Figure 1. Part of the DQF-COSY spectrum of the **1**-TOTO11Et complex obtained at 750 MHz. Assignments of linker protons are shown together with the resonances of the N-ethyl protons of benzothiazole. The spectrum was used to make an unequivocal assignment of the linker protons. The cross-peak intensities between the H19′/H19″ and H20′/H20″ protons shows that H19′ is positioned trans to H20″ and gauche to H20′ and H19″ vice versa.

MARDI calculations returned 472 interproton distances based on the eight sets of NOE cross-peak intensities. The distribution of these is given in Table 1.

Covalently fixed distances within TOTO11Et were deliberately left out of the calibration in MARDIGRAS in order to provide a check on the performance of RANDMARDI. Good agreement between the covalently fixed distances and the corresponding distances derived from RANDMARDI indicated that the RANDMARDI procedure yielded accurate interproton distance bounds. The covalently fixed interproton distances within TOTO-11Et returned by RANDMARDI were not used in the rMD calculations. Unfortunately, no long covalently fixed interproton distances within TOTO11Et were calculated by RANDMARDI to provide a check on the performance of RANDMARDI for long interproton distances. Therefore, we decided to add 0.2 Å to all upper bounds so to compensate for any underestimated distances.

No symmetry was enforced during the RANDMARDI procedure. The bounds for symmetry-related restraints were calculated by averaging the symmetry-related upper and lower bounds for use in the rMD calculations.

Interproton distances involving exchangeable DNA amino and imino protons were derived from the NOESY spectrum of the complex recorded in H_2O. The normalized volume for the cross-peak between C7H5 and C7H6 was used as a reference for calculating the interproton distances involving exchangeable protons using the isolated spin pair approach (Borgias et al., 1990). Due to the inherent error in this approach, upper and lower bounds of ±1 Å were assigned to all distance restraints. Furthermore, 0.8 and 1.0 Å were added to the upper bounds for restraints involving methylene and methyl protons, respectively.

An additional 22 distance restraints were included to mimic Watson−Crick hydrogen bonds in the rMD calculations. Three hydrogen bonds were included for each of the six GC base pairs, and two hydrogen bonds were included for each of the two AT base pairs with upper and lower bounds of 1.7 and 2.1 Å, respectively.

Twenty final structures for each of the two starting structures were generated. All the structures converged to one family of conformations. The average all atom root-mean-square (rms) deviation of the coordinates of the 40 structures was 0.52 Å. The average sum of violations was 11.1 Å for both the A-form starting structures and the B-form starting structures. We observed two violations greater than 0.3 Å and none greater than 0.6 Å. Different views of the structure are presented in Figures 2 and 3.

The reliability of the structure calculations was carefully evaluated. rMD calculations were performed where the force constants of the distance restraints were varied between 25 and 100 kcal mol^{-1} $Å^{-2}$. All the calculations generated structures that converged to the same family of structures as with force constants of 50 kcal mol^{-1} $Å^{-2}$. A lower force constant resulted in a higher rms deviation and more violations. A higher force constant resulted in a lower rms deviation and fewer violations. The structure obtained is not strongly dependent on the exclusion of any of the restraints. In particular, calculations performed without the Watson−Crick restraints yielded exactly the same structure.

Helix Parameters. Helical parameters for the 40 final structures were analyzed with the program CURVES 5.1 (Lavery and Sklenar, 1988, 1989). Plots of some global helical parameters for the **1**-TOTO11Et complex are shown in Figure 4. The helical parameters for **1** (Spielmann, 1998a) along with the parameters for the **1**-TOTOEt complex (Petersen and Jacobsen, 1998) are included in Figure 4 for comparison.

Deoxyribose Ring Conformations. Due to the dyad symmetry of the **1**-TOTO11Et complex, only eight distinct deoxyribose residues are observed in the DQF-COSY

[a] The restraints were derived from MARDIGRAS calculations unless otherwise stated. Restraints derived from the NOESY spectrum recorded in H_2O are tabulated in parentheses. The 246 NOE connectivities gave a total of 492 symmetry related distance restraints; 22 distance restraints ensuring Watson−Crick base pairing were also included in the rMD calculations. [b] One restraint was derived directly from inspection of the spectra and used with loose bounds.

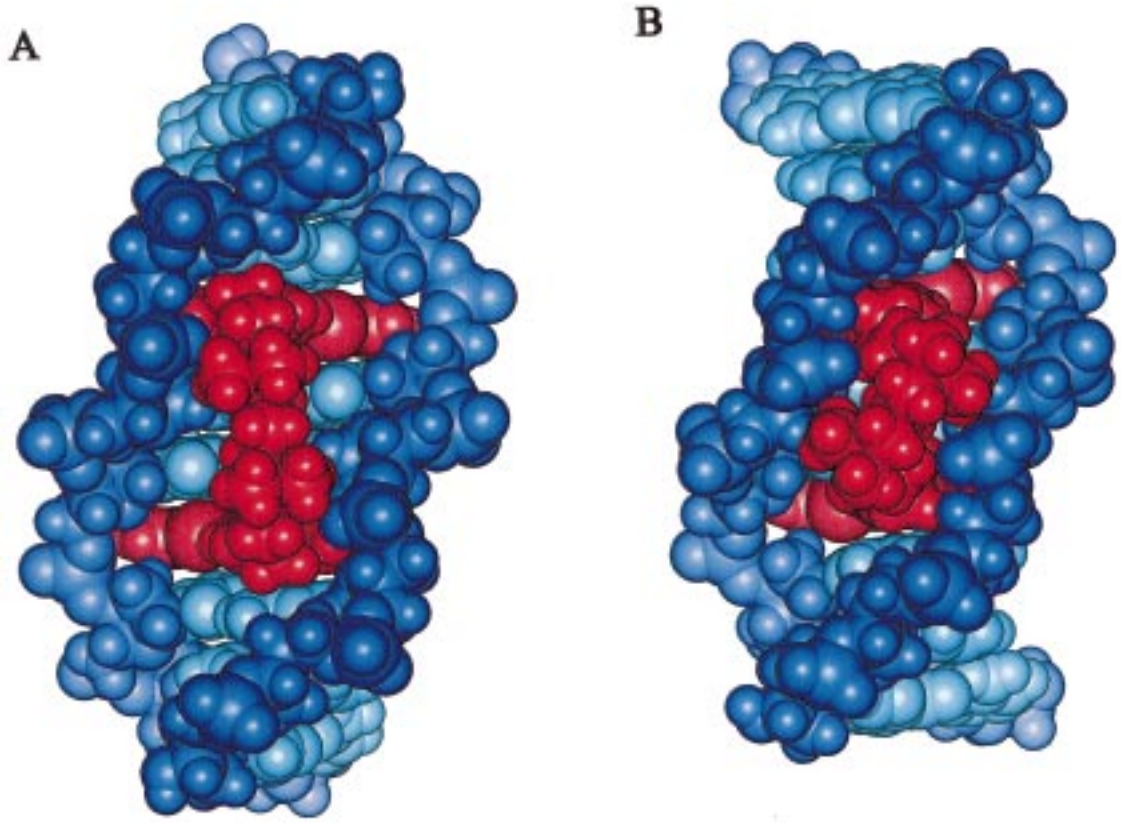

Figure 2. Structure of (A) **1**-TOTOEt and (B) **1**-TOTO11Et looking into the minor groove. The bis-intercalators are shown in red, the nucleobases are in light blue, and the sugar−phosphate backbones are in dark blue.

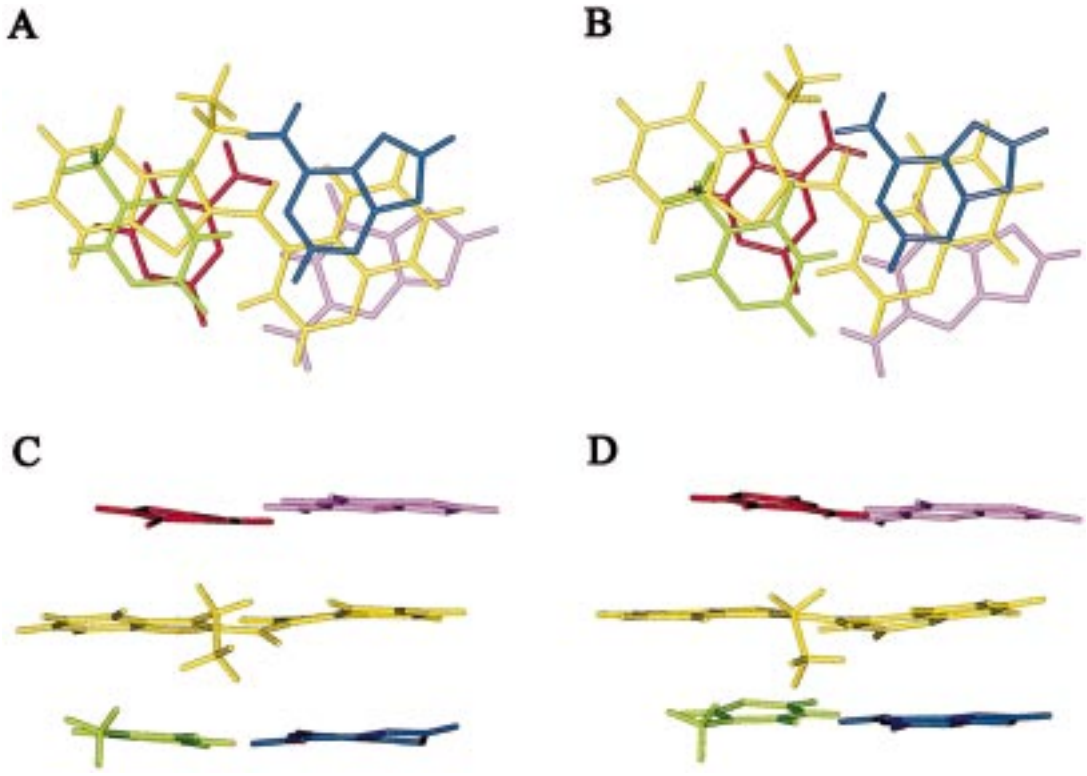

Figure 3. Stacking of the chromophore in the CpT·GpA binding site: (A) **1**-TOTOEt and (B) **1**-TOTO11Et viewed down the helix axis. (C) **1**-TOTOEt and (D) **1**-TOTO11Et viewed from the major groove side. Only nucleobases and chromophores are shown. It is evident that the chromophore in **1**-TOTO11Et is positioned toward the major groove compared with **1**-TOTOEt. The following coloring scheme is used: the chromophore, yellow; the adenine base, blue; the thymine base, green; the cytidine base, red; the guanine base, magenta.

spectrum. Simulation of G6 by CHEOPS was impossible due to severe overlap of the H2′ and H2″ resonances for this residue. For the remaining seven residues, the CHEOPS simulations of the DQF-COSY spectrum returned values that correlated rather well with the experimental spectrum (Macaya et al., 1992). The cou-

[a] The $J_{2'2''}$ coupling constants were fixed at −15 Hz in all CHEOPS simulations and the puckering amplitudes were fixed at 37 °C in PSEUROT calculations. The standard deviations are given in parentheses. [b] G6 in **1**-TOTO11Et and G2 and G6 in **1**-TOTOEt could not be analyzed due to spectral overlap. [c] If the mole fraction of the conformer was below 30% the *P* value was not considered to be determined with sufficient accuracy. [d] The coupling constants of C3 in **1**-TOTO11Et and **1**-TOTOEt could not be fitted to a two-state model.

pling constants returned by CHEOPS were used as input for RANDPSEUROT together with estimated uncertainties of the coupling constants. The coupling constants obtained along with the fraction of S-type sugar and pseudorotation angles calculated using RANDPSEUROT are given in Table 2. Corresponding values for **1**-TOTOEt are shown for comparison.

Energy Calculations. The noncovalent association of TOTOEt/TOTO11Et and dsDNA to form a complex was divided into two steps: (i) unwinding of the free dsDNA, **1**, to the dsDNA in the complex, **1***, and (ii) association of the bis-intercalator (B) to the unwound **1***. The first step describes the conformational distortion of the dsDNA to accommodate the bis-intercalator. In the second step, the bis-intercalator binds to the unwound dsDNA. To analyze the last step in more detail, TOTOEt and TOTO11Et were partitioned into a chromophore part (C) and a linker part (L) as indicated in Figure 5. Hydrogens were added where bonds were broken. The formation of the two complexes was evaluated by the following energies (Figure 5): ΔE_c (unwinding of **1** to **1***), ΔE_b (binding of **B** to **1***), ΔE_{bl} (binding of **L** to **1***), and ΔE_{bc} (binding

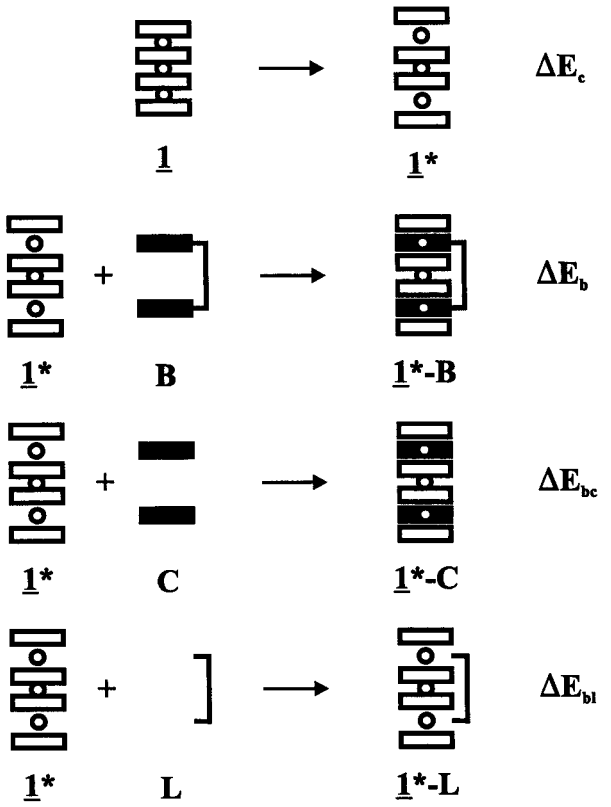

Figure 5. Schematic representation of the partition of the bis-intercalators TOTOEt and TOTO11Et (**B**) into a chromophore part (**C**) and a linker part (**L**) for energy calculations. **1** and **1*** represent free dsDNA and dsDNA in the complexes, respectively.

of **C** to **1***). We restricted the interpretation of the results only to include the calculated differences between the two complexes [e.g., $\Delta(\Delta E_c) = \Delta E_c$(TOTOEt) − ΔE_c-(TOTO11Et)] due to the approximative nature of the method.

The energies of **1***, **1***-C, **1***-L, and **1***-B for 1-TOTOEt and 1-TOTO11Et were evaluated using the structures determined by NMR spectroscopy in this work and earlier (Petersen and Jacobsen, 1998). Since the NMR structures are represented by an ensemble of 40 structures in each case, 10 structures were randomly chosen from the two ensembles and calculations were performed on all of them.

The energies of free TOTOEt, TOTO11Et, and the corresponding linkers were evaluated by finding the conformers with the lowest energy in each case. For the linkers, a systematic search through all torsional angles gave the global minimum. Unfortunately, the size of TOTOEt and TOTO11Et (18 and 20 variable torsion angles, respectively) precluded a systematic search. Instead, a number of systematic searches through subsets of torsion angles followed by 20 000 Monte Carlo steps were performed in each case. This led to more than 100 conformers with an energy within 1 kJ/mol of the lowest energy found. The conformers with the lowest energy were selected for each molecule. There is no guarantee that these conformers are the true lowest energy conformers, but due to the large number of conformers within 1 kJ/mol, it seems to be a reasonable choice. However, semiempirical PM3 calculations showed that the stacked geometry of the chromophores displayed by these lowest energy conformers of TOTOEt and TOTO11Et did not represent true energy minima, but were merely artifacts of the applied point charges. Consequently, a second set of force field calculations were done where stretched conformers of TOTOEt and TOTO11Et, optimized at the HF/3-21G* level, were used as reference geometries. The calculated energy differences with standard deviations are given in Table 3. It is important to notice that we obtain identical results for $\Delta(\Delta E_b)$ with the stacked and the stretched reference geometries of TOTOEt and TOTO11Et.

Table 3. Relative Energy Contributions to Complex Formation for TOTOEt and TOTO11Et

energy contribution	$\Delta(\Delta E)$ (kJ/mol)[a]	SD (kJ/mol)[d]
$\Delta(\Delta E_c)$	35.5	21.3
$\Delta(\Delta E_b)$	−9.4[b]	5.5
$\Delta(\Delta E_b)$	−8.6[c]	5.5
$\Delta(\Delta E_{bc})$	38.8	5.5
$\Delta(\Delta E_{bl})$	−33.8	4.1

[a] A positive value indicates more favorable reaction for TOTO-11Et compared with TOTOEt and vice versa. [b] Value with stacked reference geometries obtained by use of force field calculations guided by a Monte Carlo search (see text). [c] Value with stretched reference geometries obtained at the HF/3-21G* level (see text). [d] SD stands for standard deviation.

DISCUSSION

Description of the Structure. TOTO11Et bis-intercalates in the $(5'\text{-CTAG-}3')_2$ site. The benzothiazole moiety is intercalated between the pyrimidine bases, and the quinolinium system is intercalated between the two purine bases. The chromophore is positioned toward the edge of the major groove to optimize stacking with the nucleobases. The N-ethyl group on benzothiazole is centered in the major groove pointing toward the center of the oligonucleotide. The linker connecting the two chromophores is positioned in the minor groove. The N-methyl groups and the central part of the linker are positioned in the center of minor groove. Chemical shift values of the dsDNA protons at the binding site in TOTO11Et complex reflect intercalation similar to what was observed in the **1**-TOTO, **1**-TOTO11, and **1**-TOTOEt complexes (Spielmann et al., 1995; Stærk et al., 1997; Petersen and Jacobsen, 1998).

The structures of **1**-TOTOEt (Petersen and Jacobsen, 1998) and **1**-TOTO11Et exhibit the same overall features, but they are not identical. In fact, there are substantial differences between the two in both the dsDNA and the bis-intercalator part of the structures. These structural differences must be accredited to the longer linker in TOTO11Et. In both cases, the dsDNA part of the structures overall resembles B-DNA. The structural differences are analyzed with the aid of helical parameters and sugar conformations.

Helical Parameters. There are three major categories of helical parameters: Axis-base-pair, intra-base-pair, and inter-base-pair parameters (Dickerson et al., 1989). Plots of some of these parameters for **1**, **1**-TOTOEt and **1**-TOTO11Et are shown in Figure 4. The parameters reported for the terminal base pairs of the complex are not reliable because of the dynamic motions and are only included for completeness. Spectroscopically, the complexes were found to possess C_2 symmetry. The deviations of the structure and the calculated helical parameters from this symmetry reflect the level of uncertainty in the data.

Axis-Base-Pair Parameters. The global axes for the three structures are not completely straight but exhibit small overall bends of ∼2, ∼5, and ∼12° for **1**, **1**-TOTOEt, and **1**-TOTO11Et, respectively. The *x*-axis displacement, *y*-axis displacement, inclination, and tip are the param-

eters minimized to obtain the global helix axis (Lavery and Sklenar, 1988). The *x*-axis displacement, *y*-axis displacement, and inclination are not significantly different in the three structures, and in all cases they resemble the values for B-DNA. For **1**-TOTOEt and **1**-TOTO11Et, tip shows correlated changes from negative to positive going from C3 to G6, whereas with **1**, tip is essentially constant zero as in B-DNA. The correlated changes for **1**-TOTOEt and **1**-TOTO11Et are a consequence of a small kink in their helical axes (Petersen and Jacobsen, 1998).

Intra-Base-Pair Parameters. The values obtained for shear, stretch, stagger, and opening are partially determined by the constraints introduced to mimic Watson−Crick base pairing. However, for **1**-TOTOEt and **1**-TOTO11Et, the central part of the oligonucleotide is locked by the numerous NOEs between dsDNA and the bis-intercalators.

Shear shows large changes across the intercalation site compensating for the intercalation of the chromophores. The shear introduced is most pronounced with **1**-TOTO11Et. This is probable due to the relative position of the chromophores in the complexes (vide infra). An opening larger than for normal B-DNA narrows the minor groove essentially to the same degree for both complexes, probably due to van der Waals and electrostatic interactions between the linkers and minor groove.

The propeller twist and buckle are almost the same for the three structures, showing that the chromophore fits very well into the stacking pattern of the oligonucleotide without the introduction of propeller twist or buckle to maximize van der Waals contacts between the nucleobases and the chromophores.

Inter-Base-Pair Parameters. The twist and rise values reveal, as expected, that **1**-TOTOEt and **1**-TOTO11Et unwind relative to **1** in the C3·T4 and A5·G6 base pair steps to accommodate the chromophores. In these base pair steps, the twist is 31, 16, and 21° for **1**, **1**-TOTOEt, and **1**-TOTO11Et, respectively, showing that **1**-TOTOEt unwinds more than **1**-TOTO11Et. The twist in the central base pair step T4·A5 shows that **1**-TOTOEt does not unwind relative to **1** whereas **1**-TOTO11Et overwinds. However, the three structures have a similar rise in this base pair step, indicating that a rise smaller than ∼2.8−3.0 Å is unfavorable probably due to a large energy penalty from the exchange-repulsion contribution to the van der Waals interactions. Taking into account the five central base pair steps, **1**-TOTOEt and **1**-TOTO11Et are unwound by ∼73 and ∼22°, respectively, relative to **1**. This large structural difference between the **1**-TOTOEt and **1**-TOTO11Et complexes can be rationalized by considering the length of the linker (vide infra). The central part of minor groove in **1**-TOTO11Et is more narrow than in **1**-TOTOEt due to the larger degree of unwinding in the latter case.

Sugar Conformations. In B-DNA, the deoxyribose ring adopts an S-type conformation described by a pseudorotation angle *P* of 180 ± 90°, while the deoxyribose ring in A-DNA adopts an N-type conformation described by a pseudorotation angle *P* of 0 ± 90°. The RANDPSEUROT calculations resulted in almost pure S-type conformations (%S above ∼80%) for all residues analyzed in both **1**-TOTOEt and **1**-TOTO11Et. The analyzed sugar conformations in the two structures are nearly identical.

The inability of PSEUROT to describe C3 in **1**-TOTO11Et and **1**-TOTOEt with a two-state model shows that the dynamic behavior of these residues is complex. The $J_{2'3'}$ coupling constant in C3 is very different in **1**-TOTO11Et and **1**-TOTOEt. This is difficult to rationalize due to the inability of PSEUROT to describe these residues. However, this is in agreement with the unusual conformational properties observed by Spielmann (1998b) from NMR relaxation parameters of the **1**-TOTO complex.

Chromophore Part. The chromophore has virtually the same conformation in the two structures. In both cases, the relative conformation of the benzothiazole system and the quinolinium system is as indicated in Scheme 1. In both structures, the twist between the two flat aromatic ring systems is fairly small ∼5−10°. In **1**-TOTO11Et, the chromophore is moved toward the major groove compared with the position in the **1**-TOTOEt complex; this in turn leads to a diminution of the overlap between the chromophore and the flanking base pairs and a possible loss in stacking. In compensating for this loss, A5 is moved further into major groove to regain some overlap and by that introducing more shear in the central AT base pairs of **1**-TOTO11Et compared with **1**-TOTOEt. The separation of the chromophore and the flanking base pairs is smaller in **1**-TOTO11Et than in **1**-TOTOEt as reflected in the rise for the C3-T4 base pair step, which is ∼6.3 Å in **1**-TOTO11Et and ∼7.0 Å in **1**-TOTOEt. The relative orientation of the chromophores is ∼60 and ∼45° (C3-N11-N11′-C3′-dihedral) in **1**-TOTOEt and **1**-TOTO11ET, respectively, due to the different degree of unwinding in the two complexes.

Linker Part. The conformation of the two linkers is very different. In **1**-TOTOEt the short linker is stretched and crosses the minor groove between the two by symmetry related adenines in the oligonucleotide. The N-methyl groups are pointing toward the guanine phosphate, placing this positively charged group in an energetically favorable region caused by the negatively charged phosphate. The longer linker in **1**-TOTO11Et is curved in an S-form. The first 3−4 linker methylene groups guide the linker out into the minor groove, placing the middle part of the linker in the center of minor groove. In this complex the N-methyl groups are also positioned in the vicinity of a guanine phosphate, but now they are closest to the guanine phosphate on the other strand compared with **1**-TOTO11Et. In **1**-TOTO11Et, the linker has larger degree of van der Waals contacts to the walls of the narrow minor groove than with the **1**-TOTOEt complex.

The unwinding of **1**-TOTOEt creates a wide and shallow minor groove and enables the chromophores to be connected by a straight linker. On the other hand, **1**-TOTO11Et unwinds less, leading to a smaller vertical distance between the chromophores. At first this seems favorable for a short linker as in TOTOEt, but this is not the case because less unwinding also brings other structural changes along: the chromophore moves toward the major groove, probably due to a steric interference with the backbone, and the minor groove becomes more narrow and curved. This prevents the chromophores from being connected by a straight linker; this would lead to steric clashes between linker and backbone atoms. Instead, a longer linker as in TOTO11Et is needed to guide the linker from the chromophore out into minor groove and to follow the curved minor groove.

The dependence of unwinding of dsDNA on the linker length shows that with TOTO analogues the degree of unwinding displayed by the complexes can be controlled through the right choice of linker. An intermediate degree of unwinding compared to **1**-TOTOEt and **1**-TOTO11Et is likely obtained by choosing a linker length between the ones for **1**-TOTOEt and **1**-TOTO11Et.

Energetic. The positive value of $\Delta(\Delta E_c)$ indicates that the dsDNA is less distorted in **1**-TOTO11Et than in **1**-TOTOEt. This is probably due to the smaller degree of unwinding in the former case. The binding of the chromophores to the unwound dsDNA is more favorable for TOTO11Et than for TOTOEt as $\Delta(\Delta E_{bc}) > 0$. A closer look into the different contributions reveals that this is not due to a better stacking between the chromophores and the nucleobases in **1**-TOTO11Et. This would also be surprising considering that the position of the chromophores in terms of overlap with the nucleobases seems more favorable for TOTOEt (See above). Instead, a better electrostatic interaction with the solvent for TOTO11Et is the determining factor. Since $\Delta(\Delta E_{bl})$ is less than zero, the association of the linker to the unwound dsDNA is most favorable for TOTOEt probably due to the unfavorable curved conformation of the linker in **1**-TOTO11Et. If the linkers are preoptimized for binding (similar to the dsDNA), we find that there is a preference for binding in TOTO11Et. This indicates that the linker of TOTO11Et makes the best nonbonding contacts with dsDNA. In total, the binding of the bis-intercalators to the unwound dsDNA has a slight preference for TOTOEt over TOTO-11Et. The contributions from the linker and chromophore cancel each other partly.

Selectivity. The site selectivity of TOTO among 5′-pyrimidine-pyrimidine-purine-purine-3′ sites is explained by a subtle interplay between optimal stacking of the chromophores with the nucleobases and electrostatic interactions of the polyamine linker with the minor groove (Bunkenborg et al., 1998). The linker in **1**-TOTOEt is completely extended and therefore structurally restrictive. This makes TOTOEt prone to steric hindrance in minor groove. In **1**-TOTO11Et, the linker is curved and less restrictive on the structure. Steric hindrance in minor groove is therefore expected to more important for TOTO than for TOTO11. This is in agreement with the reduced site selectivity upon introduction of the longer linker in TOTO11 (Bunkenborg et al., 1998).

CONCLUSION

The longer linker introduced in **1**-TOTO11Et results in a much smaller degree of unwinding in **1**-TOTO11Et than in **1**-TOTOEt. This is explained by the inability of a short linker to connect the chromophores in a complex with a low degree of unwinding. In **1**-TOTO11Et, the chromophore is positioned toward the major groove compared with its position in **1**-TOTOEt. This is probably caused by a steric interference of the chromophore with the backbone in the former case. The position of the chromophore and the small degree of unwinding in **1**-TOTO11Et require a curved conformation of the linker here opposite to the extended conformation displayed by the linker in **1**-TOTOEt. The influence of the linker length on unwinding of dsDNA in complexes between dsDNA and TOTO analogues demonstrates that the degree of unwinding of dsDNA can be controlled through the choice of linker.

The binding of the bis-intercalators to the unwound dsDNA is slightly favorable for TOTOEt, but the complex formation is overall more favorable for **1**-TOTO11Et because dsDNA is distorted less upon complex formation in this case. This increase in affinity for TOTO11Et is followed by a likely decrease in site selectivity, because the linker in TOTO11Et is less restrictive on the structure than the linker in TOTOEt.

ACKNOWLEDGMENT

We thank The Instrument Center for NMR-Spectroscopy of Biological Macromolecules at The Carlsberg Laboratory, Copenhagen, granted by The Danish Natural Science Research Council for providing spectrometer time at the 750 MHz spectrometer. The authors are grateful to Dr. E. B. Pedersen for supplying the TOTO11Et and to Dr. F. Jensen for the use of MacroModel6.0 and many stimulating discussions.

Peptide-Based Intracellular Shuttle Able To Facilitate Gene Transfer in Mammalian Cells

Devender Singh,[‡] Stuart K. Bisland, Kim Kawamura, and Jean Gariépy[†]

Division of Molecular and Structural Biology, Department of Medical Biophysics, University of Toronto and the Ontario Cancer Institute, Princess Margaret Hospital, 610 University Avenue, Toronto, Canada M5G 2M9.
Received November 3, 1998; Revised Manuscript Received March 11, 1999

Loligomers are peptide-based intracellular vehicles able to penetrate cells and self-localize into distinct cellular compartments. Loligomers can be rapidly assembled by automated solid-phase approaches and were designed to act as nonviral, nonlipophilic intracellular shuttles. One nucleus-directed loligomer, termed loligomer 4, was evaluated for its ability to function as a transfection agent. Loligomer 4 readily associates with plasmids to form noncovalent complexes. The migration of loligomer 4−plasmid complexes into cells was monitored by flow cytometry and fluorescence microscopy. Populations of plasmids labeled with 7-AAD exist either free or in association with loligomer 4 inside cells and are visible throughout the cytosol and nucleus of chinese hamster ovary (CHO) cells. Loligomer 4−plasmid complexes were not cytotoxic to cells and were readily imported by most cells (>70%). CHO cells were transfected with complexes of loligomer 4 and plasmids harboring luciferase, green fluorescent protein or β-galactosidase reporter genes. The transfection efficiency of loligomer 4−plasmid DNA complexes was greater when cells were maintained as suspensions instead of monolayers. Transfections could be performed with cells suspended in serum-containing medium. The observed levels of transfection, however, were modest with 5−10% of CHO cells expressing either a green fluorescent protein or the enzyme β-galactosidase. Loligomers have recently been observed in vesicular compartments [Singh, D., Kiarash, R., Kawamura, K, LaCasse, E. C., and Gariépy, J. (1998) *Biochemistry 37*, 5798−5809] and differences between levels of cellular import and transfection efficiency may well reflect the need to optimize the release of loligomers and their complexes from these compartments in future designs. In summary, loligomer 4 behaves as a stable, soluble and effective transfection agent. These results demonstrate the feasibility of designing loligomers able to act as intracellular guided agents aimed at gene transfer applications.

INTRODUCTION

Transcription of exogenous genes in mammalian cells has proven invaluable in a wide variety of applications. These uses include the expression of foreign genes in mammalian cells, the production of proteins from cloned cDNAs, the analysis of transcriptional regulatory sequences, and the expression of molecules involved in the intracellular sorting and posttranslational processing of secreted polypeptides. A variety of methods has been developed to transfer genes into eukaryotic cells. These techniques involve the direct physical intake of DNA by the cell, either introduced in the context of a viral particle inside the cell (*1*, *2*), microinjected directly into the cell, or introduced through the use of receptor-mediated gene transfer strategies (*3*−*5*) or by utilizing nonviral gene-transfer methods in combination with a lysosomotropic agent such as chloroquine (*6*). The choice of a gene transfer technique is dependent on the cell line or cell type as well as the limitations of the experimental design. Most biochemical methods result in the disruption of cell membranes that allow the import of DNA (*7*), either through the formation of DNA complexes with inorganic salts and polycations (*8*) or with lipids (*9*, *10*). Recent examples of peptide− and polycations−DNA complexes able to act as efficient transfection agents have also been reported (*11*−*14*).

Nonviral DNA transfection techniques have historically resulted in a low efficiency transfer of the DNA into a cell population in comparison to virus-mediated transfer methods involving the use of SV40 vectors, vaccinia virus, adenovirus, and retroviruses. Although retroviral transduction can lead to a higher transfection efficiency in terms of gene transfer and integration (60−90%), the efficacy of retroviral infection itself remains limited by the titer associated with the helper-free packaging cell line, the time of infection, and its facilitated uptake with various chemical substrates (*2*, *15*). Calcium phosphate-mediated transfection (*16*) is one of the oldest approaches and is still the most popular transfection method (*17*). Other popular methods include DEAE-dextran mediated transfection (*18*), electroporation (*19*), liposome technology (*20*), lipid-mediated transfection (*21*), and electropermeabilization (*22*).

The need to design defined, guided intracellular vehicles able to act as efficient nonviral gene delivery agents is obvious and can potentially be addressed using solid-phase synthesis strategies. In particular, the concept of loligomers[1] (*23*, *24*) was recently developed as a design strategy for creating multitasking agents to target different organelles in cells. Loligomers contain functional domains presented on a tentacular scaffold. More precisely, lysine residues give rise to a branched peptide, which presents multiple domains that code for functions

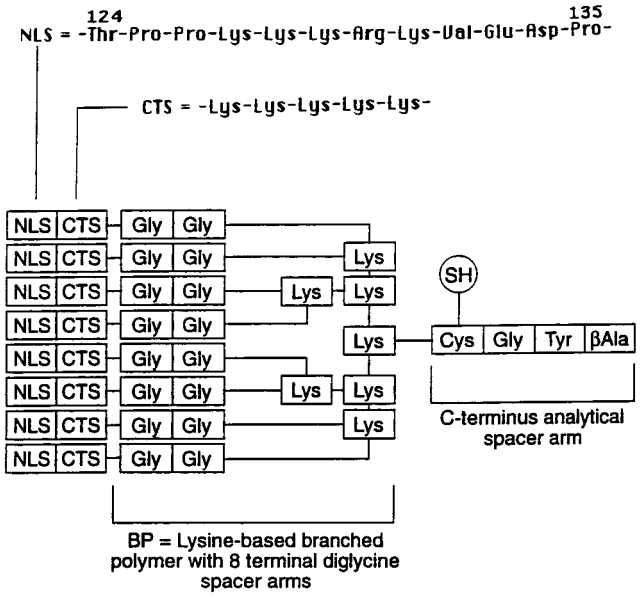

Figure 1. Structure of loligomer 4, a peptide-based intracellular vehicle (*23*, *24*). This construct consists of a 5-amino acid long, C-terminal region (analytical arm) and eight identical N-terminal arms linked together through a branched lysine polymer (BP). Each N-terminal arm contains a domain representing the nuclear localization signal of the SV40 large T-antigen (NLS; residues 124−135) and a lysine pentapeptide acting as a cytoplasmic translocation signal (CTS).

such as cellular delivery, cell signaling, and/or cytotoxicity. Prototypic loligomers have been generated that can self-localize in the nucleus of cells (*23*). The intracellular routing of a nucleus-directed loligomer was recently analyzed by microscopy and flow cytometry, indicating its presence in the cytosol, in endocytic vesicles, and in the nucleus of eukaryotic cells (*24*). In this report, we demonstrated the ability of one such loligomer, termed loligomer 4, to associate noncovalently with plasmids to form complexes that self-localize inside eukaryotic cells.

MATERIALS AND METHODS

Peptide Synthesis. The branched peptide (loligomer 4) was synthesized by classical solid phase peptide synthesis (*25*), on an Applied Biosystems 430A Synthesizer using *tert*-butoxycarbonyl (t-Boc) chemistry and phenylacetamidomethyl resin supports. The synthesis, coupling efficiencies, purification, and characterization procedures were described previously (*23*, *24*). Loligomer 4 was labeled with fluorescein via the free thiol group in the C-terminal arm of the molecule (Figure 1) as described previously (*23*, *24*). Fluorescein maleimide was purchased from Molecular Probes (Eugene, Oregon)

Gel Mobility Shift Assay. Plasmid DNA (1 μg; pGL2 Luciferase, Promega) was dispensed into microcentrifuge tubes and mixed with increasing amounts of loligomer 4 (5−1000 ηg). Aliquots of each loligomer 4−plasmid mixture (20 μL) were then incubated at room temperature for 5−10 min. A 3 μL volume of 6× loading buffer (0.25% bromophenol blue, 0.25% Xylene cyanol F. F., and 30% glycerol in water) was subsequently added to each tube. Samples were thereafter loaded into wells of a precast 0.8% agarose gel (1× TBE). Samples were electrophoresed on agarose gels for 1 h at 70 V in TBE buffer (0.09 M Tris-borate and 0.002 M EDTA). Bands corresponding to plasmid DNA were detected by staining the gel with ethidium bromide (10 μg/100 mL TBE buffer). Banding patterns were visualized under a UV light and photographed.

Cell Culture. Cells were maintained at 37 °C, 5% (v/v) CO_2, 90% humidity in Nunclon tissue culture plasticware (Gibco-BRL). CHO (Chinese hamster ovary cells subclone AUXB1; ref *26*), COS-7 (SV40 transformed African green monkey kidney cells; ref *27*), and MCF-7 cells (human breast carcinoma; ref *28*) were grown in a MEM supplemented with 10% (v/v) fetal calf serum (FCS; ImmunoCorp, Montreal, Canada), 1 unit/mL penicillin (Sigma), 100 μg/mL streptomycin sulfate (Sigma), and 1 mM L-glutamine (Gibco-BRL). Subconfluent cultures of cells were passaged by washing them with 10 mL of PBS, followed by a trypsinization step for 2 min at 37 °C with 1 mL Trypsin (Gibco-BRL). The reaction was stopped by adding growth medium once cells composing the monolayer were detached from the dish. Cells were then harvested by centrifugation for 5 min at 1500 rpm and grown either as adherent monolayers or as suspensions in plastic tubes (Nunc).

DNA Vectors. The following DNA plasmids were used in this study. The pGL2 luciferase (Ctrl) vector (Promega) contains both a SV40 promoter and an enhancer sequence inserted into the pGL2 basic vector, which harbors a luciferase gene. The pCMV β-gal vector consists of both a CMV promoter sequence and a β-galactosidase gene. The pCMV β-gal plasmid contains the major immediate early gene promoter and the enhancer region of the human cytomegalovirus (CMV) and LacZ genes (*29*). The pGFP vector (Clontech) incorporates a gene coding for a green fluorescent protein.

Transfection Methods. *Loligofection (Transfection with Loligomer 4-Plasmid Complexes).* Loligomer 4 (ranging in concentrations from 1 to 60 μg prepared in PBS) was mixed with 10 μg of either plasmids pGL2 luciferase (Promega), pGFP (Clontech), or pCMV β-gal (Clontech). Sample volumes were then adjusted to 50 μL with PBS, and the mixtures were incubated at room temperature for 10 min. Thereafter, the following methodologies were used for transfections.

Treatment of Cells as Monolayers. Two hundred thousand (2×10^5) cells were seeded in individual wells of 6-well plates and incubated overnight at 37 °C. A 50 μL sample of each loligomer 4−plasmid DNA mixture was adjusted to 500 μL with α-medium. The medium was removed from plates seeded with cells and replaced with medium containing a loligomer 4−plasmid mixture. The plates were incubated for 30 min at room temperature with occasional redistribution of the solution from the edges of the dish over the entire surface of the dish every 10 min. A 4.5 mL aliquot of fresh medium was then added and the cells were incubated at 37 °C for 48 h.

Treatment of Cells in Suspensions. Cells (2×10^5 cells) suspended in growth medium were mixed with loligomer 4−plasmid preparations giving a final volume of 500 μL. The resulting cell suspensions were incubated for up to 5 h at 37 °C in eppendorf tubes attached to a rotating shaker. The cells were subsequently plated in a 6-well dish for 48 h with an additional 4.5 mL of growth medium.

[1] Abbreviations: CTS, cytoplasmic translocation signal; GFP, green fluorescent protein; loligofection, process of transfecting cells with plasmid DNA-loligomer complexes; loligomer, a squid-like branched peptide construct that incorporates cell penetration and intracellular localization signals; loligomer 4, a loligomer harbouring 8 N-terminal arms that comprise of a pentalysine cytoplasmic translocation domain and the SV40 large T-antigen nuclear localization signal; NLS, nuclear localization signal; RLU, relative light unit.

Calcium Phosphate Method. Transfections were performed using the calcium phosphate method (*16*). Briefly, 15 μL of a 2 M $CaCl_2$ solution was added dropwise to 250 μL of DNA-HBS buffer. The cell suspension method described above was used and the medium was changed after 24 h. The cells were incubated for an additional 24 h period.

Other Methods. Superfect (Qiagen), Transfectam (Promega), Tfx-50 (Promega), and Lipofectamine (Gibco-BRL) reagents were used as described by their suppliers using cell suspensions described in the protocol for loligomer transfection (loligofection). Transfection with Lipofectamine was performed in a serum-free medium for the first 24 h. Superfect (Qiagen) is a specifically designed polycation based on dendrimer technology, Tfx-50 (Promega) consists of a synthetic cationic lipid molecule, *N*,*N*,*N*′,*N*′-tetramethyl-*N*-*N*′-bis(2-hydroxyethyl)-2−3,-dioleoyloxy-1,4-butane diammonium iodide and L-dioleoyl phosphatidyl ethanolamine (DOPE). Transfectam (Promega) contains dioctacylamidoglycyl spermine and Lipofectamine (Gibco-BRL) reagent contains 3:1 (w/w) liposome formulation of the polycationic lipid 2,3-dioleyloxy-*N*-[2-(spermine carboxamido) ethyl]-*N*,*N*-dimethyl-1-propaneminium trifluoroacetate (DOSPA) and L−α dioleoyl phosphatidylethanolamine (DOPE).

Preparation of Cell Extracts. Preparation of cell extracts was performed as described elsewhere (*30*). Briefly, cells were washed with PBS, incubated with 200 μL of a cell lysis solution (25 mM Tris, pH 7.8, with H_3PO_4; 2 mM EDTA; 2 mM DTT; 10% glycerol; 1% Triton X-100; Promega) for 5 min and finally scraped into an eppendorf tube. The cells were disrupted using one to two cycles of freezing in dry ice−ethanol or incubating at −70 °C for 30 min followed by a thawing step at 37 °C for 5 min. The extracts were centrifuged at 12 000 rpm for 5 min at 4 °C, and the resulting supernatants were transferred to new tubes. The protein concentration in cell lysates was determined using the Bradford (*31*) dye binding protein assay (Bio-Rad, Hercules, CA). The total amount of luciferase activity was reported in terms of light units per milligram of protein in the extracts.

Luciferase Assay. Luminescence was detected in cells transfected with a plasmid construct harboring a luciferase reporter gene (pGL2 luciferase control vector; Promega). The luciferase enzyme catalyzes the production of light in fireflies by oxidizing D-(−)-luciferin in the presence of ATP, Mg^{2+}, and O_2 (*32*). The reaction produces oxyluciferin, CO_2, and a photon. The level of light emitted during the reaction can be measured with a luminometer. A 20 μL aliquot of a cell extract was mixed with 100 μL of luciferase assay reagent [Promega; 20 mM tricine, 1.07 mM $(MgCO_3)_4$ $Mg(OH)_2{\cdot}5H_2O$, 2.67 mM $MgSO_4$, 0.1 mM EDTA, 33.3 mM DTT, 270 μM Coenzyme A (lithium salt), 470 μM luciferin, and 530 μM ATP; pH 7.8] maintained at room temperature. The test tube containing the reaction mixture was placed in a luminometer (Lumat LB 9507, Berthold, Princeton, NJ), and light produced (luminescence units) for 10 s was recorded.

Fluorescence Microscopy. The plasmid pGL2 Luciferase (10 μg) was incubated with the DNA 7-aminoactinomycin (7-AAD; 0.1 μg) for 5 min. The labeled plasmid was subsequently complexed with fluorescein-labeled loligomer 4 at a 2:1 loligomer 4:plasmid weight ratio. CHO cells (10^6 cells) grown in suspension were transfected with the dual-labeled complex following the procedure described in the section on transfection methods. Cells were examined by fluorescence microscopy (Leica DM-LB microscope) and photographed 4 h after transfection. Fluorescence excitation filters (fluorescein, EX filter 355/425, EM filter LP 470; 7-AAD, EX filter 530/595, EM filter LP615) were used to observe the migration of both fluorophores. The GFP fluorescence signal (EX filter 355/425, EM filter LP 470) emitted by CHO cells transfected with a plasmid harboring the gene coding for green fluorescent protein was stable and monitored directly in viable cells.

Flow Cytometry. CHO cells (10^6 cells) were transfected as described in the previous paragraph with the 7-AAD-labeled plasmid pGL2 or the complex of fluorescein-labeled-loligomer 4 and 7-AAD-labeled plasmid pGL2. Labeled cells were subsequently analyzed by flow cytometry on a FACScan unit (Becton Dickinson) to determine the extent of cell viability (forward scatter, FSC; side scatter, SSC) and the binding/internalization of 7-AAD into CHO cells (argon laser; excitation wavelength, 488 nm; emission signal, LP 650 nm filter). The dye 7-AAD is excluded by viable cells unless complexed to a molecule that is internalized by cells.

***β*-Galactosidase Staining.** The detection of β-galactosidase activity in situ in cultured cells was performed using a histochemical stain (*33*). The substrate, 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-Gal), is hydrolyzed by β-galactosidase to generate an indigo-colored precipitate which facilitates the subcellular localization of the β-galactosidase activity. A monolayer of cells was washed twice in PBS containing 2 mM $MgCl_2$. The cells were fixed in 0.75% (v/v) glutaraldehyde (Sigma) in PBS for 15 min at room temperature, and then washed with PBS/$MgCl_2$ for 5 min. A 1.5 mL volume of X-Gal (1 mg/mL) diluted in staining solution [5 mM $K_3Fe(CN)_6$, 5 mM $K_4Fe(CN)_6{\cdot}3H_2O$, 0.01% (w/v) sodium deoxycholate, 0.02% (v/v) Nonidet P40, and 2 mM $MgCl_2$ in PBS] was added to each one-chamber cover glass slide (LabTek borosilicate; Nunc). Cells were analyzed under a light microscope and photographs were taken.

RESULTS

Loligomers are intracellular vehicles able to import large cargos such as plasmids into cells. One of these constructs, loligomer 4, is a nucleus-directed vehicle. It is a structurally defined, synthetic peptide (Figure 1) which possesses properties expected of a transfection agent. Loligomer 4 is water soluble, heat stable and probably associates noncovalently with the phosphate backbone of nucleic acids. Its cellular import is insensitive to the presence of serum or medium. The ability of loligomer 4 to act as a transfection agent was analyzed using reporter plasmids.

Design and Synthesis of loligomer 4 Variants. Loligomers (*23*, *24*) are peptide-based multitasking shuttles, which are able to selectively deliver cytotoxic or therapeutic agents to the cytosol or inside cellular compartments. The term loligomer was derived from the latin root *loligo* referring to members of the squid family, thereby emphasizing the branched or "squid-like" nature of these peptides. In particular, loligomer 4 (Figure 1) contains eight nuclear localization signals (NLS) and eight pentalysine stretches acting as cytoplasmic translocation signals (CTS) which allow it to penetrate cells and relocate to their nucleus. Loligomer 4 (Figure 1) was synthesized by solid-phase peptide synthesis. Peptide branching was introduced following successive rounds of couplings of lysine derivatives harboring identical protecting groups on their α- and ϵ-amino groups (*23*). The concept of peptide branching originated from the work of Tam (*34*, *35*) dealing with the construction of multiple antigenic peptides. The thiol side chain located in the

Figure 2. A gel-retardation assay illustrating a shift in migration of plasmid DNA (pGL2 luciferase) in agarose gels when complexed with loligomer 4. Lane 1, banding pattern observed for 1 μg of pGL2 luciferase plasmid; lanes 2−11, banding patterns observed for 1 μg of pGL2 luciferase plasmid DNA complexed with increasing amounts of loligomer 4. Lane 2, 5 ng loligomer 4; lane 3, 10 ng; lane 4, 50 ng; lane 5, 100 ng; lane 6, 150 ng; lane 7, 200 ng; lane 8, 250 ng; lane 9, 500 ng; lane 10, 750 ng; lane 11, 1000 ng. Lane 12 was loaded with 0.5 μg of a 1 kb DNA ladder (Gibco BRL).

C-terminal arm of loligomer 4 (Figure 1) was modified with fluorescein maleimide to produce a fluorescein-labeled loligomer 4 for cell migration studies.

Loligomer 4 Forms a Complex with Plasmid DNA. The plasmid pGL2 luciferase was mixed at different ratios with loligomer 4 to generate noncovalently associated complexes. The resulting macromolecular aggregates were easily observed as large molecular weight species on agarose gels. Their noncovalent association is due to the fact that loligomer 4 is a cationic structure that can readily interact with the negatively charged phosphate backbone of plasmid DNA.

The migration of plasmid DNA (1μg) in agarose gels was retarded by the addition of loligomer 4, as detected with ethidium bromide (Figure 2). Plasmid DNA containing no loligomer migrated as a pair of bands representing both supercoiled and open circular forms of DNA (lane 1). The mobility of plasmid DNA (1 μg) was not altered by the presence of loligomer 4 ranging in concentrations between 5 and 100 ng (lanes 2−5). The presence of 150 ng of loligomer (lane 6) resulted in the appearance of a band migrating slightly above the supercoiled DNA plasmid band. Upon adding 200 ng of loligomer 4 (lane 7), the uncomplexed supercoiled DNA band disappeared with most of the plasmid DNA remaining in the sample well. The intensity of the plasmid DNA open circular form was further decreased by the addition of 250 ng of loligomer 4 (lane 8) and concentrations of the vehicle in the range 500−1000 ng (lanes 9−11) were sufficient to retard the migration of all the plasmid DNA. In summary, the mixing of loligomer 4 with the plasmid pGL2 luciferase at a minimal weight ratio of 0.5 resulted in an efficient complexation of all the available plasmid DNA as shown by the retardation of the DNA−peptide complex on agarose gels (Figure 2).

Complexes of Fluorescein-Labeled Loligomer 4 and 7-AAD-Labeled Plasmids Are Imported into CHO Cells. The migration of plasmids inside CHO cells occurs only in the presence of loligomer 4. The DNA intercalator 7-AAD does not enter cells that are viable and is typically used in flow cytometry to measure the extent of cell death in a cell population. This fluorescent intercalator was used to label plasmid DNA in an effort to follow the migration of plasmid inside CHO cells. Loligomer 4 was labeled with fluorescein in order to track its intracellular movement in relation to the 7-AAD-labeled plasmid. A typical distribution pattern of plasmid (red color) and loligomer 4 (green color) inside CHO cells after 4 h is presented in Figure 3 (Panel A). Zones of yellow color inside cells highlight areas of comigration of the 7-AAD and fluorescein chromophores and suggest that a significant fraction of labeled plasmid exists as complexes with loligomer 4. The overall cellular distribution of 7-AAD fluorescence (red color) also suggests the occurrence of either free plasmid inside these cells or the rapid exchange of 7-AAD originally associated with the plasmid with intracellular pools of DNA. The flow cytometric patterns of CHO cells exposed to a 7-AAD-labeled plasmid for 4 h indicate that the plasmid alone is not imported by these cells (Figure 3, panel B, right side, relative fluorescence signal less than 10 units). In contrast, CHO cells transfected with a complex of loligomer 4 and 7-AAD-labeled plasmid bind and internalize the complex rapidly (in less than a hour) with >70% of cells being labeled with the plasmid harboring the 7-AAD label (Figure 3, panel C, right side, relative fluorescence signal greater than 10). All cells analyzed for the binding and internalization of the 7-AAD-labeled plasmid were viable (gated cell population [R1] based on forward and side scatter properties, Figure 3, panels B and C, left sides), indicating that unbound 7-AAD was not responsible for the fluorescence signal observed. The viability of CHO cells also confirms that loligomer 4 at a concentration of 3 μM is not toxic to these cells when the peptide is associated with a plasmid (30 μg of loligomer 4 and 10 μg of plasmid in 500 μL).

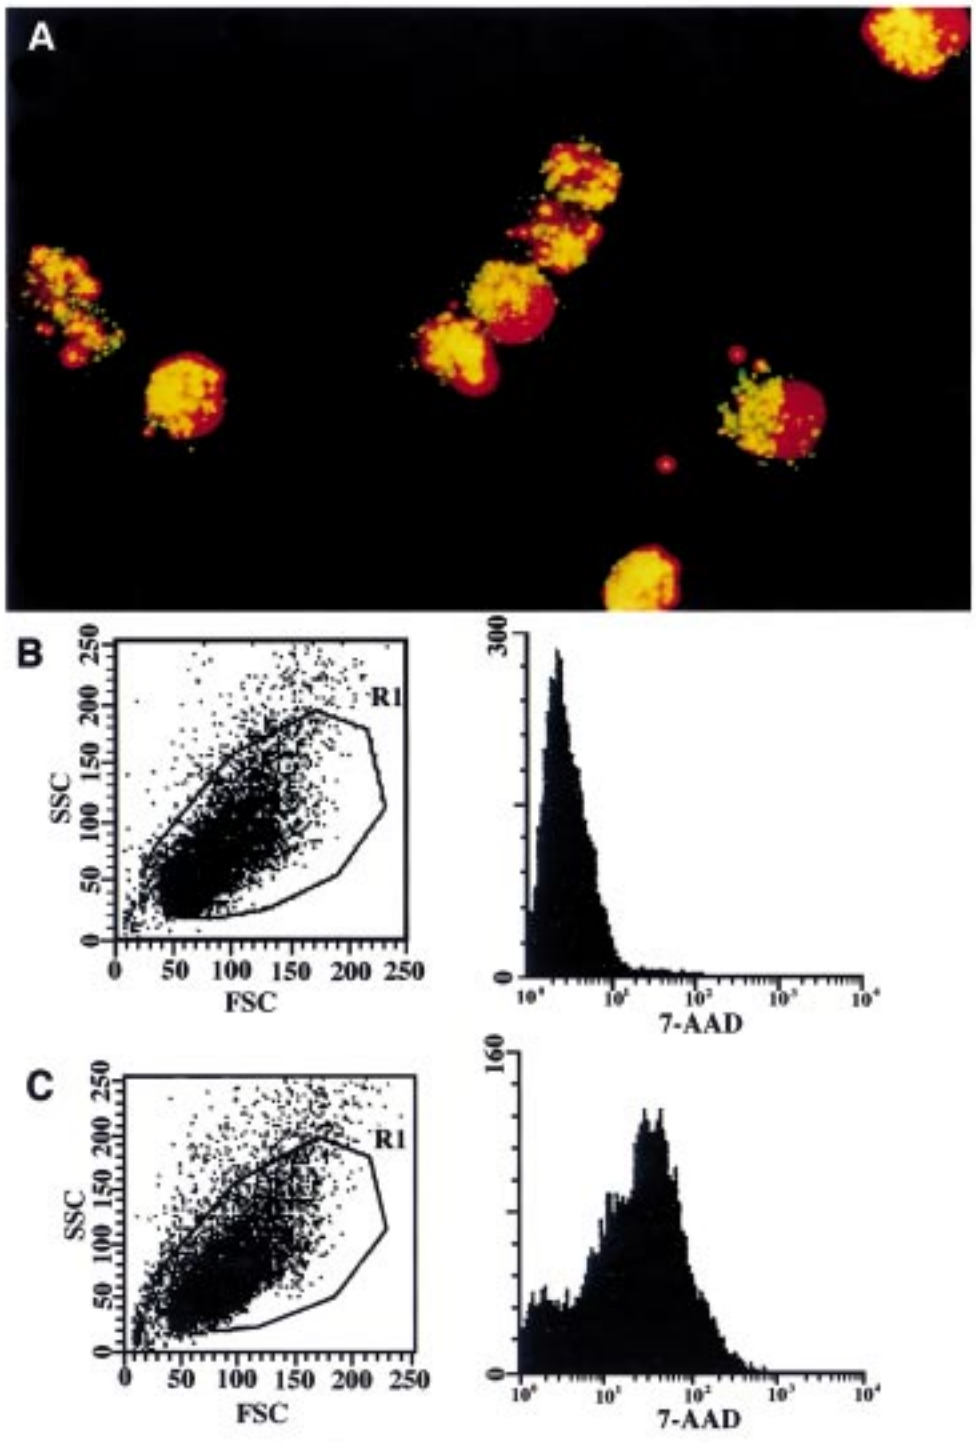

Figure 3. Localization of loligomer 4−plasmid complexes in CHO cells. (A) Photograph of an unfixed preparation of viable CHO cells after a 4 h exposure to loligomer 4−plasmid complexes depicting the intracellular distribution of fluorescein-labeled loligomer 4 (green color) complexed with 7-AAD-labeled plasmid pGL2 (red color) in CHO cells. The comigration of labeled loligomer 4 and 7-AAD-labeled plasmid gives rise to intracellular areas of yellow fluorescence. (B) FACS analysis of CHO cells after a 4 h exposure to 7-AAD labeled plasmid. (Panel B, left side) Flow cytometric pattern (forward scatter and side scatter properties) indicating that most CHO cells remained viable following this treatment. (Panel B, right side) Histogram of viable cells (R1) labeled with the 7-AAD labeled plasmid. Most cells do not bind or internalize 7-AAD (autofluorescence). (C) FACS analysis of CHO cells after a 4-hour exposure to loligomer 4- complexed with the 7-AAD labeled plasmid. (Panel C, left side) Flow cytometric pattern (forward scatter and side scatter properties) indicating that most CHO cells remained viable following their exposure to these complexes. (Panel C, right side) Histogram of viable cells (R1) labeled with the peptide- 7-AAD labeled plasmid complex. Most cells (>70%) bind and internalize 7-AAD (panel A) suggesting that the plasmid requires the presence of loligomer 4 to effectively be imported inside CHO cells.

Micromolar Concentrations of Loligomer 4 Facilitate Efficient Gene Transfer. The transfection efficiency of the pGL2 luciferase vector complexed to loligomer 4 into CHO cells was confirmed by monitoring the extent of luciferase activity present in the cytosol of CHO transfected cells. The histogram presented in Figure 3A highlights the level of luciferase activity (per milligram of protein) in CHO cell extracts as a function

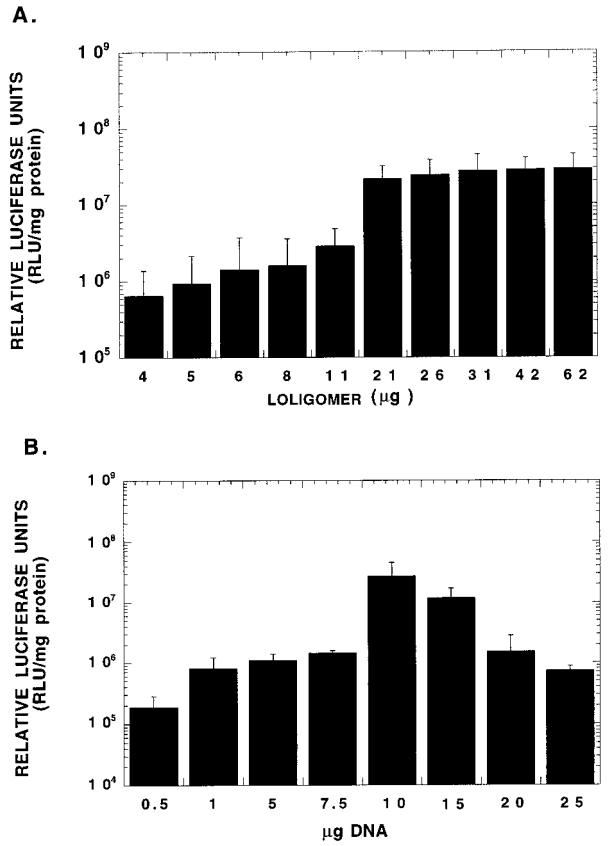

Figure 4. Levels of luciferase activity detected in extracts of CHO cells transfected with loligomer 4-pGL2 plasmid complexes. The luciferase activity present in cell lysates is reported as relative light units per milligram of protein (RLU/mg of protein). It represents a late stage measurement of the transfection efficiency of loligomer-plasmid complexes in CHO cells. (A) Effect of loligomer 4 concentration on recorded luciferase activity. The pGL2 luciferase plasmid (10 μg) was complexed with increasing amounts of loligomer 4 (4−62 μg). (B) Plasmid concentration on recorded luciferase activity. Loligomer 4 (31 μg) was complexed with increasing amounts of pGL2 luciferase plasmid (0.5−25 μg). Luciferase activity was not observed in CHO cells transfected with naked DNA only.

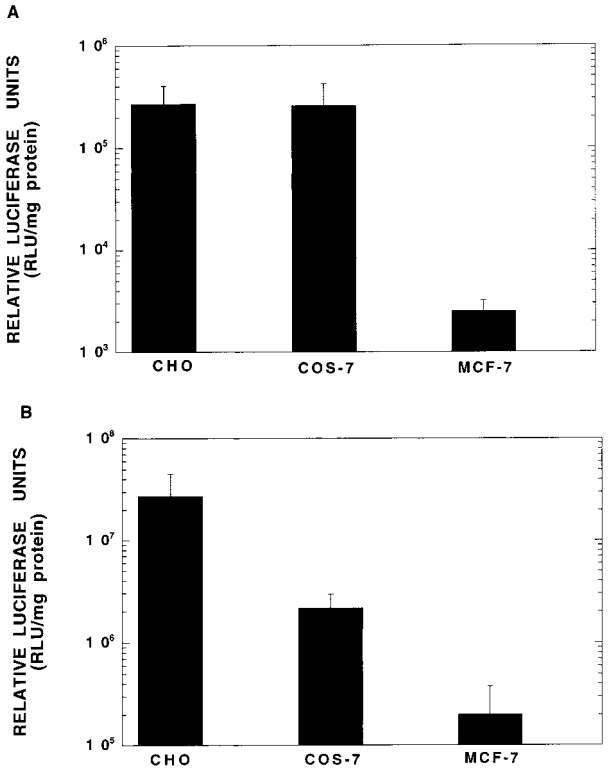

Figure 5. Comparison of transfection efficiencies for loligofection in CHO, COS-7, and MCF-7 cells. Transfections were performed on cells grown as monolayers (Panel A) or maintained in suspension (Panel B) with loligomer 4−plasmid complexes. Transfection efficiency is reported in terms of luciferase activity (RLU/mg of protein) present in cell lysates. A 31 μg aliquot of loligomer 4 was complexed with the plasmid pGL2 luciferase (10 μg). Transfection with naked DNA did not result in any luciferase activity.

of the weight ratio of loligomer 4 to plasmid used to initially transfect CHO cells. A 10 μg aliquot of the plasmid pGL2 luciferase was mixed with increasing amounts of loligomer 4. Significant levels of loligofection yielding (0.06−0.3) $\times$ 10^7 relative luciferase unit (RLU)/mg of protein were observed at loligomer 4 concentrations ranging in values from 4 to 11 μg. However, a 7-fold increase in luciferase units (2.1 $\times$ 10^7 RLU/mg of protein) was obtained when 21 μg of loligomer 4 (1.1 μmol; loligomer 4-to-plasmid weight ratio, 2.1) was used in the transfection procedure. The magnitude of the luciferase signal then reached a plateau between 21 and 62 μg of loligomer 4 (loligomer 4 to plasmid weight ratios between 2.1 and 6.2) with RLU values leveling to between 2.4 $\times$ 10^7 and 2.8 $\times$ 10^7 RLU /mg of protein.

Loligomer 4 to Plasmid Weight Ratio of 3 Is Optimal To Achieve Maximal Transfection Efficiency. A fixed concentration of loligomer 4 (31 μg; 1.67 μmol) was mixed with increasing amounts of pGL2 luciferase plasmid DNA ranging 0.5−25 μg (Figure 4B; log scale units). A low level of relative luciferase activity (1.9 $\times$ 10^5 RLU/mg of protein) could be detected in CHO cells transfected with a mixture containing 0.5 μg of plasmid DNA, reaching a maximal value of 2.7 $\times$ 10^7 RLU/mg of protein at a plasmid content of 10.0 μg (loligomer 4 to plasmid weight ratio of 3.1). Further increase in plasmid DNA content in relation to loligomer 4 resulted in a decreased transfection efficiency down to 1.2 $\times$ 10^7 RLU/mg of protein at 15 μg of pGL2 luciferase plasmid and 0.07 $\times$ 10^7 RLU/mg of protein at 25 μg of plasmid.

Transfection Efficiency of Loligomer 4 Is Greater When Cell Suspensions Are Treated with Loligomer:Plasmid Complexes Rather Than Cell Monolayers. Three cell lines (CHO, COS-7, and MCF-7) were used to evaluate the transfection efficiency of our loligomer 4−plasmid complexes. Cell lines maintained as monolayers, then transfected with 10 μg of pGL2 luciferase plasmid DNA and 31 μg of loligomer 4, exhibited very low transfection efficiency as monitored by the resulting levels of luciferase activity (Figure 5 A; log scale units). Recorded light emissions ranged in values between 2.6 and 2.7 $\times$ 10^5 RLU/mg of protein for COS-7 and CHO cells and 2.5 $\times$ 10^3 RLUs with MCF-7 cells. The transfection efficiency was found to be more prominent and efficient (up to 100-fold increases) when cells were transfected as suspensions (Figure 5B), where luciferase activity values of 2.7 $\times$ 10^7 and 0.2 $\times$ 10^7 RLUs were recorded for CHO and COS-7 cells, respectively. Finally, a value of only 2 $\times$ 10^5 RLU/mg of protein was registered when MCF-7 cells were transfected as suspension cells, suggesting that the efficiency of this procedure remains dependent on the cell line.

Comparing Loligomer 4 to Other Transfection Agents in the Context of Cells Maintained in Suspension. The efficacy of loligomer 4 as a prototypic transfection agent is significant only in the context of cells presented as suspensions. The relative ability of

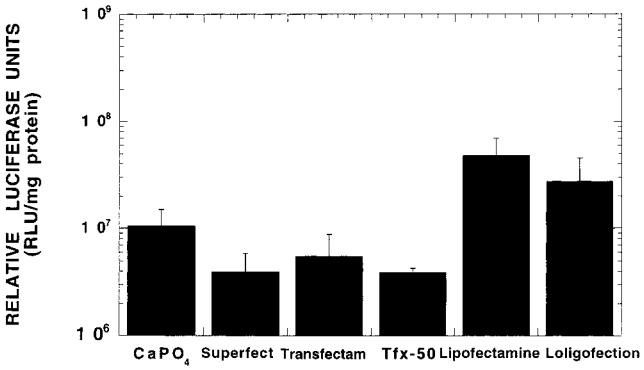

Figure 6. Comparison of transfection efficiencies (luciferase activity) in CHO cells for loligofection in relation to other established nonviral transfection methods. The luciferase activity present in cell lysates is reported as relative light units per milligram of protein (RLU/mg of protein). The luciferase activity was monitored using 10 μg of pGL2 luciferase and 31 μg of loligomer 4. Other transfection methods including calcium phosphate and commercially available agents such as Superfect (Qiagen), Transfectam (Promega), Tfx-50 (Promega), and Lipofectamine (Gibco-BRL) were compared to loligofection. No luciferase activity was observed in CHO cells transfected with naked DNA only.

loligomer 4−plasmid complexes to transfect CHO cells in suspension was compared to other available methods (Figure 6) in order to highlight their comparable potential as nonviral transfection strategies. Agents such as Superfect (Qiagen), Transfectam (Promega), and Tfx-50 (Promega) all facilitated the transfection of the pGL2 luciferase plasmid into CHO cells maintained in suspension with RLU/mg of protein values ranging between 0.4 $\times$ 10^7 and 0.6 $\times$ 10^7. Similarly, luciferase activities of the order of 1.0 $\times$ 10^7 RLU/mg of protein were recorded with the calcium phosphate method. Higher values [(2.7−4.8) $\times$ 10^7 RLU/mg of protein) were observed with Lipofectamine (Gibco-BRL) and loligomer 4. All differences in transfection efficiencies must be contrasted with the fact that none of the previous established methods were optimized for transfecting cells in suspension. Nevertheless, there is a clear indication that the loligomer 4 construct represents a useful template for designing alternate classes of transfection agents.

***β*-Galactosidase and Green Fluorescent Protein Are Expressed in Transfected CHO Cells.** CHO cells were transfected with 10 μg of pCMV β-gal or pGFP complexed to 31 μg of loligomer 4. The reporter plasmid pCMV β-gal incorporates a β-galactosidase gene. The production of β-galactosidase was monitored by the cleavage of its substrate, 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-gal), which resulted in an indigo color precipitate present in CHO cells successfully transfected with the loligomer 4−plasmid complex (Figure 7B). In contrast, no color was observed for cells exposed to the plasmid alone (Figure 7A). The plasmid pGFP harbors a gene coding for a green fluorescent protein (GFP). The transfection and expression of this plasmid in CHO cells occurs only when complexed to loligomer 4 (Figure 7C). The transfection efficiency of loligomer 4−plasmid complexes in CHO cells in terms of the percentage of cells expressing the reporter proteins ranges in value from 5 to 10% of cells.

DISCUSSION

The transfection of eukaryotic cells has become an important technique for the study of cellular genes and for the development of gene transfer studies. Advances in gene therapy depend in large part on the development of delivery systems capable of introducing DNA into a target cell or tissue. These approaches include the use of carrier molecules, such as liposomes or chemical precipitates, to self-replicating systems, such as viruses (*36*). In this study, a peptide-based, intracellular vehicle, termed loligomer 4 (*23*, *24*), was tested for its ability to form complexes with plasmid DNA and facilitate their transport into cells. Loligomer 4 contains eight copies of the SV40 large T antigen nuclear localization signal (*37*) as well as eight pentalysines sequences that act as a cytoplasmic translocation signal (CTS; ref *23*) (Figure 1).

The branched nature of loligomers is derived from a synthetic approach initially developed for the creation of multiple antigenic peptides (*34*, *35*). This tentacular geometry affords several distinct advantages in terms of incorporating tissue-targeting sequences and cytotoxic moieties. First, branching reduces the impact of proteolytic degradation on loligomers (*23*, *24*) since the cleavage of one or more arms does not destroy the overall localization properties of the construct. Second, multivalency represents an important feature of loligomers and other recent delivery strategies involving dendrimers (*14*, *38*) and peptabodies (*39*) in terms of enhancing the avidity of such constructs for a cell surface receptor or to promote their localization properties inside cells. For example, it has been demonstrated that, in the case of protein conjugates, the efficiency of their nuclear targeting property increases with the number of NLS sequences coupled to them (*40*). The attachment of the SV40 Large T antigen nuclear localization signal peptide induced the nuclear accumulation of the conjugated DNA in digitonin-permeabilized cells (*41*). In the case of loligomers, the display of eight pentalysine sequences dramatically enhances its cellular uptake (*23*).

The cellular uptake and intracellular routing of loligomer 4 has recently been studied by flow cytometry and microscopy (*24*). Loligomer 4 was shown to be irreversibly retained inside cells when its intracellular routing leads to its accumulation into the nucleus (*24*).

The major objective of this study was to determine if loligomer 4 is able to act as a vehicle in terms of delivering large molecular cargos such as plasmids inside cells. Loligomer 4 is a branched cationic peptide with a theoretical net charge of +71. This construct was thus expected to interact noncovalently with the negatively charged phosphate backbone of plasmid DNA. Loligomer 4 retarded the electrophoretic migration of plasmid DNA in agarose gels (Figure 2) starting at a 1:2 peptide:DNA weight ratio. The minimal theoretical charge ratio ($\pm$) necessary for loligomer 4 to complex plasmid DNA was calculated to be $\sim$6.5. In contrast, the optimal level of transfection in CHO cells observed for these peptide−DNA complexes occurs at a loligomer 4:plasmid DNA weight ratio of 3: 1 (Figure 4). The efficiency of this transfection approach was monitored using a plasmid incorporating a luciferase reporter gene. Overall, these results suggest that a range of peptide−DNA complexes exist in solution and that efficient levels of transfection are achieved with complexes presenting a charge ratio between 30 and 70 (loligomer 4:plasmid DNA weight ratios between 2:1 and 6:1; Figure 4). Previous studies have shown that the interaction of plasmid DNA with cationic substrates results in a marked condensation of DNA molecules into 80−100 nm diameter toroid structures (*8*). The ratio of loligomer 4 to DNA may thus regulate the fraction of "packaged" plasmid complexes optimally suited to their penetration into cells and intracellular routing.

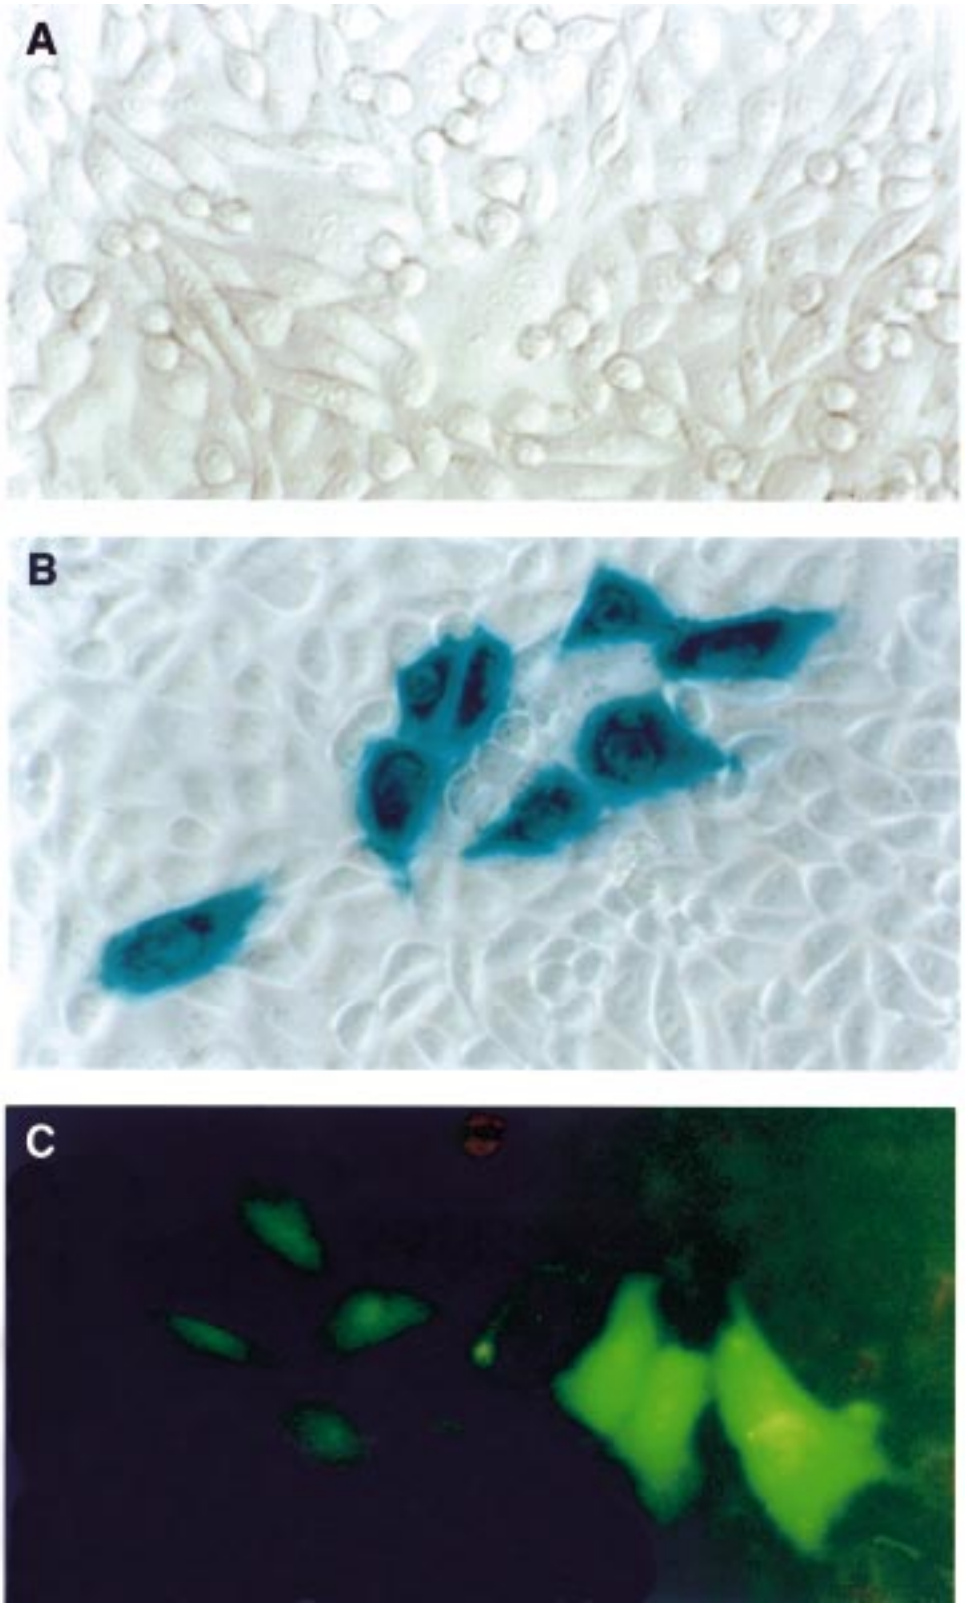

Figure 7. Expression of β-galactosidase and GFP in CHO cells. (A) CHO cells transfected with the naked plasmid pCMV β-gal showing no indigo staining of cells. (B) Indigo-colored cells are observed in this preparation of CHO cells transfected with loligomer 4-pCMV β-gal plasmid. (C) Fluorescent green cells were visualized in a field of CHO cells transfected with loligomer 4-pGFP plasmid.

The import of loligomer 4 into CHO cells occurs through absorptive endocytosis (*23*, *24*). One-arm peptide or loligomer constructs lacking the cytoplasmic translocation domains were either poorly endocytosed or unable to enter cells (*23*). Loligomer 4 is typically observed in vesicular compartments as well as in the cytosol of CHO cells within the first 30 min of exposing cells to this construct. After a few hours, a significant fraction of internalized loligomer 4 accumulates in the cell nucleus (*23*, *24*). Free loligomer 4 and loligomer 4−plasmid DNA complexes represent two (or more) distinct presentations of this peptide vehicle. The presentation of loligomer 4 as part of a peptide−DNA complex may alter its ability to enter cells. In addition, plasmid DNA may not be

routed through the same intracellular pathway as loligomer 4. The migration of loligomer 4−plasmid DNA complexes was thus analyzed by fluorescence microscopy and flow cytometry. The migration of the reporter plasmid was monitored by marking the plasmid with the fluorescent DNA intercalator 7-AAD, a dye that does not enter into viable cells. Loligomer 4 was labeled with fluorescein, and dual-labeled complexes of loligomer 4−plasmid DNA were created by mixing both fluorescent entities together. The majority of CHO cells (>70%) rapidly imported the labeled complex (Figure 3, panel A and panel C, right side) while the labeled plasmid alone was not endocytosed by cells (Figure 3, panel B, right side). An image depicting the distribution of the two fluorophores inside CHO cells after 4 h is presented in Figure 3A. No fluorescence signal was observed for cells exposed to the labeled plasmid alone (results not shown). Yellow areas in Figure 3A represent zones where plasmids (7-AAD, red fluorescence) and loligomer 4 (green fluorescence) comigrated inside CHO cells. The intracellular distribution of yellow fluorescence is reminiscent of previous patterns observed for loligomer 4 alone (*23*, *24*), suggesting that its complexation with plasmid DNA has not altered its properties as an intracellular shuttle. Intracellular regions of red fluorescence highlight areas where the labeled plasmid is not complexed to loligomer 4. Alternatively, 7-AAD may rapidly exchange between plasmid DNA and intracellular pools of DNA. Overall, these results suggest the comigration of a significant population of peptide−plasmid DNA complexes inside CHO cells and the possible dissociation of a large fraction of these complexes inside cells yielding free plasmid or the exchange of 7-AAD. The relatively global distribution of fluorescein-labeled loligomer and 7-AAD in these viable CHO cells suggests that both the cytosol and nucleus have been targeted by these agents.

The uptake of loligomer 4 into cells is greater for cells either maintained in suspension or gently trypsinized to generate a cell suspension than for cells presented as monolayers (*24*). This difference in cellular uptake is less significant, however, in the case of nonadherent cell lines such as Daudi and EL4 (*24*). It was thus predicted that the levels of transfection efficiencies observed for loligomer 4−plasmid DNA complexes would be greater for CHO, COS-7, and MCF-7 cells grown in suspension rather than monolayers. Results presented in Figure 5 confirmed this hypothesis and support the view that the import of plasmid DNA as part of a loligomer 4−plasmid complex follows the internalization mechanism proposed for loligomer 4 itself. The reason the import mechanism is enhanced by cells presented as suspensions remains unclear although effects due to cytoskeletal components have now been ruled out (*24*). No differences in transfection efficiency were observed for cells grown in spinner flasks as opposed to suspension cells arising from trypsinizing cell monolayers.

The value of loligomer 4 as a transfection agent was evaluated using two approaches. The efficiency of transfection of loligomer 4 complexed to a reporter plasmid harboring the luciferase gene was initially compared to other nonviral transfections methods. The major limitation of such an analysis stems from the fact that transfections were performed on cell suspensions (significant levels of transfection for loligomer 4−plasmid complexes are only achieved for cells presented as suspensions; Figure 5). Since other transfection strategies are typically performed on cell monolayers, the resulting transfection conditions for these methods were not optimal. Nevertheless, the transfection efficiency observed in CHO cells with loligomer 4−plasmid DNA complexes was comparable to results observed for lipofectamine and better than results obtained for other transfection agents used in this study (Figure 6). Comparable results (using luciferase as a reporter protein) have been reported for other recently developed cationic agents (*13*, *42*). A more conclusive method of evaluating the value of loligomer 4−plasmid complexes in transfecting cells is to simply tabulate the percentage of cells that either produce β-galatosidase (reporter plasmid, pCMV β-gal) or GFP (reporter plasmid, pGFP) within a field of cells. Calculated percentages for CHO cells transfected with loligomer 4−plasmid DNA complexes ranged in values from 5 to 10% depending on the vector used. Images of CHO cells expressing these reporter proteins are presented in Figure 7 (panels B and C).

Finally, a clear difference exists between the level of import of loligomer 4−plasmid complexes by cells (>70% of viable cells take up the constructs; Figure 3) and the maximal level of transfection observed (∼10% of cells). Reasons for this discrepancy probably lie in the design of loligomer 4 itself. For example, a large fraction of this construct remains trapped in vesicular compartments (*24*) since we have not yet introduced a signal in this construct to favor its escape from such compartments. Their release from cytoplasmic vesicles is at best inefficient but does occur as demonstrated in this report as well as in previous studies (*23*, *24*). Nevertheless, the fact that a prototypic peptide design such as loligomer 4 can already act as a transfection agent demonstrates the potential of creating biologically effective, multitasking peptide constructs using simple solid-phase strategies. Loligomers may thus represent useful vehicles for gene transfer experiments (*43*), antisense technologies (*38*), DNA-based immunization strategies (*44*), as well as photodynamic therapy (*45*).

Synthesis and Selective Cytotoxicity of a Hyaluronic Acid–Antitumor Bioconjugate

Yi Luo and Glenn D. Prestwich*

Department of Medicinal Chemistry, The University of Utah, 30 South 2000 East, Room 201, Salt Lake City, Utah 84112-5820. Received March 18, 1999; Revised Manuscript Received May 21, 1999

A cell-targeted prodrug was developed for the anti-cancer drug Taxol, using hyaluronic acid (HA) as the drug carrier. HA–Taxol bioconjugates were synthesized by linking the Taxol 2′-OH via a succinate ester to adipic dihydrazide-modified HA (HA-ADH). The coupling of Taxol-NHS ester and HA-ADH provided several HA bioconjugates with different levels of ADH modification and different Taxol loadings. A fluorescent BODIPY–HA was also synthesized to illustrate cell targeting and uptake of chemically modified HA using confocal microscopy. HA–Taxol conjugates showed selective toxicity toward the human cancer cell lines (breast, colon, and ovarian) that are known to overexpress HA receptors, while no toxicity was observed toward a mouse fibroblast cell line at the same concentrations used with the cancer cells. The drug carrier HA-ADH was completely nontoxic. The selective cytotoxicity is consistent with the results from confocal microscopy, which demonstrated that BODIPY–HA only entered the cancer cell lines.

INTRODUCTION

Hyaluronic acid (HA)[1] (Figure 1), a linear polysaccharide of alternating D-glucuronic acid (GlcUA) and *N*-acetyl-D-glucosamine (GlcNAc) units, adopts a three-dimensional structure in solution that shows extensive intramolecular hydrogen bonding. This restricts the conformational flexibility of the polymer chains and induces distinctive secondary (helical) and tertiary (coiled coil) interactions (*1*). HA is one of several glycosaminoglycan components of the extracellular matrix (ECM), the synovial fluid of joints, and the scaffolding comprising cartilage (*2*). The remarkable viscoelastic properties of HA and commercial cross-linked derivatives (*3*) account for their usefulness in joint lubrication. HA–protein interactions play crucial roles in cell adhesion, growth, and migration (*4*–*6*), and HA acts as a signaling molecule in cell motility, in inflammation, wound healing, and cancer metastasis (*7*). The immunoneutrality of HA makes it an excellent building block for the development of novel biocompatible and biodegradable biomaterials used in tissue engineering and drug delivery systems (*8*–*10*). For example, HA has been employed as both a vehicle and angiostatic agent in cancer therapy (*11*–*13*).

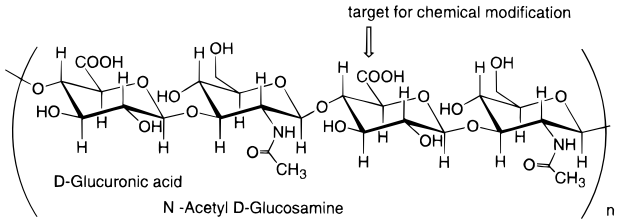

Figure 1. Tetrasaccharide fragment of HA showing the disaccharide repeat units.

The use of biocompatible polymers in the treatment of various ailments has expanded rapidly in the last two decades (*14*). Moreover, derivatization of such polymers with reporter groups (*15*) and drugs (*16*, *17*) has emerged as a powerful method for controlling delivery and release of a variety of compounds. Small drug molecules can be linked to the polymer that allows controlled release of the free bioactive group. In general, coupling of antitumor agents to biopolymers provides advantages in drug solubilization, stabilization, localization, and controlled release (*18*). For example, the linking of a cytotoxic small molecule such as adriamycin to poly(hydroxymethyl)-acrylamide (HPMA) gives a new material with improved in vitro tumor retention, a higher therapeutic ratio, avoidance of multidrug resistance (*19*), and encouraging clinical results. In work with a naturally occurring biocompatible polymer, mitomycin C and epirubicin were coupled to HA by carbodiimide chemistry; the former adduct was selectively taken up by, and toxic to, a lung carcinoma xenograft (*20*).

HA is overexpressed at sites of tumor attachment (*21*) to the mesentery and provides a matrix that facilitates invasion (*22*). HA is an important signal for activating kinase pathways (*23*, *24*) and regulating angiogenesis in tumors (*25*). Moreover, several types of cellular HA receptors respond to HA as a signal. These include CD44, a family of glycoproteins originally associated with lymphocyte activation; RHAMM, the receptors for HA-mediated cell motility (*26*, *27*); and HARLEC, responsible

(b) Purified HA−Taxol conjugate detection at λ = 227 nm. Only the Ultrahydrogel 250 column was employed. Eluent was 150 mM, pH 6.5, phosphate buffer/MeOH = 80:20 (v/v); the flow rate was 0.5 mL/min.

for receptor-mediated uptake of HA in liver. Using radiolabeled HA analogues and HA-coupled prodrugs, it

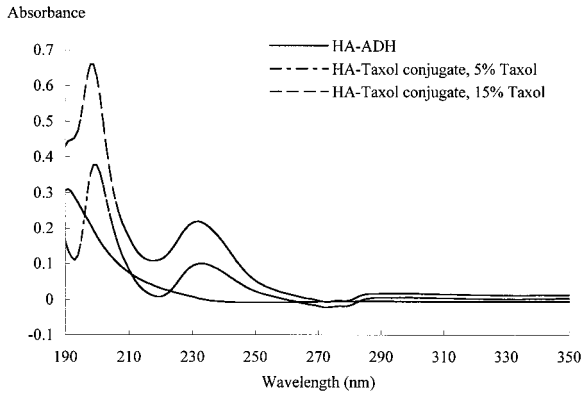

Figure 4. UV spectra of HA−Taxol conjugates.

was possible to selectively target tumor cells and tumor metastases through the use of chondroitin sulfate to block "housekeeping" receptors in the liver without affecting specific HA receptors of tumor cells (*28*−*31*). Targeting of anti-cancer agents to tumor cells and tumor metastases can be accomplished by receptor-mediated uptake of bioconjugates of these agents to HA (*20*). Since HA receptors (CD44, RHAMM) are overexpressed in transformed human breast epithelial cells and other cancers (*32*), selectivity for cancerous cells is markedly enhanced and overall dosages may be reduced. Moreover, coupling of antitumor agents to biopolymers can provide advantages in drug solubilization, stabilization, localization, and controlled release (*18*). Our methodology (*33*) for coupling antitumor agents to HA adds further value by specifically targeting the bioconjugate to aggressively growing cancers that overexpress HA receptors.

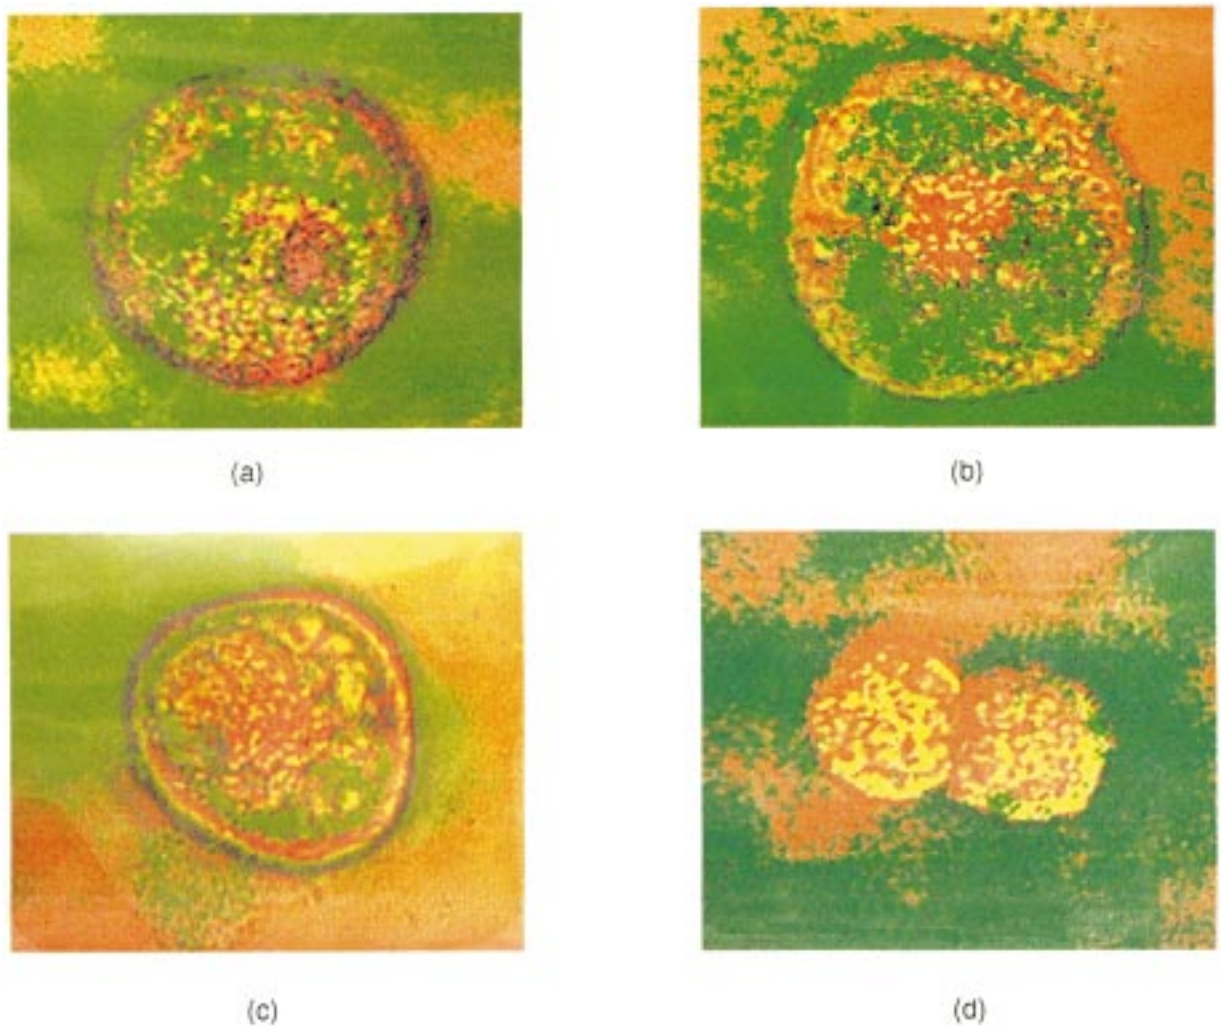

Figure 5. Targeting human breast cancer HBL-100 cells with HA-BODIPY. Panel a fluorescence image shows HA binding to cell surfaces in 3 min. Panels b and c show HA accumulation in the nucleus after 6 and 9 min. In panel d, after 20 min HA, has been completely taken up and fluorescence is dispersed throughout the cells.

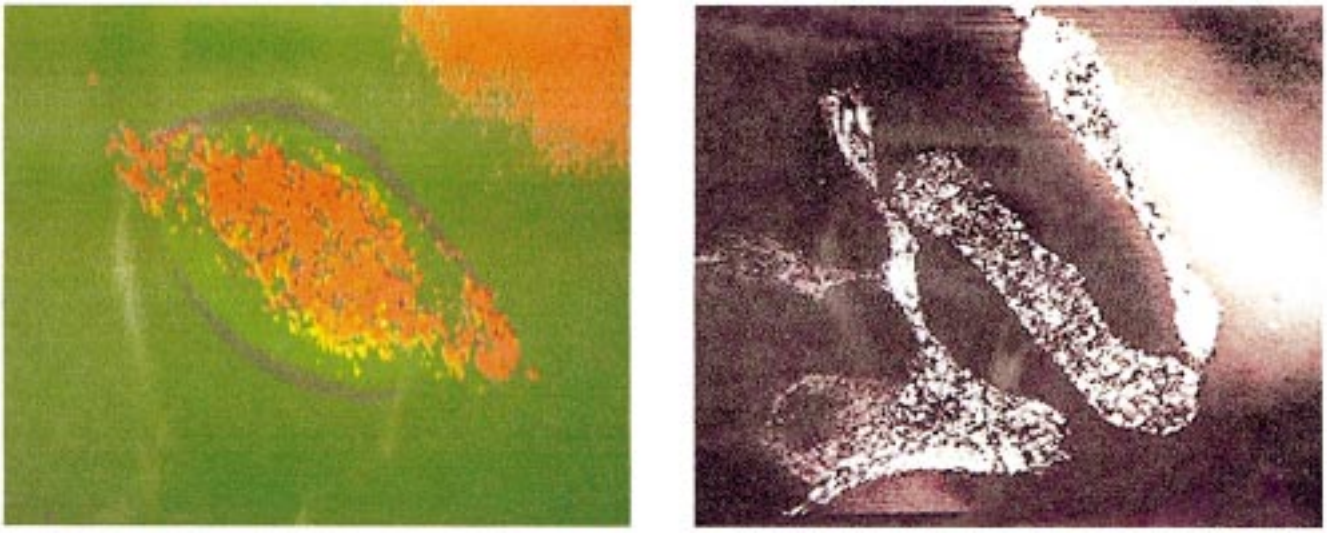

Figure 6. Targeting ovarian cancer SK-OV-3 cells with HA-BODIPY. Panel a shows HA uptake by cells in 15 min. Panel b shows HA uptake by cells in 60 min.

Paclitaxel (Taxol) (*34*), a diterpenoid originally isolated from the bark of the Pacific yew, *Taxus brevifolia*, is a powerful anti-mitotic agent that acts by promoting tubulin assembly into stable aggregated structures. It binds to microtubules and inhibits their depolymerization into tubulin. Although Taxol has shown tremendous potential as an anti-cancer compound, its use as an anti-cancer drug is compromised by its poor aqueous solubility. One attempt to address this involved preparation of 2′-OH linked water-soluble poly(ethylene glycol) derivatives

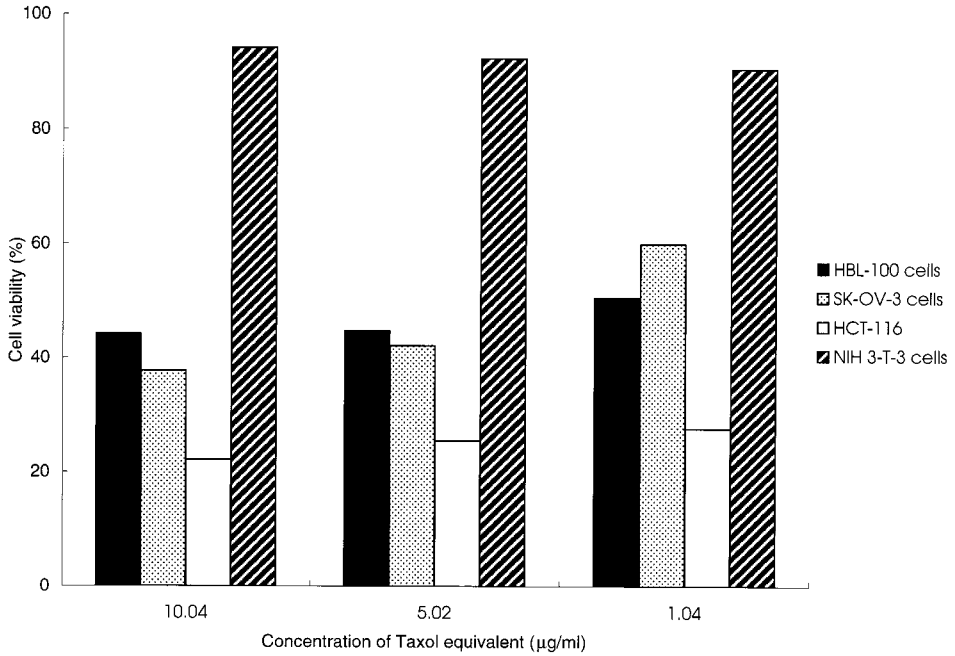

Figure 7. Cytotoxicity of HA−Taxol conjugate with 5% Taxol loading against HBL-100, SK-OV-3, HCT-116, and NIH 3-T-3 cells.

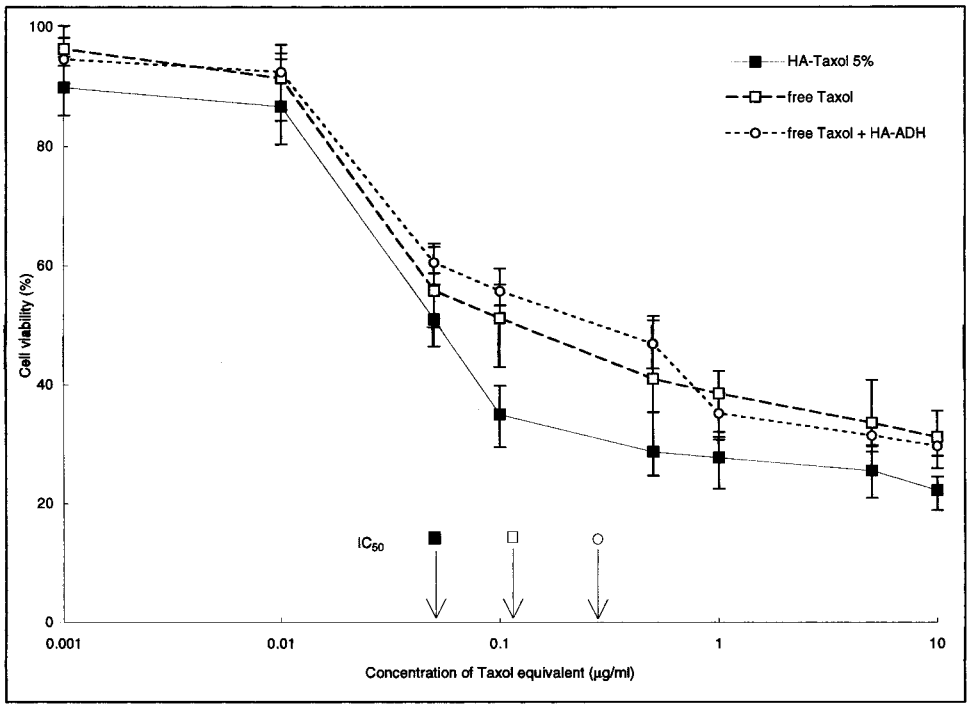

Figure 8. In vitro cytotoxicity of HA−Taxol conjugate with 5% Taxol loading against colon tumor HCT-116 cells.

(*35*). In this paper, we have taken a different approach that uses a prodrug strategy to both increase water solubility and provide cellular targeting. Thus, we selected Taxol as a model anti-cancer drug for covalent attachment to HA that had been modified with adipic dihydrazide (ADH) (*36*−*38*). The coupling of Taxol-2′-hemisuccinate NHS ester to HA-ADH was optimized to give HA−Taxol conjugates with a variety of ADH and Taxol loadings (Figure 2). Selective in vitro cell cytotoxicity was studied with an untransformed mouse fibroblast cell line (NIH 3-T-3) and with three human cell lines: HCT-116 colon tumor cells, HBL-100 breast cancer cells, and SK-OV-3 ovarian cancer cells. In addition, a fluorescent (BODIPY)-labeled HA bioconjugate was prepared and employed to visualize selective uptake of HA by confocal microscopy.

MATERIALS AND METHODS

General. Fermentation-derived HA (sodium salt, M_w 1.5 MDa) was provided by Clear Solutions Biotechnology, Inc. (Stony Brook, NY). 1-Ethyl-3-[3-(dimethylamino)-propyl]carbodiimide (EDCI), ADH, succinic anhydride, diphenylphosphoryl chloride (DPPC), *N*-hydroxysuccinimide, and triethylamine were purchased from Aldrich Chemical Co. (Milwaukee, WI). Bovine testicular hyaluronidase (HAse, 880 units/mg) was obtained from Sigma Chemical Co. (St. Louis, MO). Paclitaxel (Taxol) was purchased from CBI Tech, Inc. (Cambridge, MA). 4,4-

Difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionic acid, hydrazide (BODIPY-FL hydrazide) was obtained from Molecular Probes, Inc. (Portland, OR). All solvents were of reagent grade or HPLC grade (Fisher Scientific Co., Santa Clara, CA). CH_2Cl_2 and acetonitrile were distilled from CaH_2.

Analytical Instrumentation. All ^{1}H NMR spectral data were obtained using an NR-200 FT-NMR spectrometer at 200 MHz (IBM Instruments Inc.). UV−Vis spectra were recorded on a Hewlett-Packard 8453 UV−Vis diode array spectrophotometer (Palo Alto, CA). Gel permeation chromatography (GPC) analysis was carried out on the following system: Waters 515 HPLC pump, Waters 410 differential refractometer, Waters 486 tunable absorbance detector, Waters Ultrahydrogel 250 and 2000 columns (7.8 mm ID × 30 cm) (Milford, MA). The GPC eluent was 150 mM phosphate buffer, pH 6.5:MeOH = 80:20 (v/v), and the flow rate was 0.5 mL/min. The system was calibrated with HA standards supplied by Dr. S. Gustafson (University of Uppsala, Sweden), and thus the molecular sizes of each HA oligosaccharide and the corresponding bioconjugates were calculated from the standard samples. Confocal fluorescence images of HA-BODIPY binding and uptake by cells were recorded using a Zeiss Microscope (Carl Zeiss, Inc., Germany). Coulter Counter was from Coulter Electronics, Inc. (Hialeah, FL). Cell viability was determined by thiazoyl blue (MTT) dye uptake protocols at 540 nm, which was recorded on a Bio-Rad M-450 microplate reader (Hercules, CA).

Synthesis of Taxol-NHS Ester. To a stirred solution of 270 mg of Taxol and 38 mg (1.2 equiv) of succinic anhydride in 13 mL of CH_2Cl_2 at room temperature was added 36 μL (10-fold molar excess) of dry pyridine. The reaction mixture was stirred for 3 days at room temperature and then concentrated in vacuo. The residue was dissolved in 5 mL of CH_2Cl_2, and Taxol-2′-hemisuccinate was purified on silica gel (wash with hexane; elute with ethyl acetate) to give 258 mg of product (86%). FAB-MS calcd for $C_{51}H_{55}NO_{17}$: 953.99. Found: 954.4 (MH^+).

Next, *N*-hydroxysuccinimido diphenyl phosphate (SDPP) was prepared from 10 mmol of diphenylphosphoryl chloride, 10 mmol of *N*-hydroxysuccinimide, and 10 mmol of triethylamine in 6 mL of CH_2Cl_2 as previously described (*39*). Crude SDPP was triturated with ether, dissolved in ethyl acetate, washed (2 × 10 mL H_2O), dried ($MgSO_4$), and concentrated in vacuo to give SDPP with mp 89−90 °C (85%). To a solution of 150 mg of Taxol-hemisuccinate and 82 mg (1.5 equiv) of SDPP in 5 mL of acetonitrile was added with 88 μL (4 equiv) of triethylamine. The reaction was stirred for 6 h at room temperature, and then concentrated in vacuo. The residue was dissolved in 5 mL of ethyl acetate and 2 mL of hexane and purified on silica gel. SDPP gave superior yields in less time and under milder conditions than did any carbodiimide coupling reagent. The purified Taxol-NHS ester was dried for 24 h in vacuo at room temperature to give 134 mg (80%). FAB-MS calcd for $C_{55}H_{58}N_2O_{19}$: 1051.07. Found: 1051.5 (MH^+).

Preparation of Low Molecular Weight (LMW) HA. To a solution of 2.0 g of high molecular mass HA (1.5 MDa) in pH 6.5 PBS buffer (4 mg/mL) was added hyaluronidase (HAse) (10 units/mg of HA). The degradation was carried out at 37 °C, 190 rpm stirring for 1 h, then 95 °C for 20 min. Dialysis tubing (M_w cutoff 3 500 Da) was prepared by soaking the membrane in water at room temperature for 3−4 h and subsequently rinsing it with water. The solution was dialyzed against water for 4 days using this washed membrane tubing. The retained material was filtered through a 0.2 μm cellulose acetate membrane (Corning) and lyophilized to give 1.12 g of LMW HA (56%).

Adipic Dihydrazido-Functionalized HA (HA-ADH). HA-ADH was prepared as described previously (*37*, *38*, *40*). In a representative example, LMW HA (50 mg) was dissolved in water to give a concentration of 4 mg/mL, and then a 5-fold excess of ADH was added into the solution. The pH of the reaction mixture was adjusted to 4.75 by addition of 0.1 N HCl. Next, 1 equiv of EDCI was added in solid form. The pH of the reaction mixture was maintained at 4.75 by addition of 0.1 N HCl. The reaction was quenched by addition of 0.1 N NaOH to adjust the pH of reaction mixture to 7.0. The reaction mixture was then transferred to pretreated dialysis tubing (Mw cutoff 3 500) and dialyzed exhaustively against 100 mM NaCl, then 25% EtOH/H_2O and finally H_2O. The solution was then filtered through 0.2 μm cellulose acetate membrane, flash frozen, and lyophilized. The purity of HA-ADH was measured by GPC. The substitution degree of ADH was determined by the ratio of methylene hydrogens to acetyl methyl protons as measured by ^{1}H NMR. In this example, 37 mg of HA-ADH was obtained with an 18% loading based on available carboxylates modified.

HA−Taxol. Several loadings were prepared following a general protocol (Figure 2). In a representative example, HA-ADH with 18% ADH loading (10 mg, 4.4 μmole hydrazide) was dissolved in 3 mM, pH 6.5, phosphate buffer to give a concentration of 1 mg/mL. To this mixture was added Taxol-NHS ester dissolved in sufficient DMF (DMF:H_2O = 2:1, v/v) to give a homogeneous solution, and the reaction mixture was stirred at room temperature for 24 h. The reaction mixture was dialyzed successively against 50% acetone/H_2O and water (membrane tubing, Mw cutoff 3 500). The solution was then filtered through a 0.2 μm membrane and then lyophilized. The purity of HA−Taxol conjugate was measured by GPC analysis. Taxol loading was determined by UV absorbance (λ_{max} = 227 nm, $\epsilon = 2.8 \times 10^4$) in 80:20 CH_3CN:H_2O.

BODIPY-FL-Labeled HA. In a representative reaction, 100 mg of LMW HA was dissolved in 10 mL of H_2O, and 10 mL of an acetone solution (0.8 mg/mL) of BODIPY−FL hydrazide was added. The pH was adjusted to 4.75 with 0.1 N HCl, and then 51.5 mg (3 molar equiv) of EDCI was added in solid form into the mixture. The reaction was stirred overnight at room temperature at pH 4.75. The HA-BODIPY was purified by dialysis against H_2O, and its purity was characterized by GPC with detection at 210 nm (HA) and 502 nm (BODIPY).

In Vitro Cell Culture Cytotoxicity. The cytotoxicity of HA−Taxol conjugates was determined using a 96-well plate format in quadruplicate with increasing doses: 0.001, 0.01, 0.1, 0.5, 1, 5, 10, 50, and 100 μg/mL. Each well contained approximately 20 000 cells in 200 μL of cell culture media. Cells were cultured in the following media: HBL-100 cells, high glucose D-MEM (Dulbecco's Modified Eagle Medium) + 10% FBS (fetal bovine serum) + 1% sodium pyruvate; SK-OV-3 cells, D-MEM/F12 + 10% FBS; HCT-116 cells, α-MEM (Minimal Essential Medium, Eagle) + 10% FBS; NIH 3-T-3 cells, high glucose D-MEM + 10% FBS.

HA−Taxol conjugates and HA-ADH control were added as stock solutions in DMSO:H_2O = 1:1 (v/v); free Taxol was added as a DMSO stock solution. A 2 μL aliquot of the stock solution was added to each well of the cell culture plate. Cells were incubated at 37 °C for 3 days with the test material, and cell viability was determined using MTT dye uptake by reading plates at 540 nm.

Table 1. Optimization of ADH Modification of HA and the Reaction Condition

molar ratio of HA:ADH:EDCI	reaction time (min)	ADH loading (%)
	5	28.3
	10	31.2
	15	31.4
1:40:4	30	32.2
	60	38.6
	120	45.7
	240[a]	44.0
1:5:0.5	15	9.0
1:5:1	15	17.5
1:10:1	15	18.0
1:20:1	15	19.0
1:10:0.2	180	19.3

[a] No 0.1 N HCl was used to maintain the pH of the reaction mixture.

Response was graded as percent live cells compared to untreated controls (*41*).

RESULTS

Degradation and Modification of HA. LMW HA was generated by degradation of high molecular mass HA (1.5 MDa) with testicular HAse. This enzyme degrades HA to generate a series of even-numbered HA oligosaccharides with the *N*-acetylglucosamine moiety at the reducing terminus (*42*). Thus, incubation of a solution of high molecular mass HA in pH 6.5 PBS buffer with testicular HAse at 37 °C provided partially degraded HA. Small fragments, HA oligosaccharides, and buffer salts were removed by dialysis against H_2O (four changes per day). The final LMW HA product was lyophilized, and an aliquot was analyzed by GPC analysis: $M_n = 3883$, $M_w = 11\,199$, and molecular dispersity (DP) = 2.88. This corresponds to an average of 28 disaccharide repeats/LMW HA molecule. This preparation is quite reproducible as time, temperature, and concentrations of HA and HAse are controlled.

The use of the mild and versatile hydrazide method for preparation of chemically modified HA derivatives (*36*, *37*) allows attachment of reporter molecules, drugs, cross-linkers, and any combination of the above moieties to HA (*10*, *33*, *40*). Covalent attachment of ADH to the carboxylic acid groups of HA provides a controlled loading of pendant hydrazide functionalities arrayed along the hyaluronate backbone, used herein for the attachment of an antitumor agent. We selected LMW HA for modification in this study for four main reasons. First, it was possible to perform reproducible chemical modifications and to monitor the extent of modification by simple proton NMR methods. Second, LMW HA can be cleared from the body via ultrafiltration by the kidney. Third, the LMW HA bioconjugates were expected to provide a readily injectable nonviscous solution at concentrations up to 10 mg/mL, and the LMW materials should suffer minimal further degradation in plasma and would be rapidly taken up by cells. Finally, with LMW HA bioconjugates, we were confident that future efforts to cross-link the material into a hydrogel could also be easily controlled.

Thus, LMW HA (4 mg/mL) was mixed with ADH at several concentrations (Table 1). The pH of the reaction mixture was adjusted to 4.75, and then different quantities of solid EDCI were added in solid form to initiate the reaction. An increase in pH was observed immediately corresponding to proton uptake in the coupling reaction. The pH of the reaction mixture was maintained at 4.75 by addition of 0.1 N HCl. Preliminary studies had provided guidelines as to ratios of HA:ADH:EDCI suitable to achieve a given percentage modification of the glucuronate functions of HA. The reaction was stopped by addition of 0.1 N NaOH to adjust the pH of reaction mixture to 7.0. The HA-ADH was purified by sequential dialysis against 100 mM NaCl, 25% EtOH/H_2O, and H_2O. The dialyzed solutions were filtered through a 0.2 μm membrane, and then lyophilized to give HA-ADH in yields ranging 50−70%.

Table 2. Optimization of Taxol Loading. Both the Total ADH Modification of HA and the Molar Ratio of ADH to Taxol-NHS Ester during the Conjugation Reaction Were Varied

[a] The molar ratio used in the grafting reaction of HA-ADH and Taxol-NHS that resulted in the composition of the HA−Taxol conjugates. [b] Total ADH loading for modified HA = $y + z$. [c] Limited solubility; only soluble below 0.1 mg/mL due to high loading of Taxol.

The purity and molecular size distribution of the HA-ADH was measured by GPC. The narrow single-peak GPC profile detected by UV (210 nm) (Figure 3a) and RI indicated that both large and small impurities had been completely removed. It is essential to establish this fact rigorously to ensure that all subsequent molecules added also become covalently attached, rather than remaining noncovalently associated. In addition, the GPC results showed that there was virtually no molecular weight decrease due to further HA degradation or increase due to bifunctional cross-linking during the modification reaction. The loading of ADH on the polymer backbone was determined by ^1H NMR spectroscopy studies with D_2O as a solvent. The degree of substitution could be calculated by integration of the ADH methylene signals using the methyl resonance ($\delta = 1.95-2.00$ ppm) of the acetamido moiety of the GlcNAc residues of HA as an internal standard (*37*). Thus, ^1H NMR integration confirmed that different ADH loadings occurred with different ratios of reactants and for different reaction times. The relationship between the degree of substitution of ADH and the reaction conditions, i.e., molar ratio of HA:ADH:EDCI, and reaction time was optimized. The results are shown in Table 1. Importantly, the degree of ADH substitution on HA was influenced primarily by the HA:EDCI ratio, with the amount of excess ADH varying from 5 to 25-fold having little effect. The carbodiimide quantity is thus the controlling factor for determining ADH loading on HA.

Taxol (paclitaxel) is a taxane natural product that promotes polymerization of tubulin and stabilizes the structure of intracellular microtubules. This process has the effect of inhibiting the normal dynamics reorganization of the microtubules, which is necessary for inter-

Table 3. In Vitro Cytotoxcity of HA−Taxol Conjugates against Different Cell Lines

[a] Dissolved in 3:1 DMSO/H_2O. [b] The data in these columns show the IC_{50} of HA−Taxol conjugates against the tumor cell line. [c] The data in these columns are calculated as the Taxol equivalents present in the HA−Taxol bioconjugate using the molar ratios in Table 2. This calculation allows comparison of conjugated and free Taxol. [d] The IC_{50} value is the molarity at which 50% of tumor cell death was observed after 72 h under standard tissue culture conditions. [e] Cell type.

phase and mitotic functions. Because of the problems in administering emulsified forms of this water-insoluble drug, Taxol was selected as the model anti-cancer drug in our study. Taxol was first converted to its 2′-hemisuccinate derivative by standard methods (*43*), and its structure was confirmed spectroscopically. Second, the activated Taxol-NHS ester was prepared by coupling with SDPP. Taxol-NHS was then coupled to HA-ADH in 3 mM phosphate buffer at pH 6.50 using DMF as a cosolvent to maintain a homogeneous solution. The purification of HA−Taxol bioconjugate was carried out by dialysis of the reaction mixture against 50% acetone/H_2O. The purity of the HA−Taxol conjugate was determined by GPC analysis, monitoring absorbance at 227 nm (Figure 3b) and RI. The single symmetrical GPC peak showed that no free Taxol or other small molecular impurities remained in this preparation. The Taxol was quantified by UV absorbance at 227 nm (Figure 4) in 80% acetonitrile: H_2O. To obtain the optimal modification on HA for anticancer ability, HA−Taxol conjugates with different Taxol loading were synthesized. Table 2 shows the optimization of Taxol loading and the molar ratio of HA-ADH to Taxol-NHS during the conjugation reaction. These data demonstrate that the molar ratio of ADH to Taxol-NHS during the grafting reaction is critical in determining the Taxol loading of the bioconjugate.

Fluorescently labeled HA has been prepared with several chemistries and used in other studies of receptor-mediated uptake. Most recently, RHAMM-mediated uptake and trafficking of HA by transformed fibroblasts (*44*) was observed with Texas Red-HA. Previously, fluorescein-HA was employed to study HA uptake in a variety of systems, e.g., cells expressing CD44 variants (*21*, *45*−*48*), uptake by tumor cells for correlation with metastatic potential (*49*, *50*), internalization by chondrocytes (*51*), and as a measure of liver endothelial cell function (*52*). In this study and in the Texas Red study, hydrazide derivatives of the dyes were used to form covalent bishydrazide linkages to the HA carboxylic acid functions under the mild all-aqueous conditions employed for other hydrazide modifications of HA (*33*).

To study the binding ability of HA to tumor cells and uptake by cells, a variety of fluorescently labeled HA derivatives were prepared. Of those evaluated for use with cancer cells, we obtained the best results with the BODIPY fluorophore (Y. Luo, M. R. Ziebell, unpublished results). Thus, BODIPY−FL hydrazide was coupled to LMW HA using EDCI as the condensing agent to give HA-BODIPY, which was purified by dialysis against H_2O; the loading of GPC-homogeneous HA-BODIPY was determined spectrophotometrically to be 1.8% (based on available glucuronates).

Cell-Based Assays for Uptake and Toxicity. An aliquot (2 μL) of a 1.5 mg/mL aqueous stock solution HA-BODIPY was added to 100 μL cell culture media with tumor cells cultured on cover slips. Confocal images of HA-BODIPY uptake by HBL-100 cells can be seen in Figure 5. Initially, the HA-BODIPY can be seen on cell membrane; over the course of several minutes, it is taken up into the cell and then gradually begins to accumulate in the nucleus. After 20 min, cells showed HA-BODIPY in most compartments. Uptake of HA-BODIPY into SK-OV-3 cells occurred with a similar appearance and time course (Figure 6). These data suggest that HA binds readily to tumor cell surface and is rapidly taken up via HA receptor-mediated pathways. This supports the notion that HA should be a good targeting polymer for selective delivery of anti-cancer drugs to tumor cells. Similar results were observed independently with HA−Texas Red uptake by transformed fibroblasts (*44*). Importantly, nontransformed cells, such as the NIH 3-T-3 fibroblasts, did not show this binding and rapid uptake of HA-BODIPY.

Next, the cytotoxicity of HA−Taxol conjugates was measured using a 96-well plate format in quadruplicate with increasing doses from 0.001 to 100 μg/mL. The cytotoxicity of HA−Taxol conjugates was studied by using the MTT assay to identify cells still active in respiration (*41*). HA−Taxol conjugates showed effective cytotoxicity against SK-OV-3, HBL-100, and HCT-116 cell lines, while no cytotoxicity against NIH 3-T-3 cells was observed at concentrations up to 10 μg/mL of Taxol equivalents (Figure 7). These results confirm the selective toxicity of HA−Taxol toward different cells lines, and the known overexpression of CD44 by HBL-100 (*53*) and SK-OV-3 cells (*54*) suggests that this selective toxicity is due to receptor-mediated binding and uptake of the HA−Taxol bioconjugate.

The HA-BODIPY binding and uptake results support the hypothesis that selective toxicity of HA−Taxol is due to receptor-mediated events. This was further explored by investigating the relative toxicity of polymer-bound and free Taxol, as well as examining the effect of the polymeric carrier itself on the toxicity of the drug. Thus, Figure 8 summarizes the cytotoxicity data for HA−Taxol (5% Taxol loading) with HCT-116 colon cancer cells. The bioconjugate showed increased cytotoxicity, e.g., lower IC_{50}, relative to free Taxol or free Taxol mixed with the HA-ADH carrier. In a further control experiment, we had established that HA-ADH alone elicited no detectable change in cell viability at a concentration 10 times higher than the maximal concentration of HA−Taxol conjugate used. These data support the notion that the increased cytotoxicity of HA−Taxol conjugates requires cellular uptake of the complex followed by hydrolytic release of the active Taxol by cleavage of the labile 2′ ester linkage.

The in vitro cytotoxicity results of HA−Taxol conjugates with different modifications against different cell lines are shown in Table 3. For the least-modified HA (9% ADH modification), higher cytotoxicity was observed

as Taxol loading increased. However, the cytotoxicity of highly modified HA actually decreased at the highest Taxol loading. Apparently, high loading of Taxol decreased the solubility of HA−Taxol conjugate, masked the HA receptor recognition elements of HA, caused aggregation of the polymeric conjugate, and thus limited the toxicity of the conjugate relative to that of free drug. Clearly, the cytotoxicity of HA−Taxol conjugates depends on a balance between minimal HA modification and maximal Taxol loading.

ACKNOWLEDGMENT

Financial support for this work was provided by Department of Army (DAMD 17-9A-1-8254) and by the Huntsman Cancer Foundation at The University of Utah. Initial studies of HA modification and degradation were performed with M.R. Ziebell (UUtah) and we thank Drs. D.M. Marecak and C.M. Amann (UUtah) for assistance with Taxol modification. We are grateful to D. Schmehl and Dr. L. R. Barrows (UUtah) for assistance with cell cytotoxicity experiments and Mr. Ziebell and Dr. W. G. Pitt (Brigham Young University, Provo, UT) for assistance with confocal microscopy. We thank Dr. L. Y.-W. Bourguignon (University of Miami Medical School, Miami, FL) for providing HBL-100 and SK-OV-3 cells. We are grateful to Clear Solutions Biotech, Inc. (Stony Brook, NY) for providing HA and the Center for Cell Signaling (UUtah) for equipment and facilities.

Effect of Albumin and Polyanion on the Structure of DNA Complexes with Polycation Containing Hydrophilic Nonionic Block

David Oupický,*,† Čestmír Koňák,† Philip R. Dash,‡ Leonard W. Seymour,‡ and Karel Ulbrich†

Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, Heyrovsky Sq. 2, 162 06 Prague 6, Czech Republic, and CRC Institute for Cancer Studies, University of Birmingham, Birmingham B15 2TA, U.K. Received January 15, 1999; Revised Manuscript Received April 29, 1999

Self-assembling systems based on ionic complexes of DNA with block copolymer of *N*-(2-hydroxypropyl)-methacrylamide with 2-(trimethylammonio)ethyl methacrylate were studied as systems suitable for gene delivery. In this study, the influence of albumin and polyanion on parameters of the DNA polyelectrolyte complexes in aqueous solutions was investigated. Static and dynamic light-scattering methods were used as a main tool for characterizing these interactions. It was found that albumin is not able to release free DNA, but it can rather bind to the complexes forming ternary DNA−polycation−albumin complexes with increased hydrodynamic radii of about 10 nm. Polyanion tested, sodium poly(styrenesulfonate), was able to release free DNA in the presence of a low-molecular-weight electrolyte. In the absence of a low-molecular-weight electrolyte, only formation of ternary complexes and no DNA release was observed. The in vivo biodistribution analysis of DNA complexes showed no effect of the presence of hydrophilic nonionic poly(HPMA) on the circulatory time or organ distribution. The interaction of DNA complexes with albumin and other plasma proteins was suggested to be a major reason for the short circulatory times.

INTRODUCTION

The concept of using diblock or graft copolymers of cationic and hydrophilic nonionic monomers has been introduced as a potential way in development of nonviral gene delivery vectors (*1, 2*). So far, several different polycations have been used in combination with hydrophilic nonionic polymers to produce complexes with DNA. These include block copolymers of poly(ethylene glycol) (PEG) with poly(L-lysine) (PLL) (*3, 4*) (studied most widely) and with spermine (*5*), poly[*N*-(2-hydroxypropyl)-methacrylamide] [poly(HPMA)] with poly[2-(trimethylammonio)ethyl methacrylate chloride] [poly(TMAEM)] (*2, 6*) or graft copolymers of PEG with PLL, dextran with PLL, poly(HPMA) with PLL and poly(TMAEM) (*7, 8*).

Most of the above-mentioned block and graft copolymers have shown improved solution properties of their complexes with DNA (*2*−*4*). Block and graft copolymers offer the possibility of improving the solubility of the DNA complexes due to solubilization by the hydrophilic blocks. It has been shown in our previous papers (*6, 8, 9*) that using block or graft copolymers of *N*-(2-hydroxypropyl)-methacrylamide (HPMA) with 2-(trimethylammonio)-ethyl methacrylate chloride (TMAEM) offered such improvement in solubility of stoichiometric complexes with DNA. There was a clear relation between the content of poly(HPMA) in the copolymers and the molecular weight and size of their complexes with DNA. High contents of poly(HPMA) suppressed more efficiently aggregation of the complexed DNA through hydrophobic interactions and thus the complexes were smaller and had lower molecular weight, approaching that of the complexes containing only one DNA molecule. The effect of the presence of poly(HPMA) was even more pronounced if the complexes were formed by slow titration of polycation into DNA solution, in contrast to the complexes formed by rapid titration. While DNA complexes of poly(TMAEM) formed in water by slow titration have precipitated from the solution when the charge ratio close to unity was reached, the complexes formed by the same method using both the block and the graft copolymers of TMAEM were fully soluble. Although DNA complexes of poly(TMAEM) formed in water by the rapid titration were soluble at all the charge ratios studied (0−2), the complexes formed at charge ratios close to unity showed high degrees of aggregation. We have assumed that the solubility of the DNA−poly(TMAEM) complexes formed by the rapid titration was caused by imperfect compensation of DNA phosphate groups; the slow titration method facilitates their better compensation and thus formation of more hydrophobic and insoluble complexes.

It has also been shown (*8*) that the presence of NaCl considerably influences solution properties of the formed complexes. The complexes formed in 0.15 M NaCl solution exhibited significantly higher sizes and molecular weights than those formed in water. The formation of the complexes in distilled water resulted in small complexes, which were relatively stable when transferred into 0.15 M NaCl solution. The study showed that a relatively high content of HPMA in block or graft copolymers with TMAEM was a necessary prerequisite for achieving good stability in 0.15 M NaCl. Complexes of DNA with poly(TMAEM) and block copolymers with low contents of HPMA precipitated shortly after NaCl addition, thus, not fulfilling basic requirements for gene delivery vector intended for the in vivo use. Whereas the stability in NaCl solution and parameters of the DNA complexes (molecular weight, hydrodynamic radius) were strongly affected by the presence of hydrophilic blocks in copolymers, the ability of the polycationic part of block

or graft copolymer to interact with DNA was unaffected (*8*). Analysis of the complexes by atomic force microscopy revealed that whereas most block copolymers produce common spherical complexes, PEG−PLL complexes showed a mixture of extended toroidal and linear strands and spherical structures (*10*).

It has been shown that complexation of DNA with PLL can protect it from degradation by nucleases (*11*); however, in the presence of mung bean nucleases, Dash (*3*) found partial degradation of DNA−PLL complexes, while DNA−PEG−*b*-PLL complexes remained completely intact.

The ability to transfect cells in vitro was shown for most of the above-mentioned block and graft copolymers, although the transfection efficiency could vary considerably depending on the type of the copolymer used. DNA−PEG−*b*-PLL complexes showed an impressive ability to transfect *293* cells, the effect thought to result from the ability of PEG to dehydrate cell membranes (*2*). Presumably, the clusters of PEG exposed in closed juxtaposition can cause local permeability of the cell membrane of 293 cells. On the other hand, DNA complexes formed with poly(HPMA)-*b*-poly(TMAEM) mediated only limited transfection efficiency compared with that of DNA−PEG−*b*-PLL complexes (*2*). The low level of transfection in the case of DNA complexes with poly(HPMA)-*b*-poly(TMAEM) suggests that they do not enter the cell in such a nonspecific manner as PEG-based systems and thus this type of copolymer could be a good candidate for in vivo applicable targeted gene delivery systems after attachment of specific targeting moieties into the poly(HPMA) blocks.

The complexes of DNA, similarly to other colloidal particles (like liposomes), show very low stability in the bloodstream (*12, 13*). They are rapidly removed from the bloodstream, which decreases their potential for specific targeting in vivo. It has been proposed that interaction of the complexes with plasma proteins (either adsorption or breaking of the complexes by proteins) can be the major obstacle for their successful in vivo use. In analogy with STEALTH liposomes (*14*), it was suggested that incorporation of hydrophilic, nonionic polymer onto the surface of the complexes can help to solve this problem (*2, 7*). The concept of using block or graft copolymers, having been developed in our laboratories for several years, seems to offer that possibility. It was suggested that the complex formation may proceed with a degree of orientation, leaving the hydrophilic blocks on the surface of the complex free to provide a protective layer (*7*).

In this work, we have studied the interactions of the polyelectrolyte complexes of DNA with poly(TMAEM) containing hydrophilic poly(HPMA) block with albumin and synthetic polyanion. The interactions were studied by combination of several methods, including dynamic and static light-scattering and measurements of ζ-potential. The ability of albumin and polyanions to release free DNA from the complexes was tested using dynamic light scattering and agarose gel electrophoresis. Finally, the body distribution analysis was performed in order to obtain more information on the effect of the hydrophilic poly(HPMA) block on biological properties of complexes.

EXPERIMENTAL PROCEDURES

Chemicals. Calf-thymus DNA and bovine serum albumin were purchased from Sigma. Sodium poly(styrenesulfonate) (PSS) (M_w = 74 000) was from PolySciences. All other chemicals were of analytical grade.

Synthesis of Polymers. Block copolymer was prepared by the reaction of active succinimidyl esters of carboxylic end groups in semitelechelic poly(HPMA) with semitelechelic poly(TMAEM) containing terminal amino group.

Synthesis of Poly(HPMA) with Carboxylic Acid End Group [Poly(HPMA)-COOH]. Precipitation polymerization of HPMA in acetone was carried out in the presence of a chain transfer agent 3-sulfanylpropionic acid (SPA) at 50 °C for 24 h. The concentrations were as follows: initiator 2,2′-azobisisobutytonitrile (AIBN) 3×10^{-3} M, HPMA 0.8 M and SPA 7.6×10^{-3}. The polymer was purified by double precipitation from methanol solution into 20-fold excess of a mixture of acetone and diethyl ether (3:1). Yield 45%. Weight (M_w)- and number-average (M_n) molecular weights determined by size-exclusion chromatography (SEC) were M_w = 14 700 and M_n = 8400. Molecular weight calculated from the content of end carboxylic acid group was M_n = 8500.

Synthesis of Poly(TMAEM) with Amino End Group [Poly(TMAEM)-NH_2]. The polymer was prepared by a solution radical polymerization in methanol in the presence of 2-aminoethanethiol hydrochloride (AET.HCl) at 50 °C for 24 h. The concentrations were as follows: initiator AIBN, 4.8×10^{-3} M; TMAEM, 0.6 M; and AET·HCl, 8.5×10^{-2} M. The polymer poly(TMAEM)-NH_2 was isolated by precipitation into acetone, purified by dialysis (dialyzing tubing with molecular weight cutoff 3500), and freeze-dried. Yield 35%. Molecular weights determined by SEC using poly(HPMA) calibration were: M_w = 10 600; M_n = 7470. Molecular weight calculated from the content of end amino groups was M_n = 5000.

Synthesis of Active Succinimidyl Ester of Poly(HPMA)-COOH. The end carboxylic acid group was converted into succinimidyl ester by the reaction common in peptide synthesis. Poly(HPMA)-COOH (0.17 mmol) and *N*-hydroxysuccinimide (HOSu) (1.70 mmol) were dissolved in 6 mL of dimethylformamide (DMF) (dried with P_2O_5, freshly distilled before use) and cooled to −20 °C; to this solution was added a solution of *N*,*N*′-dicyclohexylcarbodiimide (1.70 mmol) and 4-(dimethylamino)pyridine (0.33 mmol) in 5 mL of DMF. The solution was left overnight at 0 °C. The *N*,*N*′-dicyclohexylurea precipitated during the reaction was removed by filtration and polymer was isolated by precipitation into 15-fold excess of a mixture of dry acetone and diethyl ether (3:1). The succinimidyl ester of poly(HPMA)-COOH [poly(HPMA)-COOSu] in quantitative yield was dried and used directly in the subsequent reaction.

Synthesis of Block Copolymer [Poly(HPMA)-block-poly(TMAEM)]. Poly(HPMA)-COOSu was dissolved in dimethyl sulfoxide (10 wt % solution) and added to a solution of poly(TMAEM)-NH_2. Molar ratio of polymer end groups COOSu:NH_2 was 1.2:1. The mixture was stirred at room temperature for 8 h and polymer was isolated by precipitation into 40-fold volume excess of acetone. The polymer (BLOCK-1) was dried in vacuo, excess of poly(HPMA) was removed from dry copolymer by extraction with DMF, and the product was washed with acetone and dried in vacuo. Molecular weight of the copolymer BLOCK-1 determined by SEC using poly(HPMA) calibration was M_w = 21 000. The content of HPMA block determined by elemental analysis was 63 wt %.

Formation of Polyelectrolyte Complexes. The complexes were formed in deionized water by titration of DNA solution (concentration 20 μg/mL, concentration of phosphate groups 0.0615 mM) with polycation stock

solution (positive charge concentration 0.012 M). Two modes of preparation were used in this study.

(1) Rapid titration: a polycation stock solution was added as quickly as possible (typically in 1 s) to 3 mL of a stirred DNA solution.

(2) Slow titration: a polycation stock solution was slowly added using a programmable syringe pump to 3 mL of a stirred DNA solution, the rate of addition being 30 μL/h (full compensation of negative DNA phosphate groups was achieved in 30 min).

Calf-thymus DNA was used in all experiments, unless otherwise stated.

Characterization of Polymers. Molecular weights of poly(HPMA)-COOH and poly(TMAEM)-NH_2 were determined by size-exclusion chromatography (SEC) in 0.05 M Tris buffer (pH 8.1) on a Superose 12 column (Pharmacia). Number-average molecular weights (M_n) were also calculated from the content of the end functional carboxylic or amino groups, assuming one functional end group per macromolecule. The content of the end carboxylic groups of poly(HPMA)-COOH was determined by titration with 0.05 M NaOH using automatic titrator (Radiometer). The amount of amino end groups of poly(TMAEM)-NH_2 was determined by the 2,4,6-trinitrobenzenesulfonic acid assay using molar absorption coefficient 10 500 L/(mol cm).

Agarose Gel Electrophoresis. The ability of albumin or polyanion to release free DNA from the complexes was also determined by agarose gel electrophoresis. DNA complexes in water in the presence of various concentrations of albumin or polyanion were electrophoresed on agarose gel (0.5%) in 0.05 M Tris buffer, pH 7.5, for 30 min at 90 V. Ethidium bromide (1 μg/mL of gel) was incorporated in the gel to show the location of DNA using UV detection (254 nm).

Analysis of ζ-Potential. The charge of the calf-thymus DNA complexes was determined by using a Zetamaster system (Malvern Instruments). The system was calibrated using a −55 mV standard. Solutions of the complexes (5 mL) were measured five times for 30 s at 1000 Hz with zero field correction.

Static Light Scattering (SLS). Static light-scattering measurements were performed with a commercial Fica 40 apparatus in vertically polarized light at wavelength $\lambda_0 = 632.8$ nm, angle $\theta = 90°$, and temperature 25 °C. The apparatus was calibrated with benzene at $\theta = 90°$. The data are expressed as the scattered light intensity at 90 ° normalized with intensity scattered by benzene.

