDI-ToF mass spectrometer. A 337 nm UV Nitrogen laser producing 3 ns pulses was used in the reflection mode. The samples were prepared by mixing 10 μL of a 50% acetonitrile/water solution of the sample with 20 μL of a solution of 3 mg/L α-cyano-4-hydroxycinnamic acid or dihydroxybenzoic acid in water. Of that solution, 1 μL was loaded on the gold-sample plate.

HP−SEC. The conjugates were analyzed by HP−SEC on a Superdex 200 column. The system used was a Beckman System Gold HPLC system including an autosampler (type 507), a programmable solvent module (type 126), a column thermostat (Separations, type SPH99), a programmable detector module (type 166) or diode array detector module (type 168), and PC plus software (System Gold version 5.10). As the mobile phase, a filtered (0.45 μ type HA Millipore filter) 0.2 N Na_2HPO_4 solution of pH 6.8 was used at a rate of 0.4 mL/min and 60 min/run. A typical procedure consisted of equilibration of the column with the buffer solution, followed by a blank run (injection of 100 μL buffer solution), injection of 50 μL of a SEC-6 calibration mixture, and another blank run. The absorbance at 210 nm was monitored. Subsequently, 100 μL of protein solutions, diluted with the buffer solution to approximately 0.1 μg/μL, were injected. After the last sample, the column was tested by analysis of a calibration mixture and a blank run.

Table 3. MALDI-ToF MS Results of HSA-Calix[4]arene 9[a]

expt	molar ratio calix[4]arene: biomolecule	*m/z* maximum (no. of conjugated calix[4]arenes)
9	5:1	68.0×10^3 (1)
10	10:1	68.0×10^3 (1)
11	25:1	72.4×10^3 (5)
12	50:1	73.3×10^3 (6)

[a] The *m/z* ratio for the unmodified HSA was found to be 67.0×10^3. The *m/z* ratio for one calix[4]arene-GMBS moiety is 1042.



IEF. IEF of the calixarene conjugates was essentially carried out according to the procedures of Pham et al. (*22*).

SDS−PAGE. The conjugates were analyzed by SDS−PAGE on 4−26% T and 3% C gels using the discontinuous buffer system of Laemmli under reducing and nonreducing conditions as described by Hoes et al. (*23*).

ELISA. The immunoreactivity of the conjugates of mAb 506-A was determined in an ELISA. Microtitration plates were coated with 1 μg/mL β-hCG in PBS. After an overnight incubation at 4 °C, the contents of the wells were discarded and the plates were washed thoroughly with PBS-Tween. Then, the plates were incubated for 1 h with PBS-Tween at ambient temperature. A dilution series of the antibody and the conjugates starting at 10 μg/mL was pipetted into the wells. Incubation was performed for 1 h at ambient temperature. The plates were washed three times with PBS-Tween and then a goat anti mouse IgG_1−HRP conjugate of appropriate dilution in PBS-Tween was added. After a 1 h incubation at ambient temperature, the plates were washed three times with PBS-Tween and twice with distilled water. Subsequently, the TMB−H_2O_2 substrate solution was added. After the color had sufficiently developed, the reaction was stopped by the addition of 4 N H_2SO_4 and the absorbance at 450 nm was read in an ELISA-reader. The reduction of immunoreactivity was easily derived by comparing the reaction curves of the nonconjugated antibody and the immunoconjugates.

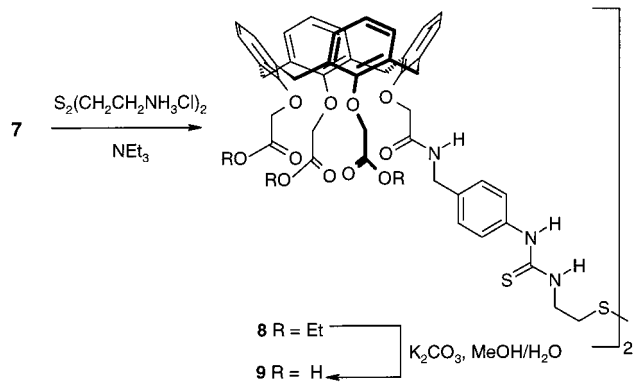
Immune Response Study. *Animal Tests.* Prior to use in the study, the HSA− and MSA−calix[4]arene conjugates were filtered over a 0.2 μm filter. Fifteen groups of five mice, which differed in injection method, antigen, and amount of antigen (see Table 4), were used. In the first method, the mice were injected i.p. at day 1 in the presence of Freund's Complete Adjuvant. At days 14, 28, and 42, an s.c. injection with Freund's Incomplete Adjuvant followed. The second method consisted of an i.p. injection without adjuvant at day 1, and an s.c. injection at days 14, 28, and 42. In the last method, only i.v. injections without adjuvant were applied at days 1, 14, 28, and 42. Prior to each injection blood was collected via an orbita punction. One week after the last series of

Scheme 1. Synthesis of Calix[4]arene Isothiocyanate 7

immunizations, all animals were bled by the intracardiac route. Three of the five mice that died during the study were replaced. All blood samples were centrifuged, and the sera were collected and stored at −20 °C.

Synthesis of OVA-Calix[4]arene Conjugate. A buffer solution consisting of Na_2HPO_4 (0.1 M) and NaCl (0.1 M) in milli Q water was prepared. The pH was adjusted to 7.5 with H_3PO_4. A 10 mg/mL solution of OVA in this buffer was prepared and chromatographed on a PD-10 column equilibrated with this buffer solution. The three 0.5 mL fractions with the highest absorbance at 280 nm were collected and diluted to give a final concentration of 5 mg/mL. To 1.4 mL of this solution, 190 μL of a 12.5 mg/mL solution of SPDP in 100% ethanol was added (molar ratio OVA:SPDP = 1:50) and incubated at ambient temperature for 30 min. The mixture was chromatographed (7 fractions of 0.5 mL were collected) on a PD-10 column equilibrated with the same buffer solution. The degree of substitution was determined by measuring the absorbance at 280 (A_{280}) and 343 nm (A_{343}) and of a 20-fold diluted sample, in the absence and presence of DTT. The degree of substitution is expressed by eq 1 and was 22.4 equiv of SPDP/molecule of OVA.

$$\text{degree of substitution} = \frac{\left(\frac{\Delta A_{343}}{8080}\right)}{\left(\frac{A_{280,\text{noDTT}} - 5100\frac{\Delta A_{343}}{8080}}{0.6 \times 46\,000}\right)} \quad (1)$$



To a solution of 15 mg/mL of calix[4]arene **9** in DMF was added 103 μL of a 0.08 M solution of tributylphosphine in 1-propanol under a nitrogen atmosphere. After 15 min of incubation, 250 μL of this solution was added to the OVA-SPDP solution (molar ratio OVA:calix[4]-arene thiol = 1:44.8) and incubated for 90 min. The solution was chromatographed on PD-10 columns equilibrated in PBS. The conjugates were analyzed by UV measurements, IEF (which failed due to precipitation of the conjugate on the gel, whereas the unmodified protein can be applied without difficulties), and SDS−PAGE.

Analysis of Mouse Sera by ELISA (*Vide Supra).* Microtitration plates were coated with 1 μg/mL OVA−calix-[4]arene conjugate. The sera to be tested were diluted 10-fold with PBS-Tween. The second antibody [goat anti mouse Ig-HRP conjugate] was diluted 5000-fold with PBS-Tween.

RESULTS AND DISCUSSION

Synthesis of Bifunctional Ligands. Because of the frequent use of aryl isothiocyanate groups in coupling reactions to biomolecules (*17*, *24*−*26*), we decided to synthesize a calix[4]arene containing such a group at the *lower rim*. To obtain a binding site for cation complexation, e.g., a cavity consisting of the phenolic oxygen atoms and carboxylic acid groups or amides, as was shown to be useful for binding lanthanide ions (*11*, *27*), the synthesis route (Scheme 1) started with calix[4]arene tetraethyl ester **3** (*21*). Via selective monohydrolysis under acidic conditions (*28*), calix[4]arene monocarboxylic acid triethyl ester **4** was obtained. Activation of the carboxylic acid with oxalyl chloride afforded the corresponding acid chloride, which was reacted with *p*-nitrobenzylamine to give calix[4]arene monoamide **5** in 73% yield. Clearly distinguishable signals for the aromatic hydrogen atoms of the nitrophenyl moiety in the ^{1}H NMR spectrum indicated the successful introduction of this functionality. Aminocalix[4]arene **6** was obtained by reduction of the nitro group of calixarene **5** using H_2 and 10% palladium on charcoal in a mixture of ethanol and THF. Because of a tendency to oligomerize, due to a reaction between the amino group and the ethyl ester moieties, calix[4]arene **6** was immediately converted to calix[4]arene isothiocyanate **7** by reaction with thiophosgene and triethylamine as a base. After column chromatography, bifunctional calix[4]arene isothiocyanate **7** was obtained in 55% yield based on nitrocalix[4]arene **5**. The conversion of the nitro group was evidenced by a shift of the signals in the ^{1}H NMR spectrum of the aromatic hydrogen atoms of the isothiocyanate bearing phenyl ring and by the presence of a characteristic isothiocyanate peak at 2099 cm^{-1} in the infrared spectrum of calix[4]-arene isothiocyanate **7**. Calix[4]arene triethyl ester monoamide **7** may be regarded as a bifunctional ligand, because of its ability to complex cations in organic media and of the presence of a moiety with which it can be linked to biomolecules. However, for a strong binding to trivalent cations the ester groups of calix[4]arene **7** must be hydrolyzed to the corresponding calix[4]arene tricarboxylic acid monoamide. This was attempted by an acidic hydrolysis because of the sensitivity of isothiocyanate groups toward alkaline conditions and reactivity to refluxing methanol (*29*), in which solvent this reaction is usually accomplished (*27*). However, only partial hydrolysis was observed, probably because of inhibition of further hydrolysis by hydronium ion complexation, as was observed in the monohydrolysis of calix[4]arene tetraester **3** to calix[4]arene monocarboxylic acid triethyl ester **4** (*28*). Also, an attempt to enzymatically hydrolyze the ester groups did not result in the desired deprotection. Therefore, it was decided to further functionalize calix[4]arene **7** in such a way that a derivative stable to alkaline conditions was obtained.

Scheme 2. Synthesis of Calix[4]arene Dimer 9

Whereas an isothiocyanate functionality containing ligand can potentially be coupled directly to amino groups of the protein of choice, another method for the conjugation of bifunctional ligands is the coupling of the chelator to an engineered biomolecule. This is achieved by a reaction of the amino groups of the biomolecule with a so-called heterobifunctional linking agent containing two different functional groups, of which only one is reactive toward amino groups. The remaining functional group can subsequently be used in the coupling reaction with a bifunctional ligand. The ligand then has to be equipped with a reactive group, other than an amino group. For this purpose, a thiol functionality is frequently used. *S*-(2-pyridylthio)cysteamine (*30*) has been applied in our group as a precursor for a thiol group.[3] Calix[4]arene triethyl esters functionalized at the *lower rim* with this linking agent were converted to the corresponding calix[4]arene tricarboxylic acid by refluxing in a water/methanol mixture containing potassium carbonate (*27*). However, during this reaction, cleavage of the S−S bond occurred and this led to a dimer of calix[4]arene tricarboxylic acids linked by a newly formed disulfide bond. For the coupling to biomolecules, the disulfide bond is reduced, affording 2 equiv of calixarene thiols, which can be coupled to a biomolecule modified by reaction with a heterobifunctional linking agent.

Because of the scission of the disulfide bond, we decided to synthesize a calixarene dimer on purpose. Reaction of calix[4]arene isothiocyanate **7** with half an equivalent of cystamine afforded bis(calix[4]arene) thiourea disulfide **8** in 73% yield after preparative thin-layer chromatography. The bis-calix[4]arene was characterized by mass spectrometry and ^{1}H NMR spectroscopy, which proved the formation of a thiourea moiety. Selective basic hydrolysis of the ester groups (*27*) gave in 92% yield the corresponding bifunctional calix[4]arene hexacarboxylic acid **9** (Scheme 2). This gave a compound capable of binding cations in the cavity formed by the phenolic oxygen atoms, the carboxylate and the amide carbonyl groups.

Conjugation Experiments. Conjugation of bifunctional calix[4]arenes **7** and **9** was performed with two different types of biomolecules. MAb 506-A, directed against the pregnancy hormone hCG, was used as a model for the tumor specific mAbs to be applied as tools in radioimmunotherapy. HSA was used as a model for organ-specific proteins.

Conjugation of calix[4]arene isothiocyanate **7** was attempted by addition of different amounts of a solution of the calix[4]arene in DMF to aqueous solutions of the biomolecule in PBS and subsequent adjustment of the pH to 9. The mixtures in which the ratio calixarene: biomolecule was higher than 25:1 became turbid, but no precipitation occurred.

Reduction of the disulfide bond of bis-calix[4]arene **9** with 1 equiv of tributylphosphine afforded 2 equiv of a thiol-functionalized calix[4]arene. Modification of the biomolecule is necessary in this case because the biomolecule itself does not contain readily available groups to which the calixarene can be connected. The coupling was performed by reacting the proteins with the heterobifunctional linking agent GMBS, which contains an active ester moiety which reacts with the amino groups of the biomolecule to give a stable amide bond. Its maleimido functionality can be reacted in a Michael addition with a thiol like the reduced form of calix[4]arene **9**. In the first step, 15−40 equivalents of GMBS dissolved in DMF were added to a PBS solution of mAb 506-A and HSA, respectively. Subsequently, a solution of calix[4]arene thiol in DMF was added to oxygen-free solutions of the biomolecules in ratios varying from 5:1 up to 50:1, to allow the Michael addition to the maleimido group. After one night of incubation at ambient temperature in the dark, the remaining free maleimido groups were reacted with cysteamine in order to regain amino groups at positions that were not used in the conjugation to the calix[4]arene.

Conjugation Characterization. The mixtures obtained in the conjugation experiments were analyzed by MALDI-ToF MS, HP−SEC, IEF, and SDS−PAGE. All techniques indicated that the conjugation experiments with calix[4]arene isothiocyanate **7** were not successful. The reason is probably its low solubility in water. The biomolecules seem to solubilize the calix[4]arene by means of hydrophobic interactions, as was indicated by the turbidity of the mixtures and reflected by the strong aggregation that became apparent in the HP−SEC measurements.

On the other hand, the same techniques proved that the calix[4]arene thiol, obtained by reductive cleavage of the disulfide bond of calix[4]arene **9**, could be successfully linked to both mAb 506-A and HSA. MALDI-ToF MS experiments showed a clear shift to higher *m*/*z* values for the thiol derivative of calix[4]arene **9** conjugated to HSA. Upon addition of 50 equiv of the reduced calix[4]-arene to a solution of the GMBS-modified HSA, about six calix[4]arene molecules were conjugated to the protein. At a ratio of 25:1, approximately five calix[4]arene moieties are connected to the protein, and at lower ratios of 10 and 5:1, approximately only one calix[4]arene is bound (Table 3).

HP−SEC analysis of the calix[4]arene−antibody conjugate (Figure 1) shows a slight reduction in retention time as compared to the free antibody which is probably caused by the attachment of the chelator. A limited aggregation has occurred during the coupling reaction as is concluded from the UV-absorbing material in the void volume. However, the chromatographic profile shows that all contaminants can be easily removed by preparative gel permeation chromatography, leaving a homogeneous, monomeric immunoconjugate. The tendency to form aggregates was much less than observed for calix-[4]arene isothiocyanate **7**. This indicates that the enhanced solubility of calixarene **9** strongly improves its conjugation ability (data not shown).

Whenever the calix[4]arene thiol was involved in the IEF experiments (Figure 2, panels c and d), a clear anodal shift of the conjugate spots was observed (for reasons of

[3] Rudkevich, D. M., Verboom, W., and Reinhoudt, D. N., unpublished results.

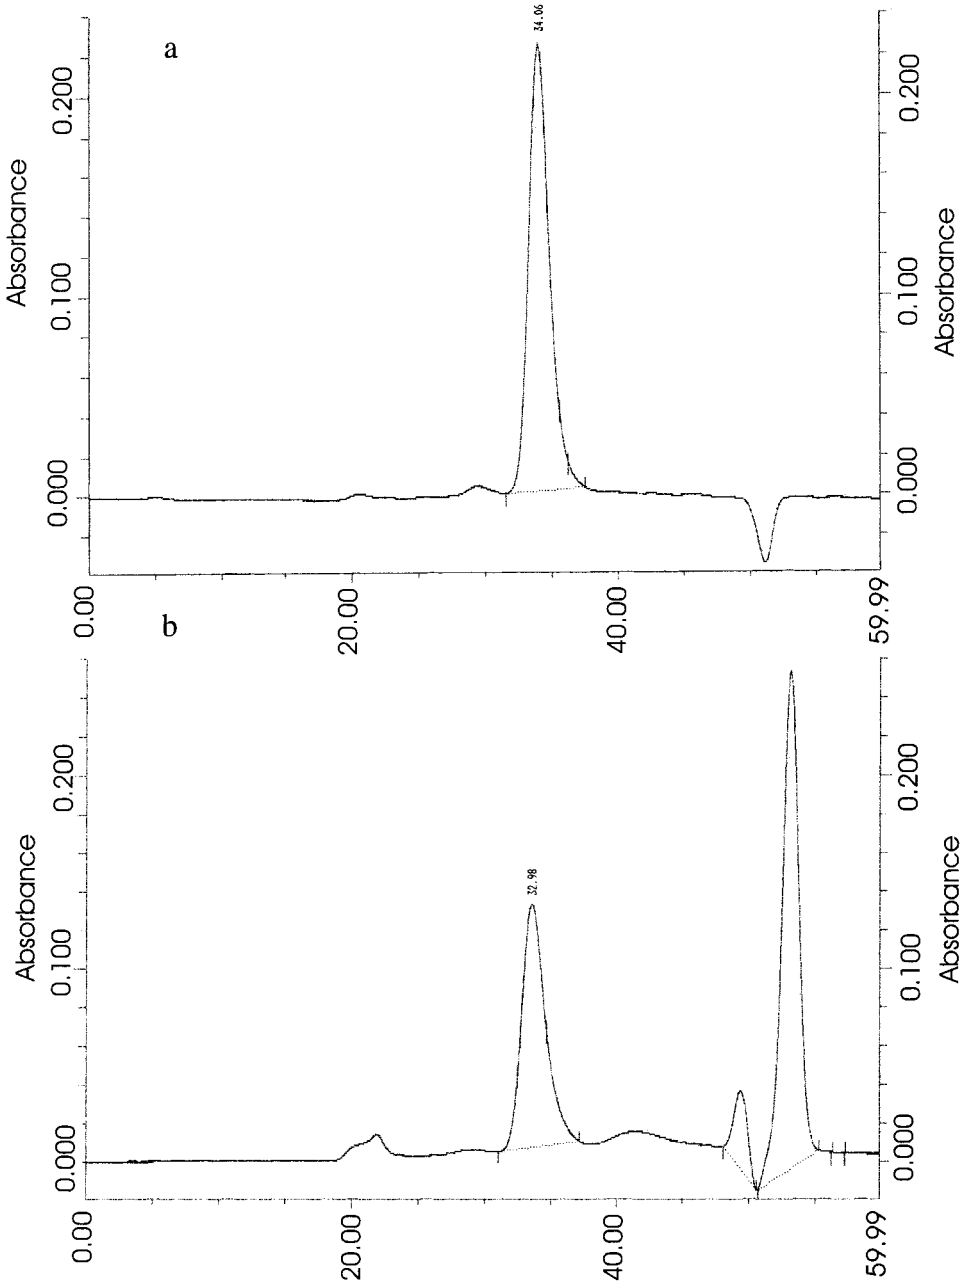


Figure 1. HP−SEC profiles of monoclonal antibody 506-A (a) and the (50:1) calix[4]arene disulfide immunoconjugate (b). Experimental details are described in the Materials and Methods.

comparison, the nonconjugated samples obtained with calix[4]arene isothiocyanate **7** are represented in Figure 2, panels a and b). These experiments indicate that the "acidity" of the calix[4]arene thiol conjugates is increased in comparison to the unmodified biomolecules due to the introduction of carboxylic acid groups.

When the calix[4]arene thiol was applied, in the SDS−PAGE experiments new bands appeared at positions corresponding to higher masses, indicative of a successful conjugation (Figure 3b). Also here, for reasons of comparison, the nonconjugated calix[4]arene **7** is presented in Figure 3a. Upon reduction of the disulfide bonds in the mAb conjugates, polypeptides with a molecular mass higher than that of the unmodified antibody were also observed.

Immunoreactivity Study. An important feature that has to be verified after conjugation of bifunctional ligands, in this case the thiol derivative of calix[4]arene **9**, to mAbs is the question whether the immunoreactivity, i.e., the binding of the antibody to its corresponding antigen, remains intact. The ELISA, described for the assessment of immunoreactivity, can be used for this purpose.

As can be concluded from Figure 4b, all conjugates tested show good immunoreactivity, indicating that this type of calix[4]arene can be coupled to mAbs without destroying the binding capabilities to antigens.

The immunoreactivity in the reaction mixtures with calix[4]arene isothiocyanate **7**, that could not be conjugated to the biomolecules, did not change significantly with the exception of the 118:1 mixture that showed no reaction at all (Figure 4a). Apparently, the binding sites of the mAb are involved in noncovalent interactions with the calix[4]arenes. It is possible that the calixarenes are kept in solution by means of hydrophobic interactions, leading to large structures which resulted in a turbid solution.

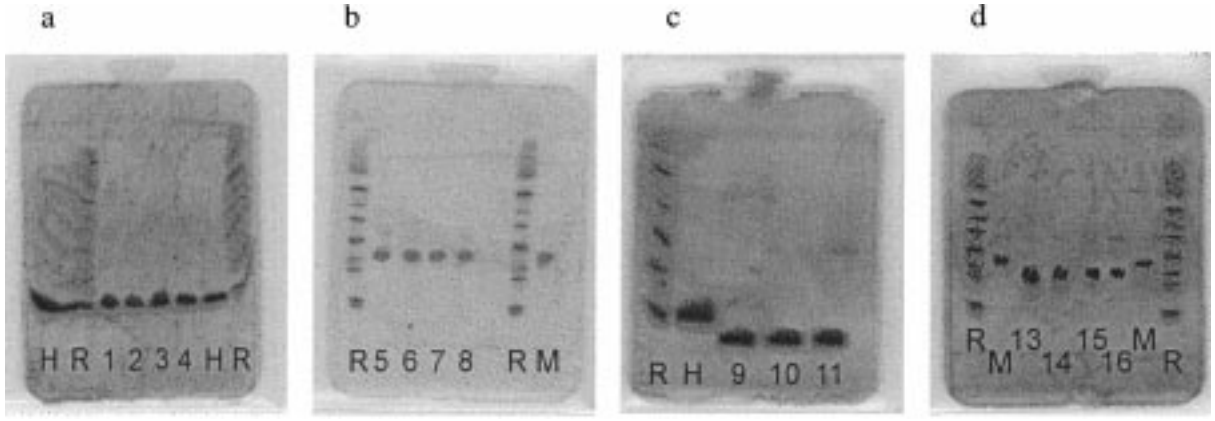

Figure 2. IEF analysis of the conjugation reactions. (a) HSA + calixarene **7**; (b) mAb 506-A + calixarene **7**; (c) HSA + calixarene **9**; (d) mAb 506-A + calixarene **9**. R represents the reference, H represents unmodified HSA, M represents unmodified mAb 506-A, the lane numbers correspond to the experiment numbers as mentioned in Tables 1 and 2.

Immunogenicity Study. The immunogenicity of protein bound calix[4]arene **9** was studied in mice. For this purpose (*31*), conjugates of the calix[4]arene with HSA and MSA were prepared as a heterologous and homologous immunogen, respectively. The study included five groups, each of 15 animals, schematically represented in Table 4. As can be seen from this table, regimen c can be compared in terms of doses and injection scheme with an immunotherapeutic or -diagnostic protocol in humans.

The sera were collected and assessed for the presence of antibodies directed against the calix[4]arene by ELISAs (Figure 5). For this purpose, a new conjugate had to be synthesized, which differed in carrier and cross-linker from the ones applied in immunization and which thus

Table 4. Experiments Performed in Immunogenicity Study[a]

group	antigen	amount of antigen (μg)
1a, b, c	HSA-calixarene	50
2a, b, c	HSA-calixarene	10
3a, b, c	MSA-calixarene	50
4a, b, c	MSA-calixarene	10
5a, b, c	− (PBS)	

[a] Each group of Table 4 was subdivided into three groups of five animals, which differed in injection method. In the first method the mice were injected i.p. at day 1 in the presence of Freund's Complete Adjuvant, an immunoresponse stimulating agent. At days 14, 28, and 42, an s.c. injection with Freund's Incomplete Adjuvant followed. The second method consisted of an i.p. injection without adjuvants on day 1 and an s.c. injection at days 14, 28, and 42. In the last method, only i.v. injections without adjuvants were applied at days 1, 14, 28, and 42. After approximately 1 week three mice of the same group died. No toxic effects of the antigen appeared, which makes it likely that the cause of death of these mice was not related to the injection with antigen. They were replaced by new mice, which were treated according to the original scheme. During the second immunization two mice, which were treated with the HSA-calix[4]arene conjugate by method 3 at both dosages, suffered from brain damage. These mice were not replaced due to shortage of antigen.

enables the selective detection of calixarene directed antibodies. OVA was selected as a carrier, which was reacted with the heterobifunctional linker SPDP (*32*). Subsequently, the calix[4]arene thiol, obtained by reduction of the disulfide bond of calix[4]arene **9**, was conjugated. UV measurements, IEF, and SDS−PAGE indicated that conjugation of the calix[4]arene was successfully performed.

The sera from mice that were injected intravenously with the homologous MSA−calix[4]arene (Figure 5b), a situation comparable to that during immunotherapy of humans with humanized mAbs (*33*), did not show a reaction against the calixarene. Neither did immunizations with MSA-calix[4]arene conjugates in the presence of adjuvants (method 1) evoke a humoral response to the chelator. However, in the experiments in which the heterologous HSA−calix[4]arene conjugates were involved, the formation of antibodies against the calix[4]arene was clearly demonstrated (Figure 5a). The adjuvants applied in injection method 1 clearly triggered the immune system. Injection method 2 gave a less severe reaction, but clearly, the presence of calix[4]arene directed antibodies in the sera was demonstrated. The results of the i.v. injection method 3 depended on the dosages. Application of 50 μg induced a response to some small degree, whereas the presence of antibodies was not demonstrated in the sera of mice that were given 10 μg of the antigen. This toxicity may be conjugate related. Although these effects were not observed with the syngeneic albumin conjugate and toxicity is considered to be beyond the scope of this study, it is a matter of serious concern and will be addressed in detail during the further development of the chelator.

The ELISAs of the sera obtained by taking a blood sample prior to each immunization were in good agreement with the results depicted in Figure 5. When the homologous systems were tested, no immune response was found, whereas there is a small response against the heterologous conjugate (except for the 10 μg dosage injected i.v.) after the first injection. In these cases, the response increased with subsequent injections.

These findings indicate that, for the future application in radioimmunotherapy in humans with humanized antibodies (*33*), an immune response against the calix[4]arene conjugate is unlikely to occur. Even after repeated administration of MSA−conjugate at a high dose, no immunoreaction was observed, which indicates that a therapeutic setting (e.g., injection method 3) with humanized mAbs is feasible. Recent studies of DeNardo et al. (*34*) show that a combination of a chimeric antibody and DOTA linked to it through a hydrolyzable peptide linker leads to an immunoconjugate that does not elicit

an antiglobulin response in humans despite five immunoconjugate infusions. Moreover, the biodegradable linker minimizes the radiation dose to critical normal tissues, thereby improving the therapeutic index. This study advocates additional attention to be focused on the introduction of biodegradable linkers in the development of novel, clinically applicable chelator molecules, which will be taken up in the studies on calix[4]arenes.

CONCLUSIONS

Bis(calix[4]arene) hexacarboxylic acid **9**, containing a masked thiol functionality, was conjugated to mAb 506-A and HSA. The immunoreactivity of the conjugates is not impaired when up to 6 equiv of calixarene are bound to the mAb. Animal tests indicated that the immunogenicity toward the calix[4]arene is strongly influenced by the nature of the carrier, the dosage, and the injection method. No reaction occurred when a homologous carrier was used or, when a heterologous carrier was applied, at a dosage of 10 μg/immunization via i.v. injection. Under all other conditions, the presence of antibodies directed against the calix[4]arene was demonstrated. Thus, for the application in radioimmunotherapy, the conjugation of a calix[4]arene to a humanized antibody will probably not lead to an immune response, while the immunoreactivity will not be disturbed.

It has already been shown that calix[4]arene tricarboxylic acids are able to chelate lanthanide cations in aqueous environments (*11*). Furthermore, Chen et al. (*18*) reported that calixarenes can be used to extract $^{225}Ac^{3+}$ from an aqueous into an organic phase. Experiments are now underway to investigate the $^{225}Ac^{3+}$ chelating properties of calix[4]arene **9**.

Caged DNA Does Not Aggregate in High Ionic Strength Solutions

Vladimir S. Trubetskoy,*,† Aaron Loomis,† Paul M. Slattum,† James E. Hagstrom,† Vladimir G. Budker,‡ and Jon A. Wolff‡

Mirus Corporation, 545 Science Drive, Madison, Wisconsin 53711, and Departments of Pediatrics and Medical Genetics, Waisman Center, University of Wisconsin—Madison, Room 361, 1500 Highland Avenue, Madison, Wisconsin 53705. Received December 28, 1998; Revised Manuscript Received March 22, 1999

The assembly of DNA into compact particles that do not aggregate in physiologic salt solution occurs naturally in chromatin and viral particles but has been challenging to duplicate using artificial constructs. Cross-linking amino-containing polycations in the presence of DNA with bisimidoester cross-linker leads to the formation of caged DNA particles that are stable in salt solutions. This first demonstration of caged DNA provides insight into how natural condensation processes avoid aggregation and a promising avenue for developing nonviral gene therapy vectors.

INTRODUCTION

The condensation of DNA is an integral process of chromatin and viral assembly (*1*−*4*). These processes have been modeled by use of low molecular weight cations such as spermine and polycations such as polylysine which compact DNA into toroid and rod structures when the DNA's negative charge is more than 90% neutralized (*5*). These practices are also important for the preparation of nonviral vectors for gene therapy (*6*−*8*). In contrast to chromatin and viral particles, these artificial DNA particles aggregate in semidilute DNA solutions containing physiologic concentrations of NaCl (*9, 10*). The aggregation of large polycation/DNA complexes is not well understood and hampers the use of such condensates for gene therapy because they are rapidly cleared from the circulation (*11*). We now show that covalent cross-linking of polyamines in complexes with DNA increases the stability of the condensed DNA particles in salt.

MATERIALS AND METHODS

Reagents. Plasmid pCILuc encoding the firefly luciferase was used as DNA throughout the study (*12*). Sodium chloride, poly-L-lysine (PLL, molecular mass 34 and 210 kDa), histone H1 (type III-S) and dextran sulfate (DS, MW 500 kDa) were obtained from Sigma. Polyallylamine, (molecular mass 10 kDa) and fluorescein isothiocyanate (FITC) were purchased from Aldrich. Cross-linking reagent, dimethyl-3,3′-dithiobispropionimidate (DTBP), was a product of Pierce (Rockford, IL). Reagents for covalent labeling of DNA (*Label*IT Fluorescein and *Label*IT Rhodamine) were products of Mirus Corp.

Labeling of Polyions with Fluorescent Moieties. DNA was labeled using *Label*IT Rhodamine reagent (13) at 1:1 reagent/DNA w/w ratio to yield covalent rhodamine−DNA conjugate (Rh-DNA). DNA was incubated with the reagent at 1 mg/mL in Hepes buffer for 1 h at 37 °C and was purified by two ethanol precipitations and immediately redissolved in water at concentration 1 mg/mL. PLL was labeled with FITC at 1:100 fluorophore/lysine initial ratio to yield fluorescein-PLL (Fl-PLL). PLL (10 mg in 1 mL of 0.1 M sodium tetraborate, pH 9.0) was mixed with 0.18 mg of FITC dissolved in 50 μL of anhydrous methyl sulfoxide (Aldrich). After 1 h of incubation at room temperature, the polymer was precipitated with 2-propanol and redissolved in the same buffer supplemented with 0.5 M NaCl.

Preparation of DNA/Polycation Complexes and Their Cross-Linking. The complexes were prepared at different amine/phosphate charge ratios in 25 mM Hepes solution adjusted to pH 8.0 with 4N NaOH (Hepes buffer) by adding stock solution of polycation (typically 10 mg/mL in 6−30 μL of water) into 1 mL of Hepes solution of DNA (50 μg/mL) and vortexing for 30 s. Cross-linking of DNA/polycation DTBP occurred at a 2:1 molar ratio of DTBP to primary amine (e.g., lysine monomer for polylysine and histone). Reaction was conducted for 3 h at room temperature. Cleavage of DTBP was performed by treating cross-linked complexes with a final concentration of 20 mM dithiothreitol (DTT) (Sigma) for 30 min at 37 °C. To premodify PLL with DTBP, PLL (10 mg in 1 mL of Hepes buffer) and DTBP (15 mg as dry powder) were incubated for 3 h at room temperature. The reaction mixture was used without further purification.

Particle Sizing and ζ-Potential Measurements. Particle sizing and ζ-potential measurements were performed at 25 °C using a Zeta Plus Particle Analyzer (Brookhaven Instruments Corp., Holtsville, NY) with a laser wavelength of 532 nm.

Dialysis of DNA/Polycation Complexes. For dialysis experiments, Rh-DNA/Fl-PLL complexes were formed at 100 μg/mL DNA concentration with a charge ratio of DNA to PLL of 1:6. DTBP modification was then done for 3 h. Samples were loaded into Spectra/Por CE (Cellulose Ester) Membrane MWCO 300 000 (Spectrum Medical Industries, Houston TX) and then dialyzed against Hepes buffer for 48 h with two buffer exchanges.

Ultracentrifugation of Rh-DNA/Fl-PLL Complexes. For ultracentrifuge precipitation experiments, Rh-DNA/Fl-PLL complexes were prepared at [DNA] = 100 μg/mL in Hepes buffer at 1:2, 1:4, and 1:6 charge ratios. Within 1 h after mixing, the complexes (1 mL) were centrifuged in Beckman TX-100 benchtop ultracentrifuge at 60 000 rpm for 1 h using a Ti 100 rotor. Spectra of the complexes

were registered before and after centrifugation in a range of 400−700 nm using Beckman DU-7 spectrophotometer. Difference spectra were derived using the instrument's software to obtain spectra of precipitated complexes. Spectra of Rh-DNA and Fl-PLL were also registered separately in order to measure absorbance at 590 and 495 nm respectively for individual components.

Polycation exchange experiments. For polycation exchange experiments, Fl-PLL was used as a reporter molecule. Its fluorescence within DNA/Fl-PLL complex is decreased due to polyelectrolyte condensation. The addition of excess of nonlabeled PLL displaces Fl-PLL from the complex and leads to fluorescence increase. Complex was formed at an initial charge ratio (3:1) and at a DNA concentration of 20 μg/mL in Hepes buffer (total volume 0.5 mL). NaCl was added up to 50 mM in order to achieve the equilibrium quicker. After the signal was stable, nonlabeled PLL (20× molar excess) was added to displace Fl-PLL from the complex. The result was expressed as the percentage of nonexchangeable Fl-PLL in the complex: $(F_0 - F)/(F_0 - F_{min}) \times 100\%$ where F_0 is the initial fluorescence of Fl-PLL, F_{min} is the fluorescence of Fl-PLL/DNA complex, and F is the fluorescence after addition of 20× excess of nonlabeled PLL.

Release of Fl-DNA from Fl-DNA/PLL Complexes in Decondensation Conditions. Release of Fl-DNA from Fl-DNA/PLL complexes in decondensation conditions was assessed by monitoring the increase in Fl-DNA fluorescence (*13*) after interaction with dextran sulfate (DS, molecular mass 500 kDa, Sigma). Fl-DNA/PLL complexes (cross-linked and non-cross-linked) were mixed in 450 μL of Hepes buffer at [Fl-DNA] = 50 μg/mL with 50 μL of increasing amount of DS for 5 min at room temperature (PLL/DS ratio was varied from 0.15 to 16). Sample fluorescence (0.5 mL of total volume) was measured using a spectrofluorometer ($\lambda_{em} = 490$, $\lambda_{ex} = 530$) and expressed as % of uncondensed Fl-DNA fluorescence.

Electron Microscopy of Condensed DNA Samples. DNA complexes were placed onto glow-discharged Formvar-coated 200-mesh grids for 1 min followed by staining with 1% uranyl acetate for 30 s. The grids were blotted dry with filter paper and examined using a JEOL JEM 100S electron microscope.

Transfection with DTBP-Treated Plasmid DNA. A luciferase expression plasmid DNA/histone H1 complex was cross-linked with DTBP. After DTT treatment, the plasmid DNA was transfected into 3T3 cells using *Trans*IT LT-1 reagent (Mirus Corp.) and luciferase expression was similar to that of non-cross-linked plasmid DNA preparation.

RESULTS AND DISCUSSION

The salt stability of polycation complexes with plasmid DNA was assessed using dynamic light scattering (Figure 1) and further confirmed using static light scattering. For PLL complexes, raising the charge ratio of PLL/DNA from 2:1 to 6:1 increased salt stability but the complexes still aggregated in 50 mM NaCl (Figure 1a). The addition of DTBP, which cross-links the amines on the PLL, substantially increased the salt stability of the complexes. DTBP was chosen because its product with primary amino groups preserves positive charge upon coupling. The salt stabilization is reversed upon addition of dithiotreithol which cleaves DTBP, indicating that it is not due to the conversion of the amines to amidines and is dependent upon the cross-linking. DTBP also stabilized complexes of DNA and polyallylamine (Figure 1b). Remarkably, cross-linking of histone H1/DNA complexes

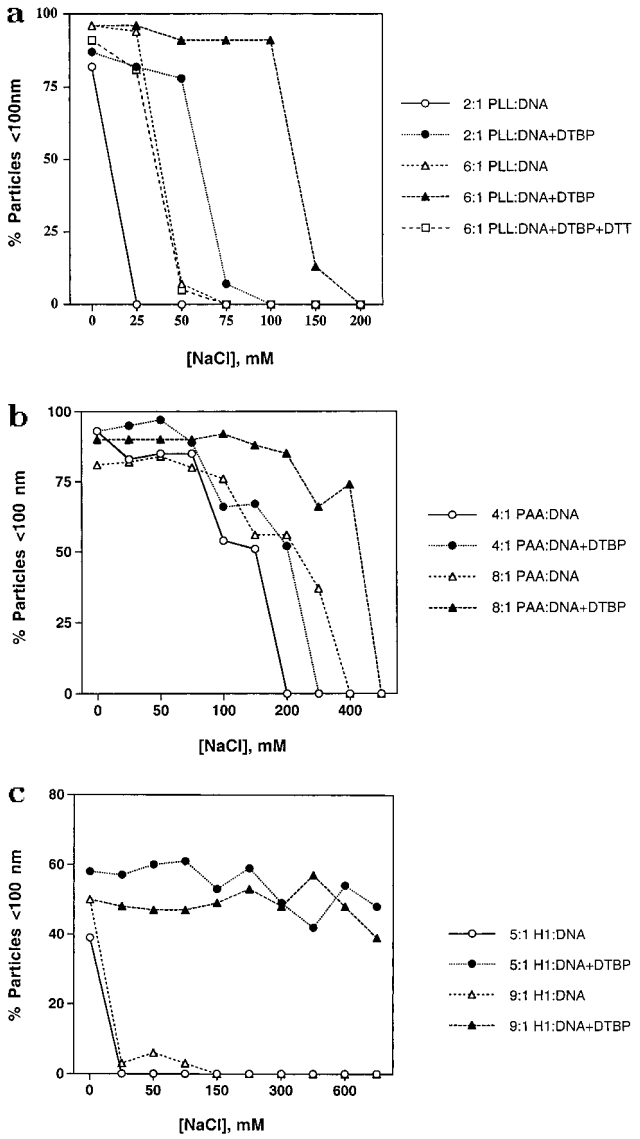

Figure 1. Relationship between particle size and NaCl concentration for polycation/DNA cross-linked complexes (filled symbols) and non-cross-linked ones (open symbols). (a) PLL (molecular mass = 34 kDa) and DNA were mixed at 2:1 and 6:1 charge ratios in low salt Hepes buffer following cross-linking of the complexes with DTBP. The 6:1 cross-linked complex was treated with 20 mM DTT. (b) PAA/DNA complex formation and cross-linking. (c) Histone H1/DNA complex formation and cross-linking. Charge ratios of polycation to DNA are indicated in the legends. The average size of all the PLL, PAA, and histone DNA particles under 100 nm with and without DTBP were ∼50, 60, and 75 nm in diameter, respectively.

created particles that were stable even in 800 mM NaCl (Figure 1c). Similar effects of cross-linking by DTBP on salt stabilization were evident when aggregation was assessed using static light scattering. The cross-linked particles did not aggregate for at least 7 days after the addition of salt. Taken together, these results suggest that the cross-linking of many polycations would stabilize their DNA complexes in salt.

The addition of the cross-linker DTBP could induce salt stabilization by either modifying the dispersion medium or the DNA-containing particles. If the DTBP was added to a concentrated solution of PLL first and this mixture is then added to DNA, no salt stabilization was observed. In addition, when the 6:1 PLL/DNA complexes (cross-linked and non-cross-linked) were dialyzed so as to reduce the net charge ratio of PLL/DNA to ∼1.7, the cross-linked

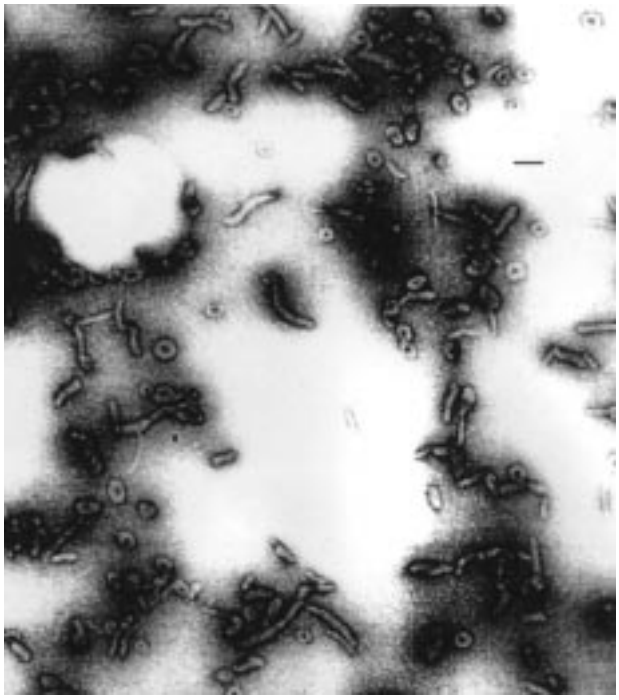

Figure 2. Transmission electron microscopy image of cross-linked PLL/DNA particles. The cross-linking reaction was carried at 6:1 PLL/DNA charge ratio. Bar length is 90 nm.

particles still had greater salt stability than the non-cross-linked complexes (data not shown). These results indicate that cross-linking increased salt stability by modifying the polyamine/DNA complex. It is noteworthy that the cross-linked DNA particles also did not aggregate in physiologic salt solutions that did not contain large amounts of excess polycation.

One possible mechanism by which cross-linking increases salt stability is by recruiting polycation to the particle thus providing electrosteric stabilization (*14*, *15*). Following cross-linking, neither ζ-potential nor particle size was significantly altered as compared to non-cross-linked DNA/PLL complexes. For example, particle size and ζ-potential for PLL/DNA 6:1 complex were found to be 61.6 nm and +59 mV for non-cross-linked vs 62.1 nm and + 53 mV for cross-linked complex, respectively. Similarly, electron microscopic analysis indicated that the cross-linked particles were toroids and rods that were similar in size and shape to non-cross-linked particles (Figure 2).

To directly determine the ratio of PLL to DNA in the complexes, the particles formed with fluorescently labeled Rh-DNA and Fl-PLL were pelleted by ultracentrifugation. The difference between the amount of PLL in solution before and after centrifugation indicates the amount of PLL in complexation with DNA. The non-cross-linked particles contained approximately a 1:1 ratio of amine/phosphate regardless of the initial ratios in the mixture (Figure 3). This is contrary to a common assumption in the polycation/DNA field, but is consistent with 1:1 charge ratios observed in some complexes of synthetic polyelectrolytes (*16*, *17*). Furthermore, cross-linking did not modify the ratio of PLL/DNA in the complexes (Figure 3). The ratio of PLL/DNA found in the precipitate was ~1:1 independent of both the initial PLL/DNA ratio and the addition of cross-linker. Similar results were obtained using analytical ultracentrifugation (data not shown). These studies indicate that cross-linking does not stabilize the DNA particles by recruiting additional polycations.

One hypothesis for the mechanism by which salt induces the aggregation of polycation/DNA complexes is by enabling the polycation on one particle to become bound to another particle by interparticle cross-bridging as it was proposed for both DNA condensates (*18*, *19*) and polyelectrolyte complexes in general (*20*, *21*). Cross-linking markedly decreases the exchange of unlabeled PLL in solution with Fl-PLL in 3:1 PLL/DNA complex. *The* percentage of nonexchangeable PLL in 3:1 complexes was found to decrease 3 times upon cross-linking (data not shown). Furthermore, cross-linking prevents high concentrations of NaCl and dextran sulfate (DS), a strong polyanion, from displacing the DNA in PLL complexes (Figure 4). DNA complexes containing larger PLL molecules of molecular mass 210 kDa were destabilized by DS (Figure 4b) and high salt (data not shown), which argues that the stabilization effect of DTBP is not merely due to increasing the size of PLL on the DNA. Taken together, these results suggest that cross-linking in fact "cages" condensed DNA inside the complexes. Even in the presence of high salt and DS, the "caged" DNA appears to be partially condensed. The cross-linked particles are more resistant to salt-induced aggregation

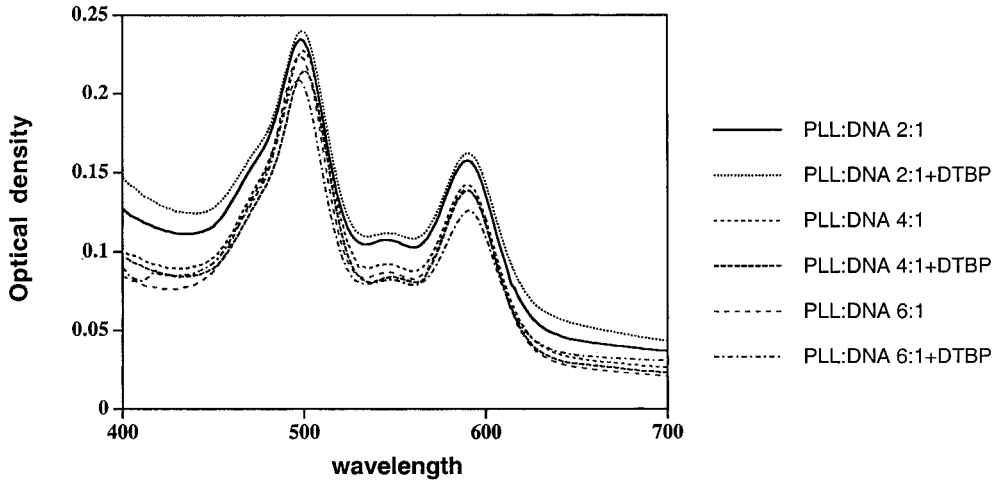

Figure 3. Difference spectra for precipitated portion of chromophore-labeled PLL/DNA cross-linked and non-cross-linked complexes with 2:1, 4:1, and 6:1 charge ratios. PLL and DNA were labeled with fluorescein isothiocyanate (λ_{max} = 495 nm) and rhodamine LabelIT (λ_{max} = 590 nm) reagent respectively (*15*). For stoichiometry measurements, the spectra were compared with the spectra of standard Fl-PLL and Rh-DNA solutions.

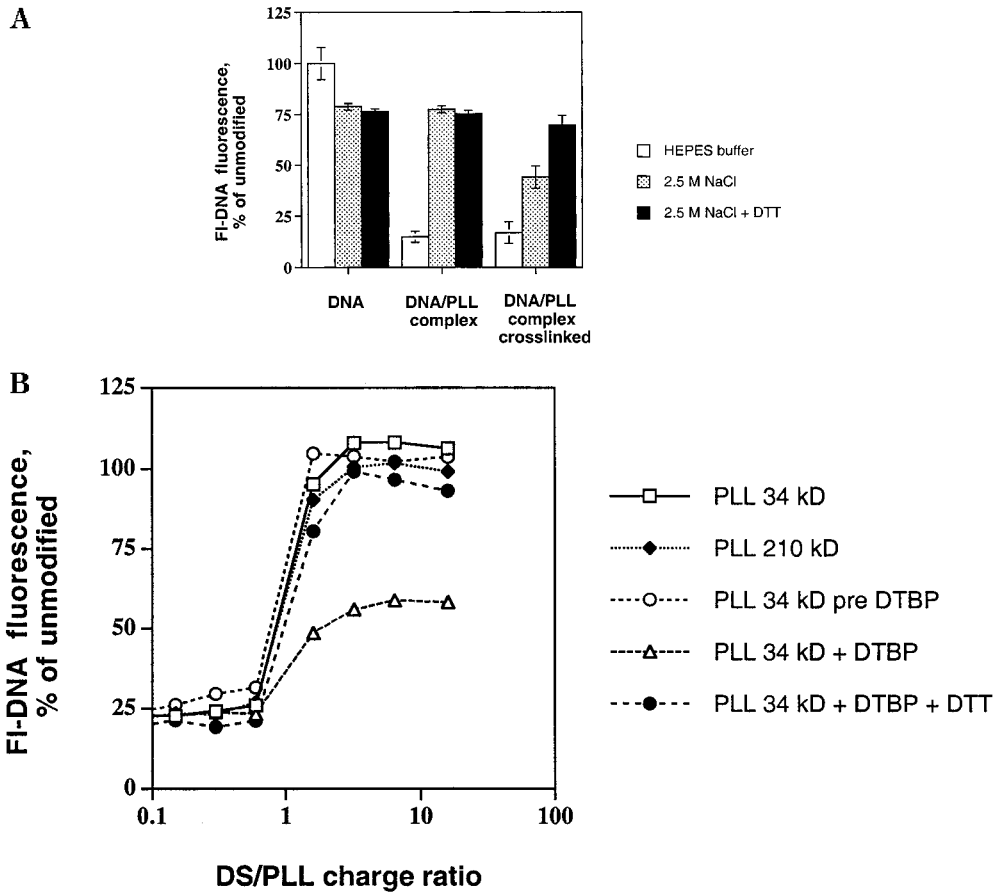

Figure 4. Decondensation of Fl-DNA in cross-linked and non-cross-linked PLL/DNA 6:1 complexes with different dissociative media. DNA covalently labeled with Fluorescein LabelIT reagent (3 fluorophore moieties per 100 base pairs) sustains considerable fluorescence quenching upon complexing with polycations. (A) Relative fluorescence of Fl-DNA and its cross-linked and non-cross-linked complexes with PLL upon decondensation in 2.5 M NaCl (*20*). (B) Decondensation of Fl-DNA with dextran sulfate. PLL (210 kDa) and pre-*cross*-linked PLL (34 kDa pre DTBP) were added as additional controls.

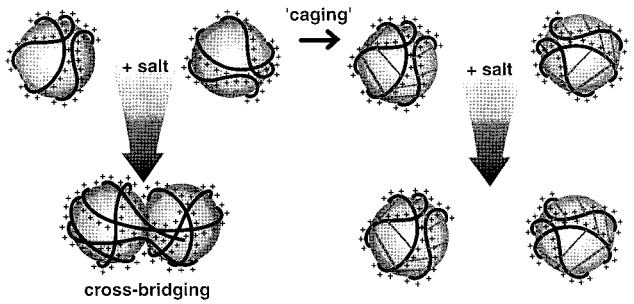

Figure 5. The model illustrates that salt induces the aggregation of polycation/DNA complexes by lowering the threshold for interparticle crossbridging with exchangeable polycations. Cross-linking of the polycation prevents this from occurring. Black, curving lines (+) indicate the polycations, and the gray, straight lines indicate the cross-links in the caged DNA.

because part of a polyamine molecule on one particle is less able to cross-bridge to another particle (Figure 5). In essence, cross-linking "freezes" the polycations on the particle.

Preliminary experiments indicated that caged complexes are inactive in gene transfer in vitro. On the other hand, experiments with cross-linked DNA/polycation (histone H1) complexes showed that DNA remains intact and expressable after reversing the cross-linking procedure with DTT treatment (data not shown). Considering intracellular reducing conditions (*22*, *23*), more labile cross-linkers may result in transfection-competent caged complexes.

Cross-linking of protein macromonomers accompanies the assembly of viral particles (*24*, *25*). Cross-linking of polyamine/DNA complexes mimics some aspects of viral particle assembly and provides a rationale for why it occurs during virus formation. The lack of aggregation of caged DNA particles in physiologic salt solutions presents an important advance in the development of nonviral vectors.

ACKNOWLEDGMENT

We would like to thank Dr. Grayson Scott for his assistance in obtaining electron microscopy images of caged DNA complexes and Dr. Darrell McCaslin for his expert advice in analytical ultracentrifugation experiments.

Novel Biotinylated Phenylarsonous Acids as Bifunctional Reagents for Spatially Close Thiols: Studies on Reduced Antibodies and the Agonist Binding Site of Reduced *Torpedo* Nicotinic Receptors

R. Moaddel, A. Sharma, T. Huseni, G. S. Jones, Jr.,† R. N. Hanson, and R. H. Loring*

Department of Pharmaceutical Sciences, Northeastern University, Boston, Massachusetts 02115. Received December 28, 1998; Revised Manuscript Received March 22, 1999

We synthesized three novel organoarsenicals as prototype bifunctional reagents for spatially close thiols, *N*-(4-arsenosophenyl) hexahydro-2-oxo-(3a*S*,4*S*,6a*R*)-1H-thieno[3,4-d]imidazole-4-pentamide (**1**), 2-[4-[(4-arsenosophenyl)amino]-1,4-dioxobutyl] hydrazide, (3a*S*,4*S*,6a*R*)-hexahydro-2-oxo- 1H-thieno-[3,4-d] imidazole-4-pentanoic acid (**2**), and [4-[[12-[[5-[(3a*S*,4*S*,6a*R*)-hexahydro-2-oxo-1H-thieno[3,4-d]imidazol-4-yl]-1-oxopentyl]amino]-1-oxododecyl]amino]phenyl]-arsonous acid (**3**) containing both biotin and arsenic with intervening varying length spacers extending from 2 to 15 Å beyond biotin bound to streptavidin. Conceptually, the arsenical group can form a stable, covalent ring structure with appropriately spaced thiols and thereby anchor the reagent to a macromolecule, while biotin allows for the detection of the reagent−macromolecule complex via avidin binding. Because the α-subunits of all characterized nicotinic receptors contain an easily reducible disulfide bond between adjacent cysteine residues, the reduced α-subunit is an attractive site for labeling. Compounds **1**−**3** all simultaneously bound streptavidin and dithiols, and all three decreased the number of [^{125}I]α-bungarotoxin-binding sites in reduced *Torpedo* nicotinic receptors (IC_{50s} 10−300 nM). Moreover, arsenylation of the receptors prevented their reoxidation with dithio-bis(nitrobenzoic acid), was reversible with 2,3-dimercaptopropanesulfonic acid, and protected the receptor from irreversible alkylation by bromoacetylcholine. However, in no case did **1**−**3** allow simultaneous binding to reduced nicotinic receptors and to [^{125}I]streptavidin, although **3** alone allowed simultaneous labeling of a spatially close dithiol located in reduced antibodies.

INTRODUCTION

Nicotinic receptors play an important role in vertebrate neuromuscular and ganglionic transmission and are believed to be important in the pharmacology of nicotine dependence (*1*). In addition, nicotinic agonists are currently being investigated for use as therapeutic agents in the treatment of Alzheimer's disease, Parkinson's disease, Tourette's syndrome, and ulcerative colitis (*1*). Muscle nicotinic receptors are pentameric membrane proteins consisting of two α1-subunits, and one *β*-, *γ*-, and *δ*-subunits. Multiple subtypes of neuronal nicotinic receptors are known, and all subtypes contain at least one kind of α-subunit. Currently, eight different neuronal α-subunits (α2−α9) and at least 3 neuronal *β*-subunits (*β*2−*β*4) are known (*2*). Since α-subunits from both muscle and nerve have an easily reducible disulfide bond between adjacent cysteine residues located within 0.9 nm of the agonist-binding site (*3*), the reduced α-subunit is an attractive site for labeling all known subtypes of nicotinic receptors. Bifunctional reagents that could label the agonist-binding site disulfide and give some spatial information relative to the rest of the receptor molecule would be very useful.

Of all multimeric receptors, the *Torpedo* nicotinic receptor is the best characterized, since it is so abundant in electroplax tissue. The *Torpedo* receptor has two agonist-binding sites located at the interface between the α−*δ* and the α−*γ* subunits (*4*, *5*). Both sites bind α-bungarotoxin (BGT), but a variety of evidence suggests that these two sites are not equivalent. The α−*γ* site binds D-tubocurarine with high affinity (*6*) and is easily reduced with dithiothreitol (DTT)[1] and alkylated with bromoacetylcholine (BAC), while the α−*δ* site shows low affinity for D-tubocurarine and is not as easily reduced or alkylated. Monoclonal antibodies are available from a variety of laboratories that discriminate between these two sites [referred to as the A and B sites, respectively (*7*)], indicating that the interfaces have different conformations. On the other hand, Unwin (*8*−*10*) has visualized *Torpedo* nicotinic receptors to a 9 Å resolution and suggests that two similar pits about 20 Å deep are the agonist-binding sites. Although one of those pits is located near the area mapped by an antibody against the α−*γ* binding site (*11*), there is no information as to where the corresponding disulfide bond is located relative to the three-dimensional structure of the receptor. The *Torpedo* nicotinic receptor is the best characterized, but there are still questions about the location and structure of the agonist-binding sites. Thus, we chose this receptor as our initial target.

We previously reported on the utility of simple trivalent organoarsenicals, which formed stable adducts with

reduced nicotinic receptors (*12*), from both *Torpedo* electroplax (ganglionic), and chick retina (neuronal). The findings were consistent with covalent As−S bond formation between trivalent arsenic and the adjacent cysteines generated upon reduction of the receptor. The decrease in [^{125}I]BGT binding upon arsenylation of receptors reduced with DTT was long-lasting but reversible upon treatment with the competitive dithiol, 2,3-dimercaptopropane sulfonic acid (DMPS). Monothiols such as 2-mercaptomethanesulfonic acid are not effective reagents to reverse the effects of arsenylation (*13*), and arsenylation prevented irreversible alkylation by BAC. Thus, our preliminary results suggested that trivalent arsenic could be used to anchor labeling groups in the *Torpedo* agonist-binding site. These novel bifunctional reagents would be potentially useful tools for receptor localization and quantification studies and mapping the nicotinic receptor and, thereby, provide a more rational basis for the design of agonists.

p-Aminophenylarsine oxide[2] was envisioned as a potentially useful starting material in our design strategies. The commercial sources were solubilized with HCl or could be freshly synthesized by reducing *p*-arsanilic acid (*14*). Here, we describe the synthesis of three novel biotinylated arsenical compounds with varying length spacers, demonstrate that these reagents are bifunctional for dithiols and streptavidin and that they each block [^{125}I]BGT binding when covalently attached to *Torpedo* nicotinic receptors. These compounds were then used to deduce information about the location of the disulfide in the *Torpedo* agonist-binding site, and one was found to be potentially useful as a labeling agent for antibodies.

MATERIALS AND METHODS

Chemicals and Reagents. *p*-Aminophenyl arsine oxide, *p*-arsanilic acid, and all other chemical precursors were obtained from Aldrich Chemical Co. (Milwaukee, WI) unless otherwise noted. Biotin, streptavidin, goat anti-rat IgG agarose beads, 4-chloro-1-naphthol, and β-galactosidase were purchased from Sigma Chemical (St. Louis, MO). Solvents and other materials, chemicals, and reagents were all analytically pure or of reagent grade and used without further purification. TLC (Whatman silica gel 60 F-254 plates; 0.25 mm layer thickness) and PTLC (Analtech Uniplate silica gel GF plates; 20 × 20 cm; 1 mm layer thickness) were used. Maleimidopropionylbiocytin (MPB) was purchased from Molecular Probes (Eugene, OR), streptavidin-horseradish peroxidase (SA-HRP) from Bio-Rad (Richmond, CA), and the peptide corresponding to residues 181−198 of the Torpedo nicotinic α-subunit (YRGWKHVYYTCCPDTPPY) obtained from Chiron Mimetopes (Raleigh, NC). Membranes rich in *Torpedo* nicotinic receptors were a generous gift of Dr. Jonathan Cohen, as was the monoclonal antibody mAb210 from Dr. Jon Lindstrom. α-Bungarotoxin (BGT; Biotoxins Inc., St. Cloud, FL) was radioiodinated using Iodogen (Pierce Chemical Co., Rockford IL) as previously described (*15*). ^{125}I-Labeled streptavidin was produced similarly, and specific activities of both radioligands ranged 300−500 Ci/mmol determined by isotope dilution (*16*).

Equipment. Melting points were determined with a Thomas−Hoover melting point apparatus. The NMR spectra were recorded with a Varian-300 spectrometer, and IR spectra (KBr) were recorded on a Perkin-Elmer 1600 FTIR spectrometer. MS and MS/MS data were obtained on a VG Quattro triple quadrupole mass spectrometer (Micromass Instruments, Beverly, MA) in the positive electrospray (ESI) mode. For product ion analyses by collision induced dissociation (CID), high-purity argon gas was used as the collision gas and a cell pressure of ≈1.0 X 10^{-3} mbar was maintained. A collision energy of 30 eV was employed for all product ion experiments. Elemental analyses were performed by Atlantic Microlab, Inc. (Norcross, GA).

Chemical Synthesis. *N-(4-Arsenosophenyl) hexahydro-2-oxo-(3aS,4S,6aR)-1H-thieno[3,4-d]imidazole-4-pentamide (**1**) (212391-23-6])*.[3] Commercial *p*-aminophenyl arsine oxide (92 mg, 0.5 mmol) was dissolved in water (1 mL) containing 1 M equiv of HCl. After filtration, the filtrate was diluted with 2 vol of acetone, followed by addition of sodium carbonate (3 M equiv). A suspension of biotinoyl chloride (0.5 mmol) in 3 mL of acetone was added dropwise to this solution. After 48 h, the white precipitate was collected by filtration and was purified by preparative TLC on silica gel using 10% methanol:dichloromethane as the eluant. The product (32 mg, 14% yield) tested positive for both biotin and the trivalent arsenic. mp 223−224 °C; TLC (10% methanol:dichloromethane) $R_{\times a6}$ = 0.6. Anal. Calcd for $C_{16}H_{22}AsN_3O_4S$, 0.5H_2O: C, 44.03; H, 5.31; N, 9.63. Found: C, 44.34; H, 5.33; N, 9.51. ^{1}H NMR (CH_3OH-d_4): δ 7.67 (d,2H; J = 8.5 Hz), 7.60 (d,2H; J = 8.6 Hz), 4.49 (m, 1H), 4.30 (m,1H), 2.93 (dd,-1H), 2.70 (d,1H), 2.41 (t,2H), 1.75 (m,4H), 1.66 (m,1H), 1.51 (m,2H). p-(N-Carbomethoxypropionyl) Aminophenyl Arsonous Acid (4). Commercial *p*-aminophenylarsine oxide (366 mg, 2 mmol) was placed in 8 mL of anhydrous DMF to which 1 M HCl in ether (2 mL, 1 equiv) was added. The precipitate was removed by filtration, and triethylamine was added (310 mg, 3 mmol) to the filtrate. The mixture was stirred, filtered, and 3-carbomethoxypropionyl chloride (150 mg, 1 mmol) in 1 mL of anhydrous DMF was added dropwise to the filtrate. After 24 h, the precipitated 3-carbomethoxy propionic acid was removed by filtration and the filtrate was evaporated to dryness under nitrogen. The oily residue was triturated with a small amount of water, and the precipitate was collected via filtration. The crude product was purified by column chromatography on silica gel using chloroform:methanol:triethylamine (95:5:2) as the eluant. The desired product was isolated as a yellow oil (41 mg, 13% yield). ^{1}H NMR (CH_3-OH-d_4): δ 7.66 (d,2H, J = 8.7 Hz) 7.57 (d,2H, J = 8.7

[2] The authors are aware that the terms arsine oxide/arsenoxide are archaic, and chemically incorrect, but these are the terms most widely used in the literature for this class of compounds which are sold as such commercially. The structures of members of this class of compounds reported in the literature, typically have not been convincingly established, but are probably not monomeric, particularly the commercial samples, since they are not soluble in the same solvents as the freshly synthesized compounds. For that reason, we distinguish between starting materials that were obtained commercially or freshly synthesized. See ref *36* for descriptions of oligomers. Also, in laser desorption MS of iodophenylarsine oxide, sodium adducts of various oligomeric species were observed (*37*). However, by all tests at our disposal including MS, the freshly synthesized products we made appear monomeric. Finally, *p*-aminophenylarsine oxide is no longer commercially available and now must be freshly made (*14*).

[3] The naming of compounds was provided by CAS services. CAS Registry Numbers: compound **1**, 212391-23-6; compound **2**, 212391-25-8; compound **3**, 212391-26-9.

Hz), 3.80 (s,3H), 2.70 (s,4H). Molecular weight was confirmed by electrospray mass spectrometry. $C_{11}H_{12}AsNO_4$ ($M + H^+$) Calcd: 297.9. Found: 297.8.

p-(N-Carbomethoxypropionyl) Aminophenyl Arsanilic Acid. *p*-Arsanilic acid (217 mg, 1 mmol) was placed in 3 mL of methanol and 1 mL of THF. To this solution, 3-carbomethoxypropionyl chloride (150 mg, 1 mmol) was added dropwise. After 24 h, the solution was taken to dryness. The residue was dissolved in methanol and purified by normal-phase preparative TLC with the eluant chloroform:methanol:ethyl acetate (65:5:5). The desired product was isolated as yellow crystals (222 mg, 67% yield). mp 179−180 °C. ^{1}H NMR (CH_3OH-d_4): δ 7.88 (d,2H; $J = 9.0$ Hz), 7.49 (d,2H; $J = 9.0$ Hz), 3.80 (s, 4H), 2.61 (s,3H). Molecular weight was confirmed by electrospray mass spectrometry. $C_{11}H_{13}O_6NAsNa^+$ (M^+H^+) Calcd: 354.0. Found: 354.7.

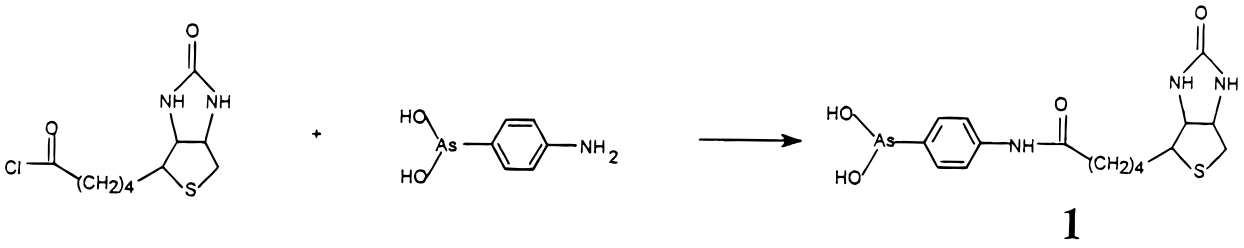
p-(N-Hydrazidopropionyl) Aminophenyl Arsonous Acid (5). A solution consisting of 12 mL of hydrazine hydrate (85%, 10.5 g, 0.2 mol) in 25 mL of ethanol was brought to a gentle reflux. A solution of *p*-(*N*-carbomethoxypropionyl) aminophenyl arsonous acid (60 mg, 0.20 mmol) in 4 mL of methanol was added dropwise to the stirred refluxing solution. After 2 h, the solution was concentrated and the resultant oil was purified by column chromatography on silica gel using chloroform:methanol: ethyl acetate (50:5:5) as the eluant (32 mg, 52% yield). IR (KBr) (C═O) amide 1652 cm^{-1}, (C═O) hydrazide 1588 cm^{-1}, N−H stretch(amide) 3290 cm^{-1}. Molecular weight was confirmed by electrospray mass spectrometry. $C_{10}H_{14}AsN_3O_4$ ($M + H^+$) Calcd: 316.2. Found: 316.4.

*2-[4-[(4-Arsenosophenyl)amino]-1,4-dioxobutyl] Hydrazide, (3aS,4S,6aR)-Hexahydro-2-oxo-1H−thieno[3,4-d]-imidazole-4-pentanoic Acid (**2**) (212391-25-8)*. *p*-(*N*-Hydrazidopropionyl) aminophenyl arsonous acid (93 mg, 0.3 mmol) was placed in a flask containing 1 mL of DMSO. Biotinyl-NHS (68 mg, 0.2 mmol) in 1 mL of DMF was added to this solution and stirred at ambient temperature for 16 h, and then the products were evaporated to dryness. The residue was triturated with methanol, and the precipitate was collected by filtration (23 mg, 21% yield). ^{1}H NMR (DMSO-d_6): δ 7.71 (d,2H, $J = 7.50$ Hz), 7.64 (d,2H, $J = 7.95$ Hz), 6.43 (d,1H; $J = 19.32$), 4.31 (m,1H), 4.12 (m,1H), 3.55(d,2H), 3.20 (s,2H), 3.11 (t,1H), 2.81 (dd,1H), 2.60 (m,2H), 2.50 (s,2H), 2.3 (m,1H), 2.13 (m,2H), 1.2−1.8 (m,5H). Molecular weight was confirmed by negative ion electrospray mass spectrometry. $C_{20}H_{28}AsN_5O_6S$ ($M - H^+$) Calcd: 540.5. Found: 540.6.

N-Biotinylaminododecanoic Acid (6). A solution of biotinyl-NHS (170 mg, 0.5 mmol) (*17*) in 10 mL of DMF was added dropwise to a heated solution (60 °C) of 12-aminododecanoic acid (129 mg, 0.6 mmol) in 6 mL of 0.2 M $NaHCO_3$. The resulting solution was stirred at 60 °C for 4 h and then at ambient temperature for 16 h. The resulting precipitate was collected, washed sequentially with water and 0.01 M HCl, and then dried under vacuum. 12-Biotinylaminododecanoic acid was obtained (61 mg, 0.16 mmol) in 28% yield. mp 216−217 °C (Lit. mp 217 °C) (*18*).

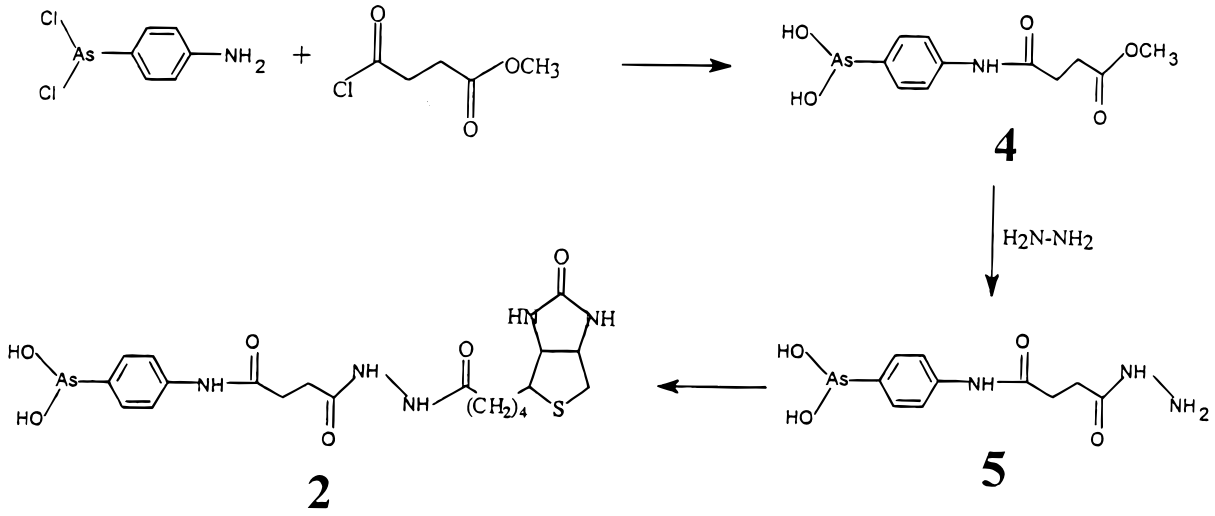
*[4-[[12-[[5-[(3aS,4S,6aR)-Hexahydro-2-oxo-1H-thieno-[3,4-d]imidazol-4-yl]-1-oxopentyl]amino]-1-oxododecyl]-amino]phenyl]-arsonous Acid (**3**) (212391-26-9)*. *N,N′*-Carbonyldiimidazole (32.4 mg, 0.2 mmol) was added to a solution of *N*-biotinyl-aminododecanoic acid (88 mg, 0.2 mmol) in 5 mL of DMF at 95 °C. The reaction was maintained at 95 °C until the evolution of carbon dioxide ceased. The solution was stirred for 1 h at ambient temperature, during which time a precipitate formed. A solution of freshly prepared *p*-aminophenyl arsine oxide (74 mg, 0.4 mmol) in 5 mL of acetone was added to the stirred reaction mixture. The solution was heated at 50 °C for 5 days, cooled to room temperature and filtered. The filtrate was evaporated to dryness and triturated with ether. The precipitate was collected by filtration and stirred in hot 2-propanol. The insoluble product was collected by filtration and dried to give 32 mg, 25% yield. mp 172−173 °C. Anal. Calcd for $C_{28}H_{43}AsN_4O_4S$·TEA: C, 57.77; H, 8.16; N, 10.34. Found: C, 57.77; H, 8.26; N, 9.9. ^{1}H NMR (DMSO-d_6): δ 7.63 (d,2H, $J = 7.4$ Hz), 7.54 (d,2H, $J = 7.8$ Hz), 6.40 (d,1H; $J = 20.52$), 4.30 (m,1H), 4.13 (m,1H), 2.9−3.2 (m,4H), 2.83 (dd,2H), 2.6 (d,1H), 2.29 (t,2H), 2.19 (t,1H), 2.04 (t,2H), 1.2−1.8 (m,24H). Molecular weight was confirmed by electrospray mass spectrometry. $C_{28}H_{43}AsN_4O_4S$ ($M + H^+$) Calcd: 607.6. Found: 607.4. TLC (75 $CHCl_3$:5CH_3OH:5EtOAc) $R_f = 0.1$.

Assays. *Quenching Effects of Compounds **1**−**3** on the Ellman Assay (19) of 2,3-Dimercaptopropanesulfonic Acid*. Varying concentrations (range 0−74 μM) of compounds **1**−**3** or *p*-aminophenyldichloro-arsine hydrochloride (APA) were incubated with DMPS (50 μM final concentration) for 10 min. Tris buffer (pH 8.1; 0.3 mM final concentration) and 5,5′-dithio-bis(2-nitrobenzoic acid) (DTNB; 200 μM final concentration) were added to a final volume of 1.5 mL, and absorbance at 412 nm was recorded.



*Confirmation of the Biotin Moiety in Compounds **1**−**3***. Varying concentrations (range 0−1 mM) of **1**−**3** or d-biotin were added to avidin complexed with 4-hydroxyazobenzene-2-carboxylic acid (HABA). Absorbance at 500 nm was measured and plotted as the mean and range of duplicate samples, according to the method of Green (*20*). In addition, a dimethylaminocinnamaldehyde spray reagent (*21*) was used to qualitatively confirm the presence of biotin on TLC plates.

Displacement of [^{125}I]α-Bungarotoxin Binding from Torpedo Nicotinic Receptors. Solubilized *Torpedo* receptors were immunoprecipitated with mAb210 or mAb35 coupled to goat anti-rat IgG agarose beads in phosphate-buffered saline (PBS; 145 mM NaCl and 10 mM sodium phosphate, pH 7.2) containing 1% Triton X-100 (*13*). After reduction by 2 mM DTT for 20 min, receptors were treated with varying concentrations (range 1 nM−100 μM) of either the biotinylated arsenicals or APA or with 30 μM BAC. After reoxidation with 1 mM DTNB for 20 min, the remaining BGT-binding sites were assayed. Nonspecific binding was determined in the presence of 1 μM unlabeled BGT. In other experiments, receptors were treated with 1 mM DMPS for 20 min to remove bound arsenicals.



Staining of Dot-Blotted Torpedo Peptide and β-Galactosidase. Varying concentrations of *Torpedo* peptide or β-galactosidase in Burnette's buffer (*22*) (20 mM Tris, 150 mM glycine, and 20% methanol, pH 8.3) were applied under vacuum to PVDF membranes (Polyscreen, NEN-Dupont, Boston, MA) using a Schleicher and Schuell dot-blotter. PVDF membranes were cut into strips and blocked for 45 min at RT with 3% bovine serum albumin (BSA) in PBS. The individual strips were then treated with MPB or compounds **1** or **2** dissolved in PBS and then treated with SA-HRP and stained with 4-chloronaphthol as indicated by Bio-Rad. The strips were reassembled and digitally scanned using a UMAX Astra 1200 S scanner and Adobe Photoshop software.

[^{125}I]Streptavidin Binding. Quadruplicate goat anti-rat IgG-coated agarose beads were treated in 1.5 mL centrifuge tubes with 2 mM DTT in PBS, varying concentrations of compounds **1**−**3** (usually 10 μM), and then treated with 1 mM DTNB for 20 min each treatment.

Scheme 1

Scheme 2

The beads were washed between treatments and three times afterward by centrifuging for 5 s, aspirating the supernatant, and resuspending in 1 mL of PBS. [^{125}I]-Streptavidin (1 nM) was added to each sample in 0.1 mL of PBS with 1 mg/mL bovine serum albumin (BSA). After incubation at RT with mixing for 2 h, unbound streptavidin was removed by washing three times (1 mL at 4 °C) with PBS/BSA. Nonspecific binding was established by incubating with 100 nM streptavidin. Samples were counted in a Wizard γ-counter.

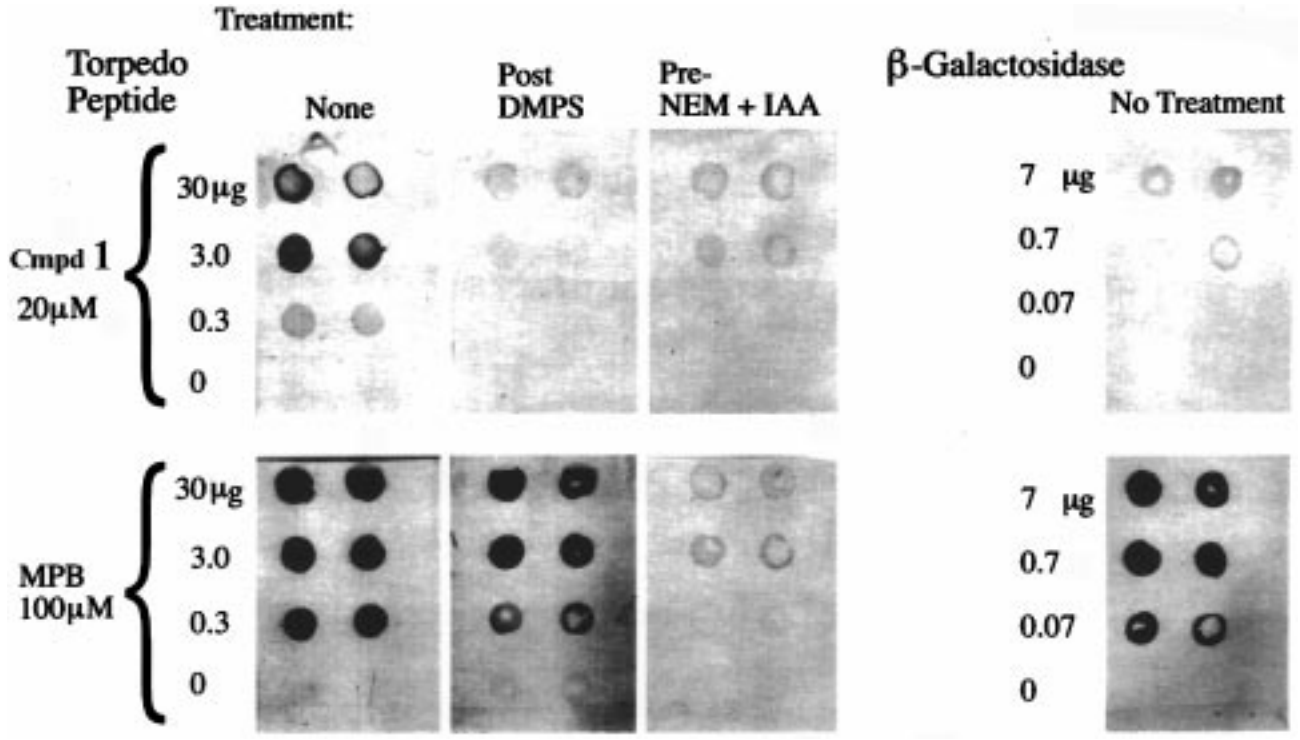
Molecular Modeling. Molecular modeling was performed on a Silicon Graphics O_2 system running Quanta 96 (Molecular Simulations, Inc.) to determine interatomic distances. Molecular structures of **1**−**3** were generated in their most extended conformation, and the length was measured from the carboxy group of the biotin to the arsenic group.

RESULTS AND DISCUSSION

The use of biotinylated bifunctional reagents to characterize macromolecules is well documented (*23*); however, the incorporation of a *p*-aminophenylarsonous acid moiety is unprecedented. Although this compound is isosteric to *p*-aminophenylboronic and *p*-aminobenzoic acid, which are well characterized, the presence of the arsonous acid group created unique synthetic challenges. Unlike the carboxylic and boronic acids, the arsonyl group can be oxidized to a higher valence which is unreactive toward the targeted vicinal dithiol moiety. Therefore, synthetic transformations and isolation methods required care to avoid oxidation. Second, the synthetic transformations required that the arsonous acid remain in its unprotected state as opposed to the boronate or carboxylate esters which could be hydrolyzed at a later stage of the synthesis. Consequently, the chemical transformations and isolation steps were performed in the presence of a polar, ionizable functionality that compromised the reactivity of the para-amino group and complicated chromatographic separations.

The syntheses of the target compounds are shown in Schemes 1−3. Preparation of the simplest biotinylated arsenical **1** was achieved using classical Schotten−Baumann chemistry. Although the isolated yield was low (14%), it was substantially better than methods employing the biotin-activated esters [*N*-hydroxysuccinimide (NHS), or pentafluorophenyl] or a diimide conjugating reagent [dicylohexylcarbodiimide, 1-[3-(dimethylamino) propyl]-3-ethylcarbodiimide]. The free arsonous acid exerted a dominating effect on the chromatographic behavior of the product, necessitating a polar solvent to elute it from the column. Compound **2** was prepared in three steps from *p*-aminophenylarsonous acid. Acylation of *p*-aminophenyl arsonous acid with 3-carbomethoxypropionyl chloride (13% yield) followed by hydrazinolysis (52%) and acylation with biotinyl NHS ester gave the final product (21%). The intermediates were purified by column chromatography and the final product by crystallization. Compound **3** was prepared in two steps beginning with the reaction of biotinyl NHS ester with 12-aminododecanoic acid. The intermediate was converted to its acyl imidazolide with 1,1′-carbonyldiimidazole and reacted with *p*-aminophenylarsonous acid (Scheme 3). The crude product was recrystallized to give the final derivative in a 25% yield.

Compounds **1**−**3** were characterized by various instrumental methods. In addition to the absorptions expected for the biotin-containing compounds, the infrared spectra contained strong absorptions in the 660−750 cm^{-1} region which were characteristic of the As−O stretching frequencies. The ^{1}H NMR spectra were consistent with the proposed structures, confirming the presence of biotin, phenyl, and spacer groups. The NMR data also corroborated the valence of the arsenic group. Comparison of the NMR spectra of *p*-(*N*-carbomethoxypropionyl)



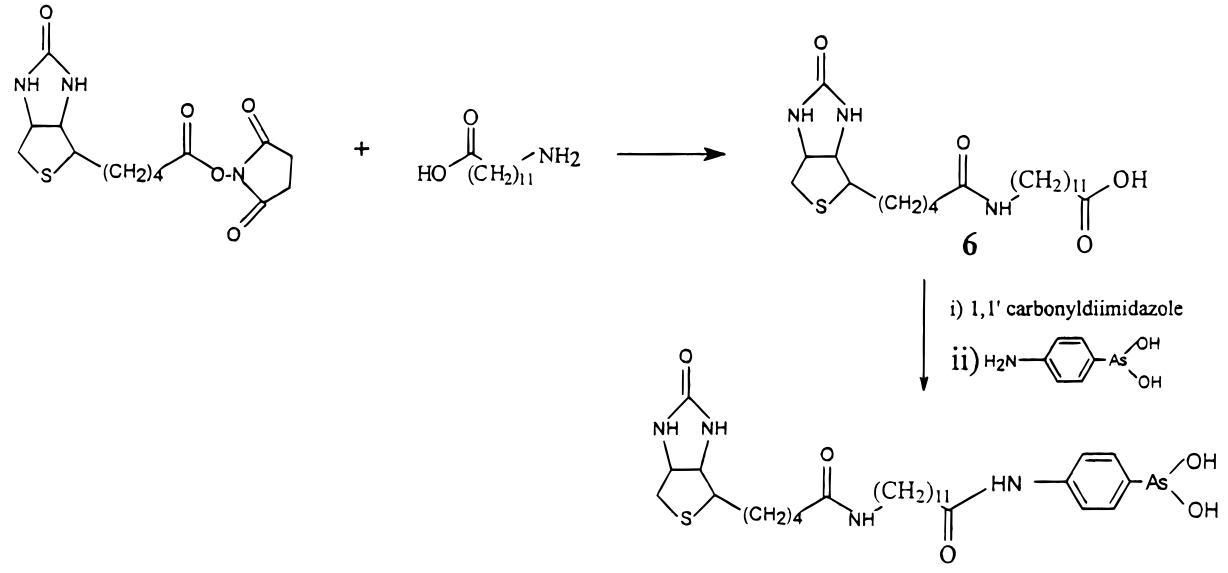


Figure 1. SA-HRP labeling with Compound **1** or MPB. Varying concentrations of *Torpedo* peptide (0−30 μg) or β-galactosidase (0−7 μg) in Burnette's buffer (*22*) were applied under vacuum to PVDF as described in the Materials and Methods. The individual strips were then treated with either 100 μM MPB or **1** (20 μM) in PBS, and then treated with SA-HRP and stained with 4-chloronaphthol and H_2O_2. The *Torpedo* peptide samples in the second column were further treated with 1 mM DMPS for 20 min, while the peptide samples in the third column were pretreated with 1 mM NEM and 1 mM IAA for 20 min. Compound **1** labeled only the untreated *Torpedo* peptide but did not bind with the thiols on β-galactosidase (fourth column). In contrast, MPB, which will react with single thiols and is irreversibly bound, labeled both β-galactosidase and *Torpedo* peptide that was posttreated with DMPS.

Scheme 3

aminophenyl arsonous acid and the corresponding arsanilic acid demonstrates a clear and distinctive difference in the chemical shift of the protons ortho to the arsenic group, occurring at 7.66 ppm in the former and 7.88 ppm in the latter.

Electrospray ionization mass spectrometry was also valuable in confirming the molecular structure of the products. The full-scale mass spectrum for **1** gave major ions at *m*/*z* 478, 464, 450 (100%), 428, 424, and 410. Assignments could be made for each ion and were consistent with the proposed structure. Mass spectra analysis for each of the other products were equally revealing. Elemental analyses also supported the proposed structure assignments.

Preliminary Characterization of the Compounds. The trivalent nature of arsenic in **1**−**3** was inferred from the results of an assay in which the Ellman response of DMPS to DTNB was quenched in a concentration-

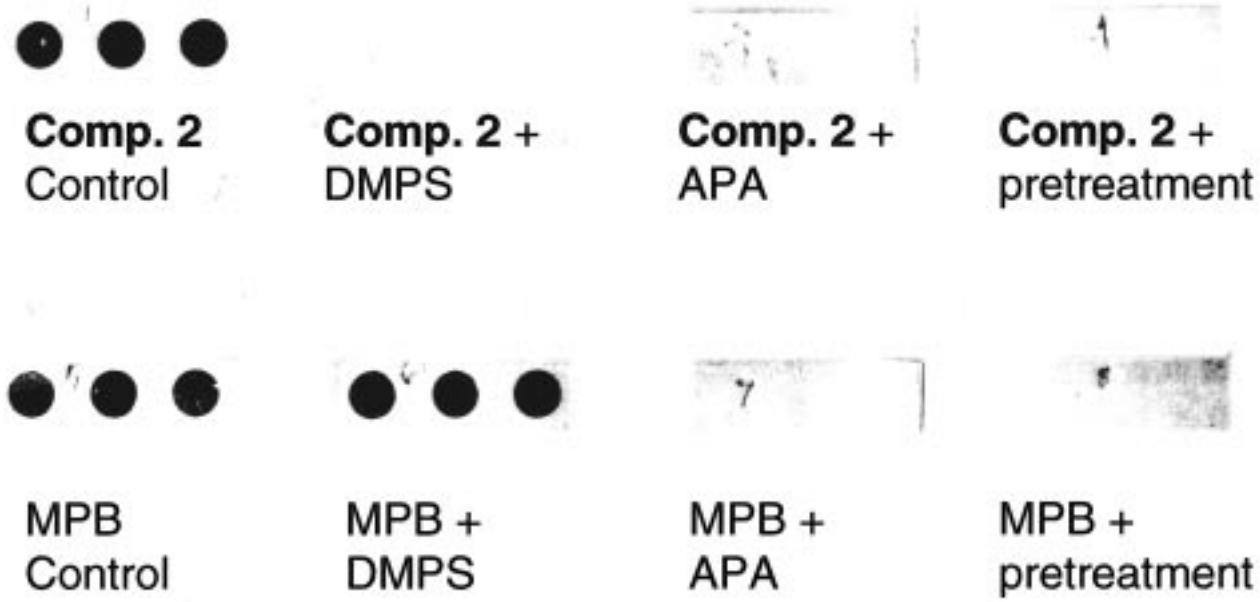

Figure 2. Compound **2** labels dot-blotted *Torpedo* peptides. Triplicate samples of 30 μg of *Torpedo* peptide blotted onto PVDF membranes were incubated for 20 min with either compound **2** (10 μM, top row) or MPB (100 μM, bottom row) and then stained. Further treatment with 1 mM DMPS for 20 min removed compound **2** but not MPB (second column), while prior treatment with either 1 mM APA (third column) or 1 mM NEM and 1 mM IAA (fourth column) blocked labeling by both compounds.

dependent fashion (not shown). Compounds **1**−**3** also gave a positive color reaction on TLC with *p*-dimethylaminocinnamaldehyde spray reagent, which has been used as a qualitative assay for the presence of biotin (*21*), and were equipotent with biotin in their ability to displace HABA from avidin (not shown). To demonstrate that compound **1** could simultaneously bind to streptavidin while covalently linked to a dithiol, reduced *Torpedo* peptide was blotted onto PVDF membranes at varying concentrations and then treated with either **1** (20 μM) or the sulfhydryl labeling agent MPB (100 μM) (Figure 1). Staining with compound **1** but not MPB was blocked if the samples were subsequently treated with the bissulfhydryl containing DMPS (1 mM). Pretreatment with 1 mM *N*-ethylmaleimide (NEM) and 1 mM iodoacetamide (IAA) substantially blocked the labeling of the peptide by both **1** and MPB. β-Galactosidase is a protein that binds well to PVDF membranes and has 14 free thiols per molecule, none of which are spatially close (*24*). MPB strongly stains β-galactosidase, while **1** shows no staining above the background seen for *Torpedo* peptide treated with NEM and IAA (Figure 1). This result demonstrates the selectivity of the arsenical for spatially close dithiols. The staining effects of **1** on *Torpedo* peptide are concentration dependent (data not shown) and the lowest concentration that stains peptide above background is 30 nM. Compound **2** also demonstrated labeling of *Torpedo* peptide that could be blocked by subsequent treatment with DMPS, simultaneous addition of 1 mM APA, or pretreatment with NEM and IAA (Figure 2). The simultaneous binding of **3** to spatially close dithiols and [^{125}I]streptavidin was demonstrated independently (see below).

Displacement of [^{125}I]α-Bungarotoxin Binding from Torpedo Nicotinic Receptor. In a previous study, we showed that aromatic trivalent arsenicals, e.g., *p*-APA, decreased the number of [^{125}I]BGT-binding sites in reduced *Torpedo* nicotinic receptors to the same level seen after alkylation with BAC (*12*). Furthermore, arsenylation of *Torpedo* receptors prevented their reoxidation with DTNB, was reversible with DMPS, and protected the receptor from irreversible alkylation by BAC. Compounds **1**−**3** displayed similar behavior and blocked [^{125}I]-BGT binding to DTT-treated *Torpedo* receptors to the same extent as alkylation with BAC (Figure 3). In other experiments (not shown), treatment of nonreduced receptors with **1**−**3** or reoxidation of DTT-treated receptors with DTNB before adding **1**−**3** prevented the blockade of [^{125}I]BGT binding by these compounds. As we previously demonstrated with APA (*12*, *13*), DMPS reverses the effects of **1**−**3** (Figure 4). Furthermore, adding compounds **1**−**3** to DTT-treated receptors before BAC and then treating with DMPS to remove the arsenicals restores [^{125}I]BGT binding. These data suggest that **1**−**3** and BAC are competing for the same site, and since BAC and other affinity-labeling agents attach to the reduced

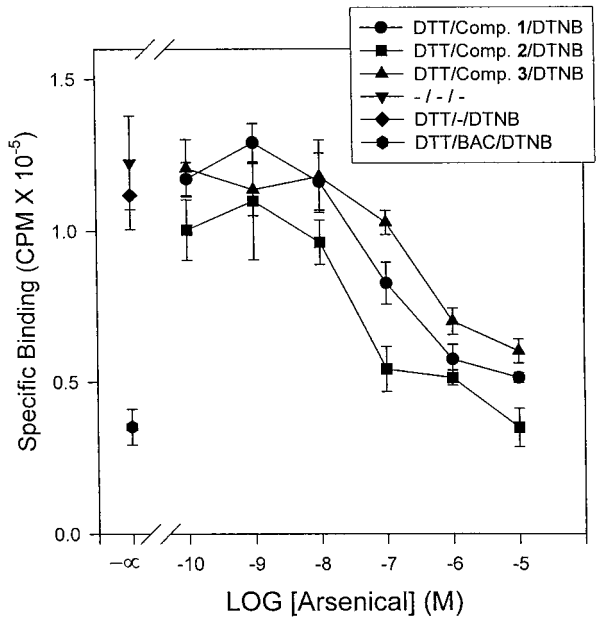

Figure 3. Effects of arsenylation on the binding of [^{125}I]BGT to reduced *Torpedo* nicotinic receptors: **1** (●); **2** (■); **3** (▲); control treatment (▼), DTT reduction followed by oxidation with DTNB (◆); DTT reduction, alkylation with 30 μM BAC, followed by oxidation with DTNB (⬢).

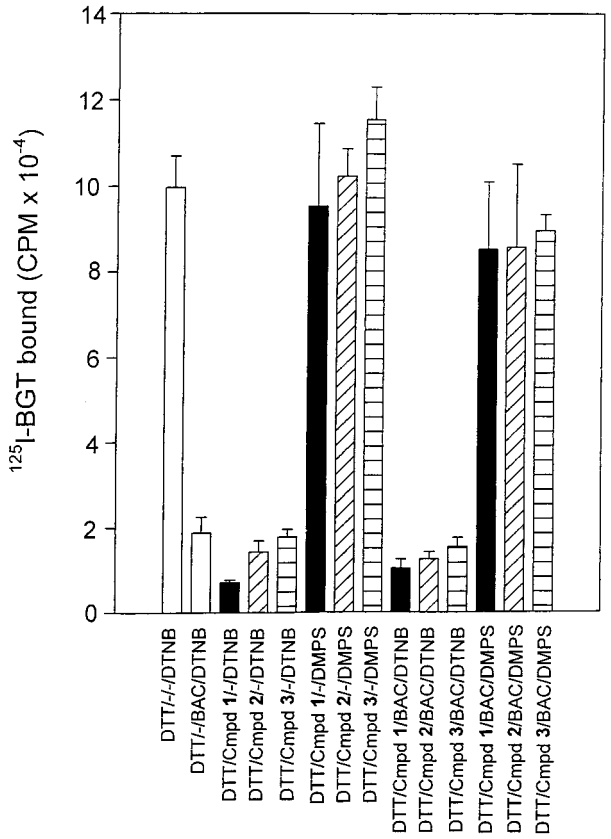

Figure 4. Compounds **1**−**3** are reversible with DMPS and protect [^{125}I]BGT binding sites against irreversible alkylation with BAC. Solubilized *Torpedo* receptors were immunoprecipitated using agarose beads as outlined in the Materials and Methods. After reduction with 2 mM DTT, 10 μM **1**−**3** (black bars, diagonally striped bars, and striped bars, respectively) all blocked [^{125}I]BGT binding to about the same extent as did 30 μM BAC. However, unlike BAC (not shown), the effects of **1**−**3** were completely reversed by treatment with 1 mM DMPS. Furthermore, DMPS reversed the effects of **1**−**3** even after the application of BAC.

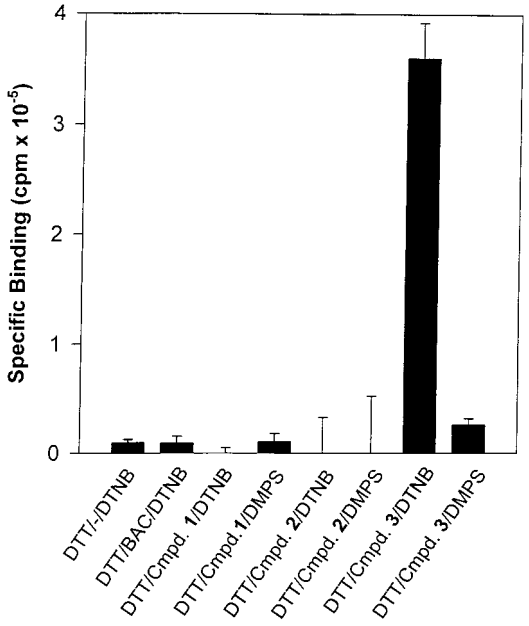

Figure 5. Compound **3**, but not **1** or **2**, labels DTT-treated antibody-coated beads. Quadruplicate samples (20 μL packed beads) of goat-anti rat IgG beads were treated for 10 min with 1 mM DTT before the DTT was removed, and then the beads were treated an additional 10 min with the compounds shown. All beads were then treated with 1 mM DTNB to oxidize any unreacted thiols. The beads were then incubated for 2 h in 1 nM [^{125}I]streptavidin and then washed three times in PBS before counting. Nonspecific binding was determined in quadruplicate samples incubated in the presence of 100 nM unlabeled streptavidin.

disulfide in the agonist binding site of nicotinic receptors (*25, 26*), we infer that **1**−**3** also react with the reduced disulfide in the agonist site.

[^{125}I]Streptavidin Binding to Arsenylated Macromolecules. In no case did **1**−**3** simultaneously block [^{125}I]BGT binding to *Torpedo* receptors and bind [^{125}I]-streptavidin (data not shown) if the arsenylating reagents were first added to DTT-reduced receptors and then the receptors were solubilized in Triton and immunoprecipitated. However, we observed significant [^{125}I]streptavidin binding to **3** reacted to DTT-treated antibody-coated beads. Figure 5 demonstrates that this effect is only observed for DTT-treated antibody-coated beads treated with **3** but not **1** or **2**, and that DMPS treatment significantly removes this binding. In other experiments (not shown), **3** did not label antibody-coated beads if the beads were not treated with DTT or if DTT-treated beads were reoxidized with DTNB before the addition of **3**. Since we had previously shown that APA forms a very stable complex with *Torpedo* receptors (*12*), we investigated the stability of **3** complexed with antibodies (Figure 6). We observed no change in the binding of [^{125}I]-streptavidin to beads treated with **3** over a period of 24 h, but DMPS could be used at any time to substantially remove the labeling agent.

The disulfide bonds located in the hinge regions of IgG isotypes are known to be important for the effector functions of these molecules, such as complement activation (*27*). It has been known for over 20 years that gentle reduction of the interheavy chain disulfides in the hinge region yields an antibody that can strongly bind antigen but not C1q (*28*), the trigger for the complement cascade. Furthermore, electron microscopic (*29*), gel filtration (*30*), and immunological and X-ray scattering data (*31*) all show conformational changes in immunoglobulins upon reduction of the interheavy chain disulfide bonds. This site is a well-established target for antibody-labeling agents, and we infer that this is the most likely site of labeling by **3** since Fab fragments are not labeled (data not shown). One potential advantage of arsenical-based labeling agents is that they could maintain the conformation of the immunoglobulins better than other reagents, since the arsenic interposes itself between spatially close dithiols and reestablishes an approximation of a disulfide bond. In addition, our data suggests that arsenical-based chromatography may be useful in purifying immunoglobulins (*32*).

Tsigelny et al. (*33*) modeled the extracellular domains of the nicotinic receptor based on homology with copper-binding proteins and current site-directed mutagenesis and affinity-labeling data. In their model, the disulfide bond in the agonist-binding site (Cys192−193) is highly exposed on the outer surface of the α-subunit. Unless glycosylation of the α-subunits prevents streptavidin binding to **3** due to unforseen steric block, the location of the disulfide in the agonist-binding site in that model does not seem to be very likely.

Our results might suggest that the disulfide bond in the agonist-binding site is located greater than 15 Å from the surface of the receptor. Two recent reports by Fairclough et al. (*11, 34*) appear to contradict that interpretation. They used a monoclonal antibody (mAb 383C) that binds to a peptide epitope corresponding to amino acids 187−199 on the *Torpedo* α-subunit, with

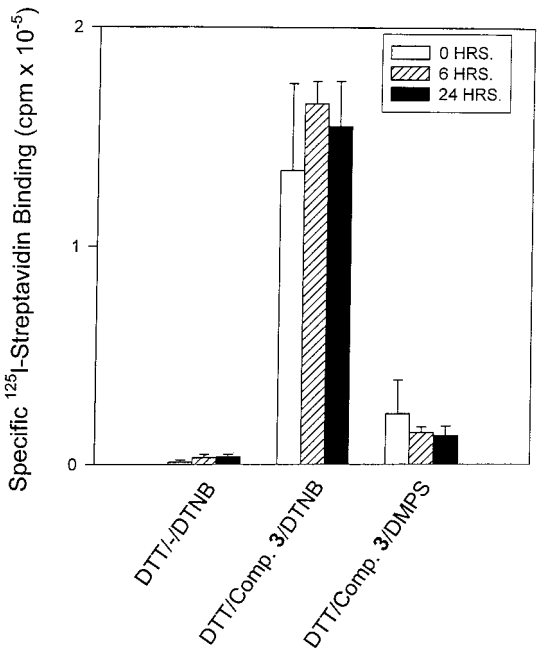

Figure 6. The complex of compound **3** and reduced antibodies is stable up to 24 h, but can be dissociated at any time by treating with DMPS. DTT-treated goat anti-rat IgG agarose beads were then either incubated with PBS [(−) left bars) or with 10 mM **3** (in PBS for 10 min, center and right bars) at time zero. At different times, immediately (clear bars), 6 (crosshatched bars) and 24 (reversed crosshatched bars) h later, the beads were then treated with either 1 mM DTNB (left and center bars) or 1 mM DMPS (right bars) for 10 min, and then assayed for specific [^{125}I]streptavidin binding. All samples were in quadruplicate with nonspecific binding determined in the presence of 100 nM unlabeled streptavidin.

specificity for the A site (the α−α interface). This antibody bound to intact receptors, and mapped to a site very near one of the two pits suggested by Unwin (*11*) to be the agonist-binding sites [but at some distance from where Tsigelny et al. place the disulfide bond in their model (*33*)]. We propose two possible explanations for this apparent difference in results using these two techniques.

First, monoclonal antibodies are well-known to induce conformational changes in the proteins to which they bind. For instance, a monoclonal antibody to avidin is reported to not only dissociate tetrameric avidin into monomers but also to cause the avidin to release bound biotin (*18*). Using fluorescence resonance energy transfer (FRET), Valenzuela et al. (*35*) report that binding of a different antibody [mAb A6 against the A site of *Torpedo* receptors (*7*)] induced the other agonist-binding site (the α−δ interface) to move about 30 Å closer to the membrane than observed for receptors without the bound antibody. This implies that monoclonal antibodies that selectively bind to one of the two agonist-binding sites can potentially induce major conformational changes. Also, the fact that an antibody binds suggests that the epitope is at least transiently exposed in one conformation of the receptor. It is possible that monoclonal antibodies can "trap" the receptor into a conformation that is relatively rare but in which the epitope including the disulfide bond is much more exposed than in other conformations. Second, our labeling method requires breaking the disulfide bond normally forming an eight-atom ring in the agonist binding site, and reforming a nine-atom ring structure including the arsenic atom. This could also induce an abnormal conformation. In addition, the protein folding could point our arsenicals with the biotin groups going into, rather than out of, the receptor molecule. If this is the case, then one might expect that arsenical-based reagents should abruptly stop working when some critical distance of the biotin spacer has been reached. Finally, the spacer groups are fairly hydrophobic, and it is possible that the biotin is too closely associated with hydrophobic groups in the receptor molecule to be recognized by streptavidin. We plan to address these last two issues, by using spacer groups that are longer, more rigid and hydrophilic. However, the data using **1**−**3** on antibody-coated beads clearly indicates that the length of the biotin spacer group is critical and that once the biotin group extends sufficiently far from the molecular surface, streptavidin binding ensues.

ACKNOWLEDGMENT

This work was supported by a grant from the Smokeless Tobacco Research Council, Inc., and by NIH NS22472. We thank John Lindstrom for the generous gift of mAb210, Jonathan Cohen for *Torpedo* membranes, and Ban-Ahn Khaw for a sample of Fab fragments. We thank Jack Cunniff and Jeannine Delaney for the mass spectra data and XiaoGong Zhang and Abdullah Baaj for some of the preliminary binding data. Igor Tsigelny generously provided us with a file specifying the atomic locations of his model for the extracellular domains of the *Torpedo* nicotinic receptor. We thank William N. Green for helpful discussions.

Biopharmaceutical Properties of Uricase Conjugated to Neutral and Amphiphilic Polymers

Paolo Caliceti,* Oddone Schiavon, and Francesco M. Veronese

Department of Pharmaceutical Sciences, University of Padova, Via F. Marzolo 5, 35131 Padova, Italy.
Received December 29, 1998; Revised Manuscript Received March 30, 1999

A comparative pharmacokinetic and biodistribution investigation of polymer−protein conjugates prepared with various amphiphilic polymers was carried out using uricase as a model. Four polymer-uricase derivatives have been obtained by covalent binding of a similar number of polymer chains of (a) linear poly(ethylene glycol) (M_w 5000 Da); (b) branched poly(ethylene glycol) (M_w 10 000 Da); (c) poly(*N*-vinylpyrrolidone) (M_w 6000 Da); (d) poly(*N*-acryloilmorpholine) (M_w 6000 Da). By intravenous administration to Balb/c mice, the conjugates displayed different pharmacokinetic and organ distribution behaviors. (1) The unmodified enzyme and the poly(*N*-vinylpyrrolidone) conjugate were the enzyme forms with the shortest and the longest permanence in blood respectively (mean residence time 45 and 4378 min). (2*)* Native uricase was found to localize soon after administration significantly in heart, lungs, and liver from where it was also rapidly cleared. (3) The poly(*N*-acryloilmorpholine) derivative showed the highest concentration levels in liver (up to 25.5% of the dose) and considerable accumulation took also place in the other considered organs. (4) Poly(*N*-vinylpyrrolidone)-uricase displayed a relevant tropism for liver but low uptake indexes were found for the other organs. (5) The branched poly(ethylene glycol) derivative accumulated preferentially in liver and spleen. (6) The linear poly(ethylene glycol) conjugate was, among the various uricase forms, the species with the lowest distribution levels in all the examined organs. (7) Finally, all the enzyme forms slowly disposed in kidneys with higher levels for the poly(*N*-acryloilmorpholine) derivative (15% after 2880 min) and unmodified uricase (14% after 1440 min).

INTRODUCTION

The modification of protein and peptide drugs with soluble biocompatible polymers largely demonstrated to be a successful method to enhance their therapeutic performance. A number of studies report, in fact, that polymer-conjugated proteins usually present, as compared to the native counterparts, prolonged permanence in blood, lowered immunogenicity, improved physical, chemical, and enzymatic stability, and increased solubility.

To date, monomethoxypoly(ethylene glycol) (PEG) is receiving the lion's share in protein modification (*1*−*3*) and some PEG−protein conjugates are already in clinical use. However, despite the impressive results obtained with PEG, new synthetic and natural polymers are currently investigated for protein derivatization (*3*−*11*) in order to provide for macromolecules that, since their chemical and physical character, may dictate new properties and fate of the conjugate in the body. Indeed the polymeric portion, which often represents the major part of the construct, is more exposed than the protein to the biological environment and, therefore, can influence the interaction with biological structures and dictate body targeting and disposition.

Besides polymers designed for a selective recognition of biological receptors such as polysaccharides, antibodies, and neoglycoproteins (*12*−*14*), most of the macromolecules devised for protein modification do not mediate specific biological events or selective interactions. Anyhow, also, these polymers may possess tropism for organs and tissues that reflects in body disposition of their conjugates by passive mechanisms based on diffusion or by endocytosis.

Studies reported in the literature point out the effect of charge and molecular mass of macromolecular carriers on organ distribution of the conjugates (*15*−*18*). A typical example is the conjugation of an antitumor agent bound to a low molecular mass cationic dextran that showed a rapid disappearance from circulation due to accumulation in liver and spleen. High molecular mass cationic and anionic dextrans also promoted the localization of the conjugates in solid tumors (*17*, *18*). In addition proteins, peptides and antitumor agents covalently modified with negatively charged divinyl ether-maleic anhydride copolymer (DIVEMA) or styrene-maleic anhydride copolymer (SMA) showed tumoritropism, lymphotropism and captation by phagocytic cells (*6*, *19*).

Also, uncharged amphiphilic olygomers can passively interact with biological structures stimulating endocytosis (*20*−*24*). On the basis of these properties, several polymeric carriers have been developed for lysosomotropic delivery of antitumoral drugs and successful results have been obtained, for example, with poly(hydroxypropyl)methacrylamide and polyaspartamide-poly(oxyethylene) (*25*−*27*). Furthermore, poly(ethylene glycol)-derivatized proteins have been found to enter endothelial cells as well as blood cells (*28*, *29*), while conjugates of poly(vinyl alcohol) have been found to accumulate in small amounts in various organs (*30*).

All of these evidences indicate that biopharmaceutical properties of the conjugates must be carefully investigated since also slight differences in polymer structure may be reflected on different therapeutic performance of the conjugates (*31*−*33*).

To give a further contribution to understand the influence of the physicochemical and structural properties of neutral macromolecules on the biopharmaceutical properties of the conjugates, four different monofunctional soluble polymers have been considered: poly(*N*-vinylpyrrolidone) (PVP), poly(*N*-acryloilmorpholine) (PAcM), linear monomethoxypoly(ethylene glycol) (PEG), and branched monomethoxypoly(ethylene glycol) (PEG2). Uricase, an enzyme of potential therapeutic value in urea clearance, has been used as protein model (*34*, *35*) and a pharmacokinetic and biodistribution investigation of the native enzyme and its polymer conjugates was carried out in mice following intravenous administration. The concentration profiles in plasma, liver, kidney, spleen, heart, and lungs were evaluated and the main pharmacokinetic parameters have been calculated.

MATERIALS AND METHODS

Uricase from *Candida utilis* was obtained from Toyobo (Osaka, Japan). [^{3}H]succinimidyl propionate was from Amersham International (Amersham, U.K.) and Soluene 350, Instagel and Ionic Fluor were from Canberra Packard (Groninghen, The Netherlands). The Superose column and FPLC system were furnished by Pharmacia Biotech (Uppsala, Sweden), and the ultrafiltration system was from Amicon Inc. (Beverly, MA). All other reagents, of analytical grade, were purchased by Fluka (Buchs, Switzerland).

Male Balb/c mice, weighing 30 ± 2 g and fed ad libitum, obtained from Charles River (Calco, Italy), were used for "in vivo" experiments.

Polymer Preparation and Activation. Linear monomethoxypoly(ethylene glycol), M_w 5000 Da, obtained from Shearwater (Huntsville, AL), was end-carboxylated by introduction of a nor-leucine residue, and the free carboxylic group was activated as succinimidyl ester (*36*). Branched monomethoxypoly(ethylene glycol), M_w 10 000 Da, was prepared and activated as described in the literature (*37*). Carboxy-terminating poly(*N*-vinylpyrrolidone), M_w 6000 Da, and carboxy-terminating poly(*N*-acryloilmorpholine), M_w 6000 Da, were synthesized, fractionated, and activated according to the methods developed in our laboratory (*38*, *39*).

Preparation of Protein−Polymer Conjugates. Polymer activated as succinimidyl ester [15.4 μmol in the case of linear monomethoxypoly(ethylene glycol); 26.95 μmol of branched monomethoxypoly(ethylene glycol); 19.25 μmol of poly(*N*-vinylpyrrolidone); 23.1 μmol of poly(*N*-acryloilmorpholine)] was added under stirring to uricase (77 nmol) dissolved in 1 mL of 0.2 M borate buffer and 77 mM uric acid, pH 8.0. The reaction mixture was maintained under stirring at room temperature for 1 h, added to 9 mL of 0.1 M borate buffer, pH 8.0, and ultrafiltered using a membrane with 10 000 Da cut off to reach a volume of 1 mL. The remaining solution was diluted with 5 mL of the buffer reported above, and the ultrafiltration procedure was repeated three times. The ultrafiltered product was further purified by gel filtration chromatography using a Superose 12 preparative column eluted with 10 mM of phosphate buffer and 0.15 M NaCl, pH 7.2. The elution fractions were analyzed by OD at 280 nm for protein evaluation, by iodine assay for polymer determination (*40*) and by enzyme activity (*41*). The protein−polymer conjugate peak was concentrated by ultrafiltration. The protein concentration was finally determined by biuret method (*42*), the degree of modification by a trinitrobenzensulfonic acid colorimetric method (*43*) and by amino acid analysis on the basis of the nor-leucine content (*36*). The residual activity was assessed by enzyme assay.

Preparation of Tritium-Labeled Proteins. Native or polymer conjugated uricase (77 nmol) in 1 mL of borate buffer, pH 8.0, was added under vigorous stirring to 20 μL of toluene containing 1 nmol of succinimidyl [^{3}H]-propionate. After 30 min of reaction, the solution was chromatographied using a Superose 12 preparative column eluted with 10 mM of phosphate buffer and 0.15 M NaCl, pH 7.2. The protein peak was collected and radioactivity was assessed by β-counter and expressed as disintegrations per minute per protein milligram (DPM/protein mg).

Mouse serum albumin (144 nmol) was tritium-labeled following the procedure reported above for uricase.

The radioactivity of the ^{3}H-labeled derivatives was in the range of $0.6 \times 10^6 - 0.8 \times 10^6$ DPM/mg.

Pharmacokinetic and Biodistribution Studies. Animal treatments for the "in vivo" studies were performed according to institutional European guidelines.

Five groups of 10 Balb/c male mice (30 ± 2 g) each were separately treated by injection in the tail vein of the tritium-labeled compounds: native uricase, linear monomethoxypoly(ethylene glycol)-uricase, branched monomethoxypoly(ethylene glycol)-uricase, poly(*N*-vinylpyrrolidone)-uricase, and poly(*N*-acryloilmorpholine)-uricase (450 μg in 0.1 mL of 20 mM phosphate buffer, 0.15 M NaCl, pH 7.2). The animals were sacrificed at scheduled times, and blood samples, liver, spleen, lungs, heart, and kidneys were taken.

The blood samples were put in heparinized vials, centrifuged and the enzyme content in plasma was estimated by enzyme activity and by radioactivity evaluation after addition of 4 mL of Instagel cocktail to 50 μL of plasma.

The organs were carefully washed in saline solution, dried on paper, and weighted. Soluene 350 was added to the organs (10 mL/g tissue) and steeped at 100 °C for 2 h. Two hundred and fifty microliters of samples was added to 2.75 mL of Ionic Fluor, and the radioactivity was evaluated by β-counter.

Tritium-labeled mouse serum albumin (450 μg in 0.2 mL of sterile saline solution) was injected in the tail vein of 10 mice. The animals were sacrificed and blood samples and organs were taken and processed as described above for the estimation of the residual plasma in the organs.

Data Elaboration. The plasma concentration means and the standard deviations (±SD) of the native and conjugated uricase as well as the mouse serum albumin were estimated on the basis of the enzyme activity and the radioactivity obtained from the plasma samples.

The pharmacokinetic parameters were determined by computer elaboration of the enzyme concentrations in plasma obtained at the scheduled times according to the equation

$$C(t) = Ae^{-\alpha t} + Be^{-\beta t}$$

The concentration means and the standard deviations (±SD) of the native and conjugated uricase were determined on the basis of the values of the radioactivity obtained from the organ samples. The residual plasma volume in each organ was estimated by the [^{3}H]MSA levels, and the obtained data were used to correct the disposition levels of the various uricase forms in the organs (*22*).

The organ uptake indexes (CLin) were calculated, on the basis of the standard method reported in the litera-

Table 1. Protein/Polymer Molar Ratios Used in Conjugate Preparation and Main Properties of Native Uricase, PAcM-Uricase, PVP-Uricase, PEG2-Uricase, and PEG-Uricase

	protein NH_2/polymer molar ratio	extent of modification (% derivatized amino groups)	molecular mass (Da)
native uricase			130 000
PacM-uricase	1:3	47	400 000
PVP-uricase	1:2.5	43	380 000
PEG-uricase	1:3	44	350 000
PEG2-uricase	1:3.5	40	530 000

ture, according to the following expression:

$$\mathrm{CLin} = \frac{T(t)}{\int C(t)\,\mathrm{d}t} = \frac{T(t_1)}{\mathrm{AUC}_{0\rightarrow t1}}$$

where $T(t_1)$ is the percentage of dose per gram at 15 min and AUC_{0-t1} is the area under the curve in the range 0−15 min (*23*).

RESULTS

Polymer−Protein Conjugate Preparation. To carry out a comparative study, conjugates at similar molecular mass or degree of modification were prepared with the various polymers. This could be realized using polymers with close molecular masses (in the range 5000−6000 Da) and by attachment of a similar number of polymer molecules to the protein. To overcome the different reactivity of the activated polymers, proper protein NH_2/polymer molar ratios in the conjugation reaction were used. Table 1 reports the conjugate preparation conditions, degree of modification, and molecular mass of unmodified uricase and of the four polymer-uricase derivatives. The table shows that, in the case of PAcM, PVP, and PEG, molecular mass in the range 350000−400000 Da were obtained. The higher molecular mass of the PEG2 derivative (530 000 Da) is due to the fact that the reaching of the same degree of modification as the other conjugates was preferred to obtain a close overall mass.

The conjugation reaction was carried out in the presence of uric acid in order to prevent the dramatic loss in enzyme activity that the polymer binding can provoke in the absence of any active-site protection. Following this procedure, the conjugates could maintain enzyme activity in the range 20−80% of the unmodified uricase (*44*).

Pharmacokinetic Studies. The pharmacokinetic behaviors obtained by intravenous injection to mice of native and polymer conjugated uricases are depicted in Figure 1. The time course profiles were obtained by radioactivity determination of the enzyme concentration in plasma. For the radioactivity evaluation few amino groups of native and conjugated proteins were covalently labeled with [^{3}H]propionate, a method that prevents the "in vivo" release of the radioactive probe. Of note to report that in few samples the concentrations were also evaluated by enzyme activity and the values have been found in agreement with those obtained by radioactivity.

The patterns in plasma were found to fit a biexponential curve, indicating that the various enzyme forms are cleared from circulation following a bicompartimental pharmacokinetic model. Furthermore the figure shows that, although the performance of the conjugates deeply depends on the polymer, in any case they are eliminated from blood much more slowly with respect to the native enzyme.

The pharmacokinetic data reported in Table 2 point out that PVP-UC is, among the various uricase forms, the longest lasting in blood. The mean residence time (MRT) of PVP-UC is in fact about 10-fold of the native uricase, 3-fold of PAcM-UC, and 1.3-fold that of PEG-uricase and PEG2-uricase. The β phase half time ($t_{1/2}\beta$) and the elimination rate constants (k_e) also reflect the slow PVP-UC elimination from the body, followed in the order by PEG-UC and PEG2-UC, PAcM-UC and native uricase.

With regard to the distribution phase, the native uricase and the PAcM derivative show comparable α phase half times ($t_{1/2}\alpha$). These values that are about 10-fold shorter than the ones obtained with the other enzyme forms indicate that a rapid distribution process takes place. The high distribution rate constants (k_{12} and k_{21}) of native uricase and the PAcM derivative confirm

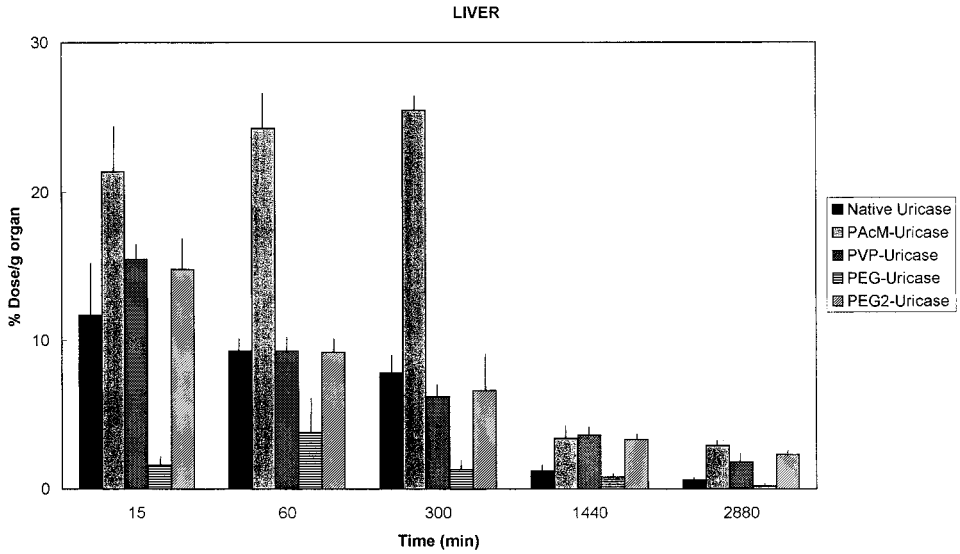

Figure 2. Disposition profiles in liver of native uricase, PAcM-uricase, PVP-uricase, PEG-uricase, and PEG2-uricase after intravenous administration to mice; ±SD values are reported.

the rapid equilibration of these enzyme forms with organs and peripheral tissues. On the other side PVP-UC, PEG-UC and PEG2-UC display high $t_{1/2}\alpha$ values and low k_{12} and k_{21} supporting that they slowly distributed in the peripheral tissues and slowly reach the equilibrium between blood and other tissues. In consideration of the $t_{1/2}\alpha$ and k_{12} and k_{21} values it is therefore possible to state that the peripheral distribution process follows the order native uricase > PAcM-UC > PEG2-UC > PEG-UC > PVP-UC.

Finally PVP-UC, PEG-UC, and PEG2-UC show similar high area under the curve (AUC), values indicating their significantly higher systemic availability, with respect to PAcM-UC and native enzyme.

Organ Disposition. The uricase accumulation levels in liver, kidneys, spleen, heart, and lungs, obtained after intravenous administration to mice of the native and polymer conjugated enzyme and expressed as a percentage of the dose per gram of tissue up to 48 h from the administration are depicted in Figures 2−6. After this time, low levels of enzyme accumulation have been observed in the tissues with exception of kidneys that displayed a prolonged retention of the various enzyme forms, in particular of PAcM-UC and PEG2-UC.

Liver. The distribution profiles reported in Figure 2 show an impressive amount of PAcM-UC in liver. The PAcM-UC disposition is practically instantaneous, and its concentration gradually increases by time to reach the maximal level of approximately 26% within 5 h. After 24 h from injection, the PAcM-UC concentration drastically drops to 4%. Native uricase, PVP-UC, and PEG2-UC also rapidly dispose in this organ and their distribution behaviors are very similar. Soon after administration these enzyme forms exhibit concentration levels ranging between 12 and 16%, but the clearance from this organ takes also place rapidly indicating a low affinity for the hepatic tissue. A different behaviour has instead been observed for PEG-UC that does not show any significant accumulation in liver in comparison to the other uricase forms. Levels below 4% of the dose were in fact found during the experiment.

Kidneys. PAcM-UC is the uricase species with the highest affinity for kidneys. Figure 3 shows that the disposition process in this organ is practically instantaneous and the concentration increases with the time reaching the level of about 15% in 5 h, a value constantly retained up to 48 h. The kidney distribution time courses during the first 24 h of native uricase and the PAcM derivative are very similar, but after this time, the native form is rapidly cleared. PVP-UC, PEG-UC, and PEG2-UC exhibit lower concentration values with respect to the native enzyme and the PAcM conjugate. Their accumulation is at the limit of detection after 15 min from injection and gradually rises to reach values of 3.3 and 4.8% after 24 h for the PVP and PEG2 derivatives, respectively, and of 5.6 after 48 h for the PEG one.

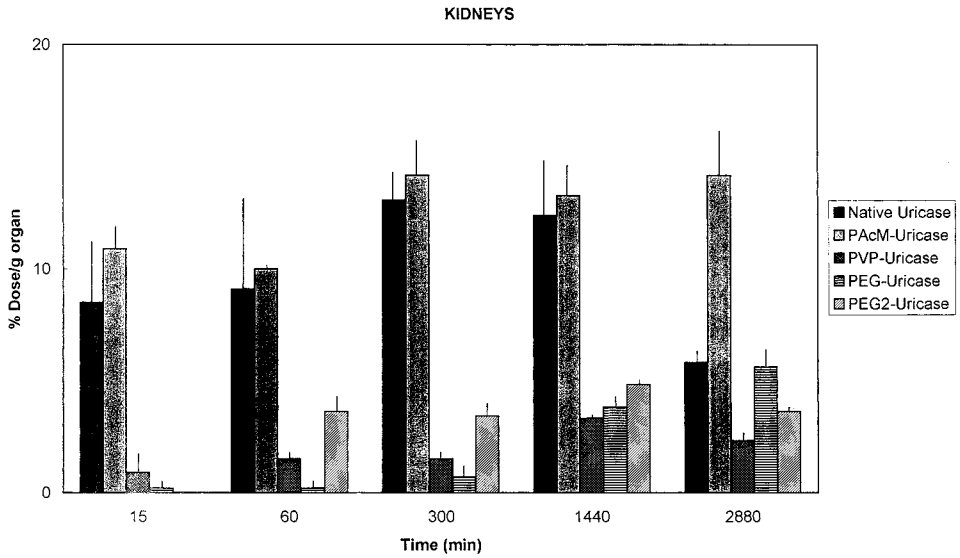

Figure 3. Disposition profiles in kidneys of native uricase, PAcM-uricase, PVP-uricase, PEG-uricase, and PEG2-uricase after intravenous administration to mice; ±SD values are reported.

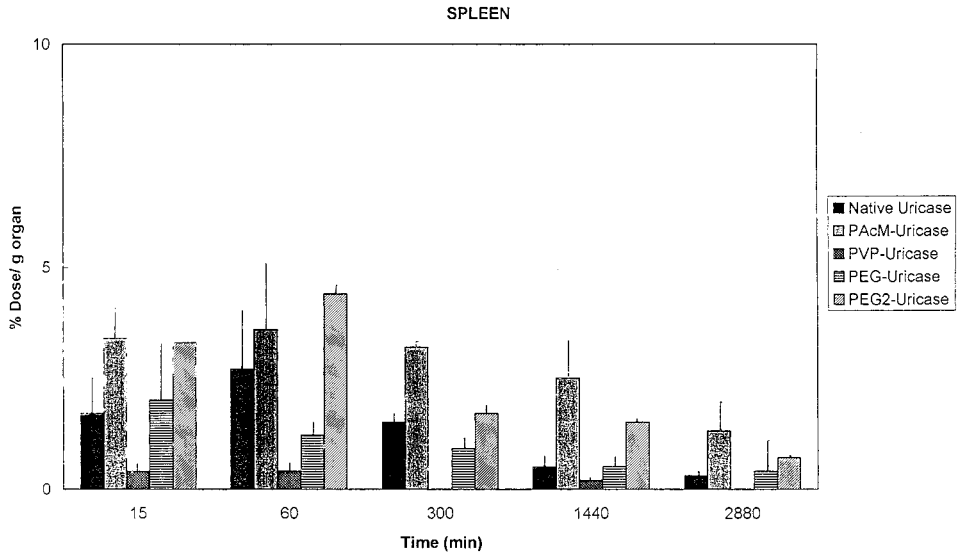

Figure 4. Disposition profiles in spleen of native uricase, PAcM-uricase, PVP-uricase, PEG-uricase, and PEG2-uricase after intravenous administration to mice; ±SD values are reported.

Spleen. The time courses of distribution in spleen depicted in Figure 4 indicate that PEG2-UC and PAcM-UC undergo a rapid accumulation in spleen that reaches the maximal concentration level after 1 h from administration: 4 and 5%, respectively. After this time, the PEG2 derivative concentration is reduced by 2/3, while the PAcM conjugate is cleared much more slowly. Native uricase and PEG derivative dispose in spleen at a lower extent with respect to the PEG2 and PAcM counterparts but with a similar trend, while PVP-UC accumulation is practically negligible.

Heart. Figure 5 describes the rapid and remarkable localization in heart of native uricase and PAcM-UC. In particular, the PAcM conjugate maintains constant concentration levels of about 3.5% for up to 5 h from the administration time, whereas the unmodified uricase is quickly cleared from this organ. Only a reduced localization in heart is instead found for PEG-UC and PEG2-UC. These conjugates, that present a similar behavior, have concentration levels constantly maintained below 1%. PVP-UC failed to accumulate in heart and its concentration levels are practically undetectable.

Lungs. The distribution patterns in lungs depicted in Figure 6 show that native uricase, PAcM-UC, and PVP-UC are rapidly localized in lungs and rapidly cleared from it. A high level of native enzyme is found after 15 min (13%). PEG-UC and PEG2-UC show, instead, a different disposition trend in comparison to the other uricase forms. Their concentrations gradually increase with time reaching a level of about 3% within 24−48 h.

Organ Uptake Index. Table 3 reports the organ uptake rate indexes that quantitatively define the differences in organ translocation of the various uricase forms.

Native uricase and PAcM-UC display, in the examined organs, the higher uptake rate values according to their consistent tissue disposition already observed in Figures 2−6. Interestingly the liver uptake of PAcM-UC is 1.3-fold of the native uricase one, while the latter presents higher lungs and heart uptake indexes. PVP-UC is rapidly taken up only by liver, which is the organ involved in polymer elimination (*45*). The data of the table point out a rapid translocation of the PEG2-UC in liver and spleen, two organs rich of reticulo-endothelial

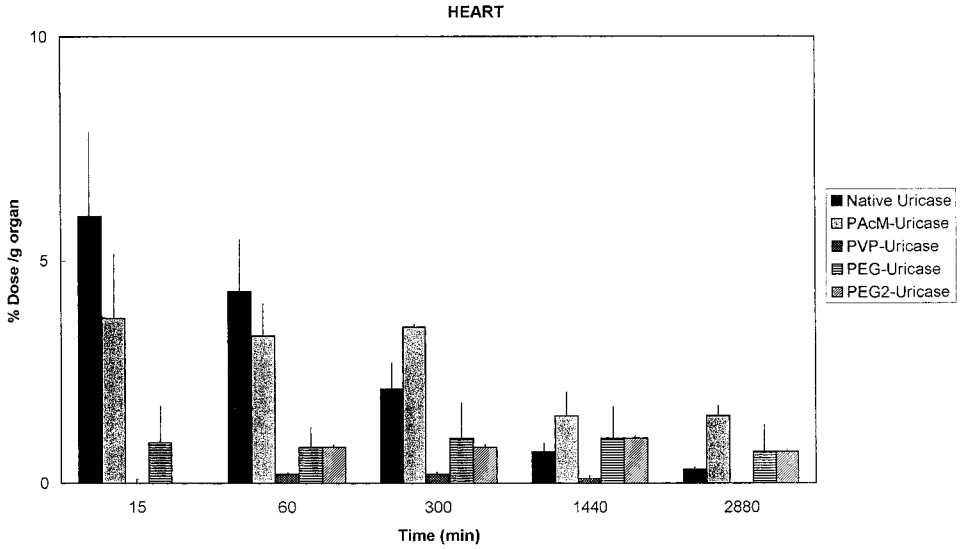

Figure 5. Disposition profiles in heart of native uricase, PAcM-uricase, PVP-uricase, PEG-uricase, and PEG2-uricase after intravenous administration to mice; ±SD values are reported.

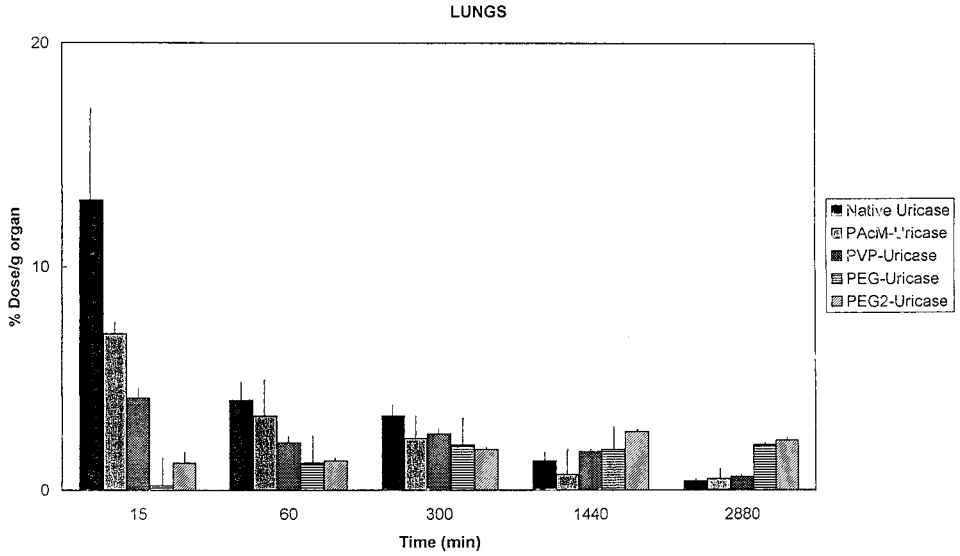

Figure 6. Disposition profiles in lungs of native uricase, PAcM-uricase, PVP-uricase, PEG-uricase, and PEG2-uricase after intravenous administration to mice; ±SD values are reported.

Table 3. Organ Uptake Rate Indexes Obtained with Native Uricase, PAcM-Uricase, PVP-Uricase, PEG2-Uricase, and PEG-Uricase

	CLin (μL/g/h)				
	native uricase	uricase-PAcM	uricase-PVP	uricase-PEG	uricase-PEG2
liver	816	1056	749	83.4	532
kidneys	624	762	45	9.6	0.9
spleen	128.4	241.6	19.8	108	120.2
heart	441	255	2.79	46.7	0
lungs	958	493	43.9	9.7	41.7

cells, while the linear PEG does not present significant index values in any studied organ. These results are in agreement with the enhanced uptake by Kuppfer cells observed with high molecular mass poly(ethylene glycol)s (*23*).

DISCUSSION

The present study was aimed at evaluating the influence of different neutral amphiphilic polymers on biopharmaceutical properties of polymer−protein conjugates. This is of primary importance in the choice of the polymer for protein modification because polymers with apparently similar physicochemical properties can affect in different way the biopharmaceutical properties of the conjugates.

Uricase was chosen for this investigation since its therapeutic value in the treatment of hyperuricemia-associated diseases such as nephropathologies and haematological malignancies and poly(ethylene glycol) and dextran conjugates have been recently prepared in order to overcome its considerable immunological and pharmacokinetic character (*15*, *34*, *35*).

The four polymers used in this study were selected because of their relevance in the preparation of protein conjugates for medical use. Indeed they have the prerequisites for medical use and possess similar properties such as good solubility in both aqueous and organic solvents, absence of charge, molecular shape, mass, and monofunctionality in reaction. Furthermore, previous studies carried out in our laboratories already demonstrated that monofunctional PVP, PAcM, and PEG2 provide for an excellent alternative to the most used linear PEG in protein modification (*37*−*39*, *46*−*48*).

The biopharmaceutical investigation reported here clearly indicates that the protein conjugation with these polymers yields derivatives with prolonged permanence in blood, although different clearance from circulation and organ distribution behaviors have been obtained.

With regard to the permanence in blood, we can say that the increased residence time of the conjugates, with respect to the native counterpart, can only partially be ascribed to reduction in renal ultrafiltration due to their high molecular volume, as often reported with other proteins. Native uricase "per se" has in fact a high molecular mass (128 000 Da) and Stokes' radius (42.7 Å) that overcome the renal filtration limit and therefore its main elimination route is by hepatic route (*15*). The organ disposition behaviors and uptake indexes of native uricase suggest that its rapid disappearance is by localization in organs, a behavior that is certainly followed by the uricase conjugates also. In particular, the high disposition of native uricase in reticulo-endotelial cell rich organs such as liver and lungs seems to suggest that its elimination takes place by phagocytic processes, followed by biliary excretion and/or degradation to low molecular mass peptides that can be cleared with urine. It is therefore worth noting that the changes in protein organ disposition determined by the polymer binding are accompanied by enhancing the uricase permanence in blood.

In addition, the resistance of the conjugates to proteolytic digestion and to recognition by the immunosystem already observed in our laboratories (*44*) also contribute to prevent the uricase conjugate disappearance from circulation. In this regard it may be of interest to remember the agreement between the enzyme activity and radioactivity levels in blood of the conjugated uricase a behavior that is in favor of the stability in blood of the conjugates despite their long permanence in it. This behavior points out that the protein degradation to inactive long circulating fragments does not take place.

If we now examine the "in vivo" performance of the four polymer conjugates, we can observe that PAcM promotes significantly the organ accumulation of the derivative in the main organs, in particular in liver, spleen, and kidneys. The high uptake rate indexes of these organs, and especially of liver, explains its rapid disappearance during the distribution phase (α phase). Nevertheless, the conjugate has a considerable higher permanence in blood (β phase) compared to the native enzyme probably due to a reduced degradation and a slow release from the tissues that guarantee sustained levels in blood.

For what the PVP derivative is concerned its long permanence in plasma reflects the low levels of tissue translocation. The conjugate in fact disposes significantly only in liver, in agreement with the data reported in the literature that indicate the hepatic uptake by endocytosis of this polymer as the main PVP elimination route (*24*).

Interesting results have been obtained with the PEG and PEG2 derivatives that show very different accumulation profiles in the examined organs. According to the literature data, the linear PEG derivative does not show specific localization in peripheral districts, and low amounts of its conjugate are found in all the tissues (*23*). On the other hand, the PEG2 adduct accumulates at significant extent in liver and spleen, two organs rich of reticulo-endothelial cells. These results suggest that the branched shape of this polymer can affect the cell/conjugate interaction process and the higher accumulation of the PEG2 derivative is probably related to the higher molecular volume of this conjugate that, with respect to the linear one, can more efficiently stimulate the cell phagocytic process.

The reasons that are at the basis of the differences in organ disposition among the conjugates are difficult to be understood. Differences in stability to proteolytic enzymes of the various enzyme forms, observed in "in vitro" experiments, seem not to be relevant in determining the disposition profiles of the various enzyme forms since all of them were found do not degrade in the experiment time. We can instead suggest that peculiar lipohilic/hydrophilic properties of the polymers can play a significant role in the interaction with the organ cell membranes indicating the importance of their amphiphilic character.

CONCLUSIONS

A careful choice of the polymer used for protein modification allows for controlling the "in vivo" fate of the conjugates. However, charge and molecular mass are not the only parameters playing a role in dictating the biopharmaceutical properties of the conjugates as often reported in the literature. The data reported here indicate that neutral polymers, with apparently similar physicochemical properties but different chemical composition and architecture, can confer to the conjugates peculiar biopharmaceutical properties. Therefore, the assumption that the covalent conjugation of uncharged and relatively low molecular mass polymers to proteins avoids the organ disposition of the conjugates, based on the low disposition properties of the most studied PEG derivatives, must be carefully reconsidered.

This suggests the possibility to use uncharged amphiphilic polymers for preparation of tailored conjugates that can preferentially accumulate in organs where their therapeutic effect is expected or from where they can be slowly released in the active form in order to ensure sustained concentrations in plasma.

Furthermore, in addition to the therapeutic value of the conjugates, also their toxicological aspect must be considered. Accumulation of the conjugates in organs where they can house for a long time can in fact represent a serious limit of their application, also in consideration of the usual high stability to degradation processes of the conjugates that prevents their elimination. However, it is important to observe that the non biodegradable polymers studied here do not induce any irreversible accumulation of the conjugates in organs that could cause toxicity problems.

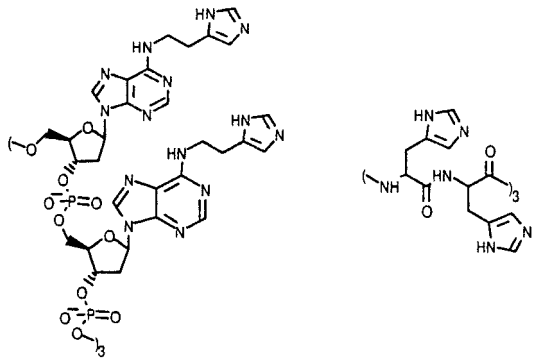
Bifunctional Phosphoramidite Reagents for the Introduction of Histidyl and Dihistidyl Residues into Oligonucleotides

Thomas H. Smith,* John V. LaTour, Dmitry Bochkariov, Grigoriy Chaga, and Paul S. Nelson

Nucleic Acids Chemistry Division, CLONTECH Laboratories, Inc., 1020 East Meadow Circle, Palo Alto, California 94303 . Received January 11, 1999; Revised Manuscript Received March 16, 1999



The synthesis and characterization of reagents for the incorporation of histidyl residues into oligonucleotides by automated chemical synthesis is described. Automated oligonucleotide synthesis utilizing a bifunctional reagent for the incorporation of a dihistidyl residue into oligonucleotides is described. Oligonucleotides incorporating one to three dihistidyl residues were prepared and characterized. The interaction of these oligonucleotides with a metal chelating IMAC matrix was explored.

INTRODUCTION

Oligonucleotides containing imidazole residues are of potential biological interest for a number of reasons. The metal complexing property of imidazole rings offers a potential handle for the purification of imidazole-tagged oligonucleotides and nucleic acids. Histidine- or imidazole-containing oligonucleotides can act as artificial nucleases due to the ability of imidazole rings to complex metal ions and cleave nucleic acid chains (*1*, *2*).

IMAC (immobilized metal affinity chromatography) is a widely used technique for the purification of recombinant proteins tagged with metal-coordinating peptide sequences (*3*, *4*) such as hexahistidine (*5*). Due to the binding strength and reversible nature of the imidazole-transition metal ion coordination, IMAC also has potential as a useful technique for nucleic acid applications. In 1995, Orum et al. reported the use of oligohistidine-PNA chimeras to purify cDNAs via an IMAC process (*6*). In 1996, Min and Verdine (*7*) reported the use of IMAC in a DNA application. In their work, the metal-coordinating peptide sequence was replaced by a tag composed of six consecutive 6-histaminylpurine nucleotide residues Figure 1 (1). This tag was constructed via automated incorporation into the oligonucleotide of O^6-phenyl-2′-deoxyinosine residues via phosphoramidite chemistry followed by postsynthesis reaction of the resulting oligonucleotide with aqueous histamine. This tag was shown to allow selective retention of a DNA strand to a Ni^{2+}-NTA (nitrilotriacetic acid)-agarose chromatography matrix (*8*).

The nature of the complex between the immobilized metal ion chromatography matrix and the polyhistine tag has never been fully understood. However, it has been shown that consecutive histidine residues are favored for optimal binding (*8*). With this in mind, we felt that the Min and Verdine structure **1**, with a 24-atom spacer between the imidazole rings versus the 6-atom distance between the imidazoles in a dihistidine peptide fragment **2**, may not be the optimal arrangement. We also wanted to introduce the metal-coordinating fragment in a single automated step on the DNA synthesizer without any postsynthetic manipulations. Our goal therefore became the design, synthesis, and evaluation of a reagent which meets these criteria. Herein we report the results of this study.

EXPERIMENTAL PROCEDURES

General Methods. 2-Cyanoethoxy-*N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite was obtained from Dalton Laboratories (Toronto, Ontario). Tetrazole and diisopropylethylamine (DIPEA) were obtained from Chem-Impex (Wood Dale, IL). N^{α}-Fmoc-N^{im}-Boc-L-histidine cyclohexylamine (CHA) salt was obtained from Nova Biochem (LaJolla, CA). All other reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI). All reactions were carried out under an Ar atmosphere. Solvent extracts of aqueous solutions were dried over anhydrous Na_2SO_4. Solutions were concentrated under reduced pressure using a rotary evaporator. Thin-layer chromatography (TLC) was done on Analtech Silica Gel GF (0.25 mm) plates. Chromatograms were visualized with either UV light or sulfuric acid. All compounds reported were homogeneous by TLC. HPLC analyses were performed on a Rainin (Emeryville, CA) Rabbit HPX system using either C18 Microsorb (4.6 × 150 mm, 5 μm) reversed-phase or Pharmacia (Piscataway, NJ) Mono Q HR 5/5 ion-exchange columns. UV measurements were obtained with a Perkin-Elmer Lambda 2 spectrophotometer

equipped with a Peltier temperature controller and a six cell transport device. NMR spectra were obtained by Acorn NMR (Fremont, CA) at 360 MHz in $CDCl_3$. Mass spectra were obtained on a MALDI time-of-flight mass spectrometer from Ciphergen Biosystems, Inc. (Palo Alto, CA). Elemental analyses were obtained from the Microanalytical Laboratory of the Department of Chemistry, University of California, Berkeley.

***N*-(N^{α}-Fmoc-N^{im}-*t*-Boc-L-histidyl)-6-amino-2-hydroxymethyl-1-hexanol Dimethoxytrityl Ether (7)**. N^{α}-Fmoc-N^{im}-Boc-L-histidine CHA salt (35.0 g, 60.7 mmol) was placed in a separatory funnel containing EtOAc (800 mL) and 5% citric acid (800 mL) and shaken until the salt had fully dissolved. The organic layer was separated and the aqueous layer extracted with EtOAc (200 mL). The organic layers were combined, washed with water (200 mL) and brine (200 mL), dried, and evaporated to provide the free acid **5**. Separately, **3** (34.0 g, 50.6 mmol) was dissolved in 20% (v/v) piperidine in toluene (600 mL) and stirred at 22 °C for 2 h. The reaction mixture was evaporated, azeotroped with toluene (100 mL), redissolved in EtOAc (300 mL), washed with brine (2 × 100 mL), dried, evaporated, and azeotroped with toluene (100 mL) to afford the crude amine **4**. The residue was dissolved in DMF (80 mL) containing DIPEA (15 mL). The amino acid **5** from above was also dissolved in DMF (80 mL) containing DIPEA (16.7 mL) and combined with the solution of **4**. 1-Hydroxybenzotriazole (HOBT) (8.20 g, 60.7 mmol) was added followed by benzotriazol-1-yloxytripyrrolidinophosphonium hexafluorophosphate (PyBOP) (31.6 g, 60.7 mmol). The solution was stirred for 0.5 h at 22 °C, diluted with EtOAc (800 mL), washed with 10% Na_2CO_3 (2 × 800 mL), water (800 mL), and brine (800 mL), dried, evaporated, and azeotroped with toluene (100 mL). The residue was flash chromatographed on silica gel (1100 g) and eluted with 99:1 to 98:2 DCM/MeOH to afford 32.5 g (71%) of **7** as a diastereomeric mixture. ^{1}H NMR ($CDCl_3$): δ 8.02 (singlets, 1H), 7.76 (doublets, 2H), 7.59 (d, 2H), 7.35−7.45 (m, 4H), 7.13−7.34 (m, 10H), 6.83 (m, 4H, DMT), 6.77 (singlets, 1H), 6.45 (br, 1H), 4.32−4.50 (m, 3H), 4.09 (t, 1H), 3.78 (singlets, 6H), 3.74 (dd, 1H), 3.62 (m, 2H), 2.90−3.30 (m, 6H), 1.75 (br, 1H), 1.60 (singlets, 9H, Boc), 1.13−1.50 (m, 6H).

***N*-(N^{α}-Fmoc−N^{im}-*t*-Boc-L-histidyl)-6-amino-2-(*O*-DMT-hydroxymethyl)-1-hexanol (2-Cyanoethoxy)-*N*,*N*-diisopropylphosphoramidite (*12*)**. **7** (1.00 g, 1.1 mmol) was dissolved in dichloromethane (11 mL). Tetrazole (93 mg, 1.33 mmol) was added and the mixture stirred at 22 °C for 15 min. 2-Cyanoethoxy-*N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite (398 mg, 1.32 mmol) was added and the mixture stirred an additional 10 min at 22 °C. The mixture was filtered and the precipitate washed with EtOAc (10 mL). The combined filtrate and washing were diluted to 50 mL with EtOAc, washed with 10% Na_2CO_3 (2 × 15 mL) and brine (15 mL), dried, evaporated, and azeotroped with toluene. The residue was flash chromatographed on silica gel (40 g) and eluted with 70:30:3 to 50:50:3 hexane/EtOAc/TEA to afford 945 mg (78%) of **12** as a diastereomeric mixture. ^{1}H NMR ($CDCl_3$): δ 8.01 (s, 1H, His), 7.77 (d, 2H, Fmoc), 7.59 (d, 2H), 7.40 (m, 5H), 7.23−7.33 (m, 7H), 7.19 (m, 3H), 6.81 (dt, 4H, DMT), 6.42 (br, 1H, NH), 4.40 (m, 3H, His, Fmoc), 4.22 (t, 1H, Fmoc), 3.70 (s, 6H, DMT), 3.71 (m, 3H), 3.48−3.67 (m, 3H), 3.05−3.20 (m, 5H), 2.95 (dd, 1H), 2.53 (q, 2H, CH_2CN), 1.81 (septet, 1H), 1.57 (s, 9H, *t*-BOC), 1.30−1.42 (m, 4H), 1.60 (d, 8H), 1.11 (d, 6H). ^{31}P NMR ($CDCl_3$): δ 148.2 (singlets). Anal. Calcd for $C_{63}H_{77}N_6O_{10}P$: C, 68.21; H, 7.00; N, 7.58. Found: C, 68.33; H, 6.96; N, 7.80.

***N*-(N^{α}-Fmoc-N^{im}-*t*-Boc-L,L-dihistidyl)-6-amino-2-hydroxymethyl-1-hexanol Dimethoxytrityl Ether (9)**. **7** (1.37, 1.5 mmol) was dissolved in 20% (v/v) piperidine in toluene (15 mL) and stirred at 22 °C for 10 min. The reaction mixture was evaporated, azeotroped with toluene (15 mL), dissolved in EtOAc (100 mL), washed with brine (2 × 15 mL), dried, evaporated, and azeotroped with toluene (15 mL) to afford the crude amine **8**. N^{α}-Fmoc-N^{im}-Boc-L-histidine CHA salt (1.13 g, 2.25 mmol) was placed in a separatory funnel containing EtOAc (25 mL) and 5% citric acid (25 mL) and shaken until the salt had fully dissolved. The organic layer was separated, washed with water (25 mL) and brine (25 mL), dried, and evaporated to afford the free acid **5**. This was dissolved in DMF (6.9 mL). DIPEA (1.0 mL) was added, and this solution was added to the residue of the crude free amine **8**. When everything had been dissolved, PyBOP (1.02, 2.25 mmol) was added, and the solution was stirred at 22 °C for 30 min. The reaction mixture was diluted with EtOAc (50 mL), washed with 10% Na_2CO_3 (2 × 50 mL), water (50 mL), and brine (50 mL), dried and evaporated. The residue was flash chromatographed on silica gel (60 g) and eluted with 99:1 to 97.5:2.5 dichloromethane/MeOH to afford 1.35 g (78%) of **9** as a diastereomeric mixture. ^{1}H NMR ($CDCl_3$): 8.53 (br, 0.5H, NH), 8.40 (br, 0.5H), 7.98 (singlets, 1H), 7.76 (m, 3H), 7.59 (m, 3H), 7.13−7.44 (m, 14H), 6.82 (m, 4H), 6.75 (d, 1H), 6.58 (m, 1H), 4.71 (m, 1H, His), 4.26−4.44 (m, 3H), 4.22 (q, 1H, Fmoc), 3.78 (singlets, 6H, DMT), 3.70 (dt, 1H), 3.52−3.64 (m, 2H), 2.97−3.30 (m, 6H), 2.81 (m, 2H), 1.72 (m, 1H), 1.56 (singlets, 18H, *t*-BOC), 1.10−1.45 (m, 6H).