Dynamic Light Scattering (DLS). Polarized DLS measurements were made in the angular range 30−130° using a light-scattering apparatus equipped with an He−Ne (632.8 nm) and Ar-ion laser (514.5 nm) and an ALV 5000, multibit, multi-tau autocorrelator covering approximately 10 decades in delay time τ. The time autocorrelation functions were fitted assuming the Pearson distribution of characteristic relaxation times, τ_c:

$$z(\tau_c) = \tau_o^{\,p} p \tau_c^{\,-p-1} \exp(-\tau_c/\tau_o)/\Gamma(p) \qquad (1)$$

where τ_o and p are parameters, and $\Gamma(p)$ is the gamma function of parameter p. The Pearson distribution was chosen for the simplicity of its mathematical treatment. The apparent hydrodynamic radius, R_h, was calculated from the zero angle limit of apparent collective diffusion coefficient, D^a, using the Stokes−Einstein equation:

$$R_h = kT/6\pi\eta D^a \qquad (2)$$

where k is the Boltzmann constant, T is absolute temperature, and η (0.894 cP) is the viscosity of water at 25 °C.

The experimental error of the aggregate size determination was typically about 3%.

Radiolabeling of DNA. The linearized plasmid pCMV-β-Gal was radiolabeled using the Ready-to-Go DNA Labeling Kit (-dCTP) from Pharmacia Biotech. The DNA was purified from unincorporated nucleotides using MicroSpin DNA purification columns from Pharmacia Biotech.

Body Distribution Analysis. Radiolabeled DNA (50 ng/mL) was added to a calf-thymus DNA solution (20 μg/mL), and the complexes were formed using different polycations and various charge ratios. The complex solutions were diluted with PBS buffer to balance the solution osmotically prior to injecting 100 μL into the tail vein of BALB/c mice. After 30 min, the animals were killed and their liver, kidneys, intestines, heart, and lungs were removed. The blood and tissue samples were analyzed for radioactivity in a Packard Scintillation Counter. The total amount of radioactivity in blood was determined by assuming that the volume of blood in a mouse is 8.64 mL/100 g. In all cases, the tails of the mice were removed prior to dissolution and were not assayed for radioactivity. The percentage of radioactivity in each organ is given as a percentage of the recovered dose.

RESULTS

Good candidate for in vivo delivery of DNA should exhibit prolonged circulation times in the bloodstream in order to accomplish targeting. In analogy with other particulate systems (liposomes, nanoparticles), the use of cationic block copolymers containing hydrophilic blocks is thought to reduce the removal of polyelectrolyte DNA complexes by the immune system. Since hydrophobic forces are thought to be the main driving force in phagocytosis of nanoparticles and liposomes, the presence of hydrophilic polymers decreases hydrophobic nature of these delivery systems. Particles containing hydrophilic polymers usually display reduced protein adsorption and consequently increased circulation times and altered body distribution (*15*).

We have evaluated several block and graft copolymers of HPMA and TMAEM (*8*, *9*). We have chosen the block copolymer BLOCK-1 as a polymer that can form polyelectrolyte complexes with DNA that are relatively small and are sufficiently stable in saline solution. Before testing the biodistribution of its complexes with DNA, we have studied the interaction of these complexes with albumin.

Proteins can interact with DNA complexes among others by electrostatic and hydrophobic interactions. To investigate electrostatic interactions, it is important to measure the charge of the complexes, and in order to suppress these interactions, it is reasonable to attempt to form them charge-neutral. The charge of the complexes was evaluated by measuring their ζ-potentials. Figure 1A shows the dependencies of ζ on the ratio of positive charges of polycation and negative charges of DNA (φ) for poly(TMAEM)-NH_2 and block copolymer BLOCK-1 used for the formation of DNA complexes by the rapid titration method. In both cases, ζ monotonically increases and crosses zero between charge ratios 0.7 and 0.8. The complexes gain positive charge at higher charge ratios ($\varphi > 0.8$). Since the ζ-potential is related to the sum of all charges of complexes, the shift of complete neutralization of charges to φ values lower than 1 might be due to

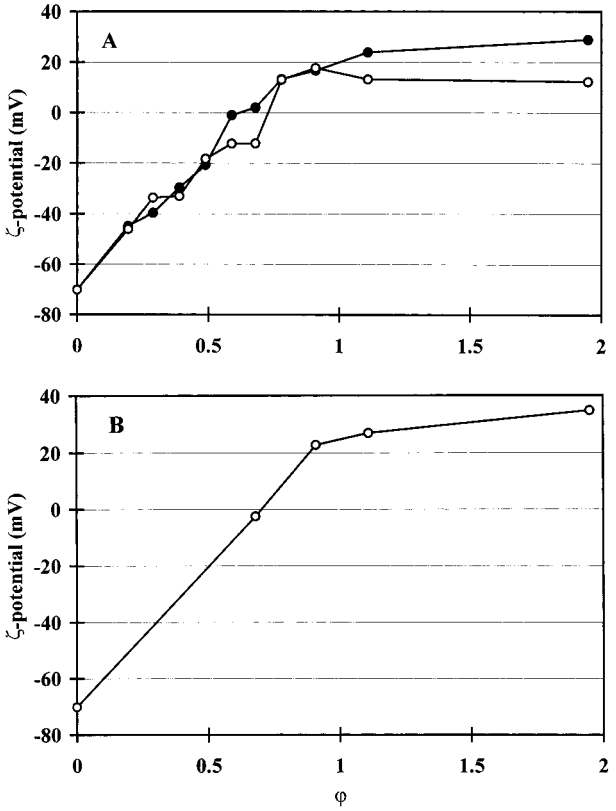

Figure 1. Dependence of ζ-potential on the ratio between positive charges of polycation and negative charges of DNA (φ). (A) complexes formed by rapid titration using poly(TMAEM)-NH_2 (●) and BLOCK-1 (○); (B) complexes formed by slow titration using BLOCK-1.

positive counterions entrapped inside the complexes by electrostatic interactions with DNA. It has been shown by Manning (*16*) that when DNA is neutralized by polycations to the critical φ (0.88), the hydrophobicity of DNA is so high that it cannot stay in its extended form and collapses. The collapse then may cause entrapping of remaining free phosphate groups inside the complex. The incorporation of excess block copolymer to the complexes at $\varphi > 0.8$ manifested in positive ζ-potential values is probably caused by partly neutralized copolymer molecules on the surface of the complexes. Similar behavior was already observed by several other authors (*2, 7, 17*). On the contrary, formation of DNA complexes with almost neutral charge was reported by Kataoka using PEG−*b*-PLL (*4*). The point of zero ζ-potential around $\varphi \approx 0.8$ also well corresponds to a maximum in the size and molecular weight dependencies observed in our previous paper (*9*). This confirms that these maxima are caused by the hydrophobically driven aggregation, which most easily proceeds if the complexes are uncharged ($\zeta = 0$). To our surprise, there was no significant difference in ζ-potential between complexes formed by slow or rapid titration (Figure 1B). On the basis of our previous data, we have intuitively anticipated that the slow titration method facilitates formation of complexes with better compensated DNA negative charges. In such case, the recharging of the complexes after reaching zero ζ-potential could be avoided, and as a consequence, neutral complexes could be easily obtained. Since this assumption was not justified, we have attempted to obtain neutral complexes by finding the exact charge ratio of neutrality (Figure 2). The change from the negatively to positively charged complexes occurs suddenly in a very narrow interval of charge ratios and thus,

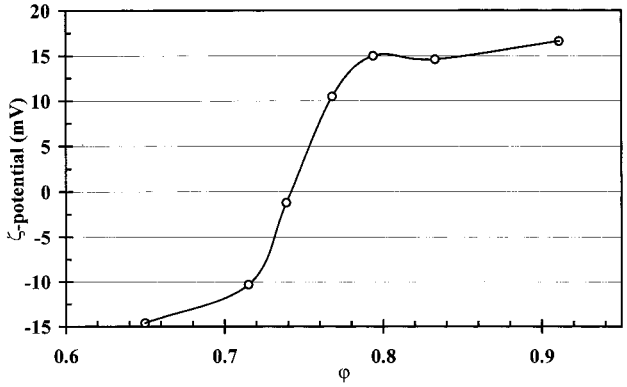

Figure 2. Dependence of ζ-potential on the ratio between positive charges of polycation and negative charges of DNA (φ) for DNA−BLOCK-1 complexes. The complexes were formed at $\varphi = 0.65$ by rapid titration and the aliquots of BLOCK-1 solution were added up to $\varphi = 0.9$.

from the practical point of view, charge-neutral complexes cannot be easily obtained. Since the recharging of the complexes coincides with the maxima of molecular weight and size of the complexes and with sudden repulsion of intercalated ethidium bromide from DNA (*8*), the dramatic conformation change (coil−globule transition) of DNA structure (collapse) is assumed to occur in this charge ratio interval.

To induce collapse of the extended DNA structure, it is necessary to use charge ratios higher than 0.8. Then, the positive charge of the complexes (Figures 1 and 2) has to be considered when evaluating their interactions with proteins. After interaction with proteins, positive charges of the complexes could promote binding of negatively charged proteins. In certain cases, negatively charged protein could possibly replace DNA in the complex, and free DNA may be released. Since the major protein with negative net charge occurring in blood plasma in high concentrations is albumin, we have used it in this study. A possible release of free DNA from the complexes was assessed by agarose gel electrophoresis.

We have shown by electrophoresis that albumin is not able to destroy the complexes and release free DNA, but it could probably interact with positively charged complexes and form ternary albumin−DNA−polycation complexes. In that case, some parameters of the DNA complexes, such as charge, molecular weight, and hydrodynamic radius, have to be changed. To verify this possibility, we have used static and dynamic light-scattering and ζ-potential techniques. DNA complexes with BLOCK-1 were first formed in water at $\varphi = 0.9$, and then increments of albumin solution were added. The dependence of ζ-potential of the complexes on the concentration of albumin is shown in Figure 3A. The increasing concentration of albumin causes gradual change in ζ from positive to negative values. Reaching constant negative ζ above 1 mg/mL of albumin suggests possible saturation of the complexes with albumin. Almost all the positively charged complexes of BLOCK-1 formed at different charge ratios altered their ζ-potential to negative in the presence of 1 mg/mL of albumin (Figure 3B). The complexes formed with high excess of polycation ($\varphi = 6$) are an exception. In this case, substantial quantity of polycation is free in solution and forms additional complexes with albumin having hydrodynamic radii in the range 10−100 nm and ζ varying from negative to positive values depending on the polycation/albumin ratio. In consequence, polycation−albumin complexes may interfere with DNA complexes and distort the

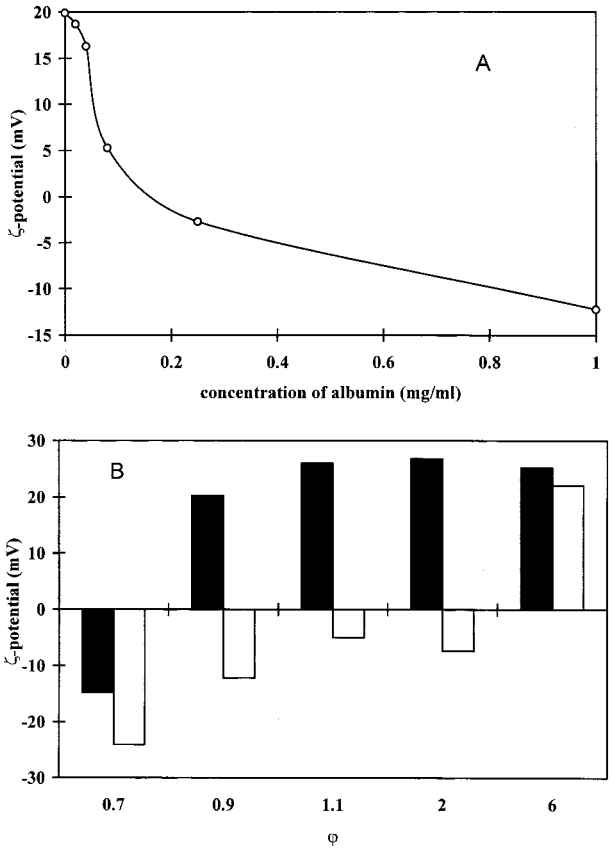

Figure 3. Effect of albumin on ζ-potential of DNA complexes. (A) DNA−BLOCK-1 complexes were formed at $\varphi = 0.9$ and effect of increasing albumin concentration on ζ-potential was monitored. (B) DNA−BLOCK-1 complexes were formed at $\varphi =$ 0.7, 0.9, 1.1, 2, and 6, their ζ-potential was measured (■) and then effect of 1 mg/mL of added albumin on ζ-potential was monitored (□).

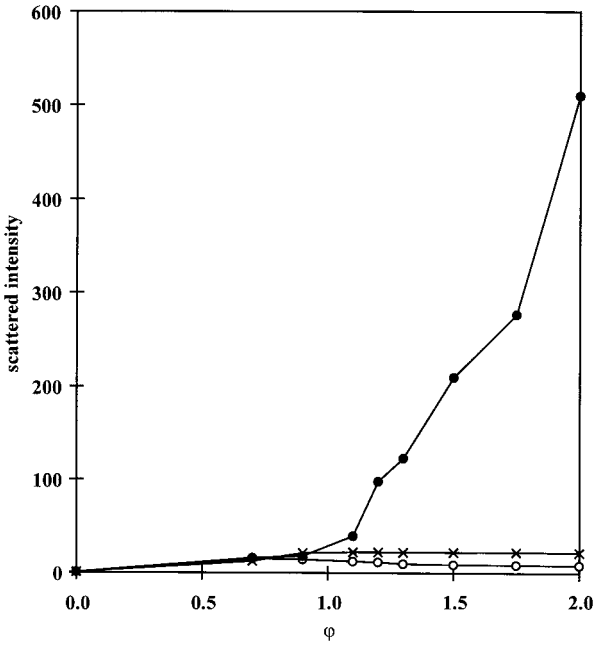

Figure 4. Effect of the addition of 1 mg/mL of albumin to DNA−BLOCK-1 complexes formed at different φ on the scattering intensity at 90°. The complexes were formed in water, scattering intensity was measured (○), then albumin was added and scattering intensity of the solution was again measured (●). The scattering intensity of the DNA−BLOCK-1 complexes in the presence of 1 mg/mL of albumin on addition of 0.15 M NaCl was finally measured (×).

results of ζ-potential measurements as in the case of the complexes formed at $\varphi = 6$ (Figure 3B). Polycation−albumin complexes are positively charged at high φ values and most albumin is probably consumed in the formation of the complexes with free polycation. As a consequence, the overall measured ζ-potential remains positive.

Light-scattering techniques can contribute to better understanding of the effect of albumin on the DNA complexes. Figure 4 demonstrates the effect of an addition of albumin (1 mg/mL) on the normalized intensity of scattered light (the scattered light intensity at 90 ° normalized with intensity scattered by benzene) of complexes formed at different charge ratios in water. Scattering intensity is used instead of customary molecular weights because the concentration of albumin built in DNA complexes is unknown. A minor increase in the scattering intensity is observed after albumin addition to the complexes at $\varphi = 0.9$. This corresponds well with the observed positive ζ of the complexes formed at $\varphi =$ 0.9 (Figure 1). The increase in scattering intensity suggests an increase in molecular weight of the complexes due to their interaction with albumin. In addition, an abrupt break above the charge ratio 1.1 is observed. We suppose that the abrupt break is provoked mostly by the interaction of albumin with free polycation. The polycation−albumin complexes bring additional scattering to that of DNA complexes. The scattering intensity is again decreased if NaCl is added (Figure 4) to the complexes in the presence of albumin. A markedly dramatic decrease is observed for the complexes formed at $\varphi > 1.2$. We assume that this decrease is mainly caused by break-up of the polycation−albumin complexes. The polycation−albumin complexes are not stable in the presence of a low-molecular-weight electrolyte (NaCl) due to only weak interactions. This is in contrast to the complexes of DNA with polycations, where a strong cooperative effect induces high stability. The decrease in scattering intensity after NaCl addition is significant but yet it has not reached the scattering intensity of DNA−BLOCK-1 complexes. This observation suggests that some albumin could be possibly entrapped inside the DNA complex (by hydrophobic interactions) increasing thus molecular weight of the complex (manifested by increased scattering intensity).

The static light-scattering methods require precise knowledge of particle concentrations in solution to calculate their molecular weights. Dynamic light scattering, on the contrary, offers the possibility of determining directly the hydrodynamic radii of the complexes without precise knowledge of the particle concentration. The effect of increasing concentration of albumin on the distribution of hydrodynamic radii [$A(R_h)$] of the complexes (DNA−BLOCK-1) formed in water by slow titration ($\varphi = 0.9$) is demonstrated in Figure 5. An addition of albumin causes a shift of radii distribution to higher values. Saturation of the complexes with albumin was observed above 0.7 mg/mL of albumin where the hydrodynamic radius of the complexes was found to be almost independent of albumin concentration. We assume that the shift of the size distribution is caused predominantly by albumin binding on the surface of the complexes forming there a "protein layer" (hydrodynamic radius of albumin $\approx$ 4 nm). The average hydrodynamic radius of the complexes in the presence of 1 mg/mL of albumin increased by about 10 nm compared with the original complex.

The complexes formed at $\varphi = 2$ exhibited considerably higher shifts of the hydrodynamic radii distributions after

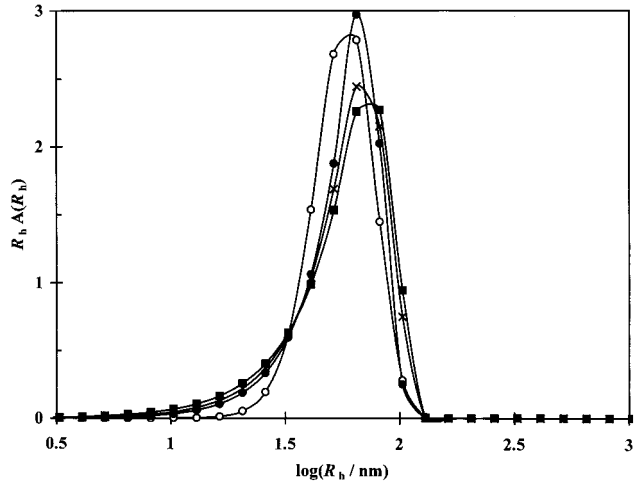

Figure 5. Effect of increasing concentration of albumin on the distribution of hydrodynamic radii of DNA−BLOCK-1 complexes. The complexes were formed at $\varphi = 0.9$ (○), and then the distribution of hydrodynamic radii of DNA−BLOCK-1 complexes was measured after albumin addition [final concentrations of albumin: 0.4 (●), 0.7 (×), and 1 mg/mL albumin (■)].

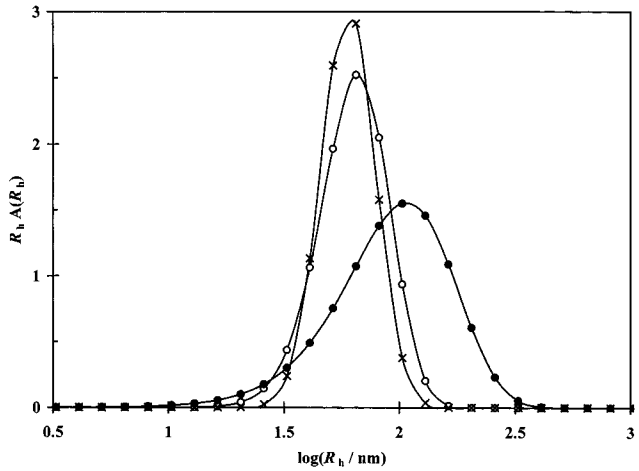

Figure 6. Effect of 1 mg/mL albumin and 0.15 M NaCl on the distribution of hydrodynamic radii of DNA−BLOCK-1 complexes. The complexes were formed at $\varphi = 2$ (○). Effect of albumin (●) and subsequent addition of NaCl (×) on the distribution of hydrodynamic radii of the complexes is shown.

albumin addition (1 mg/mL) (Figure 6) in water, compared with the complexes formed at $\varphi = 0.9$ (Figure 5). A significant increase in average hydrodynamic radius and polydispersity was observed after albumin addition due to the formation of polycation/albumin complexes. In agreement with our previous results, large complexes formed mostly between albumin and free polycation have broken after addition of NaCl to their solutions (final concentration 0.15 M) (Figure 6). The solution then contained DNA−BLOCK-1 complex particles similar to those prior to the albumin addition. Corresponding experiment with the complex formed at the 0.9 charge ratio showed that a slight increase in the complex size only slightly decreased in 0.15 M NaCl, suggesting that the interaction of albumin with the complexes is relatively more stable than that with free polycations. This is in agreement with the static light-scattering experiments (Figure 4), which indicate that some albumin could be bound to the complexes even in 0.15 M NaCl. The complexes in the presence of albumin were stable over a period of hours, but after 24 h, the starting aggregation was observed. From the practical standpoint, the complexes should remain in circulation until they reach their target site; as the required half-life in the bloodstream is several hours (*13*), the observed stability could be sufficient.

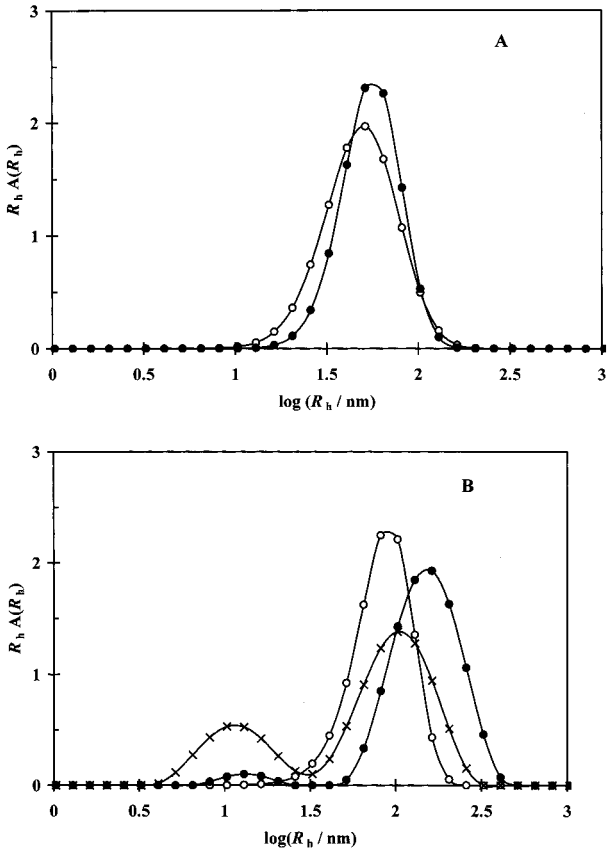

Figure 7. Effect of PSS on the distribution of hydrodynamic radii of DNA−BLOCK-1 complexes. (A) The complexes were formed at $\varphi = 1.1$ in distilled water (○), effect of an addition of PSS is shown (●). (B) The complexes were formed at $\varphi = 1.1$ in 0.15 M NaCl (○), effect of an addition of PSS is shown 30 min (●) and 3 days (×) after addition.

It has been shown that certain polyanions (polyaspartic acid, heparin) can release free DNA from the complexes (*3*). This reaction can also possibly account for the low stability of the complexes in the bloodstream. We have studied the ability of synthetic polyanion sodium poly(styrenesulfonate) (PSS) to release free DNA from its complexes with BLOCK-1 by agarose gel electrophoresis and dynamic light scattering.

To compare the effect of PSS on DNA complexes in water and in 0.15 M NaCl, we have used a high concentration of PSS. The ratio of positive charges of BLOCK-1 used for complex formation and negative charges of PSS was 1:25. The use of a high excess of PSS should ensure that in the case of exchange polyelectrolyte reaction between DNA and PSS in DNA complexes with BLOCK-1, the possibly formed complexes PSS-BLOCK-1 have relatively small size and thus do not interfere with the DNA complexes. Figure 7 shows the distribution of hydrodynamic radii of the DNA−BLOCK-1 complexes prior to and after addition of PSS. The complexes in water (Figure 7A) showed only a small increase in the hydrodynamic radius. Similarly to the interaction of complexes with albumin, a shift of the size distribution to higher values was observed. The hydrodynamic radius of these complexes virtually did not change during the 3 days of observation. The same experiment in 0.15 M NaCl (graph B) showed a similar increase in R_h and shift of the R_h

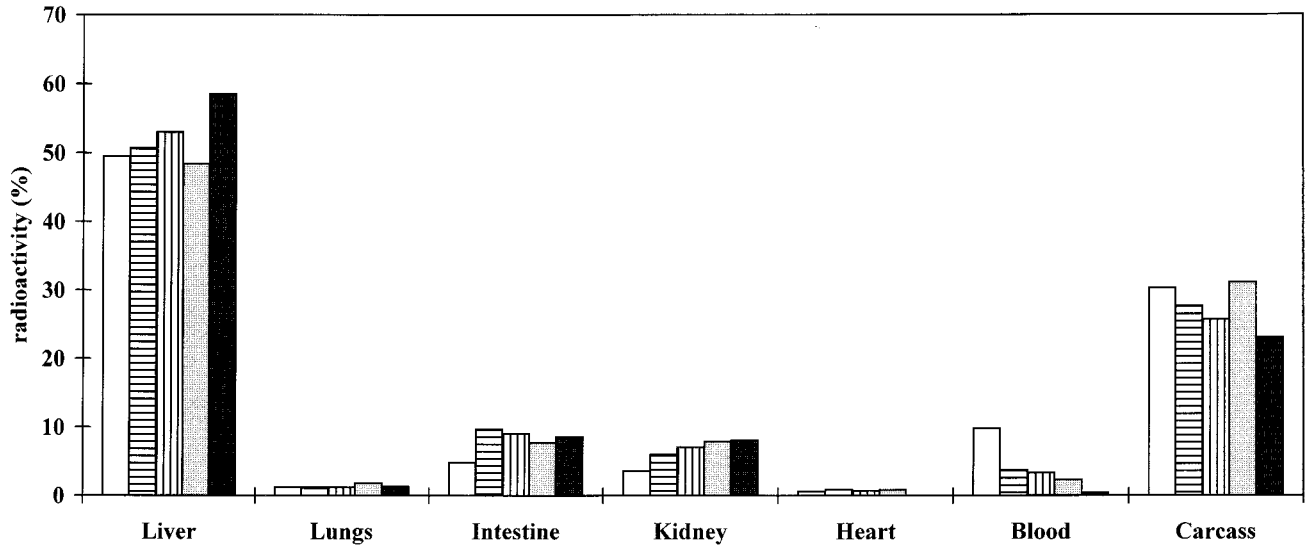

Figure 8. Body distribution of radiolabeled DNA (■) and of the complexes of radiolabeled DNA with poly(TMAEM)-NH_2 (□) or BLOCK-1. The latter complexes were formed in water at $\varphi = 0.7$ (□), 0.9 (□), and 1.1 (□). The complex or DNA solutions were diluted with PBS buffer prior to injecting. The mice were killed after 30 min, and the blood and tissue samples were analyzed for radioactivity.

distribution immediately after a PSS addition. From the very beginning, a second population of small particles with the hydrodynamic radius around 10 nm was apparent. The proportion of these particles increased with time at the expense of the DNA complexes. Together with the alteration of the relative content of these two populations, the intensity of the scattered light of the solution at 90° decreased, indicating dissociation of the DNA complexes. This means that large, highly scattering particles slowly disappear. We suppose that, in the absence of NaCl, the exchange polyelectrolyte reaction virtually does not take place and only formation of ternary complexes DNA−BLOCK-1−PSS occurs, as manifested by a minor increase in the mean hydrodynamic radius. In the presence of 0.15 M NaCl, the exchange reaction can take place. This is manifested by an increasing quantity of 10 nm particles and by a decrease in intensity of scattered light. These observations agree with the results published in ref *18*. They have demonstrated that the exchange polyelectrolyte reactions can take place only in the presence of a low-molecular-weight electrolyte. We suppose that the particles with $R_h = 10$ nm correspond to complexes PSS−BLOCK-1. The exchange reaction is relatively slow and thus the interaction of DNA complexes in the bloodstream with possibly present polyanions does not have to be an obstacle in successful in vivo gene delivery.

Agarose gel electrophoresis was used in order to observe release of free DNA from the complexes. Since DNA complexes do not migrate in the gel, the released free DNA can be easily monitored by this method. PSS was able to release free DNA from the complexes and the amount of DNA released from the complexes increases with increasing concentration of PSS in solution.

We have studied the organ distribution of different DNA complexes 30 min after an i.v. tail vein injection (Figure 8). The figure compares the organ distribution of DNA−BLOCK-1 complexes formed at three different φ (0.7, 0.9, 1.1) and that of the complex DNA−poly(TMAEM)-NH_2 ($\varphi = 0.9$). To our surprise, the DNA−BLOCK-1 complexes have manifested almost no difference in their biodistribution compared with DNA−poly(TMAEM)-NH_2 complexes. Unlike STEALTH liposomes, the presence of poly(HPMA) in the complexes has apparently no effect on the prolongation of circulation times of the complexes. Neither did exhibit the effect of varying charge ratio in the complex formation and any significant difference in the organ distribution, although the complexes formed at $\varphi = 0.7$ had a negative ζ-potential. No explanation for such an observation was available until now. The accumulation of the complexes in the liver could be probably a consequence of both the charge and relatively high hydrodynamic radius of the complexes (*19*).

DISCUSSION

It has been shown that DNA−PLL complexes are rapidly cleared from the bloodstream, with a half-life of less than 5 min. The interaction of the complexes with albumin was proposed to have a major impact on the circulation of the complexes in blood (*13*). It was suggested that the main reason could be an increase in the size of the complexes. To test this hypothesis we have studied the interaction of DNA complexes with albumin by combination of several analytical techniques.

As we have shown above, albumin is able to interact with DNA−BLOCK-1 complexes and increase their hydrodynamic radii, nevertheless, the increase was not so significant to explain the observed biodistribution.

The exchange reaction between DNA and polyanions which caused a release of free DNA is relatively slow, and thus the interaction of DNA complexes in the bloodstream with possibly present polyanions does not have to be an obstacle in successful in vivo gene delivery.

On the basis of these promising observations, we have expected prolonged plasma circulation of DNA complexes with block copolymers. In analogy with STEALTH liposomes, we have expected the hydrophilic poly(HPMA) block to increase the circulatory times of the complexes. To explain the fact, that using block copolymers we have observed no significant improvement of the biodistribution of the complexes, it is necessary to review the analogy with STEALTH liposomes. In our previous physicochemical study (*9*), we have shown that increasing relative HPMA content in both the block and graft copolymers used for the formation of DNA complexes resulted in decreasing density of the complexes. In the case of a graft copolymer containing 80% of HPMA, the

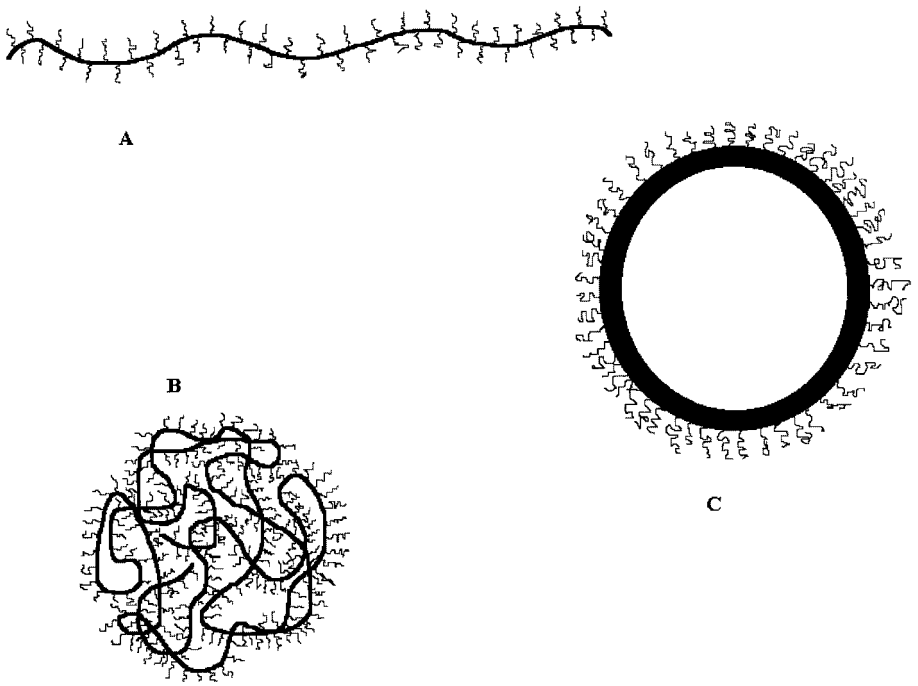

Figure 9. (A) structure of brush polymer (DNA fully compensated with block copolymers). (B) Proposed structure of DNA complexes with block or graft copolymers in solution. (C) Structure of STEALTH liposome.

complexes displayed an expanded structure that was very close to that of a flexible polymer coil, as assessed by the ratio of radius of gyration and hydrodynamic radius of the complexes. Then, the complexes have "swollen and expanded" structure, where their hydrophobic parts might tend to concentrate in the central core of the complex and hydrophilic poly(HPMA) blocks on the surface, but microphase separation of the hydrophobic and hydrophilic parts is virtually impossible. The frequently suggested micelle-like structure with hydrophobic core surrounded by hydrophilic poly(HPMA) or PEG shell seems to be not fully realistic (*4*, *7*) in case for high-molecular-weight DNA. To better explain a possible structure of the DNA complexes with block or graft copolymers, it is necessary to realize that full compensation of DNA with molecular weight of almost 7 million requires several hundreds of polycation macromolecules (molecular weight $\approx$ 20 000). Then the complexes have the structure of so-called brush polymers (Figure 9A). The DNA complexes are usually about 100 nm in diameter, and thus it is not possible for poly(HPMA) blocks located on the DNA parts in the center of the complex to reach the surface and they must be also located in the core of the complex, where they cause an internal swelling (Figure 9B). In STEALTH liposomes, the protecting polymer layer is located on the surface (Figure 9C), where it sterically stabilizes the liposome due to osmotic and entropic effects of an inert, nonionic, hydrophilic, and flexible polymer coating, which increases repulsive pressure above these surfaces (*20*). The complexes with the structure closer to STEALTH liposomes, i.e., those with hydrophobic DNA−polycation core surrounded by hydrophilic protecting surface layer, would be more stable in the bloodstream, due to the ability of the compact surface layer to sterically stabilize the particle. We could conclude that a compact surface layer of hydrophilic nonionic polymer is probably required to efficiently decrease interaction with proteins and, consequently, to achieve good stability in the bloodstream. The absence of such compact continuous layer of poly(HPMA) in the DNA complexes studied in this work results in facile binding of albumin or other proteins to the complexes. The complexes then may have a structure of "large albumin spheres" with positive or negative surface charge dependent on the amount of bound albumin. Then, other plasma proteins (opsonins) could bind and also promote removal of the DNA complexes from the bloodstream, preferably by the liver.

A potential way of obtaining the DNA complexes with poly(HPMA) chains located only on their surface might be the chemical modification of the preformed complexes containing surface reactive groups with a reactive poly(HPMA) derivative.

Received February 4, 1999; Revised Manuscript Received May 19, 1999

To define the minimal peptide length needed for gene delivery into mammalian cells, we synthesized several peptides with shortened chain lengths from the amino-termini of the original amphiphilic peptides (4_6, Ac-LARL-LARL-LARL-LRAL-LRAL-LRAL-NH_2, and Hel 11-7, KLLK-LLLK-LWKK-LLKL-LK), which have been known to have gene transfer abilities into cells. Each synthetic peptide was studied for its ability to bind and aggregate with plasmid DNA and the structural change of the peptide caused by binding with the DNA to establish a relative in vitro gene transfection efficiency in COS-7 cells. As a result, the deletion of eight amino acid residues of 4_6 had little influence on their ability, whereas that of 12 amino acid residues remarkably reduced the abilities to make aggregates and transfer the DNA into the cell. In the case of the Hel 11-7 series peptides, deletion of amino acid residues caused a considerable reduction in abilities to bind and form aggregates with DNA and to transfer the DNA into cell in due order. In summary, 16 and 17 amino acid residues were sufficient to form aggregates with the DNA and transfer the DNA into the cells in the deletion series of 4_6 and Hel 11-7, respectively. Furthermore, it was indicated that reduction of membrane perturbation activity of the peptide−DNA complex due to deletion of the peptide chain length caused suppression of the transfection efficiency even if the complex was incorporated into the cells. Transfer of the complex to cytosol mediated by membrane perturbation activity of the peptide is an important step for efficient protein expression from its cDNA. The results of this study will make it easy to design and synthesize a functional gene carrier molecule such as a carbohydrate-modified peptide used in targeted gene delivery.

INTRODUCTION

An efficient gene-transfer technique is necessary for the development of gene therapy. Various methods are being developed to transfect mammalian cells with foreign genes. In these situations, nonviral gene delivery systems are expected to introduce genes into cells without several problems, which are pointed out in transfection methods using viral vectors, such as endogenous virus recombinations, oncogenic effects and immunogenic reactions (*1*, *2*). Nonviral delivery systems generally consist of a cationic polymer such as polylysine delivartives (*3*−*5*), polyethyleneimines (*6*) and polyamidoamine dendrimers (*7*), or cationic lipids (*8*) that electrostatically form a complex with the negatively charged DNA that can be taken up by the cells. Furthermore, Gottschalk et al. and Wadhwa et al. reported that synthetic peptides containing several cationic amino acids are useful as a gene carrier molecule (*9, 10*). The low molecular and homogeneous peptides are expected to easily construct a functional carrier molecule by attaching to a receptor ligand such as a carbohydride or peptide.

Recently, novel gene transfer techniques, in which an amphiphilic α-helical peptide containing cationic amino acids is used as a gene carrier into cells, have been reported. Wyman et al. employed a peptide, KALA (WEAK-LAKA-LAKA-LAKH-LAKA-LAKA-LKAC-EA), which is derived from the sequence of the amino-terminal segment of the HA-2 subunit of the influenza virus hemagglutinin involved in the fusion of the viral envelope with the endosomal membrane (*11*). This peptide showed several functions in the transfection process, e.g., condensing DNA and causing an endosome−membrane perturbation, which enables it to deliver the incorporated DNA to the cytosol, which is essential for efficient transfection. Similarly, we have also reported the transfection technique, which is mediated by some amphiphilic α-helical peptides consisting of 24 amino acids, including six arginines (e.g., Ac-LARL-LARL-LARL-LRAL-LRAL-LRAL-$NHCH_3$, 4_6) (*12*, *13*). Furthermore, to clarify in detail the importance of the hydrophobic region in the amphiphilic peptide in relation to its transfection efficiency, we have employed the Hel series peptides (e.g., KLLK-LLLK-LWLK-LLKL-LL, Hel 13−5), which consist of 18 residues and have systematically varied the hydrophobic−hydrophilic balance in the amphiphilic structures (*14*, *15*). As a result, the peptide with a large hydrophobic region could strongly bind to the plasmid DNA and form large aggregates with the DNA. In addition, it could be said that the hydrophobic region of the peptides plays an important role in the disruption of the endosomal membrane in the targeted cell, which can transfer the incorporated DNA to cytosol and prevent the degradation of the DNA in the lysosomal vesicles.

As is well-known, a peptide is readily synthesized due to the development of an automatic peptide synthesis

apparatus and reagents for synthesis. From this point of view, it is expected that the transfection method mediated by the peptide is easily accepted by many researchers taking part in a gene therapy study. Development of an efficient gene transfer system using peptide with simple structure will cause many applications to gene therapy.

In this paper, for the purpose of refining of the peptide structure, we investigated the influence of the peptide chain length on gene transfer ability. We synthesized several peptides with shortened chain lengths from the amino-termini of amphiphilic peptides 4_6 and Hel 11-7, which have transfection abilities (*13*, *15*), and then evaluated the DNA-binding, aggregate-forming, and transfection abilities into cultivated cells.

MATERIALS AND METHODS

Chemicals and Instruments. Reagents used for the synthesis and analysis were of reagent grade. All amino acid derivatives and reagents for peptide synthesis were purchased from Watanabe Chemical (Hiroshima, Japan). Ethidium bromide and alamer Blue were purchased from Wako chemicals (Osaka, Japan). Egg yolk phosphatidylcholine, bovine brain phosphatidylserine, and bovine brain sphingomyeline were purchased from Sigma (St. Louis, MO).

Peptide purification was carried out on a Hitachi L7100 system (Tokyo, Japan) with a semipreparative RP-HPLC[1] column, YMC-Pack ODS column (10 × 250 mm, Kyoto, Japan) using the following solvent system: 0.1% trifluoroacetic acid (TFA)−0.08% TFA in acetonitrile. Flow rate was 3.0 mL/min, and elution was monitored at 220 nm. Mass spectra were obtained by fast-atom bombardment mass spectrometry (FAB-MS) using a JEOL JMS-DX303 mass spectrometer (Tokyo, Japan) or by matrix-assisted time-of-flight mass spectrometry (MALDI TOF-MS) using a Shimadzu Kratos Kompact MALDI III apparatus (Kyoto, Japan). Plasmid DNA which contains a luciferase gene and SV40 promoter (PicaGene control vector, PGV-C) was purchased from Toyo Ink (Tokyo, Japan). Closed circular plasmid DNA was purified by ultracentrifugation in CsCl gradients. The plasmid preparations showed a major band of closed circular DNA and minor amount (<20%) of nicked plasmid. COS-7 cells (a monkey kidney cell line, RCB accession no. RCB0539), HeLa cells (a human cervix, RCB accession no. RCB0271), and CHO cells (a chinese hamster ovary, RCB accession no. RCB0285) were purchased from RIKEN Cell Bank (Tsukuba, Japan). HuH-7 cells (a human hepatoma cell line, JCRB accession no. JCRB0403) were purchased from Health Science Research Resources Bank (Osaka, Japan). DMEM, RPMI1640, media supplements, and heat inactivated FCS were from IWAKI GLASS (Chiba, Japan).

Peptides Synthesis. Peptides were synthesized by the stepwise elongation of Fmoc-amino acid on Rink amide resin [4-(2′,4′-dimethoxyphenyl-Fmoc-aminomethyl)-phenoxy resin, 0.43 mmol/g resin] or Wang resin (*p*-benzoyloxy alcohol resin, 0.70 mmol/g resin) on a 0.05 mmol scale. The Fmoc amino acid derivatives used were as follows: Ala, Arg(Mtr), Leu, Lys(Boc), and Trp. The coupling protocol was as follows: 1, wash, DCM (x3); 2, wash, DMF (x3); 3, wash, 20% piperidine/DMF (x1); 4, deprotection, 20% piperidine/DMF (15 min); 5, wash, DMF (x5); 6, coupling Fmoc-amino acid (0.15 mmol), HBTU (0.15 mmol), HOBt (0.15 mmol), and DIEA (0.3 mmol) (15 min); 7, wash, DMF (x3); and 8, Kaiser Test (*16*). When the coupling was incomplete, the protocol was repeated from step 6. In the case of modifying by acetyl group to amino-terminal of peptide, the Fmoc-deprotected peptide resin was treated with acetic anhydride (10 equiv) in DMF for 20 min. The protecting groups and the resin were removed with TFA (1.0 mL) in the presence of *m*-cresol (30 μL), ethandithiol (90 μL) and thioanisole (180 μL) at room temperature for 60 min. In the case of the peptides containing Arg(Mtr), the filtered solution was shaken with trimethylbromosilane (350 μL) at 0 °C for 1 h (*17*). The crude peptides were precipitated by diethyl ether and then purified by RP-HPLC on a YMC-Pack ODS column (10 × 250 mm). The purified peptides were identified by the amino acid analysis and FAB-MS or MALDI TOF-MS.

Agarose Gel Electrophoresis. The peptide−DNA complex formation was examined by the electrophoretic mobility of the complex on an agarose gel stained with ethidium bromide at the various ratios of peptide to a double stranded DNA. The tests were performed by mixing 0.1 μg of the plasmid DNA (PGV-C) with the peptides in 10 μL of HBS (21 mM Hepes-NaOH buffer containing 135 mM NaCl, 5.0 mM KCl, and 0.76 mM Na_2HPO_4 pH 7.4), in which the positive (peptide)/negative (DNA) charge ratios were 0, 0.10, 0.25, 0.50, 1.0, 2.0, 4.0, and 8.0, respectively. Gel electorophoresis sample buffer was added to each sample, and it was electrophoresed on 1% (w/v) agarose gel for 40 min at 100 V. TBE (45 mM Tris-Borate and 1 mM EDTA, pH 8.0) buffer was used as electrophoresis buffer. The gel was stained with ethidium bromide (0.5 μg/mL) for 30 min and illuminated with a UV illuminator to show the location of the DNA.

Fluorescence Titration Assay. Binding abilities of the peptides were monitored by a fluorescent titration assay (*18*). A total of 10 μg of the plasmid DNA was mixed with the peptides in 980 μL of HBS, in which the positive (peptide)/negative (DNA) charge ratios were 0, 0.25, 0.50, 0.75, 1.0, 1.25, 1.5, 1.75, 2.0, 2.5, 3.0, and 4.0, respectively. After the solution stood for 20 min at room temperature, 20 μL of 20 μg/mL of ethidium bromide solution was added to the peptides−DNA mixtures. The fluorescence of the intercalated dye was measured on a spectrofluorometer F-3010 (Hitachi, Japan) by exciting at 530 nm while monitoring emmision at 590 nm, with the slits set at 20 nm. Fluorescence intensity blanks were subtracted from all values before data analysis.

Circular Dichroism. Circular dichroism (CD) spectra were recorded on a JASCO J-720W spectropolarimeter using a quartz cell of 1.0 mm path length. The peptides were dissolved at the concentration of 10 μM in HBS. Measurements were performed in the presence of the plasmid DNA at peptide/DNA charge ratio of 2.0 and in the absence of the plasmid DNA at 25 °C.

Particle Size Analysis. Samples were prepared by mixing 0.5 μg of the plasmid DNA with the peptides at peptide/DNA charge ratio of 2.0 in 50 μL of HBS and analyzed using a Nicomp submicron particle sizer model 370 in the solid particle mode. The mean diameter and population distribution were computed from the diffusion coefficient using functions supplied by the instrument.

[1] Abbreviations: Fmoc, 9-fluorenylmethoxycarbonyl; HBTU, *O*-benzotriazolyl-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate; HOBt, 1-hydroxybenzotriazol; RP-HPLC, reversed-phase high-performance liquid chromatography; DCM, dichloromethane; DIEA, ethyldiisopropylamine; DMF, *N*,*N*-dimethylformamide; TFA, trifluoroacetic acid; FAB-MS, fast-atom bombard mass spectrometry; MALDI TOF-MS, matrix-assisted time-of-flight mass spectrometry; HBS, 21 mM Hepes-NaOH buffer (pH 7.4) containing 135 mM NaCl, 5.0 mM KCl; CD, circular dichroism; DMEM, Dulbecco's modified Eagle's medium; FCS, fetal calf serum.

Transmission Electron Microscopy. Samples were prepared by mixing 0.5 μg of the plasmid DNA with the peptides at peptide/DNA charge ratio of 2.0 in 50 μL of HBS. These were then left standing for 20 min at room temperature. Peptide−DNA complexes were processed for transmission electron microscopy (TEM) using a negative stain technique. Fifteen microliter drops of aliquot of the mixture was placed on glow-discharged carbon-coated 200-mesh copper grids for 3 min. Solution was wicked off with filter paper and replaced with 1% aqueous uranyl acetate for 30 s. After removal of the solution, grids were rinsed in distilled water and allowed to dry. Grids were imaged in a JEOL JEM-100S transmission electron microscope.

Peptide-Mediated Gene Transfer. COS-7 cells, a simian kidney cell line transformed with simian virus 40 (SV40), were grown to just before confluence in 16 mm dishes in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal calf serum (FCS) and 50 μg/mL kanamycin in an atmosphere of 5% CO_2 at 37 °C, and washed twice with 1 mL of HBS. Mixture of peptide and DNA was prepared by mixing 2.5 μg of the plasmid DNA (PGV-C) with the peptides at peptide/DNA charge ratio of 2.0 in 250 μL of HBS and allowed to stand for 20 min at room temperature. The mixture was poured gently to the cells in 250 μL of serum free DMEM. After incubation for 3 h at 37 °C, 1 mL of DMEM with 10% FCS was added. After incubation for 24 h, the medium was replaced with 1 mL of a fresh medium and the cells were furthermore incubated for 24 h. Treatment of the cells with chloroquine was performed at 50 μM during transfection procedure. Harvesting of cells and luciferase assays were performed as described in the protocol of PicaGene luminescence kit (Toyo Ink; Tokyo, Japan). Luciferase relative light units (RLU) were analyzed by luminometer (Maltibiolumat LB9505, Berthold, Germany). The protein concentrations of the cell lysates were measured by Bradford assay using bovine serum albumin as a standard (*19*). The light unit values shown in the figures represent the specific luciferase activity (RLU/mg of protein) which is standardized for total protein content of the cell lysate. The measurement of gene transfer efficiency was performed in triplicate. In the case of other cell lines, the same protocol was applied except for the case of HuH-7 cells, in which RPMI1640 with 5% FCS was used instead of DMEM with 10% FCS as a medium.

Cytotoxic Activities of Peptides. Cytotoxic activities of the peptides were evaluated using alamer Blue. COS-7 cells were plated at 1×10^4 cells/well in a 96-well tray and incubated for 12 h at 37 °C. Mixture of peptide and DNA was prepared by mixing 0.25 μg of the plasmid DNA with the peptides at a charge ratio of 2.0 in 25 μL of HBS and allowed to stand for 20 min at room temperature. The mixture was poured gently to the cells in 25 μL of serum-free DMEM. After incubation for 3 h at 37 °C, 100 μL of DMEM with 10% FCS was added. After incubation for 24 h, the medium was replaced with 100 μL of a fresh medium and the cells were furthermore incubated for 24 h. The medium was removed and replaced by 10 μL of the alamer Blue solution. After incubation for 3 h, fluorescence at 590 nm (excitation wavelength, 544 nm) of each well was measured using a Labsystems Fluoroskan II (Helsinki, Finland). Results are expressed as the percentage of fluorescence reduction in cells treated according to the transfection protocol to fluorescence reduction in cells treated with HBS. The measurement was performed in duplicate.

Dye Leakage from Phospholipid Vesicles by the Action of Peptides. The dye-leakage experiment was carried out as reported by Suenaga et al. (*20*). The tests were performed by mixing 25 μL of the complex solution containing the peptide and the plasmid DNA with 975 μL of the small unilamellar vesicle suspension containing 100 μM calcein to give a vesicle solution with a final concentration of 70 μM lipid, which consists of egg phosphatidylcholine, phosphatidylserine, and bovine brain sphingomyeline at molar ratio of 7, 1, and 2, respectively, in HBS (pH 7.4) or 20 mM sodium citrate buffer (pH 5.0) containing 150 mM NaCl. The complex of the peptide and the plasmid DNA was prepared mixing peptide at a final concentration of 400 μM with the plasmid DNA in 25 μL of HBS, in which charge ratio was 2.0. The fluorescence intensities of calcein were monitored at 515 nm (excitation wavelength, 495 nm) and measured 2 min after the addition of the peptides. To measure the fluorescence intensity for 100% dye release, 10 μL of Triton X-100 (10% in H_2O) was added to dissolve the vesicles. The percentage of the dye release caused by the peptides was evaluated by the equation $100 \times (F - F_0)/(F_t - F_0)$, where F is the fluorescence intensity achieved by the peptides, and F_0 and F_t are intensities observed without the peptides and after Triton X-100 treatment, respectively.

Table 1. Structures of Peptides Deleted from Amino Termini of Gene Carrier Peptides, 4_6, and Hel 11-7

peptide	sequence	chain length	cationic charge
4_6	Ac-LARL-LARL-LARL-LRAL-LRAL-LRAL-NH_2	24	6
$4_6\Delta_4$	Ac-LARL-LARL-LRAL-LRAL-LRAL-NH_2	20	5
$4_6\Delta_8$	Ac-LARL-LRAL-LRAL-LRAL-NH_2	16	4
$4_6\Delta_{12}$	Ac-LRAL-LRAL-LRAL-NH_2	12	3
Hel 11-7	KLLK-LLLK-LWKK-LLKL-LK	18	7
Hel 11-7Δ1	LLK-LLLK-LWKK-LLKL-LK	17	6
Hel 11-7Δ2	LK-LLLK-LWKK-LLKL-LK	16	6
Hel 11-7Δ3	K-LLLK-LWKK-LLKL-LK	15	6
Hel 11-7Δ8	LWKK-LLKL-LK	10	4

RESULTS AND DISCUSSION

Peptide Design. Cationic α-helical peptides were designed to probe the minimal size needed to mediate efficient gene transfer into mammalian cells. As shown in Table 1, we synthesized several peptides with shortened chain lengths from the amino-termini of amphiphilic peptides, 4_6, and Hel 11-7, which have transfection abilities (*13*, *15*). The deletion of 4_6 was done with tetrapeptide-repeat units up to 12 residues (3 repeat units) ($4_6\Delta4$, Δ8, and Δ12). The number of cationic charges (arginine residues) of the 4_6 series peptides was reduced one by one by deletion of one unit of the repeat. In the case of Hel 11-7, the amino acids were deleted one by one up to three residues (Hel 11-7Δ1, Δ2, and Δ3). In addition, a peptide deleted with eight amino acid residues (Hel 11-7Δ8) was also prepared. As the amino- and carboxyl-terminals of the Hel series peptides are not protected, the net charge of the peptides also corresponded to the number of the lysine residues. Therefore, Hel 11-7Δ1 to Δ3 and Δ8 has six and four cationic charges, respectively. All peptides were synthesized by stepwise elongation using Fmoc-amino acid. However, a sufficient amount of $4_6\Delta4$ could not be obtained due to its poor solubility in buffer solution. It is likely that $4_6\Delta4$ accidentally forms a strong aggregation. The purified peptides except for $4_6\Delta4$ were identified by FAB-MS or MALDI TOF-MS.

Binding Ability of Peptide to DNA. The formation of peptide−plasmid DNA complexes was examined by

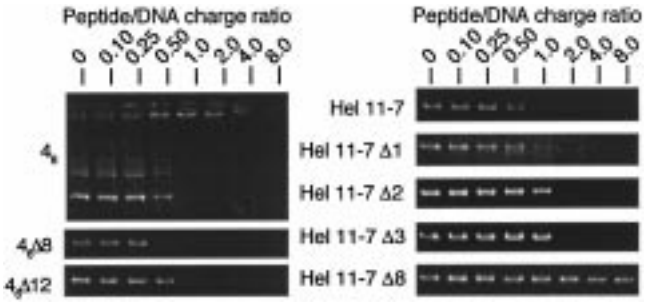

Figure 1. Agarose gel electrophoresis of the complexes of the peptides and the plasmid DNA. The plasmid DNA (100 ng) and several amounts of the peptides were mixed, followed by electrophoresis on an agarose gel (1% w/v) stained with ethidium bromide. The charge ratio (peptide:DNA) is indicated *above* each *lane*. Bands of the migrated DNA are indicated except for the case of 4_6.

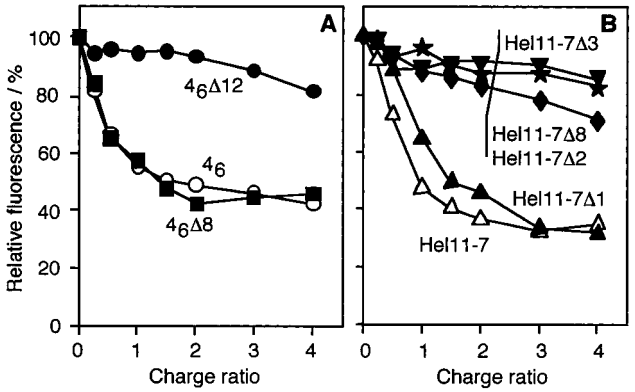

Figure 2. Fluorescence titration assay. A total of 10 μg of the plasmid DNA was mixed with the peptides in 980 μL of HBS at various charge ratios. After the solution stood for 20 min at room temperature, 20 μL of 20 μg/mL of ethidium bromide solution was added to the peptide−DNA mixtures. The fluorescence was measured on a spectrofluorometer by exciting at 530 nm while monitoring emmision at 590 nm. (A) 4_6 series peptides; 4_6 (○), $4_6\Delta8$ (■), and $4_6\Delta12$ (●). (B) Hel series peptides; Hel 11-7 (△), Hel 11-7Δ1 (▲), Hel 11-7Δ2 (◆), Hel 11-7Δ3 (▼), and Hel 11-7Δ8 (★×9a).

their electrophoretic mobility on an agarose gel stained with ethidium bromide at the various charge ratios of the peptide to a plasmid DNA (Figure 1). In the case of the 4_6 series peptides, no migration of the plasmid DNA band occurred at charge ratios of 1.0, 0.5, and 1.0 for 4_6, $4_6\Delta8$, and $4_6\Delta12$, respectively. This lack of migration was due to neutralization of the nucleic acid by the cationic peptide and/or formation of a large complex between the peptide and the DNA. This result indicated that $4_6\Delta8$ had a slightly stronger DNA-binding ability compared to 4_6 and $4_6\Delta12$. On the other hand, in the case of the Hel 11-7 series peptides, the charge ratio at which no migration of the plasmid DNA occurred was increased by increasing the number of deleted amino acids in the peptide. The deletion of amino acids of Hel 11-7 clearly decreased the binding abilities of the peptides. Especially, Hel 11-7Δ8 with four cationic charges similar to $4_6\Delta8$, which has DNA-binding ability, could not bind to the plasmid DNA even if the charge ratio of the peptide/DNA increased to 8.0. This result indicates that not only the number of cationic amino acids but also the structural feature of the peptide such as chain length or width of the hydrophobic region in the amphiphilic structure is necessary for binding to the DNA.

The binding ability was also estimated by the ethidium bromide-titration assay (*18*). Peptides bound to DNA leads to exclusion of ethidium bromide intercalation and a decrease in fluorescence. Increasing the amount of 4_6 or $4_6\Delta8$ caused a reduction in the fluorescence to about 40% at a charge ratio of 2.0. The fluorescence intensities versus charge ratio flatten out at charge ratios above 2.0 (Figure 2A). This result indicated that these peptides are not highly efficient DNA-compacting agents. On the other hand, little reduction of the fluorescence was observed by the addition of $4_6\Delta12$, whereas this peptide inhibited the migration of the plasmid DNA on agarose gel. It is also likely that binding of $4_6\Delta12$ to the DNA could not cause compaction of the DNA. The titration of Hel 11-7 and Hel 11-7Δ1 with DNA led to a reduction within the charge ratio of 2.0 and 3.0, respectively (Figure 2B). These fluorescences also reached plateaus at 30%. Hel 11-7Δ2 showed moderate exclusion of the ethidium bromide from DNA compared with Hel 11-7Δ3 and Δ8, which caused only a slight reduction in fluorescence. These data from the ethidium bromide titrations for the Hel series peptides correspond to those from the agarose gel shift assay.

Structural Change in Peptide. To analyze the structural changes in the peptides by binding to the plasmid DNA, the CD spectra of the peptides were measured. As shown in Figure 3, panels A-C, the 4_6 series peptides showed a typical α-helix CD pattern with double minima at 208 and 222 nm in the HBS. The ellipticity at 222 nm indicated that these peptides took α-helical structures with helical contents of 73, 81, and 62% for 4_6, $4_6\Delta8$, and $4_6\Delta12$, respectively (*21*). Among the 4_6 series peptides, $4_6\Delta8$, which showed the strongest DNA-binding ability as already described, strongly formed α-helical structures compared with 4_6 and $4_6\Delta12$. In the presence of the plasmid DNA at a charge ratio of 2.0, 4_6 and $4_6\Delta8$ showed a large valley at 222 nm, and another valley at 208 nm became shallower. This result would mean aggregation of the peptide with DNA (*13*, *22*). The CD spectrum of peptide $4_6\Delta12$, which showed no ability to exclude the ethidium bromide from the DNA, was only slightly influenced by the addition of the plasmid DNA.

These changes in ellipticities at 208 nm by the addition of the plasmid DNA are summarized in Figure 3D. It is clear that a larger change in spectra was observed for $4_6\Delta8$ versus 4_6. In the case of the Hel series peptides, longer peptides such as Hel 11-7, Hel 11-7Δ1, and Hel 11-7Δ2 took α-helical structures with helical contents of 46, 37, and 8% in the absence of the plasmid DNA, respectively. On the other hand, shorter peptides such as Hel 11-7Δ3 and Hel 11-7Δ8 took mainly a random coil structure in HBS (data not shown). With the addition of the plasmid DNA, changes in the spectra were observed for the longer peptides and the differences decreased depending on the deleted number of amino acids residues.

Particle Size and Distribution of Peptide-DNA Complex. The size distribution of the peptide-plasmid DNA complexes at a charge ratio of 2.0 was compared using the dynamic light-scattering data (Table 2). A population of particles with a mean diameter of 0.5−9.6 μm was determined for these peptides except for $4_6\Delta12$ and Hel 11-7Δ8, of which the sizes could not be estimated due to the little light scattering of its complex with the DNA. Especially, $4_6\Delta8$ and Hel 11-7 formed aggregates of 5.3 and 9.6 μm, respectively, along with a large standard deviation of the average particle size. Although these values already exceeded the precisely measurable range by this method, it can be considered that the peptides with strong binding abilities induced larger aggregates with wider particle size distributions than the peptides with moderate binding abilities to DNA. Among

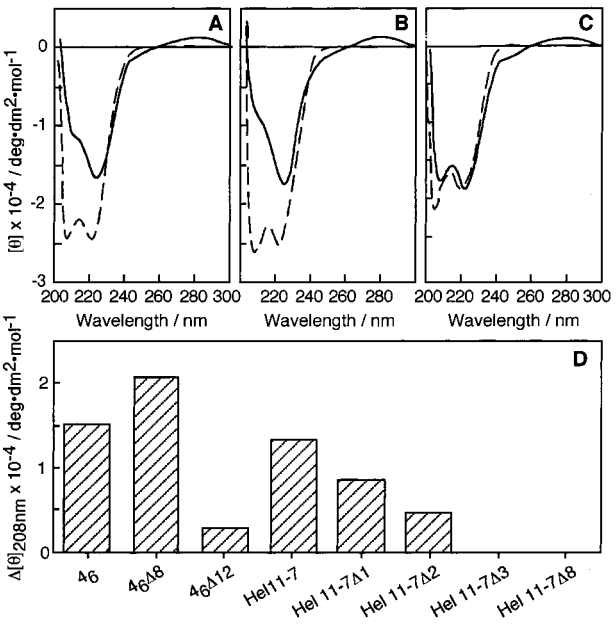

Figure 3. Circular dichroism spectra of the peptides with or without the plasmid DNA. The peptide was dissolved at 10 μM in HBS. Measurement was performed in the absence (*broken line*) or in the presence (*solid line*) of the plasmid DNA at 25 °C. Panels A, B, and C show the spectra of 4_6, $4_6\Delta8$, and $4_6\Delta12$, respectively. Panel D shows the difference between the mean residue ellipticities at 208 nm in the absence and presence of the plasmid DNA.

Table 2. Size Distribution of Peptide−Plasmid DNA Complexes

	particle size population	
peptide−DNA condensate[a]	diameter (nm)[b]	σ (nm)[c]
4_6	2330	1640
$4_6\Delta_8$	5300	4080
$4_6\Delta_{12}$	nd[d]	nd[d]
Hel 11-7	9610	9030
Hel 11-7Δ1	3050	1810
Hel 11-7Δ2	1810	1020
Hel 11-7Δ3	574	315
Hel 11-7Δ8	nd[d]	nd[d]

[a] Peptide DNA condensates were prepared by mixing 0.5 μg of the plasmid DNA with the peptides at peptide/DNA charge ratio of 2.0 in 50 μL of HBS. [b] Represents the mean diameter of particles. [c] Standard deviation of the population. [d] Correct values could not be determined due to little light scattering of the complex.

the Hel series peptides, the mean diameter of the peptide−DNA complex was decreased with decreasing chain length of the peptide. The chain length of the peptide plays an important role in the formation of aggregates between the peptide and DNA. It is likely that the hydrophobic interaction among the peptides is increased by extending its chain length.

Particle sizes determined by dynamic light scattering were also confirmed by observation of the peptide−DNA complexes using transmission electron microscopy with negative staining. As a result, all the peptides formed several sizes of aggregates, and twisted fiberlike structures were common, except for $4_6\Delta12$ and Hel 11-7Δ8, of which the aggregates could not be observed (*13*, *15*). Large DNA aggregates for $4_6\Delta8$ and Hel 11-7 were observed with diameters of approximately 1−10 μm. In the case of 4_6 and Hel 11-7Δ1 to Δ3, DNA aggregates were also observed within the ranges of the size distributions determined using dynamic light scattering (data not shown).

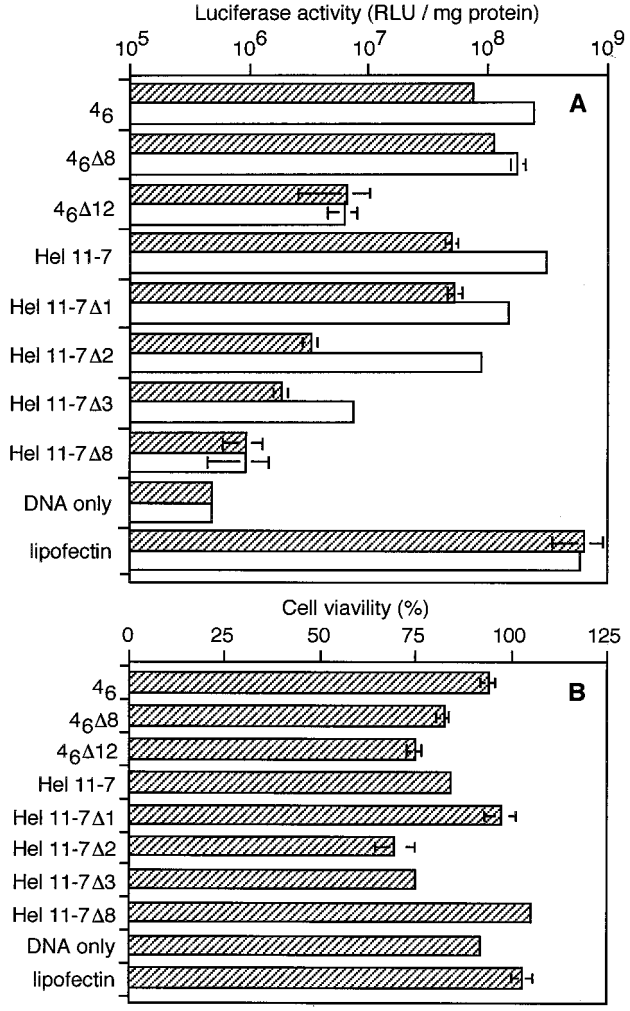

Figure 4. Transfection efficiencies of the peptides into COS-7 cells, and the cytotoxic activities of the peptides and their complexes with the plasmid DNA. (A) COS-7 cells were incubated with peptide-DNA complexes containing 2.5 μg of the plasmid DNA (PGV-C) and the peptides at peptide/DNA charge ratio of 2.0 for 3 h at 37 °C. Harvesting of the cells and luciferase assays were performed 48 h after transfection as described in the Materials and Methods. *Crosshatched bars* indicate the efficiency without chloroquine treatment. *Open bars* indicate the efficiency with chloroquine treatment. (B) Cytotoxitic activities of the peptides−DNA complexes evaluated using alamer Blue.

Gene Transfer Efficiency of Peptide in Vitro. The transfection efficiencies of these peptides into COS-7 cells were tested with the plasmid DNA, which contains a reporter gene encoding firefly luciferase. In Figure 4A, the *crosshatched bar* shows the gene transfer efficiency of the peptides when the peptides were mixed with 2.5 μg of the plasmid DNA at a charge ratio of 2.0 without chloroquine treatment. In these cases, 4_6, $4_6\Delta8$, Hel 11-7, and Hel 11-7Δ1 had remarkable abilities. These observations indicated that the transfection ability of the peptide was correlated to its ability to form aggregates with the DNA.

Furthermore, current treatment of the cells with chloroquine, which inhibits the degradation of the DNA by lysosomal hydrolases, made the efficiencies of 4_6, $4_6\Delta8$, Hel 11-7, and Hel 11-7Δ1 to Δ3 increase (Figure 4A, *open bar*). Particularly, the enhanced efficiency of Hel 11-7Δ2 by chloroquine was 30-fold higher than that in the absence of chloroquine and reached the efficiency of Hel 11-7 and Hel 11-7Δ1. This result suggested that the DNA complexes of Hel 11-7Δ2 could be well incorporated into

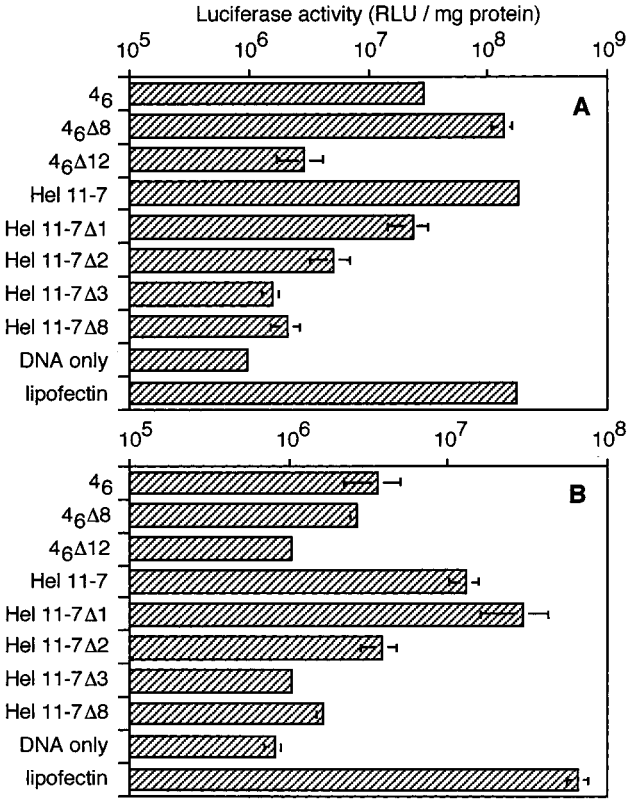

Figure 5. Transfection efficiencies of the peptides into several cell lines. Panels A and B show the efficiencies into HuH-7 and HeLa cells, respectively.

cells mediated by the endocytosis pathway, but most complexes would be transferred to the lysosome and digested in the absence of chloroquine.

Cytotoxic activities of the peptides−DNA complexes were evaluated using alamer Blue under the same conditions as those in the transfection procedure. As shown in Figure 4B, considerable cytotoxic activities of the complexes could not be observed except for Hel 11-7Δ2, of which the complex with the DNA had moderateactivity (70% cell viability). At this stage, we cannot explain the cytotoxic activity of Hel 11-7Δ2.

To prove the universality of the transfection efficiencies, we also tested the efficiencies of the peptides into several cell lines. As shown in Figure 5A, in the case of HuH-7 cells (a human hepatoma cell line), 4_6, $4_6\Delta8$, Hel 11-7, and Hel 11-7Δ1 showed remarkable efficiencies. The result in the case of CHO cells (a chinese hamster ovary) was also similar to that of HuH-7 cells (data not shown). In the case of HeLa cells (a human cervix), high efficiencies were also observed in 4_6, $4_6\Delta8$, and then Hel 11-7 and Hel 11-7Δ1 Hel series peptides were more advantageous than 4_6 series peptides (Figure 5B). From these results, although there were the some differences in transfection efficiencies of the peptides depending on several cell lines, the general tendencies were common, that is, high efficiencies were observed in the peptides with 16 or 17 residues.

Membrane Perturbation Activity of the Peptide−DNA Complex. The reason the efficiency of Hel 11-7Δ2, of which the DNA complex would be incorporated into cells, was low in the absence of chloroquine might be explained by the result that this peptide had a lower membrane perturbation activity, which would be considered to contribute to the transfer of the complex from the endosomal compartment to cytosol, compared with Hel 11-7 and Hel 11-7Δ1. To clarify this point, the membrane

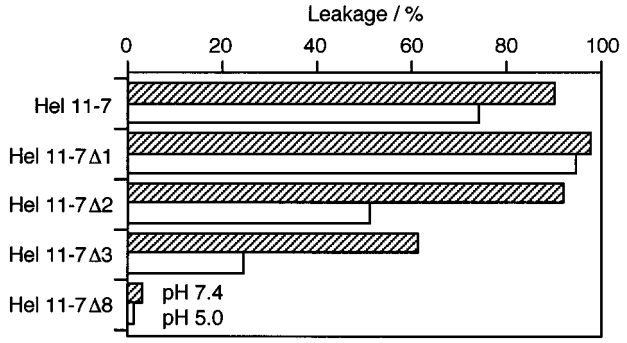

Figure 6. Dye-leakage from phospholipid vesicles by the action of peptides. The tests were performed by mixing the peptide−DNA complex with small unilamellar vesicle suspension, which consists of egg phosphatidylcholine, phosphatidylserine and bovine brain sphingomyeline at molar ratios of 7, 1, and 2, respectively, in HBS (pH 7.4; *crosshatched bars*) or 20 mM sodium citrate buffer containing 150 mM NaCl (pH 5.0; *open bars*) as described in the Materials and Methods.

perturbation activities of the Hel series peptide−DNA complexes were measured in neutral (pH 7.4) and acidic (pH 5.0) conditions (Figure 6). As the lipid membrane, we employed small unilamellar vesicles composed of phosphatidylcholine, phosphatidylserine, and sphingomyeline at molar ratios of 7, 1, and 2, respectively, which mimicked the endosomal membrane (*23*). As a result, DNA complexes of Hel 11-7 and Hel 11-7Δ1 showed strong membrane perturbation activities under both the neutral and acidic conditions. However, the DNA complex of Hel 11-7Δ2 showed a significantly weaker membrane perturbation activity compared with that of Hel 11-7 and Hel 11-7Δ1 under the acidic conditions, whereas a strong activity was observed under the neutral conditions. We speculate that, in the absence of chloroquine, the DNA complex of Hel 11-7Δ2 could not be transferred from acidic endosomal compartment to cytosol due to its weak membrane perturbation activity under the acidic conditions, even if the complex was incorporated into the cells. In the presence of the chloroquine, which inhibits the acidification of the endosome, the incorporated complex could be transferred to cytosol because the complex was continuously exposed in neutral condition. These findings strongly suggest that the perturbation activity of the peptide complexed with DNA plays an important role for delivery to cytosol in the cells, and consequently, leads the efficiently gene expression.

CONCLUSIONS

The results reported in this paper demonstrate that 16 amino acid residues including four cationic amino acids and 17 amino acid residues including six cationic amino acids were sufficient to form aggregates with the DNA and then transfer DNA into the cells in the deletion series of 4_6 and Hel 11-7, respectively. From the standpoint of the chain length and number of cationic amino acids, the 4_6 series peptides were advantageous. It is reasonable to postulate that the arginine residues as cationic amino acids in the peptide were favorable for efficient transfection. Practically, we have confirmed that the substitution of arginine residues for all lysine residues of Hel 11-7 enhanced its transfection efficiency by about five times (unpublished data).

Furthermore, in the deletion process, the 4_6 and Hel series peptide showed different behavior. A reasonable correlation between the chain length of the peptide, DNA binding, aggregate formation, and transfection efficiency was found in the case of the Hel series peptides. On the

other hand, although deletion of the 4_6 series peptide by 12 amino acid residues had little influence on their binding abilities for the gel retardation assay, a remarkable reduction in abilities to form aggregates with DNA and the transfection efficiencies occurred. The result from the 4_6 series peptides indicated that the binding to the DNA does not necessarily result in the formation of transfection-competent aggregates. Peptides 4_6 and $4_6\Delta8$, which have transfection abilities, showed high α-helical contents in HBS compared with $4_6\Delta12$ (Figure 1), indicating that stable oligomers of the peptides were formed with a well-defined number of monomers by self-association with their hydrophobic faces (*12*, *14*, *15*). In contrast, $4_6\Delta12$ could not compact the DNA and form large aggregates, although this peptide could bind to the DNA. It is, therefore, likely that the formation of some stable oligomer of the peptides plays an important role in transfection.

Finally, such as in the case of Hel 11-7Δ2, deletion of the peptide chain length caused a reduction in the membrane perturbation activity of the peptide−DNA complex under the acidic conditions. Simultaneously, suppression of the transfection efficiency was observed in the absence of chloroquine, whereas the complex could be incorporated into the cells. This suggests that transfer of the complex to cytosol mediated by the membrane perturbation activity of the peptide is an important step for efficient protein expression from cDNA encoded in the plasmid DNA.

We could minimize the peptide for gene transfer into cells to 16−17 amino acids residues in this study. It is considered that the result that we could achieve shortening the chain length to this size was due to use of the α-helical peptides with an amphiphilic structure, which have been known to show various interesting multibehaviors such as forming an oligomer, membrane perturbation, etc. The results obtained in this study allow us to easily design and synthesize the functional gene carrier molecule such as the carbohydrate modified peptide for targeted gene delivery.

University, Budapest, Hungary. Received February 10, 1999; Revised Manuscript Received May 12, 1999

For the construction of macromolecule−drug conjugates, it is important to provide rational basis to the selection of proper carrier. With respect to the importance of the side-chain structure and charge of the branched polypeptides in biological properties, we have prepared a new class of branched polypeptides with single or multiple hydroxyl groups and studied their solution conformation, in vitro cytotoxicity, biodistribution, and immunoreactivity. For comparative studies, polypeptides were designed to contain serine at various positions of the side chains, varying also the number. Ser was attached to the end of oligo(DL-Ala) side chains grafted to polylysine resulting polypeptides with the general formula poly[Lys(Ser$_i$-DL-Ala$_m$)], (SAK). Ser was also coupled directly to the polylysine backbone poly[Lys(Ser$_i$)] (S$_i$K) and then elongated by polymerization of *N*-carboxy-DL-Ala anhydride resulting poly[Lys(DL-Ala$_m$-Ser$_i$)] (ASK). An additional polymer was also prepared, but instead of the oligo(DL-Ala) branches, oligo(DL-Ser) side chains were introduced (poly[Lys(DL-Ser$_m$)], SK). The presence of hydroxyl groups resulted in compounds with improved of water solubility. CD spectra of polypeptides showed significant differences correlating with the position and numbers of Ser residues in the side chains. Under physiological conditions, polycationic polypeptides assumed ordered secondary structure (S$_i$K and LSK) or partially unordered conformation (SK, SAK, and ASK). Data of selected polymers demonstrate that these polycationic compounds are essentially nontoxic in vitro on normal rat liver or mouse spleen cells and have no cytostatic effect on mouse colorectal carcinoma C26 cells. The blood clearance and biodistribution of these derivatives were greatly dependent on the position and number of Ser residues in the branches and possess a rather extended blood survival in mice. Polypeptides were taken up predominantly by the liver and kidney (S$_i$K, LSK, and ASK) or kidney and lung (SK and SAK). The best survival in the blood was found with SAK, representing the first polycationic branched polypeptide, which show extended blood clearance. The relative position of Ser residue had also a marked influence on the immunogenicity of polypeptides. The characteristics of the antibody response to polypeptide containing Ser at the end of the branches (SAK) or adjacent to the polylysine backbone (ASK) was also dependent on the genetic background of the mouse strains. We also found that these compounds have no effect on to the SRBC-specific humoral immune response, indicating the lack of nonspecific immunostimulatory potential. In conclusion, these studies suggest that synthetic branched polypeptides with Ser can be considered as candidates for constructing suitable conjugates for drug/epitope delivery. It is not only due to the presence of hydroxyl group to be used for oxime chemistry but also to their beneficial biological features.

INTRODUCTION

There is an increasing interest in the development of target-specific delivery systems for various drugs and isotopes as well as preparation of long-acting drug−macromolecule conjugates (*1*−*3*). Appropriate carrier molecules are required also for the construction of synthetic antigens for vaccination and/or for the production of conventional or monoclonal hapten specific antibodies (*4*, *5*).

In our laboratory different types of branched polypeptide have been synthesized to establish structure−function relationship (*6*, *7*). The synthetic branched polymeric polypeptides were characterized by their chemical (size, primary structure, and conformation) and biological (toxicity, pyrogenicity, biodegradation, immunoreactivity, and biodistribution) properties. Correlation has been demonstrated between the side-chain structure of polymers and some biological activities such as biodistribution (*8*) or in vitro cytotoxicity (*9*).

Branched polypeptides were also used successfully as carriers for peptide epitopes of glycoprotein D of Herpes

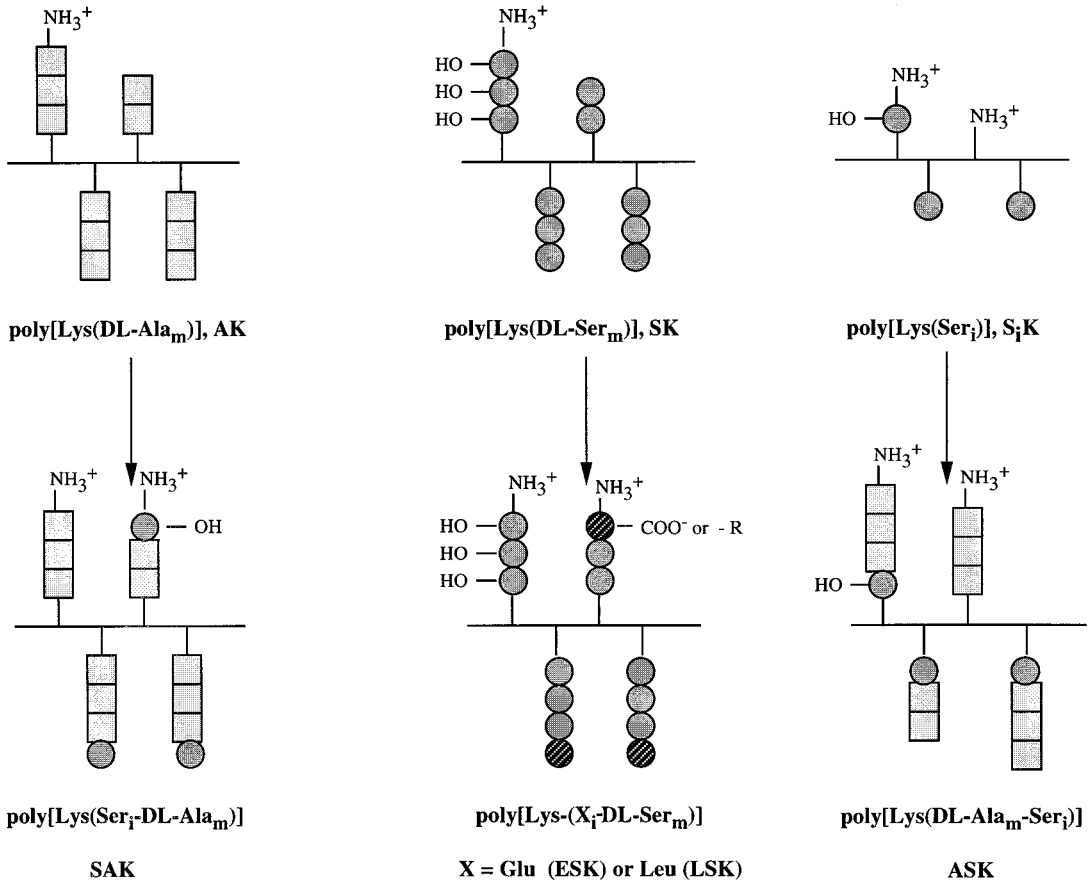

Figure 1. Schematic presentation of branched polypeptides.

Simplex virus (*10*), mucin 1 glycoprotein (*11*), and of *M. tuberculosis* proteins (*12*). Antitumor activity of daunomycin-EAK[1] conjugate (*13*, *14*) or Ac-[D-Trp$^{1-3}$, D-Cpa^2, D-Lys^6, D-Ala^{10}]-GnRH-AcEAK conjugate (*15*, *16*) has shown very promising results. These studies have also demonstrated that the biological properties (e.g., epitope-related immunogenicity or drug-related antitumor effect) and pharmacokinetics (e.g., blood survival, tissue distribution) of conjugates are greatly influenced by the chemical structure of the carrier.

Several authors have reported the application of poly(ethyleneglycol) (PEG) or PEG-containing polymers as water soluble drug carriers (*17*, *18*). It has been reported that PEG attached to proteins or synthetic polymers can increase their water solubility, blood survival, and/or lower the immunogenicity.

In view of these observations published in the literature, we have designed and synthesized a new class of branched polypeptides with single or multiple hydroxyl groups (*19*). For comparative biodistribution, in vitro cytotoxicity and immunological studies, these polypeptides were designed to contain serine at various positions of the side chains, varying also the number of the Ser residues (Figure 1). Serine was attached to the end of oligo(DL-Ala) side chains grafted to polylysine resulting polypeptides with the general formula poly[Lys(Ser$_i$-DL-Ala$_m$)] (SAK). Ser was also coupled directly to the polylysine backbone poly[Lys(Ser$_i$)], (S$_i$K) and then elongated by polymerization of *N*-carboxy-DL-Ala anhydride-resulting poly[Lys(DL-Ala$_m$-Ser$_i$)], (ASK). An additional polymer was also prepared, but instead of the above used oligo(DL-Ala) branches, oligo(DL-Ser) side chains were introduced (poly[Lys(DL-Ser$_m$)], SK) (*19*). The presence of hydroxyl functional groups could provide a new feature for oxime-based conjugation (*20*, *21*) of branched polypeptides with appropriate biologically active molecules leading to compounds with improved water solubility.

In this communication, we describe new branched polypeptides with a rather extended blood survival in mice. Data of selected polymers demonstrate that these compounds are essentially nontoxic in vitro on normal rat liver or mouse spleen cells and have no cytostatic features on mouse colorectal carcinoma C26 cells. The results of immunological experiments presented in this paper indicate that the position of Ser residue in the branches influences markedly the immunoreactivity of these polymers.

[a] Code of branched polypeptides, based on one letter symbol of amino acids. [b] Determined by amino acid analysis after hydrolysis in 6 M HCl at 105 °C for 24 h. [c] X = Leu or Glu. [d] Calculated from the number average degree of polymerization of polylysine ($\overline{DP}_n$ = 280) and from the amino acid composition of the branches.

brevity, codes of branched polypeptides were constructed by us using the one-letter symbols of amino acids (Table 1). All amino acids are of the L configuration unless otherwise stated.

Polypeptides. Branched polypeptides containing Ser residues were prepared in our laboratory by previously (*19*) published methods. Briefly, poly(L-Lys) was produced by the polymerization of N^{α}-carboxy-N^{ϵ}-(benzyloxycarbonyl)-lysine anhydride under conditions that allowed an average degree of polymerization of ~300. After cleavage of the protecting groups with HBr in glacial acetic acid, poly[Lys(DL-Ala$_{6.5}$)] (AK), or poly[Lys(Ser$_{2.9}$)] (SK) were formed by grafting of short oligomeric DL-Ala or DL-Ser side chains onto the ϵ-amino groups of polylysine using the respective *N*-carboxy-DL-amino acid anhydride (NCA). The side chain of DL-Ser was protected by the benzyl group, which was removed with HBr/glacial acetic acid. For poly[Lys(Ser$_i$-DL-Ala$_m$)] (SAK), attachment of suitably protected and activated Ser residues to AK was carried out by the active ester method. Similarly, SK was reacted with *Z*-Leu-OPcp or with *Z*-Glu(OBzl)-OPcp to produce poly[Lys(Leu$_i$-DL-Ser$_m$)] (LSK) or poly[Lys(Glu$_i$-DL-Ser$_m$)] (ESK), respectively. Poly[Lys(Ser$_i$)] (S$_i$K) was prepared by the attachment of protected and activated Ser residue to the ϵ-amino groups of polylysine followed by the removal of protecting groups, while poly[Lys(DL-Ala$_m$−Ser$_i$)] (ASK) was synthesized from S$_i$K by polymerization of DL-Ala-NCA. After the deblocking, branched polypeptide samples were purified by extensive dialysis using Visking tubing followed by lyophilization. The removal of blocking groups was verified by UV spectroscopy (*19*). The average molar mass of the branched polypeptides was estimated from the number average degree of polymerization ($\overline{DP}_n$) of polylysine backbone (*24*) and from the amino acid composition of the side chains determined by quantitative amino acid analysis (Table 1). The synthesis of LSK and ESK is described in detail.

Synthesis of Poly[Lys(Leu$_i$-DL-Ser$_m$)] and poly-[Lys(Glu$_i$-DL-Ser$_m$)] (LSK and ESK). One and a half grams of DL-Ser(Bzl)-NCA (7.3 mmol) was dissolved in 3 mL dioxan, and it was added to 300 mg of polylysine·HBr (1.4 mmol) dissolved in 3 mL of deionized water and neutralized with 200 μL of triethylamine. The reaction mixture was stirred for 45 min and then allowed to stand for 24 h. The poly[Lys(DL-Ser(Bzl)$_m$)] sample was dialyzed for 2 days and freeze-dried. The product was dried over P_2O_5 for 24 h, and then the Bzl-protecting groups were removed by 35% HBr/acetic acid (50 mL) in an overnight reaction at 4 °C. The product was precipitated by addition of dry ether (100 mL). The precipitate was washed with ether several times and dried over P_2O_5 and KOH. The poly[Lys(DL-Ser$_m$)] (SK) sample dissolved in deionized water was dialyzed in Visking tube (cutoff 8000−12000) against deionized water for 2 days and freeze-dried.

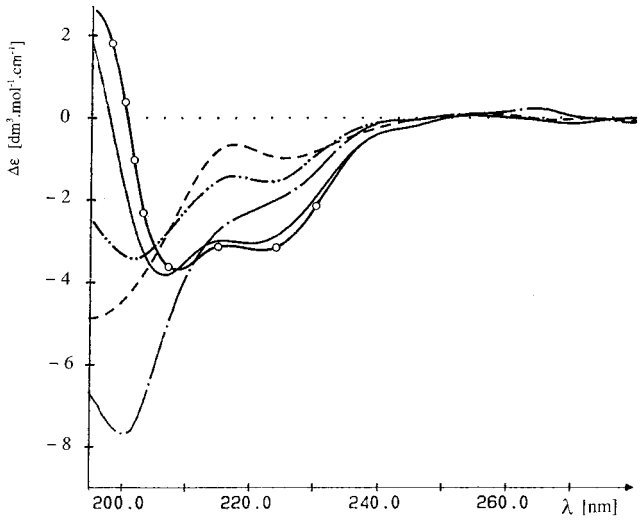

Figure 2. CD spectra of branched polypeptides at pH 7.3 in PBS: S$_i$K (—), SAK (- - -), ASK (-·-·), SK (-··-··), and LSK (○).

A total of 115 mg (0.25 mmol) of SK was dissolved in 1 mL of deionized water, and then the solution was diluted with 5 mL of DMF. One and the half equivalent amount of *Z*-Leu-OPcp (193 mg; 0.375 mmol) or *Z*-Glu-(OBzl)-OPcp (233 mg; 0.375 mmol) dissolved in 3 mL of DMF was added to the polymer solution. Equivalent amount of HOBt (61 mg, 20% water content) calculated according to the active ester derivatives was added in 1 mL of DMF to the reaction mixture. Finally, the pH of the solutions was adjusted to 7.5−8.0 with *N*-methylmorpholine. The mixture was stirred at RT for overnight, then the solvent was removed by evaporation. The remaining oil was solidified with ether, and the precipitate was washed several times with 10% DCM/ether, respectively. The dried product was suspended in 2 mL of abs. acetic acid and was treated with 20 mL of 35% HBr/acetic acid for overnight at 4 °C. The deprotected polymer samples were precipitated by addition of dry ether. The products were worked up as described above in case of SK polymer.

Amino Acid Analysis. The amino acid composition of polypeptides was investigated by amino acid analysis using a Beckman (Fullerton, CA) model 6300 amino acid analyzer. Prior to analysis, samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h.

Circular Dichroism Spectroscopy. Circular dichroism (CD) was measured with a Jobin-Yvon Mark VI dichrograph (Jobin-Yvon, Longjumean, France). CD spectra from 195 to 260 nm were recorded in a quartz cell with optical path of 0.02 cm at room temperature under constant nitrogen flush. The dichrograph was calibrated with D-(−)-pantoyllactone at 220 nm (*25*). CD spectra were recorded in PBS solution at pH 7.3, the concentrations of solutions being about 0.5 mg/mL (Figure 2.). The data of CD in the figure are expressed in terms of $\Delta\epsilon$, calculated for one Lys residue in the polypeptide backbone carrying an average side chain. The interpretation of CD spectra was based on the CD curves of polylysine (*26*), from which the branched polypeptides have been derived. The CD spectrum characterized by negative maxima at 208 and 221 nm of about the same intensity were considered helical, while the unordered structure is indicated with a strong negative maximum at 199 nm,

a weak negative maximum at 234 nm, and a weak positive maximum at 218 nm (*7*).

In Vitro Cytotoxicity Assays. In vitro toxicity was evaluated by measuring the viability of isolated rat liver (method A) or mouse spleen (method B) cells after incubation with various amount of polypeptides.

Method A. Isolated rat liver cells were prepared by the collagenase perfusion method of Seglen (*27*). Cells were incubated with varying amounts of polymers in rapidly shaking centrifuge tubes in suspension buffer (*28*) for 1 h at 37 °C. Controls were incubated with buffer alone. Viability of liver cells was measured by the trypan blue exclusion test. Three parallel samples were incubated for each polymer at each concentration, and 200−300 cells were counted for staining with trypan blue. Percentage viability was calculated from the mean of the three measurements (*28*).

Method B. Spleen cells were prepared from spleens of six 10−11 week old 22−24 g female BDF1 mice and resuspended in RPMI medium (*28*). Cells were taken at 3 mL (6×10^7 cells/mL) and incubated at 37 °C for 1 or 4 h. Polypeptides dissolved in PBS were diluted with RPMI. Each dilution was added in 100 μL to triplicate culture tubes, the concentration stated in the Results being the final concentration in the test tube. Control culture tubes were treated with 100 μL of RPMI alone. Viability of spleen cells was measured by the trypan blue exclusion test. Three parallel experiments were carried out with each polypeptide at each concentration. Percentage viability was calculated from the mean of the three measurements. Values for cell samples are given as percentage of mean of control samples incubated without any compound.

Cytostatic Assay. In vitro cytostatic properties were evaluated by measuring the viability of mouse colorectal carcinoma C26 cells after incubation with various amount of polypeptides. C26 cells were grown in tissue culture flasks at 37 °C in a humidified atmosphere in DMEM: Ham F12 medium and supplemented with 10% (v/v) heat inactivated foetal bovine serum (Biological Industries, Israel). Routine test showed the cells to be free of Mycoplasma.

C26 cells in logarithmic growth were trypsinized, resuspended in medium, and adjusted to a concentration of 1.5×10^4 cell/mL. A total of 200 μL of cell suspension was plated in a 96-well-flat-bottom tissue culture grade microtiter plates (Costar, Cambridge MA) and incubated at 37 °C for 24 h. A total of 100 μL of polymer solutions in serum-free medium at different concentrations was added in quadruplicate. After incubation at 37 °C for 3 h, medium was removed by aspiration, the cells were washed twice, and 200 μL of fresh complete medium containing FCS was added. Incubation for an additional 72 h was followed by the viability measurements using MTT assay (*29*). The absorbance was measured at $\lambda =$ 540 nm using a microplate reader (Titertek Multiskan). Absorbance of treated wells was compared to the control wells corresponding to the metabolically active cells. Cytostasis was calculated as a measure of growth inhibition, expressed as percentage of controls and calculated by the formula (100 − absorbance of treated wells) x 100/ absorbance of control wells.

Labeling with ^{125}I. ^{125}I labeling of polypeptides was carried out with *N*-succinimidyl 3-(4-hydroxy-phenyl)-propionate prelabeled with ^{125}I (Amersham International plc, Amersham, U.K.) as described before (*3*). The labeled polypeptides were purified of unreacted [^{125}I]sodium iodide by passage through Sephadex G-25, elution being in PBS at pH 7.2, using prepacked PD-10 columns (Pharmacia, Milton Keynes, U.K.). Electrophoresis on native polyacrylamide gel with a continuous 8 to 25% gradient was applied to assess the low molecular weight labeled product content of the preparation. The labeling efficacy was 35−40%. Specific activities of the final products were ∼2 MBq/mg.

Blood Clearance and Biodistribution Studies. All in vivo studies were carried out in adult (∼20 g) female BALB/c mice (Biomedical Services Unit, University of Nottingham) with appropriate licenses from the U.K. Home Office and with due consideration for animal welfare. Groups of mice ($n = 4$) were injected intravenously via a tail vein 5−10 mg of labeled polypeptides in 0.2 mL of PBS. Serial blood samples (10 mL) were taken from the tail tip at 1, 10, and 30 min and at 1, 2, and 3 h after injection directly into microcapillary pipets (Drummond Microcaps, Drummond Scientific Co., Broomhall, PA).

Blood clearance curves were constructed of the percent of the total initially injected count rates in the total blood volumes against time. The total intravascular blood volumes were calculated assuming the blood volume of the mice (in milliliters) to be 11.2% of the body weight (in grams). Areas under curves (AUC), as percent dose per hour, were calculated using the trapezoidal rule. At 4 h after injection, mice were killed, and weighed samples of blood, visceral organs, and residual carcass were assayed for radioactivity. Earlier comparative studies with ^{125}I, ^{111}In, and ^{51}Cr labeled branched polypeptides showed no significant differences in radioactivity in tissue samples (*31*). On the basis of these data, we assumed that ^{125}I-labeled marker is associated with the polypeptide during the study period. Results of the tissue-distribution analysis were expressed as a percentage of the total initially injected count rate recovered per gram of tissue.

Immunization. C57/Bl/6 (H-2^b, Igh-1^b), CBA (H-2^k, Igh-1^e), and BALB/c (H-2^d, Igh-1^a) mouse strains (LATI, Gödöllö, Hungary) were used for immunization. One experimental group consisted of six 10−12-week old male mice. Twenty micrograms of synthetic polypeptide dissolved in sterile saline (50 μL, 2 mg/mL) was emulsified in complete Freund's adjuvant (1:1, v/v) and injected sc into the backpaws and also ip. Serum samples were taken 7 and 14 days after antigen administration and titrated for IgM and IgG type antibodies and for IgG subclasses. Four weeks later the primed mice were boosted with the same amount of antigen emulsified in incomplete Freund's adjuvant (1:1, v/v) and administered as before. Serum samples were collected 20 days after the injection. A third challenge was given ip in PBS on day 55, and blood samples were taken 14 days after antigen administration.

Measurements of Antibody Titers by Solid-Phase Indirect Enzyme Immunoassay. Detection of the antigen-specific serum antibodies was performed by solid-phase indirect enzyme immunoassay using antigen-coated plates as described previously (*9*). SAK or ASK were coated on the surface of PVC plates (Propilén, Pécs, Hungary) at 5 μg/mL. After the washing and blocking procedures, various dilutions of the immune sera of mice were added. The bound antibodies were detected by horseradish-peroxidase-labeled anti-mouse IgM or IgG antibodies (Sigma, St. Louis, MO). Antibody titers were characterized by serum dilution corresponding to a fixed OD value (∼30%) chosen from the linear phase of the binding curve. For specificity studies, SAK or ASK were coated to the surface of the plates at graded concentrations (0.1−10 μg/mL) and a pretitrated dilution of pooled sera were added. For titration of IgG subclasses antibody

binding was developed by biotin-labeled subclass specific antibodies (Southern Biotechnology Associates Inc., Birmingham, AL). Titers were calculated from four or five independent titrations and mean values ±SD were given. Results of separate experiments were compared on the basis of reference sera used in all tests.

Immunomodulatory activity. Sheep red blood cells (SRBC) as immunogen were injected at 10^8 cell/0.2 mL of sterile saline ip into 10−12 week old mice. Control mice were injected with 0.2 mL of saline. The branched polypeptides and levamisole as potential immunomodulators were used at 0.2 and 1.0 mg/kg of body weight and were administered simultaneously with SRBC.

The hemolytic plaque-forming cell (PFC) assay, first described by Jerne and Nordin (*32*) and modified by Behling and Nowotny (*33*), was applied for the assessment of immunomodulatory ability of polypeptides. Spleens from each treatment group of five mice were obtained 4 days after immunization with SRBC and pooled. The washed spleen cells were resuspended in TC-199 medium, filtered, and adjusted to concentrations of 1:10 and 1:100 (v/v) for plating. Two milliliters of a 0.7% Noble agar solution, containing 0.1 mL of 1% DEAE dextran, 0.1 mL of a 10% suspension of freshly washed SRBC, and 0.1 mL of any of the various spleen cell concentrates were carefully mixed at 45 °C and layered on plates covered with 4 mL of 1.4% solidified but prewarmed agar. The plates were incubated for 60 min at 37 °C, and 2.5 mL of guinea pig complement diluted with 1:10 (v/v) balanced salt solution was added. The plates were incubated for an additional 30 min. Hemolyzed plaques in the agar were counted in triplicate and analyzed blind.

RESULTS AND DISCUSSION

In the present study, the development of a new series of branched polypeptides, which contain hydroxyl groups in their side chains, is reported. Ser was attached by HOBt-catalyzed active ester method to the N-terminals of oligo(DL-Ala) chains grafted to a polylysine backbone resulted poly[Lys(Ser_i-DL-Ala_m)] (SAK). Ser was coupled also directly to the ϵ-amino groups of polylysine followed by polymerization of DL-Ala NCA resulting oligo(DL-Ala) chain terminals. In this way, a reverse sequence was built up in the side chains corresponding to the poly[Lys(DL-Ala_m Ser_i)] (ASK). The number of hydroxyl groups in the polymer was increased by oligo(DL-Ser) branches instead of oligo(DL-Ala) ones [poly[Lys-(DL- Ser_m)] (SK)] (Figure 1).

Solution Conformation. Classification of solution conformations as an important property of branched polypeptides was carried out by CD spectroscopy. The CD curves of S_iK, SK, SAK, ASK, and LSK in PBS at pH 7.3 are shown in Figure 2. In the 190−250 nm wavelength region, the circular dichroic spectra, originated from the optical activity of amide bonds, indicate the formation of a helical secondary structure for S_iK and LSK, but only partially ordered conformation for SAK, ASK, and SK (Figure 2). It should be noted that the CD spectrum of polypeptide AK corresponds to a disordered conformation (*35*).

The incorporation of hydroxyl groups in side chains of branched polypeptides resulted in slightly more ordered conformation than observed with oligo(DL-Ala) side chains. In line with the hydrophilic character of the Ser residue(s), the aggregation of polymers was not detectable neither in solution nor after storage in solid state. Branched polypeptides with a number of hydroxyl groups described in this paper represent a new class of polycationic biodegradable polymers (*36*) with significantly increased water solubility. Polycationic polypeptide, LSK, assumed essentially ordered (helical) secondary structure (Figure 2).

Effect of Polypeptides on the Viability of Isolated Liver and Spleen Cells. In vitro cytotoxicity against isolated rat liver and mouse spleen cells was investigated and compared with data obtained earlier using the same cellular assays (*28*). Polypeptides at various concentrations (1.5−50.0 μg/mL) were incubated with rat liver cells or with mouse spleen cells, and the percentage of cell viability was determined (Figure 3, panels A and B). As reported previously, poly(L-Lys) proved to be rather toxic to the liver cells in the above concentration range (*28*). The present set of data indicate that the attachment of a single Ser residue to the ϵ-amino group of polylysine resulted in an essentially nontoxic polypeptide, S_iK. Cell toxicity of AK for spleen or liver cells was also reported earlier at $c = 50$ μg/mL concentration (*28*). In contrast, treatment with SK containing oligo(DL-Ser) instead of oligo(DL-Ala) did not reduce the viability of liver or spleen cells (Figure 3, panels A and B). ASK on spleen cells and LSK on liver cells were marginally toxic (5% decrease), while in case of other polypeptides, the number of viable liver or mouse cells even after 4 h incubation period was almost identical to the controls.

Effect on Growth of C26 Cells. Estimation of cytotoxicity was extended to the evaluation of the growth of C26 mouse colorectal carcinoma cells in the presence of various amounts of polycationic polymers. Cytostatic effect of polymers was determined by MTT assay (*29*). Results are demonstrated in Figure 3C. As described previously, poly[L-Lys] was shown to retard the growth of various tumor cells (*9*, *34*). The treatment of C26 cells with poly[L-Lys] resulted in a similar effect. Elongation at the ϵ-amino groups by oligo(DL-Ala) branches in AK reduced the cytostatic effect by more then 1 order of magnitude. Similar effect was observed with ASK. Interestingly, S_iK the backbone of ASK exhibit greatly reduced cytostatic effect as compared to poly[L-Lys], but the extension of Ser with oligo(DL-Ala) resulted in an elevated growth (Figure 3C). In contrast to ASK, much diminished cytostatic effect could be demonstrated with polypeptide SAK containing one Ser residue attached to oligo(DL-Ala) side chains. Poly[Lys(DL-Ser_m)], comprising only oligo(DL-Ser) branches exhibited no cytostatic effect in the concentration range studied.

Our data summarized in Figure 3 clearly suggest that there is a correlation between the number and location of Ser residues and cell killing activity of branched polypeptides. The incorporation of hydroxyl amino acid(s) could reduce markedly the in vitro cytotoxic effect of polycationic polypeptides.

Biodistribution of Polymeric Polypeptides. ^{125}I-labeled polypeptides were prepared by introduction of *N*-succinimidyl 3-(4-hydroxyphenyl)propionate containing ^{125}I onto the α-amino groups of the side-chain terminals as described before (*30*). The blood clearance profile and tissue distribution of polypeptides after iv administration are depicted in Figure 4 and Table 2. We found no significant difference in the area under the curve (AUC 0−4 h) for polypeptides prepared with either single Ser residue (S_iK) adjacent to the polylysine backbone or its oligo(DL-Ala) elongated version (ASK) (Figure 4A). Percentage of the total injected dose 4 h after injection was somewhat elevated for S_iK (38.3 ± 3.1% injected dose vs 27.8 ± 3.6% injected dose for ASK). Besides an increased kidney uptake of S_iK, the tissue distribution profiles of

ESK	161.8 ± 3.0	41.4 ± 1.2	13.9 ± 0.7	4.0 ± 0.3	11.8 ± 0.7	11.5 ± 0.5	4.8 ± 0.3	1.2 ± 0.1

these polymers were similar (Table 2.), both compounds being taken up predominantly by kidney and liver. The presence of multiple Ser residues in the branches (SK) resulted in significantly increased blood survival (Figure 4A) with an AUC of 97.1% dose/h (Table 2). Interestingly, branched polypeptide with oligo(DL-Ala) branches (AK) in accord with earlier published data was cleared rapidly from circulation with an AUC of only 17.8% dose/h (*8*). Elongation of the side chains of AK by a single Ser residue led to a dramatic increase in blood survival (AUC of 177.5% dose/h). The major sites of retention of ^{125}I-labeled SAK at the 4 h dissection time were the kidney with about 6% of the injected dose/g and the lung with about 4% (Table 2).

As described earlier, the branched polypeptide containing Leu at the end of the oligo(DL-Ala) branches (LAK)

BALB/c	667 ± 51	1122 ± 8	1459 ± 5	3119 ± 190	10 321 ± 1651	19 688 ± 2473

[a] Antibody titer ± SD. Pooled serum samples taken at different points of time were titrated using solid-phase indirect immunoassay as described in the Experimental Section. Mean values ± SD of three parallel titrations are given.

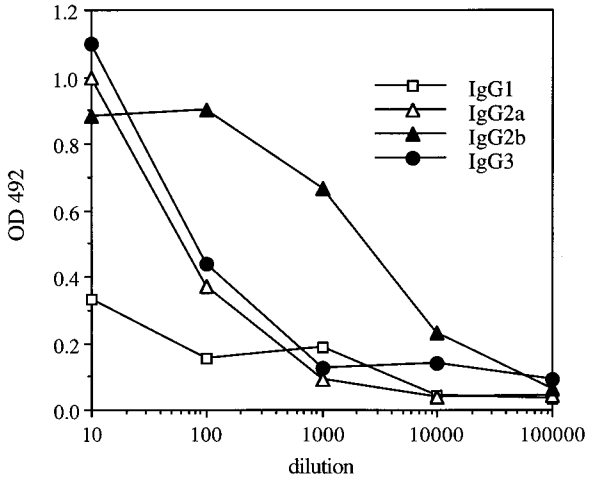

Figure 6. The distribution of different IgG subclasses during the memory antibody response of BALB/c mice immunized with ASK. The relative levels of specific antibody isotypes was determined as described in the Experimental Section.

was cleared rapidly from circulation (*8*). In contrast, LSK with oligo(DL-Ser) showed a longer blood survival (Figure 4B) with an AUC of 95.8% dose/h and the whole body retention was the highest value observed among polypeptides with Ser residue (47.7% dose/h) (Table 2). The blood clearance curve and AUC of amphoteric [^{125}I]EAK (*8*) was virtually identical to that of the labeled polypeptide ESK with oligo(DL-Ser) in the branches (Figure 4B, Table 2). It should be noted that the amphoteric ESK displayed greater blood survival than its polycationic counterpart LSK (Figure 4B). There was also a different pattern of tissue biodistribution, with reduced levels in the lung (3.8% for LSK vs 4.8% for ESK) but higher levels in spleen and liver (19.5% and 14.5% for LSK vs 11.8% and 11.5% for ESK) (Table 2.)

The results of this comparative study suggest that the survival of polycationic polypeptides is prolonged, and their tissue distribution is altered by the incorporation of Ser residue into the side chains. The substitution of Ala residues by Ser ones (AK vs SK, LAK vs LSK) elevated significantly the blood circulation time. Interestingly enough, the relative position of Ser in the branches influenced markedly the biodistribution of the polycationic polypeptides. The most favorable blood clearance profile and tissue distribution were obtained with SAK in which Ser is situated at the end of the side chain. For the evaluation of these findings, it should be borne in mind that this is the first branched polypeptide reported in the literature which is capable to circulate in the blood for an extended period of time despite its polycationic feature. This observation has to be taken in consideration for the design of future conjugates.

Immunoreactivity of branched polypeptides. The immunoreactivity of two representatives of polycationic Ser-containing polypeptides was characterized by their immunogenicity and immunomodulatory properties. In the first set of experiments SAK and ASK were used as immunogen and their capability of provoking antibody responses was investigated. In another assay we studied the effect of these polypeptides on sheep red blood cell (SRBC) antigen-induced immune responses.

Antibody Response. The immune response induced by the branched polypeptides was studied in three inbred mouse strains of different H-2 haplotype and Igh-1 allotype (*37*). The qualitative and quantitative features of the antibody response of polycationic polypeptides were characterized by IgM- and IgG-type antibody levels (Figure 5., Table 3), IgG isotype distribution (Figure 6), and fine specificity of antibodies (Figure 7) produced during the primary and memory response of BALB/c, CBA, and C57/Bl/6 mice.

The magnitude of the IgM and IgG type antibody response was measured at different points of time. As summarized in Table 3 and in Figure 5, SAK and ASK induced negligible level of IgM or IgG type antibodies in C57/Bl/6 mice even after the secondary antigen challenge. After repeated immunization of BALB/c mice with SAK or CBA mice with ASK, the antibody titers were rela-

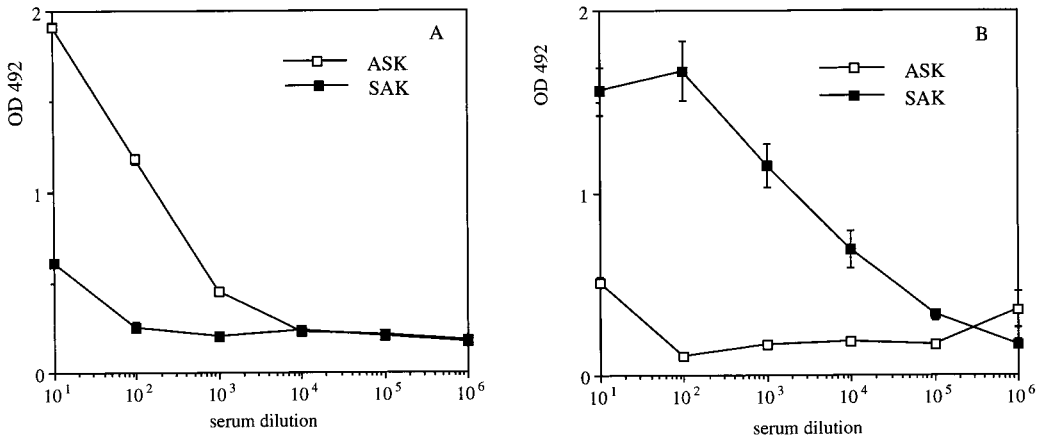

Figure 7. Cross reactivity pattern of antibodies induced by ASK in BALB/c mice (A) and by SAK in CBA mice (B). Mean antibody titers ±SD measured in the serum of immunized mice taken 14 days after antigen challenge on ASK- or SAK-coated plates.

tively low. Increased levels of IgG-type antibodies could be only detected after the third injection of ASK to BALB/c and of SAK to CBA mice (Figure 5). These findings indicate that the immunogenicity of branched polypeptides is highly dependent on the responsiveness of the inbred mouse strain (e.g., SAK is capable to elicit antibody response in CBA, but this compound is nonimmunogenic in C57/Bl/6 and poor immunogen in BALB/c) as well as on the amino acid sequence of the branches (e.g., SAK is not immunogenic, while ASK induced antibody response in BALB/c). The elevated level of ASK- and SAK-specific IgG isotypes in memory response of BALB/c and CBA mice of different MHC class II haplotypes (H-2^d vs H-2^k) point to a helper T-cell-dependent antibody response against these antigens (Figure 6).

Fine specificity of the polyclonal IgG type antibodies after hyperimmunization with ASK in BALB/c or with SAK in CBA was also studied (Figure 7). We found that the ASK-induced antibodies of BALB/c mice react with ASK but do not recognize SAK adsorbed to the solid phase (Figure 7A). Similarly, antibodies raised by SAK in CBA mice react with the immunizing antigen, but do not bind to ASK (Figure 7B). The recognition pattern of ASK- and SAK-specific antibodies demonstrate the lack of significant cross-reactivity between the two analogues, indicating that their antigenic determinants are different.

Immunomodulatory Effect. In a separate experiment the ability of SAK and ASK of modulating the ongoing immune response of BDF1 mice against sheep red blood cells (SRBC) was tested by the hemolytic direct PFC assay. On the basis of earlier data obtained from branched polypeptide studies in the same assay (*28*), the immunomodulatory activity of these polypeptides was studied at two concentrations (0.2 mg/kg and 1.0 mg/kg). The results are presented in Figure 8. Polypeptides administered in aqueous solution simultaneously with primary SRBC immunization have no pronounced effect on PFC levels expressed as adjuvant index. Small but concentration-independent enhancement could be detected in PFC formation after administration of ASK (AI $= 1.2 \pm 0.1$) Treatment with levamisol used as positive control increased PFC formation (AI $= 3.2 \pm 0.4$). These data indicated that the polypeptides had apparently no effect on the SRBC specific immune responses under the conditions studied.

CONCLUSION

For the construction of macromolecule−drug conjugates, it is important to provide rational basis for the selection of a proper carrier. With respect to the importance of the side-chain structure and charge of the branched polypeptides in various chemical and biological properties (*6*, *7*), we have studied the conformation, the immunoreactivity, the biodistribution, and in vitro cytotoxicity of a new set of branched polypeptides containing Ser residue. We found that the water solubility of these polycationic compounds with single or multiple OH group(s) was higher than of those containing only amino groups at the end of the branches.

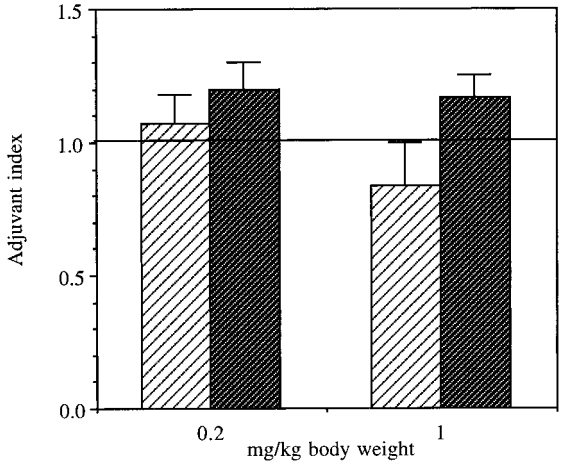

Figure 8. Dose-dependent effect of branched polypeptide ASK (dark bars) and SAK (light bars) on the PFC immune response to SRBC in BDF1 mice. Polypeptides and SRBC were applied simultaneously, ip, in saline.

CD spectra of polypeptides showed significant differences correlating with the position and numbers of Ser residues in the side chains (*19*). Under physiological conditions, polycationic polypeptides assumed ordered (helical) secondary structure (S_iK and LSK) or partially unordered conformation (SK, SAK, and ASK). It should be noted that in case of Ala-containing polypeptides an expressed tendency could be demonstrated in the formation of more ordered structure as compared to the respective serine analogues (SK vs AK and LSK vs LAK) (*7*). Consequently, the incorporation of even a single Ser could have an effect on the solution conformation by promoting its transition toward unordered secondary structure. The data summarized in this report indicate that these new compounds under in vitro conditions are essentially nontoxic on rat liver or mouse spleen cells up to a concentration of 50 μg/mL.

The blood clearance, biodistribution, and immunogenicity of these derivatives were dependent on the position

and number of Ser residues in the branches. The polypeptides investigated were taken up predominantly by the liver and kidney (S_iK, LSK, and ASK) or kidney and lung (SK and SAK). The best survival in the blood was found with SAK, representing the first polycationic branched polypeptide which show extended blood clearance similar to various proteins or the amphotheric polypeptide EAK (*8*, *37*). The investigation of the immunostimulatory capacity of the new analogues indicate that these compounds have no effect on to the SRBC specific humoral immune response in the dose interval investigated.

In contrast to the high pK_a value of the ϵ-NH_2 groups of polylysine, branched polypeptides, including compounds described in this paper, possess α-NH_2 groups with lower pK_a. The introduction of Ser residue(s) does not change the number of amino functional group in the polypeptides; therefore, the reduced cytotoxicity and prolonged blood circulation observed could mainly be attributed to the presence of OH groups, which might iniciate a further acidic shift in the pK_a of the free α-NH_2 groups positioned at the end of the branches.

In conclusion, these studies have indicated that synthetic branched polypeptides with Ser can be considered as potential candidates for constructing suitable conjugates for drug/epitope delivery. It is not only due to the presence of hydroxyl functional group to be used for oxime chemistry, but also to their beneficial biological features. Data summarized here indicate that the incorporation a single Ser residue preferably at the N-terminal position of the side chain provide optimal biological properties. No additional improvements were observed in case of polypeptides possessing oligo(DL-Ser) branches. These polypeptides are essentially nontoxic, nonimmunomodulatory under conditions studied and can be present in the circulation for a much longer period of time than previously described polycationic polymers.

Use of Dithiodiglycolic Acid as a Tether for Cationic Lipids Decreases the Cytotoxicity and Increases Transgene Expression of Plasmid DNA in Vitro

Fuxing Tang and Jeffrey A. Hughes*

Department of Pharmaceutics, College of Pharmacy, University of Florida, P.O. Box 100494, Gainesville, Florida 32610. Received February 12, 1999; Revised Manuscript Received May 16, 1999

Two major barriers that limit cationic lipids in gene delivery are low transfection efficiency and toxicity. In the present studies, we used dithiodiglycolic acid as a new tether for the polar and hydrophobic domains of a cationic lipid, cholesteryl hemidithiodiglycolyl tris(aminoethyl)amine (CHDTAEA). We compared the transfection activity and toxicity of CHDTAEA with its nondisulfide analogue and cholesteryl *N*-(dimethylaminoethyl) carbamate (DC-Chol). The liposomes of CHDTAEA had more than 2 orders of magnitude greater transfection activity than DC-Chol in CHO cells and 7 times greater transfection activity in SKnSH cells. CHDTAEA also demonstrated much less toxicity than the other two lipids. Dithiodiglycolic acid may act as an excellent linker in the application of cationic lipid syntheses.

INTRODUCTION

Cationic lipids are popular nonviral gene transfer vectors (Felgner et al., 1995; Gao and Huang, 1995; Rolland, 1998). However, two major barriers for cationic lipid-mediated gene transfer limit the application of cationic lipids. First, the low transfection efficiency compared to the virus system, and second, the toxicity. Since Felgner et al. first reported application of *N*-[1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (DOTMA) in transfection of plasmid DNA in 1987 (Felgner et al., 1987), many cationic lipids have been synthesized and used in plasmid DNA delivery (Gao and Huang, 1995; Lee and Huang, 1997; Rolland, 1998). Most of these efforts have been focusing on improving the transfection activity and decreasing the cytotoxicity. The uses of ester, amide, and carbamate linkages to tether polar and hydrophobic domains are common strategies to lower the toxicity. However, no intracellular degradation studies have been conducted for any cationic transfection lipid (Aberle et al., 1998). 3-β-[*N*-(*N*′,*N*′-dimethyl amino ethane) carbamoyl] cholesterol (DC-Chol)[1] was the first lipid used in clinical trials because of its combined properties of transfection efficiency, stability, and low toxicity (Gao and Huang, 1995). Recently, Nantz et al. reported a novel tetraester construct that reduced the cationic lipid-associated cytotoxicity compared to DC-Chol (Aberle et al., 1998). However, the introduction of the ester bond may also decrease the stability of liposome in systemic circulation when the liposomes are used in clinical trials. We proposed a strategy of taking advantage of the high intracellular reductive environment to make a disulfide linker-containing cationic lipid, which is stable outside cells whereas it can be reduced in cells by intracellular reductive substance (Tang and Hughes, 1998). The reduction of the disulfide bond will enhance the release of DNA from DNA−liposomes complexes. Dissociation of DNA from DNA−liposomes complexes is one of the major barriers for cationic liposome-mediated gene transfection (Escriou et al., 1998; Rolland, 1998; Zabner et al., 1995). Previously, we reported that a disulfide lipid—1′,2′-dioleoyl-*sn*-glycero-3′-succinyl-2-hydroxyetheyl disulfide ornithine conjugate (DOGSDSO)—could increase the plasmid gene transfection compared to its nondisulfide cationic lipid. However, the toxicity of the lipid was not significantly altered by the addition of disulfide bond (Tang and Hughes, 1998). We demonstrated that dithiothreitol (DTT) could reduce the part of disulfide cationic lipid and help to release part of DNA from DNA−liposomes complexes. However, DTT is not a cellular substance. When we tried to use a cellular reductive substance (e.g., glutathione) in the same experiment, no DNA was released. DTT is a stronger reductive reagent than glutathione since it forms a stable six member ring product (Hermanson, 1996). We hypothesized that the disulfide linker in DOGSDSO might be too strong so that it could not be degraded fast enough to significantly decrease the cytotoxicity. Since the disulfide bond of dithiodiglycolic acid is weakened by the strong electric withdrawing effects of two carboxyl groups which are symmetrically connected to the two α-carbons of disulfide bond (Figure 1), we hypothesized that introduction of dithiodiglycolic acid to tether the polar group and lipophilic domains will increase the transfection activity and decrease the toxicity of cationic lipid. Also the favorable results obtained with DC-Chol in vivo demonstrated that cholesterol is a suitable backbone as a starting reagent for cationic lipids. We synthesized cholesteryl hemidithiodiglycolyl tris(aminoethyl)amine (CHDTAEA) with a dithiodiglycolyl linker, its nondisulfide analogue cholesteryl hemisuccinyl tris(aminoethyl)-amine (CHSTAEA). We compared their transfection activities and cytotoxicity of CHDTAEA, CHSTAEA, and DC-Chol in mammalian cells. The results demonstrated

dithiodiglycolic acid as a linker in cationic lipid can greatly increase the transfection activity and decrease the toxicity of cationic lipids.

MATERIALS AND METHODS

Syntheses of CHDTAEA and CHSTAEA. CHDTAEA was synthesized as outlined in Figure 2. A total of 2.0 g (6 mmol) of cholesterol and 1.9 g of dithiodiglycolic acid (12 mmol) was dissolved in 30 mL of ethyl acetate under nitrogen. A total of 12 mmol of 1,3-dicyclohexylcarbodiimide (DCC), 0.19 g of 4-pyrrolidinopridine (1.2 mmol), and 1.43 mL of triethylamine (12 mmol) were added at 0 °C. The mixture was warmed to room temperature naturally and stirred under nitrogen at room temperature overnight. The reaction mixture was filtered and washed by 5% citric acid followed by brine three times. The organic layer was separated and dried over anhydrous sodium sulfate. The organic solvent was evaporated. The product cholesteryl hemidithiodiglycolate was purified on silica gel with a developer of hexane:ethyl acetate:acetic acid (30:10:1) (R_f = 0.3, 2.4 g, yield = 80%). *N*,*N*-BOC_2-tris (2-aminoethyl) amine was prepared by treating tris(2-aminoethyl)amine with 2 equiv of 2-(*tert*-butoxycarbonyloxyimino)-2-phenylacetonitrile (BOC-ON) in wet THF. A total of 0.30 g (0.5 mmol) of cholesteryl hemidithiodiglycolate, 0.24 g of *N*,*N*-BOC_2-tris(2-aminoethyl)amine (0.65 mmol), and 0.007 g of 4-pyrrolidinopridine (0.005 mmol) was dissolved in 20 mL of dichloromethane. A total of 0.6 mmol of DCC in dicholormethane and 0.06 mL of triethylamine was added dropwise at 0 °C. The mixture was stirred under nitrogen at room temperature overnight. The product *N*,*N*-BOC_2-[cholesteryl hemidithiodiglycolyl tris(aminoethyl)amine] was separated and purified on silica with a developer of dichlorometnae:methanol (10:1) (R_f = 0.35, 0.37 g, yield = 85%). The molecular weight was determined by a Micromass Quattro-LC-Z triple quadrupole mass spectrometer equipped with an atmospheric pressure chemical ionization (APCI) ion source (Beverly, MA). $M + H^+$= 881.5 (calculated, 881.3 for $C_{47}H_{82}N_4O_7S_2+H^+$). ^{1}H NMR ($CDCl_3$, 300 MHZ): 0.69 (s, CH_3), 0.830−2.04 [m, 3× (CH_3), 10× (CH_2), and 6× (CH)], 1.02 (s, CH_3), 1.42 [s, 2× $(CH_3)_3CO$], 2.38 [m, CH_2C═C], 2.52−2.68 [m, $(CH_2)_3N$], 3.28 [m, 2× (CH_2NCO)], 3.35 (m, CH_2NCO), 3.50 (s, CH_2-SS), 3.60 (s, CH_2SS), 4.68 (m, CHO), 4.99−5.32 (m, 3× NHCO), 5.38 (m, C═CH). BOC groups were detached (CF_3COOH, 0 °C, 15 min), and excessive trifluoroacetic acid was dried under high vacuum to produce CHDTAEA. This step is quantitative as reported by Behr (Behr et al., 1989). After the reaction, the purity was checked by TLC, and CHATAEA were used to prepare liposomes without further purification. Similar synthesis strategy was used to synthesize the nondisulfide analogue CHSTAEA (Figure 1) with slight modifications. Commercial available cholesteryl hemisuccinate was directly used to conjugate with *N*,*N*-BOC_2-tris (2-aminoethyl)amine to obtained the BOC protected CHSTAEA. $M + H^+$= 817.5 (calculated, 817.2 for $C_{47}H_{82}N_4O_7 + H^+$). ^{1}H NMR ($CDCl_3$, 300 MHZ): 0.69 (s, CH_3), 0.830−2.04 [m, 3× (CH_3), 10× (CH_2), and 6× (CH)], 1.02 (s, CH_3), 1.44 [s, 2× $(CH_3)_3$-CO], 2.30 (m, CH_2C═C), 2.48−2.70 [m, $(CH_2)_3N$], 3.15 [m, 2× (CH_2NCO)], 3.29 (m, CH_2NCO), 4.61 (m, CHO), 4.99−5.32 (m, 3× NHCO), 5.35 (m, C═CH). The same method was applied to detach the BOC group as mentioned above.

Liposome Preparation. CHDTAEA or CHSTAEA was dissolved in chloroform and mixed with a neutral helper lipid DOPE [1:1 molar ratio, which was optimized (data not shown)] (Felgner et al., 1994). DC-Chol was dissolved in chloroform and mixed with DOPE at the optimal molar ratio of 6:4 according to Gao and Huang (1991). The mixtures were evaporated to dryness in a round-bottomed flask using a rotary evaporator at room temperature. The lipid film was dried by nitrogen for a further 10 min to evaporate residual chloroform, and the lipid film was resuspended in sterile water to a concentration of 1 mg/mL based on the weight of cationic lipids. The resultant mixtures were shaken in a water bath at 30 °C for 30 min. The liposomes were hydrated at 4 °C overnight. The suspensions were sonicated using a Sonic Dismembrator (Fisher Scientific) for 2 min at 4 °C to form homogenized liposomes. The particle size distribution and ζ-potential of liposomes were measured using a NICOMP 380 ZLS instrument (Santa Babara, CA). The diameters were expressed by the volume-weight distribution parameter. The average diameters of CHDTAEA/DOPE, CHSTAEA/DOPE, and DC-Chol/DOPE were 121.7 ± 14.2, 154.7± 19.8, and 165.8± 19.9 nm, respectively. The ζ-potentials were +8.04, +7.68, and +6.98 mV, respectively. Liposomes were stored at 4 °C and used in 3 months.

Gel Electrophoretic Analysis of Release of DNA from DNA−Liposome Complexes by Glutathione. One microgram of plasmid DNA was dissolved in 10 μL of phosphate-buffered saline (PBS). Cationic liposomes CHATAEA/DOPE or CHSTAEA/DOPE were added to pDNA solution at the increasing weight ratios of 2/1, respectively. All calculations of the weight of liposomes in this paper were based on the weight of cationic lipids only. After the complexes were incubated for 30 min at

room temperature, 10 μL of 20 mM of glutathione in PBS (pH = 7.3) was added to the mixture to reach a final concentration of glutathione of 10 mM. The mixtures were incubated at 37 °C for 20 h. Released DNA was visualized by 1% agarose gel electrophoresis.

Cell Culture and Luciferase Gene Transfection. Chinese hamster ovary (CHO) and SKnSH cells were obtained from American Tissue Type Collection (Rockville, MD). The cells were maintained in RPMI 1640 or α-MEM media, respectively. All cells were kept in 5% CO_2 and at 37 °C in humidified air. Cells of same passage from same flask were cultured and seeded in three 24 well plates (2×10^5 cells/well) and grown to 60−80% confluence in 1 mL of serum-containing media. pGL3 luciferase DNA−liposome complexes were made and incubated at room temperature in serum free media for 30 min and used for transfection. The plasmid was isolated as previously described (Tang and Hughes, 1998). Before transfection, growth media containing serum was changed to 400 μL of serum free media. DNA−liposome complexes in 100 μL of serum free media were added to each well and incubated for 4.5 h. After the 4.5 h transfection time, the transfection media were changed to growth media and cells were incubated for another 24 h. Luciferase activity was measured using a standard luciferase assay (Thierry et al., 1997). Luciferase activity in transfected cells was expressed as RLU per well. All conditions for transfection were strictly kept the same for each different kind of liposomes. Experiments were repeated at least twice, and experiments were done in triplicate within a given series.

Toxicity Assay. The toxicity of CHDTAEA/DOPE, CHSTAEA/DOPE, and DC-Chol/DOPE in the CHO and SKnSH cell line was determined using a CARE-LASS (a calcein release assay) (Lichtenfels et al., 1994). Before the assay, cells were plated in a 96 well plate (1×10^5-cells/well) and grown to 60−80% confluence overnight. To test the toxicity of the DNA−liposome complexes, a fixed amount of DNA (1 μg/well) was used to complex with increasing amount of liposomes. The ratios of DNA to liposome of different treatments were the same as the ratios used in transfection studies. The cytotoxicity of three liposomes were measured and expressed according to our previous procedure (Tang and Hughes, 1998). Each experiment was performed in triplicate and repeated at least twice.

Flow Cytometry Analysis of the Delivery of Fluorescein (FITC)-Labeled pDNA into CHO Cells. The nucleic acid fluorescein labeling kit was purchased from PanVera Corporation (Madison, WI), and pDNA was labeled according to the product directions. One microgram per well of fluorescein-labeled pDNA was complexed with CHDTAEA/DOPE, CHSTAEA/DOPE, or DC-Chol/DOPE with the weight ratio of cationic lipid to DNA of 2/1, respectively. The complexes were used for transfection as stated in preceding methods in CHO cells. After a 4.5 h transfection period, the cells were quickly washed with PBS three times. One hundred microliters of trypsin-EDTA was added to each well. The cells were trypsinized for 2−3 min, and the reaction was stopped by 200 μL of 1% of bovine serum albumin (BSA) in PBS. The cells were collected and centrifuged at 250 g for 10 min. The supernatant was decanted, and the cell pellet was resuspended in 500 μL of 1% BSA and centrifuged for another 10 min to further wash phenol red and possible residue FITC-DNA. After the BSA solution was discharged, the cell pellet was resuspended in 500 μL of PBS followed by 500 μL of 2% of paraformaldehyde PBS solution. The cells were fixed at 0 °C for 15 min then stored at 4 °C overnight. Cell fluorescence was measured using a Becton Dickinson FACSort flow cytometer (San Jose, CA). A total of 10 000 cells were counted for each treatment. Cells, which were treated with nonlabeled DNA−liposome complexes, were used in compensation experiments. Cells were gated with their morphological properties. The mean fluorescence intensity of the cells was measured in terms of arbitrary units using a LYSYS II software program (Becton Dickinson, San Jose, CA). Each experiment was performed in triplicate and repeated twice.

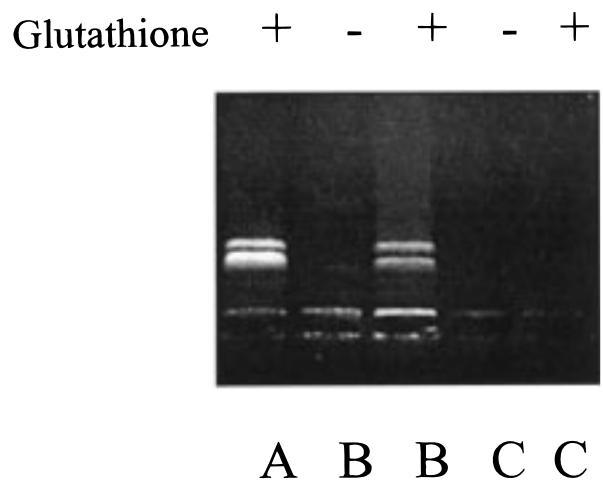

Figure 3. Gel electrophoretic analysis of the release of pDNA from cationic liposomes−DNA complexes in 10 mM glutathione in phosphate-buffered saline. (A) DNA, (B) CHDTAEA/DOPE + DNA (2/1, w/w), (C) CHSTAEA/DOPE + DNA (2/1, w/w).

Statistical Analysis. Statistical analyses were performed using one way ANOVA (Stat View 4.53, Abacus Concepts, Inc., Berkeley, CA). A probability of less than 0.05 was considered significantly different.

RESULTS

Release of DNA from Disulfide Cationic Liposomes−DNA Complexes by Glutathione. In this experiment, DNA was complexed with a disulfide cationic liposome CHDTAEA/DOPE or its nondisulfide cationic liposome analogue CHSTAEA/DOPE at the cationic lipid to DNA ratio of 2/1. As indicated in Figure 3, DNA was tightly complexed by both cationic liposomes. In the absence of glutathione, disulfide liposomes/DNA complexes did not release DNA after a 20 h incubation in PBS at 37 °C. In the presence of 10 mM of glutathione, >50% of DNA was released from complexes after the incubation. In both reductive and nonreductive environments, nondisulfide liposome CHSTAEA−DNA complexes did not release any DNA. The results suggested cationic liposome−DNA complexes were fairly stable and that cellular reductive substance (i.e., glutathione) can destabilize the complexes and help DNA to dissociate from liposomes. The complexes with the ratios of cationic liposome−DNA from 3/1 to 5/1 were also used to do the release assay with similar same results (data not shown).