***N*-(N^{α}-Fmoc-N^{im}-*t*-Boc-L, L-dihistidyl)-6-amino-2-(*O*-DMT-hydroxymethyl)-1-hexanol (2-Cyanoethoxy)-*N*,*N*-diisopropylphosphoramidite (13)**. **9** (1.27 g, 1.1 mmol) was dissolved in dichloromethane (11 mL). Tetrazole (93 mg, 1.33 mmol) was added and the mixture was stirred at 22 °C for 20 min. 2-Cyanoethoxy-*N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite (398 mg, 1.32 mmol) was added, and the mixture stirred an additional 10 min at 22 °C. The mixture was filtered and the precipitate washed with EtOAc (10 mL). The combined filtrate and washing were diluted to 70 mL with EtOAc, washed with 10% Na_2CO_3 (2 × 50 mL) and brine (50 mL), dried, evaporated, and azeotroped with toluene. The residue was flash chromatographed on silica gel (40 g) and eluted with 50:50:3 to 30:70:3 hexane/EtOAc/TEA to afford 1.05 g (71%) of **13** as a diastereomeric mixture. ^{1}H NMR ($CDCl_3$): δ 8.28 (br d, 1H), 7.96 (s, 1H), 7.76 (d, 3H), 7.60 (t, 3H), 7.39 (t, 4H), 7.13−7.32 (m, 11H), 6.80 (d, 4H), 6.53 (br d, 1H), 4.69 (m, 1H), 4.35 (m, 3H), 3.22 (dd, 1H), 3.01−3.15 (m, 6H), 2.76 (m, 1H), 2.51 (q, 2H), 1.78 (m, 1H), 1.56 (d, 18H), 1.24−1.36 (m, 6H), 1.12 (doublets, 12H). ^{31}P NMR ($CDCl_3$): δ 148.0 (singlets). ***N*-(N^{α}-TFA-N^{im}-*t*-Boc-L,L-dihistidyl)-6-amino-2-hydroxymethyl-1-hexanol Dimethoxytrityl Ether (11).** *Method 1*. **9** (2.9 g, 2.5 mmol) was dissolved in 20% (v/v) piperidine in toluene (25 mL) and stirred at 22 °C for 10 min. The reaction mixture was evaporated, azeotroped with toluene (15 mL), dissolved in EtOAc (100 mL), washed with brine (2 × 15 mL), dried, evaporated, and azeotroped with toluene (15 mL) to afford the crude amine **10**. The residue was dissolved in dichloromethane (13 mL). Triethylamine (1.8 mL) and ethyl trifluoroacetate (1.5 mL) were added, and the solution was stirred at 22 °C for 16 h. Water (10 mL) was added, and stirring was continued for 1 h. The reaction mixture was diluted with EtOAc (20 mL) and 10% Na_2CO_3 (20 mL). The organic layer was separated, washed with 10% Na_2CO_3 (10 mL) and brine (10 mL), dried, evaporated, and azeotroped with toluene (10 mL). The residue was flash chromatographed on silica gel (90 g) and eluted with 99:1 to 95:5 dichloromethane/MeOH to afford 1.85 g (72%) of **11** as a diastereomeric mixture.

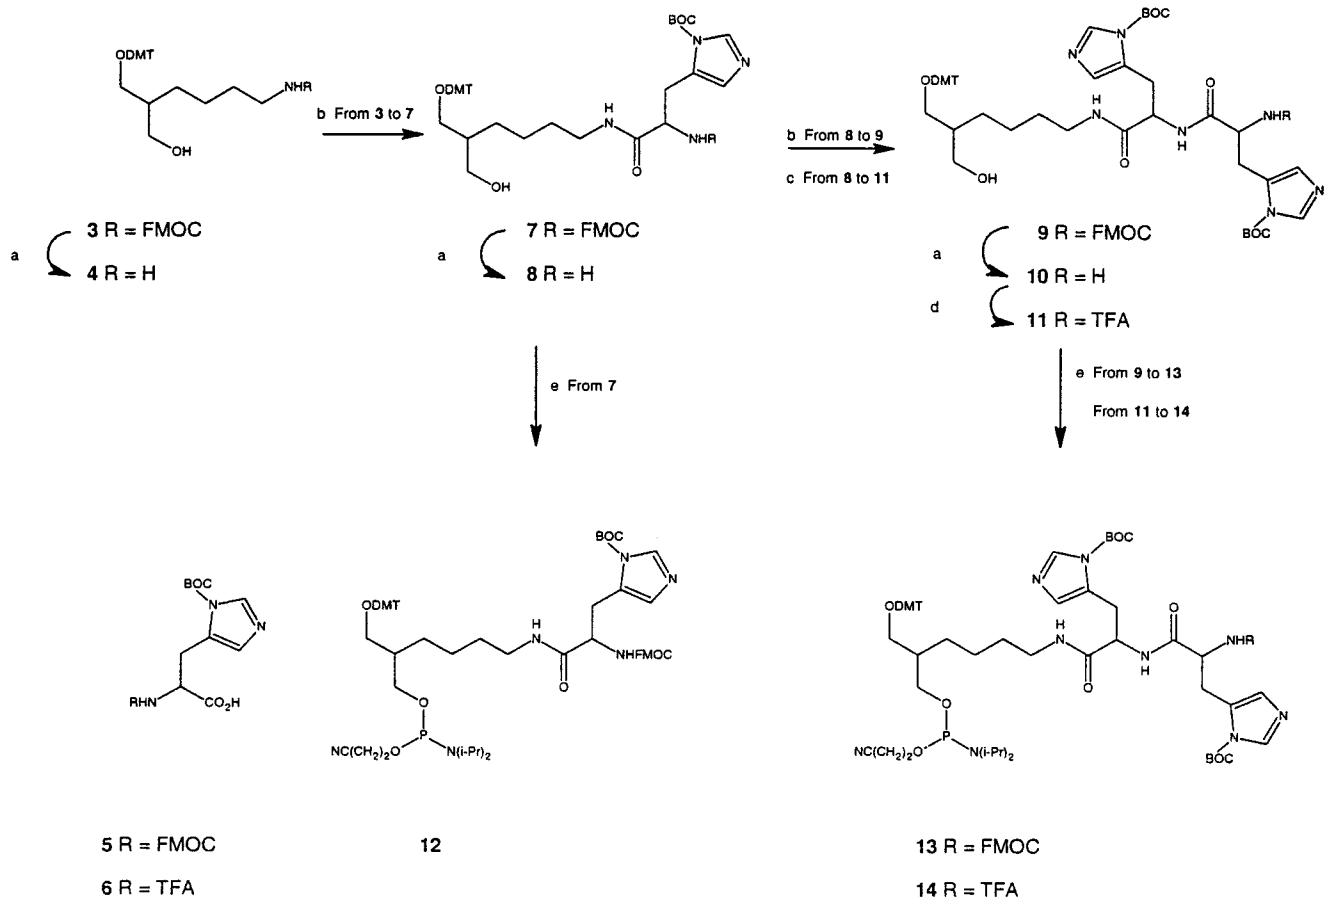
Method 2. **7** (20 g, 22 mmol) was dissolved in 20% (v/v) piperidine in toluene (220 mL) and stirred at 22 °C for 10 min. The reaction mixture was evaporated, azeotroped with toluene (150 mL), dissolved in EtOAc (500 mL), washed with brine (2 × 100 mL), dried, evaporated, and azeotroped with toluene (100 mL) to afford the crude amine **8**. Separately, **6** (9.27 g, 26.4 mmol) was dissolved in 5.5:1 dichloromethane/DMF (130 mL). *N*-Hydroxysuccinimide (NHS) (6.08 g, 52.8 mmol) was added and the mixture was cooled in an ice bath. Dicyclohexylcarbodiimide (DCC) (5.45 g, 26.4 mmol) was added, and the mixture stirred at 0 °C for 15 min. To this mixture was added a solution of **8** (prepared above) in dichloromethane (35 mL). This was stirred at 0 °C for 20 min. DIPEA (9 mL) was added, and stirring at 0 °C was continued for 10 min. The reaction mixture was filtered, and the filtrate concentrated to approximately 100 mL. This was diluted with EtOAc (400 mL) and washed with 10% Na_2CO_3 (2 × 100 mL). The carbonate washings were combined and extracted with EtOAc (200 mL). The organic layers were combined, washed with brine (100 mL), dried, evaporated, and azeotroped with toluene (50 mL). The residue was flash chromatographed on silica gel (1 kg) and eluted with 99:1 to 96:4 dichloromethane/MeOH to afford 16.1 g (72%) of **11** as a diastereomeric mixture. ^{1}H NMR: δ 8.52−8.72 (m, 2H, NH), 7.94 (doublets, 2H, His), 7.47 (br t, 1H, NH), 7.40 (m, 1H), 7.14−7.31 (m, 9H), 6.83 (m, 4H, DMT), 6.74 (d, 1H), 4.66 (m, 2H, His), 3.79 (singlets, 6H, DMT), 3.73 (m, 1H), 3.54−3.64 (m, 2H), 3.00−3.30 (m, 6H), 2.75 (m, 2H), 1.73 (m, 1H), 1.61 (singlets, 18H), 1.12−1.48 (m, 6H).

***N*-(N^{α}-TFA-N^{im}-*t*-Boc-L, L-dihistidyl)-6-amino-2-(*O*-DMT-hydroxymethyl)-1-hexanol (2-Cyanoethoxy)-*N*,*N*-diisopropylphosphoramidite (14).** **11** (14.2 g, 14 mmol) was dissolved in dichloromethane (140 mL). Tetrazole (1.17 g, 16.7 mmol) was added and the mixture stirred at 22 °C for 20 min. 2-Cyanoethoxy-*N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite (5.57 g, 18.5 mmol) was added, and the mixture stirred an additional 10 min at 22 °C. The mixture was filtered and the precipitate washed with EtOAc (100 mL). The combined filtrate and washing were diluted to 600 mL with EtOAc, washed with 10% Na_2CO_3 (2 × 400 mL) and brine (400 mL), dried, evaporated, and azeotroped with toluene. The residue was flash chromatographed on silica gel (500 g) and eluted with 50:50:3 to 30:70:3 hexane/EtOAc/TEA to afford 13.4 g (79%) of **14** as a diastereomeric mixture. ^{1}H NMR ($CDCl_3$): δ 8.57 (s, 1H, NH), 8.50 (d, 1H, NH), 7.94 (s, 1H, His), 7.90 (s, 1H, His), 7.40 (m, 3H), 7.12−7.33 (m, 9H, DMT), 6.80 (dt, 4H, DMT), 4.64 (m, 2H, His), 3.78 (s, 6H, DMT), 3.69 (m, 3H), 3.54 (m, 3H), 3.22 (d, 1H), 3.05 (m, 4H), 2.68 (dd, 1H), 2.52 (q, 2H, CH_2CN), 1.78 (m, 1H), 1.58 (singlets, 18H, *t*-BOC), 1.25−1.35 (m, 6H), 1.12 (singlets, 12H). ^{31}P NMR: δ 148.1 (singlets). Anal. Calcd for $C_{61}H_{81}F_3N_9O_{12}P$: C, 60.04; H, 6.69; N, 10.33. Found: C, 59.81; H, 6.72; N, 10.30.



Oligonucleotide Synthesis. Phosphoramidites were used as 0.1 M solutions in acetonitrile in automated DNA synthesis using an Applied Biosystems 394 DNA/RNA synthesizer according to the manufacturer's suggested DNA synthesis protocols on a 1 μmol scale. Coupling efficiencies were measured by using the dimethoxytrityl cation concentration. Deprotection was accomplished with concentrated ammonium hydroxide at 55 °C for 16 h. Purification was accomplished using OPEC columns (CLONTECH Laboratories, Inc.) according to recommended procedures. Oligonucleotides were analyzed by gel electrophoresis (20% PAGE-denaturing) and ion-exchange HPLC (Mono Q column) and in every case demonstrated single band purity.

Ion-Exchange HPLC Analysis. The 5′-modified $(T)_7$ oligonucleotides **15a**−**c** synthesized from phosphoramidite **14** were analyzed by ion-exchange HPLC on a Pharmacia Mono Q HR 5/5 column (5 mm × 5 cm). The mobile phases employed were A = 50 mM Tris (pH 7.5) and B = 800 mM NaCl, 50 mM Tris (pH 7.5). A gradient of 5−45% B over 40 min at a flow rate of 1 mL/min was used.

RESULTS AND DISCUSSION

Reagent Design. A number of factors need to be taken into consideration in the design of an optimal labeling reagent to permit IMAC purification of DNA fragments. Several methods have been reported for the synthesis of oligonucleotide−peptide conjugates (*9*). However, we sought to avoid approaches which required both peptide and oligonucleotide couplings to prepare the desired conjugate. Therefore, we have designed a reagent which incorporates the peptidelike moiety in a form that can be directly utilized in oligonucleotide synthesis. Since introduction during the standard automated synthesis process without extraneous synthetic operations is clearly desirable, the reagent needs to be in the form of a suitably protected phosphoramidite. The nature of the chemical "backbone" which supports the labeling moiety must also be considered. While a 5′-labeling reagent based on 6-aminohexanol or a similar molecule would probably be suitable for many applications, added flexibility would be attained by a bifunctional scaffold which permitted multiple incorporations. For this purpose, we selected the 2-(4-aminobutyl)-1,3-propanediol backbone (*10*), although structures such as allonic acid (*11*, *12*) and others (*13*, *14*) could be considered. The number of imidazole moieties per reagent molecule is yet another issue. While a hexahistidine fragment is popular, and probably optimal (*5*), for protein purification, it has not been shown that the entire fragment is absolutely necessary. It is also unclear whether the optimal tag for protein purification would be the best choice for nucleic acid applications. Also, the molecular weight of a phosphoramidite reagent incorporating a suitably protected hexahistidine fragment

Scheme 1[a]

[a] Reagents: (a) 20% piperidine in toluene; (b) **5**, PyBOP, HOBt, DMF; (c) **6**, NHS, DCC, DCM; (d) $EtOCOCF_3$, TEA, DCM; (e) $NC(CH_2)_2OP(N(i\text{-}Pr)_2)_2$, tetrazole, DCM.

would be rather high, making its performance on the synthesizer and its cost-effective preparation questionable. The synthesis of a reagent incorporating one imidazole moiety should be fairly straightforward. However, in terms of mimicking the possible importance of consecutive histidines in transition metal coordination, such a reagent would offer no advantage over the method developed by Min and Verdine (*7*). We felt that a dihistidine fragment would best address these issues. The benefit of consecutive histidines is retained, and multiple couplings can be used to achieve the optimal number of histidine residues.

Chemistry. The chemistry utilized to prepare the tagging reagents used in this study is outlined in Scheme 1. A major chemical challenge in this problem is the identification of a suitable method for protection of the imidazole nitrogen. The protection of the imidazole ring has long been problematic in synthetic peptide chemistry (*15*). In addition to meeting the needs of peptide synthesis, suppression of side reactions, and racemization, the desired protecting group in this application must survive the conditions of phosphoramidite and oligonucleotide synthesis and yet be removable under mild conditions, preferably without requiring additional operations, after the completion of oligonucleotide synthesis. After considerable experimentation, *t*-butoxycarbonyl (BOC) was found to meet these criteria and appeared to be the best choice for our purposes. It survives the phosphoramidite and oligonucleotide synthesis conditions, and yet it is readily removed during the standard ammonium hydroxide cleavage and deprotection operation. Other possible protecting groups considered included fluorenylmethoxycarbonyl (Fmoc) and 2,4-dinitrophenyl (DNP) which were found to be too labile, and the trityl series which were either too labile as in the case of dimethoxytrityl or too difficult to remove as in the case of trityl.

The Fmoc group of the 2-(4-aminobutyl)-1,3-propanediol synthon **3** (*9*) was removed with piperidine and the resulting amine **4** coupled to N^{α}-Fmoc-N^{im}-Boc-L-His **(*5*)** via the BOP/HOBT procedure to afford **7** in 71% yield. Phosphitylation of this material with 2-cyanoethoxy-*N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite and tetrazole afforded the monoHis reagent **12** in 78% yield. **7** also serves as an intermediate in the preparation of the diHis reagents. Piperidine treatment to provide **8** followed by BOP-mediated coupling of **5** afforded **9** in 78% yield. Phosphitylation of **9** provided the diHis reagent **13**. Occasionally, we have observed instability with Fmoc-protected alkylamino oligonucleotide synthesis reagents. Such problems can be avoided by the use of N-trifluoroacetyl protection. Therefore, we designed **14**, the N-TFA protected version of the diHis reagent **13**. Exchange of the protecting group of **9** was readily achieved via piperidine Fmoc cleavage followed by reaction of the resulting amine **10** with ethyl trifluoroacetate to afford **11**. Phosphitylation of **11** provided the desired N-TFA-protected diHis reagent **14**. Alternatively, **11** can be obtained in good yield via NHS/DCC mediated coupling of **6** with **8**. The preparation of the protected histidine **6** was straightforward, involving sequential reaction of histidine with ethyl trifluoroacetate followed by di-*t*-butyl dicarbonate. The BOP-mediated coupling, which was successful with **5**, failed using **6** as substrate resulting in extensive racemization. This is not particularly sur-

Table 1. Summary of Ion-Exchange HPLC and MALDI-TOF Mass Spectroscopy Results

oligonucleotide	HPLC retention time (min)	mol. wt. calcd	mol. wt. actual
$(T)_7$	22.8		
15a	19.8	2549.9	2547.7
15b	20.5	3033.4	3032.2
15c	21.3	3516.9	3515.8

prising in view of the known propensity of TFA-protected amino acids to undergo racemization during coupling (*15*). Racemization when using **6** as a substrate was suppressed by utilizing the NHS/DCC coupling procedure.

Oligonucleotide Synthesis. Phosphoramidites **12**−**14** were successfully employed in automated DNA synthesis using a commercial instrument under standard conditions. The performance of the diHis reagents **13** and **14** was equivalent, and subsequent experiments were carried out with the more stable TFA-protected reagent **14**. A series of modified $(T)_7$ oligonucleotides **15a**−**c** were prepared incorporating 1, 2, or 3 additions of **14,** respectively, at the 5′-terminus. These oligos were assayed for purity by ion-exchange HPLC, and their identities confirmed by MALDI-TOF mass spectroscopy. These results are summarized in Table 1. Also prepared using **14** was a series, **16a**−**c**, of longer, 24-mer, mixed oligonucleotides incorporating 1, 2, and 3 additions of **14**. These syntheses also proceeded without incident. While the size of these molecules precluded acquisition of mass spectral data, the resulting oligonucleotides were analyzed by PAGE (Figure 2). This analysis demonstrates the effect of the introduction of multiple histidine residues on oligonucleotide gel mobility. Also demonstrated is the high efficiency with which dihistidyl residues can be incorporated into oligonucleotides with **14**.

IMAC Retention. The retention of the "His-tagged" oligonucleotides **16a**−**c** by a common IMAC matrix, Ni-IDA (iminodiacetic acid), was investigated, and the results were outlined in Figure 3. Samples were applied in denaturing phosphate buffer (pH 8), and the absorbed

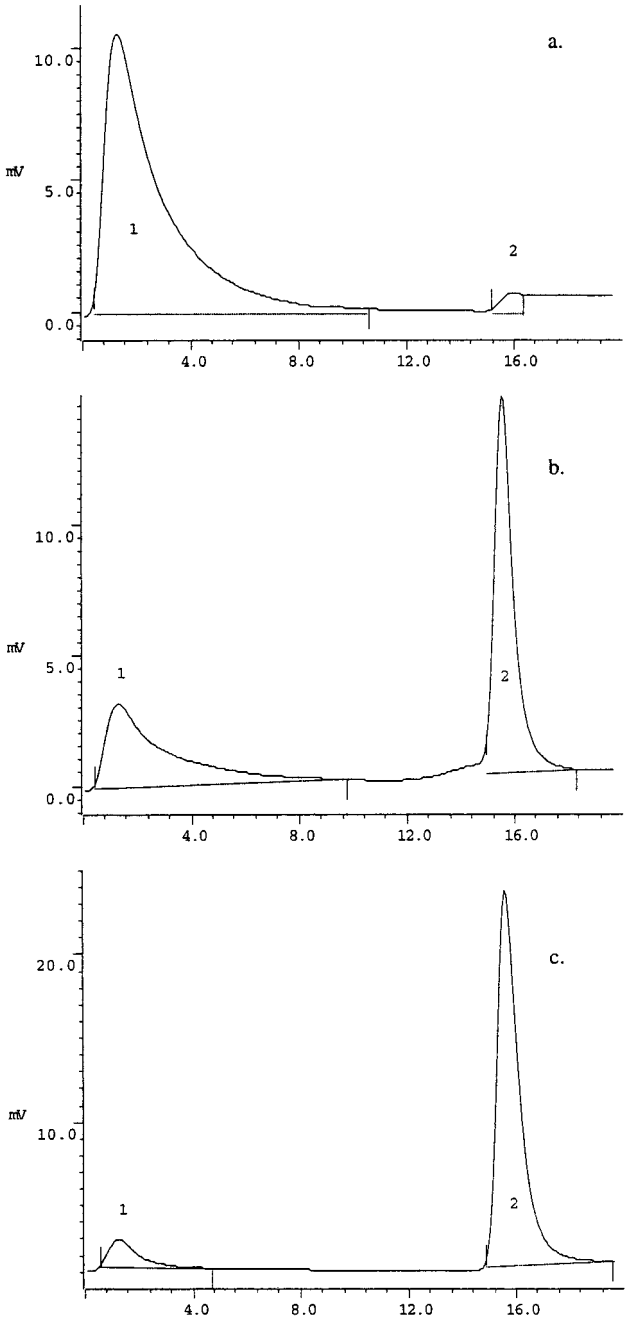

Figure 3. IMAC of 2-, 4-, and 6-His-Oligos (24-mer) (Figure 1) on Ni^{2+}-IDA-Superflow 6. Approximately 1.0 AU (254 nm) was loaded ona 5 × 1 cm.i.d. column packed with IDA-Superflow 6, charged with Ni^{2+} ions and equilibrated with 50 mM sodium phosphate; 0.25 M NaCl; 8.0 M Urea, pH 8.0, at a flow rate of 1 mL/min. The nonadsorbed material was washed out with the equilibration buffer and the adsorbed material was eluted with 150 mM imidazole in the equilibration buffer. a. 2-His-Oligo (24-mer) **16a**. b. 4-His-Oligo (24-mer) **16b**. c. 6-His-Oligo (24-mer) **16c**.

material eluted with 150 mM imidazole. Under these conditions, IMAC retentivity increased with increasing numbers of imidazole residues. Very little of oligonucleotide **16a**, with two His residues, was retained by the matrix while almost all of **16c**, with six His residues, was retained.

Summary. Synthesis of a bifunctional reagent for the incorporation of dihistidyl residues into oligonucleotides has been reported. Any number of dihistidyl residues can be incorporated at any position in the oligonucleotide. Preliminary experiments indicate feasibility of modifying

oligonucleotides with this reagent to permit their purification by IMAC methods. Histidine- or imidazole-containing oligonucleotides are also of interest as artificial nucleases due to the ability of imidazole rings to complex metal ions and cleave nucleic acid chains (*1*, *2*). The reagents reported herein provide a convenient and flexible way to introduce imidazole moieties into oligonucleotides.

Lipid conjugates of oligo-(14-amino-3,6,9,12-tetraoxatetradecanoic acid) (ATTA*n*) were synthesized as monodisperse analogues of poly(ethylene glycol) (PEG) derivatives used in liposomal drug delivery systems. The new lipids were shown to be at least equivalent to MePEGA-2000-DSPE in assays designed to evaluate the effectiveness of polymers as steric barrier molecules in liposomes. Liposomes containing 1−5% of ATTA8−DSPE (octamer) showed comparable long circulation behavior relative to PEG-2000-DSPE analogues. Surprisingly, the shorter ATTA4−DSPE (tetramer) appeared to be quite effective in reducing clearance. Liver enzyme levels and systemic single dose tolerability of ATTA8−DSPE liposomes were comparable to controls, suggesting that the new materials are nontoxic. Prolonged exposure of ATTA8−DSPE liposomes to splenocytes in vitro showed no evidence of mitogenicity relative to controls or MePEGA-2000-DSPE liposomes. ATTA8−DSPE was as effective as MePEGC-2000-DSPE in preventing complement activation by cationic liposome systems. Repeat dosage in vivo regimes in ICR mice using DSPC/cholesterol liposomes, with and without 5% ATTA8−DSPE and MePEGC-2000-DSPE, showed no evidence of enhanced clearance on successive doses. Splenocytes recovered after repeat doses showed no significant evidence of mitogenicity on restimulation with liposomes. Cellular differentiation and activation marker levels in splenocytes recovered after the fourth in vivo administration were at normal levels. These results suggest that ATTA*n* oligomers do not induce an immune response in isolation. It was demonstrated that ATTA8−DSPE could be used to replace PEG−lipids in the formulation of doxorubicin, plasmid DNA and oligonucleotides using a variety of formulation techniques. The study demonstrates that ATTA*n* oligomers can be safely and effectively used in place of poly(ethylene glycol) as well-defined biomaterials in liposomal applications where reproducible behavior is critical.

INTRODUCTION

Liposomes are currently being developed as drug delivery vehicles for a wide range of pharmaceutically active materials. These include conventional drugs, such as doxorubicin or vincristine, and genetic drugs, such as plasmid DNA or antisense molecules. In many cases, these formulations suffer from aggregation phenomena or rapid clearance in vivo. Poly(ethylene glycol) (PEG) lipid conjugates have been widely used to address some of these issues (*1*, *2*). Incorporation of small amounts of nonexchangeable PEG−lipids into bilayers has a marked effect on the clearance behavior of liposomes. This is believed to be due to a steric barrier effect on the part of the PEG molecules, which results in inhibition of adsorption of proteins to the membrane surface (*3*) and interactions with cells responsible for clearance in vivo (*4*, *5*). Other important applications of PEG−lipids in liposomes include the prevention of cross-linking when conjugating or adsorbing polyvalent entities, such as proteins (*6*) or nucleic acids (*7*), to vesicle surfaces and for attaching targeting vectors, such as proteins (*8*), peptides (*9*), oligosaccharides (*10*), and vitamins (*11*).

We are currently developing liposome drug delivery systems which depend on regulated exchange of PEG−lipids to reveal functional surfaces over time (*7*, *12*−*14*). Liposomes need to be able to release their contents either at the disease site or after cellular uptake in order to be effective as delivery vehicles. In the latter case, we are particularly interested in fusogenic liposomes which are capable of delivering their payloads into the cytoplasm. Much of our recent work has focused on plasmid DNA or antisense oligonucleotides, but similar strategies are also potentially useful for conventional drugs. These fusogenic systems, however, are typically cleared very rapidly in vivo and do not have time to accumulate at many tissue types of therapeutic interest. To address the problem, we include exchangeable PEG−lipids in these formulations that allow reasonable circulation lifetimes but which exchange out of the liposomes after accumulation in the disease tissue, thus allowing the fusogenic systems to function as designed. The PEG−lipids inhibit fusogenic activity and must be removed from the surface to restore functionality. Control of the PEG−lipid exchange process in these dynamic systems is therefore very important.

A major limitation of PEG is the fact that it is comprised of a set of oligomers with a wide range of molecular masses. The exchangeability and steric properties of PEG−lipids are dependent on the length of the PEG group; therefore, it is important that the polydispersity and size distribution be as narrow as possible so as to ensure that the pharmaceutical properties of PEGylated liposomal formulations are consistent. Most

commercially available PEG has wide polydispersity and is available only in a few average molecular masses. Polydispersity generally results in the oligomer distribution being skewed to lower molecular masses. These factors make it difficult to determine the structural requirements of PEG−lipids for optimal liposome performance, particularly in applications where complete exchange of the PEG−lipid is required since residual low molecular mass oligomers are likely to exchange significantly more slowly than the mean. An additional problem relates to the inherent variability in the average molecular mass of each batch of polymer; for example, commercial PEG-2000 has been shown to comprise of a mixture of oligomers, of which 67% falls in the range 1600−2400 Da (*1*). The remaining material falls outside of this molecular mass range, most likely primarily at the lower end. This is an undesirable characteristic when trying to develop a reproducible pharmaceutical product based on our technology.−

We have recently developed a set of polyamide oligomers based on 14-amino-3,6,9,12-tetraoxatetradecanoic acid (ATTA*n*)[1] to address these issues (*15*). These compounds were designed to mimic the activity of PEG in liposomal formulations as well as in other applications. Our intent was to devise a process whereby we could rapidly generate a library of well-defined PEG mimics that might or might not incorporate additional functionality as the need arose. Since these compounds are not polymers, they can be used as tools (when suitably labeled) to determine the performance characteristics required to optimize a particular liposome application and will not cause batch variations when used in our applications.

This work describes the synthesis of some ATTA*n* lipid conjugates and evaluates their application in simple liposomal systems in comparison to existing PEG analogues. This was important since we first had to show that ATTA*n* was equivalent to PEG in current applications before we could develop more sophisticated applications based on ATTA*n*. Consequently, we have demonstrated that these new lipid conjugates are at least as effective as PEG−lipids as steric barrier molecules and could be used to replace PEG−lipids in current liposome based drug formulations. The toxicity and immunogenicity of ATTA*n*−lipid conjugates in liposomes is obviously critical. We show that these lipids do not induce an appreciable immune response, and do not cause any discernible gross toxicity.

EXPERIMENTAL METHODS

General. MePEGA-2000-DSPE (*16*) and **2**, **20**, and **25** (*15*) were synthesized as previously described. All reagents were obtained from Sigma-Aldrich, except for phospholipids (Northern Lipids, Vancouver); MePEGC-2000-DSPE (Avanti Polar Lipids, Alabaster); and Picogreen (Molecular Probes). AL-1 was purchased as the free base from Avanti (DODAP) and converted to the hydrochloride salt by a series of hydrochloric acid/saline washes. MePEGS-2000-Mcer and DODAC were obtained from Inex Pharmaceuticals Corp., Vancouver. [^{3}H]Cholesterylhexadecyl ether was obtained from NEN, Boston. Female Balb/c and ICR mice (6−8 weeks old) were obtained from Harlan Sprague Dewley (Indianopolis). Mice were provided food and water ad libidum. All studies involving animals were conducted in accordance with the guidelines established by the Canadian Council on Animal Care (CCAC).

***N*-(*ω*-Azido-tetra-(14′-amino-3′,6′,9′,12′-tetraoxatetradecanoyl))-1,2-distearoyl-sn-3-phosphoethanolamine 1.** Compound **1** was synthesized from **25** using the procedure described previously for **2** (*15*). Isolated as a colorless powder after lyophilization. ^{1}H NMR ($CDCl_3$): δ 5.17 (bs, 1H), 4.33 (dd, 1H), 4.12 (dd, 1H), 3.8−4.05 (m, 12H), 3.4−3.8 (m, 64H), 3.35 (t, J = 5 Hz, 2H), 2.26 (m, 4H), 1.55 (bs, 4H), 1.22 (s, 56H), 0.85 (t, J = 7.5 Hz, 6H).

Synthesis of Dimyristylamine 23. A solution of myristic acid (5 g) in benzene (40 mL) was treated with oxalyl chloride (2.5 mL) for 2 h. The solvent was removed on a rotovap and the residue dissolved in benzene (20 mL). A solution of tetradecylamine **21** (2.5 g) in benzene was added. The solution was warmed to 60 °C, stirred and treated with Et_3N (1 mL, slow addition). The reaction mixture was then allowed to stir at room-temperature overnight. The suspension was diluted with water, acidified and extracted with methylene chloride. The organic phase was dried over magnesium sulfate and the solvent removed under vacuum. The residue was passed down a silica gel column in order to remove any unreacted **21**, yielding **22** (2 g) as a colorless solid. The product was suspended in ether and treated with excess $LiAlH_4$ (added slowly until vigorous evolution of gas ceased). The mixture was stirred at room temperature for 1 h. Methanol was then slowly added, followed by water and finally enough dilute hydrochloric acid to acidify the mixture. The suspension was extracted with methylene chloride (the precipitate suspends in the organic phase) and the combined organic phases washed with aqueous sodium hydroxide. Column chromatography yielded **23** as a white powder (1.86 g). ^{1}H NMR ($CDCl_3$): δ 2.55 (t, J = 7.1 Hz, 6H), 1.45 (m, 4H), 1.23 (s, 44H), 0.85 (t, J = 6.7 Hz, 6H). Anal. ($C_{28}H_{58}N$) calcd: C; H; N, 14.30. Found: C; H; N, 13.72.

Synthesis of *N*-(*ω*-azido-octa-(14′-amino-3′,6′,9′,12′-tetraoxatetradecanoyl))-dimyristylamine 3. A solution of **20** (1.04 g) in methylene chloride (20 mL) was treated with NHS (0.10 g) and DCC (0.12 g) at room temprature for 1 h. The solution was filtered and added to a solution of **23** (0.30 g) in methylene chloride (20 mL). Triethylamine (10 drops) was added and the reaction mixture allowed to stir for half an hour. The solution was then washed with dilute hydrochloric acid. The combined organic fractions were dried under vacuum and the residue redissolved in water, filtered, and extracted with methylene chloride. Column chromatography yielded **3** as a colorless oil (0.62 g). ^{1}H NMR ($CDCl_3$): δ 7.2 (bs, ∼7H), 4.16 (s, 2H), 3.98 (s, 14H), 3.1−3.7 (m, 132H), 2.2 (bm, 10H), 1.49 (bs, 4H), 1.23 (s, 44H), 0.85 (t, J = 6.4 Hz, 6H). Anal. ($C_{108}H_{209}O_{40}N_{11}$) calcd: C, 56.35; H; N. Found: C, 55.43; H; N.

Dipalmitylamine 24. Compound **24** was synthesized from hexadecylamine using the method described for **23**. Isolated as a white powder. ^{1}H NMR ($CDCl_3$): δ 2.57 (t, J = 7.1 Hz, 6H), 1.47 (m, 4H), 1.23 (s, 52H), 0.86 (t, J =

Synthesis of rac-3-(*N*-BOC)-aminopropan-1,2-diol 13. *rac*-Glycidol **11** (15 g) was treated with concentrated ammonia (150 mL) overnight. The solvent was removed on a rotovap, and the residue dried by azeotropic removal of water using ethanol. A solution of the residue in ethanol was treated with *tert*-butoxypyrocarbonate (35 g) and thriethylamine (20 mL) for 4 h at room temperature. Workup followed by column chromatography yielded **13** as a colorless oil which slowly crystallized on standing. The resultant solid was dried under vacuum, yielding **13** as a colorless crystalline solid (22 g). ^{1}H NMR ($CDCl_3$): δ 5.39 (m, 1H), 4.08 (m, 1H), 3.94 (m, 1H), 3.70 (m, 1H), 3.52 (m, 2H), 3.17 (m, 2H), 1.40 (s, 9H).

Synthesis of *N*-*tert*-butoxycarbonyl-1,2-*rac*-dimyristoyloxypropyl-3-amine 14. A suspension of myristic acid (3.0 g) in benzene (50 mL) was treated with oxalyl chloride (1 mL), with occasional warming, until all of the solid was dissolved and gas evolution had largely ceased. The solvent and excess oxalyl chloride was removed on a rotovap. The residue was dissolved in benzene (50 mL) and treated with **13** (0.86 g), followed by triethylamine (1 mL). The mixture was then allowed to stir at room-temperature overnight. Workup, followed by column chromatography, yielded **14** (1.38 g) as a colorless powder. ^{1}H NMR ($CDCl_3$): δ 5.07 (m, 1H), 4.73 (m, 1H), 4.25 (dd, J = 4.1 Hz, J' = 11.9 Hz, 1H), 4.10 (dd, J = 5.7 Hz, J' = 11.9 Hz, 1H), 3.33 (bs, 2H), 2.29 (t, J = 7.3 Hz, 4H), 1.59 (bm, 4H), 1.42 (s, 9H), 1.24 (s, 44H), 0.86 (t, J = 6.5 Hz, 6H). Anal. ($C_{36}H_{69}O_6N$) calcd: C; H, 11.37; N. Found: C; H, 11.78; N.

***N*-*tert*-butoxycarbonyl-1,2-*rac*-dipalmitoyloxypropyl-3-amine 15**. A colorless powder (1.06 g) synthesized as for **14** from palmitic acid (3.28 g). ^{1}H NMR ($CDCl_3$): δ 5.07 (m, 1H), 4.73 (m, 1H), 4.25 (dd, J = 4.1 Hz, J' = 11.9 Hz, 1H), 4.10 (dd, J = 5.7 Hz, J' = 11.9 Hz, 1H), 3.33 (bs, 2H), 2.29 (t, J = 7.3 Hz, 4H), 1.59 (bm, 4H), 1.42 (s, 9H), 1.24 (s, 48H), 0.86 (t, J = 6.5 Hz, 6H). Anal. ($C_{40}H_{77}O_6N$) calcd: C; H, 11.62; N. Found: C; H, 12.07; N.

***N*-*tert*-butoxycarbonyl-1,2-*rac*-distearoyloxypropyl-3-amine 16**. A colorless powder (1.38 g) synthesized as for **14** from stearic acid (3.00 g). ^{1}H NMR ($CDCl_3$): δ 5.06 (m, 1H), 4.72 (m, 1H), 4.25 (dd, J = 4.1 Hz, J' = 11.9 Hz, 1H), 4.09 (dd, J = 5.6 Hz, J' = 11.9 Hz, 1H), 3.32 (bs, 2H), 2.28 (t, J = 7.4 Hz, 4H), 1.58 (bm, 4H), 1.41 (s, 9H), 1.24 (s, 56H), 0.85 (t, J = 6.5 Hz, 6H). ***N*-(*ω*-azido-octa-(14′-amino-3′,6′,9′,12′-tetraoxatetradecanoyl))-*rac*-1′,2′-distearoyloxypropyl-3-amine 7**. Compound **7** was synthesized from **19** (0.43 g, 0.113 g of NHS, 0.133 g of DCC, 1.07 g of **20**) in the same way as **5**, yielding **7** as a colorless wax (0.80 g). ^{1}H NMR ($CDCl_3$): δ 5.10 (m, 1H), 4.20 (dd, J = 3.4 Hz, J' = 12 Hz, 1H), 4.08 (dd, partially hidden, J = 6.0 Hz, J' = 12 Hz, 1H), 3.98 (s, 16H), 3.2−3.8 (m, 130H), 2.28 (t, J = 7.5 Hz, 4H), 1.57 (m, 4H), 1.22 (s, 56H), 0.85 (t, J = 6.5 Hz, 6H). Anal. ($C_{129}H_{227}O_{44}N_{11}$) C; H; N.

Preparation of Liposomes. Unless otherwise specified, liposomes were prepared as described by Hope et al. (*17*). Briefly, lipid mixtures of the appropriate composition were dissolved in chloroform and concentrated to a homogeneous film under a nitrogen stream in a warm water bath. The film was then dried overnight on a lyophilizer. The dried lipid was hydrated in HBS and extruded through stacked polycarbonate 100 nm filters (Nucleopore) using a previously dried extrusion press device (Lipex Biomembranes, Inc., Vancouver, Canada) at room temperature. The filters were inspected after extrusion to ensure that all of the lipid was in the liposome solution. Lipid concentrations were assumed by extrapolation from the original mass of lipid and volume of buffer.

In Vivo Immunogenicity. Female Balb/c mice (6−10 weeks old, 12 per group) were injected intravenously (i.v.) with 200 μL of 5 mM lipids [HBS control; DSPC/chol (55:45); DSPE/chol/MePEGA-2000-DSPE (50:14:5); DSPC/chol/ATTA8−DSPE (50:45:5)]. Four injections were given (at intervals of 7 days) over a period of 3 weeks. A group of mice injected with 200 μL of diluent over the course of administration served as a baseline control. Three mice from each group were sacrificed 24 h after each lipid administration. Spleens were harvested and assayed for lipid-specific clonal expansion (mitogenicity assay below) and cytokine release (ELISA assay below). The phenotypic profiles of the recovered cells were analyzed by measuring the expression of differentiation (CD22, CD4, CD8, and CD11b) and activation (CD25, CD54, CD86, Ly6A/E, MHC−II) markers. Spleen cells (1×10^6) were stained with appropriate PE-conjugated antibodies (PharMingen, CA), and phenotypic analysis was performed on a FACSsort flow cytometer (Becton Dickinson, CA).

Mitogenicity Assay. The mitogenicity of liposomes was evaluated by measuring the cellular immune response following stimulation of primary immune cells in vitro. Splenocytes from 8 week old Balb/c untreated mice

were used in the cell proliferation assay. Splenocytes were tested for their ability to proliferate upon in vitro stimulation with liposomes or with polyclonal activators for T (Concanavalin A; Con A) and B cells (Lipopolysaccharide, LPS). Single-cell suspensions of lymphocytes were prepared from whole spleens in complete RPMI medium, supplemented with 5% heat-inactivated fetal bovine serum (FBS). Viability of cells was examined by trypan blue dye exclusion and exceeded 95% viability. Cells were counted on a Coulter Counter and were adjusted to a density of 5×10^6/mL. Volumes 100 μL of the cell suspensions were placed into triplicate flat-bottom wells of 96-well plates along with equal volumes of the appropriate liposomes. Cells were labeled with 1 μCi/well of [^{3}H]thymidine for 48 h after incubation for 3 days with the test solutions (37 °C, 5% CO_2). Cells were harvested on glass filters (Skatron harvester) and levels of incorporated radioactivity were measured in a beta scintillation counter (Beckman, LS 6500). Appropriate controls (mitogens or medium alone) were set up on each plate.

Cytokine ELISA Assays. Splenocytes (1×10^6 cells/mL) were cultured in either the presence or the absence of various concentrations of lipids in 24-well plates. The supernatants were collected at different times after culture initiation (24 and 48 h), and the levels of cytokine release (Interleukin-2 and Interleukin-4) were determined by ELISA assays using antibodies provided by reagent mini-kit from Endogen (Endogen, MA.). Briefly, 96-well Immulon II plates were coated overnight with anti-IL-2 or anti-IL-4 antibody. Plates were washed with PBS-Tween 20 (0.05%) and blocked with PBS/BSA (2%) for 1 h at room temperature. Supernatant samples and standards (diluted in blocking buffer), were added and allowed to incubate overnight. Plates were washed and biotinylated anti-IL-2, or anti-IL-4 antibody, was added. After 2 h of incubation, the plates were washed, and HRP-extravidin, followed by TMB, was added to each well. Plates were read at OD_{450}. The amount of cytokine was determined by comparing the OD of test supernatants to a standard curve constructed from OD of serially diluted cytokine standards.

Complement Activation Assay. Activation of the complement system by cationic lipid vesicles was assessed using a two step complement consumption assay as previously described (*18*, *19*). Briefly, liposomes containing various SBL were prepared in VBS (20 mM, pH 7.50) and extruded through two stacked 100 nm polycarbonate filters using an extrusion apparatus (Lipex Biomembranes, Vancouver, Canada). Serial dilutions of the lipid vesicles (100 μL aliquoted volume) were added to an equal volume of 5×-diluted normal human serum and incubated for 30 min at 37 °C. Samples were subsequently diluted with 300 μL of ice-cold DGVB2+. Aliquots (100 μL) were incubated with an equal volume of hemolysin-sensitized sheep red blood cells (2×10^7 cells) for 30 min at 37 °C. At the end of the incubation, EDTA-GVB (1 mL) was added to the sample to inhibit further complement activity. Samples were centrifuged at 1500 rpm for 5 min at 4 °C to remove cells. The supernatant was then analyzed for hemoglobin content at 410 nm using a 96-well plate reader. All samples and reagents were maintained at 4 °C throughout the assay procedure unless otherwise noted. Hemolysin-sensitized sheep erythrocyte target cells and normal human serum pool, prepared from the blood of 10 healthy male and 10 healtlthy female donors, were prepared as previously described (*18*).

In Vitro Cytotoxicity. Various cell lines (all obtained from ATCC) were grown as monolayer cultures in T-75 flasks. The cells were subcultured twice a week at 37 °C in an atmosphere containing 5% CO_2 and maintained at a low passage number (5−10). The cells used in the assay were plated at 1×10^4 cells/well (inoculation volume, 100 μL/well) and left for 24 h at 37 °C to resume exponential growth. An equal volume (100 μL) of either complete culture medium (control wells) or test solution containing twice the final ATTA8 concentration diluted to volume with complete culture medium was added 24 h later. Final ATTA8 concentrations ranged from between 5 and 1000 μM. Eight replicate wells for each test concentration were used. Cytotoxicity was evaluated 24 h later by means of the Crystal Violet assay (*20*). Data were expressed as a percentage of control optical density.

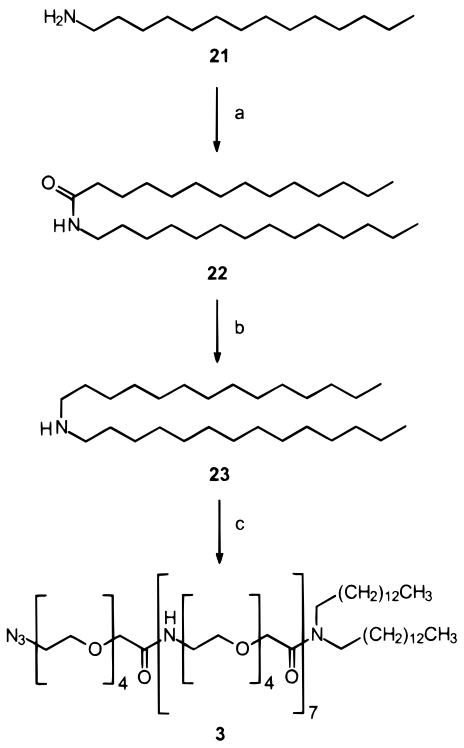
In Vivo Tolerability of Polymer Modified Cationic Liposomes. Female, ICR mice, 6−8 weeks old, were used for tolerability studies. Each time group consisted of at least 4 mice. The plasma circulation levels of DSPC:CHOL:AL-1:ATTA8−DSPE (20:45:25:10) and DSPC:CHOL:AL-1:MePEGS-2000-Mcer (20:45:25:10) liposomes (prepared as described for in the *antisense formulation* section) containing a radiolabeled lipid marker, [^{3}H]cholesterylhexadecyl ether, were evaluated at 24 h post administration. Mice received a single bolus dose of liposomes up to 750 mg/kg via intravenous administration in the lateral tail vein. At 24 h, mice were anesthetized with halothane and blood was collected into EDTA tubes after cardiac puncture. Mice were then terminated by cervical dislocation. Plasma levels of lipid were determined by standard liquid scintillation techniques. Plasma volumes were estimated to be 5% of total body weight. Tolerability of increasing doses of DSPC:CHOL:AL-1:ATTA8−DSPE (20:45:25:10) and DSPC:CHOL:AL-1:MePEGS-2000-Mcer (20:45:25:10) was evaluated by monitoring changes in tissue weights and enzymes typically associated with liver damage. At 24 h postinjection, tissues were excised, trimmed of fat, and weighed on an analytical balance. An aliquot of the collected blood was placed in a serum tube and allowed to clot for 30 min at room temperature, and the serum was assayed kinetically for alanine aminotransferase (ALT), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) using a Vitros DT60II analyzer with a DTSCII module (Johnson & Johnson).

Encapsulation of Doxorubicin. Liposomes (25 mM) were prepared in citrate buffer (300 mM citric acid, pH 4.0). Aliquots (100 μL) were added to sodium citrate buffer (300 mM sodium citrate, pH 8.0; 356 μL). An aliquot (43.5 μL) from a stock solution of doxorubicin hydrochloride (10.0 mg/mL) was immediately added. Aliquots (10 μL) of potassium hydroxide solution (1 N) were added until the red color turned purple. The solutions were then warmed in a water bath at 60 °C for a few minutes with occasional shaking until the solutions turned dark red. The liposome suspensions were immediately passed down Sephadex G-50 columns (HBS, pH 7.4) to exchange buffer and remove any external doxorubicin. Doxorubicin content was assayed at 480 nm against a standard curve after lysis in 1% (net) Triton X-100. Lipid content was determined using a phosphate assay as previously described (*21*).

Picogreen Assay. A picogreen working solution was prepared by diluting 1 μL of stock solution/mL of HBS. A DNA standard solution was prepared at 20μg/mL in water. DNA standards (0−50 μL) and lipid/DNA samples (3 μL) were added to tubes. Picogreen working solution (3 mL) was added to each tube and the fluorescence

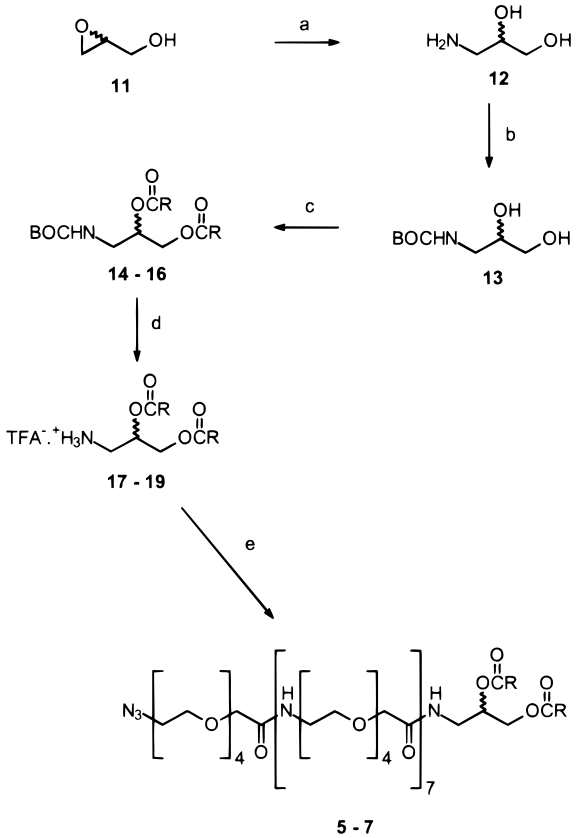
recorded (T_0) at 520 nm using excitation at 480 nm. Triton X-100 (10%, 30 μL) was then added, and the flourescence recorded again (T_f). Entrapped DNA was calculated using the standard curve or with the equation %DNA trapped = $100(1 - T_0/T_f)$.

Antisense Formulation. A stock solution of lipid (DSPC/chol/AL-1/SBL, 20:45:25:10 mol ratio, 13 μmol of total lipid) in ethanol (0.4 mL) was slowly added to a solution of 22 mer c-myc antisense DNA (0.6 mL, 2 mg/mL in citrate buffer, 300 mM, pH 4) at 65 °C with constant vortexing. The mixture was extruded through two 100 nm filters at 65 °C as described above. The liposomes were dialyzed (3500 MW cutoff SpectraPor membrane) against citrate buffer (300 mM citrate, pH 4.0, 4000 mL) for 1−2 h against HBS (pH 7.4, 4000 mL) overnight and then passed down a DEAE Sepharose CL-6B column (3 mL in HBS). The lipid content was analyzed by HPLC. Antisense DNA content was determined after dispersion in water/chloroform/methanol (10 μL of sample in 250 μL of water, followed by addition of 750 μL of 2:1 chloroform/methanol and 100 μL of methanol) at 260 nm using the equation [DNA] (mg/mL) = A_{260}/29.6. Vesicle sizes were determined using a Nicomp model 370 particle sizer. The formulation was scaled up on a proportional basis when larger quantities were required.



RESULTS AND DISCUSSION

Chemistry. The ATTA*n* oligomers (n = 4, 8) used to prepare the lipid conjugates in this study were synthesized as described elsewhere (*15*). The ethyl protecting group of ATTA*n* was deprotected by mild alkaline hydrolysis followed by acidification and extraction of the acid. It was necessary to ensure that the pH did not drop below 2 during the extraction step, since the amide bonds become protonated under very low pH conditions and the oligomer becomes too hydrophilic to extract into organic phases. The crude free acid was activated with DCC/NHS and conjugated to various amino lipids using procedures similar to those used in the preparation of PEG−lipids (*16*). The amino lipids included phosphatidylethanolamines (DSPE), dialkylamines (**23** and **24**), and 2,3-diacyloxypropylamines (**17**, **18**, and **19**).



The dialkylamines were synthesized by acylating a primary alkylamine with the corresponding acyl chloride, followed by reduction with $LiAlH_4$ (Scheme 1). This procedure worked reasonably well in the synthesis of **23** and **24**, provided that any residual primary amine was removed prior to the reduction step. Difficulties were experienced when trying to prepare the C-18 analogue distearylamine. These appeared to stem primarily from the limited solubility of the saturated C-18 intermediates under the reaction conditions used. The problem can be solved by synthesizing dioleylamine instead and then hydrogenating it, either before or after conjugation to the ATTA*n* oligomer.

Compounds **17**−**19** were synthesized as shown in Scheme 2. Glycidol was ring opened using aqueous ammonia. Removal of water followed by BOC protection of **12** and column chromatography yielded the common precursor **13** in reasonable yield. The work was conducted using *rac*-glycidol, but we have prepared the R and S isomers as well since the relevant glycidol precursors are readily available from commercial sources. **13** was acylated with the appropriate acid chlorides and deprotected using neat TFA. The TFA salts had low solubility in most organic solvents at room temperature and could be purified easily by recrystalization. The amine should be stored as the salt form since the free base readily rearranges to the N-acyl analogue.

Formulation Characteristics. We attempted to formulate the ATTA*n*−lipid derivatives in liposomes either

by inclusion in the lipid mixture prior to vesicle preparation or by exchange into preformed vesicles. Previous studies (*22*) have shown that PEG−lipid micelles undergo almost complete inclusion at subsaturation concentrations in vesicles at temperatures above the membrane phase transition after 1 h. The obvious advantage to the exchange approach is the short preparation time required to make a range of liposomes with various "steric barrier lipid" (SBL) concentrations. In addition, parameters such as vesicle size and lipid composition can be kept constant in this type of experiment. Experiments were also conducted using liposomes prepared with the polymer−lipid included prior to hydration. Incorporation before preparation results in vesicles with polymer associated with both leaflets whereas exchange results in association with the outer leaflet only. Obviously, this difference may cause problems at high polymer concentrations due to the induced asymmetry of the bilayer, however, these effects are likely to be minimal at the polymer−lipid levels used in most applications.

In practice the exchange method caused considerable problems since it appeared that the lipid did not always fully exchange into the vesicles. For example, aggregation was observed in antibody-coupling experiments, both for PEG−lipids and ATTA*n*−lipids. In addition, studies looking at the effect of polymer−lipid concentration (0−5% MePEGA-2000-DSPE; 0−5% ATTA8−DSPE or 0−10% ATTA4−DSPE) on liposome clearance yielded results which contradicted earlier studies (*15*) in that ATTA*n*−DSPE ($n = 4, 8$) was relatively ineffective compared to MePEGA-2000-DSPE. The difference between preformulated and exchanged ATTA*n*−DSPE was confirmed in this work when the experiments were repeated using the equivalent preformulated compositions. MePEGA-2000-DSPE behaved in much the same way in both sets of experiments, implying that the ATTA*n*−DSPE micelles were more stable in solution. The reasons for this behavior are not clear. All experiments reported in this work, unless denoted otherwise, were performed using preformulated compositions as a result of these observations. The term "steric barrier lipid" (SBL) is used in this work as a general term for the ATTA*n*−lipids and PEG−lipids.

Evaluation of Effectiveness as Steric Barriers. Polymers bound to the surface of liposomes act as steric barriers which inhibit interactions between the membrane surface and the environment. Many of the applications which use PEG−lipids rely on this property. For example, PEG bound to the membrane surface inhibits aggregation of liposomes during the preparation of protein−liposome conjugates (*6*) or polyanion−cationic lipid complexes (*13*). PEG also inhibits the adsorption of molecules, such as serum proteins, onto vesicle surfaces (*23*). The steric barrier effect is believed to be very important in protecting liposomes from rapid clearance in vivo (*24*). We therefore undertook a number of studies designed to evaluate the equivalence of the ATTA*n*−lipid and PEG−lipid conjugates in terms of their effectiveness as steric barrier molecules.

We are particularly interested in the development of cationic lipid based formulations of nucleic acids. Cationic liposomes are toxic to erythrocytes since the cationic lipids rapidly exchange into the anionic erythrocyte membrane on contact (*25*) and induce lysis (*26*). Polymers such as PEG inhibit this process when attached to the liposome surface as a result of steric interactions which prevent contact between the two membranes. The phenomena can be used as a crude assay to evaluate the potential of new SBLs under development as steric barrier molecules for situations where liposomes are exposed to cellular membranes in physiological ionic strength solutions.

DODAC/POPC (50:50) vesicles with and without 10% ATTA8−DSPE, MePEGA-2000-DSPE and MePEGS-2000-Mcer were incubated with erythrocytes at various concentrations (Figure 2). As expected, the unprotected vesicles induced lysis in a dose-dependent manner. Similar behavior was observed with MePEGS-2000-Mcer compositions, since that lipid undergoes rapid exchange when exposed to environmental membranes. This leaves the cationic membrane unprotected and capable of direct contact with the erythrocyte membrane. The liposomes containing the two DSPE-based SBLs do not induce lysis. Ionic lipid exchange in this case occurs primarily either through transient direct membrane-membrane contact events, which are unlikely at the SBL concentrations used, or by very slow monomer diffusion mechanisms. These results imply that ATTA8−DSPE is effective in preventing interactions with cell surfaces in a biological environment and does not undergo significant exchange on the time scale of the experiment.

PEG−lipid conjugates are known to inhibit the absorption of serum proteins in vivo (*23*). These proteins include complement (*18*), serum albumin, and other opsonins (*27*), and are believed to mediate enhanced clearance of liposomes in vivo (*28*). To assess the ability of ATTA*n*−lipids to protect liposomes from protein absorption, we used an adaption of a complement activation assay previously reported (*18*). Sheep erythrocytes sensitized with hemolysin activate complement in serum, causing lysis and release of hemoglobin. The hemoglobin levels can be assayed spectroscopically after removal of the cells by centrifugation. Pretreatment of the serum with some other particle which activates complement would decrease the available pool of protein, which in turn would result in lower levels of hemolysis when the treated serum was added to sensitized erythrocytes. In this particular case, we used DODAC/POPC (50:50) liposomes as the complement activating agent. The ability of these liposomes to inhibit complement induced lysis of sensitized sheep erythrocytes was compared against that for DODAC/POPC/SBL (50:40:10) liposomes (SBL = ATTA8−DSPE, MePEGS-2000-Mcer, or MePEGA-2000-DSPE; Figure 3). In all cases, the SBL caused significant inhibition of the ability of the cationic liposomes to consume complement. All SBLs tested were equally effective, suggesting that (a) ATTA8−DSPE inhibited protein binding to liposomes much like PEG−lipids, and (b) ATTA8−DSPE in itself did not bind or activate complement. Exchange phenomena are not relevant in the case of MePEGS-2000-Mcer in this experiment since the pretreatment with complement occurs before exposure to a membrane sink (the erythrocyte membranes).

Evaluation of in Vivo Clearance Behavior. The clearance of liposomes in vivo is dependent on a number of factors, including vesicle size (*29*), membrane outer leaflet composition (*30*, *31*), and lipid dose (*3*). In drug delivery applications, it is desirable to maintain the encapsulated drug in circulation for a reasonable length of time. In mice, however, even relatively innocuous compositions are largely removed from circulation within 24 h. The clearance rate can be reduced in a number of ways, the easiest of which is to simply increase the lipid dose. This is not always acceptable. In situations where low lipid doses are used, the circulation half-life can be increased by including nonexchangeable PEG−lipids in the composition (*2*, *32*). We therefore undertook a number

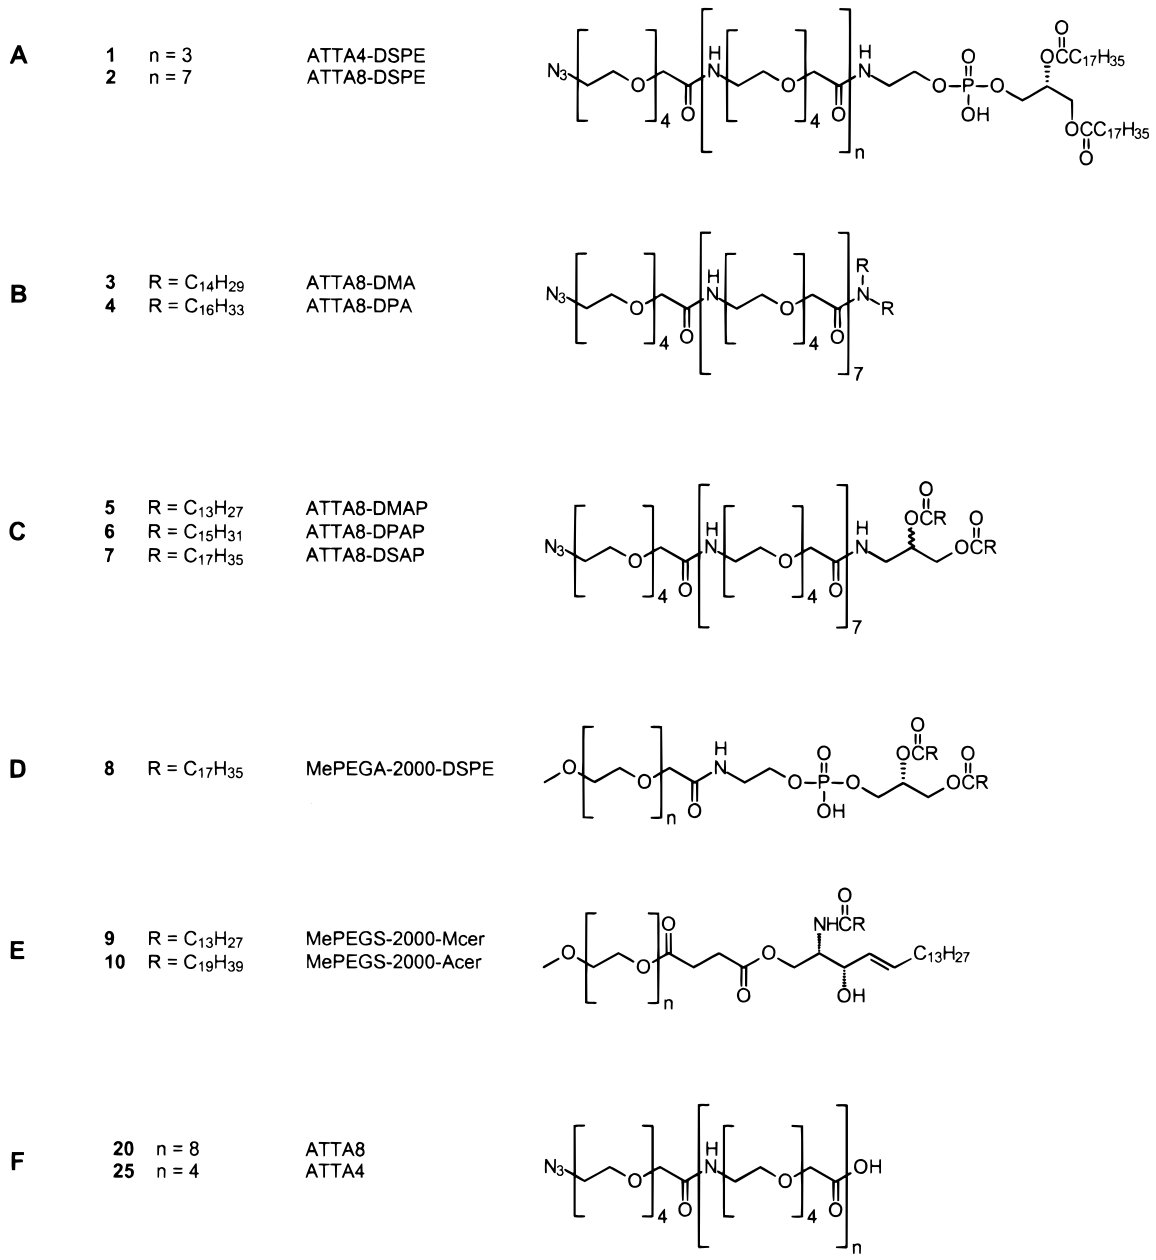

Figure 1. Structures of ATTA*n*–lipids and PEG–lipids: (A) ATTA*n*-DSPE; (B) ATTA8–D*x*A; (C) ATTA8–D*x*AP; (D) MePEGA-2000-D*x*PE; (E) MePEGS-2000-*x*cer; (F) ATTA*n* precursors.

of clearance studies to compare the performance of the ATTA*n*–lipids to PEG–lipids in this application.

We initially looked at the effects of SBL (MePEGA-2000-DSPE, ATTA8–DSPE and ATTA4–DSPE) concentration on the clearance of a single dose (30 mg/kg lipid) 20 h postadministration (Figure 4). The relative effects of an SBL in DSPC/cholesterol liposomes are most evident between 16 and 24 h since unprotected liposome levels fall (at this dose in mice) to ~2–3% whereas fully protected liposomes are still present at significant levels (25–30% initial dose). SBLs which exchange slowly out of the membrane in this time frame show intermediate clearance behavior, the magnitude of which depends on the exchange rate. MePEGA-2000-DSPE is an example of a widely used nonexchangeable SBL which fully protects the liposome surface at optimal concentrations and therefore was used as a control standard for optimal clearance inhibition behavior. The experiment was performed using 0–5% MePEGA-2000-DSPE or ATTA8–DSPE (1% steps) or 0–10% ATTA4–DSPE (2% steps). MePEGA-2000-DSPE and ATTA8–DSPE have similar sizes. The ATTA4–DSPE steps were chosen so that the bulk surface polymer load in the three systems was equivalent. The performance of ATTA8–DSPE and MePEGA-2000-DSPE were similar, achieving optimal clearance behavior at ~3 mol %. The ATTA8–DSPE showed slightly better performance at low concentrations ($P < 0.20$ at 1%; $P < 0.31$ at 2%), although these differences are probably due to small errors in the actual SBL concentration. We expected that ATTA4 would be equivalent to ATTA8 on a mass basis but were surprised to find that it compared well on a mole basis as well.

The effect of exchangeable SBL anchors was examined using a number of ATTA8 dialkylamine and 2,3-diacyloxypropylamine derivatives with different alkyl chain lengths. These particular lipids were designed as exchangeable neutral SBLs for applications involving cationic liposomes. SBLs based on DSPE are anionic and consequently form ion pairs with the cationic lipids in these formulations, greatly reducing the exchange rate.

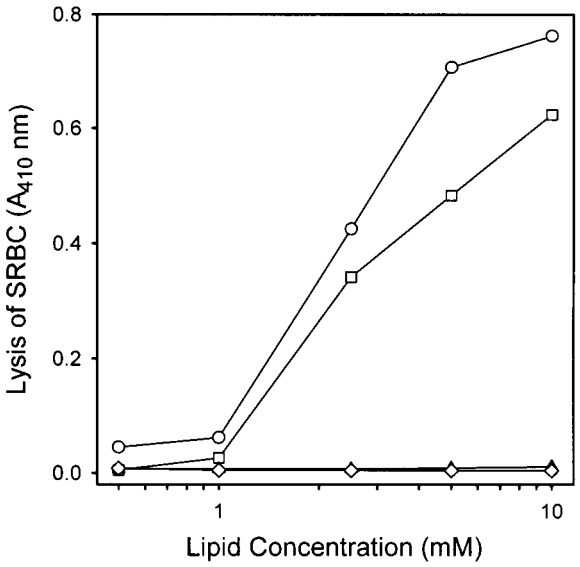

Figure 2. Inhibition of cationic lipid induced hemolysis of erythrocytes. Serial dilutions of DODAC/POPC (50:50, circles), DODAC/POPC/ATTA8−DSPE (50:40:10; diamonds), DODAC/POPC/MePEGA-2000-DSPE (50:40:10; triangles) and DODAC/POPC/MePEGS-2000-Mcer (50:40:10; squares) liposomes (all 20 mM in VBS, 100 μL) were incubated with an equal volume of sheep red blood cells (5×10^5 cells) for 30 min at 37 °C. The sample was diluted with 1.0 mL of EDTA-GVB, centrifuged at 1500 rpm for 5 min, and the absorbance of the supernatant analyzed at 410 nm.

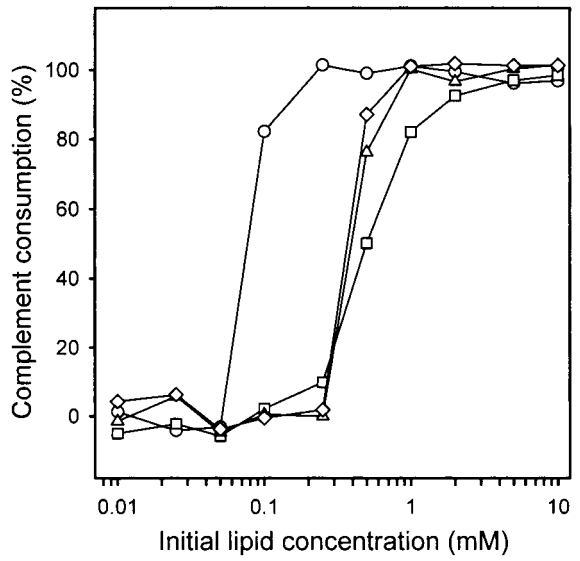

Figure 3. Inhibition of complement activation by DODAC/POPC/SBL vesicles. DODAC/POPC (50:50, circles), DODAC/POPC/ATTA8−DSPE (50:40:10; squares), DODAC/POPC/MePEGA-2000-DSPE (50:40:10; triangles) and DODAC/POPC/MePEGS-2000-Mcer (50:40:10; diamonds) vesicles were prepared and evaluated as described in the Experimental Methods.

The lipids were formulated at 5 mol % in POPC/cholesterol liposomes and circulation levels compared against ATTA8−DSPE, MePEGA-2000-DSPE, and unprotected vesicles, after 4 and 20 h (Figure 5). The di-C14 anchors (ATTA8−DMA and ATTA8−DMAP) showed little difference in clearance behavior compared to the unprotected control, suggesting that the SBLs rapidly exchange out of the bilayers in vivo and consequently do not inhibit clearance. Similar results have previously been observed for MePEGS-2000-Mcer (*33*), a SBL which has a lipid anchor that is equivalent to the di-C14 anchors used here in terms of hydrophobicity and size.

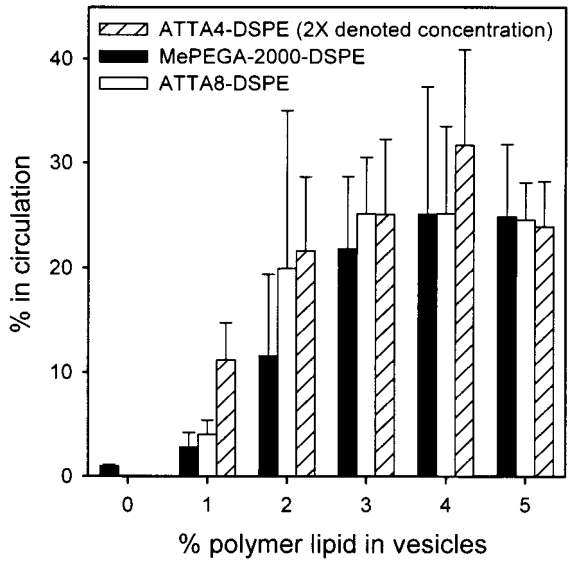

Figure 4. Clearance of sterically stabilized liposomes 20h post administration in female ICR mice (6−8 weeks old). [^{14}C]CHE labeled liposomes composed of POPC/chol/SBL (55-n:45:n; 5 mM) were prepared in HBS (25 mM Hepes, 150 mM NaCl, pH 7.4) and administered to mice (200 μL/animal) by intravenous tail vein injection. Serum was collected after 20 h and analyzed for radioactivity by liquid scintillation counting. SBL = MePEGA-2000-DSPE; ATTA8−DSPE; or ATTA4−DSPE. Error bars represent standard deviation for five animals.

Small but significant improvements in clearance behavior were observed for the pair of di-C16 derivatives (ATTA8−DPA and ATTA8−DPAP). The exchange rates of these lipids are significant on the time scale of the experiment but do not result in complete loss of the SBL, at least initially. This is particularly evident at the 4 h time point where the differences with the pair of DSPE-anchored SBLs is relatively small. The difference in clearance is larger at 20 h, presumably because most of the di-C16 SBL has exchanged out by then. An unexpected result was obtained with ATTA8−DSAP, a di-C18 analogue, in that it performed very much like the two di-C16 derivatives. The reason for this is not clear since we would have expected the C-18 analogue to be more securely anchored in the bilayer. These experiments were performed with the SBL formulated directly with the liposome. Experiments where the SBL was exchanged into preformed liposomes gave similar results.

Lipid dose plays an important role in the clearance behavior of liposomes. The process is believed to be mediated in part by the adsorption of serum proteins to liposomes in vivo. Increasing doses of lipid decrease the available pool of these proteins, resulting in decreases in the levels of bound proteins and reduced clearance. Nonexchangeable SBLs reduce the amount of adsorbed protein and thereby increase circulation levels. Direct inhibition of contact with the cells responsible for clearance probably also plays a significant role in the modulation of the clearance behavior. We compared the clearance behavior of ATTA8−DSPE vesicles comprised of DSPC/cholesterol/AL-1/SBL (20:45:25:10) with analogous MePEGS-2000-Mcer vesicles using a range of lipid doses (0−750 mg/kg) 24 h postinjection (Figure 6). We are currently using similar compositions to encapsulate antisense oligonucleotides. The MePEGS-2000-Mcer is required in these formulations to inhibit aggregation during the formulation process, but exchanges out rapidly in vivo and consequently has little or no effect on the clearance behavior. ATTA8−DSPE exchange rates would be negligible due to ion pair formation with the AL-1.

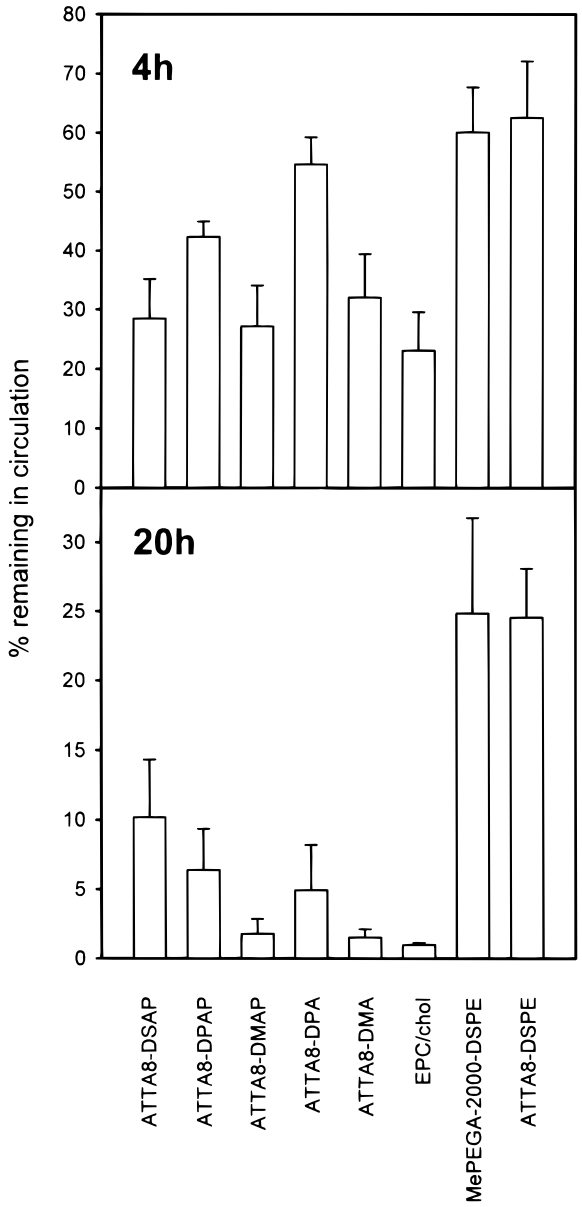

Figure 5. Clearance of sterically stabilized liposomes 4 h and 20 h post administration in female ICR mice (6−8 weeks old) using neutral SBL components. [^{14}C]CHE labeled liposomes composed of POPC/chol/SBL (50:45:5; 5 mM) were prepared in HBS (25 mM hepes, 150 mM NaCl, pH 7.4) and administered to mice (200 μL per animal) by intravenous tail vein injection. Blood (25 μL) was collected 4 h postinjection by tail nicks. Blood samples were digested in solvable and analyzed for radioactivity by liquid scintillation counting. Liposome levels were estimated based on estimated blood volume of 8%. Serum was collected after 20 h and analyzed for radioactivity by liquid scintillation counting. Liposome levels were estimated based on estimated serum volume of 4.55%. Error bars represent standard deviation for five animals.