Transfection of pGL3-Luciferase Plasmid in Mammalian Cells. Transfection activities of liposomes of CHDTAEA/DOPE, CHSTAED/DOPE, and DC-Chol/DOPE were compared in CHO and SKnSH cells (Figure 4). The experiment conditions were strictly controlled. The same cell lines with the same passage number and from the same flask were plated in three plates. The cells were transfected and the transgene expression was analyzed at the same time. We found the data was

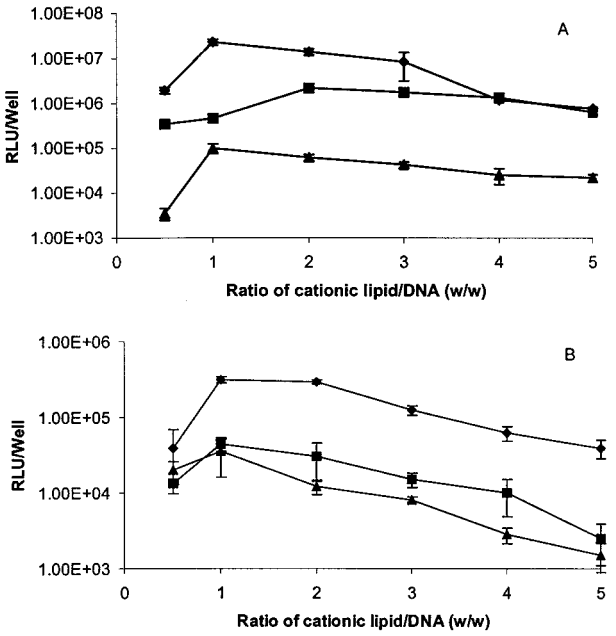

Figure 4. Comparison of the transfection of pGL3-luciferase plasmid by CHDTAEA/DOPE, CHSTAEA/DOPE, and DC-Chol in CHO and SKnSH cells. A fixed dose 2 μg/well of pGL3 DNA was mixed with increasing weight ratios of cationic liposomes (calculation based on cationic lipid) and used for transfection. Experiments were repeated at least twice. The trends were consistent in all experiments and the absolute values of transgene expression (RLU/well) were variable. (A) Transfection in CHO cells, (B) transfection in SKnSH cells. (◆) CHDTAEA/DOPE, (■) CHSTAEA/DOPE; (▲) DC-Chol/DOPE. Data are shown as mean ± SD (n = 3).

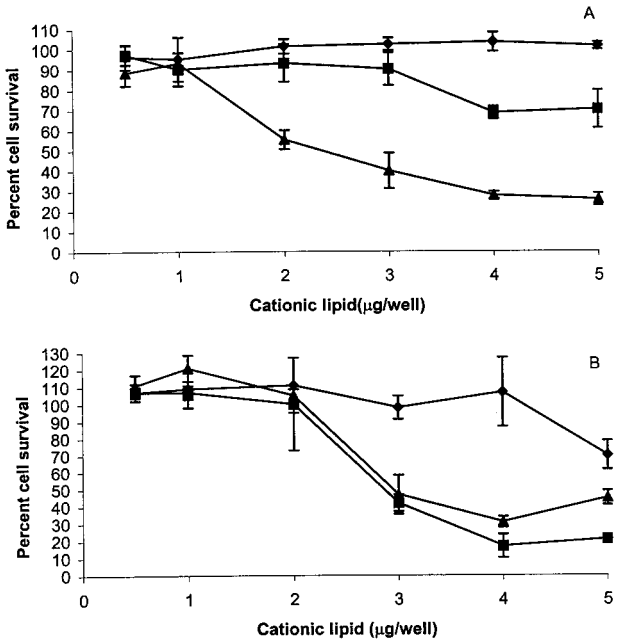

Figure 5. Toxicity assays. Cytotoxicity of the liposome−DNA complexes was studied in CHO and SKnSH cells. A fixed dose of 1 μg/well of pDNA was mixed with increasing amount of cationic liposomes and used in the toxicity assay. Cell viability was calculated as percentage of survival cells as stated in the Materials and Methods. (A) Toxicity in CHO cells. (B) Toxicity in SKnSH cells. (◆) CHDTAEA/DOPE, (■) CHSTAEA/DOPE; (▲) DC-Chol/DOPE. Data are shown as mean ± SD (n = 3).

variable from time to time although the same cell line, the same liposomes, and the same transfection period were used. It is safe to compare the transfection activities of different liposomes only in the same experiments. However, although the values from different experiments were variable, the trends were consistent. For example, the results that CHDTAEA had more than 100 times higher transfection activities were consistent in all experiments whereas the absolute value of RLU/well for each liposome in different experiments would fluctuate. In CHO cells, the transfection activities of liposomes CHDTAEA/DOPE and DC-Chol/DOPE peaked at the weight ratio of cationic lipid to DNA of 1/1, and CHSTAEA/DOPE peaked at the weight ratio of 2/1 (Figure 4A). At the optimal ratios of each liposome, CHDTAEA/DOPE had more than 100 times higher transfection activities than DC-Chol/DOPE, and 7 times higher transfection activities than its nondisulfide analogue CHSTAEA/DOPE. In SKnSH cells, all three transfection agents peaked at weight ratio of 1/1. CHDTAEA/DOPE had 7 times greater transfection activities than both CHSTAEA/DOPE and DC-CHOL/DOPE (Figure 4B).

Cytotoxicity of Liposome−DNA Complexes. The cytotoxicity of DNA−liposome complexes was tested in both CHO and SKnSH cells. Cell viability was variable between CHO cells and SKnSH cells (Figure 5). As indicated in Figure 5A, CHDTAEA/DOPE was not toxic to CHO cells up to the dose of 5 μg/well ($p > 0.05$) (Figure 5A). The nondisulfide analogue CHSTAEA/DOPE had higher toxicity than CHDTAEA/DOPE at the doses of 4 μg/well and 5 μg/well ($p < 0.05$). DC-Chol/DOPE had only about 30% cell survival at the dose of 5 μg/well. In SKnSH cells, CHDTAEA/DOPE also demonstrated lower toxicity, and it did not show significant toxicity until to the dose of 5 μg/well ($p > 0.05$). At the dose of 5 μg/well, about 70% of cells survived for the toxicity of CHDTAEA/DOPE. CHSTAEA/DOPE and DC-Chol/DOPE had much higher toxicity than CHDTAEA/DOPE at the doses of 3, 4, and 5 μg/well ($p < 0.05$). In both cell lines, the data suggested that application of dithiodiglycolic acid as a linker could greatly decrease the toxicity of cationic liposomes.

Cellular Associated DNA by Different Liposomes. To investigate if the greater transgene expression by CHDTAEA/DOPE liposomes resulted from greater amount of delivered pDNA by the liposomes, cell-associated fluorescein-pDNA after a 4.5 h transfection period was analyzed by using flow cytometric analysis. The relative amount of FITC-pDNA associated with cells after transfection period in CHO cells was measured by relative fluorescence intensity by using flow cytometry. The weight ratio of cationic lipid to DNA of 2/1 was used for each liposome (i.e., CHDTAEA/DOPE, CHSTAEA/DOPE, and DC-Chol/DOPE) (Figure 6). It was suprising to find that CHDTAEA/DOPE liposomes delivered less DNA to cells than either the CHSTAEA/DOPE or DC-Chol/DOPE liposomes, even though it had more that 100 times higher transgene expression than DC-Chol/DOPE and 7 times higher than CHSTAEA/DOPE at the weight ratio (i.e., 2/1) (Figure 4 A). It is also worth noting that the cell-associated pDNA of CHSTAEA/DOPE liposome and DC-Chol/DOPE liposome treatments were not significantly different, whereas the transfection activity of CHSTAEA/DOPE was higher than that of DC-Chol/DOPE (Figure 4A).

DISCUSSION

The use of ester, amide, and carbamate linkages to tether polar and hydrophobic domains is a common strategy to lower the toxicity of cationic lipids. However, the introduction of an ester also sacrifices the stability of cationic lipids because of hydrolysis reaction in the aqueous extracellular environment. The application of

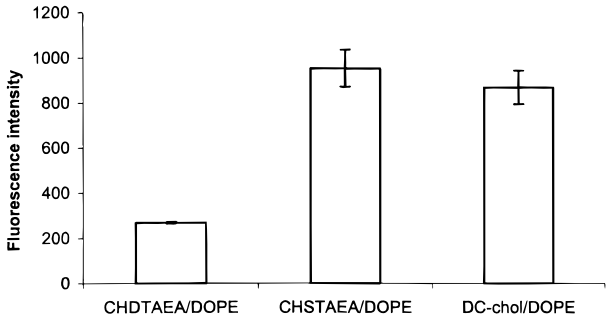

Figure 6. Comparison of the delivery of pDNA by CHDTAEA/DOPE, CHSTAEA/DOPE, and DC-Chol/DOPE in CHO cells. One microgram per well of fluorescein-labeled pDNA was complexed with CHDTAEA/DOPE, CHSTAEA/DOPE, or DC-Chol/DOPE with the weight ratio of cationic lipid to DNA of 2/1, respectively. The relative amount of pDNA, which was delivered into cells by different cationic liposomes, was measured as relative mean fluorescence intensity of cells as indicated in the Materials and Methods. Data are shown as mean ± SD ($n = 3$).

disulfide as a linker in cationic lipid is an alternative strategy to decrease the toxicity and increase the transfection activity of cationic lipids. The disulfide is stable at nonreductive extracellular environments and is unstable in the presence of high concentration of reductive intracellular substance, e.g., the concentration of glututhione in human tissue such as liver and lens is up to 10 mM (Halliwell, 1988). Disulfide conjugate techniques have widely been used in drug delivery to achieve high delivery efficiency (Boutorine and Kostina, 1993; Legendre et al., 1997; Trail et al., 1997) in the development of treatments for cancer. The normal method used involves crossing-linking or modification reactions using disulfide exchange processes to form disulfide linkage with sulfhydryl-containing molecules (Boutorine and Kostina, 1993; Legendre et al., 1997; Trail et al., 1997). This method will result in the more stable disulfide compound. A reductive substance such as dithiothreitol (DTT) is usually used to prove the hypothesis that the disulfide conjugate linker can be broken after delivery of conjugated drug in vivo. However, DTT is not a cellular substance. In this study, we used a cellular reductive substance (i.e., glutathione) to reduce the disulfide and release the complexed DNA. In CHDTAEA lipid, the disulfide bond is weakened by the strong electric withdrawing effects of two carboxyl groups, which is symmetrically connected to the two α-carbons of disulfide bond (Figure 1). CHDTAEA liposomes released more than half of complexed DNA in the presence of glutathione (Figure 3). As shown in Figure 3, CHDTAEA was as stable as its nondisulfide analogue CHSTAEA in a nonreductive environment since DNA/CHDTAEA/DOPE liposomes did not release any pDNA after incubation. Therefore, the introduction of this weak disulfide bond did not sacrifice the stability of DNA−liposome complexes outside cells. Without a disulfide bond, its analogue CHSTAEA did not release DNA at any conditions after incubation for 20 h. The release of DNA from DNA/liposomes complexes is a major barrier for cationic lipid-mediated gene transfection (Escriou et al., 1998, Rolland, 1998, Zabner et al., 1995). An interesting finding was observed during this study, very little DNA was released at the early time points of incubation until about 20 h (data not shown), after this time a large portion of the DNA was released. This result implies that a certain fraction of the liposome has to be degraded before the plasmid is released. More DNA released from the delivery system should result in greater transgene expression if the transcription machine has not been saturated.

The results of transgene expression demonstrated that CHDTAEA liposomes had greater transfection activity than its nondisulfide analogue CHSTAEA in both CHO and SKnSH cells. A second major concern is the toxicity of the delivery system. Common sense dictates that less toxic agent should have greater transfection. An optimal cationic lipid should be able to complex DNA and deliver DNA into cells, then release DNA from complexes for transcription (Pollard et al., 1998, Zabner et al., 1995). Finally, cationic liposome should be quickly degraded, otherwise freed liposome will fuse with cell membrane and result in cytotoxicity. In a dithioglcolyic acid linker, the disulfide is relatively weak and can be easily degraded by cellular substance such as glutathione. This facet of the lipid should lower toxicity, increase the amount of free plasmid DNA within the cell, and ultimately both of these events should increase transfection. As shown in Figure 5, in CHO cells, complexes of DNA/CHDTAEA/DOPE did not show cytotoxicity at all tested concentrations ($p > 0.05$). In SKnSH cells, it did not show cytotoxicity until at the concentration of 5 μg/well. Without the dithiodiglycolic acid linker, CHSTAEA and DC-Chol had much greater cytotoxicity (Figure 5). To investigate whether the greater gene transfection of CHDTAEA/DOPE liposomes resulted from more DNA delivered into cell instead of released into the cytosol, we investigated the cell-associated DNA after transfection period. Although CHDTAEA/DOPE had greater transfection activity, it had less cellular associated DNA than CHSTAEA/DOPE and DC-Chol ($p < 0.05$). More work is needed to understand the reason CHDTAEA delivered less DNA than its analogue CHSTAEA. On the other hand, the results supported the previous hypothesis that the association of DNA from DNA/cationic liposomes is a one of the majors barrier for gene delivery.

In summary, the application of dithiodiglycolic acid as a linker to tether polar domain of lipophilic domain of cationic lipid can enhance the transfection activity and decrease the cytotoxicity of cationic lipids. Dithiodiglycolic acid may be used in synthesizing new cationic lipids and may also be used as a drug conjugation linker. In the future, we will continue our work in CHDTAEA-mediated gene transfection in animal trials.

ACKNOWLEDGMENT

The authors thank the National Institutes of Health R29-HL 55779-04 and PO1-AG10485-08 for financial support and the University of Florida Gene Therapy Center and the Center for Neurobiology of Aging. The technical help of Sriram Krishnaswami in obtaining mass spectrum of the compounds was also greatly appreciated.

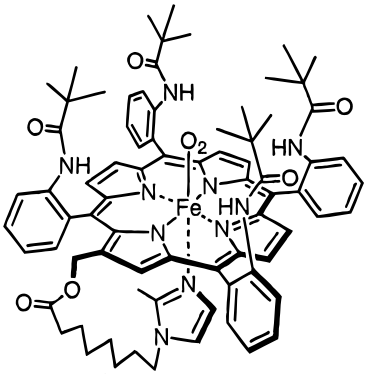
Human Serum Albumin Incorporating Tetrakis(*o*-pivalamido) phenylporphinatoiron(II) Derivative as a Totally Synthetic O_2-Carrying Hemoprotein

Eishun Tsuchida,* Teruyuki Komatsu, Yasuko Matsukawa, Kazuyoshi Hamamatsu, and Jian Wu

Department of Polymer Chemistry, Advanced Research Institute for Science & Engineering, Waseda University Tokyo 169-8555, Japan. Received February 22, 1999; Revised Manuscript Received May 24, 1999



2-[8-{*N*-(2-Methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(*o*-pivalamido)phenylporphinatoiron(II)s (FePs) were incorporated into hydrophobic cavities of recombinant human serum albumin (rHSA), providing a totally synthetic O_2-carrying hemoprotein (rHSA-FeP). An rHSA host absorbs maximally eight FeP molecules. Solution properties of the obtained albumin hybrid [[rHSA] = 5 wt %; FeP/HSA = 1−8 (mol/mol)] are almost identical to those of the rHSA itself; the specific gravity is 1.013 and the viscosity is 1.1 cP. Circular dichroism spectroscopy and isoelectric focusing measurement revealed that the second-order structure and surface charge distribution of rHSA were always constant independent of the binding numbers of FeP. Hydrophobic interaction is probably a major molecular force of the incorporation of this synthetic heme. rHSA-FeP can bind and release dioxygen reversibly under physiological conditions (in aqueous media, pH 7.3, 37 °C) like hemoglobin and myoglobin. Its O_2-coordination structure was evaluated by resonance Raman spectroscopy. The O_2 rebinding after the laser flash photolysis showed three-phases decay, which were analyzed by triple-exponential kinetics. The O_2-binding affinity and O_2-association and -dissociation rate constants of rHSA-FeP satisfy the initial clinical requirements for O_2 infusion as a red cell substitute.

INTRODUCTION

In the blood stream of the mammals, serum albumin is the major transport protein and binds a great variety of metabolites and organic compounds (Kragh-Hansen, 1981; Peters, 1985, 1997). Employing this nonspecific binding ability, it has been used in sustaining the release of therapeutic drugs injected into the blood stream. For example, the circulation time of the antitumor agent, *Adriamycin*, is prolonged by coupling to albumin (Gupta et al., 1990). The binding properties of porphyrin derivatives to serum albumin have also been widely studied, because they are the most attractive chromophores in biological systems (Little et al., 1960; Beaven et al., 1974; Muller-Eberhand et al., 1975; Adams et al., 1980). However, little attention has been paid to the clinical application of these albumin−porphyrin conjugates (Marden et al., 1989; Bonaventura et al., 1994).

Despite numerous researches on ligand bindings, there are only a few reports on the crystal structure of human serum albumin (HSA). Therefore, there is current interest in the three-dimensional structure of this very usual protein. The Protein Data Bank (Brookhaven) contains only three entries of HSA (PDB ID codes 1uor, 1ao6, and1bj5). The 585 amino acids consist of a unique heart-shaped structure, which is made of three repeating domains I−III (He et al., 1992; Carter et al., 1989, 1994). The majority of the ligands is bound at one or both sites within special hydrophobic cavities of the subdomains IIA and IIIA with typical equilibrium constants (*K*) ranging 10^6−10^4 M^{-1} (Kragh-Hansen, 1981). The crystal structure of the rHSA hybrid with five myristate molecules was resolved at 2.5 Å resolution (Curry et al., 1998). The five binding sites of the fatty acid were distributed asymmetrically throughout the rHSA molecules: one in subdomain IB, one between IA and IIA, two in IIIA, and one in IIIB.

More recently, we have found that a tetraphenylporphinatoiron(II) derivative with a covalently linked axial base, 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(α,α,α,α-*o*-pivalamido)phenylporphinatoiron(II) (FeP) is efficiently incorporated into recombinant HSA, which is manufactured on a large scale by expression in *Pichia pastoris* (Sumi et al., 1993). The obtained rHSA-FeP hybrid can bind and release dioxygen reversibly under physiological conditions (in aqueous media, pH 7.3, 37 °C) in a fashion similar to hemoglobin and myoglobin. We report for the first time the physicochemical properties and O_2-coordination behavior of this *totally synthetic hemoprotein*, rHSA-FeP, as a new type of red cell substitute.

EXPERIMENTAL PROCEDURES

Materials and Methods. FeP was synthesized according to our previously reported procedures (Tsuchida et al., 1995). An rHSA (25 wt %) was provided from Yoshitomi Pharmaceutical Ind., Ltd. and a natural plasma HSA was purchased from Bayer Co., Ltd. (Albumin Cutter, 5 wt %). Ethanol (>99.5%, Kanto Chemical Co., Ltd.) was used for the solvent of FeP. The preparation of rHSA-FeP was carried out as follows. Aqueous ascorbic acid (0.15 mM, 10 mL) was added to an ethanol solution of Fe(III)P (0.15 mM, 400 mL) under carbon monoxide atmosphere to reduce the central iron of Fe(III)P, affording a bright red carbonyl Fe(II)P complex. This Fe(II)P(CO) in ethanol was slowly added dropwise to the phosphate buffer solution (10 mM, pH 7.3) of rHSA (18.8 μM, pH 7.3, 400 mL) and ethanol was evaporated by a rotary evaporator. In this step, pH adjustment was essential. If the pH value was not 7.3, red precipitation was immediately formed after mixing with the ethanol solution of FeP. This is very different from the case of plasma HSA (Albumin Cutter). The mixture was then ultrafiltrated (ADVANTEC ultrafilter, cut off M_w, 50 000, 4 kg cm^{-2}) and dialyzed with cellulose membrane against phosphate buffer (pH 7.3) for 2 h and another 15 h, giving rHSA-FeP(CO) solution ([rHSA] = 5 wt %; FeP/rHSA = 4 mol/mol, 10 mL). UV−vis absorption spectra were obtained on a Shimadzu V-570 spectrometer.

Binding Numbers of FeP into rHSA. During the course of preparation of the rHSA-FeP hybrid with different FeP/rHSA mixing ratios, the precipitated carbonyl FeP [FeP(CO)] was extracted with $CHCl_3$, and its concentration was assayed by the absorption spectrum (ϵ_{max} at 427 nm, 2×10^5 M^{-1}cm^{-1}). On the basis of the quantitative analysis of this free FeP(CO) molecule, the binding numbers of FeP were determined (Komatsu et al., 1999).

Solution and Physicochemical Properties. The viscosity and density of the rHSA-FeP solution were measured at 37 °C according to the previously reported procedures (Komatsu et al., 1999). For optical microscopy observation, an OLYMPUS BX60 equipped with an OLYMPUS PM-10AK camera was used. Isoelectric points and molecular weights were measured by a Pharmacia Phastsystem using isoelectric focusing (IEF) in pH 3−9 Phast Gel IEF 3-9 and native PAGE in Phast Gel Gradient 8-25, respectively (Komatsu et al., 1999). Colloid osmotic pressure was measured by a Wescor 4420 colloidosmometer at 25 °C.

Circular dichroism (CD) spectra were obtained by a JASCO J-725 spectropolarimeter. The rHSA concentration was 1 μM (FeP/HSA = 1, 4, 8 mol/mol), and quartz cuvettes with 1 and 10 mm thickness were used for measurements over the range 190−250 and 250−700 nm, respectively.

Resonance Raman (RR) Spectroscopy. RR spectra were obtained on a JASCO NRS-2000 laser Raman spectrometer equipped with a CCD multichannel detector. Excitation was carried out by the 457.9 nm line of an NEC GLG2162 Ar^+ ion laser at 25 °C. The details of the measurements were reported elsewhere (Komatsu et al., 1999).

O_2-Binding Equilibrium and Kinetics. O_2-binding to the FeP was expressed by

$$\mathrm{FeP} + \mathrm{O_2} \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} \mathrm{FeP(O_2)} \qquad (1)$$

$$(K = k_{on}/k_{off})$$

The O_2-binding affinity (gaseous pressure at half O_2 binding for FeP, $P_{1/2} = 1/K$) was determined by spectral changes at various partial pressure of O_2 as in previous literatures (Tsuchida et al., 1993; Collman et al., 1983). FeP concentrations of 20 μM were normally used for UV−vis absorption spectroscopy. The spectra were recorded within the range 350−700 nm. The thermodynamic parameters for O_2 binding (ΔH, ΔS) were determined by van't Hoff plots of K. The O_2-association and -dissociation rate constants (k_{on}, k_{off}) were measured by a competitive rebinding technique using a Unisoku TSP-600 laser flash photolysis apparatus (Tsuchida et al., 1993; Collman et al., 1983; Traylor et al., 1985). The absorption decays accompanied O_2 association to FeP in rHSA obeyed triphases of the first-order kinetics. We employed triple-exponential rebinding kinetics to analyze the absorption decays, $\Delta A(t)$,

$$\Delta A(t) = C_1 \exp(-k_1 t) + C_2 \exp(-k_2 t) + C_3 \exp(-k_3 t) \qquad (2)$$

where k_1, k_2, and k_3 are apparent rate constants for the each reaction. The data were fit to this equation using a Solver in Excel 5.0.

RESULTS AND DISCUSSION

FeP Binding to rHSA. A maximum of eight FeP molecules were incorporated into certain domains of human serum albumin with binding constants from 10^6 to 10^4 M^{-1} (Tsuchida et al., 1997; Komatsu et al., 1999). FeP was expected to bind to rHSA in a similar manner, and the association sites would also be identical, namely, subdomains IB-IIA, IIA, and IIIB, etc. From the quantitative analyses of the free FeP(CO) in the prepared rHSA-FeP solution, the binding ratios were calculated to be 99% for FeP/rHSA = 8 and 70% for 9. Thus, the maximum binding numbers of FeP to an rHSA were determined to be eight, the same as that of HSA-FeP.

Solution and Physicochemical Properties. The red solution of rHSA-FeP was stored for more than 3 months at 4 °C without any aggregation and precipitation. The long-term stability and absence of a specific blood type are great advantages for O_2 infusion as a red cell substitute.

The solution properties of rHSA-FeP satisfy the physiological requirements. Specific gravities were 1.013 (FeP/rHSA = 1−8 mol/mol). The viscosity of 1.1 cP (at a high shear rate of 230 s^{-1}) was much lower than that of human blood (4.0 cP) and exhibited Newtonian type shear rate dependence just as such as as rHSA itself (Figure 1). Furthermore, rHSA-FeP possessed good compatibility with human blood [1/1 (v/v)]; the viscosity of the mixed dispersion with freshly drawn human whole blood showed 1.8 cP (at 230 s^{-1}). Optical microscopic observation also revealed that the homogeneous morphology of the red cells were not affected by mixing with the whole blood (Figure 2).

The isoelectric points (pI) of the rHSA-FeP [FeP/rHSA = 1−8 (mol/mol)] were 4.8, exactly the same as those of rHSA (Figure 3). Fatty acid binding, for example, induced the significant reduction of the pI value due to partial neutralization of the surface charge. The FeP molecule without any ionic residue interacts nonspecifically with a hydrophobic cavity of rHSA, such that its surface charge distributions are not changed. The colloid osmotic pressure (COP) of the rHSA-FeP solution ([rHSA] = 5 wt %) showed 18 Torr, which is also identical to the 5 wt % rHSA. Consequently, the essential biologi-

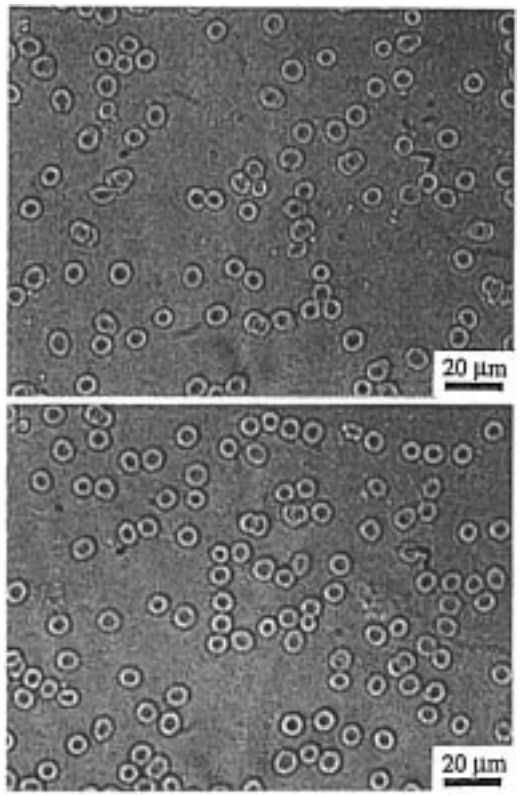

Figure 2. Optical microscopic observation of (a) rHSA + human whole blood and (b) rHSA-FeP(8) + human whole blood.

cal roles as serum albumin, i.e., control of COP and plasma expansion, are completely sustained after incorporation of FeP.

The secondary and tertiary structures of rHSA and the deformation upon the FeP binding were measured by circular dichroism (CD) spectroscopy. The spectral pattern showed typical double-minimum negative peaks in the UV region independent of the binding numbers of FeP. There were no differences when compared to that of rHSA (Figure 4). The estimated α-helix content was approximately 60%, suggesting that the FeP association did not cause any high-ordered structural change of rHSA. Moreover, rHSA-FeP showed no CD peaks in the Soret region (400−500 nm). The porphyrinatoiron binding to the serum albumin is accompanied by a rise to an extrinsic negative Cotton effect in the Soret region, because it binds to an albumin through a coordination

between the imidazole of histidine and the central iron, allowing a high degree of immobilization (Beaven et al., 1974; Casella et al., 1993). We concluded that hydrophobic interaction is the major molecular force of the FeP binding to rHSA, and its incorporation does not induce any changes in the highly ordered structure and surface charge distribution of the host albumin.

O_2-Coordination Properties of rHSA-FeP. The UV−vis absorption spectrum of the aqueous rHSA including carbonyl FeP complex [FeP(CO)] displayed a typical CO-coordinated low-spin tetraphenylporphinatoiron(II) derivative (λ_{max} = 427 and 539 nm) (Figure 5). Light irradiation with 500 W incandescent lamp on this solution under flowing O_2 led to CO dissociation, giving the dioxygenated species (λ_{max} = 426 and 552 nm). Upon exposure of rHSA-FeP(O_2) to argon, the UV−vis absorption spectrum changed to that of a five-N-coordinated species (λ_{max} = 443, 542, and 567 nm). This dioxygenation was reversible and kinetically stable under physiological conditions (pH 7.3, 37 °C). The HSA hybrid incorporating tetrakis (α,α,α,α-*o*-pivalamido)phenylporphinatoiron(II) without axial imidazole showed a similar spectrum under an argon atmosphere like HSA-FeP, but the ferrous complex immediately oxidized after exposure of dioxygen. This result suggested that the covalently bound imidazole arm is necessary for O_2-adduct formation.

Resonance Raman spectroscopy was then employed to characterize the coordination structure of the FeP com-

plex in rHSA. Under argon, a medium band at 198 cm^{-1} was assigned to the Fe(II)-N(imidazole) stretching mode, $\nu(Fe-N_\epsilon)$, based on a similar assignment for other porphyrinatoiron(II) systems (Figure 6) (Hori et al., 1980). The covalently linked imidazole moiety coordinates to the central iron(II) of the porphyrin in rHSA. After exposure to O_2, a new $\nu(Fe-O_2)$ vibration of dioxygenated FeP appeared at 560 cm^{-1}. This frequency suggests a typical end-on type O_2 coordination to the porphyrinatoiron(II) (Hirota et al., 1996; Wu et al., 1998). The deformation modes of the porphyrin ring (ν_8 and ν_4) were also upshifted from 370 and 1346 cm^{-1} to 394 and 1364 cm^{-1}, respectively. These observations indicate the conversion of the five-coordinated high-spin state to the six-coordinated low-spin state of FeP (Desobois et al., 1989; Hori et al., 1980). All the observed shifts were reversibly dependent on the O_2 concentration. We conclude that the rHSA-FeP definitely binds and releases O_2 molecule in aqueous solution.

The autoxidation reaction of the oxy state (λ_{max} = 552 nm), however, occurred, and the absorption band of 552 nm almost disappeared after 24 h, leading to the formation of inactive Fe(III)P. The half-life of the dioxygenated species ($\tau_{1/2}$) was 8 h at 25 °C and 2 h at 37 °C (pH 7.3, [NaCl] = 150 mM). The relatively low stability of dioxygenated rHSA-FeP seems insufficient to meet clinical requirements, however, the $\tau_{1/2}$ was significantly prolonged in the bloodstream (Tsuchida et al., 1999). This observation preliminary shows that some plasma contents, i.e., ascorbic acid, contribute to the apparent long-lifetime of the dioxygenated FeP in vivo.

Table 1. O_2-Association and -Dissociation Rate Constants of rHSA-FeP at 25 °C (pH 7.3, [NaCl] = 150 mM)

	10^{-7} k_{on} (M^{-1} s^{-1})	10^{-6} k'_{on} (M^{-1} s^{-1})	10^{-2} k_{off} (s^{-1})	10^{-2} k'_{off} (s^{-1})
rHSA-FeP(4)	3.2	10	7.2	2.2
rHSA-FeP(8)	3.4	9.5	7.5	2.0
Hb(T-state)α[a]	0.29		1.8

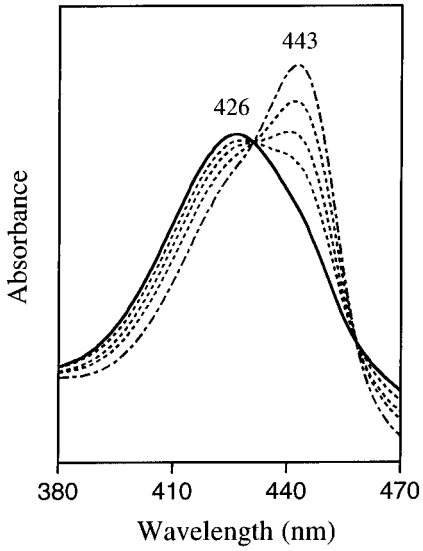

Figure 7. UV−vis absorption spectral changes of the rHSA-FeP(4) on O_2 titration in phosphate buffer solution (pH 7.3) at 37 °C.

The O_2-association and -dissociation rate constants (k_{on}, k_{off}) were explored by laser flash photolysis. The absorption decays accompanied O_2 recombination were composed of three-phases of the first-order kinetics, the curves were therefore fit by triple-exponential equation. The minor, less than 10%, component k_1, which is the fastest rate constant, was always independent of the O_2 concentration. It is presumably correlated with a base elimination reaction (Geibel et al., 1979). From the slope of linear plots of k_2 and k_3 versus O_2 concentration, two association rate constants for the fast O_2 rebinding (k_{on}) and the slow O_2 rebinding (k'_{on}) were obtained (Table 1). The k_{on} values are 3-fold larger than k'_{on}. The ratio of the fast reaction and the slow reaction was approximately 2 for rHSA-FeP(4) and 3 for rHSA-FeP(8). In the case of rHSA-FeP(1), k_{on} (3.2×10^7 M^{-1} s^{-1}) was only major ingredient. Thus, we concluded that the O_2 association to FePs incorporated into the certain domains of serum albumin are largely influenced by the molecular microenvironments around the each FeP, for example, steric hindrance by the protein residues and polarity.

The O_2-binding affinities [$P_{1/2}$, gaseous pressure at half O_2 binding for the porphyrinatoiron(II)] of the rHSA-FeP were determined on the basis of the UV−vis spectral changes by O_2 titration. The isosbestic points were maintained in all cases (Figure 7). According to the results of the kinetics experiments, the $P_{1/2}$ values were divided by two components using eq 3,

Table 2. O_2-Binding Affinities of rHSA-FeP at 25 °C and the Thermodynamic Parameters (pH 7.3, [NaCl] = 150 mM)

	O_2-binding affinities (Torr)		ΔH (kJ mol^{-1})	ΔS (J K^{-1} mol^{-1})
rHSA-FeP(4)	$P_{1/2}$	13	−60	−114
	$P'_{1/2}$	13	−61	−116
rHSA-FeP(8)	$P_{1/2}$	14	−60	−112
	$P'_{1/2}$	13	−61	−101
red blood cell	$P_{1/2}$	9		
Hb(T-state)α[a]	$P_{1/2}$	40[a]	−57 to −65[b]	−116 to −133[b]

[a] pH 7, 20 °C, Sawicki et al. (1977). [b] pH 7.4, Imai et al. (1975).

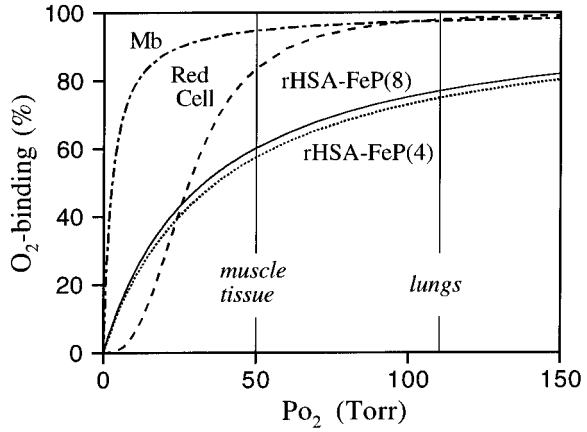

Figure 8. O_2-binding equilibrium curves of rHSA-FeP at 37 °C. The O_2-binding affinities of rHSA-FeP represented are averages of the two components.

$$Y = A[K[O_2]/(1 + K[O_2])] + B[K'[O_2]/(1 + K'[O_2])] \quad (3)$$

where Y is total O_2 saturation of FeP in rHSA, $K = (P_{1/2})^{-1}$, and $K' = (P'_{1/2})^{-1}$. The values A and B determined from the kinetic experiments were used. The obtained $P_{1/2}$ and $P'_{1/2}$ are relatively close, and the thermodynamic parameters for each O_2 binding are nearly identical for rHSA-FeP(4) and rHSA-FeP(8) (Table 2). The O_2-dissociation rate constants were also calculated by k_{on}/K (Table 1). 2-Methyl-substituted imidazole covalently bound to the parent porphyrin plays a role for adjustment of the $P_{1/2}$ value suitable for picking up dioxygen in the lungs and releasing it to the myoglobin in the tissues, namely T-state model (Collman et al., 1978; Geibel et al., 1979). The CO-binding affinity of rHSA-FeP(4) was ca. 0.1 Torr at 25 °C; therefore, the active ferrous porphyrins may be partially poisoned by the small amount of CO at the cellular level.

As expected, monomeric FeP in rHSA did not show a cooperative O_2-binding profile like that seen in hemoglobin; the Hill coefficient was 1.0 (Figure 8). Although the $P_{1/2}$ at 37 °C is slightly lower than that of hemoglobin, the O_2-transporting efficiency (OTE) of rHSA-FeP between the lungs (P_{O_2} = 110 Torr) and muscle tissue (P_{O_2} = 40 Torr) becomes 22%, which is nearly the same value (23%) as that of the red cells.

In conclusion, recombinant human serum albumin incorporating tetraphenylporphinatoiron(II) derivatives as O_2-binding sites provides a totally synthetic O_2-carrying hemoprotein. The FeP binding is a hydrophobic interaction, that did not lead to a change in the physicochemical properties of the rHSA molecule, e.g., surface charge, highly ordered structure, as well as the solution properties. All eight Fe(II)P complexes, in which the imidazolyl group is intramolecularly coordinated to the central iron(II), form reversible dioxygen adducts in the albumin. The O_2-binding ability (O_2-binding affinities = 31−37 Torr, OTE = 22% at 37 °C, etc.) satisfies the initial clinical requirements for O_2 infusion as red cell substitutes.

^{99m}Tc-Labeling of Hydrazones of a Hydrazinonicotinamide Conjugated Cyclic Peptide

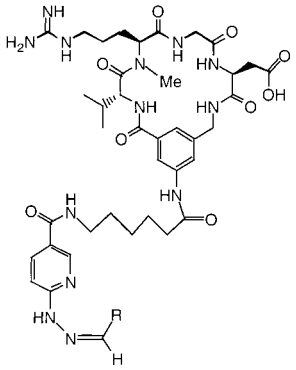
D. Scott Edwards, Shuang Liu,* Anthony R. Harris, Michael J. Poirier, and Barbara A. Ewels

DuPont Pharmaceuticals Company, Medical Imaging Division, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received February 24, 1999; Revised Manuscript Received April 9, 1999

Eight HYNICtide hydrazones (three with aliphatic substituents and five with aromatic groups) were studied for their potential use as the final intermediate for preparation of RP444, a new radiopharmaceutical under development for imaging thrombosis. The goal of this study is to screen various hydrazones through stability testing and radiolabeling and find those which are able to remain stable without significant degradation in the manufacturing process and at the same time are reactive to produce enough free hydrazine in situ for successful ^{99m}Tc-labeling. In an initial screening study, only hydrazones **6** and **8**, which contain aliphatic substitients, gave satisfactory (≥90%) yields of RP444 using 50 °C and 30 min of heating. However, their solution instability excludes them from being used as commercial reagents. Hydrazones **1** and **4** gave ≥90% yields when the reaction mixtures were heated at 80 °C for 30 min. Both hydrazone **1** and hydrazone **4** can be used as the final intermediate for preparation of RP444. The combination of 40 mg of tricine, 1−10 mg of TPPTS, 20−40 μg of hydrazone **1** or **4** for 50 mCi of [^{99m}Tc]pertechnetate, 20−50 μg of stannous chloride, pH 4.5 ± 0.5, and heating at 80 °C for 30 min gives the best yield for RP444. It is surprising that hydrazones **1** and **4** have both the solution stablity with respect to decomposition and to reaction with aldehydes and ketones and yet are able to hydrolyze in situ to produce enough free HYNICtide for the ^{99m}Tc-labeling.

INTRODUCTION

Recently, Abrams and co-workers (*1*−*3*) reported the use of organic hydrazines such as hydrazinonicotinamide (HYNIC) in labeling polyclonal IgG with ^{99m}Tc for imaging focal sites of infection. This technology has also been used for the ^{99m}Tc-labeling of a variety of biologically active molecules. These include chemotactic peptides (*4*−*7*) for infection imaging, somatostatin analogues (*8*, *9*), and antisense DNA oligonucleotides (*10*−*12*) for tumor imaging.



We are interested in the ^{99m}Tc-labeling of glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonists for the development of thrombosis imaging agents (*13*−*20*). Recently, we labeled an HYNIC-derivatized cyclic peptide [HYNICtide, cyclo(D-Val-NMeArg-Gly-Asp-Mamb(5-(6-(6-hydrazinonicotinamido)hexanamide)))] using tricine and TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate) as coligands (*19*). The combination of HYNICtide with tricine and phosphine produces a new ternary ligand system which forms stable technetium complexes, [^{99m}Tc(HYNICtide)(tricine)(TPPTS)] (RP444) in high yield and high specific activity (≥20 000 Ci/mmol). In the canine arteriovenous (AV) and deep vein thrombosis (DVT) models, RP444 has been shown to be able to detect rapidly growing arterial and venous thrombi (*20*). The phase I clinical trials demonstrated an excellent safety profile and acceptable dosimetry. Preliminary results from phase II trials showed that RP444 can detect DVT within 60 min with 93% sensitivity, 75% specificity, and 82% accuracy (*21*).

In the manufacturing process, we found that the final intermediate HYNICtide itself is not stable in aqueous solution, particularly under basic conditions, and reacts readily with aldehydes or ketones. The presence of aldehydes and ketones in small quantities is unavoidable in a commercial pharmaceutical manufacturing setting, because they can be extracted from various plastic and rubber materials, and are also found in common disinfectants. In a recent patent application (*22*), Schwartz et al. disclosed the use of a lower alkyl hydrazone (propylaldehyde hydrazone) to stabilize HYNIC-modified proteins. Although its use can prevent the cross-reaction of the hydrazine with other reactive groups on the proteins, it can also be displaced by other aldehydes, formaldehyde in particular, and ketones to form different hydrazones. This presents a significant problem in maintaining the purity of the final intermediate and, thus, renders lower alkyl hydrazones unattractive as commercial reagents. To prevent the decomposition or degradation of the HYNICtide in the manufacturing process, several stable hydrazones have been synthesized (*23*, *24*) and studied for their solution stability in the presence of formaldehyde. It was found that for a hydrazone to be stable in aqueous solution there must be a conjugated π-system (*23*, *24*).

The radiolabeling efficiency of the HYNICtide is dependent on the availability of the free hydrazine group, relative component levels, and reaction conditions. The formation of hydrazones stabilizes HYNICtide and prevents its degradation or decomposition, but it reduces the availability of the free hydrazine group for ^{99m}Tc-labeling. To assess the impact of hydrazone formation on the ^{99m}Tc-labeling of the HYNICtide, we performed a series of radiolabeling studies and explored the factors influencing the ^{99m}Tc-labeling kinetics of several stable hydrazones (Figure 1). The results are described in this report.

EXPERIMENTAL SECTION

Materials. TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate) and tricine were purchased from Aldrich Chemical Co. TPPTS was purified according to the literature method (*25*) before use for the radiolabeling. $Na^{99m}TcO_4$ was obtained from a commercial DuPont Pharma $^{99}Mo/^{99m}Tc$ generator, N. Billerica, MA. The syntheses of hydrazones **1**−**8** of the HYNICtide with benzaldehyde, 4-(*N*,*N*-dimethylamino)benzaldehyde, 4-carboxy-benzaldehyde, sodium 2-formylbenzenesulfonate, 4-pyridinecarboxaldehyde, propylaldehyde, crotonaldehyde, and glyoxylic acid will be reported as a separate communication (*24*).

General Procedure for the ^{99m}Tc-Labeling of Hydrazones. To a clean 10 mL vial were added 0.4 mL of tricine solution (100 mg/mL in H_2O), 0.2 mL of the hydrazone solution (50 μg/mL in H_2O), 0.1 mL of phosphine coligand solution (10 mg/mL in H_2O), 0.5 mL of $Na^{99m}TcO_4$ solution (100 mCi/mL in saline), and 20 μL of $SnCl_2 \cdot 2H_2O$ solution (1.0 mg/mL in 0.1 N HCl). The pH was adjusted to 4.5 ± 0.5, if necessary. The reaction mixture was heated at 50 or 80 °C for 30 min. After cooling at room temperature, the reaction mixture was analyzed by radio-HPLC and ITLC.

The HPLC method used a heated (50 °C) Zorbax C_{18} column (4.6 mm × 250 mm, 80 Å pore size) at a flow rate of 1 mL/min. The mobile phase is isocratic from 0 to 14 min using 100% mobile phase A [90:10 (0.025 M phosphate buffer, pH 8):acetonitrile] and from 14 to 25 min using 100% mobile phase B [50:50 (0.025 M phosphate buffer, pH 8):acetonitrile]. The ITLC method used Gelman Sciences silica gel ITLC paper strips and 1:1 mixture of acetone and saline as eluant. Using this ITLC method, RP444 and [^{99m}Tc]pertechnetate migrate while the [^{99m}Tc]-colloid remains at the origin.

RESULTS AND DISCUSSION

In the development of a new ^{99m}Tc-based radiopharmaceutical, several factors need to be considered. These include biological efficacy (high target uptake, high target-to-background ratio, and favorable pharmacokinetics), high radiochemical purity (RCP ≥ 90%), and high solution stability (≥6 h). In addition, a kit formulation is often required due to the 6 h half-life of ^{99m}Tc. A kit contains the final drug intermediate (a chelator−peptide conjugate for peptide-based radiopharmaceuticals), a reducing agent such as stannous chloride, if necessary, and other components such as a bulking agent or a weak transfer ligand. Kits can be purchased and stored for daily preparation. In many cases, the ^{99m}Tc-labeling can be accomplished simply by adding [^{99m}Tc]pertechnetate to the kit.

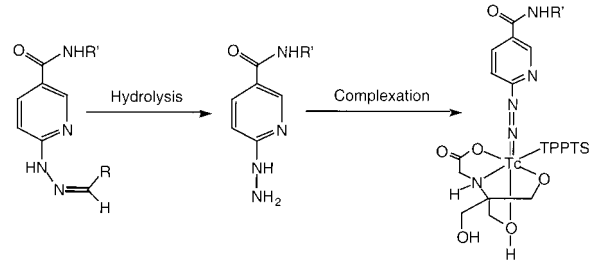

Figure 2. Synthesis of RP444 from HYNICtide hydrazones.

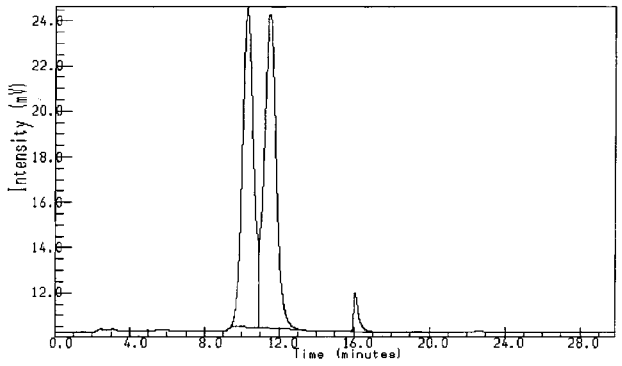

Figure 3. HPLC chromatogram of RP444 prepared from hydrazone **4**.

RP444 contains three different ligands (HYNICtide, TPPTS, and tricine) in the technetium chelate. All of them are considered as active ingredients or final intermediates. Tricine and TPPTS are relatively stable to oxidation and inert to reactions with chemicals often found in commercial pharmaceutical manufacturing settings. The free hydrazine group of the HYNICtide is not stable to oxidation, particularly under basic conditions, and reacts readily with aldehydes or ketones, which are extracted from various plastic and rubber materials. This makes it very difficult to maintain the purity and the stability of the HYNICtide. To solve the problem, several aromatic aldehydes have been used to form stable hydrazones with the HYNICtide. These hydrazones were found to be stable to the challenge of 10-fold excess formaldehyde (*23*, *24*).

Hydrazones are used only as protecting groups for the HYNICtide. In the radiolabeling process, the hydrazones must hydrolyze (Figure 2) to produce sufficient quantity of the hydrazine that binds to the technetium via either a Tc−hydrazino or Tc−diazenido bond. However, the hydrolysis does not need to go to completion since there are typically 50−100 equiv of the hydrazone to total Tc in each reaction. All the hydrazones react with [^{99m}Tc]-pertechnetate in the presence of stannous chloride, excess tricine, and TPPTS coligands to form the same ternary ligand complex RP444 as that prepared from the unprotected HYNICtide. Figure 3 shows a representative radio-HPLC chromatogram of RP444 prepared from hydrazone **4**. The presence of two radiometric peaks in the radio-HPLC chromatogram is due to the resolution of diaster-

Table 1. Radiolabeling Yields of RP444 Using Hydrazones at 50 °C

hydrazone	RCP (%)[a]	*n*	hydrazone	RCP (%)[a]	*n*
1	85.7 ± 2.5	4	**5**	31.3 ± 5.5	3
2	79.0 ± 1.0	3	**6**	94.5	1
3	74.5 ± 0.7	3	**7**	81.0 ± 7.9	3
4	79.7 ± 1.5	5	**8**	91.3 ± 0.6	3

[a] Calculated by subtracting the percent peak area for the [^{99m}Tc]colloid determined by ITLC from the percent peak area of RP444 in the radio-HPLC. In all the cases, the [^{99m}Tc]colloid was less that 2%.

eomers, which result from the presence of chiral cyclic peptide and the formation of two enantiomers of the technetium chelate (*19*, *26*). The small peak at ~16 min is from a combination of several radioimpurities. To develop an accurate RCP method for RP444, we intentionally "squeezed" these radioimpurities into a single peak using the chromatographic conditions described in the experimental. Since these radioimpurities are less than 1.0%, no further characterization was performed.

The yield of RP444 depends largely on the kinetics of hydrolysis, as well as the total concentration of the unprotected HYNICtide in the reaction mixture. The higher degree of the hydrolysis of the hydrazone, the more free hydrazine groups available for Tc-binding, and the higher the radiolabeling yield of RP444, within certain limits. The goal of this study was to screen various hydrazones through stability testing and radiolabeling and find those which are able to remain stable without significant degradation in the manufacturing process and at the same time are reactive to produce enough free hydrazine in situ for successful ^{99m}Tc-labeling.

There are several factors influencing the hydrolysis of these hydrazones. These include the type of hydrazone, the heating temperature, the reaction time, and the pH of the reaction mixture. The initial labeling study was focused on the screening of hydrazones. The hydrazones screened included three with aliphatic substituents and five with aromatic groups functionalized by electron withdrawing or electron donating substituents. In this study, we fixed the amount of hydrazone (10 μg), tricine (40 mg), TPPTS (1 mg), $^{99m}TcO_4$- (50 mCi), and stannous chloride (25 μg). The total volume for each radiolabeling kit was ~1.2 mL. The pH was adjusted to 4.0 ± 0.5. After heating in a 50 °C water bath for 30 min, the reaction mixtures were analyzed by HPLC and ITLC. The RCP of RP444 was corrected for the contribution from [^{99m}Tc]-colloid. The results are summarized in Table 1. It is obvious that the type of hydrazone has dramatic impact on the yield of RP444.

The hydrazones **6** and **8** contain aliphatic substituents and gave highest yield (>90%) of RP444 because they can be easily hydrolyzed in situ to produce the free HYNICtide for the ^{99m}Tc-labeling. However, both of them were found to be unstable to the challenge of 10-fold excess formaldehyde (*23*, *24*). Therefore, they were not suitable as commercial reagents for the preparation of RP444. Hydrazone **5** contains a substituted pyridine ring and gave very low yield (~30%) of RP444 probably because it is too stable in aqueous solution to produce enough free HYNICtide for the ^{99m}Tc-labeling. Therefore, it is not suitable to be used as a commercial reagent either. Hydrazones **1**−**4** contain an aromatic benzene ring with various substituents, while the hydrazone **7** has propenyl substituent (Figure 1). These five hydrazones gave yields between 75 and 85% and were studied in the next radiolabeling experiment using higher heating temperature to see if the yield of RP444 could be improved.

Table 2. Radiolabeling Yields of RP444 Using Hydrazones at 80 °C

hydrazone	RCP (%)	*n*	hydrazone	RCP (%)	*n*
1 (TFA salt)	94.0 ± 1.4	4	**3**	79.5	1
1 (mesylate salt)	92.0 ± 1.0	3	**4**	91.0 ± 2.0	5
2	86.0 ± 1.7	3	**7**	83.3 ± 1.5	3

[a] Calculated by subtracting the percent peak area for the [^{99m}Tc]colloid determined by ITLC from the percent peak area of RP444 in the radio-HPLC. In all the cases, the [^{99m}Tc]colloid was less that 2%.

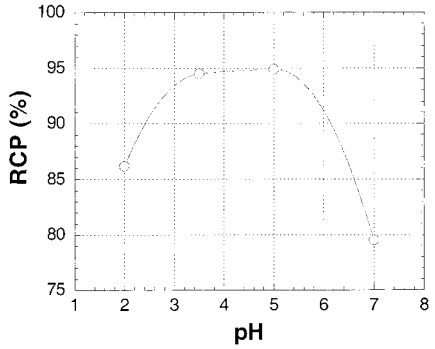

Figure 4. Plot of RCP of RP444 versus pH. Each vial contains 12.5 μg of hydrazone **4**, 3.5 mg of TPPTS, 40 mg of tricine, and 40 μg of $SnCl_2 \cdot 2H_2O$ with pH varying from 2.0 to 7.0.

In this experiment, all the component levels and reaction conditions remain the same as those used in the screening study except that the reaction mixtures were heated at 80 °C for 30 min. After radiolabeling, the reaction mixtures were analyzed by HPLC and ITLC. The RCP of RP444 was corrected for the contribution from [^{99m}Tc]colloid. The results are shown in Table 2. In general, the higher temperature and longer reaction time gave better yield for RP444, probably due to faster hydrolysis at higher temperatures.

Hydrazones **1** and **4** gave yields of RP444 higher than 90% using 80 °C and 30 min heating. Different salt forms (trifluoroacetate and mesylate) of hydrazone **1** did not have a detectable effect on the yield of RP444. The remaining three hydrazones did not give significantly higher yields than those obtained at 50 °C. On the basis of these data, it was concluded that hydrazones **1** and **4** can be used as the final intermediate for preparation of RP444 under the radiolabeling conditions descibed in the Experimental Section. It should be noted that these conditions are not optimized. Under more forcing conditions (such as heating at 100 °C), hydrazones **2** and **7** may also give ≥90% yields.

We also explored the effect of varying pH and the component levels on the yield of RP444 using hydrazone **4**. The component levels are shown in Figures 4−7. Vials containing these components were reconstituted by adding 0.5 mL of [^{99m}Tc]pertechnetate solution (100 mCi/mL). The prior elution time for the generator was 24 ± 2 h, and the eluate age was 0−2 h. The total volume of the reaction mixture was ~1.5 mL. The stannous chloride concentration was fixed at 40 μg/vial. The pH of the reaction mixture was adjusted using 1.0 N HCl. Reactions were carried out in duplicate by heating reaction mixtures at 80 °C for 30 min. The resulting solutions were analyzed by radio-HPLC and ITLC. The RCP was corrected for the contribution from [^{99m}Tc]colloid.

pH Effect. The pH of the reaction mixture has a dramatic impact on the RCP of RP444 (Figure 4). At pH

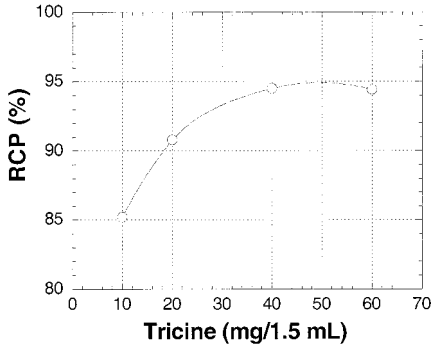

Figure 5. Plot of RCP of RP444 versus tricine concentration. Each vial contains 12.5 μg of hydrazone **4**, 3.5 mg of TPPTS, 40 μg of $SnCl_2 \cdot 2H_2O$, and various amounts of tricine with pH 3.5.

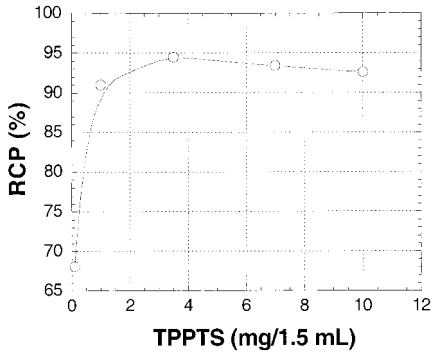

Figure 6. Plot of RCP of RP444 versus TPPTS concentration. Each vial contains 12.5 μg of hydrazone **4**, 40 mg of tricine, 40 μg of $SnCl_2 \cdot 2H_2O$, and various amounts of TPPTS with pH 3.5.

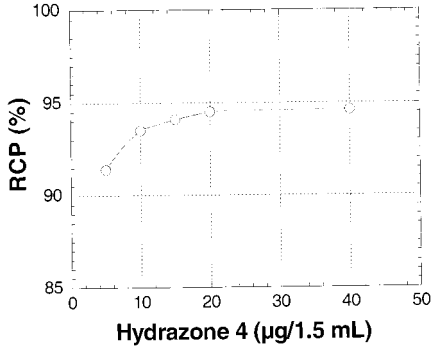

Figure 7. Plot of RCP of RP444 versus HYNICtide concentration. Each vial contains 3.5 mg of TPPTS, 40 mg of tricine, 40 μg of $SnCl_2 \cdot 2H_2O$, and various amounts of hydrazone **4** with pH 5.0.

≤3.5, the tricine coligand may become protonated, and is not able to stabilize the [^{99m}Tc]tricine intermediate. This may lead to decomposition of the [^{99m}Tc]tricine intermediate, and formation of a significant amount of [^{99m}Tc]pertechnetate. At pH ≥5.0, the hydrazone remains highly stable in solution. There is not enough hydrolyzed free hydrazine for ^{99m}Tc-labeling. Therefore, the yield of RP444 was also low. The ideal pH range for successful radiolabeling is 3.5−5.0.

Tricine Concentration. Tricine is both a stabilizing agent for the [^{99m}Tc]tricine intermediate and a coligand in the ternary ligand system at the same time. Increasing the amount of tricine from 40 to 60 mg did not have significant impact on the yield of RP444 (Figure 5). At a lower tricine level (≤20 mg), [^{99m}Tc]colloid formation became significant, and resulted in lower yield for RP444. The optimum concentration for tricine is 40−60 mg/vial.

TPPTS Concentration. In the reaction mixture, TPPTS reacts with the binary complex [^{99m}Tc(HYNICtide)(tricine)$_2$] to form RP444. Figure 6 shows the effect of TPPTS concentration on the RCP of RP444. If the amount of TPPTS was lower than 1.0 mg/1.5 mL, the yield of RP444 was dramatically reduced. Increasing the amount of TPPTS from 1.0 mg/1.5 mL to 10.0 mg/1.5 mL had no significant effect on the yield of RP444 within the experimental error. Under ideal radiolabeling conditions, the TPPTS concentration could be varied from 1.0 mg/1.5 mL to 10 mg/1.5 mL.

Hydrazone Concentration. Hydrazone concentration also affects the RCP of RP444. When the hydrazone is in large excess over the total Tc (^{99m}Tc and ^{99}Tc) in each reaction vial, hydrolysis of a small percentage of hydrazone should produce enough free HYNICtide for radiolabeling. Thus, it is not surprising that increasing the amount of hydrazone **4** from 10 to 40 μg did not have a significant effect on the yield of RP444 (Figure 7). The optimum concentration for hydrazone **4** is 20−40 μg/1.5 mL for 50 mCi of [^{99m}Tc]pertechnetate.

It should be noted that the purity of hydrazones also has dramatic impact on the yield of RP444. HYNICtide hydrazones are prepared by conjugation of cyclic peptide with slight excess succinimidyl 6-(2-aldehydehydrazino)-nicotinate (*23*, *24*). The excess succinimidyl ester is then converted to 6-(2-aldehyde-hydrazino)nicotinamide for the purpose of easy separation. Hydrazones used in this study often contain a small amount of the HYNIC-amide hydrazone as impurities. For example, hydrazone **1** contains a trace amount of 6-(2-benzaldehydehydrazino)-nicotinamide. Since the molecular weight of 6-(2-benzaldehydehydrazino)nicotinamide is only ∼1/5 of that of hydrazone **1**, one percent of it will cause at least a 5% decrease in the yield of RP444.

Stannous chloride is a reducing agent for [^{99m}Tc]-pertechnetate. If the stannous chloride level is too low (≤5 μg/mL), [^{99m}Tc]pertechnetate is often not completely reduced, and the yield of RP444 is low. If a large amount (≥100 μg/vial) is used, [^{99m}Tc]colloid formation becomes a major problem, and the corrected yield of RP444 is also low. During these radiolabeling studies, we found that the optimum range of stannous chloride is 20−50 μg/mL.

CONCLUSION

In conclusion, eight HYNICtide hydrazones (three with aliphatic substituents and five with aromatic groups functionalized by electron withdrawing or electron donating substituents) were screened and studied for their potential use as the final intermediate for preparation of RP444. It was found that using 50 °C and 30 min, heating only hydrazones **6** and **8** gave satisfactory (≥90%) yields of RP444. However, their solution instability excludes them from being used as commercial reagents. Hydrazones **1** and **4** gave ≥90% yields when reaction mixtures were heated at 80 °C for 30 min. The salt forms (trifluoroacetate and mesylate) of hydrazone **1** did not show a detectable effect on the yield of RP444. Both hydrazone **1** and hydrazone **4** can be used as the final intermediate for preparation of RP444. It seems that the combination of 40 mg tricine, 1−10 mg of TPPTS, 10−40 μg of hydrazone for 50 mCi of [^{99m}Tc]pertechnetate, 20−50 μg of stannous chloride, pH 4.5 ± 0.5, and heating at 80 °C for 30 min gives best yield of RP444. Under more forcing conditions (such as heating at 100 °C for 30 min), hydrazones **2** and **7** may also be used as the final intermediate for RP444 and give ≥90% yields.

Both hydrazones **1** and **4** have demonstrated their solution stability. They do not react with other aldehydes

and ketones (*23*, *24*). It is surprising that both hydrazones are stable enough to withstand a 10-fold excess of formaldehyde, and at the same time are reactive enough to hydrolyze in situ producing free HYNICtide for successful ^{99m}Tc-labeling.

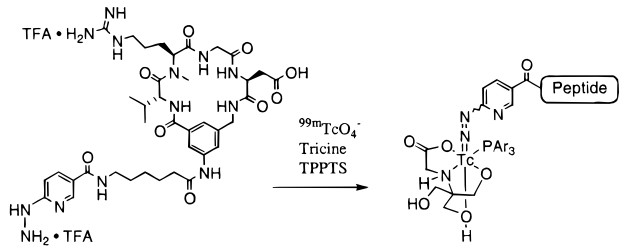
Synthesis of Stable Hydrazones of a Hydrazinonicotinyl-Modified Peptide for the Preparation of ^{99m}Tc-Labeled Radiopharmaceuticals

Thomas D. Harris,*,† Michael Sworin,† Neal Williams,† Milind Rajopadhye,† Paul R. Damphousse,† Danuta Glowacka,† Michael J. Poirier,‡ and Karmine Yu†

DuPont Pharmaceutical Co., 331 Treble Cove Road, North Billerica, Massachusetts 01862, and Upsher-Smith Laboratories, Inc., 14905 23rd Avenue North, Minneapolis, Minnesota 55447. Received February 25, 1999; Revised Manuscript Received May 10, 1999



Hydrazones of a 6-hydrazinonicotinyl-modified cyclic peptide IIb/IIIa receptor antagonist were prepared in order to protect the hydrazine moiety from reaction with trace aldehyde and ketone impurities encountered during the process of manufacturing and compounding lyophilized kits used in radiolabeling with ^{99m}Tc. Hydrazones were prepared by either a direct reaction of the 6-hydrazinonicotinyl-modified cyclic peptide with carbonyl compounds or by conjugation of the cyclic peptide with hydrazones of succinimidyl 6-hydrazinonicotinate. Stability of the hydrazones was evaluated by treatment with formaldehyde. Hydrazones derived from simple aliphatic aldehydes underwent an exchange reaction with formaldehyde, while hydrazones of aromatic aldehydes and ketones provided the greatest level of stability when challenged with formaldehyde. We have been successful in protecting 6-hydrazinonicotinyl-modified cyclic peptides from reacting with formaldehyde, while still allowing sufficient reactivity for radiolabeling with ^{99m}Tc. The hydrazones of succinimidyl 6-hydrazinonicotinate are convenient and general reagents for forming 6-hydrazinonicotinyl conjugates with amino-functionalized bioactive molecules.

INTRODUCTION

There is currently a great need for new methods for the noninvasive diagnosis of a variety of diseases such as thromboembolic disease, infection, and cancer. Radiopharmaceuticals comprised of biomolecules labeled with gamma-ray emitting radionuclides have shown promise in fulfilling this need. The biomolecule serves to selectively localize the radionuclides at sites of disease and thus allow the sites to be visualized by gamma scintigraphy. The preferred method of introducing the radiolabel is by the use of a heterobifunctional molecule containing a moiety for coordination of the radionuclide and a moiety for covalent attachment to the biomolecule.

Abrams and co-workers have recently described the modification of polyclonal IgG with the 6-hydrazinonicotinyl group (Hynic) for labeling with ^{99m}Tc and subsequent imaging of focal sites of infection (*1*−*3*). Focal infections have also been imaged using Hynic-modified chemotactic peptides (*4*−*6*) and Hynic-modified LTB4 antagonists (*7*−*9*). Hynic derivatives of somatostatin and monoclonal antibody fragments have shown promise as tumor imaging agents (*10*−*11*). We recently reported the synthesis of a Hynic-modified cyclic peptide glycoprotein IIb/IIIa receptor antagonist (**1**) containing the N-Me-Arg-Gly-Asp motif, as shown in Scheme 1 (*12*). Hynic is tethered to the meta-aminobenzoic acid (Mamb) group via a 5-aminocaproic acid (5-Aca) spacer. For labeling with ^{99m}Tc, the Hynic-modified cyclic peptide is reacted with ^{99m}Tc pertechnetate in the presence of tricine and trisodium triphenylphosphine-3,3′,3″-trisulfonate (TPPTS).

Scheme 1. Synthesis of Ternary Ligand Complex RP444

1 **RP444**, Ar = 3-sulfonatophenyl

This forms the ternary ligand system **RP444** (Scheme 1) in which the technetium is bound to Hynic through a diazenido linkage with the coordination sphere of technetium completed by the tricine and TPPTS ancillary ligands (*13*). The combination of tricine, TPPTS, and Hynic−peptide conjugate **1** can be rapidly labeled with 25 mCi of ^{99m}Tc to >90% radiochemical purity using as little as 0.02 μmol of conjugate **1**. Evaluation of **RP444** in the canine arteriovenous and deep vein thrombosis models has demonstrated its ability to rapidly detect growing thrombi under both mixed arterial and venous conditions (*12*). **RP444** is a developmental candidate currently in clinical trials for the rapid detection of thromboembolic events.

During the process of manufacturing and compounding the lyophilized kit used in the preparation of **RP444**, we discovered that Hynic−peptide conjugate **1** reacts readily with aldehydes and ketones to form various hydrazone impurities. The presence of aldehyde and ketone impurities is unavoidable in a commercial pharmaceutical manufacturing setting, because they are extracted from various rubber and plastic materials and are also used in common disinfectants. Formaldehyde is particularly

ubiquitous. Given the very small quantity of Hynic−peptide conjugate **1** present in a single-dosage vial (∼20 μg), the low level of aldehyde and ketone-derived impurities became significant. We began a search for a hydrazine-protecting group which would block the reaction of the hydrazine moiety of **1** with aldehyde and ketone impurities present during the manufacturing process, but which would be sufficiently labile to form a free hydrazine during labeling with ^{99m}Tc. Schwartz et al. have described the use of lower alkyl hydrazone protecting groups to prevent cross-reaction between the hydrazine moiety and protein-reactive substituents during Hynic modification (*14*). While these alkyl hydrazones prevent the formation of hydrazone-modified protein, they undergo an exchange reaction with other aldehydes and ketones, especially formaldehyde, to form different hydrazones. Thus, the lower alkyl hydrazones are unsuitable for the protection of the hydrazine moiety of Hynic during the manufacturing process. In this paper, we describe the synthesis of several stable hydrazones of Hynic−peptide conjugate **1**, and examine their solution stability in the presence of formaldehyde. The majority of these hydrazones do not react appreciably with formaldehyde under simulated manufacturing conditions, but are still reactive enough to form ternary ligand complexes with ^{99m}Tc. The radiolabeling of these hydrazones with ^{99m}Tc to form **RP444** is reported in a companion paper in this issue. We have also demonstrated the use of succinimidyl esters of Hynic hydrazones (Figure 1) as general reagents for forming stable Hynic hydrazone conjugates with amino-functionalized bioactive molecules.

EXPERIMENTAL PROCEDURES

General. ^{1}H NMR spectra were obtained on a Varian 270 MHz spectrometer in the indicated solvent. Chemical shifts are expressed in δ units downfield from TMS. Low-resolution MS data were obtained on a VG Trio 2000 spectrometer using the indicated ionization method. High-resolution MS data were obtained on a VG 70-VSE spectrometer using the indicated ionization method. Analytical HPLC separations were accomplished on a Zorbax-Rx C18 column, 4.6 × 250 mm, operated at 50 °C using a 2.0%/min gradient of 10−50% ACN containing 50 mM ammonium acetate at a flow rate of 1.5 mL/min. UV detection was set at 240 nm. Preparative HPLC separations were accomplished at ambient temperatures using the column and gradient conditions indicated in individual procedures. UV detection was set at 220 nm. Products were isolated from HPLC eluant by freeze-drying. Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(5-Aca)] and cyclo-(D-Val-NMeArg-Gly-Asp-Mamb(Hynic-5-Aca)] were synthesized as previously described (*12, 15*). Succinimidyl 6-(2-propenylhydrazone)nicotinate was prepared as previously described (*14*). Deionized water was obtained from a Milli-Q Water System and was of >18 MΩ quality. HPLC-grade ACN was obtained from J. T. Baker. All other reagents and solvents were obtained from Aldrich Chemical Co. and Fluka Chemical Corp.

General Procedure for the Preparation of Hynic Hydrazone Succinimidyl Esters 3−9. To a suspension of 6-hydrazinonicotinic acid (6.5 mmol) in DMF (40 mL) was added the aldehyde or ketone (6.9 mmol), and the reaction mixture was allowed to stir at room temperature for 3 h. To the homogeneous reaction solution was added N-hydroxysuccinimide (748 mg, 6.5 mmol) and DCC (2.76 g, 13.4 mmol), and the reaction was allowed to stir at room temperature for 18 h. The DCU precipitate was removed by filtration. The filtrate was concentrated, diluted with EtOAc (50 mL), and the mixture was heated at reflux for 1 h. Filtration of the hot mixture provided the hydrazone as a pale yellow powder. This material was used without further purification.

Succinimidyl 6-(2-Benzaldehydehydrazono)nicotinate (3). Benzaldehyde provided 1.78 g (81%) of the title compound. ^{1}H NMR (D_6-DMSO): 11.86 (s, NH), 8.82 (dd, Py-H), 8.20 (dd, Py-H), 8.20 (s, =CH), 7.75 (dd, 2 Ar−H), 7.43 (m, Py-H & 3 Ar−H), 2.89 (s, 2 CH_2). DCI(NH_3)-MS calcd for $C_{17}H_{15}N_4O_4$ [M+H]: 339.1093. Found: 339.1084.

Succinimidyl 6-[2-(2-Sulfo)benzaldehydehydrazono]nicotinate Sodium Salt (4). Sodium 2-formylbenzenesulfonate provided 1.63 g (85%) of the title compound. ^{1}H NMR (D_6-DMSO): 11.91 (s, NH), 9.16 (s, =CH), 8.79 (dd, Py-H), 8.16 (dd, Py-H), 8.03 (dd, Ar−H), 7.79 (dd, Ar−H), 7.35 (m, Py-H & 2 Ar−H), 2.88 (s, 2 CH_2). FAB(NBA)-MS calcd for $C_{17}H_{15}N_4O_7S$ [M + H]: 419.0661. Found: 419.0654. Anal. calcd for $C_{17}H_{14}N_4NaO_7S\cdot(H_2O)_{1.5}$: C, 43.69; H, 3.45; N, 11.99; Na, 4.92; S, 6.86. Found: C, 43.66; H, 3.62; N, 12.10; Na, 4.75; S, 6.43.

Succinimidyl 6-[2-(4-Dimethylamino)benzaldehydehydrazono]nicotinate (5). 4-Dimethylaminobenzaldehyde provided 1.20 g (48%) of the title compound. ^{1}H NMR (D_6-DMSO): 11.58 (s, NH), 8.76 (dd, Py-H), 8.13 (dd, Py-H), 8.07 (s, =CH), 7.54 (d, 2 Ar−H), 7.29 (d, Py-H), 6.75 (d, 2 Ar−H), 2.97 (s, 2 NCH_3), 2.88 (s, 2 CH_2). DCI(NH_3)-MS calcd for $C_{19}H_{20}N_5O_4$ [M + H]: 382.1515. Found: 382.1513.

Succinimidyl 6-(2-Cyclopentanonehydrazono)nicotinate (6). Cyclopentanone provided 1.78 g (86%) of the title compound. ^{1}H NMR (D_6-DMSO): 10.33 (s, NH), 8.76 (dd, Py-H), 8.11 (dd, Py-H), 7.15 (d, Py-H), 2.88 (s, 2 CH_2), 2.41 (q, 2 CH_2), 1.75 (m, 2 CH_2). DCI(NH_3)-MS calcd for $C_{15}H_{17}N_4O_4$ [M + H]: 317.1250. Found: 317.1259.

Succinimidyl 6-(2-Acetophenonehydrazono)nicotinate (7). Acetophenone provided 2.11 g (92%) of the title compound. ^{1}H NMR (D_6-DMSO): 10.86 (s, NH), 8.84 (dd, Py-H), 8.21 (dd, Py-H), 7.86 (dd, 2 Ar−H), 7.41 (m, Py-H and 3 Ar−H), 2.89 (s, 2 CH_2), 2.39 (s, CH_3). DCI(NH_3)-MS calcd for $C_{18}H_{17}N_4O_4$ [M + H]: 353.1250. Found: 353.1244.

Succinimidyl 6-[2-(1-Methoxycarbonyl)acetaldehydehydrazono]nicotinate (8). Methyl pyruvate provided 0.90 g (41%) of the title compound. ^{1}H NMR (D_6-DMSO): 11.21 (s, NH), 8.91 (dd, Py-H), 8.33 (dd, Py-H), 7.42 (d, Py-H), 3.78 (s, OCH_3), 2.89 (s, 2 CH_2), 2.18 (s, CH_3). DCI(NH_3)-MS calcd for $C_{14}H_{15}N_4O_6$ [M + H]: 335.0991. Found: 335.1004.

Succinimidyl 6-[2-(2-Methoxycarbonyl)cyclopentanonehydrazono]nicotinate (9). 2-Methoxycarbonylcyclopentanone provided 1.80 g (74%) of the title compound. ^{1}H NMR (D_6-DMSO): 10.56 (s, NH), 8.79 (dd, Py-H), 8.15 (dd, Py-H), 7.11 (d, Py-H), 3.67 (s, OCH_3), 3.55 (t, CH), 2.88 (s, 2 CH_2), 2.50 (m, CH_2), 1.90 (m, 2 CH_2). DCI(NH_3)-MS calcd for $C_{17}H_{19}N_4O_6$ [M + H]: 375.1304. Found: 375.1310.

Synthesis of the 2-Formylbenzenesulfonic Acid Hydrazone of Cyclo-(D-Val-NMeArg-Gly-Asp-Mamb-[hydrazinonicotinyl-5-Aca)] (10). *Method A*. A solution of succinimidyl 6-[2-(2-sulfo)benzaldehydehydrazono]nicotinate sodium salt (**4**) (220 mg, 0.50 mmol), cyclo-[D-

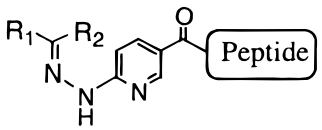
Val-NMeArg-Gly-Asp-Mamb(5-Aca)]·2 TFA (465 mg, 0.50 mmol), and TEA 0.208 mL, 1.50 mmol) in anhydrous DMF (3 mL) was stirred at ambient temperatures under nitrogen for 18 h. The DMF was removed under vacuum, and the residue was triturated with EtOAc to give crude product as a pale yellow powder (0.54 g). A 36 mg sample was purified by reversed-phase HPLC on a Vydac C18 Protein and Peptide column (22 × 250 mm) at a flow rate of 15 mL/min using a 0.30%/min gradient of 18 to 27% ACN containing 50 mM ammonium acetate. The product fraction (retention time 20.6 min) was lyophilized to give the title compound as a fluffy colorless solid (20 mg, 66%). Analytical HPLC indicated a product purity of 97.7%. DCI(NH_3)-MS calcd for $C_{45}H_{59}N_{13}O_{12}S$ [M + H]: 1006.4205. Found: 1006.4200.

Method B. Sodium 2-formylbenzenesulfonate (3.9 mg, 0.019 mmol) and cyclo-[D-Val-NMeArg-Gly-Asp-Mamb-(hydrazinonicotinyl-5-Aca)] (10 mg, 0.0094 mmol) were dissolved in 0.05 M sodium phosphate buffer, pH 7.0 (1.0 mL) and allowed to stand at ambient temperatures for 1.5 h, at which time the entire reaction had turned to a gel. The gel was dissolved in 90:10 0.1M ammonium acetate:ACN (1.0 mL) and purified using reversed-phase HPLC on a Zorbax-RX C18 column (21.2 × 250 mm) at a flow rate of 15 mL/min using 10% ACN containing 0.1 M ammonium acetate for 2 min, followed by a 2.22%/min gradient of 10 to 50% ACN containing 0.1 M ammonium acetate. The product fraction (retention time 12.9 min) was lyophilized to give the title compound as a fluffy colorless solid (7 mg, 74%). Analytical HPLC indicated a product purity of 97.3%. DCI(NH_3)-MS: [M + H] = 1006.3.

General Procedure for the Synthesis of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] Hydrazones 11−17 from Succinimidyl Hydrazononicotinates. To an equimolar solution of cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(5-Aca)]·2 TFA and succinimidyl hydrazononicotinate in DMF (1 mL) was added 4 equiv of TEA, and the reaction mixture was allowed to stir at ambient temperatures for 42 h. The reaction mixture was concentrated, dissolved in 50% ACN, and lyophilized to provide the crude title compound as an off-white powder. Purification was accomplished by reversed-phase HPLC on a Vydac C18 Protein & Peptide column (22 × 250 mm) using the specified ACN gradient containing 0.1% TFA at a flow rate of 15 mL/min to give the TFA salt of the title compound as a colorless fluffy solid.

Benzaldehyde Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (11). Succinimidyl 6-(2-benzaldehydehydrazono)nicotinate (**3**) (7.5 mg, 0.022 mmol) provided 17.5 mg (71%) of the title compound after HPLC purification (1.65%/min gradient of 6 to 72%, retention time 30.9 min). ^{1}H NMR (D_6-DMSO): 11.30 (br s, OH), 10.02 (s, NH), 8.94 (d, 1H), 8.61 (d, 1H), 8.55 (d, 1H), 8.41 (m, 2H), 8.10 (s, =CH), 8.09 (m, 1H), 7.70 (m, 4H), 7.61 (m, 1H), 7.52 (t, 1H), 7.42 (m, 3H), 7.27 (d, 1H), 7.07 (s, 1H), 5.18 (dd, 1H), 4.53 (m, 2H), 4.34 (dd, 1H), 4.20 (dd, 1H), 4.02 (dd, 1H), 3.25 (q, 2H), 3.13 (q, 2H), 2.99 (s, NCH_3), 2.72 (dd, 1H), 2.50 (m, 1H), 2.33 (t, 2H), 2.10 (m, 2H), 1.60 (m, 5H), 1.35 (m, 4H), 1.10 (d, CH_3), 0.92 (d, CH_3). FAB(NBA)-MS calcd for $C_{45}H_{60}N_{13}O_9$ [M + H]: 926.4637. Found: 926.4625.

4-Dimethylaminobenzaldehyde Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (12). Succinimidyl 6-[2-(4-dimethylamino)-benzaldehydehydrazono]nicotinate (**5**) (13.5 mg, 0.034 mmol) provided 29.7 mg (72%) of the title compound after HPLC purification (2.2%/min gradient of 6 to 72%, retention time 26.2 min). ^{1}H NMR (D_6-DMSO): 10.03 (s, NH), 8.94 (d, 1H), 8.55 (d, 1H), 8.50 (s, 1H), 8.42 (t, 1H), 8.15 (br s, 1H), 8.06 (s, 1H), 7.70 (d, 2H), 7.61 (m, 4H), 7.16 (d, 1H), 7.07 (s, 1H), 7.00 (br s, 2H), 6.76 (d, 2H), 5.17 (dd, 1H), 4.52 (m, 2H), 4.33 (dd, 1H), 4.20 (dd, 1H), 3.25 (q, 2H), 3.12 (q, 2H), 2.98 (s, 3 NCH_3), 2.72 (dd, 1H), 2.50 (m, 1H), 2.33 (t, 2H), 2.10 (m, 2H), 1.60 (m, 5H), 1.35 (m, 4H), 1.10 (d, CH_3), 0.92 (d, CH_3). FAB(NBA)-MS calcd for $C_{47}H_{65}N_{14}O_9$ [M + H]: 969.5059. Found: 969.5043.



Cyclopentanone Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (13). Succinimidyl 6-(2-cyclopentanonehydrazono)nicotinate (**6**) (35 mg. 0.108 mmol) provided the crude title compound (131 mg) as a pale yellow powder. HPLC purification (2.2%/min gradient of 2 to 90%, retention time 24.1 min) of a portion of this material gave pure title compound. ^{1}H NMR (D_6-DMSO): 10.02 (s, NH), 8.93 (d, 1H), 8.61 (d, 1H), 8.55 (d, 1H), 8.51 (s, 1H), 8.41 (t, 1H), 8.10 (m, 1H), 7.70 (s, 2H), 7.55 (m, 1H), 7.52 (t, 1H), 7.10 (br s, 3H), 7.06 (s, 1H), 5.17 (dd, 1H), 4.52 (m, 2H), 4.33 (dd, 1H), 4.19 (dd, 1H), 4.02 (dd, 1H), 3.62 (d, 1H), 3.24 (q, 2H), 3.12 (q, 2H), 2.99 (s, NCH_3), 2.72 (dd, 1H), 2.50 (m, 1H), 2.41 (m, 4H), 2.33 (t, 2H), 2.10 (m, 2H), 1.75 (m, 3H), 1.68 (m, 4H), 1.34 (m, 4H), 1.10 (d, CH_3), 0.92 (d, CH_3). FAB(NBA/TFA)-MS calcd for $C_{43}H_{62}N_{13}O_9$ [M + H]: 904.4793. Found: 904.5136.

Acetophenone Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (14). Succinimidyl 6-(2-acetophenonehydrazono)nicotinate (**7**) (38 mg, 0.108 mmol) provided the crude title compound (30 mg) as a colorless powder. HPLC purification (2.2%/min gradient of 2 to 90%, retention time 31.1 min) gave pure title compound. ^{1}H NMR (D_6-DMSO): 10.03 (s, NH), 8.93 (d, 1H), 8.62 (s, 1H), 8.55 (d, 1H), 8.42 (m, 2H), 8.13 (br s, 1H), 7.87 (d, 2H), 7.70 (m, 2H), 7.55 (m, 2H), 7.40 (m, 4H), 7.07 (s, 1H), 5.17 (dd, 1H), 4.52 (m, 2H), 4.33 (dd, 1H), 4.20 (dd, 1H), 4.02 (dd, 1H), 3.63 (dd, 1H), 3.26 (q, 2H), 3.12 (q, 2H), 2.98 (s, NCH_3), 2.72 (dd, 1H), 2.50 (m, 1H), 2.35 (s, CH_3), 2.33 (m, 2H), 2.10 (m, 2H), 1.60 (m, 5H), 1.35 (m, 4H), 1.10 (d, CH_3), 0.92 (d, CH_3). FAB-(NBA)-MS calcd for $C_{46}H_{62}N_{13}O_9$ [M + H]: 940.4793. Found: 940.4818.

Methyl Pyruvate Hydrazone of Cyclo-[D-Val-N-MeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (15). Succinimidyl 6-[2-(1-methoxy-carbonyl)acetaldehydehydrazono]nicotinate (**8**) (36 mg, 0.108 mmol) provided the crude title compound (123 mg) as a pale yellow powder. HPLC purification (2.2%/min gradient of 2 to 90%, retention time 22.3 min) gave pure title compound. ^{1}H NMR (D_6-DMSO) 10.69 (s, NH), 10.02 (s, NH), 8.92 (d, 1H), 8.70 (d, 1H), 8.55 (d, 1H), 8.44 (m, 2H), 8.14 (dd, 1H), 7.70 (s, 2H), 7.56 (m, 2H), 7.28 (d, 1H), 7.07 (s, 1H), 5.17 (dd, 1H), 4.52 (m, 2H), 4.33 (dd, 1H), 4.19 (dd, 1H), 4.04 (m, 1H), 3.76 (s, OCH_3), 3.63 (dd, 1H), 3.26 (q, 2H), 3.13 (q, 2H), 2.99 (s, NCH_3), 2.72 (dd, 1H), 2.50 (m, 1H), 2.33 (t, 2H), 2.13 (s, CH_3), 1.60 (m, 5H), 1.35 (m, 4H), 1.10 (d, CH_3), 0.92 (d, CH_3). FAB(NBA)-MS calcd for $C_{42}H_{60}N_{13}O_{11}$ [M + H]: 922.4535. Found: 922.4539.

2-(Methoxycarbonyl)cyclopentanone Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(Hynic-5-Aca)] (16). Succinimidyl 6-(2-(2-methoxycarbonyl)cyclopentanonehydrazono)nicotinate (**9**) (41 mg, 0.108 mmol) provided the crude title compound (138 mg) as a pale yellow powder. HPLC purification (2.2%/min gradient of 2 to 90%, retention time 24.9 min) of a portion of this material gave pure title compound. ^{1}H NMR (D_6-DMSO): 10.01 (s, NH), 8.90 (m, 1H), 8.57 (m, 2H), 8.39 (m, 2H), 8.07 (d, 1H), 7.71 (s, 2H), 7.59 (m, 2H), 7.09 (m,

Table 1. Stability of Hynic Hydrazones in the Presence of 1 equiv of Formaldehyde

Hynic Hydrazones **10-27**

hydrazone	carbonyl compound	R_1	R_2	% hydrazone remaining at 2 h
10	2-formylbenzenesulfonic acid	2-$NaO_3S-C_6H_4$	H	100
11	benzaldehyde	C_6H_5	H	100/100[a]
12	4-dimethylaminobenzaldehyde	4-$Me_2N-C_6H_4$	H	100
13	cyclopentanone	-$CH_2CH_2CH_2CH_2$-		100
17	propionaldehyde	CH_3CH_2	H	23

19	crotonaldehyde	$CH_3CH{=}CH$	H	100
20	5-nitro-2-furaldehyde	5-$NO_2-C_4H_2O$	H	100
21	glyoxylic acid	COOH	H	>99
22	4-pyridinecarboxaldehyde	4-C_5H_4N	H	100
23[b]	phenylacetaldehyde	$C_6H_5-CH_2$	H	75
24[b]	glycolaldehyde	$HOCH_2$	H	60
25[c]	benzaldehyde-2,4-disulfonic acid	2,4-$(NaO_3S)-C_6H_3$	H	
26[c]	3-pyridinecarboxaldehyde methiodide	I^- 3-$(Me-C_5H_3N)^+$	H	
27[c]	4-pyridinecarboxaldehyde methiodide	I^- 4-$(Me-C_5H_3N)^+$	H	

[a] Also tested with 10 equiv of formaldehyde and found to be completely stable. [b] Hydrazone formed in situ by treatment with 1 equiv of aldehyde. [c] Hydrazone failed to form in situ.

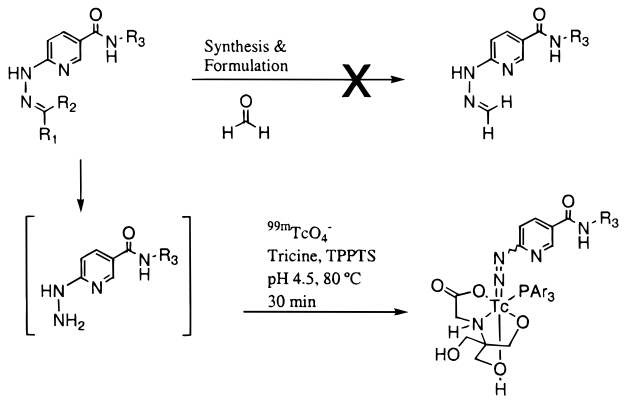
2H), 5.17 (dd, 1H), 4.52 (m, 2H), 4.34 (dd, 1H), 4.20 (dd, 1H), 4.02 (d, 1H), 3.67 (s, OCH_3), 3.24 (q, 2H), 3.12 (m, 2H), 2.99 (s, NCH_3), 2.71 (dd, 1H), 2.50 (m, 1H), 2.34 (t, 2H), 2.10 (m, 4H), 1.60 (m, 5H), 1.34 (m, 3H), 1.25 (m, 2H), 1.10 (d, CH_3), 0.93 (d, CH_3). ESI-MS: 962.5 [M + H].

Propionaldehyde Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(Hynic-5-Aca)] (17). Succinimidyl 6-(2-propionaldehydehydrazono)nicotinate (7.0 mg, 0.022 mmol) provided 8.4 mg (39%) of the title compound after HPLC purification (2.2%/min gradient of 2 to 90%, retention time 22.3 min). FAB(NBA)-MS calcd for $C_{41}H_{60}N_{13}O_9$ [M + H]: 878.4640. Found: 878.4622.

General Procedure for the Synthesis of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] Hydrazones 18−21 Directly from the Peptide−Hynic Conjugates. A mixture of cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)]·2 HBr (50 mg, 0.05 mmol) and aldehyde or ketone (0.70 mmol) in DMF (1 mL) was stirred at ambient temperature under nitrogen for 4 h. The solvent was removed under vacuum, the residue was dissolved in 50% ACN, and lyophilized to dryness. The crude mixture was purified by reversed-phase HPLC on a Zorbax-RX C18 column (21.2 × 250 mm) at a flow rate of 15 mL/min using 10% ACN containing 50 mM ammonium acetate for 2 min followed by the specified ACN gradient containing 50 mM ammonium acetate to give the title compound as a colorless fluffy solid.

4-Carboxybenzaldehyde Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (18). 4-Carboxybenzaldehyde gave 7.0 mg (14%) of the title compound after HPLC purification (0.54%/min gradient of 10 to 25%, retention time 22.5 min). DCI-(NH_3)-MS calcd for $C_{46}H_{60}N_{13}O_{11}$ [M + H]: 970.4535. Found: 970.4535.

Crotonaldehyde Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (19). Crotonaldehyde gave 4.5 mg (10%) of the title compound after HPLC purification (6.0%/min gradient of 10 to 28%, followed by a 0.28%/min gradient of 28 to 35%, retention time 12.6 min). DCI(NH_3)-MS calcd for $C_{42}H_{60}N_{13}O_9$ [M + H]: 890.4636. Found: 890.4637.



5-Nitro-2-furaldehyde Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (20). 5-Nitro-2-furaldehyde gave 2.0 mg (4.2%) of the title compound after HPLC purification (6.0%/min gradient of 10 to 28%, followed by a 0.08%/min gradient of 28 to 30%, retention time 11.9 min). DCI(NH_3)-MS calcd for $C_{43}H_{57}N_{14}O_{12}$ [M + H]: 961.4280. Found: 961.4280.

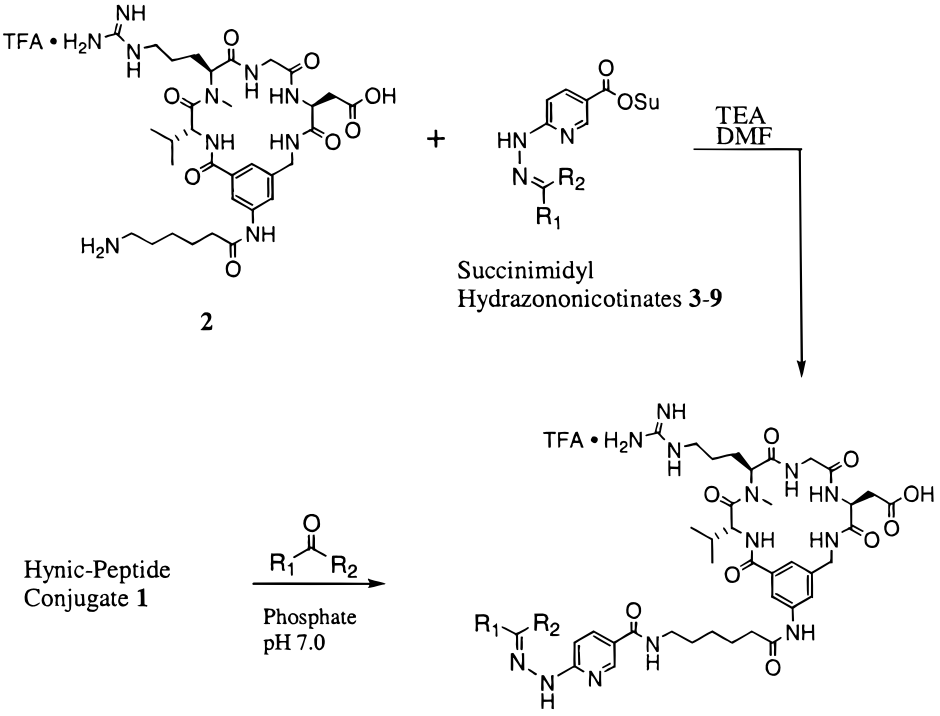
Glyoxylic Acid Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (21). Glyoxylic acid gave 4.6 mg (10%) of the title compound after HPLC purification (0.43%/min gradient of 10 to 25%, retention time 21.1 min). DCI(NH_3)-MS calcd for $C_{40}H_{56}N_{13}O_{11}$ [M + H]: 894.4222. Found: 894.4225.

Synthesis of the 4-Pyridinecarboxaldehyde Hydrazone of Cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-Aca)] (22). 4-Pyridinecarboxaldehyde (1.14 mg, 0.011 mmol) and cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(Hynic-5-Aca)] (10 mg, 0.0094 mmol) were dissolved in 0.05 M sodium phosphate buffer, pH 7.0 (5.0 mL) and allowed to stand at ambient temperature for 72 h. The now slightly yellow solution was lyophilized to dryness, and the resulting solid was purified using reversed-phase HPLC with a preparative Zorbax-RX C18 column (21.2 × 250 mm) at a flow rate of 15 mL/min using 10% ACN containing 0.1 M ammonium acetate for 2 min, followed by a 2.22%/min gradient of 10 to 50% ACN containing 0.1 M ammonium acetate. The product fraction (retention time 10.9 min) was lyophilized to give the title compound as a fluffy colorless solid (8 mg, 74%). Analytical HPLC indicated a product purity of 100%.

Hydrazone Stability Testing. Hydrazones were dissolved in 50 mM phosphate, pH 7.0, at ambient temperatures and a concentration of 0.1 mg/mL, and treated with 1 equiv of formaldehyde. The solutions were evaluated at 2 h using HPLC. Other hydrazones were generated in situ by reacting cyclo-[D-Val-NMeArg-Gly-Asp-Mamb(Hynic-5-Aca)] with 1 equiv of the aldehyde or ketone to be tested. The solutions were monitored by

Scheme 2. Reactivity Requirements of the Hydrazone Protecting Group[a]

[a] R_3 = bioactive targeting group.



HPLC until the hydrazone-forming reaction was complete and then treated with 1 equiv of formaldehyde and monitored for reaction by HPLC. As a further test of hydrazone stability, benzaldehyde hydrazone **11** was dissolved in 50 mM phosphate, pH 7.0, at ambient temperatures and a concentration of 0.1 mg/mL, and treated with 10 equivalents of formaldehyde. The resulting solution was analyzed by HPLC at 2 h. The results of these tests are shown in Table 1.

RESULTS AND DISCUSSION

Thrombus imaging agent **RP444** is a ternary ligand complex prepared from Hynic−peptide conjugate **1**, tricine, TPPTS, and ^{99m}Tc pertechnetate, as shown in Scheme 1. Early formulation work using Hynic−peptide conjugate **1** revealed the presence of hydrazone impurities resulting from the reaction of **1** with trace aldehyde and ketone impurities present in the manufacturing environment. Because of the very small amount of Hynic−peptide conjugate **1** present in a single-dosage vial (20 μg), this presented a serious manufacturing problem. We sought to prevent the formation of these impurities by protecting the hydrazine moiety as a stable hydrazone which would not undergo an exchange reaction with other aldehydes or ketones, such as formaldehyde, as shown in Scheme 2. However, efficient formation of ^{99m}Tc complex **RP444** requires an unprotected hydrazine moiety. Thus, the hydrazone protecting group must be sufficiently labile to undergo hydrolysis during the labeling procedure to form a free hydrazine (Scheme 2). This hydrolysis need not be a high-yield reaction, for the Hynic−peptide conjugate is present in large excess relative to the total amount of technetium added to each kit. In addition to stability issues, we were also concerned with the physical properties of the active drug substance in the formulation. Therefore, we were especially interested in hydrazones having polar and ionic groups that would increase water solubility and crystallinity.

The Hynic hydrazone conjugates used in this study were prepared by two different methods as shown in Scheme 3. Reaction of cyclic RGD peptide **2** with succinimidyl hydrazononicotinates (**3**−**9**) gave Hynic hydrazone conjugates **10**-**16** in good yields and in high purity after HPLC purification. The maximum purity achieved with propionaldehyde hydrazone **17** was 80% due to hydrolysis of the hydrazone during lyophilization of the HPLC eluant. Not surprisingly, of the hydrazones tested in this study, **17** showed the least stability toward formaldehyde. Succinimidyl hydrazononicotinates **3**−**9** were prepared in a one-pot, two-step sequence of reactions by treatment with the carbonyl compound to form the hydrazone, followed by treatment with DCC and N-hydroxysuccinimide to form the active ester. Hynic hydrazone conjugates **18**−**22** were synthesized directly from Hynic−peptide conjugate **1** by reaction with an excess of the corresponding aldehyde in either DMF or phosphate buffer, pH 7.0. These hydrazones were isolated, purified, and characterized prior to the formaldehyde stability

Scheme 3. Synthesis of Hynic Hydrazone Conjugates

studies. Two additional hydrazones (**23** and **24** in Table 1) were not isolated, but prepared in situ by reaction with 1 equiv of aldehyde, using HPLC to monitor the completeness of the reaction. The solutions were then used directly in the formaldehyde stability studies. Three other hydrazones (**25**−**27** in Table 1) failed to form by this latter method. In all three cases, the carbonyl compound was a strongly electron-deficient aromatic aldehyde.

Of the large number of carbonyl compounds which are potential trace contaminants in a pharmaceutical manufacturing setting, formaldehyde is the most ubiquitous. It is also likely to be the most reactive, and surviving a formaldehyde challenge therefore became our minimum requirement for hydrazone stability. The stability studies were carried out at ambient temperatures in phosphate buffer, pH 7.0 at a Hynic hydrazone conjugate concentration of 0.1 mg/mL, and using 1 equiv of formaldehyde. This level of formaldehyde is far in excess of anything likely to be encountered in a real-world manufacturing setting. The results of these studies are shown in Table 1. All of the hydrazones derived from aromatic aldehydes (entries **10**−**12**, **18**, **20**, and **22**) are completely stable to the formaldehyde challenge. It appears not to matter if the ring is unsubstituted (entry **11**), electron rich (entry **12**), or electron deficient (entries **10**, **18**, **20**, and **22**). Conjugation of the hydrazone moiety to an olefin (entry **19**) or carbonyl group (entry **21**) also confers stability toward formaldehyde. Three aldehyde-derived hydrazones without such conjugation (entries **17**, **23**, and **24**) showed significant reactivity toward formaldehyde, with the simple alkyl hydrazone of propionaldehyde being the most reactive. Only one ketone-derived hydrazone was examined (entry **13**), and it was completely stable to formaldehyde, despite the fact that there is no unsaturated group in conjugation with the hydrazone. Hydrazone **11** was also challenged with 10 equiv of formaldehyde and found to be completely stable at this higher concentration.

CONCLUSIONS

We have shown that the hydrazine moiety of Hynic-modified peptides can be protected from undergoing hydrazone-forming reactions with formaldehyde by the use of stable hydrazones. Conjugation of the hydrazone with the unsaturation of an aromatic ring, an olefin, or a carbonyl group greatly enhanced its stability. Hydrazones lacking such conjugation readily underwent a hydrazone exchange reaction with formaldehyde. We also developed general methods for the preparation of the hydrazone-protected Hynic−peptide conjugates. The hydrazone protecting group can be introduced directly by reaction of the Hynic-peptide conjugate with a carbonyl compound. Alternatively, Hynic can be introduced with the hydrazone protecting group in place via its NHS ester.

The ability to prevent the formation of hydrazone impurities during the manufacturing process will greatly simplify the commercialization of radiopharmaceuticals containing the Hynic bifunctional coupling agent. The stability we have demonstrated here is, however, only half of the picture. While resisting reaction with formaldehyde and other carbonyl impurities, the hydrazones must be reactive enough to undergo hydrolysis to the free hydrazine during labeling with ^{99m}Tc. Several of the hydrazones described here have shown this balance of reactivity and can be used as the final intermediate for the preparation of **RP444**. The preferred method of preparing **RP444** is via Hynic hydrazone conjugate **10**, which is prepared by the use of NHS ester **4**. The hydrazone of 2-formylbenzenesulfonic acid provides the best combination of stability toward formaldehyde, lability during ^{99m}Tc labeling, ease of preparation, and water solubility. A full description of the ^{99m}Tc work is reported in the preceding paper in this issue.

Aminooxy Functionalized Oligonucleotides: Preparation, On-Support Derivatization, and Postsynthetic Attachment to Polymer Support

Harri Salo,*,† Pasi Virta,† Harri Hakala,† Thazha P. Prakash,‡ Andrei M. Kawasaki,‡ Muthiah Manoharan,‡ and Harri Lönnberg†

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland, and Department of Medicinal Chemistry, Isis Pharmaceuticals, 2292 Faraday Avenue, Carlsbad, California 92008. Received February 25, 1999; Revised Manuscript Received June 29, 1999

Three novel phosphoramidites, each bearing a phthaloyl-protected aminooxy tail, were prepared and applied in automated oligonucleotide synthesis. After chain assembly, the phthaloyl protection was removed with hydrazinium acetate. Normal succinyl linker turned to be stable under these conditions, and hence the support-bound oligonucleotide could be converted to a pyrene oxime conjugates by reacting with pyrene carbaldehyde or *cis*-retinal. Standard ammonolytic deprotection then released the deprotected conjugate in solution. Alternatively, the crude aminooxy-tethered oligonucleotide was immobilized to microscopic polymer particles by reacting the aminooxy function with the particle-bound aldehyde or epoxide groups. These immobilized oligonuceotides were shown to serve properly as probes in a mixed phase hybridization assay.

INTRODUCTION

The expanding use of mixed-phase hydridization assays for the detection of specific nucleic acid sequences has made the covalent immobilization of oligonucleotides to solid supports an object of increasing interest (*1*−*19*). Although the oligonucleotide probes may be assembled in situ on the support employed in the assay (*5*−*7*, *12*, *20*−*26*), postsynthetic attachment of purified oligonucleotide conjugates to the support may still be advantageous for some applications. A variety of methods for tethering of oligonucleotides to solid supports have been reported. Most of the methods are based on reactions of 5′-aminoalkyl conjugates of oligonucleotides with various functional groups on the support. Accordingly, oligonucleotides bearing a 5′-terminal amino function have been attached (i) to carboxyalkylated polymer supports by carbodiimide assisted acylation (*27*, *28*), (ii) to aminoalkylated polymer supports by activation with 2,4,6-trichloro-1,3,5-triazine and subsequent displacement of one of the remaining chloro substituents with a resin bound amino group (*29*), (iii) to aldehyde-derivatized surfaces by reductive amination (*30*), and (iv) to phenyldiisothiocyanate-activated (*8*) or epoxide-derivatized glass (*31*) surfaces by direct nucleophilic substitution. 5′-Phosphorylated oligonucleotides have been immobilized to aminoalkylated supports by carbodiimide-assisted phosphoramidate coupling (*27*), and 5′-mercapto-functionalized oligonucleotides to mercaptoalkyl supports by disulfide formation (*32*). The latter oligonucleotides have also been successfully immobilized to iodoacetamido-derivatized supports by nucleophilic α-substitution (*33*). Oligonucleotides bearing a 5′-terminal aldehyde function have been attached to aminoalkylated supports by reductive amination (*30*) and to latex microspheres bearing hydrazine residues (*34*). 2,4,6-Trichloro-1,3,5-triazine activation and disulfide bond formation have also been exploited in immobilization of 3′-amino and 3′-mercapto functionalized oligonucleotides, respectively (*35*). Homopolymer-tailed oligomers have been attached to a nylon membrane by UV irradiation (*3*).

The aminooxy group, NH_2O, is more nucleophilic than the primary amino group, the enhanced nucleophilicity being usually attributed to the so-called α-effect (*36*). Moreover, it is well-known that the *O*-alkyl oximes formed upon the reaction of *O*-alkylhydroxylamines with carbonyl compounds are much more stable than the imines derived from primary amines (*37*). Accordingly, one might assume that the aminooxy conjugates of oligonucleotides react more rapidly than their amino counterparts with support-bound aldehyde functions and give oxime-type linkers which tether the oligonucleotides to the support in a virtually irreversible manner without any additional reduction step. Aminooxy chemistry has not been previously applied to oligonucleotide immobilization, although several related conjugations in solution have been described. For example, 5′-*O*-amino-2′-deoxyribonucleosides have been prepared and used in hammerhead ribozyme studies (*38*) and in construction of non-phosphorus analogues of dinucleoside 3′,5′-monophosphates (*39*). Oligonucleotides have also been tethered with aminooxy-functionalized probes, reacting either at the apurinic sites (*40*−*42*) or at aldehydic sites generated in modified base residues (*43*). Furthermore, aminooxy linkers have been attached to oligonucleotides by transamination with the cytosine 4-amino group (*44*).

We now report on incorporation of three phosphoramidites (**1**−**3**), bearing a masked aminooxy group, into oligodeoxyribonucleotides. These building blocks enable tethering of the aminooxy group either at the 5′-terminus of the oligonucleotide (**1**) or at any desired position within the sequence (**2** and **3**). The protected aminooxy functionality was introduced into the building blocks by displacing a hydroxy group with *N*-hydroxyphthalimide

under Mitsunobu reaction conditions (*45*). The phthaloyl protection was removed from the aminooxy functions of the assembled oligonucleotide conjugates with hydrazinium acetate. The normal succinyl linker is not cleaved by this treatment, and hence the support-bound oligonucleotides may be converted, when desired, to more stable oxime conjugates before the conventional ammonolytical base moiety deprotection and release from the support. The deprotected aminooxy-tethered oligonucleotides were finally immobilized to polymer microparticles bearing either aldehyde or epoxide functions. The oligonucleotide-coated particles obtained were shown to behave in mixed-phase hybridization assays (*19*, *25*, *35*) in exactly the same manner as those prepared by methods established previously for postsynthetic immobilization.

EXPERIMENTAL SECTION

General. The reagents for oligonucleotide synthesis were products of Glen Research. The aldehyde-derivatized Tentagel supports were from Rapp Polymere Gmbh (Tübingen, Germany), and the epoxy-modified microparticles were from SINTEF Applied Chemistry (Trondheim, Norway). All the other reagents were from Aldrich Chemical Co. Adsorption chromatography was performed on silica gel 60 (Merck). NMR spectra were recorded on JEOL GX-400 spectrometer operating at 399.8 and 100.5 MHz for ^{1}H and ^{13}C, respectively, and 161.9 MHz for ^{31}P. $CDCl_3$ and DMSO-d_6 were used as solvents, and TMS as an internal (^{1}H) and H_3PO_4 as an external (^{31}P) standard. Electron spray ionization mass spectra were recorded with PE SCIEX API 365 LC/ESI-MS/MS. UV measurements were carried out on a Perkin-Elmer Lambda 2 UV−vis spectrometer.

TLC. Analytical TLC was conducted on silica gel 60 F_{254} plates (Merck). Eluent systems: A (1/19, MeOH/CH_2Cl_2, v/v); B (1/9, MeOH/CH_2Cl_2, v/v); C (17/34/49, Et_3N/MeOH/CH_2Cl_2, v/v/v).

HPLC Techniques. The oligonucleotides were analyzed by ion-exchange chromatography (column, Synchropak AX-300, 4.0 × 250 mm, 6 μm), flow rate 1 mL min^{-1}, buffer A = 0.05 KH_2PO_4 in 50% (v/v) formamide, pH 5.6; buffer B = buffer A + 0.6 mol L^{-1} $(NH_4)_2SO_4$, linear gradient from 10 to 80% B in 30 min. The reversed-phase conditions (also LC/ESI-MS/MS) were as follows: column Nucleosil C18 (300, 4.6 × 250 mm, 5 μm), linear gradient from 5 to 60% B in 30 min and from 60 to 100% B from 30 to 50 min, flow rate 1 mL min^{-1}, buffer A = 0.05 M NH_4OAc(aq), buffer B = buffer A in 65% MeCN.

Oligonucleotide synthesis. The protected oligonucleotides were assembled on an Applied Biosystems 392 DNA Synthesizer in 0.2 and 1.0 μmol scales using commercial solid supports and phosphoramidite chemistry. Phosphoramidites **1** and **2** were used as 0.1 mol L^{-1} solution in dry MeCN, with 600 s coupling time, otherwise unaltered and recommended synthesis protocols were used. After synthesis, the support-bound oligonucleotides were first treated with 0.5 mol L^{-1} hydrazine hydrate in Pyr/AcOH (4:1 v/v) for 30 min and then with ammonia for 8 h at 55 °C.

11-(4,4′-Dimethoxytrityloxy)-3,6,9-trioxaundecanol (4). Tetraethyleneglycol (14.0 g, 72 mmol) was coevaporated with dry pyridine (2 × 50 mL), dissolved in dry dioxane, and 4,4′-dimethoxytrityl chloride (8.0 g, 23.6 mmol) was added portionwise to the stirred solution. The reaction was followed by TLC. After overnight stirring at ambient temperature, the reaction mixture was evaporated and dissolved in dichloromethane (200 mL), washed with saturated $NaHCO_3$(aq) (3 × 100 mL) and brine (100 mL). The organic phase was dried over Na_2SO_4 and concentrated. Purification on silica gel column using a stepwise gradient of MeOH (0 to 10%) in CH_2Cl_2 containing 0.2% pyridine yielded 8.5 g (73%) of **4**. ^{1}H NMR ($CDCl_3$; δ, ppm): 7.25−7.45 (9H, m, DMTr), 6.81 (4H, d, J = 8.8, DMTr), 3.77 (6H, s, 2×OMe), 3.70−3.65 (12H, m, 3×OCH_2CH_2), 3.59 (2H, m, HOCH_2), 3.23 (2H, t, J = 5.4, DMTrOCH_2). ^{13}C NMR ($CDCl_3$; δ, ppm): 158.3, 145.0, 136.3, 130.0, 129.0, 128.2, 127.7, 126.6, 125.2, 113.0, 85.9, 72.5, 70.3−70.7 (5×C), 63.1, 61.7, 55.1 (2×C). TLC: R_f(A) = 0.4.

***N*-[11-(4,4′-Dimethoxytrityloxy)-3,6,9-trioxaundecanyloxy]phthalimide (5)**. *N*-Hydroxyphthalimide (0.7 g, 4.3 mmol) and triphenylphosphine (1.1 g, 4.2 mmol) were added to a solution of **4** (2.0 g, 4.0 mmol) in THF (60 mL). Diethylazodicarboxylate (DEAD, 0.7 mL, 3.6 mmol) was added dropwise, and the stirring was continued overnight at ambient temperature. The reaction mixture was evaporated to oil, applied onto a silica gel column, and eluted with a linear gradient from neat CH_2Cl_2 to a 97:3 (v/v) mixture of CH_2Cl_2 and MeOH. The purification was repeated to yield 2.1 g (80%) of **5**. ^{1}H NMR ($CDCl_3$; δ, ppm): 7.70−7.85 (4H, m, phthaloyl), 7.45−7.25 (9H, m, DMTr), 6.80 (4H, d, J = 9.0, DMTr), 4.35 (2H, t, J = 4.6, DMTrOCH_2), 3.84 (2H, t, J = 4.6, DMTrOCH$_2$CH_2), 3.77 (6H, s, 2×OMe), 3.70−3.55 (10H, m, 5×CH_2), 3.21 (2H, t, J = 5.4, CH_2ON). ^{13}C NMR ($CDCl_3$; δ, ppm): 163.41, 158.38, 149.82, 145.10, 137.85, 136.35, 134.39, 130.06, 129.00, 182.22, 127.73, 126.64, 125.29, 123.45, 113.03, 85.91, 77.17, 70.81, 70.70, 70.66, 70.58, 69.34, 63.13, 55.19, TLC: R_f(A) = 0.9.

***O*-(11-Phthalimidooxy-3,6,9-trioxaundecyl)-*O*-(2-cyanoethyl)-(*N*,*N*-diisopropyl)phosphoramidite (1)**. A solution of dichloroacetic acid in dichloromethane (100 mL, 3:97, v/v) and 20 mL of methanol was added to **5** (2.3 g, 3.6 mmol), and the reaction mixture was stirred for 18 h. All volatile material was evaporated in vacuo, and the residue was dissolved in CH_2Cl_2 (10 mL). Silica gel column purification using an eluent system with a stepwise gradient of acetic acid in CH_2Cl_2 (0−4%) gave 0.88 g (72%) of 11-(phthalimidooxy)-3,6,9-trioxaundecan-1-ol after coevaporation of the pooled fractions with water and pyridine. ^{1}H NMR ($CDCl_3$; δ, ppm): 7.90−7.75 (4H, m, phthaloyl), 4.39 (2H, t, J = 4.6, *H*-11), 3.87 (2H, t, J = 4.6, *H*-10), 3.90−3.50 (12H, m, 3×OCH_2CH_2). TLC: R_f(A) = 0.3. The alcohol (0.37 g,1.09 mmol) was further dried with coevaporation with dry MeCN and finally in vacuo. 2-Cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (0.45 mL, 1.42 mmol), MeCN (1.0 mL) and 1*H*-tetrazole (0.45 mol L^{-1}, 2.43 mL, and 1.10 mmol) were added, and the reaction mixture was stirred at ambient temperature. After 60 min, 100 mL of saturated $NaHCO_3$(aq) solution was added and the mixture was extracted with ethyl acetate (3 × 50 mL). The organic phase was dried with Na_2SO_4, and evaporated. The crude product was almost pure, the yield being 0.58 g (98%). ^{1}H NMR ($CDCl_3$; δ, ppm): 7.90−7.75 (4H, m, phthaloyl), 4.38 (2H, t, J = 4.6, *H*-11), 3.87 (2H, t, J = 4.6, *H*-10), 3.90−3.50 (16H, 3×OCH_2CH_2, POCH_2, and 2×PNC*H*), 2.66 (2H, t, J = 6.6, CH_2CN), 1.30−1.10 (12H, 4×CH_3CHN). ^{31}P NMR($CDCl_3$): 147.63. TLC: R_f(A) = 0.3.

***N*^{4}-Benzoyl-2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)cytidine (6)**. 2′-Deoxycytidine (5.82 g, 25.6 mmol) was dried by evaporation with dry pyridine (2 × 50 mL) and taken up in dry pyridine (100 mL). To this suspension was added trimethylsilyl chloride (11.5 mL, 90.6 mmol), and

the mixture was stirred at ambient temperature for 2 h. The reaction mixture was cooled on an ice−water bath, and benzoyl chloride (4.60 mL, 39.6 mmol) was slowly introduced. The ice−water bath was removed, and the mixture was stirred at room temperature for additional 2 h. The reaction was quenched by adding methanol (15 mL), concentrated to one-half of the original volume and filtered. To the filtrate was added water (30 mL), and the solution was evaporated to oil. Additional evaporations with water (3 × 30 mL) were performed to remove pyridine, and the resulting residue was partitioned between water and ethyl acetate. After vigorous stirring, the product crystallized from the aqueous layer. The crystals were washed with cold water and ethyl acetate, and they were used in the next step without further purification. TLC: R_f(A) = 0.7. Crude N^4-benzoyl-2′-deoxycytidine was dried by evaporation with dry pyridine (3 × 50 mL) and then dissolved in the same solvent (100 mL). 4,4′-Dimethoxytrityl chloride (7.4 g, 22 mmol) was added portionwise to the reaction mixture, and the stirring was continued overnight at ambient temperature. The reaction mixture was evaporated to oil and dissolved in dichloromethane (100 mL). The organic phase was washed with saturated $NaHCO_3$(aq) (50 mL) and water (3 × 100 mL) and dried with anhydrous Na_2SO_4. After coevaporation with toluene, the residue was applied onto a silica gel column and eluted with a gradient of MeOH in CH_2Cl_2 (0 to 8% MeOH). The product (**6**) was obtained in 65% yield (9.0 g) starting from 2′-deoxycytidine. ^{1}H NMR ($CDCl_3$; δ, ppm): 8.30 (1H, d, J = 7.6, *H*-6), 7.45−7.10 (9H, m, DMTr), 6.84 (4H, m, DMTr), 7.90−7.40 (5H, m, benzoyl), 6.31 (1H, t, J = 5.9, *H*-1′), 4.55 (1H, m, *H*-3′), 4.19 (1H, m, *H*-4′), 3.78 (6H, s, 2×OMe), 3.49 (1H, dd, J = 3.2 and 11.0, *H*-5′), 3.42 (1H, dd, J = 3.9 and 10.8, *H*-5″), 2.77 (1H, m, *H*-2″). TLC: R_f(B) = 0.85.

2′-Deoxy-N^4-(5-hydroxypentyl)-5′-*O*−(4,4′-dimethoxytrityl)cytidine (7). A solution of 5-aminopentanol (10.0 g, 96.9 mmol) in 2-propanol (10 mL) was added to **6** (2.61 g, 4.12 mmol) and stirred until the mixture was clear. 1,5,7-Triazabicyclo[4.4.0]dec-5-ene (TBD, 2.40 g, 17.2 mmol) was added and the reaction mixture was stirred at ambient temperature for 48 h. The reaction mixture was evaporated to oil with an oil pump, dissolved in $CHCl_3$ (100 mL), extracted with 0.1 mol L^{-1} NaOH(aq) (2 × 50 mL) and water (4 × 50 mL). The organic phase was dried with anhydrous Na_2SO_4, evaporated, and dissolved in CH_2Cl_2. Silica gel column purification (eluents: 2/4/94 Et_3N/MeOH/CH_2Cl_2 and 2.5/5/92.5 Et_3N/MeOH/CH_2Cl_2; v/v/v) was hampered by the presence of 2′-deoxy-5′-O-(4,4′-dimethoxytrityl)-cytidine, formed as a side product, and that is why the separation had to be repeated until a reasonably pure product was obtained. The yield was 18% (0.53 g). ^{1}H NMR ($CDCl_3$; δ, ppm): 7.75 (1H, d, J = 7.3, *H*-6), 7.45−7.15 (9H, m, DMTr), 6.82 (4H, d, J = 8.5, DMTr), 6.33 (1H, t, J = 5.9, *H*-1′), 5.40 (1H, d, J = 7.3, *H*-5), 4.49 (1H, m, *H*-3′), 4.05 (1H, dd, J = 3.7, *H*-4′), 3.77 (6H, s, 2×OMe), 3.60 (2H, t, J = 5.9, CH_2OH), 3.50−3.30 (4H, m, H-5′, H-5″, HNCH_2), 2.17 (1H, m, H-2′), 1.57 (4H, m, 2×CH_2), 1.40 (2H, m, CH_2). TLC: R_f(C) = 0.7.

2′-Deoxy-5′-*O*-(4,4′-dimethoxytrityl-N^4-(5- phthalimidooxypentyl)cytidine (8). Compound **7** was dried by evaporation with dry pyridine (2 × 20 mL). *N*-Hydroxyphthalimide (0.17 g, 1.04 mmol) and triphenylphosphine (0.14 g, 0.53 mmol) were added, and the mixture was dissolved in dry THF (30 mL). Diethylazodicarboxylate (DEAD, 0.089 mL, 0.57 mmol) was added dropwise, and the reaction mixture was stirred at ambient temperature for 18 h. All volatile material was evaporated in vacuo, and the residue was dissolved in a small volume of dichloromethane and applied onto a silica gel column. Triphenylphosphine oxide was eluted first from the column with a mixture of ^{i}PrOH and CH_2Cl_2 (1/19, v/v) and the product with a mixture of MeOH and CH_2Cl_2 (1/9, v/v). The purification afforded 0.24 g of compound **8** (40%). ^{1}H NMR ($CDCl_3$; δ, ppm): 8.61 (1H, m, N*H*), 7.85−7.65 (4H, m, phthaloyl), 7.45−7.15 (9H, m, DMTr), 6.83 (4H, m, DMTr), 6.30 (1H, t, *H*-1′), 5.47 (1H, d, J = 7.3, *H*-5), 4.51 (1H, m, *H*-3′), 4.21 (2H, t, J = 5.9, CH_2ON), 4.05 (1H, m, *H*-4′), 3.78 (6H, s, 2×OMe), 3.60−3.10 (4H, m, H-5′,H-5″, CH_2N), 2.60 (1H, m, *H*-2′), 2.20 (1H, m, *H*-2″), 1.79 (2H, m, CH_2), 1.70−1.40 (4H, m, 2×CH_2). TLC: R_f(B) = 0.5.

2′-Deoxy-5′-*O*-(4,4′-dimethoxytrityl)-N^4-(5-phthalimidooxypentyl)cytidine 3′-[*O*-(2-cyanoethyl)-*N*,*N*-diisopropyl)]phosphoramidite (2). Compound **8** (0.22 g, 0.29 mmol) was dried by evaporation with dry acetonitrile (3 × 20 mL) and finally in vacuo for 30 min. 2-Cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (0.12 mL, 0.38 mmol) and dry acetonitrile (1.0 mL) were added, and the mixture was stirred until all material dissolved. 1*H*-Tetrazole (0.45 mol L^{-1} in MeCN, 0.64 mL, 0.29 mmol) was added, and the reaction mixture was shaken. After 1 h at ambient temperature, 100 mL of saturated $NaHCO_3$(aq) solution was added to the reaction mixture, and the resulting solution was extracted with ethyl acetate (2 × 40 mL). The organic phase was dried with anhydrous Na_2SO_4 and evaporated to dryness, affording 0.24 g (97%) of almost pure compound **2**. ^{1}H NMR ($CDCl_3$; δ, ppm): 7.75−7.70 (4H, m, phthaloyl), 7.45−7.20 (9H, m, DMTr), 6.83 (4H, m, DMTr), 6.36 (1H, m, *H*-1′), 5.41 (1H, d, J = 5.6, *H*-5), 4.60 (1H, m, *H*-3′), 4.22 (2H, t, J = 5.4, CH_2ON), 4.10 (1H, m, *H*-4′), 3.78 (6H, s, 2×OMe), 3.65−3.30 (8H, m, *H*-5′,*H*-5″, CH_2N, POCH_2, 2×PONC*H*), 2.63 (2H, m, CH_2CN), 2.60 (1H, m, *H*-2′), 2.25 (1H, m, *H*-2″), 1.85−1.50 (6H, m, 3×CH_2), 1.30−1.00 (12H, m, 4×CH_3). ^{31}P NMR ($CDCl_3$, δ, ppm): 149.2 and 148.7.

5′-*O*-(4,4′-Dimethoxytrityl)-2′-*O*-(2-phthalimidooxyethyl)-5-methyluridine 3′-[*O*-(2-cyanoethyl)-*N*,*N*-diisopropyl)]phosphoramidite (3). The compound was synthesized as published previously (*46*).

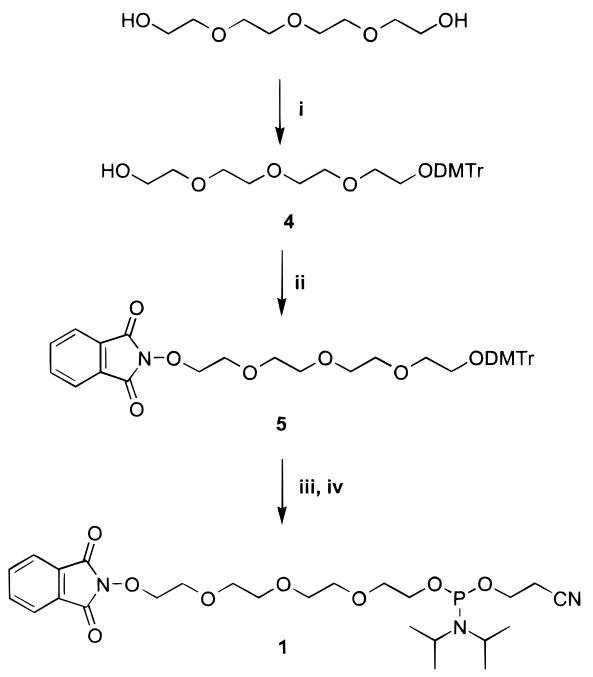
Immobilization of Oligodeoxyribonucleotide Conjugates to Microparticles. The ODN conjugates 5′-d(NH_2O-TEG-ACACCAAAGATGATAT)-3′ (**9**) and 5′-d[ACACCAAAGATGATATmC(ONH_2)T]-3′ (**10**) [TEG stands for tetraethyleneglycol and mC for N^4-(5-hydroxypentyl)-2′-deoxycytidine] were assembled according to the phosphoramidite protocol, using building blocks **1** and **2** to obtain **9** and **10**, respectively. A modified coupling time of 600 s was used to insert **1** and **2**. Deprotection and cleavage were performed with a double syringe method employing a 0.5 mol L^{-1} hydrazine acetate solution (0.124/4/1 H_2NNH_2·H_2O/pyridine/AcOH, v/v/v) for 30 min, followed by ammonolysis with concentrated ammonia at 55 °C for 8 h. The crude ODN conjugates (**9** and **10**) were evaporated to dryness and dissolved in 1.0 mL of water and mixed immediately with the aldehyde derivatized microparticles (90 nmol of **9** and 2.8 mg of Tentagel, 0.6 μmol of CHO groups, or 80 nmol of **10** and 3.5 mg of Tentagel, 0.8 μmol of CHO groups). ODN conjugate **10** (1.0 mL, 80 nmol) was also mixed with epoxide-modified microparticles (3.0 mg, 0.3 μmol epoxide groups). The progress of the reactions was followed by UV absorbance change at 260 nm. According to the observed decrease in the absorbance, a loading of 1 μmol of oligonucleotides in 1 g of the microparticles was obtained. After reaction,

Table 1. Properties of the Oligonucleotide Conjugates

oligonucleotide	retention time (min)[a]	observed mass	calculated mass	product ratio (%)
18a	27.9	2246.4	2246.6	41
18b	41.8	2301.2	2300.8	51
19a	36.7/37.4[b]	2352.6	2356.9	70
19b	38.3	2104.4	2104.8	52

[a] RP-HPLC, for detailed chromatografic conditions, see Experimental Section. [b] E/Z isomers, both peaks exhibited same molecular mass (Figure 4).

the derivatized microparticles were washed with water, dried, and used in hybridization assays.



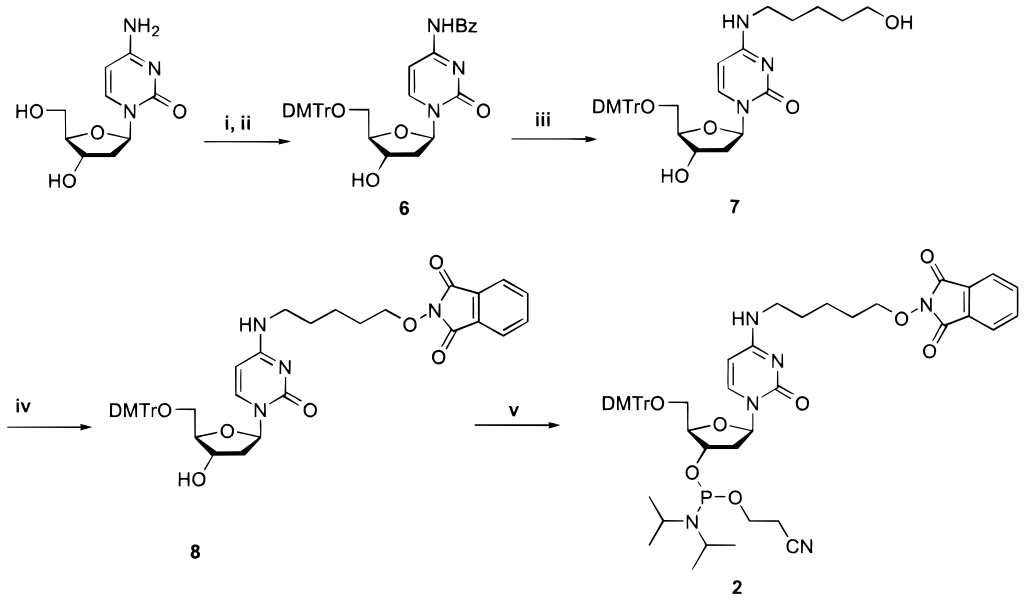
Hybridization Assays. The ODNs attached to microparticles were used as capture probes for a complementary 16-mer sequence, 5′-d(X_5ATATCATCTTTGGTGT)-3′ (**11**), where X stands for N^4-(6-aminohexyl)-2′-deoxycytidine tethered to a photoluminescent europium(III) chelate, {2,2′,2″,2‴-{{4′-{4‴-[(4,6-dichloro-1,3,5-triazin-2-yl)amino]phenyl}-2,2′:6′,2″-terpyridine-6,6″-diyl}bis(methylenenitrilo)}-tetrakis(acetato)}europium(III) (*47*). To evaluate the contribution of unspecific binding to the solid phase, a sequence 5′-d(X_5TCATGAGTCAAGTCTA)-3′(**12**) was used instead of **11**. The signal intensity of time-resolved fluorescence of europium from one microparticle was measured with a microfluorometer as a function of added **11** or **12**. A detailed description of the measuring system and the hybridization conditions has been described previously (*19*, *35*, *48*). With the aldehyde-derivatized Tentagel, a slightly modified mode of measurement was applied. Instead of capillary tubing, the microparticles were collected on a filter and the signal was collected from one bead with the microfluorometer.

Labeling of Aminooxy Functionalized Oligonucleotides with Aldehydes on Solid Support. Oligonucleotide sequences 5′-(PhthNO-TEG-T_6)-3′ (**16**) and 5′-(PhthNOEt-MeU-T_5)-3′ (**17**), where PhthNOEt-MeU stands for a 2′-*O*-(2-phthalimidooxyethyl)-5-methyluridine (**3**) unit, were synthesized on standard CPG-succinyl-thymidine support as described previously for **9**, with the exception that a standard 30 s coupling time was used to introduce **3** into **17**. The support-bound oligonucleotides were treated with 0.5 mol L^{-1} hydrazine acetate solution (0.124/4/1 $H_2NNH_2 \cdot H_2O$/pyridine/AcOH, v/v/v) for 30 min and washed with pyridine, methanol, acetonitrile, and dried. The supports (2.0 mg/sample, 50 nmol of ODN) were transferred to microcentrifuge tubes, and a solution of either pyrenecarbaldehyde (100 μL, 40 μmol in DMF) or *cis*-retinal (100 μL, 3.5 μmol in MeCN) was added, and the mixture was shaken 16 h at ambient temperature in dark. The excess of reagents was washed with several portions of DMF and MeCN until no color was released from the supports. The supports were then dried and finally treated with concentrated ammonia at ambient temperature for 24 h to release the resulting oligonucleotide−oxime conjugates: **18a** (reaction of **16** with pyrenecarbaldehyde), **18b** (reaction of **16** with *cis*-retinal), **19a** (reaction of **17** with pyrenecarbaldehyde), and **19b** (reaction of **17** with *cis*-retinal). Evaporation, dissolution in water and analysis by HPLC/ESI-MS/MS verified the formation of the expected oligonucleotide conjugates and complete disappearance of the starting material (see Table 1).

RESULTS AND DISCUSSION

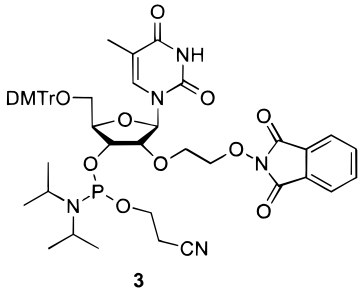
Synthesis of the Phosphoramidites. The synthesis of phosphoramidite **1** is described in Scheme 1. One of the hydroxy functions of tetraethyleneglycol was initially

Scheme 1[a]



[a] (i) DMTrCl/dioxane/Pyr; (ii) *N*-hydroxyphthalimide/Ph_3P/DEAD/THF; (iii) dichloroacetic acid/CH_2Cl_2/MeOH; (iv) 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite/1-*H*-tetrazole/MeCN. Ph_3P: triphenylphosphine.

dimethoxytritylated (to get **4**) by treating an excess of the glycol with 4,4′-dimethoxytrityl chloride in a mixture of pyridine and dioxane. The remaining hydroxy function of **4** was then subjected to Mitsunobu reaction (*45*), using *N*-hydroxyphthalimide as a nucleophile and diethyldiazodicarboxylate (DEAD) and triphenylphosphine as activators. The desired *O*-phthalimido derivative **5** was obtained in 80% yield. Detritylation of **5** with dichloroacetic acid afforded the corresponding alcohol in 72% yield. Subsequent reaction with *N*,*N*,*N*′,*N*′-tetraisopropyl-2-cyanoethylphosphorodiamidite in the presence of 1-*H*-tetrazole then gave **1** in excellent yield (98%).



The synthesis of phosphoramidite **2** is described in Scheme 2. 2′-Deoxycytidine was first N^4-benzoylated according to the method of Jones (*49*) and the 5′-oxygen was then dimethoxytritylated, affording **6** in a 65% overall yield. The product was subjected to transamination reaction using 5-aminopentanol as the entering amine and TBD as a catalyst (*50*). The reaction was not optimized, and the yield of the product, 2′-deoxy-N^4-(5-hydroxypentyl)-5′-*O*-(4,4′-dimethoxytrityl)cytidine (**7**) was low (18%). The major product formed was debenzoylated 5′-*O*-(4,4′-dimethoxytrityl)cytidine, which could be collected and recycled. No other side products were detected. Application of Mitsunobu reaction to **7** gave **8** in 40% yield, and the latter was finally converted to **2** (97%). The amidite **3** (Figure 1) was synthesized as described previously (*46*).

Synthesis of Oligodeoxyribonucleotide Conjugates (9, 10), and Their Immobilization. To test the coupling efficiency of phosphoramidites **1** and **2** and the removal of the phthaloyl group with hydrazine acetate, a T_6 sequence was first assembled and elongated with **1**. On the basis of HPLC analysis and DMTr-cation assay (data not shown), a reaction time of 600 s was selected for the coupling and a 30 min treatment with 0.5 mol L^{-1} hydrazinium acetate followed by standard ammonolysis at 55 °C for the deprotection. Although this treatment has previously been used in solid-phase oligonucleotide

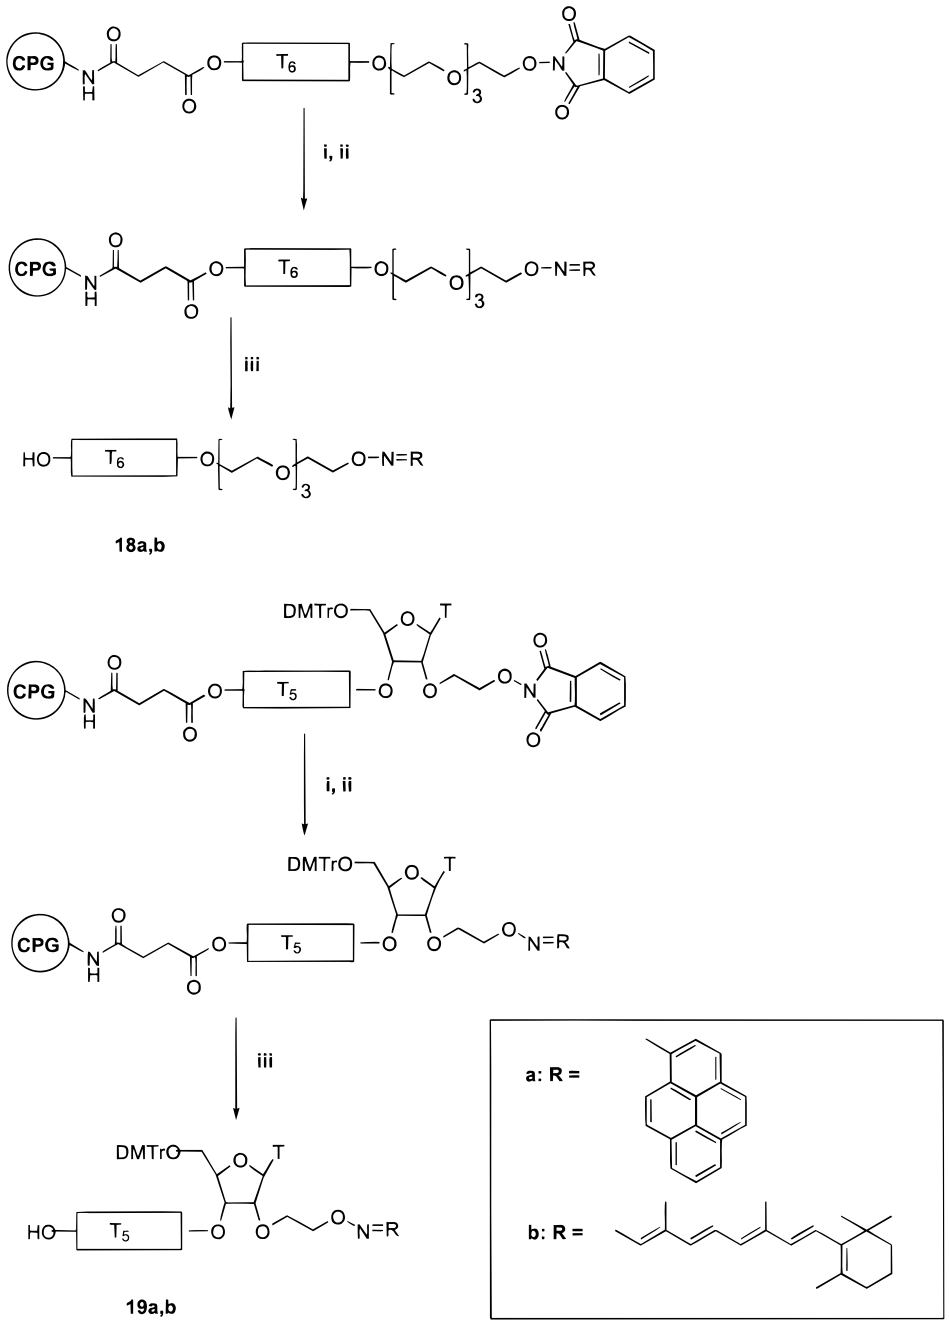
Scheme 3. A Schematic View of the Attachment of ODNs 9 and 10 to the Microparticles Forming the Particle-Bound Conjugates 13, 14, and 15



synthesis (*51*), we checked the effect on each nucleoside separately. A sample of each CPG-bound nucleoside (dA, dG, dC, and T) was treated according to the deprotection protocol and analyzed by RP-HPLC. No additional peaks were detected in the chromatograms of the hydrazine-treated nucleosides compared to those referring to nucleosides released from the support by mere ammonolysis.

The applicability of the developed protocol was verified by synthesis of two 16mer heterosequences, **9** and **10,** using phosphoramidites **1** and **2**, respectively (see Scheme 3). All attempts to isolate the oligonucleotide conjugates by RP-HPLC after deprotection of the aminooxy group failed, in all likelihood owing to the high nucleophilicity of the aminooxy function. For this reason, the crude deprotected conjugate was used for immobilization without any purification. The ammoniacal solution containing the deprotected conjugate was simply evaporated to dryness, and the residue was dissolved in water. Tentagel or polyacrylate particles bearing aldehyde or epoxide groups were then immediately added to the resulting solution, and the mixture was gently stirred at room temperature. The disappearance of **9** and **10** from the solution phase was monitored by UV absorbance decrease at 260 nm. According to these observations, less than 10% of the ODN conjugate became immobilized, the loading achieved being of the order of 1 μmol g^{-1}. With the aldehyde supports and epoxy supports, the immobilization took place for 24 h.

Hybridization Assays. The success of immobilization of **9** and **10** to the microparticles was verified by showing that the oligonucleotide-coated particles obtained were able to bind highly selectively the complementary sequence (**11**) from solution. The measurements were carried out by our previously reported (*19*) method that is based on time-resolved detection of a fluorescently tagged oligonucleotide directly from the surface of a single particle. According to these measurements, the intensity of the fluorescence emission signal obtained on treating the particles with a complementary fluorescently tagged oligonucleotide (**11**) was always more than 2 orders of magnitude higher than that resulting from unspecific binding of a noncomplementary fluorescently labeled oligonucleotide (**12**) to the particles. The following systems were tested: (i) oligonucleotide conjugate **9** immobilized to aldehyde-coated Tentagel (**13**), (ii) conjugate **10** immobilized to aldehyde-coated Tentagel (**14**), and (iii) conjugate **10** immobilized to epoxide-coated polyacrylate particles (**15**) (Scheme 3). As illustrative examples, the signals of specific and unspecific binding of oligonucleotides to particles **14** and **15** are shown in Figures 2 and 3 as a function of the oligonucleotide concentration in solution (**11** or **12**). As seen, the epoxide-modified microparticles exhibit a somewhat higher ratio of specific to unspecific binding signal than the aldehyde-derivatized Tentagel particles. These results and our previous findings using this hybridization assay indicate that, first, the amount of oligonucleotide immobilized on the particles was sufficient for efficient and specific

Scheme 4[a]

hybridization. Second, the use of crude oligomer in the immobilization step did not result in loss of selectivity in the hybridization, which is in good agreement with our previous results. (*19*, *25*)

Labeling Oligonucleotides with Aldehydes on the Support. To verify the authentity of the aminooxy functionalized oligomers (**9**, **10**) and to illustrate more general applicability of aminooxy tethering in the field of oligonucleotide chemistry, some additional experiments with the aminooxy-derivatized oligonucleotides were conducted. Since the aminooxy functionality could be deprotected with a pyridine-buffered hydrazinium-acetate solution without cleaving the succinyl linker, the support-bound aminooxy oligonucleotide conjugates could be converted to oxime conjugates by reacting them with aldehydes. Very recently, the methodology of on-column conjugation with amino-tethered oligonucleotides and acids via PyBOP mediated amide bond formation has been successfully exploited by Greenberg et al. (*52*, *53*). To show the applicability of oxime bond formation, model sequences T_6 and T_5 elongated at the 5′-end with building blocks **1** and **3**, respectively, were reacted both with pyrenecarbaldehyde and *cis*-retinal, forming the corresponding oxime conjugates (Scheme 4). Excess of reagents was washed and ammonolytic treatment of the supports released the crude oxime conjugate in solution. Analysis of the reaction mixtures revealed clearly the formation of E/Z isomers, especially in the case of **19a** (Figure 4). The conjugates were then characterized with ESI-MS, which definitely proved the formation of correct products. According to the areas of the HPLC signals, the total amount of products in the crude ammonolysis mixtures could be estimated to fall in the range 40−70% (Table 1).

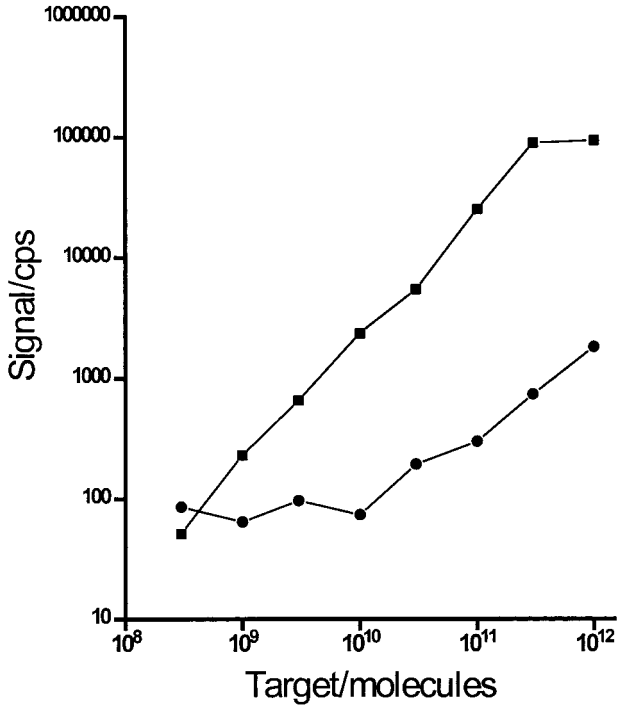

Figure 2. Hybridization of an aminooxy oligonucleotide immobilized to an aldehyde functionalized particle (**14**) with a fluorescently tagged complementary (**11**) and noncomplementary (**12**) sequence. The signal intensity measured from the surface of **14** plotted against the concentration of **11** (squares) or **12** (circles).

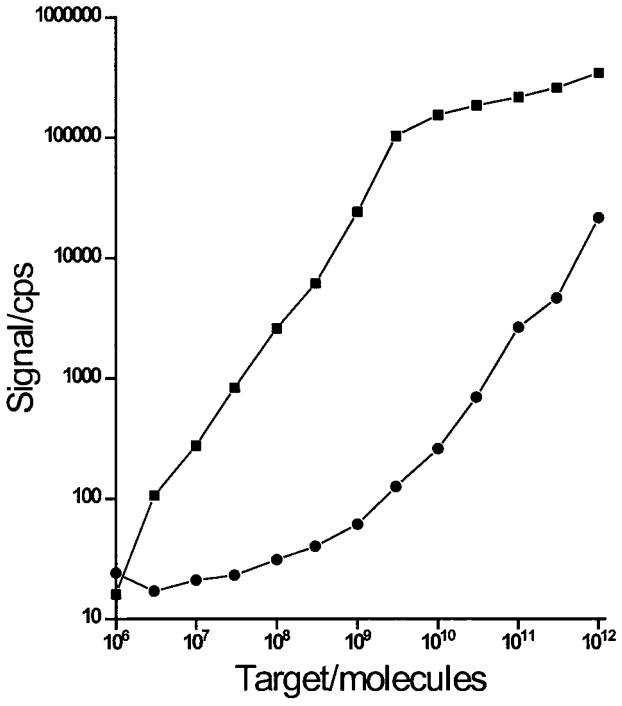

Figure 3. Hybridization of an aminooxy oligonucleotide immobilized to an epoxide functionalized particle (**15**) with a fluorescently tagged complementary (**11**) and noncomplementary (**12**) sequence. The signal intensity measured from the surface of **15** plotted against the concentration of **11** (squares) or **12** (circles).

CONCLUSIONS

Three phosphoramidites that allow tethering of an oligonucleotide with a phthalimidooxy moiety have been prepared and introduced in oligodeoxyribonucleotides. Treatment with hydrazinium acetate have been shown to convert the phthalimidooxy group to an aminooxy group, which as a powerful nucleophile may be exploited in immobilization of oligonucleotides to aldehyde or epoxide modified polymer particles. The immobilized oligonucleotides are shown to serve properly as capture probes in mixed phase hybridization assays. In addition, the aminooxy functionalized oligonucleotides may conveniently be conjugated with aldehydes on solid support, giving oxime conjugates of oligonucleotides.

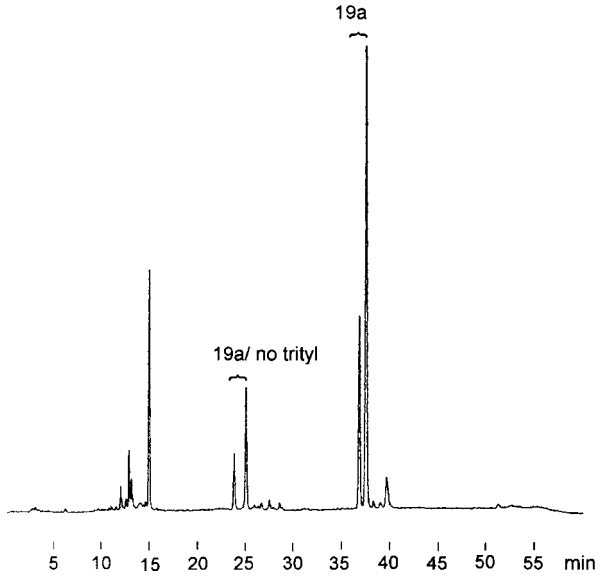

Figure 4. The HPLC profile of an oligonucleotide conjugate (**19a**) obtained by labeling with pyrenecarbaldehyde on support and subsequent ammonolytical release in solution. The product shows two peaks referring to the E/Z isomers of both tritylated and detritylated compounds. For the conditions, see Experimental Section.

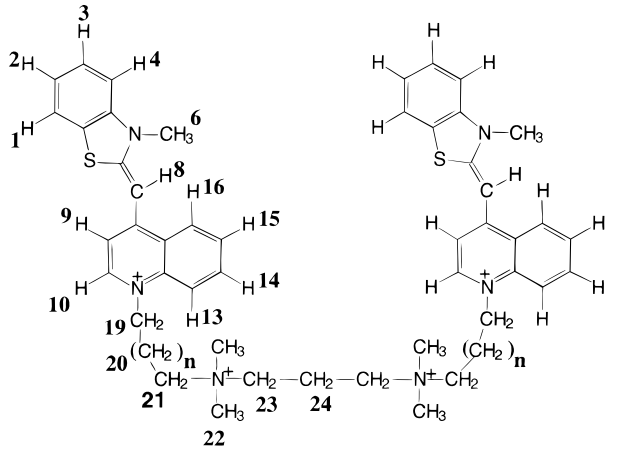
On the Sequence Selective Bis-Intercalation of a Homodimeric Thiazole Orange Dye in DNA

Jakob Bunkenborg, Maria Munch Stidsen, and Jens Peter Jacobsen*

Department of Chemistry, Odense University, DK-5230 Odense M, Denmark. Received March 15, 1999; Revised Manuscript Received June 24, 1999



The thiazole orange dye 1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis-4-[(3-methyl-2,3-dihydro(benzo-1,3-thiazolyl)-2-methylidene]quinolinium tetraiodide (TOTO) binds sequence selectively to double-stranded DNA (dsDNA) by bis-intercalation. Each chromophore is sandwiched between two base pairs in a d(5′-py-p-py-3′):d(5′-pu-p-pu-3′) site, and the linker spans over two base pairs in the minor groove. We have examined the binding of TOTO to various dsDNA oligonucleotides containing variations of the 5′-CTAG-3′ binding motif by introducing inosine (I = inosine, 2-desaminoguanosine) and 5-methylcytosine (^{me}C). A one- and two-dimensional NMR spectroscopy characterization yielded detailed structural information on the binding mode and for the well-defined TOTO-complexes competition experiments allowed determination of the relative binding strengths resulting from the various structural alterations. The experimentally observed base pair preference of TOTO in the palindromic sequences investigated is ^{me}CG > CG > CI > TA for the flanking base pair and ^{me}CI > CI > TA > CG > UA for the central base pair. The best binding site observed so far is the d(5-C^{me}CIG-3′)$_2$ site. This site is much more favorable than the d(5′-CTAG-3′)$_2$ site formerly believed to be the best binding site. The present paper discusses these results in terms of different contributions to the binding affinity and offers some explanations for the site selectivity of TOTO.

INTRODUCTION

DNA[1]-intercalating agents (Denny, 1989) have attracted much attention since Lerman (Lerman, 1961) first described the intercalation binding motif as the insertion of a flat, aromatic chromophore between two base pairs, and many compounds have been found to interact with DNA in this way (Denny, 1989). The noncovalent binding of small molecules to DNA may occur with high affinity and varied sequence selectivity. Much of the affinity and specificity is derived from the small molecules having a structure capable of forming hydrogen bonds with DNA. However, several other factors influence the affinity and selectivity such as steric complementarity, base stacking ability, and electrostatic properties.

Recent work in our laboratory has concerned the binding properties and sequence selectivity of the homodimeric bis-intercalating cyanine dye TOTO [1,1′-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis-4-[(3-methyl-2,3-dihydro-2(3H)-benzo-1,3-thiazolylidene]-methyl]quinolinium tetraiodide; Scheme 1), which was developed by Glazer and co-workers (Glazer and Rye, 1992) as a flourescent probe for DNA detection. On the basis of a linear relationship between fluorescence intensity and DNA concentration in base pairs, Glazer concluded that TOTO does not show strong sequence specificity. However, we have shown (Jensen et al., 1998; Hansen et al., 1996) that TOTO binds preferentially to 5′-pyrimidine-pyrimidine-purine-purine-3′ (5′-py-py-pu-pu-3′) sequences with 5′-CTAG-3′ as the preferred binding site. The binding of TOTO to various symmetric double-stranded DNA sequences was found to be quite sensitive to changes in the base sequence (Jensen et al., 1998; Hansen et al., 1996). TOTO certainly binds to all the oligonucleotides investigated as evidenced by the

disappearance of NMR resonances from the free dsDNA, but TOTO does not always form well-defined complexes that permits spectral assignments and thus NMR characterization. The main reasons for this are line broadening arising from exchange of TOTO between different sites or from different binding modes. Previous studies have shown that there is at least a 100-fold preference for bis-intercalating in the (5′-CTAG-3′)$_2$ site over any other site contained in the d(5′-CGCTAGCG-3′)$_2$ sequence. This site selectivity seems somewhat surprising in view of the rather nonspecific intercalator and electrostatic binder motif, neither of which are capable of forming hydrogen bonds, that is combined into the TOTO molecule. On the basis of the solution structure of the TOTO−CTAG complex (Spielmann et al., 1995), it was suggested that the sequence selectivity is influenced by the ability of the thiazole orange chromophores to adapt to the propeller twist of the bases in the binding step. The benzothiazole moiety of the chromophore is intercalated between the two pyrimidine bases and the quinolinium part is intercalated between the two purine bases. The optimal stacking displayed by this structure may explain why TOTO prefers a 5′-py-py-pu-pu-3′ site but does not explain the selectivity within this type of sequences.

NMR studies of polyamines (Padmanabhan et al., 1988; Wemmer et al., 1985; Padmanabhan et al., 1991) indicate a nonselective, electrostatic binding mode to DNA. Consequently, it was concluded that although adding significantly to the binding strength, the polyamine linker of TOTO is only a spectator with respect to the sequence selectivity. Thus, the sequence selectivity seems to be governed by the interaction of the intercalated thiazole orange chromophores with the bases. It is not really well understood what causes the preference of TOTO for the 5′-CTAG-3′ site, but several contributions have been suggested. The solution structure indicates that the 5′-py-py-pu-pu-3′ binding motif offers the best stacking of the chromophores. Competition experiments have shown that the substitution of thymine with uracil (Jensen et al., 1998) causes a weaker binding of TOTO, leading to the conclusion that the methyl group on thymine causes some stabilization of the complex. This stabilization could be attributed to dispersion attractions between the methyl group and the benzene moiety of the benzothiazole ring, or to hydrophobic interactions between the two. The lack of the methyl group could also explain why 5′-CCGG-3′ is a worse site, but is certainly not sufficient to explain why neither d(5′-CGTCGACG-3′)$_2$ nor d(5′-CGTTAACG-3′)$_2$ form well-defined complexes with TOTO.

Theoretical (Sponer et al., 1996) and experimental (Joireman et al., 1998) studies on aromatic−aromatic interactions suggest that there are three major components in determining the geometry and strength of the stacking interaction. The exchange repulsion is the short-range interaction that determines how close two nonbonding atoms can get. The dispersion attraction is an attractive electron correlation phenomenon that favors the close contact between nonbonding atoms, while the electrostatic interactions can be both attractive and repulsive and show a strong orientational dependence. The exchange repulsion and the dispersion attraction are often collectively referred to as van der Waals forces. The electrostatic and van der Waals forces often have conflicting demands on the optimum structure of an intermolecular complex leading to different binding motifs when either dispersion or electrostatic interactions dominate.

To investigate the structural basis of the site selectivity of TOTO, we have studied some variations of the 5′-CTAG-3′ binding motif by introducing inosine (I = inosine, 2-desaminoguanosine) and 5-methylcytosine (^{me}C). The NMR characterization by the NOESY spectra yields detailed structural information on the binding mode, and for the well-defined TOTO complexes, the competition experiments allow a determination of the binding strength as a result of the various structural alterations. While replacement of the outer guanosine with inosine destabilized the complex, replacement of the central T−A base pairs with C−I improved the stability. The best binding site observed so far was obtained with the d(5′-C^{me}CIG-3′) site. Our new results indicate that the linker is not altogether a passive spectator to the sequence selectivity, and we therefore included a TOTO analogue with a longer linker into the study. This analogue contained two more methylene groups in the linker and is named TOTO11 [1,1′-(5,5,9,9-tetramethyl-5,9-diazatridecamethylene)-bis-4-[(3-methyl-2,3-dihydro(benzo-1,3-thiazolyl)-2-methylidene]quinolinium tetraiodide; Scheme 1]. Combined with earlier results, the present study offers some elucidation of TOTO's site selectivity.

EXPERIMENTAL SECTION

Materials. TOTO and TOTO11 were kindly provided by Dr. E. B. Pedersen (Department of Chemistry, Odense University, Denmark). The self-complementary oligonucleotides shown in Scheme 2 were purchased from DNA-Technology, Aarhus, Denmark, and were delivered redissolved in doubly distilled H_2O after being ethanol precipitated from 500 mM NaCl buffer, pH 8.0. The purity of the oligonucleotides was assessed by 1-D H NMR spectroscopy, and they were used without further purification. The complexes of TOTO with the oligonucleotides were prepared by the procedure described earlier (Jacobsen et al., 1995). The NMR samples were prepared by dissolving the complexes in 500 μL of 10 mM sodium phosphate buffer (pH 7.0) containing 50 μM EDTA, 10 μM NaN_3, and 100 μM DSS. For experiments carried out in D_2O, the solid complex lyophilized twice from D_2O was redissolved in 99.96% D_2O (Cambridge Isotope Laboratories). A mixture of 90% H_2O and 10% D_2O was used

for experiments examining exchangeable protons. The samples were kept in NMR tubes under nitrogen. The final concentrations of the complexes ranged 1.7−2.0 mM.

Methods. NMR experiments were performed on a 500 MHz Varian Unity 500 spectrometer. NOESY spectra in D_2O were acquired with a 200 ms mixing time using 1024 complex points in t_2 and a spectral width of 5000 Hz. A total of 512 t_1 experiments were recorded using the States phase cycling scheme with 64 scans for each t_1 value. The residual signal from HOD was removed by presaturation. TOCSY spectra with mixing times of 30 and 90 ms were obtained in the TPPI mode using 1024 complex points in t_2 and 512 t_1 experiments with 64 scans each. The NOESY spectra in H_2O were acquired with a spectral width of 12.000 Hz for the inosine containing oligonucleotides and 10.000 Hz for the rest using 2048 complex points and a pulse sequence where the last 90° pulse is replaced with a shaped 90° pulse containing a notch to avoid excitation of the solvent signal (Stein et al., 1995). This ensured suppression of the water signal together with a linear excitation profile over the whole spectral width. Most spectra were acquired at 298 K, but the oligonucleotide sequences containing a central inosine formed a hairpin minor form, and to minimize the hairpin-concentration, the spectra were acquired at low temperature (either 274 or 283 K). The acquired data were processed using either FELIX (version 95.0 or 97.0, MSI/Biosym Technologies, San Diego). For the competition experiments, at least 2048 scans were acquired at 283 K and the integration of the imino resonances was done using the line fitting procedure in FELIX. The spectra were analyzed by conventional methods (Boelens et al., 1985; Feigon et al., 1983; Hare et al., 1983; Scheek et al., 1984; Wüthrich, 1986).

RESULTS

Spectral Analysis. The DNA complexes formed by TOTO with the oligonucleotides listed in Scheme 2 yielded proton resonances with line widths ranging 6−15 Hz. Narrow lines are certainly indicative of a well-defined complex, but broad lines may result from a slight overtitration of TOTO. Except for CCGI, all the complexes of TOTO with the palindromic oligonucleotides exhibit dyad symmetry as evidenced by the occurrence of resonances from only one dsDNA strand and half of the TOTO resonances expected for an asymmetric complex. CCGI and TOTO formed a symmetric major form and an asymmetric minor form, for the other sequences, there were no discernible minor forms.

Figure 1 shows the aromatic to aromatic and H1′ region of the NOESY spectra of the C^{me}CIG−TOTO complex, which is spectroscopically representative for the complexes included in this study. The NOESY spectra of the TOTO complexes exhibit the characteristic dsDNA sequential connectivities, but the sequential pathway is disconnected in the 5′-C3-p-^{me}C4-3′ and 5′-I5-p-G6-3′ base pair step. Several of the C3 and ^{me}C4 resonances are shifted upfield compared to the position in the free oligonucleotide and there are a number of cross-peaks between the TOTO chromophores and the surrounding DNA residues. All these observations unambiguously place each thiazole orange chromophore sandwiched between two base pairs in an overall symmetric bis-intercalative binding mode. The spectra were assigned as previously described (Jacobsen et al., 1995; Spielmann et al., 1995). The cross-peaks between the purine H8 and the protons H13, H14, and H15 of the quinoline moiety position the quinoline ring between the two purine bases. Cross-peaks between I5H2 and H9/H10 place the H9/H10 end of the quinoline ring above the purine base at the center of the minor groove. The cross-peaks between the methyl group of the central pyrimidine and H1−H4 of the benzothiazole part indicates that the benzene ring is situated between the pyrimidines and pointing toward the pyrimidine side of the major groove. Although minor changes in the structure are to be expected, all these NOE contacts are in rough accordance with the CTAG−TOTO solution structure. It therefore seems reasonable to make inferences about the substitution of new bases on the basis of this structure. The poly(propylenamine) linker is without doubt placed in the minor groove for all the well-defined complexes. Cross-peaks (not shown) between the H2 proton of inosine and the H21, H22, and H23 linker protons and between the H1′ of I5 and the H19, H20, and H21 linker protons unambiguously locate the linker in the minor groove. The NOESY spectra recorded in H_2O exhibit the normal Watson−Crick NOE connectivities for the exchangeable protons with an interruption at the 3−4 and 5−6 base pair steps where the chromophores are inserted.

Site Selectivity of TOTO. To gain insight into the causes of the site selectivity of TOTO, we performed NMR competition studies between various oligonucleotides containing the (5′-py-py-pu-pu-3′)$_2$ binding motif. In the competition experiments, the distribution of TOTO between almost equal amounts of two oligonucleotides was measured by the intensities of the imino proton resonances from both the two free oligonucleotides and the two complexes. This procedure requires one isolated imino proton resonance for each species. The oligonucleotides CCGI, CCIG, CCII, and C^{me}CIG competed against CTAG, but due to the similarity of CTAG and ^{me}CTAG and the resulting spectral overlap, ^{me}CTAG competed against CCII. The imino region of the competition experiment between C^{me}CIG and CTAG is displayed in Figure 2, where the resonances in the mixture are unambiguously identified by the single species assignments of the free oligonucleotides and TOTO complexes. The equilibrium

$$\text{CTAG-TOTO} + \text{C}^{me}\text{CIG(free)} \rightleftarrows \text{CTAG(free)} + \text{C}^{me}\text{CIG-TOTO}$$

is established very fast and has an equilibrium constant given by

$$K = \frac{[\text{CTAG(free)}][\text{C}^{me}\text{CIG-TOTO}]}{[\text{CTAG-TOTO}][\text{C}^{me}\text{CIG(free)}]}$$

The values of K measured from the integral of the imino resonances at 10 °C are given in Table 1 together with the results from previous studies (Jensen et al., 1998; Hansen et al., 1996). The results have been normalized with the CTAG sequence as the reference. A general problem with this approach is that only the relative affinity between two different well-defined sites having nonoverlapping resonances can be measured, and therefore, the affinity of the ill-defined sites cannot be measured. It is therefore not possible to establish an affinity scale that encompasses all the possible sites. Furthermore, there is a large uncertainty when comparing sequences with very disparate affinities.

The present study has yielded a new binding sequence for TOTO that is much better than the previously best

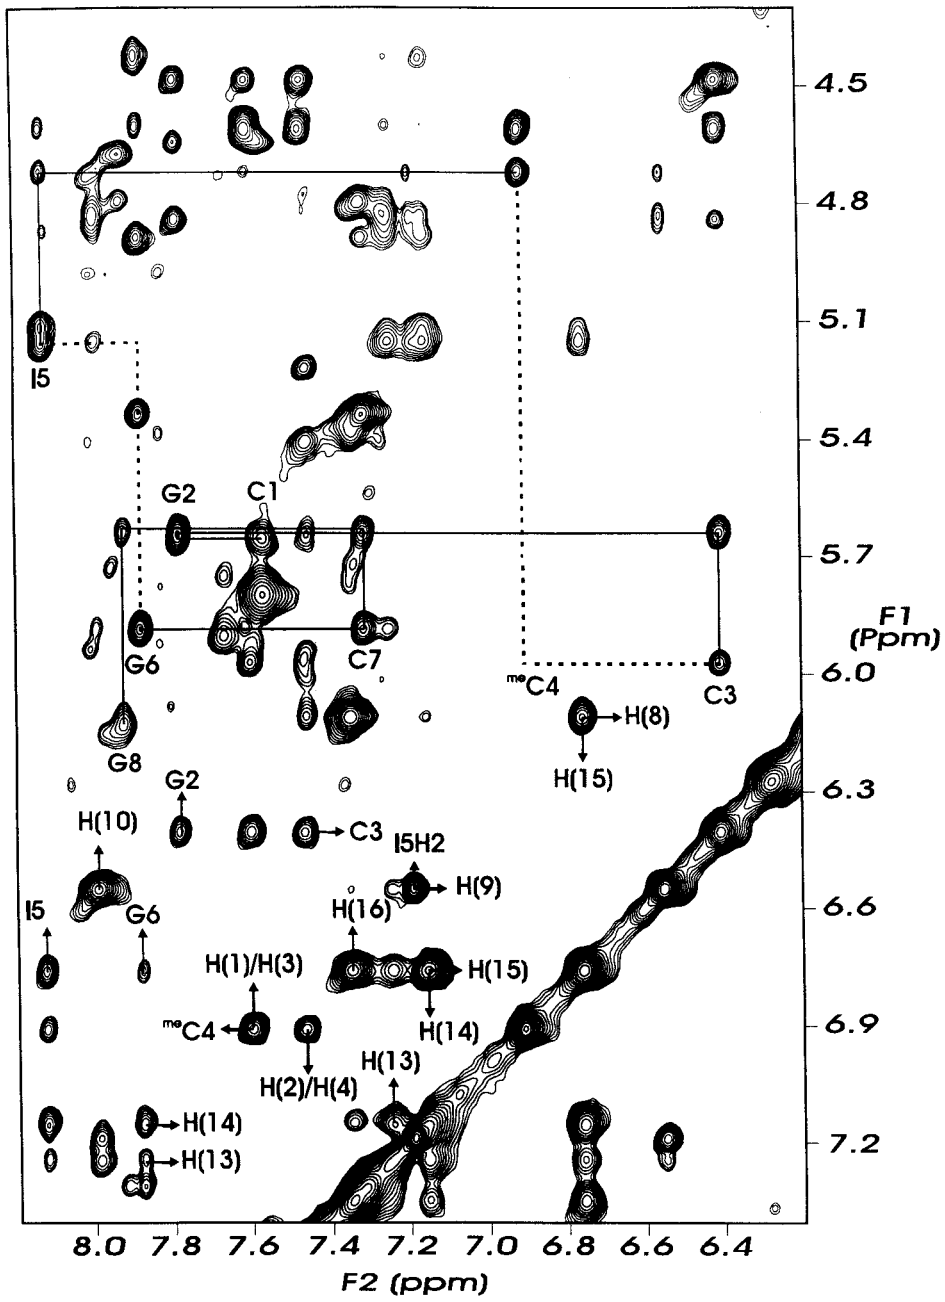

Figure 1. The aromatic to H1′ and aromatic part of the 200 ms NOESY spectrum of the C^{me}CIG−TOTO complex. The sequential H1′−H6/H8−H1′ connectivity pathway is indicated by a solid line. The interrupted connectivities at the 5′-C3-p-^{me}C4-3′ and 5′-I5-p-G6-3′ base pair steps due to intercalation sites are indicated by dotted lines. Some of the observed cross-peaks between TOTO and the oligonucleotide are also marked. The connectivities between H(8)−H(16)-H(15)−H(14)-H(13) have been indicated together with the connectivities between the two H(9) and H(10) protons.

sequence d(5′-CTAG-3′)$_2$ by a factor of about 68—namely d(5′-C^{me}CIG-3′)$_2$. The new competition experiments have also augmented the number of well-defined TOTO-binding sites, with a number of new sites including several superior to d(5′-CTAG-3′)$_2$. Within the 5′-py-py-pu-pu-3′ (and here only substitutions that retain Watson−Crick base pairing have been included), our data yield the following preferences: The preferred flanking purine is guanine followed by inosine both base pairing with cytosine, all of which are better than an AT pair. For the central base pair, inosine is the favorite choice for purine followed by adenine and then guanine. The pyrimidine ^{me}C is better than cytosine in accordance with the earlier result that thymine (5-methyl uracil) is better than uracil. Thus, the experimentally observed base pair preference from Table 1 may be summarized for the palindromic sequences:

Flanking base pair: ^{me}CG > CG > CI > TA

central base pair: ^{me}CI > CI > TA > CG > UA

DISCUSSION

The binding strength of TOTO is largely determined by the intercalation of the chromophores and by the interactions of the cationic charges of TOTO and the anionic phosphate backbone of DNA. Thus, the site selectivity obviously must stem from an interplay of the binding contributions from the linker and the chromophores.

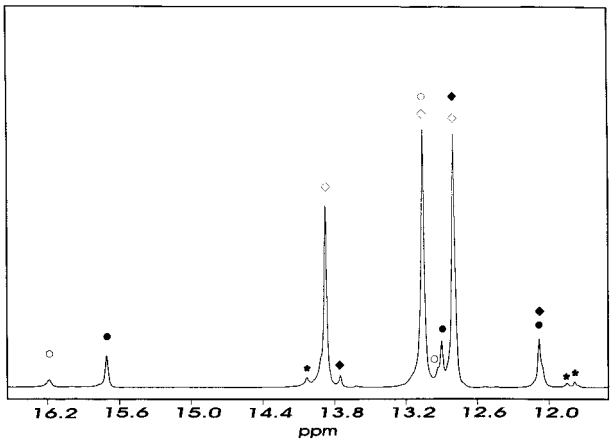

Figure 2. The imino proton region of the 1D spectrum obtained in 90% H_2O/10% D_2O of the mixture of C^{me}CIG, CTAG, and TOTO in the ratio 1.1:4.3:1.0. Resonances from the C^{me}CIG−TOTO (●), CTAG−TOTO (◆) complexes and the free oligonucleotides C^{me}CIG(F) and CTAG (◇) are observed. (★) These resonances were not assigned.

Table 1. the Affinity of TOTO and TOTO11 to 5′-py-py-pu-pu-3′ Sites Relative to the CTAG Sequence[a]

	TOTO	TOTO11
TCGA	more	
TTAA	than one	
CTGA	complex	
CCGI	is formed	
CUAG	0.15	
CCGG	0.16	0.70
CTAI	0.55	
CTAG	1.00	1.00
^{me}CTAG	1.4	
CCII	5.6	3.3
CCIG	12	
C^{me}CIG	68	

[a] The values are given as the ratio of the values of the equilibriums constant at 10 °C. The values given for the TOTO and TOTO11 cannot be compared directly since it is not possible to determine the relative affinity af these two drugs.

Chromophores. The site selectivity of TOTO is to some extent governed by the interactions of the intercalated chromophores with the bases. Simple planar intercalators exhibit little or no sequence selectivity. Footprinting studies indicate that intercalators are relatively excluded from runs of A and T (Fox and Waring, 1987) while differential dialysis experiments show that there is some preference for GC base pairs (Müller and Crothers, 1975), and the ellipticine chromophore has been shown to prefer GC regions (Bailly et al., 1990). However, these preferences are only weak and to our knowledge there have not been reports on any simple intercalator preferences for a (5′-CT-3′):(5′-AG-3′) site. The diversity and general low specificity of intercalators makes it quite difficult to make any inferences of the specificity of the thiazole orange chromophore on the basis of other intercalative compound. Therefore, the properties of the thiazole orange chromophore will be considered from a more theoretical point of view.

Some of the changes in binding site affinity on base pair replacement may be rationalized by considering the dipole moments and polarizabilities of the nucleobases involved to reflect the strength of the electrostatic interactions, the induction, and the dispersion attractions, respectively. The close relationship between the strength of the base-stacking interactions for pyrimidines and the molecular polarizability in an aqueous environment has been experimentally shown by Sowers et al.

Table 2. Dipole Moments (μ) and Dipole Polarizabilities (α) of Nucleobases[a]

	U	T	C	^{me}C	A	I	G
μ	1.71	1.7	2.49	2.67	1.06	2.02	2.52
α	71.3	83.7	79.3	91.3	97.4	91.3	103.3

[a] The size of the dipole moments and dipole polarizabilities are given in atomic units. These MP2\[5s3p2d]\[3s2p]\\MP2\6-31G(d,p) results are taken from Johnson et al. (1996).

(Sowers et al., 1987). Qualitatively, we may assume that the electrostatic interactions are dominated by the ion−dipole interaction, the induction interaction by the ion polarizability interaction and the dispersion attraction is by the polarizability (viz., induced dipole−induced dipole). MP2 calculations on nucleobases by Johnson et al. (Johnson et al., 1996) yield the dipole moments and polarizabilities shown in Table 2.

For the flanking bases of the intercalation site, the position of the linker is of little consequence and guanine with the largest polarizability and dipole moment is the preferred flanking base followed by inosine with intermediate dipole moment and low polarizability both base pairing with cytosine (with the largest dipole moment). The methylation of cytosine enhances the dipole moment and polarizability, and this leads to an enhanced affinity. The TA flanking base pair is the least favored with relatively small dipole moments. Earlier, we proposed that the low affinity of (5′-TTAA-3′)$_2$ probably was due to steric hindrance caused by the methyl groups of the flanking thymine (Hansen et al., 1996), but the very similar ^{me}CTAG forms a well-defined complex, suggesting that the steric hindrance due to the methyl groups is not the cause of the low affinity.

There are two contributions to be considered when discussing the central base pairs: the minor groove environment experienced by the linker and the stacking of the chromophores. Although the CG base pair following the above lines of thought should be the best central base pair, the amino group protruding into the minor groove interacts detrimentally with the linker as described below. Replacing thymine with uracil lowers the affinity because the removal of the methyl group reduces the dispersion attraction. Substituting the central TpA with CpI enhances the affinity (due to larger dipole moments), which may be further enhanced by the introduction of ^{me}C facilitating better dispersion attraction.

The enhanced affinity of the methylated pyrimidines could also stem from hydrophobic interactions between the benzothiazole moiety and the methyl group. The simple relationship between polarizability and base stacking for the nucleobases is obviously a bit too crude when applied to DNA, because the sugar−phosphate backbone and hydrogen-bonding demands on the optimal geometry are not identical to those of base stacking. The NMR solution structure does offer some explanation why the methylation of the flanking pyrimidine (leading to higher polarizability) doesn't lead to as large an affinity enhancement as exhibited by the central pyrimidines. The methyl group of the central pyrimidine is situated right above the benzene moiety of the benzothiazole ring, thereby making contact with the whole ring. The CTAG−TOTO solution structure suggests that a methyl group on the flanking pyrimidine would be positioned above the N-methyl group of TOTO. The dispersion attraction favors geometries that maximize the number of close contacts with as many atoms as possible, and the methyl group of the flanking pyrimidine does not have as good van der Waals contacts with the thiazole chromophore as the central pyrimidine.

Linker. The polyamine linker of TOTO is analogous to a family of linear positively charged molecules (including spermine and spermidine) that has been intensely studied but, unfortunately, has proven quite elusive to most spectroscopic techniques and there seems to be little consensus on the binding mode of these polycationic polyamines. NMR studies by Wemmer (1985) of spermine binding to the Dickerson−Drew dodecamer have shown that the spermine molecule does not form a tight well-defined complex with DNA and its mobility is effectively independent of that of DNA. These data suggested a nonselective electrostatic binding mode, and therefore it was proposed that the polyamine linker of TOTO only contributes to the binding strength and not to the sequence selectivity (Jacobsen et al., 1995). However, photoaffinity cleavage with polyaminobenzene-diazonium salts and competition experiments with the minor groove binder distamycin (Schmid and Behr, 1991) have shown that polyamines have a strong preference for the minor groove and a weak 2−3-fold preference for AT-rich regions. Spermine blocking of both mechloroethamine (nitrogen mustard) guanine N7 alkylation (Hartley et al., 1990) and 5′-GC interstrand cross linking by 2,5-diaziridinylbenzoquinone (Yuki et al., 1996) indicate that the major groove is preferred for GC sequences. It has recently been proposed that the linker of N^1-(acridin-9-ylcarbonyl)spermine interacts with the phosphate backbone (Blackbrough et al., 1998), but this phosphate strand binding is claimed to be ruled out by the results of Schmid (Schmid and Behr, 1991).

Before drawing any conclusions from the somewhat bewildering material presented above, it should be made clear that the polyamine linker of TOTO differs in several respects from spermine and spermidine. The alkylated polyamine chain rules out any possibility of hydrogen bond formation, but a study on the affinity of several polyamines has shown that the affinity of the alkylated linear polyamines generally lie only a little under that of the protonated polyamines (Schneider and Blatter, 1992). The intercalation of the chromophores also puts some restrictions on the mobility and binding possibilities of the linker. The linker cannot interact with the phosphate backbone in the way described by Blackbrough (1998). Furthermore, the alkylated polyamine is more hydrophobic than its nonalkylated analogues, and the narrow minor groove offers protection from the solvent and van der Waals contacts with the walls of the groove.

The electrostatic environment created by DNA may be represented by an electrostatic potential map as shown by Pullman (Lavery and Pullmann, 1981). The electrostatic potential maps for the Watson−Crick base paired AT and GC in Figure 3 show that the two base pairs offer different binding possibilities. While the GC base pair has a very negative electrostatic region in the major groove, the AT base pair has two negative contact points in the minor groove. The NOESY cross-peaks between TOTO and the oligonucleotide unambiguously place the linker in the minor groove for all the assigned 5′-py-py-pu-pu-3′ complexes. The structure of the CTAG−TOTO complex (Spielmann et al., 1995) positions the linker dimethyl nitrogens in the vicinity of the adenine N3. The electrostatic potential maps also lend some credibility to this position, since it must be energetically favorable to position the charged group in a region with negative electrostatic potential. The guanine amino group protruding into the minor groove does hamper this interaction, and on removing the amino group by the introduction of inosine the affinity is enhanced. Thus, to some extent the linker does affect the site selectivity of TOTO.

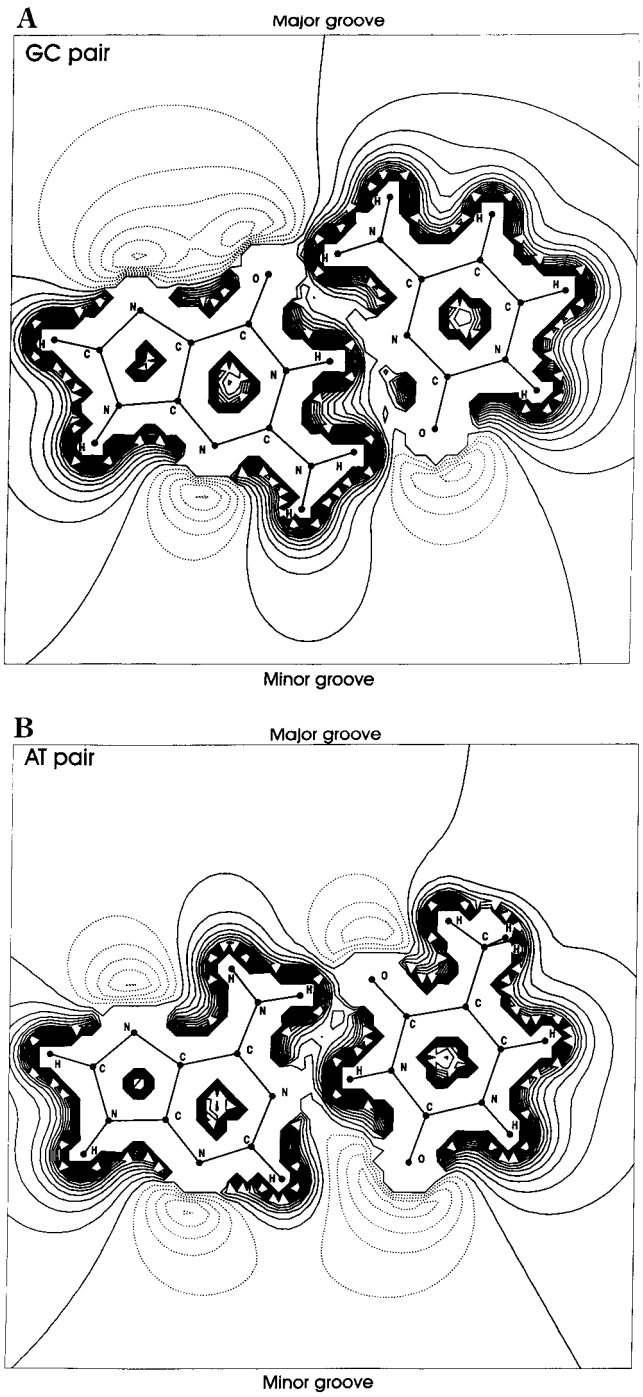

Figure 3. The liniarly spaced electrostatic potential contours around the GC (A) and AT (B) base pairs. Negative contours are dashed. The base pair geometries were taken as the standard B-DNA base pair in InsightII, and the electrostatic potential was calculated and displayed by MOLDEN (Schaftenaar, 1991) on the basis of a Gaussian94 (Frisch et al., 1995) RHF[\]6-31G single point calculation.

To investigate how the position and length of the linker affected the affinity, we performed two competition experiments with TOTO11. The site selectivity was diminished in the sense that the affinity for CCGG is less reduced while the affinity for CCII is less enhanced. This could indicate that the steric hindrance by the amino groups is also an important factor together with the minor groove electrostatic potential. However, a high-

resolution NMR structure of the TOTO11Et−CTAG complex (Bondensgaard and Jacobsen, 1998) shows that the longer linker shifts the position of the dimethyl nitrogens toward the thymine minor groove oxygen making any inference on the relative size of the two factors quite difficult.

CONCLUSION

The affinity pattern of the various complexes indicates that the site selectivity of TOTO is not solely due to an absolute preference of the thiazole orange chromophores for the CT base step. Actually, the chromophore seems to prefer the CC base step among the binding sites offered by the four common DNA bases, but the restraints imposed by the favorable positioning of the polyamine linker in the minor groove results in a compromise that utilizes the favorable ion−dipole interactions between the flanking CG pair and the chromophore, while the charged linker benefits from the electrostatic potential of the AT minor groove. Thus, the removal of the guanosine amino group by the introduction of inosine partly offers the electrostatic benefits of guanosine while having a minor groove wall very similar to that of the TA pair. The affinity can be enhanced by introducing methyl groups on the pyrimidines thereby enhancing the dispersion attraction/hydrophobic interaction. This enhancement is much more pronounced for the central pyrimidines where the methyl group is able to make van der Waals contacts with the benzene part of the benzothiazole than the flanking base pairs, where the methyl group seems mainly to interact with the N-methyl group of TOTO.

Convenient Preparation of No-Carrier-Added Technetium-99m Radiopharmaceuticals Using Solid-Phase Technology

Robert Dunn-Dufault,[†,‡] Alfred Pollak,[†] John R. Thornback,*[,†] and James R. Ballinger[‡,§]

Resolution Pharmaceuticals Inc., 6850 Goreway Drive, Mississauga, Ontario, Canada, L4V 1V7, Faculty of Pharmacy, University of Toronto, Ontario, Canada, Division of Experimental Therapeutics, Ontario Cancer Institute, Toronto, Ontario, Canada, and Division of Nuclear Medicine, University Medical Imaging Centre, Toronto, Ontario, Canada . Received March 17, 1999; Revised Manuscript Received June 14, 1999

A solid-phase technetium chelation chemistry was developed as a means of preparing ^{99m}Tc radiopharmaceuticals at high effective specific activity (HSA). Three peptidic N_3S ^{99m}Tc ligands [mercaptoacetyl-Gly-Gly-Gly (MAG3), picolinyl-Ser-Cys-Gly-Thr-Lys-Pro-Pro-Arg (RP063), and dimethyl-Gly-Ser-Cys-Gly-Thr-Lys-Pro-Pro-Arg (RP128)] were used. The free thiol of Cys in each was attached to a series of commercially available amine-functionalized supports in a two-step process. The amine groups on the solid supports were converted to maleimide groups followed by the attachment of the ^{99m}Tc chelators through a thiol ether linkage with Cys. The optimized loading of the supports ranged 6−122 μmol/g support as determined by amino acid analysis. Each of the peptide-loaded supports (50−100 mg) was placed in either glass syringe vessels or disposable chromatography columns. Labeling with [^{99m}Tc]pertechnetate (200−800 MBq) in the presence of stannous gluconate was achieved at room temperature for 30−60 min or in a 100 °C water bath for 10 min. Up to 80% of the activity was eluted from the column with saline to give products with purity up to 99.8% as determined by HPLC. Amino acid analysis indicated as little as 100 pmol of peptide present in the ^{99m}Tc products, demonstrating that extremely high effective specific activity can be achieved without the need for purification.

INTRODUCTION

Most radiopharmaceutical kits contain a quantity of the ligand which is in vast excess of the amount of ^{99m}Tc complex formed (i.e. the effective specific activity is low), but this quantity of ligand is safe for administration to patients. For example, a kit for the preparation of a bone-scanning agent might contain 10 mg of diphosphonate; thus, each dose would contain on the order of 1 mg, but this presents no hazard. However, with newer radiopharmaceuticals, such as bioactive peptides and receptor-binding agents, administration of milligram or in some cases even microgram quantities could produce pharmacological or toxic effects or could saturate the receptor sites of interest. A purification step may be required to separate the ^{99m}Tc chelate from the excess free ligand. Purification can be as simple as a syringe column or as complex as high-pressure liquid chromatography (HPLC). Alternatively, it may be possible to prepare the ^{99m}Tc chelate at sufficiently high effective specific activity (HSA) by starting with extremely large amounts of pertechnetate. Babich et al. have prepared ^{99m}Tc-labeled chemotactic peptides by both approaches (*1*). However, all of these procedures are unsuitable for routine use, being labor intensive, time consuming, and inefficient in yield with respect to the radiotracer, requiring special equipment, and involving higher radiation exposure.

The term "specific activity" refers to the ^{99m}Tc content of a product relative to the total technetium present (i.e., ^{99m}Tc plus ^{99}Tc). Specific activity is determined by ingrowth time between elutions of the generator and decay time since elution. "Effective specific activity" refers to the ^{99m}Tc content per total mass present and is determined by the amount of ligand, ^{99m}Tc-labeled and free, in solution.

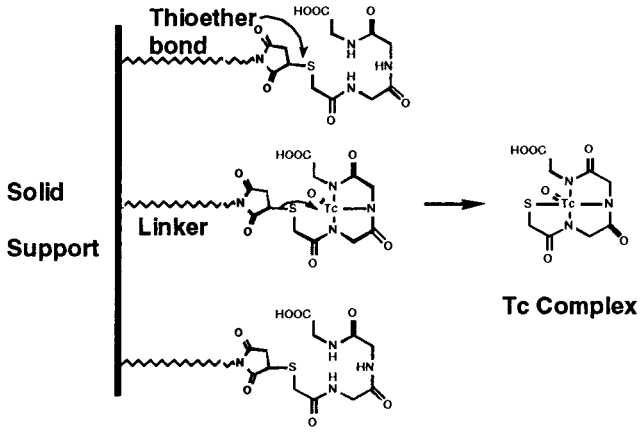

Figure 1. Release of an N_3S HSA ^{99m}Tc radiopharmaceutical from a solid phase. Unreacted ligand remains covalently bound.

We have developed a simple method of preparing ^{99m}Tc chelates at extremely high effective specific activities by making use of a solid-phase technology (Figure 1). Many of the new N_2S_2 and N_3S chelators require that the sulfur atom(s) be protected prior to labeling. If the protecting group is attached to a solid support, only molecules which have been released by chelating ^{99m}Tc will be present in solution while the excess precursor remains covalently attached to the support. This labeling technology can be incorporated into a kit from which an

argogel	ARG	400

HSA product can be eluted simply and safely in a process amenable to preparation of a sterile product. We have evaluated this approach using a variety of solid supports and demonstrated its utility in the preparation of three ^{99m}Tc radiopharmaceuticals: the renal imaging agent MAG3 (*2*) and two peptides for imaging inflammation, RP063 and RP128 (*3, 4*).

EXPERIMENTAL PROCEDURES

Materials. Affi-Gel 102 (amine-functionalized cross-linked agarose) and Affi-Prep (N-hydroxysuccinimide-functionalized acrylic polymer), Bio-Spin polypropylene chromatography columns (sterile with filter, 1.5 mL capacity) and accessories were purchased from Bio-Rad Laboratories (Hercules, CA). 3-Aminopropyl-functionalized silica and glass were purchased from Sigma-Aldrich Canada (Oakville, ON). Amine-functionalized controlled-pore glass was purchased from CPG Inc. (Fairfield, NJ). Argogel [amine-functionalized poly(ethylene glycol)-grafted polystyrene] was obtained from Argonaut Technologies Inc. (San Carlos, CA). The amine functionalization of each support is reported in Table 1.

Radioactivity was measured in a Capintec CRC-15R dose calibrator using the ^{99m}Tc setting. ^{1}H/^{13}C NMR spectra were recorded on a Bruker 300AC spectrometer. Electrospray mass spectra (ESMS) were obtained on a Sciex API#3 mass spectrometer in the positive ion mode. Amino acid analysis (AAA) was conducted on a Waters Picotag system at the Banting Institute (Toronto, ON). Analytical RP-HPLC of each of the ^{99m}Tc-labeled products was run on a Vydac reversed-phase C-18 protein and peptide column (5 μm, 0.46 cm $\times$ 25 cm) using a Beckman Instruments (Fullerton, CA) system employing both radiometric detection set on a ^{99m}Tc window (Beckman 171 radioisotope detector with a modified yttrium silicate scintillant) and UV absorbance detection (Beckman 168 UV detector set at 215 nm wavelength). The column was eluted using a linear gradient of 100% A to 90% B over 20 min at a flow rate of 1.5 mL/min where solvent A was 0.1% trifluoroacetic acid (TFA) in water and solvent B was 0.1% TFA in acetonitrile.

Reagents for peptide synthesis including solvents, resins, and protected amino acids were obtained from Applied Bioresearch Inc. (Foster City, CA) and Bachem Biosciences Inc. (Philadelphia, PA). Buffers, inorganic salts, and reagent chemicals were purchased from Sigma-Aldrich Canada. HPLC-grade acetonitrile was purchased from BDH Inc. (Toronto, ON). Solutions of stannous chloride (90 mM, 20 mg/mL in 1 N HCl) and sodium gluconate (60 mM, 13 mg/mL in Milli-Q water) used for radiolabeling were prepared in advance and were stored frozen until use. ^{99m}Tc in the form of sodium pertechnetate solution was obtained from Mallinckrodt Medical Inc. (Mississauga, ON) or from a DuPont ^{99}Mo/^{99m}Tc generator.

Syntheses of Peptides. Three different peptidic N_3S technetium chelators were prepared to explore the universality of the solid-phase labeling method outlined. MAG3 (mercaptoacetyl-Gly-Gly-Gly-COOH) was synthesized with a benzoyl-protected sulfur whereas RP063 (picolyl-Ser-Cys-Gly-Thr-Lys-Pro-Pro-Arg-COOH) and RP128 (*N*,*N*-dimethyl-Gly-Ser-Cys-Gly-Thr-Lys-Pro-Pro-Arg-COOH) were prepared with acetamidomethyl (Acm) protection on the Cys. Each was synthesized using standard 9-fluorenylmethoxycarbonyl (Fmoc) chemistry starting with the carboxy-terminal amino acid (Fmoc-Gly or Fmoc-Arg) preloaded on Sasrin resin (Bachem Biosciences Inc.) using an ABI 433A automated peptide synthesizer. The products were cleaved from the resin in 95% TFA (100 mg of resin/mL) at room temperature for 2 h. The resin was removed by filtration and the peptides were precipitated by dripping the supernatant into 50 mL of *tert*-butyl methyl ether at 5 °C. The solids were centrifuged to a pellet, the ether decanted, and the pellet dried in vacuo. The pellets were dissolved in water and lyophilized to white powders.

MAG3, RP063, and RP128 were purified by reversed-phase HPLC on a Beckman Instruments HPLC system (System Gold) using a Millipore-Waters radial compression module (RCM, 0.8 cm $\times$ 10 cm) C-18 column with 0.1% TFA in water as solvent A and 0.1% TFA in acetonitrile as solvent B. The column was eluted using a linear gradient of 100% A to 100% B over 25 min at a flow rate of 1 mL/min. For each peptide, the fractions containing the correct species were pooled and lyophilized to a white powder. The authenticity of each product was confirmed by mass spectral analysis. benzoyl-MAG3: MW 367.0. ESMS: 368.0 (MH^+). RP063: MW 1020.1. ESMS: 1021.1 (MH^+). RP128: MW 1000.2. ESMS: 1001.0 (MH^+).

Free-thiol MAG3 was obtained by hydrolysis of the benzoyl sulfur-protecting group. Care was taken to exclude oxygen where possible. Free-thiol RP063 and RP128 were prepared by removal of the Acm protecting group. To the Acm-protected peptide (120 mmol) in aqueous acetic acid (30%, 2 mL) purged with argon was added mercuric acetate (180 mmol). The reaction was stirred under argon for 2.5 h at room temperature. Water (10 mL) was added and hydrogen sulfide gas was bubbled through the solution where a black precipitate formed. The black suspension was centrifuged to a clear solution and a black pellet. Each solution was decanted and filtered through a 0.2 μm PVDF syringe filter. The solutions were frozen in liquid nitrogen and lyophilized to white powders. Products were analyzed by HPLC and were typically >95% pure with traces of the Acm-protected species. Correct species were also identified by mass spectral analysis.

Loading of Supports. Each of the supports, Affi-Gel 102 (AGR), silica (SIL), controlled-pore glass (CPG), glass (GLA), and Argogel (ARG) were commercially available with amine functionalization. Affi-Prep 10 acrylic polymer (ACR) was obtained N-hydroxysuccinimide-functionalized and required conversion to amine functionalization by reaction with 1,4-diaminobutane in DMF. Carbethoxymaleimide was synthesized by a literature method (*5*).

The maleimide-functionalized supports were prepared as follows. To the amine-functionalized support (1 g) in saturated sodium bicarbonate (4 mL) at 0 °C was added powdered carbethoxymaleimide (100 mg). The reaction was shaken for 15 min after which water (15 mL) was added. The reaction was continued at room temperature for 15 min. The support was filtered and washed copiously with water.

The MAG3- and RP063-loaded supports were prepared by reacting the corresponding maleimide-functionalized

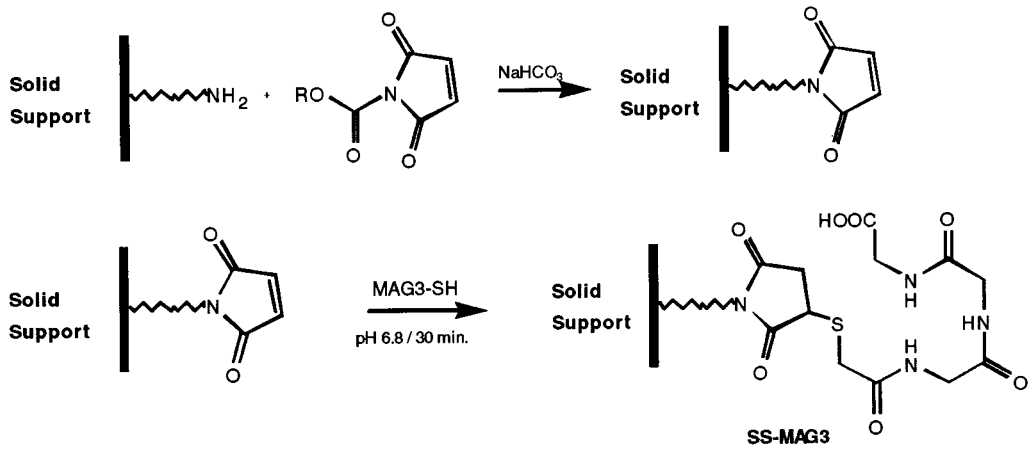

Figure 2. Synthetic scheme for loading MAG3 to a solid support. R = ethyl or methyl.

support (1 g) at 0 °C with an argon-purged solution of MAG3-SH (15 mg) or RP063−SH (25 mg) in sodium bicarbonate (0.2 N, 4 mL). After 30 min of shaking the solution, the reaction was allowed to warm to room temperature. The reaction was shaken for 3−16 h, after which the support was filtered, washed copiously with water and then an organic solvent (acetone, chloroform, dichloromethane, or diethyl ether), and dried in vacuo. Loading was determined by AAA, and the results are presented in Table 2.

The RP128-loaded supports were prepared by a slightly different procedure. To each amine-functionalized support (1 g) in saturated sodium bicarbonate (3 mL) at 0 °C was added powdered carbethoxymaleimide (30 mg). The reaction mixture was shaken for 30 min and then water (5 mL) was added. The shaking was continued at room temperature for 30 min. The support was then filtered and washed copiously with water and methanol and dried in vacuo. To each support (300 mg) was added an argon-purged solution of RP1280-SH (10 mg) in phosphate-buffered saline (PBS, 0.02 N, 1 mL). After 1 h at room temperature, each support was filtered, washed with copious water and then methanol, and dried in vacuo. Each was analyzed by AAA, and results are reported in Table 2.

^{99m}Tc Labeling of Supports. Typically, to each peptide-loaded support (50−100 mg) in a glass syringe barrel or a Bio-Spin disposable chromatography column were added saline (100 μL), [^{99m}Tc]pertechnetate (200−800 MBq, 100 μL), and aqueous stannous gluconate (100 μL) containing 20 μg of stannous chloride and 1.3 mg of sodium gluconate. The reaction mixture was capped, swirled, and left to proceed for 30−60 min at room temperature or for 10 min in a 100 °C water bath. The cap was removed and the column was fitted with a luer-lock stopcock and needle. Three portions of saline (300 μL, 1 mL, and 1 mL) were added sequentially, and the dose eluted from the column into three evacuated vials. The activity of each was measured in a dose calibrator. An aliquot from fraction 1 was analyzed by HPLC. The balance of fraction 1 of each labeling was submitted for AAA in order to confirm that the dose liberated from the support was free of excess unlabeled peptide. For comparison, standard solution-phase low effective specific activity (LSA) labeling was performed as described elsewhere (*2*−*4*), and the products were analyzed by HPLC.

RESULTS

Each of the support types used in this study was loaded with the free-thiol peptides by the methods outlined for MAG3 in Figure 2. Each of the three peptides was conveniently synthesized by an automated solid-phase peptide synthesizer in high yields and with typical purity of >95% based on HPLC analysis of the cleaved products. As appropriate, the sulfur-protecting groups were removed in preparation for loading to the supports. The supports were first rapidly functionalized with maleimide under mild conditions in buffered aqueous solutions, typically for 1 h. The maleimide-functionalized supports were then quenched with the thiol-containing peptides, again under mild aqueous conditions. The loading of each, reported in Table 2, was determined by AAA and ranged 6−122 μmol/g. These values represent the final loading of the peptides but do not indicate at which step the variability occurred.

The final evaluation of the technology is the labeling step with ^{99m}Tc. The labeling of MAG3, RP063, and RP128 from each of the solid supports was evaluated with respect to three parameters: radiochemical yield, radiochemical purity, and the level to which the eluted fractions were free of excess unlabeled peptides. Optimal labeling was observed with RP128 loaded to Argogel and is shown in Figure 3, where it can be seen that >96% of the injected radioactivity elutes in a peak at 8.5 min (solid line) and that there is no UV absorbance associated with this peak (dotted line).

To confirm that the dose liberated from the support was free of excess unlabeled peptide, the first eluted fraction from each support was tested by amino acid analysis. In each case, AAA showed only background levels of the amino acids found in MAG3, RP063, or

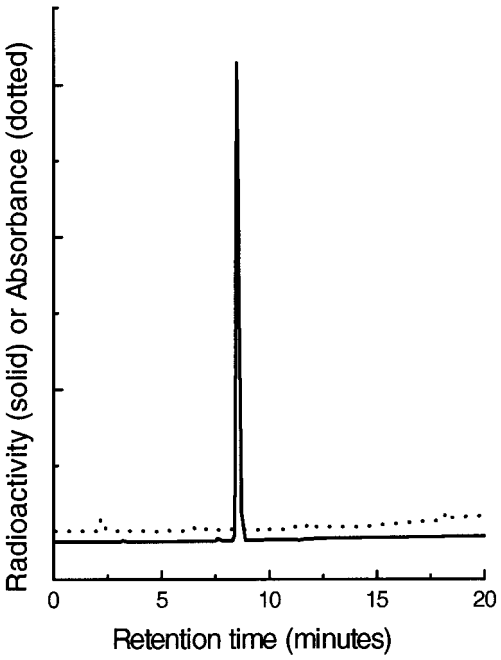

Figure 3. HPLC radiometric trace of a HSA [^{99m}Tc]RP128 labeling from Argogel support. Injection of 50 μL onto a C-18 column (5 μm, 0.46 cm × 25 cm). The column was eluted using a linear gradient of 100% A to 90% B over 20 min at a flow rate of 1.5 mL/min where solvent A was 0.1% TFA in water and solvent B was 0.1% TFA in acetonitrile. The system was run with dual detection: ^{99m}Tc (solid line), UV detection at 215 nm (dotted line).

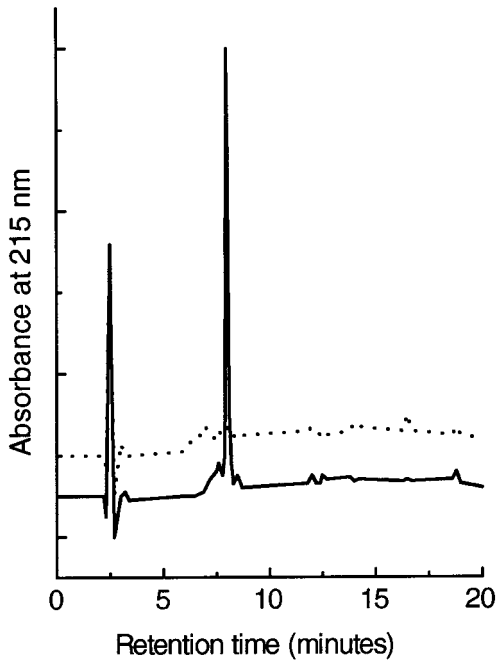

Figure 4. A comparison of the HPLC UV traces of HSA [^{99m}Tc]RP128 (dotted line) labeled from Argogel and LSA [^{99m}Tc]-RP128 (solid line) labeled in solution. The major peak in the LSA trace corresponds to unlabeled Acm-protected RP128. HPLC conditions as in Figure 3.

RP128. These values ranged from 100 pmol to 1 nmol per sample and were a function of contaminants on the detection column. Accordingly, these background levels were used in estimation of effective specific activity. Since the various supports have different adsorption properties, each was washed thoroughly to minimize any noncovalent peptide binding to the support. As supporting evidence, the UV traces of the HPLC-analyzed products showed essentially no peak corresponding to unlabeled ligands. Typical UV traces of LSA and HSA formulations of [^{99m}Tc]RP128 are shown in Figure 4, where it can be seen that the major peak at 8.0 min in the LSA preparation (solid line), representing unlabeled Acm-protected RP128, is absent in the HSA product (dotted line).

The radiochemical yield and radiochemical purity of the three peptides on each of the supports is shown in Table 2. For most of these measurements, $n = 1$; however, in subsequent work, the yield and purity were found to be reproducible, with a typical coefficient of variation of <5% for five determinations. Low yield represents loss of ^{99m}Tc through adsorption onto the support, while low purity represents inefficient reaction between [^{99m}Tc]-gluconate and the immobilized peptide. The purity of the released products eluted in fraction 1 as determined by HPLC ranged from a modest 8.1% for RP128 loaded to silica to as high as 99.8% for the same peptide loaded to agarose. The yield of total activity used in each labeling recovered in these first fractions also ranged greatly from 13.3% for RP063 loaded on control pore glass to 80.8% for MAG3 loaded on silica.

DISCUSSION

The theoretical specific activity of carrier-free ^{99m}Tc is ~20 000 TBq/mmol (520 000 Ci/mmol). However, ^{99m}Tc obtained from a ^{99}Mo/^{99m}Tc generator is never truly carrier free, since 13% of the decays of ^{99}Mo form ^{99}Tc directly. On the basis of the equations developed by Lamson et al. (*6*), the maximum mole fraction of ^{99m}Tc obtained from a generator 30 min after the previous elution is 0.84, and after the usual 24 h of in growth, the mole fraction is 0.28. Thus, maximization of the specific activity of ^{99m}Tc by repeated elutions produces a net gain of only a factor of 3 in specific activity and is of importance only with purified materials. In any procedure which does not use purification, the effect of the remaining excess ligand is far greater. For example, 3700 MBq of a ^{99m}Tc radiopharmaceutical containing 10 μg of a ligand with a molecular weight of 1000 (i.e. 10 nmol) represents an effective specific activity of 370 TBq/mmol (10 000 Ci/mmol). Thus, even 10 μg of ligand reduces the specific activity by 50-fold. Therefore, a method of avoiding excess ligand has been developed.

The need for a simple preparation of HSA ^{99m}Tc radiopharmaceuticals is an immediate one. Widespread clinical application of agents which show toxicity or which are designed to target specific receptor populations would require simple preparation of HSA formulations (*7*−*15*). Efforts to improve specific activity by reducing the amount of ligand in the labeling or by using extremely high quantities of pertechnetate have been demonstrated to improve imaging but are not practical where a routine kit is to be developed (*1*). A recent report of post-labeling purification is applicable to ligands having a free thiol (*16*), though for most agents HPLC or solid-phase cartridge purification is still required. The present solid-phase technology developed has been shown to be an effective means of generating some peptidic ^{99m}Tc agents in high specific activity without the need for postlabeling purification. This is analogous to the use of immobilized precursors for radioiodination (*17*, *18*).

The peptide content of the HSA products obtained using amino acid analysis ranged from 100 pmol to 1 nmol of the total decayed doses. To some extent this directly reflects the specific activity of the HSA products, but the values obtained approach the detection limits of

AAA under the conditions used for testing. For this reason, a modest estimate of the typical effective specific activities of the radiolabeled products is 1850 TBq/mmol (50 000 Ci/mmol), though the true effective specific activity may be far higher.

From the data, it is clear that not all supports were equally effective at generating high radiochemical yield and purity of the three ^{99m}Tc-labeled agents (Table 2). This is in part a function of the efficiency of the ligand to coordinate ^{99m}Tc as well as the labeling environment. Of the two parameters, radiochemical purity is more important since it determines whether the eluate is suitable for use (generally >90% purity is required) while a yield which is only moderate may still be acceptable. The preparation of the supports involves a two-step loading process which results in a loading value for each ligand loaded to each support type tested. The loading of the ligand to the supports varied greatly, from 6 to 122 μmol/g, despite similar loading conditions. The loading differences are in part due to differences in the level of amine functionalization on the supports (Figure 2) and in the reactivity of the amines with carbethoxymaleimide under the given conditions in the first step.

Discrepancies between the loading levels of the ligands and their effective labeling suggests that simple AAA indicates the amount of total ligand bound to the support but not necessarily the amount of ligand that is structurally available to coordinate ^{99m}Tc. For example, RP128-loaded silica gave 19 μmol/g loading but a meager 8% radiochemical purity upon ^{99m}Tc labeling, whereas RP063 loaded to silica showed only 7 μmol/g loading with a 45% radiochemical purity of [^{99m}Tc]RP063. This indicates the interaction of the ligand with the support greatly affects the success of the labeling.

In addition, the data show a large variation in the recovered yields from the supports, ranging from 13% to as high as 81% of the dose in the collected fractions. The loss of a high percentage of the dose is undesirable in that the use of higher activities would be required to generate a suitable dose for patient use. This binding to the supports was found to be partly physical trapping of colloids, partly ionic interaction of ^{99m}Tc species with the support, and potentially some weak coordination with the vast excess of ligand still covalently attached to the supports. Recoveries from agarose and Argogel were both influenced by the length of time the supports were soaked in saline before elution, indicating diffusion out of the beads played a role in dose recovery. Ultimately, it appears that the interaction of the ligand with the supports during loading and both of these with ^{99m}Tc species during coordination with ^{99m}Tc dictates the purity of the ^{99m}Tc complex and the yield recovered.

Optimization of the loading of each ligand to each type of support would be required in order to make strong evaluative comparisons. However, in general, supports with the highest amine functionalization, with the least possibility for unwanted charge interaction, and which best approximate solution-like conditions, should provide the best labeling results with the highest recovered yields. For these reasons, Argogel or a similar PEGylated support shows great potential, provided that there is no release of PEG.

Initially, the supports studied were chosen for their commercial availability with amine functionalization. The mechanical and surface properties of the supports vary greatly. Silica, glass, and acrylic are rigid supports. Silica and glass have charged surfaces where acrylic is neutral. Cross-linked agarose and PEG Argogel are flexible and have gel characteristics. Agarose is 95% water when swollen, has moderate mechanical stability, and completely dissolves in extremes of pH, whereas Argogel swells slightly and equally well in aqueous and organic solvents, with high mechanical and chemical stability, although release of trace amounts of PEG may be a problem.

With the rapid pace of developments in solid-phase chemistry, the type and quality of supports are becoming broader and the tailoring of supports to specific needs is or will soon be a possibility. The ability to use supports with high mechanical and chemical stability, coupled with a diversity of commercially available linking groups, makes a solid-phase radiopharmaceutical kit design a very real possibility.

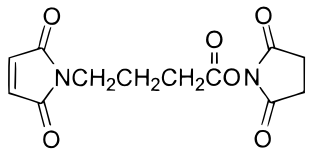
Conversion of Proteins to Diazeniumdiolate-Based Nitric Oxide Donors

Joseph A. Hrabie,*,† Joseph E. Saavedra,‡ Peter P. Roller,§ Garry J. Southan,‡ and Larry K. Keefer||

Chemical Synthesis and Analysis Laboratory and Intramural Research Support Program, SAIC Frederick, NCI-FCRDC, Frederick, Maryland 21702, Chemistry Section, Laboratory of Comparative Carcinogenesis, National Cancer Institute-Frederick Cancer Research and Development Center, Frederick, Maryland 21702, and Laboratory of Medicinal Chemistry, National Cancer Institute, Bethesda, Maryland 20892. Received March 19, 1999; Revised Manuscript Received April 29, 1999

Michael reaction of the methoxymethyl-protected monodiazeniumdiolate of piperazine (MOM-PIPERAZI/NO) with 4-maleimidobutyric acid followed by its conversion to the N-hydroxy-succinimido ester produces a reagent capable of transferring the nitric oxide (NO)-donating diazeniumdiolate group to the terminal amines of the lysine residues contained in proteins. The reagent has been used to produce diazeniumdiolated bovine serum albumin (D-BSA) and diazeniumdiolated human serum albumin (D-HSA) containing 22 and 19 modified lysyl groups, respectively. Upon dissolution in pH 7.4 phosphate buffer at 37 °C, these albumin derivatives gradually released all of their contained NO (approximately 40 mol/mol of protein) with initial rates of about 30−40 pmol/min/mg and half-lives on the order of 3 weeks. This methodology is now available for use in exploiting the unique specific metabolic interactions of proteins to target NO therapy to specific physiological processes in vivo.

INTRODUCTION



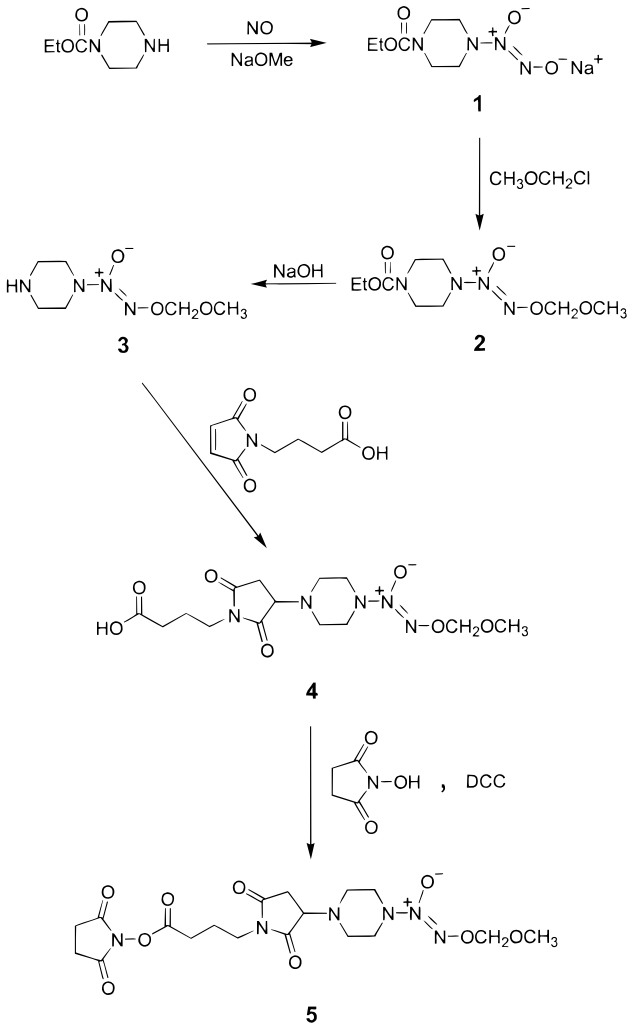
Every new discovery of yet another bioregulatory role for nitric oxide (NO) presents both a promising opportunity for the development of novel therapeutic agents and another barrier to be overcome in any attempt to target any such agents to a specific physiological process. Given the ever increasing number of such processes known to involve NO as well as the possible harmful effects (*1*) of this toxic chemical, it is apparent that, in those instances where an input of NO is necessary to achieve a desired clinical result, one of the key attributes of any pharmaceutical will be the ability to deliver the molecule to a highly specific site. Fortunately, virtually every life process presents a potential solution to this specificity problem in the form of the molecular recognition inherent in protein function.

This report describes the development of a method for converting proteins into NO donors via the attachment of methoxymethylated diazeniumdiolates. The process employs several modifications of the chemistry involved in the use of the traditional cross-linking reagent *N*-(γ-maleimido-butyryloxy)succinimide (GMBS) (*2*) as well as the judicious use of protecting groups both to assemble the protein-derivatizing reagent and to regulate NO release from the resulting conjugate. The method has been used to prepare serum albumin conjugates which have been studied by mass spectrometry and by analysis of their NO-releasing properties.

RESULTS AND DISCUSSION

Reagent for Diazeniumdiolate Protein Conjugation. Despite the short half-lives and acid-labile nature of most diazeniumdiolates (*3*), it has proven possible to prepare versions suitable for linkage to protein-reactive reagents. As shown in Scheme 1, monoprotected piperazine can be reacted with nitric oxide to afford bifunctional compound **1**. The nitrogen in this compound remains protected by the ethoxycarbonyl group while the diazeniumdiolate is available for alkylation by previously described methods (*4*). We chose reaction with chloromethyl methyl ether to produce the methoxymethyl (MOM) derivative **2** since this protecting group was found to hydrolyze slowly in aqueous solution at physiological pH. Removal of the ethoxycarbonyl group in refluxing ethanolic sodium hydroxide afforded amine **3**. These reactions have been described in detail elsewhere (*5*).

We envisioned a reagent which would link our diazeniumdiolate **3** to the ϵ-amino group of the lysines since this would be the best way to guarantee that hydrolysis to release NO would not be impeded by close proximity to the bulky protein. The widely used heterobifunctional cross-linking reagent **6** (GMBS) (*2*) is usually utilized to



6

link the lysyl groups of proteins (via the reaction of the ϵ-amines with the *N*-hydroxysuccinimidyl ester) with the sulfhydryl group of the same or another protein (via reaction of the thiol with the maleimide). While the reaction of the ester with the free amines of a protein is conducted without interference from the maleimide in aqueous solution at carefully controlled pH, the Michael reaction of amines with maleimides in organic solvents is well-known (*6*). We used this method to prepare acid

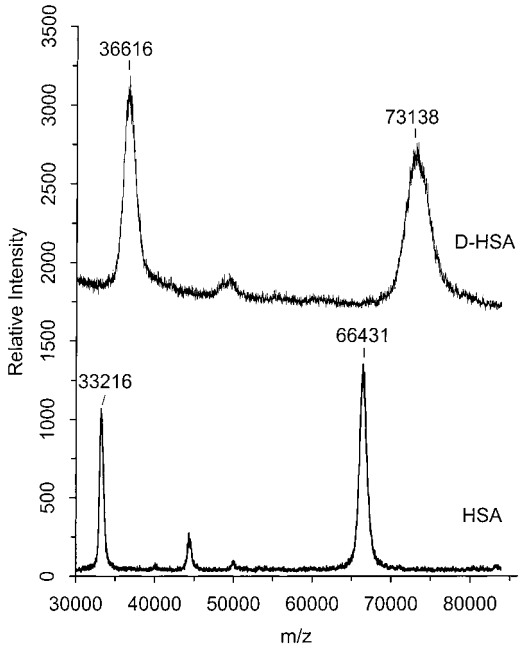
Scheme 1. Synthesis of Protein Diazeniumdiolation Reagent

4, which was then esterified to yield a diazeniumdiolated GMBS derivative, N-hydroxysuccinimide ester **5**.

Serum Albumin Conjugates. As a demonstration of the usefulness of reagent **5** and to gain information about the properties of diazeniumdiolated proteins, we prepared diazeniumdiolated bovine serum albumin (D-BSA, **7**) and human serum albumin (D-HSA, **8**).

7: D-BSA x = ~22
8: D-HSA x = ~19

Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry was used to compare the initial molecular mass (M_r) to that of the conjugate as a means of determining the number of lysines which had reacted with the ester. Figure 1 shows the result for D-HSA. The initial M_r of HSA (66.4 kDa) (*7*) was raised by 6.7 kDa, which shows that an average of 19 diazeniumdiolate-bearing side chains (the M_r of each side chain is 356) have been added to each albumin molecule. As is customary, we employed a large excess



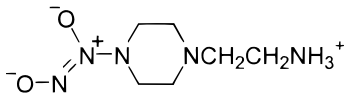


Figure 1. MALDI-TOF mass spectra of HSA and D-HSA compared.

(250 molar equiv) of **5** in these conjugations to compensate for the hydrolysis of the reagent which competes with the desired protein reaction. It is interesting to note that while both HSA (*8*) and BSA (*9*) contain 59 lysine residues, our reagent derivatizes an average of 22 of these in the latter but only 19 in the former. We assume that the higher reactivity of the lysyl residues in BSA is in some way related to their increased degree of exposure to the proteins' surface.

Our exploration of the NO-releasing characteristics of D-BSA was begun with several assumptions based upon the small molecule chemistry already known. While the synthesis conditions required for the preparation of both reagent **5** and the protein conjugates themselves prevent the isolation of the corresponding unprotected diazeniumdiolates, the half-life of NO release in pH 7.4 phosphate buffer for the closely related piperazine **9** has been

9

reported to be short (5.0 min at 22 °C) (*10*). In contrast, the rate of hydrolytic cleavage of the methoxymethyl protecting group attached to the diazeniumdiolate of compound **3** has been reported to be very slow (>17 days at pH 7.4 and 37 °C, consistent with expectations for an acetal) (*5*). This tremendous contrast in rates caused us to believe that we could observe the release of NO from these protein conjugates as a relatively simple pseudo-first-order process uncomplicated by the formation of significant concentrations of intermediates. This belief was further supported by the knowledge that diazeniumdiolates such as **9** release two full equivalents of NO on decomposition with no apparent byproducts other than the original amino compound (*10*). In fact, pseudo-first-order kinetics has been observed even when some nitrosamine does form during diazeniumdiolate decomposition (*11*). While reports that S-nitros(yl)ation of proteins may serve as a transport mechanism for NO in vivo (*12*) are cause for some concern to anyone interested in analytical

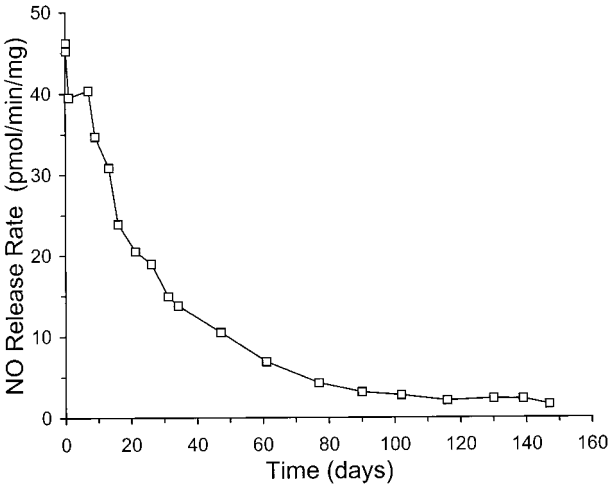

Figure 2. Release of NO from D-BSA as a solution in pH 7.4 phosphate buffer at 37 °C.

measurements of NO in their presence, our selection of serum albumin, a robust globular material in which all but one of the cysteine thiols are usually tied up in disulfide bonds, suggested that all of the initially released NO could be detected successfully.

With these considerations in mind, we selected an assay based upon the detection of NO by chemiluminescence which we had previously employed in a study of synthetic polymers (*13*). The release of NO was not monitored continually but rather a solution of D-BSA (**7**) in phosphate buffer at pH 7.4 was maintained at 37 °C, and periodically all of the accumulated NO gas was flushed from the sample so that the rate of NO release could be measured for a period of time after the chemiluminescence trace became stabilized. Figure 2 shows the result of monitoring the NO production of a sample of D-BSA for almost half a year. This experiment indicates that the half-life for NO release from D-BSA is on the order of 20 days. While a sample of D-HSA (**8**) has not as yet been studied over the same lengthy interval, preliminary results suggest a similar, though perhaps somewhat shorter, half-life for that protein as well as a release profile similar to Figure 2. The area under the curve shown in Figure 2 suggests that essentially all of the 44 equiv of NO that one would expect to be produced by hydrolytic breakdown of all 22 of the attached diazeniumdiolated piperazines are released during this experiment. Since this type of study does not lend itself conveniently to any statistical analysis to remove what can be significant variations in any single analysis for NO, we also measured the initial NO generation rate using fresh samples of D-BSA and D-HSA dissolved in the same buffer system at 37 °C. The slightly lower degree of substitution (19 vs 22) of D-HSA vs D-BSA was reflected in a slightly slower initial NO release rate [30 $\pm$ 5 pmol/min/mg for D-HSA ($n = 2$) vs 40 $\pm$ 5 pmol/min/mg for D-BSA ($n = 4$)].

It should be noted that the requirement that the methoxymethyl protecting group undergo an acid-catalyzed hydrolysis as the first step toward NO release means that these protein conjugates should generate 1 equiv each of formaldehyde and methanol for every 2 mol of NO. We have verified the increase in formaldehyde concentration with time in a solution of decomposing D-BSA but have made no attempts to quantify the production of this chemical which is both highly reactive and a ubiquitous contaminant of most laboratory equipment.

Significance. The diazeniumdiolates have emerged as an important class of NO donor compounds (*14*). The successful conjugation of these prodrugs to serum albumin will serve as a guide in the development of NO-releasing derivatives of peptide hormones, antibodies, and other proteins whose receptor-mediated interactions may be used to target NO delivery to specific points in the body. This study shows that relatively large numbers of diazeniumdiolate-containing groups can be introduced into a typical protein without causing fragmentation or denaturation (although some conformational changes undoubtedly occur and the consequences of these will have to be investigated for each protein on a case-by-case basis) and that the material can be stored for long periods of time (so far up to one year) as a solid in a freezer with no apparent decrease in activity upon reconstitution in phosphate buffer. The procedures reported herein should be applicable to diazeniumdiolates derivatized with a large variety of protecting groups which may be devised as an additional mechanism for introducing specificity into possible clinical agents based on these compounds.

Very importantly, D-HSA itself may prove to be an important clinical agent. The cardiovascular system offers many targets for NO-based therapeutic intervention (*15*), and as a principal component of that system, serum albumin is an obvious candidate for exploitation as a drug carrier. Previous studies have shown that diazeniumdiolate-based NO donation can inhibit thrombosis (*16*, *17*), and D-BSA has been shown to reduce thickening of the arterial wall following coronary angioplasty in the pig (*18*). Accordingly, D-HSA may offer an excellent treatment for those cardiovascular problems that can be rectified by addition of excess NO even though it does not provide the types of targeting opportunities offered by other proteins which we hope to exploit in the future.

EXPERIMENTAL SECTION

Nitric oxide was obtained from Matheson Gas Products (Montgomeryville, PA) and used as received. Unless noted otherwise, reagents and solvents were obtained from Aldrich Chemical Co. (Milwaukee, WI). A suitable apparatus for NO reactions has been described previously (*10*) as has the preparation of compounds **1**−**3** (*5*). Nuclear magnetic resonance (NMR) spectra were recorded at 300 MHz with a Varian Unity INOVA 300WB spectrometer. Ultraviolet spectra were recorded on a Hewlett-Packard model 8451A diode array spectrophotometer. Melting points were obtained on a hot stage and are uncorrected. Elemental analyses were performed by Atlantic Microlab, Inc. (Norcross, GA). General procedures for the handling of diazeniumdiolates have been described elsewhere (*3*) and all compounds containing this functional group are routinely stored in a freezer. Routine mass spectra were obtained with a VG Micromass 70-OPUS double focusing mass spectrometer. Protein mass spectra were obtained with a Bruker Reflex 2 MALDI-TOF mass spectrometer using a 2-mercaptobenzothiazole matrix. Nitric oxide release rates were measured as previously described for polymeric diazeniumdiolates (*13*) except that the proteins give homogeneous solutions. This NO analysis method employs a Thermal Energy Analyzer, thermostated reaction vessel, and flow system as described by Feelisch and Noack (*19*).

***O*^{2}-(Methoxymethyl) 1-[4-(3′-ω-Succinimidylbutyric acid)piperazin-1-yl]diazen-1-ium-1,2-diolate (*4*)**. A solution of 6.23 g (32.7 mmol) of **3** in 30 mL of

benzene was treated with 6.00 g (32.7 mmol) of 4-maleimidobutyric acid and allowed to stir at room temperature for 18 h. The product precipitated as an off-white solid which was isolated by filtration, washed with cold benzene and then ether, and dried under vacuum. Yield 9.04 g (75%); mp 139−140 °C dec. ^{1}H NMR (CD_3OD): δ 1.8−1.9 (2H, m), 2.28−2.34 (2H, m), 2.69 (1H, dd, J_1 = 5.2 Hz, J_2 = 18.2 Hz), 2.87 (1H, dd, J_1 = 8.8 Hz, J_2 = 18.2 Hz), 3.0−3.1 (2H, m), 3.45 (3H, s), 3.4−3.5 (4H, m), 3.5−3.6 (4H, m), 3.95 (1H, dd, J_1 = 5.2 Hz, J_2 = 8.8 Hz), 5.21 (2H, s). UV λ_{max} (0.1 M NaOH): 234 nm (ϵ = 8.28 mM^{-1} cm^{-1}). Exact mass calcd for $C_{14}H_{24}N_5O_7$ (MH^+): 374.1676. Found: 374.1680.

Anal. calcd for $C_{14}H_{23}N_5O_7$: C, 45.04; H, 6.21; N, 18.76. Found: C, 45.83; H, 6.18; N, 18.27.

***O*^{2}-(Methoxymethyl) 1-[4-(3′-ω-Succinimidylbutyric acid)piperazin-1-yl]diazen-1-ium-1,2-diolate, *N*-Hydroxysuccinimide Ester (*5*)**. A solution of 1.617 g (14.1 mmol) of *N*-hydroxysuccinimide in 500 mL of dry ethyl acetate was heated to just below reflux. The heat was removed and 5.25 g (14.1 mmol) of **4** was added followed by 3.20 g (15.5 mmol) of dicyclohexylcarbodiimide. The resulting mixture was stirred for 18 h, filtered, and concentrated, and the residual oil was dried under vacuum. Yield 6.60 g (100%); mp 56−57 °C. ^{1}H NMR ($CDCl_3$): δ 1.9−2.1 (4H, m), 2.5−2.8 (5H, m), 2.83 (4H, s), 2.8−3.1 (3H, m), 3.49 (3H, s), 3.5−3.7 (4H, m), 3.78−3.87 (1H, m), 5.22 (2H, s). UV λ_{max} (CH_3CN): 234 nm (ϵ = 7.67 mM^{-1} cm^{-1}).

Anal. calcd for $C_{18}H_{26}N_6O_9$: C, 45.96; H, 5.57; N, 17.86. Found: C, 46.09; H, 6.08; N, 17.90.

Diazeniumdiolated Bovine Serum Albumin. A solution of 4.00 g (0.0597 mmol) of bovine serum albumin (Calbiochem, LaJolla, CA) in 265 mL of 50 mM, pH 8.5, borate buffer was treated with a solution of 6.18 g (13.1 mmol) of N-hydroxysuccinimide ester **5** in 23 mL of tetrahydrofuran. After stirring for 2 h, the solution was loaded into SpectraPor 4 dialysis tubing (Spectrum, Houston, TX) and dialyzed against distilled water for a total of 7 h at 0 °C, during which time the 4 L reservoir of distilled water was changed five times. The resulting material was centrifuged to remove ca. 20 mg of residue and then freeze-dried to yield 4.8 g of puffy white product. MALDI-TOF MS showed this material to have a M_r of 74.2 kDa.

Sample purity was checked by capillary zone electrophoresis (CZE) employing a Beckman Model P/ACE System 5500 instrument fitted with a 50 μm ID 10% polyacrylamide-coated fused silica column with a total length of 47 cm (operative length was 40 cm). Using a mobile phase of 50 mM phosphoric acid adjusted to pH 2.5 with triethylamine and a voltage of 12 kV (current: 16 μA), underivatized BSA eluted at 10.8 min, while D-BSA eluted at 12.3 min. The D-BSA sample contained neither underivatized BSA nor any other impurity detectable by UV at 214 nm and produced a clean Gaussian-shaped peak.

Diazeniumdiolated Human Serum Albumin. A solution of 3.00 g (0.0457 mmol) of human serum albumin (Calbiochem, LaJolla, CA) in 200 mL of 50 mM pH 8.5 borate buffer was treated with a solution of 5.35 g (11.4 mmol) of N-hydroxysuccinimide ester **5** in 15 mL of tetrahydrofuran. After stirring for 2 h, the solution was loaded into SpectraPor 4 dialysis tubing (Spectrum, Houston, TX) and dialyzed against 50 mM, pH 8.5, borate buffer for a total of 7 h at room temperature, during which time the 3 L reservoir of buffer was changed five times. The resulting solution was centrifuged to remove ca. 20 mg of residue. The total volume of this solution was 270 mL. The solution was freeze-dried to yield 4.42 g of puffy white product calculated to contain 3.24 g of diazeniumdiolated HSA and 1.18 g (26.6%) of buffer salts. MALDI-TOF MS showed this material to have a M_r of 73.1 kDa.

ACKNOWLEDGMENT

We thank Terry Sumpter for obtaining the mass spectra and George Janini for the CZE analysis. This project has been funded in part with Federal funds from the National Cancer Institute, National Institutes of Health, under Contract NO1-CO-56000.

DNA Complexing with Polyamidoamine Dendrimers: Implications for Transfection

Anna U. Bielinska,[†] Chunling Chen,[†] Jennifer Johnson,[†] and James R. Baker, Jr.*[,†]

Department of Internal Medicine and Center for Biologic Nanotechnology, University of Michigan Medical School, 9220 MSRB III, 1150 West Medical Center Drive, Ann Arbor, Michigan 48109. Received March 22, 1999; Revised Manuscript Received June 11, 1999

DNA and polyamidamine (PAMAM) dendrimers form complexes on the basis of the electrostatic interactions between negatively charged phosphate groups of the nucleic acid and protonated (positively charged) amino groups of the polymers. Charge neutralization of both components and subsequent increases of the net positive charge of the complex result in changes in the physicochemistry and biological properties of the complexes. The formation of soluble, low-density and insoluble, high-density complexes was analyzed using UV light absorption and measurements of radioactive labeled DNA. Formation of high molecular weight and high-density complexes depended mainly on the DNA concentration and was enhanced by increasing the dendrimer−DNA charge ratio. Electrostatic charge related effects (attraction or repulsion of charged particles) appeared to be modulated by the generation of dendrimer (size of the polymer). With the progressive increases in the dendrimer−DNA charge ratio (above 20), an increase in the amount of low-density, soluble complexes was observed. Functional analysis revealed that the great majority (>90%) of transfection is carried by low-density, soluble, complexes which only represent approximately 10−20% of total complexed DNA. The ability of the dendrimer to complex and form aggregates with DNA is crucial for efficient transfection and the function of the complexed DNA.

INTRODUCTION

Formation of a complex between DNA and a synthetic carrier appears to be the initial and possibly the critical parameter for nonviral gene delivery. A number of synthetic vector systems, including polylysines, cationic liposomes, cationic polymers, or various types of block copolymers, have been utilized for the transfer of DNA molecules into cells (*1*−*3*). All these cationic systems have been shown to self-assemble with plasmid DNA expression vectors. In certain conditions, the interaction of DNA with polyvalent cations results in compaction of extended DNA structures, that then aggregate and precipitate from the solution (*4*−*6*). Physicochemical properties of the formed complexes depend mainly on the type of cationic agent used (*7*−*9*). Among cationic polymers, dendrimers have recently emerged as a novel synthetic carrier for DNA transfer (*10*−*12*). Starburst PAMAM dendrimers are nanoscopic polyamidoamine polymers with a molecular architecture characterized by the regular dendritic branching and radial symmetry (*10*, *13*, *14*). The perfectly spheric topological structure and homogeneity of these polymers is achieved by the ordered assembly of polymer subunits in concentric, dendritic tiers surrounding an initiator core. Physical and chemical properties of dendrimers are an outgrowth of their shape as well as the presence of charged groups on the surface. High positive charge density in these molecules is due to the presence of protonized primary amine groups on the surface of the molecules. Together with high solubility in water, these characteristics have led to the use of these polyamines to mediate efficient DNA transfer. Dendrimers appear to be highly efficient for in vitro transfection and are not cytotoxic (*12*, *15*). Other evidence suggests that these polymers are not immunogenic or carcinogenic, enhancing their potential as vectors for an in vivo gene transfer system (*16*).

The alterations of DNA structure caused by complexation with dendrimers and the function of the complexed genetic material are yet to be clarified. In other trivalent or higher valency cationic polyamines, nucleic acid complexation affects DNA structure and physicochemical properties both in vitro (*17*−*19*) and in vivo (*20*, *21*). In particular, high molecular weight cationic polymers such as polylysine, protamine, spermidine, spermine, and histones are known to complex and condense DNA and alter transcription efficiency in vivo (*17*, *22*−*24*). Complexing DNA with dendrimers leads to changes in transcription efficiency in vitro, but also increases DNA survival upon delivery in vitro and in vivo (*15*, *25*). Thus, the physicochemical properties and biological function of dendrimer−DNA complexes appear to be an important issue for the development of artificial, self-assembling systems for gene transfer (*17*, *26*).

Our previous studies suggested that transfection efficiency and functionality of DNA complexed with dendrimers may depend on the structure, size, and charge density of the polymer (*12*, *17*). The defined structure of dendrimers and the ability to alter a single parameter in the structure of the molecule make these polymers unique reagents to study the interaction between DNA and polycations. Structural studies on dendrimer-complexed condensed DNA may reveal the geometric and stoichiometric interactions relevant for the in vivo function. We therefore set out to examine the interactions occurring during DNA−dendrimer complex formation for use in in vitro transfections. This focused our work on

complexes formed in DNA concentrations up to 1 mg/mL and in salt-free, water solutions. In the present studies, we characterize the processes involved with the formation of DNA−dendrimer complexes and the implications of this phenomenon for gene transfer.

MATERIAL AND METHODS

Dendrimers. The synthesis of Starburst PAMAM dendrimers has been previously described in detail (*10*, *11*). In these studies we have used dendrimeres with ethylenediamine (EDA) as a tetravalent polymerization initiator core. Generations (G) 4, 5, 6, 7, and 9 EDA core dendrimers have molar masses of 14 215, 28 826, 58 048, 116 493, and 467 162 kDa, respectively; the number of surface charges (amine groups) is 64, 128, 256, 512, and 2048.

Preparation of Polycation−DNA Complexes. Methyl alcohol stocks of dendrimers were diluted to an appropriate concentration in water and stored at 4 °C. Dendrimer−DNA complexes were formed by incubating the two components together in 100 μL of double distilled water for a minimum of 10 min at room temperature (RT) unless indicated otherwise. Ratios of dendrimer to nucleic acids were based on the calculation of the electrostatic charge present on each component, the number of terminal amine groups on a dendrimer vs the number of phosphate groups in the nucleic acid. For example, a G7 EDA dendrimer has approximately 2.65×10^{15} positive charges (protonized surface amine groups $NH3^{+}$)/μg (1 μg); the number of bases in a microgram (1 μg) of DNA is 1.71×10^{15}, resulting in approximately 1.71×10^{15} negative charges (ionized P, of phosphodiester groups, in pH 7)/1 μg of DNA. To obtain the theoretical charge ratio equal 1 (neutralizing conditions), 0.65 μg of this dendrimer is mixed with 1 μg of DNA. Similar calculations and mixing were used to make DNA complexes with the spermidine and spermine (1.8×10^{24} and 2.4×10^{24} positive charges/ mol, respectively). Charge ratios are presented as positive equivalents of the cationic component to negative charge equivalents of the nucleic acid components, as recommended in Nomenclature for Synthetic Gene Delivery Systems (*27*).

DNA for Precipitation Studies. Herring sperm DNA (from Promega or Gibco BRL-LifeTechnologies) preparations of sonicated double stranded DNA with a particle size ranging 100−1000 kb, where the majority of DNA fragments ranged 600−800 bp, were utilized in most of the precipitation studies. Plasmids pGL-2 control (Promega, 6 kb), pBK-RSV (Stratagene, 4.4 kb) and pCMV-Luc (*11*) were amplified in *E. coli* XL1Blue cells and isolated by double cesium chloride gradient (*28*) to ensure the purity of the DNA preparation. Single-stranded deoxyribonucleotide 27 base long oligonucleotide was synthesized using a DNA/RNA synthesizer (Model 394, Applied Biosystems) and purified by HPLC in the Biomedical Core Facility of the University of Michigan.

Analysis of Polycations−DNA Interactions. A number of polycations, such as dendrimers, spermidine, or spermine, were mixed with DNA samples in double distilled water, gently vortexed, incubated for 10 min RT and centrifuged at 11750*g* in an Eppendorf centrifuge for 5−7 min unless indicated otherwise. The supernatant and pellet were separated and the amount of DNA present in supernatant, denoted as "low density", was analyzed by spectrophotometry of DNA absorption at 260 nm or by measurement of the radioactivity of ^{32}P-labeled DNA. For UV absorbance measurement, an aliquot (100 μL) of the supernatant was diluted in water up to 400 μL. For the radioactive assay, 2.0−5.0 ng of tracer DNA, either 27 bp oligonucleotide or herring sperm DNA 5′-end labeled with ^{32}P, was added to the nonlabeled DNA. After centrifugation the radioactivity in supernatants was determined by counting in a Wallac 1409 Liquid Scintillation Counter.

Cells and Media. COS-1 and Rat2 cells were maintained in D-MEM medium (Gibco BRL) with 5% −10% FCS (Hyclone), 1% penicillin-streptomycin and 2 mM L-glutamine. D5 cells were cultivated in RPMI 1640 (Life Technologies) supplemented with 10% fetal calf serum, 1% penicillin-streptomycin, 2 mM L-glutamine, 50 μM 2-mercaptoethanol, 1 mM nonessential amino acids). All cell lines were incubated at 37 °C in 5% CO_2.

Transfection Methods. Transfections with dendrimer−plasmid DNA complexes were performed and analyzed using assays for luciferase activity expression from pCMV-Luc reporter plasmid (*15*). Indicated amounts of pCMV-Luc DNA were mixed with dendrimers at a variety of dendrimer to DNA charge ratios (ranging 1−50) and were then allowed to complex for 5−10 min at RT. The 24-well plates seeded 24 h before the transfection with approximately 2×10^4 cells/well, were washed once with serum-free media. The dendrimer−DNA complexes were then added, and transfection was carried for 3 h at 37 °C. After transfection, mix containing the complexes was washed out of the cells and standard growth media was added for incubation. The cells were harvested 24 h later and assayed for the expression of luciferase. To further analyze transfectional properties of complexes, dendrimer-complexed DNA was fractionated by centrifugation at 8160−11750*g* in water or using 0 to 2% and 0 to 5% step glycerol gradients. For the transfections 25 μL of the solution containing DNA−dendrimer complexes either not fractionated (suspension) or after centrifugation (low density) was added to 200 μL of serum-free media in each well of cells. Transfections and posttransfectional incubations proceeded as above. Luciferase activity was determined by measuring the light emission from 10 μL of cell lysate incubated with 2.35×10^{-2} μmol of luciferin substrate (Promega, Technical Bulletin no. 101). Light emission was measured in a relative light units (RLU) using chemiluminometer LB96P (EG&G Berthold), and adjusted to the protein concentration of the sample. The protein concentration in the cell lysates was measured in a standard protein assay (DC protein assay, Bio-Rad Richmond, CA).

Statistical Analysis. Statistical analysis was performed using Systat 5.2 software for Macintosh. Mean and standard deviations of the samples were determined and differences between them were analyzed by ANOVA.

RESULTS

Complexing with Dendrimers Results in DNA Precipitation. Formation of dendrimer complexes with supercoiled plasmid DNA, single- and double-stranded oligonucleotides, and linear forms of high molecular weight DNA has been previously demonstrated by retardation of electrophoretic mobility as well as by electronmicroscopy. Binding of DNA to dendrimer changes the molecular structure of DNA and results in condensation and aggregation of DNA particles (*12*, *15*, *17*). To examine the general physicochemical properties of dendrimer−DNA complexes and the changes in solubility of DNA upon interaction with dendrimers, several studies were performed. Complexes of dendrimer/herring sperm DNA at charge ratios ranging 0.01−100 were formed in 100 μL of water containing 10 μg of DNA (concentration

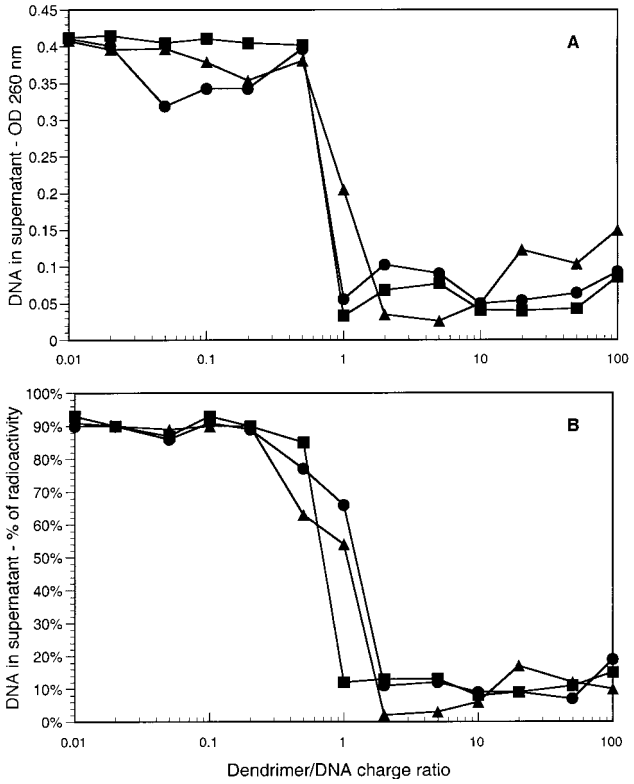

Figure 1. The formation of insoluble DNA aggregates with different generations of EDA core dendrimers. Comparison of the data obtained with spectrophotometric assay of DNA absorption at 260 nm (A) and measurement of radioactive DNA (B) present in supernatants after separation of precipitated complexes and soluble DNA fractions. EDA dendrimers G5 (■), G7 (●), and G9 (▲).

0.1 μg/μL) and increasing amounts of G 5, 7, and 9 EDA dendrimers. All complexing was performed in the absence of other ions in double-distilled water. DNA remaining in supernatant after centrifugation was analyzed using DNA absorption at 260 nm (Figure 1A) and by measuring the presence of radioactivity in the supernatant (Figure 1B). A simple spectrophotometric assay was possible because dendrimers, in the concentrations used in the experiments, have very low absorption across the broad spectrum of wavelengths (including the 260 nm maximum of DNA absorption; data not shown). The course of the precipitation curves in Figure 1 illustrates that both methods of measurement can accurately reflect formation of DNA precipitate. At 0.1 μg/μL concentration, DNA is completely neutralized at dendrimer−DNA charge ratio of 1 when complexed with three different generations of EDA core dendrimer (*12*, *17*). Approximately 95% of these complexes precipitate and the transition of DNA from soluble to condensed form seemed to be abrupt. Charge ratios lower than 1 (e.g., 0.5), did not result in a significant formation of the precipitate, and increasing of the dendrimer−DNA charge ratio (to 10−15) did not further enhance the precipitate formation. However, complexing at a charge ratio of 20 or greater resulted in higher DNA content in the soluble fractions reaching approximately 10−20% (of the total DNA). This phenomenon seems to be somewhat dependent on the generation of dendrimer used (Figure 1B). We also observed increased UV light absorption at these ratios (up to 25−30%), suggesting the generation of low-density particles containing both DNA and dendrimers (Figure 1A).

DNA Concentration Effects. We have studied the effect of DNA concentration on the formation of dendrimers−DNA complexes using plasmid pGL-2 DNA and G7 EDA. A broad range of DNA concentrations (from 0.01 to 1 μg/μL) was mixed with dendrimer at increasing concentrations from 0.0065 to 26 μg/μL (Figure 2). Plasmid DNA at the lowest concentration of 0.01 μg/μL did not form insoluble complexes with G7 EDA dendrimers at any polycation concentration or charge ratio (for this DNA concentration, analyzed dendrimer−DNA charge ratios are 1−4000). Increasing the DNA concentration to 0.1−1 μg/μL and complexing with 3.25 μg/μL of G7 EDA resulted in a 50% of DNA present in precipitates. Complexing DNA at a concentration of 1 μg/μL with G7 EDA at the charge ratio of 10 (concentration 6.5 μg/μL) resulted in the formation of 95% aggregated dendrimer−DNA complexes. The formation of the precipitate increased as the DNA concentration grew from 0.01 to 1 μg/μL, and less dendrimer and a lower dendrimer−DNA charge ratio were sufficient to generate insoluble aggregates in this conditions (Figure 2). We have observed that further increases of DNA concentration resulted in resolubization of the complexes, particularly at greater than 10 dendrimer−DNA charge ratios (data not shown).

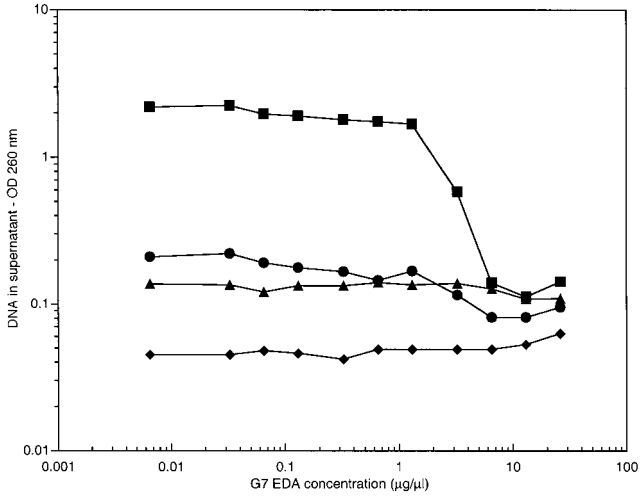

Figure 2. Effect of DNA concentration on the formation of aggregated dendrimer−DNA complexes. Note that a logarithmic scale is used for dendrimer concentration (μg/μL). DNA concentrations: (■) 1 μg/μL, (●) 0.1 μg/μL, (▲) 0.05 μg/μL, (◆) 0.01 μg/μL.

Dendrimers Form Complexes with Various Forms of Nucleic Acid. G7 EDA dendrimer formed complexes with 27 base oligonucleotides, herring sperm DNA (average length of DNA particle 600−800 bp) or pGL2—the latter, a supercoiled, covalently closed 6 kb plasmid (Figure 3). All DNA preparations were prepared at 0.1 μg/μL concentration and mixed at the appropriate charge ratio with G7 EDA. To increase the capability to detect differences in dendrimer−DNA complex formation with various forms of nucleic acids, the separation of the low- and high-density fractions was performed by centrifugation at 5220*g* instead of the standard conditions (Materials and Methods). All three types of DNA formed insoluble complexes when mixed with G7 EDA at increasing dendrimer−DNA charge ratios. However, 50% of 0.1 μg/μL plasmid DNA remained in supernatant when complexed with G7 EDA dendrimer at a dendrimer−DNA charge ratio of 5 (Figure 3A). In contrast, the oligonucleotides or herring sperm DNA complexed at the same charge ratio resulted in approximately 20% of the total DNA remaining in the supernatant. While similar patterns of the precipitation curves were obtained with all three forms of DNA, aggregation of plasmid DNA proceeded at higher G7 EDA/DNA charge ratio.

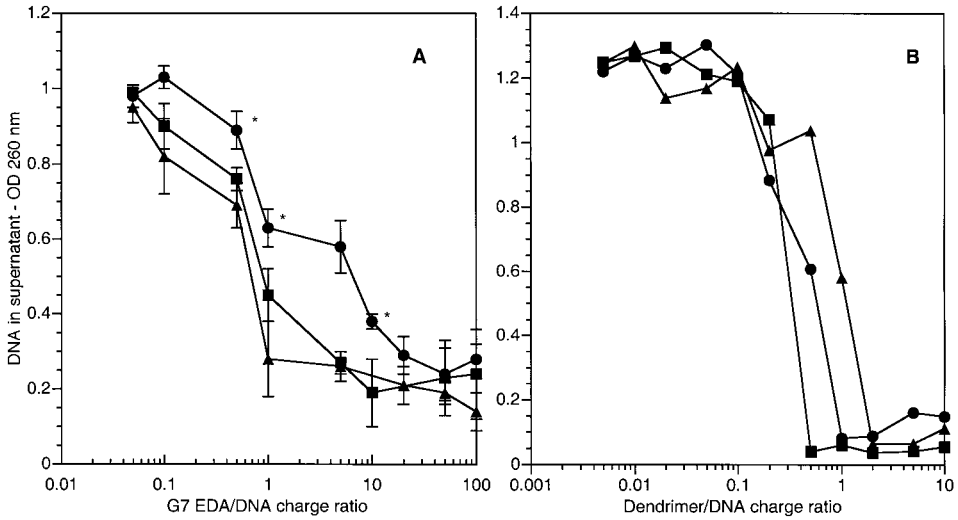

Figure 3. Formation of the aggregates with various types of nucleic acids. (A) G7 EDA complexed with 0.1 μg/μL of the different types of DNA: (■) low molecular weight, single-stranded 27 base DNA (oligo); (●) heterogeneous population of double stranded sonicated herring sperm DNA (hs DNA); and (▲) uniform population of covalently closed plasmid DNA (pGL-2). [The asterisk (*) indicates data points where $p < 0.05$ for herring sperm DNA or oligo and plasmid DNA]. (B) Plasmid DNA (pBK RSV) at 1 μg/μL complexed with EDA dendrimers. EDA dendrimers G5 (■), G7 (●), and G9 (▲).

Soluble dendrimer−plasmid DNA complexes were not observed with higher concentrations of plasmid DNA (Figure 3B). When 100 μg of pBK RSV plasmid DNA (4 kb) at a final concentration of 1 μg/μL was complexed with G5, G7, and G9 EDA in dendrimer−DNA (charge ratios ranging 0.05−1), the precipitation curves indicated that at this DNA concentration and at a dendrimer−DNA charge ratio equal to 1, all generations of dendrimers precipitated >95% of plasmid DNA. The profiles of the precipitation curves are similar, but there are subtle differences in maximum of complexation with different generations of dendrimers. Smaller dendrimers, G5 and G7 EDA, tend to form insoluble DNA complexes at lower charge ratios (~0.5) than the larger G9 EDA dendrimer (Figure 3B). This result may suggest that the electrostatic process of complexing and aggregation of DNA may be uniquely affected by the size of the dendrimer.

To further analyze the effect of size, surface charge, and molar concentration of dendrimer on complex formation, herring sperm DNA at 0.025 μg/μL was incubated with increasing concentrations of G4, G5, G6, G7, and G9 EDA dendrimers (Figure 4). As previously observed with plasmid, at a charge ratio of 1, 95% of DNA complexed with dendrimers was found in the insoluble fractions. The efficiency of precipitation with dendrimers, defined here by the lowest molar concentration of polymer in which the maximum precipitation of DNA occurs, was proportional to the increase in size of the dendrimer. This is not unexpected given the primarily electrostatic nature of dendrimer−DNA interaction, since larger dendrimers carry higher surface charge than smaller ones (*10*). Maximum formation of insoluble complex with 0.025 μg/μL of herring sperm occurs in 0.054 μM G9 EDA, 0.215 μM G7 EDA, 0.429 μM G6 EDA, 0.57 μM G5 EDA, and 0.86 μM G4 EDA dendrimers. Consequently, calculations of the ratios between molar concentrations of G6/G7 (~2), G7/G9 (~4), and G6/G9 (~8) generations reflect the inverse correlation of surface charge ratios between these dendrimers. Interestingly, the molar concentrations of larger G9, G7, and G6 EDA dendrimers most effective in the precipitation of DNA are ~1.5 times higher than those required for neutralizating of the DNA (dendrimer−DNA charge ratio equal 1). In contrast, for the G5 and G4 EDA dendrimers, these concentrations are ~1.3 times lower than expected for charge neutralization

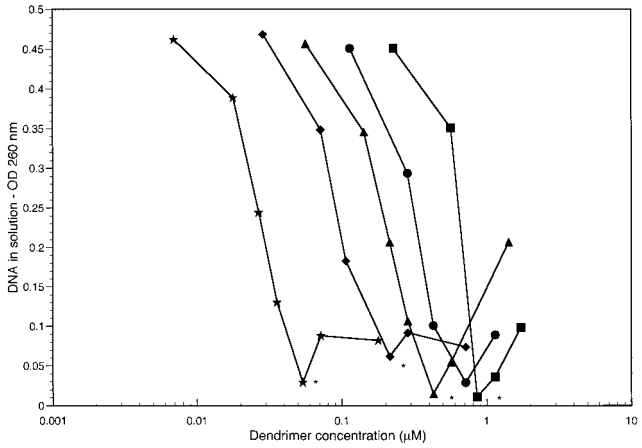

Figure 4. Effect of the size of dendrimer on the formation of aggregated dendrimer DNA complexes. Complexes were formed in a constant DNA concentration (0.025 μg/μL) with increasing concentrations of various generations of dendrimers. Data from dendrimers G4 (■), G5 (●), G6 (▲), G7 (◆), and G9 EDA (★) is described. Differences (*) between molar concentrations of dendrimers were significant with $p < 0.02$.

(Figure 4). These subtle differences in the threshold formation of an insoluble complex again suggest that the overall process of DNA aggregation is not strictly electrostatic, but also involves the size and, consequently, amount of dendrimer particles in the complex.

Efficiency of DNA Precipitation with Dendrimers and Polyamines. Spermidine and spermine are multivalent cations with charges of +3 and +4 per molecule, respectively. Both are known to induce condensation of DNA in aqueous solutions (*5*, *19*, *29*, *30*). To compare the condensation and precipitation with dendrimers, spermidine, and spermine 1 μg/μL of herring sperm DNA with radiolabeled DNA tracer was mixed with the increasing concentrations of each of the polycations. As has been reported previously, 10 mM spermine and spermidine precipitate the majority 80−90% of DNA. When the concentration reaches 100 mM, both polycations resolubilize the DNA pellet, and this transition is significantly enhanced by the presence of 25 mM NaCl (*5*). In contrast, G7 EDA at 1.12 μM (charge ratio 1) precipitates almost 90% of DNA and at 27.7 μM resolubilizes approximately

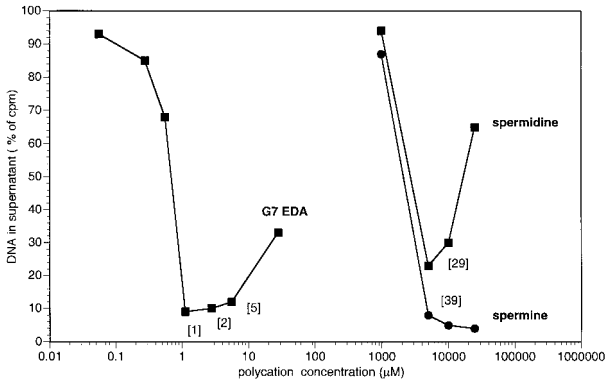

Figure 5. Comparison of DNA complex formation with G7 EDA dendrimer vs polyamines spermidine and spermine. Polycation/DNA charge ratios at the maximum of the DNA aggregation are indicated in the brackets.

30% of dendrimer−DNA complexes. Approximate polycation−DNA charge ratios of the most precipitation-effective molar concentrations of polymers are 1−5 for G7 EDA, 29 for spermidine, and above 39 for spermine (Figure 5). This indicates that spermidine and spermine require 30−40 times higher charge ratios and (5−10) × 10^3 higher molar concentrations than dendrimer to induce a similar degree of DNA condensation.

Transfection Studies with Fractionated DNA−Dendrimer Complexes. To test transfection efficiency of soluble and insoluble complexes, 100 μL of mix containing 4 μg of pCMV-Luc plasmid (0.04 μg/μL) and increasing amounts of G9 EDA dendrimer were fractionated by centrifugation at 5220*g*. Two cell lines, Rat2 and D5, were transfected with either 25 μL of whole complex suspension or 25 μL of supernatant from the centrifuged samples. In all dendrimer−DNA charge ratios the majority of in vitro transfection appears to be mediated by the supernatant fractions of DNA−dendrimer complexes (Figure 6). Analysis of DNA distribution using radioactive tracer DNA, indicated that from 11% (at a charge ratio of 1) to 26% (at a charge ratio of 50) of total dendrimer−DNA complexes is in the supernatant fractions (Figure 6, insert). Although the amount of DNA in supernatant samples at charge ratios 1 and 50 differs approximately 2.5-fold, the efficiency of transfection is 5−6 orders of magnitude higher at the 20 and 50 charge ratios as compared to a charge ratio of 1. This result may suggest that the composition of the complexes is the most important factor for the efficient in vitro transfection and not simply the amount of complexed, compacted, and neutralized DNA. Transfections performed with complexes from the resuspended pellets yielded various degrees of reporter gene expression. This indicates that highly aggregated insoluble dendrimer−DNA complexes can be reconstituted to a functional form for transfection. By comparison, the efficiency of transfections performed using DNA complexed with spermidine or spermine was not better than transfections with DNA alone (data not shown).

To further analyze the nature of the most effective for transfection dendrimer−DNA complexes, G7 EDA dendrimer complexed with pCMVLuc plasmid DNA at 0.02μg/μL (charge ratio 10) was fractionated using 0 to 5% step glycerol gradient. The 100 μL samples of fractionated complexes were used in transfection of Rat2 cells. Control cells were transfected with 100 μL of regular transfection mix prepared in 2.5% glycerol solution. Transfection was augmented with 50 μM chloroquine in medium. Most efficient transfection complexes were found in the two least-dense fractions (Figure 7). Calculation of glycerol density (Sigma catalog, 1998) of these fractions enabled estimation of equilibrium density for dendrimer−DNA complexes. Lowest density fractions 1 and 2 contained complexes of density of 1.000−1.004 g/mL. Radioactive tracing of the fractionated DNA indicated almost uniform distribution across the density gradient, reflecting the polydyspersed, nonuniform nature of the dendrimer−DNA complex population (Figure 7). The approximately 30% of total DNA present in the two lowest density fractions transfeced Rat2 cells twice as effectively as unfractionated control preparations.

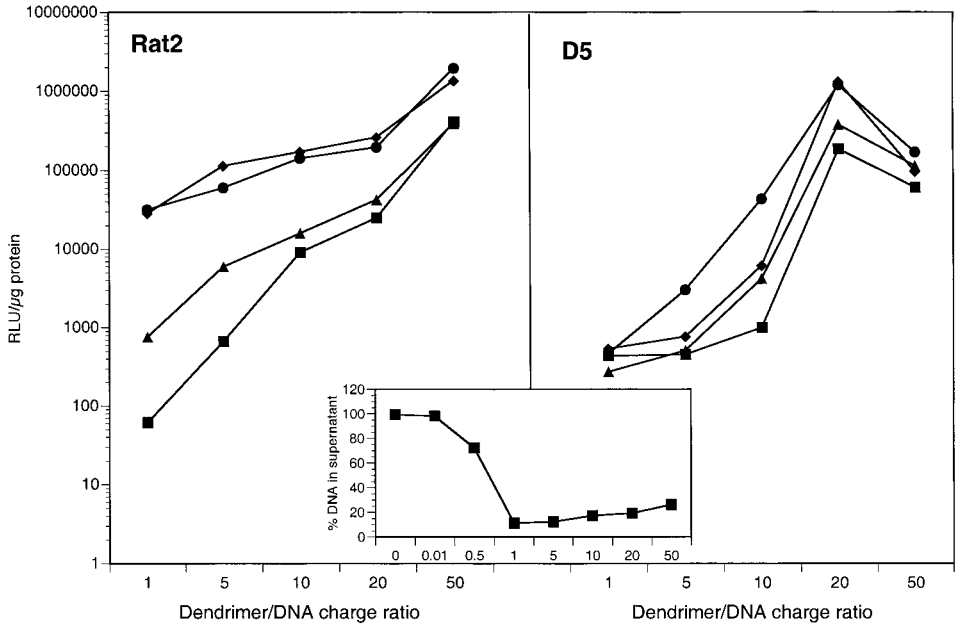

Figure 6. In vitro transfection of Rat2 and D5 cells with unfractionated dendrimer−DNA complexes vs low-density fractionated complexes. Transfection of cells with a suspension of dendrimer−DNA complexes performed either without (■) or with (●) 0.5 μM DEAE-dextran. Transfection with supernatant fractions containing soluble dendrimer−DNA complexes without (▲) and with (◆) augmentation with DEAE-dextran. Insert illustrates data obtained from radioactive tracing of fractionated G7 EDA/pCMV-Luc DNA complexes.

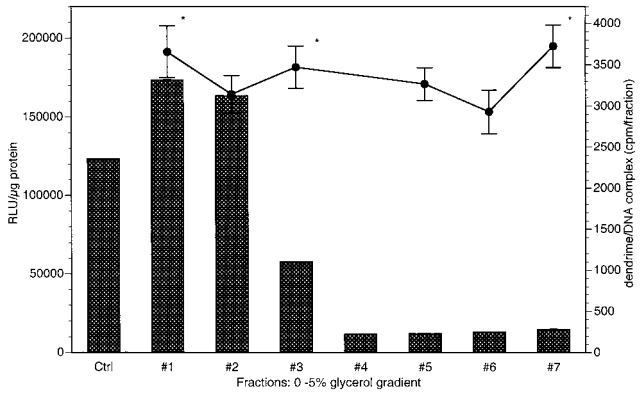

Figure 7. In vitro transfection of Rat2 cells with G7 EDA/DNA complexes. Complexes were fractionated by centrifugation on 0−5% glycerol gradient. Line (●) represents the distribution of the radioactively labeled dendrimer−DNA complexes in the gradient (right side axis). (*) $p > 0.5$ (± S.D.). The columns represent luciferase expression after transfection with unfractionated complexes vs the fractions 1−7 (left side axis).

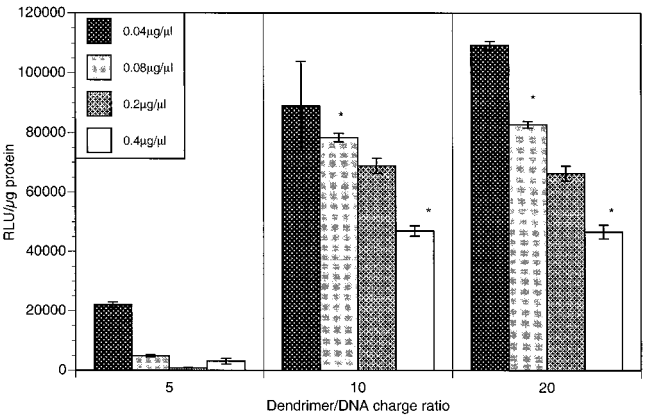

Figure 8. Effect of DNA concentration on the efficiency of in vitro transfection. COS-1 cells transfection with 1 μg of pCMV-luc plasmid DNA. DNA concentrations during complex formation with dendrimers (from 0.04 to 0.4 μg/μL) are indicated in the legend. (*) $p < 0.05$ (mean ± S.D.).

Figure 8 illustrates another approach to analyze the effect of DNA concentration-dependent compacting and aggregation on the efficiency of transfection in vitro. The G9 EDA dendrimer−DNA complexes were prepared with constant amount (1 μg) of pCMVLuc DNA at concentrations of 0.04, 0.08, 0.2, and 0.4 μg/μL and at the varying dendrimer−DNA charge ratios. The most efficient transfection of COS-1 cells occurred at the lowest DNA concentrations during complex formation, particularly in the high dendrimer−DNA charge ratios 10 and 20 (Figure 8). The precipitation experiments (Figures 2 and 3A) indicated that complexing dendrimers with DNA at lower concentrations (e.g., 0.05 μg/μL) resulted in the generation of lower density complexes which did not form precipitates. This type of complex mediated at least 2.5 times more efficient transfection of COS-1 cells than the higher density (less soluble) complexes obtained at higher DNA concentrations.

DISCUSSION

Various types of cationic molecules, including cationic lipids, polylysines, recombinant histones, and, recently, PAMAM dendrimers, have been employed as nonviral vectors for gene transfer into eukaryotic cells (*1*−*12*, *31*, *32*). These diverse materials have in common the ability to bind DNA binding via charge-based interactions, this property appearing to be necessary for transfection (*17*, *33*). The subsequent processes involved in the transfer and expression of the genetic material are not fully understood, but the compaction of DNA into condensed structures is also thought to play an important role in the cellular internalization of the genetic material. Alterations in the structure of the DNA polycation complex appear to affect the transfer and expression of the genetic material in cells and may be a critical issue in the development of nonviral gene transfer systems.

PAMAM dendrimers are an interesting new class of highly defined, spherical, cationic polymers (*10*, *14*). Recent studies have shown that these polymers can bind genetic material and facilitate gene transfer to a wide variety of cells (*11*, *12*, *15*, *26*). The characterization of the physiochemical properties of the DNA−dendrimer complex, including aggregation and precipitation are documented for the first time in this paper. We have identified that in DNA concentrations ranging 0.01−1 μg/μL, complexation with dendrimers may result in the formation of aggregates and precipitation. The primary mechanism of this process involves the electrostatic interaction between DNA and dendrimer molecules (*17*). This is illustrated in Figures 1, 3, and 4 by the generally identical shape of precipitation curves observed with dendrimers of different generations (sizes). However, the shift in the position of the curve indicates there is an influence of other parameters such as size and concentration of both dendrimers and DNA. Although all generations of PAMAM dendrimers have the same surface charge density, the interaction of smaller dendrimers G5 and G7 EDA with DNA led to formation of insoluble DNA complexes at lower charge ratios than with larger G9 EDA dendrimers. While dendrimers will form complexes with various forms of nucleic acid, including single-stranded oligonucleotides, larger fragments of salmon sperm DNA, or circular plasmid DNA, aggregation of plasmid DNA required higher dendrimer−DNA charge ratios. This indicates that average density of particles in populations of complexes formed at a specific charge ratio may differ depending on the type of DNA.

Various forms of synthetic and natural polyamines, spermidine, spermine, cobalthexamine, or polylysine interact physicochemically with DNA. Our data revealed similarities between the dendrimer mediated aggregation of DNA and that observed with other polycationic polymers (*5*, *6*, *11*, *13*, *20*, *34*). All these compounds bind various forms of DNA through charge−charge interactions, and efficiency of precipitation is dependent on the concentrations and charge ratios of both components as well as chemical structure of polycation (*5*, *26*). However, some specific differences are observed. Although the actual binding constants of large polyvalent compounds such as DNA and dendrimers are not readily determined (*5*, *8*, *35*) the high-density surface charge of the dendrimer molecules, the molar concentrations and dendrimer−DNA charge ratios that yield maximum DNA complexing are much lower for dendrimers than for other polycations. Another interesting difference is observed when comparing concentrations of DNA involved in complex formation. Spermidine and spermine seem to be most effective at forming insoluble complexes at lower DNA concentrations up to 0.01 μg/μL (*5*), while all generations of dendrimers are most effective at forming aggregates with higher DNA concentrations ranging from 0.04 to 1 μg/μL.

It is important to note that all experimental conditions tested correspond to those used for transfection in vitro and are not associated with cytotoxic effects. The excess of dendrimer provides DNA complexes with a positive net

charge. This is necessary for the efficient cellular uptake of dendrimer−DNA complexes through both energy-dependent and -independent mechanisms, as well as prolongs the survival of the transfected DNA (*12*, *17*, *25*).

In light of the precipitation studies, we have considered the link between compacting DNA and transfection in vitro. As other high molecular weight polycations, dendrimers form neutralized complexes with DNA at a charge ratio equal to 1. If compacting DNA is a crucial feature for the gene transfer as has been suggested (*1*, *2*, *9*, *32*), then one could expect that most efficient transfection with dendrimer−DNA complexes would be obtained with this conditions. Our results indicate otherwise and suggest in general that the transfection efficiency of complexes increase with an excess of cationic dendrimer (*12*). Such complexes display several unique properties in comparison to complexes formed at neutralizing concentrations of dendrimers. In particular, the appearance of the populations of low-density particles occurs only at these ratios. These low-density complexes, not yet fully characterized for structure and stoichiometry, seem to be important for achieving gene transfer since the transfection activity is contained in these soluble fractions. The complexity of polymeric polyelectrolite theories currently prevents a reliable theoretical calculation of complex stoichiometry (*5*, *34*, *35*). However, our results indicate that the conditions of complex formation (e.g., DNA concentration) define the transfection efficiency of the complex and in turn suggest that the initial complex formation may determine the final functionality of complexed DNA.

Naturally occurring polyamines are involved in numerous cellular processes (*21*) and are often used for in vitro studies of the functional properties of DNA (*18*). The correlation between condensation and aggregation of DNA and the stimulatory effect on DNA replication and transcription (*21*, *36*, *37*) have lead to the suggestion that these aggregates are fluid (*5*, *38*). Some forms of polyamine-condensed DNA are known to acquire liquid crystalline structure (*5*, *39*), and it is possible that dendrimer−DNA complexes may display properties of liquid crystals (*5*). The generation of the low-density particles at high DNA concentrations and high charge ratios closely resembles the resolubilization of DNA, which has been documented for spermidine, spermine, cobalthexamine (*5*, *29*), and other polyamines (*40*). However, the relevance of this phenomenon for gene transfer is not clear, since none of the these low molecular weight polycations is effective by itself for transfection even if they are frequently used as modifying moieties for lipid, liposome or polylysine based synthetic gene carriers (*30*−*33*).

In conclusion, the dendrimer−DNA interactions described in this study offer several insights into how these complexes form and mediate transfection. They also provide structural possibilities to enhance these polycations as carriers for cellular delivery of DNA and other genetic materials. Further characterization of the dendrimers with possible modifications of the charge and structure will clarify which properties of DNA−dendrimer complex absolutely determine its biological activity.

Polyion Complex Micelles with Protein-Modified Corona for Receptor-Mediated Delivery of Oligonucleotides into Cells

Serguei Vinogradov, Elena Batrakova, Shu Li, and Alexander Kabanov*

Department of Pharmaceutical Sciences, College of Pharmacy, 986025 Nebraska Medical Center Omaha, Nebraska 68198-6025. Received March 22, 1999; Revised Manuscript Received July 6, 1999

Graft-copolymers, containing poly(ethylene glycol) (PEG) and polyethyleneimine (PEI) chains have been proposed as carriers for delivery of phosphorothioate oligonucleotides (SODNs). Complexes of such copolymers with SODN self-assemble into particles having a core of neutralized PEI and SODN and a corona of PEG. Transferrin molecules are attached to the PEG corona using avidin/biotin construct. For this purpose, biotin moieties are covalently linked to the free ends of the PEG chains in the PEG-*g*-PEI copolymer. SODNs are reacted with mixtures of biotinylated and biotin-free PEG-*g*-PEI copolymers of various compositions to adjust the number of the biotin moieties in the complex. Resulting complexes have small size (ca. 40 nm) and do not aggregate in aqueous solutions for at least several days. To attach transferrin, they are supplemented first with avidin and then with biotin−transferrin conjugate. This increases the effective diameter of the particles to ca. 75−103 nm, depending on the composition of the complex. Cellular accumulation and fluorescence microscopy studies characterize the effects of these modifications on interaction of fluorescently labeled SODNs with KBv cell monolayers. The data suggest significant enhancement of SODN association with cells resulting from modification of the complex with transferrin. SODN complimentary to the site 546−565 of human *mdr 1*-mRNA was used to inhibit expression of the drug efflux transporter, P-glycoprotein (P-gp), in multiple drug resistant (MDR) cancer cells (KBv, MCF-7 ADR). Accumulation of a P-gp specific probe, rhodamine 123, in the cell monolayers is used to characterize the effects on P-gp efflux system following the treatment of the cells with antisense SODN or its complexes. This study suggests that antisense SODN incorporated in the complexes retain the ability to inhibit P-gp efflux system, while complexes of the randomized control SODN are inactive. Therefore, the antisense SODN is released from the complex and interacts with its intracellular target upon interaction of the complexes with the cells. Furthermore, modification of the complexes with transferrin leads to a significant increase of the effects of the antisense SODN on the P-gp efflux system in the cells. Overall, this study suggests that polyion complex micelles with protein-modified corona are promising tools for the delivery of antisense SODN.