The MePEGS-2000-Mcer vesicles are largely cleared from circulation at low doses after 24 h. Higher doses show significantly elevated liposome levels, but are still less than even the lowest dose of ATTA8−DSPE liposomes. Small increases in clearance behavior were observed as the ATTA8−DSPE liposome dose was increased. Depletion of the serum protein pool is likely not an issue in this case, so the observed minor increases either relate to saturation of other clearance mechanisms or are not significant. The result also implies that increasing the ATTA8−lipid dose does not in itself activate clearance mechanisms.

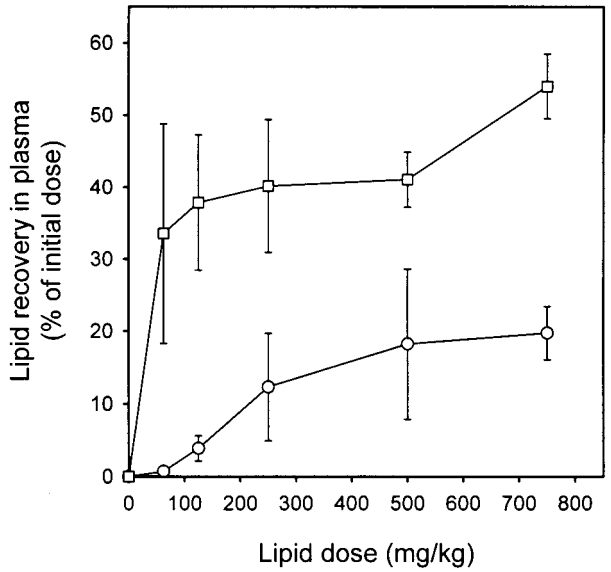

Figure 6. Effect of lipid dose on circulation levels of antisense encapsulated in DSPC/chol/AL-1/SBL (20:45:25:10) vesicles at 24 h. SBL = MePEGS-2000-Mcer, circles; ATTA8−DSPE, squares. Experiment conducted as described in the in vivo tolerability section of the experimental methods. Error bars represent standard deviation.

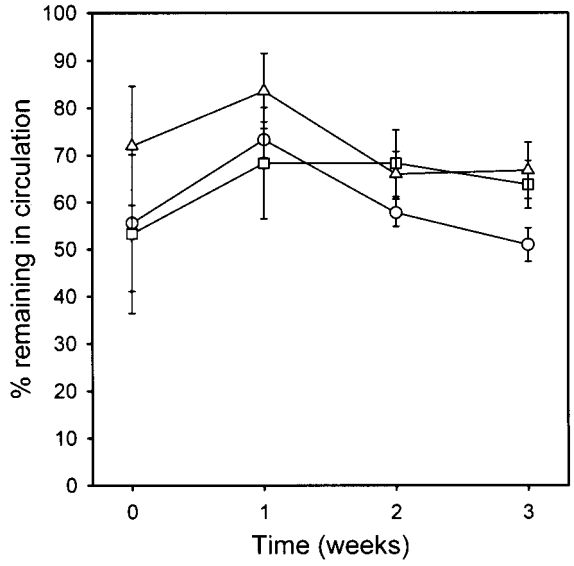

Figure 7. Clearance of liposomes 1 h postadministration in female ICR mice (6−8 weeks old) subjected to weekly administrations. Liposomes [DSPC/chol (55:45, circles); DSPC/chol/ATTA8−DSPE (50:45:5, triangles); DSPC/chol/MePEGC-2000-DSPE (50:45:5, squares)] labeled with [^{3}H]cholesteryl hexadecyl ether were prepared in HBS (Hepes-buffered saline; 20 mM Hepes, and 145 mM NaCl, pH 7.4) and diluted such that the injected lipid dose was 50 mg/kg/week. Lipid was administered by intravenous tail vein injections (200 μL) at weekly intervals for 3 weeks. Blood (50 μL) was collected 1 h postinjection by tail nicks. Mice were weighed at weekly intervals to estimate blood volume (8% body weight). Blood samples were digested in solvable and analyzed for radioactivity by liquid scintillation counting. Error bars represent standard deviation for six animals per time point.

The effect of repeat dosage regimes on clearance was evaluated using DSPC/cholesterol (55:45) or DSPC/cholesterol/SBL (50:45:5) liposomes at 50 mg/kg administered at weekly intervals. Blood was recovered 1 h postinjection and analyzed for liposome content (Figure 7). In the experiment, no significant difference was observed in the behavior of control, ATTA8−DSPE, and

[a] Cells were recovered from mice after the fourth injection following repeated weekly administrations of buffer or the listed liposome compositions. Restimulation was performed with the same compositions used for the treatment. Cells recovered from animals treated with buffer only were treated with all compositions as a control for non-specific effects. The animal protocol, cytokine ELISA assay and mitogenicity assays were performed as described in the in vivo immunogenicity section of the Experimental Methods.

MePEGC-2000-DSPE liposomes. DSPC/cholesterol liposomes are cleared more slowly than most liposome compositions and at 50 mg/kg are present at 60−80% of the injected dose 1 h postinjection. Liposomes with full steric protection are typically at similar levels. This behavior should remain the same after repeat administrations if there is no activation of some adaptive clearance mechanism, such as an immune response. An immune response would result in rapid clearance on repeat injection and very low levels of liposomes in circulation at 1 h postinjection (*34*). Obviously, this is very important if these materials are to be used in a practical pharmaceutical product. The results suggest that ATTA8−DSPE in isolation does not activate additional clearance mechanisms on repeat administration.

Evaluation of Immunogenicity. It is important that any polymer which has been designed for liposome applications in pharmaceutical products does not induce immune responses in vivo. The fact that ATTA8−DSPE liposome clearance in vivo does not change after repeat administration suggests that the conjugate is nonimmunogenic. To confirm this, we recovered spleens from mice 24 h after admininstration using a repeat dosage regime. Mice were administered up to four injections of DSPC/chol/ATTA8 (50:45:5), DSPC/chol/MePEGA-2000-DSPE (50:45:5), or DSPC/chol/ATTA8 (55:45) at weekly intervals for a total of 3 weeks. A control experiment using HBS buffer was run concurrently. Spleen cells were recovered after each time point and processed for analysis of phenotypic markers, mitogenic response after restimulation with liposomes, and cytokine release.

To analyze the expression of phenotypic markers, spleen cells from all groups were isolated, stained, and assayed within 5 h following isolation. Up-regulated expression of activation markers is associated with activation of immune cells. The analysis of phenotypic markers shows that there are no appreciable differences in the expression of differentiation (CD22, CD4, CD8, and CD11b) and activation (CD25, CD54, CD86, Ly6A/E, and MHC−II) markers between the control group and experimental groups receiving various lipid formulations (Table 1). The absence of any differences in expression of activation markers, between the control and experimental groups, suggests that in vivo treatment with ATTA8−DSPE formulations did not induce measurable activation of spleen cells.

Unseparated spleen cells from all experimental groups were tested in vitro for their ability to proliferate upon restimulation with the same lipid formulation [final concentration = 0.31 (data not shown), 0.62, or 1.25 (data not shown) mM] that was administered in vivo. Spleen cells from control mice (diluent treated group) were stimulated with the same set of liposomes in order to determine their mitogenic effect in vitro. Clones of memory cells would be generated if in vivo treatment with any of the lipid formulations had induced immunostimulation. In vitro restimulation of those cells with the same immunogen would then result in augmented cell proliferation. Our results show that when mice were primed with lipids, secondary responses to same formulations were practically undetectable, indicating that there was minimal immunostimulation (Table 2). Stimulation of splenocytes with polyclonal activators such as ConA and LPS induced strong mitogenic responses that were significantly different (5−10×) compared to those obtained from lipid-treated groups.

The recovered splenocytes were cultured in the presence of the various lipid formulations [final concentrations = 0.31 (data not shown), 0.62, and 1.25 (data not shown) mM]. Culture supernatants were collected at various times after culture initiation (24 or 48 h), and the levels of released cytokines (IL-2 and IL-4) measured. There was no significant difference in cytokine release between the groups that received the various lipid formulations or the buffer control.

The results show that following successive in vivo administration of DSPC/chol (55:45) or DSPC/chol/SBL (50:45:5; SBL = MePEGC-2000-DSPE or ATTA8−DSPE) liposomes, (a) there were no differences in expression of phenotypic and activation markers, (b) there was no induction of measurable cellular immune response (cell proliferation or cytokine release) to tested lipids, and (c)

lipid formulations were not mitogenic in control splenocytes stimulated in vitro. Together with the fact that repeated systemic administration of the liposomes did not result in rapid plasma clearance after subsequent injections, the results suggest that ATTA8 is nonimmunogenic in vivo, at least in terms of conjugates associated with normal liposome formulations.

Evaluation of Toxicity. The toxicity of any new polymer used in SBLs is obviously important. PEG is for the most part relatively nontoxic, although it is known to cause contact hypersensitivity under some circumstances (*35*). High concentrations of PEG−lipids will cause cell lysis through detergent action, although this should not be an issue at the concentrations typically used in liposome applications (otherwise the liposomes themselves would be dispersed). A full toxicity study of the ATTA*n* derivatives was beyond the scope of this work; however, some preliminary studies were performed to evaluate parameters that are potentially important in liposome applications.

ATTA8 was tested in various human (MB 231, HeLa, COLO 205, U87, SKOV-3, and MCF-7) and rodent (B16, 9L, and BHK-21) cell lines to evaluate any intrinsic cytotoxicity of the oligomer (Figure 8). Cell survival was determined using the crystal violet assay and expressed as a percentage of the optical density obtained after analysis of untreated cells. In most cases, the observed cytotoxic effects were negligible, although some cell lines showed significant falloff in survival at higher doses. Survival levels in all cell lines investigated, except SKOV-3 and 9L, exceeded those observed in the presence of cytostatic amounts of paclitaxel, indicating that cell growth continued at the highest ATTA8 doses used in the study.

Liposomes accumulate primarily in the liver and to a lesser extent in the spleen after clearance from circulation in vivo. Toxic effects from any consitituent lipids are therefore primarily associated with these organs. In the case of the liver, toxicity is associated with the release of enzymes, such as LDH, AST, and ALT, into the circulation. Levels of these enzymes can be assayed after recovery of serum and used as evidence of liver toxicity. We treated mice with a cationic liposome formulation normally used to encapsulate antisense DNA oligonucleotides (DSPC/chol/AL-1/SBL; 20:45:25:10; SBL = MePEGS-2000-Mcer or ATTA8−DSPE) at a range of lipid doses (50−750 mg of lipid/kg of body weight) and recovered plasma after 24 h. A SBL is required in these formulations to inhibit aggregation during the DNA formulation process. At least half of the MePEGS-2000-Mcer exchanges out of the formulation rapidly in vivo, however, much of it is still present when the vesicles accumulate in the liver. This model allowed us to assess the relative toxicity of ATTA8−DSPE in a real world situation. Analysis of LDH, AST, and ALT levels in recovered plasma samples indicated that there was no significant difference between the MePEGS-2000-Mcer and ATTA8−DSPE formulations (Figure 9). Slight increases in enzyme levels observed over the dose range are likely due to the encapsulated drug. Organs recovered (liver, kidney, lung an spleen) after the experiment (Figure 10) showed no evidence of change in weight or gross morphology over the dose range used. The data suggests that ATTA8−lipids do not result in significant gross toxicity to the organism and that the materials are well tolerated.

Evaluation of Utility. PEG−lipids are used for a variety of purposes in a wide range of liposomal drug formulations. Typical applications include reducing rates

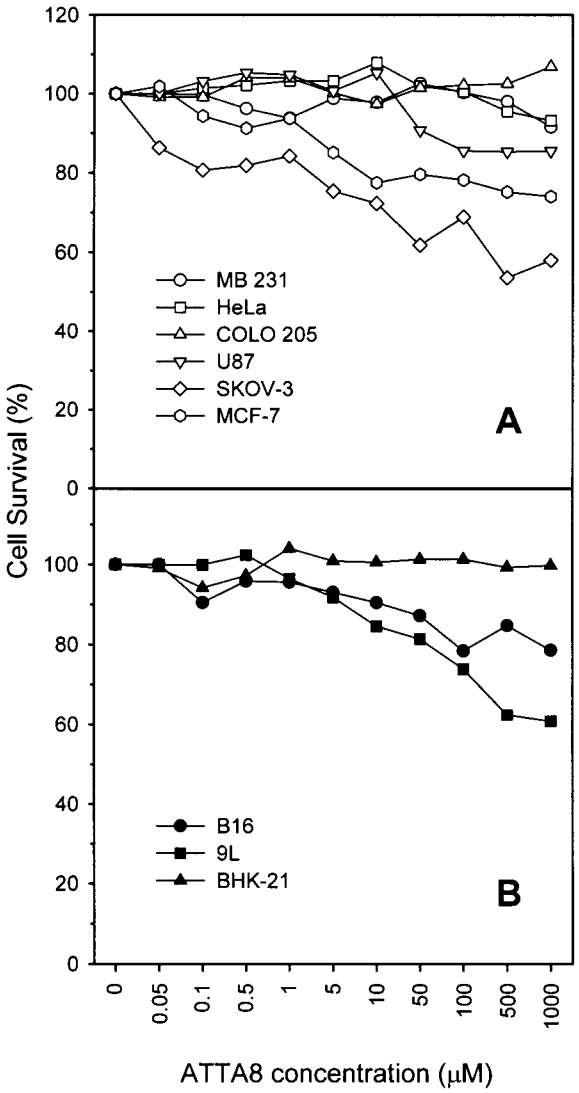

Figure 8. In vitro cytotoxicity of ATTA8. Panel A (human cell lines): MB 231, HeLa, Colo 205, U87, B16, 9L. Panel B (rodent cell lines): MCF-7, SKOV-3, and BHK-21. The experiments were performed in duplicate as described in the Experimental Methods. Error bars (standard deviation) have been omitted for clarity, but are available in the Supporting Information.

of clearance in vivo and inhibiting aggregation during the drug formulation process. In all of these applications, the PEG itself does not interact with the drug during the formulation process. Any molecule which is used in place of PEG would be required to behave in a similar manner. To evaluate the utility of ATTA*n*−lipids in drug formulation, we compared the performance of various ATTA8−lipids to PEG−lipids in the formulation of (a) doxorubicin using a pH gradient, (b) plasmid DNA, and (c) antisense DNA.

A commonly used procedure for encapsulating weak bases in liposomes involves generating vesicles with a pH gradient across the membrane. Typically, this involves an internal pH of ∼4. Neutral forms of the base cross the membrane and become trapped in the inner aqueous compartment in the protonated form. Many pharmaceutically useful drugs may be encapsulated in vesicles in this way (*36*). PEG−lipids are often included in these formulations in order to reduce rates of clearance in vivo. These SBLs can be exchanged into the membranes after drug loading but are more commonly incorporated prior to vesicle formation. Therefore, it is important that PEG, or any other polymer conjugate used

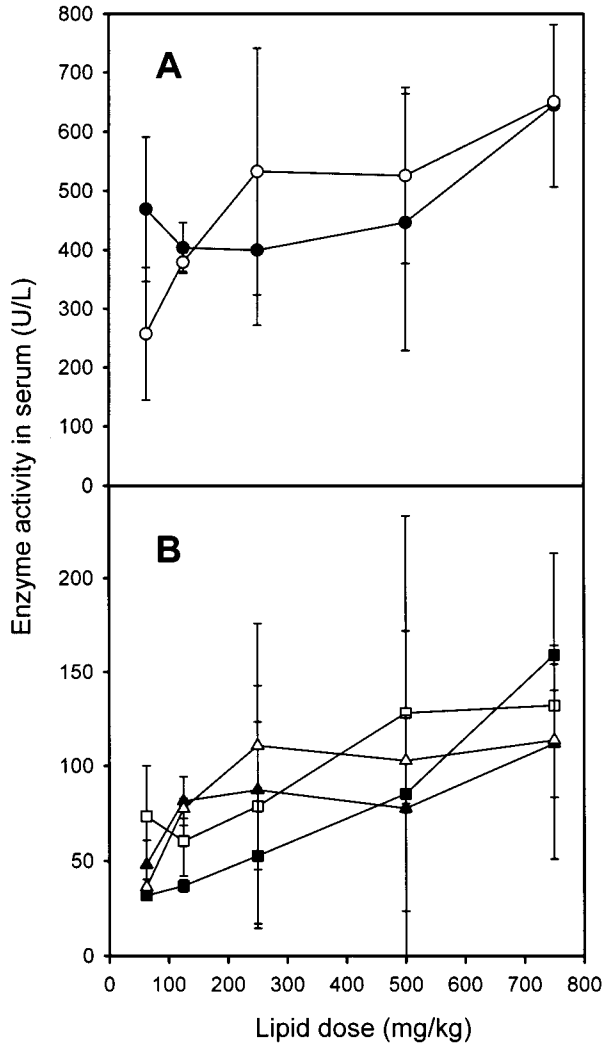

Figure 9. Liver enzyme levels after administration of antisense encapsulated in DSPC/chol/AL-1/SBL (20:45:25:10) vesicles. Shaded symbols represent SBL = MePEGS-2000-Mcer, open symbols represent SBL = ATTA8−DSPE. (A) LDH levels (circles); (B) AST levels (squares); ASL levels (triangles). Experiment conducted as described in the in vivo tolerability section of the Experimental Methods. Error bars represent standard deviation.

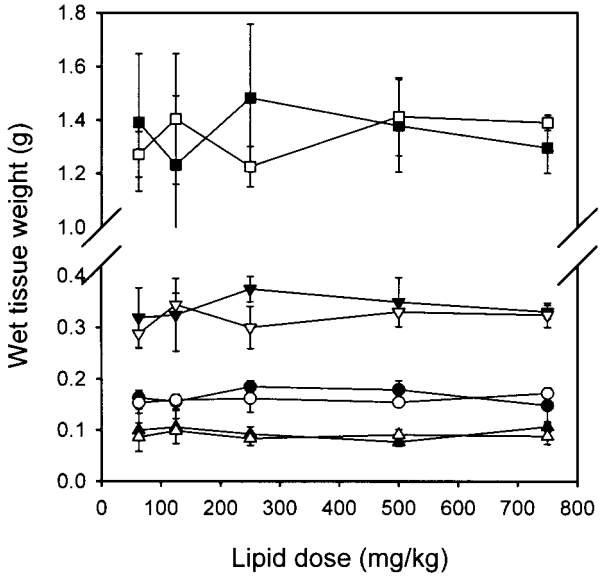

Figure 10. Single dose tolerability of encapsulated antisense oligonucleotide liposomes incorporating MePEGS-2000-Mcer (closed symbols) or ATTA8−DSPE (open symbols). Organs excised include liver (squares), kidney (inverted triangle), lung (circles) and spleen (triangle). Experiment conducted as described in the in vivo tolerability section of the Experimental Methods. Error bars represent standard deviation.

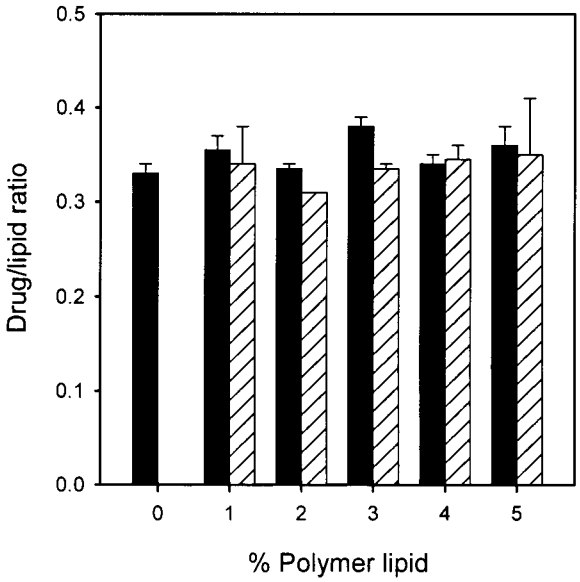

Figure 11. Effect of SBL on drug loading. Liposomes [POPC/chol/SBL (55-n:45:n; n = 0 to 5; SBL = MePEGA-2000-DSPE (solid bars) or ATTA8−DSPE (hatched bars); 25 mM] prepared in citrate buffer (300 mM, pH 4.0) were loaded with doxorubicin using an initial drug-to-lipid ratio of 0.3 as described in the Experimental Methods. Data represents the mean of two separate experiments. Error bars represent the range.

as a SBL, should not interact with the drug during the loading procedure or induce leakage of the internal contents after the creation of the pH gradient. Previous studies have shown that PEG−lipids do not affect drug loading across pH gradients (*37*).

In this study, we compared the effects of 0−5% of MePEGA-2000-DSPE or ATTA8−DSPE on the loading efficiency of doxorubicin into POPC/cholesterol (55-n:45) vesicles with a pH gradient of ∼Δ4 (internal pH 4.0, external pH ∼8). In all cases drug loading efficiency approached ∼100%, within the accuracy of the experiment (Figure 11). The results showed that ATTA8−DSPE does not adversely affect the stability of the vesicles or inhibit the drug loading process under the conditions of the experiment.

The formulation of plasmid DNA in cationic lipid vesicles is currently of great interest since the resultant complexes are potentially useful as gene therapy delivery vehicles. Traditionally, these complexes are formed by mixing cationic liposomes with free DNA to form aggregates which are capable of transfecting cells in vitro. These aggregates are typically large and suffer from very poor pharmacokinetics in vivo. Associates of ours have developed an elegant approach to address this problem (*13*). The DNA is encapsulated in vesicles comprised of neutral lipids, a cationic lipid, and an SBL, using a detergent dialysis procedure. The cationic lipid acts to catalyze the association of the DNA with the forming bilayer while the SBL prevents intervesicle cross-linking. The SBL may also induce asymmetric encapsulation of the DNA as a result of steric interactions between the polymer chains. Exchangeable and nonexchangeable SBLs may be used; however, transfection is adversely affected by the presence of SBLs, and as a result, we typically use a readily exchangeable SBL in these for-

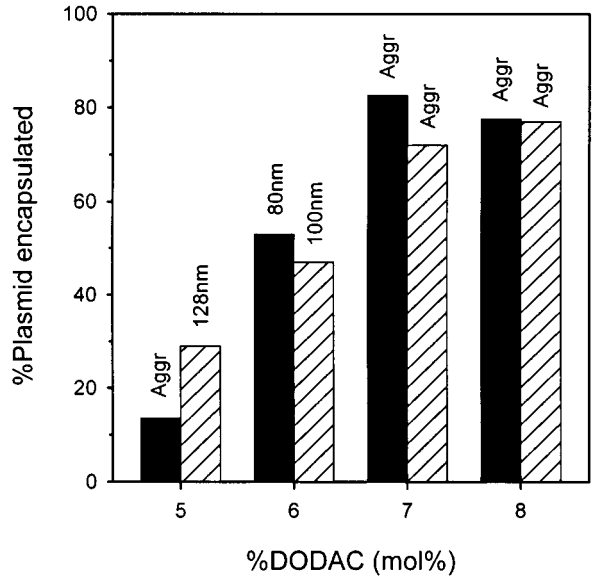

Figure 12. Effect of SBL on plasmid formulation. pINEXL018 was encapsulated in DODAC:DOPE:SBL [n:90-n:10; $n = 5-8\%$; SBL = ATTA8−DMAP (black bars) or ATTA8−DSAP (hatched bars)] vesicles by detergent dialysis as previously described [13]. Vesicle sizes were measured using a Nicomp Model 370 particle sizer. Encapsulation efficiency was determined using the PicoGreen assay as described in the Experimental Methods.

mulations. Formation of 100 nm vesicles with encapsulated DNA is critically dependent on the cationic lipid concentration. When MePEGS-2000-Mcer is used as an SBL in DOPE/DODAC formulations, the critical DODAC content is ~6%. Encapsulation efficiency falls off at lower concentrations while aggregation becomes a problem as DODAC levels increase. Similar behavior was observed when the MePEGS-2000-Mcer was replaced by ATTA8−DSAP or ATTA8−DMAP (Figure 12).

We have developed a similar procedure for encapsulating antisense DNA molecules (*7*). These drugs are much smaller than plasmid DNA. This results in many copies being encapsulated instead of one as is the case with plasmid DNA. In addition, antisense DNA oligomers associate with both leaflets of the bilayer rather than just the inner leaflet as with plasmid DNA. We resolved the problem by replacing the quaternary cationic lipid DODAC with the protonatable amine AL-1 (20%). This lipid is charged at low pH (~4) but is largely neutral at physiological pH (*38*). A SBL (typically MePEGS-2000-Mcer) is incorporated (10%) into these formulations to inhibit DNA induced cross-linking during vesicle formation. The vesicles themselves are formed at low pH using an ethanol dilution procedure followed by extrusion. The externally bound DNA was removed by replacement of the external buffer with HBS at pH 7.4 by dialysis followed by passage down a DEAE Sepharose CL-6B column. All versions of ATTA8−lipids (DSAP, DPAP, and DMAP) gave results similar to the MePEGS-2000-Mcer control formulation in terms of encapsulation efficiency, size, and stability against aggregation. Formulations prepared using ATTA4−DMAP and ATTA4−DLAP (the di-C12 analogue) were unstable and aggregated during preparation. We have preliminary data for formulations using novel MePEG-750-lipid derivatives which show similar behavior, suggesting that the polymer moiety of a SBL has to be larger than a minimum size to stabilize the liposomes against aggregation.

These results indicate that ATTA*n*−lipids may be used in most liposome drug formulations where PEG−lipids are currently employed. The only other major application of PEG−lipids in liposomes which we have not tested involves the use of the PEG as a cross-linker for attaching targeting ligands to the vesicle surface. We see no reason ATTA*n* lipids could not be used in this way, in fact, ATTA*n* may well be superior in these applications due to it's intrinsic heterobifunctionality and monodisperse nature.

CONCLUSION

In this work, we evaluated ATTA8−lipid conjugates as monodisperse replacements for PEG−lipids in most liposome applications. The ATTA*n* oligomers were conjugated to a range of amino lipids to form anionic (ATTA*n*−DSPE conjugates) or neutral species (ATTA*n*−DxAP or ATTA*n*−DxA conjugates). These conjugates were soluble in water and most organic solvents, allowing formulation in liposomes using a wide range of techniques commonly employed in the preparation of liposomes. The ATTA*n* liposomes showed no evidence of physical instability under normal circumstances. ATTA*n*−DSPE conjugates were shown to be at least as effective as PEG−lipids in assays designed to evaluate the ability of an SBL to inhibit interactions between liposomes and other membranes. Nonexchangeable ATTA*n*−lipids were effective in reducing the rate of liposome clearance in vivo, while exchangeable versions showed intermediate clearance behavior consistent with the predicted properties of the anchors used. There was no evidence that ATTA8−DSPE activated additional clearance mechanisms at high doses or on repeat administration, or activated any immune response in isolation. The lipids appeared to be relatively nontoxic in vitro and in vivo. On the basis of these results, we have concluded that ATTA*n*−lipids may be safely used in most liposome applications where PEG−lipids are currently used. We anticipate that the new compounds will facilitate the development of better defined and characterized SBL-liposome systems, particularly targeted liposomes, environmentally responsive systems, and those that undergo dynamic evolution in vivo based on loss of the SBL over time.

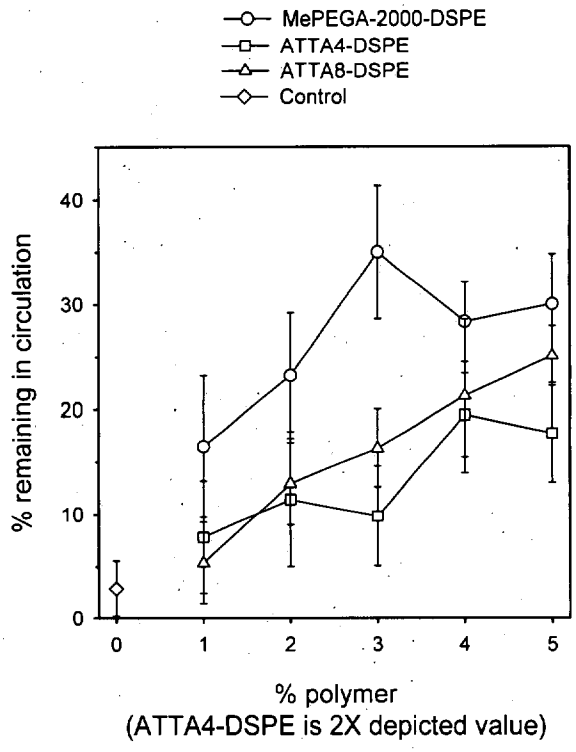

Figure 13. Clearance of sterically stabilized liposomes 20h post administration in female ICR mice (6-8 weeks old). [^{14}C]-CHE labeled liposomes composed of POPC/chol (55:45; 50mM) were prepared in HBS (25mM hepes, 150mM NaCl, pH7.4). Aliquots of the liposome solution were treated with aliquots from SBL stock solutions (0, 0.5, 1.0, 1.5, 2.0 and 2.5mol % of total lipid), diluted to 5mM lipid and incubated at 45°C for an hour. The liposomes were filtered through 0.22μm filters and administered to mice (200μl per animal) by intravenous tail vein injection. Serum was collected after 16h and analysed for radioactivity by liquid scintillation counting. SBL = MePEGA-2000-DSPE, circles; ATTA8-DSPE, triangles; ATTA4-DSPE, squares; no SBL, diamond. Error bars represent standard deviation for 5 animals.

These results demonstrate the effects of incomplete exchange of an SBL into preformed liposomes. The MePEGA-2000-DSPE data is comparable to that obtained using preformulated systems. The ATTA8-DSPE and particularly the ATTA4-DSPE systems, on the other hand, compare very poorly to their preformulated counterparts, suggesting that the ATTAn-DSPE micelles are stabilized against monomer exchange in some way.

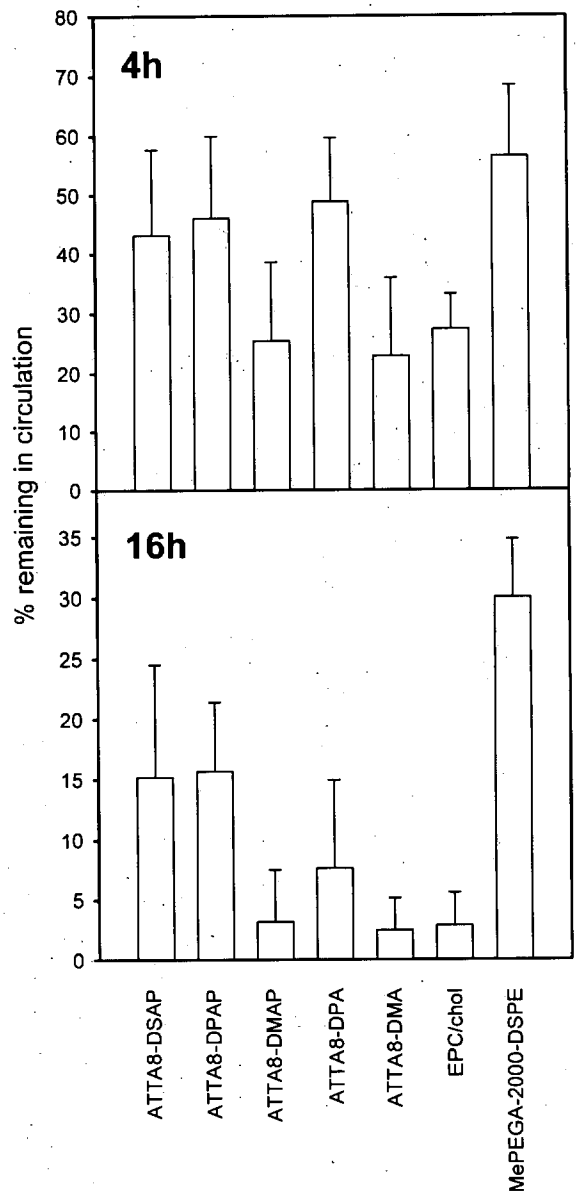

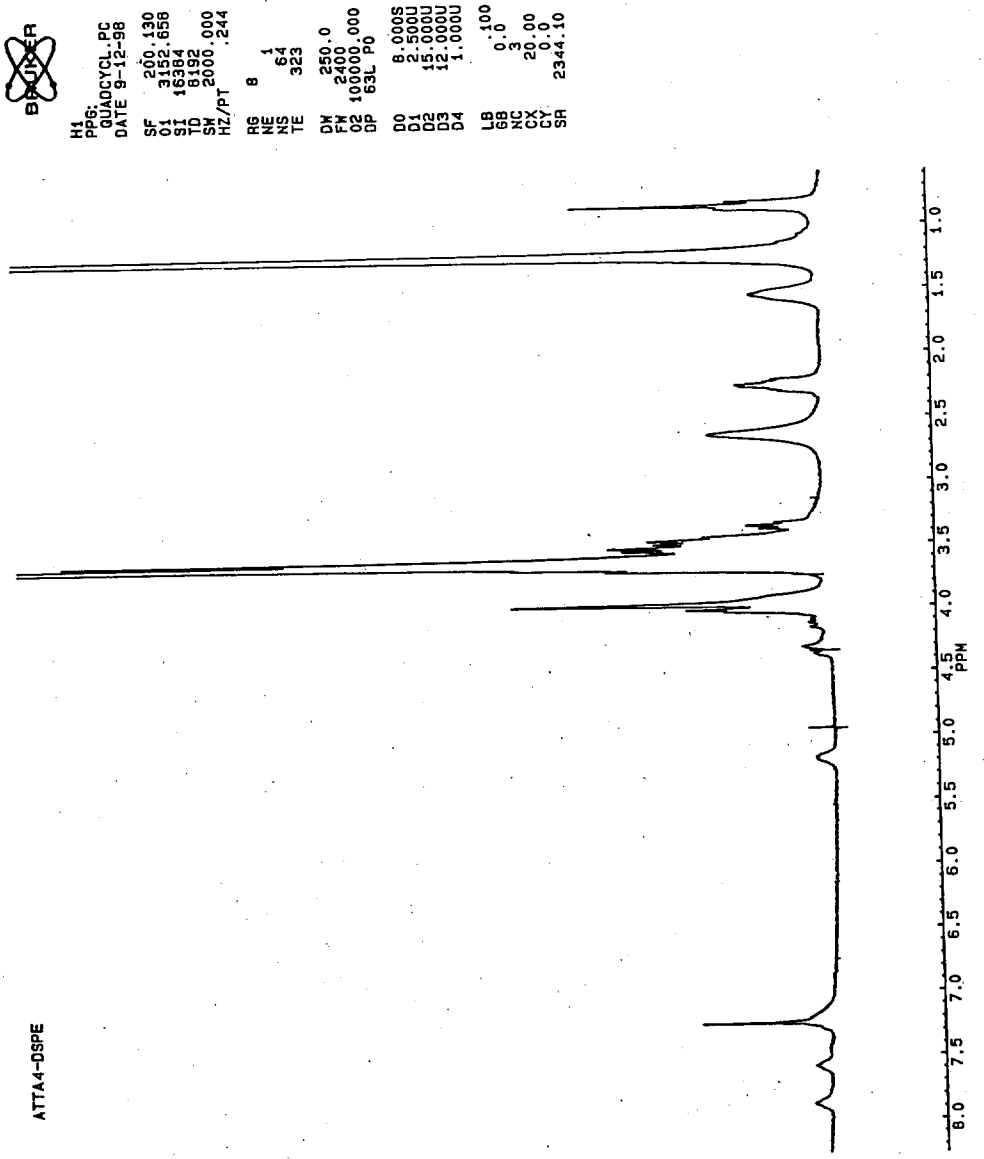

Figure 14. Clearance of sterically stabilized liposomes 4h and 20h post administration in female ICR mice (6-8 weeks old) using neutral SBL components. [^{14}C]-CHE labeled liposomes composed of POPC/chol (55:45; 50mM) were prepared in HBS (25mM hepes, 150mM NaCl, pH7.4). Aliquots of the liposome solution were treated with aliquots from SBL stock solutions (0, 0.5, 1.0, 1.5, 2.0 and 2.5mol % of total lipid), diluted to 5mM lipid and incubated at 45°C for an hour. The liposomes were filtered through 0.22μm filters and administered to mice (200μl per animal) by intravenous tail vein injection. Blood (25μl) was collected 4h post injection by tail nicks. Blood samples were digested in solvable and analyzed for radioactivity by liquid scintillation counting. Liposome levels were estimated based on estimated blood volume of 8%. Serum was collected after 16h and analysed for radioactivity by liquid scintillation counting. Liposome levels were estimated based on estimated serum volume of 4.55%. Error bars represent standard deviation for 5 animals.

Functionalized Congeners of 1,4-Dihydropyridines as Antagonist Molecular Probes for A_3 Adenosine Receptors

An-Hu Li, Louis Chang, Xiao-duo Ji, Neli Melman, and Kenneth A. Jacobson*

Molecular Recognition Section, Laboratory of Bioorganic Chemistry, National Institute of Diabetes, Digestive and Kidney Diseases, National Institutes of Health, Building 8A, Room B1A-19, Bethesda, Maryland 20892-0810. Received February 4, 1999; Revised Manuscript Received March 26, 1999

4-Phenylethynyl-6-phenyl-1,4-dihydropyridine derivatives are selective antagonists at human A_3 adenosine receptors, with K_i values in a radioligand binding assay vs [^{125}I]AB-MECA [N^6-(4-amino-3-iodobenzyl)-5′-*N*-methylcarbamoyl-adenosine] in the submicromolar range. In this study, functionalized congeners of 1,4-dihydropyridines were designed as chemically reactive adenosine A_3 antagonists, for the purpose of synthesizing molecular probes for this receptor subtype. Selectivity of the new analogues for cloned human A_3 adenosine receptors was determined in radioligand binding in comparison to binding at rat brain A_1 and A_{2A} receptors. Benzyl ester groups at the 3- and/or 5-positions and phenyl groups at the 2- and/or 6-positions were introduced as potential sites for chain attachment. Structure−activity analysis at A_3 adenosine receptors indicated that 3,5-dibenzyl esters, but not 2,6-diphenyl groups, are tolerated in binding. Ring substitution of the 5-benzyl ester with a 4-fluorosulfonyl group provided enhanced A_3 receptor affinity resulting in a K_i value of 2.42 nM; however, a long-chain derivative containing terminal amine functionalization at the 4-position of the 5-benzyl ester showed only moderate affinity. This sulfonyl fluoride derivative appeared to bind irreversibly to the human A_3 receptor (1 h incubation at 100 nM resulting in the loss of 56% of the specific radioligand binding sites), while the binding of other potent dihydropyridines and other antagonists was generally reversible. At the 3-position of the dihydropyridine ring, an amine-functionalized chain attached at the 4-position of a benzyl ester provided higher A_3 receptor affinity than the corresponding 5-position isomer. This amine congener was also used as an intermediate in the synthesis of a biotin conjugate, which bound to A_3 receptors with a K_i value of 0.60 μM.

INTRODUCTION

Medicinal chemists are currently developing agonists and antagonists that interact selectively with adenosine receptors, of which A_1, A_{2A}, A_{2B}, and A_3 subtypes are known (*1*). As the only subtype identified through cloning (*2*, *3*), the A_3 adenosine receptor has demonstrated unique biological effects, SAR profile, and tissue distribution (*4*). Intense activation of A_3 receptors induces apoptosis (programmed cell death) (*4*). The A_3 receptor has also a cytoprotective action at low agonist concentrations (*4*). The first cytoprotective effects of an A_3 agonist [IB-MECA,[1] N^6-(3-iodobenzyl)-5′-*N*-methylcarbamoyladenosine] were shown following its chronic administration in gerbils in a model of stroke (*5*). The agonist was highly cerebroprotective and depressed nitric oxide synthase (*5*, *6*). In cultured chick cardiac myocytes, a brief prior exposure to nanomolar concentrations of the related 2-chloro derivative, Cl-IB-MECA, protected cells from damage induced by subsequent hypoxia (*7*), thus mimicking a phenomenon termed "preconditioning". The protective effects of an A_3 receptor agonist on cardiac myocytes were also evident when added during the prolonged ischemia (*8*). A_3 receptor agonists at micromolar concentrations were found to induce apoptosis a variety of cell types, including tumor cell lines (*9*) and rat cardiac myocytes (*10*). Thus, the varied effects of A_3 receptor agonists appear to be dual and opposite, i.e., either cytoprotective or cytotoxic, depending on the level of receptor activation and the system studied.

A_3 adenosine receptor antagonists, although only recently introduced (*11*−*16*), were previously hypothesized to act as potential antiasthmatic (*17*), antiinflammatory (*17*), or cerebroprotective agents (*18*).The most promising leads for A_3 receptor antagonists have appeared recently among chemically diverse nonxanthine heterocycles (Figure 1). For example, the 1,4-dihydropyridines, that are potent blockers of L-type calcium channels (*19*, *20*) and used widely in treating coronary heart disease, were found to bind with intermediate affinity to human A_3 receptors and consequently were structurally optimized for subtype selectivity (*12*). In the present and previous studies, we have used the 1,4-dihydropyridine (DHP) nucleus as a template for probing structure−activity relationships (SAR) at adenosine receptors. By careful

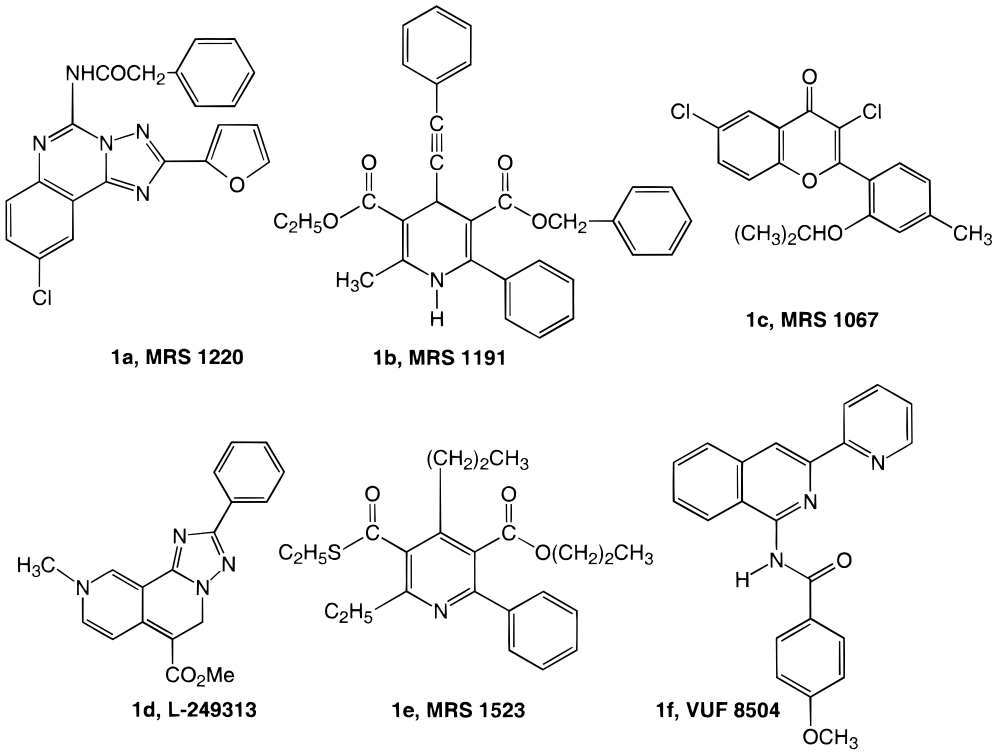

Figure 1. Structures of key A_3 adenosine receptor selective antagonists reported previously.

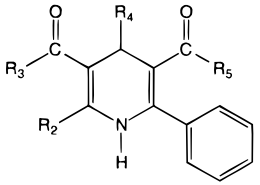
structural modification, it has been possible to select for affinity at adenosine receptors and deselect for affinity at L-type Ca^{2+}-channels.

The most potent antagonist of the human A_3 receptor yet reported is MRS 1220 (Figure 1, **1a**) (*16*), a derivative of the nonselective triazoloquinazoline antagonist CGS 15943. Within the series of DHP derivatives, affinity and selectivity for the human A_3 receptor were further enhanced in the trisubstituted analogue MRS 1191, 3-ethyl 5-benzyl 2-methyl-6-phenyl-4-phenylethynyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (Table 1, **1b**) (*12*). Other A_3 selective antagonists that have been recently reported include a flavonoid derivative (MRS 1067, **1c**) (*11*), a triazolonaphthyridine (L-249313, **1d**) (*13*), a pyridine (MRS 1523, **1e**) (*14*), and a pyridyl isoquinoline (VUF 8504, **1f**) (*15*).

In the present study, the SAR of 1,4-dihydropyridines as antagonist ligands for adenosine receptors has been expanded using a "functionalized congener approach" (*21*). By this approach, a chain substituent is attached to the pharmacophore at a strategic position, such that conjugation to other large molecules is made possible through an easily derivatized functional group, without losing the ability to bind to the receptor. This approach leads to increased flexibility of substitution and enhancement of potency/selectivity via distal interactions at the receptor. This approach has been developed for other selective adenosine receptor agonists and antagonists, such as the potent xanthine amine congener, XAC (8-[4-[[[[(2-aminoethyl)-amino]carbonyl]methyl]oxy]phenyl]-1,3-dipropylxanthine) (*34*), and ligands for other receptors (*35*), leading to irreversibly binding affinity probes, fluorescent probes, etc.



A typical means of derivatization in the design of functionalized congeners is to locate a position on the pharmacophore that may readily accommodate substitution with a phenyl group (*34*), without losing affinity for the receptor. In the present study, we have systematically explored the DHP template for additional sites of incorporation of phenyl substituents and various functional groups followed by chain extension. Fluorosulfonyl groups (*29*) were included in the analogues as an electrophilic group for potential covalent reaction with the receptor, which was indicated in binding experiments with one derivative. Finally, the incorporation of easily derivatizable amino groups at strategic positions was accomplished.

MATERIALS AND METHODS

Synthesis. *Materials and Instrumentation*. Phenylpropargyl aldehyde (**25**), benzyl acetoacetate (**26a**), ethyl benzoyl acetate (**26b**), 2-methoxyethyl acetoacetate (**26i**), 2,2,6-trimethyl-4*H*-1,3-dioxin-4-one (**27**), ethylene glycol (**28d**), 2-mercaptoethanol (**28e**), ethylene dithiol (**28f**), 2-trimethylsilylethanol (**28h**), *p*-nitrobenzyl alcohol (**29**), *p*-toluenesulfonyl fluoride (**30a**), *p*-toluenesulfonamide (**30b**), NBS, 2-(trimethylsilyl)ethanethiol, α-bromo-*p*-toluic acid, chloromethyl methyl ether, and 2-bromoethanol were purchased from Aldrich (St. Louis, MO). 2-Trimethylsilylethylthioethanol (**28g**) was prepared by reaction of 2-(trimethylsilyl)ethanethiol (1.1 mmol), 2-bromoethanol (1.0 mmol), and potassium hydroxide (1.5 mmol) in CH_3CN at room temperature for 4 h (yield, 78%). Compounds **1b**−**4** were prepared as described Jiang et al. (*12*). Dihydropyridines **21** [3-ethyl 5-[4-(2,2,2-trichloroethoxycarbonyl])benzyl] 2-methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate], **22** [3-ethyl 5-[4-(2-aminoethyl)aminocarbonyl-benzyl]-2-methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarbox-ylate], 1-(ethoxymethyl)-3-(ethoxycarbonyl)-2-methyl-4-(phenylethynyl)-6-phenyl-1,4-dihydropyridine-5-carboxylic acid (**32b**), compound **30c**, and bromide **31c** were prepared according to the method of Jiang et al. (*12*). Compounds **24a**, **24b**, and benzyl benzoyl acetate (**26c**) were prepared in our previous paper (*14*). All other materials were obtained from commercial sources.

Proton nuclear magnetic resonance spectroscopy was performed on a Varian GEMINI-300 spectrometer and

[f] Bound to human A_3 receptors irreversibly (see Figure 2), K_i value is apparent. [g] Same as compound 25 in Jiang et al. (*12*) K_i values have been redetermined.

Scheme 1. Synthesis of 6-Phenyl-4-phenylethynyl-1,4-dihydropyridine Derivatives Using the Hantzsch Reaction[a]

[a] Silyl-, hydroxyl-, and thiol-containing ester groups are included. The 2-position contains either a methyl or a phenyl group.

all spectra were taken in $CDCl_3$. Chemical ionization (CI) mass spectrometry was performed with a Finnigan 4600 mass spectrometer and electron-impact (EI) mass spectrometry with a VG7070F mass spectrometer at 6 kV. Elemental analysis was performed either by Atlantic Microlab Inc. (Norcross, GA) or by Galbraith Laboratories, Inc. (Knoxville, TN).

General Procedure for Preparation of Substituted 1,4-Dihydropyridine (5−8a, 9−12, and 33, Scheme 1). Equimolar amounts (0.5−1.0 mmol) of the appropriate *β*-enaminoester (**24**), aldehyde (**25**), and *β*-ketoester (**26**) were dissolved in 2−5 mL of absolute ethanol. The mixture was sealed in a Pyrex tube and heated, with stirring, at 80 °C for 18−24 h. After cooled to room temperature, the solvent was evaporated and the residue was purified by preparative TLC [silica 60; 1000 or 2000 μm; Analtech, Newark, DE; petroleum ether-ethyl acetate (1:1−4:1)].

*3,5-Dibenzyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**5**).* ^{1}H NMR ($CDCl_3$): 2.34 (s, 3 H, 2-CH_3), 5.01 (AB, 2 H, J = 12.6 Hz, 3-OCH_2Ph), 5.24 (s, 1 H, 4-H), 5.27 (AB, 2 H, J = 13.8 Hz, 5- OCH_2Ph), 6.05 (s, br, 1 H, NH), 7.04−7.11 (m, 2 H, aromatic H's), 7.15−7.30 (m, 9 H, aromatic H's), 7.33−7.40 (m, 7 H, aromatic H's), 7.44−7.47 (m, 2 H, aromatic H's). MS (EI): *m*/*z* 539 (M^+), 448 ($M^+ - CH_2$-Ph), 404 ($M^+ - CO_2CH_2Ph$), 91 ($^+CH_2Ph$, base).

*3-Ethyl 5-Benzyl 4-phenylethynyl-2,6-diphenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**6**).* ^{1}H NMR ($CDCl_3$): 1.10 (t, 3 H, J = 7.8 Hz, 3-OCH$_2CH_3$), 4.16 (q, 2 H, J = 7.8 Hz, 3- OCH_2CH$_3$), 5.11 (s, 1 H, 4-H), 5.14 (AB, 2 H, J = 12.9 Hz, 5-OCH_2Ph), 6.86−8.10 (m, 21 H, NH and aromatic H's). MS (EI): *m*/*z* 539 (M^+), 448 ($M^+ - CH_2$-Ph), 404 ($M^+ - CO_2CH_2Ph$), 91 ($^+CH_2Ph$, base).

*3,5-Dibenzyl 4-Phenylethynyl-2,6-diphenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**7**).* ^{1}H NMR ($CDCl_3$): 5.07 (AB, 4 H, J = 12.6 Hz, 3- and 5-OCH_2Ph), 5.35 (s, 1 H, 4-H), 6.15 (s, br, 1 H, NH), 7.07−7.45 (m, 25 H, aromatic H's). MS (EI): *m*/*z* 601 (M^+), 510 ($M^+ - CH_2$-Ph), 466 ($M^+ - CO_2CH_2Ph$), 91 ($^+CH_2Ph$, base). MS (CI−NH_3): *m*/*z* 619 ($M^+ + NH_4$), 602 ($M^+ + 1$). HRMS calcd: 601.2253. Found: 601.2255.

*3-(2-Methoxyethyl) 5-Benzyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**8a**).* ^{1}H NMR ($CDCl_3$): 2.35 (s, 3 H, 2-CH_3), 3.37 (s, 3 H, 3-OCH$_2$CH$_2$OCH_3), 3.67 (s, 2 H, J = 5.7 Hz, 3-OCH$_2CH_2$-OCH$_3$), 4.34 (m, 2 H, 3-OCH_2CH$_2$OCH$_3$), 5.01 (AB, 2 H, J = 13.0 Hz, 5-OCH_2Ph), 5.18 (s, 1 H, 4-H), 6.06 (s, br, 1 H, NH), 7.05−7.09 (m, 2 H, aromatic H's), 7.17−7.22 (m, 3 H, aromatic H's), 7.24−7.26 (m, 3 H, aromatic H's), 7.31−7.39 (m, 7 H, aromatic H's). MS (EI): *m*/*z* 507 (M^+), 448 ($M^+ - CH_3OCH_2CH_2$), 416 ($M^+ - CH_2Ph$), 372 ($M^+ - CO_2CH_2Ph$), 268 ($M^+ + 1$-CO_2CH_2Ph-$CO_2CH_2CH_2OCH_3$, base). MS (CI−NH_3): *m*/*z* 525 ($M^+ + NH_4$), 508 ($M^+ + 1$).

*3-(2-Methoxyethyl) 5-(4-Nitrobenzyl) 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**8b**).* 2-Methoxyethyl acetoacetate (**26i**, 160 mg, 1 mmol), phenylpropargyl aldehyde (**25**, 130 mg, 1 mmol), *p*-nitrobenzyl benzoyl acetate (**26j**, 299 mg, 1 mmol), and ammonium acetate (154 mg, 2 mmol) were dissolved in 3 mL of absolute ethanol. The mixture was stirred under N_2 at 95 °C for 24 h. After cooled to room temperature, the solvent was evaporated and the residue was purified by preparative TLC [silica 60; 1000 μm; Analtech, Newark, DE; petroleum ether-ethyl acetate (1:1)] to give 127 mg (yield = 23%) of the product. ^{1}H NMR ($CDCl_3$): 2.38 (s, 3 H, 2-CH_3), 3.40 (s, 3 H, 3-OCH$_2$CH$_2$OCH_3), 3.68 (m, 2 H, 3-OCH$_2CH_2$OCH$_3$), 4.37 (m, 2 H, 3-OCH_2CH$_2$-OCH$_3$), 5.12 (AB, 2 H, J = 13.5 Hz, 5-OCH_2Ph), 5.20 (s, 1 H, 4-H), 6.04 (s, br, 1 H, NH), 7.17−7.44 (m, 12 H, aromatic H's), 8.02 (m, 2 H, aromatic H's). MS (CI−NH_3): *m*/*z* 570 ($M^+ + NH_4$), 553 ($M^+ + 1$), 282 ($M^+ - CH_3$-$CO_2CH_2C_6H_4NO_2$-MeOCH$_2$CH$_2$O, base).

*3-(2-Hydroxyethyl) 5-Benzyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**9**).* ^{1}H

NMR ($CDCl_3$): 2.35 (s, 3 H, 2-CH_3), 3.84 (m, 2 H, 3-OCH_2CH_2OH), 4.17 (m, 1 H, 3-OCH_2CH_2OH), 4.45 (m, 1 H, 3-OCH_2CH_2OH), 4.99 (AB, 2 H, J = 12.6 Hz, 5-OCH_2Ph), 5.17 (s, 1 H, 4-H), 6.20 (s, br, 1 H, NH), 7.02−7.39 (m, 15 H, aromatic H's). MS (EI): *m/z* 493 (M^+), 448 ($M^+ - HOCH_2CH_2$), 432 ($M^+ - HOCH_2CH_2O$), 404 ($M^+ - HOCH_2CH_2O_2C$), 402 ($M^+ - CH_2Ph$), 358 ($M^+ - CO_2CH_2Ph$), 91 ($^+CH_2Ph$, base).

*3-(2-Mercaptoethyl) 5-Benzyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**10**).* ^1H NMR ($CDCl_3$): 1.77 (t, 1 H, J = 8.7 Hz, SH), 2.36 (s, 3 H, 2-CH_3), 2.82 (m, 2 H, 3-OCH_2CH_2SH), 4.23 (m, 1 H, 3-OCH_2CH_2SH), 4.42 (m, 1 H, 3-OCH_2CH_2SH), 5.01 (AB, 2 H, J = 12.6 Hz, 5-OCH_2Ph), 5.17 (s, 1 H, 4-H), 6.07 (s, br, 1 H, NH), 7.05−7.37 (m, 15 H, aromatic H's). MS (EI): *m/z* 509 (M^+), 448 ($M^+ - HSCH_2CH_2$), 419 ($MH^+ - CH_2Ph$), 404 ($M^+ - HSCH_2CH_2O_2C$), 374 ($M^+ - CO_2CH_2Ph$), 91 ($^+CH_2Ph$, base).

*3-(2-Mercaptoethylsulfanyl) 5-Benzyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**11**).* ^1H NMR ($CDCl_3$): 1.69 (t, 1 H, J = 8.7 Hz, SH), 2.36 (s, 3 H, 2-CH_3), 2.75 (dt, 2 H, J = 8.7, 6.9 Hz, 3-SCH_2CH_2SH), 3.20 (t, 1 H, J = 6.9 Hz, 3-SCH_2CH_2SH), 5.04 (AB, 2 H, J = 12.6 Hz, 5-OCH_2Ph), 5.32 (s, 1 H, 4-H), 6.14 (s, br, 1 H, NH), 7.05−7.41 (m, 15 H, aromatic H's). MS (EI): *m/z* 525 (M^+), 432 ($M^+ - HSCH_2CH_2S$), 404 ($M^+ - HSCH_2CH_2SOC$), 330 ($MH^+ - CO_2CH_2Ph$-SCH_2CH_2SH, base), 91 ($^+CH_2Ph$). HRMS calcd for MH+: 526.1511. Found: 526.1466.

*3-(2-Trimethylsilylethylthioethyl) 5-Benzyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**12**).* ^1H NMR ($CDCl_3$): 0.00 (m, 9 H, 3-$SiCH_3$), 0.85 (m, 2 H, 3-$SCH_2CH_2SiMe_3$), 2.34 (s, 3 H, 2-CH_3), 2.60 (m, 2 H, 3-$SCH_2CH_2SiMe_3$), 2.82 (m, 2 H, 3-$CO_2CH_2CH_2SCH_2CH_2SiMe_3$), 4.33 (m, 2 H, 3-$CO_2CH_2CH_2SCH_2CH_2SiMe_3$), 5.00 (AB, 2 H, J = 12.9 Hz, 5-OCH_2Ph), 5.15 (s, 1 H, 4-H), 6.03 (s, br, 1 H, NH), 7.04−7.40 (m, 15 H, aromatic H's). MS (CI−NH_3): *m/z* 609 (M^+), 518 ($M^+ - CH_2Ph$), 448 ($M^+ - CH_2CH_2SCH_2CH_2SiMe_3$, base).

*3-(2-Trimethylsilylethyl) 5-Ethyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**33**).* ^1H NMR ($CDCl_3$): 0.00 (m, 9 H, 3-$SiCH_3$), 0.99 (t, 3 H, J = 7.8 Hz, 5-OCH_2CH_3), 1.12 (t, 2 H, J = 8.8 Hz, 3-$OCH_2CH_2SiMe_3$), 2.57 (s, 3 H, 2-CH_3), 4.02 (m, 2 H, 3-$CO_2CH_2CH_2SiMe_3$), 4.33 (t, 2 H, J = 7.8 Hz, 5-OCH_2CH_3), 5.13 (s, 1 H, 4-H), 5.87 (s, br, 1 H, NH), 7.25−7.44 (m, 10 H, aromatic H's).

General Procedure for Preparation of 1,4-Dihydropyridine-3,5-dicarboxylate Esters 13−15, 32c−d, and 19−20 (Scheme 3). (Condition a) Compound **32a** or **32b** (0.04 mmol) was dissolved in dry acetone (2 mL) and anhydrous potassium carbonate (0.1 g), and the appropriate benzyl bromide (**31a−d**, 5 equiv.) was added, and the mixture was refluxed for 2−6 h. After filtering the mixture, the solvent was evaporated in vacuo. The residue was separated by preparative TLC (4:1 hexanes/EtOAc), and the desired *N*-protected 3- or 5-benzyl ester DHP was isolated. (Condition b): Deprotection was achieved by dissolving these *N*-ethoxymethyl-protected DHPs in acetone (1 mL) and adding excess 1 N HCl (200 μL) and heating at 45 °C for 2−3 h. The solvent was evaporated followed by purification with preparative TLC (4:1 hexanes/EtOAc or 10:1 $CHCl_3$/MeOH) to afford the desired 3- or 5-benzyl ester DHP.

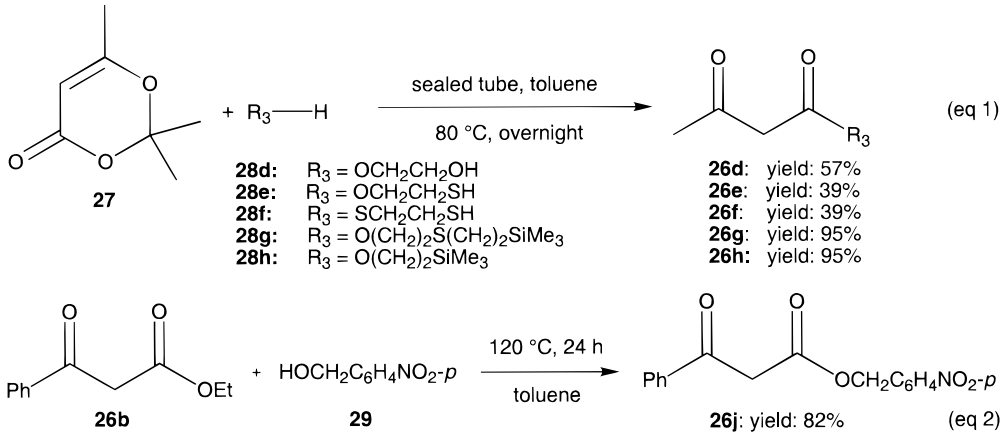
*3-(4-Fluorosulfonylbenzyl) 5-Ethyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate (**13**).* ^1H NMR ($CDCl_3$): δ 0.93 (t, 3H, J = 6.84 Hz, 5-CH_2CH_3), 2.39 (s, 3H, 2-CH_3), 4.12 (q, 2H, J = 6.83 Hz, 5-OCH_2), 5.20 & 5.58 (AB, 2H, J = 14.65 Hz, 3-OCH_2), 5.21 (s, 1H, H-4), 6.23 (br, 1H, NH), 7.28−7.44 (m, 10H, 4-C_6H_5 and 6-C_6H_5), 7.71−7.89 (m, 4H, 3-C_6H_4).

*3-(4-Sulfonylamidobenzyl) 5-Ethyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate (**14**).* ^1H NMR ($CDCl_3$): δ 0.93 (t, 3H, J = 6.84 Hz, 5-CH_2CH_3), 2.38 (s, 3H, 2-CH_3), 3.99 (m, 2H, 5-OCH_2), 4.77 (br, 2H, NH_2), 5.20 & 5.49 (AB, 2H, J = 13.67 Hz, 3-OCH_2), 5.19 (s, 1H, H-4), 5.97 (br, 1H, NH), 7.27−7.84 (m, 14H, 3-C_6H_4, 4-C_6H_5 and 6-C_6H_5). HPLC retention time: 7.66 min (> 95% purity) using solvent system 0.1 M TEAA (pH 5.0)/CH_3CN, 80:20 to 20:80, in 20 min with flow rate 1 mL/min.

*3-[4-(2,2,2-Trichloroethoxycarbonyl])benzyl] 5-ethyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate (**15**).* ^1H NMR ($CDCl_3$): δ 0.95 (t, 3H, J = 6.84 Hz, 5-CH_2CH_3), 2.38 (s, 3H, 2-CH_3), 4.00 (m, 2H, 5-OCH_2), 4.96 (s, 2H, CH_2CCl_3), 5.22 and 5.51 (AB, 2H, J = 14.65 Hz, 3-OCH_2), 5.21 (s, 1H, H-4), 5.97 (br, 1H, NH), 7.25−8.07 (m, 14H, 3-C_6H_4, 4-C_6H_5 and 6-C_6H_5).

*3-[4-(2-Aminoethyl)aminocarbonylbenzyl] 5-Ethyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate (**16**).* Compound **15** (13.4 mg, 0.02 mmol) was mixed with ethylenediamine (0.175 mL). After stirring at room temperature for 4 h, the ethylenediamine was evaporated and the product purified by preparative TLC (5:1 $CHCl_3$/MeOH) to yield 7.0 mg of a white solid (59%). Compound **16** (R_f = 0.68, EtOAc) was shown to be pure by TLC.

^1H NMR ($CDCl_3$): δ 0.95 (t, 3H, J = 6.84 Hz, 5-CH_2CH_3), 2.37 (s, 3H, 2-CH_3), 2.78 (s, 2H, NH_2), 2.96 (t, 2H, J = 5.86 Hz, $-CH_2$-), 3.50 (m, 2H, $-CH_2$-), 4.00 (m, 2H, 5-OCH_2), 5.21 and 5.45 (AB, 2H, J = 13.68 Hz, 3-OCH_2), 5.20 (s, 1H, H-4), 5.92 (br, 1H, NH), 6.75 (br, 1H, $-CH_2NH$-), 7.27−7.73 (m, 14H, 3-C_6H_4, 4-C_6H_5 and 6-C_6H_5).



*3-(4-Carboxybenzyl) 5-Ethyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate (**17**).* Compound **32c** [3-(4-methoxyethoxycarbonylbenzyl) 5-ethyl 2-methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate] was prepared according to the general procedure using 30 mg of **32a** (0.067 mmol) and 86.8 mg of **31d** (0.335 mmol). The crude product was dissolved in 2 mL of acetone. To 1 mL of such acetone solution was added 0.2 mL of 1 N HCl. The mixture was stirred at 45 °C for 2 h. The solution was removed in vacuo and residue was purified by preparative TLC (silica 60; 1000 μM, 10:1 $CHCl_3$/MeOH) to give 13.2 mg of white solid, yield = 38%. Compound **17** (R_f = 0.17, MeOH) was shown to be pure by TLC.

^1H NMR ($CDCl_3$): δ 0.89 (t, 3H, J = 6.84 Hz, 5-CH_2CH_3), 2.38 (s, 3H, 2-CH_3), 4.01 (m, 2H, 5-OCH_2), 4.61 (s, 1H, OH), 5.21 and 5.49 (AB, 2H, J = 13.67 Hz, 3-OCH_2), 5.21 (s, 1H, H-4), 5.96 (br, 1H, NH), 7.35−8.04 (m, 14H, 3-C_6H_4, 4-C_6H_5 and 6-C_6H_5).

*3-[4-(2-D-biotinylaminoethyl)aminocarbonylbenzyl] 5-Ethyl 2-Methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate (**18**).* Compound **16** (6.1 mg, 0.01 mmol) and *N*-hydroxysuccinimide biotin (4.4 mg, 0.01 mmol) were dissolved in 0.5 mL of anhydrous DMF and stirred at room temperature overnight. The solvent was evaporated and the product was purified by preparative TLC [12:1 $CHCl_3$/MeOH followed by 6:1 $CHCl_3$/MeOH] to yield 5.6 mg of a yellow solid (64%). Compound **18** (R_f = 0.73, MeOH/EtOAc = 1/3) was shown to be pure by TLC.

^1H NMR ($CDCl_3$): δ 0.90 (t, 3H, J = 6.84 Hz, 5-CH_2CH_3), 1.32 (br, 1H, H-4′), 1.60 (t, 1H, J = 6.84 Hz, H-2′), 1.74 (br, 1H, H-3′), 2.17 (m, 4H, 2 X $-CH_2$-), 2.37

Scheme 2. Synthesis of β-Ketoesters

(s, 3H, 2-CH_3), 2.63 (d, 2H, J = 12.70 Hz, $-CH_2$-5′), 2.82 (m, 2H, $-CH_2$-), 2.97 (m, 2H, $-CH_2$-), 3.47 (br, 1H, NH), 3.55 (br, 1H, NH), 3.94 (q, 2H, J = 6.84 Hz, 5-OCH_2), 4.12 (br, 2H, $-CH_2$-), 4.39 (br, 2H, $-CH_2$-), 5.16 (s, 1H, H-4), 5.21 and 5.40 (AB, 2H, J = 13.67 Hz, 3-OCH_2), 5.60 (br, 1H, NH), 6.29 (br, 1H, NH), 6.54 (br, 1H, NH), 7.16−7.77 (m, 14H, 3-C_6H_4, 4-C_6H_5 and 6-C_6H_5).

*3-Ethyl 5-(4-Fluorosulfonylbenzyl) 2-Methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate (**19**).* ^{1}H NMR ($CDCl_3$): δ 1.36 (t, 3H, J = 6.83 Hz, 3-CH_2CH_3), 2.39 (s, 3H, 2-CH_3), 4.30 (m, 2H, 3-OCH_2), 5.04 and 5.13 (AB, 2H, J = 14.66 Hz, 5-OCH_2), 5.19 (s, 1H, 4-H), 6.32 (br, 1H, NH), 7.23−8.00 (m, 14H, 4-C_6H_5, 5-C_6H_4, and 6-C_6H_5).

*3-Ethyl 5-(4-Sulfonamidobenzyl) 2-Methyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3,5-dicarboxylate (**20**).* ^{1}H NMR ($CDCl_3$): δ 1.35 (t, 3H, J = 6.84 Hz, 3-CH_2CH_3), 2.38 (s, 3H, 2-CH_3), 4.29 (m, 2H, 3-OCH_2), 4.74 (br, 2H, NH_2), 5.10 and 5.18 (AB, 2H, J = 13.68 Hz, 5-OCH_2), 5.18 (s, 1H, 4-H), 5.93 (br, 1H, NH), 7.16−7.83 (m, 14H, 4-C_6H_5, 5-C_6H_4, and 6-C_6H_5). HPLC retention time: 7.42 min (>95% purity) using solvent system 0.1 M TEAA (pH 5.0)/CH_3CN, 80:20 to 20:80, in 20 min with flow rate 1 mL/min.

*3-Ethyl 5-(4-Carboxybenzyl) 2-Methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate (**23**).* Compound **32d** [3-ethyl 5-(4-methoxyethoxycarbonylbenzyl) 2-methyl-4-phenylethynyl-6-phenyl-1,4(±)-dihydropyridine-3,5-dicarboxylate] was prepared in quantitative yield according to the general procedure using 35 mg of **32b** (0.0786 mmol) and 102 mg of **31d** (0.392 mmol). An acetone solution (1 mL) of 25.3 mg (0.041 mmol) of **32d** was mixed with 1 N HCl (0.15 mL), and the mixture was stirred at 45 °C for 2 h. The solution was removed in vacuo and residue was purified by preparative TLC (silica 60; 1000 μM, 10:1 $CHCl_3$/MeOH) to give 10.9 mg of light yellow solid, yield = 51%.

^{1}H NMR ($CDCl_3$): δ 1.34 (t, 3H, J = 6.84 Hz, 3-CH_2CH_3), 2.37 (s, 3H, 2-CH_3), 4.26 (m, 2H, 3-OCH_2), 5.00 & 5.15 (AB, 2H, J = 13.68 Hz, 5-OCH_2), 5.17 (s, 1H, 4-H), 5.99 (br, 1H, NH), 7.07−7.92 (m, 14H, 4-C_6H_5, 5-C_6H_4, and 6-C_6H_5).

Synthesis of β-Ketoesters 26d−h (Scheme 2). β-Ketoesters **26d−h** were prepared by the reaction of 2,2,6-trimethyl-4*H*-1,3-dioxin-4-one (**27**) and an alcohol or a thiol (eq 1 in Scheme 2). Equimolar amounts (for example, 3 mmol) of compound **27** and an alcohol or a thiol were heated with a little toluene (1−2 mL) at 80 °C in a sealed tube overnight. After cooled to room temperature, the solvent was removed under reduced pressure and the residue was chromatographed to give desired products in satisfactory yields (57% for **26d**, 39% for **26e**, 39% for **26f**, 95% for **26g**, 95% for **26h**).

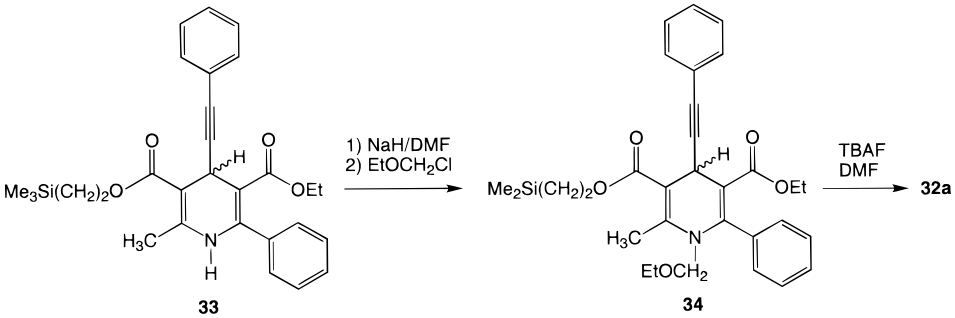
[a] Reagents: (a) NBS; (b) CH_3OCH_2Cl, Et_3N; (c) K_2CO_3, acetone, reflux; (d) 1 N HCl, acetone, 45 °C; (e) $H_2N(CH_2)2NH_2$, rt., 4 h; (f) N-hydroxysuccinimidyl biotin, DMF, rt.

parative TLC to yield the desired products (yield = 65% for **31a** and 62% for **31b**).

p-(Bromomethyl)benzenesulfonyl Fluoride (***31a***). ^{1}H NMR ($CDCl_3$/TMS): δ 4.52 (s, 2 H, CH_2), 7.65 (d, J = 7.8 Hz, 2 H, aromatic H's), 8.00 (d, J = 7.8 Hz, 2 H, aromatic H's).



(p-Bromomethyl)benzenesulfonamide (***31b***). MS (EI): 249 and 251 (M^+).

Preparation of Methoxymethyl 4-(Bromomethyl)-benzoate (31d) (Scheme 3). α-Bromo-*p*-toluic acid (3.37 g, 15.7 mmol) was dissolved in DMF (10 mL). Chloromethyl methyl ether (1.26 g, 1.19 mL, 15.7 mmol) was then added, followed by adding triethylamine (1.9 g, 2.62 mL, 18.8 mmol). The reaction was stirred at room temperature overnight. Water (10 mL) was added, and the mixture was extracted with dichloromethane, washed with water, brine, and dried over $MgSO_4$. Column chromatography (hexanes/ethyl acetate = 5/1) gave 0.588 g of light yellowish oil, yield = 15%. ^{1}H NMR ($CDCl_3$/TMS): δ 3.55 (s, 3 H, OCH_3), 4.62 (s, 2 H, BrCH_2), 5.50 (s, 2 H, OCH_2O), 7.48 (d, J = 7.8 Hz, 2 H, aromatic H's), 8.08 (d, J = 7.8 Hz, 2 H, aromatic H's). MS (EI): 259 (M^+).

Preparation of 1-Ethoxymethyl-2-methyl-5-ethoxycarbonyl-4-phenylethynyl-6-phenyl-1,4-(±)-dihydropyridine-3-carboxylic acid (32a) (Scheme 4). Sodium hydride (60% in mineral oil, 107 mg, 4.46 mmol) was added to compound **33** in solution of DMF (10 mL). The mixture was stirred for 30 min, chloromethyl ethyl ether (422 mg, 0.414 mL, 4.46 mmol) was added slowly to the solution under N_2 at room temperature and stirred for 2h. The reaction was quenched by adding cold water (10 mL), extracted with ethyl acetate (10 mL x 2), the organic layer was washed with water (10 mL × 2), brine (10 mL × 2), dried with sodium sulfate. The solvent was evaporated and residue was purified with preparative TLC (silica gel 60, hexanes/EtOAc: 4/1) to give N-protected product **34** 497 mg, yield = 49%. ^{1}H NMR ($CDCl_3$): 0.00 (m, 9 H, 3-SiCH_3), 0.88 (t, 3 H, J = 6.8 Hz, 5-CH_2CH_3), 0.95 (t, 2 H, J = 6.8 Hz, 1-OCH_2CH_3), 1.12 (t, 2 H, J = 8.8 Hz, 3-OCH_2CH_2SiMe_3), 2.62 (s, 3 H, 2-CH_3), 3.15 (m, 1 H, 1-OCH_2CH$_3$), 3.69 (m, 1 H, 1-OCH_2CH$_3$), 3.92 (q, 2 H, J = 6.8 Hz, 5-OCH$_2$CH$_3$), 4.33 (t, 2 H, J = 6.8 Hz, 3-CO_2CH_2CH$_2$SiMe_3), 4.47 and 4.88 (AB, 2 H, J = 10.7 Hz, N-CH_2O), 5.09 (s, 1 H, 4-H), 7.24−7.42 (m, 10 H, aromatic H's). MS (CI−NH_3): m/z 563 ($M^+ + NH_4$), 546 ($M^+ + 1$).