INTRODUCTION

Development of efficient delivery systems for oligonucleotides (ODN) has been a major challenge in practical application of antisense therapeutics (*1*, *2*). The set of properties required from these systems is quite complex, and not surprisingly, only limited successes were achieved with simple delivery systems such as cationic liposomes and polymers (*2*). A novel class of cationic carriers has recently been proposed which might advance the field of ODN delivery (*3*). These carriers have block or graft copolymer architecture and consist of a polycation linked to a nonionic water-soluble polymer, most commonly, poly(ethylene glycol) (PEG). Examples of such carriers include PEG-*b*-polyspermine (*4*), PEG-*b*-poly(L-lysine) (*5*), and PEG-*g*-polyethyleneimine (PEG-*g*-PEI) (*6*). All these carriers bind with ODNs due to electrostatic interaction of the polycation and ODN chains. The complexes self-assemble into small, micelle-like aggregates termed "polyion complex micelles" (*5*), which have a hydrophobic core from neutralized polycation and ODN chains and hydrophilic corona from PEG chains. One clear advantage of such systems is their improved solubility compared to most other cationic carriers, which commonly aggregate after interaction with ODNs (*3*). Also, prevention of binding of ODN with serum proteins and digestion of ODN by nucleases as a result of incorporation of ODN into such complexes has recently been demonstrated (*6*). Furthermore, increased activity of antisense ODNs incorporated into such systems has been reported based on in vitro and in vivo studies (*7*, *8*).

This work examines complexes of ODN and cationic copolymers displaying transferrin at the surface of the complex that can promote uptake of ODN in the cell and increase transfection. The complexes were prepared using biotin-modified PEG-*g*-PEI copolymer. As a result, biotin moieties linked to the free ends of PEG chains became incorporated in the PEG corona. These moieties were then used to anchor biotinylated transferrin at the surface of the complex using avidin as a linker. Both the increased binding of phosphorothioate ODN (SODN) with cells and increased sequence-specific activity of the SODN were observed as a result of such modification. Fluorescently labeled SODN was used to examine transport and localization of SODN in the cells. 20-mer phosphodiester sequence directed to the human *mdr1*-mRNA was used to characterize effects of SODN on expression of P-glycoprotein (P-gp) in multiple drug

resistant (MDR) cancer cells: human oral epidermoid carcinoma (KBv) and human breast carcinoma (MCF-7 ADR).

MATERIALS AND METHODS

Materials. PEG, 8 kDa (as determined by viscometry) (lot no. 01925EG); PEI, 2 kDa (M_w, $M_w/M_n = 1.1$) (lot no. 40870-0), other reagents for copolymer synthesis, and fluorescent labels were obtained from Sigma-Aldrich Chemical Co. (St Louis, MO). PEG(8K)-*g*-PEI(2K) and dimethoxytrityl-PEG, 8 kDa (DMT-PEG), were synthesized in our laboratory as previously described (*6*). FITC-avidin (10−15 units/mg of protein; 1 unit binds 1 μg of d-biotin) and biotinylated human transferrin (biotin-transferrin) (6.7 biotin moieties/protein molecule) were purchased from Sigma-Aldrich Chemical Co. (St Louis, MO).

Synthesis of Monoamino-PEG. A total of 0.18 mmol of DMT-PEG was coevaporated twice in vacuo with anhydrous acetonitrile (10 mL), treated with 0.54 mmol of 1,1′-carbonyldiimidazole in 10 mL of anhydrous acetonitrile for 4 h at 40 °C, and then reacted with 10.5 mmol of ethylenediamine for 18 h at 25 °C. Thin-layer chromatography (TLC) using Silicagel and dichloromethane-methanol (9:1) (product R_f 0.3, DMT-PEG Rf 0.45) showed that the reaction was complete. Colorimetric reactions of the product with ninhydrine and 1% trifluoroacetic acid showed presence of amino groups and DMT groups, respectively. An excess of ethylenediamine was removed in vacuo, the product was treated with 30 mL of 2% trifluoroacetic acid in dichloromethane (5 min, 25 °C) to remove DMT group, the solvents were evaporated and the residue was dissolved in 15 mL of 40% ethanol containing 1% of triethylamine. This solution was filtered and dialyzed (Membra-Cel dialysis tubes with cutoff 3500) against 40% ethanol for 24 h, and the solvents were evaporated again. Finally, the product was redissolved in methanol (15 mL), precipitated into ether (300 mL), filtered, and dried in vacuo. The yield of monoamino-PEG was 1.20 g. Primary amine content in the product was 93% as shown using fluorescamine titration (*9*).

Synthesis of Biotin-PEG. A total of 0.145 mmol of monoamino-PEG was reacted with 0.145 mmol of d-biotin *p*-nitrophenyl ester in 5 mL of dimethylformamide containing 1% (v/v) of triethylamine for 18 h at 40 °C. TLC (using the same solvent as above) revealed appearance of a new product with R_f 0.25. This product showed no reaction with ninhydrine in contrast to the initial monoamino-PEG (Rf 0.1). It was purified by gel-permeation chromatography (GPC) using a column (3 × 30 cm) with Sephadex LH-20 (Pharmacia Biotech, Piscataway, NJ) and 50% methanol as an eluent (elution rate 2 mL/min, fractions 6 mL). After lyophilization, 0.79 g of biotinylated PEG (biotin-PEG) was obtained.

Synthesis of 1,1′-Carbonyldiimidazole-Activated Biotin-PEG. A total of 0.75 g of biotin-PEG was dried by coevaporation with anhydrous acetonitrile (10 mL) and then treated at 25 °C with an excess of 1,1′-carbonyldiimidazole (1 mmol) in 5 mL of anhydrous acetonitrile. The reaction was terminated after 18 h by addition of 0.2 mL of water, and the reaction mixture was dialyzed as previously described against 20% ethanol for 2 days and lyophilized. This produced 1,1′-carbonyldiimidazole activated biotin-PEG with the quantitative yield.

Synthesis of Biotin-PEG(8K)-*g*-PEI(2K). A total of 0.04 mmol of activated biotin-PEG in 5 mL of 80% ethanol was added dropwise under vigorious stirring to 5% solution of PEI, 2 kDa in 80% ethanol (10 mL). Reaction mixture was allowed to stand for 18 h at 25 °C then was diluted twice by water and dialyzed as previously described against 20% ethanol for 2 days. After solvent evaporation the product was twice precipitated from methanol into ether and dried in vacuo yielding 0.27 g of slightly yellow solid.

Molecular Mass Determination. Molecular masses of the cationic copolymers were determined by GPC analysis (M_{GPC}) using the SigmaChrom GFC-1300 column (7 mm × 30 cm) and 20% ethanol in 50 mM aqueous ammonium, pH 10.0, as a mobile phase. The column was calibrated using PEG and PEI with the molecular mass ranging 0.9−200 kDa, obtained from Shearwater Polymers Inc. (Huntsville, AL), Monomer-Polymer Dajac Laboratories Inc. (Feasterville, PA), and Sigma-Aldrich Chemical Co. (St Louis, MO).

PEG and PEI Ratio. The ratio of PEG and PEI in the copolymer samples was determined from ^{1}H NMR spectra using integral values obtained for the CH_2CH_2O protons of PEG and CH_2NH protons of PEI. Prior to NMR measurements all copolymers were purified from admixtures of nonconjugated PEG by preparative thin-layer chromatography on Silicagel using dichloromethane-methanol mixture (6:4) for elution.

Determination of the Nitrogen Groups. The total content of the nitrogen in the copolymers was determined by elemental microanalysis. The ratios of primary, secondary and tertiary amino groups were determined from ^{1}H NMR spectra.

Determination of the Biotin Content. The ratio of the biotin moieties and PEI chains in the biotin-PEG-(8K)-*g*-PEI(2K) copolymer was determined by elemental microanalysis from the sulfur and nitrogen contents. Also, biotin content in the biotin-PEG(8K)-*g*-PEI(2K) copolymer was determined using competitive displacement of 2-anilinonaphthalene-6-sulfonic acid in avidin (*10*). In a typical experiment, 20 μL of white egg avidin solution (14 units/mg of protein, 93 units/mL) were diluted with phosphate buffered saline (PBS), pH 7.4, to a total volume of 1 mL, and then supplemented with 15 μL of 5 mM 2-anilinonaphthalene-6-sulfonic acid in dimethyl sulfoxide. The resulting solution was shaken thoroughly and mixed with various amounts of the copolymer. Fluorescence of the mixture was measured at λ_{ex} = 328 nm and λ_{em} = 408 nm using Shimadzu RF5000 fluorescent spectrophotometer. The dependence of the fluorescence intensity on the amount of the copolymer added revealed a break indicating saturation of biotin binding sites in avidin, which was used to determine the biotin content in the copolymer.

Polynucleotides. Oligonucleotides and their 3′-aminolinker derivatives were synthesized at the Oligonucleotide Core Facility, UNMC (Omaha, NE). To introduce fluorescent label, fluorescein isothiocyanate (FITC) or rhodamine isothiocyanate (RITC) were taken into reaction with 3′-amino-modified SODN using manufacturer's protocol. All oligonucleotides were purified by precipitation from 0.3 M NaCl solutions into 2-propanol. In the experiments on *mdr1*-gene inhibition, the following SODNs were used: GTCAAGCCAATTTGAATAGC (**S4**) complementary to *mdr1*-mRNA binding site 546−565, and randomized control SODN, CGATATAGATTGC-CTAAAACG (**RS4**). For RT-PCR procedure, two sets of PCR-primers were used: GGGACCGCAATGGAGGAG and CAGATTCATGAAGAACCCTG to amplify *mdr1*-gene fragment of 308 bp (*439*−*746*) (*11*), as well as ACCCCCACTGAAAAAGATGA and ATCTTCAAACCTC-

Table 1. Characteristics of Synthesized Cationic Copolymers

	molecular characteristics of the synthesized copolymers				
copolymer name[a]	*N* (μmol/mg)[b]	biotin content (mg/g)[c]	PEG:PEI[d]	biotin:PEI[e]	molecular mass (kDa)[f]
PEG(8K)-*g*-PEI(2K)	2.2	0	1.7	0	15.5
Biotin-PEG(8K)-*g*-PEI(2K)	2.1	26	2.3	2.5	18.5

[a] The nomenclature for PEG and PEI copolymers accounts for the molecular masses of the PEG and PEI fragments [i.e., "PEG(8K) for PEG, 8 kDa or "PEI(2K)" for PEI, 2 kDa]. [b] Nitrogen concentration as determined by elemental analysis. [c] Milligrams of biotin per gram of copolymer as determined by avidin titration. [d] As determined by ^{1}H NMR analysis of the copolymer samples. [e] As determined by elemental analysis. [f] M_{GPC}.

CATGATG to synthesize β-microglobulin (*bmg*) gene fragment of 120 bp (*12*).

Preparation of the Complexes of SODN and Cationic Copolymers. Solutions of cationic copolymers and SODNs were prepared in 50 mM phosphate buffer, pH 7.4, filtered through 0.22 μm sterile filters, and mixed with each other to obtain desired *N*/*P* ratio (molar ratio of total nitrogen in cationic copolymers to thiophosphate groups in SODN). After incubation for 1 h at 25 °C, these mixtures were supplemented with the solution (8 mg/mL) of egg white avidin in phosphate buffer, pH 7.4, at avidin/biotin molar ratio 1. These mixtures were incubated for additional 1 h at 25 °C and then supplemented with the solution (8 mg/mL) of human biotinylated transferrin in phosphate buffer, pH 7.4, at transferrin/avidin molar ratio 1. The final system was equilibrated for at least 2 h at 25 °C prior to further use.

Particle Size Determination. Effective hydrodynamic diameter of particles was measured by photon correlation spectroscopy as described elsewhere (*6*).

Cell cultures. KBv and KB cells were provided by Dr. D. W. Miller (UNMC, Omaha, NE) while MCF7 and MCF7 ADR cells were provided by Dr. V. Yu, Alakhov (Supratek Pharma Inc., Laval, Canada). Cells were seeded at a density 5×10^4 cells/well and maintained in DMEM medium supplemented with 10% FBS in 5% CO_2 incubator.

Interaction of FITC−SODN with Cells. Cells were grown in 24-well plates (Falcon Co., Becton Dickenson, Lincoln Park, NJ) for 24 h prior to the treatment. After 30 min preincubation with the serum-free assay buffer (122 mM sodium chloride, 25 mM sodium bicarbonate, 10 mM glucose, 10 mM Hepes, 3mM potassium chloride, 1.2 mM magnesium sulfate, 1.4 mM calcium chloride, and 0.4 mM potassium phosphate dibasic), cells were exposed to 10 μM FITC−SODN or FITC−SODN complexes with cationic copolymers in serum-free media for 6 h at 37 °C. Thereafter, cells were washed three times with ice-cold PBS and solubilized in 1% Triton X-100 solution. Fluorescence was measured at $\lambda_{ex} = 488$ nm and $\lambda_{em} = 520$ nm using a Shimadzu RF5000 fluorescent spectrophotometer and normalized by protein content in each sample determined by Pierce BCA method. All experiments were carried out in four repeats.

Fluorescence Microscopy. KBv cells grown on chamber slides (Fisher Sci., Pittsburgh, PA) were exposed to 5 μM free RITC−SODN or complexes of RITC−SODN with cationic copolymers for 3 h at 37 °C in serum-free media. After that, cellular accumulation of RITC-labeled SODN was examined using fluorescent Nikon Microphot FXA microscope equipped with CCD camera (Photometrics, Tucson, AZ) and Rhodamine filter set (Omega Optical).

Cell Exposure to Antisense SODN. KBv or MCF-7/ADR cells were seeded in 24-well plates at a density of 50 000 cells/well, grown for 24 h, and then exposed to 0.5n 5 μM free SODN or SODN complexes in cell culture medium containing 10% FBS for 2 days. The treatment solutions were replaced for the fresh ones after first 24 h of exposure. Thereafter, the cells were further incubated in the fresh DMEM medium containing 10% FBS for 24 h before harvesting for analysis.

Accumulation of Rhodamine 123 (R123) in Cells. Following exposure of cells to SODNs rhodamine 123 (R123), accumulation studies were performed as previously described (*13*).

Quantitation of mdr1-mRNA by RT-PCR. Total RNA was isolated from cell lysates using an RNA isolation system, RNAgents (Promega, Madison, WI). Access RT-PCR system with Tfl DNA polymerase (Promega, Madison, WI) was used for quantitative RT-PCR. PCR reagent mixture was prepared as follows: (i) 21.5 μL of RNase-free water, (ii) 10 μL of 5× reaction buffer, (iii) 1 μL of 1/8x RNasin RNase Inhibitor, (iv) 3 μL of primer mixture 1 (50 pmol each of *mdr1*-specific ODNs), (v) 3 μL of primer mixture 2 (50 pmol each of *bmg*-specific ODNs), (vi) 1 μL of 10 mM nucleoside triphosphates mixture, (vii) 2 μL of 25 mM magnesium sulfate, (viii) 1 μL of AMV reverse transcriptase, and (ix) 1μL of Tfl DNA polymerase. A total of 43 μL of this solution was added to cellular RNA solution, and the mixture was incubated for 45 min at 48 °C. DNA fragments were amplified during 27 cycles: 0.5 min at 94 °C, 1 min at 60 °C, 2 min at 68 °C, using Perkin-Elmer PCR amplificator. PCR products were analyzed by electrophoresis in 2% low-melting agarose gels. PCR markers (Promega, Madison, WI) were used to determine the size of DNA fragments. Bands at 308 bp (*mdr1*-gene) and 120 bp (*bmg*-gene) were cut, and DNA was extracted from agarose in 1 mL of 20 mM tris-EDTA buffer for 15 min at 80 °C. The amount of the extracted DNA was quantified using PicoGreen solution (Molecular Probes, Eugene, OR) as described elsewhere (*14*).

Western Blot Experiment. Western blot analysis of P-gp was done as described previously (*15*).

RESULTS

Synthesis of Cationic Copolymers. The nomenclature and characteristics of the cationic copolymers synthesized are presented in Table 1. PEG(8K)-*g*-PEI(2K) copolymer was synthesized by grafting PEG chains to the amino groups of PEI as previously described (*6*). The scheme of synthesis of biotin-PEG(8K)-*g*-PEI(2K) copolymer is presented in Figure 1. According to this scheme, PEG was initially converted to monoamino-PEG (stages a, b, c, d), which was then modified with biotin *p*-nitrophenyl ester yielding biotin-PEG (stage e). After that, the free end hydroxyl group of the biotin-PEG was activated by 1,1′-carbonyldiimidazole (stage f), and then activated biotin-PEG was conjugated to the PEI (stage g). The product was separated by precipitation into ether and further analyzed by GPC on SigmaChrom GFC-1300 column in 20% ethanol. This analysis showed no significant impurities of the initial reaction components (less that 5% total).

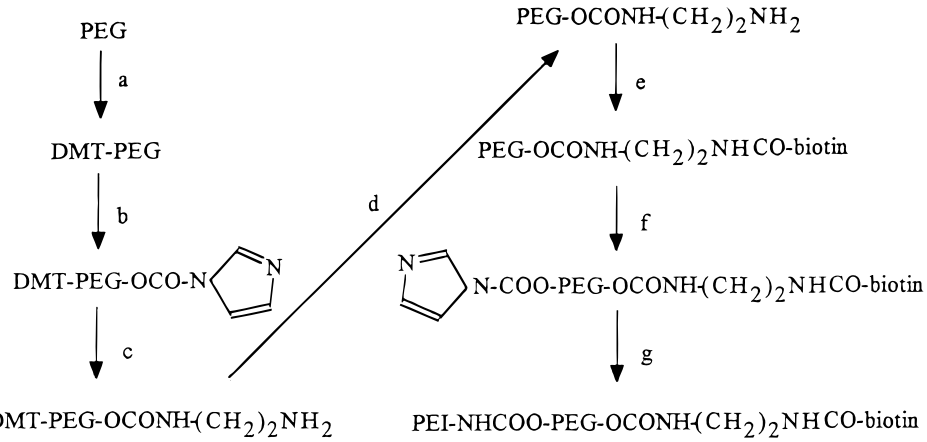

Figure 1. Synthesis of biotinylated copolymers. (a) Dimetoxytrityl chloride, pyridine, 4 h; (b) 1,1′-carbonyldiimidazole, acetonitrile, 18 h; (c) ethylenediamine, ethanol, 18 h; (d) 2% trifluoroacetic acid, dichloromethane, 5 min; (e) biotin *p*-nitrophenyl ester/triethylamine, dimethylformamide, 18 h; (f) 1,1′-carbonyldiimidazole, acetonitrile, 18 h; (g) PEI, ethanol, 18 h.

The ratios of the PEG and PEI chains in the copolymer samples were determined from ^{1}H NMR spectra using integral values obtained for the CH_2CH_2O protons (PEG) and CH_2NH protons (PEI). The molecular masses (M_{GPC}) of these copolymers were determined by GPC analysis. For both copolymer samples used in this work, PEG(8K)-*g*-PEI(2K) and biotin-PEG(8K)-*g*-PEI(2K), the molecular masses were in reasonable agreement with the ^{1}H NMR analysis of the contents of the PEG and PEI fragments in these copolymers (Table 1).

Comparison of the PEG:PEI ratio 2.3 obtained from ^{1}H NMR with biotin:PEI ratio 2.5 obtained from the elemental analysis suggests that within the margin of the experimental error, every PEG chain in the biotin-PEG(8K)-*g*-PEI(2K) copolymer contains approximately one biotin moiety (Table 1). The biotin content in this copolymer determined using the functional assay based on displacement of the fluorescent probe 2-anilinonaphthalene-6-sulfonic acid in avidin binding centers was 26 mg/g of the copolymer (Table 1). This amount corresponds to ca. 2.0 functionally active biotin groups in the biotin-PEG(8K)-*g*-PEI(2K) molecule, suggesting that at least 80% of biotin groups in this copolymer can interact with the avidin.

Coupling of Biotinylated Copolymers with Biotin-Transferrin through Avidin. Binding of (*1*) the biotin-PEG(8K)-*g*-PEI(2K) copolymer with avidin and (*2*) the biotin-PEG(8K)-*g*-PEI(2K)/avidin complexes with biotin-transferrin conjugate was further studied by analytical chromatography using Sephadex G-100 column. An example of the typical result obtained during chromatography experiments is presented in Figure 2. In this example, the retention time of the biotin-PEG(8K)-*g*-PEI(2K) copolymer is decreased when avidin is added to the copolymer at 1 mol equiv of avidin/1 mol equiv of biotin. There were no peaks corresponding to either free biotin-PEG(8K)-*g*-PEI(2K) copolymer or free avidin in the mixture, suggesting that binding of the biotinylated copolymer and avidin is complete. Further addition of biotin-transferrin to the preformed biotin-PEG(8K)-*g*-PEI(2K)/avidin complex altered the chromatographic profile of the mixture, suggesting that the three component biotin-PEG(8K)-*g*-PEI(2K)/avidin/biotin-transferrin complex is formed. The resulting complex was eluted in the free volume of the column. This experiment demonstrates that biotin-PEG(8K)-*g*-PEI(2K) copolymer can be effectively linked to biotin-transferrin using the avidin "bridge".

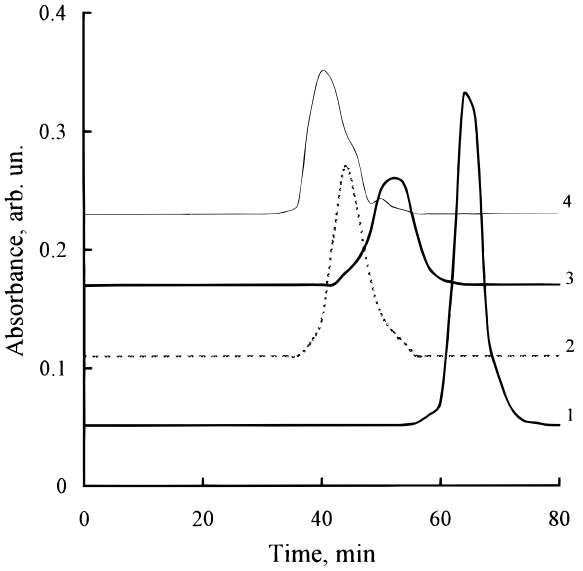

Figure 2. Chromatographic profiles of biotin-PEG(8K)-*g*-PEI(2K) alone (**1**), biotin-PEG(8K)-*g*-PEI(2K) and FITC-avidin mixture (**2**); FITC-avidin alone (**3**), and biotin-PEG(8K)-*g*-PEI(2K)/FITC-avidin complex mixed with biotin-transferrin (**4**). Biotin-PEG(8K)-*g*-PEI(2K) and FITC-avidin were mixed at 1 equiv of avidin per 1 equiv of biotin and incubated for 1 h at 25 °C; biotin-transferrin was added to this mixture at 1 equiv of biotin-transferrin per 1 equiv of avidin and incubated 2.5 h. Chromatography: Sephadex G-75 (fine) column (1 × 30 cm), eluent PBS, pH 7.4, elution rate 0.2 mL/min, UV-light absorption at 230 nm.

Incorporation of SODN in the Complexes. SODNs were mixed with the cationic copolymers to prepare SODN−copolymer complexes. At this stage mixtures of biotin-free PEG(8K)-*g*-PEI(2K) (*F*) and biotin-PEG(8K)-*g*-PEI(2K) (*B*) copolymers at various weight ratios (*F*/*B*, w/w) were used to adjust the number of the biotin moieties linked at the surface of the SODN−copolymer complex. The ratio of the amounts of total nitrogen groups (N) in the copolymers and thiophosphate groups (P) in SODN was kept constant at $N/P = 4$ based on the results of the previous report (*6*) to ensure complete incorporation of the SODN in the complexes. As is seen in Table 2, the sizes of particles formed by SODN and PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K) mixtures practically did not depend on the *F*/*B* ratio and were ca. 40 nm. After addition of avidin to these complexes, the sizes were increased reaching from ca. 57 to 62 nm,

Table 2. Effective Diameters of Particles Formed by S4 SODN and PEG(8K)-*g*-PEI(2K)/Biotin-PEG(8K)-*g*-PEI(2K) Mixtures at Various *F*/*B* Ratios without Avidin and Biotin-Transferrin and in the Presence of Avidin and Biotin-Transferrin

system studied[a]	effective diameter (nm)[b]		
	F/*B* = 24	*F*/*B* = 11.5	*F*/*B* = 7.3
S4/copolymer complex alone	39.9 ± 0.1	40.5 ± 0.5	39.1 ± 0.2
S4/copolymer complex + avidin	62.6 ± 2.9	59.4 ± 0.5	57.0 ± 3.3
S4/copolymer complex + avidin + biotin-transferrin	75.5 ± 0.8	103 ± 1	91.6 ± 0.2

[a] Complexes were prepared as described in the Materials and Methods in 50 mM phosphate buffer, pH 7.4, at **S4** concentration 5 μM and total *N*/*P* ratio 4. [b] Means ± SD, $n = 3$.

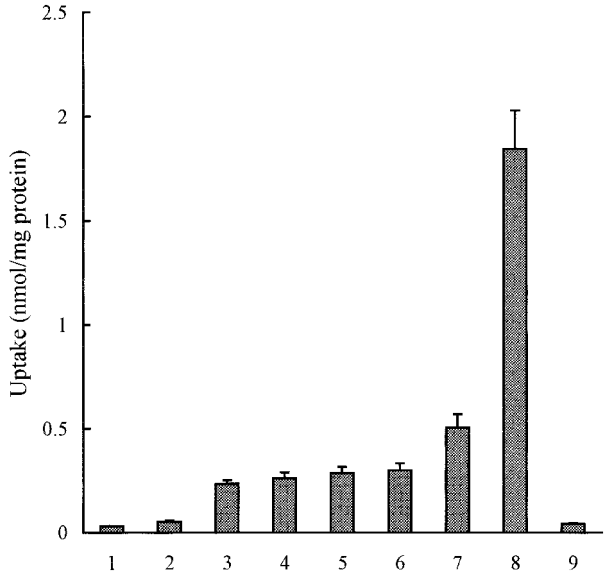

Figure 3. Cellular accumulation of FITC−SODN following exposure of KBv cells to free FITC−SODN (column 1), avidin- and transferrin-free complex FITC-SODN/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K) (column 2), transferrin-free complexes FITC-SODN/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K)/avidin (columns 3, 4, 5), transferrin-containing complexes FITC−SODN/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K)/avidin/biotin-transferrin (columns 6, 7, 8), avidin-free mixtures of biotin-transferrin and FITC−SODN/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K) complex (column 9). In the cases of complexes containing mixtures of the biotin-free and biotin-modified copolymers *F*/*B* ratios were 24 (columns 3, 6), 11.5 (columns 4, 7), and 7.3 (columns 2, 5, 8, 9) and *N*/*P* ratios were fixed at 4. In all cases, SODN concentration in the treatment solution was 10 μM. Data are mean ± SEM, $n = 4$.

suggesting that avidin became incorporated into the complex. Finally, the sizes were further increased upon addition of the biotin−transferrin conjugate to this complex and reached from 75 to 103 nm depending on the *F*/*B* ratios, suggesting that tranferrin became incorporated in the complex particles. No aggregation was observed with all these complexes stored at 4 °C for at least several days.

Cellular Accumulation of SODN. For the cellular accumulation studies, KBv cell monolayers were exposed for 6 h to free SODN or various complexes. After that, the cellular levels of FITC−SODN were determined as described in Materials and Methods. As shown in Figure 3 binding of SODN incorporated into complexes containing avidin (columns 3, 4, and 5) was 5- and 9-times higher than that in the cases of avidin-free complex (column 2) and free SODN (column 1), respectively. Cellular levels of SODN in avidin-modified complexes revealed no apparent dependency on the *F*/*B* ratio that determines the number of the biotin residues in the complex. In contrast, complete constructs containing both transferrin and avidin exhibited strong dependency of the SODN levels in cells on the *F*/*B* ratio (columns 6, 7, and 8). At *F*/*B* ratio 7.3 (corresponding to the highest studied content of biotin moieties), the cellular levels of SODN were ca. 80 times higher that those of the free SODN. At the same time, biotin-transferrin conjugate added to the complex in the absence of avidin had no effect on the cellular levels of SODN, which remained the same as in the case of both avidin- and transferrin-free complex (line 9). Therefore, the presence of avidin is essential for exhibition of the transferrin effects in the studied system, presumably, because avidin is necessary for bridging the SODN/copolymer complex with transferrin moieties.

In a separate experiment, SODN localization in the cells was characterized by fluorescent microscopy following a 2 h incubation of KBv cells with SODN−copolymer complexes. For this study, a different fluorescent label, RITC, was used with SODN to decrease the bleaching of the label upon examination of the cells in the fluorescent microscope. As is seen in Figure 4, incorporation of the RITC−SODN in the transferrin-modified complex resulted in increased fluorescence staining of the cells, suggesting stronger cellular accumulation of SODN compared to that observed with the transferrin-free complex. Further localization studies are needed to confirm cytoplasmic and nuclear localization of the SODN, which are apparent in microphotographs in the case of the transferrin-modified complex.

Mdr1 Inhibition by SODNs and Their Complexes. Specific activity of antisense SODN incorporated in the complexes with cationic copolymers was evaluated using MDR cancer cells, KBv, and MCF-7 ADR, expressing P-gp efflux transport protein. To inhibit the expression of P-gp in these cells, antisense SODN **S4** complimentary to the site 546−565 of human *mdr 1*-mRNA was used. This sequence was determined using a computer search for loop-forming sites downstream of the start codon in the *mdr1*-mRNA nucleotide sequence. To confirm that **S4** SODN is able to inhibit the expression of mRNA responsible for the P-gp synthesis in MDR cells, *mdr1*-mRNA levels were quantified by RT-PCR technique following exposure of the cells to SODN as described in Materials and Methods. Two sets of primers were used in the RT-PCR reaction, one set flanking the SODN binding site in the *mdr1*-mRNA and another set specific to the sequence of *bmg*-mRNA. The *bmg*-mRNA was used as an internal standard, and the quantities of *mdr-1*-mRNA fragments were normalized by the quantities of *bmg*-mRNA fragments determined by the RT-PCR reaction in the same mixture. As is shown in Table 3, treatment of the cells with 5 μM **S4** SODN alone decreases the *mdr-1*-mRNA expression level to ca. 51% of that observed in the untreated control. In the same experiment, the effect of the **S4**/PEG(8K)-*g*-PEI(2K) complex on the *mdr-1*-mRNA expression was assessed. As is seen in Table 3, cells treated with this complex expressed ca. 30% of *mdr-1*-mRNA observed in the untreated control groups. Reduction in P-gp expression

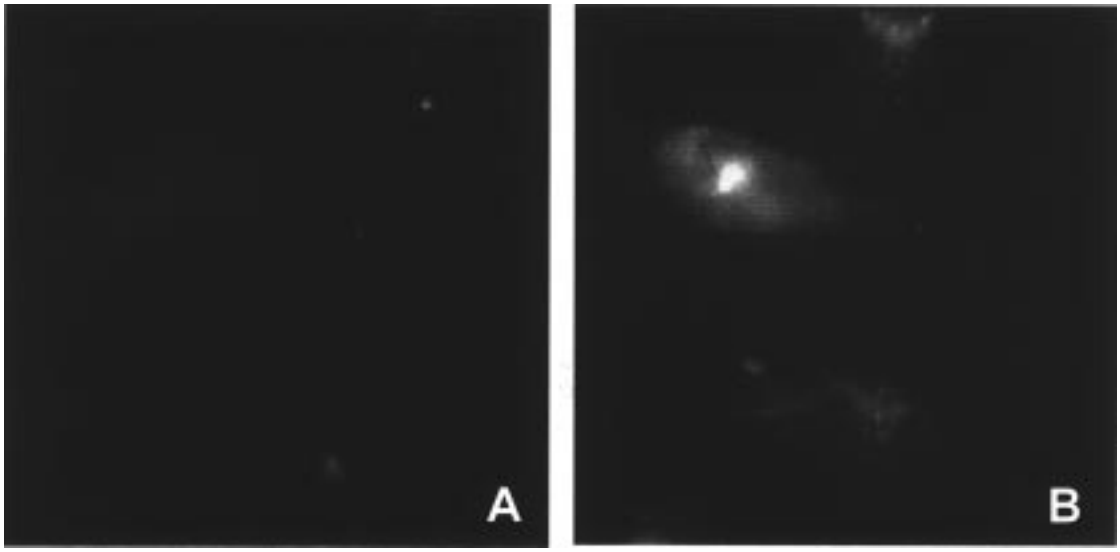

Figure 4. Fluorescent microphotographs of the monolayers of KBv cells following 3 h exposure to (A) RITC-SODN/PEG(8K)-*g*-PEI(2K) complex or (B) RITC-SODN/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K)/avidin/biotin-tranferrin complex at *N*/*P* ratio 4 and *F*/*B* ratio 9. RITC-SODN concentration in the treatment solution was 5 μM.

Table 3. Inhibition of *mdr-1* mRNA Levels in KBv Cells Following Treatment with S4 SODN or S4/Peg(8K)-*g*-PEI(2K) Complex

treatment[a]	*mdr-1* mRNA, arb. un.[b]	P-gp expression, arb. un.[c]
untreated control	1.58 ± 0.12	90
S4 SODN	0.80 ± 0.03	97
S4/PEG(8K)-*g*-PEI(2K) complex	0.49 ± 0.06	58
PEG(8K)-*g*-PEI(2K)	nd	100

[a] **S4** concentration in the treatment solution was 5 μM (RT PCR) or 4 μM (Western blot); **S4**/PEG(8K)-*g*-PEI(2K) complex was prepared at N/P ratio 4. [b] Levels of *mdr-1* mRNA fragments are normalized by the quantities of *bmg*-MNA fragments determined by the RT-PCR reaction in the same mixture. Data are means ± SD, $n = 4$. [c] Levels of P-gp expression are presented based on the densitometry of the Western blot film presented in Figure 5.

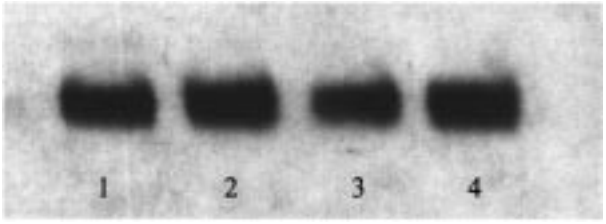

Figure 5. Western blot analysis of P-gp expression in untreated KBv cells (lane 1) and KBv cells treated with free **S4** SODN (lane 2), **S4**/PEG(8K)-*g*-PEI(2K) complex (lane 3) and free PEG(8K)-*g*-PEI(2K) (lane 4). SODN concentration in the treatment solutions was 4 μM (lanes 1−3); PEG(8K)-*g*-PEI(2K) concentration was 0.15 mg/mL (lanes 3, 4) and SODN/PEG(8K)-*g*-PEI(2K) complexes were prepared at *N*/*P* ratio 4 (lane 3).

following exposure of the cells to the **S4**/PEG(8K)-*g*-PEI(2K) complex was demonstrated in the independent Western blot experiment (Figure 5 and Table 3). Western blot shows no changes in the P-gp expression following cell exposure to the PEG(8K)-*g*-PEI(2K) carrier alone. The results of the RT PCR and Western blot experiments suggest that (i) SODN can be released from the complex and reach its molecular target inside the cell, (ii) the specific activity of SODN is increased as a result of its incorporation into the complex. The magnitudes of reduction in the message and protein levels observed in these experiments are consistent with the previous reports describing antisense oligonucleotide inhibition of *mdr1* gene in MDR cells (*16*, *17*).

These conclusions were further validated in the experiments measuring the P-gp functional activity following the exposure of the cell monolayers to the treating solutions containing SODN and various SODN complexes. In these experiments, the functional activity of the P-gp was assessed by accumulation of the P-gp-specific substrate R123 in the cell monolayers. Increased R123 accumulation in the MDR cells is indicative of the inhibition of the P-gp efflux system (*18*, *19*). On the basis of the studies of the kinetics of R123 accumulation in the KBv and MCF-7 ADR cells used in these studies, changes in R123 cellular levels at 60−120 min are indicative of the effects on the P-gp functional activity in these cells (*19*). The R123 accumulation enhancement factors were calculated at the 90 min time point as ratios of R123 accumulation in the treated cells to those in the nontreated cells:

$$\text{enhancement factor} = \frac{\text{R123 accumulation in the treated cells}}{\text{R123 accumulation in the nontreated cells}}$$

Figure 6 presents R123 accumulation factors measured in KBv cell monolayers following treatment of the cell monolayers by **S4** SODN or **S4**/PEG(8K)-*g*-PEI(2K) complex at SODN doses varying from 0.5 to 2 μM. Free SODN at 0.5 and 1 μM practically did not affect R123 accumulation levels (columns 1 and 3). At 2 μM of the free SODN, the treatment resulted in a two times increase in R123 accumulation (column 5). When the **S4**/PEG(8K)-*g*-PEI(2K) complex was used instead of the free SODN, the R123 accumulation was increased at all doses studied reaching ca. two times at 2 μM SODN (columns 2, 4, and 6). It is noteworthy that the complex of the randomized SODN, **RS4**/PEG(8K)-*g*-PEI(2K) at 2 μM was practically inactive (column 7). This suggests that the effects of SODN complexes on R123 accumulation were sequence specific.

The final experiment reported here characterizes the effects of transferrin bound to the SODN−copolymer complexes on the activity of antisense SODN incorporated into these complexes. To incorporate transferrin, the complexes displaying biotin groups were supple-

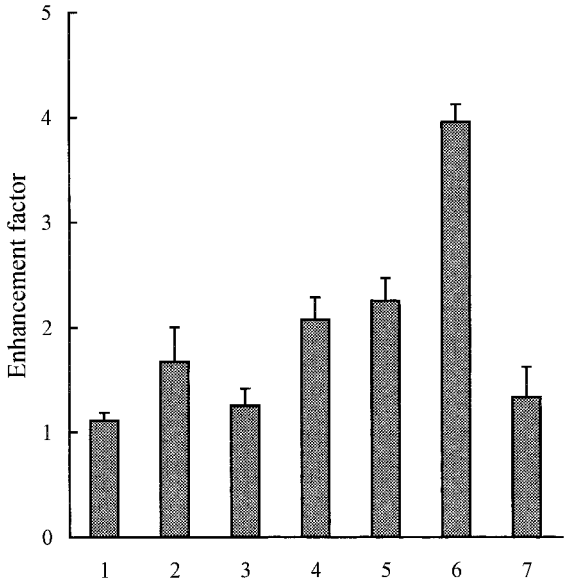

Figure 6. Enhancement of R123 accumulation in KBv cell monolayers following treatment of the cells with free **S4** SODN (columns 1, 3, 5), **S4**/PEG(8K)-*g*-PEI(2K) complex (columns 2, 4, 6) and **RS4**/PEG(8K)-*g*-PEI(2K) (column 7). SODN concentrations in the treatment solutions were 0.5 μM (columns 1, 2), 1 μM (columns 3, 4), and 2 μM (columns 5, 6, 7). SODN/PEG(8K)-*g*-PEI(2K) complexes were prepared at *N*/*P* ratio 4. Data are mean ± SEM, $n = 3$.

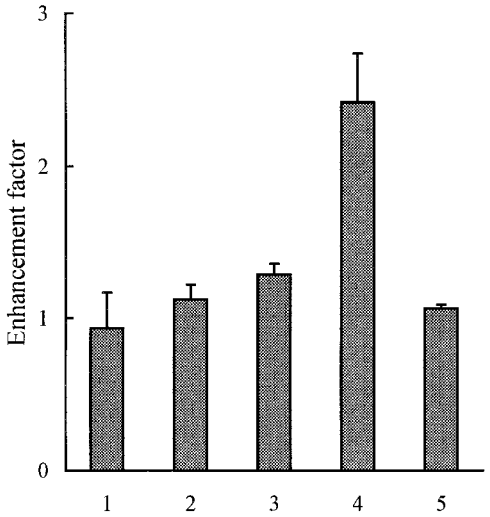

Figure 7. Enhancement of R123 accumulation in MCF-7 ADR monolayers following treatment of the cells with free **S4** SODN (column 1), **S4**/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K) complex (column 2), **S4**/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K)/avidin/biotin-transferrin complexes (columns 3, 4) and **RS4**/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K)/avidin/biotin-transferrin complexes (column 5). In the cases of complexes containing mixtures of the biotin-free and biotin-modified copolymers *F*/*B* ratios were 9 (columns 2, 4, 5) and 19 (column 3) and *N*/*P* ratios were fixed at 4. In all cases, SODN concentration in the treatment solution was 0.5 μM. Data are mean ± SEM, $n = 3$.

mented first by avidin and then by biotin−transferrin conjugate. The monolayers of MCF-7 ADR cells were treated with 0.5 μM SODN or its complexes of various composition and the P-gp activity was determined in the R123 accumulation experiment. As is seen in Figure 7, the free **S4** SODN or its complex with cationic copolymers without avidin and transferrin did not affect R123 accumulation in the cells under conditions studied (columns 1 and 2). Also transferrin-containing complex of

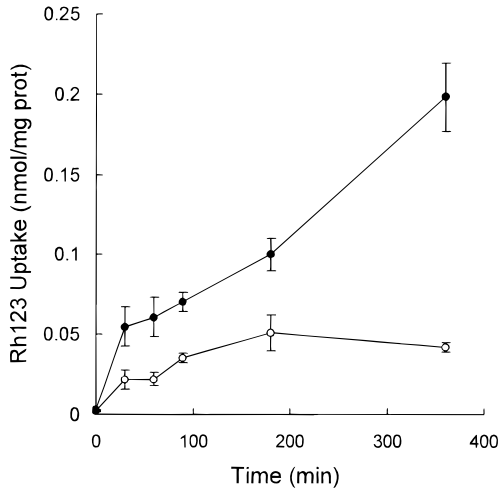

Figure 8. Kinetics of R123 accumulation in MCF-7 ADR cell monolayers following treatment of the cells with free **S4**/PEG(8K)-*g*-PEI(2K) complex (empty circles) and **S4**/PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K)/avidin/biotin-transferrin complex (filled circles). Complexes were prepared at *N*/*P* ratio 4 and *F*/*B* ratio 9 (transferrin-containing system). SODN concentration in the treatment solution was 0.5 μM. Data are mean ± SEM, $n = 3$.

S4 prepared at *F*/*B* ratio 19 appeared to be practically inactive (column 3). At the same time, there was a significant increase in R123 accumulation following treatment of the cells with transferrin-containing complex of **S4** prepared at *F*/*B* ratio 9 corresponding to higher transferrin content (column 4). In contrast, the transferrin-containing complex of nonspecific oligomer **RS4** with the same content of transferrin practically did not affect the R123 accumulation, which suggests that the effects observed with the **S4** complex were sequence specific. The kinetics of R123 accumulation in MCF-7 ADR cell monolayers following treatment of the cells with transferrin-modified and transferrin-free complexes of antisense SODN are shown in Figure 8. It is noteworthy that no effect on R123 accumulation was observed in non-MDR cells, KB, and MCF-7, following cell exposure to **S4** or its various complexes described in this work (data not shown).

DISCUSSION

Previous work reported a novel type of polycationic carrier for delivery of antisense SODNs on the base of PEG and PEI graft copolymers (*6*). PEG(8K)-*g*-PEI(2K) copolymer was shown to form spontaneously electrostatic complexes with SODN in aqueous solutions at physiological pH and ionic strengths. These complexes self-assemble in small supramolecular particles with a core from neutralized PEI and SODN chains and a corona from PEG. Due to the effect of the PEG corona, these particles are stable in aqueous solution for apparently unlimited amounts of time. Thermodynamic stability of such complexes in aqueous solutions appears to be an intrinsic property of the whole class of polyion complex micelles (also termed "block ionomer complexes") to which such systems belong (*20*, *21*). From, the drug delivery standpoint, it is important that SODNs incorporated in the complex with PEG(8K)-*g*-PEI(2K) are resistant against digestion by nucleases (*6*). Furthermore, these complexes were shown to be stable in the presence of serum proteins, such as negatively charged bovine serum albumin, which does not displace the SODN in the complex

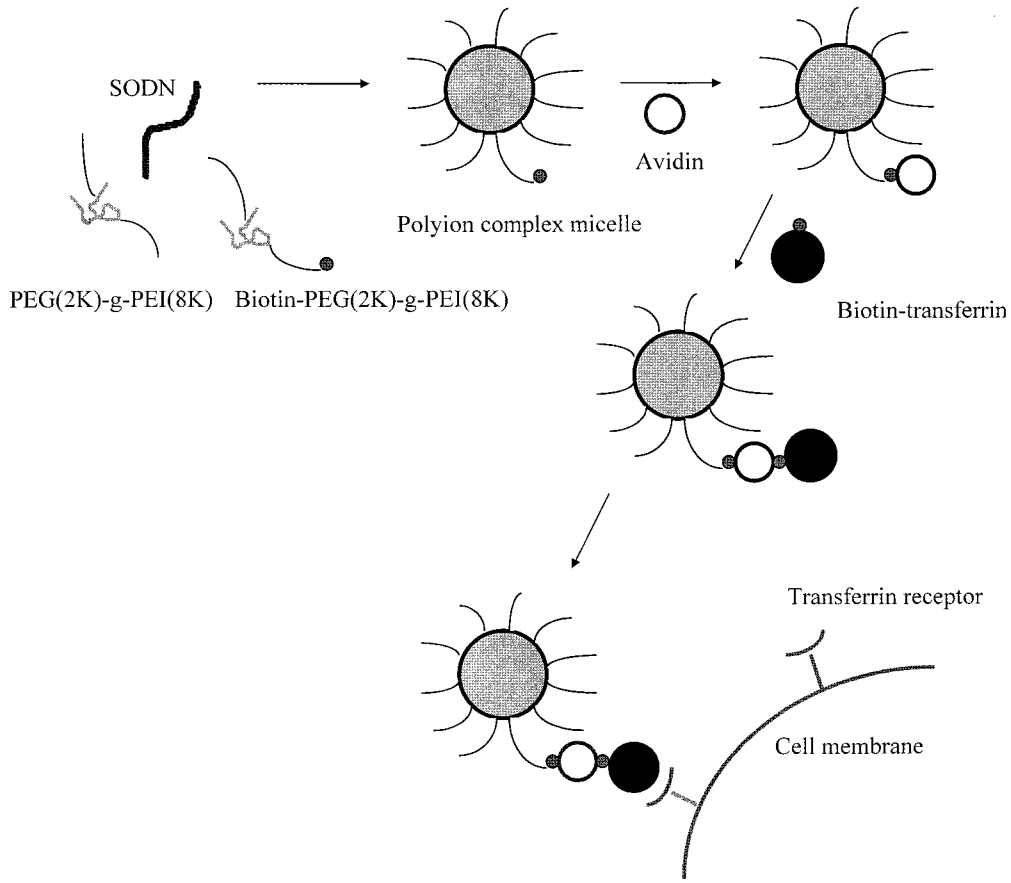

Figure 9. Schematic illustrating formation of transferrin-modified polyion complex micelle using avidin/biotin construct and its binding to transferrin receptor at the cell surface.

with PEG(8K)-*g*-PEI(2K), although it can bind electrostatically to the copolymer in the absence of the SODN (*6*).

The results of the study for the first time show that SODN incorporated in the complex with PEG(8K)-*g*-PEI-(2K) exhibit significant activity in inhibition of *mdr 1* gene expression in cells. This means that despite high stability of the SODN/PEG(8K)-*g*-PEI(2K) complex the SODN is released from this complex upon interaction with a cell and reaches its molecular target inside a cell. Further, this study shows that the polyion complex micelles from SODN and PEG-*g*-PEI copolymers can be additionally modified by transferrin that promotes uptake of the complex in the cell and increases transfection. The modification is carried out in this work using avidin/biotin construct. The biotin moieties are introduced at the free ends of the PEG chain in the PEG-*g*-PEI copolymer. Molecular characteristics of the resulting biotin-PEG(8K)-*g*-PEI(2K) copolymer (molecular mass, PEG:PEI ratio, nitrogen content) are relatively close to those of the PEG(8K)-*g*-PEI(2K) copolymer. The complexes formed between SODN and PEG(8K)-*g*-PEI(2K)/biotin-PEG(8K)-*g*-PEI(2K) mixtures are stable in solution and have small sizes of ca. 40 nm, appearing to be very similar to SODN/PEG(8K)-*g*-PEI(2K) complexes. These complexes, however, contain biotin moieties in the corona, which was used to attach transferrin through the biotin/avidin construct as is schematically shown in Figure 9. For this purpose, the particles of the complex were first supplemented with avidin and then supplemented with biotin−transferrin conjugate. Egg white avidin contains four biotin-binding sites and serves in this construct as a linker between biotin containing complex and biotin−transferrin conjugate.

Interestingly enough, cellular accumulation studies using fluorescently labeled SODN suggest that avidin alone (without transferrin) attached to the surface of the complex increases the uptake of the SODN into cells. A marked enhancement of cellular uptake of biotinylated ODN in the presence of avidin has previously been reported (*22*). This effect was explained by the binding of avidin, a cationic protein, with the cell membrane stimulating the adsorption-mediated endocytosis of the biotinylated ODN−avidin complex. It is likely that similar reason underlies the enhanced uptake of the avidin-modified polyion complex micelles observed in this work. Attachment of transferrin to such complexes further enhances the uptake of the SODN into cells. Furthermore, transferrin-modified complexes carrying antisense SODN targeted to human *mdr1* gene were shown to be the most effective in inhibition of the P-gp functional activity in MDR cancer cells. Transferrin conjugates with polylysine have previously been described as efficient carriers for DNA delivery into cells (*23*). These conjugates promote DNA uptake and transfection as a result of transferrin interaction with the transferrin receptor at the cell surface. We hypothesize that the effects of surface modificatioin of the polyion complex micelles with transferrin on cell accumulation and activity of SODNs incorporated in the complex are due to a similar mechanism involving binding of transferrin with a cell receptor (Figure 9).

In conclusion, this work provides a method for incorporation of the protein molecules in the PEG corona of the polyion complex micelles using avidin/biotin construct. The use of biotinylated copolymers described in this work provides a universal and convenient way to modify the surface of the DNA−copolymer complexes

with various peptides, which can be applied to screen peptide sequences to enhance gene transfer. One promising candidate for future studies using such complexes is the peptide containing R-G-D sequence, which binds to α_v integrin (*24*). Attachment of this peptide to the plasmid DNA−lipofectin complex was shown to improve gene transfer in several cell lines, which was mediated by the interaction of this peptide with integrin. Another promising candidate is 30 amino acid long peptide P3, derived from monoclonal anti-DNA auto-antibodies that were shown to spontaneously penetrate into cells and accumulate into nucleus (*25*). This peptide conjugated to a polylysine sequence was shown recently to be an efficient vector for gene transfer in several cell lines. While conjugates of polycations with peptides has been evaluated as carriers for nonviral gene delivery, there has been a concern about immunological reactions and related side effects during administration of such conjugates in vivo. It is known that conjugation of natural or synthetic haptene with a polycation dramatically enhances the immune response of an organism with respect to that haptene (*26*). In contrast, modification of peptides with PEG chains is known to decrease the immune response with respect to these peptides (*27*). Therefore, using specific peptides linked to cationic copolymers via PEG chains might have practical significance in the future by decreasing the side effect problem for the in vivo applications.

ACKNOWLEDGMENT

The National Science Foundation (BES-9712657) and Nebraska Research Initiative (Gene Therapy Initiative) supported this work. Supratek Pharma Inc. sponsored the synthesis and characterization of the cationic copolymers. Dr. Kabanov serves as a consultant to this company. M-H-W Laboratories (Phoenix, AZ) did elemental analysis. Core laboratories at the University of Nebraska Medical Center (Omaha, NE) carried out the NMR measurements and SODN synthesis. The authors thank Dr. Valery Alakhov (Supratek Pharma Inc.) for very useful discussions of the block copolymer based gene delivery systems. Dr. Tatiana Bronich (UNMC) is acknowledged for determining the molecular masses of the copolymers. Dr. Ludmila Chystiakova (Supratek Pharma Inc.) is provided helpful advice on RT-PCR experiment.

Identification of Fluorescein-5′-Isothiocyanate-Modification Sites in Proteins by Electrospray-Ionization Mass Spectrometry

Volker Schnaible and Michael Przybylski*

Fakultät für Chemie, Universität Konstanz, 78457 Konstanz, Germany. Received April 9, 1999; Revised Manuscript Received June 1, 1999

Model peptides and proteins, such as hen eggwhite lysozyme, have been modified with fluorescein-5′-isothiocyanate (FITC) to yield the corresponding fluorescein-thiocarbamoyl (FTC) conjugates (*N,N′*-disubstituted thiourea and dithiourethane adducts). The extent of FITC incorporation, i.e., number of modified residues, has been identified by direct molecular weight determination using matrix-assisted laser desorption−ionization and electrospray-ionization mass spectrometry (MALDI-MS; ESI-MS). A specific fragmentation by cleavage of the FTC moiety from modified residues occurs by nozzle-skimmer dissociation in ESI mass spectra at increased declustering potential. This fragmentation pathway is easily obtained and renders ESI-MS an efficient tool for the characterization of FITC-modified proteins, and identification of modification sites in FTC−peptide mixtures.

INTRODUCTION

The modification of proteins by fluorescein-5′-isothiocyanate (FITC)[1] is an established method to generate fluorescent proteins, e.g., in antibodies (*1*), which then can be detected in low quantities according to the number of FITC molecules incorporated into the protein. FITC reacts with amino and thiol groups of proteins to yield fluorescein-5′-thiocarbamoyl (FTC) conjugates, *N,N′*-disubstituted thiourea and dithiourethane adducts (as shown in the reaction scheme in Figure 1) (*2, 3*). According to the general pathway of the Edman coupling with aryl-isothiocyanate, only the thiourea adducts are stable at alkaline pH and in the presence of nucleophiles such as β-mercaptoethanol (*4*).

Eukaryotic ATPases (*5*) and recombinant partial ATPase sequences have been specifically modified by FITC at the ATP-binding region (*6, 7*). To obtain structural information about FITC modified ATPases, e.g., by fluorescence energy transfer (*8*), the molecular characterization of the number and the precise location of FITC-modified amino acid residues are crucial. To determine the sites modified by FITC, enzymatic digestion of the modified proteins is usually carried out, and the proteolytic peptide mixture separated by HPLC. FITC-labeled peptides are then identified by Edman degradation (*9*) or mass spectrometry (*10, 11*). However, pure peptide samples for Edman degradation are frequently difficult to obtain (*11*). The direct analysis of proteolytic peptides from complex mixtures, e.g., upon enzymatic digestion has been employed by mass spectrometric peptide mapping with both electrospray-ionization and matrix-assisted laser desorption−ionization mass spectrometry (ESI-MS, MALDI-MS) (*12*−*15*). As shown in several recent studies, mass spectrometric peptide mapping provides the exact information of the number and distribution of covalent modification sites in the protein (*16, 17*). Furthermore, it has been shown that peptide backbone fragmentation in ESI-MS can be induced at increased declustering potential (*18, 19*) (ΔCS), normally used to assist the desolvation of the initial charged microdroplets. This fragmentation occurs in the nozzle-skimmer region of the electrospray ion source, and is therefore readily observed, e.g., with single quadrupole instruments (*18, 20*). In the present study, a specific fragmentation of FITC-modified side chains at increased declustering potential has been investigated and used for the identification of FITC-modification sites. This is illustrated by an FITC-modified model peptide (LGYLGYL-$CONH_2$), hen eggwhite lysozyme (HEL) as a well characterized model protein, and by peptides of FITC modified HEL following trypsin digestion.

EXPERIMENTAL PROCEDURES

Materials. Solvents and reagents were of highest available purity from Merck (Darmstadt, Germany). The following reagents and proteins were obtained from Sigma (St. Louis, MO): DTT, FITC Isomer I, HCCA, hen eggwhite lysozyme (HEL), and trypsin (TPCK treated). The model peptide LGYLGYL-$CONH_2$ was synthesized by solid-phase peptide synthesis (SPPS) using the Fmoc strategy on a semiautomatic peptide synthesizer EPS 221 from Abimed (Langenfeld, Germany). The synthesis product was purified by HPLC. Homogeneity of the peptide was ascertained by MALDI and ESI-MS.

FITC Modification of HEL. (a) A total of 100 μg of HEL was dissolved in 100 μL of 50 mM NaH_2PO_4 buffer, pH 8. A total of 39 μg of FITC was added using a freshly prepared stock solution (c = 1.95 μg/μL) in DMSO. The molar ratio of FITC:HEL is 14 under these conditions. The reaction was carried out for 17 h at 25 °C in the dark and quenched by addition of 400 μL of acetone at −20 °C followed by centrifugation (5 min at 13000*g*) after storage at −20 °C for 1 h. The supernatant containing free excess FITC was discarded and the pellet washed twice with 500 μL of acetone at −20 °C. The pelleted protein was then redissolved in 200 μL of acetonitrile/aqueous 0.1% TFA (v/v = 2:1) and purified by HPLC. (b) A total of 3 mg of HEL were dissolved in 1.08 mL of 50 mM NaH_2PO_4-buffer, pH 8. A total of 480 μg of FITC were added using a freshly prepared stock solution in (c = 3.9 μg/μL) 120 μL of DMF. The molar ratio FITC:HEL is 6 under these conditions. The reaction was carried out at 25 °C. A total of 200 μL samples were taken from the reaction mixture after 0, 30, 60, 120, and 300 min and 55 h reaction time. The reaction was quenched by the addition of 800μL of −20 °C cold acetone to the 200 μL samples. The protein was pelleted after 1 h storage at −20 °C by centrifugation (5 min at 13000*g*). The supernatant was discarded and the pellet washed twice with 500 μL of −20 °C cold acetone. The pelleted protein then was subjected to trypsin digestion.

FITC Modification of Synthetic Peptide LGYL-GYL-$CONH_2$. FITC modification of the synthetic peptide, LGYLGYL-$CONH_2$, was carried out with 90 μg of the peptide dissolved in 280 μL of 100 mM sodium borate buffer, pH 9. A total of 20 μL of a freshly prepared 20 mM solution of FITC in DMF was added. The reaction was terminated after 12 h. The reaction mixture was purified by HPLC, since the removal of unbound reagent by acetone precipitation was not possible. The HPLC fraction containing FITC-derivatized peptide was analyzed by ESI-MS.

Trypsin Digestion of FITC-Modified HEL. A 500 μg sample of FITC-modified HEL, prepared by a reaction time of 55 h, was redissolved in 50 mM NH_4HCO_3 buffer, pH 8, containing 30% methanol (*21*) to yield a final protein concentration of 1 μg/μL. The high methanol content is crucial to achieve digestion of HEL, which is highly resistant to proteolysis in the native state. A solution of freshly prepared trypsin in 50 mM NH_4HCO_3 was added to yield an enzyme-to-substrate ratio of 1:30. The digestion was carried out for 18 h at 37 °C. A 10-fold excess of DTT per cysteine residue was added, the reduction was carried out for 1 h, and then stopped by addition of 10 μL of 10% TFA. A 1 μL aliquot of the reaction mixture was taken for mixture analysis by MALDI-MS. The digestion mixture was centrifuged for 5 min at 13000*g* in order to remove partially digested protein which precipitates upon DTT reduction. The supernatant was subjected to HPLC separation and subsequently analyzed by MALDI-MS. A complete coverage of the HEL-sequence was achieved, although some of the protein is lost due to the precipitation.

HPLC Separation. All HPLC separations were performed with a Waters/Millipore solvent delivery system (high-pressure pumps model M 510 and M 45) using a binary gradient of 0.1% TFA in water and 0.07% TFA in acetonitrile. Separation was carried out on a (250 × 8 mm) Macherey & Nagel C_8-Nucleosil RP-HPLC column using linear gradients of 45 min (1% acetonitrile/min from 40 to 60%) for the FITC-modified HEL and of 80 min (1% acetonitrile/min from 5 to 55%) for the tryptic digestion mixtures. Peak detection was performed with a Waters 490 E multiwavelength detector system at a wavelength of 220 nm. FITC-modified peptides were also detected with a Shimadzu RF-551 fluorescence detector with the excitation wavelength set to 447 nm and the emission wavelength set to 514 nm. All fractions were manually collected and characterized by MALDI-MS.

Mass Spectrometry. MALDI-MS analyses were carried out with a Bruker Biflex linear time-of-flight spectrometer (Bruker-Franzen, Bremen, Germany) equipped with a UV nitrogen laser (λ = 337 nm) and a dual microchannel plate detector. The acceleration voltage was set to 25 kV. Lyophilized HPLC fractions were redissolved in acetonitrile/aqueous 0.1% TFA (v/v = 2:1) and 1 μL of the solution was mixed with 1 μL of a saturated HCCA solution in acetonitrile/aqueous 0.1% TFA (v/v = 2:1). The digestion mixture of HEL was prepared by mixing 1 μL of the DTT-containing digestion mixture solution with 1 μL of saturated HCCA solution. The dried sample spot was washed with 3 μL of 0.1% TFA, redissolved in acetonitrile/0.1% TFA (v/v = 2:1) and spotted again on the target. Spectra were recorded after evaporation of the solvent and processed by means of the X-MASS data system. Peptide spectra were calibrated internally with insulin and HCCA reference ions. Protein spectra were calibrated externally with the singly and doubly charged molecular ions of HEL.

Nano-ESI-MS (*22, 23*) was carried out with a Vestec A201 single-quadrupole mass spectrometer (Vestec, Houston, TX) fitted with a 10 kV conversion dynode and a 2000 m/z mass range. A home-built nano-ESI source was used (*24*). Borosilicate glass capillaries of the type GC120F-10 from Clark Electromedical Instruments (Pangbourne, U.K.) were used for preparation of the microcapillaries. Capillaries were pulled with a capillary puller model P-97 from Sutter Instruments (Novato, CA) in a two-step cycle. The capillaries were then coated with a thin layer of a gold/palladium alloy using a Polaron SC7610 sputter coater (VG Microtech, Uckfield, U.K.), for providing the high voltage connection. Protein and peptide samples were dissolved in 2% aqueous acetic acid:methanol mixtures (v/v = 9:1 unless otherwise stated). An aliquot of 1−4 μL of the sample solution was loaded by dipping the capillary tip into the sample solution. In case of plugging, the capillary was reopened by briefly touching a glass plate. The loaded capillary was fixed via a PTFE screw in a metal mounting and then pushed forward into the ion source region. The voltage at the capillary tip was set to 1.4−1.5 kV. To obtain a stable spray the capillary was manually adjusted to the nozzle of the ion source. The declustering potential between nozzle and skimmer was adjusted in a range of 10−120 V for recording ESI-MS spectra of intact and fragmented peptides and proteins.

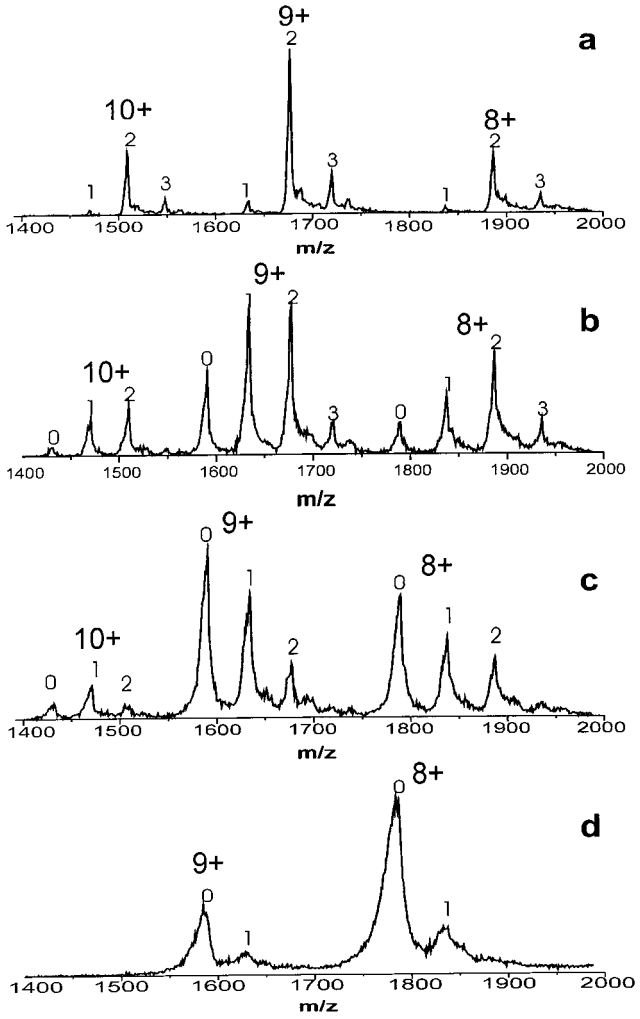

Figure 2. ESI spectra of HPLC purified HEL containing predominantly two FITC groups. Spectra were recorded with different declustering potentials. (a) 10 V; (b) 60 V; (c) 80 V; (d) 120 V. Numbers at the peaks indicate the number of FITC molecules incorporated.

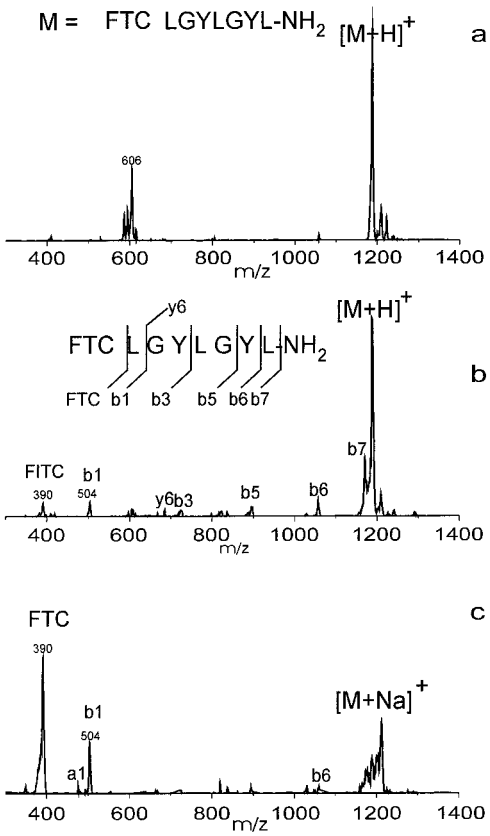

Figure 3. ESI-mass spectra of the FITC modified model peptide LGYLGYL-$CONH_2$ recorded at three different declustering potentials. (a) 10 V; (b) 40 V; (c) 80 V.

RESULTS

HEL was modified for 17 h at 25 °C at pH 8 using a molar ratio of FITC:HEL of 14. After the removal of unbound FITC by acetone precipitation, MALDI-MS was used to ascertain the number of FITC molecules incorporated into the protein. The MALDI-MS spectrum indicated an average incorporation of two FITC groups into the protein. It also revealed that the extent of FITC incorporation is heterogeneous. To isolate homogeneous protein derivatives, FITC-treated HEL was subjected to HPLC separation on a C_8-RP-HPLC column. HEL species with one to four FITC groups were isolated, although the isolation of a single, homogeneous HEL derivative was not achieved. ESI-mass spectra of a HPLC fraction of modified HEL containing predominantly two FTC groups were recorded by application of different declustering potentials as shown in Figure 2. With a declustering potential of 10 V (Figure 2a), the main protein species is 2-fold FITC-modified HEL (molecular mass 15 083 Da). An increase of the declustering potential of the ESI-ion source to 60 V revealed significant fragmentation at the FTC residues of HEL as shown in Figure 2b. The base peak at *m*/*z* 1677 is still corresponding to the $[M + 9H]^{9+}$ molecular ion of a HEL derivative containing two FTC groups, but in addition intense ions of mono-FTC-HEL (molecular mass 14 694 Da) and free HEL (molecular mass 14 305 Da) are detected. At a declustering potential of 80 V (Figure 2c), the $[M + 9H]^{9+}$ molecular ion of unmodified HEL (i.e., removal of all FTC groups) at *m*/*z* 1591 is the base peak of the spectrum. A further increase of the declustering potential up to 120 V (Figure 2d) resulted in a spectrum with broad signals showing complete removal of all FTC residues.

To test whether the nozzle skimmer fragmentation of FTC residues occurs also with FITC-modified peptides, a synthetic model peptide (LGYLGYL-$CONH_2$), (molecular mass 797 Da) was investigated. The N-terminus is the only amino group in this peptide. Since the removal of excess FITC was not possible by acetone precipitation, the reaction mixture was purified by HPLC. The HPLC fraction containing the FITC-modified peptide was subjected to ESI-MS analysis. Figure 3 shows ESI spectra of the modified peptide (molecular mass 1186 Da). Under standard conditions (declustering potential set to 10 V, Figure 3a), the singly and doubly charged molecular ions of the peptide carrying one FTC group are detected. A doubly charged species representing the sodium adduct of the modified peptide was additionally found. With the declustering potential set to 40 V (Figure 3b) sequence fragments of the modified peptide belonging to the b series (*25*), still containing the FTC group and the $[M + H]^+$ ion of the free FTC moiety were observed. With the declustering potential set to 80 V (Figure 3c), predominantly, the $[M + H]^+$ ion of the free FTC moiety was found at *m*/*z* 390. This result with the model peptide confirmed the predominant fragmentation of the FTC-N bond by release of the FTC moiety.

Tryptic digest mixtures of FITC-modified HEL were analyzed by MALDI-MS. Figure 4 shows the MALDI-MS spectrum of a reduced digestion mixture of HEL after

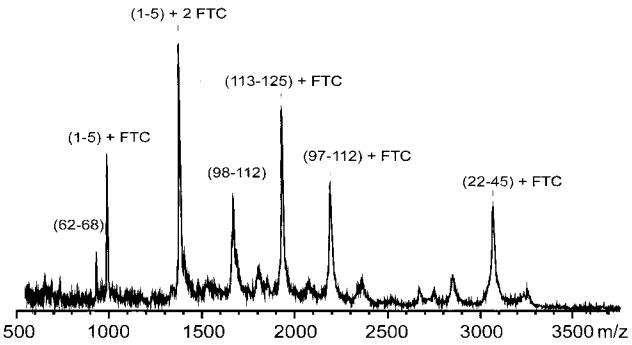

Figure 4. MALDI mass spectrum of a reduced tryptic digest mixture of HEL treated 55 h with 1 mM FITC. Partial tryptic sequences and the number of incorporated FITC labels are assigned.

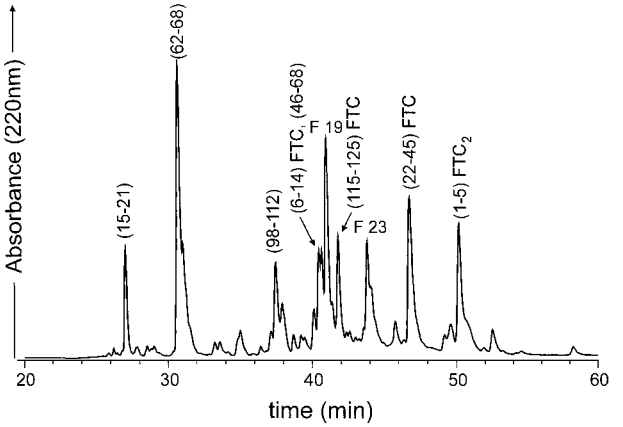

Figure 5. RP-HPLC chromatogram of a reduced tryptic digest mixture of HEL treated 55 h with 1 mM FITC. Partial peptides of HEL are assigned. Fractions 19 and 23 were subjected to ESI-MS (see Figure 6 and Figure 7).

Table 1. Localization of FTC-Residues in HPLC Separated HEL Derivatives

molecular ion with highest intensity (MALDI-MS)	number of FTC-residues incorporated	major modification sites identified by tryptic MALDI-MS peptide mapping
14 693	1	α-NH_2, K-33, K-97
15 110	2	α-NH_2, K-33 K-97
15 503	3	α-NH_2, K-1, K-33, K-97, K-116
15 890	4	α-NH_2, K-1, K-33, K-97, K-116

modification for 55 h at pH 8 at a molar ratio FITC:HEL of 6. The peptide fragments and the number of FITC groups incorporated are assigned to the molecular ions. These results (summarized in Table 1 for HEL derivatives with different degrees of modification) revealed that α-NH_2, K-1, K-33, K-97, and K-116 amino groups were predominantly modified by FITC. The digestion mixture was subsequently separated by RP-HPLC on a C_8 column; the corresponding chromatogram is shown in Figure 5. The isolated peptides were analyzed by MALDI-MS, which showed that K-13 was detected as an additional modification site. No modification was found at K-96, which is consistent with previous results of the amino-acylation of HEL (*26*, *27*). This lysine residue has a particularly low accesibility to chemical modification due the hydrogen bonding to the carbonyl oxygen of H-15.

The HPLC-separated tryptic peptides of FITC-modified HEL were also analyzed by ESI-MS. The effect of different declustering potentials on FTC peptides is illustrated in Figure 6 and Figure 7. Spectra of the homogeneous peptide (97−112) modified with FITC at K-97 (molecular mass 2193 Da) are shown in Figure 6.

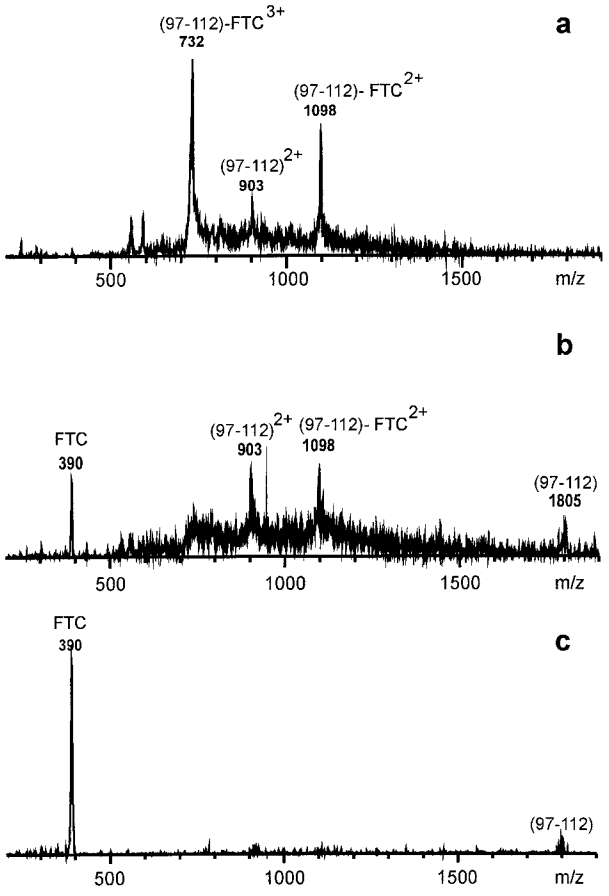

Figure 6. ESI mass spectrum of HPLC fraction 23 (see Figure 5) containing the peptide (97−112) carrying a FITC group at K-97. The sample was dissolved in 2% acetic acid/methanol (v/v = 8/2). Spectra were recorded with declustering potentials of (a) 20 V, (b) 40 V, and (c) 80 V.

The spectrum recorded with a declustering potential of 20 V (Figure 6a) is dominated by signals of the intact FTC peptide. Upon increasing the declustering potential to 40 V (Figure 6b), the signal intensity of the unmodified peptide (97−112) is comparable to the intensity of the FTC peptide, and the free FTC moiety is detected at *m/z* 390. Upon further increase of the declustering potential up to 80 V (Figure 6c), the molecular ions of the FTC peptide had disappeared and only an intense $[M + H]^+$ signal of the FTC moiety together with a weak $[M + H]^+$ signal of the unmodified peptide were observed.

Further studies were carried out to identify FITC-modified peptides from more complex mixtures. Figure 7a shows a spectrum from an HPLC fraction containing several peptides at a declustering potential of 20 V. The abundant signal at *m/z* 1168 (indicated by an asterisk) is due to a trimer of FITC, formed during lyophilization and storage of the HPLC fractions (*28*). (In MALDI-MS spectra recorded directly after HPLC separation, no signal at *m/z* 1168 was detected.) The triply charged molecular ion of the FTC peptide (1−5) (molecular mass 995 Da; B) at *m/z* 333 and the doubly and triply charged molecular ions of the FTC peptide (113−125) (molecular mass 1936 Da; A) at *m/z* 969 and 647 were identified. The unmodified peptide (74−97) (molecular mass 2466 Da; C) was found as doubly and triply charged ions. The $[M + H]^+$ ions of the FTC moiety (*m/z* 390) strongly increased by increasing the declustering potential to 50 V (Figure 7b), and a strong signal at *m/z* 775 corresponding to the doubly charged molecular ion of unmodified peptide (113−125) (molecular mass 1547 Da) was now

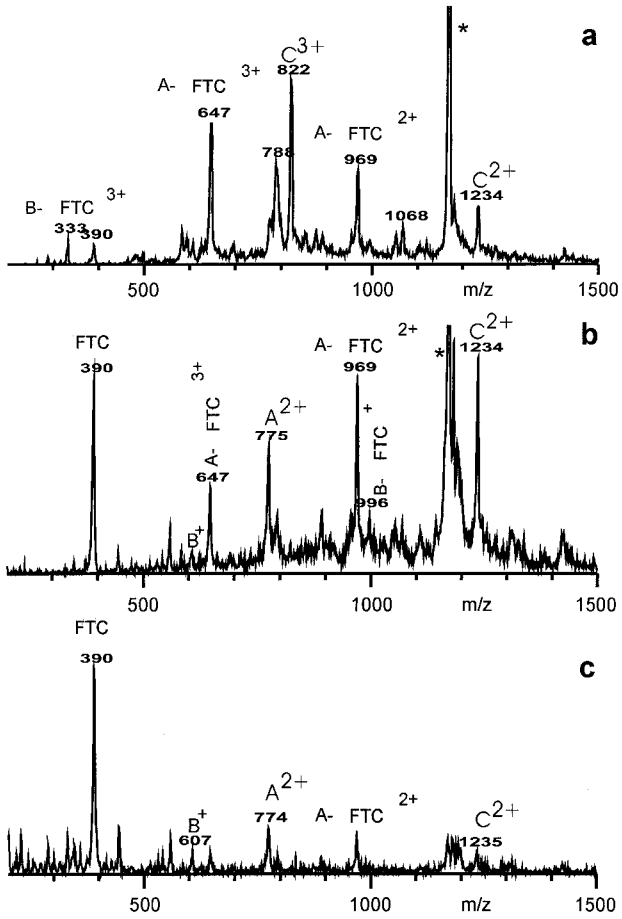

Figure 7. ESI mass spectrum of HPLC fraction 19 (see Figure 5) containing a complex mixture of peptides. The sample was dissolved in 2% acetic acid/methanol (v/v = 8/2). Spectra were recorded with declustering potentials of (a) 20 V, (b) 50 V, and (c) 80 V. A corresponds to the peptide (113−125) (molecular mass 1547 Da). B corresponds to the peptide (1−5) (molecular mass 606 Da). C corresponds to the peptide (74−97) (molecular mass 2466 Da).

observed. The intensity of these ions was further increased at a declustering potential of 80 V (Figure 7c). The identification of the FTC peptide (1−5) was somewhat more difficult since the ion intensities of these signals were very low in all spectra.

DISCUSSION

The results of this study show that the FITC modification provides a broad, inhomogeneous distribution of FTC groups at lysine residues at the conditions employed, as shown for the FITC modification of HEL. For example, the modification of the highly reactive K-97 (*26*) is not quantitative as shown by the intense ions for the peptide (98−112) (molecular mass 1676 Da) in the digestion mixture (see Figure 4); the quantitative modification of K-97 would have abolished the tryptic cleavage at this site. Furthermore, signals of the peptide (1−5) as singly (molecular mass 995 Da) and doubly modified species (molecular mass 1384 Da) were detectable with high intensity, indicating partial modification of the amino groups of K-1. These results are consistent with the MALDI-MS data of the intact, modified proteins where 2−5-fold modified species were found (see Table 1).

The ESI-MS spectra of FITC-modified peptides and proteins show that covalently bound FITC is specifically removed by simple increase of the declustering potential in the ESI ion source. This fragmentation is equally occurring with peptide and protein derivatives, and for α- and ϵ-FTC-amino groups. The site of each FITC modification can be readily assigned by this specific fragmentation.

The direct identification of FITC-labeling sites is possible even when other molecular ions of different intensities are present, as shown by the ESI spectra of a peptide mixture (see Figure 7). Thus, the identification of the number of FTC groups by MALDI-MS and the facile characterization of the specific modification sites by peptide mapping using ESI-MS with increased declustering potentials applied should render this approach an efficient tool for the molecular characterization of fluorescence labeled peptides and proteins, even from complex mixtures.

ACKNOWLEDGMENT

We thank Klaus Hägele for expert assistance in ESI-mass spectrometric procedures. This work has been supported by the Deutsche Forschungsgemeinschaft, Bonn, Germany ("Struktur und Funktionssteuerung an zellulären Oberflächen"), the EU network "Peptide and Protein Structure Elucidation by Mass Spectrometry", and the Fonds der chemischen Industrie, Germany.

Preparation and Characterization of Anti-Tenascin Monoclonal Antibody−Streptavidin Conjugates for Pretargeting Applications

Catherine F. Foulon,* Darell D. Bigner, and Michael R. Zalutsky

Departments of Radiology and Pathology, Duke University Medical Center, DUMC 3808, Durham, North Carolina 27710. Received April 12, 1999; Revised Manuscript Received June 17, 1999

Radioimmunopretargeting is based on the separate injection of a modified mAb and the radionuclide and most frequently exploits the very high avidity of biotin for streptavidin (SA). Currently, we are evaluating the therapeutic potential of directly labeled monoclonal antibody (mAb) 81C6, reactive with the extracellular matrix protein tenascin, in surgically created glioma resection cavity patients. To be able to investigate pretargeting in this setting, the synthesis of 81C6 mAb−SA conjugates was required. In the current study, we have evaluated five methods for preparing both murine 81C6 (m81C6) and human/mouse chimeric 81C6 (c81C6) SA conjugates with regard to yield, biotin-binding capacity, immunoreactivity, and molecular weight. The 81C6 mAb and SA were coupled by covalent interaction between sulfhydryl groups generated on the mAb via *N*-succinimidyl-*S*-acetylthioacetate, dithiothreitol or 2-iminothiolane (2IT), and maleimido-derivatized SA, prepared via sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) or *N*-succinimidyl-3-(2-pyridyldithio)-propionate. A noncovalent approach involving reaction of a biotinylated mAb, prepared using biotin caproate, and SA also was studied. The evaluation criteria were yield of mAb−SA 215 kDa monomer, as well as conjugate biotin-binding capacity and immunoreactive fraction. The optimal procedure involved activation of m81C6 or c81C6 with 30 equiv of 2IT and reaction of SA with 10 equiv of SMCC and yielded a conjugate with excellent biotin-binding capacity and immunoreactivity. The (^{125}I-labeled m81C6)-2IT-SMCC-SA was stable and did not lose biotin-binding capacity after a 72 h incubation in human glioma cyst fluid in vitro. Although the conjugate was stable in murine serum in vivo, its biotin-binding capacity declined rapidly, consistent with high endogenous biotin levels in the mouse. After injection of the radioiodinated conjugate into athymic mice with subcutaneous D-54 MG human glioma xenografts, high tumor uptake (36.0 ± 10.7% ID/g at 3 days) and excellent tumor:normal tissue ratios were observed.

INTRODUCTION

One of the most significant limitations of monoclonal antibodies (mAbs)[1] for radioimmunotherapeutic application is that their large molecular mass impedes homogeneous tumor uptake and clearance from normal tissues. To circumvent this problem, pretargeting strategies have been pursued in which the mAb and the radiolabel are injected separately. In such a protocol, a modified mAb conjugate is injected, and once optimal tumor-to-normal tissue ratios have been achieved (usually, within 2−4 days), a low molecular mass radiolabeled ligand that exhibits high-affinity binding to the conjugate is administered (*1*).

Most pretargeting investigations have attempted to exploit the high-affinity binding of biotin, a 244 Da vitamin, for 65 kDa avidin or 54 kDa streptavidin (SA). Although many different approaches have been described (*2*−*4*), theoretical calculations predict that administration of mAb−SA conjugates, followed by a radiolabeled biotin derivative, should provide optimal tumor targeting (*5*). Indeed, some of the most promising clinical results to date have been achieved with pretargeting protocols that utilize biotin as the radionuclide carrier (*6*, *7*).

Monoclonal antibodies directed against tenascin, an extracellular matrix protein found on gliomas, melanomas, and breast carcinomas (*8*−*10*), might be useful for pretargeting because they do not internalize after antigen binding. Currently, we are investigating the therapeutic potential of the ^{131}I-labeled anti-tenascin mAb m81C6 administered into surgically created glioma resection cavities and via the intrathecal route in patients with neoplastic meningitis (*11*, *12*). Encouraging results have been obtained in many patients with these directly labeled mAbs; however, pretargeting approaches using 81C6-SA conjugates and radiolabeled biotin molecules might offer significant advantages. Recent results suggest that it might be possible to deliver high radiation doses to intracranial malignancies using pretargeting, even when reagents are administered intravenously (*7*). In addition, by labeling biotin instead of the mAb, radiotherapy with promising short half-life radionuclides, such as the 7.2 h half-life α-emitter ^{211}At, should be facilitated.

Prior to initiating clinical investigations, methodologies for the preparation, purification, and characterization of reagents with optimal properties for pretargeting must

be developed. We have recently described the synthesis of radiohalogenated biotin conjugates including (3-[$^{125/131}$I]-iodobenzoyl)norbiotinamide (IBB) and its ^{211}At-labeled analogue and documented their resistance to degradation by biotinidase (*13*, *14*). In the current study, we have investigated several methods for preparing anti-tenascin 81C6-SA conjugates and evaluated them with regard to yield, biotin-binding capacity, immunoreactivity and molecular mass. Approaches involving the noncovalent interaction between biotinylated 81C6 (via sulfo-NHS-BnLC) and SA, as well as covalent binding between SA and thiolated mAb, were investigated. Variables that were studied included SA maleimido-activation (SMCC and SPDP), mAb thiolation (reduction of existing disulfide bonds via DTT, addition of sulfhydryl groups using 2IT or SATA), and mAb (m81C6 and c81C6). Our results indicate that using covalent approaches, a 215 kDa mAb−SA monomer, consisting of one SA molecule and one mAb molecule, can be prepared in reasonable yield and with excellent biotin and antigen binding capacities. Furthermore, (^{125}I-labeled m81C6)-2IT-SMCC-SA exhibited excellent in vitro stability in human glioma tumor cyst fluid and a tissue distribution in athymic mice with subcutaneous D-54 MG human glioma xenografts that compares favorable with that of directly radioiodinated m81C6.

MATERIALS AND METHODS

Materials. Murine 81C6 (m81C6) is an IgG_{2b} that binds to domain 12 of alternatively spliced fibronectin type III repeats of tenascin (*8*, *15*). Details concerning the generation and characterization of human/mouse chimeric 81C6 (c81C6), consisting of human IgG_2 constant regions and m81C6 variable regions, can be found in a previous publication (*16*). Both mAbs were purified using Protein A Sepharose and an ion-exchange method compatible with mAb isoelectric point (*17*). Streptavidin, 2-IT, iodoacetamide, and BnLCsNHS were purchased from Sigma Chemical Co. (St. Louis, MO); all other reagents were purchased from Pierce (Rockford, IL). Radioiodine ($Na^{125}I$ or $Na^{131}I$) in 0.1 N NaOH was obtained from Dupont-NEN (Boston, MA). The radioiodinated biotin conjugates [^{131}I]IBA and [$^{131/125}$I]IBB were prepared as described elsewhere (*13*, *18*).

General. For spin column purification, Sephadex G-25 (Pharmacia, Pistacaway, NJ) was reconstituted in PBS containing 0.05 M EDTA and added to a 3 mL syringe fitted with a cotton ball. The column was conditioned with 200 μL of 0.1% BSA and washed with 3 mL of the above buffer. The column was spun at 1000 rpm for 3 min, the sample (<250 μL) was added, and the column was spun again at 1000 rpm for 3 min in tandem with a 2 mL conical receiving tube. HPLC was conducted on a Beckman system (126 pumps, 168 UV detector set at 280 nm, 170 radioactivity detector, 406 Analogue Interface Module) using either an analytical (60 × 7.5 cm) or semipreparative (60 × 21.5 cm) gel filtration TSK 3000 column (TosoHaas, Montgomeryville, PA), fitted with an appropriate guard column. The eluent recommended by the manufacturer was filtered through a 0.22 μm membrane prior to use and run at flow rates of 1 and 5 mL/min for the analytical and semipreparative columns, respectively. Amicon Centriplus-100 Concentrators were supplied by Millipore (Bedford, MA). Protein quantification was performed at 595 nm using the Bio-Rad Protein Assay based on the method of Bradford (Bio-Rad, Hercules, CA). The extinction coefficient measured for IgG and SA were 71 000 and 1600, respectively. Silica-gel-impregnated glass fiber instant TLC (ITLC) plates were purchased from Gelman Science (Ann Arbor, MI) and cut into 1.5 × 8 cm strips. SDS−PAGE (7.5% polyacrylamide) was run under nonreducing and nonboiling conditions (150 V, 1.5 h) to minimize SA degradation. Nonradioactive materials were analyzed by silver staining while radioactive bands were analyzed by phosphoimaging with a Molecular Dynamics Storm 360 system (Sunnyvalle, CA). Radioactivity was quantified using a LKB 1282 Compugamma automated γ counter run in either single- or dual-channel mode. Higher levels of activity were measured using a Capintec CRC-7R radioisotope calibrator.

Activation of m81C6 with BnLCsNHS. m81C6 (16 mg/mL PBS) was dialyzed overnight in 0.1 M borate buffer, pH 8.5. Biotinylation was carried out by mixing m81C6 (2 mg, 125 μL of borate buffer) and 10 equiv of BnLCsNHS (72 μL, 1 mg/mL 0.9% saline) at room temperature for 30 min. The biotinylated mAb was purified with a Sephadex G-25 spin column.

Activation of m81C6 with SATA and $HONH_2$. m81C6 (16 mg/mL PBS) was dialyzed overnight in 0.1 M borate buffer, pH 8.5, and 2 mg of m81C6 and 10 equiv of SATA (31 μL, 1 mg/mL DMSO) were incubated at room temperature for 30 min. The activated mAb was purified with a Sephadex G-25 spin column and incubated with hydroxylamine (10 μL, 10 mg/mL PBS containing 0.05M EDTA) at room temperature for 1 h. The thiolated mAb was purified by Sephadex G-25 spin column prior to reaction with activated SA.

Activation of 81C6 with DTT. m81C6 or c81C6 (16 mg/mL PBS) was dialyzed overnight in 0.1 M borate buffer, pH 8.5, and 2 mg of m81C6 or c81C6 were incubated at room temperature for 30 min with 10 equiv of DTT (21 μL, 1 mg/mL PBS). After Sephadex G-25 spin-column purification, the thiolated mAb was ready for reaction with activated SA.

Activation of 81C6 with 2IT. c81C6, m81C6, or radioiodinated m81C6 (125 μL, 2 mg) in PBS and 2IT (18 μL, 1 or 3 mg/mL 0.9% saline, 10 or 30 equiv, respectively) were incubated at room temperature for 30 min. The thiolated mAb was purified by Sephadex G-25 spin column prior to reaction with activated SA.

Activation of SA with SMCC. SA (80 μL, 10 mg/mL) in 0.1 M borate buffer pH 8.5 and 10 equiv of SMCC (29 μL, 2 mg/mL 0.9% saline) were incubated at room temperature for 30 min. The maleimido-derivatized SA was purified by Sephadex G-25 spin column prior to reaction with the thiolated mAb.

Activation of SA with SPDP. SA (80 μL, 10 mg/mL 0.1 M borate buffer, pH 8.5) and 10 equiv of SPDP (5 μL, 8 mg/mL DMSO) were incubated at room temperature for 30 min. Prior to reaction with thiolated mAb, the maleimido-derivatized SA was purified using a Sephadex G-25 spin column.

Preparation and Purification of 81C6-SA Conjugates. These reactions were performed on an equimolar basis; generally, 2 mg of mAb and 0.8 mg of SA were used. For mAb−BnLC-SA conjugates, biotinylated m81C6 and SA were incubated at room temperature for 45 min. Preparation of covalent mAb−SA conjugates involved incubation of thiolated 81C6 (unlabeled m81C6, c81C6 or radiolabeled m81C6) and maleimido-derivatized SA at room temperature for 45 min. The reaction was quenched by addition of iodoacetamide (5 μL, 100 mg/mL PBS containing 0.05 M EDTA). All reaction mixtures were purified on the analytical-scale TSK 3000 gel filtration column at a flow rate of 1 mL/min. On this system, m81C6, SA, and iodoacetamide eluted at 15.5, 20.1, and 25.5 min, respectively. Comparison to molecular mass

standards (Bio-Rad) indicated that the peak at 11−12 min was consistent with the presence of the 215 kDa mAb−SA monomer.

When upscaling the preparation of m81C6-2IT-SMCC-SA for the biodistribution study, the reaction mixture was purified by four injections of 11.2 mg of protein on the semipreparative TSK 3000 at a 5 mL/min flow rate. In this system, the conjugate, m81C6 and SA eluted at 17, 22.5, and 29 min, respectively. Excess solvent was removed by concentration over Centriplus 100 (5000 rpm, 40 min), to reach the concentration required (150 μg/200 μL) for the animal experiment.

Analysis of the Conjugates. After HPLC purification, each isolated fraction was subjected to protein assay and SDS−PAGE to determine the molecular mass profile of the species present after the reaction of mAb and SA. HPLC fractions also were evaluated with regard to binding capacity for radiolabeled IBB and immunoreactive fraction.

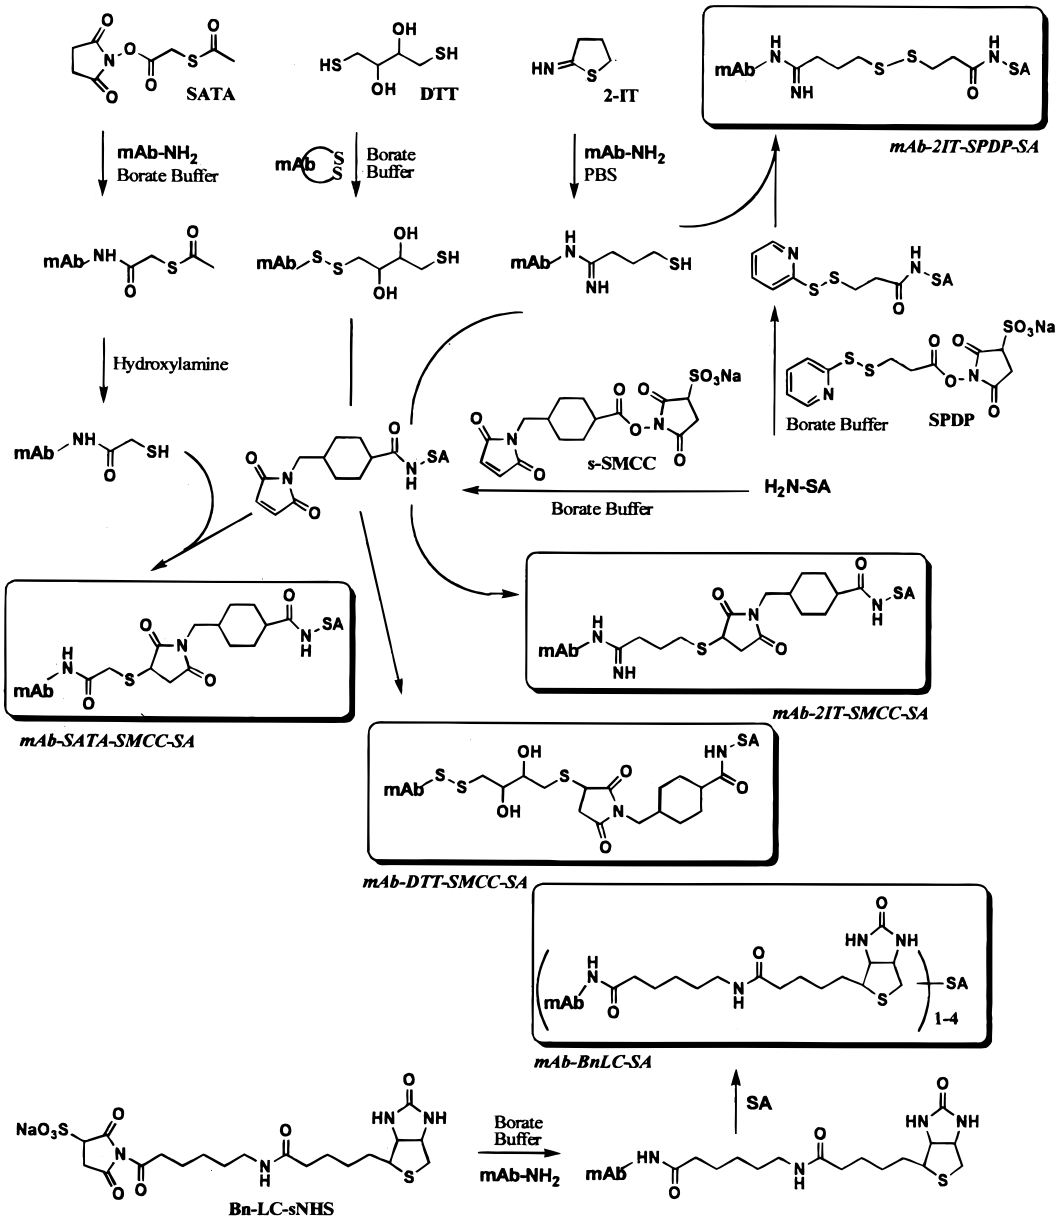
Radiolabeled Biotin Binding Potency. Aliquots (50 μL) from HPLC fractions of interest were incubated with [^{125}I]IBB or [^{131}I]IBB (4 μCi, 10 μL) in 100 μL of saline for 1 h at room temperature. An aliquot (3 μL) was analyzed on ITLC using saline:ethanol (95:5) as the solvent and the fraction of input counts bound to protein was calculated as described (*18*).

Immunoreactivity. SA-coated MPG magnetic beads (5 μm) were obtained from CPG (Lincoln Park, NJ). The beads (1 mL) were mixed with biotinylated recombinant tenascin TnFn 6-12 (positive) or TnFn 6-11 (negative) fragments (100−150 μL, 1 mg/mL) for 3 h at room temperature and rinsed with 115 mM phosphate buffer, pH 7.4, containing 0.05% BSA and 0.05% Brij 35 to remove nonbound proteins. The beads were resuspended in 1 mL of this buffer and stored at 4 °C. Prior to use, beads were incubated with biotin (100 μL, 5 mg/mL saline) for 1 h at room temperature to block any free SA on the beads. Likewise, each mAb−SA conjugate was incubated with an excess of biotin (100 μL, 5 mg/mL saline) to avoid binding of mAb−SA to any free biotin on the tenascin fragments. The immunoreactive fraction was determined by incubating 50 μL of mAb−SA conjugate, labeled with [$^{131/125}$I]IBB as described above, or (^{125}I-labeled mAb)-SA, in triplicate with increasing volumes of beads (10, 20, or 40 μL) in 500 μL of 115 mM phosphate buffer. After 45 min agitation at room temperature, beads were isolated from the supernatant using a magnetic separator, and beads and supernatant assayed for radioactivity on the gamma counter. The specific binding was determined by subtracting nonspecific binding to TnFn 6-11 beads from the binding to TnFn 6-12 beads. The immunoreactive fraction was calculated according to the method of Lindmo et al. (*19*) by plotting the inverse of % specific binding versus the inverse of bead concentration.

Preparation of ^{125}I-Labeled m81C6-2IT-SMCC-SA Conjugate. To a vial coated with Iodogen (10 μg) was added m81C6 (62.5 μL, 16 mg/mL) in PBS and Na^{125}I (∼1 mCi). The vial was placed on an orbital shaker at room temperature for 5 min, and the mixture purified on a Sephadex G-25 spin column. Cold m81C6 (1 mg) was then added, and the m81C6-2IT-SMCC-SA conjugate was prepared by reacting the labeled mAb with 30 equiv of 2IT, followed by a 1:1 reaction with SMCC-SA.

In Vivo Stability of the Conjugate in Normal Mice. Five normal Balb/c mice weighing 20−25 g were injected intravenously with (^{125}I-labeled m81C6)-2IT-SMCC-SA (150 μg, 4 μCi). Blood samples were obtained by retro-orbital bleed 2, 6, 24, and 48 h later. Serum was separated by centrifugation, incubated in triplicate with [^{131}I]IBA (10 μL in saline, 2 μCi) for 30 min at room temperature, and biotin binding monitored by ITLC as described above. Serum samples also were analyzed by SDS−PAGE.

Tissue Distribution Measurements. The HPLC fractions containing the ∼215 kDa peak were pooled and administered intravenously to athymic mice weighing 25−30 g and bearing subcutaneous D-54 MG human glioma xenografts (*20*). Groups of five animals received 150 μg/4 μCi of (^{125}I-labeled m81C6)-2IT-SMCC-SA and were killed by halothane overdose 2, 3, or 4 days later. Organs were harvested, weighed and the ^{125}I activity levels were measured in the gamma counter. The percentage of injected dose per gram of tissue was calculated by comparison to injection standards of appropriate count rate.



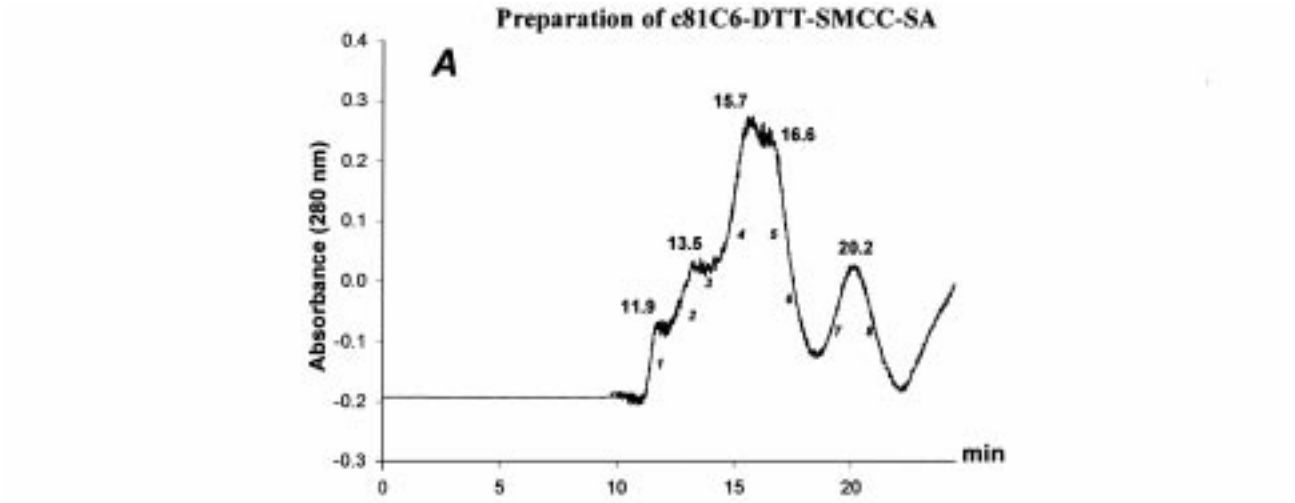
In Vitro Stability of mAb−SA Conjugate in Tumor Cyst Fluid. Tumor cyst fluid was obtained from a patient with a surgically created glioma resection cavity and stored at −170 °C. Aliquots of tumor cyst fluid (20 μL) were mixed with saline (50 μL) and incubated at 37 °C with (a) (^{125}I-labeled m81C6)-2IT-SMCC-SA (20 μL, 1.16 mg/mL), (b) SA (20 μL, 1 mg/mL) as a positive control, or (c) saline (20 μL) as a negative control. At various time intervals (2, 8.5, 19, 31, 48, and 72 h), [^{131}I]-IBA (10 μL, 1 μCi) was added in duplicate. The biotin-binding capacity was monitored by ITLC after a 30 min incubation at room temperature, as described above. In addition, the molecular mass profile of (^{125}I-labeled m81C6)-2IT-SMCC-SA in tumor cyst fluid (in the absence of [^{131}I]IBA) was monitored as a function of time by SDS−PAGE.

RESULTS

Preparation and Characterization of the mAb−SA Conjugates. In Scheme 1, the synthetic approaches utilized for preparing 81C6 mAb−SA conjugates are illustrated. Reaction mixtures were analyzed by size-exclusion HPLC and SDS−PAGE, and biotin-binding capacity and immunoreactive fraction also were determined. The goal was to maximize yield and binding capacity of the desired monomeric mAb_1-SA_1 ∼215 kDa species and determine the presence and binding profile of other macromolecular contaminants. Conjugation yields were calculated by dividing the protein concentration in the 215 kDa peak, isolated by HPLC, by the initial amount of mAb added to the reaction mixture. This approach was taken because of the more than 40-fold lower extinction coefficient of SA compared with mAb in the protein assay. No corrections were applied for transfer losses during the multistep procedure.

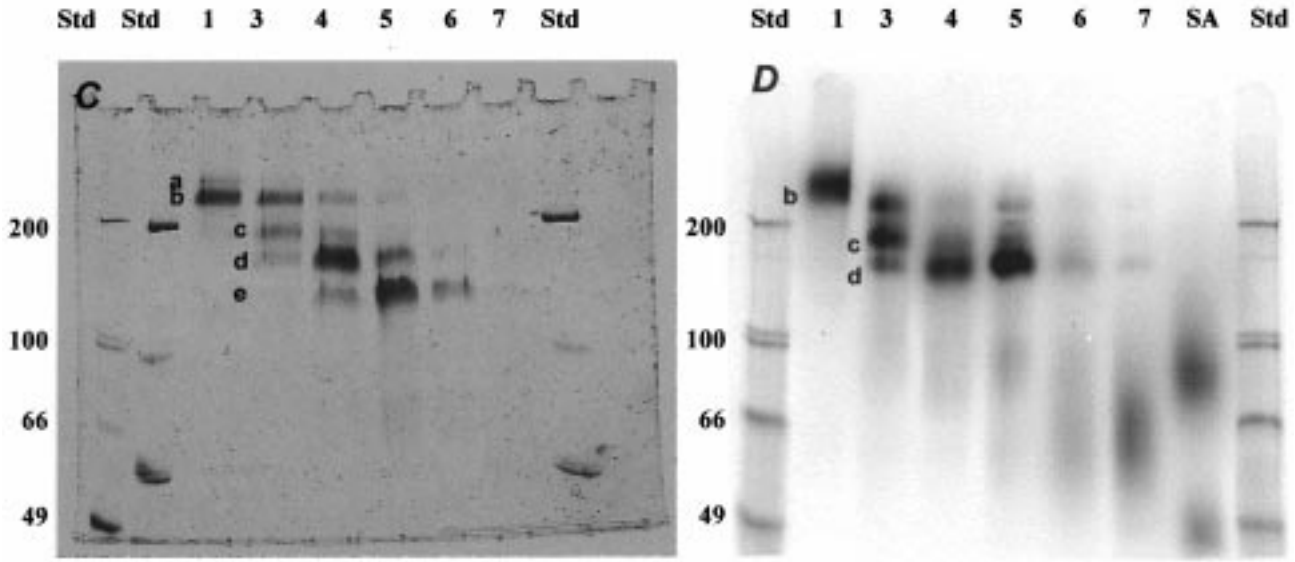
Figure 1 illustrates the type of analyses that were performed for evaluating the mAb−SA conjugates. These are the results of a preliminary experiment in which c81C6 was activated with 10 equiv of DTT, SA was activated with 10 equiv of SMCC, and the two proteins reacted at an equimolar ratio. As shown in Figure 1A, size-exclusion HPLC indicated the presence of multiple peaks in the reaction mixture including those with retention times corresponding to authentic samples of c81C6 (15.5 min) and SA (20.2 min). Comparison to molecular mass standards indicated that the peak eluting at 11.9 min was consistent with the desired mAb−SA monomer. Aliquots from fractions eluting at 12, 13.5, 15.7, 16.6, 17.3, and 20.2 min were analyzed for biotin-binding capacity and immunoreactive fraction (Figure

Scheme 1. Synthetic Schemes for the Five Methods Used to Prepare 81C6 mAb-SA Conjugates



1B), SDS−PAGE with silver staining (Figure 1C) and after incubation with [^{131}I]IBB, by autoradiography (Figure 1D).

On SDS−PAGE, the HPLC fraction eluting at 11.9 min consisted of a major band at the desired ~215 kDa, as well as a minor band at 230 kDa. Protein quantification of this fraction indicated formation of the desired conjugate in 23% yield. Biotin-binding capacity (87%) and immunoreactive fraction (100%) for this fraction were excellent, consistent with the formation of a functional mAb−SA monomer. The SDS−PAGE autoradiograph obtained after incubation with [^{131}I]IBB indicated that the band at 230 kDa did not bind biotin, suggesting that it did not contain a functional SA subunit. These analyses also demonstrated that HPLC fractions eluting at 13.5, 15.7, and 16.6 min were capable of binding to both biotin and tenascin, and included species with molecular masses of 140, 165, and 180 kDa.



Although the above set of reaction conditions provided a mAb−SA conjugate with excellent binding properties, yields of this product were less than ideal. To improve recovered yield while maintaining conjugate function, a series of experiments was then performed with m81C6 using the methods outlined in Scheme 1. A representative analytical HPLC profile for the standards (HPLC-isolated and SDS−PAGE-confirmed mAb-2IT-SMCC-SA, mAb, and SA) is shown in Figure 2A and chromatograms for mAb-BnLC-SA, mAb-DTT-SMCC-SA, mAb-SATA-SMCC-SA, mAb-2IT-SMCC-SA, and mAb-2IT-SPDP−SA prepared at 10:1 activating agent:mAb and reagent:SA ratios are shown in Figure 2, panels B−F. Conjugation yields, biotin-binding capacities, and immunoreactive fractions for these and other reactions carried out at 30:1 activating agent:mAb ratios, and with c81C6, are summarized in Table 1. The HPLC fraction eluting at 12 min was incubated with [^{131}I]IBB and analyzed by SDS−PAGE. Silver-staining and autoradiography of this gel were performed, and the results are presented in Figure 3.

All five methods yielded 81C6 mAb−SA conjugate; however, results with the noncovalent approach involving reaction of biotinylated mAb with SA were least favorable (Figure 2, Table 1). The immunoreactive fraction for conjugate prepared by this approach was only 49%, presumably due to continuing polymerization due to the

lack of appropriate quenching method for this type of coupling. In comparison, immunoreactive fractions for conjugate prepared by the covalent coupling approaches were >68% for m81C6 and >79% for c81C6, values comparable to those for native mAbs. In addition, SDS−PAGE indicated the presence of a single ~215 kDa peak capable of biotin binding. The exception was the reaction run at a 30:1 DTT:mAb molar ratio where a 75 kDa species that did not bind biotin, as well as multiple 150−180 kDa species that did bind biotin, was observed. On the basis of ease of synthesis, yield, and binding properties of the resultant conjugate, the method selected for further study involved activation of mAb with 30 equiv of 2IT followed by reaction with SMCC-SA (prepared at 10:1 molar ratio). Representative size-exclusion HPLC chromatograms obtained using this procedure with m81C6

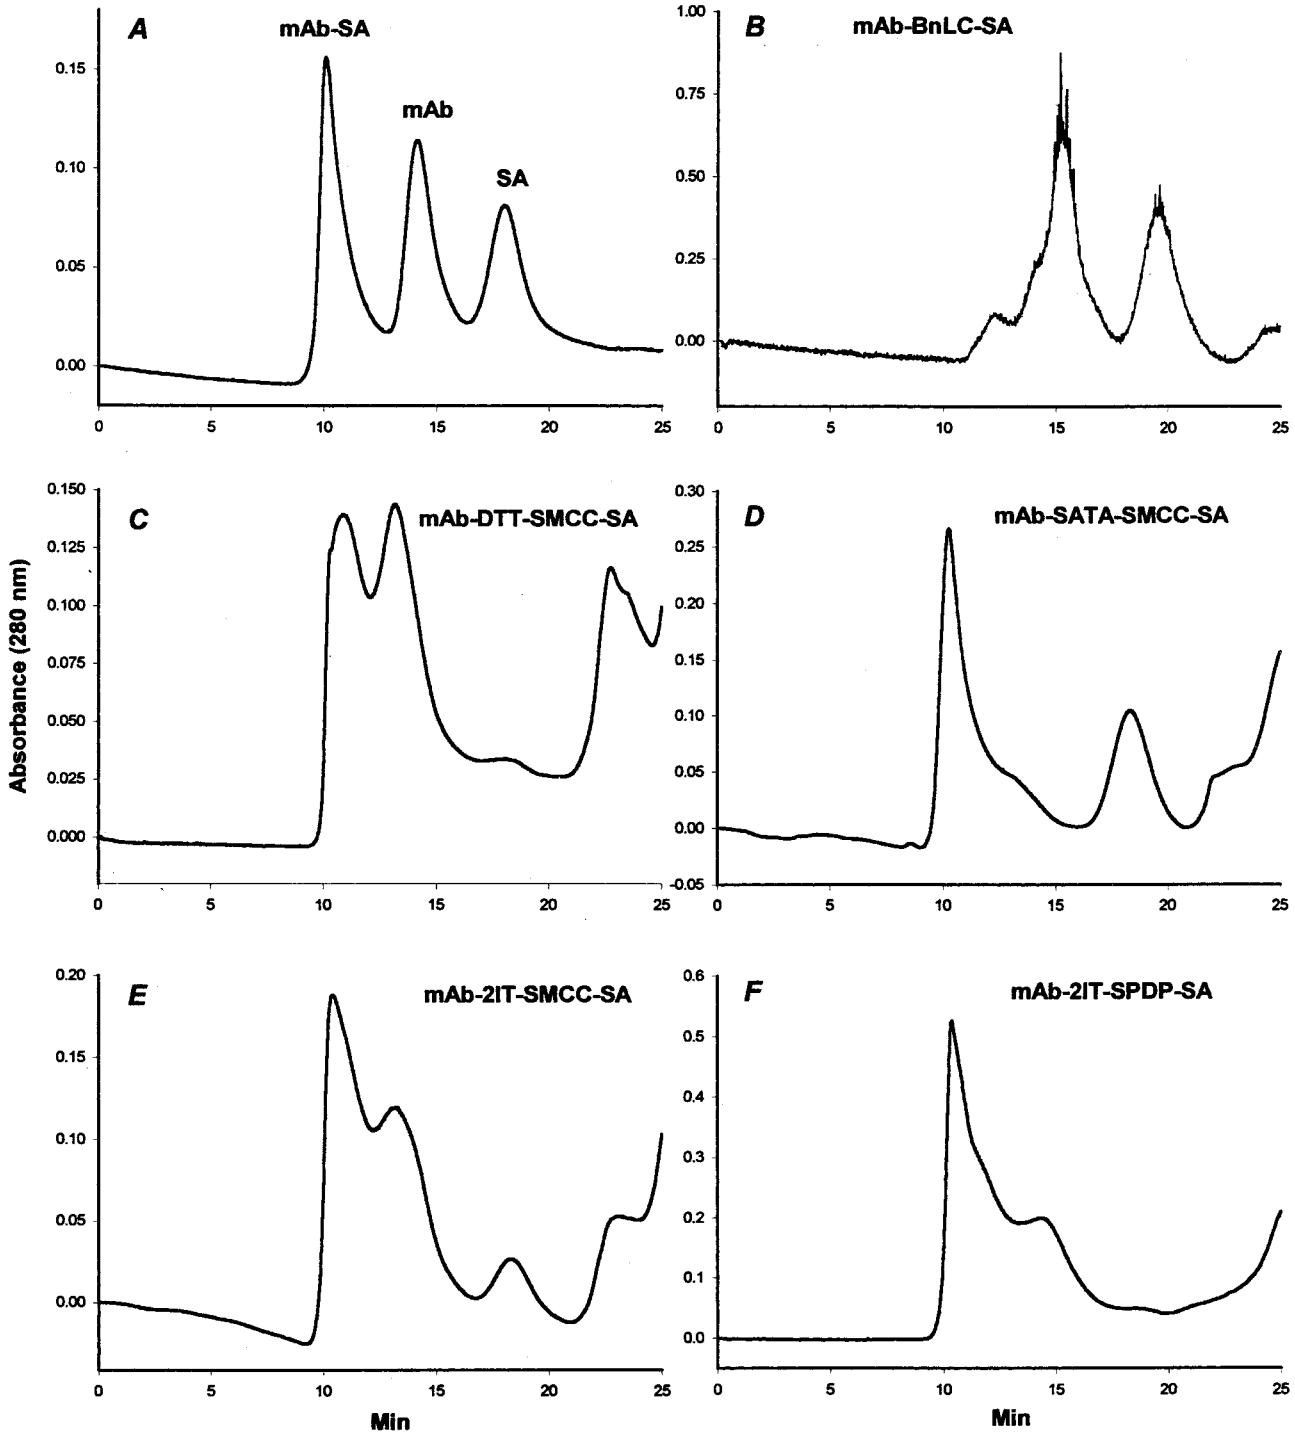

Figure 2. Size-exclusion TSK 3000 profile (UV absorbance at 280 nm) of (A) monomeric mAb−SA, mAb, and SA standards, and (B−F) conjugate reaction mixtures prepared at 10:1 reagent:mAb and reagent:SA molar ratios. Peak at approximately 25 min corresponds to iodoacetamide.

and c81C6 are illustrated in Figure 4. Even though the mAbs had different elution times on this column (m81C6, 15.5 min; c81C6, 16.5 min), with both mAbs, the predominant peak in the reaction mixture eluted at 12 min, corresponding to the desired mAb−SA conjugate.

In Vivo Stability of (^{125}I-Labeled m81C6)-2IT-SMCC-SA in Normal Mice. The in vivo stability of (^{125}I-labeled m81C6)-2IT-SMCC-SA was investigated after injection of the conjugate to normal mice. Figure 5 presents an SDS−PAGE autoradiograph comparing the molecular mass profile of the conjugate to those present in murine serum samples obtained 2−48 h after injection. The only radioactive band observed in serum had a molecular mass of ∼215 kDa with no evidence for the generation of lower molecular mass labeled catabolites. The biotin-binding capacity of the mAb−SA conjugate in serum, measured using [^{131}I]IBA, was 92.1 ± 3.1% at 2 h, 32.4 ± 4.0% at 6 h, 11.5 ± 0.5% at 24 h, and 16.6 ± 1.1% at 24 h.

In Vivo Distribution of (^{125}I-Labeled m81C6)-2IT-SMCC-SA. Murine 81C6 was labeled with ^{125}I, thiolated using 2IT, and reacted with SMCC-SA. Table 2 summarizes the tissue distribution of this conjugate in athymic mice bearing subcutaneous D-54 MG human glioma xenografts. The radioiodinated mAb−SA conjugate exhibited high tumor uptake, reaching a maximum

[a] Reagent used for mAb modification (reagent:mAb molar ratio). [b] Reagent used for SA modification (reagent:SA molar raito). [c] Yield of 215 kDa product calculated based on initial mAb concentration. [d] Percentage of labeled biotin counts bound in vitro. [e] Immunoreative fraction.

of 36.04 ± 10.69% ID/g at 3 days. Deiodination of the conjugate was reflected by the fact that about 3% of the injected dose was taken up by the thyroid at all three time points. Three days after injection, tumor-to-blood ratios were 3.6:1, while tumor-to-normal organ ratios were greater than 10:1, demonstrating that this SA coupling method did not compromise the tumor localizing capacity and normal tissue clearance of m81C6.

In Vitro Stability of (^{125}I-Labeled m81C6)-2IT-SMCC-SA in Tumor Cyst Fluid. No evidence for degradation of the conjugate was observed on SDS−PAGE autoradiographs during the 72 h incubation period. Incubation in glioma resection cyst fluid had no effect on the biotin-binding capacity of the conjugate. The percentage of [^{131}I]IBA bound decreased only slightly, from 98.8% after 2 h to 94.3% after 72 h. For comparison, after incubation of SA in cyst fluid, [^{131}I]IBA binding ranged 98.9−94.7% from 2 to 72 h. As a control, the binding of [^{131}I]IBA to cyst fluid alone was measured and, as expected, was less than 1−5% during the 72 h incubation period.

DISCUSSION

Our ongoing radioimmunotherapy trials for the treatment of brain tumors involve direct administration of radiolabeled anti-tenascin mAbs into surgically created glioma resection cavities (*12*). As one of our second-generation strategies, we envision investigating a two-step pretargeted approach in which the 81C6-SA conjugate would be injected into the cavity in order to saturate tenascin-binding sites on the tumor. The radiolabeled biotin derivative would be delivered about 2 days later, also into the resection cavity. By associating the radiolabel with a small molecule instead of the mAb, we hope to increase the diffusion of the labeled moiety into the tumor and extend the zone of effective treatment beyond the regions adjacent to the cavity interface.

With this goal in mind, we have previously designed a series of biotin conjugates derivatives, including [^{131}I]IBA, [^{131}I]IBB, and their ^{211}At-labeled analogues (*13*, *14*, *18*, *21*) with varying degrees of resistance to biotinidase degradation. Herein, we have attempted to optimize the production of the other reagent needed for pretargeting, the anti-tenascin mAb−SA conjugate. Some of the methods that were investigated have been described in the literature; however, evaluation of their relative merit is complicated by the fact that different mAbs, reagent amounts, reaction times, and conjugate isolation methods were used. In addition, to the best of our knowledge, the use of SATA and SPDP for the preparation of mAb−SA conjugates has not been reported.

The simplest method for preparing mAb−SA conjugates is by reaction between a biotinylated mAb and SA, thereby exploiting the SA-biotin reaction itself to form the conjugate. This approach is attractive because several activated biotin agents are commercially available, and it can be used for generating the conjugate in vivo by preinjection of the biotinylated mAb, followed by intravenous injection of SA (*22*, *23*). Furthermore, biotinylation results in negligible structural modification of the protein with retention of immunoreactivity (*24*). On the other hand, a limitation of this approach, when used in vitro, is that no form of quenching is available, and polymerization and cross linkage can take place, resulting in high molecular mass proteins with compromised binding properties and tissue distribution.

The results that we obtained with m81C6-BnLC-SA were consistent with the formation of higher molecular mass species than the desired 215 kDa mAb_1-SA_1 conjugate. The immunoreactive fraction of m81C6-BnLC-SA was less than 50%, considerably lower than that observed with other conjugate formation methods. In addition, this conjugation method makes use of the highest affinity SA biotin-binding site in the conjugation process and decreases the binding capacity of the conjugate for subsequently administered radiolabeled biotin. For these reasons, we decided to focus our efforts on covalent methods for coupling mAb and SA.

Covalently linked mAb−SA have been generated using classical cross-linking chemistry involving the high reactivity of sulfhydryl residues with maleimido groups. Typically, free thiols are generated on one protein by direct reduction of existing disulfide bridges using mercaptoethylamine (MEA) or DTT, or by addition of sulfhydryl groups on the lysyl residues with 2IT or SATA. Maleimido groups are substituted on the lysyl residues of the other protein using sulfo-SMCC or SPDP. Several of the possible combinations have been applied to the coupling of mAb and SA including mAb-SMCC-2IT-SA (*25*, *26*), mAb-2IT-SMCC-SA (*27*), mAb-MEA-SMCC-SA (*25*, *27*), and mAb-DTT-SMCC-SA (*28*). In addition, site-specific biotinylation of thiolated mAbs also has been described (*29*, *30*).

Our goals were to identify a covalent approach for producing anti-tenascin mAb−SA conjugates with high biotin-binding capacity and immunoreactivity, and good yield of the 215 kDa mAb−SA monomer. We decided to focus on this molecule because it is the smallest product containing both intact mAb and SA, and thus should diffuse more rapidly through the tumor than larger conjugates. Only limited information is available concerning the molecular mass profiles of mAb−SA conjugates. After reaction of a disulfide-reduced mAb with SMCC-SA, FPLC analysis indicated the formation of a single ∼210 kDa species capable of binding biotin (*25*). However, in a subsequent study using similar reaction conditions, the molecular mass of the mAb−SA conjugate was determined to be about 350 kDa by size-exclusion HPLC (*31*). SA−mAb conjugates in the 440−600 kDa range also have been reported (*32*).

Initially, we attempted covalent synthesis of mAb−SA conjugates using the approach described by NeoRx Corporation (*28*). This procedure involves thiolation of the mAb with 10 equiv of DTT, activation of SA with 10 equiv of SMCC, and reaction of the proteins at an equimolar ratio. Although biologically active 81C6 mAb−SA conjugates were obtained, yields of the 215 kDa

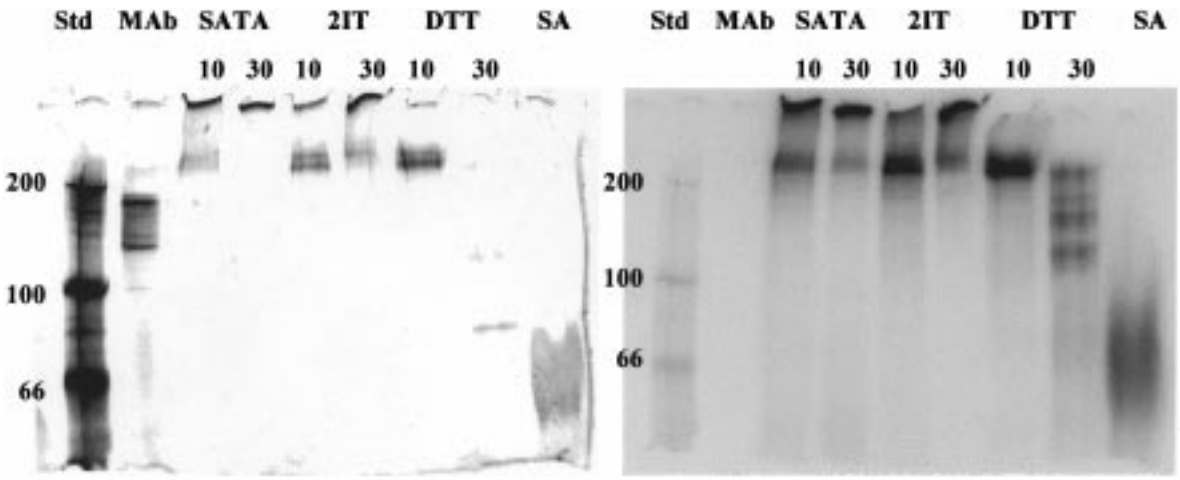

Figure 3. SDS−PAGE of size-exclusion-HPLC-purified m81C6-SA; silver stain on left, autoradiograph after exposure of reaction mixture to [^{125}I]IBB on right, of the same gel. Lane 1, molecular mass standards; lane 2, murine mAb; lane 3, SATA:mAb 10:1; lane 4, SATA:mAb 30:1, lane 5, 2IT:mAb 10:1, lane 6, 2IT:mAb 30:1; lane 7, DTT:mAb 10:1; lane 8, DTT:mAb 30:1; lane 9, streptavidin.

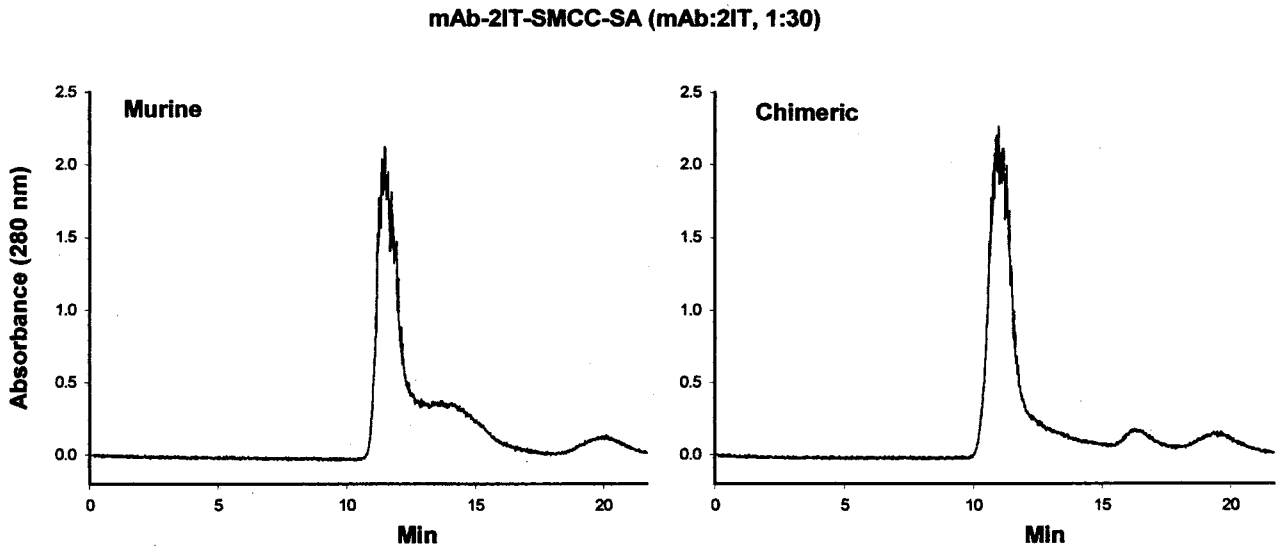

Figure 4. Size-exclusion TSK 3000 profile (UV absorbance at 280 nm) of (A) murine and (B) chimeric 81C6-streptavidin conjugate prepared at 30:1 2IT:mAb molar ratio.

monomer were less than 5% in our hands. Interestingly, the c81C6 reaction mixture contained higher levels of unreacted SA and mAb while, with m81C6, prominent peaks in the 170−200 kDa and <50 kDa range were observed. At higher DTT:m81C6 molar ratios, nearly complete fragmentation of the mAb was observed. The average number of free sulfhydryl groups on the mAb determined using Ellman's reagent was higher for m81C6 (4.5 SH, 10:1; 6.9 SH, 30:1) than for c81C6 (3.4 SH, 10:1; 4.9 SH, 30:1) (data not shown). Thus, even though there are four intrachain disulfides on human IgG_2 compared with three on murine IgG_{2b}, treatment of m81C6 with DTT yielded more free SH groups, presumably resulting in the generation of more lower molecular mass degradation products. These differences also are consistent with the increased in vivo stability of c81C6 compared with m81C6, which appears to be related to differences in reduction of hinge-region disulfides (*33*).

As summarized in Table 1, the other covalent methods could be used to produce 81C6 mAb−SA conjugates in reasonable yield, biotin-binding capacities equivalent to native SA, and immunoreactive fractions comparable to those obtained with native m81C6 and c81C6 (*17*, *34*). Coupling efficiencies were similar to those reported previously by Karacay et al. (*27*) but lower than those

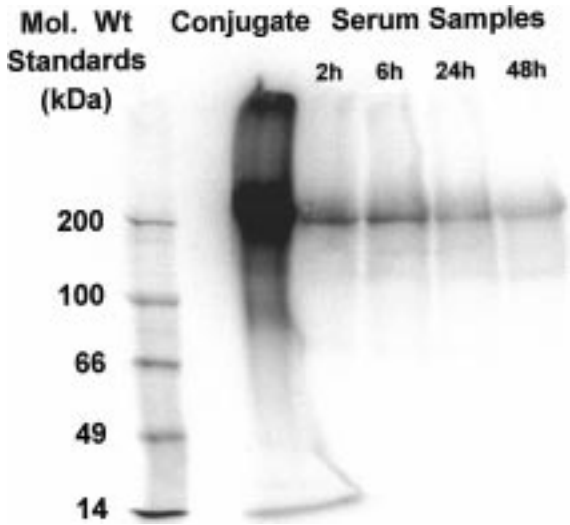

Figure 5. SDS−PAGE autoradiograph of serum samples (Lanes 3−6) obtained 2−48 h after injection of (^{125}I-labeled m81C6)-2IT-SMCC-SA in normal mice. Band at approximately 215 kDa corresponds to monomeric mAb−SA conjugate. Molecular mass standards and preinjection sample of conjugate shown in lanes 1 and 2 for comparison.

obtained by Ngai et al. (*25*) using similar methods. However, it should be noted that in the later study, yields were based on levels of unreacted SA remaining in the reaction mixture, and the principal product had a molecular mass greater than 350 kDa.

Size-exclusion HPLC analysis of conjugation reaction mixtures (Figures 1A, 2, and 4) indicated the presence of multiple peaks including those with retention times corresponding to the desired ~215 kDa mAb−SA conjugate as well as unreacted mAb and SA. When iodoacetamide was used to terminate the reaction, an additional peak was observed at about 24−25 min corresponding to this species. Although these HPLC chromatograms suggested the existence of other products, the resolution was not sufficient to make reasonable molecular mass assignments. For this reason, SDS−PAGE analyses also were performed. Gels were not subjected to reducing and boiling conditions in order to minimize degradation of SA; however, this may have contributed to incomplete entry of the samples into the gel. As illustrated in Figure 1, panels C and D, multiple bands between 140 and 180 kDa were observed. We speculate that those at about 165 and 180 kDa, and capable of binding radiolabeled biotin, could represent mAb coupled to 1 or more SA subunits. In most cases, SDS−PAGE indicated that the HPLC peak eluting at about 12 min contained both the anticipated 215 kDa product as well as an unidentified 230 kDa product that did not possess biotin-binding capacity. One possibility is that this peak is the reaction product between intact IgG and an 75 kDa Fab/Fc monomer, a species observed previously in the catabolism of this mAb (*33*).

The procedure involving thiolation of mAb using 30 equiv of 2IT, and reaction of SA with 10 equiv of SMCC, gave the highest yield of 81C6 mAb−SA monomer. In more recent runs, the overall yield of 81C6 mAb-2IT-SMCC-SA has been increased to 75−80% by using Bio-Rad Poly-Prep columns (catalog no. 731-1550) as spin columns. Compared with SATA, use of 2IT is advantageous from a practical perspective because it is a one-step instead of a two-step procedure and does not require a buffer exchange dialysis. Although use of SPDP for SA modification might result in slightly higher conjugation yields, the resultant mAb−SA conjugate is formed via a disulfide bond that might be susceptible to rapid degradation in vivo.

Because of our interest in applying pretargeting strategies to the treatment of surgically created glioma resection cavities (*12*) the effect of human glioma cyst fluid on the integrity of (^{125}I-labeled m81C6)-2IT-SMCC-SA was investigated in vitro. Biotin-binding capacity was greater than 94% over a 72 h incubation period indicating that the conjugate remained functional in this environment. No evidence for degradation of the conjugate in tumor cyst fluid was observed by SDS−PAGE (data not shown). In contrast, the results of a similar assay indicated ~20% degradation of m81C6 after only 4 h in this milieu (*33*). The enhanced stability of the m81C6-SA conjugate compared with mAb alone warrants further investigation.

The in vivo properties of (^{125}I-labeled m81C6)-2IT-SMCC-SA were investigated in normal mice and athymic mice bearing subcutaneous D-54 MG human glioma xenografts. SDS−PAGE autoradiographs of serum samples obtained from normal mice demonstrated that the conjugate was quite stable in vivo. The biotin-binding capacity of the conjugate decreased rapidly with time (Figure 5), an observation that likely reflects saturation of the conjugate due to the high endogenous concentration of biotin in murine serum (*35*). Indeed, subsequent experiments have shown that when mice are placed on a biotin-deficient diet, the biotin-binding capacity of the conjugate is retained in vivo (C.F.F. and M.R.Z., manuscript in preparation). The tissue distribution of (^{125}I-labeled m81C6)-2IT-SMCC-SA was similar to that reported previously in this animal model for m81C6 radioiodinated using the Iodogen method (*16*, *34*). Three days after injection, tumor:blood ratios were 3.6:1 and greater than 10:1 for all other organs. These results compare favorably with those reported for an anti-CEA mAb−SA conjugate prepared via a procedure involving reduction of mAb sulfhydryls with (2-mercaptoethyl)-amine (*27*).

In summary, m81C6 and c81C6 mAb−SA monomeric conjugates could be prepared in good yield by thiolation of the mAb with 30 equiv of 2IT and formation of maleimido groups on SA by reaction with 10 equiv of SMCC. Conjugates retained the biotin-binding capacity and immunoreactivity of unmodified SA and 81C6, respectively. Further evaluation of (^{125}I-labeled m81C6)-2IT-SMCC-SA revealed that this conjugate possessed excellent in vitro and in vivo stability and tumor localizing capacity. This conjugate, in tandem with our radiohalogenated biotin derivatives, will now be evaluated for use in pretargeted radioimmunotherapy.

ACKNOWLEDGMENT

The excellent technical assistance of Susan Slade (animal experiments) and Phil Welsh (gel electrophoresis) is gratefully appreciated. This work was supported by the National Institutes of Health (CA42324, NS20023, and CA14236) and the Department of Energy (95ER62021).

Synthesis of Polyallylamine Derivatives and Their Use as Gene Transfer Vectors in Vitro

Otmane Boussif,*,† Thierry Delair,‡ Catherine Brua,† Laurent Veron,‡ Andrea Pavirani,† and Hanno V. J. Kolbe†

TRANSGENE S.A., 11 rue de Molsheim, 67082 Strasbourg Cedex, France, and Unité Mixte CNRS-BioMérieux, ENS de Lyon, 46, allée d'Italie, 69364 Lyon Cedex 07, France. Received April 12, 1999; Revised Manuscript Received June 24, 1999

Cationic polymers possessing primary amine groups are inefficient in transferring nucleic acids into eukaryotic cells. With appropriate chemical modification, namely glycolylation of the amine groups of polylysine and polyallylamine, the actual number of free amino groups was decreased, hydrophilic residues were introduced, and the cytotoxicity of both polymers decreased significantly. Furthermore, in the case of polyallylamine, its ability to mediate gene transfer into cells increased by several orders of magnitude. Transfection efficiency was found to be dependent on the substitution level of amino groups and reached highest levels in the presence of lysosomotropic and/or fusogenic agents. At optimal conditions, glycolylated PAM was shown to be as efficient as the linear polyethylenimine of 22 kDa.

INTRODUCTION

Viral and synthetic gene transfer methods for applications in gene therapy are one of the major developing domains of biological research. The fact that selective gene delivery to target tissues still needs improvement with respect to transfer efficiency and expression persistence is a limiting factor for this approach to become routine therapy.

Various types of cationic polymers have been shown to be efficient agents for gene delivery into eukaryotic cells (Haensler and Szoka, 1993; Kabanov and Kabanov, 1995; Boussif et al., 1995; Boussif, 1996). Polyethylenimines (PEI)[1] and polyamidoamine dendrimers (PAMAM), which possess buffering capacity below physiological pH, are efficient carriers per se (Boussif et al.,1995; Behr, 1996). On the other hand, cationic polymers such as poly(L-lysine) are inefficient except when conjugated to specific ligands which lead to receptor-mediated endocytosis and when used in the presence of lysosomotropic and/or fusogenic agents (Zenke et al., 1990; Wagner et al., 1992; Midoux et al., 1993; Zauner et al., 1996). The aim of our work is to develop new cationic polymer families for efficient gene transfer. Rather than synthesizing new types of polymers, we have taken the approach of studying whether appropriate chemical modification of otherwise relatively cytotoxic polymers, e.g., poly-L-lysine (PLL) or polyallylamine (PAM), can reduce their toxicity and, at the same time, retain their capability to efficiently condense DNA. In this context, it has been shown that the transfection capacity of PLL could be improved by substituting to a certain extent the ϵNH_2 groups of the polypeptide with δ-gluconoyl (Erbacher et al., 1997) or poly(ethylene glycol) (Choi et al., 1998) moieties.

PAM contains, regularily spaced along its polymeric hydrocarbon backbone, a high density of primary amino groups existing either as free amine or as cationic ammonium salt. Here we report the successful modification of PAM and PLL by transamidification with methylglycolate leading to the decrease of their toxicity. Further glycolylation was shown to increase drastically the efficiency of PAM to mediate gene transfer. PAM at different degrees of glycolylation was compared to nonmodified or glycolylated PLL in in vitro cell transfection assays.

EXPERIMENTAL PROCEDURES

Chemicals. Polyallylamines (PAM x HC1, 50−65 kDa and 8.5−11 kDa), poly-L-lysine (PLL × HC1, 30−70 kDa) and triethylamine were purchased from Aldrich (France). Methylglycolate and methoxymethyl acetate were from Fluka (France). MTT [3-(4,5-dimethylthiazol-2-yl)- 2,5-diphenyltetrazolium bromide], chloroquine, and dimethyl sulfoxide (DMSO) were from Sigma. ExGen500, a linear PEI of 22 kDa (polyethylenimine), was purchased from Euromedex (Souffelweyersheim, France).

Cell Lines and Cell Culture. A549 human lung carcinoma, MRC-5 human fetal lung epithelium, HepG2 human hepatocarcinoma, and HeLa human cervix carcinoma cell lines were purchased from ATCC (Rockville, MD) and grown in Dulbecco's modified Eagle medium (DMEM, Gibco BRL, Cergy-Pontoise, France). Cell culture medium was supplemented with 10% FCS (fetal calf serum, Sigma) and 2 mM L-glutamine (Gibco BRL). Cells were maintained at 37 °C in a 5% CO_2 humidified atmosphere.

Cell Transfection. Cells were seeded (in 48 multiwell plates) 18 h before transfection to reach ~70% confluence at the time of transfection. Before adding the transfecting complexes, the medium (DMEM, Gibco BRL) was removed and replaced by 0.5 mL of serum-free medium or medium supplemented with 10% serum.

The polymer−DNA complexes were obtained as follows: 2 μg of plasmid pTG11033 (encoding the *Photinus pyralis* luciferase gene under the control of the cytome-

galovirus immediate early enhancer/promoter) and the desired amount of cationic polymer [from 10 mM stock solutions in terms of protonated amine, in water at pH 7.4; 1 *N*/*P* equivalent corresponds to the amount of polymer necessary to have one amino group per phosphate of nucleic acid (330 Da mean M_W) (Zanta et al., 1997)] were each diluted in 50 μL (or 10 μL) of Hepes buffer (20 mM, pH 7.4) and vortexed. The two solutions were then mixed and gently vortexed. After 30 min of incubation at room temperature, the polyplexes were added to the cells. The plate was immediately centrifuged for 5 min at 1500 rpm [~280 g (Boussif et al., 1996)]. After 3−4 h, the medium was replaced by 0.5 mL of medium supplemented with 10% fetal calf serum. When transfection was performed in the presence of 100 μM chloroquine, 5 μL of 10 mM chloroquine solution was added to the medium immediately before the addition of the polyplexes. After 48 h, the medium was removed, cells were washed twice with PBS (Gibco), 100 μL of lysis buffer (Promega) were added and cells were frozen at −80 °C until analysis for luciferase activity. A total of 20 μL of supernatant was analyzed using the luciferase assay system (Promega) in 96 multiwell plates (Biolumat LB 9500, Berthold, Wilbach, Germany). Each transfection was done in triplicate. Values are given as mean relative light units (RLU) per milligram of cell protein (BCA assay, Pierce).

MTT Assay. Evaluation of cytotoxicity was performed by the MTT assay (Mossman, 1983). The cells were incubated with increasing amounts of the desired polymer in serum-free medium. After 4 h, the medium was replaced by 1 mL of medium supplemented with 10% fetal calf serum, and cells were incubated for an additional 24 h. MTT in PBS (20 μL/well of a 5 mg/mL MTT solution) was added 5 h before the end of the incubation period (Sgouras and Duncan, 1990). The medium was then removed, and the cells were carefully washed twice with PBS. The insoluble blue formazan crystals were dissolved in 200 μL of DMSO, and the absorbance was measured at 550 nm. Untreated cells were used as control (100% viability).

Synthesis of 0.5G-PAM. (Approximately 50% of primary amines was substituted with glycolate.) A total of 898 mg of PAM × HCI, 50−65 kDa (9.6 mmol NH_3^+) was dissolved in 1 mL of MilliQ water. A total of 540 mg (6 mmol, i.e., 0.625 equiv) of methylglycolate was added at room temperature followed by addition of 2.7 mL triethylamine (19.4 mmol, i.e, 2 equiv). After 72 h, the mixture was evaporated, and the obtained residue was redissolved in 35% ammonia/water (50:50 v/v). This treatment was repeated twice followed each time by evaporation under vacuum to completely eliminate triethylamine. The residue was dissolved in water at pH 1 (adjusted with 6 N HCl) and then precipitated in acetone. The precipitate was filtered and redissolved in water for lyophilization. A total of 858 mg of 0.5G-PAM was obtained as a white powder, with a yield of 86%. The ^{1}H NMR spectrum was recorded in D_2O containing 10 μL of 4 N NaOH with trimethylsilyl deuterated propionic acid (TSPD4) as an internal reference: δ (ppm) 4.09 (-CH_2-OH); 3.22 (-CH_2-NH-CO-); 2.81 (-CH_2-NH_2); 1.77−1.25 (aliphatic protons).

Synthesis of 0.68G-PAM. A similar protocol was used for the synthesis of 0.68G-PAM (approximately 68% of primary amines substituted with glycolate) with minor modifications. Briefly, 500 mg of PAM × HCl, 50−65 kDa (5.37 mmol of NH_3^+) was dissolved at room temperature in 1.75 mL of MilliQ water. A total of 418 mg (4.57 mmol, i.e., 0.85 equiv) of methylglycolate was added at room temperature followed by addition of 1.5 mL of triethylamine (10.7 mmol, i.e 2 equiv). The subsequent steps were similar to those described above. This synthesis was reproduced three times; modification levels were 68.7, 68.2, and 67.4%, respectively, as determined by ^{1}H NMR integration.

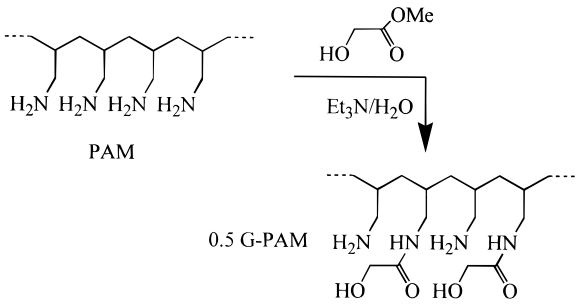

Figure 1. Scheme of the synthesis of glycolylated PAM.

Synthesis of 0.7G-PLL. A total of 108 mg of PLL × HCl (0.4 mmol of NH_3^+) was dissolved in 3 mL of MilliQ water. After addition of 3 mL of triethylamine (21.5 mmol, i.e 54 equiv), 237 mg (2.59 mmol, i.e., 6.48 equiv) of methylglycolate was added at room temperature in four portions over 4 days. The reaction mixture was then diluted with 16% ammonia in water and concentrated under reduced pressure. This dilution−concentration process was repeated twice. The mixture was then acidified with concentrated HCl, and the polymer was precipitated in 400 mL of acetone. The precipitate was dissolved in water and lyophilized. The polymer was analyzed by ^{1}H NMR in D_2O, containing traces of sodium hydroxide (reference: trimethylsilyl propionic acid, TSPD4): δ 4.25 ppm, 1H; 4.07 (-CH_2-OH); 3.25 (-CH_2-NH-CO-); 2.96 (-CH_2-NH_2); 2−1.2 (6H). The level of derivatization (69.6%) was determined by the ratio of the integration of the peak at 3.25 ppm versus the integration of the peaks at 3.25 and 2.96 ppm corresponding to the methylene group bearing the primary amine.

Amidation of PAM with Methylmethoxyacetate. The synthesis was carried out in analogy to the protocol using methylglycolate. ^{1}H NMR, D_2O: δ 4.01 ppm, 2H (CH_2-O-CH_3), 3.43 3H (CH_2-O-CH_3), 3.22 2H (CH_2NH-CO), 2.78 2H (C$H_2$$NH_2$), 1.77−1.28 (aliphatic protons).

RESULTS

We have derivatized the amino groups of PAM and PLL with methylglycolate to study its effect on their cytotoxicity and cell transfection efficiency in vitro. Below, the influence of various parameters such as degree of polymerization, level of glycolylation, ratio of polymer amino groups to DNA phosphate groups (*N*/*P* ratio), amount of DNA used in the assay, and the presence of serum or helper agent is described.

Synthesis of Glycolylated PAM. A series of derivatives of PAM was synthesized by random substitution of the primary amino groups with methylglycolate residues (Figure 1). Such a modification reduces the intrinsic charge of the polymer and introduces hydrophilic residues (hydroxyl groups) which may increase the solubility of the polymer−DNA complex. Glycolylated PAM products were characterized by ^{1}H NMR in D_2O with 10 μL of NaOH as solvent (signal at 4.6−4.7 ppm). The percentage of glycolyl group derivatization was estimated from the peak area of the amido methylene group (3.22 ppm) divided by the sum of the peak areas of the amido methylene and the amino methylene groups (3.22 and 2.81 ppm, respectively). In the case of 0.68G-PAM,

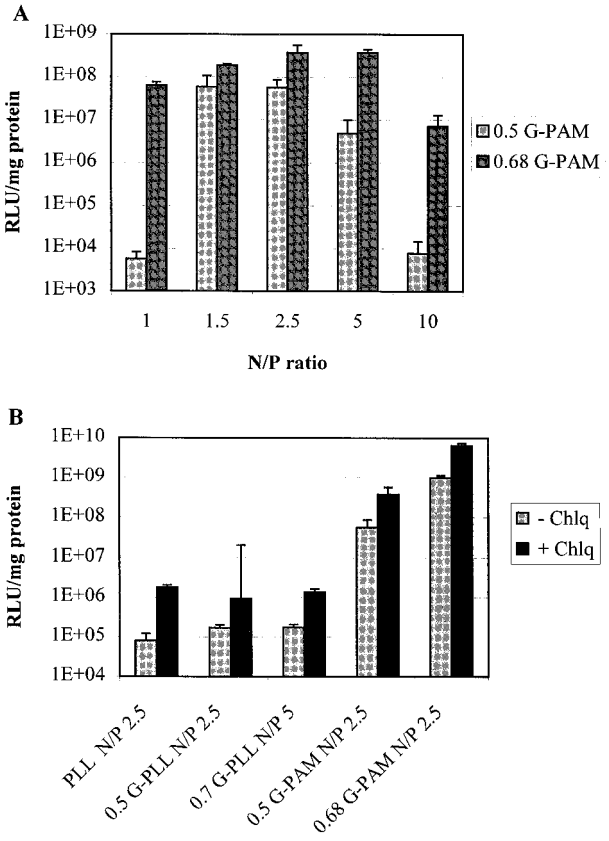

Figure 2. (A) Polyfection with Glycolylated PAM vs *N/P* ratio. A549 cells were transfected with 2 μg of pTG11033 and increasing amounts of polymer. (B) Polyfection with glycolylated PLL and chlorocuine effect. A549 cells were incubated in the presence or absence of chloroquine (100 μM) with pTG11033 (2.9 μg) formulated with the desired polymer at *N/P* 2.5 or 5. Transgene expression was measured 48 h posttransfection. Each point was determined in triplicate and results are expressed as mean values ± SD.

repeated synthesis yielded three different batches of 0.68G-PAM with 68.1 ± 0.66% of glycolylation. This attests to the relatively high reproducibility of such chemistry. Two glycolylated PAMs, 0.5GPAM and 0.68G-PAM (50.3 and 68.7%, respectively, of amino groups converted to amidylglycolate) were thus obtained and used to define the optimal conditions to reach high transfection efficacy.

Transfection Efficiency of Glycolylated PLL and PAM vs *N/P* Ratio. In vitro studies, with both lipoplexes and polyplexes (Felgner et al., 1997), have shown that electrostatic interactions between the negatively charged cell membranes and the positively charged DNA complexes are enhanced by increasing the overall charge of the complexes, which in turn is achieved by increasing the ratio of carrier to DNA. We wanted to study the relationship between the level of transgene expression and *N/P* ratio. 0.5G-PAM and 0.68G-PAM polyplexes were tested on A549 human lung carcinoma cells at different *N/P* ratios. Indeed, it is believed that for efficient gene delivery polycation−DNA complexes must bear a net positive charge (Behr, 1994; Boussif et al., 1995). A series of experiments was performed in the presence or absence of 100 μM chloroquine, an endosomolytic agent which leads to an enhancement of transfection with PLL carrier systems. The results are shown in Figure 2. Both polymers, 0.5G-PAM and 0.68G-PAM, showed transfection activity at all *N/P* ratios tested (Figure 2A). Luciferase expression after 48 h was high even in cells transfected with complexes at low *N/P* ratios: at a ratio

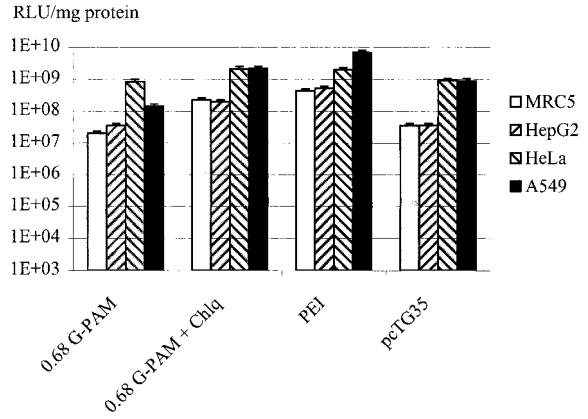

Figure 3. Polyfection of various cell lines with glycolylated PAM. Cells were transfected with 2 μg of pTG11033 complexed to 0.68 G-PAM, PEI, or pcTG35 at *N/P* 2.5, 5, and 5, respectively. Transgene expression was measured 48 h posttransfection. Values are the mean of three independent experiments made in triplicate.

of 2.5, the expression levels reached 10^8-10^9 RLU/mg of protein. The transfection efficiency was always higher when experiments were performed in the presence of 100 μM chloroquine (Figure 2B). Using 0.5- and 0.7G-PLL, the expression levels were variable, even in the presence of chloroquine, and in the same order of magnitude as those obtained with nonmodified PLL (Figure 2B). Importantly, in all cases, the levels of expression were approximately 100- to 1000-fold lower than those obtained with the corresponding 0.68G-PAM, indicating the importance of the hydrophobic backbone of PAM for efficient gene transfer.

Transfection efficiency of synthetic gene delivery systems also depends on the cell type (Boussif et al., 1996). We therefore performed transfection in three widely used cell types, MRC-5 (human fetal lung epithelium), HepG2 (human hepatocarcinoma), and HeLa (human cervix carcinoma) cells. Different cationic polymers at different *N/P* ratios were used to define optimized transfection conditions. As shown in Figure 3, a high level of luciferase expression (at least 5×10^7 RLU/mg of protein) was achieved with glycolylated PAM. A significant increase of efficiency was observed in the presence of 100 μM chloroquine (Figure 3) or 14% glycerol (not shown). At optimal conditions, transgene expression levels were similar to or even higher than those obtained with PEI and the cationic glycerolipid pcTG35 (Schughart et al., 1999).

Dose Response Study. DNA dose dependency was analyzed by observing the transfection efficiency of 0.68G-PAM as a function of the amount of DNA polyplexes at *N/P* ratio 2.5. Again, the transfection was performed in the presence or absence of chloroquine. Although transfection efficiency decreased with decreasing amount of polyplexes, at low amounts of DNA, e.g., 0.1 μg, significant transgene expression was still obtained (Figure 4). However, like other synthetic vectors, transfection efficiency decreased more than 2 orders of magnitude when less than 0.5 μg of DNA was used. It should be noted that using 4 μg of plasmid and 0.68G-PAM/DNA polyplexes at *N/P* ratio 5, no chloroquine was required to achieve optimal transfection, and by increasing the amount of DNA up to 6 μg, no cell damage was seen reflecting the low toxicity of the modified PAM (see also below).

Cytotoxicity of Glycolylated PAM. We examined the effect of glycolylation on cytotoxicity on A549 cells

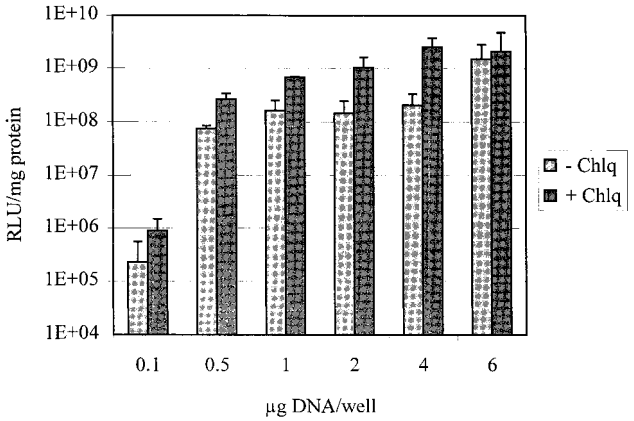

Figure 4. DNA dose−response effect on polyfected cells. A549 cells were transfected in the presence or absence of chloroquine (100 μM) with various amounts of pTG11033 (0.1−6 μg) complexed with 0.68 G-PAM at *N*/*P* 2.5. Transgene expression was measured 48 h posttransfection. Each point was realized in triplicate and results are expressed as mean values ± SD.

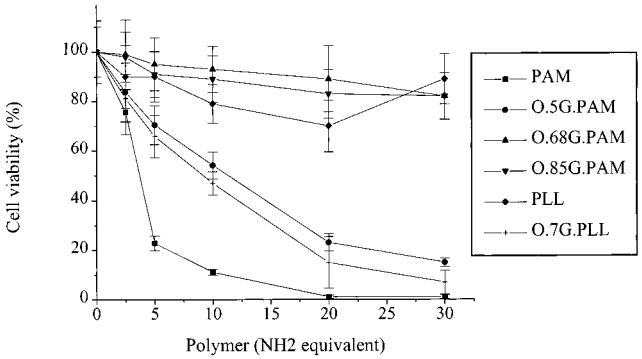

Figure 5. Glycolylation effect on cytotoxicity of PLL and PAM. A549 cells were incubated in the absence of serum with increasing amounts of polymer for 4 h. After replacing medium with fresh one supplemented with 10% serum, the cells were grown for another 40 h. Each point was realized in triplicate and results are expressed as mean values ± SD.

by using a tetrazolium-based MTT colorimetric assay (Sgouras and Duncan, 1990). Cells were incubated for 4 h with increasing amounts of polymer (corresponding to the amount of the polymer needed for 4 μg of plasmid to obtain *N*/*P* ratios ranging 2.5−30) in the absence of serum. The results are expressed as percentage of cell viability relative to nontreated cells.

Modified PLL and PAM showed a better biocompatibility than the corresponding non-modified polymers (Figure 5). 0.5G-PAM was less toxic than PAM but a residual toxicity comparable to that of nonmodified PLL was still detectable. When the level of glycolylation was increased to above 70%, glycolylated PAM exhibited only very slight cytoxicity even at high concentrations (more than 75% cell viability with *N*/*P* ratio 30).

A similar assay was carried out with polymer−DNA complexes (polyplexes). A549 cells were polyfected with 4 μg of plasmid complexed to increasing amounts of 0.5G-PAM, 0.68G-PAM, PLL, or 0.7G-PLL. The general behavior of polymers alone or polyplexes was similar: nonmodified polymers were relatively toxic and their biocompatibility increased with increasing degree of glycolylation (data not shown).

Transfection Efficiency Depends on the Degree of Glycolylation. To study the influence of the degree of substitution of amino groups, we synthesized several PAM derivatives differing by their degree of glycolylation (50−85%) according to the protocol described above by

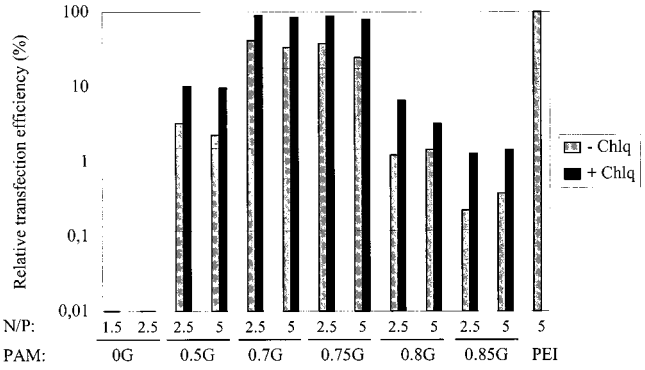

Figure 6. Effect of glycolylation level on transfection efficiency. A549 cells were transfected with 2 μg of pTG11033 complexed with different glycolylated PAM (0−85%; see legend) at *N*/*P* of 2.5 or 5. Luciferase activity was measured 48 h after transfection. Values are given as relative transfection efficiency to PEI (100%). Results represent the mean of four independent experiments.

adjusting the ratio of methylglycolate. Transfection of A549 cells with polyplexes was performed at *N*/*P* ratio 2.5 and 5; agarose gel electrophoresis of polyplexes was carried out in parallel to the in vitro assays to verify that DNA was completely retarded by interaction with the polymer (data not shown). Figure 6 summarizes the mean transfection efficiencies of four independent experiments. The results are presented as relative activity as compared to the value obtained with PEI (100%). The substitution levels from 70% to about 75% gave the highest luciferase expression. Beyond this substitution level, the transfection efficiency decreased gradually. As assessed by agarose gel retardation assay (data not shown), this phenomenon is not due to a partial complexation of the DNA with highly modified polymer. It may be due to a decreased affinity of the polymer for DNA leading to a faster decomplexation by interaction of the polyplex with constituents present in the culture medium or in the target cell.

Influence of Polymer Size. It has been shown that transfection efficiency of cationic polymers such as polylysine or PAMAM dendrimers depends on their degree of polymerization (Haensler and Szoka, 1993; Boussif, 1996; Erbacher et al., 1995). To see whether the size of polyallylamine may influence its transfection ability, polyallylamines with different degrees of polymerization were glycolylated to the same extent. The resulting transfection efficiencies were compared under various conditions. 0.74G-PAM (∼10 kDa) and 0.68G-PAM (∼60 kDa) gave similar results. Both polymers showed high levels of expression even at low *N*/*P* ratio (Figure 7A). Their transfection efficiencies in the presence of serum were affected to about the same extent (Figure 7B). Therefore, the size of the polymer, at least within the range 10−60 kDa, does not interfere with its ability to mediate gene transfer into cells in vitro.

Requirement of Glycolate Hydroxyl Residue for Efficient Polyfection. To examine whether the presence of free glycolate hydroxyl groups influences the transfection efficiency, we substituted the hydroxyl group with a methoxy group. Thus, referring to the protocol described for the synthesis of glycolylated polymers, two methoxyacetylated PAMs were prepared (0.45MeG-PAM, and 0.65MeG-PAM: 45% and 65% of amino groups of PAM substituted with methoxyacetate, respectively). Transfections of A549 cells were performed with these polymers complexed to 2 μg of DNA in the absence and presence of 100 μM chloroquine. Methoxyacetylated PAM

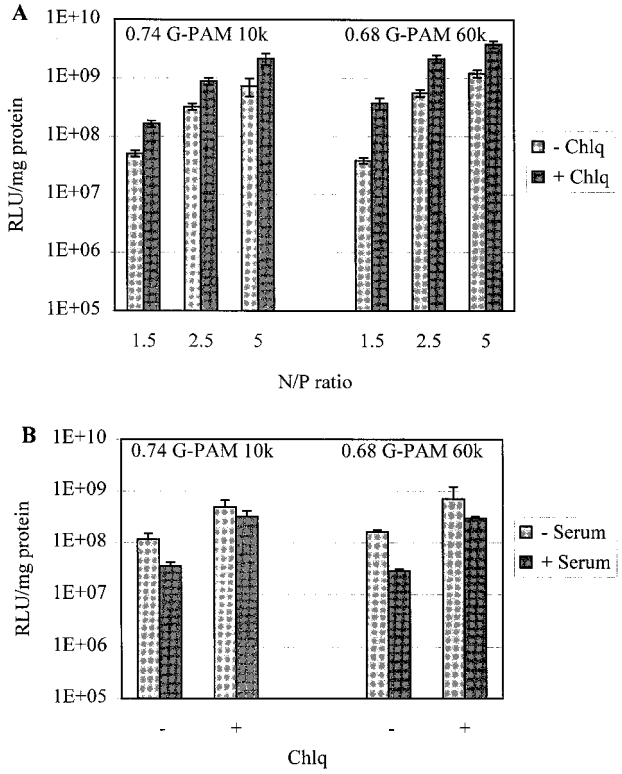

Figure 7. Effect of polymer size on transfection efficiency. (A) Effect of *N*/*P* ratio. A549 cells were transfected with 2 μg of pTG11033 and the amount of the desired polymer (0.74G-PAM or 0.68G-PAM). Expression was stopped 48 h later. Values are the mean ± SD of triplicate. (B) Serum effect on polyfection with glycolylated PAM. A549 cells were incubated in the presence or absence of serum (10%) with pTG11033 (2 μg) complexed with the desired polymer (0.74G-PAM or 0.68G-PAM) at *N*/*P* 2.5. Experiment was performed with and without chloroquine (100 μM). Results are the mean values ± SD of triplicate.

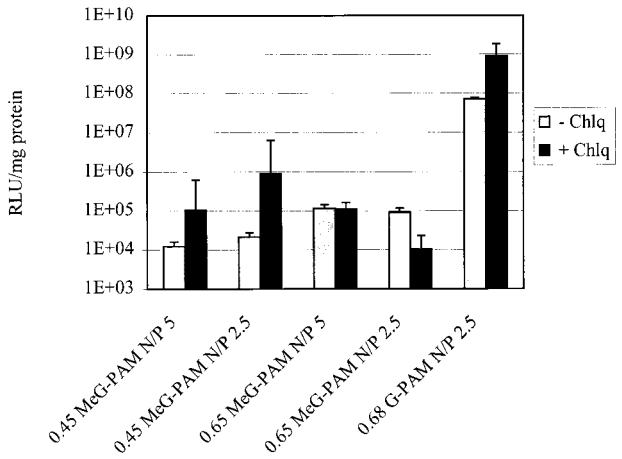

Figure 8. Effect of the substitution of glycolyl-hydroxyl group with methoxyl on glycolylated PAM transfection efficiency. A549 cells were transfected with 2 μg of pTG11033 complexed to the desired amount of polymer tested. Transgene expression was measured 48 h posttransfection. Each point was determined in triplicate and results are expressed as mean values ± SD.

efficiencies were found to be irreproducible and at least 100−1000-fold lower than those obtained with glycolylated PAM (Figure 8), demonstrating that the hydroxyl group is required to achieve high and reproductible gene transfer and expression. However, it should be noted that methoxyacethylated PAMs were more efficient than the native polymer, showing that reducing free primary amines of the polymer is also required.

DISCUSSION

Several cationic polymers have been used for in vitro and in vivo gene transfer (Kabanov et al., 1991; Wu et al., 1987; Wu and Wu, 1988; Boussif et al., 1995; Haensler and Szoka 1993; Cherng et al., 1996). Cationic polymers such as PLL and PAM possessing only primary amines are relatively toxic (Sgours and Duncan, 1990) and are, when complexed to DNA, inefficient transfection agents (Boussif, 1996). PLL, when conjugated to specific ligands (Wagner, 1998) and/or substituted with δ-gluconoyl (Erbacher et al., 1997) or poly(ethylene glycol) residues (Choi et al., 1998) to a certain extent, becomes more efficient especially when transfection is performed in the presence of lysosomotropic and/or fusogenic agents (Zenke et al., 1990; Wagner et al., 1992; Erbacher et al., 1997; Zauner et al., 1996).

We hypothesized that, by reducing the density of primary amino groups and by introducing hydrophilic groups, such polymers could be detoxified and their ability to mediate transfection of eukaryotic cells could be enhanced. Thus, glycolylated PAMs and PLLs were synthesized. First, the modified molecules were significantly less toxic than the original polymers (Figure 5). Second, in the case of PAM, transfection efficiency increased by several orders of magnitude (Figure 2). Below 75% modification, polymers reached high levels of transgene expression, similar to those obtained with the linear PEI of 22 kDa (Boussif, 1996) and the cationic glycerolipid pcTG35 (Schughart et al., 1999) (Figure 6). Efficient transfection was achieved even at low *N*/*P* ratios (Figure 2). According to a potentiometric study with nonmodified PAM reported by Suh et al. (1994), polyplexes in the range of the *N*/*P* ratio used (1.5−5) should have an overall negative charge or at most a slightly positive charge. Indeed, at about pH 7 only ∼14% of amino groups are protonated showing that the ammonium ions of PAM are sufficiently proximal to enhance mutual deprotonation (Suh et al., 1994). This is a relevant feature as it was shown that lipoplexes as well as polyplexes activate the complement system, but the activation decreases when a low charge ratio is used (Plank et al., 1996). Further glycolated PAM polyplexes, in contrast to PAM polyplexes, could be easly formulated at high DNA concentration (at least 0.25 g/L), and as measured by laser light scattering (Coulter N4plus), their sizes were relatively small (∼200 nm).

As endocytosis is the main route for polyplexes to enter the cell, they should escape the endosomal pathway as rapidly as possible to avoid DNA degradation and, therefore, increase their probability of reaching the nucleus. Thus, the presence of 100 μM chloroquine (Zenke et al., 1990; Midoux et al., 1993) or 14% glycerol (Zauner et al., 1996) (data not shown) enhanced significantly the expression levels of reporter gene in the various cell types tested. Furthermore, it was reported that chloroquine could participate in the dissociation of polyplex in the endosomes (Erbacher et al., 1996), allowing the release of DNA into the cytosol.

The comparison of glycolylated PAMs of different degrees of derivatization showed that the highest transgene expression was obtained between 70 and 75% (Figure 6). Beyond 75% glycolylation, the transfection efficiency decreased rapidly. As assessed by gel retardation, in contrast to PLL (Plank et al., 1992; Erbacher et al., 1995), even highly substituted PAM (>80%) is still able to complex DNA. The decrease of efficiency is not likely to be due to a difference in DNA complexation. It may be due to a decrease in the polymer−DNA interac-

tion leading to decomplexation by interaction of the polyplex with constituents of the culture medium or the cellular membrane followed by faster degradation of plasmid DNA.

Using two PAMs of different size, the in vitro transfection efficiency was found to depend neither on the *N*/*P* ratio nor on the amount of polyplex within the molecular mass range 10−60 kDa. Indeed, the results obtained with 0.74G-PAM, 10 kDa, and 0.68G-PAM, 60 kDa, were quite similar under all conditions tested (Figure 7).

One factor which strongly influences transfection efficiency is the presence of the glycolate hydroxyl group. Transamidification of PAM with methoxymethyl acetate (methoxyl group) instead of methyl glycolate (hydroxyl residue) led to low and irreproducible expression levels of the reporter gene (Figure 8). This could be due to the higher viscosity of ether functions leading to more hydrophobic and/or rigid polyplexes. In fact, Tang and Szoka (1996) reported that transfection efficiency is related to the flexibility of the polymer.

In contrast, although complete gel retardation of DNA was achieved at low polymer/DNA ratios with all modified PLLs (0.7 G-PLL), they showed rather weak gene delivery into A549 cells (Figure 2). Expression levels obtained in the presence of 100 μM chloroquine were still 100−1000-fold lower than those of glycolylated PAM and were comparable to those of unmodified PLL ($\sim 10^5-10^6$ RLU/mg of protein). According to our cell viability studies, this is not be due to residual cytotoxicity (Figure 5). Improvement of PLL efficiency may require extended hydrophilic moieties (Erbacher et al., 1997; Choi et al., 1998). The differences between PLL and PAM seem to underline the importance of the nature of the backbone of the polymer: PLL being less hydrophobic than PAM. A good hydrophilic/lipophilic balance could facilitate the trafficking of DNA into the cytoplasm and/or toward the nucleus.

Because glycolylated PLLs are less cytotoxic than unmodified PLL and although their transfection efficiency is low, it would be interesting to study whether glycolylated PLL conjugated to a ligand for receptor-mediating endocytosis could achieve efficient gene transfer to permissive cells.

Chloroquine was recently used to enhance in vivo gene delivery (Baru et al., 1995; Merwin et al., 1994), but this approach would not be suitable in the development of gene delivery systems for use in humans. Thus, we plan to substitute the chloroquine function by additional chemical modifications of PAM such as the generation of secondary amino leading, hopefully, to an intrinsic buffering capacity of the polymer and/or even enhancing its solubility and flexibility. Further presence of primary and secondary amines could modulate favorably the interactions between the polymer and DNA.

In conclusion, the detoxification of cationic polymers seems to be a feasible approach to develop new polymer-based synthetic gene delivery systems. Although detoxification is not sufficient to systematically improve the capacity of the polymer to mediate gene transfer, it will be interesting to investigate glycolylation of other polymers used for gene transfer to determine if the phenomenon of detoxification can be applied in general terms.

ACKNOWLEDGMENT

We would like to thank Dr. Bruno Cavallini and Isabelle Renardet for providing us with plasmid DNA. We are grateful to Dr. Michael Courtney for critical reading of the manuscript. This work was partially supported by the Association Francaise contre les Myopathies (AFM) and the Association Française contre La Mucoviscidose (AFLM).

A HYNIC-conjugated chemotactic peptide (fMLFK-HYNIC) was labeled with ^{99m}Tc using tricine and TPPTS as coligands. The combination of fMLFK-HYNIC, tricine, and TPPTS with ^{99m}Tc produced a ternary ligand complex [^{99m}Tc(fMLFK-HYNIC)(tricine)(TPPTS)] (RP463). RP463 was synthesized either in two steps, in which the binary ligand complex [^{99m}Tc(fMLFK-HYNIC)(tricine)$_2$] (RP469) was formed first and then reacted with TPPTS, or in one step by direct reduction of [^{99m}Tc]pertechnetate with stannous chloride in the presence of fMLFK-HYNIC, tricine, and TPPTS. The radiolabeling yield for RP463 was usually ≥90% using 10 μg of fMLFK-HYNIC and 100 mCi of [^{99m}Tc]pertechnetate. Unlike RP469, which decomposed rapidly in the absence of excess tricine coligand, RP463 was stable in solution for at least 6 h. [^{99}Tc]RP463 was prepared and characterized by HPLC and electrospray mass spectrometry. In an in vitro assay, [^{99}Tc]RP463 showed an IC_{50} of 2 nM against binding of [^{3}H]fMLF to receptors on PMNs. [^{99}Tc]RP463 also induces effectively the superoxide release of polymorphonuclear leukocytes (PMNs) with an EC_{50} value of 0.2 ± 0.2 nM. The localization of RP463 in the infection foci was assessed in a rabbit infection model. RP463 was cleared from the blood faster than RP469 and was excreted mainly through the renal system. As a result of rapid blood clearance and increased uptake, the target-to-background ratios continuously increased from 1.5 ± 0.2 at 15 min postinjection to 7.5 ± 0.4 at 4 h postinjection. Visualization of the infected area could be as early as 2 h. A transient decrease in white blood cell count of 35% was observed during the first 30 min after injection of the HPLC-purified RP463 in the infected rabbit. This suggests that future research in this area should focus on developing highly potent antagonists for chemotactic peptide receptor or other receptors on PMNs and monocytes.

INTRODUCTION

Accurate and rapid localization of infectious and inflammatory foci facilitate elucidation of the cause of disease, and the implementation of a tailored therapeutic regiment. Numerous diagnostic imaging procedures have been developed in the past three decades. Morphological imaging modalities such as X-ray-computed tomography (CT), ultrasound (US), conventional radiography, and magnetic resonance imaging (MRI) rely primarily on focal changes in tissue density to define lesions. In the early stage of an inflammatory lesion, however, lesion localization using these procedures may be difficult because the tissue changes associated with necrosis have not occurred (*1*).

White blood cells (WBCs), particularly polymorphonuclear leukocytes (PMNs) and monocytes, accumulate in high concentrations at the site of infection. Therefore, recent attention has been directed toward radiolabeling small molecules that bind to both circulating granulocytes and leukocytes. These include chemotactic peptides, analogues of *N*-formyl-methionyl-leucyl-phenylalanine (fMLF) (*1*−*8*), small peptides based on platelet factor 4 (*9*), and tuftsin receptor antagonists (*10*−*12*).

The chemotactic peptide, fMLF, is a bacterial product. It binds with high affinity to a specific receptor expressed on the surface of WBCs, stimulates chemotaxis of granulocytes, upregulates expression of adhesion molecules, and increases vascular permeability. In 1991, Fischman and co-workers (*13*) first reported the potential diagnostic use of ^{111}In-labeled chemotactic peptide analogues of fMLF. Since then, they have studied a series of radiolabeled chemotactic peptides as infection/inflammation imaging agents (*1, 3*−*8*). These peptides were modified with either HYNIC (for ^{99m}Tc) or DTPA (for ^{111}In) at the C-terminus. The ^{99m}Tc labeling of HYNIC-modified chemotactic peptides (such as fMLFK-HYNIC) can be achieved

using coligands such as glucoheptonate, mannitol, and glucamine (*4*). It was reported that very high specific activity (≥20 000 mCi/μmol) could be achieved using glucoheptonate as the coligand. Different biodistributions were observed using different coligands (*4*). Recently, van der Laken and co-workers (*14*) also reported the use of a ^{99m}Tc-labeled chemotactic peptide fMLFK-HYNIC for imaging acute infection and sterile inflammation. Animal studies have shown evidence of binding to leukocytes in vivo and localization at the infection site (*1, 5*−*8, 15*).

Recently, we found that both tricine and glucoheptonate form binary technetium complexes, [^{99m}Tc(fMLFK-HYNIC)(L)$_2$] (L = tricine and glucoheptonate), which exist in many isomeric forms and are not stable in solution in the absence of excess coligand (*16*). Although the biological data from animal studies show that these agents are able to localize at the infection site (*14*−*16*), it would still be difficult to develop them for routine clinical use, due to solution instability and the presence of many isomers.

In this study, a ternary ligand system was used to prepare the stabilized complex [^{99m}Tc(fMLFK-HYNIC)-(tricine)(TPPTS)] (RP463). The goal was to minimize the number of isomeric forms and increase the solution stability of the ^{99m}Tc complex. RP463 was prepared, and its solution stability was compared to that of the binary ligand complex, [^{99m}Tc(fMLFK-HYNIC)(tricine)$_2$] (RP469). RP463 was evaluated in a rabbit focal infection model for its potential use as an infection imaging agent.

EXPERIMENTAL SECTION

Materials. TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate) and tricine were purchased from Aldrich Chemical Co. Na^{99m}TcO$_4$ was obtained from a Technelite ^{99}Mo/^{99m}Tc generator, DuPont Pharmaceuticals Co., North Billerica, MA. Deionized water was obtained from a Millipore MilliQ Water System and was of >18 MΩ quality. The peptide fMLFK was synthesized and conjugated to 6-hydrazinonicotinic acid (HYNIC) according to the literature procedure (*3*).

Instruments and Methods. The electrospray mass spectrum of [^{99}Tc]RP463 was obtained using a HP 1100 Series LC/MSD (G1946A) mass spectrometer and 0.1% formic acid/acetonitrile as the mobile phase. The HPLC methods used a Hewlett-Packard model 1050 instrument with a NaI radiometric detector. The ITLC method used Gelman Sciences silica gel strips and a 1:1 mixture of acetone and saline as the eluant.

HPLC method 1 used a Zorbax C_{18} reversed-phase column (4.6 mm × 250 mm, 80 Å pore size) at a flow rate of 1 mL/min. Solvent A contained 90% 25 mM phosphate buffer (pH 8) and 10% acetonitrile while solvent B was a 50:50 (v:v) mixture of acetonitrile and 25 mM phosphate buffer (pH 8). A linear gradient from 0% B to 20% B over 40 min was used.

HPLC method 2 used a Zorbax C_{18} reversed-phase column (4.6 mm × 250 mm, 80 Å pore size) and a Rainin Dynamax UV−vis detector (model UV-C, λ = 230 nm). The flow rate was 1 mL/min with a gradient from 90% solvent A (0.01 M phosphate buffer, pH 6) and 10% solvent B (acetonitrile) to 70% solvent A and 30% solvent B at 30 min.

Synthesis of RP463. *Two-Step Labeling Using Stannous Chloride*. To a 10 mL vial were added 0.2 mL of fMLFK-HYNIC solution (50 μg/mL in H_2O), 0.4 mL, of tricine solution (100 mg/mL in H_2O), 0.5 mL of Na^{99m}TcO$_4$ solution (100 mCi/mL in saline), and 25 μL of $SnCl_2 \cdot 2H_2O$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was allowed to stand at room temperature for 30 min. The labeling yield for the resulting complex RP469 was usually ≥90%. To the solution above was added 0.3 mL of TPPTS solution (50 mg/mL in H_2O). The reaction mixture was heated at 50 °C for 30 min and then analyzed by radio-HPLC (method 1). ITLC was used to determine the amount of [^{99m}Tc]colloid. The product RP463 migrated while the [^{99m}Tc]colloid remained at the origin.

One-Step Labeling Using Stannous Chloride. To a shielded 10 mL vial was added 0.5 mL of Na^{99m}TcO$_4$ solution (100 mCi/mL in saline), 0.4 mL of tricine solution (100 mg/mL in H_2O), 0.2 mL of the fMLFK-HYNIC solution (50 μg/mL in H_2O), 0.3 mL of TPPTS solution (50 mg/mL in H_2O), and 25 μL of $SnCl_2 \cdot 2H_2O$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 80 °C for 30 min and then analyzed by radio-HPLC (method 1) and ITLC. RP463 prepared by this method was shown by HPLC to be identical to that prepared according to the two-step synthesis. The radiolabeling yield was ≥90%.

RP463 was purified by HPLC (method 1) to remove excess reactants, particularly unlabeled fMLFK-HYNIC. The fraction at 10−12 min was collected into a 25 mL round-bottom flask. Volatiles were removed under reduced pressure. The residue was dissolved in saline at a concentration of 1.5 mCi/mL for animal studies. The resulting solution was reanalyzed by radio-HPLC.

One-Step Labeling without Stannous Chloride. To a shielded 10 mL vial were added 0.5 mL of Na^{99m}TcO$_4$ solution (100 mCi/mL in saline), 0.1 mL of tricine solution (100 mg/mL in H_2O), 0.2 mL of the fMLFK-HYNIC solution (50 μg/mL in H_2O), and 0.2 mL of TPPTS solution (50 mg/mL in H_2O). The reaction mixture was heated at 80 °C for 30 min and then analyzed by radio-HPLC (method 1). RP463 prepared by this method was shown by HPLC to be identical to that prepared using the stannous formulation.

Solution Stability Studies. Complexes RP463 and RP469 were prepared and separated from the kit matrix by HPLC (method 1). Fractions of interest were collected into a 25 mL round-bottom flask. Volatiles in the collected fractions were removed under reduced pressure. The residue was dissolved in saline to give a concentration of 1.5 mCi/mL. The stability of RP463 and RP469 was monitored by HPLC (method 1) over ∼6 h.

Synthesis of [^{99}Tc]RP463. To a 10 mL vial were added tricine (41.7 mg, 0.230 mmol), followed by [NH_4]-[^{99}TcO$_4$] (3.7 mg, 0.021 mmol) in water (1 mL), fMLFK-HYNIC (16.5 mg, 0.022 mmol) in methanol (1 mL), and TPPTS (50 mg, 0.088 mmol). The vial was crimped and heated in a boiling water bath for 30 min. The product [^{99}Tc]RP463 was separated from the reaction mixture by HPLC (method 2). The product fraction was collected, and volatiles were removed under reduced pressure. Analysis of the product by HPLC (method 2, λ = 230 nm) showed no residual starting peptide.

Receptor Binding Assays. Human PMNs were isolated from heparinized venous blood obtained from healthy donors. Blood samples of 40 mL were mixed with an equal volume of Hanks' balanced salt solution (HBSS), layered on a Ficoll−Hypaque gradient and centrifuged at 10 °C and 1300 rpm for 30 min. The supernatant was discarded, and the PMN-rich pellet was resuspended in cold HBSS, to which cold 2% dextran solution (in saline) was added to remove residual red blood cells. After 25 min of sedimentation at room temperature, the suspended cells were removed and centrifuged at 10 °C and 1300 rpm for 10 min. The supernatant was discarded,

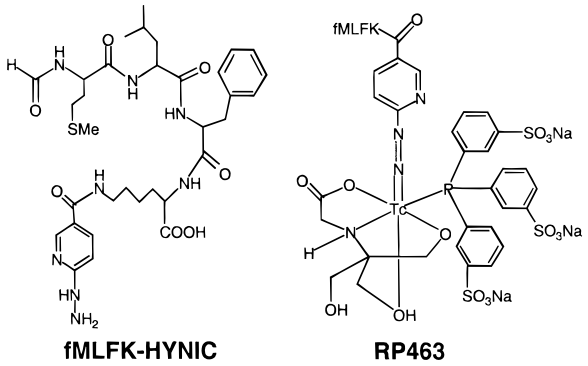
and the pellet was resuspended in 10 mL of cold hypotonic lysing buffer for a 5-min lysis of residual RBC. After lysis, cold HBSS (40 mL) was added, and the cells were centrifuged at 10 °C and 1300 rpm for 10 min. This final PMN pellet was washed once and resuspended to the desired cell concentration in phosphate incubation buffer containing 140 mM NaCl, 1.0 mM KH_2PO_4, 5 mM Na_2HPO_4, 0.5 mM $MgCl_2$, 0.15 mM $CaCl_2$, and 0.5% BSA (pH 7.4) for fMLF binding assays. For the cytochrome *c* reduction assays, cells were resuspended in HBSS.

fMLF Binding Assay. [^{3}H]fMLF (10 nM), [^{99}Tc]RP463, and 100 μL of PMN solution (8×10^6 PMNs/mL) were added to a 96-well microplate with filters (0.65 μm pore size). The microplate was incubated for 60 min at room temperature with gentle agitation. The microtiter plate was then placed on a filtration system. The wells were washed with incubation buffer three times and dried. The filters were removed from the microplate, placed into scintillation vials, and agitated for 1 h at room temperature in the presence of scintillation fluid. Percentage inhibition of [^{3}H]fMLF binding to PMNs was calculated by dividing the specific binding (total binding -nonspecific binding) obtained in the presence of technetium complex by that obtained in the absence of the technetium complex. IC_{50} values were calculated by fitting the percentage inhibition values to a regression line.

Cytochrome c PMN Free Radical Release Assay. The biological activity of [^{99}Tc]RP463 was determined by measuring superoxide release of PMNs after they are exposed to the technetium complex. Typically, the PMN solution (1 mL, 1×10^6 PMNs/mL) was incubated with cytochalasin B (10 μM) and 100 μL of cytochrome *c* (40 μM) for 10 min at 37 °C. Then [^{99}Tc]RP463 was added, and the tubes were incubated for 10 min at room temperature. After centrifugation (200 × g, for 10 min at 10 °C), the supernatants were transferred to cuvettes for spectrophotometric analysis to measure reduction of cytochrome *c*, reflecting the amount of superoxide release by PMNs. Superoxide release in the presence of [^{99}Tc]-RP463 was expressed as a percentage of maximal response. EC_{50} values were calculated by fitting a curve to the data generated.

Animal Studies. Absesses were induced in the left thigh muscle of female New Zealand rabbits (2.2−2.8 kg) with 1.5×10^{10} colony forming units of *Escherichia coli* in 0.5 mL. During the procedure, the rabbits were anesthetized with subcutaneous injection of a 0.5 mL mixture of 0.315 mg/mL fentanyl and 10 mg/mL fluanisone. After 24 h, when swelling of the muscle was apparent, groups of four rabbits were immobilized, and were placed prone on the gamma camera.

RP463 was administered (1.0 mCi/kg, i.v.) in the lateral ear vein. Serial images were acquired using a gamma camera (Digital Dyna Camera, Picker International, Cleveland, OH) every 15 min for 4 h. The scintigraphic results were analyzed quantitatively by drawing regions of interest over the abscess, the uninfected contralateral thigh muscle (background), and the whole body. Abscess-to-background ratios and percentage residual activity in the abscess (abscess-to-whole body ratio × 100%) were calculated. Arterial blood was withdrawn prior to administration and every 30 min thereafter for determination of blood clearance. At the end of the protocol, the animal was euthanized with an overdose of pentobarbital. Samples of blood, infected thigh muscle, uninfected contralateral thigh muscle, bone, bone marrow, lung, spleen, liver, kidneys, and intestines were collected. The dissected tissues were weighed and counted in a gamma well counter (LKB 1282, Wallac Inc., Gaithersburg, MD).



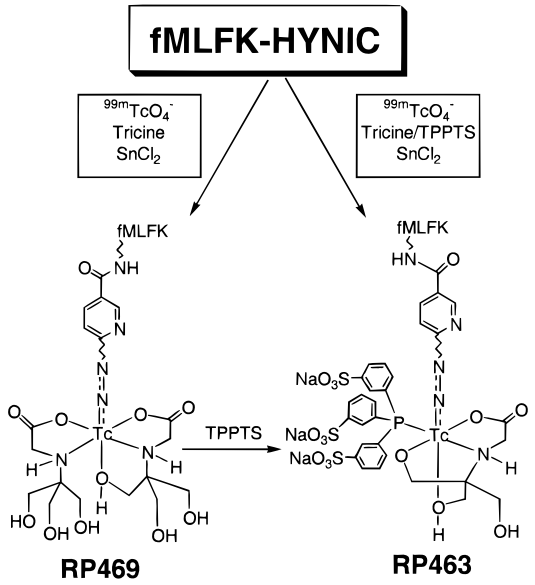


Figure 1. Structures of fMLFK-HYNIC and RP463.

Chart 1. Synthesis of RP463

To correct for radioactive decay, injection standards were counted simultaneously. The measured activity in samples was expressed as injected dose per gram (% ID/g). Abscess-to-contralateral muscle ratios and abscess-to-blood ratios were calculated.

RESULTS

Synthesis of RP463. RP463 was synthesized either in two steps, in which the binary ligand complex RP469 is formed first and then reacts with TPPTS, or in one step by direct reduction of [^{99m}Tc]pertechnetate with stannous chloride in the presence of fMLFK-HYNIC, tricine, and TPPTS (Chart 1). The radiolabeling yield for the complex RP463 is usually ≥90% using 10 μg of fMLFK-HYNIC and 100 mCi of [^{99m}Tc]pertechnetate. The formation of [^{99m}Tc]colloid is minimal. Since the radiolabeled kit contains excess unlabeled peptide (fMLFK-HYNIC), which has been shown to be a strong agonist (*3*, *14*), RP463 has to be purified by HPLC before animal studies.

HPLC Characterization RP463 and RP469. RP463 and RP469 were characterized using the same reversed-phase HPLC method. Figure 2 shows the chromatograms (method 1) for the binary ligand complex RP469 (top) and the ternary ligand complex RP463 (bottom). There are several radiometric peaks for RP469 at retention times between 20 and 45 min, suggesting that there are many ^{99m}Tc-species in solution. The ratios of the peak areas in the radio-HPLC chromatograms change with time, reaction temperature, and pH. Using the same method, the

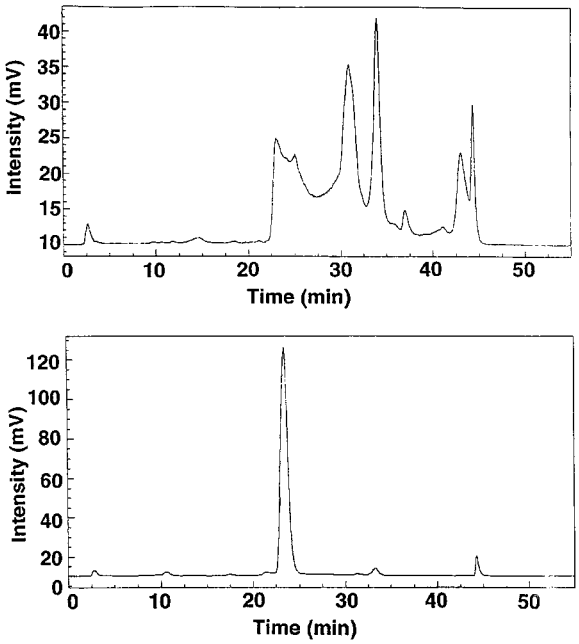

Figure 2. Radio-HPLC chromatograms (method 1) for RP469 (top) and RP463 (bottom).

chromatogram of RP463 showed only one peak at 23 min (bottom in Figure 2). RP463 prepared by the two-step synthesis was found to be exactly the same as that prepared by the one-step synthesis.

The technetium chelate moiety is chiral, due to the tricine ligand being pro-chiral, and should be formed in an equal mixture of D and L enantiomers. These enantiomers in combination with the chiral centers on the peptide backbone should result in two diastereomers, DLLLL and LLLLL. Theoretically, these two diastereomers should be separable under ideal conditions. We tried several different reversed-phase HPLC methods under either gradient or isocratic conditions and were unable to resolve these two diastereomers, probably due to the high flexibility of the linear peptide.

Solution Stability Studies. The solution stability of HPLC-purified RP463 was examined, and was compared to that of RP469. Both complexes were separated from the kit matrix. Their solution stability in saline (pH ~6) was monitored by HPLC (method 1) for 6 h. Figure 3 shows the plot of RCP vs time for RP463 and RP469. It is clear that the HPLC-purified RP469 was not stable in solution. The RCP dropped to ~50% at 6 h post HPLC purification. The ternary ligand complex RP463 remained relatively unchanged in solution. The RCP only dropped slightly from 94% to 91% at 6 h post HPLC purification.

[^{99}Tc]463. [^{99}Tc]RP463 was prepared in one step by reacting fMLFK-HYNIC with [NH_4][$^{99}TcO_4$], in the presence of excess tricine and TPPTS. It was isolated by HPLC purification (method 2). The HPLC concordance (Figure 4) of RP463 and [^{99}Tc]RP463 showed that the same complexes were prepared at the tracer (^{99m}Tc) and macroscopic (^{99}Tc) levels. Electrospray mass spectrometry gave m/z 1476 for [^{99}Tc]RP463 ([$C_{57}H_{72}N_9O_{21}S_4Tc]^+$) in its acid form.

In Vitro Studies. The binding of [^{3}H]fMLF to receptors on PMNs could be completely inhibited by [^{99}Tc]-RP463. The concentration of [^{99}Tc]RP463 required for 50% inhibition against [^{3}H]fMLF binding to PMNs (IC_{50}) was 2 nM. Nonspecific binding on average was less than 15%. Like the unlabeled peptide (fMLFK-HYNIC), [^{99}Tc]-

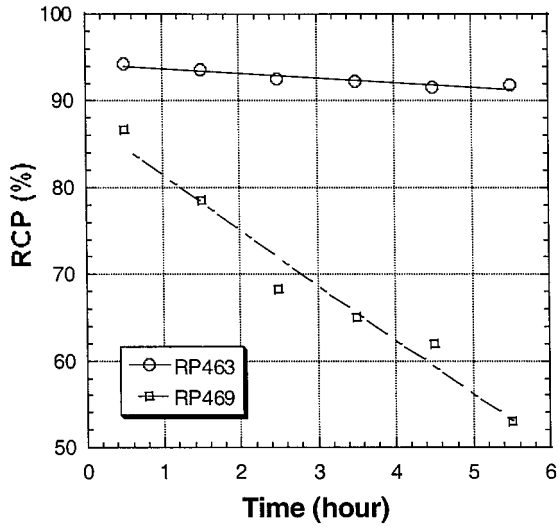

Figure 3. Solution stability of HPLC purified RP463 and RP469.

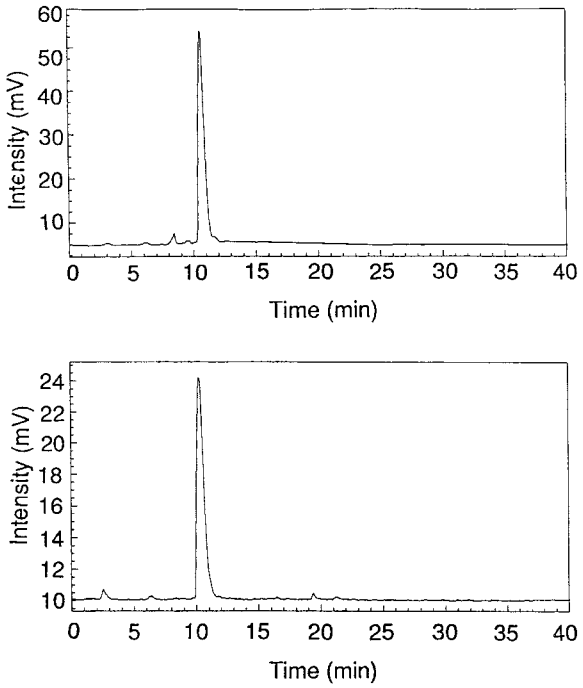

Figure 4. HPLC concordance (method 2) for RP463 (top, NaI radio-detector) and [^{99}Tc]RP463 (bottom, UV detector).

RP463 is also an effective inducer of superoxide release of PMN, with an EC_{50} value of 0.2 ± 0.2 nM (n = 3).

In Vivo Animal Studies. RP463 was evaluated in rabbits infected with *E. coli*. After injection of RP463 into infected rabbits, a minimal transient reduction in peripheral leukocyte levels was observed. Immediately after injection, the WBC count decreased to 65% of the initial level and then returned to 90−95% within 30 min postinjection (Figure 5). Similar phenomena were observed for the complex RP469 in both the healthy and the infected rabbit (*14*). RP463 cleared from the blood rapidly (Figure 6). The biodistribution data (Figure 7) at 4 h postinjection showed that RP463 excreted via both the renal and hepatobillary systems and were consistent with the imaging data. Compared with RP469, RP463 showed comparable renal excretion and less blood residence. Despite fast blood clearance, images clearly showed rapid accumulation of RP463 in the infected site, and the

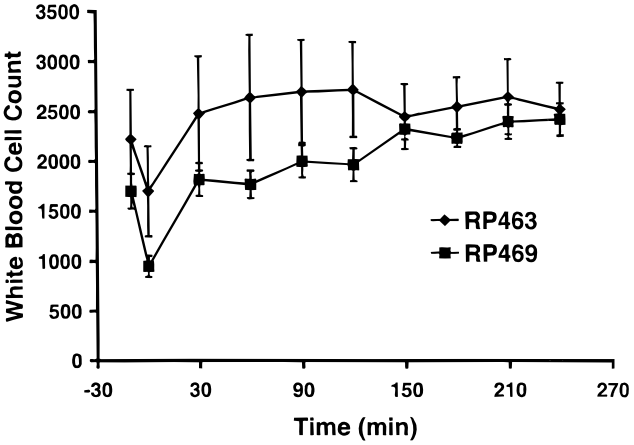

Figure 5. White blood cell counts in blood of the infected rabbits after injection of the HPLC purified RP463 and RP469.

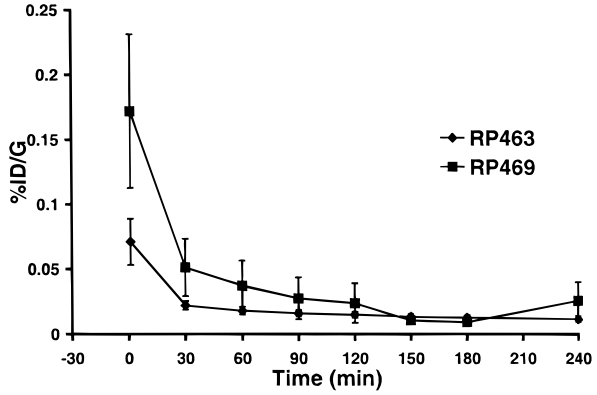

Figure 6. Blood clearance of RP463 and RP469 in the infected rabbits. Data expressed as percentage of the injected dose per gram (% ID/g, mean values ± sem).

uptake at the infection site increased with time (Figure 8). The infection foci could be clearly visualized at 2 h postinjection. As a result of rapid blood clearance and increased uptake, the target-to-background ratios continuously increased from 1.5 ± 0.2 at 15 min postinjection to 3.5 ± 0.4 at 2 h postinjection and to 7.5 ± 0.4 at 4 h postinjection (Figure 9).

DISCUSSION

In the development of a new receptor-based ^{99m}Tc infection imaging agent, several factors need to be considered to satisfy the clinical requirements. The agent has to demonstrate the biological efficacy, including high specificity and high uptake at the infection site. It should also have favorable pharmacokinetics, show rapid blood clearance, and be renally excreted. A kit formulation is often required due to the 6 h half-life of ^{99m}Tc. Injection of the whole or part of the reconstituted kit should not cause any significant biological effect such as neutropenia. The agent should have high radiochemical purity (RCP = 90%) and high solution stability with a shelf life of preferably 6 h. Finally, the ^{99m}Tc labeling should be accomplished in 10−30 min, preferably at room temperature.

Development of a specific agent for imaging focal infection remains a major challenge for investigators in nuclear medicine. For a number of years, imaging inflammation and infection has been performed using [^{67}Ga]citrate. But the specificity is low and the exact mechanism of localization is still not well understood. ^{111}In- and ^{99m}Tc-labeled nonspecific polyclonal IgGs were also used for detection of infection foci (*17*−*24*). However, it usually takes 24 h to obtain diagnostically useful images due to their slow clearance from the blood pool. [^{99m}Tc]HMPAO-WBCs (*25*−*27*), and [^{99m}Tc]albumin colloid-WBCs (*28*) have specificity for the infected foci since WBCs, particularly PMNLs and monocytes, accumulate at the site of acute infection as part of the inflammatory response induced by bacteria. Imaging using both agents can be completed on the same day, but these procedures may impose significant risks to laboratory personnel and patients, particular with the increasing prevalence of human immunodeficiency virus in the population (*29*, *30*).

^{99m}Tc labeling of biologically active small peptides is of current interest because small peptides are necessary elements in many biological processes and, in some cases, have affinities significantly higher than those of antibodies or antibody fragments (*5*). Small peptides are easy to synthesize and modify, are less likely to be immunogenic, and can have rapid blood clearance. The faster blood clearance results in adequate *T*/*B* ratios earlier so that it is practical to use ^{99m}Tc, which is the preferred radionuclide for diagnostic nuclear medicine. Examples

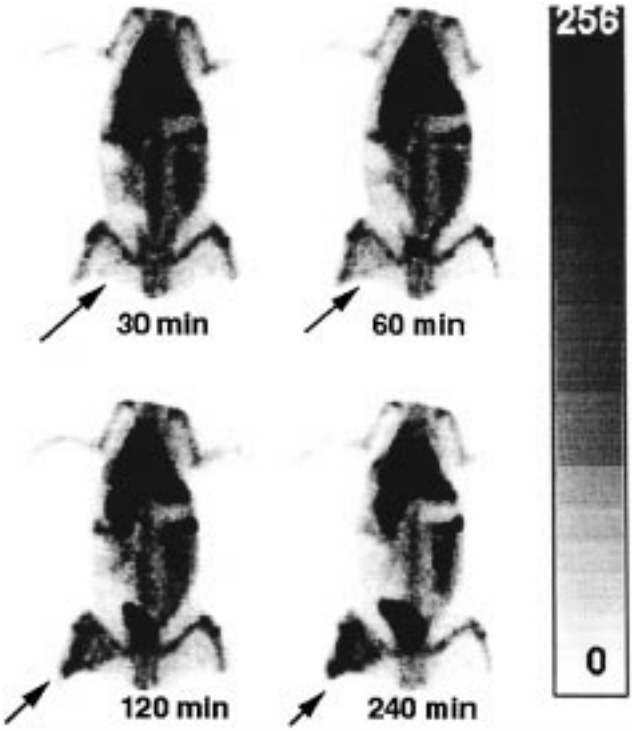

Figure 8. Representative images (anterior view) of rabbits infected with *E. coli* at 30, 60, 120, and 240 min after injection of the HPLC purified RP463. Arrows indicate location of the infected thigh.

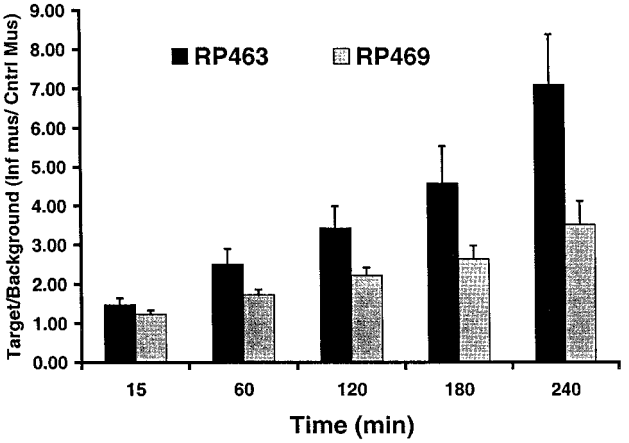

Figure 9. Target-to-background (infected muscle to contralateral muscle) ratios, calculated from rabbits infected with *E. coli* at 15, 60, 120, 180, and 240 min after injection of HPLC-purified RP463 and RP469.

of ^{99m}Tc-labeled small peptides for imaging infection or inflammation include chemotactic peptides (*1*−*8*), small peptides based on platelet factor 4 (*9*), and tuftsin receptor antagonists (*10*−*12*).

The ^{99m}Tc-labeled fMLFK-HYNIC has been studied for infection imaging using several different animal models (*3*, *4*, *6*−*8*, *15*). Various coligands such as glucoheptonate, mannitol, and glucamine have been used for the ^{99m}Tc labeling. Different biodistributions were observed depending on the coligand (*4*). However, these studies did not address problems associated with the presence of multiple species of the binary ligand complexes such as RP469 and the solution stability of the ^{99m}Tc-labeled peptides.

In this study, it has been clearly demonstrated by a reversed-phase HPLC method that the binary ligand complex RP469 exists in solution as a mixture of several isomeric forms. Similar results were obtained for the complex [^{99m}Tc(fMLFK-HYNIC)(glucoheptonate)$_2$] (*16*) and for the ^{99m}Tc complex of a HYNIC-conjugated cyclic platelet GPIIb/IIIa receptor antagonist (*31*). In addition, RP469 was found to be unstable in the absence of excess tricine coligand (Figure 3). Thus, it would be difficult to develop RP469 into a product for routine clinical use because of the solution instability and the presence of the many isomeric forms even though animal studies showed that the agent was able to localize at the site of infection (*1*−*8*, *14*, *15*).

To minimize the formation of various isomeric forms and increase the solution stability of the ^{99m}Tc complex, a ternary ligand system was used to prepare RP463. This new ligand system has been successfully used for the ^{99m}Tc labeling of an HYNIC-conjugated cyclic GPIIb/IIIa antagonist for the development of a thrombus imaging agent, RP444 (*32*, *33*). Using the combination of fMLFK-HYNIC, tricine, and TPPTS, RP463 can be synthesized in high yield and high specific activity (>10 000 mCi/μmol fMLFK-HYNIC) without HPLC purification. It was found that RP463 was stable for up to 6 h in solution. Apparently, the addition of TPPTS coligand dramatically reduces the number of isomeric forms and significantly increases the solution stability of ^{99m}Tc-labeled peptide. The composition of RP463 and the 1:1:1:1 ratio for Tc:fMLFK-HYNIC:tricine:TPPTS was confirmed by mass spectral data of [^{99}Tc]RP463.

In an in vitro binding assay, [^{99}Tc]RP463 was able to effectively compete with [^{3}H]fMLF for receptors on PMNs, with an IC_{50} value of 2 nM. Like the unlabeled peptide, fMLFK-HYNIC ($IC_{50} = 3 \pm 2$ nM; $EC_{50} = 0.8 \pm 0.4$ nM) (*14*), [^{99}Tc]RP463 also induces superoxide release of PMN with an EC_{50} value of 0.2 ± 0.2 nM. These data clearly show that RP463 is a high affinty agonist of the fMLF receptors on PMNs, and the ^{99m}Tc-labeling did not significantly alter the binding affinity even though the molecular weight after radiolabeling is more than doubled.

After injection of RP463 in the rabbit, a transient reduction in peripheral leukocyte levels was observed. Since RP463 was purified by HPLC, it should be free of unlabeled fMLFK-HYNIC. The injected dose for the rabbit was 1 mCi/kg. For a generator with 24 h prior elution time, the total amount of Tc (^{99m}Tc + ^{99}Tc) in 1 mCi of activity is $\sim 7 \times 10^{-12}$ mol. The total amount of technetium complex (RP463 + [^{99}Tc]RP463) injected into each infected rabbit (~2.5 kg) is ~25 ng (MW = 1542 for [^{99}Tc]RP463 in its sodium salt form). A study in primates showed that the minimal amount of peptide causing decrease of white blood cells is 10 ng/kg for fNleLFNleYK-DTPA (*6*). Therefore, it is not surprising that even the HPLC purified RP463 could cause the biological effect at a dose of 1 mCi/kg.

The use of ^{99m}Tc-labeled highly potent agonists as radiopharmaceuticals suffers a major drawback: severe reduction of peripheral leukocyte count. In general, there are three approaches to avoid this problem. The first approach is to separate the radiolabeled peptide from the excess unlabeled peptide using HPLC. This results in a product almost at its theoretical specific activity but is inconvenient for routine clinical use. The results described in this study clearly show that even the HPLC purified ^{99m}Tc-labeled peptide can cause a neutropenic effect if the ^{99m}Tc complex itself is a very potent agonist. The second approach involves using less active agonists with similar binding characteristics (*15*). However, lower binding affinity may result in less accumulation of the radioactivity at the receptor sites. The third approach is

to use antagonist peptides, which bind to the receptor but do not cause any neutropenic response, as targeting molecules. Unfortunately, the receptor binding affinity of the antagonists tested to date appear to be much lower than that of the agonists (*34*).

Recently, van der Laken and co-workers (*14*) have demonstrated that accumulation of the ^{99m}Tc-labeled fMLFK-HYNIC (RP469) in acute infection and sterile inflammation took place by virtue of binding to receptors on locally present PMNs and monocytes. Both the scintigraphic and biodistribution data showed that RP469 was cleared via both the kidneys and the liver. The high blood activity is probably related to the instability of RP469 and plasma protein binding. This assumption is supported by the fact that imine-N containing heterocycles can act as coligands and form stable ternary ligand complexes with the ^{99m}Tc-labeled HYNIC-peptide conjugate (*35*). The use of TPPTS coligand significantly increases the solution stability and hydrophilicity of the radiolabeled fMLFK-HYNIC. As a result, the excretion route for RP463 is mainly the renal system. The fast accumulation of RP463 at the infection site in combination with its rapid clearance results in continuously improving target-to-background ratios over 4 h.

Traditionally, modification of pharmacokinetics of a radiopharmaceutical is achieved either by attaching a pharmacokinetic modifier on the targeting biomolecule or by using a linker between the targeting biomolecule and the technetium chelate. The lipophilicity of the linker depends on pharmacokinetic requirements for the radiopharmaceutical. Results from this study and others (*4*) clearly show that the coligand of the technetium chelate can also be used for modifying pharmacokinetics and biodistribution of the radiopharmaceutical. As a matter of fact, one of the advantages using HYNIC as BFCA is that various coligands can be used for synthesis of ternary ligand technetium chelates.

CONCLUSION

The HYNIC-conjugated chemotactic peptide (fMLFK-HYNIC) has been labeled with ^{99m}Tc using a ternary ligand system (fMLFK-HYNIC, tricine and TPPTS). The complex [^{99m}Tc(fMLFK-HYNIC)(tricine)(TPPTS)] (RP463) was prepared in high yield (≥90%) and high specific activity (10 000 mCi/μmol fMLFK-HYNIC). The use of TPPTS as a coligand dramatically reduced the number of ^{99m}Tc species in the radiolabeled kit and increased the solution stability of the radiolabeled peptide. Compared to the unlabeled fMLFK-HYNIC ($IC_{50} = 3 \pm 2$ nM against binding of [^{3}H]fMLF to receptors on PMNs; $EC_{50} = 0.8 \pm 0.4$ nM), RP463 remains to be a strong agonist for the chemotactic receptor ($IC_{50} = 2$ nM against binding of [^{3}H]-fMLF to receptors on PMNs; $EC_{50} = 0.2 \pm 0.2$ nM) even though the molecular weight of RP463 is more than twice that of fMLFK-HYNIC.

The localization of RP463 in the infection foci was assessed in the rabbit infection model. Visualization of the infected foci could be as early as 2 h postinjection with the target-to-background ratio increasing from 1.5 ± 0.2 at 15 min postinjection to 7.5 ± 0.4 at 4 h postinjection as a result of a faster blood clearance mainly through the renal system. However, a 35% transient decrease in WBC count was observed during the first 30 min after injection of the HPLC-purified RP463. Because of this limitation, further research in this area should focus on the development of ^{99m}Tc-labeled antagonists with similar binding affinity for chemotactic peptide receptor or other receptors on PMNs and monocytes.

Preparation of a Cathepsin D Sensitive Near-Infrared Fluorescence Probe for Imaging

Ching-Hsuan Tung,* Sebastian Bredow, Umar Mahmood, and Ralph Weissleder

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, 149, 13th Street, Room 5406, Boston, Massachusetts 02129-2060. Received April 28, 1999; Revised Manuscript Received June 28, 1999

A variety of proteases are overexpressed or activated during pathogenesis and represent important targets for therapeutic drugs. We have previously shown that optical imaging probes sensitive in the near-infrared fluorescence (NIRF) spectrum can be used for in vivo imaging of enzyme activity. In the current study, we show that these probes can be designed with specificity for specific enzymes, for example, cathepsin D which is known to be overexpressed in many tumors. A NIR cyanine fluorochrome served as the optical reporter and was attached to the amino terminal of an 11 amino acid peptide sequence with specificity for cathepsin D. The peptides were subsequently attached to a synthetic graft copolymer for efficient tumoral delivery. The close spatial proximity of the multiple fluorochromes resulted in quenching of fluorescence in the bound state. A 350-fold signal amplification was observed post cleavage during in vitro testing. Cell culture experiments using a rodent tumor cell line stably transfected with human cathepsin D confirmed enzyme specific activation within cells. This sequence but not a scrambled control sequence showed enzyme specificity in vitro. We conclude that activatable NIRF optical probes can be synthesized to potentially probe for specific enzymes in living organisms.

INTRODUCTION

Cathepsin D (EC 3.4.23.5) (CaD) is an aspartic proteinase that is normally localized in lysosomes of various mammalian tissues. Its main function is in protein catabolism; however, a 2−50-fold increase in enzyme levels has been reported in breast cancers, demonstrated by immunohistochemistry (*1*) and in situ hybridization (*2*). High cathepsin D levels in tumors have also been associated with higher metastatic potential (*3*), invasion (*4, 5*), angiogenesis and degradation of basement membrane (*6*), and activation of other proteolytic enzymes (*4, 7*) as part of the metastatic cascade. Given its central role in different tumor pathways, cathepsins may represent unique targets for therapeutic (*4, 8*) or imaging applications (*9*).

We have recently reported a novel near-infrared fluorescence (NIRF)[1] probe for in vivo imaging of enzyme activity (*9*). The generic probes were designed to (1) have a long circulation time (*10*), (2) have high tumoral accumulation (*11*), and (3) contain quenched fluorescent markers which become fluorescent in the near-infrared spectrum after enzyme activation. The delivery vehicle consisted of a synthetic graft copolymer [partially methoxy poly(ethylene glycol) modified poly-L-lysine] onto which multiple NIR fluorochromes were attached to free poly-L-lysine residues. The graft copolymer has been used as delivery vehicle in several applications (*11*−*13*). Among them, ^{99m}Tc chelated graft copolymer used in blood pool imaging has been tested in phase I clinical trials (*14*). More recently, we also applied it to deliver NIRF probe for in vivo optical imaging of other lysosomal enzymes (*9*).

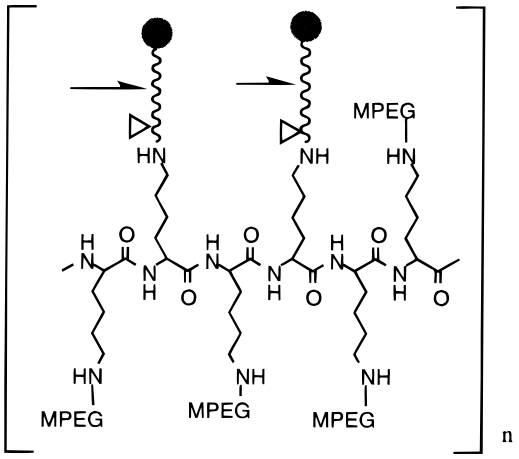

Figure 1. Schematic structure of NIRF probes. The undulating line represents the enzyme specific substrate peptide. The Cy5.5 fluorochrome is depicted as a dark circle and FITC as an open triangle. The cleavage position by target protease is indicated by the arrows.

The hypothesis underlying the current study was that cathepsin D sensitive peptide sequences could be used as linkers between the protected graft copolymer (PGC) and the NIRF fluorochrome and would act as substrates releasing fluorochrome after enzyme activation (Figure 1). Following optimization of reaction conditions, a CaD

sensitive probe and a scrambled nonsense control probe were synthesized and tested in vitro.

MATERIALS AND METHODS

Peptide Synthesis. A peptide with cathepsin D substrate specificity was synthesized on an automatic synthesizer (PS3, Rainin, Woburn, MA) by Fmoc chemistry using 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU)/*N*-hydroxybenzotriazole (HOBt) as the activating agent. All amino acids, resin, and reagents for peptide synthesis were purchased from Calbiochem-NovaBiochem (San Diego, CA), except Fmoc-Cys(Et) was obtained from Bachem (King of Prussia, PA). The sequences are Gly-*Pro-Ile-Cys(Et)-Phe-Phe-Arg-Leu*-Gly-Lys(FITC)-Cys-NH_2 [the italicized amino acids correspond to cathepsin D substrate (*15*)] for the CaD sensitive peptide (CDF), and Gly-Pro-Phe-Cys(Et)-Ile-Arg-Phe-Leu-Gly-Lys(FITC)-Cys-NH_2 for the scrambled control peptide (SCDF). Fmoc-Cys(Trt) was anchored to 0.1 mmol of Rink amide MBHA and followed with other amino acids, i.e., Fmoc-Lys(Dde), Fmoc-Gly, Fmoc-Leu, Fmoc-Arg(Pbf), Fmoc-Phe, Fmoc-Cys(Et), Fmoc-Ile, and Fmoc-Pro. The N-terminal was finally capped with t-Boc-Gly. Thereafter, the lysine side-chain protecting group, Dde, was selectively removed with 10 mL of 2% hydrazine in DMF (2 × 3 min), and the deprotected amino group was reacted with 0.4 mmol of fluorescein isothiocyanate (FITC) (Aldrich, Milwaukee, WI) in 5 mL of DMSO/diisopropylethylamine (20% v/v) overnight. The peptide was cleaved by 5 mL of TFA/thioanisole/ethandithiol/anisole (90/5/3/2) and purified by C18 reversed-phase HPLC using 0.1% TFA and acetonitrile as elution buffers. MALDI-MS $(M + H)^+$: CDF peptide, 1658.5 (calcd), 1658.2 (found); SCDF peptide 1658.5 (calcd), 1659.1 (found).

Specificity of Peptide Substrate. CDF or SCDF peptide (0.5 μmol) was incubated with 1 unit of CaD or positive control protease, chymotrypsin, in 200 μL of buffer and 20 μL of acetonitrile for 15 min (Sigma, St Louis, MO). PBS and 50 mM Gly-HCl, pH 3.5, buffers were used in chymotrypsin and CaD assays, respectively. The degradation was analyzed by reversed-phase HPLC (Brownlee, Spheri-5, ODS, 30 × 4.6 mm), using 0.1% TFA and acetonitrile as elution buffers.

Synthesis of NIRF Probes. Protected graft copolymer (PGC) consisting of a poly-L-lysine (PL) backbone and methoxy poly(ethylene glycol) (MPEG) side chains was prepared as described (*12*). The available amino groups for chemical conjugation is quantitated using TNBS (trinitrobenzene sulfonic acid) assay (*16*). There were 55 free amino groups per PGC molecule. The PGC (1 mg, MW = 450 000) in 200 μL of 50 mM $NaHCO_3$ was iodoacetylated by reaction with excess of iodoacetic anhydride (3.5 mg, 10 μmol) in 100 μL of DMF for 3 h. A microconcentrator, 50 kDa cutoff (Amicon, Beverly, MA), was used to separate the product from excess reagents, byproducts, and solvents. No free amino group on PGC was detected using TNBS assay.

The iodoacetylated PGC was then coupled to 3.2 mg (2 μmol) of CDF or SCDF through thiol specific reaction in 200 μL of acetonitrile and 200 μL of 0.1 M sodium acetate, pH 6.5, buffer for 3 h. Excess peptide and byproducts was separated from peptide−PGC conjugate by P-10 Bio-gel (Bio-Rad, Hercules, CA) size-exclusion chromatography. The coupling efficiency of peptide to PGC was determined by measuring fluorescein absorption at 494 nm ($\epsilon = 7.3 \times 10^4\ M^{-1}\ cm^{-1}$) divided by initial available amino groups. A total of 42 CDF or 44 SCDF peptide chains were coupled per PGC molecule.

Monoactivated near-infrared dye Cy5.5 (Amersham-Pharmacia, Piscataway, NJ), 1 μmol, was reacted to the N-termini of the peptide-PGC (0.5 mg) in 2 mL of 50 mM $NaHCO_3$. The reaction mixture was incubated at room temperature for 1 h, and products were purified using a 50 kDa cutoff Microcon concentrators. The loading efficiency of Cy5.5 was determined by dividing molarity of Cy5.5 to FITC. Extension coefficients $250 \times 10^3\ M^{-1}\ cm^{-1}$ and $73 \times 10^3\ M^{-1}\ cm^{-1}$ of Cy 5.5 at 675 nm and FITC at 494 nm were used. The average loading percentage was 50−60% for both probes.

Enzyme Activation. Fluorescence activation of the Cy-CDF-PGC probe (containing 0.5 nmol of Cy5.5 in 2

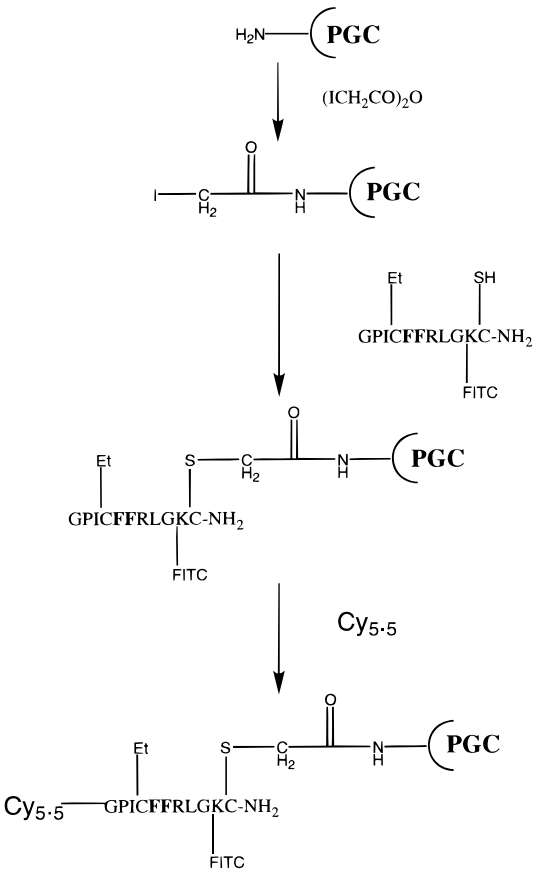

Figure 3. Synthetic scheme of the Cy-CDF-PGC probe.

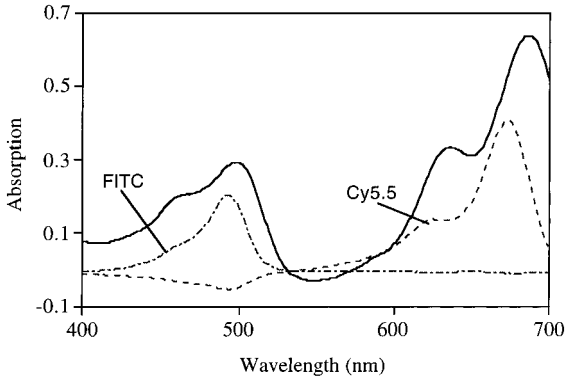

Figure 4. Absorption spectrum of Cy-CDF-PGC probe (solid line), free FITC and free Cy5.5. Absorption maximum for bound FITC and Cy5.5 are 498 and 687 nm, respectively.

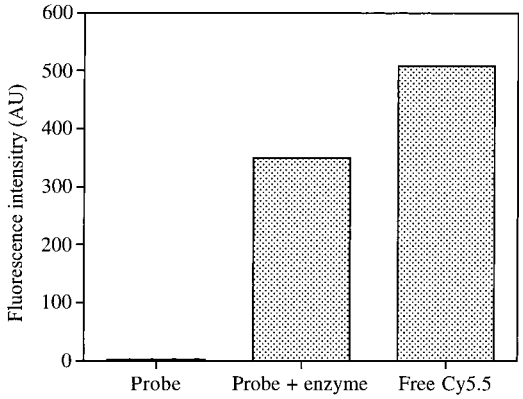

Figure 5. NIRF activation of Cy-CDF-PGC (ex = 675 nm and em = 694 nm). Initially, the Cy-CDF-PGC probe was completed quenched. At same concentration of Cy5.5, the fluorescence intensity of Cy-CDF-PGC, Cy-CDF-PGC with chymotrypsin and free Cy5.5 is 1 AU, 350 AU, and 509 AU, respectively.

mL of previously described buffer) with CaD or chymotrypsin was determined at different time point using a fluorescence spectrophotometer (Hitachi, U4500, Tokyo, Japan). Fluorescence intensity was measured at λ_{ex} 675 nm/λ_{em} 694 nm. The same concentration of free Cy5.5 fluorochrome solution was prepared, and its fluorescence intensity was collected as a reference.

Cell Culture Experiments. The NIRF probe was subsequently tested in cell culture using a rodent cell line stably transfected with human cathepsin (Cath D-1), which was kindly provided by Dr. Henri Rochefort (INSERM, Montpellier, France) (*7*). Cath D-1 cells were cultured in RPMI medium containing 10% FCS and 400 μg/mL G418 on glass cover slips in a 12-well plate (Becton Dickinson, Bedford, MA). CaD expression was confirmed by RT-PCR and Western blotting (*17*). Culture medium was then replaced with 500 μL of fresh medium containing 1 nmol of the NIRF probe. After 1 h at 37 °C, the cells were washed three times and analyzed by fluorescence microscopy. Cells were viewed in phase contrast or fluorescence mode using an inverted epifluorescence microscope (Zeiss, Axiovert, Thornwood, NY) with a cooled charged coupled device (CCD) camera (Sensys, Photometrics, Tuscon, Az) interfaced to a Power Macintosh 7600/120 computer. The microscope was equipped with appropriate excitation and emission filters for FITC (485/530 nm) and Cy5.5 (670/700 nm) (Omega Optical, Brattleboro, VT). Images were analyzed using Spectrum Analysis software, and images were fused using Adobe Photoshop software.

RESULTS AND DISCUSSION

NIRF Probe Preparation. To impart enzyme specificity onto the optical probe, a CaD substrate spacer was used to link the NIR fluorochrome to the PGC backbone (Figure 1). The CaD-specific substrate, Pro-Ile-Cys(Et)-Phe-Phe-Arg-Leu, was selected from published literature (*15*). This peptide has a K_m and k_{cat} of 27.5 μM and 196 S^{-1}, respectively. Glycine residues were added to both termini as spacers. The peptide was furthermore modified to accommodate fluorescein isothiocyanate (FITC) as a tracing tag during conjugation and for quantitation. A cysteine amide residue was then incorporated to obtain a mono reactive sulfhydryl group. The overall sequence of this CaD fluorescein (CDF) peptide is Gly-Pro-Ile-Cys(Et)-Phe-Phe-Arg-Leu-Gly-Lys(FITC)-Cys-NH_2. In addition, a scrambled peptide (SCDF), Gly-Pro-Phe-Cys(Et)-Ile-Arg-Phe-Leu-Gly-Lys(FITC)-Cys-NH_2, was prepared as a control.

Before synthesizing the NIRF probe, the specificity of the peptide substrates was determined with CaD and a nonspecific endoprotease, chymotrypsin (Figure 2). The latter served as an in vitro positive control; in vivo, chymotrypsin is exclusively present in exocrine pancreas but not in other solid organs, tumors, muscle, or fat or within the vasculature. As expected, CaD recognized the CDF and cleaved the peptide between two phenylalanine residues. The HPLC elution chromatogram indicates one major cut of the CDF peptide. Two fragments were eluted at 4.8 and 5.5 min (Figure 2C). Since the scrambled control peptide SCDF was not a substrate of CaD, the peptide remained intact and eluted at the original time, 6.4 min (Figure 2, panels B and D). In contrast, chymotrypsin, a nonspecific endoprotease, recognized and cleaved the C-termini of hydrophobic amino acids, e.g., Phe and

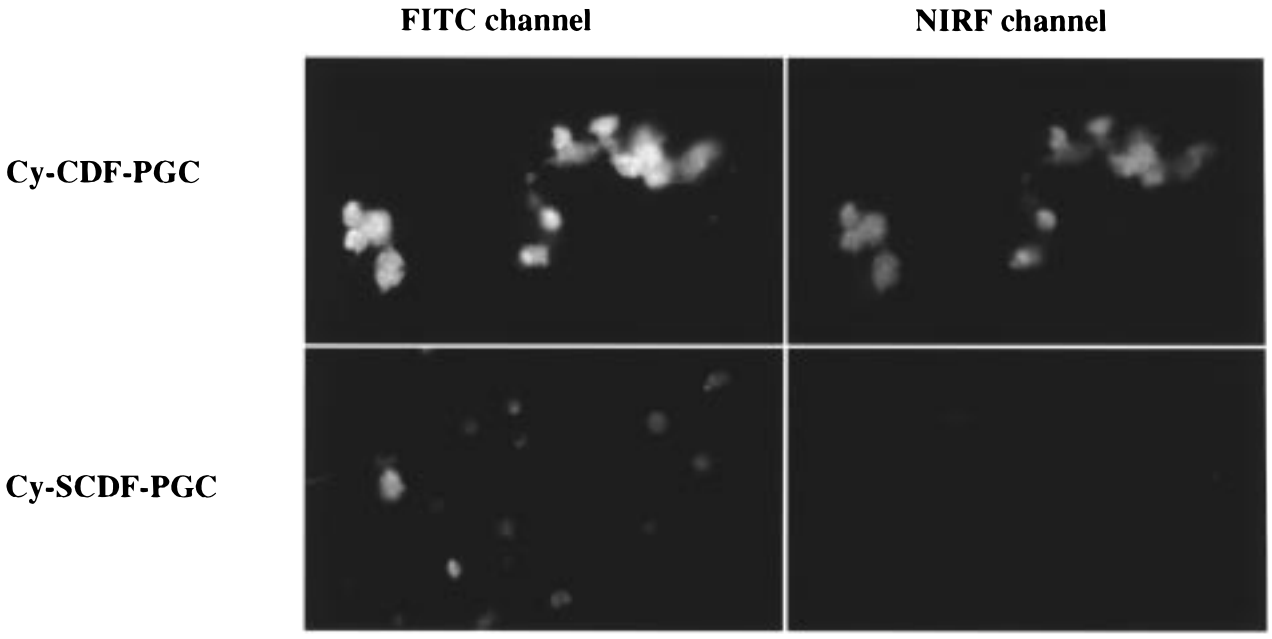

Figure 6. Testing of Cy-CDF-PGC and control Cy-SCDF-PGC probes in rodent tumor cells stable transfected with human cathepsin D. Cellular internalization of the probes is monitored in the FITC channel while probe activation through CaD is observed in the NIRF channel.

Leu in these peptides, resulting in complex chromatograms for both peptides (Figure 2, panels E and F).

The conjugation of the peptide to PGC was initiated by iodoacetylation of PGC (Figure 3) using a large excess of iodoacetic anhydride. All free amino groups on PGC were converted into iodoacetyl group. CDF or SCDF was then coupled to functionlized PGC in 50% acetonitrile and 50% sodium acetate buffer, 0.1 M, pH 6.5. Due to the relative hydrophobicity of the peptides, higher loading of PGC caused precipitation of the entire complex. The achieved loading of the peptide to PGC was 42 peptide chains per PGC molecule, i.e., 80%.

A monoreactive activated ester of the NIR fluorochrome, Cy5.5, was subsequently attached to the N-terminus of the peptide under a basic condition. Since Cy5.5 and FITC have their absorption and emission at different wavelengths, no energy transfer was observed between these two fluorochromes (Figure 4). Wavelength shifts of the fluorescein and Cy5.5 were observed; the absorption maximum shift ranged from 493 to 498 nm and 674 to 687 nm, respectively. The loading efficiency of Cy5.5 was determined by absorption at 675 nm, compared to the absorption of FITC at 494 nm. Approximately 60% of the peptide chain was labeled with Cy5.5, which is equivalent to 24 Cy5.5 fluorochromes/PGC molecule. A larger excess of Cy5.5 was also used to achieve more complete loading, however, precipitation was observed, despite the excellent aqueous solubility of Cy5.5. The prepared NIRF probes were named Cy-CDF-PGC and Cy-SCDF-PGC.

Quenching and Dequencing Effect. The NIRF probe was designed to have minimal fluorescent signal while in circulation, important for in vivo use. Ideally, only specific proteases under investigation would activate the probe and initiate NIR fluorescence. The quenching effect of the prepared NIRF probes was examined using fluorescent spectroscopy. In PBS, a solution of free Cy5.5 fluorochrome had a fluorescence intensity of 509 AU, while an equimolar solution of Cy-CDF-PGC had an emission signal of only 1 AU at 694 nm (i.e., more than 99% quenching) (Figure 5). Although we only achieved 60% loading of the peptide-PGC, the local density of fluorochrome was sufficiently high for autoquenching to occur.

The activation of the fluorescence signal of the NIRF probe was tested with CaD at its optimal condition, a 50 mM Gly-HCl, pH 3.5, buffer (*15*). Surprisingly, neither Cy-CDF-PGC nor Cy-SCDF-PGC was activatable under this experimental condition. The reason of inactivation of NIRF probe with pure CaD at acidic condition in vitro is somewhat unclear. One possibility is that the intramolecular interaction between peptides or fluorochromes causes collapse of the macromolecule.

However, when Cy-CDF-PGC was incubated with the in vitro positive control protease, chymotrypsin, a 350-fold NIRF signal increase was obtained within 8 h of incubation (Figure 5). The regained NIRF signal is equal to 70% of theoretical signal of free Cy5.5 fluorochrome. In contrast, a previously described probe, which had the same Cy5.5 fluorochrome directly attached to the backbone of PGC without any peptide spacer between, had only a 15-fold increase in NIRF signal recovery. However, this was sufficient for in vivo selective imaging of tumors (*9*). The improved ratio of signal generation compared with background of the quenched state in the new probe is due to the increased number of fluorochromes attached per PGC, resulting in more complete quenching, as well as a better release of fluorochromes from each backbone.

Activation in Cell Culture. The usefulness of the NIRF probe for imaging was subsequently evaluated in cell culture. We utilized murine 3Y1-AD12 embryonic tumor cells which were stably transfected with human CaD (CathD-1) (*7*). In tissue culture, the CathD-1 cells were incubated with 1 nmol of Cy-CDF-PGC at 37 °C for 1 h. Subsequently, the live cells were studied by fluorescence microscopy at FITC and Cy5.5 channels with appropriate filter sets. The fluorescein signal indicated internalization of the probe, and the Cy5.5 signal indicated the cellular CaD activity. When Cy-CDF-PGC was applied, the fluorescein signal correlated with NIR signal in the CathD-1 cells. In contradistinction, only fluorescein

signal was observed in Cy-SCDF-PGC; no NIR signal was detected at the Cy5.5 channel (Figure 6).

These results indicate that cellular internalization of the Cy-CDF-PGC probe occurs presumably into the lysosomal compartment, and NIRF is generated due to CaD activity. The specificity was confirmed when virtually no NIRF signal was recovered using the Cy-SCDF-PGC probe. These data from cellular activation assays suggest potential usage of this CaD sensitive probe for in vivo optical imaging.

CONCLUSION

The developed biocompatible, enzyme activatable NIRF imaging probe represents a critical link toward development of in vivo molecular optical imaging (*9*). The enzyme specific probe could potentially be used to image exogenous or endogenous enzyme expression. Whereas the former has far reaching applications in gene therapy and developing marker genes detectable by imaging, the latter can be used to probe for enzyme activities in various disease states. One specific application is to use the probe for tumor detection based on overexpressed proteolytic enzymes involved in tumorigenesis, angiogeneis, or matastagenesis. Ultimately, the technique can be extended to other enzymes, for example matrix metaloproteinases, caspases, or prostate specific antigen among others.

ACKNOWLEDGMENT

We would like to thank Dr. Alexei Bogdanov for providing PGC and Dr. H. Rochefort for Cathepsin D cell lines. This study was supported in part by grants from NIH (RO1 NS35258) and the MGH Center for Innovative Minimally Invasive Therapy (CIMIT).

Received May 4, 1999; Revised Manuscript Received June 29, 1999

The presence of hypoxic cells in solid tumors is a marker for therapy-resistant, aggressive disease. The noninvasive detection of hypoxic cells in tumors by radiolabeled 2-nitroimidazoles is a diagnostic technique under current evaluation. Two peptidic agents, dimethylglycyl-L-seryl-L-cysteinyl-lysyl{N_ϵ-[1-(2-nitro-1*H*-imidazolyl)acetamido]}glycine (RP435) and dimethylglycyl-*tert*-butylglycyl-L-cysteinyl-glycine-[2-(2-nitro-1*H*-imidazolyl)ethyl]amide (RP535) have been synthesized. Both agents contain an N_3S class chelator for ^{99m}Tc and Re and a 2-nitroimidazole group which can be enzymatically reduced and selectively trapped in cells under hypoxic conditions. Two isomers of ^{99m}TcO-RP435, which are assumed to be syn and anti conformations, were observed on HPLC analysis. The interconversion of the two isomers in aqueous solution was investigated. In contrast, RP535 chelated ^{99m}Tc to form a single isomer and no conversion to its counterpart has been observed on HPLC analysis. The *tert*-butyl group on the chelator may inhibit the formation and interconversion of the syn and anti isomers of ^{99m}TcO-RP535. Both tracers showed a significant degree of hypoxia-specific accumulation in an in vitro assay, with ^{99m}TcO-RP535 showing higher selectivity for hypoxic cells than ^{99m}TcO-RP435. These results suggest that ^{99m}TcO-RP535 represents a lead compound worthy of further investigation as an agent for imaging hypoxia in tumors.

INTRODUCTION

Detection of regions of hypoxia is important in several medical conditions. It is important to delineate hypoxic but viable tissue following interruption of blood flow in cerebral or myocardial infarction (*1*). Furthermore, it has recently been recognized that hypoxia in tumors plays a role not only in response to radiation, through the oxygen effect in fixation of DNA damage, but also in metastatic potential and response to other forms of therapy (*2*−*4*). However, hypoxia is heterogeneous, and tumors which appear identical by all other clinical measures can vary greatly in their proportion of hypoxic cells. At present, hypoxia is measured clinically with a polarographic oxygen electrode inserted into tumors; however, this is invasive, operator dependent, limited to accessible tumors, and not readily repeatable (*2, 4*). In recent years, several radiopharmaceuticals have been developed which are targeted to hypoxic tissues via a 2-nitroimidazole (2-NI) moiety (*1, 5*). 2-NIs are electron-affinic compounds which undergo an enzyme-mediated one-electron reduction; in normoxic tissue, the resultant radical anion is immediately oxidized back to the starting compound, whereas under hypoxic conditions there is further reduction to products which are trapped by binding to macromolecules (*6*). A radiolabeled 2-NI would therefore be selectively trapped in hypoxic tissues.

Clinical studies have been performed with several radiolabeled 2-NIs, including [^{18}F]fluoromisonidazole (FMISO) (*7*, *8*) and [^{123}I]iodoazomycin arabinoside (IAZA) (*9, 10*). However, the search continues for a ^{99m}Tc-labeled analogue that would be more widely applicable. BMS181-321, a 2-NI linked to a PnAO chelator, has been evaluated in several model systems and shows promise, but its high lipophilicity and metabolic instability result in high background levels of radioactivity (*11*−*14*). BRU59-21 (previously known as BMS194796) appears to possess improved biodistribution characteristics, but only limited information is available about it (*15, 16*). In addition, butyleneamine oxime (BnAO or HL91; Prognox, Nycomed-Amersham) is a nonnitro ^{99m}Tc complex that shows localization in hypoxic myocardium and tumors via an undetermined mechanism (*17*−*20*).

Recent work involving radioiodinated sugar derivatives of 2-NI has suggested that an octanol/water partition coefficient (PC) of ∼1 confers optimal biodistribution properties for tumor imaging (*5*). BMS181321 and BRU59-21 have PCs which are much higher (40 and 12, respectively) and cannot be readily modified to achieve a lower PC. As part of our radiopharmaceutical development program, we designed two compounds in which peptidic chelators for ^{99m}Tc were linked to 2-NI and evaluated the complexes in an in vitro model of tumor hypoxia. Dimethylglycyl-L-seryl-L-cysteinyl-glycinamide (RP294, Figure 1), which contains a sulfur atom (protected by an acetoamidomethyl group), one amine nitrogen atom, and two

amide nitrogen atoms, is an N_3S class chelator for $^{99m}Tc^{v}O$ and $Re^{v}O$ in a distorted square pyramidal geometry with the oxo moiety in the apical position. The metal complexes exist in syn and anti isomers with respect to the position of the metal−oxo bond and serine hydroxymethyl side chain. Interconversion of the two isomers in aqueous solution at room temperature has been observed (*21*).

In the present work, *N*,*N*-dimethylglycyl-L-seryl-L-cysteinyl-lysyl{N_ϵ-[1-(2-nitro-1*H*-imidazolyl)acetamido]}-glycine (RP435, Figure 1) was prepared by attaching 2-NI-acetic acid to a lysine linker connected to the RP294 chelator. RP435 chelates ^{99m}Tc at room temperature, and two peaks, assumed to be the syn and anti isomers, were detected by HPLC. However, the PC of ^{99m}TcO-RP435 is far lower than what is believed to be the optimum value. Accordingly, a new N_3S class peptide, *N*,*N*-dimethylglycyl-L-*tert*-butylglycyl-L-cysteinyl-glycin[2-(2-nitro-1*H*-imidazolyl)ethyl]amide (RP535, Figure 1) was designed and synthesized. The chelator (RP455, Figure 1) contains a *tert*-butyl group, which should increase the lipophilicity of the corresponding ^{99m}Tc complex and inhibit the interconversion of syn and anti isomers. The labeling, stability, and in vitro cellular accumulation of these compounds was studied.

EXPERIMENTAL PROCEDURES

2-Nitroimidazole, 2-bromoethylphthalimide, *N*,*N*-dimethylformamide (DMF), 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (DECI), 2,3,5,6-tetrafluorophenol (TFP), and trifluoroacetic acid (TFA) were purchased from Aldrich Chemical Co. (Milwaukee, WI). *N*,*N*-Dimethylglycyl-L-*tert*-butylglycyl-L-cysteinyl-glycine (RP455) was custom synthesized by Bachem Bioscience Inc. (Philadelphia, PA). *N*,*N*-Dimethylglycyl-L-seryl-L-cysteinyl-glycinamide (RP294) and ReO-RP455 precursor were provided by Resolution Pharmaceuticals Inc. (Mississauga, ON). Sodium $^{99m}TcO_4$ in saline was obtained from a ^{99}Mo/^{99m}Tc generator (DuPont Pharma, Billerica, MA). α-MEM and fetal bovine serum were purchased from Sigma Chemical Co. (St. Louis, MO).

NMR data (^{1}H, ^{13}C, COSY, HSQC, HMQC, TOCSY) were recorded on a Varian UNITYplus-500 spectrometer (500 MHz) with TMS as external standard. Electrospray mass spectra were obtained on a Sciex API#3 spectrometer in the positive ion mode. Reversed-phase high-pressure liquid chromatography (HPLC) analyses of peptide and ^{99m}Tc−peptide complexes were carried out on a Beckman model 125 System Gold (Fullerton, CA), with Zorbax SB or Beckman ODS 4.6 × 250 mm 5 μm C_{18} columns. Purification of peptides was accomplished by HPLC with a Waters C_{18} RCM 8 × 10 semipreparative column. UV and radiometric detectors were connected in series. Two mobile phases were used for HPLC analysis of ^{99m}Tc tracers. Mobile phase I was composed of H_2O/ACN containing 0.1% TFA, whereas mobile phase II was 0.02 M, pH 4.6, NH_4OAc buffer/MeOH; both were run as gradients. The flow rate was 1.0 mL/min for analysis and 2.0 mL/min for purification.

Synthesis of 2-Nitroimidazole Acetic Acid. To 1.0 g (8.8 mmol) 2-nitroimidazole and 2.0 g (14.5 mmol) potassium carbonate in 10 mL dry acetonitrile was added 1.20 mL (10.6 mmol) of bromoethyl acetate. The reaction mixture was stirred for 24 h at room temperature followed by filtration and washing of the solid product with acetone. Evaporation of the pooled filtrates under reduced pressure yielded 2.29 g of crude 2-nitroimidazole ethyl acetate as a yellow oil. To the crude oil was added a solution of NaOH (4 N, 2.5 mL), water (10 mL), and MeOH (10 mL). The solution was stirred and monitored

by thin-layer chromatography (silica gel; CH_2Cl_2:MeOH:NH_3, 50:7:1) until none of the ester remained (~30 min). The solution was acidified by addition of a cation-exchange resin (Bio-Rad, 4 g), which had been converted to the protonated form by washing with H_2SO_4 (1 N, 60 mL). Following filtration and evaporation of MeOH, the concentrated solution was lyophilized for 4 days to yield 1.16 g (6.8 mmol, 77%) of 2-nitroimidazole acetic acid. ^{1}H NMR (275 MHz, DMSO): δ 7.5 (s, 1H), 7.1 (s, 1H), 4.8 (s, 2H).

Synthesis of *N*,*N*-Dimethylglycyl-L-seryl-L-cysteinyl-lysyl{N_ϵ-[1-(2-nitro-1*H*-imidazolyl)acetamido]}-glycine (RP435). The peptide backbone was prepared on an automated peptide synthesizer (Applied Biosystems Inc., model 433A, Foster City, CA) using Sasrin resin and 9-fluorenylmethoxycarbonyl-protected amino acids. When the backbone was complete, the 1-(4,4-dimethyl-2,6-dioxocyclohexylidine)-ethyl protecting group on the ϵ-amine of lysine was cleaved with 2% hydrazine and the free amine was coupled with 2-nitroimidazole acetic acid. The peptide was cleaved from the resin by stirring with 95% aqueous TFA at 0 °C for 30 min and then at room temperature for 60 min. The resin was filtered, and the filtrate was evaporated under vacuum. The residue was washed with a minimum amount of *tert*-butyl methyl ether, which caused the precipitation of the peptide. The ether was removed, and the residue was dissolved in a minimum amount of water and then lyophilized to yield 190 mg of crude product, of which 110 mg was further purified by HPLC, yielding 35 mg (31%) pure RP435. ^{1}H NMR (500 MHz, d_6-DMSO): δ 1.33 [m, 2H, H(18)], 1.43 [m, 2H, H(19)], 1.59 [m, 1H, H(17a)], 1.72 [m, 1H, H(17b)], 1.86 [s, 3H, H(30)], 2.58 [broad, 6H, H(1, 2)], 2.68 [dd, 1H, H(13a), $J_{H13a-H11}$ = 9.89 Hz, $J_{H13a-H13b}$ = 14.04 Hz], 2.95 [dd, 1H, H(13b), $J_{H13b-H11}$ = 3.91 Hz, $J_{H13b-H13a}$ = 13.92 Hz], 3.05 [m, 2H, H(20)], 3.61 [m, 2H, H(7)], 4.13 [m, 1H, H(15)], 4.20 [dd, 1H, H(27a), $J_{H27a-H28}$ = 5.86 Hz, $J_{H27a-H27b}$ = 13.67 Hz], 4.32 [dd, 1H, H(27b), $J_{H27b-H28}$ = 5.13 Hz, $J_{H27b-H27a}$ = 13.67 Hz], 4.44 [m, 1H, H(6)], 4.56 [m, 1H, H(11)], 5.07 [s, 2H, H(23)], 5.09 [broad, 1H, H(8)], 7.18 [d, 1H, H(25), $J_{H25-H24}$ = 0.97 Hz], 7.61 [d, 1H, H(24), $J_{H24-H25}$ = 0.98 Hz], 8.0 [d, 1H, H(14), J_{H14-15} = 7.57 Hz], 8.31 [m, 2H, H(*10, 21*)], 8.56 [t, 1H, H(28), $J_{H28-H27}$ = 6.47 Hz]. Electrospray mass spectrum: *m*/*z* 646.15 ([M + H]$^+$, $C_{24}H_{40}N_9O_{10}S$, calculated = 645.69).

Synthesis of 2-(2-nitro-1*H*-imidazolyl)ethylamine hydrochloride was accomplished by minor modification of a published method (*22*). A total of 0.56 g (5.0 mmol) of 2-nitroimidazole, 1.33 g (5.2 mmol) of *N*-(2-bromoethyl)phthalimide, and 0.72 g (5.2 mmol) of potassium carbonate was mixed in 15 mL of DMF and heated at 110 °C for 2 h. After removing the solvents, water was added to the residue to dissolve the salts. The precipitate was collected, washed by water, and dried under vacuum to yield 0.8 g (2.8 mmol, yield 56%) of raw product. The raw product was refluxed with 0.28 g (5.6 mmol) hydrazine monohydrate in 20 mL of EtOH for 2 h and then cooled to 4 °C, filtered, and evaporated to dryness. The residue was dissolved in 20 mL of 1 N HCl, filtered, and brought to dryness again. The residue was recrystallized from MeOH/EtOAc to yield 240 mg (1.25 mmol, 44%) of product.

Synthesis of *N*,*N*-Dimethylglycyl-L-*tert*-butylglycyl-L-cysteinylglycin[2-(2-nitro-1*H*-imidazolyl)ethyl]amide (RP535). A total of 80 mg (0.18 mmol) of RP455, 55.4 mg (0.29 mmol) of DECI, and 48 mg (0.29 mmol) of TFP was dissolved in 1 mL of DMF. The mixture was stirred in an ice bath for 10 min, followed by 30 min at room temperature, and then in a 45 °C oil bath for 60 min. A total of 37.2 mg (0.19 mmol) of 2-(2-nitro-1*H*-imidazolyl)ethylamine hydrochloride was added to the mixture which was set in an ice bath. To the mixture was added dropwise 74.7 mg (0.58 mmol) of diisopropyl ethylamine (DIEA) in 1 mL of DMF. The mixture was stirred at 45 °C for 1 h. The solvent was removed after the reaction was completed. About 2 mL of water was added and then removed. The crude product was purified by HPLC, yielding 50 mg (0.085 mmol, 47%) of pure RP535. ^{1}H NMR (500 MHz, d_6-DMSO): δ 0.93 [s, 9H, H(8, 9, 10)], 1.86 [s, 3H, H(28)], 2.71 [dd, 1H, H(14a), $J_{H14a-H13}$ = 9.3 Hz, $J_{H14a-H14b}$ = 13.9 Hz], 2.79 [t, 6H, H(1, 2), J = 4.0 Hz], 2.90 [dd, 1H, H(14b), $J_{H14b-H13}$ = 4.6 Hz, $J_{H14b-H14a}$ = 13.9 Hz], 4.25 [d, 1H, H(25a), $J_{H25a-H26}$ = 6.59 Hz], 4.27 [d, 1H, H(25b), $J_{H25b-H26}$ = 6.59 Hz], 4.37 [d, 1H, H(6), J_{H6-H5} = 9.27 Hz], 4.47 [m, 1H, H(13)], 7.16 [d, 1H, H(23), $J_{H23-H22}$ = 1.2], 7.51 [d, 1H, H(22), $J_{H22-H23}$ = 0.98 Hz], 7.89 [t, 1H, H(19), $J_{H19-H20}$ = 5.98 Hz], 8.14 [t, 1H, H(16), $J_{H16-H17}$ = 5.6 Hz], 8.39 [d, 1H, H(12), $J_{H12-H13}$ = 7.57 Hz], 8.45 [t, 1H, H(26), $J_{H26-H25}$ = 6.59 Hz], 8.61 [d, 1H, H(5), J_{H5-H6} = 9.27 Hz]. Electrospray mass spectrum: *m*/*z* 586.11 ([M+H]$^+$, $C_{23}H_{40}N_9O_7S$, calculated = 585.69).

Synthesis of ^{99m}TcO-RP294, ^{99m}TcO-RP435, ^{99m}TcO-RP455, and ^{99m}TcO-RP535. To a 3 mL tube were added RP294, RP435, RP455, or RP535 (100−200 μg), $Na^{99m}TcO_4$ solution (2−10 mCi in 200 μL of saline), and 100 μL of stannous gluconate solution (which contained 10−40 μg of $SnCl_2$ and 0.25−1.0 mg of sodium gluconate). The mixture was incubated at 20−100 °C for 15−30 min. The ^{99m}Tc complexes were analyzed by HPLC (Zorbax SB column, H_2O/ACN containing 0.1% TFA; gradient 100 to 90% H_2O over 45 min for ^{99m}TcO-RP294, 100 to 70% H_2O for ^{99m}TcO-RP435, and 100 to 50% H_2O for ^{99m}TcO-RP455 and ^{99m}TcO-RP535). UV detection at 320 nm was used to monitor the disappearance of the 2-NI absorption peak of the ligand. The radiochemical yields were ^{99m}TcO-RP294, >97%; ^{99m}TcO-RP435, >68%; ^{99m}TcO-RP455, >99%; and ^{99m}TcO-RP535, >78%. Formation of ^{99m}Tc-colloid was <6%. ^{99m}TcO-RP435 and ^{99m}TcO-RP535 were purified for further experiments by HPLC using the same conditions stated above.

Synthesis of ReO-RP535. A total of 10 mg (0.017 mmol) of ReO-RP455 and 13.3 mg (0.070 mmol) of DECI were dissolved in 0.6 mL of ACN solution, which contained 20% 0.01 M NaOAc/HOAc. To the mixture was added 2.89 mg (0.017 mmol) of TFP dissolved in 0.3 mL of ACN-acetate solution. The mixture was stirred at room temperature for 30 min and then at 45 °C for 1 h. To the mixture was added 3.34 mg (0.017 mmol) of 2-(2-nitro-1*H*-imidazolyl)ethylamine HCl in 0.5 mL of ACN-acetate solution, followed by 2.6 mg (0.20 mmol) of DIEA. After stirring at 45−50 °C for 2 h, the solvent was removed, and the crude product was purified by HPLC (Zorbax SB column, H_2O/ACN containing 0.1% TFA, flow rate 1.0 mL/min; gradient 100 to 50% H_2O in 45 min). The fraction with a retention time of 11.62 min was collected and lyophilized. ^{1}H NMR (500 MHz, d_6-DMSO): δ 1.03 [s, 9H, H(8, 9, 10)], 2.44 [s, 3H, H(1)], 3.55 [s, 3H, H(2)], 3.83 [d, 1H, H(14a), $J_{H14a-H13}$ = 12.2 Hz], 4.02 [d, 1H, H(3a), $J_{H3a-H3b}$ = 14.9 Hz], 4.40 [t, 1H, H(21a), $J_{H21a-H20}$ = 5.62 Hz], 4.41 [t, 1H, H(21b), $J_{H21b-H20}$ = 5.6 Hz], 4.46 [s, 1H, H(6)], 4.82 [d, 1H, H(3b), $J_{H3b-H3a}$ = 14.9 Hz], 5.08 [d, 1H, H(14b), $J_{H14b-H13}$ = 6.84 Hz], 6.99 [d, 1H, H(23), $J_{H23-H22}$ = 1.22 Hz], 7.44 [d, 1H, H(22), $J_{H22-H23}$ = 1.22 Hz], 7.72 [t, 1H, H(19), $J_{H19-H20}$ = 5.86 Hz], 8.19 [t, 1H, H(16), $J_{H16-H17}$ = 5.62 Hz]. ES-MS: *m*/*z* 712.93 ([M + H]$^+$, $C_{20}H_{32}N_8O_7{}^{185}ReS$, calculated = 712.58) and *m*/*z* 714.94

([M + H]$^+$, $C_{20}H_{32}N_8O_7{}^{187}ReS$, calculated = 714.58), confirming a 1:1 ratio of ligand to metal ion.

Partition Coefficient (*n*-Octanol/PBS) Determination for ^{99m}TcO-RP435 and ^{99m}TcO-RP535. A total of 10 μL of HPLC purified ^{99m}TcO-RP435 or ^{99m}TcO-RP535 was added to a tube which contained 1.0 mL of *n*-octanol and 1.0 mL of 0.1 M, pH 7.4, PBS. The tube was shaken for 1 min. After partial separation of the phases by gravity, 0.7 mL of each phase was transferred to a tube and centrifuged at 12000*g* for 5 min. Duplicate 0.2 mL aliquots of each phase were taken for γ-radioactivity counting.

Cellular Accumulation in an in Vitro Model. Each complex was evaluated in an in vitro model which has been used in the study of other tracers of hypoxia (*14, 16, 20, 23*). Suspensions of Chinese hamster ovary (CHO) cells were incubated at 37 °C with stirring under an atmosphere of air or nitrogen (both containing 5% CO_2) to generate aerobic or hypoxic conditions, respectively. The tracer was added and aliquots were removed over the course of 4 h and centrifuged, and the radioactivity associated with the cell pellet was measured in a γ well counter. The results were expressed as the ratio of concentration of radioactivity in the cell pellet to that in an equivalent volume of supernatant medium (C_{in}/C_{out}) as a function of time, as described previously (*14*). To demonstrate the involvement of the 2-NI group in localization, experiments were performed in which 5 mM misonidazole or 8 mM metronidazole were added 30 min before the tracer. We have demonstrated previously that an unlabeled 2-NI, such as misonidazole, can inhibit the hypoxic accumulation of ^{99m}Tc-labeled 2-NI, and that an unlabeled 5-NI, such as metronidazole, which has a lower electron affinity than 2-NI, can enhance the cellular accumulation of ^{99m}Tc-labeled 2-NI (*24*).

RESULTS

Synthesis of RP435 and RP535. RP435 was prepared by attaching 2-NI-acetic acid to a lysine connected to a peptidic N_3S chelator (Figure 1). After being cleaved from the resin, RP435 was purified by reversed-phase HPLC. The purity was shown to be >98%. RP535 was prepared by coupling 2-(2-nitro-1*H*-imidazolyl)ethylamine to RP455 (Figure 1). The purity of RP535 was analyzed by two HPLC gradients (100 to 70% H_2O and 100 to 50% H_2O over 45 min) and shown to be >97% based on UV detection at 214 and 320 nm.

The molecular weight of RP435 determined by mass spectrometry was consistent with the proposed structure. The ^{1}H NMR (500 MHz) spectrum of RP435 revealed the two protons of the 2-nitroimidazole at 7.19 and 7.61 ppm with a weak mutual coupling (J = 0.97 Hz). The proton of the hydroxyl H(8) appeared at 5.09 ppm as a broad peak. Four of the five amide protons of RP435, H(10), H(14), H(21), and H(28), were identified. H(10) and H(21) overlapped each other at 8.31 ppm. The six protons of H(1) and H(2) formed a broad peak at 2.57 ppm, while the two protons of H(3) were merged in the solvent peak ranging from 3.26 to 3.36 ppm.

MS analysis of RP535 showed the molecular ion signal at the expected mass. The ^{1}H NMR spectrum of RP535 exhibited signals of all five amide protons (Figure 1), with H(5) at 8.61 ppm, H(26) at 8.45 ppm, H(12) at 8.39 ppm, H(16) at 8.13 ppm, and H(19) at 7.89 ppm, respectively. Similar to RP435, the two protons of the 2-nitroimidazole of RP535 showed a weak mutual coupling ($J_{H22-H23}$ = 1.1 Hz). The nine protons of the *tert*-butyl group, H(8, 9, 10), appeared as a singlet peak at 0.91 ppm. It is interesting to note that the six protons, H(1, 2), of the two methyl groups of dimethylglycine produced triplet peaks, instead of a singlet peak, at 2.80 ppm. The signals of H(3), H(17), and H(20) were partly merged in the solvent peak ranging from 3.50 to 3.66 ppm, while H(13) and H(21) overlapped each other at 4.45 ppm (m, 3H). These data indicated that RP535 contained the N_3S chelator, a 2-nitroimidazole group, and the acetamidomethyl protecting group for the sulfur atom of cysteine.

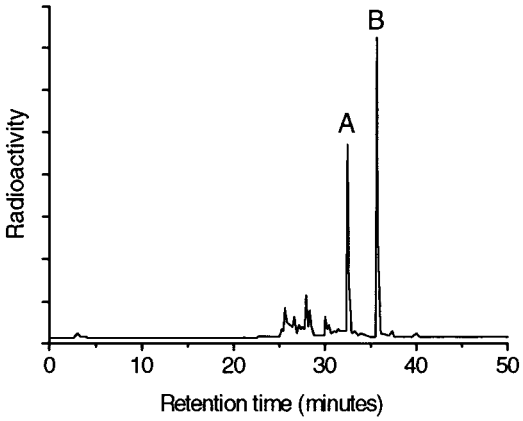

Figure 2. HPLC analysis of ^{99m}Tc labeling of RP435 demonstrating formation of two main products, peak A and peak B, in a total yield of ~70%. Zorbax C_{18} column eluted with H_2O/ACN containing 0.1% TFA; gradient 100% to 70% H_2O over 45 min; flow rate 1 mL/min.

^{99m}Tc Labeling of RP294, RP455, and RP435. ^{99m}Tc labeling of RP294 and RP435, which have the same N_3S chelator, can be carried out at room temperature via transchelation from ^{99m}Tc-gluconate. However, ^{99m}Tc labeling of RP455, which has a *tert*-butyl group on the chelator, requires heating in a boiling water bath for 10−15 min. ^{99m}TcO-RP294 showed two peaks on HPLC in 0.1% aqueous TFA/ACN in a total yield >97%. In contrast, ^{99m}TcO-RP455 showed one single peak (yield >99%). When analyzed in acetate/MeOH, ^{99m}Tc-RP294 showed two major peaks, at 33.69 min (39.6%) and 36.81 min (59.3%), with a gradient of 100% to 10% acetate over 45 min, while ^{99m}Tc-RP455 showed a major peak at 35.55 min (84.8%) with the same gradient (data not shown).

Stannous gluconate was used as reducing agent for $Na^{99m}TcO_4$ in the presence of 100−200 μg of RP435. Two main peaks (peak A: 32.42 min, yield 26.4%; peak B: 35.59 min, yield 42.5%) were detected on HPLC (Figure 2) with aqueous TFA/ACN (gradient: 100% to 70% H_2O over 45 min). The ratio of peaks A and B in the reaction mixture varied with time, while their retention times remained unchanged. The difference in retention times of peaks A and B of ^{99m}TcO-RP435 was 3.1 min, while that of the two peaks from ^{99m}TcO-RP294 was 0.7 min.

Stability of ^{99m}TcO-RP435. Peaks A and B of ^{99m}TcO-RP435, after being separated, were reanalyzed by HPLC after different time intervals. A slow interconversion of the two isomers in aqueous solution containing 0.1% TFA was observed. For example, 4.2% of B was detected 103 min after the isolation of A from the labeling mixture, and 4.0% of A was detected 118 min after isolation of B (data not shown). The interconversion of A and B could be greatly accelerated when they were mixed with an equal volume of 0.25 M pH 7.4 phosphate buffer (PB). Figure 3 shows the interconversion of purified A to B and of purified B to A, and it is evident that an approximate 1:1 equilibrium was reached within 1 h.

^{99m}Tc Labeling of RP535. RP535 (100−200 μg) was labeled with 2−10 mCi ^{99m}Tc with stannous gluconate

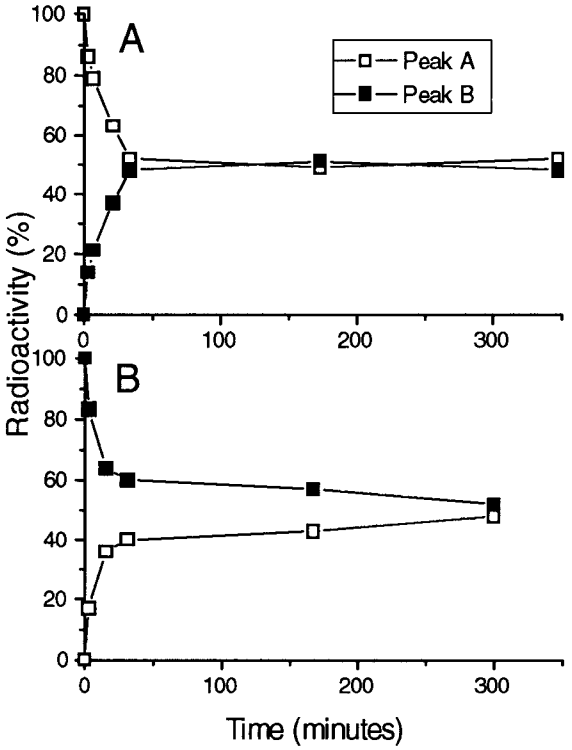

Figure 3. Time course of interconversion of syn and anti conformations of ^{99m}TcO-RP435 in phosphate buffer (PB). The isomers (peak A and peak B) were isolated by HPLC, mixed with an equal volume of PB, and aliquots reanalyzed after different time intervals. (A) Conversion of peak A to peak B. (B) Conversion of peak B to peak A.

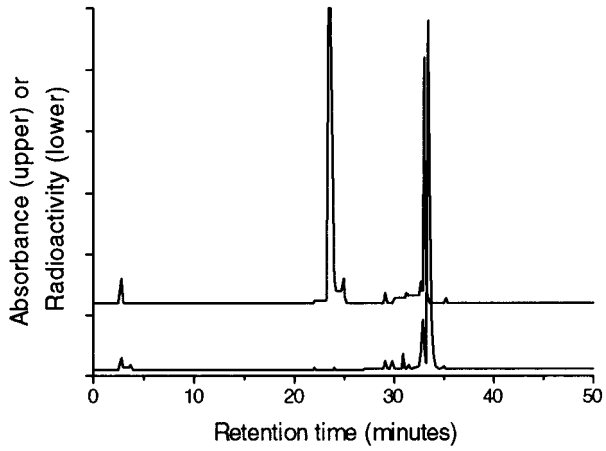

Figure 4. HPLC analysis of co-injection of ^{99m}TcO-RP535 and ReO-RP535. ^{99m}TcO-RP535 was monitored by radiometric detector (lower trace) and ReO-RP535 by UV detector at 320 nm (upper trace). The UV peak at 23.4 min is free RP535 while the peak at 33.0 min is ReO-RP535. ^{99m}TcO-RP535 eluted at 33.4 min. Zorbax C_{18} column eluted with H_2O/ACN containing 0.1% TFA; gradient 100 to 30% H_2O over 45 min; flow rate 1 mL/min.

as reducing agent. Higher temperatures (60−100 °C) were required to label the compound. One major labeled peak (yield >78%) was obtained when the reaction mixture was incubated in a boiling water bath for 30 min (Figure 4, lower trace). Varying the pH from 2 to 7 did not significantly affect the labeling yield. Although the nitroimidazole group of RP535 was stable under the labeling conditions, significant reduction was noted (analyzed by HPLC and monitored by the UV detector at 320 nm) when larger amounts of $SnCl_2$ were added, resulting in a dramatic decrease in the yield of ^{99m}TcO-RP535. For example, the yield of ^{99m}TcO-RP535 dropped to less than 5% of the total detected radioactivity on HPLC when 100 μg of $SnCl_2$ was used, and no intact RP535 remained when 600 μg of $SnCl_2$ was added.

Determination of Octanol/Water Partition Coefficients (PC) of ^{99m}TcO-RP435 and ^{99m}TcO-RP535. The PC values obtained were ^{99m}TcO-RP435, peak A, 0.0009 ± 0.0001; ^{99m}TcO-RP435, peak B, 0.0011 ± 0.0001; and ^{99m}TcO-RP535, 2.8 ± 0.1, $n = 4$. Thus, the difference in partition coefficients of ^{99m}TcO-RP535 and ^{99m}TcO-RP435 is over 2000-fold.

Preparation of ReO-RP535 and Co-Injection with ^{99m}TcO-RP535. It is difficult to determine directly the structure of a ^{99m}Tc complex because of the extremely small amount of the compound present. ^{99}Tc is a long-lived radioactive isotope ($t_{1/2} = 2.1 \times 10^5$ years) which restricts its application. However, the composition and structure of ^{99m}TcO-RP535 could be indirectly determined by comparison with ReO-RP535, which can be prepared in weighable quantities and characterized. Re belongs to the same group (VIIb) of the periodic table as Tc and thus possesses similar chemical properties; furthermore, Re and Tc are similar in size because of the lanthanide contraction.

ReO-RP535 was prepared by coupling 2-(2-nitro-1*H*-imidazolyl)ethylamine with ReO-RP455. The compound was purified by HPLC. ^{1}H NMR data showed that the two amide protons, H(5) and H(12), disappeared after the chelation of RP535 to ReO^{3+}, while those of H(16) and H(19) of the uncoordinated RP535 (Figure 1) remained. The protons of the acetamidomethyl protecting group also disappeared, indicating the involvement of sulfur in the coordination with ReO. The two methyl groups and the methylene group of dimethylglycine could no longer freely rotate around the C(3)−N_{amine} bond in ReO-RP535, which made the protons of these groups become chemically nonequivalent. For example, the protons of H(1) shifted from 2.80 to 2.44 ppm, and H(2) shifted from 2.80 to 3.55 ppm upon the formation of ReO-RP535. This indicated that the N atom of the dimethylglycine was coordinated with the ReO^{3+} core. The two protons of H(3) of ReO-RP535 were in a chemically nonequivalent environment as well. H(3a) appeared at 4.02 ppm and H(3b) at 4.82 ppm with a coupling constant $J_{H3a-H3b}$ at 14.9 Hz. H(14a) coupled H(13) with $J_{H14a-H13}$ for 6.8 Hz, while H(14b) coupled H(13) with $J_{H14a-H13}$ for 12.2 Hz. However, no signals of H(14a) coupling with H(14b) were found. Taken together, this evidence supported the assumption that the ReO^{3+} core was complexed with the N_3S chelator.

No evidence of the coexistence of the syn and anti isomers of ReO-RP535 was found in the ^{1}H NMR spectrum. The prepared ReO-RP535 could be either a syn or anti isomer. The electrospray mass spectrum exhibited the characteristic two molecular ions at *m*/*z* 712.93 ([M + H]$^+$), which corresponded to a 1:1 ^{185}ReO to RP535 complex, and *m*/*z* 714.94 ([M + H]$^+$), which corresponded to another 1:1 ^{187}ReO to RP535 complex. Moreover, the relative abundances of the two peaks (36.5 and 63.5%) are consistent with the natural abundances of ^{185}Re and ^{187}Re (37.4 and 62.6%).

An aqueous solution of ReO-RP535 was mixed with the ^{99m}TcO-RP535 labeling mixture and co-injected into the HPLC for analysis. Two gradients of aqueous TFA/ACN were used: 100 to 30% and 100 to 50% water over 45 min. Two detectors, UV and radiometric, were connected in series with the eluent entering the UV detector first and then the radiometric detector. There was a time delay of 0.3−0.4 min for signal response between the UV and radiometric detectors. Figure 4 shows the chromato-

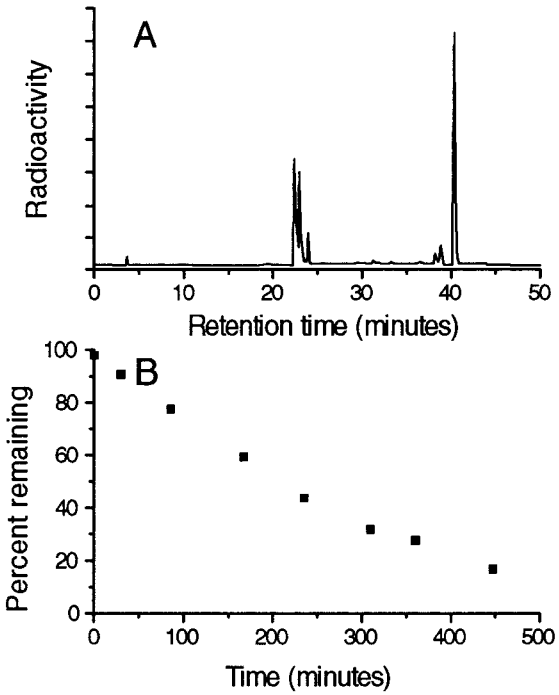

Figure 5. Stability of ^{99m}TcO-RP535 diluted in an equal volume of phosphate buffer (PB). (A) HPLC analysis of sample obtained 235 min after mixing demonstrates appearance of decomplexation products with retention times of 22−24 min but little release of free pertechnetate (retention time 3 min). Zorbax C_{18} column eluted with H_2O/ACN containing 0.1% TFA; gradient 100 to 50% H_2O over 45 min; flow rate 1 mL/min. (B) Time course of stability of ^{99m}TcO-RP535 diluted in PB.

gram of the co-injection of ReO-RP535 with ^{99m}TcO-RP535 with the 100 to 30% water gradient. The retention time of ReO-RP535 was 33.04 min (upper trace), while that of ^{99m}TcO-RP535 was 33.35 min (lower trace). The UV peak at 23.37 min was free RP535 (upper trace). The retention times of ReO-RP535 and ^{99m}TcO-RP535 became 39.91 and 40.51 min, respectively, when a 100 to 50% water gradient was used. The retention times of ReO-RP535 and ^{99m}TcO-RP535 are the same when the time delay in signal response is taken into account. This implies that ^{99m}TcO-RP535 has the same composition and structure as ReO-RP535, i.e., ^{99m}Tc is coordinated by the N_3S chelator of RP535, there is a ^{99m}Tc═O core, and the ratio of ^{99m}Tc to RP535 is 1:1.