TBAF (hydrate, 2.49 mmol, 1 M solution in THF) was added to a solution of **34** (340 mg, 0.623 mmol) in DMF

(2 mL). The mixture was stirred under N_2 at room temperature for 2 h, diluted with ethyl acetate (20 mL), washed with 1 N HCl (5 mL), H_2O (20 mL × 2) and brine (20 mL × 2), and dried with magnesium sulfate. The solvent was evaporated, and residue was separated with preparative TLC to give 271 mg of compound **32a** as a yellow solid, yield = 98%. ^{1}H NMR ($CDCl_3$): δ 0.95 (m, 6 H, OCH_2CH_3x2), 2.67 (s, 3H, 2-CH_3), 3.16 and 3.69 (m, 2 H, N−$CH_2OCH_2CH_3$), 3.94 (q, 2 H, J = 6.8 Hz, 5-OCH_2), 4.50 and 4.90 (AB, 2 H, N-CH_2O), 5.13 (s, 1 H, 4-H), 7.18 (br, 1 H, COOH), 7.24−7.43 (m, 10 H, 2 x C_6H_5). MS (EI): m/z 445 (M^+).

Pharmacology. Radioligand Binding Studies. Binding of [^{3}H]*R*-*N*^{6}-phenylisopropyladenosine ([^{3}H]*R*-PIA) to A_1 receptors from rat cerebral cortex membranes and of [^{3}H]-2-[4-[(2-carboxyethyl)phenyl]ethylamino]-5′-*N*-ethylcarbamoyladenosine ([^{3}H]CGS 21680) to A_{2A} receptors from rat striatal membranes was performed as described previously (*22*, *23*). Adenosine deaminase (3 units/mL) was present during the preparation of the brain membranes, in a preincubation of 30 min at 30 °C and during the incubation with the radioligands.

Binding of [^{125}I]*N*^{6}-(4-amino-3-iodobenzyl)-5′-*N*-methylcarbamoyladenosine ([^{125}I]AB-MECA) to membranes prepared from HEK-293 cells stably expressing the human A_3 receptor (*2*), clone HS-21a (Receptor Biology, Inc., Beltsville, MD) or to membranes prepared from CHO cells stably expressing the rat A_3 receptor was performed as described (*11*, *24*). The assay medium consisted of a buffer containing 10 mM Mg^{2+}, 50 mM Tris, and 1 mM EDTA, at pH 8.0. The glass incubation tubes contained 100 μL of the membrane suspension (0.3 mg of protein/mL, stored at −80 °C in the same buffer), 50 μL of [^{125}I]AB-MECA (final concentration 0.3 nM), and 50 μL of a solution of the proposed antagonist. Nonspecific binding was determined in the presence of 100 μM *N*^{6}-phenylisopropyladenosine (*R*-PIA).

All nonradioactive compounds were initially dissolved in DMSO and diluted with buffer to the final concentration, where the amount of DMSO never exceeded 2%.

Incubations were terminated by rapid filtration over Whatman GF/B filters, using a Brandell cell harvester (Brandell, Gaithersburg, MD). The tubes were rinsed three times with 3 mL of buffer each.

At least five different concentrations of competitor, spanning 3 orders of magnitude adjusted appropriately for the IC_{50} of each compound, were used. IC_{50} values, calculated with the nonlinear regression method implemented in the Prism program (Graph-PAD, San Diego, CA), were converted to apparent K_i values using the Cheng−Prusoff equation (*25*) and K_d values of 1.0 and 14 nM for [^{3}H]*R*-PIA and [^{3}H]CGS 21680, respectively, and 0.59 nM for binding of [^{125}I]AB-MECA at human A_3 receptors, respectively.

For studies of irreversible binding, membranes were incubated with the indicated (Figure 2) concentration of ligand for 1 h at RT. Membranes were then washed 10 times by sequential resuspension and centrifugation with buffer (50 mM Tris, 10 mM Mg^{2+}, and 1 mM EDTA) at pH 7.4 containing 0.02% CHAPS. Adenosine deaminase (3 units/mL) was present during all steps. The final pellet was suspended in a fixed volume of the above buffer solution for the A_3 receptor binding assay as described.

RESULTS

Synthesis. The structures of the 1,4-dihydropyridines and related derivatives (**1b**−**23**) tested for affinity in

radioligand binding assays at adenosine receptors are shown in Table 1. As in the previous studies (*12*, *14*), the basic synthesis of the DHP nucleus consisted of the Hantzsch condensation (Scheme 1, reviewed in ref *19*). This method involves a three component reaction of a 3-amino-2-propenoate ester, such as benzyl 3-amino-3-phenyl-2-propenoate (Scheme 1), **24a**, an aldehyde, such as phenylpropargyl aldehyde, **25**, and a β-ketoester, such as benzyl acetoacetate, **26a**, that were dissolved in ethanol and refluxed. β-Ketoesters containing free hydroxyl and thio groups, **26d**−**f**, for use in the unprotected form in the condensation reaction, were synthesized as shown (Scheme 2). A silyl-protected thiol, **26g**, was also included.

The synthesis of DHP derivatives containing benzyl esters at the 3- and 5-positions, that were substituted with various acyl and sulfonyl groups, some of which were chemically reactive, was best approached through the alkylation of a free carboxylic acid using the corresponding benzyl bromide (Scheme 3). The benzyl bromides, **31a**−**c**, were synthesized by bromination of the corresponding toluene derivatives, **30a**−**c**, using *N*-bromosuccinimide. Use of compounds **30c** and **31c** in this context was described previously (*12*). The appropriate 3- or 5-carboxy derivative of the 6-phenyl-4-phenylethynyl-DHP was prepared by the methodology described (for the 5-carboxy derivative) in Jiang et al. (*12*). This approach incorporates a protecting group, a (2-trimethylsilylethyl)ester, at the 5-ester (*12*) or 3-ester (Scheme 4) position, that allows for facility of substitution of this ester and protection of the 1-position with the ethoxymethyl group (*12*). The 5-(2-trimethylsilylethyl)ester group was introduced at the stage of the Hantzsch condensation and subsequently removed using TBAF to provide **32b**. The resulting free carboxylic acid was then esterified in high yield by means of alkylation using the appropriate benzyl bromide, **31**, with potassium carbonate in acetone. The 1-ethoxymethyl group was finally removed upon heating at 45 °C for 1 h with 1 N HCl in acetone, to provide 5-position substituted benzyl esters, **19**−**21**, or 3-position esters, **13**−**15**.

Several additional modifications of functionality at the p-position of these benzyl esters were carried out. The 2,2,2-trichloroethyl derivatives (*12*), **15** and **21** (Scheme 3 and Table 1), were aminolyzed selectively using neat ethylenediamine at room temperature, to provide the amine functionalized congeners, **16** and **22**, respectively. As demonstrated by Jiang et al. (*12*), the ester groups at the 3- and 5-positions of the DHP were not susceptible to reaction with ethylenediamine under these conditions. Also, the methoxymethyl groups of **33** and **34** were removed using 1 N HCl to provide the corresponding carboxylic acid derivatives, **17** and **23** (Table 1). One of the primary amine congeners, **16**, was also acylated using a biotin-active ester to provide the biotin conjugate, **18**.

Pharmacology. Compounds **2** and **3** are 3,5-diethyl ester derivatives of 6-phenyl-1,4-dihydropyridines previously shown to act as selective A_3 receptor antagonists. Furthermore, the incorporation of a single benzyl ester at the 3- or 5-position was shown to enhance selectivity for the A_3 subtype. Several related benzyl esters, **4** and **5**, were included. As previously reported, the 3-benzyl ester, **4**, is >600-fold selective, although not as potent as the 3,5-diethyl ester, **3**, while the 5-benzyl ester, **1b**, is twice as potent at A_3 receptors as **3**. Combining both benzyl esters, in **5**, did not alter the receptor affinity of the 3-benzyl ester, **4**. However, at the 2- and 6-positions, double substitution with phenyl groups, as in compounds **6** and **7**, prevented binding to adenosine receptors.

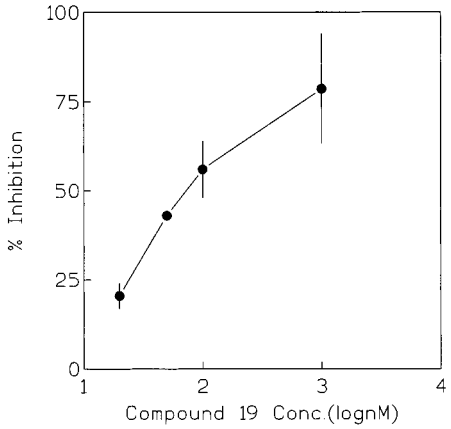

Figure 2. Irreversible inhibition of radioligand ([^{125}I]AB-MECA) binding to human A_3 adenosine receptors in HEK-293 cell membranes, following a 1 h incubation with the sulfonyl fluoride derivative, **19** (n = 2−6).

Transformation of the 3-ethyl ester of **1b** into a β-methoxyethyl ester, **8a**, enhanced affinity at A_3 receptors by ~15-fold. Incorporation of a p-nitro group in the 5-benzyl ester substituent, **8b**, which was shown previously to enhance A_3 receptor affinity by roughly an order of magnitude (*12*), had no further enhancing effect on the affinity of the β-methoxyethyl ester. Incorporation of a β-hydroxyl group in the 3-ethyl ester substituent, **9**, had an affinity-enhancing effect at A_3 adenosine receptors. Curiously, a thiol group at the same position was much less favorable for affinity at A_3 receptors, both for the 3-ester analogue, **10**, and the corresponding 3-thioester, **11**. A β-trimethylsilylethyl derivative, **12**, only weakly bound to adenosine A_3 receptors.

The structure activity relationships of p-substituted 3- and 5-ester positions were probed, as potential sites for attachment of functionalized chains. Ring substitution of the 5-benzyl ester with a 4-fluorosulfonyl group, **19**, provided enhanced selectivity of >30000-fold for the A_3 receptor, while similar substitution of the corresponding 3-benzyl ester, **13**, was not affinity enhancing. The corresponding sulfonamides, **14** and **20**, displayed only moderate potency and selectivity, with only minor affinity differences between 3- and 5-isomers. The corresponding 3- and 5- carboxylates, **17** and **23**, were prepared, and only **17** bound to A_3 receptors with moderate potency. A DHP containing a long amine-functionalized chain attached at the 3-position, **16**, displayed moderate affinity, while the corresponding 5-isomer, **22**, was 5-fold less potent at A_3 receptors and nonselective.

Since an amine-functionalized chain attached at the 4-position of a benzyl ester at the 3-position of the DHP ring provided higher affinity A_3 receptors, **16** was used as an intermediate in the synthesis of a biotin conjugate, **18**. The biotin derivative showed >100-fold selectivity for human A_3 receptors.

Unlike related derivatives not containing a reactive, electrophilic group, the sulfonyl fluoride derivative, **19**, appeared to irreversibly bind to the A_3 receptor in a concentration-dependent manner (Figure 2). A 1 h preincubation with this derivative resulted in the loss of binding in a subsequent experiment following exhaustive washing of the membranes. At 100 nM **19**, approximately 56% of human A_3 receptor radioligand binding sites in transfected HEK-293 cell membranes were irreversibly inhibited. As control experiments, similar preincubation with other A_3 receptor antagonists was carried out. Preincubation with 8-*p*-sulfophenyltheophylline (10 μM),

CGS 15943 (1 μM) (*16*), and MRS 1067 (1 μM) (*12*) failed to affect the level of subsequent A_3 receptor radioligand binding. Preincubation with compound **1b**, or its highly potent 4-nitrobenzyl derivative (*12*), at 100 nM did not significantly affect the level of subsequent A_3 receptor radioligand binding (loss of <10% of total binding). Compound **13**, another fluorosulfonyl derivative which bound considerably more weakly to human A_3 receptors, resulted in only 11 and 62% irreversible inhibition of radioligand binding at 1 and 5 μM, respectively.

DISCUSSION

Previously, we have applied a "functionalized congener approach" (*21*) to the design of ligands for G protein-coupled receptors, such as adenosine receptors (*12*), muscarinic receptors (*35*), and nucleotide receptors (*36*). By this approach, an easily derivatized functional group is incorporated at the end of a strategically designed and attached chain-substituent Several of the derivatives in Table 1, such as the amines, **16** and **22**, and the carboxylic acids, **17** and **23**, represent easily reacted functionalized congeners of dihydropyridines, derivatives of which would retain moderate affinity and/or selectivity as A_3 receptor antagonists.

The indication that the 5-ester position is the most flexible for substitution in relation to A_3 receptor affinity has suggested the design of the amine-functionalized congener, **22**. As in our previous studies of purines derivatized with long chains for the purpose of conjugating with other molecules while retaining the biological potency, this derivative may prove to be a key intermediate in the design of much higher molecular weight derivatives bearing "carrier" moieties, reporter groups, prosthetic groups, etc. The presence of the amino group in **22** also increased water solubility; unfortunately, it was not potent in binding at human A_3 receptors.

Irreversible inhibitors of binding of A_1 and A_{2A} subtypes of adenosine receptors have been reported (*26*−*29*). Furthermore, an irreversibly binding A_3 receptor agonist, MRS 1163, derived from IB-MECA was characterized (*30*). Among the pharmacological applications of such affinity labels are establishing the levels of spare receptors in native tissues, such as the heart (*31*−*33*). The irreversibly binding A_3 receptor antagonists presented in this study may prove to be useful tools in the characterization of this receptor subtype. Since the DHP antagonists (*12*) are selective for the human A_3 receptor vs other species, the design of irreversible ligands for A_3 receptors in rat (*14*) and other species remains to be accomplished.

ACKNOWLEDGMENT

We thank the Cystic Fibrosis Foundation (Silver Spring, MD) for financial support and Dr. Mark Olah and Dr. Gary L. Stiles of Duke University Medical Center for helpful discussions.

TECHNICAL NOTES

Bioactive Surfaces via Immobilization of Self-Assembling Polymers onto Hydrophobic Materials

Lev Bromberg* and Lawrence Salvati, Jr.

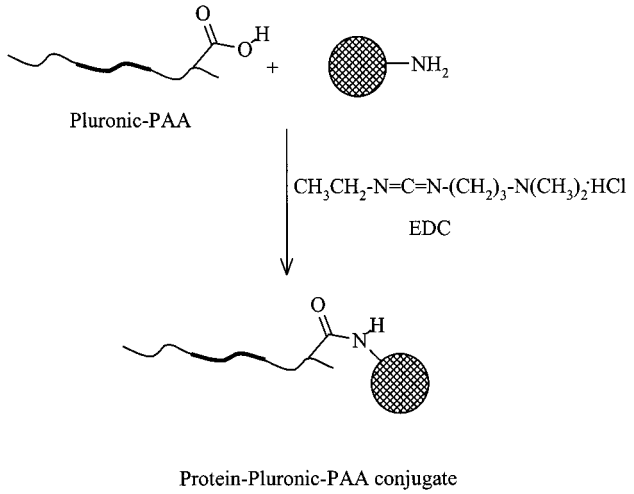
Abbott Laboratories, MediSense Products. Received August 5, 1998;
Revised Manuscript Received December 29, 1998

Conjugation of proteins to copolymers from poly(acrylic acid) grafted onto PEO−PPO−PEO backbone (Pluronic-PAA) following adsorption of the conjugates onto hydrophobic surfaces is reported. Insulin-Pluronic-PAA conjugates show negligible internalization of insulin into human uterine smooth muscle cells as well as enhancement of mitogenic activity. Glucose-induced release of glycated albumin complexed with a Pluronic-PAA-concanavalin conjugate and adsorbed onto polystyrene nanospheres may provide a model for a glucose-responsive protein delivery system or a heterogeneous diagnostic device.

INTRODUCTION

Immobilization of biomolecules such as enzymes, antibodies, and nucleic acids onto various particulates and films is a widespread method of producing bioactive surfaces for use in immunoassays, chromatography, cell proliferation, drug delivery, etc. (*1*). Hydrophobic polymers, and particularly polystyrene, are often quite useful as neutral carriers readily available in a variety of shapes and sizes. Since polystyrene causes nonspecific adsorption and also lacks functional groups, it is customary to modify it with hydrophilic polymers (*2*). This modification is usually accomplished by surface treatment, e.g., by glow discharge (*3*) or copolymerization (*4*). In this study, a novel strategy toward bioactive surfaces by adsorption of self-assembling copolymers modified by proteins and enzymes onto polystyrene was explored. The self-assembling copolymers possess sufficiently hydrophobic blocks that strongly interact with polystyrene and yet carry polyelectrolyte segments, which are accessible for modification. Recently, a novel class of hydrophobically modified polyelectrolytes was introduced whereby poly(propylene oxide) (PPO) group acts as a temperature-sensitive hydrophobe (*5*−*20*). Attachment of the PPO group onto a polyelectrolyte is a means of creating a dually responsive, self-assembling material by adding temperature sensitivity to an already pH- and ion-sensitive polymer. In the present work, ongoing study is continued that is concerned with a distinct species of such dually responsive polymers whereby multiple poly(acrylic acid) (PAA) segments are grafted onto Pluronic poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide) (PEO−PPO−PEO) block copolymers via C−C bonding (*10*). High molecular weights and extreme sensitivity to temperature distinguish these PEO−PPO−PEO−PAA copolymers. Above certain temperatures, their semidilute aqueous solutions can form reversible gels with significant elastic moduli (*9*). Gelation is due to appearance of micelle-like aggregates that serve as physical cross-links between Pluronic-PAA chains, as shown by rheological methods (*8*), probe solubilization (*17*), light scattering (*7*, *15*), NMR (*20*), SANS (*12*), SEC (*11*), and DSC (*11*) techniques. Herein, we have taken interest in the use of the self-assembling polymers as matrixes for conjugation of biomolecules. The conjugates appear to adsorb strongly onto hydrophobic surfaces, as described below.

EXPERIMENTAL SECTION



Unless stated otherwise, all chemicals were obtained from Sigma-Aldrich Co. and were used as received. Pluronic F127 NF ($EO_{100}PO_{65}EO_{100}$) was purchased from BASF Corp. (Parsippany, NJ). Poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide)-*g*-poly(acrylic acid) (PEO−PPO−PEO−PAA) (CAS no. 186810-81-1) was synthesized by dispersion/emulsion polymerization of acrylic acid along with simultaneous grafting of poly(acrylic acid) onto the Pluronic backbone using initiators lauroyl peroxide and 2,2′-azobis(2,4-dimethylpentanenitrile) (DuPont Specialty Chemicals) as described in detail elsewhere (*14*). Copolymer fraction used in this study had a M_w of 3.2×10^6 and PAA and Pluronic contents of 55 and 45%, respectively (*11*, *14*). Polystyrene (PS) nanospheres were obtained from Seradyn, Inc. (Indianapolis, IN) and had a nominal diameter of 69 nm. Albumin-2-amido-deoxy-D-glucose (bovine, ∼15−20 mol of glucose/mol of albumin) and α-D-glucosylated-FITC-albumin (bovine, ∼15−20 mol of glucopyranose and 2−3 mol of FITC/mol of protein) were obtained from Sigma and dissolved at 1:1 molar ratio in 10 mM phosphate buffer following lyophilization prior to use.

Conjugation of Proteins with Pluronic-PAA Copolymers. Conjugation of fluorescein isothiocyanate (FITC)-labeled concanavalin A (Con A, 1.5 mol of FITC/mol of protein, ∼95% protein) onto Pluronic-PAA was carried out by simultaneous activation and coupling with a water-soluble condensing agent, 1-ethyl-3-(3-dimethy-

Scheme 1. Conjugation of a Protein and Pluronic-PAA Copolymer

laminopropyl)carbodiimide (EDA) (Scheme 1). The Pluronic-PAA, FITC-Con A, and EDA components were dissolved in 10 mM phosphate buffer (pH 7.4) at 4 °C to result in final concentrations of 10 mg/mL, 2 mg/mL, and 2 mg/mL, respectively. The mixture was then gently shaken for 24 h at 4 °C. The resulting conjugate was precipitated by addition of 1 M HCl at pH 4.8, quickly filtered off, and redissolved in chilled 10 mM phosphate buffer. The conjugated FITC-Con A was assayed fluorometrically (typical λ_{ex} 490 nm, λ_{em} 520 nm). To verify that the FITC-Con A was covalently attached to Pluronic-PAA, a control experiment was conducted as follows. A mixture of FITC-Con A and the polymer was run without addition of the EDC activation reagent. After the same treatment as that with EDC, a negligible amount of protein and FITC-Con A was detected in the precipitate. Gel-permeation chromatography (GPC) of Pluronic-PAA and Con A-Pluronic-PAA conjugates was run at 15 °C on a Shimadzu LC-10A Series HPLC set up which included an RF-551 fluorescence HPLC detector, LC-10 AD solvent delivery unit, an SCL-10A system controller, and a Viscotek differential laser refractometer. An aliquot of 50 μL of 1.0 mg/g sample of conjugate solution in 0.05 M $NaNO_3$ was loaded onto a PL aquagel-OH analytical temperature-controlled 3-column system (particle size 8 or 15 μm; dimensions 300 × 7.5 mm, Polymer Laboratories, Inc.) and then eluted with 0.05 M $NaNO_3$ using a pump speed of 0.8 mL/min. Representative chromatograms of FITC-Con A-Pluronic-PAA conjugate are shown in Figure 1. GPC confirmed covalent binding of Con A and Pluronic-PAA. The conjugates were lyophilized and kept in sealed vials at 4 °C.

Zn^{2+}-insulin (from porcine pancreas, crystalline) and [^{125}I]insulin (porcine, 80−120 μCi/μg, NEN Life Science Products, Boston, MA) were conjugated to Pluronic-PAA copolymers as follows. Stock solution of Zn^{2+}-insulin and [^{125}I]insulin (50:1 mol ratio, total insulin concentration 500 μg/mL) was prepared in 10 mM phosphate buffer (pH 7.4). Pluronic-PAA and EDA were added to the stock solution at 4 °C to result in final concentrations of 10 and 2 mg/mL, respectively, and the mixture was gently shaken for 24 h at 4 °C. Then an equal volume of 10 mM glycine in phosphate buffer was added, and the solution was stirred at 4 °C for 6 h and filtered off using 0.45 μm membrane filter. The conjugate was then dialyzed against phosphate buffer at 4 °C for 24 h using Spectra/Por cellulose ester membrane (molecular weight cutoff 50 000, Spectrum, Laguna Hills, CA), lyophilized, and stored at

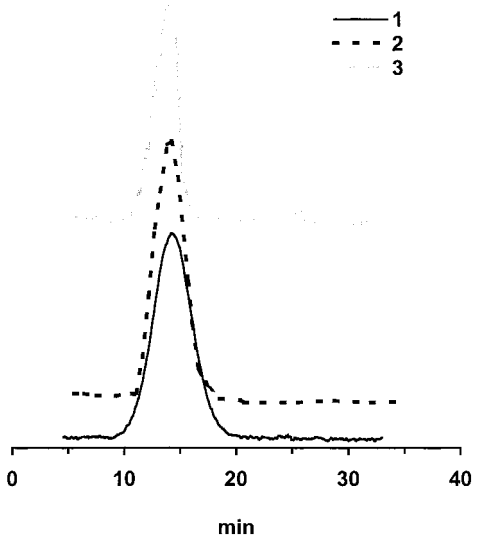

Figure 1. Gel-permeation chromatograms illustrating the conjugation of FITC-Con A with Pluronic-PAA copolymers. (1, 2) FITC-Con A-Pluronic-PAA; (3) FITC-Con A-Pluronic-PAA as in chromatogram 1 blended with FITC-Con A. Fluorescence at 515 nm (1 and 3) and refractive index (2) detection was used. Unbound FITC-Con A appears as a small peak in chromatogram 3.

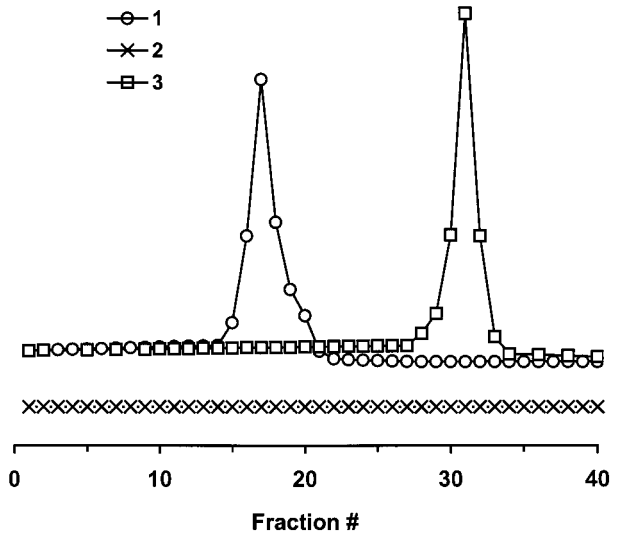

Figure 2. Gel-permeation chromatograms illustrating the conjugation of [^{125}I]insulin with Pluronic-PAA copolymers. (1) Insulin-Pluronic-PAA synthesized in the presence of EDA following dialysis; (2) Pluronic-PAA blended with [^{125}I]insulin without EDA following dialysis; (3) insulin.

4 °C in a sealed vial. To quantify conjugation of insulin onto Pluronic-PAA, identical synthetic procedure (but without EDA) was conducted followed by dialysis. A 0.01 mg/mL solution of the insulin-Pluronic-PAA conjugate or the initial mixture of [^{125}I]insulin and unlabeled insulin was passed through a TSK-gel G3000PW GPC column (600 × 7.5 mm, Toyo Soda) at 15 °C. The flow rate of 0.2 mL/min with 10 mM phosphate buffer as an eluent was used and a Gilson FC205 automatic fraction collector was applied. Collected fractions were kept in sealed vials at 4 °C and subjected to γ-radioactivity measurement. Figure 2 shows chromatograms pertaining to the insulin-Pluronic-PAA conjugate and Pluronic-PAA made with and without EDA, respectively, as well as insulin mixture. As can be seen, the polymer that participated in the control experiment without EDA did not contain detectable level of insulin, whereas the conjugate made

Table 1. Effect of Conjugate Adsorption on Surface Characteristics of Polystyrene Films

polystyrene	composition by XPS/ESCA (%) C	O	N	air-in-water contact angle (deg)
as received, bare surface	97.4	2.6	nd	86 ± 4 (6)
Pluronic-PAA	73.3	26.7	nd	33 ± 4 (10)
insulin-Pluronic-PAA	71.7	18.4	9.9	33 ± 6 (10)

with EDA exhibited well-defined peak clearly distinguishable from the original insulin. Fractions around the peak were collected and total radioactivity was measured. The yield of conjugation reaction of insulin onto Pluronic-PAA in the presence of EDA was estimated to be about 60%, based on relative radioactivity levels.

Conjugate Adsorption onto Polystyrene Surfaces. Polystyrene nanospheres were coated with FITC-Con A-Pluronic-PAA conjugates by first dispersing 2 mg/mL nanospheres in 10 mM chilled phosphate buffer following addition of equal volume of 2 mg/mL FITC-Con A-Pluronic-PAA conjugate. The resulting suspension was kept at 37 °C for 16 h, then snap-frozen and lyophilized. The resulting material was resuspended in 10 mM phosphate buffer (pH 7.4). The conjugate-coated particles were concentrated by centrifugation at 37 °C using Micropure Filtration Device (pore size 0.22 μm) (Millipore Co.), and the supernatant was removed. After resuspension in phosphate-buffered saline the particles were again concentrated and the supernatant collected for fluorescence measurement. Washing cycles were repeated until no FITC was detected in the washouts. Surface concentration of the conjugate was estimated spectrofluorometrically to be about 0.6 μg of FITC-Con A/cm^2. Adsorption of unconjugated FITC-Con A onto polystyrene particles under identical conditions was below 0.1 μg/cm^2.

Flat-well, polystyrene plates (Corning) with untreated surfaces were modified with insulin-Pluronic-PAA conjugates by placing 2 μL of 2 mg/mL conjugate solution in 10 mM phosphate buffer on the bottom of the well following evaporation of aqueous solution on air at 37 °C. A mixture of [^{125}I]insulin and unlabeled insulin was used for the conjugate preparation. Adsorption procedure was repeated up to 20 times for each well. The wells were gently rinsed by deionized water at 37 °C until γ-radioactivity in the washouts did not exceed that of a blank solution. In the control experiments, polystyrene surfaces were treated by identical Pluronic-PAA conjugate solutions without insulin or by insulin without conjugate. Insulin contents were calculated by comparing the radioactivity in the wells with that of [^{125}I]insulin per unit weight, as described elsewhere (*3*, *21*, *22*). The effect of conjugate adsorption on the properties of the polystyrene surfaces is presented in Table 1. Figure 3 shows adsorption isotherms (37 °C) of the insulin conjugated with Pluronic-PAA and that without conjugation. It can be seen that the amount of the adsorbed conjugated insulin at saturation by an order of magnitude exceeded that of unconjugated insulin.

Quantification of the Polymer Adsorption onto PS Particles. The mass of Pluronic-PAA conjugates and Pluronic F127 adsorbed on PS nanoparticles was determined by radioisotope method as follows (*23*, *24*). Amino-terminated Pluronic F127 was synthesized via the sequence of quantitative modifications (*25*):

$$\text{Pluronic-OH} \rightarrow \text{Pluronic-SO}_2\text{CH}_3 \rightarrow \text{Pluronic-N}_3 \rightarrow \text{Pluronic-NH}_2$$

with the amino group attached to one end of the Pluronic

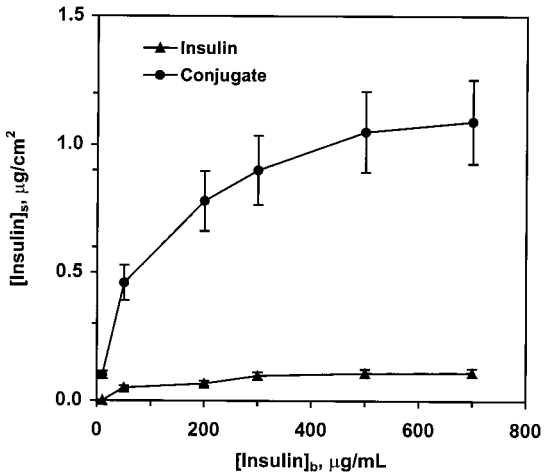

Figure 3. Adsorption isotherms (37 °C) of insulin and insulin-Pluronic-PAA conjugates onto polystyrene plate wells. Each point represents an average of six independent measurements.

molecule. Activation of only one terminal hydroxyl out of two present in a polyether is ensured by the proper ratio of equivalents of OH groups and an activation agent and is a commonly used technique (*25*−*27*). Marginal fractions with both end-groups modified are separated by HPLC (*27*). The 4-hydroxyphenyl moiety was then introduced into Pluronic-NH_2 by reaction with *N*-succinimidyl-3-[4-hydroxyphenyl]propionate (Bolton-Hunter reagent) (Pierce Chemical, Rockford, IL) in tetrahydrofuran following iodination reaction with Na^{125}I as described elsewhere (*28*).

For ^{125}I labeling, an aqueous solution of 3 w/v% Pluronic-PAA and 5 mg/mL *N*-hydroxysulfosuccinimidyl-4-azidosalicylic acid (sulfo-NHS-ASA) (Pierce) was deaerated under vacuum and illuminated by a Light-Welder 3010 EC UV spot/wand lamp (spectral output <500 nm and intensity of 600 mW/cm^2, Dymax Co., Torrington, CT) for 5 min. UV-irradiation results in formation of nitrenes of sulfo-NHS-ASA that attack tertiary H−C groups (*29*) thereby covalently binding the sulfo-NHS-ASA to Pluronic-PAA. The resulting solution (2 × 1 mL) was iodinated by using IODO-GEN solid-phase reagent kit (Pierce). IODO-GEN comprises 1,3,4,6-tetrachloro-3α,6 α-diphenylglycouril, a water-insoluble oxidizing agent that reacts with ^{125}I$^-$ to form a highly reactive mixed halogen species, ^{125}ICl. This intermediate adds radioactive iodine atoms to reagents possessing phenyl rings with electron-donating constituents, such as sulfo-NHS-ASA. The procedure of iodination using sulfo-NHS-ASA and IODO-GEN kit is recommended by Pierce Chemical Co. and is described in detail in Hermanson's monograph (*30*). Specific activity of ^{125}I-labeled Pluronic-PAA conjugate was in the range of 10^4 cpm/μg.

Aqueous solutions (3 w/v%) of labeled Pluronic or Pluronic-PAA conjugates mixed with their unlabeled counterparts at 1:20 weight ratios were used for adsorption onto PS nanospheres. Following a 24 h adsorption at 37 °C, the coated nanospheres were concentrated by centrifugation using Microcon-30 Microconcentrator (molecular weight cutoff 30 000) and Micropure Filtration Device (pore size 0.45 μm) (Millipore Co.) for Pluronic and Pluronic-PAA solutions, respectively, and the supernatant was removed. Due to high molecular weight of Pluronic-PAA, its (gelled) aqueous solutions could not be filtered with a pore size below 0.45 μm. Slurry of agglomerated polymer-coated PS particles was effectively concentrated by the filtration, without significant loss. After resuspension in phosphate-buffered saline, the

Table 2. Pluronic-PAA and Pluronic F127 Adsorption at 37 °C onto Polystyrene Nanoparticles

species	m_p (ag/particle)[a]	surface density (nm^2/molecule)
Pluronic-PAA	35 600 ± 6000 (5)	2.1 ± 0.4 (5)

[a] ag stands for attograms (10^{-18} g), as defined by SI.

particles were again concentrated and the supernatant was collected for radioactivity measurement. Washing cycles were repeated until supernatant radioactivity did not exceed that of a blank. Then the radioactivity of the separated solids was measured and related to the known amount of particles and known radioactivity per mass of the polymer. The value for the surface area occupiedper Pluronic or Pluronic-PAA molecule was calculated as (*24*)

$$\frac{\text{surface area}}{\text{molecule}} = \frac{\pi d^2 \times \text{MW}}{m_p N_A}$$

where $d = 69$ nm is the particle mean diameter, MW = 12 600 and 3×10^6 are molecular weights of the Pluronic and Pluronic-PAA conjugate, respectively, m_p is the mass of the adsorbed polymer, and N_A is Avogadro's number.

Results of quantification of polymer adsorption are collected in Table 2. Pluronic F127 adsorption correlated well with reported data on adsorption of other Pluronics onto the same particles (*23*).

In Vitro Protein Binding and Release Studies. A normal human uterine smooth muscle cell line from a single donor was used for conjugate−cell interaction studies. The cells were grown in 25 mL flasks at 37 °C, under 5% CO_2, in a minimum essential medium (MEM) supplemented with 10% fetal bovine serum, 50 mg/mL Gentamicin, and 50 μg/mL Amphotericin B. The cells of about 90% confluence were harvested using 0.025% trypsin/0.01% EDTA buffer solution at exponential growth phase (6−8 days after seeding), washed and incubated in 96-well plates at approximately 7200 cells/well. Four series of experiments were conducted where each well contained (i) a mixture of [^{125}I]insulin and Zn^{2+}-insulin (molar ratio 1:100) dissolved in MEM (dissolved insulin); (ii) a labeled insulin-Pluronic-PAA conjugate dissolved in MEM (dissolved conjugate); (iii) a mixture of [^{125}I]-insulin and Zn^{2+}-insulin adsorbed onto plate well (adsorbed insulin); and (iv) a labeled insulin-Pluronic-PAA conjugate adsorbed onto plate well (adsorbed conjugate). The insulin binding with the cells was measured after 3, 16, 24, and 48 h incubation following repeated cell washing with the binding buffer [15 mM Tris, 120 mM NaCl, 1.2 mM $MgSO_4$, 5 mM KCl, 10 mM glucose, 15 mM sodium acetate, 1% bovine serum albumin, 20 μg/mL bacitracin, and 50 μg/mL methiolate (*31*)]. The cells were detached from the plates by 0.025% trypsin/0.01% EDTA buffer solution. The fractions of bound and free insulin were separated by centrifugation. The cell pellet was resuspended in 200 μL of binding buffer. Insulin internalization was expressed as *Ins.In* (%) = $100 \times R_c/R_o$, where R_o (cpm) is the radioactivity of the well immediately after seeding, and R_c (cpm) is the radioactivity of the cells detached from the well. Cell growth was measured by the procedure of 6-[^{3}H]-thymidine uptake as described elsewhere (*32*−*34*). Confluent cells were incubated for 48 h and pulsed with ~1 μCi/well with [^{3}H]-thymidine for 3 h. The plates were then washed and DNA was precipitated by 10% trichloroacetic acid. The resulting precipitate was solubilized with 0.1% sodium dodecyl sulfate/0.1 M NaOH. The lysate was neutralized with 5 M HCl, and the incorporated radioactivity was assayed by β-liquid scintillation counting. Five series of experiments were conducted where a well contained one of the following: (i) Zn^{2+}-insulin dissolved in MEM (dissolved insulin); (ii) insulin-Pluronic-PAA conjugate dissolved in MEM (dissolved conjugate); (iii) Zn^{2+}-insulin adsorbed onto plate well (adsorbed insulin); and (iv) insulin-Pluronic-PAA conjugate adsorbed onto plate well (adsorbed conjugate). Relative cell growth rate [CGR (%)] was measured with and without (control) designated species and was calculated as an amount of DNA normalized to that in the control experiment. Quadruplicate CGR determinations were conducted for each insulin concentration.

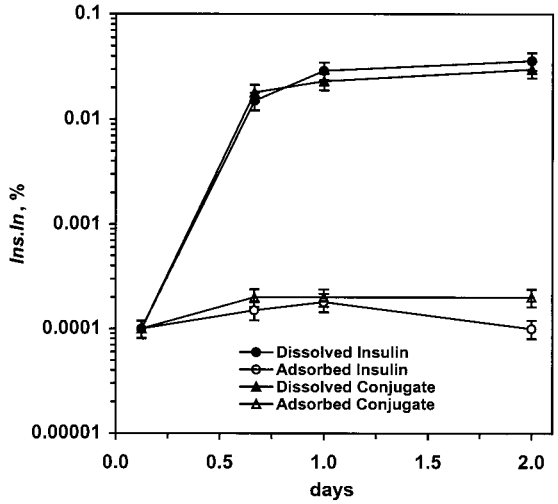

Figure 4. Internalization of different forms of insulin (*Ins.In*) into human uterine smooth muscle cells. For *Ins.In* definition, see the Experimental Section.

Glucosylated albumin binding to and release from FITC-Con A-Pluronic-PAA conjugates adsorbed onto PS nanoparticles was measured at 37 °C in 10 mM phosphate buffer at pH 7.4. A nanoparticle suspension (1 mL) with adsorbed concanavalin (effective Con A concentration 5 mg/mL, as measured by fluorescence) was mixed in a centrifuge tube with 1 mL of 1:1 mixture of albumin-2-amido-deoxy-D-glucose (G-Alb) and α-D-glucopyranosyl-FITC-albumin (G-FITC-Alb) (total glucosylated albumin concentration 0.2 mg/mL). The suspension was gently shaken at 37 °C for 8 h. The mixture was then centrifuged, and the pellet containing PS nanoparticles was separated from the supernatant and resuspended at 37 °C in 1 mL of 10 mM phosphate buffer. Total fluorescence of the G-Alb/G-FITC-Alb solution before contact with the conjugate-treated particles and of the supernatant after particle removal was measured. The weighted amount of particle suspension was mixed with 1 mL of either 10 mM phosphate buffer or 100 mg/dL glucose solution in the same buffer and the suspensions were gently shaken for 16 h at 37 °C. The suspensions were centrifuged and the fluorescence of the supernatant was measured. The procedure of loading and release was repeated. Identical experiments were conducted with nanoparticle suspension with 100 mg/dL glucose solution in 10 mM phosphate buffer without albumin.

Relative albumin release in the presence of glucose was expressed as R_g (%) = $100 \times (I_G - I_{wo})/(I_o - I_n)$, where I_G and I_{wo} is the maximum intensity of the supernatant with and without glucose, respectively (after corresponding cycle of albumin loading and release), and I_o and I_n is the maximum intensity of the FITC-Con A aqueous solution (corresponding to initial concentration of adsorbed Con A) and that of supernatant in the control experiment without albumin, respectively. Relative re-

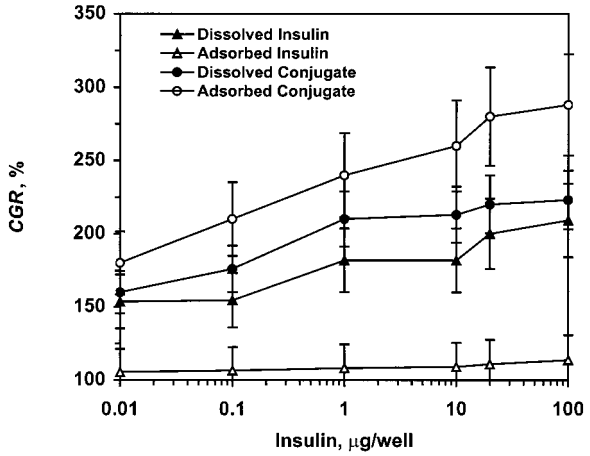

Figure 5. Relative cell growth rate (CGR) of human uterine smooth muscle cells in the presence of either native insulin or insulin conjugated onto Pluronic-PAA. Insulin or insulin-Pluronic-PAA conjugate were either dissolved in minimum essential medium or adsorbed onto plate wells as described in the Experimental Section.

lease without glucose was expressed by R_o (%) = 100 × $[I_{wo}/(I_o - I_n)]$. Cumulative desorption of Con A-Pluronic-PAA conjugates from nanoparticles was expressed as

$$z = 100\sum_{1}^{n}[1 - (I_o - I_n)/I_o]$$

Procedures. The β and γ radioactivity was determined using Wallac 1409 DSA liquid scintillation (EG&G Wallac) and COBRA gamma (Packard Instrument Co.) counters, respectively.

Fluorescence spectra were recorded on a SPEX FluoroMax spectrofluorometer applying 1 nm band-pass. Three scans were averaged and the spectra were corrected for scattering in blank solutions without FITC-Con A or G-FITC−Alb.

X-ray photoelectron spectroscopy (XPS/ESCA) was conducted using a 5000 Series spectrophotometer (Physical Electronics, Inc.). Air-in-water contact angles were measured using CAM-Micro optical device (KSV Instruments).

RESULTS

The binding/internalization of insulin into cells during culturing of human uterine smooth muscle cells for 2 days is depicted in Figure 4. It can be seen that either insulin or insulin-Pluronic-PAA conjugates exhibited almost identical association with the cells when dissolved in MEM, whereas adsorbed insulin or conjugate had negligible internalization. This result shows availability, in solution, of insulin conjugated with Pluronic-PAA, despite the high molecular weight of the conjugates.

Despite the lack of binding/internalization, adsorbed insulin-Pluronic-PAA conjugates appeared to stimulate the DNA synthesis to a higher degree (1.5−2.0-fold) when compared to free insulin (Figure 5). Although dissolved conjugates were less potent mitogenic agents than ad-

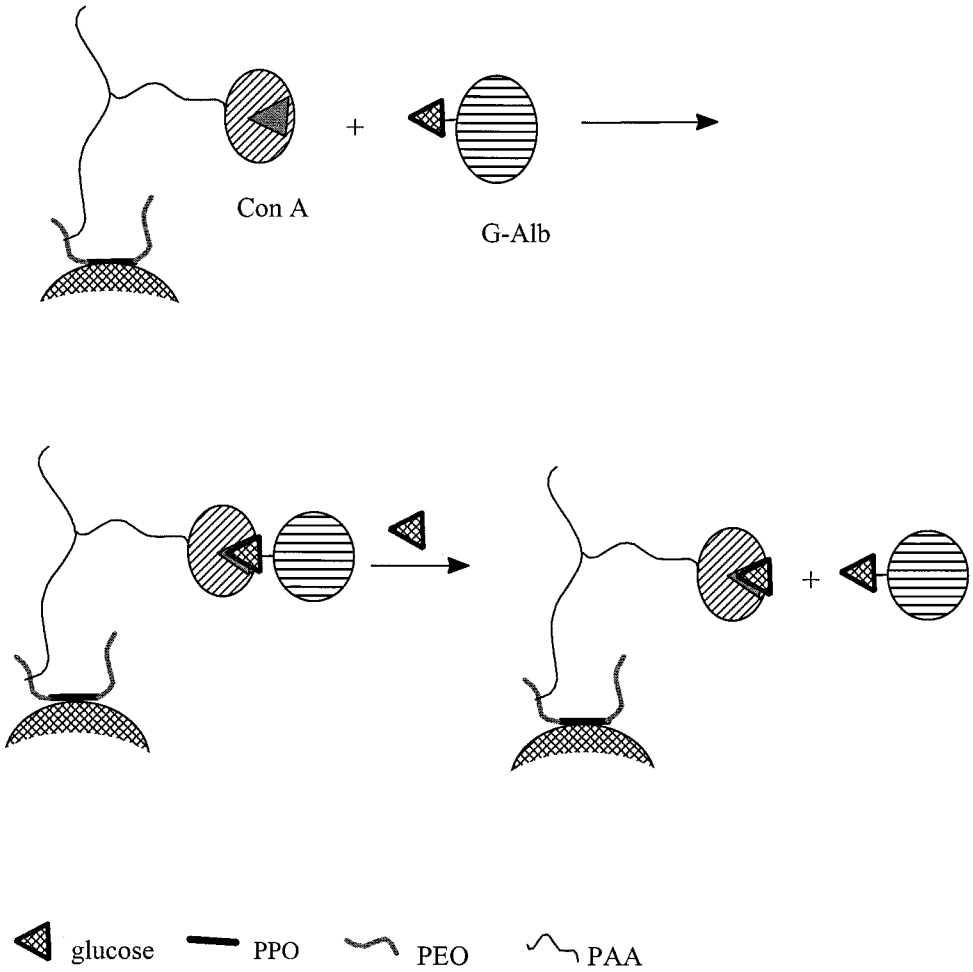

Figure 6. Scheme of interaction of glycosylated albumin (G-Alb) with Pluronic-PAA-Con A conjugates adsorbed onto polystyrene surfaces, followed by glucose-triggered G-Alb release.

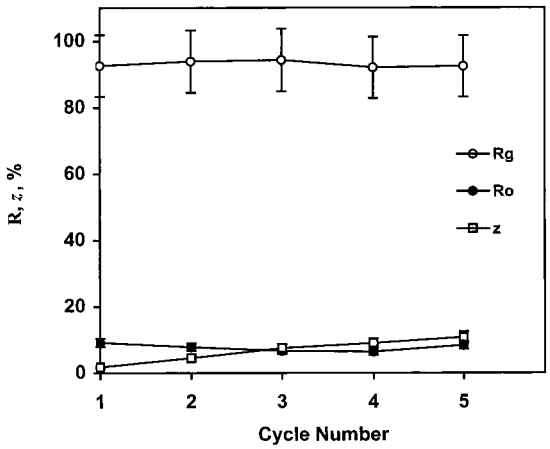

Figure 7. Relative release of glucosylated albumin in the presence (R_g, %) and absence (R_o, %) of glucose into 10 mM phosphate buffer (pH 7.4, pH 37 °C) from polystyrene nanoparticles treated by Con A-Pluronic-PAA conjugates. The R_g is found at 100 mg/dL glucose. Relative desorption of FITC-Con A-Pluronic-PAA conjugates from nanoparticles into 10 mM phosphate buffer at 37 °C is designated by *z*. Each point represents an average of 4 independent measurements. For parameter definition, see the Experimental Section.

sorbed ones, they exhibited 1.1−1.4-fold higher mitogenic activity than free insulin. Conversely, adsorbed insulin itself (without Pluronic-PAA) did not enhance the rate of DNA synthesis.

Glucose-stimulated release of glycosylated albumin (G-Alb) from complexes with Con A conjugated with Pluronic-PAA and adsorbed onto PS nanoparticles is shown schematically in Figure 6. The release was nearly complete, during at least five loading-desorption cycles (Figure 7). Cumulative desorption (*z*) of the FITC-Con A-Pluronic-PAA conjugates after same cycling was about 10% thereby demonstrating considerable stability of adsorbed conjugates on the PS particles under shear stresses applied due to handling. Release without glucose (R_o) was 10-fold lower than that with glucose and could be attributed to desorption of G-Alb-concanavalin complexes from the nanoparticles.

DISCUSSION

There have been numerous reports demonstrating applications of self-assembling poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide) (PEO−PPO−PEO) copolymers (Pluronic surfactants), for surface treatment. Pluronics are among a small number of surfactants approved by the U.S. Food and Drug Administration for the use in food and pharmaceuticals (*35*). The benign nature, lack of attractive interaction with proteins, and strong micelle-forming capability of Pluronics impart useful properties to Pluronic-modified surfaces, such as reduction of platelet adhesion (*36*), protein adsorption (*21*, *37*, *38*), bacterial adhesion (*39*), phagocytosis (*40*, *41*), and cell penetration enhancement in drug delivery (*7*). Conjugation of enzymes or antibodies to Pluronics following physical adsorption to hydrophobic surfaces is a means of tethering biomolecules to surfaces for use in heterogeneous assays (*28*). The tendency of many enzymes to denature on hydrophobic surfaces (*42*) may be overcome by tethering. The PPO block entropically interacts with the hydrophobic surface, while the hydrophilic PEO blocks extend to the hydration environment preventing direct exposure of the conjugated enzyme to the surface. Li et al. (*28*) developed a route of chemical modification of Pluronics via biomolecule conjugation to the OH end groups that produced robust coating for polystyrene surfaces. However, the end-group modification of Pluronics is inherently disadvantageous, if a high biomolecule loading is required. From this standpoint, recently developed copolymers of Pluronic and poly(acrylic acid) (Pluronic-PAA) (*5*−*20*) are attractive, as they combine spontaneous micellization capability of Pluronics and numerous carboxyl groups available for modification. An excess of carboxyl groups imparts an additional advantage to Pluronic-PAA conjugates such as mucoadhesive properties (*19*).

In this study, the concept of Pluronic-PAA copolymers conjugated with biomolecules for noncovalent surface modification is introduced. The grafting onto water-soluble polymers can alter biological activity of insulin (*34*, *43*−*45*). Insulin coupled with PEO possessed lower mitogenic activity than the native insulin, whereas PAA-insulin conjugates were shown to stimulate the growth of the mouse fibroblast cells more than the native insulin (*3*). It was intriguing to investigate mitogenic activity of the Pluronic-PAA copolymers, given their structure that combines PAA, PPO, and PEO segments. The overall enhancement of mitogenic activity observed for insulin conjugated to Pluronic-PAA (Figure 5) suggested that PAA-linked insulin might enhance receptor aggregation and formation of insulin conjugate−receptor complex. Conversely, lowering mitogenic activity by linking insulin to PEO (via A1-glycine and B29-lysine active sites) can be due to hindered access of the insulin-PEO to the receptor (*3*). Further enhancement of mitogenic activity by adsorption of the insulin-Pluronic-PAA complex (Figure 5) may be due to the lack of internalization and inhibited downregulation (*46*). Chen et al. (*3*) speculated that modification of polystyrene surface with PAA leaves no hydrophobic space available on PS for nonspecific interaction with insulin and reduces the roughness of the surface. On the basis of molecular weight and composition of Pluronic-PAA copolymers under study, their formula can be presented as $[EO_{100}PO_{65}EO_{100}AA_{132}]_{142}$ (*14*). The presence of ladder-like structures in these copolymers can be suggested (*9*) whereby PPO and PEO separate relatively long (over 10^2 units) PAA segments. Pluronic-PAA conjugates possess large area-per-molecule (~5.50 nm^2 at 20 °C and 4.0 nm^2 at 37 °C and pH 7.4) in dilute aqueous solutions (*8*). Using radioisotope method, we determined surface concentrations of Pluronic-PAA conjugates and Pluronic F127 on PS nanoparticles (Table 2). Surface concentration of Pluronic F127 correlated very well with that of other Pluronics (*23*). The area-per-molecule for various Pluronic surfactants at the air/water interface at 35 °C was reported to be in the range of 0.4-1.4 nm^2 (*47*). When compared with the surface density of 13−20 nm^2/molecule (Table 2 and ref *23*) this affords a conclusion that the surface density of Pluronic on nanoparticles is relatively low and no substantial adlayer is formed. The result is consistent with the observation of high mobility, in the absence of overlapping, of PEO segments of Pluronics on PS particles with $d = 69$ nm (*23*, *24*). More than 1400-fold higher m_p observed with Pluronic-PAA than with the parent Pluronic (Table 2) suggests large thickness of the adsorbed layer of the copolymer. The drastic difference between the adsorption of Pluronic and Pluronic-PAA copolymers can be understood based on the substantially different nature of their 3% solutions (*14*). Namely, the Pluronic solution at 3% and 37 °C exists in the form of micelles; no micellar cubic "gel" where PEO segments interpenetrate, is formed (*47*−*51*). At these same conditions, the Pluronic-PAA system forms a viscoelastic gel where large micellar aggregates are stabilized by domains of dense PPO segments (*8*−

11, 15). Most likely location of PS nanoparticles is within these domains (*15*). Low surface coverage in case of Pluronics causes the polymer chains to collapse into a "mushroom" conformation (*23, 24*), whereas Pluronic-PAA can form gellike layers on the PS surface (Figure 8). These relatively thick layers may completely maskthe roughness and hydrophobicity of the PS surface and reduce internalization/binding of insulin, "hidden" inside the layers (Figure 5). Low dissociation/internalization rate may explain increased mitogenic activity of the high molecular weight conjugates in viscous, gellike solutions. It has been argued (*52*) that enhanced mitogenicity of some insulin analogues is due to the longer association time with the insulin receptors. On the other hand, the gel layers of Pluronic-PAA are unlikely to inhibit diffusion of low molecular weight species (e.g., glucose) (*16, 20*). Hence, the complete recovery of G-Alb from Con A-Pluronic-PAA complexes was observed (Figure 7). This is the first encounter of a glucose-sensitive protein delivery system based on self-assembling Pluronic-PAA copolymer.

CONCLUSIONS

Applications of poly(acrylic acid) grafted onto PEO−PPO−PEO backbone (Pluronic-PAA) copolymers for polystyrene surface modification by adsorption were reported in this study. Insulin-Pluronic-PAA conjugates exhibited substantial association with the human uterine smooth muscle cells in solution, whereas the adsorbed conjugate had negligible internalization. It may be hypothesized that the lack of internalization contributed to the increase of mitogenic activity of the adsorbed Pluronic-PAA copolymers. Dramatic enhancement in the adsorption of Pluronic-PAA onto polystyrene nanospheres was observed when compared to that of the parent Pluronic due to adsorption of large domains of aggregated PPO segments. The glucose-induced release of glycated albumin complexed with concanavalin A conjugated with Pluronic-PAA and adsorbed onto polystyrene nanospheres may provide a model for a feedback-responsive protein delivery system or a heterogeneous detection device.

Received October 28, 1998; Revised Manuscript Received March 29, 1999

Random copolymers of 2-(dimethylamino) ethyl methacrylate (DMAEMA) with aminoethyl methacrylate (AEMA) were synthesized by radical polymerization. The amount of incorporated primary amino groups could be controlled by the feed ratio of AEMA to DMAEMA, and was varied from 2 to 6 mol %. Subsequently, protected thiol groups were introduced in a derivatization step with *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) and subsequent treatment with dithiothreitol (DTT). The obtained thiolated p(DMAEMA-*co*-AEMA) was conjugated to transferrin (Tf) or the F(ab′) fragment of mAb 323/A3 via a disulfide linkage. Moreover, the maleimide derivative of the nuclear localization signal (NLS) decapeptide Gly-Pro-Lys-Lys-Lys-Arg-Lys-Val-Glu-Asp-NH_2 was coupled to the thiolated polymer via a thioether linkage. The coupling efficiency, as determined by GPC (Tf), SDS−PAGE [F(ab′)], or ^{1}H NMR (NLS peptide) was 90−95% for the Tf conjugate, and more than 95% for the F(ab′) conjugate and the NLS conjugate. The synthetic strategy described in this paper is a universal method for the preparation of conjugates of proteins and peptides with pDMAEMA in particular. This method can possibly be used to synthesize protein−polymethacrylate conjugates in general.

INTRODUCTION

Water-soluble methacrylate/methacrylamide polymers are presently under investigation for the delivery of anticancer drugs (*1*, *2*) and for the delivery of genetic material (*3*). These polymers can be easily synthesized by the radical polymerization of the corresponding monomers, and their molecular weight can be controlled by the polymerization conditions. To deliver the polymer-drug conjugates or polymer−DNA complexes selectively into the target cell, a homing device (protein, sugar moiety) is often required. These homing devices are covalently coupled to the polymer of interest via established conjugation reactions using functional groups in both the polymer and the protein. Functional groups are intrinsically present in the polymer or can be introduced by copolymerization. Jelinkova et al. reported on the synthesis of conjugates of poly(hydroxypropyl methacrylamide) (HPMA) with monoclonal antibodies (MAb) by reaction of active esters of HPMA with MAb in aqueous solution (*4*). Besides methods based on active esters, protein conjugates can also be synthesized using methods based on the formation of disulfide bridges. The SPDP method, as first described by Carlsson et al. (*5*), is successfully and frequently applied for the synthesis of protein−protein conjugates (e.g., α-amylase-urease and ribonuclease-albumin) as well as for the synthesis of polymer-protein conjugates, e.g., pLys−Tf[1] conjugates (*6*) and PEI-protein conjugates (*7*). Within our group, we are working on poly[2-(dimethylamino)ethyl methacrylate] (pDMAEMA) as polymeric gene transfer agent. This polymer has good transfection potential as compared to other nonviral systems (pLys, lipofectin) (*3*). We are therefore interested in the design of systems based on this polymer, which selectively deliver the plasmid DNA into the nucleus of the target cell. It can be anticipated that by using a homing device the cell selectivity will increase and that by introduction of a so-called nuclear localization signal (NLS) peptide, nuclear targeting can probably be accomplished.

For the synthesis of pDMAEMA-protein/peptide conjugates, the polymer has to be functionalized, since in pDMAEMA, no groups are available for the covalent linkage of a homing device. The aim of this research is to develop a universal method to couple proteins or peptides to pDMAEMA. Therefore, pDMAEMA was first functionalized with primary amino groups by copolymerization of DMAEMA with a limited amount of 2-aminoethyl methacrylate (AEMA). Next, (part of) the amino groups were translated into thiol groups, using the SPDP method, after which this thiolated polymer was coupled to three different homing devices. First, transferrin was selected as a homing device since this protein is predominantly taken up by proliferating cells (*8*). Second, a F(ab′) fragment of the mouse monoclonal antibody 323/A3 was

coupled. This antibody is recognized by a M_r 43 kDa membrane glycoprotein, which is highly expressed on a variety of carcinomas (*9*). Last, thiolated pDMAEMA was coupled via a thioether linkage to a maleimide derivatized NLS peptide. As NLS sequence, the SV40 Slarge T antigen NLS sequence (Gly-Pro-Lys-Lys-Lys-Arg-Lys-Val-Glu-Asp-NH_2) was chosen because many NLS peptides contain (a variant of) this sequence (*10*, *11*).

MATERIALS AND METHODS

General. *Materials*. The following compounds were used as received: 2-aminoethyl methacrylate hydrochloride (AEMA, Polysciences Inc., Warrington, PA), ammonium peroxydisulfate (APS, Fluka, >98%), apotransferrin (*12*) (Sigma, low endotoxin, approximately 98%), dithiothreitol (DTT, Acros, 99%), 4-(2-hydroxyethyl)-1-piperazine-ethanesulfonic acid (Hepes, Acros, 99%), 1-hydroxybenzotriazole (HOBt), trifluoroacetic acid (TFA, peptide grade, Biosolve, The Netherlands), 9-fluorenylmethoxycarbonyl (Fmoc) protected amino acids, *N*-methylpyrrolidone (NMP, peptide grade Biosolve), succinimidyl 4-(p-maleimidophenyl butyrate) (SMPB, Pierce), N-succinimidyl 3-(2-pyridyldithio)propionate (SPDP, Pharmacia Biotech), and tris(hydroxymethyl)-aminomethane (TRIS, Acros, 99+ %).

N,*N*-Dimethylformamide (DMF, peptide synthesis grade, Biosolve, The Netherlands) was dried on molecular sieves before use. 2-(Dimethylamino)ethyl methacrylate (DMAEMA, Fluka, >98% by GC) was purified by distillation under reduced pressure just before use. All other chemicals were of analytical grade. Water was purified by reversed osmosis. The PBS used in this study contained 0.1 M phosphate, pH 7.5, with 0.1 M NaCl, whereas the HBS buffer was composed of 20 mM Hepes, pH 7.4, and 0.155 M NaCl.

Methods. Solid-phase peptide syntheses were carried out on an ABI 433A Peptide Synthesizer. The Fmoc-deprotection reaction was monitored at 301 nm. Tentagel S RAM resin was purchased from Rapp Polymere (Tübingen, Germany). Fast-atom bombardment (FAB) mass spectrometry (MS) was carried out on a JEOL JMS SX/SX 102A four-sector mass spectrometer, coupled with a HP-9000 data system. ^{1}H NMR spectra were recorded with a Gemini 300 MHz spectrometer (Varian Associates Inc. NMR Instruments, Palo Alto, CA). Approximately 30 mg of material was dissolved in 0.8 mL of ^2H_2O. The ^{2}HOH signal at 4.8 ppm was used as the reference line. A pulse length of 4.5 ms ($PW_{90} \approx 12$ ms) was used with a relaxation delay of 15 s. The molecular weights and molecular weight distributions of p(DMAEMA-*co*-AEMA) and its conjugates were determined by gel permeation chromatography (GPC) with an LC Module 1 Plus system (Waters Associates Inc., Milford, MA) and three thermostated (35 °C) columns in series (Shodex Ollpak KB-802 and KB-80, Showa Denko, Japan), equipped with a model 410 differential refractometer. The mobile phase was 0.1 M Tris (pH 7.2)/0.7 M $NaNO_3$, and the column was calibrated using dextran standards of known molecular weights (Fluka). The amount of free transferrin (Tf) in the p(DMAEMA-*co*-AEMA)-Tf conjugates was determined by GPC using a TSK 3000 column, eluted with 0.1 M phosphate (pH 6.7)/0.1 M Na_2SO_4. Conjugated Tf eluted in the void volume of the column (5 min), whereas the retention time of free Tf was 7 min and was quantified via a calibration curve (linear range 0.01−1.0 mg/mL Tf). Purification of derivatized polymer or protein was performed by gel filtration using Sephadex G-25 superfine columns with a void volume of 2.5 mL (PD-10, Pharmacia, Sweden). The intrinsic viscosity of p(DMAEMA-*co*-AEMA) was determined by measuring the specific viscosity of polymer solutions in 0.7 M $NaNO_3$/0.1 M Tris, pH 7.2, at 1.0, 0.66, and 0.33% w/v and extrapolating to zero concentration. The analysis was done with an Uhbelohde viscometer at 35 °C. The pDMAEMA concentration was quantified by Bio-Rad protein assay in water at 588 nm. The absorption was corrected for the protein present in the sample, and the calibration curve was linear from 0.5 to 4 mg/mL. SDS−PAGE was performed using the mini-PROTEAN II electrophoresis cell (Bio-Rad). The separating gel was 0.75 mm thick and contained 12.5% acrylamide. The gels were stained with Coomassie Blue.

Synthesis of Poly(dimethylaminoethyl methacrylate-*co*-aminoethyl methacrylate) [p(DMAEMA-*co*-AEMA)]. The DMAEMA-based copolymers were synthesized essentially according to Van de Wetering et al. (*3*). Freshly distilled 2-(dimethylamino)ethyl methacrylate (5.0 mL, 30 mmol) and varying amounts of aminoethyl methacrylate hydrochloride (0.75, 1.5 or 3 mmol) were dissolved in 25 mL of 1.3 M hydrochloric acid, and the pH was adjusted to 3. The solutions were deoxygenated by vacuum and nitrogen purging, and a calculated amount of APS (*M*/*I* 25, 50, or 100 mol/mol) was added. After polymerization in a water bath at 60 °C for 16 h, the polymers were purified by extensive dialysis against demineralized water and isolated by lyophilization. Yield: ca. 6 g (95−99%).

^{1}H NMR (^2H_2O): d 0.9−2.4 [5H, several bs, $-CH_2-CR(CH_3)-$], 3.0 [6H, bs, $-N(CH_3)_2$], 3.45 (small, bs, CH_2-NH_2), 3.6 [2H, bs, $(CH_3)_2NCH_2-$], 4.4 (2H, bs, $-OCH_2-$).

Thiolation of p(DMAEMA-*co*-AEMA). To a solution of p(DMAEMA-*co*-AEMA) (25 mg/mL in PBS) was added a calculated amount of SPDP (40 mM in ethanol) under vigorous mixing. After 30 min at room temperature, excess reagent and *N*-hydroxysuccinimide were removed by gel filtration (PD-10/PBS).

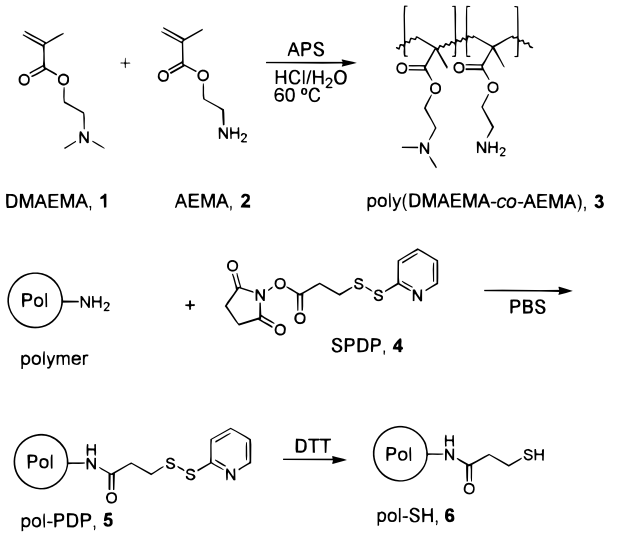
The pDMAEMA concentration was quantified by Bio-Rad protein assay in water at 588 nm. The amount of incorporated PDP groups was determined by quantifying 2-mercaptopyridine (pyrSH) at 343 nm, which was released from the PDP groups by treatment of 950 mL of PDP-derivatized polymer with 50 mL of 100 mM DTT in water (molar absorptivity of pyrSH: 8.08×10^3 M^{-1} cm^{-1}) (*5*). The thiol groups in p(DMAEMA-*co*-AEMA-PDP) were deprotected by treatment with excess dithiothreitol (DTT) (about 25 mg/100 mg of derivatized polymer) for 15−30 min at room temperature and subsequent gel filtration (PD-10/PBS), resulting in a solution of 11 mg/mL p(DMAEMA-*co*-AEMA)-SH (abbreviated as pol-SH).

Thiolation of Transferrin. To a solution of transferrin (10 mg/mL) was added a calculated amount of SPDP (40 mM in ethanol) under vigorous mixing. After 30 min at room temperature, excess reagent and *N*-hydroxysuccinimide were removed by gel filtration (PD-10/ PBS).

The transferrin concentration was quantified by UV absorbance at 280 nm. The amount of incorporated PDP-groups was determined as described for PDP-derivatized p(DMAEMA-*co*-AEMA).

Preparation of F(ab′) Fragments of the Mouse Monoclonal Antibody 323/A3. The mouse Mab 323/A3 was incubated with pepsin as described before (*13*) to yield $F(ab')_2$ fragments. It has been shown that under the selected conditions reduction of the disulfide bond between the heavy chains occurs, while the disulfide bond between the heavy and the light chain stayed intact (*13*).

The fragments were incubated at 3 mg/mL with 25 mM DTT in acetate buffer pH 5.5 (100 mM NaAc, 100 mM NaCl, and 1 mM EDTA) for 90 min at room temperature. DTT was removed by gel filtration (PD-10/deoxygenated HBS), yielding 2.1 mg/mL F(ab′) fragments in HBS. The F(ab′) fragments, which contain a thiol group, were used immediately for covalent coupling to PDP-derivatized p(DMAEMA-*co*-AEMA).



Synthesis of the 4-(4-Maleimidophenyl)butyrate Derivative of Gly-Pro-Lys-Lys-Lys-Arg-Lys-Val-Glu-Asp (NLS-MPB). The NLS decapeptide was synthesized by solid-phase synthesis. First, the amino acid Asp was attached to the resin (TentaGel S RAM). Coupling and deprotection cycles were carried out on a ABI 433A Peptide Synthesizer using ABI FastMoc 0.25 mmol protocols (*14*). Repetitive Fmoc cleavage was accomplished with 20% piperidine in NMP. Peptide couplings were performed using 4 molar equivalents of Fmoc-amino acid, BOP, and HOBt in the presence of DiPEA in NMP for 45 min. The Fmoc was removed by 20% piperidine in NMP. The Fmoc removal and formation of dibenzofulvene-piperidine adduct was followed by UV at 301 nm. A small portion of the resin was used for cleavage of the peptide by stirring in 95% TFA/H_2O for 2 h. The resin was removed by filtration, and the filtrate was lyophilized to give the deprotected peptide, which was characterized by HPLC, ^{1}H NMR, and FAB MS (*m*/*z* 1183.7 $[M + H]^+$).

The remaining peptide on resin (105 mg, 0.017 mmol of peptide) was weighed into a 10 mL flask, the Fmoc-group was removed using a 20% piperidine solution in NMP (stirred for 1 h at ambient temperature), after which the resin was washed with NMP (5×). The resin was suspended in NMP, after which 5 equiv (0.08 mmol) of SMPB, and 3 equiv of DiPEA were added. After 1.5 h stirring, the resin was filtered and washed with NMP. The product, containing a maleimide group, was cleaved from the resin by stirring with 95/5 TFA/water (v/v) for 2 h. The reaction mixture was filtered and the residue was washed with water. The total filtrate was lyophilized, yielding 0.039 g of peptide (0.018 mmol). ^{1}H NMR (^2H_2O): d 7.02 (s, 2H, maleimide), 7.25 (m, 2H, Ph), 7.40 (m, 2H, Ph). FAB MS: *m*/*z* 1424.8 $[MH]^+$.

Synthesis of Conjugates. *Conjugates of Transferrin with pDMAEMA*. The p(DMAEMA-*co*-AEMA)-Tf conjugate was prepared by addition of 0.67 mL of 15 mg/mL Tf-PDP (2.5 mol of PDP/mol of Tf) to 2.0 mL 10 mg/mL of pol-SH [1 mol of SH/150 mol of monomeric unit; p(DMAEMA-*co*-AEMA) with 6 mol % AEMA, M_n 30 kDa, M_w 785 kDa (relative to dextran)]. After incubation for 16 h, the low molecular mass compounds were removed from the reaction mixture by gel filtration (PD-10/HBS). The composition of the conjugate was determined by UV-analysis [A_{280} nm for Tf, Bio-Rad at 588 nm in water for p(DM)AEMA], whereas the conjugation efficiency was determined by quantification of free Tf by GPC chromatography.

Conjugates of F(ab′)-Fragment 323/A3 with pDMAEMA. The p(DMAEMA-*co*-AEMA)-F(ab′) conjugate was prepared by addition of 3.5 mL of 2.1 mg/mL F(ab′) in PBS to 0.88 mL of 17 mg/mL pol-PDP [1 PDP/140 monomeric units; p(DMAEMA-*co*-AEMA) with 6 mol % AEMA, M_n 30 kDa, M_w 785 kDa (relative to dextran)]. After incubation for 16 h, the low molecular mass compounds were removed from the reaction mixture by gel filtration (PD-10/HBS). The composition of the conjugate was determined by UV-analysis [A_{280} nm for F(ab′), Bio-Rad at 588 nm for p(DM)AEMA], whereas the conjugation efficiency was determined by SDS−PAGE analysis.

Scheme 1. Reaction Scheme of the Synthesis of Poly[2-(dimethylamino)ethyl Methacrylate-*co*-2-aminoethyl Methacrylate] and Subsequent Thiolation with *N*-Succinimidyl 3-(2-Pyridyldithio)propionate (SPDP)

Conjugation of NLS-MPB. To 3.5 mL of 12 mg/mL p(DMAEMA-*co*-AEMA)-SH in PBS [1 SH/50 monomeric units; 6 mol % AEMA, M_n 30 kDa, M_w 785 kDa (relative to dextran)], 0.011 g (0.0077 mmol) of NLS-MPB dissolved in 0.28 mL of water was added. After reacting for 18 h at room temperature, the polymer−peptide conjugate was obtained by gel filtration (PD-10/water) and subsequent lyophilization.

RESULTS AND DISCUSSION

Synthesis of pDMAEMA with Primary Amines. To obtain pDMAEMA with primary amino groups, which are necessary for the coupling of ligands, 2-(dimethylamino)-ethyl methacrylate (DMAEMA, Scheme 1-**1**) was copolymerized with aminoethyl methacrylate (AEMA, **2**). Since AEMA is only available as its HCl-salt, water was selected as solvent and ammonium peroxydisulfate (APS) as radical initiator (Scheme 1). The pH of the aqueous solution was set at 3−5 with hydrochloric acid in order to minimize saponification of DMAEMA (*15*) and to prevent reaction of the primary amino group with ester groups. The polymers were obtained in high yield (95−99%). The polymer was worked up by dialysis against water at pH 7 and subsequent lyophilization.

A ^{1}H NMR spectrum of the copolymer (Figure 1A) showed, besides the signals of the dimethylaminoethyl methacrylate signals, a small signal at 3.45 ppm, which can be ascribed to the methylene protons adjacent to the primary amino group in the aminoethyl methacrylate monomer. The intensity of this peak indeed increased with increasing amounts of AEMA in the feed of the polymerization. However, the amount of incorporated amino groups cannot be determined accurately by NMR, due to partly overlapping signals. For the determination of the amount of incorporated AEMA, the primary amines in the copolymer were quantitatively derivatized with an excess of the thiolating reagent SPDP. Subsequent spectrophotometric analysis of the incorporated amount of PDP-groups yielded an accurate determination of the primary amine content of p(DMAEMA-*co*-AEMA). Figure 2 shows the influence of the feed ratio of AEMA on the total methacrylate content of the copolymer. It can be seen that the incorporation efficiency of AEMA is about

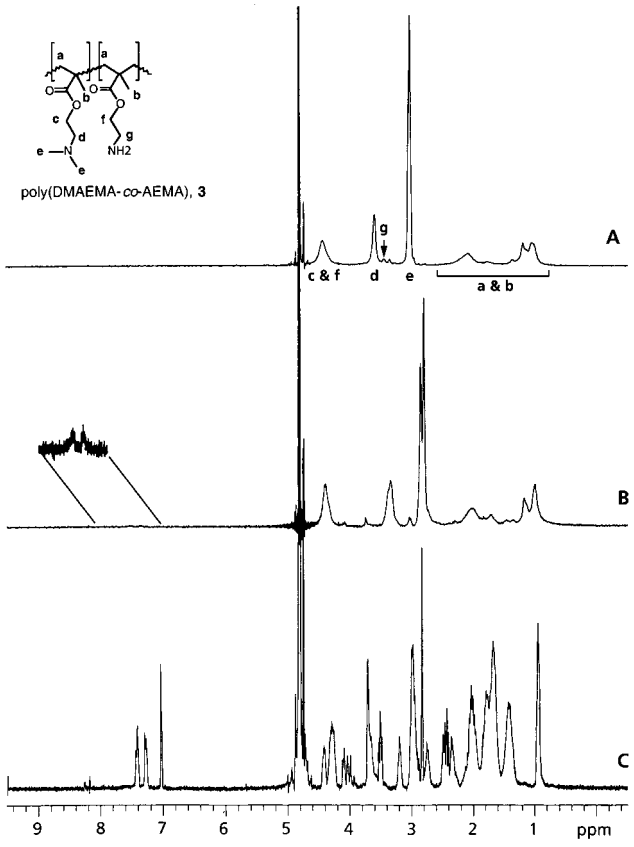


Figure 1. ^1H NMR spectrum in ^2H_2O of p(DMAEMA-*co*-AEMA) with 5.4 mol % AEMA (A), p(DMAEMA-*co*-AEMA)-NLS conjugate (B), and the MPB derivative of the NLS peptide (C).

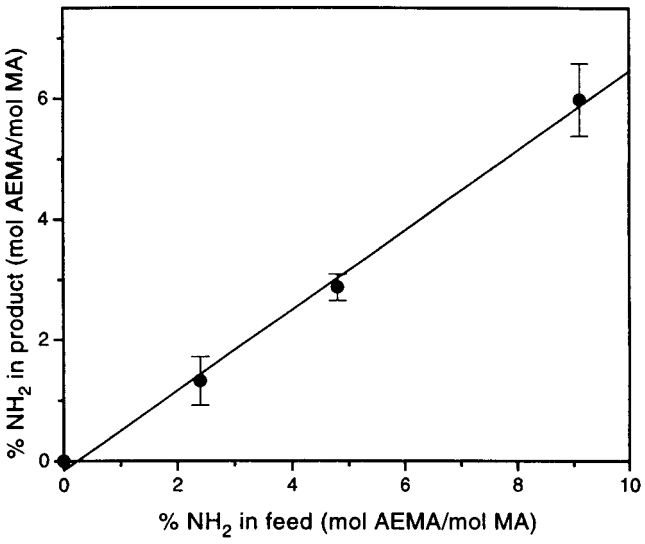

Figure 2. Correlation between feed ratio of AEMA to total methacrylate content and the incorporation of primary amines in p(DMAEMA-*co*-AEMA).

70% and the primary amine content can be tailored by the amount of AEMA in the feed.

The polymerization was carried out at varying ratios of monomer to initiator (*M*/*I* ratio). Figure 3 shows the influence of the *M*/*I* ratio on the molecular weight (GPC) of p(DMAEMA-*co*-AEMA) with 6 mol % AEMA. For comparison, the intrinsic viscosity of the polymer is also given. It can be concluded that, as expected, the molecular weight of p(DMAEMA-*co*-AEMA) increases with increasing *M*/*I* ratio.

Conjugation of Peptides and Proteins. p(DMAEMA-

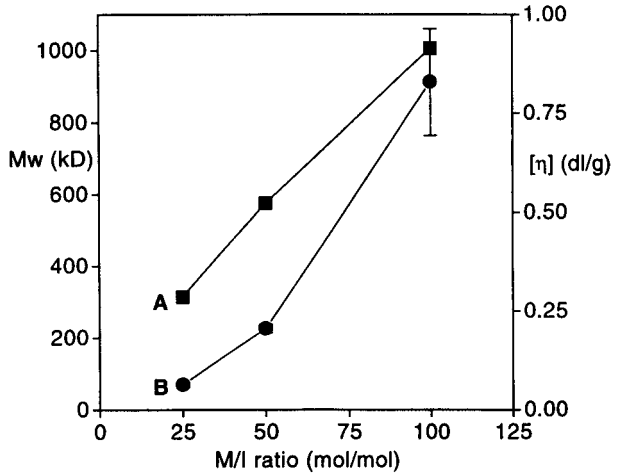

Figure 3. Molecular weight by intrinsic viscosity (A) and by GPC (relative to dextran, panel B) of p(DMAEMA-*co*-AEMA) as a function of the monomer/initiator ratio during synthesis.

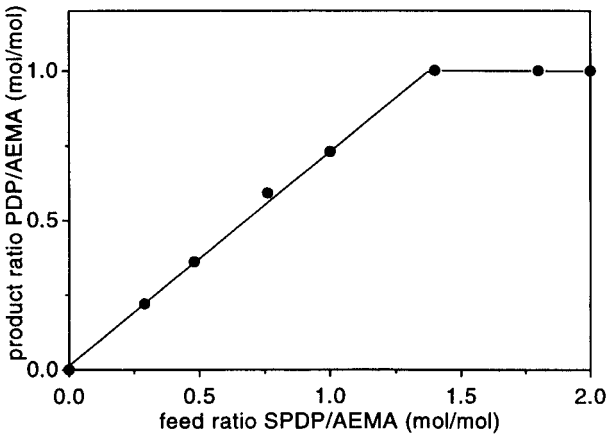

Figure 4. Correlation between feed ratio of SPDP/AEMA and the incorporation of thiol groups in p(DMAEMA-*co*-AEMA).

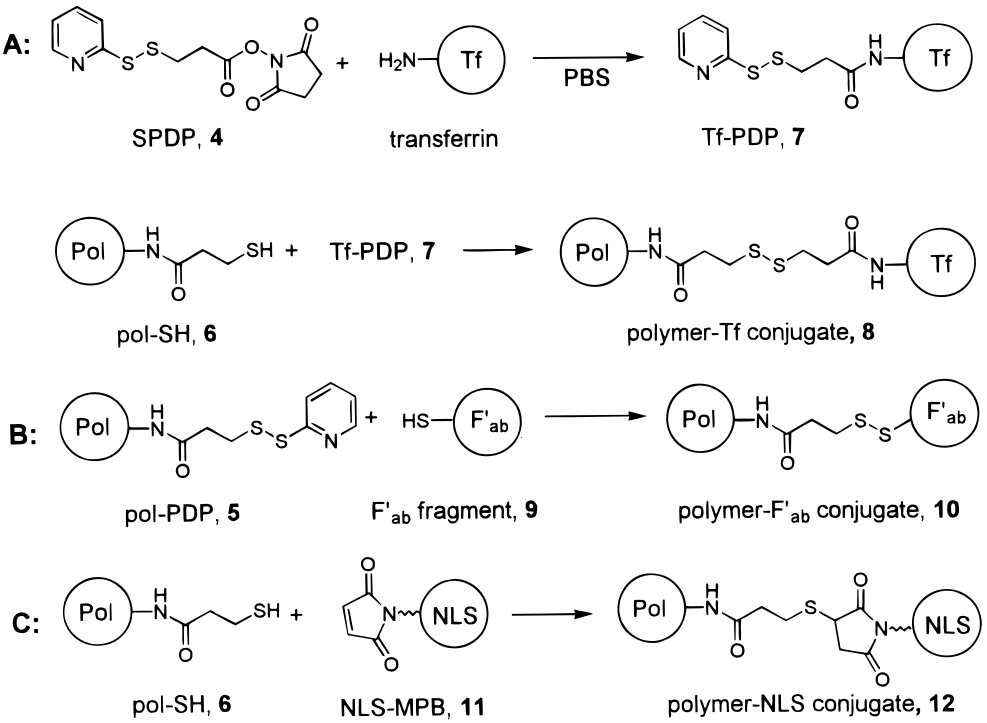

co-AEMA) contains primary amino groups which can be used to introduce (masked) thiol groups on the polymer backbone. These thiol groups can subsequently be used to couple a variety of compounds by a disulfide linkage. Therefore, p(DMAEMA-*co*-AEMA) is first derivatized with *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP, Scheme 1, compd **4**) in PBS at pH 7.5, yielding p(DMAEMA-*co*-AEMA) with masked thiol groups (pol-PDP). Subsequent removal of the protecting thiopyridyl group by reaction with 1,4-dithio-2,3-dihydroxybutane (dithiothreitol, DTT) resulted in p(DMAEMA-*co*-AEMA) with free thiol groups (pol-SH, Scheme 1, compd **6**).

Figure 4 shows the amount of incorporated dithiopyridine groups as a function of the feed ratio of SPDP to AEMA residues. It can be concluded that the amount of incorporated PDP groups can be easily tailored by varying the ratio of SPDP to AEMA residues in the polymer, and that the incorporation efficiency of SPDP is about 70%. Above 1.4 molar equivalents of SPDP to amino groups, a plateau value was reached, indicating complete derivatization of the amino groups.

Both the polymer with the masked and the free thiol groups can be used for conjugation with compounds such as peptides and proteins via a variety of ways.

Transferrin can be easily conjugated to p(DMAEMA-*co*-AEMA) after introduction of PDP groups in Tf and subsequent reaction with pol-SH, yielding p(DM)AEMA-Tf conjugate (Scheme 2, compd **8**). For conjugation purposes with Tf, p(DMAEMA-*co*-AEMA) with a rela-

Scheme 2. Coupling of Transferrin (A), a F(ab′) Fragment (B), and NLS-MPB (C) to Derivatized p(DMAEMA-*co*-AEMA)

tively low amount of (masked) thiol groups [1 SH/150 (DM)AEMA units] was used to prevent possible cross-linking of polymer and protein. Incubation of underivatized Tf with thiolated p(DMAEMA-*co*-AEMA) did not result in the formation of pol-Tf conjugate, indicating that PDP groups are necessary for conjugation (results not shown). The degree of derivatization of Tf was dependent on the feed ratio of SPDP to Tf and could be tailored from 2.5 to 14 mol of PDP/mol of Tf. The higher the degree of derivatization, the more turbid the conjugation reaction mixture became, indicating the formation of cross-linked products. Therefore, Tf with a relatively low degree of derivatization (2.5 mol of PDP/mol of Tf) was used for conjugation. The conjugation efficiency could be determined by quantifying the amount of nonconjugated Tf by GPC chromatography. Above a ratio of 1:1 mol of PDP/mol of SH, the conjugation efficiency was 90−95% and was independent of the ratio of Tf-PDP to pol-SH. The conjugate contained 1.0 mg/mL p(DMAEMA-*co*-AEMA) and 0.41 mg/mL Tf.

Monoclonal antibody 323/A3, directed against the EGP-2 receptor on OVCAR-3 cells, was treated with pepsin to yield the corresponding $[F(ab')]_2$ molecule. After reaction with DTT, the F(ab′) fragment (Scheme 2, compd **9)** was subsequently coupled via its free thiol group to p(DMAEMA-coAEMA) with masked thiol groups [p(DM)-AEMA-PDP, Scheme 2, compd **5]** to yield the p(DM)-AEMA-F(ab′) conjugate (Scheme 2, compd **10**). The conjugate contained 2.1 mg/mL p(DMAEMA-*co*-AEMA) and 1.0 mg/mL F(ab′), with a coupling efficiency of more than 95% (SDS−PAGE analysis, results not shown).

After synthesis of the NLS peptide, analysis by HPLC, ^{1}H NMR, and FAB MS indicated that the expected product had been formed. A reaction between the immobilized NLS peptide and SMPB resulted in the formation of the maleimide derivative of the NLS peptide, which was analyzed by FAB MS and ^{1}H NMR. The MS analysis showed the expected mass for the derivatized peptide sequence *m*/*z* 1424.8 $[MH]^+$). Figure 1C shows the ^{1}H NMR of the NLS-MPB. Although the ^{1}H NMR spectrum was too complex for complete elucidation, some specific amino acids (e.g., Val at 0.9 ppm) and the maleimide group (at 7.0 ppm) could be distinguished.

The NLS-MPB (Scheme 2, compd **11**) was subsequently incubated with thiolated p(DMAEMA-*co*-AEMA) and purified by gel filtration (PD-10). The yield after lyophilization was 37 mg (70%), and the incorporation efficiency of NLS peptide, determined by ^{1}H NMR, was more than 95% based on SH groups, and 50% based on NLS-MPB. The isolated polymer-NLS conjugate (Scheme 2, compd **12**) was characterized with ^{1}H NMR (Figure 1B). Comparison of the NMR spectrum of NLS-MPB (Figure 1C) with the spectrum of the conjugate (Figure 1B) shows that the maleimide signal at 7.0 ppm has disappeared while the phenyl protons of the MPB group are still visible at 7.25 and 7.4 ppm. This and the presence of certain amino acid peaks in the spectrum indicates that the NLS peptide is covalently bound to the polymer. The incorporation efficiency of NLS peptide, estimated by ^{1}H NMR, was more than 95% based on thiol groups in the polymer, and 50% based on NLS-MPB.

It has been demonstrated that conjugates held together via disulfide bonds introduced via the SPDP method may be reduced in vivo (*16*). However, it can be envisaged that protein/polymer conjugates can be synthesized via a more stable thioether linkage essentially using the method described for the NLS−PDMAEMA conjugate. In addition, other methods described in the literature (e.g., as described in ref *17*) can also be applied to synthesize PDMAEMA-protein conjugates using essentially the same strategy as described in this paper.

CONCLUSIONS

pDMAEMA can be functionalized with primary amines by copolymerization of DMAEMA with low amount of AEMA. The molecular weight and the primary amine content of the resulting polymer can be tailored by the feed ratio of these monomers. Thiol groups can be

incorporated via a controlled derivatization step. Subsequently, proteins and peptides can be coupled to the polymer with high coupling efficiencies via a disulfide bond or a thioether linkage.

Characterization of Lysozyme-Estrone Glucuronide Conjugates. The Effect of the Coupling Reagent on the Substitution Level and Sites of Acylation

C. Mark Smales, Christopher H. Moore, and Leonard F. Blackwell*

Institute of Fundamental Sciences, Chemistry, Massey University, Private Bag 11 222, Palmerston North, New Zealand. Received January 27, 1999

Estrone glucuronide conjugates of hen egg white lysozyme were prepared by the mixed anhydride and active ester coupling procedures. Both methods gave good yields of conjugates, but the active ester procedure gave a more diverse range of products, making it less suitable for preparing conjugates for homogeneous enzyme immunoassay. Conjugation of lysozyme with estrone glucuronide by the mixed anhydride procedure gave one major derivative exclusively acylated at lysine residue 33 whereas conjugation by the active ester method gave six derivatives which were acylated at one or more of lysine residues 33, 97, and 116. None of the lysine residues 1, 13, and 96, or the N-terminal α-amino group, were acylated in any of the conjugates isolated. The correlation of the conjugate structures with the protein environments of the amino groups in the crystal structure of lysozyme suggested that the sites of acylation were determined not only by the chemical nature of the acylating reagent but also by the surface accessibility and nucleophilicity of the individual lysine residues.

INTRODUCTION

The Ovarian Monitor home test for measuring the levels of the metabolites of ovarian estradiol (estrone glucuronide, or E1G) and progesterone (pregnanediol glucuronide, or PdG) in urine (*1*−*5*) allows the daily monitoring of a woman's menstrual cycle and accurate identification of her fertile period. The basis of the home test is an homogeneous enzyme immunoassay, which has been used successfully for the determination of a variety of analytes in biological fluids (*6*, *7*). The attraction of the homogeneous enzyme immunoassay format lies in the fact that the enzyme activity of hapten conjugates of some enzymes (hen egg white lysozyme in this case) is extensively inhibited by anti-hapten antibodies in the immune complex. As a result, a simple kinetic measurement serves to differentiate between bound and free enzyme label (*8*) without the need for time-consuming and technically demanding physical separation procedures.

Hen egg white lysozyme is one of a limited number of enzymes which have been employed successfully in homogeneous enzyme immunoassays. It possesses an apparent specific activity with its bacterial substrate *Micrococcus lysodeikticus* which renders it ideal for the measurement of menstrual cycle levels of urinary E1G and PdG (*9*) without excessive dilution of the samples. Lysozyme possesses six lysine residues and a free α-NH_2 terminal amino group, all of which can be acylated by a variety of acylating reagents (*10*) to give stable conjugates which retain lytic activity providing that the total number of lysine residues acylated is less than four (*11*). However, the lytic activity of lysozyme is adversely affected whenever any of the amino groups are modified by moieties that result in the loss of positive charge from the surface of the enzyme (*12*). It has been proposed that this loss in activity reflects an alteration in the electrostatic interaction between the positively charged enzyme and the negatively charged *M. lysodeikticus* cell wall (*13*). Hence, in developing procedures for conjugation of lysozyme with steroid glucuronides, it is desirable to use conditions which maximize the concentration of conjugate(s) with low degrees of steroid substitution.

The estrone glucuronide−lysozyme conjugate mixtures utilized in the Ovarian Monitor assay system have been prepared with a mixed anhydride acylating reagent (*1*), but currently they are uncharacterized. Identification of the amino groups in a protein which are modified by various acylating reagents can be carried out by analysis of proteolytic digest patterns (*14*), mass spectrometric peptide mapping (*15*), and immunological studies (*16*). It has been suggested on the basis of these previous studies that the acylation position and orientation of haptens in enzyme conjugates is an important factor in determining the recognition and strength of binding of the hapten by antihapten antibodies (*17*). However, all of these studies have been undertaken on conjugates produced using a large excess of hapten to enzyme in the coupling procedure, therefore producing protein adducts with high levels of hapten substitution.

The present study was undertaken to characterize the preferred acylation positions in the E1G−lysozyme conjugates and hence to evaluate the effect of the acylation reagent on the acylation positions. The conjugates were characterized using proteolytic digestion and electrospray mass spectrometry to identify (1) the positions of acylation in the steroid glucuronide lysozyme conjugates and (2) the effect of the coupling procedure on the conjugate products and sites of acylation as a prerequisite to an understanding of the factors which are important in determining the mechanism of inhibition by anti-E1G antibodies.

EXPERIMENTAL PROCEDURES

Reagents. The following reagents were obtained from the sources indicated: 17-oxoestra-1,3,5−3-β-yl-D-glucopyranosiduronic acid (estrone glucuronide or E1G[H]) was synthesized essentially according to Conrow and Bernstein (*18*) as described previously (*19*). Commercial hen egg white lysozyme (Grade 1, three times recrystallized and lyophilized, Sigma, St. Louis, MO) was further purified before use as described previously (*19*). Antisera were raised in sheep against thyroglobulin−estrone glucuronide conjugates. Trypsin (L-1-tosylamino-2-phenylethyl chloromethyl ketone treated) and *M. lysodeikticus* were obtained from Sigma. All other chemicals were analytical or reagent grade.

Preparation Of Estrone Glucuronide (E1G[H])−Lysozyme Conjugates. Conjugation of lysozyme with E1G[H] was achieved by both the mixed anhydride procedure of Erlanger et al. (*20*) and the *N*-hydroxysuccinimide/dicyclohexylcarbodiimide coupling method (*21*) at a 1.6:1 molar ratio of steroid glucuronide to lysozyme as described previously (*19*). The mixed anhydride reagent was prepared from E1G[H] (7.2 mg, 16.1 μmol) in dimethylformamide (116 μL) in a 0.5 mL glass reaction vial. The vial was placed in an aluminum block preequilibrated at 10 °C in a refrigerator and allowed to equilibrate for 3 h. Tri-*n*-butylamine (4.5 μL, 18.9 μmol), preequilibrated at 10 °C, was then added and the E1G[H] solution left for 5 min at 10 °C before the aluminum block was cooled to 0 °C. Once the aluminum block had cooled to 0 °C, it was removed from the freezer and placed in a cold room at 4 °C and left to equilibrate for 15 min. Isobutyl chloroformate (2.5 μL, 19.2 μmol) preequilibrated at 4 °C was then added and the resulting E1G[H] solution left to stand for 30 min. The mixed anhydride reagent was then stabilized by placing the aluminum block at the bottom of a refrigerated centrifuge preequilibrated at approximately −15 °C. Purified lysozyme (144 mg, 10.1 μmol) was dissolved in Milli-Q water (3.7 mL) with stirring and the pH adjusted to 8.00 with 0.5 M NaOH at room temperature. Ice was packed around the lysozyme reaction vessel, which was then placed in the cold room at 4 °C and left to equilibrate for 45 min with stirring while the pH was monitored. The temperature setting of the pH meter was set at 0 °C and stabilized at pH 8.54 after the equilibration period. After the solution stood at −15 °C for 1 h, the mixed anhydride reagent was added dropwise, with a dry 10 μL pipet at 4 °C, to the stirred lysozyme solution over 15 min. Associated with each addition of mixed anhydride reagent was a drop in the pH of the lysozyme solution which was readjusted back to approximately 8.54 with 0.5 M NaOH. The lysozyme solution was left with stirring for 2 h upon the final addition of mixed anhydride reagent (while 0.5 M NaOH was added as required to readjust the pH) after which time the reaction mixture, which appeared opaque, had stabilized at pH 8.39 and was stored at −10 °C until purified by cation-exchange chromatography.

In a typical active ester experiment, the reagent was prepared from E1G[H] (7.6 mg, 17.0 μmol) in dimethylformamide (52 μL). *N*-Hydroxysuccinimide (22.5 mg, 195 μmol) and dicyclohexylcarbodiimide (29.9 mg, 145 μmol) were each separately dissolved in dimethylformamide (100 μL). From these stock solutions, *N*-hydroxysuccinimide (20 μL, 39 μmol) was added to the E1G[H] solution followed by the addition of dicyclohexylcarbodiimide (20 μL, 29 μmol). After a stirred solution of purified lysozyme (152 mg, 10.7 μmol), dissolved in 1% aqueous sodium hydrogen carbonate (6 mL, pH 9.10) at 0 °C in an ice bath, stood at room temperature for 1 h, the active ester reagent was added dropwise. After standing overnight with stirring at 4 °C, the reaction mixture, which appeared opaque, was dialyzed against Milli-Q water (3 × 2 L) and then stored at −10 °C until purified by cation−exchange chromatography.

Purification of Estrone Glucuronide−Lysozyme Conjugates. The success of the conjugation experiments and purity of the derivatives was determined by analytical chromatography on a Mono-S cation-exchange column in 7 M urea buffers (*19*). Estrone glucuronide−lysozyme conjugates were purified from the conjugation reaction mixture by cation-exchange chromatography, also in 7 M urea buffers, on an S-Sepharose (fast flow) column (50 × 1.6 cm i.d.) connected to a Pharmacia Fast Protein Liquid Chromatography system. To the reaction mixture were added sufficient solid urea to give a 7 M solution and a calculated amount of solid sodium dihydrogen phosphate dihydrate to give a 50 mM phosphate solution. After the solution had been adjusted to pH 6.0 with 1 M NaOH, it was loaded, with a peristaltic pump, onto the column preequilibrated with 7 M urea/50 mM sodium dihydrogen phosphate dihydrate buffer (pH 6.0). The column was eluted with a linear salt gradient from 0 to 0.24 M NaCl in 792 min at a flow rate of 1.5 mL/min. The absorbance of the eluent fractions (6 mL) was read at 280 nm and the enzymic activities were determined from the rate of lysis of *M. lysodeikticus* using an Ovarian Monitor (*1*). Fractions from each peak were combined, dialyzed extensively against Milli-Q water, and freeze-dried before rechromatography on the same column. This procedure gave chromatographically homogeneous estrone glucuronide−lysozyme conjugates when analyzed by Mono-S cation-exchange chromatography (*19*). The purified conjugates were extensively dialyzed against Milli-Q water, freeze-dried, and then stored at −10 °C until required for digestion experiments.

Enzyme Assays for Lytic Activity of Chromatography Column Fractions. The assays for lytic activity of the various column fractions were performed in a plastic 1 mL cuvette (Adindas Plastics, Melbourne, Australia) designed specifically for the Ovarian Monitor (*1*). The appropriate volume from each fraction was added to a cuvette, 0.04 M tris-maleate buffer (pH 7.0) was added to make the volume up to 340 μL, and the solution was equilibrated at 40 °C. *M. lysodeikticus* (10 μL of a 7.5 mg/mL suspension in 75 mM tris-maleate buffer, pH 7.0) was then added with vortex mixing and the initial transmission noted. After 20 min, the final transmission was noted, and the lytic activity, expressed as the change in transmission (ΔT) per 20 min, was calculated. The volume of each fraction to be used in the assay was calculated from the concentration of the peak tube as determined by the absorbance at 280 nm. The dilution of this peak tube required to give an apparent change in transmission of 350 units in 20 min was determined. The same dilution was then used for all of the other fractions to measure their relative lytic activities. The inhibition of the lytic activity of each eluent fraction from the ion-exchange columns by anti-E1G antibodies was measured using the Ovarian Monitor assay by adding a slight excess of the antiserum to the assay mixture and comparing it with the appropriate control.

Reduction and Alkylation of Estrone Glucuronide−Lysozyme Conjugates with Iodoacetic Acid. Conjugates were reduced and alkylated with iodoacetic acid essentially as described by Rutherfurd et al. (*22, 23*). Typically, conjugate (5 mg) was dissolved in a mixture of 8 M urea and 0.25 M tris-HCl buffer (pH 8.75, 300

μL) containing 1 mM EDTA prior to the addition of dithiothreitol (0.84 mg, 5.4 μmol). The resulting solution was flushed with argon gas, and the reduction allowed to proceed at 37 °C for 3 h prior to the addition of iodoacetic acid (1.57 mg, 8.4 μmol). Alkylation was allowed to proceed in the dark at room temperature for 45 min. Excess β-mercaptoethanol was then added and the alkylated protein was dialyzed against 8 M urea (3 × 200 mL).

Tryptic Digestion. Tryptic digestion of the alkylated estrone glucuronide−lysozyme conjugates and unmodified lysozyme was carried out in 2 M urea solutions. After dialysis against 8 M urea, the alkylated protein solutions were diluted with 1% ammonium bicarbonate buffer (pH 8.50) to give 2 M urea solutions allowing for the volume of the trypsin solution. L-1-Tosylamino-2-phenylethyl chloromethyl ketone treated trypsin (2 mg) was dissolved in 330 μL of 1% ammonium bicarbonate (pH 8.50) and then the appropriate volume was added to the digest solution so that an enzyme-to-substrate ratio of 1.5:100 (w/w) was achieved. Digestion was allowed to proceed for 3.5 h at 37 °C after which the reaction mixture was stored at −10 °C until analysis by HPLC.

Separation of Trypsin Fragments. The separation of the tryptic fragments was carried out on a Vydak C18 reversed-phase column (4.6 × 250 mm) using a Spectra Physics SP8800 high-performance liquid chromatography (HPLC) system. Aliquots from the completed tryptic digests were loaded onto the column preequilibrated with deionized, distilled water (containing 0.1% TFA) and then eluted with a linear gradient from 0 to 40% acetonitrile (containing 0.08% TFA) in 80 min at a flow rate of 1 mL/min. Detection of the tryptic peptides was carried out at 220 nm with a Spectra Physics SP8490 detector and they were collected manually into 1 mL Eppendorf tubes. Peptides were concentrated on a Savant Speed Vac Concentrator to a volume of approximately 15 μL and then stored at −10 °C until analysis.

Analysis of Tryptic Peptides. Tryptic peptides were analyzed by both peptide sequencing and electrospray mass spectrometry. Peptide sequencing was undertaken on an Applied Biosystems Edman degrading gas phase 476A Protein Sequencer. Mass spectral analyses were obtained on a VG Platform II Electrospray Mass Spectrometer.

Immunochemical Analysis of Tryptic peptides. Peptides were screened for the presence of estrone glucuronide using the Ovarian Monitor (*1*). An assay mixture was prepared containing amounts of estrone glucuronide−lysozyme conjugate and E1G antibody such that a partially inhibited ΔT value of approximately 150 units in 40 min was obtained. To the assay mixture was added 5 μL of the concentrated peptide, and the change in transmission over 40 min was recorded. The difference between the ΔT value in the presence and absence of the peptide in the partially inhibited assay mixture was calculated as the immune reactivity.

RESULTS

Preparation and Purification of Estrone Glucuronide−Lysozyme Conjugates. Acylation of hen egg white lysozyme with estrone glucuronide by the mixed anhydride and *N*-hydroxysuccinimide/dicyclohexylcarbodiimide coupling procedures resulted in two distinctly different reaction mixtures (Figure 1). The mixed anhydride procedure produced two major chromatographically distinct peaks (Figure 1a) when passed though an S-Sepharose fast-flow column, the largest being unreacted

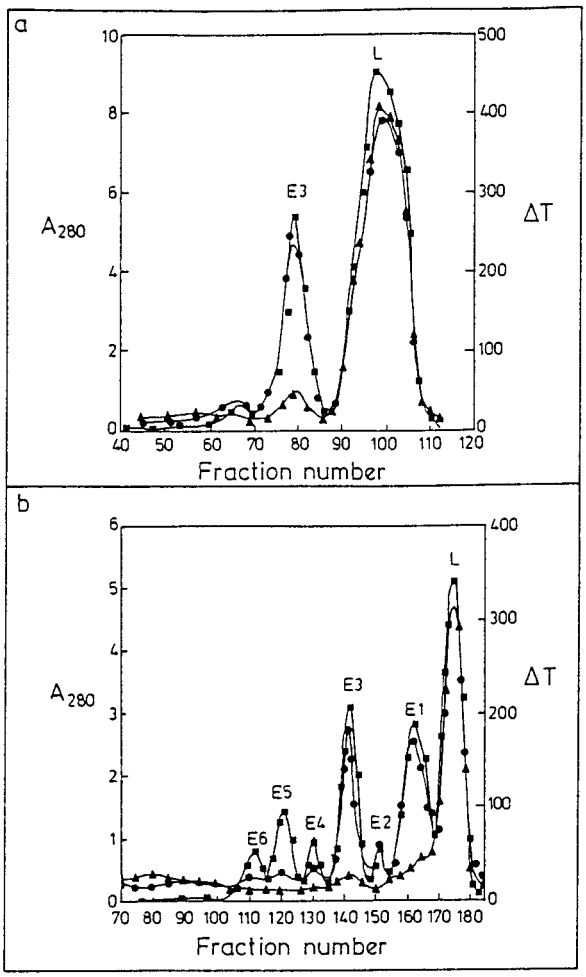

Figure 1. E1G−lysozyme reaction mixtures in 7 M urea on a S-Sepharose (fast flow) column. Mixed anhydride method (a), and active ester method (b). The profiles show A_{280} (■) and lytic activity profiles in the absence (● = ΔT) and presence (▲ = ΔT) of excess E1G antibody. L = lysozyme and E1-E6 are E1G−lysozyme conjugates. For conditions and details see text.

lysozyme (L). The material which eluted earlier consisted almost entirely of conjugate family E3. E refers to the nomenclature of Smales et al. (*19*) where E1 is the estrone glucuronide lysozyme peak which elutes next to lysozyme and E6 is the peak which elutes furthest from lysozyme (the first peak eluted). On the other hand, when lysozyme was conjugated by the *N*-hydroxysuccinimide/dicyclohexylcarbodiimide coupling procedure, seven chromatographically distinct peaks were obtained (Figure 1b). Again the largest peak was unreacted lysozyme and of the six conjugate peaks (E1−E6) which eluted earlier, E1 and E3 together comprised over half of the total conjugate yield. These six conjugate peaks were characteristic of acylation of lysozyme by steroid glucuronides at low concentrations of reagent, appearing in varying amounts in all conjugations. Even at a molar ratio of 3:1 for the active ester reagent the same six peaks were found but the amounts of E4, E5, and E6 were increased relative to E1, E2, and E3.

All of the conjugate families (E1−E6) and unreacted lysozyme from both conjugation procedures had lytic activities which paralleled their A_{280} profiles (Figure 1), and the conjugates were inhibited by 70−80% when excess E1G antibody was present in the assay mixture as reported previously (*19*). The unreacted lysozyme (designated L) was not affected by the anti-E1G antiserum as expected, and this was shown by the congruence

of the lytic activity in the presence and absence of the antiserum. Conjugate families E4, E5, and E6 had much lower specific activities relative to lysozyme (60.8, 57.6, and 42.3%, respectively) than the E1, E2, and E3 conjugate families (95.1, 88.2, and 94%, respectively) which had specific activities similar to that of native lysozyme. It was necessary to rechromatograph each conjugate family by passage twice through the S-Sepharose (fast flow) column to obtain chromatographically homogeneous derivatives.

Characterization of the E1G−Lysozyme Conjugate Families. The identities of the lysine residues acylated by estrone glucuronide in the chromatographically homogeneous conjugates were determined by tryptic digestion of the reduced, S-carboxymethylated derivatives in 2 M urea solutions at pH 8.5 and 37 °C. The resulting tryptic peptides were analyzed by reversed-phase chromatography (Figures 2, 3, and 4), peptide sequencing, and electrospray mass spectroscopy (Tables 1 and 2). The tryptic peptides from the native lysozyme digest are shown in Figure 2a and are numbered in their order of elution from the reversed-phase column. Twenty major peaks were observed in the digest of native lysozyme (Figure 2a) of which peaks 2 (T1 + 2, K1), 7−10 (T3 and T3 + 4, K13), 15 (T6, K33), 16−18 (T13 and T12 + 13, K97), and 20 (T11, K96) contained lysine residues as shown by amino acid sequencing. T refers to the nomenclature of Canfield (*24*) for the tryptic peptides of hen egg white lysozyme. The small lysine dipeptide T15 (K116) was not observed. The potential cleavage sites between T1 and T2 and between T17 and T18 (under peak 3) could not be hydrolyzed as was previously reported by Noda et al. (*25*) and Okazaki et al. (*26*) for S-carboxymethylated lysozyme derivatives in the absence of 2 M urea. The potential cleavage sites between T3 and T4 and T12 and T13 were only partially hydrolyzed. Peptide T13 appeared as two peaks in the present work, and Yamada et al. (*27*) have suggested that this is due to the presence of a monomer−dimer mixture which presumably persists also in 2 M urea.

In the tryptic maps for each conjugate family, certain lysine-containing peptides disappeared or diminished in height relative to the tryptic map of lysozyme. For example, it was found that peaks 6, 15, and 16−18, which contained the tryptic peptides T7 (6), T6 (15) and T13 + (T12 + 13) (*16*−*18*), respectively, were reduced in height in one or more of the conjugate digest profiles (see Figures 2−4 for examples). Associated with these changes, specific new peaks appeared later in the HPLC gradient than the native peptides (after peak 20 in Figure 2a). The amino acid sequence and mass of these later eluting lysine acylated peptides (c−m) were matched with the sequences and masses of the tryptic peptides from hen egg white lysozyme (*28*) (Table 2). By comparing the experimental data with the expected data, the acylated peptide, and thus the acylated lysine residue, could be assigned (Tables 1 and 2). Acylation with E1G could be readily determined in this way, and it was shown that conjugates resulting from both the active ester and mixed anhydride procedures, which eluted in the same place on the Mono S cation-exchange column (e.g., active ester E3 and mixed anhydride E3) were indeed equivalent (Table 1). For several of the acylated peptides, deamidation had occurred from glutamine to glutamic acid or asparagine to aspartic acid (as shown by amino acid sequencing, Table 2), while in other cases chymotryptic cleavage had occurred (Table 2). In all cases, the calculated and experimental mass spectral data were in good agreement and unambiguously identified the assigned

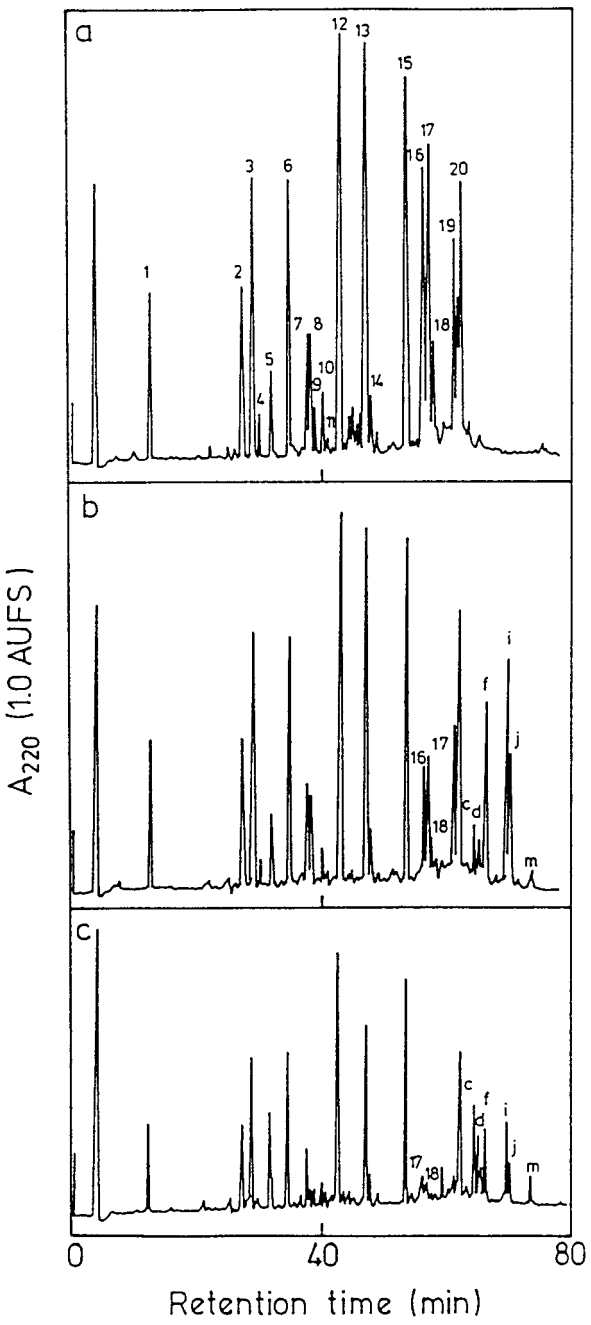

Figure 2. Reversed-phase HPLC separation of tryptic digests of unmodified lysozyme (a), and active ester E1G−lysozyme conjugates E1 (b), and E2 (c). The numbers refer to unmodified tryptic peptides and the letters to acylated tryptic peptides. For details see text.

peptide as confirmed by amino acid sequencing (Table 2). However, the acylated peptides did not exhibit a lysine peak where expected from the known tryptic peptide sequences during sequence analysis. Instead, a new peak was observed which eluted from the sequencer HPLC column after all of the other amino acid peaks. This peak was always present when sequencing the modified peptides and was presumably due to an estrone glucuronide acylated lysine residue. Since the new peak eluted last from the sequencer HPLC column, it did not interfere with detection of any of the other amino acids in the sequence. No evidence was found for acylation occurring via ester linkages as has been observed previously in conjugation experiments (*14*).

From the tryptic maps, it is evident that the N-terminal α-amino group and lysine residues 1, 13, and

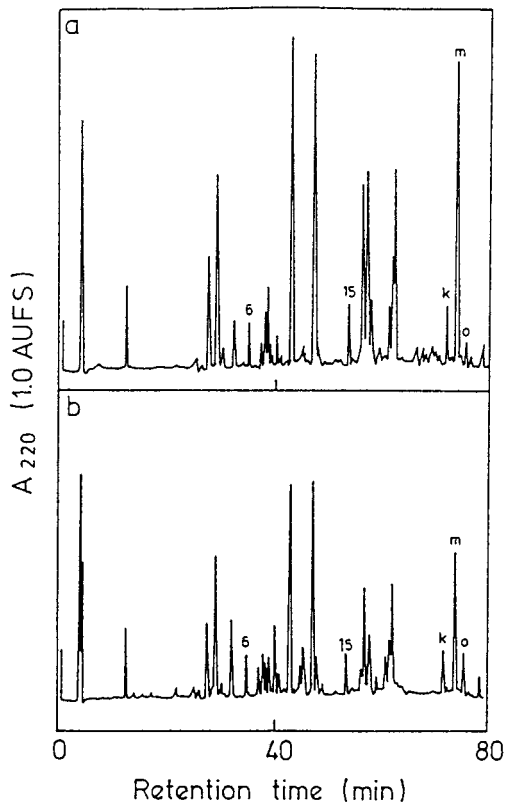

Figure 3. Reversed-phase HPLC separation of tryptic digests of active ester E1G−lysozyme conjugate E3 (a), and mixed anhydride E1G−lysozyme conjugate E3 (b). The numbers refer to unmodified tryptic peptides and the letters to acylated tryptic peptides. For details see text.

96 were unmodified in all of the conjugates since the peptide peaks T1 + 2 (residues 1−5, peak 2, Figure 2a), T3 + (T3 + 4) (residues 6−14, peaks 7−11, Figure 2a), and T11 (residues 74−96, peak 20 Figure 2a) remained unchanged in height and area relative to the tryptic map for the lysozyme control. Thus, acylation of lysozyme with estrone glucuronide was specific for the ϵ-amino groups of lysine residues at positions 33, 97, and 116 when using the active ester method and almost solely for the ϵ-amino group of lysine 33 when the mixed anhydride reagent was used (Table 1). Active ester conjugates E1 and E2 were found to be acylated at the same positions, lysines 97 and 116 (Table 1). However, E1 consisted of two monoacylated conjugates, one where acylation has occurred at lysine 97 and the other where acylation has occurred at lysine 116 (Table 1). Partial acylation at lysine residue 97 can be clearly seen as peptide peaks 16−18 had diminished in height by approximately 60% relative to the native digest (Figure 2b). On the other hand, conjugate E2 appears to be a disubstituted conjugate with both lysine residues 97 and 116 acylated on each lysozyme molecule. Peptide peaks 16−18 had almost disappeared in the tryptic digest of conjugate E2, indicating that residue 97 was almost completely acylated. Both active ester conjugate E3 and mixed anhydride conjugate E3 were acylated at lysine residue 33 (Table 1). Active ester conjugates E4 and E5 were disubstituted conjugates acylated at lysine residues 33 and 116 (E4) and 33 and 97 (E5), respectively (Table 1). The most highly substituted conjugate (active ester E6) was trisubstituted at lysine residues 33, 97, and 116 (Table 1).

Enzyme inhibition assays carried out in the presence of the native lysozyme tryptic peptides (peaks 1−20, Figure 2a) did not significantly increase the lytic activity

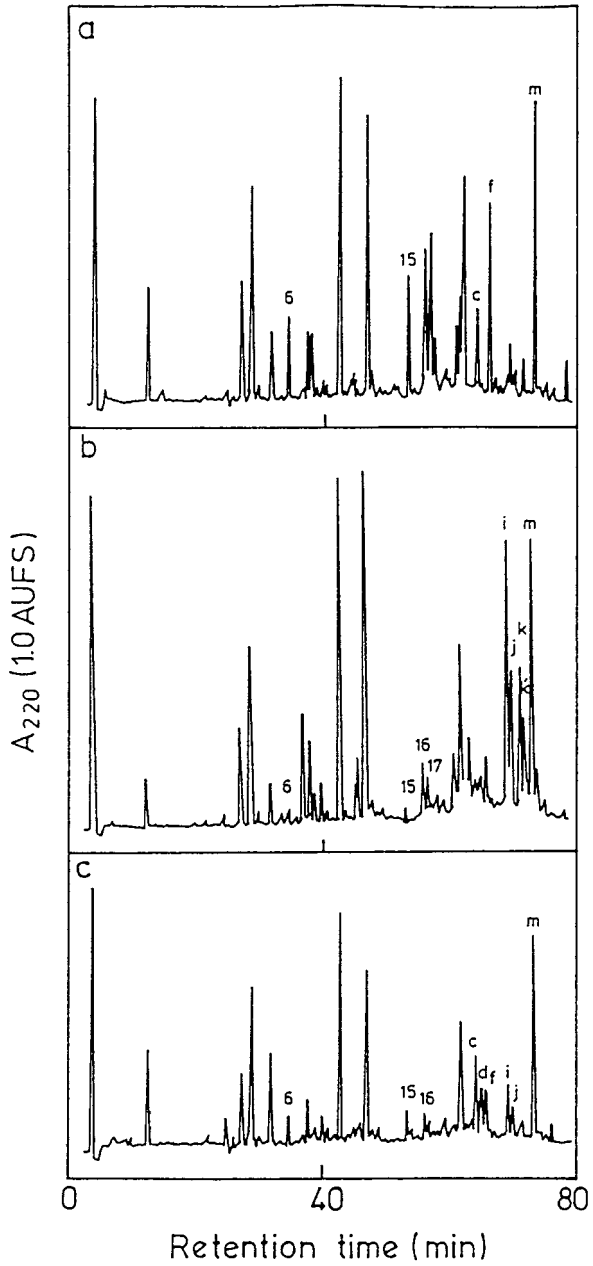

Figure 4. Reversed-phase HPLC separation of tryptic digests of active ester E1G−lysozyme conjugates E4 (a), E5 (b), and E6 (6). The numbers refer to unmodified tryptic peptides and the letters to acylated tryptic peptides. For details see text.

of the intact E1G−lysozyme mixed anhydride E3 conjugate in the inhibition assay (Figure 5a). The same result was obtained for peaks 1−20 obtained from the tryptic digest of E1 (Figure 5b) which therefore did not contain E1G after conjugation. However, inhibition assays carried out in the presence of the active ester E1 tryptic peptides f, i, and j increased the enzymic rates of lysis to approximately 350 units/40 min. This rate was the same as obtained for the control assay in the absence of the E1G antibody, thus the immune reactivities for these three peptides were high (Figure 5b), confirming the presence of at least one estrone glucuronide moiety.

DISCUSSION

Since the active ester methodology is easier to perform than the mixed anhydride method, it is used more often in protein conjugation reactions, especially in the hands of nonorganic chemists. However, close inspection of the

[a] Determined from proteolytic studies and titration of lysine groups (*19*). [b] See Figures 2, 3, and 4.

present data showed that there were significant differences between the two methods in terms of the conjugates they produced, and hence, careful consideration needs to be given to the choice of reagent depending on the aims of the study. The active ester reagent was more reactive and, hence, less selective than the mixed anhydride reagent as it gave a more diverse range of conjugate products at the same ratio of E1G to lysozyme (Figure 1). Hence, a greater overall yield of conjugate was obtained than with the mixed anhydride reagent, and the reaction was less time consuming. However, the complexity of the product mixtures made purification of the different conjugates more difficult. For immunoassays, the extra complexity of the less selective active ester reaction was undesirable since the relatively large amounts of the more highly substituted conjugates produced, E4, E5, and E6, had lower specific activities. A greater concentration of these conjugates was required, therefore, in the assays for a given rate of lysis than for the lower substituted conjugates. E4, E5, and E6 also required more antiserum to inhibit their lytic activities due to their higher substitution levels with E1G, hence, less sensitive standard curves were obtained, making them less suitable for homogeneous enzyme immunoassay. The mixed anhydride reagent is thus preferable to the active ester reagent as a source of conjugate for homogeneous enzyme immunoassay as it gives an almost pure mono E1G conjugate in good yield and with a high specific activity.

The difference between the two reagents is possibly due to the difference in their intrinsic reactivities. In support of this suggestion, the active ester reaction was almost instantaneous, as shown by the similarity of the FPLC traces for the reaction mixtures after 2, 5, 60, and 180 min and overnight when analyzed by chromatography on a Mono-S column in 7 M urea (*19*). On the other hand, the more selective mixed anhydride reagent reacted much more slowly, taking several hours as evidenced by the slow drop in pH as the reagent reacted with lysozyme. Under these conditions the estrone glucuronide moiety is more likely to react with the most reactive lysine residue having sufficient lifetime in solution to select among various possibilities.

The identification of the acylation positions in the conjugates obtained with both acylating reagents was relatively straightforward using tryptic digestion experiments. However, it was necessary to use 2 M urea to maintain the solubility of the hydrophobic reduced and S-carboxymethylated acylated conjugates and peptides. Under the 2 M urea conditions used for the digestion experiments, trypsin was active (*29*) and highly reproducible tryptic digests were obtained (Figures 2, 3, and 4). After calibration of the HPLC peaks by sequence data and mass analysis, visual inspection of the traces allowed ready identification of the major sites of acylation from a combination of the loss in amplitude of the lysine-containing tryptic peptides in the native digest and the appearance of new characteristic acylated peptides in the conjugate digest (peaks i, j, etc.).

As the coupling reactions were carried out under limiting conditions of reagent, the fact that conjugate E3 (lysine 33) was the major product of the mixed anhydride reaction indicates that lysine 33 is the most reactive residue at pH 8.5. The elution position of the mixed anhydride minor conjugate peak (Figure 1a) suggests that it is E5 with both lysines 33 and 97 acylated (Table 1) which in turn indicates that lysine 97 is the next in order of reactivity. This reactivity order suggested from the mixed anhydride reaction also holds for the active ester reaction. Conjugate E3 was still one of the major peaks, and of the two disubstituted conjugate fractions (E4 and E5 of Table 1), E5 was present in the greatest amount. Hence, the reactivity order suggested by the combined data is K33 > K97 > K116. Previous work involving the acylation and modification of the amino groups of hen egg white lysozyme has also shown a differential selectivity in the reactivity of the lysine residues (*14*−*15*). For example, when Suckau et al. (*15*) aminoacetylated lysozyme with acetic anhydride, the reactivities of the amino groups showed an order, K97 = K33 > K1 (ϵ-NH_2 and α-NH_2) > K13 = K116 > K96. The accessibility of the lysine side-chain ϵ-amino groups in hen egg white lysozyme as determined from their degree of extension in the crystal structure decreases in a similar order, K97 > K33 ≫ K1 (ϵ-NH_2) > K13 > K116 > K96 > α-NH_2 (*15*). Nuclear magnetic resonance studies have shown that the solution environments of the amino groups in lysozyme are similar to those in the crystalline protein (*30*), hence the difference in the reactivities of the lysine residues can be related to the different protein environments as revealed by crystallography. Thus, the reactivity data of Suckau et al. (*15*) shows that lysine availability or exposure is a major factor in determining chemical reactivity during acylation reactions.

The preferential acylation of lysozyme with estrone glucuronide at lysines 33 and 97 in the present work is consistent with the reactivity preference shown in the data of Suckau et al. (*15*) as lysines 33 and 97 are by far the most accessible of the seven having surface accessibilities of 40.1 and 47.4%, respectively. However, the preference for lysine 33 exhibited in the present work shows that other factors are involved. The p*K* value calculated for lysine 33 (9.7) is less than for lysine 97 (10.5) (*31*) which would result in an almost 10-fold higher concentration of the lysine 33 free base at pH 8.5 (relative to lysine 97) and, hence, could explain the greater reactivity. However, according to the results of Suckau et al. (*15*), acylation of lysine 116 with estrone glucuronide should not have occurred until after the acylation or partial acylation of lysine 1 (α and ϵ-NH_2) and lysine 13. The acylation of residue 116 with estrone glucuronide in preference to lysine 1 (α and ϵ-NH_2), lysine 13, or lysine 96 may be a result therefore of a relatively high local concentration of the E1G reagent in the vicinity of lysine 116. This could be achieved if E1G has an affinity for one or more of the sugar-binding sites in the active-site cleft since lysine 116 is situated just above this.

The present results show that the lysozyme molecule

Table 2. Sequence and Mass Spectral Data of E1G Acylated Tryptic Peptides

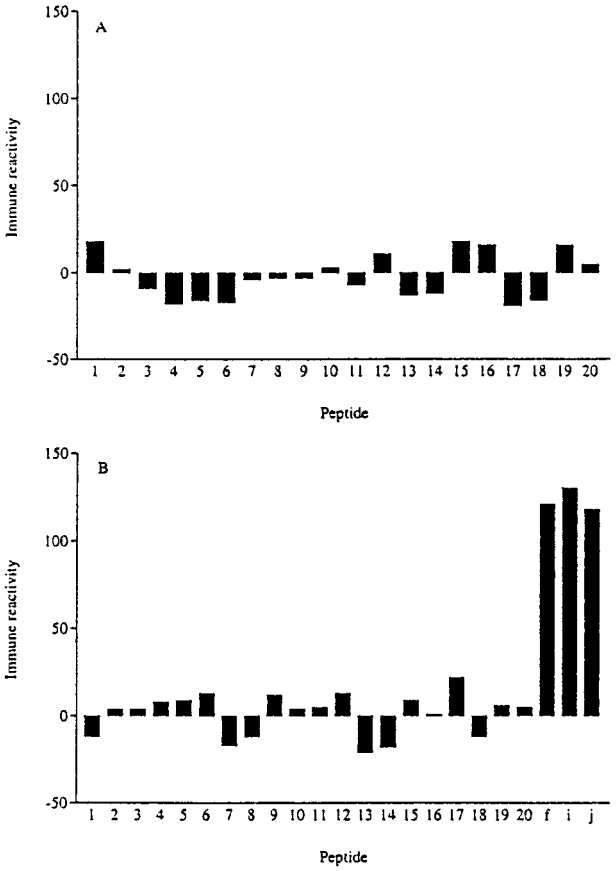

Figure 5. Immune reactivities of the tryptic peptides from unmodified lysozyme (A) and active ester E1G−lysozyme conjugate E1 (B) as measured using an Ovarian Monitor. The high immune reactivity of peptides f, i, and j (B) confirmed the presence of E1G.

is ideally constituted for homogeneous enzyme immunoassays for steroid glucuronides, since the most reactive lysine residues with respect to steroid glucuronide acylation are located near the active site. Steroid glucuronide conjugates of lysozyme, with low substitution levels and which are highly inhibited (>90%), can therefore be obtained using stoichiometric ratios of acylating reagent. Binding of the anti-hapten antibody to haptens attached at any of lysines 33, 97, or 116 results in a strong inhibitory effect on the lytic activity of the Ovarian Monitor conjugates, undoubtedly due to steric blocking of access of the *M. lysodeikticus* substrate to the active site. A combination of factors such as orientation of the hapten with respect to the active site (acylation position), the size of the substrate, the size of the enzyme itself, the length and rigidity of the link between the hapten and the enzyme and the binding kinetics are all important determinants of the degree of inhibition. A further understanding of the relative importance of these factors based on the structure and reactivity of the characterized conjugates E1-E6 is being carried out and may help in the rational design of other inhibitable enzyme conjugate systems.

ACKNOWLEDGMENT

We wish to thank the following people for their contributions: Associate Professor David Harding and Mr. Dick Poll for use of their chromatographic equipment, discussions, and suggestions; Dr. Brian Anderson for his help with computer graphics; and Dr. Keith Henderson for raising antibodies.

NOVEL PARAMAGNETIC MACROMOLECULAR COMPLEXES DERIVED FROM THE LINKAGE OF A MACROCYCLIC GD(III) COMPLEX TO POLYAMINO ACIDS THROUGH A SQUARIC ACID MOIETY

On page 195, the reaction arrows in Schemes 3 and 4 should be replaced with ↔. In addition, on page 195, right column, in the sixth sentence of the second full paragraph, the following change should be made. "Thus, the strong upfield shift of C-3 suggests a large decrease of its carbonylic character, which is consistent with a shift in the equilibrium represented in Scheme 4." should be changed to "Thus, the strong upfield shift of C-3 suggests a large decrease of its carbonylic character, which is indicative that A-2 contributes more to the resonance hybrid than A-1."

New Detachable Poly(ethylene glycol) Conjugates: Cysteine-Cleavable Lipopolymers Regenerating Natural Phospholipid, Diacyl Phosphatidylethanolamine

Samuel Zalipsky,* Masoud Qazen,† John A. Walker II,‡ Nasreen Mullah, Yolanda P. Quinn, and Shi Kun Huang

Alza Corporation, 1050 Hamilton Court, Menlo Park, California 94025. Received March 16, 1999

A new strategy for the reversible attachment of methoxypoly(ethylene glycol) (mPEG) to an amino-containing substrate is described. The strategy is based on formation of a benzyl carbamate linkage substituted with a disulfide in the para or ortho position. While being stable under nonreducing conditions, the dithiobenzyl (DTB) urethane linkage is susceptible to cleavage by mild thiolysis with cysteine resulting in release of the parent amino component of the conjugate in its original form. The method is exemplified by preparation of mPEG-DTB-alcohol, its activation and attachment to distearoylphosphatidylethanolamine (DSPE). The resulting lipopolymer incorporates into liposomes, which are capable of losing their polymer coating under conditions approximating those existing in vivo. Implications for drug delivery are briefly discussed.

Lipopolymers, polymer−lipid conjugates, have proven to be very useful in micellar and liposomal drug delivery systems (*1*). In particular, the use of poly(ethylene glycol)-lipid [usually distearoylphosphatidylethanolamine (DSPE)][1] conjugates (*2*) has become routine to convey favorable pharmacokinetic and in vivo distribution characteristics to various injectable particles. The presence of grafted PEG chains on the surface of particulates results in reduced nonspecific interactions with various biological cells and macromolecules. This is caused by the exclusion effect of the flexible, very mobile, well water solvated PEG chains. However, for a variety of applications interaction with target cells is desirable. These might include, for example, intracellular delivery of a liposomal drug payload, delivery of oligonucleotides, or delivery of genes. In these instances, it might be desirable to be able to facilitate a process of removal of the surface-grafted polymer chains. We recently demonstrated some of the useful properties of cleavable PEG-lipids in their liposomal formulations (*3*). The first generation of detachable PEG-bearing liposomes contained aliphatic di-

sulfide-linked conjugate with 3,3′-dithiodipropionate as the linking moiety. Consequently, cleavage of the mPEG grafts from these liposomes required a relatively potent thiolytic agent, 1,4-dithiothreitol, which is unacceptable for the in vivo use. Furthermore, a modified phospholipid, 3-mercaptopropionyl-DSPE product, was generated as a result of the disulfide cleavage (*3*). In this communication, we report the preparation and some of the properties of a new mPEG-DSPE conjugate, containing *o*- or *p*-ditiobenzyl carbamate (DTB-urethane) linkage moiety (Figure 1). In contrast to the earlier version of the disulfide-linked conjugate, these new lipopolymers are cleavable with cysteine, and as a result of this reaction, phosphatidylethanolamine lipid is regenerated in its natural, unmodified form. In essence in this application, the mPEG moiety is acting as a macromolecular protecting group, which is removable under mild thiolytic conditions achievable in vivo. To the best of our knowledge this is the first demonstration of this type of reversible PEGylation strategy applied to any substrate.

Thiolytic decomposition of benzyl urethane-linked drugs containing aromatic disulfides in the para or ortho positions has been utilized by Senter et al. as a basis for an elegant prodrug strategy (*4*). We decided to adapt the dithiobenzyl urethane as a linkage between the lipid, DSPE, and mPEG components of the cleavable lipopolymer. The main attraction of this linking strategy, as shown in Figure 1, lies in its ability to regenerate the amino component of the carbamate upon reaction with thiols. Moreover, cleavage of mixed aliphatic−aromatic disulfides is usually easier than of their symmetrical aliphatic counterparts. We anticipated that this would allow the use of a mild, nontoxic thiol such as cysteine as the cleaving reagent.

The syntheses of the polymer−lipid conjugates are schematically depicted in Figure 2. First, we prepared a novel mPEG-2000 derivative with a methoxycarbonyldithioalkyl end group. This was accomplished by reacting 2-(methoxycarbonyldithio)ethaneamine with mPEG-chloroformate. The former compound was obtained through the reaction of 2-aminoethanethiol hydrochloride with an equivalent amount of methoxycarbonylsulfenyl chloride[2] according to the previously published procedures (*6, 7*). The polymeric chloroformate was easily prepared by phosgenation of an anhydrous mPEG-OH solution (*8*). The methoxycarbonyldithio functionality, positioned in this instance at the end of mPEG, is known to be useful

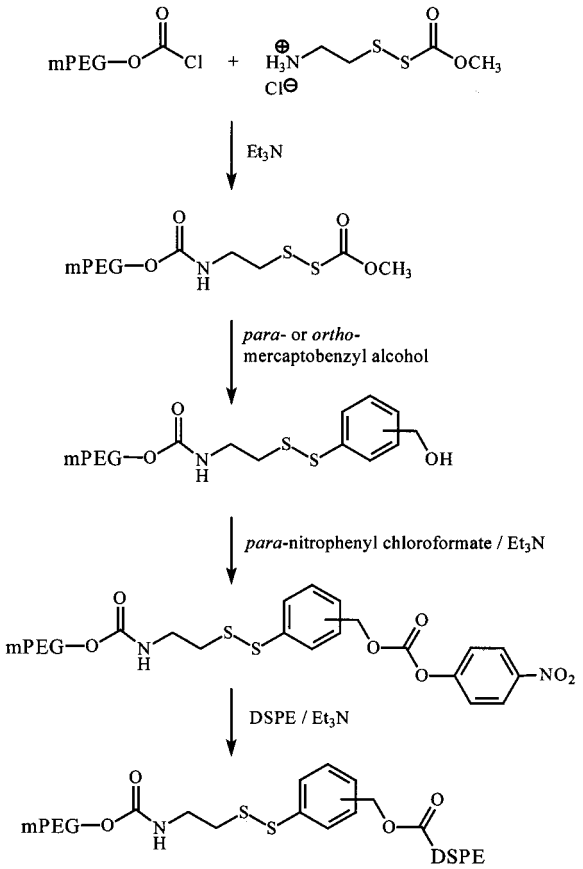

Figure 2. Schematic depiction of the synthesis of mPEG-DTB-DSPE.

for the formation of mixed disulfides (*6, 9, 10*). Furthermore, it is sufficiently active to react with even weakly nucleophilic aromatic thiols (*7*). Both para and ortho isomers of mercaptobenzyl alcohol (*11*) coupled cleanly with the polymeric acyl disulfide, yielding the mPEG-bearing dithiobenzyl alcohol end group. Active carbonate introduction proceeded as with the underivatized mPEG-

[2] To avoid complication due to various impurities potentially present in commercially available, aged methoxycarbonylsulfenyl chloride in some experiments, we used instead freshly prepared ethoxycarbonylsulfenyl chloride (*5*) with no bearing on the outcome of the syntheses.

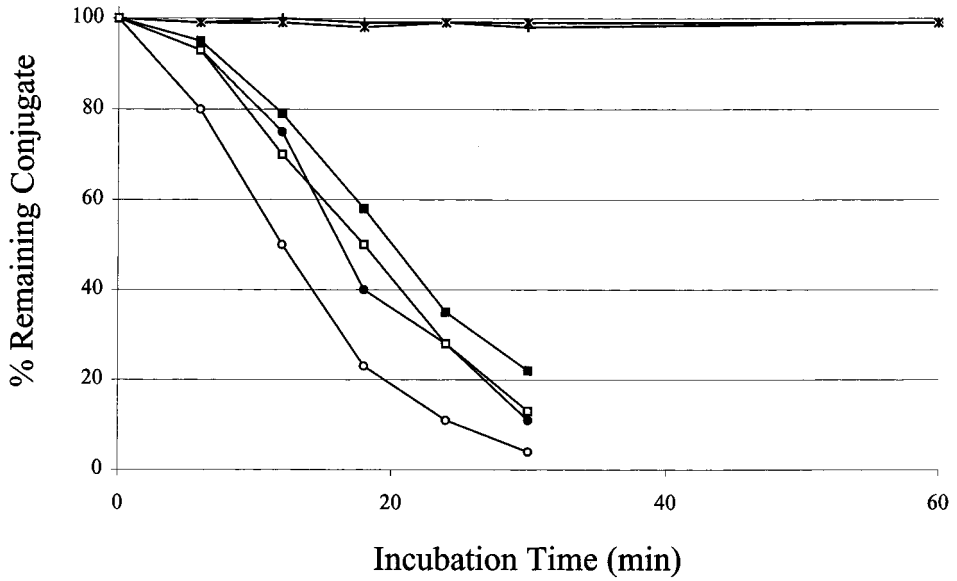

Figure 3. Cysteine-mediated cleavage of mPEG-DTB-DSPE conjugates (33 μM) in either micellar or liposomal (PHPC/cholesterol/lipopolymer at 95:5:3 mole ratio, ~120 nm diameter, closed symbols) solutions in PBS, pH 7.2, containing 5 mM EDTA at 37 °C with or without cysteine (150 μM). Disappearance of the conjugates was monitored by HPLC (Phenomenex C_8 Prodigy, 4.6 × 50 mm column, detection at 277 nm, mobile phase methanol/water 95:5 with 0.1% trifluoroacetic acid at 1 mL/min). Incubation in buffer only of ortho conjugate (*) and para conjugate (+). Incubations in cysteine-PBS of para conjugate (□), ortho conjugate (○); or liposomes containing para conjugate (■), ortho conjugate (●).

OH. We prepared both succinimidyl and *p*-nitrophenyl carbonates. However, most of the conjugation reactions with DSPE were performed with the latter derivatives, due to the ease of their preparation, shelf life stability, and avoidance of the potential side reactions associated with the succinimidyl carbonate chemistry (*12*). Both *o*- and *p*-DTB urethane linked lipopolymers were purified by silica gel chromatography (methanol gradient 0 to 10% in chloroform, ~70% isolated yield) and characterized by NMR[3] and MALDI-TOFMS. The latter technique confirmed the average molecular masses of the conjugates, 3127 and 3139 Da for para and ortho isomers, respectively (theoretical molecular mass ≈ 3100 Da). As was previously observed for various PEG conjugates (*13*, *14*), the spectra consisted of bell-shaped distributions of signals equally spaced at 44 Da, corresponding to the ethylene oxide repeating units. Consistent with the known tendency of MALDI-MS to, at least partially, cleave disulfides (*15*), separate distributions corresponding to mPEG-thiol, average molecular mass 2240 Da, were also observed.

The stabilities of both DTB-linked lipopolymers in buffered aqueous solution (pH 7.2) in the presence and absence of cysteine was monitored by HPLC. The results are illustrated in Figure 3. In these experiments, the *o*-DTB conjugate exhibited a slightly faster rate of decomposition than its para counterpart ($T_{1/2} \approx 12$ min vs ~18 min, at [Cys] = 150 μM). Both ortho and para conjugates were slightly more resistant to the thiolytic cleavage when incorporated into liposomes rather than in micellar solutions. In the absence of thiols, both conjugates appeared to be stable. Examination of completed thiolysis reactions of both para and ortho conjugates by TLC (silica gel G, chloroform/methanol/water 90:18:2) revealed the presence of DSPE as the sole lipid component (*16*) and another spot corresponding to a thiol-bearing, lipid-free mPEG derivative.

Due to the very large polar headgroup of PEG-lipid conjugates, they allow liposomal bilayer accommodation of lipids that normally do not form vesicles, e.g., DOPE, a hexagonal phase forming lipid. If a cleavable lipopolymer is used to facilitate the formation of this type of liposome, then chemical detachment of the grafted polymer chains would trigger decomposition of the vesicles and conversion of the lipids into the hexagonal phase. This, as was previously demonstrated (*3*), can be used for instant release of the liposomal contents and liposomal fusion. The content release characteristic of such liposomes, or the rate of the dequenching of the liberated fluorophores, provides for a convenient quantitative evaluation of the cleavable PEG-bearing liposomes. As illustrated in Figure 4, both dithiobenzyl-linked conjugates described here performed well in this assay, resulting in a cysteine-triggered release of encapsulated dyes. From these experiments, it is also apparent that the ortho conjugate was more susceptible to the thiolytic cleavage. For example, 300 μM cysteine liberates within 20 min most of the contents of DOPE liposomes stabilized by the *o*-DTB lipopolymer. Under the same conditions, only a very small fraction of the liposomes is decomposed when *p*-DTB-linked conjugate is used. After incubation for 20 min at 150 μM cysteine, half of the content release occurs by 20 min for *o*-DTB formulation, while only approximately 10% of the content release occurs in *p*-DTB liposomes even at the doubled cysteine concentration. Since we observed in Figure 3 that both ortho and para conjugates have half-lifetimes of less than 20 min, it is apparent that more than half of the original 3 mol % of PEG-lipids have to be cleaved in order to see a burst in the content release. Small, yet clearly not negligible, decomposition of the mPEG-DTB-DSPE/DOPE liposomes took place at 15 μM cysteine, which is the average plasma concentration in both humans and rodents (*17*), in the

[3] ^{1}H NMR for para conjugate: (d_6-DMSO, 360 MHz) δ 0.86 (t, CH_3, 6 H), 1.22 (s, CH_2 of lipid, 56H), 1.57 (m, $CH_2CH_2CO_2$, 4H), 2.50 (2xt, CH_2CO_2, 4H), 2.82 (t, CH_2S, 2H), 3.32 (s, OCH_3, 3H), 3.51 (m, PEG, ~180 H), 4.07 (t, PEG-CH_2OCONH, 2H), 4.11 and 4.28 (2 x dd CH_2CH of glycero, 2H), 4.98 (s, benzyl-CH_2, 2H), 5.09 (m, $CHCH_2$ of lipid), 7.35 and 7.53 (2 x d, aromatic, 4H) ppm. The ortho conjugate differed only in benzyl and aromatic signals at 5.11 (s, CH_2, 2H), and 7.31 (d, 1H), 7.39 (m, 2H) 7.75 (d, 1H) ppm.

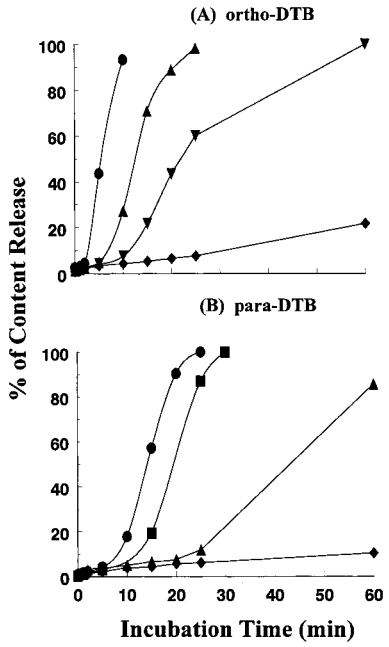

Figure 4. Fluorescent dequenching accompanying release of entrapped fluorophores (*p*-xylene-bis-pyridinium bromide, trisodium 8-hydroxypyrenetrisulfonate, 30 mM each) from liposomes (DOPE/mPEG-DTB-DSPE at 100: 3 molar ratio, ~100 nm diameter) incubated in HEPES buffer, pH 7.2, at 37 °C in the presence of cysteine (concentrations indicated for each curve). [Cys] = 15 μM (◆), 150 μM (▼), 300 μM (▲), 1 mM (■), 1.5 mM (●). The assays and calculations were performed according to the previously published procedures (*3*). Control experiments in the absence of reducing agents or with noncleavable urethane-linked mPEG-DSPE containing liposomes produced no content release.

time frame of these experiments (60 min). This suggests that DTB-linked lipopolymers should have sufficiently long lifetimes in plasma to allow the PEG-grafted vesicles to distribute systemically in vivo or to accumulate in a specific site either passively or through ligand-mediated targeting. Furthermore, these results suggest that a prolonged exposure to the natural plasma cysteine concentration (~15 μM) might be sufficient to decompose most of these lipopolymers. When faster cleavage is required, local or short-term increases in cysteine concentration can potentially be achieved by its intravenous or intraarterial administration.

The only example of the potential usefulness of in vivo reversible PEGylation was described by Garman and Kalindjian (*18*), who prepared acid-labile PEG-plasminogen activator by reacting mPEG-maleic anhydride reagent with amino groups of the protein. In this example, however, the conjugate was susceptible to cleavage not only under acidic conditions but even close to neutral pH and had to be stored frozen to minimize premature loss of the PEG attachments. Herein, we presented a new type of reversible PEGylation chemistry exemplified by preparation of mPEG-*o*/*p*-DTB-DSTE conjugates, which are rather stable in neutral pH in the absence of reducing agents. The linkages employed, *p*- or *o*-disulfide of a benzyl urethane, when subjected to mild thiolytic conditions can regenerate the original amine component, in this case DSPE, in its unmodified form. This is a very desirable outcome, since unnatural, modified lipids generated as a result of alternative cleavage strategies (see, for example, ref *3*) are more likely to have unpredictable, potentially negative in vivo effects. Since all the reactions shown in Figure 2 are clean high yielding transformations, the syntheses of mPEG-DTB reagents and their DSPE conjugates are of practical value. It is clear that DTB-linked PEG-lipids are cleavable with cysteine under mild conditions attainable in vivo. We are currently studying liposomes containing these cleavable lipopolymers in various biological systems. The results of these experiments will be reported in a due course. We anticipate that the new mPEG-DTB reagents and the described conjugation strategy will be of general applicability to a variety of amino-containing substrates including, peptides, proteins, aminoglycosides, and suitably functionalized biomaterials.

Functionalization of Covalent DNA−Streptavidin Conjugates by Means of Biotinylated Modulator Components

Christof M. Niemeyer,*,† Bülent Ceyhan,† and Dietmar Blohm†

Universität Bremen, FB 2-UFT, Biotechnology and Molecular Genetics, Leobener Strasse, D-28359 Bremen, Germany . Received December 28, 1998; Revised Manuscript Received May 12, 1999

Covalent DNA−streptavidin conjugates are versatile biomolecular coupling reagents, since they have binding capacity for both a complementary nucleic acid and four molecules of biotin. The DNA−streptavidin hybrid molecules have been investigated for their capabilities to bind two different types of biotinylated components. Thus, (i) a functional biomolecule, e.g., a single-stranded DNA fragment or an enzyme and (ii) low-molecular weight biotin derivatives ("modulators") were coupled stepwise with the hybrid molecules. Modulators were D-biotin, aminobiotin, and biotin-fluorescein conjugate as well as a lysine-rich 10mer peptide, containing a biotin and a fluorescein substituent. These modulators were chosen to affected the hybridization properties of the DNA−streptavidin conjugates. As investigated by surface-plasmon resonance and microplate solid-phase hybridization measurements, D-biotin, biotin-fluorescein, and aminobiotin decreased the efficiency of hybridization with complementary, surface-bound oligonucleotides to a varying extent. The basic peptide increased the conjugate's hybridization efficiency. Moreover, it was demonstrated in two examples how modulators can be utilized as additional functional domains of streptavidin-based conjugates. First, fluorescein-containing modulators were used as hapten groups, allowing a sensitive detection by means of specific antibodies directed against the modulator. Second, the biotinylated peptide was used as a carrier molecule to attach multiple fluorogenic lanthanide-chelate groups to the streptavidin conjugate, enabling its sensitive detection by time-resolved fluorometry. The applicability of this kind of bioconjugation strategy to generate sensor-probes for gene detection assays was demonstrated.

INTRODUCTION

The exploration of biomolecular recognition systems and their utilization to fabricate novel biomaterials is a central goal of nanosciences-related biotechnology. Within this area of research, self-assembling strategies are increasingly becoming recognized as a way to generate nanometer-scaled structural and functional elements (*1*). For this purpose, nucleic acids appear to be a suitable construction material (*2*, *3*). DNA has been extensively used for the fabrication of nanostructured scaffolds (*2*, *4*), which have great potential for selective positioning of molecular components, such as conducting polymers (*5*), proteins (*6*, *7*), and nanocrystalline metal clusters (*7*−*10*). We have previously reported on the synthesis of covalent conjugates of single-stranded DNA and the tetrameric protein streptavidin (STV) (*6*). In these hybrid molecules, the proteins native binding capacity for four biotin molecules is extended with a specific binding site for complementary nucleic acids. Therefore, the conjugates can be utilized as biomolecular adaptors for the positioning of any biotin-containing functional component along a nucleic acid backbone, containing complementary sequence stretches. For example, stoichiometrically defined nanoscale assemblies can be generated from several DNA−STV hybrids (Figure 1a). Each of the hybrid adapters can be functionalized with a distinctive biotin-derivatized molecule such as enzymes and antibodies (*6*) but also metal nanoclusters (*7*). Another promising application of DNA−STV hybrids is their use as reagents for the reversible, site-selective and highly efficient attachment of biotinylated compounds to various surfaces, in particular, the immobilization of enzymes or binding proteins to DNA microarrays (*11*).