Stability of ^{99m}TcO-RP535. ^{99m}TcO-RP535 was isolated by HPLC, and the collected ^{99m}TcO-RP535 in aqueous TFA/ACN was reinjected into the HPLC for analysis after different time intervals at room temperature. It was evident that ^{99m}TcO-RP535 was more stable than ^{99m}TcO-RP435 in aqueous solution, which contained 0.1% TFA, because neither decomplexation nor change in the radioactive peak was seen over 26 h.

Theoretically, the formation of syn and anti isomers of ^{99m}TcO-RP535 is possible, when the *tert*-butyl side chain on the N_3S chelator is in the syn and anti conformations with respect to the ^{99m}Tc═O core. When the isolated ^{99m}TcO-RP535 was mixed with an equal volume of 0.25 M, pH 7.4, phosphate buffer (PB) and reinjected after different time intervals, a decomplexation of the complex, instead of interconversion of syn and anti isomers, was observed (Figure 5A). ^{99m}TcO-RP535 (retention time 40.27 min) decomplexed in PB and formed three products, which appeared in the region of 22.1−23.7 min on the HPLC. These decomplexed compounds cannot be the isomers of ^{99m}TcO-RP535 because they did not exist

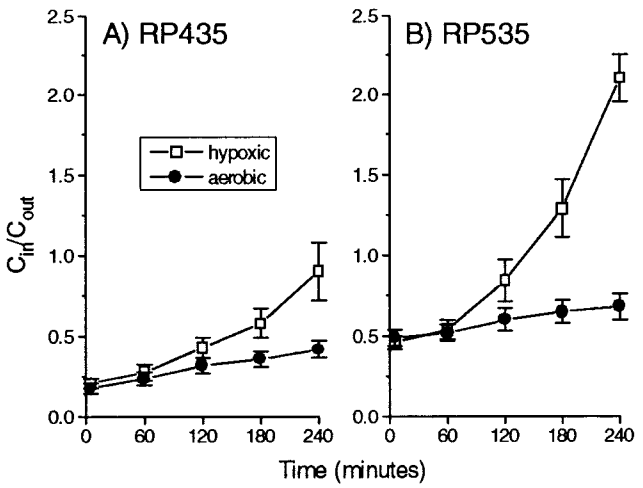

Figure 6. Time course of accumulation of ^{99m}TcO-RP435 and ^{99m}TcO-RP535 in Chinese hamster ovary cells under aerobic and hypoxic conditions. Ordinate is ratio of radioactivity concentration inside cells (C_{in}) to that in supernatant (C_{out}). Each point is mean of eight or nine experiments and error bars are SEM.

in the labeling mixture (Figure 4, lower trace; note different gradient) and they did not reach any fixed equilibrium with ^{99m}TcO-RP535 over time. The decomplexation might occur when one or more coordination bonds of the ^{99m}TcO-RP535 complex are broken. No free pertechnetate (retention time 3 min) was detected from the decomplexation of ^{99m}TcO-RP535. The half-time for decomplexation was about 200 min (Figure 5B). Interestingly, ^{99m}TcO-RP535 decomposed immediately with release of pertechnetate when mixed with 0.01 N NaOH.

To summarize, ^{99m}TcO-RP535 with its *tert*-butyl group on the N_3S chelator, is more difficult to label than ^{99m}TcO-RP435 and does not interconvert to another isomer. This suggests that the *tert*-butyl group acts as an important steric hindrant that inhibits the coexistence and interconversion of syn and anti isomers of ^{99m}TcO-RP535 and indeed forces the complex into a single conformation. However, the configuration of ^{99m}TcO-RP535 remains to be determined.

In Vitro Tests of ^{99m}TcO-RP294, ^{99m}TcO-RP455, ^{99m}TcO-RP435, and ^{99m}TcO-RP535. The ability of these ^{99m}Tc-labeled compounds to be taken up by mammalian cells under aerobic or hypoxic conditions was tested using CHO cells in suspension culture in equilibrium with air or nitrogen gas mixtures. Samples were removed as a function of time and ratios of cell-associated radioactivity (C_{in}) to that in the medium (C_{out}) were calculated. The control compounds, ^{99m}TcO-RP294 and ^{99m}TcO-RP455, which do not contain 2-NI groups, did not show selective accumulation in hypoxic CHO cells. In contrast, ^{99m}TcO-RP435 showed differential accumulation between hypoxic and aerobic cells. The C_{in}/C_{out} for aerobic cells at 4 h was 0.42, while that of hypoxic cells was 0.90 (Figure 6A), for a hypoxic/aerobic differential of 2.1 ± 0.4 (mean ± SEM, n = 8). In comparison, ^{99m}TcO-RP535 revealed a greater differential accumulation between hypoxic and aerobic cells than ^{99m}TcO-RP435. When ^{99m}TcO-RP535 was added to a suspension of CHO cells in vitro, there was a modest accumulation of radioactivity in the cells under aerobic conditions, reaching a C_{in}/C_{out} value of 0.68 at 4 h (Figure 6B). In contrast, under hypoxic conditions, there was a further increase to a C_{in}/C_{out} value of 2.10, for a 3.1 ± 0.4 (n = 9) fold hypoxic/aerobic differential.

Previous work (*24*) with the ^{99m}Tc-labeled 2-NI BMS181-321, using the same cell line and in vitro system, showed

that a large molar excess of the 2-NI compound misonidazole prevented selective accumulation in hypoxic cells while the 5-nitroimidazole metronidazole stimulated it. In the present work, addition of 5 mM misonidazole abolished the hypoxia-specific accumulation of ^{99m}TcO-RP535, whereas 8 mM metronidazole selectively increased hypoxic accumulation to 130% of the control value.

DISCUSSION

On the basis of promising results obtained with [^{18}F]-FMISO and [^{123}I]IAZA (*7*−*10*), there has been great interest in the development of ^{99m}Tc-labeled markers of hypoxia which would be convenient to prepare and widely applicable. However, the standard ^{99m}Tc-chelation systems have not all proved to be useful. The first attempt using the BATO approach resulted in a complex which was not efficiently reduced and trapped, and which showed inadequate permeability to lipophilic membranes (*25*). A bis(amine-phenol) complex similarly failed to cross cell membranes (*26*). Greatest success thus far has been obtained with amineoxime-type chelators, specifically BMS181321 (*11*), BRU59-21 (*27*), and BnAO (*17*); however, each has its limitations. BMS181321 has a PC of 40, which results in slow clearance from the blood and background tissues and extensive elimination via the gastrointestinal tract (*14*). BRU59-21 has a lower PC of 12 with resultant improved clearance from the blood, but the extent of hepatobiliary excretion remains high (*15, 16*). In contrast, BnAO undergoes extensive renal elimination, but lacking a nitro group, its mechanism of hypoxia-specific localization is unclear (*20*). BnAO has a low PC of 0.1, although this does not appear to limit its penetration of tissue (*20*). Work in the radioiodinated sugar 2-NI series has suggested an optimum PC of ∼1 (*5*).

The RP294 chelation system for ^{99m}Tc was developed by Resolution Pharmaceuticals Inc. (*21*) and is used in RP128, a peptide for imaging inflammation (*28*). Acetamidomethyl was selected as the thiol-protecting group because it can be cleaved at room temperature. The free carboxylic acid group of the molecule contributes to the hydrophilicity of the complex and RP435, the 2-NI-containing derivative of RP294, has an extremely low PC of 0.001. Therefore, an analogue containing *tert*-butylglycine in place of serine was developed. In the present work, the utility of this chelator on a 2-NI compound targeted to hypoxic tumor cells was evaluated. The partition coefficient of ^{99m}TcO-RP535 was 2.8, which is similar to that reported for IAZA (*9*).

Although the presence of the *tert*-butyl group was desirable to increase the PC of the complex, it made the chelator more difficult to label. While ^{99m}Tc labeling of RP294 and RP435 by transchelation from gluconate proceeded efficiently at room temperature, the *tert*-butyl analogues RP455 and RP535 required heating. Radiochemical yields obtained were 26 and 43% for the two peaks of ^{99m}TcO-RP435 (Figure 2) and 78% for ^{99m}TcO-RP535 (Figure 4, lower trace). It was shown that the nitro group was not reduced by the typical quantities of stannous chloride used in ^{99m}Tc labeling, but that it could be reduced by excessive amounts.

The structure of RP294 was determined by ^{13}C and ^{1}H NMR, except the assignments of the amide protons (*21*). In addition, ReO-RP294 and ^{99}TcO-RP294 have been structurally confirmed by ^{1}H NMR and X-ray crystallography, which indicated that the metal ions were coordinated by the N_3S chelator. RP435, containing the same N_3S chelator as RP294, can be presumed to chelate the $^{99m}TcO^{3+}$ core in the same manner. As has been shown previously for ^{99m}TcO-RP294 (*21*), two complexes of ^{99m}TcO-RP435 were formed, presumably syn and anti isomers (Figure 2). Following separation by HPLC, these were quite stable in acidic aqueous solution (4% interconversion in 2 h) but equilibrated in 0.25 M, pH 7.4, phosphate buffer with a half-time of ∼1 h (Figure 3), suggesting that the rate of interconversion is a function of hydroxide concentration. In contrast, ^{99m}TcO-RP535 existed as a single isomer (Figure 4, lower trace), confirmed by co-injection with its Re analogue (Figure 4, upper trace), which was extremely stable in acidic aqueous medium. When diluted in PB, ^{99m}TcO-RP535 decomplexed with a half-time of ∼3 h, resulting in the formation of several hydrophilic species but no release of free pertechnetate (Figure 5). However, when ^{99m}TcO-RP535 was diluted in 0.01 N NaOH it decomposed rapidly to pertechnetate. These results with ^{99m}TcO-RP535 also implicate the concentration of hydroxide in the decomposition process.

Following HPLC purification, ^{99m}TcO-RP435 and ^{99m}TcO-RP535 were evaluated in an in vitro model of cellular hypoxia that has been used extensively in radiation biology and investigation of bioreductive drugs, including other ^{99m}Tc-, ^{123}I-, and ^{18}F-labeled hypoxia tracers (*14, 16, 20, 23*). Both tracers showed a modest level of uptake in aerobic CHO cells, which increased slightly over the course of 4 h. In contrast, hypoxic cells accumulated 2−3 times as much radioactivity over that time period, a significant degree of hypoxia-specific accumulation (Figure 6). Moreover, the selective accumulation of ^{99m}TcO-RP535 could be modulated by coincubation with millimolar concentrations of unlabeled nitro compounds (data not shown). The 2-NI misonidazole abolished the hypoxia-specific accumulation of ^{99m}TcO-RP535 while metronidazole, a 5-NI of lower electron affinity, enhanced this accumulation. The same effects have been reported previously with the 2-NI ^{99m}Tc-BMS181321 and suggest a bioreductive mechanism of localization of the tracer (*24*).

CONCLUSIONS

RP435 and RP535 have a similar N_3S chelator in structure, but their ability to form chelates with ^{99m}Tc is different. The ^{99m}TcO-RP435 chelate could be prepared at room temperature, and showed interconversion of syn and anti isomers in aqueous solution. The interconversion of the two isomers was much faster in neutral than in acidic medium. In contrast, the *tert*-butyl group on the backbone of the N_3S chelator of RP535 hindered the chelation with ^{99m}Tc, presumably by steric effects, and blocked the formation and interconversion of the theoretically existing syn and anti isomers of ^{99m}TcO-RP535 in acidic and neutral aqueous solution at room temperature. However, the *tert*-butyl group of RP535 did have the desired effect of significantly increasing the lipophilicity of the corresponding ^{99m}Tc chelate. Both ^{99m}TcO-RP435 and ^{99m}TcO-RP535 showed selective uptake in hypoxic cells, suggesting that ^{99m}TcO-peptidic complexes containing the 2-nitroimidazole group can be a new class of hypoxia imaging agents.

ACKNOWLEDGMENT

We would like to thank Dr. Ernest Wong, Tam Nguyen, Linda Lu, and Dr. Susan Peers of Resolution Pharmaceuticals Inc. for their support and suggestions. This work was funded by the University-Industry program of the

Medical Research Council of Canada in conjunction with Resolution Pharmaceuticals Inc. (Grant UI-13558).

TECHNICAL NOTES

Boron-Enriched Streptavidin Potentially Useful as a Component of Boron Carriers for Neutron Capture Therapy of Cancer

Takeshi Sano*

A boron-enriched streptavidin has been prepared by chemical conjugation of a boron-rich compound, $B_{12}H_{11}SH^{2-}$ (BSH), to a genetically engineered streptavidin variant. The streptavidin variant used has 20 cysteine residues per molecule, derived from a C-terminal cysteine stretch consisting of five cysteine residues per subunit. Because natural streptavidin has no cysteine residues, the reactive sulfhydryl groups of the cysteine stretch serve as unique conjugation sites for sulfhydryl chemistry. BSH was conjugated irreversibly to the sulfhydryl groups of the streptavidin variant via a sulfhydryl-specific homobifunctional chemical cross-linker. Quantitative boron analysis indicates that the resulting streptavidin−BSH conjugate carries approximately 230 boron atoms/molecule. This indicates that the chemical conjugation of BSH to the streptavidin variant was highly specific and efficient because this method should allow the conjugation of a maximum of 240 boron atoms/streptavidin molecule. This boron-enriched streptavidin retained both full biotin-binding ability and tetrameric structure, suggesting that the conjugation of BSH has little, if any, effect on the fundamental properties of streptavidin. This boron-enriched streptavidin should be very useful as a component of targetable boron carriers for neutron capture therapy of cancer. For example, a monoclonal antibody against a tumor-associated antigen can be attached tightly to the boron-enriched streptavidin upon simple biotinylation, and the resulting conjugate could be used to target boron to tumor cells on which the tumor-associated antigen is overexpressed.

INTRODUCTION

Boron neutron capture therapy (BNCT)[1] is potentially a useful therapeutic modality for cancer [for recent reviews, see Barth and Soloway (1994), Barth et al. (1996), Coderre and Morris (1999), Gahbauer et al. (1998), Hawthorne (1993, 1998), and Soloway et al. (1997, 1998)]. BNCT uses the nuclear capture and fission reactions of a stable (nonradioactive) boron isotope species, ^{10}B, which occur when ^{10}B is irradiated by thermal neutrons. This process releases approximately 2.8 MeV of kinetic energy, which is distributed between $^4He^{2+}$ (α-particle) and $^7Li^{3+}$, plus weak γ-radiation (480 keV). BNCT uses this kinetic energy to kill target cancer cells where boron has accumulated. The most attractive characteristic of BNCT is that $^4He^{2+}$ and $^7Li^{3+}$ have mean ionization tracks of only 7 and 4 μm, respectively. Thus, most of the kinetic energy is deposited within about one cell diameter, minimizing radiation doses to surrounding normal tissues. Another feature of BNCT is that it is a binary method; the occurrence of two independent, relatively nontoxic events, i.e., accumulation of ^{10}B and irradiation by thermal neutrons, is needed to activate the killing reaction. These two distinct characteristics offer potential for BNCT to become an effective therapeutic modality for cancer.

For successful BNCT, selective, high-level accumulation of ^{10}B in target tumor cells (at least 25−35 μg of ^{10}B/gram tissue or 10^9 ^{10}B atoms/cell) is essential. Large amounts of ^{10}B must accumulate in target cells to minimize radiation doses to normal tissues. Thus, many current BNCT efforts are directed toward the preparation of boron-containing reagents and the development of boron-targeting strategies that allow selective, high-level accumulation of boron in target cells. Although relatively small boron-containing reagents, such as BSH and *p*-boronophenylalanine, have primarily been used in BNCT, macromolecular boron carriers are potentially very useful. For example, certain macromolecules, such as antibodies against tumor-associated antigens (antitumor antibodies), have the natural ability to bind, specifically, to the tumor cells. Such macromolecules could be used as specific boron carriers to deliver boron to the target tumor cell. In addition, such macromolecules could be attached or fused to other molecules which do no have selectivity to tumor cells but can carry large amounts of

boron. This should allow the generation of the boron-enriched molecules with specific binding affinity for target tumor cells. Thus, boronated macromolecules, such as antitumor antibodies and the ligands for cell surface receptors overexpressed on target tumor cells, have been produced and tested as potential boron carriers for BNCT [for reviews, see Barth et al. (1996), Gahbauer et al. (1998), Hawthorne (1993, 1998), Soloway et al. (1997, 1998)]. However, the properties and biological activities of such macromolecules are often altered or even lost by conjugation of large amounts of boron or by the chemical conjugation methods used. If large amounts of boron could be attached indirectly to these macromolecules, changes in their biological activities and functions could be minimized, allowing the resulting boronated macromolecules to become effective boron carriers for BNCT.

Streptavidin, a tetrameric protein produced by *Streptomyces avidinii*, binds a water-soluble vitamin, D-biotin (vitamin H), with a remarkably high affinity ($K_d \approx 10^{-14}$–10^{-15} M) (Chaiet et al., 1963; Chaiet and Wolf, 1964; Green, 1970, 1990). The extremely tight biotin binding by streptavidin and the ability of biotin to be incorporated easily into various biological materials have made the streptavidin−biotin system one of the most useful tools in the biological and medical sciences (Bayer and Wilchek, 1980; Wilchek and Bayer, 1988, 1990). Streptavidin could also be very useful as a component of macromolecular boron carriers for BNCT. For example, streptavidin carrying a large amount of boron could be conjugated easily and tightly to a macromolecular tumor-targeting reagent, such as an antitumor antibody, upon simple biotinylation. Indirect conjugation of boron to macromolecular targeting reagents via streptavidin could allow the maintenance of their biological functions and activities. The exceptionally high structural stability of streptavidin should allow a variety of chemistries to be used for conjugation of large amounts of boron without disturbing the fundamental properties of streptavidin.

In this work, a boron-enriched streptavidin was produced by chemical conjugation of a boron-rich compound to a genetically engineered streptavidin. The resulting boron-enriched streptavidin carries approximately 230 boron atoms/molecule, and it retains both full biotin-binding ability and tetrameric structure. The preparation and characterization of this boron-enriched streptavidin are described, along with its potential use as a component of macromolecular boron carriers for BNCT of cancer.

EXPERIMENTAL PROCEDURES

Materials. Disodium BSH ($Na_2B_{12}H_{11}SH$) was obtained from Boron Biologicals, Inc., Raleigh, NC. TCEP-HCl was from Pierce Chemical. MPHPD, 2-iminobiotin agarose, iodoaceticacid, and iodoacetamide were from Sigma Chemical. D-[*carbonyl*-^{14}C]Biotin (53 mCi/mmol), a sulfur-labeling reagent (*t*-butoxycarbonyl-[^{35}S]methionine *N*-succinimidyl ester; >800 Ci/mmol), and a fluorography reagent, Amplify, were from Amersham. Superdex 75 HR 10/30 and PD-10 columns were from Pharmacia Biotech.

Preparation of a Streptavidin Variant, Stv-28. A streptavidin variant containing a C-terminal cysteine stretch, Stv-28, was expressed in *Escherichia coli* strain BL21(DE3)(pLysE) carrying the expression vector pTSA-28 (Sano et al., 1993) by using the bacteriophage T7 expression system (Studier et al., 1990). Expressed Stv-28 was purified to homogeneity by the method previously described (Sano and Cantor, 1990; Sano et al., 1993). Purified Stv-28 was stored frozen at −85 °C in Tris-buffered saline (TBS; 150 mM NaCl, 20 mM Tris-Cl, pH 7.4, and 0.02% NaN_3) containing 5 mM DTT (TBS/DTT) until used.

Chemical Conjugation of BSH to Stv-28. Chemical conjugation of BSH to Stv-28 was carried out by using a two-step procedure (Figure 1). All solutions used during chemical conjugation had been equilibrated with argon gas to prevent oxidation of sulfhydryl groups. Stv-28 in TBS/DTT was dialyzed against phosphate-buffered saline (PBS; 150 mM NaCl and 50 mM sodium phosphate, pH 6.8) containing 5 mM EDTA and 2 mM TCEP-HCl (Rüegg and Rudinger, 1977) (PBS/EDTA/TCEP). The dialyzed protein (410 μg; 2.5 mL) was mixed with 7.6 μmol of MPHPD dissolved in 300 μL of PBS/EDTA/TCEP (molar ratio of MPHPD to cysteine, ∼50), and the mixture (2.8 mL) was allowed to stand at 30 °C for 30 min. Then, BSH (90 μmol), dissolved in 500 μL of PBS/EDTA/TCEP, was added, and the mixture was incubated at 30 °C for 30 min. The mixture was dialyzed against PBS/EDTA at 4 °C, and the dialyzed protein was filtered through a 0.22-μm polyvinylidene fluoride filter unit (Millex-GV; Millipore).

Purification of functional conjugates was performed at 4 °C by 2-iminobiotin affinity chromatography (Hoffman et al., 1980). The filtered protein fraction was dialyzed against 1.0 M NaCl and 100 mM Na_2CO_3, pH 11.0, and applied to a 2-iminobiotin-agarose column which had been equilibrated with the same solution. The column was washed with the same solution to remove unbound protein, and then bound protein was eluted with 2 M urea and 100 mM ammonium acetate (pH 4.0). The eluate was dialyzed against TBS and used in subsequent experiments.

Serum Stability Analysis. A boron-enriched streptavidin was labeled with ^{35}S using a sulfur labeling reagent (*t*-butoxycarbonyl-[^{35}S]methionine *N*-succinimidyl ester) to facilitate the serum stability analysis. Briefly, a boron-enriched streptavidin in 0.1 M sodium borate (pH 8.5) (protein concentration, 7.8 μg/mL; total volume, 500 μL) was mixed with approximately 10 pmol (8 μCi) of the sulfur-labeling reagent that had been lyophilized, and the mixture was incubated at room temperature (∼22 °C) for 30 min with occasional mixing. The reaction was terminated by the addition of 20 μL of 0.2 M glycine dissolved in 0.1 M sodium borate (pH 8.5), and the mixture was dialyzed against water. The dialyzed protein was filtered through a 0.22 μm polyvinylidene fluoride filter unit (Millex-GV) and lyophilized.

The lyophilized ^{35}S-labeled boron-enriched streptavidin (specific activity, approximately 90 nCi/μg) was dissolved in fetal bovine serum (Gibco-BRL) at a final streptavidin concentration of 16 μg/mL. The mixture was incubated at 37 °C, and aliquots were collected periodically. The collected samples were subjected to SDS−PAGE analysis, followed by detection of proteins by fluorography, as described below. The gel was also analyzed by using a PhosphorImager (Molecular Dynamics) for quantitation of radioactivity.

S-Alkylation of Stv-28. S-Alkylation of Stv-28 with iodoacetic acid and iodoacetamide was done by standard methods (Gurd, 1967, 1972) to block the highly reactive sulfhydryl groups which cause the aggregation of Stv-28 upon oxidation. All solutions used during S-alkylation had been equilibrated with argon gas. Stv-28 (434 μg; 2.0 mL) in PBS/EDTA containing 350 μM DTT was mixed with 5.4 μmol of iodoacetic acid or iodoacetamide dissolved in PBS/EDTA, and the mixture was incubated at 30 °C for 30 min in the dark. 2-Mercaptoethanol (56 μmol) was added to the mixture to terminate the S-alkylation

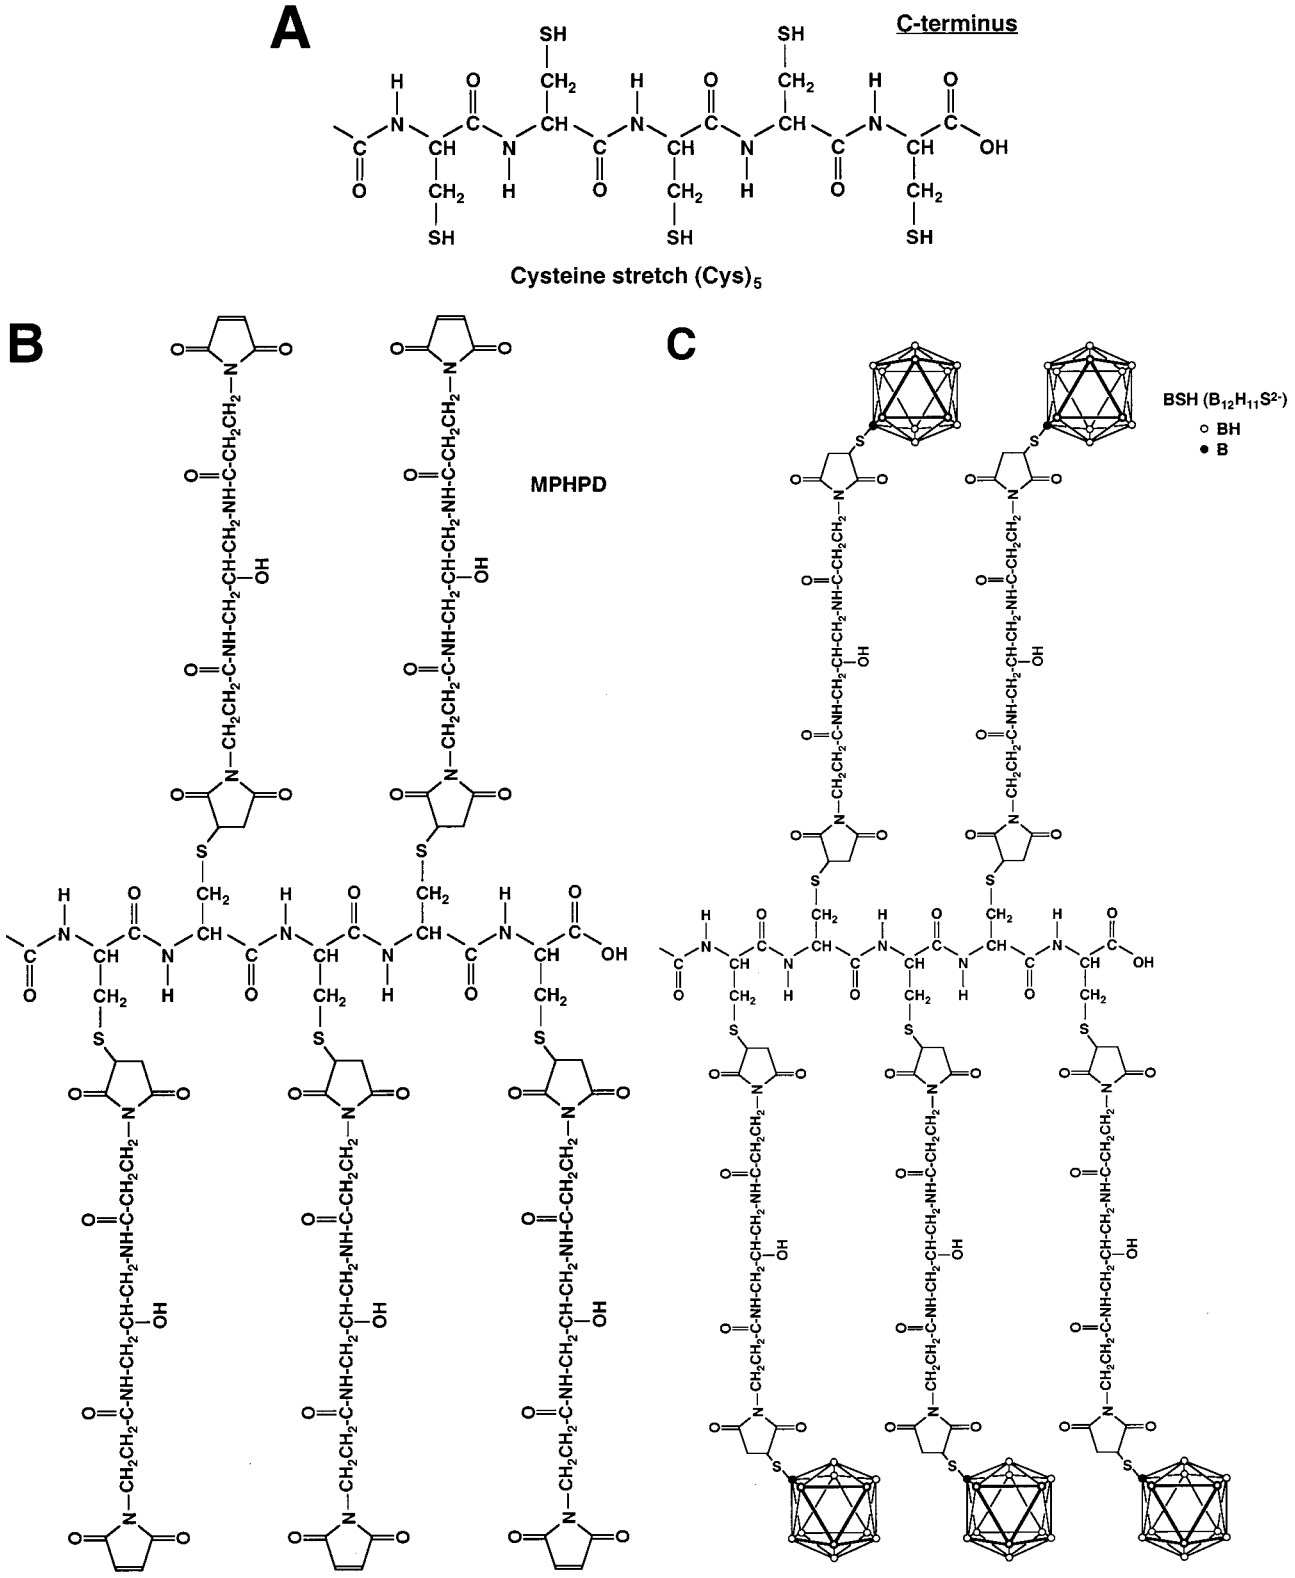

Figure 1. Chemical conjugation of a boron-rich compound, BSH, to a genetically engineered streptavidin, Stv-28, using a sulfhydryl-specific homobifunctional chemical cross linker, MPHPD. (A) Cysteine stretch of Stv-28; (B) after the addition of excess MPHPD to Stv-28; (C) after the addition of excess BSH. Not drawn to scale.

reaction. Then, the mixture was dialyzed against TBS in the dark, and the dialyzed protein was filtered through a 0.22 μm polyvinylidene fluoride filter unit (Millex-GV). The resulting S-alkylated streptavidin preparations were stored frozen at −85 °C until used.

Quantitative Boron Analysis. Quantitative boron analysis was performed by ICP-AES (inductively coupled plasma atomic emission spectrometry) using a Perkin-Elmer Optima 3000, following the method described by Tamat et al. (1987). The 249.77 nm line for boron was used with calibration using a boric acid standard solution for atomic absorption.

Biotin-Binding Assays. Biotin-binding ability was

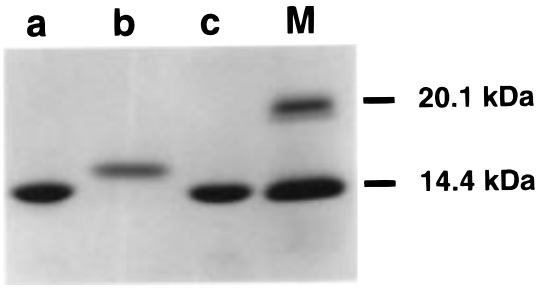

Figure 2. SDS−PAGE analysis of a boron-enriched streptavidin. Lane a, Stv-28 S-alkylated with iodoacetic acid; b, a boron-enriched streptavidin prepared from Stv-28 and BSH; c, Stv-28 S-alkylated with iodoacetamide; M, molecular mass standard proteins (soybean trypsin inhibitor, 20.1 kDa; bovine α-lactalbumin, 14.4 kDa) (Pharmacia Biotech). SDS−PAGE was carried out using a 10−20% polyacrylamide gradient gel with a Tris/tricine buffer system (Schägger and von Jagow, 1987). Approximately 2 μg of protein was applied to each lane. Proteins were stained with Coomassie brilliant blue R.

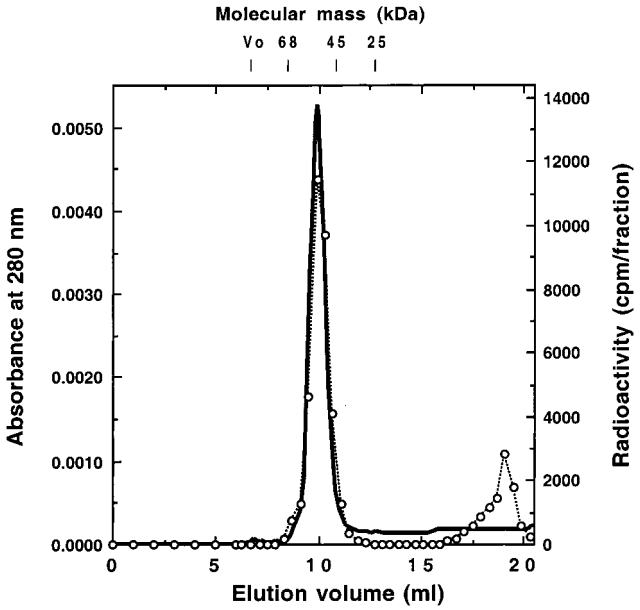

Figure 3. Gel filtration chromatography of a boron-enriched streptavidin. A boron-enriched streptavidin (approximately 3.8 μg) was mixed with excess D-[*carbonyl*-^{14}C]biotin, and the mixture was applied to a Superdex 75 HR 10/30 column (1.0 × 30 cm), which had been equilibrated with TBS. Proteins were eluted at room temperature with TBS at a flow rate of 500 μL/min, and absorbance at 280 nm (—) was monitored during elution. Eluate was collected in 400 μL fractions, and the radioactivity of each fraction (○) was determined by liquid scintillation counting. The positions where the molecular mass standard proteins (bovine serum albumin, 68 kDa; ovalbumin, 45 kDa; chymotrypsinogen A, 25 kDa; Boehringer Mannheim) eluted are indicated at the top.

determined by a gel filtration method (Wei, 1970) using D-[*carbonyl*-^{14}C]biotin and PD-10 columns.

Gel Filtration Chromatography. Gel filtration chromatography was performed using a Superdex 75HR 10/30 column with an FPLC system (Pharmacia). Detailed conditions are given in the legend to Figure 3.

SDS−PAGE Analysis. SDS−PAGE was carried out by a Tris-tricine buffer system (Schägger and von Jagow, 1987) using 10 to 20% polyacrylamide gradient gels. Proteins were stained with Coomassie brilliant blue R. For fluorography, gels were incubated at room temperature for 30 min in 25% methanol, 10% acetic acid, and 2% glycerol, followed by incubation at room temperature for 30 min in 60% Amplify, 25% methanol, and 2% glycerol. Then, the gels were dried in vacuo and exposed to Kodak BioMax MR film.

RESULTS

Chemical Conjugation of a Boron-Rich Compound to a Streptavidin Variant. The genetically engineered streptavidin Stv-28 (Sano et al., 1993) was used to prepare a boron-enriched streptavidin. Like natural streptavidin, Stv-28 is tetrameric (13.2 kDa/subunit), and each subunit has a C-terminal cysteine stretch consisting of five cysteine residues; hence, each Stv-28 molecule has 20 cysteines. Because natural streptavidin has no cysteine (Argaraña et al., 1986; Green 1990), the reactive sulfhydryl groups of the cysteine stretch can be used as specific conjugation sites for sulfhydryl chemistry. The known three-dimensional structure of natural streptavidin (Hendrickson et al., 1989; Weber et al., 19989) shows that the C-termini of streptavidin are located on the surface of the molecule and that they are distant from the biotin-binding sites and the subunit−subunit interfaces. Thus, conjugation of partner molecules to the cysteine stretch should have little, if any, effect on the fundamental properties of streptavidin, such as the biotin-binding ability and subunit association. This has previously been shown by making a radiolabeled streptavidin and a fluorescent streptavidin, in each of which either a radiolabel or a fluorescent marker, respectively, was attached covalently to the cysteine stretch of Stv-28 using sulfhydryl chemistry without disturbing the properties of streptavidin (Sano et al., 1993).

To prepare a boron-enriched streptavidin using Stv-28, a polyhedral sulfhydryl borane, BSH ($B_{12}H_{11}SH^{2-}$), was used. BSH has a reactive sulfhydryl group that can be used as a conjugation site. BSH could be attached to the sulfhydryl groups of Stv-28 by disulfide bond formation. However, it is possible that disulfide bonds between Stv-28 and BSH would be reduced or exchanged with other sulfhydryl-containing materials when used in vivo, diminishing the effectiveness of the conjugate as a boron carrier for BNCT. Thus, a water-soluble sulfhydryl-specific homobifunctional chemical cross-linker, MPHPD, was used to attach BSH irreversibly to Stv-28. MPHPD is a bis-maleimide (Weston, 1980; Wong, 1993), each moiety of which reacts with a sulfhydryl group. MPHPD has a 17 Å spacer between the two maleimide moieties. This relatively long spacer may help to avoid steric hindrance generated by conjugation of five BSH molecules to each cysteine stretch.

Chemical conjugation of BSH to Stv-28 was carried out by using a two-step procedure (Figure 1). First, MPHPD was attached to the sulfhydryl groups of the cysteine stretch of Stv-28 (Figure 1A). To avoid intra- and intermolecular cross-linking between sulfhydryl groups of Stv-28 by MPHPD, excess MPHPD was added to Stv-28 to allow only one maleimide moiety of each MPHPD molecule to react with a sulfhydryl group of Stv-28 (Figure 1B). A reducing agent, TCEP-HCl (Rüegg and Rudinger, 1977), that is not reactive with maleimide, was included in the reaction mixture to avoid disulfide formation. Then, excess BSH was added to the reaction mixture to allow the sulfhydryl group of BSH to react with the unreacted maleimide group of MPHPD which had been attached to Stv-28 (Figure 1C). The resulting mixture was dialyzed against a neutral solution to remove MPHPD−BSH complexes and unreacted MPHPD and BSH that were present in large quantities. The

dialyzed streptavidin conjugates retained at least 90% of the original biotin-binding ability, analyzed by biotin-binding assays. These conjugates showed a sharp peak with a molecular mass slightly greater than S-alkylated Stv-28 preparations on gel filtration chromatography (data not shown). No appreciable changes in solubility were seen by conjugation of BSH to Stv-28 under the conditions used. These suggest that functional conjugates between Stv-28 and BSH had been produced. However, relatively large amounts of MPHPD−BSH complexes and unreacted MPHPD and BSH were seen in the final conjugate solution, suggesting inefficient removal of these compounds by dialysis. To remove these compounds, chemical conjugates between Stv-28 and BSH were purified by 2-iminobiotin affinity chromatography (Hofmann et al., 1970). This affinity chromatography step should remove not only MPHPD−BSH complexes and unreacted MPHPD and BSH but also streptavidin conjugates which had lost the biotin-binding ability due to the chemical conjugation of BSH, if any.

Characterization of a Boron-Enriched Streptavidin. The conjugate between Stv-28 and BSH, purified by 2-iminobiotin affinity chromatography, was analyzed by SDS−PAGE for the subunit molecular mass and structural homogeneity. The conjugate showed a single band on SDS−PAGE (Figure 2), indicating its high structural homogeneity. The migration of the subunit of this conjugate is slower than those of Stv-28 molecules, which had been S-alkylated with iodoacetic acid (subunit molecular mass, 13.5 kDa) and with iodoacetamide (13.5 kDa). The subunit molecular mass of this conjugate was estimated at approximately 16 kDa by calibration with the S-alkylated Stv-28 preparations, recombinant core streptavidins (Stv-13 and Stv-25 with subunit molecular masses of 12.6 and 13.2 kDa, respectively) (Sano et al., 1995), and molecular mass standard proteins (Pharmacia Biotech). If the sulfhydryl groups of Stv-28 are saturated with BSH, the subunit molecular mass of the resulting conjugate should be 16.1 kDa. This suggests that the sulfhydryl groups of Stv-28 are fully saturated with BSH.

Quantitative boron analysis by ICP-AES (Tamat et al., 1987) shows that this conjugate contains 230 ± 15 boron atoms/streptavidin molecule. Since a maximum of 240 boron atoms (20 BSH molecules) can be attached to each Stv-28 molecule by this chemical conjugation method, the result reveals that the sulfhydryl groups of Stv-28 are fully saturated with BSH, as also suggested by SDS−PAGE analysis. This also demonstrates that the chemical conjugation, the method used to attach BSH to the sulfhydryl groups of Stv-28, was highly efficient and specific.

The biotin-binding ability and subunit association of this boron-enriched streptavidin were analyzed by biotin-binding assays and gel filtration chromatography, respectively. This boron-enriched streptavidin binds greater than 0.97 molecules of biotin/subunit, indicating that it has full biotin-binding ability. No appreciable changes in biotin-binding affinity were seen. On gel filtration chromatography (Figure 3), this boron-enriched streptavidin had a sharp peak, indicating its high structural homogeneity, and no changes in subunit association were seen. The molecular mass of the boron-enriched streptavidin was estimated to be 53 kDa by calibration with molecular mass standard proteins (Boehringer Mannheim). This reveals that this boron-enriched streptavidin is tetrameric, like natural streptavidin, suggesting that the conjugation of BSH has no apparent effect on the subunit association of streptavidin.

The serum stability of the boron-enriched streptavidin was analyzed in vitro. The boron-enriched streptavidin was labeled with ^{35}S, and the resulting radiolabeled protein was incubated at 37 °C in fetal bovine serum. Aliquots were collected periodically and analyzed by SDS−PAGE. Proteins were detected by fluorography for the changes in subunit molecular mass and structural homogeneity. In this assay, dissociation of BSH from streptavidin and degradation of streptavidin are shown by shifts to smaller molecular masses (subunit molecular mass of intact boron-enriched streptavidin, 16 kDa) and by reduction in radioactivity of the 16 kDa band. Fluorography of the gel (Figure 4) shows no apparent change of the subunit molecular mass of the radiolabeled boron-enriched streptavidin (16 kDa), and no degradation products with smaller molecular masses were seen. Quantitation of radioactivity by a PhosphorImager also showed no appreciable change in radioactivity of the 16 kDa band.

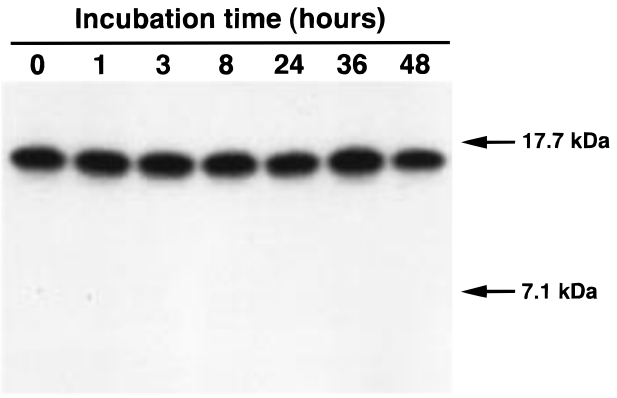

Figure 4. Serum stability of a boron-enriched streptavidin. A boron-enriched streptavidin was labeled with ^{35}S by using a sulfur labeling reagent (Amersham). The radiolabeled boron-enriched streptavidin was incubated at 37 °C in fetal bovine serum at a final streptavidin concentration of 16 μg/mL. Aliquots were collected periodically and analyzed by SDS−PAGE using a 10−20% polyacrylamide gradient gel. Proteins were visualized by fluorography. The number above each lane is the incubation time in hours. The positions of prestained molecular mass standard proteins (lysozyme, 17.7 kDa; aprotinin, 7.1 kDa; Kaleidoscope Prestained Standards, Bio-Rad) are shown by arrows.

These results reveal that the chemical conjugation of BSH to the C-terminal cysteine stretch of Stv-28 has little, if any, effect on the fundamental properties of streptavidin, such as biotin-binding ability and subunit association. They also indicate that the chemical conjugation method used is highly specific and efficient and that the resulting boron-enriched streptavidin has high structural homogeneity. In addition, the boron-enriched streptavidin has high stability in serum, suggesting that the linkage between Stv-28 and BSH may be sufficiently stable for in vivo uses. Additional analysis indicated that 2-iminobiotin affinity chromatography is not necessary to obtain functional conjugates without contaminating BSH-MPHPD complexes and unreacted BSH and MPHPD. Since the chemical conjugation of BSH is quite efficient and it does not alter the fundamental properties of streptavidin, only the removal of small compounds, i.e., BSH−MPHPD complexes and unreacted BSH and MPHPD, is needed to obtain purified boron-enriched streptavidin preparations. For example, simple gel filtration chromatography using desalting columns, such as PD-10, has shown to be sufficient to obtain pure boron-enriched streptavidin preparations. Other means, such as ultrafiltration and dialysis using membrane with larger pore sizes than that used in this study, should also

be useful for removal of these compounds. Use of these methods should facilitate the production of this boron-enriched streptavidin in large quantities due to their simplicity, as compared to that of 2-iminobiotin affinity chromatography.

DISCUSSION

A boron-enriched streptavidin has been produced by chemical conjugation of a boron-rich compound to a genetically engineered streptavidin using sulfhydryl chemistry. This boron-enriched streptavidin should be very useful as a component of boron carriers for BNCT of cancer. For example, a monoclonal antibody against a tumor-associated antigen (antitumor antibody) could be attached specifically and tightly to this boron-enriched streptavidin upon simple biotinylation. The resulting conjugate between the biotinylated antitumor antibody and the boron-enriched streptavidin could be used to deliver boron to target tumor cells which overexpress the tumor-associated antigen on their surface. Similarly, the boron-enriched streptavidin could be attached to a ligand, such as a growth factor, upon biotinylation, and the resulting conjugate could be used to target boron to tumor cells on which the cell surface receptor of the ligand is overexpressed. In these boron-targeting schemes, the extreme biotin-binding affinity of streptavidin precludes the dissociation of the boron-enriched streptavidin from biotinylated partner macromolecules, such as biotinylated antitumor antibodies and biotinylated ligands. As shown experimentally, the dissociation of BSH from streptavidin, caused by degradation of streptavidin or cleavage of the linkage between streptavidin and BSH, is also negligible. Similar targeting strategies have been tested by using monoclonal antibodies and ligands to which large amounts of boron are directly conjugated. However, the biological activities and functions of these macromolecules are often altered or even lost by either direct conjugation of large amounts of boron or the conditions used for chemical conjugation. This problem may be solved by attaching large amounts of boron indirectly to these macromolecules, for which streptavidin serves as a linker or spacer between the macromolecules and boron. The availability of a variety of biotinylation methods (Wilchek and Bayer, 1990) should allow this indirect boronation scheme applicable to a wide range of macromolecular tumor targeting reagents.

In this work, only one boron-enriched streptavidin species was produced which carries approximately 230 boron atoms/molecule. However, the length of the C-terminal cysteine stretch can easily be varied by simple genetic engineering. Thus, the number of boron atoms attached to each streptavidin molecule can be maximized, if needed, by conjugating BSH to a streptavidin variant containing a longer cysteine stretch using the same chemical conjugation method.

ACKNOWLEDGMENT

The author thanks David Friedman, Ilhan Olmez, Gordon Korse, Kent Riley, and Otto Harling at the Nuclear Reactor Laboratory, Massachusetts Institute of Technology, for their help in quantitative boron analysis using ICP-AES. The author also thanks Rolf Barth and Albert Soloway at the Ohio State University for helpful suggestions and discussions and Mark Pandori for critical reading of the manuscript. This work was supported by Research Grant Awards from the Brain Tumor Society.

Radioiodination of Cyanocobalamin Conjugates Containing Hydrophilic Linkers: Preparation of a Radioiodinated Cyanocobalamin Monomer and Two Dimers, and Assessment of Their Binding with Transcobalamin II

D. Scott Wilbur,*,† Pradip M. Pathare,† Donald K. Hamlin,† Sheldon P. Rothenberg,‡ and Edward V. Quadros‡

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195, and SUNY-Downstate Medical Center, Brooklyn, New York 11203. Received March 18, 1999; Revised Manuscript Received June 3, 1999

This report describes an investigation aimed at preparation of radioiodinated cyanocobalamin (CN-Cbl) monomers and dimers with improved water solubility and decreased nonspecific binding. In the investigation, synthesis and radioiodination reactions of one monomeric and two dimeric CN-Cbl derivatives were conducted. The initial step in the synthesis of the CN-Cbl derivatives was mild acid hydrolysis of CN-Cbl, **1**, followed by separation of the resultant corrin ring *b*-, *d*-, and *e*-monocarboxylate isomers. The investigation was limited to preparation of conjugates of CN-Cbl-*e*-carboxylate, **2**, as earlier studies had shown binding of that isomer with recombinant human transcobalamin II (rhTCII) was similar to CN-Cbl. In a second synthetic step, the hydrophilic linker moiety, 4,7,10-trioxa-1,13-tridecandiamine, **3**, was conjugated with **2** to form the adduct, **4**. The synthesis of a monomeric CN-Cbl derivative, **6a**, which can be used for radioiodination, was accomplished by reaction of **4** with *p*-tri-*n*-butylstannylbenzoate tetrafluorophenyl (TFP) ester, **5a**. Two CN-Cbl dimers containing the arylstannane radioiodination moiety were also synthesized. The first dimer, **8a**, was synthesized by cross-linking **4** with a stannylbenzoyl-aminoisophthalate di-TFP ester, **7a**. The second dimer, **11a**, was synthesized by reacting benzene tricarboxylate tri-TFP ester, **10**, in a stepwise manner with 1 equiv of the adduct of **5a** and **3** (forming **9a**), followed by 2 equiv of **4**. Iodobenzoate HPLC standards, **6b**, **8b**, and **11b**, used in the radioiodination studies, were prepared in a manner similar to that of the stannylbenzoate derivatives. Radioiodinations were performed by reacting **6a**, **8a**, or **11a** with *N*-chlorosuccinimide and Na[^{125}I]I in methanol under neutral conditions. Radiochemical yields of 17−42% were obtained. Evaluation of the binding properties of radiolabeled CN-Cbl conjugates with rhTCII showed that the dimer of CN-Cbl, **11b**, bound more avidly than the monomer, **6b**, and that the binding affinity of the dimer is essentially equivalent to that of unmodified CN-Cbl. Incubation of radioiodinated monomer, [^{125}I]**6b**, and dimer, [^{125}I]**11b**, with rhTCII followed by size-exclusion chromatographic analysis provided data that the monomer bound one rhTCII molecule whereas two rhTCII molecules were bound to approximately 30% of the dimer.

INTRODUCTION

Cobalamins (Cbl) function as coenzymes in two mammalian enzymes, methionine synthase and L-methylmalonyl-CoA mutase (*1*, *2*). Although an essential nutrient, mammalian cells do not synthesize the basic Cbl structure, rather it is a vitamin (vitamin B_{12}) obtained from microorganisms (*2*) and purified in its cyanocobalamin (CN-Cbl)[1] form (*3*). The adsorption, transport, cellular uptake, and storage of cobalamins is highly regulated (*4*−*8*). Abnormalities in various aspects of this regulated process can result in hematological and neurologic disease (*6*, *9*−*11*). Elucidation of the biochemical pathways and associated abnormalities of cobalamins have been aided greatly by the use of radiolabeled cobalamins (*9*, *12*).

The radiolabel widely used with cobalamins is ^{57}Co, but other radionuclides of cobalt (e.g., ^{58}Co and ^{60}Co) and tritium have also been used (*13*−*17*). While the cobalamins that contain ^{57}Co have many applications, cobalamins labeled with other radionuclides may offer advantages in some applications. One important advantage that can be obtained with certain radionuclides is higher specific activities of CN-Cbl derivatives. Introduction of ^{57}Co into CN-Cbl is obtained by microbial synthesis, and the specific activity can be variable due to differences in growth conditions. Once incorporated, the ^{57}Co-labeled product must be extracted and subjected to extensive purification. Tritium and ^{14}C can be used but the specific activity of the product is inadequate for most applications. Recently, high specific activity ^{99m}Tc- and ^{111}In-

labeled cobalamins have been described for in vivo imaging of the transcobalamin II (TCII) receptors (*18*). In those studies, the chelating agent DTPA was conjugated to the corrin ring via a short lipophilic linker molecule. We have also described a method for labeling cobalamins with iodine radionuclides utilizing a pendant group attached to the corrin ring (*19*). While the attachment of a pendant group to cobalamins for radiolabeling alters the structure, if the attachment is made in specific locations, the binding with TCII is only minimally affected (*20*). The radioiodinated CN-Cbl derivatives prepared bound with TCII nearly as avidly as unaltered CN-Cbl and had specific activities nearly three times that of commercially available ^{57}Co-labeled CN-Cbl (*19*).

Several CN-Cbl derivatives previously prepared in our laboratory are under investigation as new anti-neoplastic therapeutics for AIDS related lymphoma (*19*−*21*). The cobalamin derivatives initially prepared contained the lipophilic linker moiety 1,12-diaminododecane. This linker was used as a 16 Å spacer between the CN-Cbl moiety and conjugated molecules to provide adequate distance such that binding with carrier proteins (e.g., TCII) is not affected. To obtain radioiodinated CN-Cbl derivatives, an arylstannyl moiety, *p*-tri-*n*-butylstannylhippuric acid, which serves as a penultimate precursor to radioiodination (*22*), was conjugated using the lipophilic diaminododecane linker. Radioiodination of the resultant cobalamin-stannylhippurate conjugates produced compounds with high specific activities, but the compounds bound nonspecifically to glassware and syringe needles. Although the nonspecific binding was reduced by addition of bovine serum albumin (BSA), this property made the radioiodinated CN-Cbls of limited use. Dimers of CN-Cbl were also produced using similar chemistry; however, attempted iodination and radioiodination of the CN-Cbl dimers containing arylstannyl moieties were unsuccessful.

Our desire to decrease the nonspecific binding of monomeric radioiodinated CN-Cbl derivatives and to develop a method for radioiodination of CN-Cbl dimers led to an investigation of CN-Cbl derivatives that incorporate a more hydrophilic linker, 4,7,10-trioxa-1,13-tridecandiamine, of similar length (i.e., 17 Å) in the place of 1,12-diaminododecane. Only the corrin ring *e*-monocarboxylate conjugates were prepared as that regioisomer had been previously shown to bind more avidly than conjugates of the other regioisomeric corrin ring carboxylates (*20*). The CN-Cbl derivatives were prepared in sets of two similar compounds, the arylstannane used for radioiodination and the corresponding aryliodide. Thus, two monomeric CN-Cbl derivatives and four dimeric CN-Cbl derivatives were prepared. The primary difference in the CN-Cbl dimers was that in one set of compounds two trioxatridecanediamines were incorporated whereas three of the same linkers were incorporated into the second set of dimers. Once prepared, the CN-Cbl conjugates containing arylstannane moieties were evaluated in radioiodination reactions, and their binding with recombinant human transcobalamin II (rhTCII) was assessed.

EXPERIMENTAL PROCEDURES

Materials. All chemicals purchased from commercial sources were of analytical grade or better and were used without further purification. Cyanocobalamin (vitamin B_{12}) was purchased from Sigma Chemical Co. (St. Louis, MO). *N*-Hydroxysuccinimide was purchased from Lancaster Synthesis Inc. (Windham, NH). All other reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Human serum albumin was obtained from Miles, Inc. (Elkhart, IN). Strongly basic anion exchange matrix, 2% crosslinked Dowex 1 chloride form, 200−400 mesh, Amberlite XAD-2 nonionic polymeric adsorbent, and octadecyl functionalized silica gel for column chromatography were obtained from Sigma-Aldrich (St Louis, MO). Bio-Sil NH_2 (aminopropyl bonded silica) (40−63 μm) for column packing was purchased from Bio-Rad Laboratories (Hercules, CA).

Radioactivity. [^{57}Co]Cyanocobalamin was obtained from Amersham Corp. (Amersham, U.K.) at a specific activity of 200 μCi/μg. Na[^{125}I] was purchased from NEN/Dupont (Billerica, MA) as high concentration/high specific activity radioiodide in 0.1 N NaOH. Samples containing ^{57}Co were measured in a Beckman 300 gamma counter or Wallac 1480 gamma counter, and those containing ^{125}I were measured in a Capintec CRC-15R or a Capintec CRC-6A radioisotope calibrator. Procedures for safe handling of radioactive materials were followed in the manner previously described (*19*).

Spectroscopic Analysis. ^{1}H NMR spectra were obtained on a Bruker AC-500 (500 MHz) or a Bruker AC-750 (750 MHz) instrument. The chemical shifts are expressed as parts per million using tetramethylsilane as an internal standard (δ = 0.0 ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data were obtained on a VG 70SEQ mass spectrometer with 11250J data system. Fast-atom bombardment (FAB) mass spectral data were obtained at 8 kV using a matrix of MeOH/DMIX (thioglycerol/DMSO/TFAA, 90/9/1). Electrospray (ES) mass spectra were acquired on a Sciex API III triple quadrapole spectrometer fitted with a nebulization assisted electrospray source (PE/Sciex, Thornhill, Ontario).

Chromatography. Separation of compounds (nonradioactive) by HPLC was done on a Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (360 nm) and a Varex ELSD MKIII evaporative light-scattering detector. The HPLC data were analyzed using Hewlett-Packard HPLC ChemStation software. The compounds were separated by reversed-phase HPLC on an Alltech Altima C-18 column (5 μm, 4.6 × 250 mm) using one of two different gradient solvent systems at a flow rate of 1 mL/min. Gradient I used methanol as solvent A and aqueous 1% HOAc as solvent B. Starting with 40% A, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% A over the next 10 min and then held at 100% A for 5 min. Retention times, t_R, under these conditions were (min) **1** = 2.7; **2** = 5.1; **4** = 2.3; **6a** = 15.7; **6b** = 10.8; **8a** = 14.8; **8b** = 10.5; **9a** = 18.4; **9b** = 10.5; **11a** = 14.8; **11b** = 10.3 . The starting solvent mixture for gradient II was 70% A, and all other parameters were the same as for gradient I. Retention times, t_R, under these conditions were (min) **5a** = 13.8; **5b** = 20.7. Preparative scale purifications of CN-Cbl conjugates **6a**, **8a**, and **11a** for use in radioiodination reactions were conducted with a gradient of MeOH/H_2O (no HOAc).

Chromatographic separation of radiolabeled cobalamins was carried out on a system consisting of two Beckman model 110B pumps, a Beckman 420 controller, a Beckman model 153 UV detector (254 nm), and a Beckman model 170 radioisotope detector. The compounds were separated on a Hamilton PRP-1 column (10 μm, 4.6 mm × 250 mm; Alltech) using one of two gradient

solvent systems at a flow rate of 1 mL/min. The first solvent system consisted of 50% MeOH as solvent A and 50% water as solvent B. The initial solvent mixture was held for 2 min, then the gradient was increased to 100% A over the next 10 min, and 100% A was held for 5 min. Retention times, t_R, under these conditions were **6b** = 13.8; **11b** = 13.4. In the second gradient, the starting solvent mixture was 60% A, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% A over next 13 min and held there for 10 min. Retention time, t_R, under these conditions was **8b** = 12.8 min.

A preparative LC system containing a Rainin Rabbit-plus peristaltic pumping system, a Dynamax (model UV-1) UV-vis absorbance detector, and a Dynamax model FC1 fraction collector were used to obtain pure samples of **6a**, **6b**, **8a**, **8b**, **11a**, and **11b**. A glass column (150 psi, C_{18}, 25 mm × 500 mm) packed with either Bio-Sil NH_2 (for separation of CN-Cbl-carboxylates) or reversed-phase C_{18} was used. The eluant solvents and gradients were the same as above. Fractions were collected and evaluated by analytical HPLC before combining those containing only the desired compound.

Synthesis of CN-Cbl-*e*-carboxylic acid, 2. The CN-Cbl corrin ring *e*-carboxylate, **2**, was prepared by acid hydrolysis of CN-Cbl, **1**, and purified by preparative LC on Bio-Sil NH_2 as previously described (*20*).

Synthesis of 4. Conjugation of the CN-Cbl-*e*-carboxylate, **2**, with trioxatridecanediamine, **3**, to form the adduct **4** was accomplished as previously described (*21*).

Synthesis of *p*-Tri-*n*-butylstannylbenzoyltrioxatridecanediamine-CN-Cbl Conjugate, 6a. To a solution containing 0.3 g (0.193 mmol) of **4** in 20 mL of DMF and 27 μL of Et_3N was added 0.108 g (0.193 mmol) of *p*-tri-*n*-butylstannylbenzoate TFP ester, **5a**, over a 5−10 min period. The reaction mixture was stirred at room temperature for 2 h (HPLC monitored) and then evaporated to dryness. The resultant solid residue was dissolved in 10 mL of 60% methanol/H_2O, loaded on a preparative C_{18} reversed-phase LC column, and eluted with the same solvent mixture as used for loading the column. The fractions containing the final product were evaporated to dryness to yield 42% of **6a**, mp 170−172 °C. ^{1}H NMR (MeOH-d_4, 750 MHz): δ 0.35 (s, 2H); 0.7−2.6 (m, 80H); 2.76 (m, 2H); 3.0−3.65 (m, 38H); 3.8 (m, 1H); 3.95−4.1 (m, 3H); 4.2 (m, 1H); 4.4 (m, 1H); 4.6 (m, 1H); 5.95 (s, 1H); 6.18 (s, 1H); 6.47 (s, 1H); 7.02 (s, 1H); 7.16 (s, 1H); 7.45 (m, 2H); 7.65 (m, 2H). MS (FAB$^+$) mass calcd for $C_{92}H_{139}N_{15}O_{18}CoPSn$: 1952. Found: 1953 (M + H). IR (KBr): 3300, 3200, 2900, 1640, 1570, 1200, 1070.

Synthesis of *p*-Iodobenzoyltrioxatridecanediamine-CN-Cbl Conjugate, 6b. The same procedure as described for the synthesis of **6a** was used, except 0.076 g (0.193 mmol) of *p*-iodobenzoate TFP ester, **5b**, was added in place of **5a**. The product was isolated in 35% yield, mp 161−163 °C. ^{1}H NMR (MeOH-d_4, 750 MHz): δ 0.44 (s, 2H); 1.05−1.5 (m, 13H); 1.65−2.7 (m, 40H); 2.84 (m, 2H); 3.15−3.75 (m, 40H); 3.88 (m, 1H); 4.05−4.2 (m, 2H); 4.3 (m, 1H); 4.54 (m, 1H); 4.65 (m, 1H); 6.04 (s, 1H); 6.27 (s, 1H); 6.56 (s, 1H); 7.11 (s, 1H); 7.25 (s, 1H); 7.56 (m, 2H); 7.82 (m, 2H). MS (FAB$^+$) mass calcd for $C_{80}H_{112}N_{15}O_{18}CoPI$: 1787. Found: 1788 (M + H). IR (KBr): 3300, 3200, 2900, 1640, 1570, 1200, 1070.

4′-(Tri-*n*-butylstannyl)benzoyl-5-aminoisophthalate DiTFP Ester, 7a, and 4′-Iodobenzoyl-5-aminoisophthalate DiTFP Ester, 7b. These compounds were synthesized as described previously (*21*).

Synthesis of 8a. To a solution containing 0.3 g (0.193 mmol) of **4** in 20 mL of DMF was added 30 μL of Et_3N followed by 0.084 g (0.096 mmol) of **7a**. The reaction mixture was stirred at room temperature for 3 h and then evaporated to dryness. The resultant solid residue was dissolved in 10 mL of 80% methanol/H_2O, loaded on a preparative C_{18} reversed-phase LC column, and eluted with the same solvent mixture as used for loading the column. The fractions containing the final product were evaporated to dryness to yield 43% of **8a**, mp 238−241 °C (dec). ^{1}H NMR (MeOH-d_4, 500 MHz): δ 0.45 (s, 4H); 0.9−2.7 (m, 140H); 2.8−2.9 (m, 5H); 3.1−3.8 (m, 64H); 3.88 (m, 4H); 4.08−4.2 (m, 6H); 4.34 (m, 3H); 4.48 (m, 4H); 4.68 (m, 4H); 6.05 (s, 2H); 6.28 (s, 2H); 6.57 (s, 2H); 7.14 (s, 2H); 7.26 (s, 2H); 7.6−7.8 (m, 3H); 7.9−8.01 (m, 3H); 8.33 (s, 1H). MS (ES) mass calcd for $C_{173}H_{251}N_{31}O_{37}Co_2P_2Sn$: 3654. Found: 3655 (M + H). IR (KBr): 3300, 3200, 2900, 1640, 1570, 1200, 1070.

Synthesis of 8b. The same procedure was used as described for the synthesis of **8a**, except 0.067 g (0.096 mmol) of **7b** was added in place of **7a**. The product was isolated in 45% yield, mp 210−213 °C (dec). ^{1}H NMR (MeOH-d_4, 500 MHz): δ 0.44 (s, 4H); 1.0−2.65 (m, 115H); 2.8−2.9 (m, 5H); 3.1−3.8 (m, 62H); 3.88 (m, 4H); 4.04−4.2 (m, 6H); 4.34 (m, 3H); 4.48 (m, 4H); 4.67 (m, 4H); 6.04 (d, J = 5.5 Hz, 2H); 6.26 (s, 2H); 6.56 (d, J = 6.5 Hz, 2H); 7.13 (d, J = 4 Hz, 2H); 7.24 (d, J = 3.5 Hz, 2H); 7.73−7.79 (m, 3H); 7.88−8.01 (m, 3H); 8.3 (s, 1H). MS (ES) mass calcd for $C_{161}H_{224}N_{31}O_{37}Co_2P_2I$: 3491. Found: 3492 (M + H). IR (KBr): 3300, 3200, 2900, 1640, 1570, 1200, 1070.

***N*-(13′-Amino-4′,7′,10′-trioxatridecanyl)-4-tributylstannylbenzamide, 9a, and *N*-(13′-Amino-4′,7′,10′-trioxatridecanyl)-4-iodobenzamide, 9b**. Compounds **9a** and **9b** were synthesized as described previously (*23*).

Synthesis of 11a. A solution of **9a** (0.058 g, 0.095 mmol) in 25 mL of anhydrous DMF was added dropwise over 1 h to a solution of **10** (0.062 g, 0.095 mmol) and Et_3N (40 μL) in 15 mL of DMF. The reaction was stirred at room temperature for 30 min and a solution of **4** (0.190 mmol, 0.296 g) in 10 mL of DMF was added. The reaction mixture was stirred at room temperature for 24 h and then evaporated to dryness. The resultant solid residue was dissolved in 10 mL of 70% methanol/H_2O, loaded on a preparative C_{18} reversed-phase LC column, and eluted with the same solvent mixture as used for loading the column. The fractions containing the product were evaporated to dryness to obtain **11a** in 30% yield, mp 285−290 °C. ^{1}H NMR (MeOH-d_4, 750 MHz): δ 0.44 (s, 4H); 0.85−2.7 (m, 138H); 2.85 (m, 5H); 3.15−3.8 (m, 88H); 3.87 (m, 3H); 4.05−4.2 (m, 6H); 4.3 (m, 3H); 4.45−4.7 (m, 10H); 6.03 (s, 2H); 6.27 (s, 2H); 6.56 (s, 2H); 7.11 (s, 2H); 7.25 (s, 2H); 7.54 (d, J = 7.5 Hz, 2H); 7.73 (d, J = 8.5 Hz, 2H); 8.39 (s, 3H). MS (ES) mass calcd for $C_{184}H_{274}N_{32}O_{41}Co_2P_2Sn$: 3887. Found: 3886 (M − H). IR (KBr): 3300, 3200, 2900, 1640, 1570, 1200, 1070.

Synthesis of 11b. The same procedure was used as described for the synthesis of **11a**, except 0.043 g (0.095 mmol) of **9b**, which was added in place of **9a**. The product was isolated in 26% yield, mp 215−218 °C (dec). ^{1}H NMR (MeOH-d_4, 750 MHz): δ 0.49 (s, 4H); 1.15−1.55 (m, 8H); 1.7−2.75 (m, 80H); 2.9 (m, 5H); 3.2−3.85 (m, 112H); 3.96 (m, 4H); 4.1−4.27 (m, 6H); 4.4 (m, 3H); 4.55−4.75 (m, 8H); 6.1 (s, 2H); 6.34 (s, 2H); 6.63 (s, 2H); 7.18 (s, 2H); 7.31 (s, 2H); 7.6 (d, J = 8.0 Hz, 2H); 7.87 (d, J = 8.5 Hz, 2H); 8.45 (s, 3H). MS (ES) mass calcd for $C_{172}H_{247}N_{32}O_{41}Co_2P_2I$: 3724. Found: 3723 (M − H). IR (KBr): 3300, 3200, 2900, 1640, 1570, 1200, 1070.

Synthesis of CN-Cbl-*p*-[^{125}I]Iodobenzamide Derivatives [^{125}I]6b, [^{125}I]8b, and [^{125}I]11b. *Purification of **6a**, **8a**, and **11a** by HPLC.* A saturated solution of a CN-Cbl derivative was prepared in methanol. This solution was passed through a 45 μm filter and three to five 20 μL aliquots were injected on the HPLC (C_{18} column). The product peak from each injection was collected, and the collected fractions were combined. The concentration of the cobalamin derivative in the combined fractions was calculated from the UV absorbance at 360 nm. The cobalamin-containing solution was then divided into aliquots containing 0.5 mg each, dried under a stream of argon, and stored at 4 °C.

*Preparation of nca [^{125}I]**6b***. The HPLC-purified **6a** was dissolved in methanol at a concentration of 1 mg/mL and 50 μL of that solution was placed in a small vial. To the solution was added 1 μL (92 μCi) of Na[^{125}I]I in 0.1 N NaOH, followed by addition of 2 μL of 0.1 N HOAc. To the resulting solution was added 25 μL of a 1 mg/mL solution of NCS in MeOH. After 15 min, 25 μL of a 1.0 mg/mL solution of sodium metabisulfite in H_2O was added to quench the reaction. A total of 87 μCi in approximately 75 μL of solution was removed from the reaction vessel by syringe and injected on an HPLC column (PRP-1 column). The iodinated product was collected from the HPLC effluent (13.8 min), yielding 24 μCi (28%) of [^{125}I]**6b**. The radioiodinated product was evaluated by HPLC and stored at 4 °C.

*Preparation of nca [^{125}I]**8b***. A 3.5 μL (1.0 mCi) aliquot of Na[^{125}I]I in 0.1 N NaOH was added to 50 μL of a 1 mg/mL solution of **8a**, followed by the addition of 4.0 μL of 0.1 N HOAc. To the resulting solution was added 10 μL of a solution containing 1 mg/mL NCS in methanol. After 15 min, the entire reaction mixture (990 μCi) was drawn into a syringe and injected onto an HPLC column (PRP-1 column). The collected fraction (12.7 min) yielded 168 μCi (17%) of **8b**.

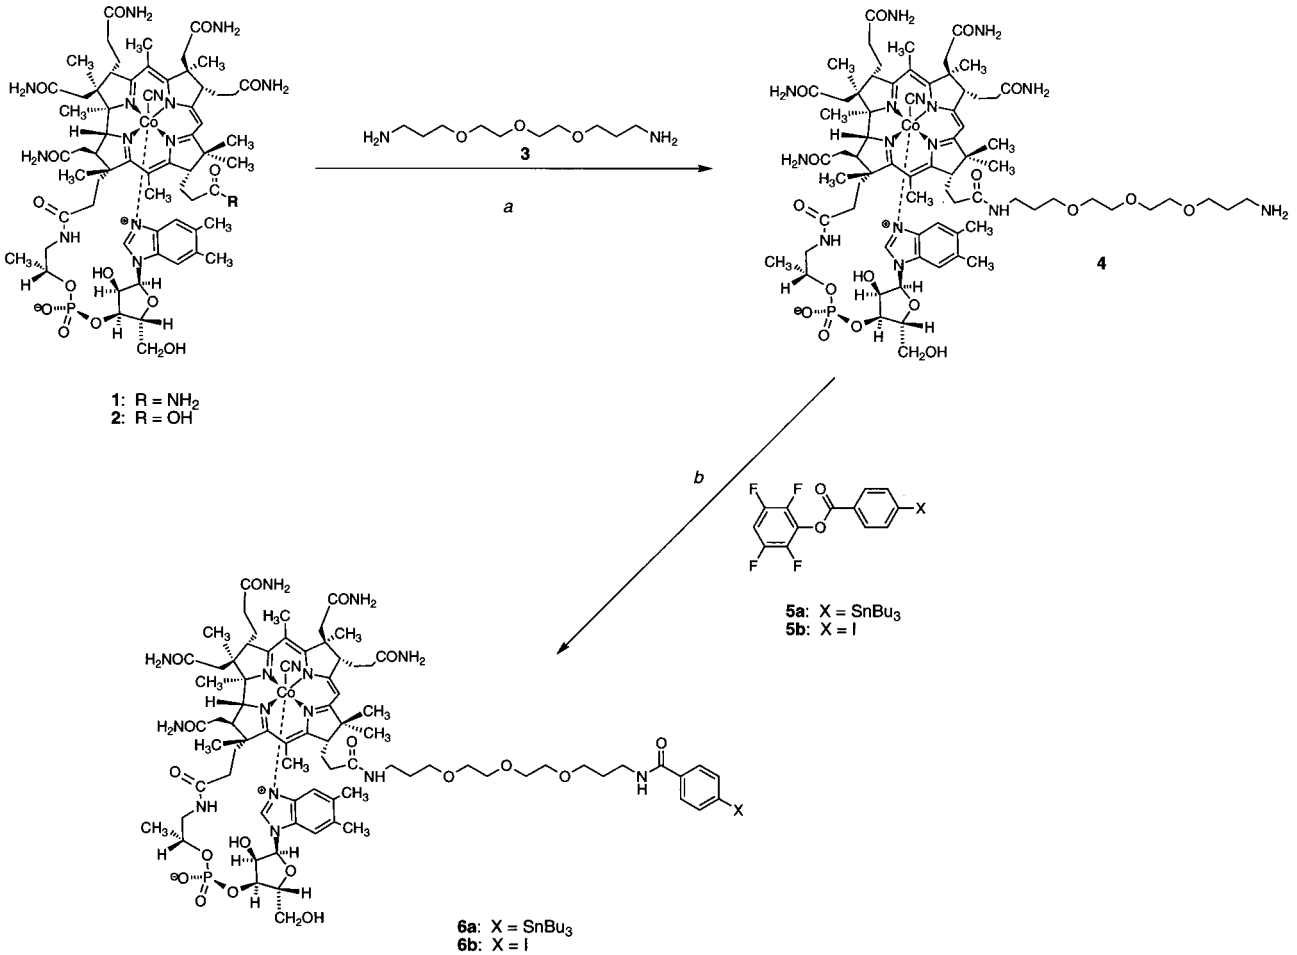
*Preparation of ca [^{125}I]**11b***. A 1 μL (253 μCi) aliquot of Na[^{125}I]I in 0.1 N NaOH was added to 50 μL of a 1 mg/mL solution of **11a**, followed by addition of 2 μL of 0.095 mg/mL solution of NaI. To the resulting solution was added 10 μL of solution containing 1 mg/mL NCS in methanol. After 15 min, the entire reaction mixture (245 μCi) was drawn into a syringe and injected onto an HPLC column (PRP-1). The collected fraction (13.5 min) yielded 103 μCi (42%) of **11b**.

Determination of Specific Activity of [^{125}I]6b and [^{125}I]11b. Specific activities of the [^{125}I]**6b** and [^{125}I]**11b** were determined by calculation (theoretical) and by TCII-binding assay. The calculation of specific activities was adjusted for time between preparation and when binding assays were run (45 days; 59% remaining) and adjusted for added NaI (ca reaction only).

In the TCII-binding assay, increasing amounts of radiolabeled CN-Cbl were incubated for 1 h with aliquots of human serum which had a predetermined Cbl-binding capacity. Protein bound and free radiolabeled compound were separated by adsorption of unbound radiolabeled CN-Cbl to hemoglobin-coated charcoal. The cpm for saturation of TCII with radiolabeled CN-Cbl provided cpm per picogram of compound. The cpm were corrected for efficiency of the counter (80%), and the values were converted into microcurie to obtain a specific activity in microcurie per microgram.

Binding of CN-Cbl-[^{125}I]iodobenzoate Derivatives with Recombinant Human Transcobalamin II (rhTCII). rhTCII was produced and partially purified as previously reported (*24*). The rhTCII was diluted in 0.025% HSA/PBS/0.1% Triton x-100 to bind approximately 1 pmol of CN-Cbl/100 μL. The [^{125}I]**6b** and [^{125}I]-**11b** were diluted respectively to 100 000 and 60 000 cpm/mL in 0.05% HSA/PBS/0.1% Triton x-100. The binding of **6b** and **11b** to rhTCII was measured in a competitive binding assay in which 100 μL of each ^{125}I-labeled or ^{57}Co-labeled CN-Cbl was mixed with 0.1−8 pmol of unlabeled CN-Cbl, followed by addition of 100 μL of rhTCII solution to each tube. The volume was adjusted to 1 mL with PBS and incubated for 1 h at room temperature. The protein-bound fraction was determined by adsorption of the free fraction to hemoglobin-coated charcoal (2.5% charcoal/0.25% hemoglobin in PBS). The amount of compound bound as a function of concentration in the reaction was calculated and plotted.

Size-Exclusion Chromatography of ^{125}I-Labeled 6b and 11b Bound to rhTCII. The quantities of 1 pmol of [^{125}I]**6b** and 2 pmol of [^{125}I]**11b** were separately incubated for 1 h at room temperature with a 10-fold molar excess of rhTCII in a 0.75 mL solution containing 20 mM tris/200 mM NaCl/0.1% Triton x-100. Blue dextran (0.25 mL, 10 mg/mL) was added to each sample to mark the void volume of the column. The sample was layered on a 1.5 × 90 cm Sephacryl S-200 column. The column was equilibrated and eluted in the same buffer at a flow rate of 1 mL/min, and 2 mL fractions were collected. The radioactivity in each fraction was determined in a gamma counter, and the elution profile of TCII-bound compound was plotted.



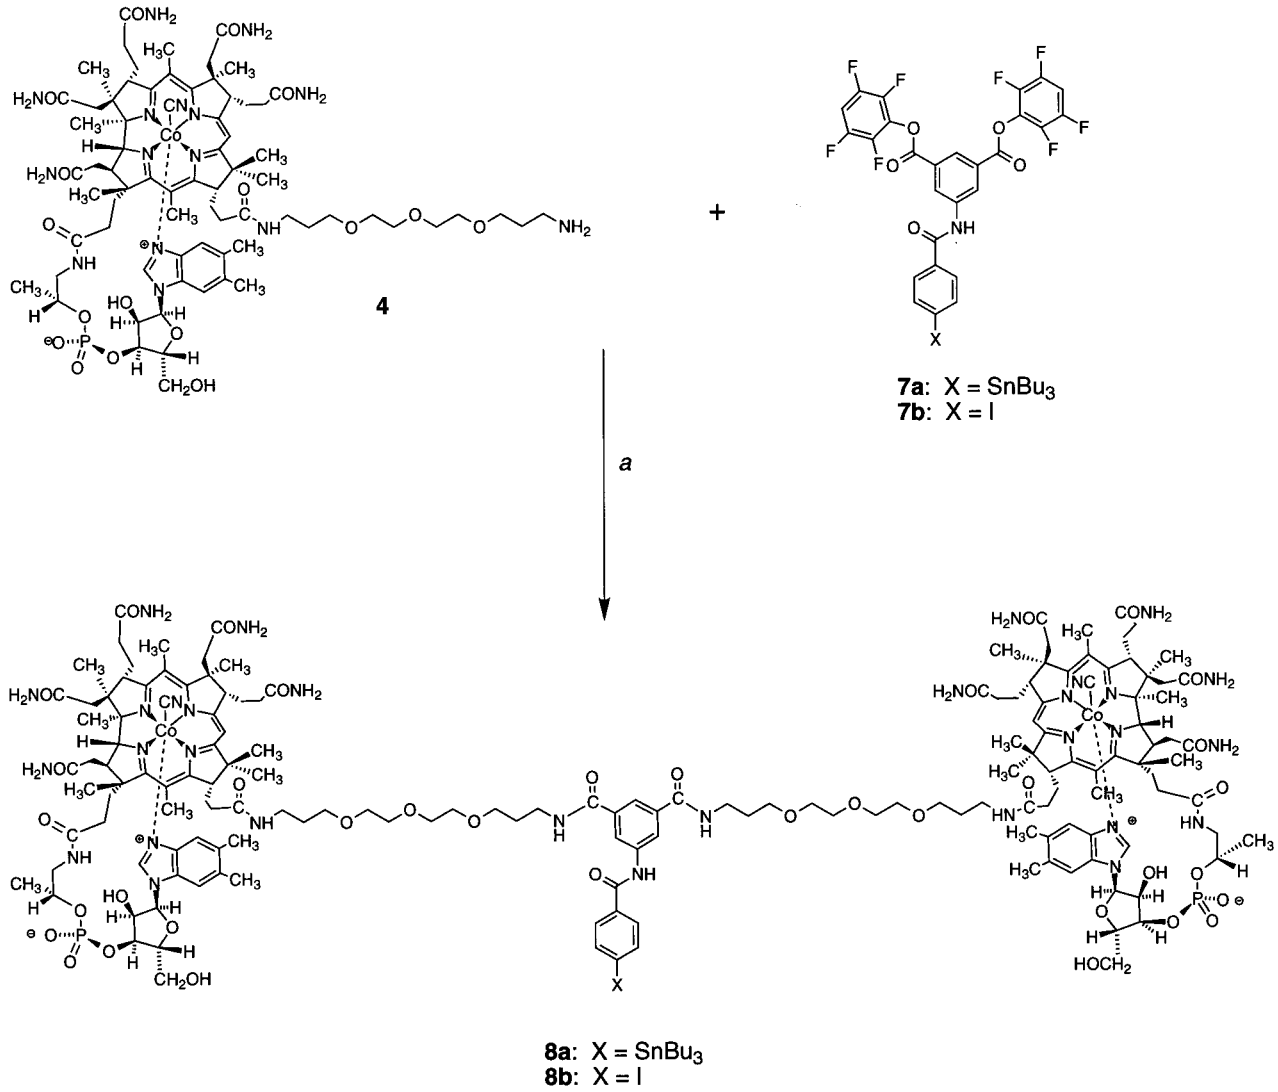
RESULTS

Synthesis of CN-Cbl Conjugates. The CN-Cbl corrin ring *e*-carboxylate, **2**, was obtained by preparative LC separation of the mixture of CN-Cbl monocarboxylic acids produced by acid hydrolysis of CN-Cbl, **1** (*20*). The isolated CN-Cbl-*e*-carboxylate, **2**, was conjugated with 4,7,10-trioxa-1,13-tridecandiamine, **3**, by reaction with a carbodiimide (EDC) in water containing NaCN/NHS to yield compound **4** as shown in Scheme 1. The stannylbenzoate conjugate, **6a**, and iodobenzoate conjugate, **6b**, were prepared by the reaction of **4** with either the TFP ester of *p*-tri-*n*-butylstannylbenzoic acid, **5a**, or the TFP ester of *p*-iodobenzoic acid, **5b**. Compounds **6a** and **6b** were isolated pure from the conjugation reaction in 42 and 35% yield, respectively.

The approaches taken to synthesize the hydrophilic CN-Cbl dimers are shown in Schemes 2 and 3. As in previous syntheses of CN-Cbl dimers (*21*), each synthesis utilized a trifunctional cross-linking reagent to couple two CN-Cbl moieties. In one synthesis (Scheme 2), the reagent used to cross-link the two CN-Cbl moieties contained an arylstannane or aryliodide moiety such that the CN-Cbl dimer could be formed in one step. Thus, reaction of **4** with either the di-TFP ester of *p*-(tri-*n*-butylstannyl)benzoylaminoisophthalate, **7a**, or the di-TFP ester of *p*-iodobenzoyl-aminoisophthalate, **7b**, provided the desired CN-Cbl dimers, **8a** and **8b** in 43 and 45% yields, respectively, after purification. The requisite aminoisophthaloyl derivative, **7b**, was prepared by conjugation of *p*-iodobenzoyl chloride with 5-aminoisophthalic acid followed by preparation of the di-TFP ester using EDC and TFP−OH in ethyl acetate (*21*). Conversion of the aryl iodide, **7b**, into the aryl stannane, **7a**, was accomplished in 62% yield using bis(tributyl)tin and palladium catalyst.

The synthesis of the second set of CN-Cbl dimers, **11a** and **11b**, was accomplished by the reaction shown in Scheme 3. In a stepwise manner, 1 equiv of either the trioxatridecanediamine-conjugated arylstannane, **9a**, or

Scheme 1. Synthetic Route Used to Prepare CN−Cbl Conjugates 6a and 6b



[a] NHS/NaCN/H_2O/**3**/HCl/EDC/rt/4 days. [b] DMF/Et_3N/**5a** or **5b**/rt/2 h

aryliodide, **9b**, was reacted with the tri-TFP ester of benzenetricarboxylic acid, **10**, followed by addition of 2 equiv of the trioxatridecanediamine adduct of CN-Cbl-*e*-carboxylate, **4**. The progress of the reaction after each addition was followed by HPLC analysis. Preparation of **9a** and **9b** was accomplished by reaction of the TFP ester of *p*-tri-*n*-butylstannylbenzoic acid or the TFP ester of *p*-iodobenzoic acid with trioxatridecanediamine, **3**, as previously described (*23*). Following this procedure, and purification by HPLC, the CN-Cbl dimers **11a** and **11b** were obtained in 30 and 26% yields, respectively.

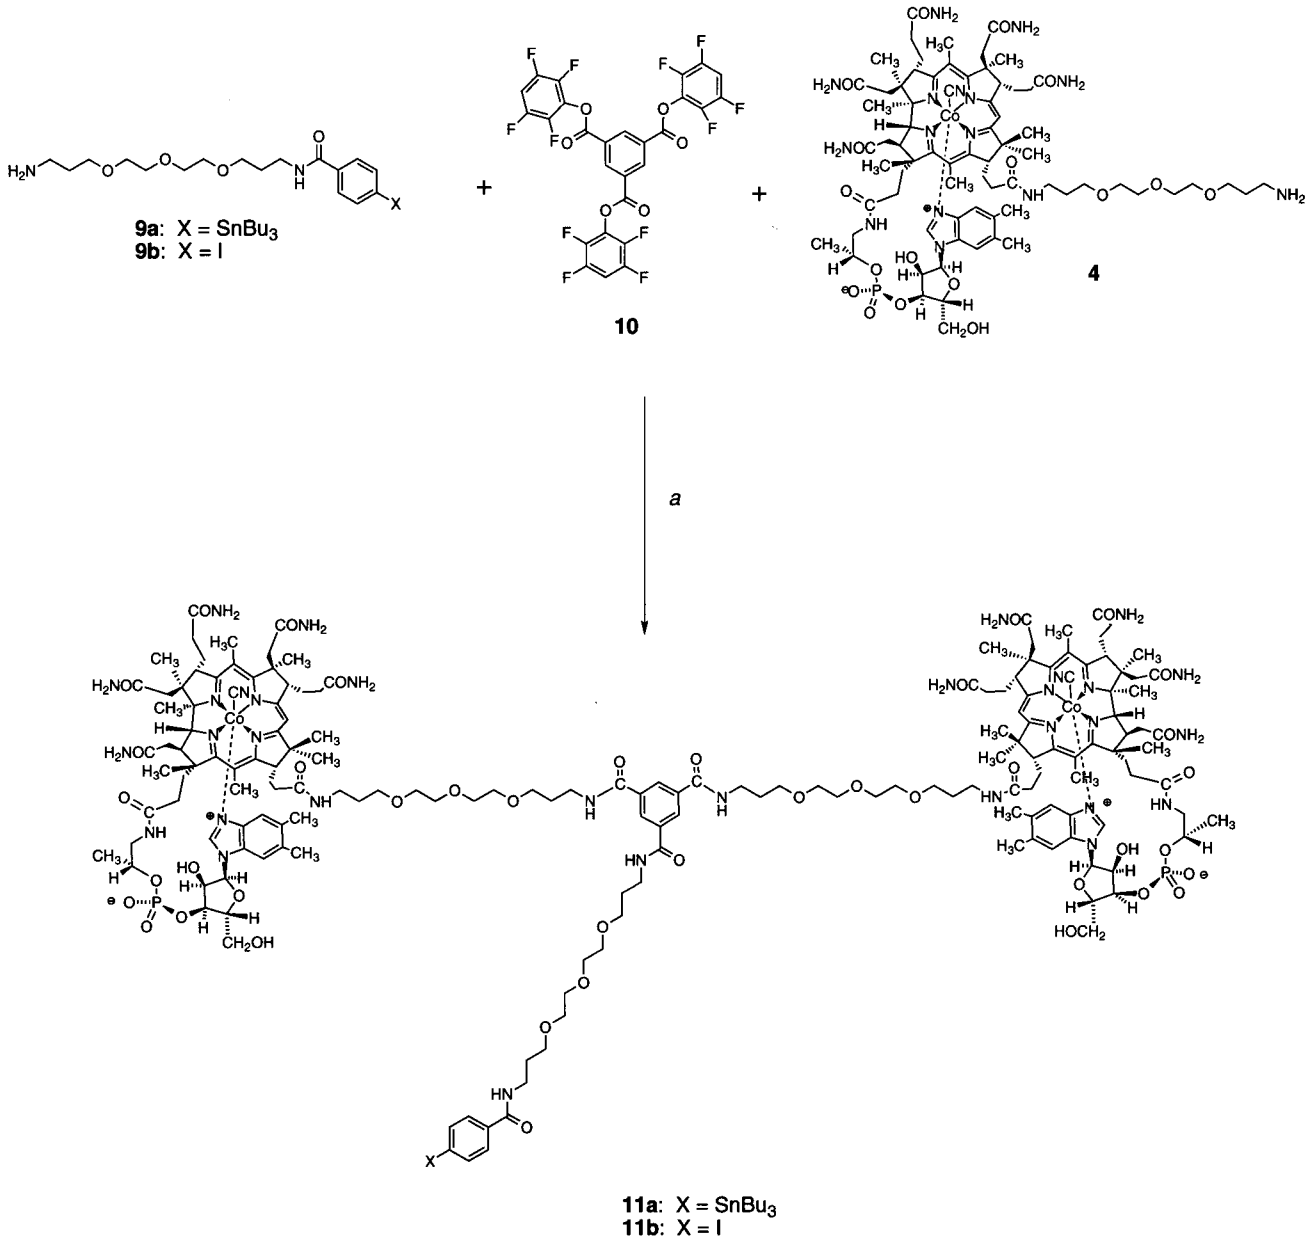
Iodination Reactions. Although the isolated arylstannanes **6a**, **8a**, and **11a** were >95% pure by HPLC analysis, the starting material was further purified by preparative HPLC prior to radioiodination to ensure that reactive minor impurities would not compete in *nca*-radioiodinations. Initial radioiodination of **6a** was carried out in MeOH employing NCS/Na[^{125}I]I. The HPLC retention time for the new radioiodinated species indicated that the arylstannane was not substituted by iodine, suggesting that the radioiodide may have undergone another reaction, such as displacement of the cyano group on the cobalt. Radioiodination in aqueous 1% AcOH provided the desired radioiodinated product, but the yield was low (20−30%), and an additional radioiodinated species which was similar in lipophilicity to the starting arylstannane was also formed. Addition of just enough HOAc to neutralize the NaOH in the added Na[^{125}I]I gave only the desired radioiodinated product, albeit again in low yields (17−42%). Although there are a number of possible causes for the low radiochemical yields, one explanation for the low yields is that recovery of the radioiodinated compound from the HPLC column did not reflect the actual yields. This statement is made since it was observed that a large proportion of the radioactivity was retained on the HPLC column even after extended elution times. Radioiodination of **11a** under the same conditions as used to prepare [^{125}I]**6b** and [^{125}I]**8b** failed to give the desired *nca* product, [^{125}I]**11b**. However, when the reaction was carried out with a small quantity of carrier NaI, the radioiodinated ca product was obtained in 42% yield. The in vitro stability of [^{125}I]**6b**, [^{125}I]**8b** (*20*), and [^{125}I]**11b** was evaluated by reexamining the radioiodinated CN-Cbl conjugates after storage at 4 °C for over 3 months. Radiochromatographic peaks of the isolated products were unchanged (peak areas were corrected for decay) after storage for 1 h, 24 h, and 3 months.

Specific activities for [^{125}I]**6b** and [^{125}I]**11b** were estimated by calculation and by measurement of the quantity of radioactivity that it takes to saturate TCII in serum which has a known binding capacity for CN-Cbl. The specific activity value for [^{125}I]**6b** obtained by calculation is 720 μCi/μg and that obtained by the binding assay was 625 μCi/μg. These numbers are very close, but the lower specific activity measured by binding is most likely closer to the actual value as one would expect some decrease in specific activity (from theoretical) due to the introduction of stable iodide in solvents and reagents. The specific activity for the carrier added [^{125}I]**11b** was calculated to be 12 μCi/μg. In contrast, the specific activity measured by TCII binding in serum was 38 μCi/μg. It is not known why there is a 3 times difference in these numbers, but

Scheme 2. Synthetic Route Used to Prepare CN-Cbl Conjugates 8a and 8b

[a] 2 equiv of **4**/DMF/Et_3N/**7a** or **7b**/rt/3 h.

they are fairly close considering the two different methods of obtaining them.



Competitive Binding with rhTCII. The CN-Cbl monomer [^{125}I]**6b** and CN-Cbl dimer [^{125}I]**11b** were evaluated for their competitive binding to (partially purified) rhTCII relative to CN-Cbl. The assay was set up such that a quantity of rhTCII that would bind approximately 1 pmol of [^{57}Co]CN-Cbl was used in each evaluation. Trace quantities of [^{57}Co]CN-Cbl, [^{125}I]**6b**, or [^{125}I]**11b** were mixed with 0.1−8 pmol of unlabeled CN-Cbl, then mixed with rhTCII. The percent radioactivity bound relative to the picomoles of unlabeled CN-Cbl was measured. The results obtained are provided in Figure 1 and show that the binding of radioiodinated monomer **6b** as well as the dimer **11b** to rhTCII is essentially unaltered and is similar to that of CN-Cbl. The initial flat portion of the graph representing 100% binding is due to having less than saturating quantities CN-Cbl present.

Evaluation of [^{125}I]6b and [^{125}I]11b Binding to rhTCII. A 1 pmol quantity of monomer [^{125}I]**6b** and 2 pmol of dimer [^{125}I]**11b** were incubated with 10-fold molar excess of rhTCII at room temperature, and the resulting adducts were examined by size-exclusion gel chromatography (Sephacryl S-200). Fractions were collected from the column and the radioactivity in each fraction was determined. The elution profile of the binding of [^{125}I]-**6b**, [^{125}I]**11b**, and [^{57}Co]CN-Cbl with rhTCII is plotted in Figure 2. The [^{57}Co]CN-Cbl, the [^{125}I]**6b** monomer, and approximately 70% of the[^{125}I]**11b** dimer eluted from the column as a single peak corresponding to ∼40 kDa, the size of the monomeric rhTCII. A second peak of ∼80 kDa was only observed with the dimer **11b** and accounted for ∼30% of the rhTCII-bound radiolabel.

DISCUSSION

This investigation was undertaken because our previous attempts to synthesize radioiodinated CN-Cbl derivatives produced compounds that were not optimal for our needs due to their poor solubility in aqueous medium and their propensity to adhere to glass and metal (needle) surfaces. Furthermore, we were unsuccessful in preparing a radioiodinated CN-Cbl dimer. Although the cause of the nonspecific binding is uncertain, we thought that this property could be due, at least in part, to the hydrophobic linker molecule, 1,12-diaminododecane. It was apparent that the hydrophobic linker made the CN-Cbl conjugates very lipophilic and resulted in their having low water solubility. Also, NMR data from the CN-Cbl dimers suggested that the tri-*n*-butylstannylbenzoate moiety was affected by the lipophilic nature of the linker, perhaps resulting in shielding it from reacting

Scheme 3. Synthetic Route Used to Prepare CN-Cbl Conjugates 11a and 11b

[a] **9a** or **9b**/DMF/Et_3N/rt/30 min; 2 equiv **4**/rt/24 h

with radioiodination reagents. Therefore, we reasoned that using a more hydrophilic linker might provide CN-Cbl derivatives with more favorable characteristics.

We have previously used the ether-containing linker 4,7,10-trioxa-1,13-tridecandiamine to increase water solubility of biotin derivatives (*23*, *25*) and CN-Cbl dimers (*21*). This linker increases the solubility of the compound greatly over that of an aliphatic linker moiety. Accordingly, we observed a marked improvement in water solubility of the radioiodinated CN-Cbl derivatives and found that, in contrast to the more aliphatic CN-Cbl derivatives, these compounds did not adhere to glass or metal (syringe needle) surfaces. Previously prepared CN-Cbl dimers which were cross-linked using aliphatic diaminododecane linkers required dissolution in DMSO and dilution with water (2−10% DMSO solutions) to prepare 1 mg/mL solutions. In contrast, 1 mg of **8b** or **11b** was found to be soluble in only 10 μL of water, indicating that the compounds have a solubility of >100 mg/mL. The reason for including three trioxatridecanediamine linkers in the CN-Cbl dimer **11b** was primarily to evaluate whether providing a greater distance between the arylstannane moiety and the cross-linking aminoisophthalate moiety would improve the radiochemical yield. Unfortunately, it appears to have done just the opposite as no radioiodinated product was obtained when the reaction was conducted under *nca* conditions. Despite this, we have been successful in obtaining radioiodinated CN-Cbl dimers, and the new radioiodinated CN-Cbl conjugates can be formulated in aqueous solution without difficulty.

To date there have been few evaluations to determine the in vitro and in vivo characteristics of the radioiodinated CN-Cbl derivatives. As in our previous studies, comparison of the binding of the corrin ring *e*-carboxylate conjugates (Figure 1) indicate that their binding with rhTCII is similar to that of unaltered CN-Cbl. It is interesting to note that the CN-Cbl monomer [^{125}I]**6b** binds with a slightly lower avidity than CN-Cbl, but binding of [^{125}I]**11b** appears to be essentially equivalent to CN-Cbl. The CN-Cbl dimers were designed to bind with two rhTCII moieties, which in turn may alter

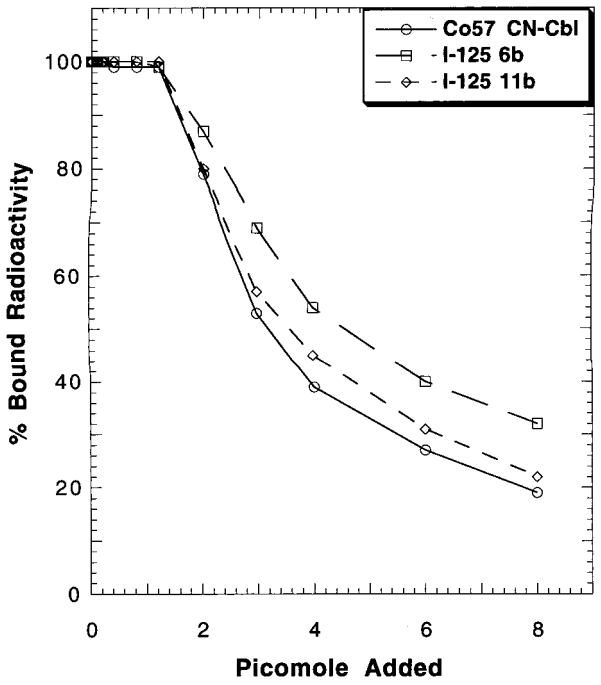


Figure 1. Competitive binding curves for [^{57}Co]CN-Cbl, **1**, and iodobenzoyl-CN-Cbl derivatives, **6b** and **11b**, with rhTCII. [^{57}Co]CN-Cbl (0.01 pmol) was mixed with increasing concentrations of **1** or Cbl derivatives **6b** or **11b**. Diluted rhTCII (100 μL) with a binding capacity of approximately 1 pmol of **1** was then added to each tube. The volume was adjusted to 1 mL with PBS and incubated at room temperature for 1 h. Free and protein bound radioactivity was separated by adsorption to hemoglobin coated charcoal, and the radioactivity in each fraction was determined and plotted.

binding with the cell surface receptor for TCII−Cbl. We hypothesized that CN-Cbl dimer cross-linked with the aminoisophthalate moiety and two trioxatridecanediamine linkers would have adequate space between the two CN-Cbl moieties (41 Å linker, fully extended) to permit binding with two rhTCII molecules. In this study, the question of whether the CN-Cbl dimer can bind with two rhTCII molecules was addressed successfully for the first time. The results obtained by size-exclusion separation of complexes formed with the CN-Cbl monomer **6b** and the CN-Cbl dimer **11b** (Figure 2) appear to indicate that at least a fraction of the CN-Cbl dimer binds with two rhTCII molecules. Additional studies need to be conducted to determine if what appears to be an equilibrium mixture can be shifted to having mostly two TCII bound and to determine if there is a difference in binding affinity between the first TCII bound and the second TCII bound. It also remains to be determined if the two TCII molecules bound to the same CN-Cbl dimer can interact with two TCII-receptors on the cell surface, and if this should occur, what effect it would have on TCII−Cbl internalization.

Summary. Three CN-Cbl conjugates containing arylstannane moieties for radioiodination have been synthesized. Use of the hydrophilic linker molecule, 4,7,-10-trioxa-1,13-tridecandiamine, in the place of 1,12-diaminododedane that was previously employed, resulted in radioiodinated CN-Cbl derivatives that are water soluble and do not have the propensity to adhere to glass and metal surfaces. From our earlier studies, it was demonstrated that the corrin ring *e*-monocarboxylate isomer bound more tightly with TCII than the other regioisomers. Therefore, in this investigation we used only *e*-carboxylate isomer. One Cbl monomer and two Cbl dimers were prepared using conjugates of CN-Cbl-*e*-carboxylate and the hydrophilic linker trioxatridecanediamine. Arylstannane CN-Cbl conjugates were prepared as reactive compounds for site-specific radioiodination, and the corresponding aryliodides were prepared as HPLC standards. Following the syntheses, attempts to develop optimal conditions for radioiodination of CN-Cbl-arylstannane conjugates were fraught with difficulties. In our earlier investigation we showed that good radiochemical yields (40−65%) could be obtained under neutral reaction conditions. In this study, the radiochemical yields ranged 17−42%. High specific activity was obtained in radioiodination of CN-Cbl monomer **6b** and CN-Cbl dimer **8b**. Radioiodination of dimer **11b** with *nca* radioiodine failed, but ca radioiodination was successful. The binding of radioiodinated CN-Cbl derivatives to rhTCII was similar to that observed with unmodified CN-Cbl. The results obtained indicate that the dimer of CN-

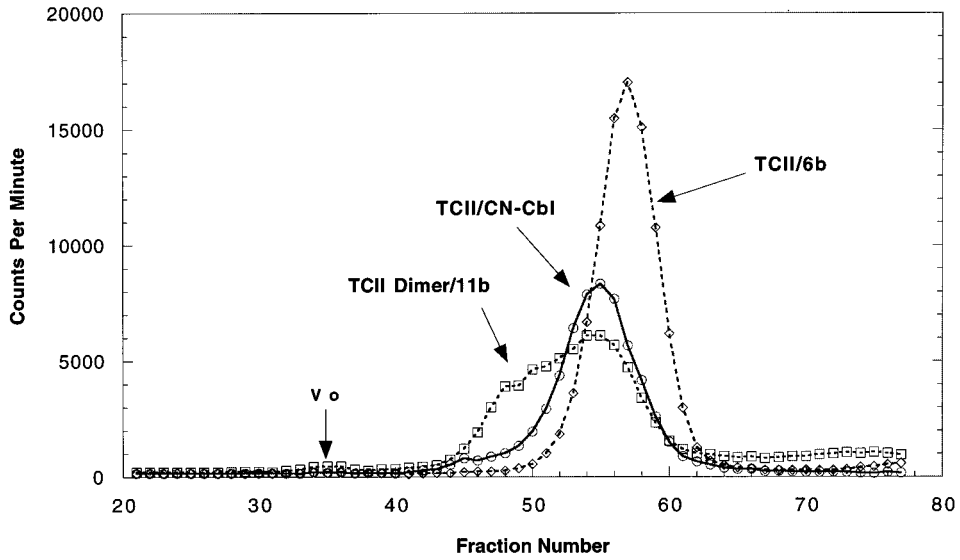

Figure 2. Elution profile of radioactivity in fractions from size exclusion chromatography of [^{57}Co]CN-Cbl, [^{125}I]**6b**, and [^{125}I]**11b** bound to rhTCII. In the experiment, 1 pmol of [^{125}I]**6b** and 2 pmol of [^{125}I]**11b** were each incubated with a 10-fold molar excess rhTCII for 1 h at room temperature. Blue dextran (0.25 mL, 10 mg/mL) was added to each sample to mark the void volume for the column. The sample was layered on a 1.5 × 90 cm Sephacryl S-200 column. The column was equilibrated and eluted in the same buffer at a flow rate of 1 mL/min and 2 mL fractions were collected. The radioactivity in each fraction was determined and plotted.

Cbl **11b** binds more avidly with rhTCII than the monomer of CN-Cbl, **6b**, and its binding affinity is essentially equivalent to that of CN-Cbl. Size-exclusion chromatographic analysis of [^{125}I]**11b** binding with TCII indicated that approximately 30% bound with two TCII molecules.

ACKNOWLEDGMENT

We thank Dr. Ross Lawrence (Medicinal Chemistry Department, University of Washington) for efforts in obtaining mass spectral data. This work was supported in part by the Department of Radiation Oncology at the University of Washington and by an NIH grant (DK 28561) to S.P.R.

Functionalization of the Sugar Moiety of Oligoribonucleotides on Solid Support

Xiaolin Wu and Stefan Pitsch*

Organisch-chemisches Laboratorium der Eidgenössischen Technischen Hochschule, Universitätstrasse 16, CH-8092 Zürich, Switzerland. Received June 24, 1999

A solid-phase method for the introduction of a variety of different side chains into oligoribonucleotides is presented. It is based on a β-D-allofuranosyl phosphoramidite with a bromopentyl-substituent tethered to the 6′-O position. After its incorporation into fully protected, immobilized RNA sequences, the bromine was substituted with a variety of soft nucleophiles which, in some cases, allowed further transformations. After deprotection and detachment, the corresponding functionalized oligoribonucleotides were purified and characterized. Incorporation of such side chains led to a slight lowering of transition temperatures, but some of them led to a significant enthalpic stabilization of an A-type RNA duplex.

Oligonucleotide conjugates are prepared routinely to create molecular probes and to attach specific reporter groups. A great, not yet exploited potential lies in the development of modified ribozymes with more functional groups able to recognize organic molecules and to catalyze organic reactions (*1*−*4*). Additional substituents are usually added to the ends of oligonucleotides and often carry an unspecific functionality which allows the postsynthetic formation of conjugates (*5*−*7*). Among the reasons for the relatively small number of base and sugar modified nucleic acid analogues (*8*−*11*) are the lengthy syntheses of corresponding building blocks which have usually to be carried out separately for every new modification. This drawback has been overcome partially by the development of building blocks containing reactive nucleobases, which during deprotection can be substituted with a variety of nucleophiles (*12*−*15*) or prior to deprotection with a variety of electrophiles (*16*).

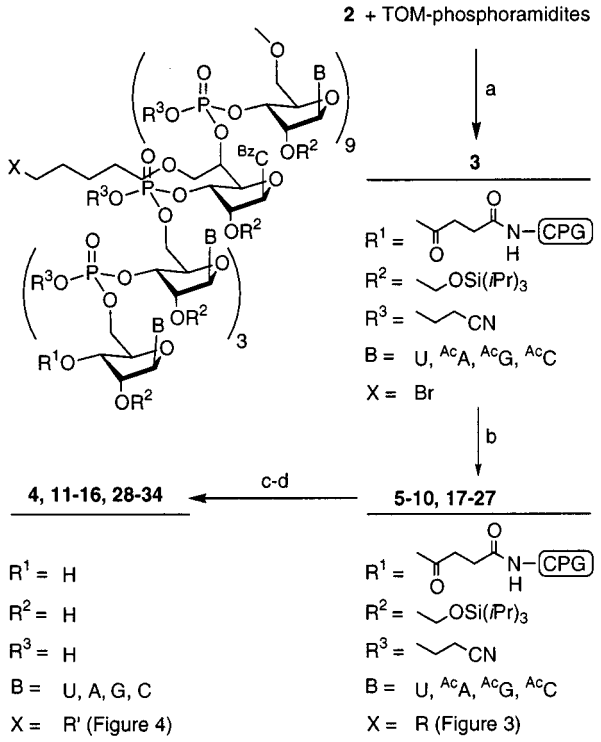

Figure 2. Conditions: (a) automated 20 μmol synthesis (500 mg of CPG, loading 40 μmol g^{-1}) on a Pharmacia Gene Assembler; detritylation with 4% $CHCl_2COOH/(CH_2Cl)_2$. Coupling: 7 min (360 μL 0.1 M TOM-phosphoramidites (*17, 19*), 360 μL of 0.12 M **2**/600 μL 0.35 M benzylthio-1*H*-tetrazol in MeCN), coupling yields >99%. Capping/oxidation: under standard conditions (*20*). (b) See Figure 3. (c) 10 M $MeNH_2$, EtOH/H_2O 1:1, 25 °C, 2 h. (d) 1 M $NBu_4F{\cdot}3H_2O$, THF, 25 °C, 3−12 h. Ac = acetyl.

In the context of our investigations toward the synthesis and the properties of hexofuranosyl oligonucleotides, we have developed fully protected nucleosides, containing reactive groups at the sugar moiety that can be substituted with additional functionalities at a very late stage of the synthesis (*17*). Extending this concept, we have now prepared the 6′-*O*-bromopentyl-substituted allofuranosyl-cytosine phosphoramidite **2** (Figure 1)[1] from

[1] **2**: A solution of **1** (*17*) (204 mg, 0.2 mmol) in CH_2Cl_2 was treated with $(iPr)_2NEt$ (85 μL, 0.5 mmol) and $(iPr)_2NP(Cl)OCH_2CH_2CN$ (62 mg, 0.26 mmol), stirred 1h at 25 °C and purified on Al_2O_3 (Act. III; hexane/EtOAc 3:2 → 3:7), 217 mg (89%) of **2** as colorless foam (2 diastereoisomers). TLC (SiO_2, hexane/EtOAc 1:1) R_f 0.67; UV (MeCN): $\lambda_{max/min}$ (ϵ) = 259 (29 600), 239 (31 500), 224 (29 700). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.97−1.07 (m, 21H), 1.17−1.25 (m, 12H), 1.37−1.41 (m, 4H), 1.77−1.82 (m, 2H), 2.54 and 2.61 (2t, J = 5.5, 2H), 3.03−3.18 (m, 3H), 3.35−3.40 (m, 2H), 3.42−3.53 (m, 2H), 3.60−3.75 (m, 4H), 3.81 (s, 6H), 4.32−4.44 (m, 2H), 4.65−4.80 (m, 1H), 4.98−5.06 (m, 2H), 6.05 and 6.07 (2d, J = 5.1, 1H), 6.83−6.91 (m, 4H), 7.21−7.63 (m, 14H), 7.80−7.87 (m, 2H), 8.65 (s, 1H). ^{31}P NMR (121 MHz, $CDCl_3$): δ 148.8, 150.2. Figure 4. (a, b) Deprotection (Figure 2). [a]R: Figure 3. [b]Area % (HPLC) of product signal, yields after purification: 15−35%. [c]1 μM functionalized sequence + 1 μM **35** (Figure 6) in 150 mM NaCl, 10 mM Tris-HCl (pH 7.4), measured according to ref *17*; the T_m-value of the unfunctionalized sequence **36** was 65.8 °C. [d]MALDI-TOF MS, [M − H]$^-$, measured according to ref *22*.

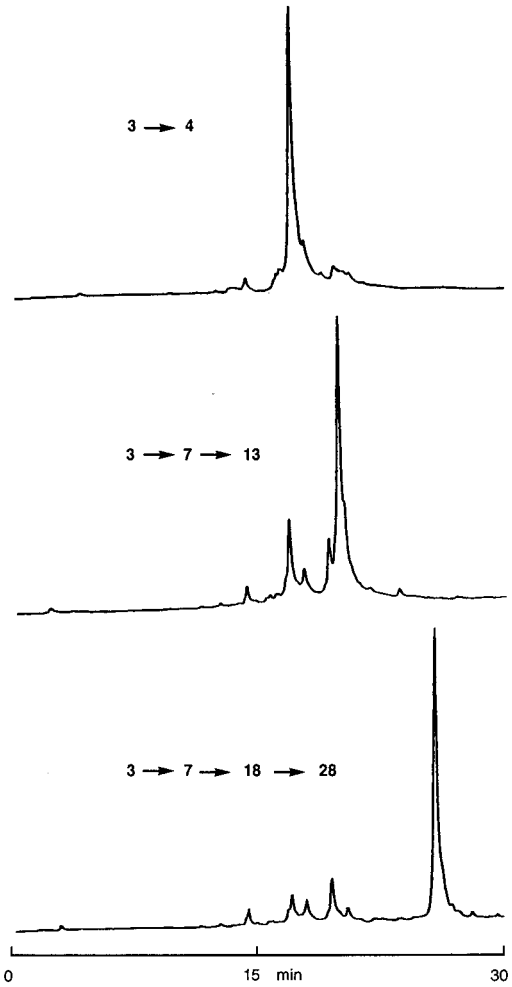
the earlier described nucleoside **1** (*17*) incorporated it into a tetradecamer sequence **3** (Figure 2, Figure 6) and investigated its functionalization on solid support (Figure 3). The sequence r(5′-CUAUCGAGC**X**UACG-3′) (**X**, vari-



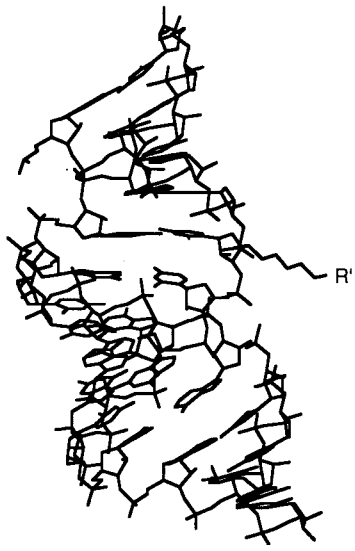


Figure 5. HPLC of crude products. Reaction conditions: Figures 2 and 3. HPLC conditions: Nucleosil 100-5 C18HD, 4.6 × 220 mm, 1 mL/min, elution (30 min) with 0.1 M (Et_3NH)OAc (H_2O, pH 7) → 0.1 M (Et_3NH)OAc (H_2O/MeCN 4:1, pH 7), detection at 260 nm.

able, from phosphoramidite **2**) was chosen, because its pairing behavior was already well documented (*17*, *18*). Molecular modeling revealed that additional functional groups connected to the side chain of the allofuranosyl nucleoside are located above the major groove of a corresponding duplex (Figure 6).

Each modification of the prefunctionalized, fully protected and immobilized sequence **3** was carried out with 5 mg (0.2 μmol sequence) of the solid support. Finally, detachment from the solid support, deprotection of the base and phosphate protecting groups and removal of the 2′-*O*-(triisopropylsilyloxy)methyl (TOM) groups (*17*, *19*) was carried out (Figure 2). The crude products were analyzed by HPLC (Figure 5), and the main products isolated in pure form and characterized by MALDI-TOF MS.

First, sequence **3** was deprotected without prior modification ($MeNH_2$, followed by Bu_4NF). The HPLC of the crude product showed a dominating main product; its MS agreeing with the methylamino substituted sequence **4**. These results reflected a clean overall process including good coupling yields, complete removal of all protecting groups, and a quantitative substitution of bromine during deprotection (Figure 2, Figure 5). Next, the solid-phase nucleophilic substitution of bromine was investigated (Figure 3). According to our analysis, almost quantitative displacement occurred with the soft nucleophiles thiophenol, 2-amino-thiophenol, thiosalicylic acid (Figure 5), propane dithiole, thioacetic acid, and sodium azide. After deprotection of the corresponding intermediates **5**−**10**, products **11**−**16** could be isolated in satisfying yields (Figure 4). These substitutions were best carried out at 25 °C in the presence of base or buffer, with concentrated solutions of the nucleophiles (0.1−1 M) in DMF or DMF/H_2O.[2]

Additional solid-phase functionalizations were carried out with some of the intermediates (Figure 3). Thioacetate **9** was transformed to thiole **17** with H_2NNH_3(OAc). From the acid **7**, amide **18** (Figure 5) and the spermine derivative **19** were obtained under peptide coupling conditions. Azide **10** was reduced with $SnCl_2$ according

Figure 6. Schematic representation of the functionalized duplexes. [a]Thermodynamic data measured in 150 mM NaCl, 10 mM Tris-HCl (pH 7.4) according to ref *23*. [b]Values of the unfunctionalized duplex **35·36**.

to ref *21*, and the resulting amine **20** was transformed to the amide **21** with Ac_2O/pyridine. Reaction of azide **10** with PPh_3 in pyridine gave the phosphoimine **22**. Substitution of **3** with thioglycolic acid, followed by condensation with $MeNH_2$ and $BuNH_2$ led to amides **24** and **25**, respectively. The thiocyanate **26** was transformed into tetrazole **27** by cycloaddition with NaN_3/NH_4Cl. After deprotection of the sequences **17**−**19**, **21**, **22**, **24**, **25**, and **27**, oligonucleotides **15** and **28**−**34** were obtained in satisfying yields of 15−35% after purification (Figure 4, Figure 5).

The transition curves from the functionalized sequences and the complementary sequence **35** revealed T_m-values which were between 0.9 and 3.9 °C lower than the values obtained from the unfunctionalized duplex **36·35** (Figure 4, Figure 6). The thermodynamic parameters of duplex formation (at 37 °C) of selected functionalized sequences showed similar or even greater negative $\Delta G°$ values than for the unfunctionalized duplex **36·35** (Figure 6). The favorable $\Delta G°$ values of for the amide-containing duplexes **32·35** and **33·35** (relative to the parent duplex **36·35**) is the consequence of a more favorable $\Delta H°$ term, which compensates for the less favorable $\Delta S°$ term.

The phosphoramidite **2** allows an efficient preparation of sugar-modified RNA sequences which can be further functionalized in solution or on solid support. The new functionalization site allows site-specific incorporation of additional substituents and labels into the major groove (of corresponding RNA duplexes). The demonstrated concept is also suited for the use in combinatorial syntheses. We meanwhile have prepared the analogous building blocks with the three other canonical nucleobases and are about to prepare and to characterize functionalized ribozymes.

ACKNOWLEDGMENT

This work was supported by the ETH Zürich and the "Alfred Werner Stipendium". We thank Patrick A. Weiss (Xeragon AG, Switzerland) for providing us with reagents and TOM-phosphoramidites.

Synthesis, Spectral Properties, and Detection Limits of Reactive Squaraine Dyes, a New Class of Diode Laser Compatible Fluorescent Protein Labels

Bernhard Oswald,[†] Leonid Patsenker,[†] Josef Duschl,[†] Henryk Szmacinski,[‡] Otto S. Wolfbeis,[†] and Ewald Terpetschnig*[,†,§]

University of Regensburg, Institute of Analytical Chemistry, Chemo- and Biosensors, 93040 Regensburg, Germany, and FluorRx Inc., 979 Keystone Way, Carmel, Indiana 46032. Received August 31, 1998; Revised Manuscript Received March 11, 1999

We describe the synthesis and spectral characterization of two reactive long-wavelength fluorescence labels (Sq635-m and Sq635-b), having either one or two *N*-hydroxysuccinimidyl esters. Both are squaraine derivatives and consist of a cyanine-type chromophore and a central squarate bridge. To improve water solubility, we introduced two sulfonic acid groups into the heterocyclic ring systems, and for covalent attachment to proteins, a reactive *N*-hydroxy-succinimide ester (NHS ester) was synthesized. The squaraine markers exhibit low quantum yields in water ($\phi = 0.15$) and high quantum yields ($\phi = 0.6-0.7$) when bound to proteins. The absorption maxima at 635 nm in water and at approximately 645 nm when bound to proteins allow excitation with commercially available diode lasers. The detection limit of a representative squaraine dye in blood was estimated to be half that of a commonly used fluorophore.

INTRODUCTION

Fluorescence detection is widely used in immunoassays, hybridization assays, enzymatic reactions and other analytical procedures (*1*−*3*). The advantages of fluorescence detection at long-wavelength excitation are the decreased autofluorescence from cells and tissues and the use of inexpensive laser light sources such as diode lasers operating at 635, 645, and 650 nm. It is well-known that the autofluorescence of biological samples decreases with increasing wavelength, particularly beyond 600 nm. Only a few fluorescent probes exist which absorb in the red or near-infrared (NIR) region and even fewer of them are available in a reactive form (*4*−*8*). Amine-reactive functionalities such as isothiocyanate and *N*-hydroxysuccinimide esters and thiol-reactive iodoacetamide and maleimide groups can be used to covalently attach marker molecules to drugs, DNA, or antibodies (*5*, *6*).

The synthesis and spectral characterization of a squaraine derivative for covalent attachment to biomolecules was already reported (*4*). Squaraines, which are 1,3-disubstituted squaric acid derivatives, show high-absorption coefficients ($\epsilon > 200.000$ L mol^{-1} cm^{-1}) in the red region, display a high photostability, and allow the introduction of reactive functional groups such as NHS[1] esters. These dyes exhibit good quantum yields on binding to proteins but insufficient water solubility. The protein conjugates precipitate, in particular at higher dye-to-protein ratios (*4*, *9*). The water solubility of dyes can be improved by introducing sulfonic acid groups (*4*).

Reactive squaraines developed by Mank et al. were used as precolumn derivatization reagents for trace analysis of small molecules (e.g., drugs) in combination with diode laser induced fluorescence and allowed detection of analyte concentrations as low as 50−100 nmol L^{-1} (*6*). We now introduce the second generation of squaraine dyes with improved spectral and chemical properties. Specifically, we report the synthesis of a symmetrical, "bis-reactive" (Sq635-b), and an unsymmetrical, "monoreactive" (Sq635-m), water-soluble, squaraine-dye, and their conjugation to BSA, HSA, and anti-HSA. We also discuss their absorption and fluorescence spectral properties and compare the detection limit of one representative dye to CY5 in blood.

EXPERIMENTAL PROCEDURES

Chemicals, Proteins, and Media. Squaric acid, squaric acid dibutyl ester, and 6-bromohexanoic acid were

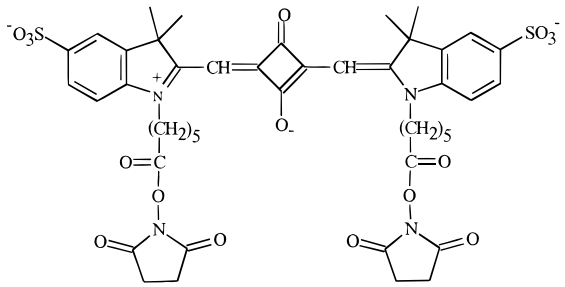
purchased from Aldrich. Cy5 was obtained from Amersham Life Science, Pittsburgh. BSA was purchased from Serva Feinchemica, Heidelberg. HSA and anti-HSA were obtained from Sigma. All other chemicals and solvents were obtained from Merck. All chemicals were used as received. Phosphate buffer of pH 7.3, 0.1 M, 3.17 g of NaH_2PO_4 and 13.7 g of Na_2HPO_4, was dissolved in 1 L of doubly distilled water. Bicarbonate buffer of pH 9, 0.05 M, 2.1 g of $NaHCO_3$, was dissolved in 500 mL of doubly distilled water.

Purification and Spectroscopic Analysis. Analytical and preparative thin-layer chromatography was carried out on RP-18 F_{254} silica plates from Merck. Ion-exchange chromatography was performed using a weakly acidic cation exchanger Amberlite IRC-50. Gel permeation chromatography was carried out using Sephadex G50 as the stationary phase (0.5 × 20 cm column) and a 100 mM phosphate buffer solution (pH 7.3) as eluent. Melting points were measured with apparatus SMP-20 from Büchi and are not corrected. pH values were measured at room temperature with a pH meter WTW 538.

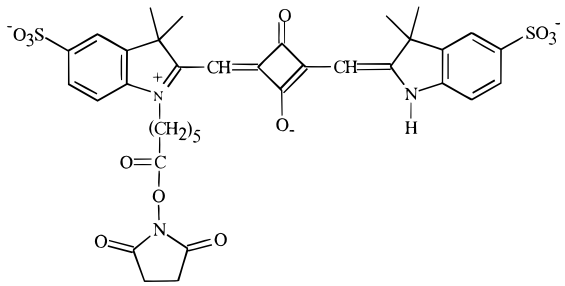


UV spectra were recorded with a U-3000 spectrophotometer (Hitachi). Emission spectra were acquired with a luminescence spectrometer from Aminco (Series 2, from SLM) with a standard 150 W xenon lamp as the excitation source. ^{1}H NMR spectra were recorded with a 250 MHz PFT-NMR spectrometer (AC 250, from Bruker). The internal standard was TMS. The chemical shifts are given in parts per million. The following abbreviations were used to describe the signals: s = singlet, d = doublet, dd = double of doubletts, t = triplet, m = multiplet. Mass spectral analysis was performed at the Central Analytical Department at the University of Regensburg, Germany.

The BSA concentration was determined using the BCA Protein Assay Reagent Kit from Pierce (Rockford, IL). Quantum yields were determined relative to Cy5 assuming a quantum yield of 0.25 for λ_{exc} = 650 nm for Cy5 using the formula $\Phi = \Phi_{Cy5}(F/F_{cy5})$, where F is $\int I(\lambda)\, d\lambda$.

Syntheses. Synthesis of *p*-hydrazinobenzenesulfonic acid (*10*), 2,3,3-trimethylindole-5-sulfonic acid potassium salt (*4*, *5*, *11*), and 1-(ϵ-carboxypentanyl)-2,3,3-trimethylindolenium-5-sulfonic acid potassium salt **(1)** (*5*) was carried out using literature procedures.

Synthesis of Sq635-b-butylester (2) (*4*). To 1 g (2.17 mmol) of 1-(ϵ-carboxypentanyl)-2,3,3-trimethylindolenium-5-sulfonic acid potassium salt (**1**) was added 120 mg (1.03 mmol) of squaric acid, and the mixture was refluxed in 50 mL of a 1-butanol:toluene (1:1, v/v) mixture for 22 h using a Dean−Stark trap filled with 4A molecular sieve. After cooling, the solvent was removed, and the product purified by preparative thin-layer chromatography using RP-18 glass plates and methanol:water (2:1, v/v) as eluent to give 90 mg (22%) of **2**. R_f: 0.47 (RP-C18, methanol:water 2:1); mp >300 °C: FAB-MS, *m/e* (M^+, dianion) for $C_{46}H_{58}N_2O_{12}S_2K_2$, calcd 895.1, found 894.8. ^{1}H NMR (D_2O): δ 7.7−7.1 (m, 6H), 5.7 (s, 2H), 3.7 (t, 4H, J = 6.5), 2.0 (t, 4H, J = 7 Hz), 1.55−0.9 (m, 24H), 1.45 (s, 12H), 0.5 (t, 6H, J = 7 Hz).



*Synthesis of Sq635-b-acid (**3**).* To 50 mg (0.05 mmol) of Sq635-b-butylester (**2**) was added 1 mL of water and 20 mL of 1 M HCl. The mixture is heated to 100 °C for 80 min. At the end of the reaction, 5 mL of 1 mol/L HCl was added. After cooling, the solvent was removed and the product vacuum dried. The product was used without further purification (43 mg, 99%). R_f: 0.75 (RP-C18, methanol:water 2:1), mp >300 °C, FAB-MS, *m/e* (M^+, dianion) for $C_{38}H_{42}N_2O_{12}S_2K_2$, calcd 782.9, found 783.0.

^{1}H NMR (D_2O): δ 7.8−7.3 (m, 6H), 5.9 (s, 2H), 4.2 (t, 4H, J = 6.5 Hz), 2.4 (t, 4H, J = 7 Hz), 1.95−1.3 (m, 12H), 1.77 (s, 12H).

*Synthesis of Sq635-b-NHS-ester (**4**) (a) with TSTU [N,N,N′,N′-tetramethyl(succinimido)uronium tetrafluoroborate] (12).* To 43 mg (0.05 mmol) of Sq635-b-acid (**3**) in 1 mL of DMF, 1 mL of dioxane, and 0.5 mL of water were added 26 μL (0.15 mmol) of diisopropylethylamine and 38 mg (0.126 mmol) of TSTU. After 30 min, the mixture was filtered, and the solvents were removed in a vacuum. The product was dried over P_2O_5 and used without further purification. Yield: 40 mg (76%). R_f: 0.82 (RP-C18, methanol:water 2:1); mp >300 °C; FAB-MS, *m/e* (M^+, dianion) for $C_{46}H_{48}N_4O_{16}S_2K_2$, calcd 977.0, found 977.1. ^{1}H NMR (d_6-DMSO): δ 7.65−7.2 (m, 6H), 5.8 (s, 2H), 4.2 (t, 4H, J = 6.5 Hz), 2.9−2.6 (m, 12H), 1.65−1.4 (m, 12H), 1.75 (s, 12H).

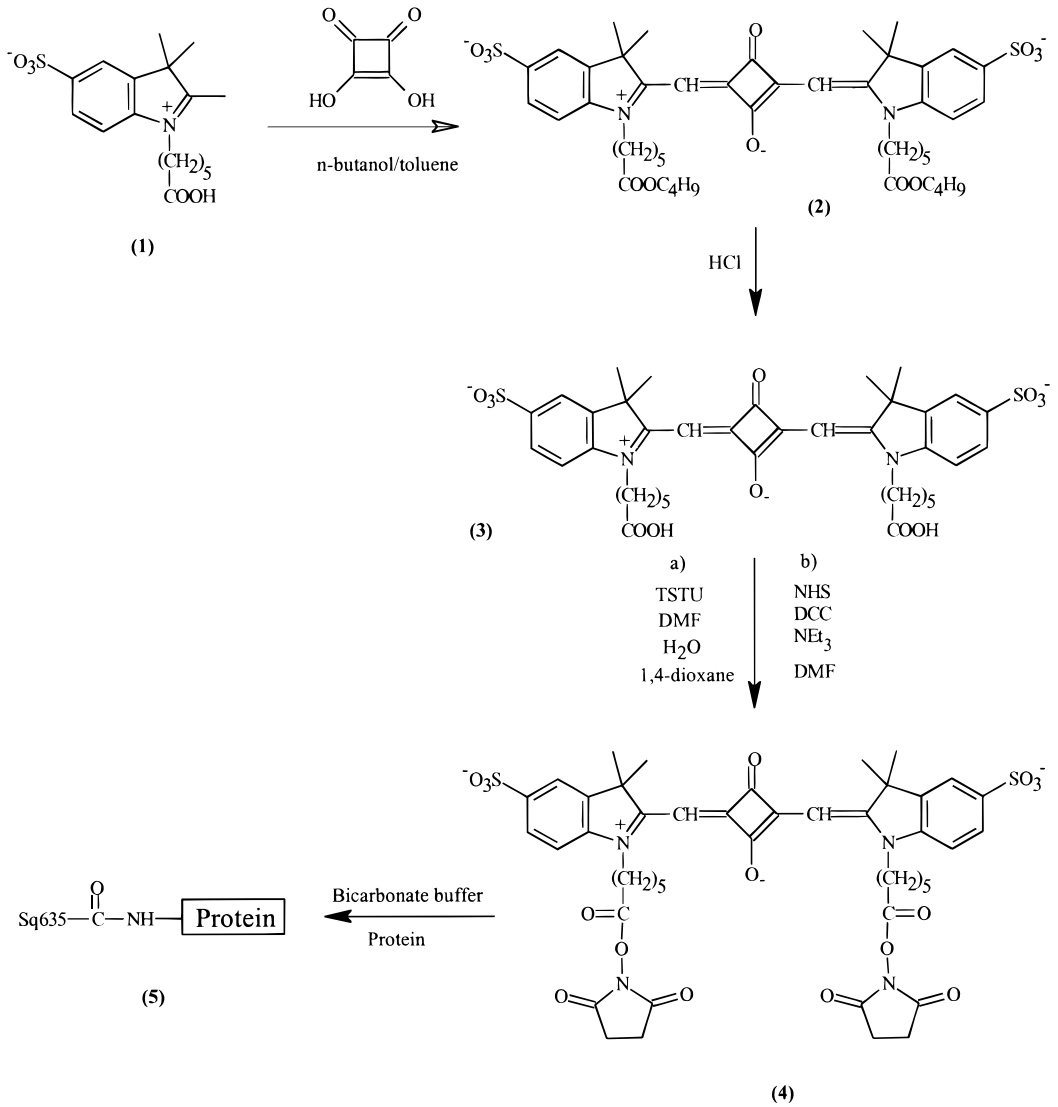

Figure 3. Synthetic pathway for the bis-functional squaraine-NHS ester.

Synthesis of Sq635-b-NHS-ester (4) (b) with NHS/DCC. A total of 14 mg (0.069 mmol) of dicyclohexylcarbodiimide (DCC) and 8 mg (0.069 mmol) of *N*-hydroxysuccinimide (NHS) was added to 20 mg (0.023 mmol) of Sq635-b-acid **(3)** in 1 mL of anhydrous DMF. The solution was stirred for 24 h at room temperature and filtered. The solvent was removed under reduced pressure, and the remaining solid was triturated with ether and dried over P_2O_5 (22 mg, 91%). R_f: 0.82 (RP-C18, methanol: water 2:1); mp >300 °C; FAB-MS, *m/e* (M^+, dianion) for $C_{46}H_{48}N_4O_{16}S_2K_2$, calcd 977.0, found 977.2. ^{1}H NMR (d_6-DMSO): δ 7.65−7.2 (m, 6H), 5.8 (s, 2H), 4.2 (t, 4H, J = 6.5 Hz), 2.9−2.6 (m, 12H), 1.65−1.4 (m, 12H), 1.75 (s, 12H).

Synthesis of Sq635-m-acid (8). To 47 mg (0.1 mmol) of 1-(ϵ-carboxypentanyl)-2,3,3-trimethylindolenium-5-sulfonic acid potassium salt **(1)** was added 22 μL (0.1 mmol) of squaric acid dibutyl ester, and the mixture was refluxed in 8 mL of ethanol with 140 μL of triethylamine for 30 min. Subsequemtly, 220 μL of 1 M aqueous NaOH was added, and the mixture was refluxed for 30 min. After cooling to room temperature, 2.3 mL of 1 M hydrochloric acid was added, and the solvent was removed under reduced pressure to obtain the monosubstituted squaraine derivative **(7)**.

The residue was refluxed with 24 mg (0.09 mmol) of 2,3,3-trimethylindole-5-sulfonic acid potassium salt in a butanol:toluene mixture (1:1 v/v) for 1 h. Water was removed as an azeotrope using a Dean−Stark trap. After cooling, the solvents were removed using a rotary evaporator. The product was treated with 100 μL of methanol, collected under reduced pressure, and purified on preparative TLC (RP-18 F_{254S}) using methanol:water (2:1 v/v) as the eluent. Yield: 31 mg (33%). R_f: 0.50 (RP-C18, methanol:water 2:1); mp >300 °C. FAB-MS, *m/e* (M^+, dianion) for $C_{32}H_{32}N_2O_{10}S_2K_2$, calcd 668.1, found 668.5. ^{1}H NMR (D_2O): δ 7.75−7.5 (m, 4H), 7.15−6.95 (m, 2H), 5.55 (s, 1H), 5.35 (s, 1H), 4.55 (t, 2H, J = 6.5 Hz), 2.05−2.3 (m, 2H), 1.5−1.2 (m, 6H), 1.25 (t, 12H).

The activation to the NHS-ester was carried out analogous to Sq635-b-acid (**3**) using procedure b. R_f: 0.55 (RP-C18, methanol:water 2:1), mp >300 °C. FAB-MS, *m/e* (M^+, dianion) for $C_{36}H_{35}N_3O_{12}S_2K_2$, calcd 766.1, found 766.4. ^{1}H NMR (D_2O): δ 7.85−7.5 (m, 4H), 7.15−6.9 (m, 2H), 5.55 (s, 1H), 5.35 (s, 1H), 4.45 (t, 2H, J = 6.5 Hz), 2.7 (s, 4H) 2.05−2.35 (m, 2H), 1.5−1.2 (m, 6H), 1.25 (t, 12H).