These applications, however, depend on the avoidance of undesired conjugates, formed from DNA−STV hybrids and excess biotinylated material. Thus, it is necessary to block the remaining free biotin-binding sites of the hybrids subsequently to the coupling with the biotinylated molecule of interest. For this purpose, typically D-biotin is used. To take advantage of the obligatory blocking, we here report on the examination of several low molecular weight biotin derivatives, "modulators", for their capability to modify and further functionalize the streptavidin conjugates. The strategy is schematically drawn in Figure 1b. A modification of the DNA−STV hybrids with two different biotinylated components is achieved by initial coupling with a macromolecular functional compound, such as an enzyme, and second, the remaining biotin-binding sites are saturated with low molecular weight modulators. We expected that a coupling of suitable modulators should affect and possibly fine-tune the bioconjugate's nucleic acid hybridization properties. Moreover, extra versatility should be obtain-

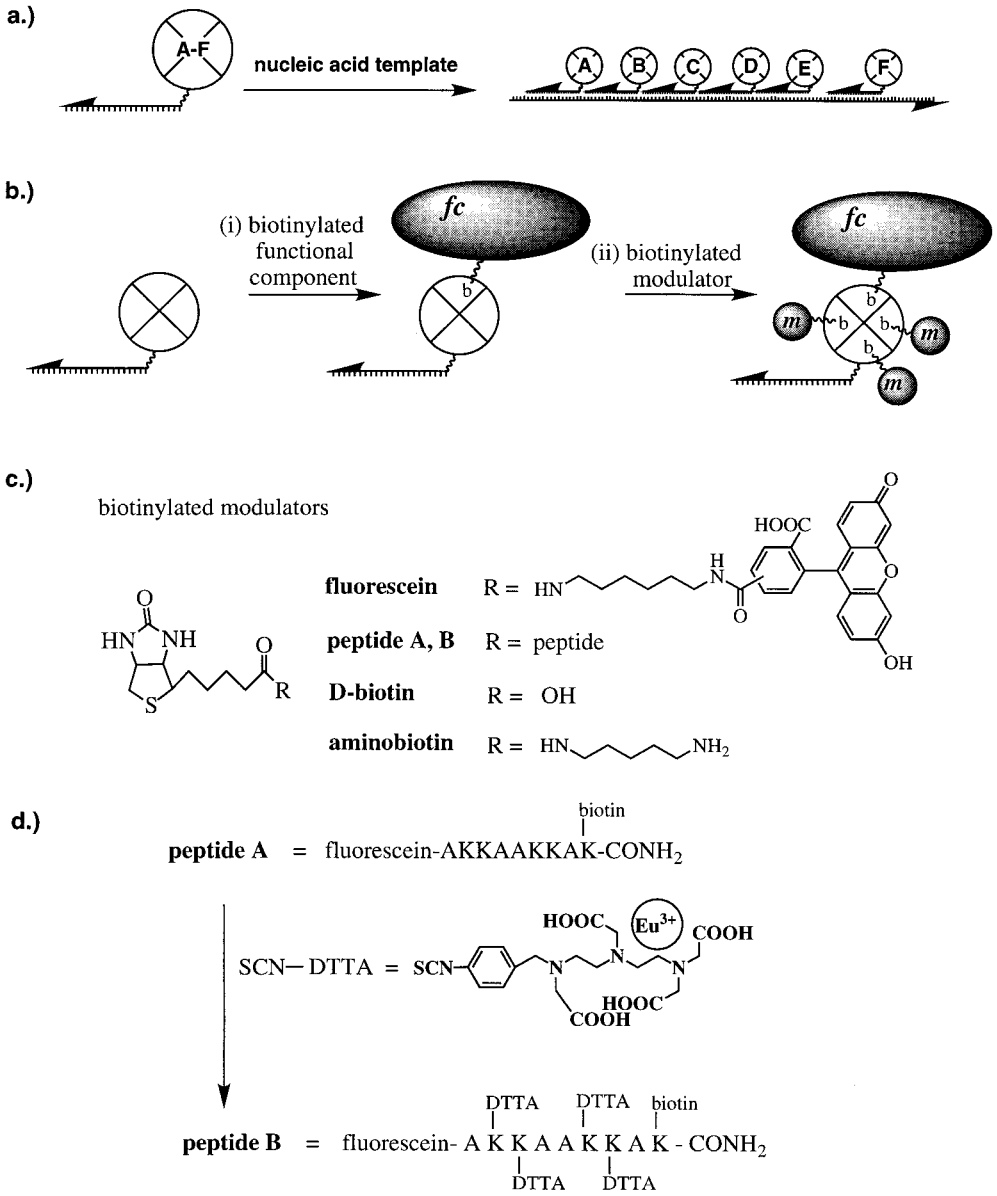

Figure 1. Schematic drawing of the bioconjugates investigated in this study. (a) Generation of supramolecular aggregates from six covalent DNA–STV hybrids, A–F, each containing an individual oligonucleotide sequence. The hybrids self-assemble in the presence of a complementary single-stranded nucleic acid template, e.g., an RNA molecule, to form supramolecular aggregates (*6*, *7*). Note that each of the six hybrids can be functionalized with individual biotinylated compounds. (b) Successive coupling of two different biotinylated compounds with a DNA–STV hybrid. In a first step, a macromolecular functional component (*fc*, represented by the shaded ellipse), such as a biotinylated enzyme or oligonucleotide, is coupled. In a second step, a biotinylated low molecular weight modulator (*m*, represented by the shaded sphere) is coupled to the remaining free biotin-binding sites. The modulator is used to modify the conjugate's hybridization properties or to enhance its functionality. (c) Chemical structure of the biotinylated modulators investigated in this study. (d) Chemical structure of the two peptides used as modulators.

able from the employment of modulators, if they contain additional functional moieties, such as chromophor or cofactor groups, chemically linked with the biotin. This should supplement the functionality of streptavidin bioconjugates, for instance, to exhibit high sensitivity as a detection tool or to enhance the catalytic turnover of enzymatic transformations.

The several modulators investigated in this study were D-biotin (bio), 5-aminopropyl-biotin (amb), fluorescein-biotin conjugate (fsc), and a biotinylated 10-mer peptide (peA), consisting of five lysine and five alanine residues in addition to a biotin substituent, attached to the carboxyl-terminal lysine, and a fluorescein substituent linked with the amino terminus (Figure 1, panels c and d). These modulators were chosen, to initially estimate any effects resulting from different molecular weights (e.g., biotin versus peptide A) or polarities of the biotin-attached side-chain groups (e.g., biotin versus aminobiotin, biotin versus fluorescein or aminobiotin versus peptide A). The stepwise modification of covalent DNA–STV conjugates, indicated in Figure 1b, was carried out by initial coupling of the DNA–STV hybrids with a biotinylated oligonucleotide (bDNA) or an enzyme as models for a macromolecular functional component. Subsequently, the low molecular weight modulators were bound. The effects of the these coupling steps have been studied with respect to the solid-phase hybridization capabilities of the conjugates. For this, a surface-plasmon resonance biosensor and also microplate measurements were used. Moreover, it was demonstrated in two examples that the binding of modulators provides additional functionality to the streptavidin conjugates.

First, modulators containing a fluorescein moiety were used as hapten groups, allowing for a sensitive detection by means of specific antibodies targeted against the chromophor. Second, peptide A was chemically derivatized with fluorogenic lanthanide-chelate DTTA groups to create a fluorogenic modulator, peptide B (Figure 1d). The coupling of this modulator with the DNA−STV hybrids allows a highly sensitive detection of the conjugates using time-resolved fluorometry (*12*). A potential application of this kind of bioconjugation strategy was demonstrated by generating biomolecular sensor probes, useful, e.g., in nucleic acid detection assays.

MATERIALS AND METHODS

Oligonucleotides and Covalent DNA−Streptavidin Hybrids. The sequences of the oligonucleotides used in this study are listed in Table 1. Various 5′-thiol-modified oligonucleotides, termed tA, tB, tD, and tL, were purchased from NAPS, Göttingen. These oligomers were used for the chemical synthesis of the DNA−STV hybrids described below. Biotinylated oligomer complements, termed bcA, bcB, bcD, and bcL (NAPS) were used as capture oligonucleotides in BIAcore and microplate hybridization measurements. Biotinylated oligomers, termed bB, bD, bG, and bK, were used for the coupling with DNA−STV conjugates (see Table 2).

Synthesis and purification of covalent DNA−STV hybrids, HA (**1**), HB (**2**), HD (**3**), and HL (**4**), were carried out from the corresponding thiolated oligonucleotides, tA through tL, respectively, and recombinant streptavidin (IBA, Göttingen), similar as previously described (*6*). In brief, STV (10 nmol) was derivatized with maleimido groups using a heterobispecific cross-linker, reacted with a 5′-thiolated oligonucleotide (10 nmol) and subsequently purified by anion-exchange chromatography. A 1:1 molar ratio of nucleic-acid and protein moiety of the hybrids was verified by gel-electrophoretic and photometric analysis, and concentrations of the preparations were determined by absorbance measurements (*6*).

Biotinylated Modulators. D-Biotin (bio) and biotin-fluorescein conjugate (fsc) were purchased from Sigma and Calbiochem, respectively. 5-Aminopropyl-biotin (amb) was synthesized from *N*-hydroxysuccinimidyl-biotin and 1,5-diaminopentane by the method of Sutoh et al. (*13*). The bifunctional modulator peptide A, containing four alanine and four lysine residues in addition to a biotin substituent, coupled to the carboxyl-terminal lysine side chain, and a fluorescein substituent, coupled to the amino terminus, was purchased from pepScan Immunoanalytik GmbH (Berlin). The peptide synthesis was carried by standard methods using Fmoc-protected amino acids. In an initial step, the ϵ-amino group of resin-bound lysine was deprotected and coupled with activated biotin. After removal of the Fmoc protection group, chain elongation of the peptide was carried out. Finally, the deprotected amino-terminus was derivatized with NHS-fluorescein, and the peptide was cleaved from the resin, yielding an amidated carboxyl-terminus. Full-length products were separated as a single peak by HPLC. MALDI-MS analysis of the product, however, revealed the presence of three major peaks at *m*/*z* 1305, 1531, and 1663. The peak at *m*/*z* 1531 corresponds to the desired peptide ($M = 1527$),

Table 2. Terminology of the Various Bioconjugates Investigated in This Report[a]

conjugate	acronyme	covalently attached DNA oligomer	biotinylated functional component	biotinylated modulator
1	HA	tA		
1a	HA_fsc	tA		fluorescein
1b	HA_peA	tA		peptide A

7d	HA_POD_amb	tA	peroxidase	aminobiotin

[a] The conjugates were generated by coupling of covalent DNA-STV hybrid molecules with biotinylated macromolecules and low-molecular weight modulators, as drawn in Figure 1b. The coupling through biotin-STV interaction is indicated by an underline dash.

while the peak at *m*/*z* 1305 likely corresponds to a product lacking the biotin moiety ($M = 227$). The presence of about 30% of this side product, possibly generated by incomplete coupling, was verified by chromatographic gel-filtration shift analysis after coupling with STV. The MALDI-MS peak at *m*/*z* 1663 likely corresponds to a biotinylated peptide containing an additional lysine residue ($M = 130$), possibly formed by elongation of deprotected lysine during the peptide synthesis.

Fluorogenic modulator peptide B was prepared from crude peptide A using Eu-labeling reagent, Eu^{3+}-N^1-(*p*-isothiocyanatobenzyl)-diethylentriamin-N^1,N^2,N^3,N^3-tetraacetic acid (DTTA, Wallac). The coupling was carried out according to manufacturer's instructions. As analyzed by MALDI-MS, all three peptides, present in the crude preparation of peptide A, gave coupling products, containing up to four DTTA moieties per peptide. An excess of the crude peptide B preparation was coupled with STV by 5 min of incubation at room temperature, and the conjugate was purified by gel filtration on a NAP-5 column (Pharmacia) and concentrated by ultrafiltration (Centricon 30, Millipore). The molar ratio of Eu^{3+} to STV was calculated from UV-vis photometry, time-resolved fluorometry, and MALDI-MS analysis.

Functionalization of DNA−STV Conjugates with Biotin Derivatives. Preconjugates of the DNA−STV hybrids and biotinylated modulators (**1a**−**4b** in Table 2) were prepared by mixing 1 mM stock solutions of the hybrids and a 16-fold molar excess (8 mM stock-solution) of biotinylated modulators in buffer A [20 mM Tris-Cl buffer, pH 7.5, 150 mM NaCl, 5 mM EDTA, and 0.01% (w/v) Tween-20]. After incubation for 30 min at room temperature, the mixtures were diluted to final concentrations, typically in the range of 200 to 5 nM of the hybrids, with buffer A. Conjugates of the DNA−STV hybrids and biotinylated oligonucleotides (**5**−**6b** in Table 2) were prepared from 0.1 mM stock solutions of the hybrids **2** and **3** and a 1−8-fold molar excess (1−8 mM stock solution) of biotinylated oligonucleotides in buffer A. After incubation for 30 min at room temperature, a 16-fold molar excess of biotinylated modulator was added, and the mixtures were diluted for BIAcore measurements as described below. Conjugates **7**−**7d** (Table 2) of the DNA−STV hybrids and biotinylated horseradish peroxidase (POD, Pierce) were prepared by mixing 0.1 mM stock solutions of the hybrid **1** and POD in buffer A. After incubation for 30 min at room temperature, a 16-fold excess of biotinylated modulator was added, the mixtures were incubated for additional 10 min and subsequently diluted to final concentrations, in the range 25 to 5 nM, with buffer A.

BIAcore Measurements. Biospecific interaction analysis was performed on a BIAcore 2000 Biosensor (Biacore AB, Upsala, Sweden) at a continuous flow of buffer B (150 mM NaCl, 30 mM sodium phosphate, 3 mM EDTA, and 0.25% Triton X-100, pH 7.4) at 10 μL/min and 25 °C, maintained throughout the entire analysis. The immobilization of capture oligonucleotides, bcA, bcB, bcD, bcL (Table 1), 10 μM in buffer B, was achieved by injection over STV-coated sensorchips (SA-Chips, Biacore AB) until an amount of about 1000 RU of the biotinylated oligomer complements was immobilized. Loosely attached material was removed by three cycles of 10 μL of 50 mM NaOH. To analyze the binding efficiencies of DNA−STV conjugates, previously modified with biotinylated compounds, various dilutions of typically 200−25 nM of the conjugates in buffer B were injected over the DNA-specific surface at 10 μL/min for 4 min. The interaction was monitored continuously as the change in SPR signal. Dissociation was affected by injecting buffer B only and was followed for 15 min. The surface was regenerated by injection of 10 μL of 50 mM NaOH. The entire process was automated, binding and dissociation curves were recorded automatically, and analytical cycles were preprogrammed. The data analysis was carried out using BIAcore Evaluation 2.1 software (Pharmacia).

Microplate Hybridization Assays. Microplate-based solid-phase hybridization assays were carried out on STV-coated microplates, prepared as previously described (*14*). Initially, 50 μL of a 240 nM solution of biotinylated capture oligomer bcA in buffer A were allowed to bind for 60 min to the STV-coated plates. After washing with buffer A containing 10 mM D-biotin, 50 μL of solutions of the conjugates **7**−**7d**, prepared as described above, were allowed to hybridize for 60 min at room temperature. Negative controls were run in parallel by applying conjugates to wells, coated with noncomplementary oligonucleotide bcB. After incubation and washing four times with buffer A and twice with buffer C (20 mM Tris, pH 7.5, and 150 mM NaCl) POD-substrate, ABTS (2,2'-azino-di-[3-ethylbenzthiazoline sulfonate], Boehringer Mannheim), prepared according to manufacturers instructions, was added and the absorbances at 405 nm were determined with a Victor 1420 Multilabel-Counter (Wallac) after incubation for 20 min at 37 °C. Standard deviations were calculated from the signal intensities of interest. Typically, duplicate determination of a particular sample revealed an error of about 10%.

Two-sided nucleic acid detection assays (see Figure 7) were carried out on microplates modified with capture oligonucleotide bB. Target DNA, prepared from M13mp18 vector as previously described (*6*), was heat denatured at 5 nM concentration in buffer A, and various dilutions ranging 2−0.005 nM were mixed with equal volumes of either oligonucleotide probe FscA (Table 1), HA_fsc (**1a**) or HA_peB (**1e**), 5 nM in buffer A. A total of 50 μL of the mixtures was allowed to hybridize to the microplate-bound capture oligomer for 60 min at room temperature. The plate was washed with buffer A, and the amount of probe **1e** immobilized was determined by time-resolved fluorometry with the Victor 1420 Multilabel-Counter after the addition of enhancement solution (Wallac). To detect probes FscA and **1a**, 50 μL of an anti-fluorescein immunoglobulin-alkaline phosphatase conjugate (Boehringer Mannheim, 1:3000 dilution in buffer A) were added to the wells and incubated for 30 min at room temperature. After washing, alkaline phosphatase-substrate, pNPP (4-nitrophenyl phosphate, Boehringer Mannheim), prepared according to manufacturers instructions, was added and the absorbance at 405 nm was determined with the Victor 1420 Multilabel-Counter after incubation for 30 min at 37 °C. Relative signal intensities were calculated by dividing signal intensities and background signals of negative controls in which no DNA target was present.

RESULTS AND DISCUSSION

Preparation of Bioconjugates. Covalent hybrids of DNA and streptavidin, HA (**1**), HB (**2**), HD (**3**), and HL (**4**), were synthesized from the analogous 5′-thiolated oligonucleotides, tA, tB, tD, and tL (for DNA sequences see Table 1) and recombinant streptavidin by chemical cross-linking as previously described (*6*). The chief products, hybrids containing a single oligonucleotide moiety per STV, were purified by chromatography (*6*).

To initially investigate the effects induced by the modulators, DNA−STV hybrids were exclusively coupled

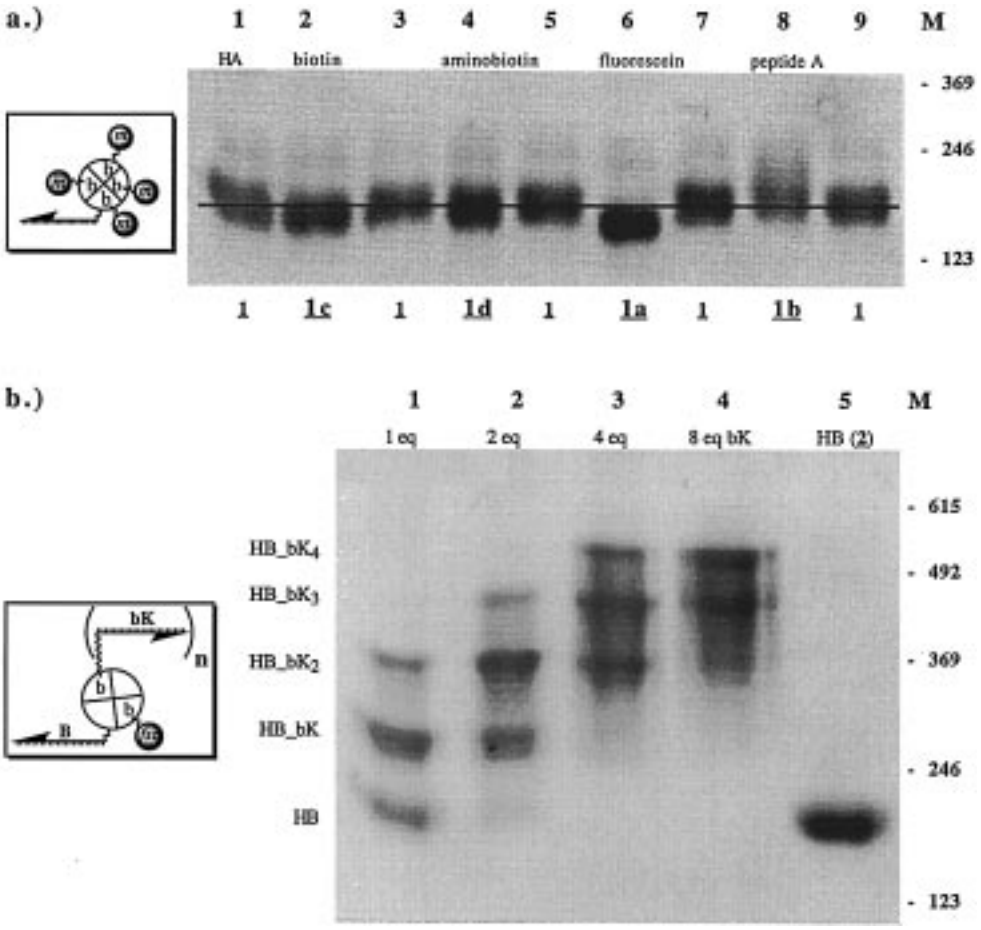

Figure 2. Analysis of DNA−STV conjugates by native 7.5% acrylamide gel-electrophoresis. (a) Influences of modulators on the conjugate's electrophoretic mobility. Conjugates **1a**−**d**, prepared from covalent DNA−STV hybrid HA (**1**) by coupling with 16 molar equivalents of the various biotinylated modulators, shown in Figure 1c. For comparison, unmodified **1** was applied to all odd-numbered lanes. (b) Analysis of bDNA conjugate **5g** prepared from DNA−STV hybrid HB (**2**) and 1, 2, 4, or 8 molar equivalents of biotinylated oligomer bK. Depending on their stoichiometric composition, HB_bK$_1$ through HB_bK$_4$ display a reduced electrophoretic mobility with increasing numbers of bK molecules bound to **2**. M: DNA molecular weight standards; the length is given in base pairs.

with the various modulators to yield conjugates **1a**−**4b** of Table 2. Gel-electrophoretic characterization was carried out with complexes prepared from DNA−STV hybrid HA (**1**) and 16 molar equivalents of the fluorescein (**1a**), peptide A (**1b**), biotin (**1c**), or aminobiotin modulator (**1d**) (Figure 2a). The coupling of the modulator caused only small changes in electrophoretic mobility. The most significant change was obtained from fluorescein, increasing the streptavidin's mobility. A faint decrease was observed for the peptide conjugate **1b**. These changes correlate with the polarity of the modulator's side chain (Figure 1c). The fluorescein affixes negative charges, while the amino groups of the lysine-rich peptide A append positive charges to the conjugates. Effects were even weaker when biotin (**1c**) or aminobiotin (**1d**) were used as modulators. However, a direct comparison of the bands suggests that the mobility of **1d** is similar to that of unmodified HA (**1**), while **1c** migrates somewhat faster than **1**. To demonstrate that the coupling of modulators is irreversible, conjugates **1a**−**d** were mixed with a biotinylated DNA oligomer. No additional bands were observed, similar as in Figure 2b (data not shown).

While conjugates of the DNA−STV hybrids and biotinylated enzymes, e.g., **7**, had previously been studied (*6*, *11*, *15*), conjugates of the hybrids with biotinylated DNA oligomers have not yet been investigated. Thus, several bDNA conjugates (**5**−**6b** in Table 2) were prepared from biotinylated oligonucleotides bB, bD, bG, and bK and covalent DNA−STV hybrids, HB (**2**) or HD (**3**). As an example, conjugate **5g** was analyzed by native gel electrophoresis. For conjugate preparation, DNA−STV hybrid **2** was mixed with increasing amounts of the biotinylated oligomer bK, incubated for 10 min, and subsequently, an excess of the fluorescein modulator was added. The resulting conjugates were analyzed on a nondenaturing acrylamide-gel (Figure 2b). The addition of 1 molar equivalent of bK oligomer already yielded the formation of several adducts. Depending on their stoichiometric composition, these adducts displayed significant differences in their electrophoretic mobility, which was reduced with increasing numbers of bK molecules bound to **2**. In the case of 1 equiv of bK, the major product was the expected monoadduct, HB_bK, formed in about 70% yield. Additional components were uncoupled **2** and also small amounts of a bis-adduct, HB_bK$_2$. The addition of 2, 3, or 8 equiv of bK led to the formation of adducts with a stoichiometry of HB_bK$_2$ and HB_bK$_3$ and also to the tetra-adduct HB_bK$_4$, containing four biotinylated oligonucleotide moieties, respectively. Further characterization of bDNA-containing conjugates, **5a** and **5e**−**g**, was carried out by BIAcore analysis described below.

To investigate whether a sequential coupling of two different biotinylated components can be achieved as proposed in Figure 1b, a series of doubly functionalized complexes (**5a**−**d** and **7a**−**d** in Table 2) was prepared from DNA−STV hybrids **2** and **1**, respectively. To prepare bDNA conjugates **5a**−**d**, **2** was initially coupled with biotinylated oligomer bD, and subsequently, the various

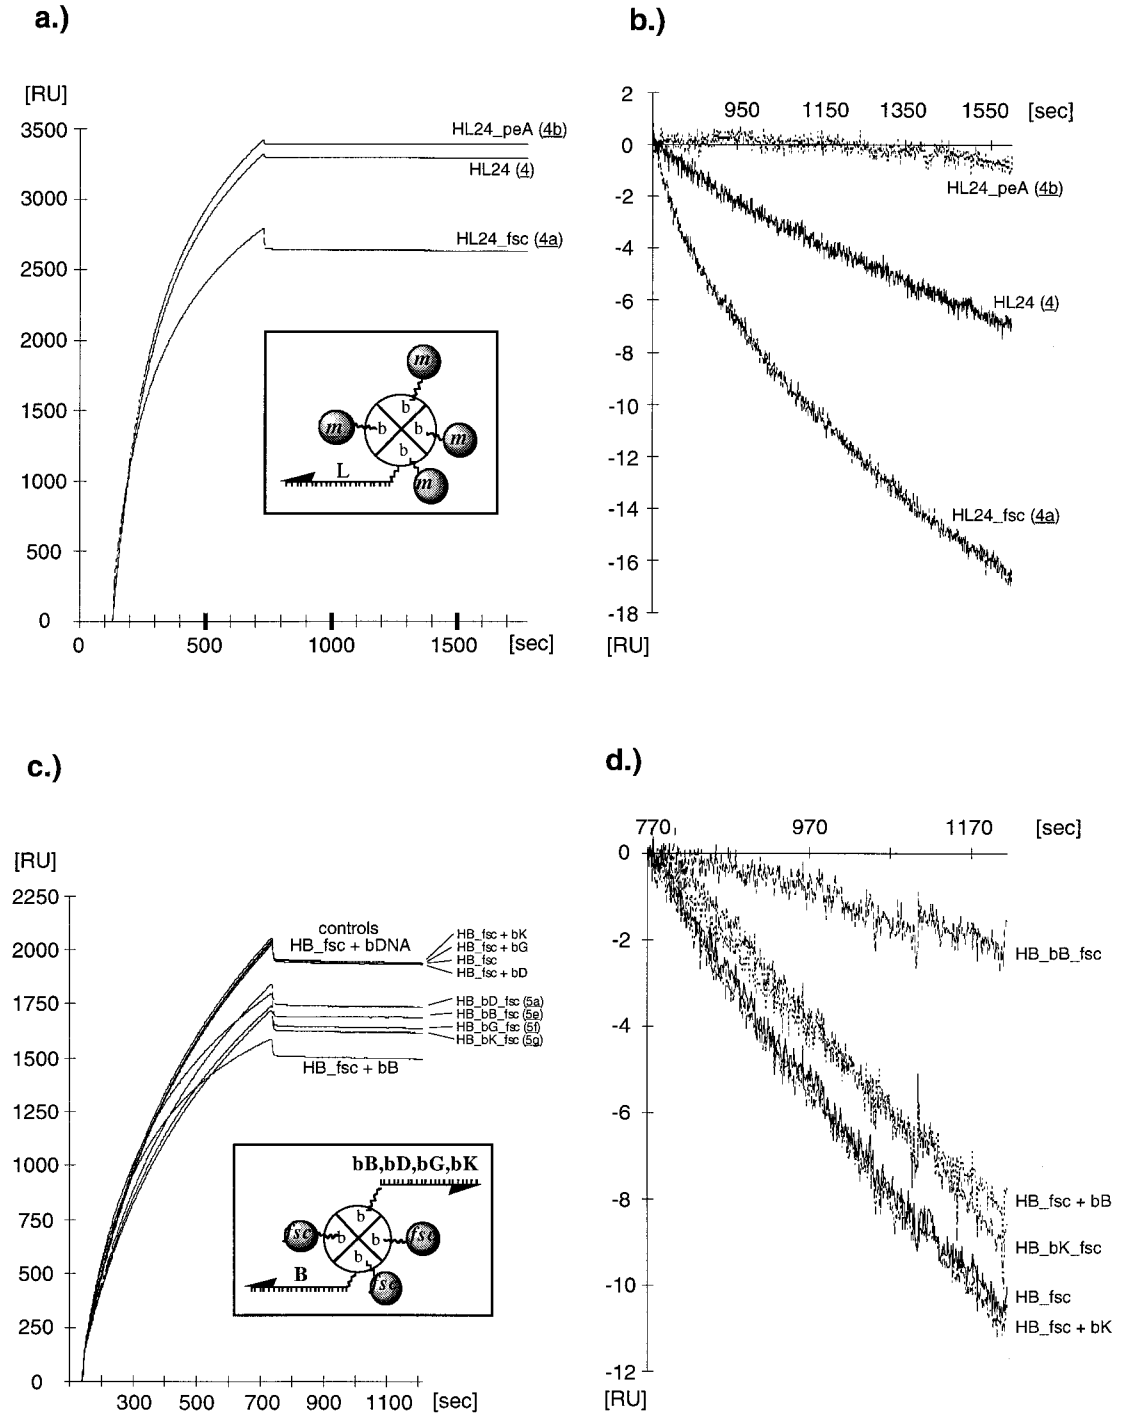

Figure 3. BIAcore analyses of solid-phase hybridization of DNA−STV conjugates. (a) Comparison of DNA−STV hybrid HL (**4**) (middle curve), and its conjugates with biotinylated fluorescein (**4a**) (lower curve) and biotinylated peptide A (**4b**) (upper curve). All analyte concentrations were 100 nM. (b) Overlay plot of the dissociation curves from Figure 3a. (c) Comparison of the binding curves of bDNA conjugates **5a** and **5e**−**g** obtained from DNA−STV conjugate HB (**2**), 1 molar equivalent of biotinylated oligonucleotides bB, bD, bG, or bK, and the fluorescein modulator. The upper set of curves was obtained from controls, in which (**2**) was saturated with fluorescein modulator prior to the addition of bDNA. The middle set of curves was obtained from the binding of conjugates **5a** and **5e**−**g**, the lower curve was obtained from the control in the presence of oligomer bB. All sample concentrations were 50 nM. (d) Overlay plot of selected dissociation curves from Figure 3c.

modulators were bound. Enzyme conjugates **7a**−**d** were prepared from DNA−STV hybrid **1** by stepwise coupling with 1 molar equivalent of biotinylated peroxidase, and the various modulators. The solid-phase hybridization capabilities of the double-functionalized streptavidin complexes were investigated using BIAcore or microplate analysis, as described below.

The fluorogenic modulator peptide B (Figure 1d) was synthesized to demonstrate how modulators can be used to extend the functionality of streptavidin complexes. To synthesize peptide B, Eu^{3+}-N^1-(*p*-isothiocyanatobenzyl)-diethylentriamin-N^1,N^2,N^3,N^3-tetraacetic acid was used as a reagent to chemically attach lanthanide-chelate (DTTA) groups to the lysine side chains of peptide A (see Figure 1d). This derivatization was carried out to obtain a modulator which is detectable with very high sensitivity by time-resolved measurement of Eu^{3+} fluorescence (*12*). The crude derivatization products were analyzed by

MALDI-MS. The spectra obtained showed peaks of peptide A coupled with two, three, or four DTTA groups. An excess of the crude peptide B was coupled with DNA−STV hybrid HA (**1**), and the resulting conjugate **1e** was purified by gel filtration chromatography and ultrafiltration. A ratio of about 10−11 Eu^{3+}/STV was calculated from UV-vis photometry and time-resolved fluorometry measurements. A similar ratio was obtained from MALDI-MS analysis of a conjugate prepared from native streptavidin and peptide B. The spectra revealed peaks at *m*/*z* 13 355 and *m*/*z* 16 438 (data not shown). The peaks were assigned to the masses of the STV subunit and its adduct with the peptide B, respectively. The difference in mass of about 3100 units suggests that on average three DTTA groups (M_r = 486 g/mol) are bound per peptide A moiety (M_r = 1527 g/mol). Conjugate **1e** was utilized as a sensor probe in the gene detection assay, described below.

Solid-Phase Hybridization Studies of the Conjugates. To study how biotinylated modulators influence the hybridization properties of DNA−STV conjugates, solid-phase hybridization studies were carried out using microplate analysis and biospecific interaction analysis (BIAcore) (*16*). The latter was performed using a biosensor based on surface plasmon resonance (SPR). With this technique, the refractive index within a gold sensor chip-immobilized dextran matrix is continuously monitored, plotted against time, and presented in a sensorgram. The change of SPR response, measured in resonance units (RU), allows a quantification of interaction between chip-immobilized and liquid-phase-diluted binding partners. Here, biotinylated oligomer complements were immobilized on streptavidin-coated sensor chips, and real-time measurements at several analyte concentrations were carried out with the various STV conjugates. A series of controls, carried out by injecting conjugates over sensor chips modified with noncomplementary capture oligomers gave no significant change in SPR response (not shown), indicating, that the binding observed is due exclusively to specific single-stranded DNA hybridization. BIAcore measurements were carried out in duplicate. Typically, the data obtained were highly reproducible, revealing errors of less than 3%. Unfortunately, kinetic analysis of the BIAcore data has not yet been achieved, although the determination of kinetic constants has previously been attained with similar analyte samples (*15*). In this study, highly irregular dissociation curves were observed (for instance see Figure 3b), suggesting that mass transport and rebinding phenomena occur which prohibit a detailed kinetic analysis (*17*). Since the signal intensities (RU values) at a given concentration directly correlate with the analyte's affinity, RU values were used instead of kinetic data to judge hybridization efficiency of the conjugates investigated.

Modulator-Induced Changes of Conjugate's Hybridization Capabilities. To initially study the influences of biotinylated modulators on the hybridization characteristics of the DNA−STV conjugates, BIAcore measurements were carried out with hybrids HA (**1**), HB (**2**), and HL (**4**) and compared with the modulator-modified analogous conjugates (Figure 3, panels a and b). The RU values obtained are summarized in Table 3. Compared to the unmodified hybrids **1**, **2**, and **4**, the hybridization efficiencies of fluorescein-modified conjugates, HA_fsc (**1a**), HB_fsc (**2a**), and HL_fsc (**4a**), were decreased by about −15, −24, and −20%, respectively. Note that these variations are well beyond the standard deviation of less than 3%. The decrease in hybridization efficiency is elucidated by a comparison of the BIAcore dissociation curves. As indicated from overlay plots (Figure 3b), the fluorescein-modified conjugates displayed an elevated dissociation, likely due to the additional negative charges introduced by the chromophor. The enhanced dissociation is probably the reason for the lower binding efficiencies observed.

Table 3. Influences of Biotinylated Modulators on the Solid-Phase Hybridization Efficiencies of DNA−STV Conjugates[a]

	conjugate/conc	50 nM	100 nM	200 nM	change [%]
1	HA	3742	4500	4973	
1a	HA_fsc	3099	3815	4411	−14.6 ± 2.2
2	HB	2566	3361	4057	
2a	HB_fsc	1955	2538	3135	−23.7 ± 0.6
control	HB_bio+fsc		2456		−26.9
2b	HB_peA	2941	3665	4433	11.6 ± 2.4
2c	HB_bio	1827	2413	2975	−27.9 ± 0.8
2d	HB_amb	2205	2906	3628	−12.7 ± 1.4
control	HB_bio+amb		2522		−25.0
3a	HD_fsc	431	709	1100

4	HL	2649	3300	3910	
4a	HL_fsc	2118	2643	3187	−19.5 ± 0.7
4b	HL_peA	2713	3393	4004	2.6 ± 0.2

[a] For terminology of the conjugates, see Table 2. The values are BIAcore resonance units (RU). All values are averaged from at least duplicate measurements with a typical standard deviation of about 3%. The values listed in the right column indicate the changes in hybridization efficiencies, averaged from the three different analyte concentrations and normalized as a percentage fraction of the signals obtained for unmodified DNA−STV hybrids.

The comparison of fluorescein- and peptide-A-modified complexes indicates that the coupling of the basic peptide increased the hybridization efficiencies of the bioconjugates (see Table 3). The increase was about 35 and 23% for HB conjugates **2a**/**2b** and HL conjugates **4a**/**4b**, respectively. The increase induced by peptide A was independent of the analyte concentration applied to the biosensor. In contrast, the increase observed from comparison of HD conjugates **3a**/**3b** was in the range of about 20−40%, depending on the analyte concentration applied. The coupling of four peptide A molecules increases the conjugate's masses by about 5% (2.8 kDa) compared to the coupling of four fluorescein modulators. Thus, the increased binding signals observed in BIAcore are not due to increased molecular weights, but rather due to enhanced hybridization capabilities of the peptide-containing conjugates. This is also evident from the comparison of BIAcore dissociation curves (Figure 3b). Overlay plots indicated that the coupling of the peptide A led to a remarkably reduced dissociation compared to fluorescein- and also to unmodified DNA−STV hybrids. This suggests that the higher binding of the peptide conjugates was due to reduced dissociation. The concentration dependency observed for HD-based conjugates **3a**/**3b** (see Table 3) is likely due to the sequence-specific hybridization properties of the D oligomer attached. HD hybridizes about 5-fold slower than HB or HL(*15*). Excess, uncoupled peptide A, which is present in the analyte solutions, can function as an intermolecular effector, accelerating nucleic acid hybridization due to its polyamine structure (*18*). This kind of intermolecular interaction is concentration dependent and more significant in slow hybridization reactions.

Further studies of modulator influences were carried out with the various HB conjugates **2a**−**d** (Table 3, see also the comparison of normalized data in Figure 5). Surprisingly, already the binding of D-biotin (**2c**) induces a significant decrease of about −28% in hybridization efficiency compared to unmodified HB (**2**). As a consequence, the signal intensity of 100 nM **2c** is similar to

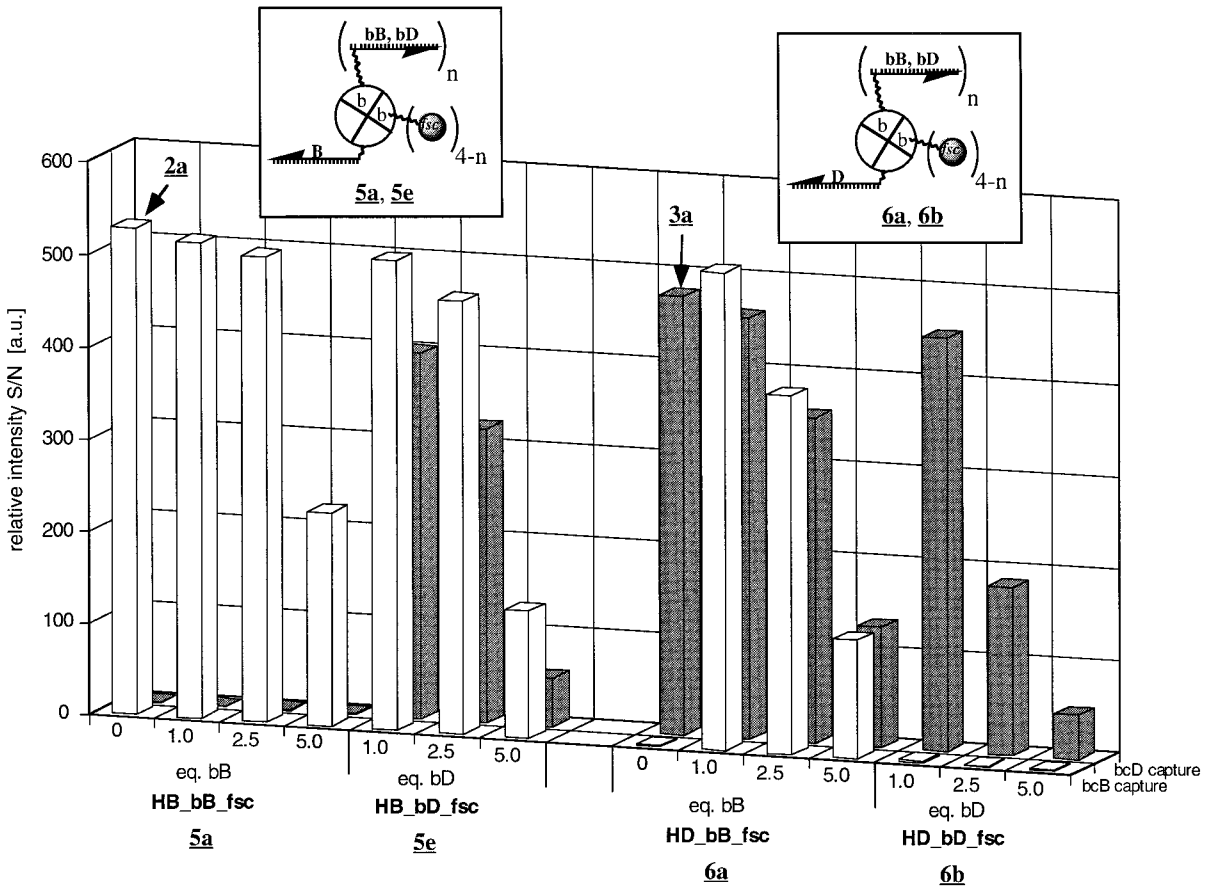

Figure 4. Microplate solid-phase hybridization of bDNA conjugates, prepared from DNA−STV hybrids HB or HD by successive coupling with either bB (**5a** and **6a**) or bD (**5e** and **6b**) oligonucleotide and the fluorescein modulator. The hybridization capabilities of the conjugates were tested in parallel with two microplate-bound capture oligomers, bcB and bcD. The detection of microplate-immobilized material was carried out using an anti-fluorescein-IgG-alkaline phosphatase conjugate and subsequent enzymatic color reaction. The height of the histograms represents relative signal intensities (*S*/*N*), obtained from the quotient of signal and background signals of the appropriate negative controls, in which the conjugates were incubated over noncomplementary capture oligomers.

Table 4. Influences of Biotinylated Modulators on the Hybridization Efficiency of HB Previously Coupled with Oligonucleotide bD[a]

	conjugate/conc	50 nM	100 nM	200 nM	change (%)
5	HB_bD	1998	2619	3221	
5a	HB_bD_fsc	1802	2307	2810	−11.5 ± 1.1
5b	HB_bD_PE	2075	2684	3280	2.7 ± 0.7
control	HB_bD_bio + PE	1755	2243	2771	−13.5 ± 0.9
5c	HB_bD_bio	1733	2208	2700	−15.1 ± 1.2
5d	HB_bD_amb	1840	2354	2867	−9.7 ± 1.2

[a] The numbers are BIAcore RU values, similar as indicated in Table 3.

that obtained from 50 nM of unmodified **2** (see Table 3). Thus, about a 2-fold reduced affinity of **2c** can be estimated. In contrast, the coupling with aminobiotin (**2d**) results in a significant smaller decrease in hybridization efficiency of about −13%, compared to unmodified **2**. Several controls were carried out by initial blocking of the biotin-binding sites with D-biotin and subsequent addition of modulators, e.g., fluorescein or aminobiotin (Table 3) or peptide A (Table 4). The controls indicated that the modulators only influence the hybridization when they are intramolecularly coupled with the streptavidin conjugate. Although systematic conclusions should not be drawn from these initial results, it seems reasonable that the biotin-binding induces conformational changes of the streptavidin molecule (*19*). The altered conformation causes altered intramolecular interactions between the surfaces of the protein and the nucleic acid moiety within the bioconjugate, and consequently, its hybridization capabilities are affected. Moreover, the results suggest that charged side chains, i.e., the carboxyl groups in D-biotin and fluorescein or the amino groups in aminobiotin and peptide A, significantly affect the hybridization properties of the bioconjugate's oligonucleotide domain. These observations are in agreement with extensive studies carried out by Corey and coworkers, who demonstrated that covalent oligolysine peptide−oligonucleotide conjugates display a significantly enhanced hybridization kinetics compared to the analogous unmodified oligonucleotides (*20*−*22*).

Conjugates Containing Biotinylated Oligonucleotides. To characterize conjugates consisting of covalent DNA−STV hybrids and biotinylated DNA oligomers (**5**−**6b** in Table 2), the binding capabilities of the two DNA domains within the complexes were initially investigated by a microplate-based hybridization assay (Figure 4). For this, the fluorescein modulator was incorporated into the conjugates to function as a hapten, allowing detection of the microplate-bound conjugates by a specific antibody directed against fluorescein. Four different bivalent complexes, **5a**, **5e** and **6a**, **6b**, were prepared from DNA−STV hybrids HB (**2**) or HD (**3**), respectively. This was achieved by initial coupling of the hybrids with various amounts of biotinylated oligonucleotides, bB or bD, followed by subsequent coupling with an excess of the fluorescein modulator. Following hybridization with microplate-immobilized, complementary capture oligonucleotides, bcB and bcD (see Table 1), the amounts of complexes bound to the plate were visualized by an anti-

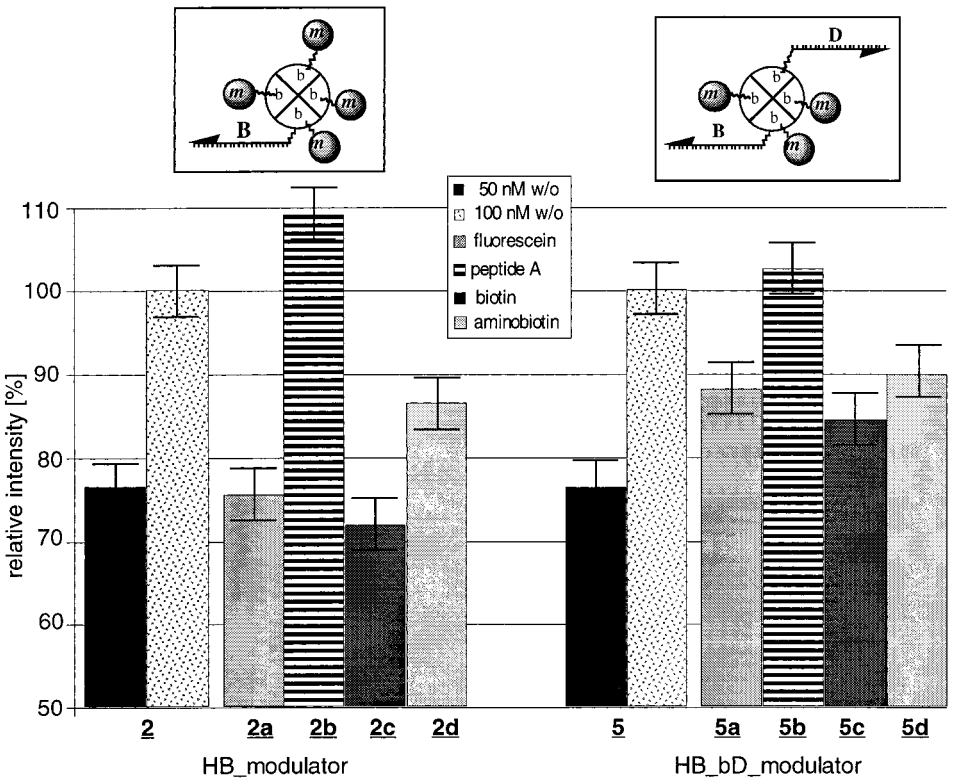

Figure 5. Comparison of modulator induced changes of the hybridization efficiency of HB conjugates **2a**−**d** (left set of bars) and bDNA conjugates **5a**−**d**, consisting of HB coupled with 1 molar equivalent of bD oligomer and the various modulators (right set of bars). The height of the histograms represents normalized binding efficiencies, obtained from the BIAcore analyses, indicated in Tables 3 and 4. The RU values obtained from 100 nM concentration of the various conjugates are normalized as a percentage fraction of the values obtained from the binding of 100 nM of **2** or **5**, respectively. Note that the coupling of fluorescein (**2a**) or D-biotin (**2c**) leads to a similar decrease in binding efficiency which is obtained from a reduction of the analyte's concentration of unmodified **2** to one-half (50 nM of **2**, left most bar).

fluorescein antibody-alkaline phosphatase conjugate and enzyme-dependent color reactions. As indicated in Figure 4, conjugates **5a**/**5e** and **6a**/**6b** displayed the bispecific binding capabilities expected, due to the presence of two DNA-binding sites coupled either covalently or through the STV−biotin interaction. A comparison of hybridization efficiencies obtained from binding of either of the two DNA domains, e.g., HB_bD_fsc (**5a**) versus HD_bB_fsc (**6a**) on bcB target oligomer, indicated that both domains have comparable hybridization capabilities which are independent of the coupling mode. The overall binding efficiency depended on the stoichiometric composition of the complexes. The comparison of signal intensities obtained from HB_fsc (**2a**) or HB_bD_fsc (**5a**) revealed that the coupling of bDNA only induced a small decrease in hybridization efficiency. It was similarly apparent for HD-based conjugates (**3a** versus **6b** in Figure 4). However, the hybridization efficiencies significantly decreased with increasing amounts of bDNA bound to the streptavidin complexes. For example, the use of 5 molar equivalents of bDNA led to a signal decrease of about 80−90% (Figure 4). This is likely due to the decreased hybridization capability of sterically hindered, highly bDNA conjugated complexes and also due to a reduced binding capacity for biotinylated fluorescein.

The hybridization properties of bDNA conjugates **5a** and **5e**−**g** (Table 2) have further been examined using the BIAcore method (Figure 3, panels c and d). **5a** and **5e**−**g** were prepared from DNA−STV hybrid HB (**2**) and 1 molar equivalent of biotinylated oligomers bB, bD, bG, or bK, respectively. The remaining free biotin-binding sites were subsequently blocked with an excess of biotinylated fluorescein. For comparison with the analogous conjugates, modified exclusively with the fluorescein modulator (e.g., **5a** versus **2a**), controls were prepared by initial coupling of biotinylated fluorescein and subsequent addition of the bDNA oligomers. As indicated in Figure 3c, hybridization measurements of the samples gave BIAcore signal intensities in the range of about 1500−2000 RU. All controls containing noncoupled bDNA led to signals, similar to that obtained from pure HB_fsc **2a** (1954 ± 3 RU). This indicated that a quantitative and irreversible blocking occurred with biotinylated fluorescein. In contrast, the binding of bDNA conjugates **5a** and **5e**−**g** gave signals, reduced by about 15% (1677 ± 48 RU). Thus, despite the high accumulation of negative charges, the coupling of bDNA affects the conjugate's hybridization properties only to an extent similar to the coupling of small biotinylated molecules, such as biotin or fluorescein (Tables 3 and 4). Similar results were obtained from the binding of HA_bDNA and HD_bDNA conjugates (data not shown).

The binding of bivalent, monospecific conjugate HB_bB_fsc (**5e**) gave interesting data. This conjugate contains two DNA-moieties of identical sequence B, bound either covalently or via biotin-STV interaction. As indicated in Figure 3c, BIAcore hybridization of the corresponding control, containing **2a** and uncoupled bB oligomer (HB_fsc + bB), led to a lower signal than controls containing bDNAs noncomplementary to surface-attached targets, for instance **2a** and uncoupled bK (1511 or 1954 RU, respectively). This can be attributed to a competition for surface-immobilized target strands of free, uncoupled bB oligomer and **2a**. The bivalent, monospecific conjugate **5e**, however, yielded similar signals

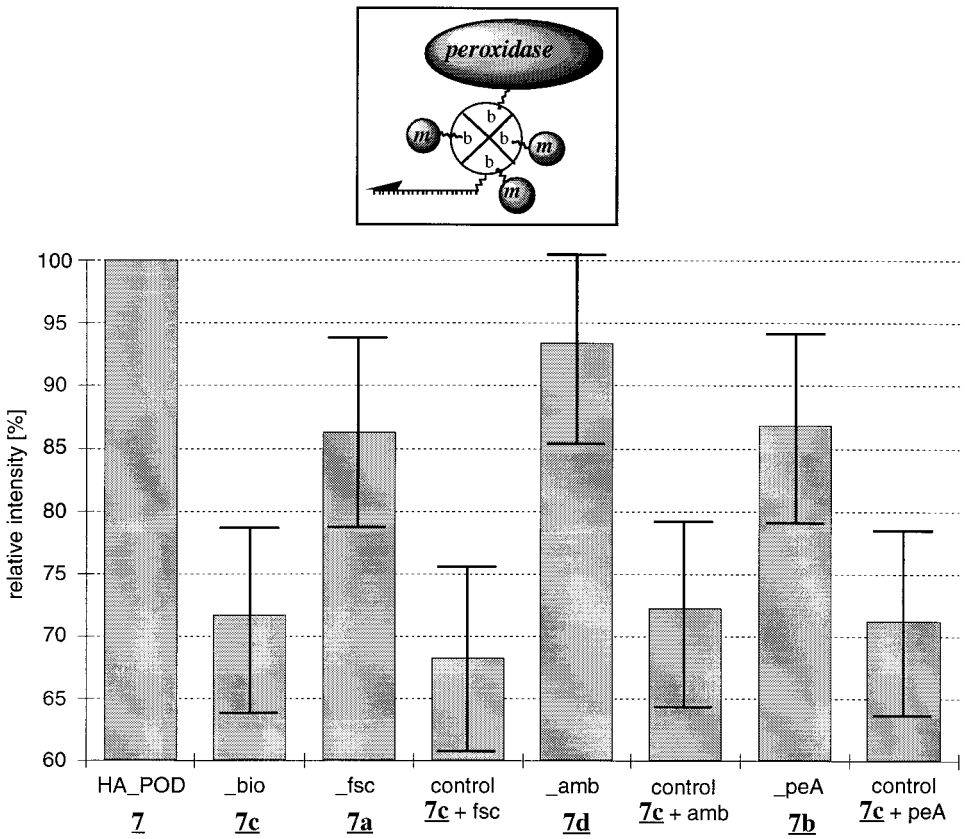

Figure 6. Influences of biotinylated modulators on the solid-phase hybridization of conjugates **7a**−**d**, generated from HA **1** and 1 molar equivalent of biotinylated peroxidase (HA_POD) which was subsequently coupled with the various modulators. The binding efficiencies of the conjugates were determined by microplate analysis. The height of the histograms represents absorbance readings obtained from POD-dependent color reactions.

than obtained for conjugates containing noncomplementary bDNAs, e.g., conjugate **5g** (1695 and 1677 RU, respectively). These observations suggest that the presence of two binding sites within a conjugate does not significantly improve its hybridization capabilities. Nevertheless, the comparison of dissociation curves indicated significant differences between **5e** and **5g**. As apparent from overlay plots in Figure 3d, a strong decrease in dissociation was observed for **5e**, suggesting that the presence of two binding sites caused enhanced rebinding with the surface-attached capture oligomers. Similar results were obtained from BIAcore analysis of conjugate **6b** (HD_bD_fsc, data not shown).

Modulator Effects in Double Functionalized Conjugates. To elucidate possible influences of modulators on the hybridization characteristics of double functionalized streptavidin conjugates (Figure 1b), a set of BIAcore measurements was carried out with bDNA conjugates **5a**−**d**. As indicated in Table 4, the modulators affected the conjugate's hybridization properties to a smaller extent than observed for nonfunctionalized DNA−STV conjugates **2a**−**d**. However, the comparison of the normalized data in Figure 5 indicated that similar effects were apparent. The binding of D-biotin and fluorescein induced a significant decrease in hybridization efficiency of about −15 and −12%, respectively. For aminobiotin, a reduction of about −10% was observed. The coupling of biotinylated peptide A, however, led to an increase in hybridization efficiency of about +3%. Controls, in which the biotin-binding sites had been blocked with D-biotin and the peptide A was subsequently added, revealed the typical, biotin-induced decrease in signal intensity (Table 4). This indicates that the peptide A acts as a hybridization promoter just in cases where it is intramolecularly coupled with the streptavidin conjugate.

The hybridization of enzyme-modified conjugates **7a**−**d** (Table 2) was investigated for modulator's influences by microplate solid-phase hybridization experiments. The conjugates were generated from DNA−STV hybrid HA (**1**) by sequential coupling of biotinylated peroxidase and the various biotinylated modulators. Additional controls were prepared from conjugate **7c** (in which the biotin-binding sites were already blocked with D-biotin) by addition of fluorescein, peptide A or the aminobiotin modulator. Samples of the conjugates were allowed to bind to microplates, previously coated with complementary capture oligomer. Following hybridization, the amount of streptavidin conjugate bound to the microplate was estimated from peroxidase activity. As shown in Figure 6, no effects were observed from the controls containing uncoupled biotinylated modulators. In contrast, distinct effects were observed for conjugates **7a**−**d**, containing modulators intramolecularly linked with the streptavidin. The effects observed were similar as described for bDNA conjugates **5a**−**d**. The enzyme complexes containing fluorescein (**7a**) and biotin (**7c**) as a modulator showed decreased hybridization efficiencies by about −14 and −28%, respectively. In contrast to the bDNA conjugates, the coupling of peptide A (**7b**) did not significantly increase the conjugate's binding compared to fluorescein (**7a**). However, the use of aminobiotin (**7d**) led to an almost unreduced hybridization efficiency compared to the HA_POD conjugate **7**, containing no modulator. Therefore, aminobiotin should be the modulator of choice to combine the obligatory saturation of the conjugate's biotin-binding capacity and high hybridization efficiency.

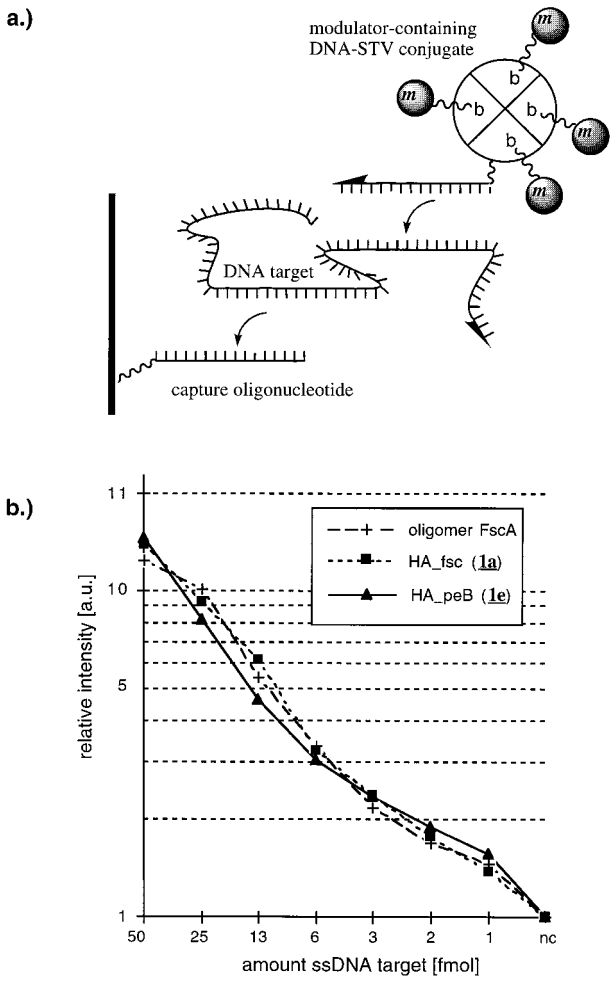

Figure 7. Utilization of streptavidin_modulator conjugates in a gene detection assay. (a) Schematic drawing of a two-sided nucleic-acid detection assay. A microplate-bound capture oligonucleotide is used for immobilization, and modulator-functionalized DNA−STV conjugates are employed as specific probes. The hapten-containing modulators fluorescein or peptide A were used. In these cases, surface-bound nucleic acid-target was detected using an anti-fluorescein antibody-alkaline phosphatase conjugate. Else, Eu^{3+}-chelate-derivatized peptide B was used as a modulator, enabling the direct detection by time-resolved fluorometry. (b) Comparison of the probe capabilities of fluorescein-labeled oligonucleotide (FscA), DNA−STV conjugate **1a** functionalized with the fluorescein modulator and conjugate **1e**, containing peptide B modulator. The curves represent relative signal intensities (*S*/*N*) obtained from alkaline phosphatase-dependent color reaction (FscA, **1a**) or time-resolved fluorometry (**1e**).

Extension of Bioconjugate's Functionality Using Modulators. To demonstrate how modulators can be utilized to extend the functionality of STV-based conjugates, the chromophor moiety of fluorescein and peptide A modulators was used as a hapten. As already shown in Figure 4, this allowed the specific and sensitive detection of the conjugate by means of an antibody directed against fluorescein. To further elucidate this approach, the probe capabilities for the detection of single-stranded DNA by fluorescein-modified HA (**1a**) were compared with an oligonucleotide directly conjugated with fluorescein through an alkyl chain linker (FscA, see Table 1). In a microplate-based, two-sided hybridization assay (Figure 7a), the surface-bound capture oligomer bB was employed for target immobilization. In addition, an oligonucleotide probe, **1a** or FscA, was used as a specific label for detecting the microplate-immobilized target. Following hybridization, the fluorescein-tagged DNA target was coupled with the commercially available anti-fluorescein antibody-alkaline phosphatase conjugate, and subsequently, alkaline phosphatase-dependent color reaction was carried out. As indicated in Figure 7b, DNA−STV conjugate **1a** functioned as a probe, equally efficient as oligomer FscA. This is remarkable since the hybridization kinetics of DNA−STV conjugates are reduced compared to their unmodified oligonucleotide analogues (*15*). Similar experiments, carried out with the fluorescein-containing peptide A modulator, led to comparable results, however, with lower signal-to-noise intensities due to elevated background signals (data not shown).

As an additional example of modulator-extended functionality, peptide B was used as a modulator. Peptide B was generated by covalently attaching Eu^{3+}-chelate (DTTA) groups to the ϵ-amino groups of the lysine residues of peptide A (Figure 1d), as described above. Due to the chemical modification, peptide B can be used as a fluorogenic modulator, since the lanthanide chelate groups enable the high sensitivity detection by time-resolved measurement of Eu^{3+}-fluorescence (*12*). DNA−STV hybrid **1** was coupled with peptide B to prepare conjugate **1e**, and the latter was tested as sensor probe in the nucleic acid detection assay, described above (Figure 7). Due to the extraordinary sensitivity of time-resolved fluorometry, detection limits of about 1 fmol of target DNA have been attained (Figure 7b). Thus, the incorporation of rare-earth chelate groups instead of hapten moieties into streptavidin conjugates not only allows high sensitivity detection without the necessity of enzymatic amplification, but it also simplifies the experimental protocol. Less reaction steps are required for signal generation and also, general drawbacks of enzymatic assays, such as batch-dependent changes in enzyme activity or possible inhibitory effects of analyte contaminants are avoided.

CONCLUSIONS

Taking advantage of streptavidin's tetravalent binding capacity for biotinylated compounds, both functional macromolecular biomolecules such as enzymes and oligonucleotides and also low-molecular weight modulator components, i.e., D-biotin, aminobiotin, and biotin-fluorescein as well as a biotin- and fluorescein-containing peptide, have been successively coupled with covalent DNA−STV conjugates. As demonstrated by solid-phase hybridization measurements, the incorporation of modulators allows a fine tuning of the hybridization properties. This is particularly useful, since many applications of the DNA−streptavidin conjugates depend on the blocking of the remaining biotin-binding sites subsequently to the coupling with a biotinylated compound of interest (*6*, *7*, *11*). As shown in this report, the use of D-biotin for this essential blocking step induces about a 2-fold decreased affinity for complementary nucleic acids. This decrease can be neutralized using biotin modulators containing amino groups.

Moreover, modulators can be used to expand the functionality of streptavidin conjugates. This was demonstrated with hapten and fluorophor-labeled modulators, enabling a highly sensitive detection of the conjugates, and thus, their utilization as probes for analytical purposes. Although the use of modulators will require further refinements for specific applications, the experiments demonstrate the advantageous applicability of low-molecular weight components for tailoring oligofunctional

bioconjugates. In particular, biotinylated peptide modulators should have great potential since they allow for convenient incorporation of basically any chemical group into streptavidin-based complexes. Besides a tuning of hybridization properties, potential applications of modulators include their use as enzyme-specific activator, cofactor, and antenna groups as well as optical or electrochemical mediator moieties. Moreover, DNA-directed assembly of molecular components can be extended to nonbiological macromolecules (*7*−*10*). Thus, DNA−STV conjugates may be anticipated as versatile building blocks in the fabrication of multifunctional supramolecular devices and also highly functionalized, nanostructured surface architectures (*23*) for applications in material sciences, enzyme process technology, biomedical analysis and also other fields of biotechnology and supramolecular chemistry.

ACKNOWLEDGMENT

We thank L. Boldt and R. Wieseke for experimental help with the microplate assays and M. Adler for critical reading of the manuscript and invaluable discussion. S. Hahner, Genom Analytik GmbH, is gratefully acknowledged for her help on MALDI-MS analysis. We also thank Biacore AB, Germany, for providing a BIAcore 2000 instrument. Financial support for this work was obtained from Deutsche Forschungsgemeinschaft, Fonds der Chemischen Industrie, and Tönjes-Vagt Stiftung Bremen.

Department of Bioengineering, University of Washington, Seattle, Washington 98195

A versatile strategy has been developed for selectively and sequentially isolating targets in a liquid-phase affinity separation environment. The strategy uses a recently developed approach for joining together molecules in linkages that are defined by the complementary pairing of oligonucleotides conjugated to the different molecules [Niemeyer, C. M., Sano, T., Smith, C. L., and Cantor, C. R. (1994) *Nucleic Acids Res. 22,* 5530−9]. In the work presented here, streptavidin was noncovalently coupled with the temperature-responsive poly(*N*-isopropylacrylamide) [poly(NIPAAM)] through the sequence-specific hybridization of oligonucleotides conjugated to the protein and polymer. A 20-mer oligonucleotide was covalently linked through a heterobifunctional linker to a genetically engineered streptavidin variant that contained a unique cysteine residue at the solvent-accessible site Glu 116. The complementary DNA sequence was conjugated to the end of a linear ester-activated poly(NIPAAM). The two conjugates were allowed to self-assemble in solution via hybridization of their complementary DNA sequences. The streptavidin−poly(NIPAAM) complex could be used to affinity-precipitate radiolabeled biotin or biotinylated alkaline phosphatase above 32 °C through the thermally induced phase separation activity of the poly(NIPAAM). The streptavidin−oligo species could then be reversibly separated from the precipitated polymer−oligo conjugate and recycled by lowering the salt concentration, which results in denaturation of the short double-stranded DNA connection. The use of oligonucleotides to couple polymer to streptavidin allows for selective precipitation of different polymers and streptavidin complexes based on the sequence-specific hybridization of their oligonucleotide appendages.

INTRODUCTION

Affinity chromatography techniques which utilize matrix-immobilized ligands are the most widely used methods for specific isolation of molecules in separations and diagnostic technologies (*1*). There has been growing interest in developing liquid-phase separation techniques such as affinity partitioning and precipitation, which typically involve ligand-bearing polymers that can be phase separated after binding to complementary biomolecules (*2*−*6*). In affinity precipitation, the phase separation of polymer and polymer-bound species can be triggered by a small change in an environmental condition, such as pH, ionic strength, or temperature. Stimuli-responsive polymers have been employed in many applications in medicine and biotechnology (*7, 8*). One of the best examples is poly(NIPAAM),[1] a water-soluble, synthetic polymer which undergoes a phase transition to a hydrophobic state when the temperature is raised above its lower critical solution temperature (LCST) (*9*). Poly(NIPAAM) has been conjugated to immunoglobulin G, β-D-glucosidase, and trypsin to enable thermoprecipitation of these proteins (*10*−*13*). These alternative systems circumvent some of the shortcomings of chromatographic methods, because the ligand association step occurs in the solution phase. These systems exhibit fewer mass transport and steric limitations which exist with solid supports.

Another potential advantage of affinity precipitation strategies is the ability to selectively and sequentially separate different targets from complex mixtures. Polymers with responses that have been engineered for different temperature or pH ranges can be conjugated to different ligands and mixed together in order to sequentially pull targets out of solution under different conditions. Here we report a versatile strategy for sequentially separating selective components from complex mixtures using stimuli-responsive polymers and streptavidin. Streptavidin is a stable, tetrameric protein that binds as many as four biotin molecules with extraordinary affinity and is utilized widely in current separations and diagnostic applications (*14*−*23*). To reversibly conjugate poly(NIPAAM) to streptavidin, we have used a recently described strategy for selectively joining two molecular species through the self-assembly of complementary oligonucleotides. Niemeyer et al. showed that oligonucleotides can direct the assembly of bispecific and bifunctional supramolecular structures, and they used this clever strategy to make streptavidin conjugates

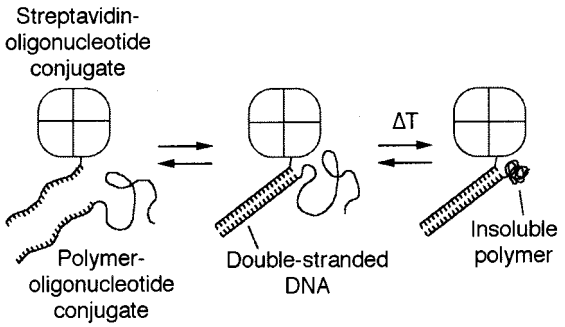

Figure 1. Schematic representation of reversible hybridization of a streptavidin−oligonucleotide conjugate and a temperature responsive polymer-oligonucleotide conjugate, and reversible phase separation of the resultant complex in response to a small temperature change.

(*24, 25*). Figure 1 illustrates the case of reversible self-assembly of streptavidin and a temperature-responsive polymer, followed by reversible phase separation of the complex. Because the assembly is DNA sequence specific, polymers with different stimuli responsiveness can be selectively attached to streptavidin conjugates that are similarly differentiated by their DNA sequences. Thus, different streptavidin−target complexes can be selectively and sequentially separated from a complex liquid mixture depending on which polymer response is triggered.

EXPERIMENTAL PROCEDURES

Materials. Oligodeoxyribonucleotide R (5′-GGACTCAGGCTTATAGCTGT-3′), modified at the 5′ end with a 6-carbon aliphatic amine, and complementary oligodeoxyribonucleotide RC (5′-ACAGCTATAAGCCTGAGTCC-3′), modified at the 3′ end with a 7-carbon aliphatic amine, were purchased from Integrated DNA Technologies (Coralville, IA). A melting temperature of ca. 65 °C for the renatured duplex R:RC (in 50 mM Tris and 150 mM NaCl, pH 7.4) was measured spectrophotometrically in our laboratory. Oligodeoxyribonucleotide S (5′-AGCGGATAACAATTTCACAC-3′), which shares no sequence complementarity with oligo R or RC, was used as a control sequence. The heterobifunctional linker sulfosuccinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (s-SMCC) and the disulfide reducing agent Tris(2-carboxyethyl) phosphine hydrochloride (TCEP-HCl) were obtained from Pierce (Rockford, IL). Tris-glycine and Tris-borate-EDTA-urea polyacrylamide gels and gel reagents were obtained from Novex (San Diego, CA). Sephadex gel (G25-medium and G50-fine) and DEAE Sepharose fast anion-exchange resin were from Pharmacia Biotech (Uppsala, Sweden). Centricon and Centriprep ultrafiltration concentrators were purchased from Amicon (Beverly, MA). D-[8,9-^{3}H]Biotin was from Amersham (Little Chalfont, England), and EcoLume liquid scintillation cocktail was from ICN (Costa Mesa, CA). Biotinylated calf intestine alkaline phosphatase was from Pierce, and *p*-nitrophenyl phosphate and diethanolamine were from Bio-Rad (Hercules, CA).

Streptavidin Production. The gene for streptavidin mutant E116C (cysteine in place of glutamic acid at amino acid position 116) was created by cassette mutagenesis, and the protein was expressed, purified, and characterized using previously described protocols (*26*).

Polymer Synthesis. Linear poly(NIPAAM), with one end having an *N*-hydroxysuccinimidyl (NHS) ester group, was produced according to the methods of Ding et al. (*13*). For the polymer used in this study, a mean molecular weight of 8500 was determined by vapor pressure osmometry (VPO, model OSV111, Knauer, Germany).

Streptavidin−Oligonucleotide Conjugation. Oligonucleotide R (∼200 nmol) was derivatized with a maleimido group by reacting it with 50-fold molar excess (4.2 mg) of s-SMCC in 1 mL of 100 mM phosphate and 100 mM NaCl, pH 7.5 (PB75). The reaction was incubated for 1 h at RT. Excess s-SMCC was removed using a Sephadex G25-medium gel filtration column (1.5 × 7 cm). Streptavidin mutant E116C (∼600 nmol) in 2 mL of PB75 was reduced by addition of 150 μL of 40 mM TCEP-HCl. The amount of streptavidin was determined using an extinction coefficient of 34 000 M^{-1} cm^{-1} for the monomer subunit (*27*). After 15 min at RT, the gel filtration fractions containing maleimide-derivatized oligonucleotide (1.5 mL total) were added. The reaction proceeded for 2 h at RT with a 50 μL addition of freshly made 40 mM TCEP-HCl at 1 h. Excess oligonucleotide was removed using Centricon-30 (30 000 MW cutoff) concentrators. The remaining unreacted oligonucleotide was removed using a Sephadex G50-fine gel filtration column (1.0 × 16 cm). Streptavidin conjugate was purified from unreacted streptavidin by anion-exchange perfusion chromatography using a BioCAD system (PerSeptive Biosystems, Farmington, MA). The sample was applied to a Poros HQ/M (PerSeptive Biosystems) 29 mL column and eluted with a salt gradient of 0.4 to 1.0 M NaCl in 20 mM Tris, pH 6.8. The fractions containing conjugate were concentrated using Centriprep-30 concentrators and analyzed by 10−20% Tris-glycine SDS−PAGE.

Poly(NIPAAM)−Oligonucleotide Conjugation. Oligonucleotide RC (∼1.5 μmol) was dissolved in 7.2 mL of 100 mM borate, 50 mM NaCl, and 5 mM EDTA, pH 9.5. A 50-fold molar excess of NHS ester-activated poly(NIPAAM) (96 mg) was dissolved in 800 μL of HPLC-grade DMF and added to the oligonucleotide solution. The reaction was gently mixed for 4 h at 4 °C, followed by 2 h at RT. To separate polymer from unreacted oligonucleotide, 100 μL of 5 M NaCl was added (to lower the LCST), and the temperature was raised to 37 °C, precipitating the polymer and conjugate. After 29000*g* centrifugation at 37 °C, the supernatant was decanted. The pellet was dissolved overnight in 4 mL of 10 mM Tris and 1 mM EDTA, pH 7.5 (TB75) at 4 °C, and the separation process was repeated twice. Polymer−oligonucleotide conjugate was purified from excess polymer by capturing it overnight with 10 μequiv of DEAE Sepharose fast anion-exchange resin at 4 °C in 4 mL of TB75. The resin-bound conjugate was washed three times with TB75 at 4 °C and eluted with 0.7 M NaCl. The conjugate was analyzed using 15% Tris-borate-EDTA-urea PAGE.

Precipitation of Biotin and Biotinylated Alkaline Phosphatase. Tritiated biotin (1.8 pmol) was incubated with an equimolar amount of STAV−1R (streptavidin with one attached oligonucleotide) and a 20-fold molar excess amount of poly(NIPAAM)−RC conjugate in 50 mM Tris, 150 mM NaCl, and 0.05% BSA, pH 7.4, buffer (TB74). Final concentrations of STAV−1R and poly(NIPAAM)−RC were 18 and 360 nM, respectively. After reaction for 1 h at RT, free poly(NIPAAM) (1 mg/mL final concentration) was added, and the sample was placed in a 37 °C bath for 10 min and then centrifuged at 16000*g* for 2 min. (Addition of the unmodified free polymer helped to enhance the precipitation.) The amount of biotin in the supernatant was measured by β-radiation counting (Beckman LS7000, Irvine, CA) using EcoLume scintillation cocktail. To show that hybridization was

occurring, oligonucleotides R, RC, or S were individually added at final concentrations ranging from 10^{-3} to 10^4 times that of STAV−1R. Recovery of pelleted STAV−1R (and bound biotin) was accomplished by overnight dissolution of the pellet in deionized water at 4 °C, followed by heating and centrifugation as described earlier.

Biotinylated alkaline phosphatase (BAP) and poly(NIPAAM)−RC were added to STAV−1R at a 1:20:400 molar ratio BAP:STAV−1R:poly(NIPAAM)−RC in TB74. Final concentrations of STAV−1R and poly(NIPAAM)−RC were 12 and 240 nM, respectively. The reaction was allowed to incubate for 1 h at RT. After addition of free poly(NIPAAM) (1 mg/mL final concentration), the sample was placed in a 37 °C bath for 10 min and then centrifuged at 16000*g* for 2 min. The supernatant activity was measured by reaction with *p*-nitrophenyl phosphate substrate in diethanolamine and UV absorbance at 405 nm.

Cloud Point Measurement. Cloud point data for poly(NIPAAM)−oligonucleotide conjugate, STAV/DNA/poly(NIPAAM) complex, and pure poly(NIPAAM) were taken using a UV−vis spectrophotometer with a jacketed cuvette holder. The heating rate was 0.2 °C/min. Polymer solutions were prepared by dissolving 8500 molecular weight poly(NIPAAM) in TB74 buffer at 0.005, 0.003, and 0.002 wt % polymer concentrations. The sample containing poly(NIPAAM)−RC (5 μM) was also prepared in TB74. The sample containing STAV/DNA/polymer complex (5 μM) was prepared by reacting equimolar quantities of STAV−1R conjugate and poly(NIPAAM)−RC conjugate in TB74 for 1 h at RT. The bioconjugate solutions were estimated to contain ca. 0.004 wt % poly(NIPAAM), assuming a molecular weight of 8500 for the conjugated polymer.

RESULTS

Preparation of Conjugates. Anion-exchange chromatography and PAGE analysis of the purified conjugation reaction products revealed three major species (Figure 2). Peaks I and II (combined in lanes 2 and 7) display only protein bands, and thus represent STAV and multimers of STAV. The bands migrated equivalently to a control sample of STAV (lane 1). Boiled samples displayed protein bands that were the correct size for streptavidin monomer subunits (lane 5). Peaks III and IV, however, displayed bands that stained positive for both protein (lanes 3 and 4, respectively) and DNA (lanes 8 and 9, respectively). These bands migrated faster than the STAV control, consistent with the increase in negative charge with the addition of a conjugated oligonucleotide. Because peak IV species migrated farther than peak III and because peak IV eluted off the cationic column under higher salt concentration compared to peak III, it is likely that peak IV represents a more highly conjugated STAV than peak III. Peak IV likely represents STAV with two oligonucleotide attachments (STAV−2R) and peak III represents STAV with one oligonucleotide attachment (STAV−1R). Secondary bands are oligomeric species which escaped disulfide reduction, e.g., STAV dimer conjugated to one oligonucleotide, or STAV dimer with a single oligonucleotide conjugated to each STAV.

Figure 3 demonstrated that the polymer−oligonucleotide conjugation reaction produced covalent poly(NIPAAM)−RC conjugates. After thermal precipitation, which removed excess oligonucleotide, the pellet was redissolved and subjected to anion exchange using DEAE-modified Sepharose beads. Poly(NIPAAM)−RC conjugate

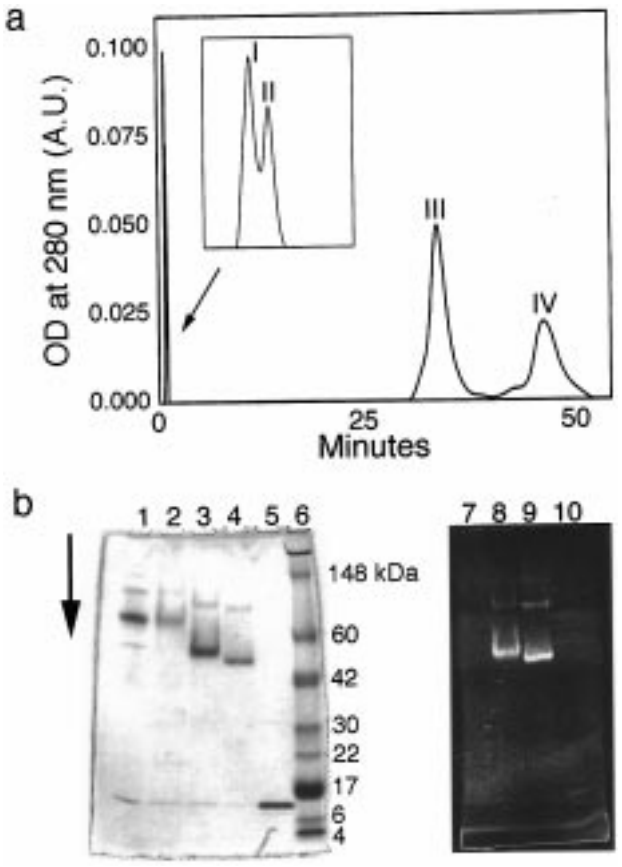

Figure 2. (a) Anion-exchange chromatography of the streptavidin−oligonucleotide conjugation reaction mixture on a PerSeptive Biosystems Poros HQ/M analytical column (4.6 × 100 mm, 1.7 mL). Four absorbance peaks (I−IV) were observed. The beginning of the chromatogram is magnified (inset) to show peaks I and II. (b) Electrophoretic analysis of the streptavidin−oligonucleotide conjugate chromatogram peaks using a 10−20% Tris-glycine-SDS polyacrylamide gel. Arrow indicates direction of migration. Samples were reduced by addition of β-mercaptoethanol to 5% volume. The gel on the left was stained for protein using Coomassie blue dye while the gel on the right was stained for DNA using ethidium bromide. Lanes 1 and 10: STAV control. Lanes 2 and 7: peaks I and II combined (STAV and multimers). Lane 5: peaks I and II combined, heated for 10 min at 99 °C to dissociate streptavidin into monomers. Lanes 3 and 8: peak III (STAV−1R conjugate). Lanes 4 and 9: peak IV (STAV−2R conjugate). Lane 6: Novex Multimark protein standard.

was expected to bind to the positively charged DEAE, while excess polymer remained in solution. The eluted product stained positive for DNA (lane 3), and gel migration was hindered compared to a control which contained oligonucleotide RC alone (lane 1). Free polymer did not impede migration of unmodified oligonucleotide (lane 2).

Precipitation of Biotin and Biotinylated Alkaline Phosphatase. Panels a and b of Figure 4 summarize the results of the [^{3}H]biotin and biotinylated alkaline phosphatase (BAP) separations, respectively. A control without poly(NIPAAM)−RC was included in each experiment to rule out nonspecific precipitation. The activity measurements were normalized against that of an internal reference composed of [^{3}H]biotin (or BAP) and STAV-1R in the same buffer, without free polymer. When poly(NIPAAM)−RC and STAV−1R were both present, most of the [^{3}H]biotin (∼76%) and BAP (∼85%) were removed from solution after heating. The pelleted [^{3}H]-biotin (and STAV−1R) could be subsequently redissolved

Figure 3. Electrophoretic analysis of the poly(NIPAAM)−oligonucleotide conjugation reaction using an ethidium bromide-stained 15% Tris-borate-EDTA-urea polyacrylamide gel. Arrow indicates direction of migration. Lane 1: oligonucleotide RC control. Lane 2: physical mixture of oligonucleotide RC and free poly(NIPAAM) (∼1 mg/mL). Lane 3: poly(NIPAAM)−RC conjugate.

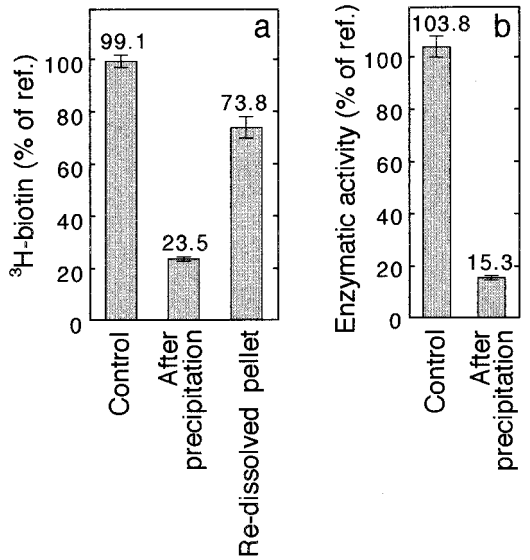

Figure 4. (a) Thermally induced affinity precipitation and recovery of [^{3}H]biotin. The solid bars represent the amount of [^{3}H]biotin in solution measured by β counting. (b) Thermally induced affinity precipitation of biotinylated alkaline phosphatase (BAP). The solid bars represent the BAP enzymatic activity in solution measured by colorimetric assay. Measurements were normalized against an appropriate reference sample (see Results). Data are the average of three different experiments. The error bars indicate standard deviations.

when the pellet was chilled in deionized water. STAV−1R is presumed to be separated from poly(NIPAAM)−RC under these conditions, which favor denaturation of the 20 base pair DNA.

The sequence-specificity of the self-assembling DNA was tested by addition of competing and noncompeting oligonucleotides in the [^{3}H]biotin experiment. In Figure 5, the free oligo RC begins to inhibit the precipitation of labeled biotin at a concentration equimolar to that of STAV−1R. Free oligo R inhibits the precipitation when its concentration is about 20 times that of STAV−1R. The inhibition curve for oligo R is shifted by a factor of about 20 relative to the curve for oligo RC, consistent with the 20:1 molar ratio of polymer−RC conjugate to STAV−1R conjugate in each of the experiments. Oligo S, which is not complementary in sequence to either R or RC, did not affect the precipitation. The results of this inhibition study indicate that a sequence-specific oligonucleotide

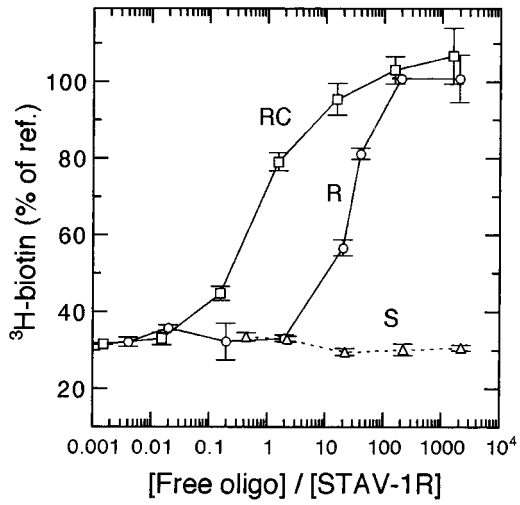

Figure 5. Free oligonucleotide inhibition curves for the thermally induced affinity precipitation of [^{3}H]biotin. Experiments were performed by adding varying amounts of a free oligonucleotide (R, RC, or S) to a solution containing a fixed amount of [^{3}H]biotin, STAV−1R, and poly(NIPAAM)−RC (molar ratio 1:1:20, respectively). The solution was allowed to react for 1 h at RT, prior to thermal precipitation. Oligo R is complementary to the sequence of RC; oligo RC is complementary to the sequence of R; and oligo S is not complementary to either R or RC. The vertical axis represents the amount (β count) of [^{3}H]-biotin remaining in the solution phase after precipitation. Measurements were normalized against a reference sample (see Results). Data are the average of three different experiments. The error bars indicate standard deviations.

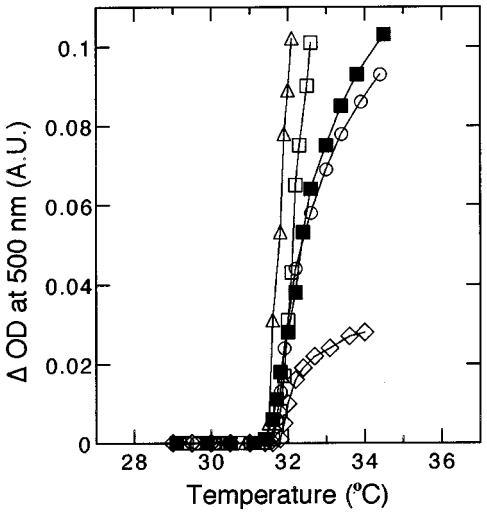

Figure 6. Cloud point curves for solutions containing 5 μM poly(NIPAAM)−RC (open squares); 5 μM STAV/DNA/poly-(NIPAAM) complex (darkened squares); and 0.005 wt % (open triangles), 0.003 wt % (open circles), and 0.002 wt % (open diamonds) pure poly(NIPAAM).

hybridization reaction occurs prior to thermal precipitation of the streptavidin−biotin complex.

Cloud Point Measurement. The reversible phase separation exhibited by poly(NIPAAM) as the solution temperature is raised above its LCST is characterized by an abrupt flocculation of the insoluble polymer chains (*28*). The thermally induced clouding of solutions containing either the poly(NIPAAM)−oligonucleotide conjugate or the STAV/DNA/poly(NIPAAM) complex was investigated and compared to solutions containing comparable concentrations of pure poly(NIPAAM) (Figure 6). The data demonstrate that the soluble-to-insoluble phase

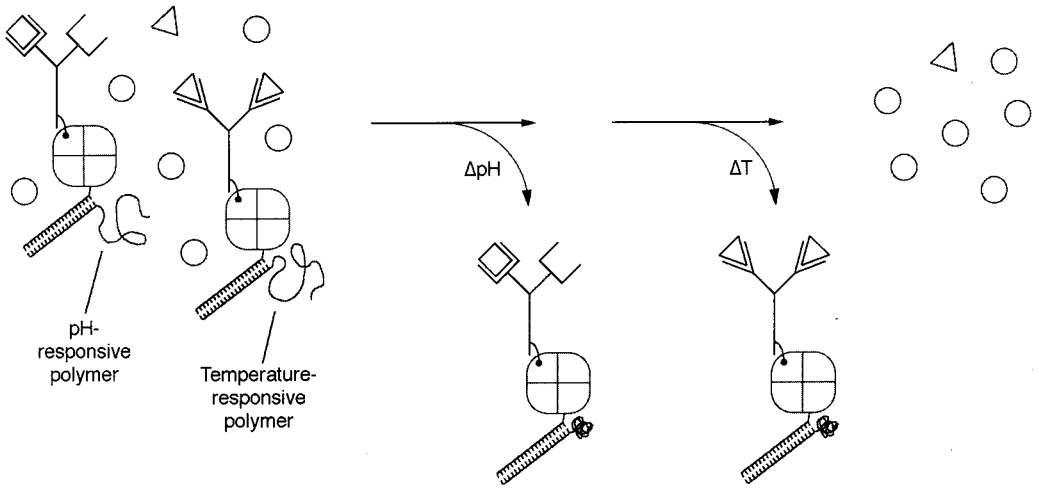

Figure 7. Proposed application of self-assembled streptavidin−DNA−polymer conjugates for sequential affinity precipitation of different target species. A complex composed of a pH responsive polymer, streptavidin, and an antibody against target 1 (open square) is mixed with a complex composed of a temperature responsive polymer, streptavidin, and an antibody against target 2 (open triangle). After binding to their respective ligand targets, the complexes can be sequentially retrieved from solution. Target 1 is coprecipitated with the pH responsive complex via a small pH change. Afterward, target 2 is coprecipitated with the temperature responsive complex via a small temperature change. A third target (open circle) does not precipitate because it shares no affinity with either complex.

transition of the polymer was not significantly affected by the conjugated biomolecules.

DISCUSSION

Chen and Hoffman introduced the concept of "smart" polymer affinity precipitation by using poly(NIPAAM)−protein A conjugates to purify IgG antibodies (*29*). Others have shown that DNA-binding proteins can be precipitated on the basis of their affinity to poly(NIPAAM)−DNA conjugates (*30, 31*). Related work has suggested that coprecipitation of hybridized poly(NIPAAM)−oligo(dT) conjugates may be a more efficient method for isolating polyadenylated mRNAs than conventional oligo(dT)-modified silica (*32*). While these strategies offer the advantages of liquid-phase binding steps, there are a number of parameters which require tailoring. For example, the activity of the conjugate may be affected depending on the number of polymer chains per biomolecule (*33*−*36*) and the location of these chains (*37*).

In the present work, we have developed a self-assembly system by which a defined polymer and a defined affinity connector, such as a biotinylated antibody, can be joined together from a mixture of polymers, connectors, and targets by using a strategy described by Niemeyer et al. to construct intermolecular linkages. Distinct target species can be separated in solution through either a direct interaction with a biotin group on the target or through a secondary interaction with a biotinylated connector. The new feature represented in this approach is the capability to sequentially separate a specific target-bound complex from a mixture. The specific stimuli-responsive polymer can be matched to a unique affinity complex, e.g., a streptavidin−antibody conjugate, by self-assembly in solution. The use of DNA tags on streptavidin and the polymer ensures conjugation of the appropriate smart polymer to the target-bound complex. For example, in step 1 a small pH change can be used to separate pH responsive polymer/antibody1/target1 complexes, while in step 2 a small temperature change can be used to separate temperature responsive polymer/antibody 2/target 2 complexes (Figure 7).

To demonstrate this technique, we have constructed a poly(NIPAAM)/DNA/streptavidin complex that self-assembles and binds biotinylated alkaline phosphatase. The entire assembly, including alkaline phosphatase (∼140 kDa), precipitates above the LCST of poly(NIPAAM) with high efficiency. Using radiolabeled biotin, we showed that the phase-separated streptavidin assembly could be fully resolubilized by lowering the temperature below the LCST of the poly(NIPAAM). If this is done under low salt conditions, the short double-stranded DNA melts, freeing the poly(NIPAAM)−DNA conjugate for recovery and recycling. Free oligonucleotides that were complementary to either the DNA tag on the streptavidin conjugate or the DNA tag on the poly(NIPAAM) conjugate could inhibit the affinity precipitation of radiolabeled biotin at stoichiometric ratios, whereas a random oligonucleotide had no effect.

Bispecific streptavidin−oligonucleotide conjugates may offer other possibilities for novel applications involving stimuli-responsive polymers. For example, we have shown that poly(NIPAAM) can reversibly manipulate the biotin-binding properties of streptavidin when it is site specifically attached near the binding pocket (*26, 38, 39*). A potential advantage of using oligonucleotide linkers is the ability to control the polymer attachment distance by ratcheting the site where the DNA sequence overlap is located. The use of polymer−oligonucleotide conjugates may also provide a convenient method for sequentially directing the adsorption of biomolecules to a surface. For the probing of genes, it may be possible to add smart polymer function to DNA targets using a pH responsive polymer−oligonucleotide conjugate that remains soluble under the thermal denaturation conditions needed to prepare the target for hybridization with the probe.

ACKNOWLEDGMENT

This work was supported by NIH Grant R01GM53771A, the Washington Technology Center, the Washington Research Foundation, and the Office of Technology Transfer. We gratefully acknowledge discussions with the Cantor group at Boston University for the initial suggestion of using oligonucleotides to assemble proteins and smart polymers.

F., México, and National Institute of Health, Rockville, Maryland . Received January 19, 1999; Revised Manuscript Received May 24, 1999

The complex ^{153}Sm(III)DTPA-bis-biotin was prepared with a 99% radiochemical purity and a specific activity of 370 MBq/mg employing a molar ratio of DTPA-bis-biotin/Sm from 2 to 4 at pH 8.0. In vitro studies demonstrated that the complex is stable after dilution in saline and in human serum. Avidity of labeled biotin for avidin was not affected by the labeling procedure. Pharmacokinetic data of ^{153}Sm-(III)DTPA-bis-biotin in normal mice showed that blood clearance is biexponential during the time interval from 0 to 24 h and that 3 h postinjection 92 ± 4.32% of the dose is eliminated in the urine. To have further evidence which could sustain that ^{153}Sm(III)DTPA-bis-biotin is stable in solution as a real coordination complex, ^{152}Sm(III)DTPA-bis-biotin was obtained in macroscopic quantities and its characterization was done by IR, TGA, and conductivity measurements. The results indicated that the complex was chemically pure, where the Sm^{3+} ion is neutralized by three carboxylate groups of the DTPA-bis-biotin ligand and coordinated to it. Using the Force Field method followed by ab initio calculations, the DTPA-bis-biotin and the Sm(III)DTPA-bis-biotin molecules were done. Accordingly, the coordination sphere of Sm(III) was totally satisfied with nitrogen and oxygen donors; the best coordination number was 9. The conformation geometry of both compounds is presented.

INTRODUCTION

The localization of tumors using radiolabeled antibodies has been improved by an approach that utilizes the high avidity of both avidin and streptavidin for biotin (*1*−*5*). Biotin (*cis*-tetrahydro-2-oxothieno[3,4-d]imidazoline-4-valeric acid) is a 244 Da vitamin found in low concentration in blood and tissue (vitamin H). Avidin and streptavidin are tetrameric proteins, and each subunit binds one molecule of biotin. Because the noncovalently bound avidin/streptavidin−biotin conjugate has an extremely low dissociation constant (K_d of about 10^{-15} M), investigators have used these two molecules as binding pairs to bridge molecules that have no affinity for each other and also to target various radionuclides (*1*). So far, the avidin−biotin system has shown that target-to-nontarget radioactivity ratios and radioimaging scanning can be significantly improved by introducing a two-step or a three-step approach. In these, the antibody and the label are administered separately, delaying the delivery of the label to a time when the ratio tumor-bound to nontumor-bound antibody has reached its maximum value. The two-step approach is based on the administration of streptavidin conjugated to the antibody followed by a radioactive biotin conjugate or else biotinylated antibody is injected followed by radioactive streptavidin (*1*, *2*, *6*). In the three-step system, biotinylated antibody is injected followed by an excess of cold avidin or streptavidin and, as a third step, radioactive biotin is administered (*1*, *4*, *5*). Either approach shows enhancement of the tumor/background ratio and tumors are visualized 20 min postinjection avoiding the prolonged circulation and nonspecific accumulation of the radiolabeled antibody in metabolic organs.

Increased effort has been made to label mAbs with rhenium-188, samarium-153, yttrium-90, and lutetium-177 because of their potential role in the radioimmunotherapy of cancer (*7*−*13*). However, the radiolabeling of mAbs or $F(ab')_2$ fragments with Sm-153 by combination of avidin−biotin strategy has not been studied.

The coordination of lanthanides with ligand containing amino acids, amide functions, and related ligands such as the diethylenetriamine pentaacetic acid (DTPA) has been widely studied (*14*−*20*). This property is revealed in the spectroscopic, magnetic, and thermal behavior of the lanthanide compounds (*14*−*20*).

The aim of this work was the preparation of ^{153}Sm-(III)DTPA-bis-biotin, the analysis of the factors affecting radiochemical purity and stability of the complex and the study of its pharmacokinetics in normal mice. To understand the behavior of the complex in solution, spectro-

[a] Dependent variable: radiochemical purity.

scopic studies, thermal characterization, and theoretical calculations of ^{152}Sm(III)DTPA-bis-biotin were performed.

EXPERIMENTAL SECTION

Preparation of $^{153}SmCl_3$ Solution. Samarium-153 chloride was obtained by neutron irradiation of 10 mg of enriched Sm_2O_3 (^{152}Sm, 99.4%, from ISOTEC Inc.) in a TRIGA Mark III reactor at a flux in the central thimble of 3×10^{13} n cm^{-2} s^{-1} for 20 h. After irradiation, 100 μL of 12 N chloride acid was added to the irradiation vial and stirred for 1 min. To this solution was added 900 μL of injectable water, and it was also stirred for 2 min. The average radioactive concentration was 37 GBq/mL.

Preparation of Radiolabeled ^{153}Sm(III)DTPA-bis-Biotin Complex. The biotin used in this investigation was covalently conjugated to diethylenetriamine pentaacetic acid (DTPA) through the use of the cyclic anhydride and lysine conjugate to biotin (biocytin) to produce DTPA-α,ω-bis(biocytinamide) (DTPA-bis-biotin, Sigma Chemical Co.) as Hnatowich et al. reported (*21*).

Sterile and apyrogenic V-vials were prepared to contain 0.5 mg (4.8×10^{-4} mmol), 1.0 mg (9.7×10^{-4} mmol), and 2.0 mg (1.9×10^{-3} mmol) of the DTPA-bis-biotin compound in 1.0 mL of 0.05 M bicarbonate buffer (pH 8.0), or 1.0 mL of 0.05 M phosphate buffer solution (pH 7.4) or 1.0 mL of 0.05 M acetate buffer (pH 5.5). Then, 10 μL of $^{153}SmCl_3$ solution (4.9×10^{-4} mmol ^{153}Sm, 370 MBq) was added to each preparation. A factorial experimental design was applied as is shown in Table 1.

Radiochemical and Chemical Quality Control. *HPLC Chromatography.* Quality control of the labeled ^{153}Sm(III)DTPA-bis-biotin was performed by size-exclusion HPLC analysis employing a Protein Pak 300 SW gel filtration column (Waters), with photodiode array detector. As the mobile phase 0.1 M phosphate, pH 7.4, at a flow rate 1.0 mL/min was used with a Waters fraction collector. The radiochromatographic profile was determined by analyzing collected samples of 0.5 mL each one in an external NaI (Tl) detector (NML, Laboratories, Inc.).

TLC Chromatography. For thin layer chromatography, aluminum cellulose sheets (MercK) were utilized as the stationary phase and a ternary mixture of methanol: water:ammonium hydroxide (20:40:2) as the mobile phase. The procedure involved spotting a 5−10 μL sample of the radiopharmaceutical onto a chromatography strip 8 cm in length. ^{153}Sm(III)DTPA-bis-biotin traveled with the solvent front R_f 0.9−1.0 and the Sm^{3+} species remained at the origin ($R_f = 0$).

Avidity of ^{153}Sm(III)DTPA-bis-Biotin for Avidin. An aliquot of the labeled biotin conjugate (100 μL, 37 MBq) was loaded onto an immobilized avidin-agarose column and incubated for 10 min and washed with 60 mL of phosphate-buffered saline (PBS) at pH 7.4. The radioactivity of the eluted sample and of the column was assayed by using a dose calibrator (Capintec Radioisotope Calibrator, model CRC-7). The percentage of ^{153}Sm(III)-DTPA-bis-biotin bound to the avidin-agarose column was calculated by dividing column radioactivity over the total activity of both sample liquid fraction plus the column. To evaluate the nonspecific link of samarium-153 to the avidin column, the same procedure was performed but $^{153}SmCl_3$ was used instead of the ^{153}Sm(III)DTPA-bis-biotin.

In Vitro Stability of ^{153}Sm-DTPA-Biotin Complex. Stability studies against dilution were carried out by diluting the ^{153}Sm(III)DTPA-bis-biotin complex solution 2− 10^5 fold with saline solution and with human serum at 310 K. After 10 min and 24 h, the radiochemical purity of each ^{153}Sm complex solution was determined by TLC as mentioned earlier.

Biodistribution and Pharmacokinetic Studies. Female Balb-c mice (27−30 g) were used in these studies which were performed in accordance with the Mexican regulations regarding animal care and handling.

An intravenous injection of 50 ± 7 μg of ^{153}Sm(III)-DTPA-bis-biotin in a volume of 50 μL was given into the tail vein of the mice. Biodistributions were obtained as follows: the mice were killed 0.5, 1, 2, 3, 6, and 24 h postinjection, the blood samples and relevant organs (blood, kidney, stomach, intestine, liver, spleen, lung, heart, urine, and reminder body) were removed and weighted and then counted in a precalibrated NaI(Tl) detector system. The uptake in each organ was calculated and expressed as percent injected dose per gram (% ID/g). All sample counts were corrected for background and physical decay by using standards of comparable volume and the adequate geometry for blood and organs.

The counts per minute per milliliter (cpm/mL) serum obtained at different times were fed into the BIEXP (*22*) microcomputer program. The algorithm for this program is given by the following formula, which presents a biexponential curve:

$$C(t) = Ae^{-\alpha t} + Be^{-\beta t}$$

where $C(t)$ is the concentration at any given time, A and B are the intercept at the y-axis of the fast α and slow β slopes, and e is the base of the natural logarithms. By least-squares regression analysis, the program calculates points A and B on the y-axis and the constants k_α, rapid distribution constant, and k_β, slow elimination constant. With these four data, BIEXP calculates all the other parameters according to conventional equations for a two-compartment open model, which are extrapolated to the human volume of distribution at central compartment (V_{dcc}), extrapolated human volume of distribution at steady state (V_{dss}), total clearance, mean residence time, and elimination constant (k_{ss}).

Preparation of ^{152}Sm(III)DTPA-bis-Biotin Complex. A total of 6.0 mg (5.7×10^{-3} mmol) of the DTPA-bis-biotin compound was dissolved in 1.0 mL of 0.05 M bicarbonate buffer (pH 8.0) and the pH adjusted to 10.0 with 2.5 N NaOH. Then, 60 μL of Sm-152 solution (5.7×10^{-3} mmol in 1.0 N HCl of ^{152}Sm, 99.4%, from ISOTEC Inc.) was added. The reaction medium was kept at 295 K for 30 min, afterward the compound in solution was purified by size-exclusion HPLC (1.0 mL loop) employing a Protein Pak 300 SW gel filtration column (Waters), with photodiode array detector. HPLC water was used as mobile phase at a flow rate of 1.0 mL/min. The synthesis procedure was repeated three times, and the biotin conjugate collected from the HPLC was evaporated under vacuum. The solid residual was characterized by spectroscopic and thermal studies. The complex was obtained three times, and the analysis indicated its reproducibility.

Table 2. Effect of pH and DTPA-bis-Biotin/Sm Molar Ratios upon Radiochemical Purity (%) and Stability of ^{153}Sm(III)DTPA-bis-Biotin Complex (Results of the experimental design)[a]

molar ratio DTPA-bis-biotin/Sm	pH 5.5		pH 7.4		pH 8.0	
	2 h	72 h	2 h	72 h	2 h	72 h
1	67.63 ± 3.9	35.42 ± 6.4	95.43 ± 0.87	93.90 ± 1.30	97.36 ± 0.96	96.98 ± 1.10
2	*b*	*b*	97.20 ± 1.10	96.87 ± 0.97	99.43 ± 0.32	99.25 ± 0.41
4	*b*	*b*	97.56 ± 0.81	97.10 ± 1.20	99.56 ± 0.30	99.41 ± 0.32

[a] $n = 3$ for each data. [b] DTPA-bis-biotin was not dissolved.

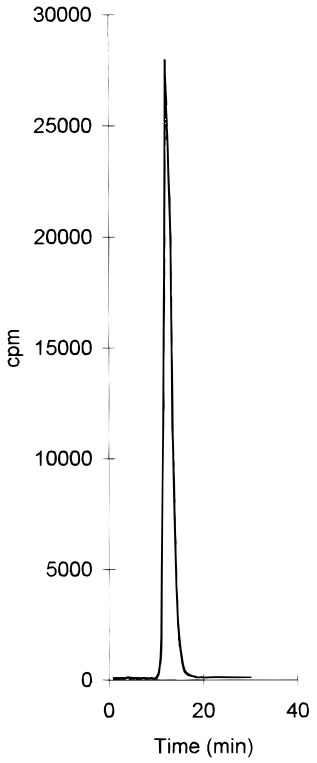

Figure 1. Radio-HPLC chromatogram of ^{153}Sm(III)DTPA-bis-biotin complex. Protein-Pak 300SW column, flow rate 1.0 mL/min, 0.1 M phosphate buffer (pH 7.4) as mobile phase.

Spectroscopic and Thermal Studies of ^{152}Sm-DTPA-Biotin. *IR Spectroscopy*. IR spectra of the reagents used for the synthesis of ^{152}Sm(III)DTPA-bis-biotin complex (97% enriched ^{152}Sm) and of the complex were recorded on a Nicolet Magna-IR Spectrometer 550 from 350 to 4000 cm^{-1} using KBr pellets.

Thermogravimetric Analyses (TGA). The TGA analyses of both the reagents and the complex were carried out in a Dupont 2000 TA Instrument with TGA 51 at 283 K min^{-1} (from 293 to 1273 K) under nitrogen flow.

Theoretical Methodology. The computational analysis was made on an Indigo 2 workstation with R10000 processor of Silicon Graphic Inc. and applying the Cerius^2 software of Molecular Simulation Inc. (*23*, *24*). A model was generated with all the corresponding conditions of hybridization bonding and atomic distribution for the free ligand DTPA-bis-biotin and for the complex, Sm(III)-DTPA-bis-biotin. A geometric analysis was done over the DTPA-bis-biotin molecule by energetic principles using the classic molecule mechanics (MM) method of force field (FF) and generated three configurations. The most stable and with the minimum potential energy was used to apply a quantum mechanics calculation and ab initio analysis to optimize the geometry configuration and to identify charge density distribution. The density functional theory (DFT) (*25*) and the local density approximation (LDA) (*26*) were applied.

3 h urine elimination (% dose)	92 ± 4.32

[a] *BIEXP* program. $n = 3$ for each data.

RESULTS

The ANOVA statistical analysis showed that the molar ratio DTPA-bis-biotin/Sm and pH have significant effect upon the radiochemical purity and stability of ^{153}Sm(III)-DTPA-bis-biotin ($p < 0.05$). As can be seen in Table 2, pH values from 7.4 to 8.0 can be considered satisfactory while pH 5.5 is definitively unsatisfactory. The mean of molar ratio values from 2 to 4 are not significantly different ($p > 0.05$).

The radio-HPLC analysis of ^{153}Sm(III)DTPA-bis-biotin solution showed a single peak with retention time of 12.1 ± 0.3 min (Figure 1).^{153}Sm-labeled biotin was 99 ± 0.5% bound to the avidin-agarose column, demonstrating that its biological properties were not affected by the radiolabeling procedure. The free $^{153}SmCl_3$ bound to the avidin-

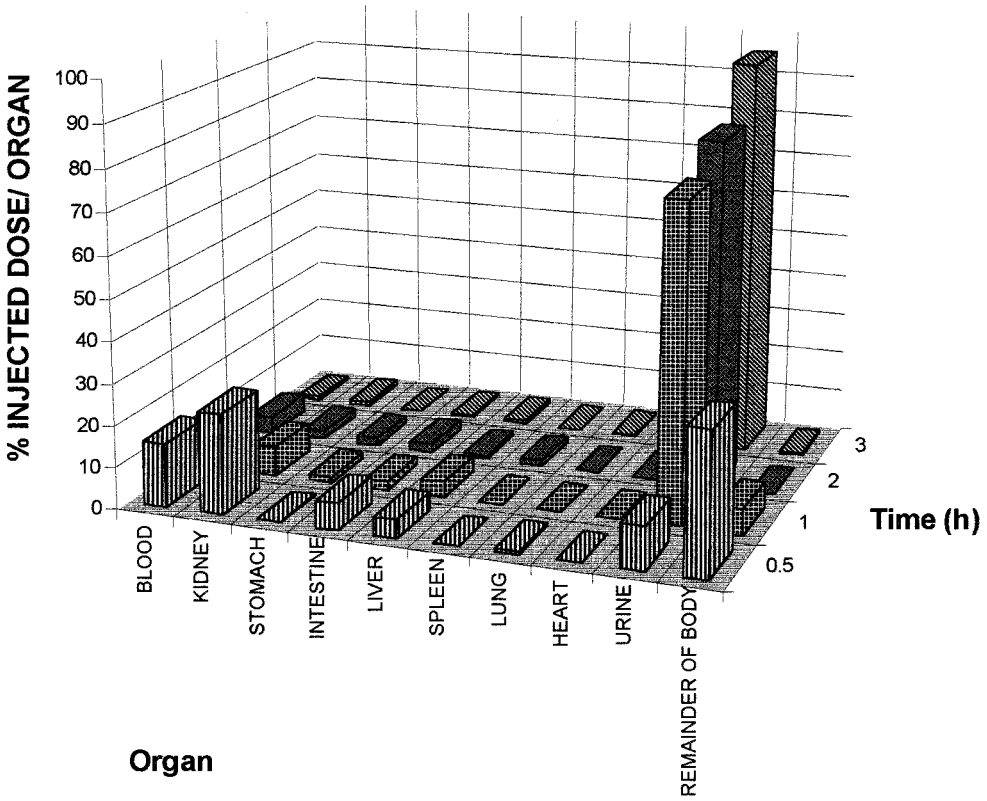

Figure 3. Average biodistribution in mice of ^{153}Sm(III)DTPA-bis-biotin complex (n = 4 for each time).

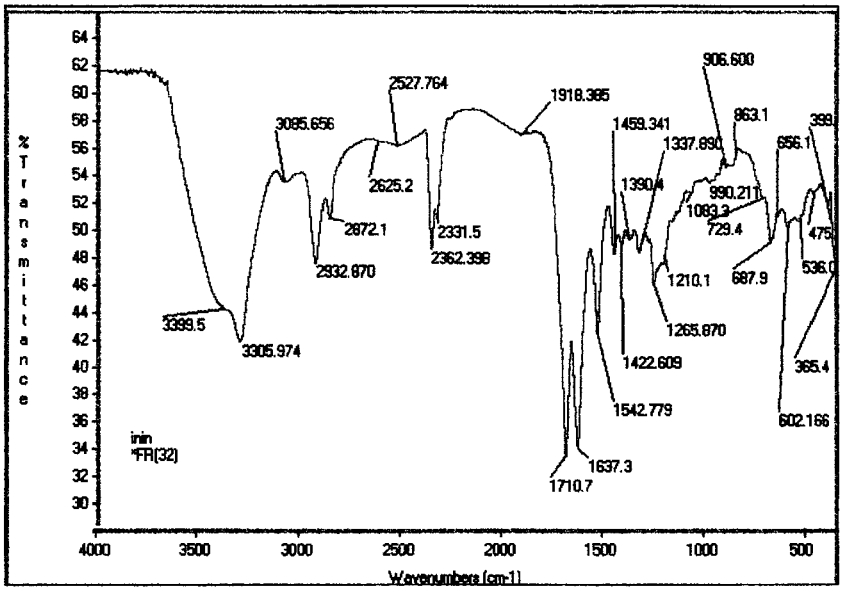
agarose column was less than 1%, and it represents the nonspecific bonding of samarium-153 to avidin column.

The results of the in vitro stability of ^{153}Sm(III)DTPA-bis-biotin in saline and human serum dilution showed that the complex was very stable since no significant change or decomposition (<2%) was detected by the TLC analyses (Figure 2).

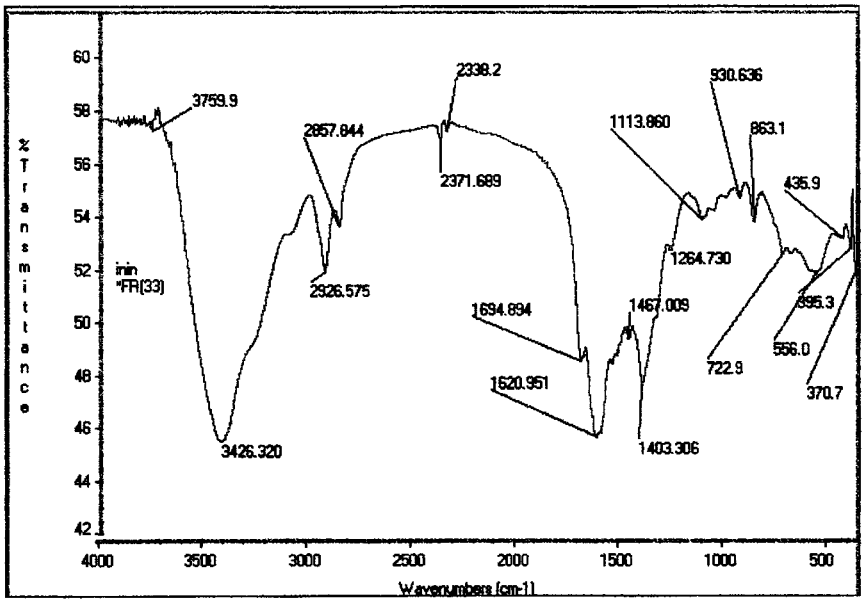
Pharmacokinetic data show that blood clearance is biexponential during the time interval studied and that 3 h after the administration of ^{153}SmDTPA-bis-biotin, 87.68−96.32% of the dose was eliminated in the urine (Table 3).The biodistribution of ^{153}Sm-labeled Biotin is shown in Figure 3.

The IR spectra of the DTPA-bis-biotin ligand and the ^{152}Sm(III)DTPA-bis-biotin complex are shown in Figure 4. The substantial change of the spectrum of the free ligand after Sm^{3+} was bound is observed. The bending vibration frequencies corresponding to NH of the amides (−NH−CO− groups) between 3430 and 3075 cm^{-1} are shifted to lower energies (5 25 cm^{-1}). The bands observed between 2930 and 2840 cm^{-1}, which are normally assigned (*27*−*29*) to bending frequencies of $-CH_2-x$ (x = CO, NH, S, OH), are also shifted to lower energies (15−10 cm^{-1}). The Sm(III)DTPA-bis-botin complex (Figure 4b) seems to be pure because bands corresponding to free DTPA, biotin, or DTPA-bis-biotin ligands were not observed.



The thermograms indicated different thermal behavior of DTPA-bis-biotin and ^{152}Sm(III)DTPA-bis-botin. After heating from 293 to 1273 K, the former exhibited five decomposition steps and the latter six. The residue was 37.45% for the ligand and 23.56% for the complex.

DTPA-bis-biotin. At 444 K and at 574 K, the weight loss of about 1.79%, and 9.29% respectively, correspond to decomposition of methylenes as methane. The two hetero bicyclic biotin rings are decomposed at 646 K, since the weight loss was 23.79%. Two biamide components are eliminated at 953 and at 1035 K, respectively, since a total weight loss of 27.69% was found. At 1035 K, the residue consisting of 37.45% was found to be a mixture of a tertiary amino acid derivative and sulfur atoms.



^{152}Sm(III)DTPA-bis-biotin complex. From 461 to 485 K, the weight loss of 2.03% is consistent with the elimination of two methylene groups. At 617 K the weight loss of 8.77%, was associated to the elimination of two groups of tetramethylenes. At 691 K, the weight loss was 3.28% and corresponds to the partial and asymmetric decomposition of the two heterocyclic biotin rings. At 828 K, the weight loss of 6.72%, reveals the total decomposition of one bicyclic ring. At 1066 K, the weight loss of 26.90% is consisting with the elimination of the remaining bicyclic rings, the partial destruction of the amino acid chain, and one of the amide group derivatives. At 1095 K, the carboxylic groups, the tertiary amines, and the another amide group derivative are decomposed and molecular oxygen is formed, the weight loss was 28.29%. The final residue was 23.56% and corresponds to O−Sm-(CO_3) + 2S.

The conductivity measurement of the complex in solution 1×10^{-4} M indicated a 1:1 electrolyte. The complex was surprisingly stable to hydrolysis, since after 24 h, the conductivity measurements did not change and it was not observed demetalation after 3 days under heating at 343 K.

On the basis of semiempirical (MM by FF) and theoretical (ab initio by DFT) calculations, the molecules of the free ligand and of the complex were built, and the best geometric arrangement acquired by the DTPA-bis-biotin ligand is shown in Figure 5. Three possible conformations with coordination number of nine were found for the ^{152}Sm(III)DTPA-bis-biotin complex, as a result of the high flexibility and multidonor characteristic of the ligand. The most stable is presented in Figure 6.

(a)

(b)

Figure 4. IR spectra recorded in KBr pellets of (a) DTPA-bis-biotin ligand and (b) Sm(III)DTPA-bis-biotin complex.

For every coordination number, a typical coordination polyhedron exists. Figure 7 is another representation of the molecule complex, and the coordinated central samarium ion is well shielded by the ligands. The heterocycle ring of the biotin groups is completely exposed to the medium (Figures 6 and 7). Final electronic densities (for the electronic configuration of each atom) and final charges (for the charge distribution of each atom) for the 150 atoms of the ligand and 148 of the complex were obtained. Changes of those parameters are observed after the coordination of the Sm(III) ion. The most important changes occur in the atoms of the amino, carboxylic, and carboxylate groups which are coordinated to the metal center. The final electronic densities and final charges of the donors N and O and of the C atoms of the ligand and of the samarium complex molecules are given in Table 4.

DISCUSSION

Preparation of ^{153}Sm(III)DTPA-bis-Biotin Complex. Results suggest that ^{153}Sm(III)DTPA-bis-biotin complex can be prepared with a specific activity of 370 MBq/mg and a radiochemical purity over 99% employing a molar ratio of DTPA-bis-biotin/Sm from 2 to 4 at pH 8.0. ^{153}Sm(III) is commercially available with specific activities up to 318.2 GBq/mg. Therefore, under the conditions described above, the samarium complex could be obtained with specific activity up to 3.2 GBq/mg for a therapeutic radiopharmaceutical, although radiolysis should be evaluated.

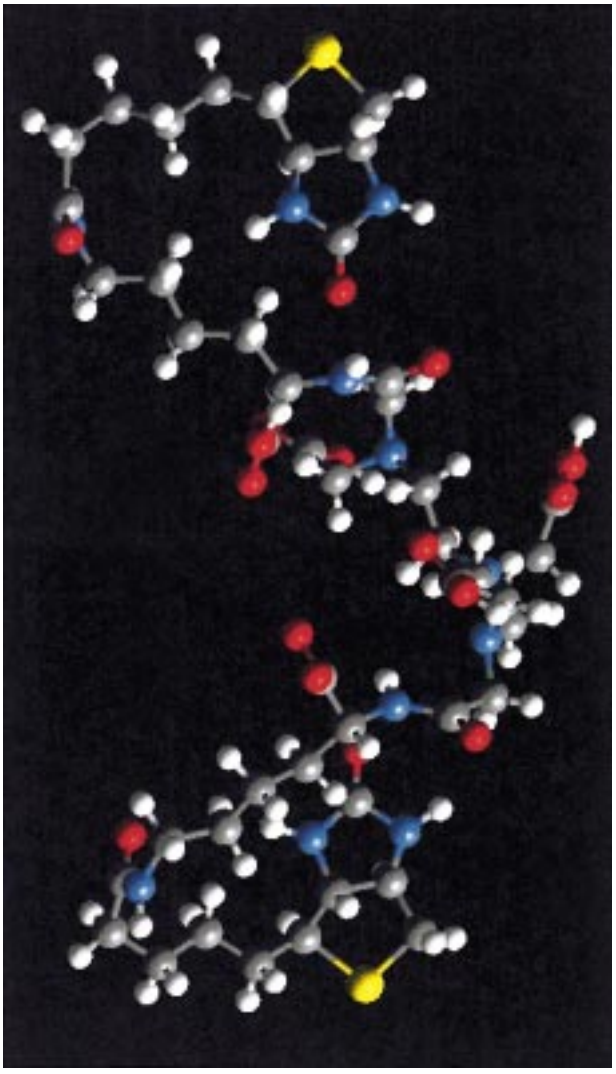


Figure 5. DTPA-bis-biotin ligand calculated by FF and DFT and simulated by Cerius[2].

The high in vitro stability of ^{153}Sm(III)DTPA-bis-biotin diluted in both saline and human serum, and taking into account its physicochemical behavior, we can propose that its stability constant has to be higher than that reported for the Sm(III)DTPA complex (log $K_f \approx 22$) (*15*).

Biodistribution and Pharmacokinetic Studies. Free samarium is captured almost in its entirety by the liver; therefore, the absence of hepatic uptake after the administration of ^{153}Sm(III)DTPA-bis-biotin demonstrates that samarium remains bound to the molecule in vivo. In this study, the tissue distribution of ^{153}Sm-(III)DTPA-bis-biotin (Figure 3) in normal mice is quite similar to that which would be expected for the renal agent ^{153}Sm(III)DTPA. As known, the biodistribution of labeled biotin depends on the chemical, and physicochemical properties of the chelating agents may be due to the action of biotinidase, which is present in high levels in murine serum (*1, 30*). Despite the effect produced by the biotinidase, Chinol et al. (*7*) have found tumor uptake of ^{90}Y-labeled biotins using three-step tumor targeting in mice and Nakamoto et al. (*4*) reported three-step tumor imaging with biotinylated mAb anti-CEA MLS128, streptavidin, and [^{111}In]DTPA-bis-biotin in mice. The use of three-step mAb tumor targeting in CEA positive patients employing [^{111}In]DTPA-bis-biotin for diagnosis was successfully applied by Paganelli (*5*). Chinol et al. (*7*) also studied the biodistribution of yttrium-90 bound to biotin through DTPA or DOTA (a polyaminemacrocycle) observing a higher stability in vivo for [^{90}Y]DOTA-biotin than for [^{90}Y(III)]DTPA-bis-biotin. However, tumor uptake was higher for the DTPA complex than for the DOTA complex which may be attributed to the presence of two biotin molecules in [^{90}Y(III)]DTPA-bis-biotin. Since it has been demonstrated that ^{153}Sm(III)DTPA-bis-biotin is highly stable, we could expect an appropriate tumor uptake because of the biotin dimeric structure.

In a pilot therapy trial (*31*), 11 patients were treated with yttrium-90-labeled DOTA-biotin by the pretargeting technique obtaining a mean absorbed dose in the tumor of 12.9 Gy. However, ^{90}Y is not a γ emitter and therefore unsuitable for scintigraphic imaging, restricting the in vivo absorbed dose calculation. Samarium-153 has favorable features as a radiotherapeutic agent: a 103 keV γ emission for scintigraphic imaging of its biological distribution, which allows the in vivo absorbed dose calculation, and it is easily handled from the point of view of radiation protection, its short half-life ($t_{1/2} = 1.8$ days) reduces the need for long patient isolation and facilitates the disposal of urine and other body fluid. Due to the absorption cross-section for thermal neutrons ($\sigma = 260$) of samarium-152, a reasonable high specific activity of samarium-153 can be produced even with fairly low flux nuclear reactors, which allows it to be applied in nuclear medicine.

IR Spectroscopy. As mentioned before, the IR spectrum of the DTPA-bis-biotin is substantially modified in the Sm(III)DTPA-bis-biotin complex. One important feature in the spectra is that the two broad signals centered at 2520 and 1910 cm^{-1} which are observed in the free ligand have been previously observed in ligands containing amino acids or amino acid derivative functions as the result of the formation of zwitterion (*28, 29*) $^{-}$OOC$-$(CH$_x$)$_y-$NH$_x^{+}$-, in KBr matrix, (*19*) and are gone in the complex, indicating that in the complex the COOH and the COO^{-} groups are strongly coordinated to the metal ion.

The stretching vibration frequencies of the carbonyls centered at 1690 cm^{-1} for the carboxylic (*CO*OH) and at 1630 cm^{-1} for the amide (*CO*NH) groups, respectively (*27*−*29*), in the free ligand, are shifted to lower energies 15 and 10 cm^{-1}, respectively, and their intensities diminish in the complex. Also the medium broad band centered at 1620 cm^{-1} is stronger than that at 1675, as a result of the coordination of the carboxylate groups (COO^{-}), since their band appear around 1620 cm^{-1} when they are coordinated. The band around 1675 cm^{-1} does not disappear at all, since two COOH remain.

The well-defined bands at 1530 cm^{-1} (*OC*NH) and at 3300 cm^{-1} (OC*NH*, *HN*CO*NH*) in the free ligand are shoulders in the complex, which is also evidence of the strong interaction between these functional groups and Sm^{3+} ion. Between 1480 and 1260 cm^{-1}, only one band survived, which is shifted to 1440 and assigned to, *CH*$_2-$N groups. The band at 1403 cm^{-1} (*−COOH*) is shifted to 1395 cm^{-1}. Moreover, the multiple bands between 1410 and 1260 cm^{-1} assigned to bending vibration frequencies of C*−OH*, which in this case are due to those of the carboxylic groups −CO*OH*, are not anymore present in the complex and only a centered medium band at 1395 with a shoulder at 1320 cm^{-1} is observed. The medium band at 1395 cm^{-1}, which is typical of coordinated carboxylate groups, is additional evidence of that the COO^{-} are not only neutralizing the charge of the metal ion but also coordinated. The C*−N* vibrations (1130−1150 cm^{-1}) of the $-CH_2-NH-CH_2-$ are clearly observed in the complex. The symmetry of the free ligand

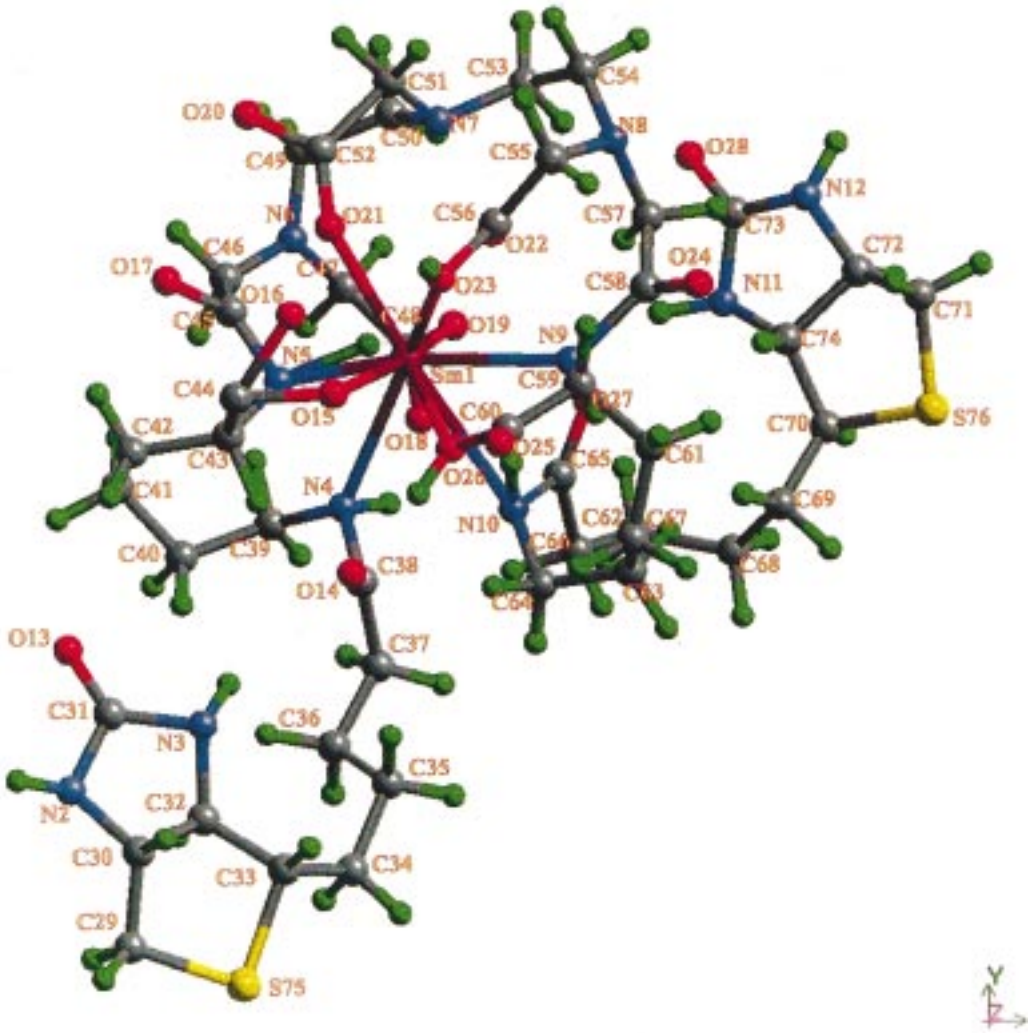

Figure 6. Sm(III)DTPA-bis-biotin calculated by FF and DFT and simulated by Cerius^2.

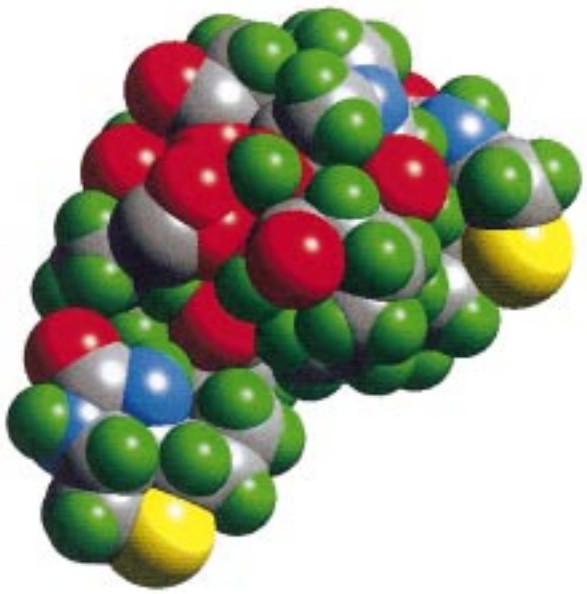

Figure 7. Sm(III)DTPA-bis-biotin calculated by FF and DFT and simulated by Cerius^2, bulky visualization.

is changed because of the coordination, as a result, the weak bands observed between 990 and 800 cm^{-1} in the free ligand and which are normally assigned to (CH_2−CH_2) groups are defined at 910 and 830 cm^{-1} in the complex and the two bands centered at 702 and 665 cm^{-1} which correspond to the rocking vibrations of the $(CH_{x=1-2})_n$ groups are shifted to lower energies, appearing at 690 and at 652 cm^{-1}, respectively. The fingerprint region between 650 and 450 cm^{-1}, where vibrations of the O−CO, C−C=O, OCN, the rock vibration of the COO^-, and the bending vibration of C−C−N− functional groups appear, is broadened in the complex (*27*). However, the broad band centered at 550 cm^{-1} fits well with the common observation of M−X vibration frequencies, when in complex interaction between N, O, and CO donors and M = lanthanide metal ion occurs (*14*−*20*).

Thus, IR spectroscopic study indicates that Sm^{3+} ion is coordinated to the DTPA-bis-biotin ligand through the three carboxylic groups of the tertiary amino acid functions, the carboxylic groups bound to the methylene of the secondary amide groups and to the amide function itself. On the basis of these results, we propose that the conformation of ligand changes by its coordination to the metal center and so the symmetry of the complex is remarkably different and, therefore, the transition vibration frequencies. Concerning the behavior of the donors (S, NH−CO−NH−) in the biheterocyclic rings of the biotins, there is no evidence which allows the proposition of the role of them in the complexation of Sm^{3+} ion. This result is important because the main contribution to the

[a] Final electronic densities and final charge distribution per atom have been calculated for the corresponding valence orbital.

binding of biotin to avidin is given by the aliphatic heterocycle including the ureido group (*1*).

Thermal Behavior (TGA). ^{153}Sm(III)DTPA-bis-biotin. The thermal decomposition pattern of this complex indicates that the Sm^{3+} was coordinated to the DTPA-bis-biotin since its thermal behavior is different from that of the free ligand.

Theoretical calculations. Semiempirical and theoretical investigation of complexes represent a valid tool for the characterization of their molecular properties. Recently, ab initio calculations by DFT for cobalt complexes (*32*) and FF and ab initio calculations for lanthanide complexes formed with polyamino carboxylate ligands (*33*) have been reported, and they were demonstrated to be useful for explaining the metal−ligand interactions and their conformational properties. In this work, molecular mechanics method as it is FF and ab initio calculations by DFT were applied to the ligand and the complex. These calculations allowed the obtaining of the best conformation for the Sm complex, that is the best geometric arrangement with the lower value of minimum potential energy (Figures 6 and 7), showing that the metal center is quite shielded by the ligand. The donors of the heterocyclic rings (N, S, and O donors) and the heterocyclic themselves do not have steric hindrance and are able to be linked to any substrate as for example the avidin.

Therefore, from these results we can establish that one of the factors which favored the high stability of the complex in solution is the shield effect which resulted from the geometrical arrangement of the molecule.

The electronic configuration or final electronic densities, and the final charge distribution (Table 4) for the atoms of the ligand compared with those of the complex revealed an important change which can be related with an important Sm−ligand interaction. The most important changes occur in the atoms of amino, carboxylic(COOH) and carboxylate groups(COO), which are coordinated to the metal center.

In general, it was observed that the final electronic densities of the donors bound to the metal ions diminished except the values of the 18-O and 21-O donors which increased. The same tendency was observed in their charge distribution. The increment in both atoms seems to be the result of retro-donation metal center- to ligand. Because of the high stability of the complex in solution, the increment cannot be assigned to no coordination of the two carboxylate groups which neutralized two positive charges of the metal center. These oxygens belong to two of the three tertiary aminocarboxylate groups. However the 15-O atoms of the third carboxylate group which belongs to a secondary aminocarboxylate derivative and which neutralized the remaining positive charge diminished, indicated that electron donation occurred. The parameters of the 4-N 5-N, 9-N, and 10-N atoms bound directly to the metal center diminished, but the most important effect is observed in the 5-N atom. The parameter values of the atoms of the carboxylic groups (COOH) diminished and indicate their coordination to the metal center. The same tendency is observed in the final charges. The general tendency to diminish the electronic densities and charge distribution of the donor atoms after the Sm(III) ion is joined to the ligand can be interpreted as the complex is a coordination compound where an important covalent character is also playing a role in the stability and inert of the complex. That is, seems that the chemical and physicochemical properties of the Sm(III)DTPA-bis-biotin is dominated by two effects: electronic and steric effects. The metal center is bound to the ligand and shielded from the medium therefore the complex is stable in vivo. It is quite probable that the two biotins are in the adequate spatial orientation to permit the molecule to be recognized by the corresponding avidin.

CONCLUSIONS

An easy preparation of a stable radiolabeled ^{153}Sm(III)-DTPA-bis-biotin complex was developed. This compound

is suitable for scintigraphic imaging and in vivo absorbed dose calculation because ^{153}Sm is a γ emitter, but in order to establish its therapeutic possibilities, it will be necessary to perform studies in normal and tumor-bearing mice.

Experimental results of radiolabeled ^{153}Sm(III)DTPA-bis-biotin and ^{152}Sm(III)DTPA-bis-biotin evidenced the high stability of the complex in solid and aqueous media (4.98×10^{-5}M) for 3 days and demetalation only occurred after heating at 363 K. Spectroscopic and thermal studies also supported the existence of a neutral high stable and chemically pure complex where three carboxylate anions are neutralizing the three positive charges of the samarium ion which is completely shielded by the ligands. These results suggest that the origin of such stability is thermodynamic and kinetic. It can be established that the conformation properties of ^{152}Sm(III)DTPA-bis-biotin complex determine its physicochemical behavior in vivo.

Solution Structure and Energy Calculation of Bis-Intercalation of Homodimeric Thiazole Orange Dye Derivatives in DNA: Effects of Modifying the Linker

Kent Bondensgaard and Jens Peter Jacobsen*

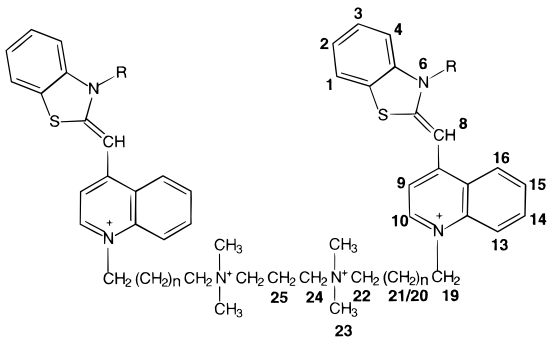
Department of Chemistry, Odense University, DK-5230 Odense M, Denmark. Received March 9, 1999; Revised Manuscript Received July 9, 1999

We have used two-dimensional ^{1}H NMR spectroscopy obtained at 750 MHz to determine a high-resolution solution structure of the double-stranded DNA oligonucleotide d(5′-CGCTAGCG-3′)$_2$ complexed with the bis-intercalating dye 1,1′-(5,5,9,9-tetramethyl-5,9-diazatridecamethylene)-bis-4-[3-ethyl-2,3-dihydro(benzo-1,3-thiazolyl)-2-methylidene]quino-linium tetraiodide (TOTO11Et). The determination of the structure was based on a complete relaxation matrix analysis of the NOESY cross-peaks followed by restrained molecular dynamics calculations. Forty final structures were generated for the TOTO11Et complex from A-form and B-form dsDNA starting structures. The root-mean-square (rms) deviation of the coordinates for the 40 structures of the complex was 0.52 Å. A conformational analysis of the deoxyribose rings based on coupling constants obtained from selective DQF-COSY spectra revealed that all ring conformations were almost pure S-type. The structure of the TOTO11Et complex was compared with the structure of a similar DNA complex with a dye containing a shorter linker (TOTOEt). Substantial differences were observed between the two structures because of the difference in the length of the linker. Most prominent was a large difference in the degree of unwinding of the dsDNA part in the two complexes. Unwinding of 73° and 22° relative to the free dsDNA was observed for the complexes with TOTOEt and TOTO11Et, respectively. The AMBER94 force field together with the GB/SA solvation model was used for energy calculations on both of the two complexes. In the calculations, the complex formation was divided into two steps: (i) unwinding of the free oligonucleotide and (ii) association of the bis-intercalators to the unwound oligonucleotide. The complex formation was in favor of TOTO11Et, mainly because the dsDNA is distorted less in the complex with TOTO11Et than in the complex with TOTOEt.

INTRODUCTION

Intercalation of small aromatic molecules (chromophores) in double-stranded DNA[1] (dsDNA) is an extremely efficient binding mode (Wakelin, 1986). Dimers with two intercalating chromophores linked with a chain of appropriate length (bis-intercalators) show high dsDNA binding affinities, greater by several orders of magnitude than those of the corresponding monomers (Wakelin, 1986).

Interest in nonradioactive detection of nucleic acids in gels has led to the synthesis and evaluation of bis-intercalating dyes that form highly fluorescent complexes with dsDNA. Glazer and co-workers (Benson et al., 1993a,b; Glazer and Rye, 1992) have synthesized and characterized a new family of high affinity fluorescent dyes for making dsDNA complexes. Among these, a homodimeric thiazole orange dye, 1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis-4-(3-methyl-2,3-dihydro-(benzo-1,3-thiazolyl)-2-methylidene)-quinolinium tetraiodide (TOTO, Scheme 1), binds with an extremely high affinity and forms complexes that are stable to a variety of conditions, in particular, gel electrophoresis. This compound allows high sensitivity detection of dsDNA by fluorescence scanners (Rye et al., 1990, 1992, 1993a,b).



The charged polyamine linker of TOTO resembles spermidine and spermine and contributes to the binding mode by electrostatic interactions in the minor groove. The TOTO chromophores are flexible and can adapt to the propellor twist of the base pairs. The length of the linker can be varied without destroying the strong bis-intercalation in dsDNA. This makes it possible to synthesize TOTO analogues with different lengths of the linker and different substituents on the chromophore so to study the binding mode in detail.

Scheme 1

TOTO: R = CH_3 and n = 1
TOTO11: R = CH_3 and n = 2
TOTOEt: R = CH_2CH_3 and n = 1
TOTO11Et: R = CH_2CH_3 and n = 2

Recent research in our laboratory has shown that TOTO binds preferentially to 5′-pyrimidine-pyrimidine-purine-purine-3′ sequences (Jensen et al., 1998; Jacobsen et al., 1995; Hansen et al., 1996). Solution structures of the CTAG−TOTO and CTAG−TOTOEt complexes (Spielmann et al., 1995; Petersen and Jacobsen, 1998) place the benzothiazole moiety intercalated between the pyrimidine bases and the quinolinium part intercalated between the two purine bases. The optimal stacking displayed by these structures may explain the preference of TOTO for a 5′-pyrimidine-pyrimidine-purine-purine-3′ site (Hansen et al., 1996). The site selectivity of TOTO within the 5′-pyrimidine-pyrimidine-purine-purine-3′ sites is explained by a subtle interplay between optimal stacking of the chromophores with the nucleobases and electrostatic interactions of the polyamine linker with the minor groove (Jensen et al., 1998; Bunkenborg et al., 1998). When introducing the longer linker in TOTO11, the site selectivity is somewhat reduced (Bunkenborg et al., 1998).

To investigate the role of the linker in the site selectivity of TOTO further, we have used ^{1}H NMR spectroscopy to determine the high-resolution solution structure of the oligonucleotide **1** complexed with TOTO11Et [1,1′-(5,5,9,9-tetramethyl-5,9-diazatrideca-methylene)-bis-4-[3-ethyl-2,3-dihydro(benzo-1,3-thiazolyl)-2-methylidene]quinolinium tetraiodide, Scheme 1]. The insolubility of TOTO and TOTO analogues in water precludes any measurements of equilibrium constants for the complex formation. Instead, we have recoursed to force field calculations in analyzing the complex formation. The molecular modeling calculations were performed on the **1**-TOTOEt and the **1**-TOTO11Et structures to compare the energetics involved in the formation of the two complexes.

EXPERIMENTAL PROCEDURES

Sample Preparation. TOTO11Et was a gift from Dr. E. B. Pedersen (Department of Chemistry, Odense University, Denmark). The purified oligonucleotide d(CGCTAGCG) was purchased from DNA technology (Aarhus, Denmark). On the basis of an analytical HPLC run and the 1D ^{1}H NMR spectrum, the oligonucleotide was assessed to contain less than 5% impurities and was used without further purification. The numbering scheme for the double-stranded oligonucleotide **1** is the following:

		1	*2*	*3*	*4*	*5*	*6*	*7*	*8*		
5'	**-**	**C**	**G**	**C**	**T**	**A**	**G**	**C**	**G**	**-**	**3'**
3'	**-**	**G**	**C**	**G**	**A**	**T**	**C**	**G**	**C**	**-**	**5'**
		16	*15*	*14*	*13*	*12*	*11*	*10*	*9*		

TOTO11Et is almost insoluble in water, and the complexes with dsDNA were therefore made using the procedure described earlier (Jacobsen et al., 1995). The NMR samples were prepared by dissolving the complexes in 0.5 mL of 10 mM sodium phosphate buffer (ph 7.0), 0.05 mM NaEDTA, 0.01 mM NaN_3, and 0.1 mM DSS. For experiments carried out in D_2O, the solid complex was lyophilized twice from D_2O and redissolved in 99.96% D_2O (Cambridge Isotope Laboratories). A mixture of 90% H_2O and 10% D_2O (0.5 mL) was used for experiments examining exchangeable protons. The final concentration of the complex was 2 mM. The sample was kept in an NMR tube under nitrogen.

NMR Experiments. NOESY and TOCSY spectra of **1**-TOTO11Et in D_2O and H_2O were obtained on a Varian Unity 500 spectrometer at 25 °C with standard experimental parameters (Petersen and Jacobsen, 1998). A selective DQF-COSY spectrum was recorded using a pulse sequence in which the first pulse was replaced with an E-BURP type selective pulse (Geen and Freeman, 1991). The spectrum was recorded with a spectral width of 5000 Hz in F_2 and 2000 Hz in F_1 using the States phase cycling scheme with 2048 complex points in t_2 and 1024 t_1 experiments with 64 scans each.

A ^{1}H,^{13}C gradient enhanced HSQC spectrum was recorded on a Varian Inova 600 spectrometer at 25 °C.

NOE buildups were obtained on a Varian Inova 750 spectrometer at 27 °C. These NOESY spectra were acquired in D_2O using 2048 complex points in t_2 and a spectral width of 7500 Hz. A total of 512 t_1 experiments was recorded using the States phase cycling scheme. NOESY spectra with mixing times of 40, 80, 140, and 200 ms were obtained sequentially without removing the sample from the magnet. 64 scans were acquired for each t_1 value with a repetition delay of 3.8 s between each scan. The residual signal from HOD was removed by presaturation. Furthermore, a DQF-COSY spectrum was obtained on a Varian Inova 750 at 27 °C with a spectral width of 7500 Hz using the States phase cycling scheme with 1024 complex points in t_2 and 1024 t_1 experiments with 64 scans each.

The acquired data were processed using Felix (version 95.0, Bioym Technologies/ MSI, San Diego, Ca). All spectra were apodized by a skewed sine bell in F_1 and F_2. The four spectra used in the buildup were zero-filled in F_1 to 2K points and baseline corrected by a second-order polynomial fit in F_2 and a first-order polynomial fit in F_1. The NOESY spectrum recorded in H_2O was zero-filled in F_1 to 2K points and baseline corrected by a third-order polynomial fit in F_2.

Distance Restraints. The upper and lower diagonal part of each of the four NOESY buildup spectra were integrated separately with FELIX, yielding a total of eight peak intensity sets. The RANDMARDI procedure (Liu et al., 1995) of the complete relaxation matrix analysis method MARDIGRAS (Borgias and James, 1990; Borgias et al., 1990) was used to calculate interproton distance bounds from the eight intensity sets. In the calculations, an absolute noise level of the same order of magnitude as the smallest integrated cross-peak was used. A relative noise level for each integrated peak was set at 5% of the integrated peak intensity. The dynamic range of observed cross-peak intensities was 1000. In the RANDMARDI procedure, 30 different intensity sets were generated from each experimental data set based on the given noise levels and MARDIGRAS calculations were performed on all of them. Resulting distances from all 8 × 30 intensity sets were combined into a single bounds file from which the rMD restraint file was generated.

Upper and lower bounds in the bounds file were average interproton distances plus or minus one standard deviation calculated from all of the MARDIGRAS runs.

Restrained Molecular Dynamics. The obtained distance restraints were incorporated into an rMD procedure using DISCOVER (version 3.0, MSI, San Diego, Ca). The two starting models for structure refinement were obtained by manually docking TOTO11Et into a model of either A-form or B-form DNA in INSIGHTII (version 97, MSI, San Diego, Ca) followed by minimization using DISCOVER to relieve any strain in the models. During minimization, 22 distance restraints were included to mimic Watson−Crick hydrogen bonds. The TOTO11Et molecule was built using INSIGHTII and was geometry optimized to a minimum at the MNDO level using Gaussian94 (Frisch et al., 1995). Point charges were calculated at the HF/6-31G* level by fitting charges to the electrostatic potential at selected points (Breneman and Wiberg, 1990). The potentials for both DNA and TOTO11Et were assigned by the AMBER force field (Weiner et al., 1984, 1986), modified to accommodate the thiazole orange chromophore of TOTO11Et.

All the distance restraints were incorporated into an rMD procedure for structure refinement. An initial energy minimization was followed by 28 ps of restrained molecular dynamics at 600 K for 4 ps, followed by cooling to 200 K in 50 K steps of 3 ps each. The final structure was then energy minimized to a maximum derivative of 0.01 Å. A distance-dependent dielectric constant ($\epsilon = r$) was employed to account for solvent effects.

The pseudo-energy term used to enforce the distance restraints was

$$E_{NOE} = \begin{cases} k_1(r-r_1)^2 & \text{when } r_1 > r \\ 0 & \text{when } r_2 \geq r \geq r_1 \\ k_2(r-r_2)^2 & \text{when } r_2 > r \end{cases}$$

where r_1 and r_2 are the lower and upper distance bounds determined from cross-peak intensities and k_1 and k_2 are the force constants. A force constant of 50 kcal mol^{-1} Å^{-2} for lower and upper bounds was assigned to all distance restraints. DISCOVER uses a limit on the magnitude of the force a distance restraint can contribute with to the force field. This limit was set to 1000 kcal mol^{-1} Å^{-1}.

Helix parameters were calculated with the program CURVES 5.1 (Lavery and Sklenar, 1988, 1989).

Deoxyribose Ring Conformations. The H1′ to H2′ and H2″ region of a selective DQF-COSY spectrum was used as input to CHEOPS to obtain the values of the *J* coupling constants for the H1′, H2′, H2″, and H3′ deoxyribose ring protons (Macaya et al., 1992; Gochin et al., 1990).

The deoxyribose ring conformations were analyzed assuming a fast two-state equilibrium between N- and S-type conformations with a modified version of the program PSEUROT (de Leeuw and Altona, 1983). The standard version of PSEUROT applies a least-squares optimization routine to obtain the best fit of the parameters P_N, P_S, $\Theta_{max,N}$, $\Theta_{max,S}$, and X_S to the experimental coupling constants. In our randomized version of PSEUROT (RANDPSEUROT), we include the effect of uncertainties in the determined set of coupling constants. RANDPSEUROT generates 1000 sets of coupling constants by adding a random number to each experimentally determined coupling constant. The random numbers are generated according to a normal distribution (Press et al., 1986) where the dispersion is set according to the uncertainty of each determined coupling constant. Uncertainties of the coupling constants are carefully assessed by how well the back-calculated spectrum correlates with the experimental spectrum and by the response of the determined coupling constants to small changes in the simulation procedure. Subsequently, PSEUROT calculations are done on all the generated sets of coupling constants and RANDPSEUROT then calculates mean values and standard deviations of the parameters returned by PSEUROT. In the statistical analysis, N-type conformations are compared with N-types, and S-type conformations are compared with S-types based on the parameters returned by PSEUROT. In cases where PSEUROT returns either two N-type or two S-type conformations, the two conformations are sorted according to the major conformer.

Energy Calculations on the 1-TOTOEt and 1-TOTO11Et Complexes. The AMBER94 force field (Cornell et al., 1995) in MacroModel (version 6.0) (Mohamadi et al., 1990), modified to accommodate the thiazole orange chromophore, was used for the energy calculations together with the GB/SA solvation model (Still et al., 1990), which approximately includes the effects of solvent. Charges for the dsDNA were taken from the force field. For TOTOEt and TOTO11Et, charges were calculated by a restrained electrostatic potential (RESP) fit (Bay et al., 1993). The electrostatic potentials were calculated at the HF/6-31G* level with geometries optimized at the HF/3-21G* level using Gaussian94 (Frisch et al., 1995).

RESULTS

Spectral Analysis. The ^{1}H NMR spectrum of the **1**-TOTO11Et complex exhibits sharp lines (line widths of 7−9 Hz). These are as narrow as those observed for the **1**-TOTO and **1**-TOTOEt complexes. Observation of lines for just one DNA strand and one thiazole orange chromophore shows that **1**-TOTO11Et has dyad symmetry. The NOESY spectrum of this complex exhibits the characteristic features of bis-intercalation in the 5′-CTAG-3′ site (Stærk et al., 1997; Jacobsen et al., 1995; Spielmann et al., 1995; Petersen and Jacobsen, 1998; Hansen et al., 1996). A part of the NOESY spectrum is shown in the Supporting Information. The NOESY spectrum of the complex recorded in H_2O displays the normal Watson−Crick NOE connectivity pattern. The dsDNA and the thiazole orange chromophore resonances of the complex were assigned as previously described (Hansen et al., 1996; Jensen et al., 1998; Jacobsen et al., 1995; Spielmann et al., 1995). The DQF-COSY spectrum was used for the assignments of the proton resonances in the linker of TOTO11Et. Part of the DQF-COSY spectrum is shown in Figure 1. The chemical shift values of the TOTO11Et complex are given in the Supporting Information.

Structure Calculations. More than 550 NOE cross-peaks were observed in the NOESY spectrum obtained with a mixing time of 200 ms. Four sets of 458 NOE cross-peak intensities and four sets of 480 NOE cross-peak intensities, giving a total of 3752 integrated cross-peak intensities, were used in the MARDIGRAS calculations. Of these, 3480 corresponded to interproton distances that are not covalently fixed. Cross-peak integrals that corresponded to fixed distances in the dsDNA were used for internal calibrations in MARDIGRAS and, therefore, not converted into distance restraints for use in the rMD simulations. A correlation time of 3.75 ns was chosen for the calculations, based on experiments with dsDNA−drug complexes of a similar size (Spielmann et al., 1995; Petersen and Jacobsen, 1998). The RAND-