General Protein Labeling Procedures and Determination of Dye-to-Protein Ratios. Protein labeling reactions were carried out using 50 mM bicarbonate buffer (pH 9.0). A stock solution of 1 mg of dye in 100 μL of anhydrous DMF was prepared; 10 mg of protein was dissolved in 1 mL of a 100 mM bicarbonate buffer, pH 9.1, and various amounts of dye from the stock solution

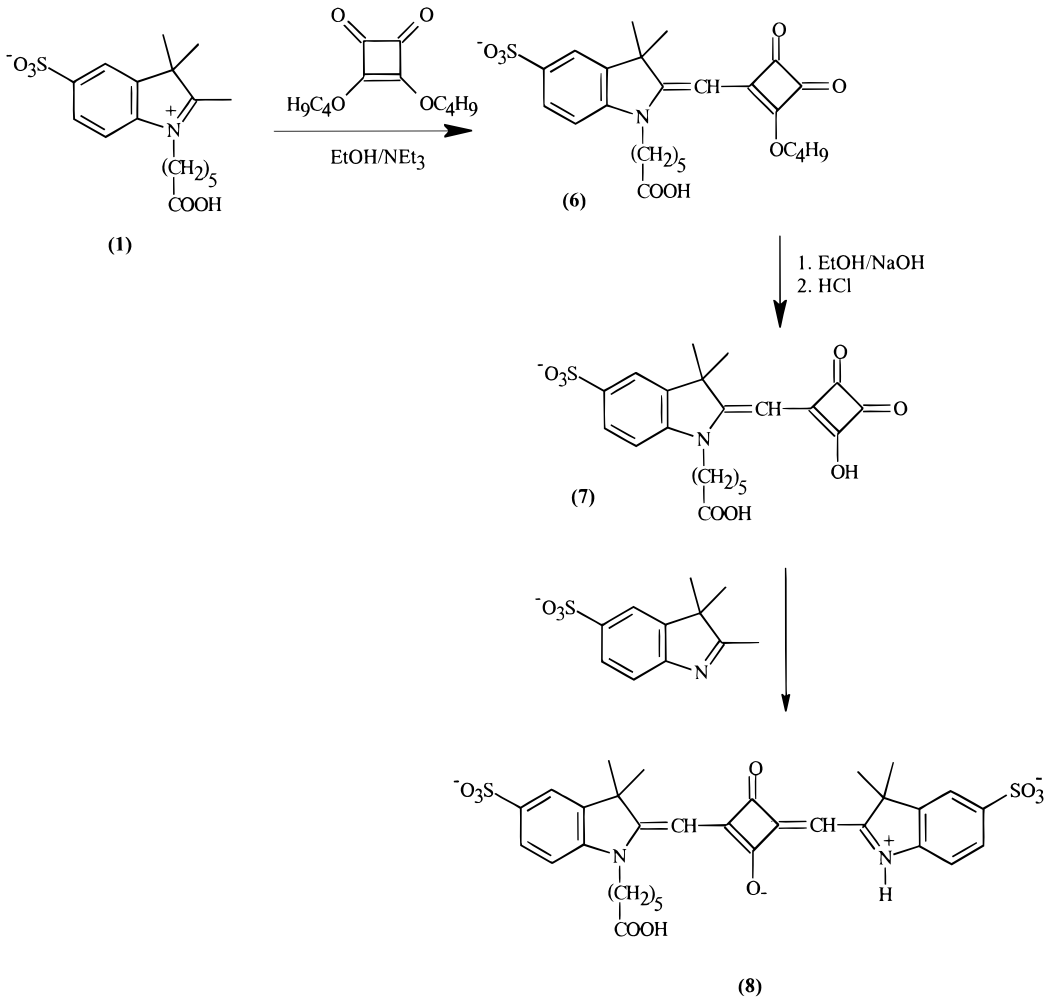

Figure 4. Synthetic pathway for the monofunctional squaraine-NHS ester.

were added, and the mixture was allowed to stir for 24 h at room temperature.

Unconjugated dye was separated from the labeled proteins using gel permeation chromatography with Sephadex G50 (0.5 cm × 20 cm column) and a 22 mM phosphate buffer solution of pH 7.3 as the eluent. The first colored band contained the dye−protein conjugate, while the blue band with a much higher retention time contained the separated free dye. A series of labeling reactions as described above was set up to obtain different dye-to-protein ratios. Compared to the free forms, the protein-bound forms of the dyes show distinct changes in their spectral properties.

The molar dye-to-protein ratio (degree of labeling) for each dye conjugate was calculated as the molarity of dye divided by the molarity of protein. The dye concentration of the conjugate was determined according to Lambert−Beer's Law from the absorbance of the dye at the absorption maximum. The protein concentration was determined using the BCA Protein Assay Reagent Kit from Pierce (Rockford, IL). The dye-to-protein ratio (*D*/*P*) gives the number of dye molecules covalently bound to the protein.

Determination of the Extinction Coefficients. Sq635-b-butylester (**2**) was purified on preparative TLC. The K^+ ions were replaced by H^+ ions by ion-exchange chromatography using Amberlite IRC-50 as the stationary phase and methanol as the eluent. Sq635-b-butylester (**2**) (0.55 mg) was dissolved in 100 mL of doubly distilled water. From this stock solution, three dilutions (1:20, 1:50, and 1:100) were made, and the absorbances were measured. The extinction coefficient was calculated according to Lambert−Beer's law and was found to be 140 000 L/(mol cm) for Sq635-b-butylester (**2**). In an analogous way the extinction coefficient for Sq635-m-acid (**8**) was determined to be 120 000 L/(mol cm). Both values refer to 634 nm.

Determination of the Detection Limits in Blood. Human blood was diluted 1:20 with phosphate buffer solution (pH 7.2). The absorbances of 50 nmol/L solutions of Sq635-b-NHS-ester (**4**), Sq635-b-anti-HSA, Cy5-NHS-ester, and Cy5-HSA were measured, and the concentrations were determined via Lambert−Beer's law assuming an extinction coefficient of 140 000 L/(mol cm) for Sq635-b-NHS-ester (**4**) and 250 000 L/(mol cm) for Cy5-NHS-ester. The emission spectra (Figure 6) of the solutions were measured by exciting at 600 nm using a standard xenon lamp (150 W) as the excitation source. The dye-to-protein ratios for Sq635-b-anti-HSA and Cy5-HSA are 0.49 and 1.1, respectively.

RESULTS

The synthetic pathway and the structures of the squaraine dyes are shown in Figures 1−4. While the synthesis of the symmetrical Sq635-b-acid (**3**) was achieved in a direct procedure (Figure 3), the synthesis of the unsymmetrical dye required the synthesis of a monosubstituted key intermediate (**6**) (Figure 4) that was hydrolyzed to the intermediate (**7**) and subsequently reacted

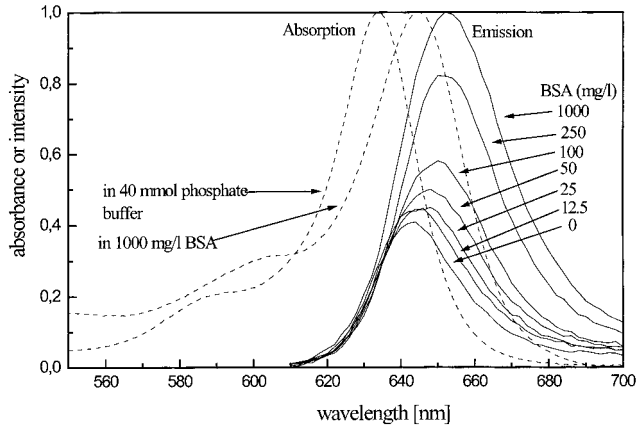

Figure 5. Absorption and relative emission spectra of Sq635-b-butylester in buffer and at various concentrations of BSA (λ_{ex} = 600 nm).

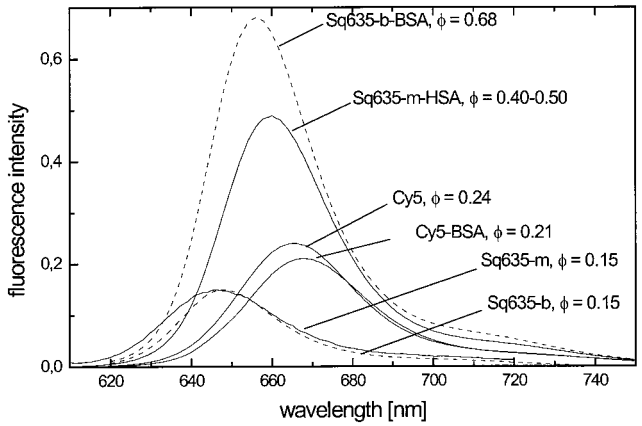

Figure 6. Relative emission spectra of Sq635-b, Sq635-m, and Cy5, free (NHS-ester) and conjugated to protein in buffer. The excitation wavelength was 600 nm using a standard 150 W xenon lamp.

with a second nonidentical methylene base to give the unsymmetrical Sq635-m-acid (**8**).

Two approaches were used to evaluate the potential of the squaraine dyes as protein labels. In the first, a nonreactive dye was mixed with increasing amounts of BSA. The extent of noncovalent binding of dyes to BSA was estimated by an increase of the relative fluorescence intensity (Figure 5). In the second approach, a reactive derivative of the dye was used for a covalent attachment procedure. In this case, the unlabeled dye was removed from the dye conjuagate using standard methods such as size-exclusion chromatography or dialysis.

The absorption and emission spectra of Sq635-b-butylester (**2**) at various concentrations of BSA are shown in Figure 5. The absorption maximum of the Sq635-b-butylester (**2**) at 635 nm shifts to 645 nm upon noncovalent binding to BSA, which makes the dye suitable for excitation with a 635 or 645 nm diode laser source. Compared to water, the emission maximum of (**2**) exhibits a small bathochromic shift of 14 nm on noncovalent binding to BSA, and the fluorescence intensity increases about two and a half times on addition of 1000 mg/L BSA. This suggests that sulfonated squaraines are suitable as fluorescent labels and would display good quantum yields when covalently bound to proteins.

Figure 6 shows a comparison of the relative emission spectra of Sq635-b, Sq635-m, and Cy5 both in free (NHS-ester) and protein-conjugated form in phosphate buffer of pH 7.3. The emission maximum of free Sq635-b-NHS-ester (**4**) at 648 nm shifts to 656 nm when covalently bound to protein. Similarly, the emission maximum of free Sq635-m-NHS-ester (**9**) at 646 nm shifts to 660 nm when bound to protein. The emission maximum of free Cy5-NHS-ester at 664 nm shifts to 668 nm when covalently linked to BSA. Importantly, the quantum yield of Sq635-b-NHS-ester (**4**) and of the Sq635-m-NHS-ester (**9**) increases on covalent attachment to protein from 0.15 to 0.68 and from 0.15 to 0.50, respectively. In contrast to the squaraine dyes, Cy5 shows a decrease in its quantum yield when bound to proteins, which lowers the ultimate sensitiviy of an assay using such dye conjugates.

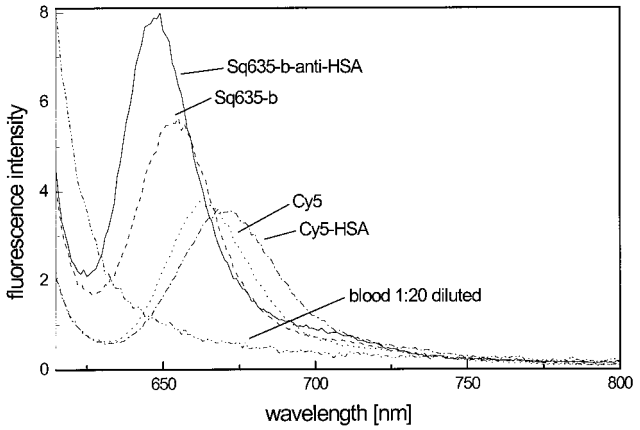

Figure 7. Comparison of the detection limits of free and protein-labeled Sq635-b and Cy5 in blood. Dye concentrations are 50 nmol l^{-1} in whole blood (dilution 1:20). λ_{ex} = 600 nm, using a standard 150 W xenon lamp. (ϵ_{600}Cy5 ≈ ϵ_{600}Sq635-b).

In Figure 7, the detection limits of free and anti-HSA labeled Sq635-b-NHS-ester (**4**) are compared to those of free and HSA-labeled Cy5-NHS-ester. The concentrations of the dyes are 50 nmol/L. At 600 nm, the Cy5-NHS-ester and the Sq635-b-NHS-ester (**4**) have similar extinction coefficients. This wavelength was used for excitation of the blood samples. The data show that the detection limit of the squaraine dye can be as much as twice that of Cy5 due to the higher quantum yields of (**4**).

Lifetime-based sensing applications (*13*−*15*) using long-wavelength probes have gained increased attention in the last couple of years since convenient and inexpensive light sources and detection systems are available in the wavelength range beyond 600 nm. There are two widely used methods for the measurement of fluorescent lifetimes: the time domain and the frequency domain method. The frequency domain method uses sinusoidally modulated light for excitation of a fluorophore, and the phase shift (phase angle) and demodulation (modulation) of the emission (Figure 8), relative to the incident light, is used to calculate the lifetime or decay time (*16*).

Table 1 summarizes the intensity decays for the Sq635-b-butylester (**2**), Sq635-b-NHS-ester (**4**), Sq635-b-BSA, and Cy5 as presented in Figure 8. The free dyes (**2** and **4**) display two similar decay times. The mean lifetime of the NHS-ester **2** appears to be longer which is due to the higher fractional intensity of its longer component (Table 1).

On binding to BSA, the mean lifetime of the Sq635-b-NHS-ester (**4**) increased more than 4-fold due to the long decay time of 2.81 ns of the major component with a fractional intensity of 0.76. In addition, the intensity of the BSA-bound form became more heterogeneous. The increase of the mean lifetime from 0.43 to 2.26 ns is in good agreement with the 4-fold increase in the quantum yield for the free and BSA-bound forms of the squaraine

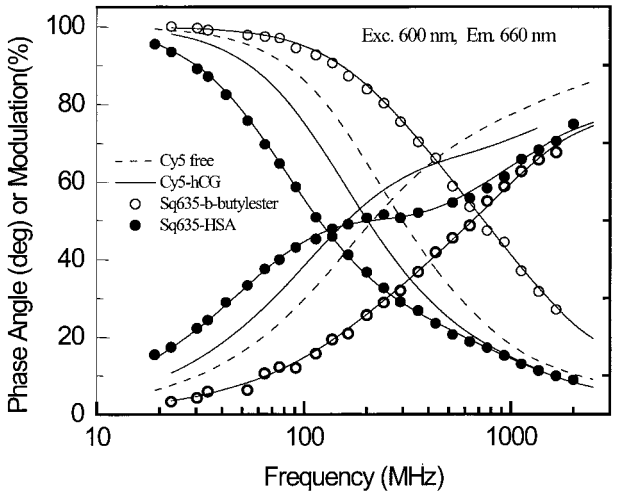

Figure 8. Frequency responses (phase angle and modulation) of Sq635-b-butylester, Sq635-b-HSA, Cy5, and Cy5-hCG, λ_{max} (exc) = 600 nm, λ_{max} (em) = 660 nm.

Table 1. Fluorescence Decay Times of Sq635-b-butylester (2), Sq635-b-NHS-ester (4), Sq635-b-HSA, Cy5, and Cy5-hCG[a]

sample	decay time (ns)	amplitude	fractional intensity	mean lifetime (ns)	χ^2
Sq635-*b*-butylester (2)	0.21	0.752	0.496	0.43	3.7
	0.65	0.248	0.504		
Sq635-*b*-NHS-ester (4)	0.20	0.558	0.286	0.51	3.8
	0.64	0.442	0.714		
Sq635-*b*-HSA	0.18	0.676	0.142		
	0.96	0.089	0.097	2.26	1.7
	2.81	0.235	0.761		
Cy5	1.01	1	1	1.01	2.1

	1.41	0.592	0.929		

[a] Experimental conditions: excitation at 600 nm (rhodamine B dye laser), emission observed through interference filter at 660 nm with 10 nm band; 20 °C (1) The quantum yield of Cy5-avidin (D/P = 2.3) was found to be reduce by 55% on addition of biotinylated BSA.

dye. Figure 8 also reveals the distinct nature of the intensity decays of the free and BSA-bound forms for the squaraine dye and Cy5. The intensity decays of the free and covalently bound Cy5 to hCG (human chorionic gonadropin) are shown for comparison.

DISCUSSION

The synthesized squaraine dyes are highly water soluble, and their conjugates are not likely to precipitate even at high dye-to-protein ratios. The reactive derivatives Sq635-b-NHS-ester (**4**) and Sq635-m-NHS-ester (**9**) exhibit useful fluorescence characteristics and are well suited for covalent attachment to amino groups of proteins. In addition, the new squaraine derivatives can be excited with a laser diode at 635 nm. Their conjugates exhibit high quantum yields relative to the quantum yield of the free dye in water (0.15). This is in contrast to Cy5, a commonly used commercially available protein marker, whose quantum yields are sometimes reduced dramatically in the presence of protein.[2] These features make Sq635-b-NHS-ester (**4**) and Sq635-m-NHS-ester (**9**) attractive alternatives as fluorescent labels in biological assays or biophysical studies of proteins. The high extinction coefficient and quantum yield of the squaraine dye allowed measurements in whole blood with a detection limit twice as low as Cy5.

We also did an analysis of the frequency domain data for the free and the protein-bound dyes (Table 1). After covalent binding to the protein, the mean fluorescence decay time of the squaraine dye (**2**) increases five times from 0.43 to 2.26 ns. The intensity decay of Sq635-b-butylester (**2**) and Sq635-b-NHS-ester (**4**) measured in water can best be described by two-exponential decays, since the three-exponential models only result in moderate improvement in χ^2 (Table 1). The intensity decay of Sq635-b-BSA is well distinct from those of the free dyes (**2** or **4**). The long component of 2.8 ns contributes 76% to the total fluorescence intensity and thus increases the mean lifetime to 2.26 ns for the protein-bound form. The lifetime increase of the squaraine dyes when covalently bound to proteins can be explained by a shielding effect of the protein. In extreme cases, the dye quasi hides in the hydrophobic pockets of the protein and is protected from the water molecules. In contrast, the mean lifetime of Cy5 increased only from 1.01 to 1.33 ns upon covalent binding to protein (Table 1). These two intensity decays are less distinct as observed for the squaraine dyes (Figure 8) and indicate that Cy5 is less sensitive to the environment than the related squaraine dyes.

CONCLUSION

The synthesis of two reactive water-soluble dyes for derivatization of primary amines and their conjugation procedure to proteins is described. The dyes show absorption and emission maxima in the red region of the visible spectra, which allows the use of inexpensive excitation sources such as diode lasers and avalanche photodiodes as detectors. Long-wavelength absorption and emission is preferred because of the reduced autofluorescence from biological samples in the red region. The dyes also exhibit lower quantum yields and shorter lifetimes in water and improved properties when bound to proteins. We are currently exploring the use of these dyes in lifetime and polarization based immunoassays.

ACKNOWLEDGMENT

The authors thank the Center for Fluorescence Spectroscopy at the University of Maryland at Baltimore for the measurement of the lifetimes of the squaraine dyes.

Synthesis and Biological Activity of Polyethylene Glycol−Mouse Nerve Growth Factor Conjugate

Nadya Belcheva, Kim Woodrow-Mumford, Melissa J. Mahoney, and W. Mark Saltzman*

School of Chemical Engineering, Cornell University, 120 Olin Hall, Ithaca, New York 14853. Received January 8, 1999; Revised Manuscript Received June 14, 1999

Conjugation of poly(ethylene glycol) derivatives with therapeutic proteins is a promising approach for enhancing protein stability and, therefore, effectiveness. An N-hydroxysuccinimidyl ester of fluorescein-PEG 2000 was used for chemical modification of mouse nerve growth factor (mNGF), a dimeric protein with therapeutic potential for Alzheimer's disease. The mNGF-PEG2000-fluorescein conjugate was characterized by RP-HPLC, spectrofluorometry, and SDS−PAGE and was biologically active, as determined by two independent NGF-specific assays (enhancement of ChAT activity in fetal neurons and neurite outgrowth in PC12 cells). The conjugate was not detectable by a standard NGF ELISA, suggesting a fortuitous reduction in protein recognition by antibodies.

INTRODUCTION

Nerve growth factor (NGF),[1] the prototypic member of the neurotrophin family of proteins, is known to be involved in the survival and maintenance of function of cholinergic basal forebrain neurons (Charles et al., 1996; Yuen et al., 1996). Mouse nerve growth factor 2.5S (mNGF) consists of two polypeptide subunits with 118 and 110 residues, respectively, in which the shorter chain has eight fewer amino acids near the NH_2-terminus (Wlodawer et al., 1975). Studies in animals suggest that NGF can reverse, halt, or slow the progression of Alzheimer's disease related atrophy (Scott and Crutcher, 1994) so there has been considerable interest in NGF as a therapeutic agent. However, NGF does not enter the brain after systemic administration, so its use in the treatment of neurological disorders is problematic. Therefore, novel protein delivery systems are needed.

A number of recent studies suggest that chemical modification of NGF can preserve biological activity, while enhancing stability and altering biodistribution. Conjugation to an antibody directed against transferrin receptor (OX-26) promoted transport across the blood-brain barrier, permitting delivery of NGF to the brain after peripheral injection (Friden et al., 1993; Kordower et al., 1994; Charles et al., 1996; Bäckman et al., 1996). Biotinylated NGF retained full binding and biological activity, as determined by a competitive radioreceptor assay and stimulation of neurite outgrowth from PC12 cells (Rosenberg et al., 1986, 1987). A highly fluorescent, biologically active rhodamine conjugate of NGF was synthesized and used to probe mobility and distribution of NGF receptors in cultured cells (Levi et al., 1980). Similar conjugates have been described for BDNF (Pardridge et al., 1998; Sakane and Pardridge, 1997), another neurotrophin with ∼50% sequence homology to NGF (Robinson et al., 1995).

The pharmacokinetic characteristics of therapeutic proteins can be altered by conjugation with synthetic polymers. Among the synthetic polymers that have been tested for protein modification, PEGs are frequently used (Zalipsky, 1995), due to their nontoxicity, biocompatiblity, high solubility in aqueous media and nonimmunogenicity (Harris and Zalipsky, 1997). Functionalized PEG derivatives are available (Shearwater Polymers, Inc.), which greatly facilitates conjugate synthesis. In this study, we sought to develop procedures for the covalent modification of mNGF using functionalized PEG derivatives.

EXPERIMENTAL PROCEDURES

Materials and Methods. All starting materials were used as received. Mouse nerve growth factor 2.5 S, grade II (mNGF 2.5S), was purchased from Boehringer Mannheim (Indianapolis, IN). Methoxy-PEG5000-amine (M-NH2-5000), *N*-hydroxysuccinimidyl ester of methoxy-PEG5000 (M-SSA-5000), *N*-hydroxysuccinimidyl ester of fluorescein-PEG2000 (Fluor-NHS-2000) were purchased from Shearwater Polymers, Inc. (Huntsville, AL).

PEGylation of mNGF. In preliminary studies, we attempted to conjugate PEG to NGF via carboxylic groups (in MES buffer) and via animo groups (in DMSO). The condensation reaction in MES was performed in 0.1 M buffer (pH 6.2−6.4) on ice. The reactants were added as follows: 50 μg (1.9 nM) of mNGF was reconstituted in 200 μL of 0.1 M MES buffer. Methoxy-PEG5000-amine, 2.5 mg (0.5 mM) dissolved in 320 μL of MES, was added to this solution in a molar ratio of PEG/carboxylic groups (24/mNGF) = 10/1. Separately, 2 mg of NHS (17.4 μM) (Aldrich) and 2 mg of EDC (10.4 μM) (Sigma) were

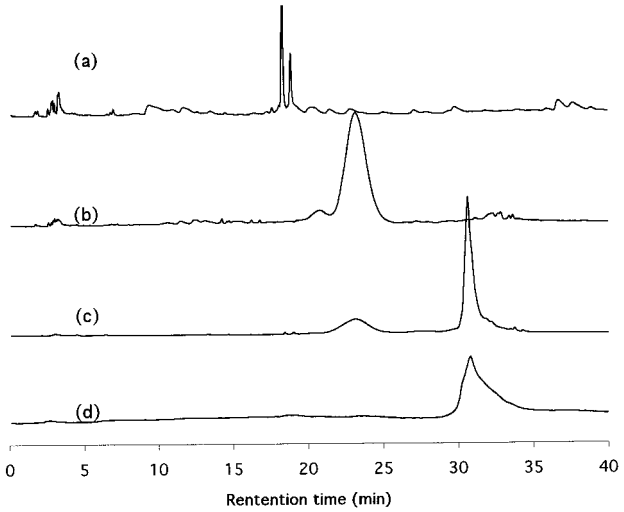

Figure 1. RP−HPLC of (a) mNGF in borate buffer (pH 8.0); (b) fluorescein-PEG2000-glycine in borate buffer (pH 8.0) after 24 h; (c) reaction mixture of mNGF with fluorescein-PEG2000-NHS in borate buffer (pH 8.0) after 24 h; (d) purifiaed mNGF-PEG2000-fluorescein conjugate after dialysis against 10 mM PBS (pH 7.4). A gradient/isocratic method was performed, 0 to 15 gradient/15 to 25 isocratic/25 to 50 gradient: gradient 0 to 80% acetonitrile (0.1% trifluoroacetic acid) for 50 min at flow rate 1 mL/min and column temperature 25 °C, monitoring at λ = 275 nm, using a Zorbax 300SB-CN 4.6 mm × 250 mm separation column.

dissolved in 200 μL of MES and added to the reaction mixture. The condensation reaction was carried out for 7 days at 4 °C under shaking. After dialysis against PBS (10 mM, pH 7.4) (MWCO = 10 000) for 7 days at 4 °C, the solution was lyophilized.

The condensation reaction in DMSO was carried out at 20 °C under stirring. In a typical procedure, 25 μg of mNGF (0.96 nM) was dissolved in 500 μL of DMSO. To this solution was added 48 μL of a methoxy-PEG5000-NHS solution in DMSO (1 mg/mL) (48 μg, 9.6 nM) in a molar ratio of PEG/mNGF = 10/1. The reaction mixture was stirred for 10 days at 20 °C, after which a 10% solution of glycine in PBS (pH 7.4) was added to deactivate the excess of methoxy-PEG5000-NHS. The reaction mixture was dialyzed (MWCO = 10 000) against PBS (pH 7.4) for 7 days.

The synthesis of mNGF-PEG2000-fluorescein conjugate was performed with mono-*N*-hydroxysuccinimidyl ester of PEG2000-fluorescein in borate buffer (pH 8.0) in a molar ratio of PEG/mNGF = 10/1. In a typical reaction, 250 μg (9.62 nM) of mNGF was reconstituted in 2.5 mL of borate buffer (pH 8.0). Fluorescein-PEG2000-NHS (192.3 μg, 96.2 nM), dissolved in DMSO (42.7 μL), was added, and the reaction mixture was stored for 24 h at 4 °C under shaking. Before dialyzing against 10 mM PBS (pH 7.4), 10 mg of BSA was added. Dialysis tubing (MWCO = 10 000) was used for purifying the conjugate from unreacted fluorescein-PEG2000-NHS as well as from the low molecular side product of the condensation reaction, NHS. The conjugation yield was estimated by RP-HPLC. The purified product was analyzed by SDS−PAGE and tested for biological activity by neurite outgrowth using PC12 cells and ChAT activity of fetal neurons.

Reversed-Phase−High-Performance Liquid Chromatography (RP-HPLC). The conjugation reaction was followed by RP-HPLC using Waters 2690 Alliance Separations Module, including Waters 996 PDA detector, on a Zorbax 300SB-CN 4.6 mm × 250 mm separation column.

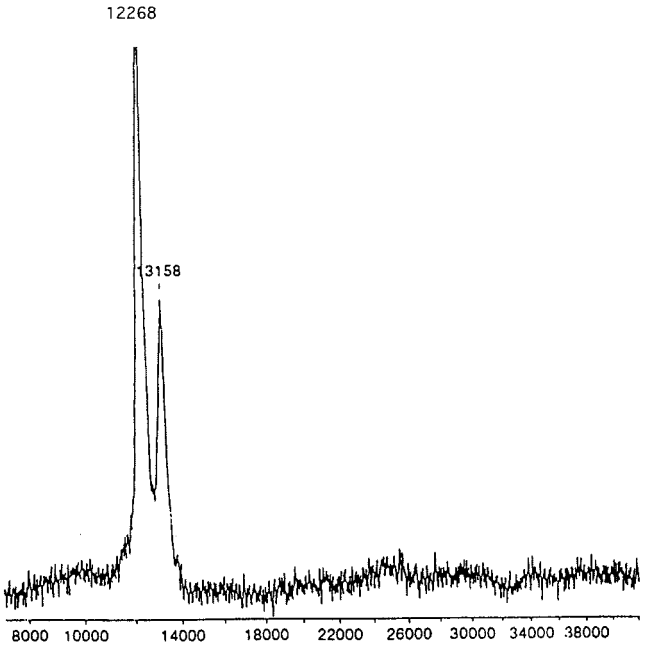

Figure 2. MALDI mass spectrum of mNGF.

An appropriate aqueous mobile phase for mNGF was found to be a gradient 0 to 80% acetonitrile (0.1% trifluoroacetic acid) at a flow rate of 1 mL/min and column temperature of 25 °C with PDA monitoring at 275 nm. A gradient/isocratic method was developed for separation of the conjugate: 0 to 15 gradient/15 to 25 isocratic/25 to 50 gradient; gradient 0 to 80% acetonitrile (0.1% trifluoroacetic acid) at a flow rate of 1 mL/min and column temperature of 25 °C, monitoring at 275 nm.

Spectrofluorometry Measurements. Fluorescence of mNGF-PEG2000-fluorescein conjugate was studied in buffered saline and supernatant of brain homogenate. Brains were retrieved from Fischer 344 rats 8−10 weeks old. The tissue was sonicated in phosphate buffer (pH 7.4) supplemented with 0.0117 g/mL NaCl and 0.5% Triton X-100. After sonication, samples were centrifuged at 14 000 rpm for 20 min at 4 °C, and the supernatant was collected. Spectra were recorded on FluoroMax-2 spectrofluorometer equipped with 150 W continuous ozone-free xenon lamp and modified Czerny-Turner spectrometers under control of DataMax spectroscopy software. Excitation (λ = 488 nm) and emission (λ = 530 nm) maxima were determined using fluorescein-PEG-NHS standard solutions for calibration. All procedures with animals were performed according to NIH guidelines and were approved by the Cornell University Institutional Animal Care and Use Committee.

Conjugate Characterization. MALDI-TOF mass spectra were obtained on a ThermoBIOANALYSIS Laser-MAT 2000 system using nitrogen laser at 337 nm and 4-hydroxy-α-cyano-cinnamic acid as a matrix (10 mg/mL in 70% acetonitrile/water).

SDS−PAGE was performed on a 18% Tris-HCl gel at room temperature for 2 h at 150 V using Mini-PROTEIN II cell (Bio-Rad) system and Bio-Rad reagents (Laemmli, 1970). Protein samples (30 mL) were solubilized and denaturated by boiling with 15 mL of SDS and DTT solution, and loaded into the wells (44 mL of each sample). Bands were visualized by silver staining.

Biological Assays for mNGF Activity. PC12 cells (pheochromocytoma cell line) were suspended in medium (85% RPMI 1640, 5% fetal bovine serum, and 10% horse serum) that was supplemented with either the conjugate

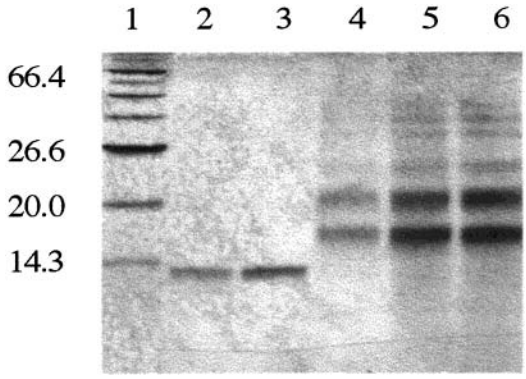

Figure 3. SDS−PAGE of (1) protein markers (each 200−400 ng); (2) mNGF (200 ng); (3) mNGF (300 ng); (4) mNGF-PEG2000-fluorescein conjugate, reaction mixture after 1 day (based on 100 ng of mNGF); 5) mNGF-PEG2000-fluorescein conjugate, reaction mixture after 1 day (based on 200 ng mNGF); and (6) mNGF-PEG2000-fluorescein conjugate, reaction mixture after 1 day (based on 300 ng mNGF).

or unmodified mNGF at concentrations in the range 0.1−800 ng/mL (based on mNGF). Twelve-well tissue culture polystyrene plates, coated with collagen (5 μg/cm^2), were seeded with the cells at a density of 5×10^4 cells/well. After 2 and 4 days of incubation, cells were examined for neurite expression.

Neural cells were retrieved from fetal rat brains at 17 days gestation as previously described (Mahoney and Saltzman, 1999). Briefly, cells were plated on poly-lysine (Collaborative Biomedical)-coated Petri dishes (2 μg/cm^2) and incubated for 24 h in sBME + 5% FBS. After this initial incubation, cells were cultured in sBME + 1% penicillin streptomycin. Medium was changed every 2−3 days. Cells were sacrificed after 4 days of culture and prepared for ChAT analysis as described previously (Mahoney and Saltzman, 1999).

The reagents and protocol for the NGF ELISA were obtained from Boehringer Mannheim Biochemicals. The wells of a microtiter plate were first coated with a monoclonal antibody directred against the subunit of mNGF and subsequently washed. Blocking buffer was added, and the wells were washed again. Samples containing the NGF conjugate were incubated on the plate at concentrations between 0.03 and 2 ng/mL (based on mass of mNGF) and mNGF standards were prepared in the concentration range 0.03 ng/mL−1 ng/mL. After incubation, the wells were treated with a secondary monoclonal antibody conjugated to β-galactosidase. CPRG, the substrate for β-galactosidase, was added to each well. Optical density measurements were obtained at 575 nm using a Thermomax plate reader with Softmax Software (Molecular Devices, Menlo Park, CA).

RESULTS

To select an appropriate reaction medium, we tested the stability of mNGF in distilled water, DMSO, MES buffer (pH 6.2−6.4) and borate buffer (pH 8.0). Using RP-HPLC, two peaks were resolved at retention time (RT) 18.5 and 19.6 min (Figure 1a), corresponding to the two polypeptide chains of mNGF. MALDI-TOF mass spectrometry confirmed the presence of two molecules with molecular mass peaks (M) at 12 268 and 13 158, respectively (Figure 2). Mouse NGF solutions were stable in MES (pH 6.2−6.4) at 4 °C for 7 days, while a 20−30% decrease in the peak area (RP-HPLC) was found for samples maintained in distilled water and borate buffer (pH 8.0) for the same period. A similar decrease in the peak area was observed with mNGF solutions in distilled water when kept frozen for 20 days at −20 °C. Chromatographic changes of mNGF in DMSO solution were complex: in addition to the usual peaks at RT = 18.5 and 19.6 min, new peaks (RT = 32.6 and 36.0 min) were detected over a period of 2 days, simultaneously with a decrease in the NGF peaks. We suspect that this sequence of changes represents slow solubilization followed by aggregation in DMSO; in any case, these changes made it difficult to identify the products of reactions, so use of DMSO was abandoned.

In preliminary studies, we attempted to react NGF with amino-PEG derivatives via activation of the carboxylic groups of the protein using water-soluble carbodiimide. Unfortunately, we could not identify experimen-

tal conditions that avoided significant cross-linking of the activated protein chains. To eliminate this problem, PEGylation via protein amino groups using fluorescein-PEG2000-NHS was considered in all subsequent experiments.

Our stability data indicated that mNGF was more stable at pH 6 and that substantial degradation (up to 30%) could occur upon incubation in distilled water or borate buffer (pH 8.0). However, the higher pH was preferable for activation of the amino groups during condensation reactions with NHS esters. To identify the optimal synthetic approach, three buffer systems—10 mM PBS (pH 7.4), borate buffer (pH 8.0), and borate buffer (pH 8.5)—were tested in model reactions with fluorescein-PEG2000-NHS and glycine. Borate buffer with pH 8.0 allowed a reasonable rate of conversion and relatively low deactivation of the active ester. The presence of the fluorophore on PEG permitted simultaneous monitoring of mNGF, fluorescein-PEG2000 derivatives and the resulting conjugate (Figure 1). In a typical reaction, fluorescein-PEG-NHS was added in a 10 molar excess to mNGF. The reaction was performed for 24 h; decrease in NGF peaks suggested 95−98% conversion (Figure 1c). The new peak (RT = 30.8 min) was related to the formation of mNGF-PEG2000-fluorescein conjugate; no such peak was detected in the model systems. Excess BSA was added to the reaction mixture (to stabilize NGF conjugates), and the mixture was dialyzed against 10 mM PBS (pH 7.4) at 4 °C. The progress of purification by dialysis was monitored by following the disappearance of the fluorescein-PEG2000-glycine peak (RT = 23.0, Figure 1d).

The dialyzed conjugate was subjected to SDS−PAGE, which revealed new protein bands with molecular masses of ∼20 kDa (Figure 3, lanes 4−6). These bands were clearly different than those observed with unmodified NGF (Figure 3, lanes 2 and 3), implying that the predominant fraction consisted of mono-PEGmers of the two different mNGF chains. The formation of multi-PEGmers with higher molecular masses was also detected although their yields were much lower.

The presence of fluorophor in the purified conjugate provided a convenient marker for analysis; we measured the fluorescence in brain homogenate supernatant of known quantities of conjugate, assuming 1:1 ratio of PEG and mNGF protomer. A slight decrease in the fluores-

cence intensity was observed for the conjugate extracted from the brain tissue, implying some quenching or incomplete extraction (Figure 4). Nevertheless, the experimental results supported the assumption that the average number of PEG molecules per protein chain was 1:1.

The conjugates were biologically active. Addition of conjugate to fetal brain cell cultures stimulated ChAT activity in a dose-dependent manner (Figure 5). The conjugate was active at higher doses of mNGF (~ 10 ng/mL), suggesting that conjugation with poly(ethylene glycol) results in a slight reduction in bioactivity. Unmodified mNGF elicited neurite growth from PC12 cells at concentrations as low as 0.1−0.2 ng/mL; the mNGF-PEG2000-fluorescein conjugate stimulated neurite outgrowth at concentrations above 3ng/mL (Figure 6). Interestingly, the mNGF-PEG2000-fluorescein conjugate was not detected by a widely used NGF ELISA, suggesting that mNGF-PEG2000-fluorescein could not bind monoclonal antibodies directed against specific epitopes of unmodified mNGF (Figure 7).

DISCUSSION

NGF is a basic protein with a pI of 9.3 (Kasaian, 1994). The amino acid sequence of the NGF subunit contains 11 carboxylic and 17 basic side groups (McDonald, 1991). Carboxylic groups originate from L-glutamic acid (pK_a = 3.9) and L-aspartic acid (pK_a = 4.3); while basic groups come from L-histidine (imidazole group, pK_a=6.0), L-lysine (primary amine, pK_a=10.5), and L-arginine (guanidine group, pK_a=12.5). Decreasing the pH of the reaction medium is known to promote both the activation of the carboxylic groups and the reactivity of the water-soluble carbodiimides (Nakajima and Ikada, 1995; Hermanson, 1996). In our hands, however, activation of mNGF by this method produced substantial cross-linking of the polypeptide chains and no detectable reactivity to amino-PEG derivatives.

The crystal structure of the mNGF dimer suggests highly flexible domains at the amino terminus (residues 1−10) and the carboxy terminus (residues 112−118). These regions are likely to be solvent accessible and, therefore, susceptible to proteolytic modification (McDonald et al., 1991; Shamovsky et al., 1996). The relative reactivity of the amino- and carboxy-terminal ends is still unknown. Rosenberg et al. reported a dose-dependent loss of receptor binding activity after biotinylation of NGF via amino groups, suggesting that carboxyl end groups were accessible to modification and not critically involved in biological activity (Rosenberg et al., 1986). However, Drinkwater et al. found that the seven most carboxyl-terminal amino acids were crucial in mediating receptor recognition and ligand binding (Drinkwater, 1993).

By varying the reaction conditions, we formed conjugate from mNGF and fluorescein-PEG2000-NHS in pH 8.0 borate buffer. The conjugate was identified by RP-HPLC and purified by extensive dialysis. On the basis of the fluorescence intensity of conjugate solutions, we estimated that approximately one fluorescein-PEG2000 chain was attached to each of the polypeptide chains of mNGF.

In summary, reaction of mNGF with fluorescein-PEG2000-NHS led to the formation of mNGF-PEG conjugate. The new fluorescein-labeled conjugate was biologically active in two NGF specific assays, yet undetected by mNGF specific antibodies in an ELISA. This new compound, mNGF-PEG2000-fluorescein, may have future applications in treatment of neurodegenerative diseases.

Effects of Dextranation on the Pharmacokinetics of Short Peptides. A PET Study on mEGF

Qinghai Zhao,[†] Vladimir Tolmachev,*[,†] Jörgen Carlsson,[†] Hans Lundqvist,[†] Johanna Sundin,[†,‡] Jan-Christer Janson,[§,||] and Anders Sundin[‡]

Biomedical Radiation Sciences, Box 535, Uppsala University, S-751 21 Uppsala, Sweden, Department of Diagnostic Radiology, Uppsala University and Uppsala University PET-Centre, Uppsala University Hospital, S-751 85 Uppsala, Sweden, Pharmacia Biotech AB, S-751 82 Uppsala, Sweden, and Centre of Surface Biotechnology, Uppsala Biomedical Centre, Box 577,S- 751 23 Uppsala, Sweden. Received January 27, 1999; Revised Manuscript Received June 1, 1999

The effects of dextranation on the biodistribution of mouse epidermal growth factor (mEGF, 6 kDa) were assessed. By reductive amination, mEGF was coupled to 13 and 46 kDa dextran. The two dextranated conjugates and free mEGF were labeled with the positron-emitting nuclide ^{76}Br ($T_{1/2}$ = 16 h). After intravenous administration to Sprague Dawley rats, the radioactivity biodistribution was evaluated by positron emission tomography (PET) and by measurements of dissected tissues. The dextranation prolonged the retention time in blood, especially when the dextran chain was long. [^{76}Br]-mEGF−dextran conjugates were shown to have significantly, more than 5 times, lower kidney accumulation than the nonconjugated [^{76}Br]mEGF. In conclusion, dextranation affects the biodistribution of mEGF in vivo giving a prolonged circulation time, a decreased uptake in kidney, and an increased spleen accumulation.

INTRODUCTION

Epidermal growth factor (EGF) is a short (53 residues, 6 kDa) regulatory protein, which is involved in growth and maturation of epithelial tissues in homeostasis as well as wound healing. The binding of EGF to the extracellular part of the EGF−receptor, EGFR, induces the signal pathway, ultimately leading to DNA replication and cell proliferation (*13*). The EGFR is overexpressed in some tumors and may therefore serve as a potential diagnostic and therapeutic target in some malignancies such as gliomas, bladder cancers, squamous cell carcinomas, and some forms of adenocarcinomas (*14*−*18*).

EGF injected intravenously (iv) has a fast blood clearance. Only 7% of the radioactivity remained in blood 2.5 min after iv administration of [^{125}I]EGF (*20*). Intravenously injected EGF is taken up by the liver. It is also to a high extent accumulated in the kidney, which is typical for short peptides such as octreotide, vasoactive intestinal peptide (VIP), or single chain Fv (*19*−*23*). Even in animals with tumors expressing high numbers of EGF receptors, the dominating EGF uptake is in the liver and kidney (*21*). Studies of human lung cancer have, however, shown a higher uptake in tumors expressing EGF receptors than in receptor negative tumors (*34*).

Glycosylation has been shown to improve the stability and prolong the retention time of proteins in vivo in mice after iv injection (*24, 25*). In this study, we used dextran for protein glycosylation. Dextran is a glucose polymer in which glucose units are bound to each other by α1−6 linkages. The branching of the dextran structure is approximately 5% and comprises mostly α1−3 linkages. By sequential degradation, which quantitatively removes nonreducing end groups, it has been found that about 40% of the side chains are only one glucose (*1, 2*). For clinical application, dextran is usually produced by fermentation using the microbes *Leuconostoc mesenteroides* NRRL B-512 (F) or the B-512 strain (*1, 3, 4*).

In the clinic, dextran is used worldwide as the plasma volume expander of choice, applied to treat shock caused by hemorrhage, burns, surgery, or trauma (*3*−*5*). An interesting application of dextran is its conjugation to biologically active substances with the aim to prolong their biological half-life and to increase their stability in vivo (*6, 7*). Dextran may also act as a carrier for various cytotoxic drugs and radioisotopes in targeted therapy and may, in addition, reduce the antigenicity of biomolecules (*8*−*12*).

The primary aim of this paper was to study general changes in the kinetics of dextranated molecules. However, a secondary interest was to see if dextranated EGF could be modified to increase the circulation time and to lower the normal tissue uptake, thus improving the targeting properties. EGF was chosen as a suitable biomolecule since it is known to have a dominating and fast receptor-mediated liver uptake and that small changes in the uptake kinetic should be possible to perceive fairly easily. The mEGF−dextran conjugates were prepared by reductive amination, in which the end aldehyde group of dextran reacted with the only amino group on the N terminal of mEGF (*26*). A positron-emitting nuclide, ^{76}Br ($T_{1/2}$ =16 h), was used to label mEGF and the mEGF−dextran conjugates in order to apply positron emission tomography (PET) for the assessment. PET was used since it can follow fast kinetic changes in vivo. It also has a spatial resolution, which

makes it possible to distinguish the liver uptake from any other organ in the rat. Excised tissues were also measured for radioactivity content in the body.

MATERIAL AND METHODS

Conjugation. Freeze-dried dextran weighting of 13 kDa (D13) and 46 kDa (D46) was obtained by fractionation of Dextran T10 or T40 (Pharmacia Biotech AB, Sweden) by gel filtration on Sephacryl 100 HR (Pharmacia Biotech AB, Sweden). Sodium cyanoboronhydride ($NaCNBH_3$, Merck-Schuchardt, Germany), mEGF (tissue culture grade, Janssen Biochimica, Belgium), and ^{125}I (Amersham Laboratories, England) were used as received from the manufacturer.

The mEGF−dextran conjugates were produced by reductive amination as previously reported (*26*). Dextran D13 or D46 (20 mg, 1.54 and 0.43 μmol, respectively) was dissolved in 100 μL mEGF (25 μg, 4.17 nmol) in 0.05 M phosphate buffer solution, pH 8.0. To this, $NaCNBH_3$ (8 mg, 127 μmol) was added and the reaction was allowed to continue for 24 h at room temperature during continuous stirring. The reductive amination reaction mixture was applied to a Sephadex G-50 Fine (Pharmacia HR 10/30) column (Pharmacia Biotech AB, Sweden), and the conjugate was eluted with distilled water at a flow rate of 0.25 mL/min and a fraction volume of 0.5 mL. The fractions containing conjugate were pooled and freeze dried.

Bromination. Br-76 was produced at the Uppsala PET Centre, Uppsala, Sweden, by the $^{76}Se(p,n)^{76}Br$ reaction using ^{76}Se-enriched Cu_2Se as target. Radiobromine was separated from target material by dry distillation (*27*). About 150−200 MBq ^{76}Br was obtained in 100 μL of ethanol after separation. The ethanol was evaporated, and freeze-dried mEGF−dextran conjugate (15−20 μg) or mEGF (20 μg) dissolved in 30 μL of citrate-phosphate buffer (pH 4, 0.05 M) was added. Adding 10 μL of Chloramine-T (4 mg/mL in 0.05 M citrate-phosphate buffer, pH 4.0) started labeling. After the solution was mixed for 3 min, the reaction was quenched with 20 μL of sodium bisulfite (4 mg/mL in 0.05 M citrate-phosphate buffer, pH 4.0). Purification was performed on a NAP-5 column (Sephadex G-25, Pharmacia Biotech AB, Sweden) equilibrated and eluted with PBS. Fractions of 0.2 mL were collected and measured for radioactivity. The high-molecular-weight fractions were pooled and used in the cell test and animal experiment.

Cell Test. A subclone (U-343MGaC12:6) of a glioma cell line U-343 was grown in HAM'S F-10 culture media (Kebo, Stockholm, Sweden), supplemented with FCS, L-glutamine, penicillin, and streptomycin, in culture dishes. Brominated mEGF−dextran conjugates and mEGF, respectively, were mixed in culture media or in the culture media containing 1 μg/mL mEGF. The incubation experiments were carried out in triplicates. After 90 min of incubation at 37 °C, the cultures were washed 6 × 1 min with HAM'S F-10 media and trypsinized. The number of cells was determined in a cell counter (Coulter ZM, Coulter Electronics Ltd, U.K.) and analyzed for cell-associated radioactivity in a γ-counter (1480 Wizard γ-counter, Wallac, Finland).

Animals. Fourteen Sprague Dawley male rats weighing 350 ± 120 g (mean ± SD) from BK Universal AB (Stockholm, Sweden) were used. After arrival at the animal department, the rats were allowed to condition for 10 days before the experiment. For anesthesia, the rats were injected intraperitoneally with 0.24−0.3 mL/100 g body weight of thiobutabarbital sodium salt 5 mg/mL (Inactin, RBI, MA).

PET Imaging. Through a groin incision, the right femoral vein was isolated and cannulated with a plastic catheter to ensure iv injection of the tracers. The rats, placed in a plastic multicompartment holder, were positioned in a Scanditronix GE 2048 PET scanner (Scanditronix, Uppsala, Sweden), which simultaneously produces 15 contiguous 6.5 mm tomographic slices and has an in-plane resolution of 5−6 mm. Before injection, a 10 min transmission scan was performed to enable attenuation corrections of the emission scan. After a rapid iv bolus of 3−10 MBq of [^{76}Br]mEGF and [^{76}Br]mEGF−dextran conjugates, a dynamic sequence was started and continued for 1 or 2 h, respectively. Tomograms were reconstructed using a 128 × 128 image matrix and a 6 mm Hanning filter. Data were corrected for attenuation and scattered radiation. The regional radioactivity concentration measured by PET was divided by injected radioactivity per gram of body weight to provide images of standardized uptake values (SUV). Regions of interest (ROI), representing liver, heart, blood, kidney, muscle, and urinary bladder, were drawn manually in the SUV images and time−activity curves were calculated and plotted.

Pharmacokinetic Analysis. Clearance of radioactivity from blood was analyzed by fitting a dual exponential function to data, $SUV = Ae^{-at} + Be^{-bt}$, using the least-squares method where A and B are constants, a and b are clearance rates, and t is time after injection.

The impact of dextranation to the blood kinetics was tested statistically. To accentuate the early, rapidly changing blood kinetics, a constant steady-state radioactivity level appearing in all the blood curves was subtracted. The time integral of the resulting radioactivity curve, divided by the maximum value, was calculated for each animal. The obtained values, the transit times, for each experimental group were tested by a two-samples Student's t-test.

The early uptake phase in the liver, i.e., the first minutes after injection, was analyzed by a simple two compartment model assuming that all radioactivity passing the liver was trapped in the liver. This can mathematically be described as

$$C_L(t) = k_1 * \int_0^t C_b(S)\, dS + \epsilon C_b(t)$$

where C_L is the radioactivity concentration in liver, C_b is the radioactivity concentration in blood, k_1 is the rate constant (min^{-1}), and ϵ is the blood volume.

The late phase of the liver uptake, i.e., the part where the liver starts to lose radioactivity was analyzed by fitting data by the least-squares method to a simple exponential function, $SUV = Ae^{-at}$, where A is a constant, a is the clearance rate of radioactivity, and t is the time after injection.

Kinetic analysis was also performed according to Patlak et al. (*28*) where the transport rate of ligand into the tissues, generated on a pixel by pixel basis was presented as images. The radioactivity concentration in blood obtained from a ROI over the heart blood pool was used as the input function. In the Patlak graphs, $Y = C_i/C_b$ was plotted against $X = \int C_b(t)\, dt/C_b(t)$, where C_i = tissue radioactivity concentration and C_b = radioactivity concentration in the blood at time t. This graphical representation is, after onset of a dynamic equilibrium, equivalent to a situation, where the blood radioactivity concentration is constant throughout the examination. For a radiolabeled compound that is trapped in the tissue, the graph shows a linear increase over time, whereas a

Table 1: Receptor Binging Test for [^{76}Br]mEGF and [^{76}Br]mEGF-Dextran Conjugate[a]

	cell associated radioactivity (cpm/10^5 cells)	
	presaturated receptors	not presaturated receptors
76Br-mEGF	3130 (410)	22 630 (1400)
76Br-mEGF-dextran	5570 (310)	12 240 (920)

[a] Test was performed on a glioma cell line U-343. For presaturation of the EGFR, 1 μg/mL mEGF was added. Cell were incubated with labeled compounds during 90 min, than washed three times. Data are presented as mean values from three dishes and maximum errors.

compound equilibrating in the tissue gives a constant value after a while. In a situation where the compound is heavily degraded and the radioactivity concentration in blood, at later times, may be dominated by labeled metabolites, the graphical presentation can show a negative slope after the initial equilibrium.

Tissue Measurements. After PET scanning, the animals were killed at different times after tracer injection. Samples of blood and urine were collected and various organs were excised, weighed, and measured for radioactivity in the γ-counter. The accumulation index (AI) of each tissue was calculated, after decay correction, according to the formula

$$\mathrm{AI} = \frac{(\text{tissue radioactivity/tissue weight})}{(\text{injected radioactivity/body weight})}$$

Assuming a tissue density of 1 g/cm^3, AI corresponds to the SUV. The use of AI for studies of biodistribution of small molecules enables comparison of data obtained from animals with different body weight and, to a certain extent, even between different species, e.g., mice and rats.

Chromatography. Serum and urine were analyzed by gel filtration with a Sephadex G-50 Fine (1 × 50 cm) column coupled with a FPLC system (Pharmacia Biotech AB, Uppsala, Sweden). The column was eluted with PBS with a flow rate of 0.5 mL/min. Fractions of 1 mL were collected and measured for radioactivity content. By calibrating the column with a conjugate (>10 kDa), mEGF (6 kDa) and salt, the high-molecular-weight (HMW) position, the mEGF position, and the low-molecular-weight (LMW) position, respectively, were defined in the chromatogram. Since the conjugates were desalted before the animal experiment and the fractionation range for globular protein with Sephadex G-50 Fine is within $(1.5 \times 10^3)-(3 \times 10^4)$ kDa, the radioactivity eluted at the salt position was considered to represent degraded fragments of mEGF.

RESULTS

Radiolabeled Conjugates. The labeling yield of bromination varied from 15 to 30%. To ensure that the EGF−receptor binding ability of the different preparations was retained before starting the biodistribution experiments, each batch was tested by incubating the [^{76}Br]mEGF and [^{76}Br]mEGF−dextran conjugates with U343 cells as described in the Material and Methods. The data concerning cell-binding tests are given in Table 1. The results of the tests demonstrated specific binding of conjugates to EGF−receptor-expressing cells, since it can be displaced by nonradioactive mEGF.

PET Pharmacokinetics. The *blood* pharmacokinetics of the different preparations measured by PET are presented in Figure 1 for the first 10 min of the experiments. All curves showed a marked two-phase behavior with an early rapid phase (mean rate constant $a = 2.28$, 1.85, and 0.58 min^{-1} for the [^{76}Br]mEGF, [^{76}Br]mEGF-D13, and [^{76}Br]mEGF-D46, respectively) and a slow phase (mean clearance rate $b = 0$, 0.06, and 0.01 min^{-1} for the [^{76}Br]mEGF, [^{76}Br]mEGF-D13, and [^{76}Br]mEGF-D46, respectively).

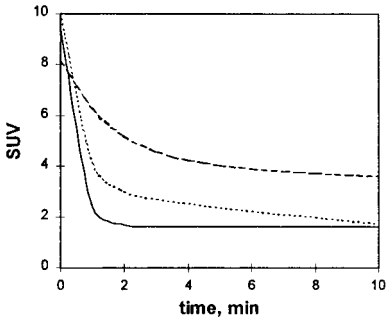

Figure 1. The kinetic standard uptake values (SUVs) of [^{76}Br]-mEGF (solid line), [^{76}Br]mEGF−dextran D13 (dotted line), and [^{76}Br]r-mEGF−dextran D46 (dashed line) in blood evaluated by PET. The experiment animals were Sprague Dawley male rats. The curve fittings were done with a formula $\mathrm{SUV} = Ae^{at} + Be^{bt}$ to evaluate the uptake within 10 min PI. [^{76}Br]mEGF, [^{76}Br]-mEGF D13, and [^{76}Br]mEGF D46 have designated b values of 0, −0.06, and −0.01, respectively. Each curve represents the result of one rat.

The transit times in blood for [^{76}Br]mEGF, [^{76}Br]-mEGF-D13, and [^{76}Br]mEGF-D46 were found to be 0.68 ± 0.18, 1.97 ± 0.37, and 5.14 ± 1.15 min (mean ± standard deviation), respectively. The differences between the different values were proved to be statistically significant in a paired t-test, giving the results [^{76}Br]-mEGF minus [^{76}Br]mEGF-D13 ($p < 0.007$), [^{76}Br]mEGF minus [^{76}Br]mEGF-D46 ($p < 0.01$), and [^{76}Br]mEGF-D13 minus [^{76}Br]mEGF-D46 ($p < 0.02$).

The liver pharmacokinetics of the three brominated compounds measured by PET are shown in Figure 2. There was a fast radioactivity uptake in the liver, which leveled out after a few minutes. After 20 min, there was a pronounced decrease in the SUV values indicating a loss of radioactivity from the liver for all three ligands although the loss was most rapid for the mEGF. The mean clearance rate of this radioactivity between 20 and 60 min was calculated to be 0.01, 0.007, and 0.006 min^{-1} for [^{76}Br]mEGF, [^{76}Br]mEGF-D13, and [^{76}Br]mEGF-D46, respectively.

The liver pharmacokinetics plotted according to the Patlak method is seen in Figure 3. All three plots show a pronounced decrease after a few minutes, which indicated a considerable influence of labeled metabolites in the analyzes. The first half-minute was analyzed using a simple linear model to compare the initial liver increase of the three ligands. The mean increase was found to be 2.14, 1.84, and 2.23 min^{-1} for [^{76}Br]mEGF, [^{76}Br]mEGF-D13, and [^{76}Br]mEGF-D46, respectively.

The uptake in the kidneys was also rapid and rather high for all three ligands. However, the variation in the pharmacokinetic pattern varied considerably between animals. The uptake of [^{76}Br]mEGF reached rapidly a plateau but showed no significant decrease with time. Radioactivity appeared in the urinary bladder 20−40 min PI for all three [^{76}Br]compounds. The kinetic pattern was similar for all three ligands although uptake values varied greatly (Figure 4).

Table 2 summarizes the PET results of the kinetic studies in which different mathematical models have been applied.

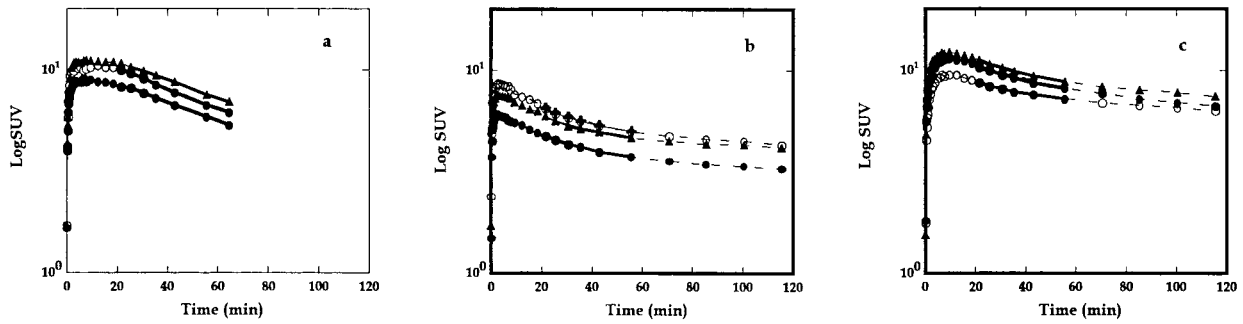

Figure 2. The kinetic standard uptake values (SUVs) of [^{76}Br]mEGF (a), [^{76}Br]mEGF−dextran D13 (b), and [^{76}Br]mEGF−dextran D46 (c) in liver evaluated by PET. The experiment animals are Sprague Dawley rats. The curve fittings were done with a formula $SUV = Ae^{at}$ between 20 and 60 min PI to evaluate the clearance after 20 min PI. Each curve represents the result of one rat.

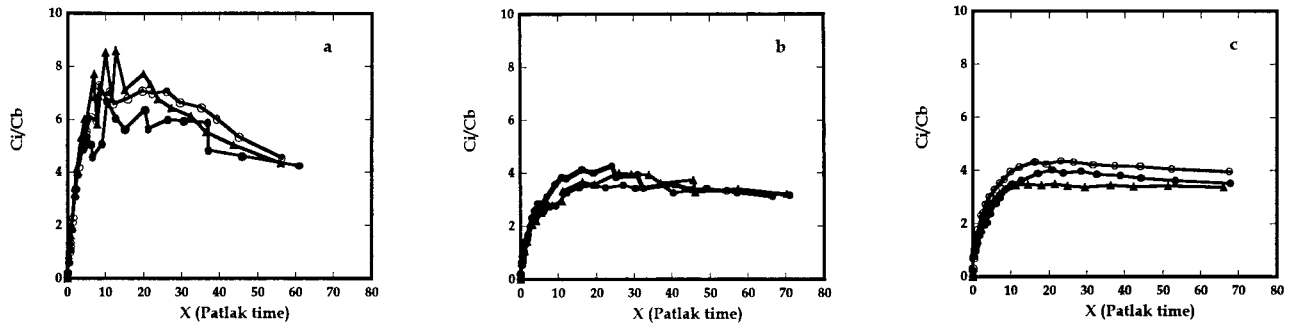

Figure 3. Patlak plot of [^{76}Br]mEGF (a), [^{76}Br]mEGF−dextran D13 (b), and [^{76}Br]mEGF−dextran D46 (c) in liver of PET study according to a two-compartment model. The experiment animals are Sprague Dawley rats. The curve fittings were done with the formula $C_i/C_b = A + BX$ between 0 and 0.5 Patlak time where $X = \int C_b(t)\, dt/C_b(t)$. Each curve represents the result of one rat.

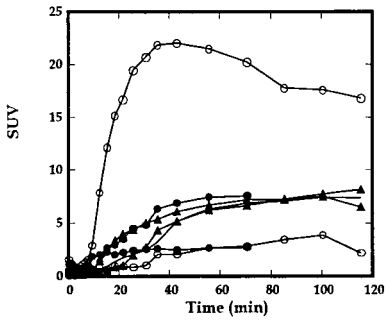

Figure 4. The kinetic standard uptake values (SUVs) of [^{76}Br]-mEGF (filled circles), [^{76}Br]mEGF−dextran D13 (open circles), and [^{76}Br]mEGF−dextran D46 (filled triangles)in urinary bladder evaluated by PET. The experiment animals are Sprague Dawley male rats. Each curve represents the result of one rat.

Measurements on Excised Tissues. The ^{76}Br accumulation at different times postinjection (PI) was measured in excised organs and tissues after intravenous injection of [^{76}Br]mEGF, [^{76}Br]mEGF−dextran D13, and [^{76}Br]mEGF−dextran D46 (Table 3). High radioactivity concentrations were measured in the urine. At 1 h PI, the dextranated conjugates were compared with mEGF. The AI for all three compounds was found to be high in the liver. The spleen showed high AI values for the dextranated compounds only, whereas the opposite was true for the kidney. In blood, AI ranged 1.4−2.4 with the lowest value for [^{76}Br]mEGF. The small intestine and colon showed higher AI for [^{76}Br]mEGF than for the dextranated compounds. In all other tissues the AI was low for all three preparations.

Chromatographic Analysis. The chromatograms of serum and urine sample are shown in Figure 5. Two hours PI, the ratio of LMW to HMW in serum was significantly lower for [^{76}Br]mEGF−dextran D46 than for [^{76}Br]mEGF−dextran D13 and [^{76}Br]mEGF. No radioactive peaks corresponding to the mEGF position were found in the serum chromatograms (Figure 5, panels a−c), not even when mEGF without dextran was administered. A radioactivity peak corresponding to mEGF was found in urine after the injection of [^{76}Br]mEGF. This was not the case for the dextranated compounds (Figure 5, panels d−f).

DISCUSSION

The aim of this study was to investigate if dextranation of a peptide changed its in vivo pharmacokinetics and biodistribution. EGF administered iv into rats was expected to be a sensitive test system since EGF is known to be effectively removed from the circulation by receptor-mediated trapping in the liver and through kidney excretion. Even a small change in the pharmacokinetic pattern due to dextranation should thus be detected. Due to the fast pharmacokinetics of mEGF, PET was used since this technique allows measurements with high temporal and spatial resolution. During the first minutes PI when free intact ligand still circulated in plasma, the measuring time was 10 s/time frame. The spatial resolution of about 6−7 mm made it possible to study the pharmacokinetics separately in liver and kidney in the rat. However, due to the limited spatial resolution, PET generally tends to underestimate the radioactivity uptake in small organs (*30*). Also, the 6.5 mm tomographic slice may only include a part of an organ, which also will change the absolute value of the measurements due to partial volume effect. In the measurements of kidney radioactivity in vivo, the spatial resolution of PET is insufficient to discriminate the radioactivity related to urine from that related to renal tissue. Thus, PET allows accurate pharmacokinetic measurements although absolute quantification of tracer uptake in the small organs of the rat may be less dependable.

Human EGF and mEGF are both 53 amino acid long peptides, with 37 amino acids in common, and with three

[a] Data are presented as mean values and maximum errors. Values lower than 0.05 are shown as zero. The number of rats killed and measured was two, four and three for [^{76}Br]mEGF, [^{76}Br]mEGF-dextran D13 ([^{76}Br]mEGF-D13), and [^{76}Br]mEGF-dextran D46 ([^{76}Br]mEGF-D46), respectively.

disulfide bonds in the same relative positions. Also, they both have approximately the same binding affinity to the human EGF−receptor (*29*). In the present study, mEGF was used since it has one single free amino group, the amino terminus (no lysine residues), which can be coupled by reductive amination to a unique position on dextran, the aldehyde group on the reducing end of the dextran chain. This yielded a well-defined complex with a 1:1 ratio of mEGF to dextran. After bromination, mEGF and conjugates retained their binding ability to the human glioma cancer cell line U343.

PET Pharmacokinetics of [^{76}Br]mEGF. The analysis of the blood clearance indicated a rapid mEGF turnover (Figure 1), in good agreement with the fast accumulation of radioactivity in liver (Figure 2a). The liver pharmacokinetics during this early phase was just an integral of the blood curve. The liver uptake reached a plateau 2−3 min PI. After this time point, the radioactivity in the blood probably represented merely labeled metabolites and not mEGF. This is also supported by the liver Patlak-plot, which after leveling out showed a pronounced decrease (Figure 3a). The liver uptake plateau, which probably lasted for about 20 min, reflects the receptor binding and the internalization process. After about 20 min, an exponential radioactivity decrease probably reflected the excretion of labeled metabolites from the liver.

The kidney also showed a rapidly increasing radioactivity uptake, which after a few minutes leveled out to a plateau and decreased only slightly during the next hour. Since the mEGF most likely was trapped quantitatively in the liver and in kidney, the high uptakes in these organs reflect their high blood perfusion.

The findings of a rapid clearance from the circulation and a high accumulation in liver and kidney of [^{76}Br]-mEGF are in agreement with previous results. It has been reported that, 2.5 min after iv injection of [^{125}I]EGF into rats, 52% was found in liver and 14% in kidney (*31*). This high accumulation of EGF in liver and kidney was also shown in a study using iv injected [^{76}Br]/[^{125}I]EGF into rats (*23*). In this latter study it was claimed that the liver and kidney were the major organs responsible for the elimination and metabolism of hEGF from the plasma. The contribution of the liver and kidney to the total body clearance was estimated to approximately 70 and 20%, respectively (*32*). Moreover, in tumor-bearing mice, ^{125}I-labeled EGF accumulated in receptor-positive tumors, but to a much lesser extent than in the liver. One hour after iv injection, the tumor-to-liver ratio was less than 0.5 (*21*).

Pharmacokinetic Analyses of Dextranated mEGF. Compared with free mEGF, dextranation somewhat prolonged the retention time of the conjugates in the circulation (Figure 1). The conjugate with the longer dextran chain also showed the longest retention time, indicating a relation between the dextran chain length and blood residence time.

The liver uptake of dextranated ligands was equally fast for all three compounds, and the maximal uptake was reached within 2−3 min (Figure 2). The rate constants obtained in the detailed analysis of the first minute were equally high and probably just reflected the blood perfusion of the liver. We concluded that the extraction of the ligand from blood to liver is close to 100% for all three ligands. The dextranated ligands thus retain their receptor binding ability although small changes in receptor affinity cannot be excluded. More refined studies with preparations of different specific radioactivity might show if such changes occur.

After the maximal liver uptake, the accumulation pattern varied. The dextranated ligands showed not an extended plateau as for native EGF but a two-phase exponential decrease in radioactivity. The first phase might represent dextranated ligand returning into circulation, which is supported by the prolonged retention times in blood. Thus, it is possible that the dextranation may prevent some of the ligand being internalized. The

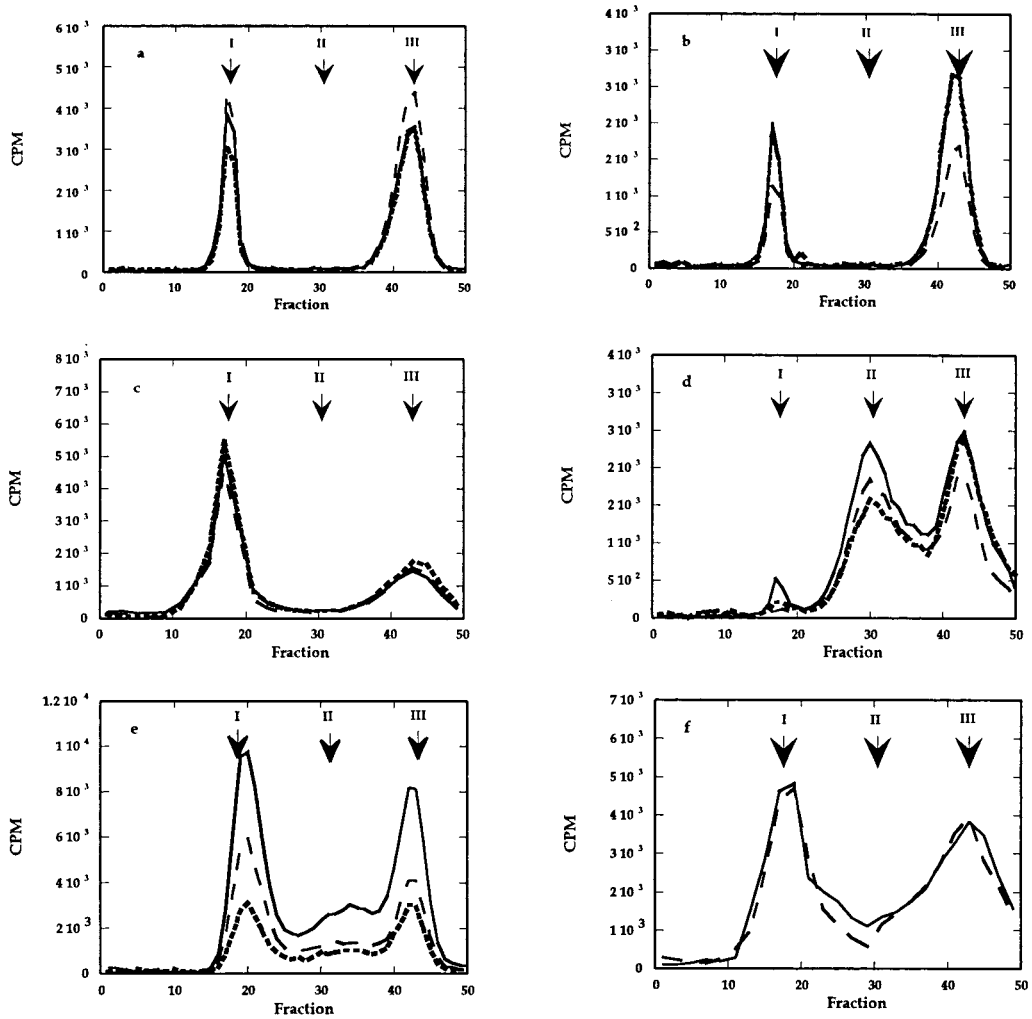

Figure 5. The chromatograms obtained by eluting serum and urine samples through Sephadex G-50 Fine column (1 × 50 cm) were shown. I, II, and III represent high molecular weight (conjugate), mEGF, and low molecular weight (salt) elution positions. The serum (a, b, and c) and urine (d, e, and f) samples from the rats administered with [^{76}Br]mEGF (a, d), [^{76}Br]mEGF−dextran D13 (b, e), and [^{76}Br]mEGF−dextran D46 (c, f) were analyzed by gel filtration. Each dotted, dashed, or solid line in the chromatogram represents the sample from one rat.

second phase may represent ligand, which was internalized and undergoing degradation. However, the rate of radioactivity loss here was less than that of free mEGF, which indicates that dextran can partly protect an internalized molecule from degradation.

Earlier, we studied the influence of dextranation of EGF on in vitro binding to EGFR-expressing tumor cells (*41*). It was shown that dextranation somewhat decreases the binding affinity to EGFR (dissociation constants were 6.6×10^{-10} and 7.1×10^{-9} for [^{125}I]mEGF and [^{125}I]-mEGF-D14, respectively). Still, the affinity after dextranation remained high. It was also noticed that dextranation slows down the internalization, but the mechanism for this process is not fully understood. We propose the following model. It is known that the activation of EGFR-associated protein kinase required dimerization of receptors (*42*). According to the model presented by Heldin and Östman (*41*), one EGF molecule binds to one receptor with one epitope and to the second receptor with another epitope. The other EGF molecule would then bind in a reciprocal manner. The presence of bulky dextran moiety might preclude the binding to the second receptor or to complicate the binding of the second EGF molecule. Thus, the internalization might be hampered. On the other hand, it has been shown for antibodies that a bivalent attachment to antigens is essential to make a binding nearly irreversible while a monovalent lead to dissociation (*43*). This might be also the truth for binding of EGF to its receptors. Such a model can explain both the delay of internalization and the release of a part of the conjugate back into blood stream.

At least a part of the ligand returning into circulation may have lost its receptor-binding ability since the plasma chromatography showed labeled high molecular complexes (Figure 5, panels b and c). The nature of this inactivation will be discussed in the chapter dealing with the results of chromatographic analysis.

The observation that the release of radioactivity associated with dextranated EGF is slower that in the case of free ligand is worth attention. Peptides and proteins are after internalization rapidly degraded in the lysosomes (*29*). The radioactivity, mainly in the form of halogenated tyrosine, leaks out from the cells. This will reduce the tumor-to-background ratio in diagnostic procedures and the tumor dose during targeted therapy. It has been demonstrated earlier in vitro that conjugation to dextran improves intracellular retention of mEGF-associated radioactivity (*12*). The results in this PET study indicate that this protective effect of dextran was true also in vivo. However, an even better retention effect can be obtained if the dextran part of the molecule is

radiohalogenated since dextran will remain intracellularly for a longer time (*35*).

Due to the fast liver uptake, the fast blood clearance and the rapid appearance of labeled metabolites in blood, the Patlak graphical analysis was not applied to calculate the transport rate constants, but used in order to make a normalized qualitative comparison between the different labeled compounds. For the liver, the Patlak plot during the first minute showed the same slope for all three ligands, indicating a similar receptor-binding rate. After reaching equilibrium, free EGF showed a more pronounced negative slope (Figure 3) and was probably more affected by the influence of labeled metabolites than that of the dextranated ligands. However, the [^{76}Br]-mEGF curve still reached a higher level than the curves for the conjugates. This was probably due to the faster release of receptor-bound dextranated ligands, which was also seen in the direct comparison of SUV in the PET measurements.

Well Counter Measurements. Consistent with the PET results, the well counter measurements showed high accumulation of radioactivity in liver, spleen, kidney, and urine, whereas the accumulation in the other organs was low (Table 3). An interesting finding of this study was that the dextranation of EGF decreased the uptake in the kidney. This result may have implications for future studies on EGF and targeted radiotherapy since the kidney is one of the dose-limiting critical organs. It is assumed nowadays that renal uptake of short proteins is facilitated by positively charged amino acids reacting with negative "receptors" on the surface of proximal tubuli (*36*). The most successful attempts to decrease renal uptake of short peptides are associated with the use of lysine and its derivatives to block these negative patches (*37*−*39*). However, it has been reported that similar reduction of labeled protein uptake in kidney may be achieved by acetylation of free amino groups (*40*), which dramatically decreases an isoelectric point of antibody fragment. The coupling of a bulky dextran to the mEGF might have reduced the binding of this molecule, due to the sterical hindrance, to the negative regions of renal tubuli. Another possible explanation to the reduced reabsorption by the kidney could be an increased hydrophilicity of the conjugate.

By contrast, in the spleen, the dextranation of mEGF resulted in increased AI values. This was most likely explained by phagocytosis of the [^{76}Br]mEGF−dextran by the reticular endothelial system cells in the spleen, a phenomenon that has previously been shown for non-conjugated dextran (*31*). The finding is consistent with the PET measurements where the spleen could only be visualized when using the D46 conjugate.

Size-Exclusion Chromatography. The serum from the rats administered with [^{76}Br]mEGF did not show any peak corresponding to the mEGF itself. Surprisingly, there was a peak found at the high-molecular-weight position in the chromatogram (Figure 5a). It has earlier been not shown that EGF binds to some component in plasma but the chromatogram suggests that such a complex was formed. The possibility of mEGF aggregation during bromination may be excluded since [^{76}Br]-mEGF showed a single peak corresponding to the mEGF position by gel filtration on Sephadex G-50 Fine (data now shown). A high-molecular-weight peak in the same position was found as well when [^{125}I]mEGF was incubated with blood plasma, taken from Sprague Dawley rats. When separated, the substance in this peak did not bind to EGFR expressing cells in vitro. It is possible that binding of EGF to some of blood component should limit the action of the growth factor to paracrine mode and prevent the activation of cell division far away from the site where it is required. It is also possible that the high-molecular-weight peaks obtained after chromatography of blood samples after injection of [^{76}Br]mEGF−dextran conjugates rather belong to such complex than free conjugate. The size-exclusion system, which was used for the analysis, is not able to resolve such high-molecular-weight compounds. A formation of a nonactive complex can explain why nonbound conjugate remains in the circulation. We believe that the formation of high-molecular weight complex of EGF with blood components deserves a thorough study in a future.

In urine, a main peak corresponding to mEGF was seen, but the high-molecular-weight peak seen in plasma was usually not present, i.e., it was only seen to a small extent in some animals. Since the urine content was integrated over the whole experiment, this can be interpreted as that mEGF was excreted in urine early, but the compound corresponding to the high-molecular-weight peak was not. The small high-molecular-weight peaks seen in some urine samples were probably caused by leakage of blood into the urinary bladder during dissection. Other possible explanations may include extreme extension of the urinary bladder during prolonged anesthesia during PET scanning or bleeding in connection with intraperitoneal anesthesia.

In urine from rats administered with [^{76}Br]mEGF−dextran conjugates, the main peaks were still of high-molecular-weight indicating that the kidneys excreted the intact ligand. Probably, longer dextran chains (>70 kDa) have to be used in order to prevent or considerably decrease the urinary excretion and thus prolong the circulation time of the conjugates even more.

To conclude, dextranation affects the biodistribution of mEGF in vivo giving a prolonged circulation time, decreased uptake in kidney, and increased spleen accumulation.

ACKNOWLEDGMENT

The authors thank laboratory engineers Veronika Asplund and Ulla Johansson and the staff at the Uppsala University PET center for valuable technical assistance. Financial support was given by the Swedish Cancer Society, the Swedish Medical Research Council and the Swedish Institute.

Folate Copolymer-Mediated Transfection of Cultured Cells

Christopher P. Leamon,*,† Debra Weigl,† and R. Wayne Hendren†

Department of Oligomer Development, GlaxoWellcome Research Institute, 5 Moore Drive, Research Triangle Park, North Carolina 27709. Received May 27, 1999; Revised Manuscript Received August 3, 1999

Poly(ethylene glycol) of various sizes was used as a molecular spacer to separate the cell-targeting ligand, folate, from the surface of poly-L-lysine. The resulting ternary macromolecule (pLys-PEG-folate) was investigated in various formulations for its ability to transfect reporter plasmids into receptor-bearing HeLa and IGROV cell lines. Formulations were optimized with respect to DNA content, ± charge ratio, and the size and amount of PEG substitution off the pLys backbone. Transfection activity was highest 48 h after sample introduction, and PEG 3400 was determined to be the most favorable spacer size tested. pLys-PEG-folate:DNA transfection was also found to be both concentration dependent and saturable; plus, it was blocked by the addition of excess-free folate, indicative of a specific mechanism of uptake. Transfection activity was virtually identical for complexes formed in 10% serum-supplemented media, deionized water, or Hepes buffer. And, cell viability remained greater than 85% at the highest concentrations of pLys-PEG-folate:DNA complexes tested (4.8 μg/mL pLys 331 000; 12 μg/mL DNA). Taken together, these observations provide evidence that pLys-PEG-folate:DNA complexes are taken up specifically by the folate endocytosis pathway, and that the intramolecular spatial distance of the ligand from the pLys backbone dramatically influences transfection.

INTRODUCTION

Poly-L-lysine (pLys)[1] is one of many polycations used to condense plasmid DNA through electrostatic interactions (*1*, *2*). Electron microscopic examination of pLys:DNA complexes has revealed that nanometer-sized particles, either as solid or toroidal conformations, form as the result of electrostatic complexation (*3*). Because these diameters closely approximate the diameter of coated pits found on the plasma membrane of endocytosing cells, pLys condensation of plasmid DNA became a popular technique for use in DNA transfection studies (*3*, *4*). Unfortunately, DNA (or oligonucleotide) condensation with pLys alone did not necessarily ensure successful transfection (*4*−*6*), probably because pLys complexes relied on nonspecific adsorptive pinocytosis mechanisms for cellular entry (*7*, *8*).

To overcome the problems associated with poor cellular uptake of pLys:DNA complexes, a portion of the ϵ-amino side chains on the pLys backbone has been derivatized with cell-specific targeting ligands. Thus, following condensation with DNA, externally oriented ligands on the pLys backbone became available for binding to specific cell surface receptors. Transferrin, insulin, asialoglycoprotein, monoclonal antibodies, mannose, lactose, and folic acid have all been shown to improve cellular uptake of pLys:DNA (or pLys:oligonucleotide complexes) into cells (*3*, *4*, *6*, *8*−*19*). However, the majority of the delivered DNA was believed to remain sequestered within endosomes/lysosomes, hence, unavailable for transfection (*7*, *8*). Fortunately, improvements such as the incorporation of fusogenic peptides (*20*), perfringolysin O (*21*), or replication-incompetent adenovirus (*13*, *14*, *17*, *22*, *23*) into the overall pLys:DNA delivery vehicle have greatly enhanced transfection levels.

Despite these improvements, the orientation of the ligand on the pLys backbone has never been optimized. Conceptually, the ligand should be (i) firmly anchored to the pLys backbone (preferably via a covalent bond), (ii) anchored in an orientation that does not destroy its affinity for its receptor, and (iii) positioned far enough away from the pLys backbone to allow good penetration into the binding pocket of its cell surface receptor. Interestingly, the latter concern may be of little importance when very large ligands (like insulin, transferrin, asialoglycoprotein, etc.) are employed for targeted pLys:DNA delivery. However, smaller ligands attached to pLys (folates, mannose, etc.) may not be effectively presented in an orientation that permits optimal receptor binding, especially when DNA is present and the overall complex is highly condensed.

In this publication we describe a method for transfecting plasmid DNA into cultured cells using a pLys-based delivery vehicle that contains an extended ligand spacer arm. The technique involves the use of a poly(ethylene glycol) (PEG) "spacer" which is derivatized with a ligand to one end and pLys to the other end. Folate was chosen as the ligand of choice for this investigation owing to its relative ease of chemical derivatization and remarkable ability to deliver covalently attached macromolecules and/or delivery systems into receptor-bearing cells (*6*, *17*, *24*−

38). Using a plasmid containing a luciferase reporter gene, we were able to quantitatively evaluate transfections mediated by various pLys-PEG-folate:DNA complexes. Importantly, this technique was further optimized by carefully evaluating the effect of complexation charge ratios, complexation medias, PEG size, and the extent of pLys derivatization.

EXPERIMENTAL PROCEDURES

Preparation of Folate-γ-Cysteine. Folate-γ-cysteine (pteroyl-γGlu-Cys) was synthesized as previously described.[2] Briefly, an Applied Biosystems Inc. 433A peptide synthesizer equipped with conductivity monitoring was used to prepare folate-γ-cysteine at 0.25 mmol scale. The compound was formed by the stepwise addition of Fmoc-Glu-OtBu followed by N^{10}-trifluoracetylpteroic acid onto a cysteine-modified *p*-hydroxymethylphenoxymethyl polystyrene resin. Following a wash with excess dichloromethane, the resin was repeatedly treated with 0.1 M aqueous piperidine (to remove the N^{10}-trifluoracetyl group) and then with a cleavage/deprotection cocktail consisting of 750 mg of phenol, 10 mL of trifluoroacetic acid, 0.5 mL of water, 0.25 mL of dithioethane, and 0.5 mL of thioanisol for 2 h at room temperature. The freely soluble compound was separated from the resin by filtration through a medium pore fritted funnel. The filtrate was then diluted with 4 vol of diethyl ether to precipitate the folate-γ-cysteine product. Following multiple ether washes, the precipitate was dried in vacuo. Barring no further purification, folate-γ-cysteine produced in this manner was typically 70−85% pure, as determined by the A_{280} peak area generated from C_{18} reversed-phase HPLC analyses, with the primary impurity being the dimerized (disulfide-linked) species. An Ellman's assay (*39*) on the crude material confirmed that the solid contained 70−85% free sulfhydryls.

Preparation of NHS-PEG-γ-Folate. A total of 5.9 μmol of commercially available or custom-synthesized *N*-hydroxysuccinimidyl-poly(ethylene glycol)-maleiimide (NHS-PEG-Mal; all of these PEG reagents along with their analytical characterization data were provided by Shearwater Polymers, Huntsville, AL) were dissolved in 1 mL of dry dichloromethane within a 10 mL round-bottom flask. A 3-fold molar excess of solid folate-γ-cysteine was added to the flask. While stirring, a 5-fold molar excess (relative to folate-γ-cysteine) of neat triethylamine was added to the flask, and the solution was stirred continuously for a minimum of 18 h at room temperature. Under these conditions, thiols can add to maleiimide groups in organic solvents (*40*).[3] Unreacted folate-γ-cysteine remained a solid while NHS-PEG-γ-folate had completely dissolved. Samples were centrifuged for 5 min at 15000*g*, and the yellow supernatants were diluted with 50 mL of diethyl ether to precipitate the NHS-PEG-γ-folate product. Samples were spun at 2500 rpm for 10 min, the supernatants were decanted, and the yellow pellets were redissolved in 1 mL of dichloromethane. The ether precipitation step was repeated two more times, and the final yellow pellet was dissolved in 1 mL of chloroform and stored at −20 °C. The concentration of NHS-PEG-γ-folate was determined as follows. A 10 μL aliquot of the chloroform sample was placed in a 1 mL eppendorf tube and dried using a Savant tabletop speedvac. The dried residue was dissolved in 1 mL of phosphate-buffered saline (PBS), and the absorbance at 362 nm was measured. Molar concentrations were determined using the extinction coefficient for folate at 362 nm ($\epsilon_{362} = 6100\ M^{-1}\ cm^{-1}$).

Preparation of pLys-PEG-γ-Folate. Stock solutions of poly-L-lysine hydrobromide (Sigma Chemical, St. Louis, MO) with an average molecular weight of 331 000 were prepared in 100 mM *N*-2-hydroxyethylpiperazine-*N*′-3-propanesulfonic acid, pH 8.0. Typically, 3 nmol of pLys were added to a 1.5 mL eppendorf tube, and additional buffer was added to give a final volume of 450 μL. An aliquot of NHS-PEG-γ-folate (in $CHCl_3$) was added to a 1.5 mL eppendorf tube. The $CHCl_3$ was removed using a speedvac, and the remaining residue was hydrated in 50 μL of deionized water. The entire volume of NHS−PEG-γ-folate solution was then mixed with the pLys sample (while vortexing), and the sample was left to react at room temperature for a minimum of 2 h. Unreacted NHS-PEG-γ-folate was removed from pLys-PEG-γ-folate by exhaustive dialysis through a 30 000 molecular weight cutoff membrane using 20 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (Hepes) and 100 mM NaCl, pH 7.30. Alternatively, conjugates were purified by using a Mono S 5/5 column (buffer = 50 mM Hepes, pH 7.9, and a NaCl gradient from 0 to 3 M over 30 min) followed by overnight dialysis against 20 mM Hepes and 100 mM NaCl, pH 7.3. Samples were filtered with a 0.22 μm membrane prior to characterization (vide infra).

Characterization of pLys-PEG-γ-Folate Conjugates. Poly-L-lysine content was measured using a modified trypan blue precipitation assay (*41*). Aliquots from a stock 1.0 mg/mL solution of pLys (mw 331 000) in deionized water were dispensed into 1.5 mL eppendorf tubes. PBS was added to each tube to bring the final volume to 990 μL. Similarly, sample aliquots estimated to contain approximately 5 μg of pLys were added to eppendorf tubes and diluted with PBS to 990 μL. A total of 10 μL of a 4 mg/mL trypan blue solution was added to each tube followed by vortexing for 5 s each. Tubes were heated to 60 °C and shaken for a minimum of 1 h. Following immersion in ice for 5 min, tubes were then spun for 5 min at 15000*g*. The absorbance at 580 nm of each supernatant was measured, and the concentrations of pLys were calculated from a standard curve.[4] Since each PEG moiety present in the pLys-PEG-folate conjugate contains one folate moiety, the PEG content from each sample was determined by measuring the absorbance due to folate at 362 nm.[5] An estimate of the degree of PEG substitution on the pLys molecule was calculated by simply dividing the concentration of PEG by the concentration of pLys.

Cell Culture. HeLa and IGROV-1 cells were grown continuously as a monolayer using folate-free Dulbecco's modified Eagles medium (FFMEM) containing 10% heat-inactivated fetal calf serum and 2 mM L-glutamine at 37 °C in a 5% CO_2/95% air humidified atmosphere. Because the heat-inactivated serum contained its normal complement of endogenous folates, the cells could be maintained indefinitely in the folate-deficient medium (*24*).

Supercoiled Plasmid DNAs. Plasmids pGL3 (for luciferase gene expression; Promega, Madison, WI) and pSV-βgal (for β-galactosidase expression; Promega) were transformed and propagated in *Escherichia coli* strain

[2] *J. Drug Targeting* (1999) (in press).

[3] We have also successfully prepared this reagent in dimethyl sulfoxide; however, an additional ether precipitation step and selective solvation in DCM is needed prior to the final workup.

[4] Neither folic acid nor PEG_{3400} caused Trypan Blue to precipitate under similar conditions.

[5] At the concentrations measured, pLys does not appreciably absorb at 362 nm.

JM109. Milligram quantities of super-coiled plasmids were prepared using Quiagen plasmid preparation kits, as suggested by the manufacturer.

Formation of pLys-PEG-folate:DNA Complexes. Complexes were formed in either polypropylene tubes or polystyrene plates. Briefly, pLys was dissolved in half the final volume of either reagent-grade water, Hepes, or 10% serum-supplemented FFMEM. Plasmid DNA was then dissolved in the second half of water, Hepes, or serum-supplemented FFMEM, and the entire solution was mixed with the pLys solution. Plasmid DNA concentrations were typically 20 μg/mL at this step. Following a 5 s vortex mix, the solution was left to complex at room temperature for 1 h. The solution was later diluted with additional serum-containing FFMEM and added to cells without further purification.

Time-Dependent Transfection. Cells were added to 96-well plates in a total volume of 100 μL of 10% serum-supplemented FFMEM, and the plates were incubated at 37 °C for 18−24 h. Spent incubation media was replaced with 100 μL of sample-containing media per well (four wells per sample), and cells were incubated at 37 °C for the indicated times. Each well was vacuum aspirated, and 20 μL of 1× Cell Lysis Buffer (Promega) was added per well. Plates were then stored overnight at −70 °C. Following a 30 min thaw at room temperature on a rocker platform, cell lysates were quantitatively transferred to wells of Dynatech Microlite plates. A Dynatech ML3000 luminometer was used to autodispense 100 μL of luciferase assay reagent (Promega)/well and to sum the relative luminescence units over a 30 s period.

Ratio Study. Cells were added to 96-well plates in a total volume of 100 μL of the media described above, and the plates were incubated at 37 °C for 18−24 h. Spent incubation media was replaced with 100 μL of sample-containing media/well (three wells per sample), and cells were incubated at 37 °C for 48 h. Importantly, the quantity of plasmid DNA was held constant at 1 μg/mL in each well, whereas the quantity of pLys or pLys-PEG_{3400}-folate was varied from 0 to 4 μg/mL to account for the various ±ratios examined. Following the incubation, cells were harvested and the luminescence activity was measured according to the procedure detailed above.

Concentration-Dependent Transfection and Related cytotoxicity. A total of 2000 HeLa cells in 100 μL of serum-supplemented FFMEM was added to each well of duplicate 96-well plates and then incubated at 37 °C for 18−24 h. Aliquots from a master pLys-PEG-folate:DNA complex mix (20 μg/mL as DNA) were added to individual polypropylene tubes and diluted with serum-supplemented FFMEM to the indicated concentrations. Spent incubation media in each well was replaced with 100 μL of the appropriately diluted complex (four wells per sample), and the cells were incubated for 48 h at 37 °C. Cells from one plate were harvested and the luminescence activity was measured according to the procedure detailed above.

Cells in the duplicate plate were used in a cytotoxicity assay (two wells per sample). Briefly, 10 μL of a 5 mg/mL 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) solution in PBS was added to each well 2 h prior to the end of the 37 °C incubation. At the end of the incubation, spent media was aspirated from each well, and 100 μL of dimethyl sulfoxide plus 10 μL of 0.1 M glycine, pH 9.0, was added per well. The absorbance at 580 nm was read for each well, and the percent cytotoxicity was calculated based on the absorbance values measured in wells that had contained untreated cells.

Cytochemical Staining for β-Galactosidase. Approximately 50 000 cells in 2.5 mL of serum-supplemented media were added to each well of a Falcon 6-well plate and then incubated for 24 h at 37 °C. Using pSV-βgal as the DNA source, pLys-PEG-folate:DNA complexes were prepared 1 h prior to the experiment according to the protocol described above. Spent incubation media was removed from each well and replaced with 1 mL of sample-containing, serum-supplemented media. Following a 48 h incubation at 37 °C, monolayers were rinsed twice with PBS and then stained for β-galactosidase activity using the protocol and reagents supplied in the β-galactosidase Staining Kit (In Vitrogen; San Diego, CA). Cells were stained for a maximum of 24 h and then photographed at 200× magnification using Kodak color slide film.

Comparison of pLys-PEG-Folate:DNA Transfection to Cationic Liposome Transfection. A total of 2000 HeLa cells in 100 μL of serum-supplemented FFMEM was added to each well of a 96-well plate and then incubated at 37 °C for 18−24 h. pLys-PEG_{3400}-folate:pGL3 complexes were formed per the method detailed above using 10% serum-supplemented FFMEM. The cationic liposomes were complexed with pGL3 in 10% serum-supplemented FFMEM using the average of the vendor-recommended quantity of liposome per unit DNA. Thus, 10 μg of Lipofectin (Life Technologies, Gaithersburg, MD), 12.5 μg of LipofectAmine (Life Technologies), 6 μg of DOTAP (Boehringer Mannheim, Indianapolis, IN), 3 μg of DOPSER (Boehringer Mannheim), 5 μg of Transfectam (Promega), or 4.7 μg of TFx-50 (Promega) were complexed/μg of pGL3. Spent incubation media in each well was replaced with 100 μL of the appropriately diluted complex (8 wells/sample; 100 ng of DNA/well), and the cells were incubated for 48 h at 37 °C. Following the incubation, cells were harvested and the luminescence activity in two-thirds of the cell lysate was measured according to the procedure detailed above. The remaining cell lysate was used to perform a DotMetric protein assay (GenoTechnologies, St. Louis, MO), per the manufacturers instructions. Luminescent activity was normalized by the protein content for each sample, and the results were expressed as relative luminescence units per milligram of cell protein.

RESULTS

Proposed Structure of pLys-PEG-Folate:DNA Complexes. Figure 1 depicts a proposed structure for pLys-PEG-folate:DNA complexes. Here we assume that polyanionic DNA will electrostatically complex with polycationic pLys to form a charge-neutral hydrophobic core, and despite a covalent linkage to pLys, we further believe that the hydrophilic PEG-folate moieties should naturally orient outward from the core and into the aqueous milieu, thus forming a targetable micelle-like DNA delivery vehicle. Interestingly, a similar micellar structure has previously been proposed for oligonucleotide-polyoxyethylene derivatives (*42*); however, that particular delivery system lacked a cell-targeting ligand component.

Time-Dependent Transfection. The first transfection parameters we examined were the effect of folate-copolymer transfection with respect to the plated cell density and the length of incubation (exposure) time. Cells were plated at increasing densities into the wells

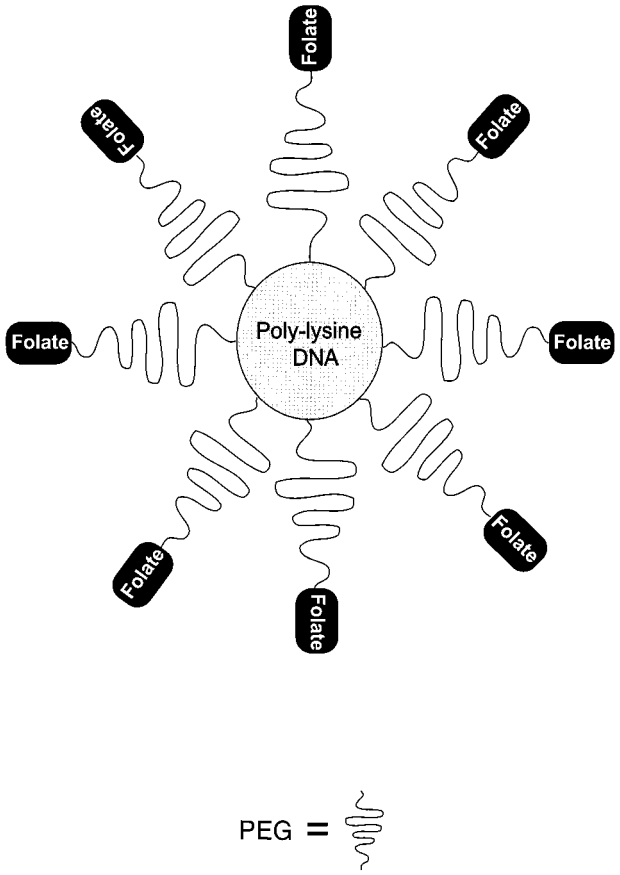

Figure 1. Proposed structure of pLys-PEG-folate:DNA complexes. Polyanionic DNA is assumed to electrostatically complex with polycationic pLys to form an electrically neutral, or hydrophobic core. The hydrophilic PEG-folate moieties naturally orient outward from this core into the bulk aqueous milieu, thus creating a targetable micelle-like DNA delivery vehicle.

of tissue-culture-treated microtitier plates and incubated for 18−24 h. Complexes between pLys-PEG_{3400}-folate (72 PEG-folates/pLys chain) and plasmid DNA (1:1 ± charge ratio) were preformed in 10% serum-supplemented FFMEM, and 100 ng of the complex (relative to DNA) was added to the wells. Following a 37 °C incubation for various time intervals, cells were harvested and assayed for luciferase activity. As shown in Figure 2, luciferase activity was not detected until >12 h of incubation, and this phenomenon was independent of cell density. However, the time of maximal luciferase expression did appear to be dependent on cell density. For example, at cell densities of >2000/well maximal luciferase activity was detected after 48 h of incubation. In contrast, maximal luciferase activity was reached and transiently sustained after 72 h for cells plated at the lower cell densities, suggesting that the extent of transfection (luciferase activity levels) was directly related to the degree of cell confluency within the wells. Interestingly, no luciferase activity was measured from cells treated with pLys:DNA (Figure 2) or pLys-PEG control complexes (not shown). Thus, for the remainder of the experiments described below, we chose to test cells plated at an initial density of 2000 cells/100 μL/well and to assess the levels of transfection 48 h later.

Charge Ratio Optimization. Theoretically, an electrostatic complex between a polycation and polyanion would carry a net neutral charge if the ± charge ratio were unity. A neutral complex would be desirable to incorporate into a ligand-targeted nucleic acid delivery vehicle, such as the one proposed here (see Figure 1), because it would eliminate the opportunity for nonspecific, adsorptive binding and uptake to nontarget cells. Unfortunately, interactions with buffer-associated ions and/or component proteins (e.g., from the serum) may alter the thermodynamically optimal ± charge ratio that would promote the formation of a neutral particle. Therefore, we elected to experimentally determine the optimal ± complexation ratios for pLys-PEG-folate and plasmid DNA, while simultaneously exploring the effect of the complexation media.

Complexes were prepared between pGL3 (5256 base pair) and increasing charge equivalents of pLys or pLys-PEG_{3400}-folate (72 PEG-folates per pLys chain), thereby spanning a large ± charge ratio spectrum.[6] Cells were exposed to the complexes for 48 h, and luciferase activity

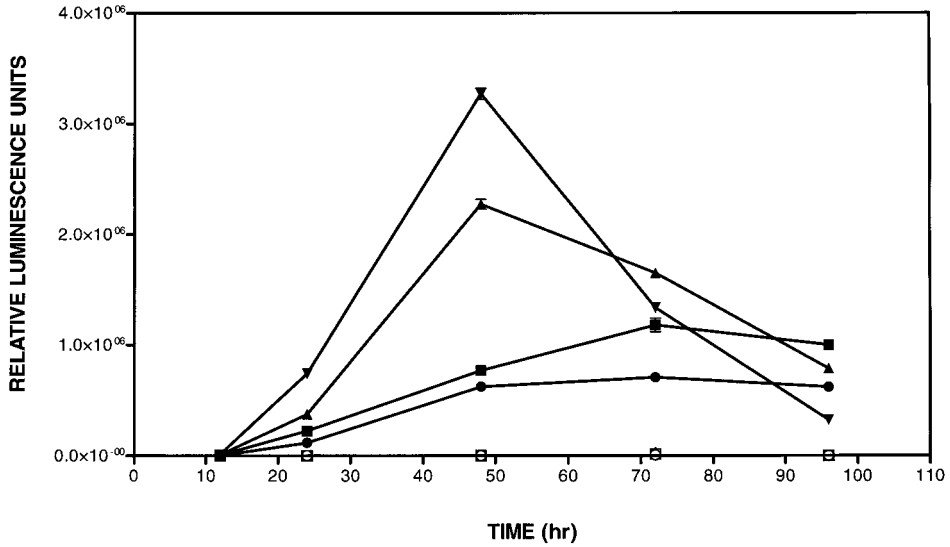

Figure 2. Effect of cell density and exposure time on pLys-PEG-folate:DNA transfection. A total of 100 μL of 10% serum-supplemented FFMEM containing pLys-PEG_{3400}-folate:DNA complexes (72 PEG-folates per pLys chain) was added to HeLa monolayers of increasing cell densities in 96 well plates. Cells were incubated at 37 °C for the indicated times. Spent incubation media was removed, and cells were assayed for endogenous luciferase activity as described in the Experimental Procedures. Number of cells originally seeded per well of a 96 well plate: (●, ○) 500 cells; (■, □) 1000 cells; (▲, △) 2000 cells; (▼, ▽) 4000 cells. Solid symbols represent pLys-PEG-folate:DNA complexes, while open symbols represent pLys:DNA complexes. *Error bars* represent one standard deviation ($n = 4$).

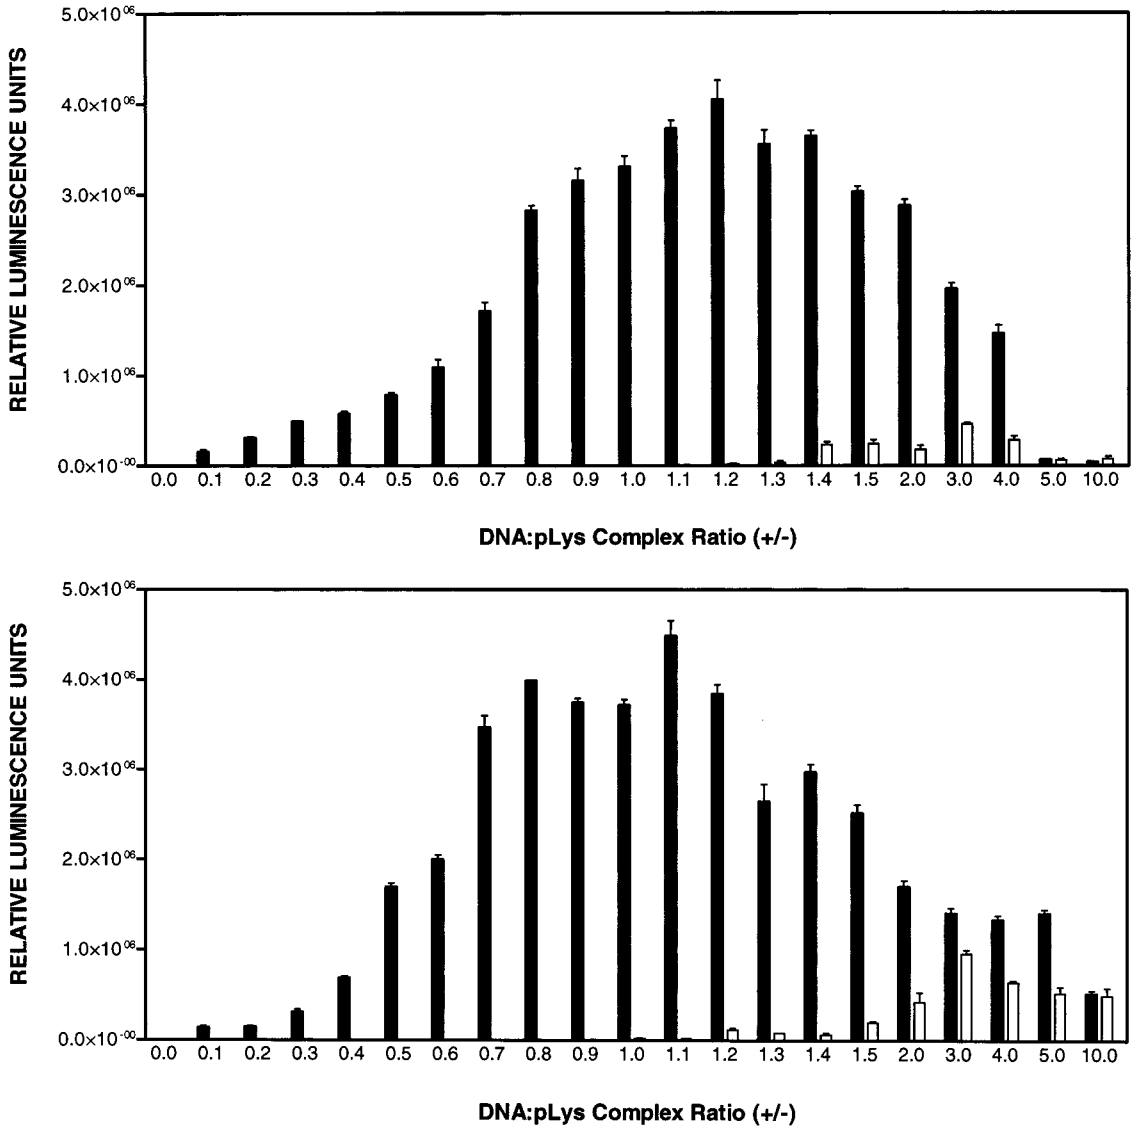

Figure 3. Effect of ± charge ratio and complexation medium on pLys-PEG-folate:DNA transfection. Complexes were prepared between pGL3 and increasing charge equivalents of pLys-PEG_{3400}-folate (72 PEG-folates per pLys chain). The quantity of plasmid DNA was held constant at 1 μg/mL in each well, whereas the quantity of pLys varied from 0 to 4 μg/mL to account for the various ± ratios examined. Cells were exposed to these complexes for 48 h, and endogenous luciferase activity was measured according to Experimental Procedures. (Solid bars) pLys-PEG-folate:DNA complexes; (open bars) pLys:DNA complexes. (A) Complexes formed in FFMEM supplemented with 10% heat-inactivated fetal calf serum; (B) Complexes formed in double deionized water. *Error bars* represent one standard deviation ($n = 3$).

was then measured. The results in Figure 3A show that luciferase activity levels gradually increased with respect to an increasing ± charge ratio until a maximum was reached at a near-neutral ratio. Beyond this optimum, the luciferase activity decreased as the charge ratio was further raised. In contrast, pGL3 titrated with unmodified pLys produced relatively large particles (easily observed at 250× magnification floating in the media) that were very ineffective transfection agents. This may partly explain why only minimal transfection activity was measured with these particles and only at the higher ± ratios (Figure 3).

All of the data presented thus far have been generated using complexes formed in 10% serum-supplemented media. This was initially done to optimize our experimental conditions for future cell studies that were intended to be performed in the presence of serum. However, we decided to determine if complexes preformed in nonserum-containing solutions were more efficient mediators of transfection. Thus, we chose to titrate pGL3 with increasing charge equivalents of pLys-PEG-folate in deionized water. As shown in Figure 3B, maximal levels of luciferase activity were achieved with a charge ratio near unity, similar to the results obtained from complexes formed in the presence of 10% serum. Interestingly, identical results were obtained when complexes preformed in Hepes-buffered saline solution were used in a similar assay (data not shown). Taken together, we interpret these results to suggest that optimal pLys-PEG-folate:DNA complexes are formed when the ± charge ratio is near unity and that the complexation process is not significantly influenced by the composition of the complexation buffer.

Effect of Increasing PEG Size. Figure 1 depicts a cartoon of a possible organizational structure formed between pLys-PEG-folate and nucleic acids. The PEG

[6] Approximately four pLys chains or four pLys-PEG_{3400}-folate copolymer units are needed to charge-neutralize 1 plasmid molecule.

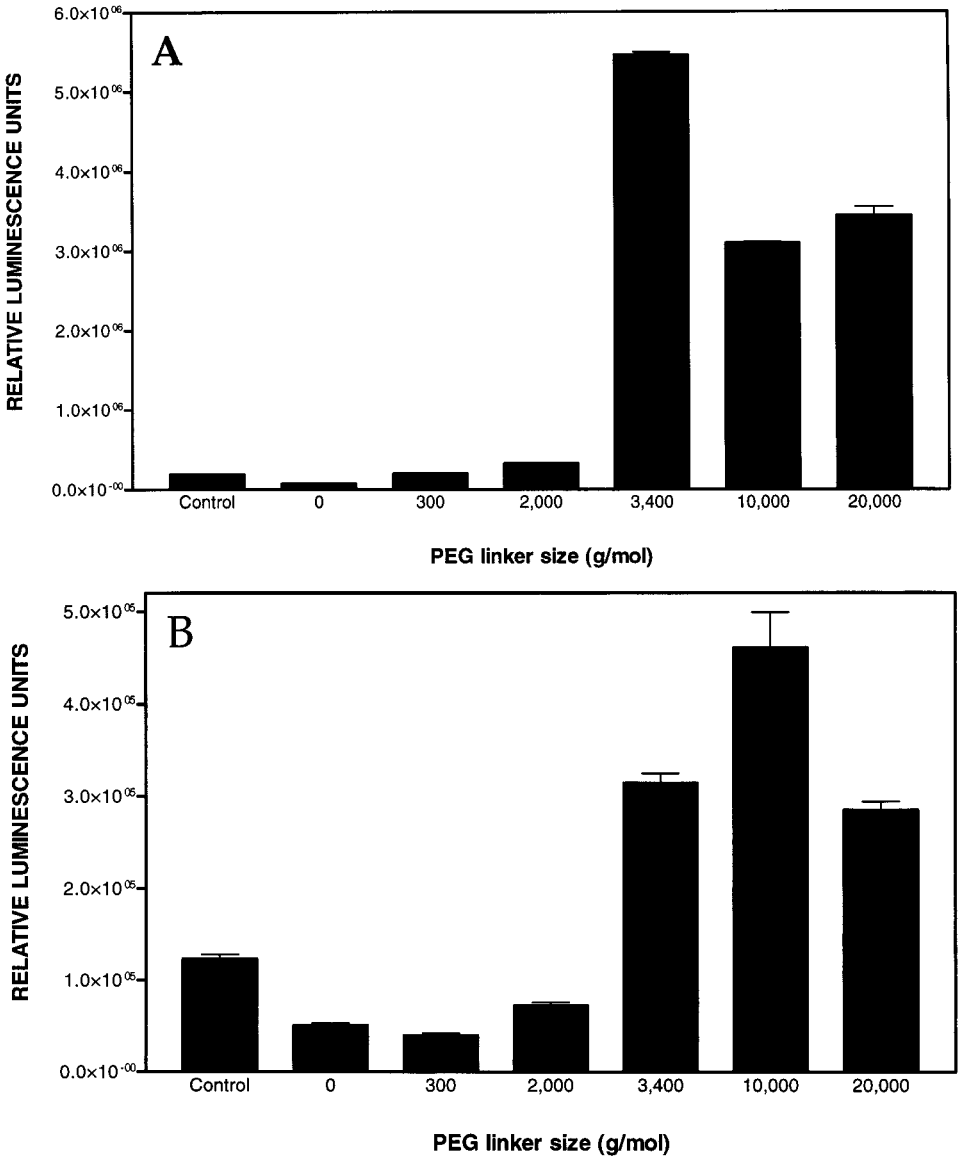

Figure 4. Effect of PEG size on pLys-PEG-folate:DNA transfection. Cells were incubated for 48 h at 37 °C in the presence of various pLys-PEG-folate:pGL3 complexes (1 μg/mL as DNA). Following the incubation, cells were harvested and the endogenous luminescence activity was measured according to Experimental Procedures. Control represents a pLys:DNA complex (no folate). Values 0−20000 represent the average molecular weight of PEG used in the particular pLys-PEG-folate conjugate assayed. (A) HeLa cells. (B) IGROV-1 cells. *Error bars* represent one standard deviation ($n = 4$).

component is assumed to orient on the outermost shell of the complex and to interact with the external aqueous environment, similar to the PEG component of Stealth liposomes (*43*, *44*). However, it is not known if transfection via pLys-PEG-folate:DNA complexes is dependent on the length of the PEG chain utilized. To evaluate this effect, we derivatized pLys with folate attached to PEG of various sizes ranging 0−20000 in average molecular weight. Complexes formed between this collection of pLys-PEG-folates and pGL3 were incubated with cultured cells for 48 h, and the levels of luciferase activity were measured. As shown in Figure 4A, very low levels of luciferase activity were measured in HeLa cells treated with complexes containing PEG components of 2000 molecular weight and smaller. However, significant luciferase activity was measured from cells transfected with PEG_{3400}-containing complexes. There was also no apparent advantage using the higher molecular weight PEG components (i.e., PEG_{10000} or PEG_{20000}). Interestingly, a similar PEG molecular weight trend was observed when a second cell type (IGROV-1) was used in this assay (see Figure 4B). This phenomenon is likely related to the observation that PEG forms "mushroom-like", or compacted, conformations at higher molecular weights (*44*), indicating that steric protection of the pLys:DNA core is a desirable property for transfection (see Figure 1). Notably, the remainder of the experiments described below was completed using pLys-PEG_{3400}-folate.

Effect of PEG-Folate Substitution. In addition to determining a favored PEG size for pLys-PEG-folate:pGL3 transfection, we investigated the effect of increasing the number of PEG-folate units conjugated per pLys chain. Thus, pLys was conjugated with increasing amounts of NHS−PEG_{3400}-folate, and following purification, the extent of PEG_{3400}-folate derivatization was determined. Complexes were formed with pGL3 and then added to HeLa cells for 48 h. As shown in Figure 5, a conjugate constructed with an average of 72 PEG_{3400}-folates per pLys chain (2.8% of the ~2586 lysine units derivatized) produced the highest measured level of luciferase activity in HeLa cells. Although no further attempt was made to determine the exact derivatization optimum, we believe

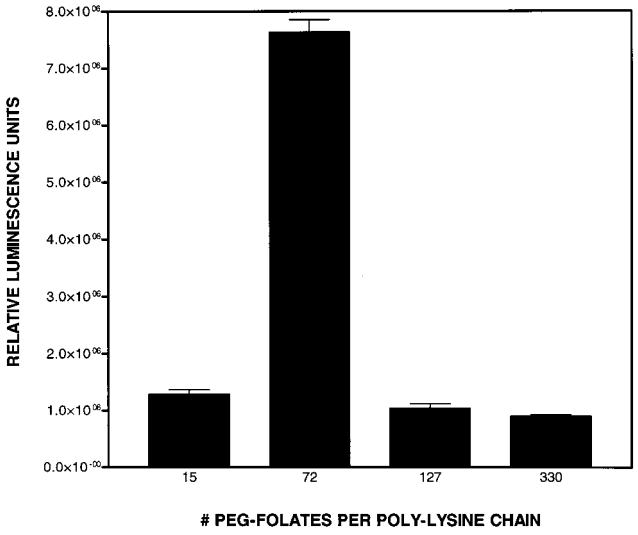

Figure 5. Effect of PEG substitution on pLys-PEG_{3400}-folate:DNA transfection. pLys (MW ≈ 331 000) was derivatized with increasing amounts of PEG_{3400}-folate and complexed to pGL3. Cells were incubated for 48 h at 37 °C in the presence of 1 μg/mL complex (as DNA). Following the incubation, cells were harvested and the endogenous luminescence activity was measured according to Experimental Procedures. *Error bars* represent 1 standard deviation ($n = 4$).

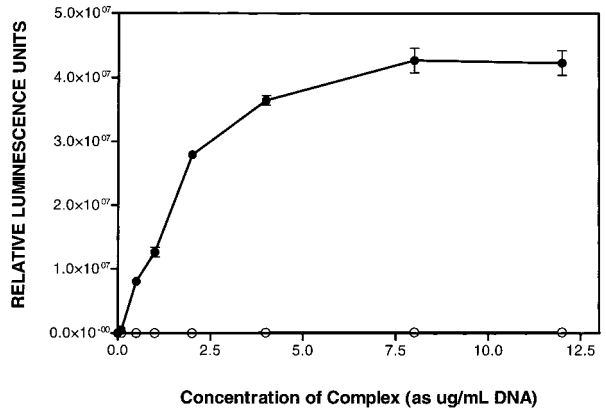

Figure 6. Concentration-dependent transfection. pLys-PEG_{3400}-folate:pGL3 complexes (72 PEG-folates/pLys chain) were formed and diluted in serum-supplemented FFMEM and then added at increasing concentrations to HeLa cell monolayers. Following a 48 h 37 °C incubation, cells were harvested and the endogenous luminescence activity was measured according to Experimental Procedures. (●) pLys-PEG_{3400}-folate:pGL3 complex; (○) pLys:pGL3 complex. *Error bars* represent 1 standard deviation ($n = 4$).

one clearly exists. Furthermore, the optimum PEG derivatization number may likely dictate the overall three-dimensional structure (and transfection potency) of these pLys-PEG-folate:DNA complexes.

Concentration-Dependent Transfection and Related Cytotoxicity. The folate moiety within the pLys-PEG-folate:DNA complex should effectively bind to external folate binding protein receptors on HeLa cells as well as mediate uptake via endocytosis. Because receptor-mediated endocytosis is a saturable process, we elected to determine the concentration dependence of pLys-PEG-folate:DNA transfection. As shown in Figure 6, luciferase activity reached a plateau at pLys-PEG_{3400}-folate:DNA concentrations of 8 μg/mL and higher (relative to DNA). Similar to what we observed in Figure 3 above, complexes formed with pLys had absolutely no transfection capability, even with concentrations as high as 12 μg/mL. Plus,

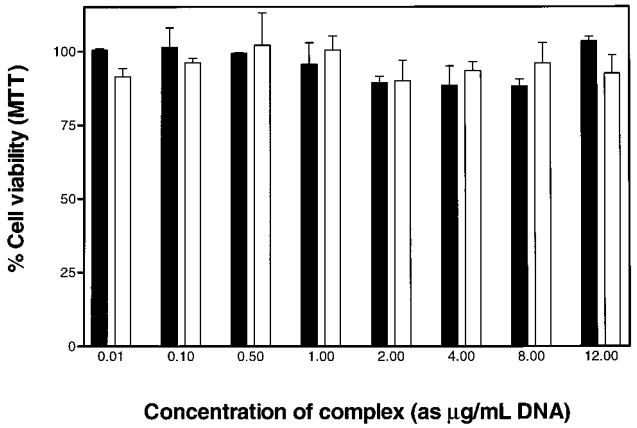

Figure 7. Cytotoxicity of pLys-$PE2G_{3400}$-folate:pGL3 complexes. Cells in a duplicate 96 well plate to that described in the legend to Figure 6 were used to evaluate the cytotoxicity of pLys-PEG_{3400}-folate:pGL3 complexes. Thus, complexes were formed and diluted in serum-supplemented FFMEM and then added at increasing concentrations to HeLa cell monolayers. Following a 46 h 37 °C incubation, cells were incubated for an additional 2 h at 37 °C in the presence of the MTT viability stain. Cells were harvested, and the percent cytotoxicity was calculated based on the viability values measured in wells that had contained untreated cells, as detailed in the Experimental Procedures. (Solid bars) pLys-PEG_{3400}-folate:pGL3 complexes; (open bars) pLys:pGL3 complexes. *Error bars* represent 1 standard deviation ($n = 2$).

a 100-fold excess of free folic acid nearly abolished (activity reduced by 95% at 5 μg/mL complex; not shown) pLys-PEG_{3400}-folate:DNA transfection, thus confirming the involvement of a receptor-mediated process.

Because there are reports that pLys:DNA complexes are toxic to some cells (*45*, *46*), we chose to examine the extent of cell toxicity on cells treated with increasing concentrations of pLys-PEG_{3400}-folate:pGL3 complexes. As shown in Figure 7, no significant cytotoxicity was measured in our HeLa cells treated with complexes up to 4.8 μg/mL pLys 331 000 molecular weight (or 12 μg/mL DNA).

Cytochemical Staining for β-Galactosidase. To better assess the extent to which treated cells are transfected by pLys-PEG-folate:DNA complexes, we elected to quantify the number of transfected cells in a population by using a β-galactosidase reporter plasmid and chromogenic staining. Complexes between pSV-βgal and pLys-PEG_{3400}-folate (72 PEG-folates/pLys chain) were formed in 10% serum-containing FFMEM per the usual protocol detailed above. A saturable concentration of the complex (9 μg, relative to DNA) was introduced to adherent cells in a 6-well Falcon culture dish, and the plate was incubated at 37 °C for 48 h. Using a commercially available kit, functionally transfected (i.e., β-galactosidase expressing) cells were detected by the visual appearance of a blue stain. Figure 8 shows a representative field of cells treated in this manner. Interestingly, positive blue staining varied among the cells. Some cells stained very heavily, and the stain was diffuse throughout the entire cell body. Other cells, however, limited their display of blue staining to vacuolar compartments. By summing the total number of cells containing blue stain (both vacuolar and diffuse) within any given field of view, we estimated that approximately 6% of the exposed cells were functionally transfected by pLys-PEG_{3400}-folate:pSV-βgal complexes (see Discussion).

Comparison of pLys-PEG-Folate:DNA Transfection to Cationic Liposome Transfection. Cationic liposomes have been widely used to transfect plasmid

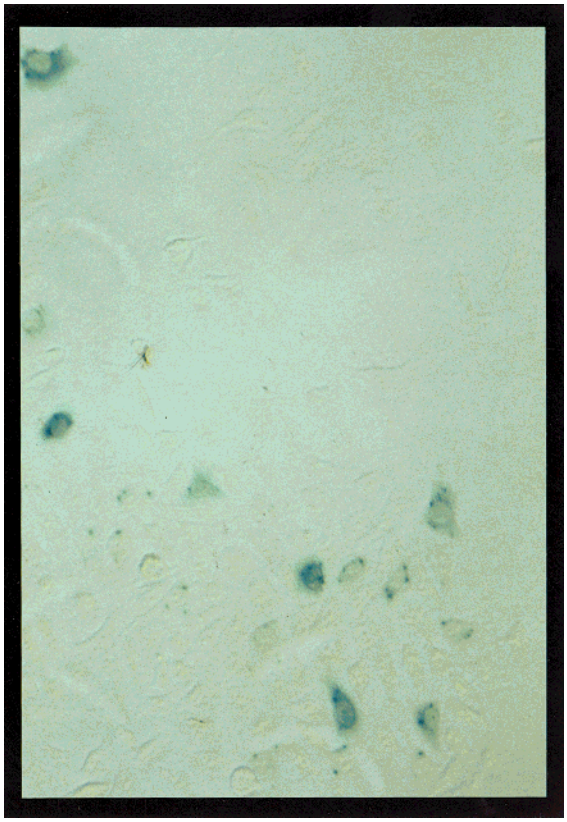

Figure 8. Cytochemical staining for β-galactosidase activity. Complexes of pSV-βgal and pLys-PEG$_{3400}$-folate (72 PEG-folates/pLys chain) were formed in 10% serum-containing FFMEM for 1 h, as described in Experimental Procedures and were then added to plated cells at saturable levels (9 μg with respect to DNA). Following 48 h of incubation at 37 °C, cells were developed using a commercially available β-galactosidase staining kit. Functionally transfected cells (blue color) were identified using bright-field microscopy. The transfection efficiency was calculated by counting the number of stained cells in a random microscope field viewed at 200× and then dividing by the total number of cells in that same field. Four fields were counted and averaged to give an overall transfection efficiency of ~6%.

DNA into cells both in vitro and in vivo (*47*−*50*). Unfortunately, cationic liposome-mediated transfection has not worked well in the presence of serum (*50*, *51*). Because our pLys-PEG-folate conjugates are typically complexed to plasmid DNA in the presence of serum, we elected to evaluate the levels of cellular transfection achieved by pLys-PEG-folate:DNA complexes to that obtained with cationic liposome:DNA complexes also prepared in the presence of 10% serum. The results in Figure 9 show that pLys-PEG$_{3400}$-folate (72 PEG-folates/pLys chain) produced equal to or greater levels of transfection relative to that of six popular commercially available cationic liposome formulations, each tested using their vendor-recommended optimal complexation ratios (~2.5−5 ± ratios; see Experimental Procedures). Importantly, the data in this figure were normalized with respect to the amount of residual cellular protein present at the end of the experiment. Many of the cationic liposome formulations produced significant cell killing (which was evident from the lower total cell protein values), whereas pLys-PEG$_{3400}$-folate complexes did not affect cell number (see Figure 7). Considering the added benefit of cell targeting via folate endocytosis, pLys-PEG$_{3400}$-folate was obviously the preferred transfection reagent for use in these studies that employed serum-containing medias.

DISCUSSION

We developed a method for transfecting plasmid DNA into cultured cells using a targetable pLys-based delivery vehicle that contains an extended poly(ethylene glycol) "spacer" arm strategically placed between the ligand and the pLys backbone. Using a luciferase reporter gene plasmid, we quantitatively evaluated transfections mediated by various pLys-PEG-folate:DNA complexes and carefully optimized this technique by studying the influence of complexation charge ratios, complexation medias, PEG size, and the extent of pLys derivatization.

We discovered that a finite lag period exists between the time that pLys-PEG-folate:DNA complexes enter the cells and the time that endogenous luciferase activity is detected (Figure 2). This latency period is crudely estimated to fall within 12−24 h postexposure to cells. Interestingly, folate−toxin conjugates have been shown to gain access to the cytosol after only a 2−8 h delay following entry into cells via receptor-mediated endocytosis (*25*, *27*). Perhaps the longer lag phase seen with our pLys-PEG-folate:DNA complexes is due to (i) the larger size of the "payload" (i.e., condensed plasmid) and (ii) the fact that this payload must further enter the nucleus, become transcribed and then translated prior to the detection of transfection activity.

Another interesting observation is that the time of maximal luciferase expression appeared to be dependent on cell density (see Figure 2). Cells in the most heavily seeded wells displayed maximal luciferase activity at the earlier time points, while cells in the lower seeded wells reached maximal luciferase activity at the later time points. Interestingly, this phenomenon may be related to a recent observation that wild-type folate receptors failed to deliver externally bound folate molecules into the cytoplasm of confluent, nondividing cells (*52*). Assuming this physiological effect occurred in our HeLa cells, one might have predicted that the more heavily seeded wells (4000 cells/well; Figure 2) would have reached confluency, or folate-endocytosis incompetentcy, faster than the lesser-seeded wells; this, in turn, would have negatively affected the luciferase activity levels (especially at the later time points). Overall, this cell-density effect may have ramifications for comparing similar results of different studies and, therefore, should be cautiously noted.

During the course of this study, we discovered that the size of PEG used to construct the pLys-PEG-folate conjugate was critical for successful mediation of DNA transfection into target cells. Thus, the results in Figure 4 show that no enhancement of DNA transfection was detected until the PEG size within the pLys-PEG-folate conjugate was increased to 3400 in molecular weight. PEGs larger than 3400 molecular weight added little (if any) benefit to the overall transfection activity, and that effect varied among the two cell types tested within this study. This linker or "cushion" effect has also been seen with Stealth liposomes, where lipids modified with PEG of molecular weights >2000 had diminished protective properties (*44*). We believe, however, that the PEG within pLys-PEG-folate conjugates serves not only to provide a hydrophilic barrier to protect the pLys-condensed DNA but that it also acts as an extended linker arm to allow the folate ligand to optimally bind to its cell-surface receptor (see Figure 1). Notably, extended linker arms have also been shown to be critically beneficial for the successful targeting of folate liposomes (*30*). In particular, folate anchored to the phospholipid headgroup by a one- or two-amino acid "spacer" failed to promote targeted

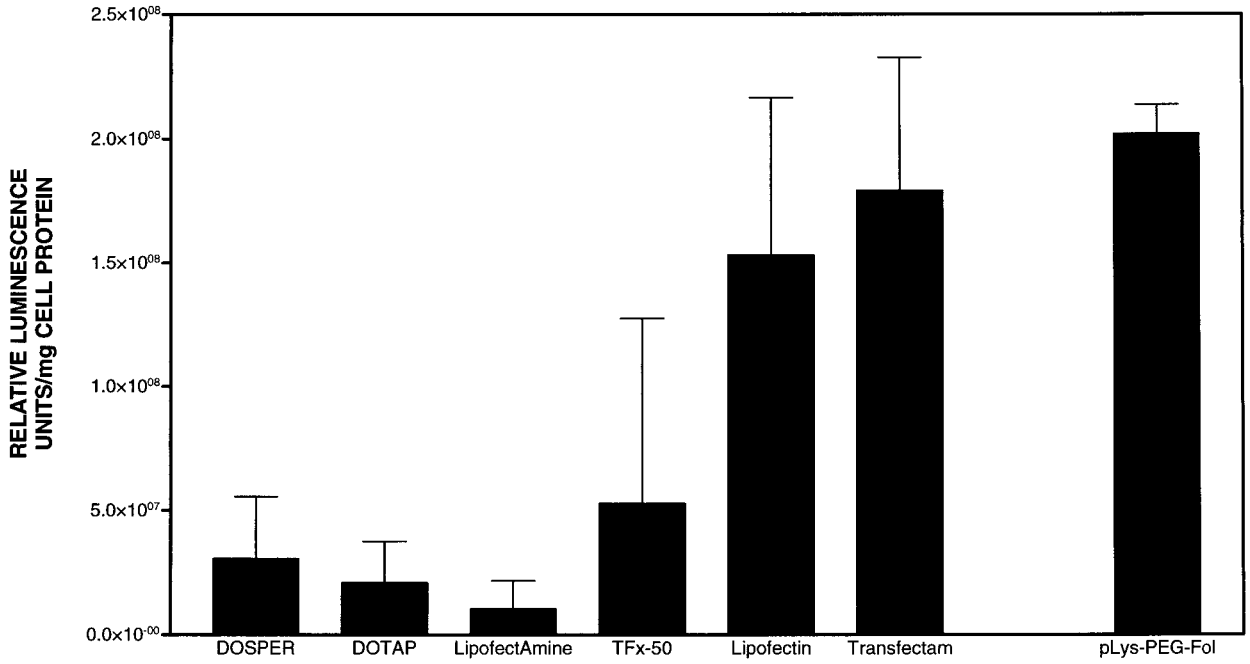

Figure 9. Comparison of pLys-PEG_{3400}-folate and cationic liposome mediated DNA transfection. pGL3 was complexed to pLys-PEG_{3400}-folate (72 PEG-folates/pLys chain) or to preformed cationic liposomes in 10% serum-supplemented FFMEM for 10−30 min at room temperature. Complexes were added to cells (1 μg/mL as DNA) and incubated for 48 h at 37 °C. Spent incubation media was removed, and cells were assayed for endogenous luciferase activity as described in Experimental Procedures. *Error bars* represent 1 standard deviation ($n = 8$).

liposome delivery to cells, whereas a ~3400 molecular weight PEG spacer produced fully targetable liposomes (*30*). Interestingly, this present study revealed that a useful PEG size for the pLys-PEG-folate transfection is also 3400 in molecular weight. And although we do not yet fully understand why the PEG 2000 spacer (or shorter) failed to mediate folate-targetable transfection, it is possible that steric constraints between the folate receptor and our pLys-PEG-folate:DNA particles prevented effective ligand binding. However, this parameter should be investigated further.

The value of including the PEG spacer within a targeted pLys:DNA complex was further revealed when we tested the ability of pLys-folate to transfect cells in parallel with pLys-PEG_{3400}-folate. The data presented in Figure 4 shows that pLys-folate is an inferior transfection agent. The simple addition of a PEG spacer afforded a 74-fold enhancement of transfection in HeLa cells and a 10-fold enhancement in IGROV-1 cells, relative to transfection levels mediated by pLys-folate. Presumably, the distinct levels of transfection enhancement between these two cell lines is due to their distinct levels of folate receptor expression ($>15 \times 10^6$ folate binding sites/HeLa cell versus $\sim 5 \times 10^5$ sites/IGROV-1 cell) (*26*, *53*). Interestingly, others have reported that transfection via pLys-folate:DNA complexes could be enhanced by co-treatment of cells with lysosomotropic agents (*8*) or adenoviral particles (*17*). Although not tested here, these techniques may also improve upon the transfection mediated by pLys-PEG-folate.

The proposed structure of pLys-PEG-folate:DNA complexes shown in Figure 1 represents what we conceive to be an effective transfection particle. It seemed logical to assume that polycationic and polyanionic polymers can, under charge neutral conditions, complex together to form a hydrophobic "core". Indeed, such a hypothesis has recently been proposed for oligonucleotide−polyoxyethylene complexes (*42*). And in a related way, it seemed logical to assume that the hydrophilic PEG-folate moiety would orient itself outward toward the bulk solution. This is evidenced by the observations that (i) free folic acid blocks the cell-association of the pLys-PEG_{3400}-folate:DNA complex and (ii) the transfection process mediated by pLys-PEG_{3400}-folate is saturable, suggesting that transfection occurs by a receptor-mediated process. Obviously, further biochemical analyses as well as electron microscopic characterization of these complexes is needed to confirm the proposed structure and to determine the effect of varying the size of the pLys component within the complex (*54*).

All of the studies presented above were conducted on cultured cells previously determined to express folate binding protein receptors. Assuming that each cell in the culture bears this receptor, one might expect that each cell would become transfected by pLys-PEG_{3400}-folate:DNA complexes. However, when we attempted to stain for transfection following the delivery of a plasmid containing a β-galactosidase gene, only 6% of these treated cells stained positively (see Figure 9). It is very unlikely that 94% of the cell population was incompetent to bind and internalize these complexes, since delivery of folate−toxin conjugates into the identical cell line effectively killed the entire population (*25*, *27*). Instead, we believe that the majority of the cells either expressed very low levels (staining not visually detectable) of β-galactosidase, or that the majority of DNA plasmid within these cells remained entrapped within organellar structures. Unlike protein toxins, plasmid DNA must breach not only the endosomal barrier but also the nuclear membrane barrier prior to eliciting an effect. Although access to the cytosol is difficult in itself, that alone would not guarantee successful translocation of DNA into the nucleus (*55*). Clearly, these results indicate that transfection mediated by pLys-PEG_{3400}-folate may be further enhanced, possibly with the co-incorporation of endosome-disrupting agents (*14*, *20*, *21*).

Prediction of *q*-Values and Conformations of Gadolinium Chelates for Magnetic Resonance Imaging

L. A. Castonguay,*,† A. M. Treasurywala,†,‡ T. J. Caulfield,§ E. P. Jaeger,†,|| and K. E. Kellar⊥

Departments of Biophysics and Computational Chemistry, Medicinal, and Analytical Chemistry, Sterling Winthrop Pharmaceutical Research Division, 1250 S. Collegeville Road, P.O. Box 5000, Collegeville, Pennsylvania 19426-0900. Received March 8, 1999; Revised Manuscript Received August 11, 1999

For gadolinium chelates, we determined that there is a linear correlation between calculated solvent-accessible surface area and *q*-value, the number of rapidly exchanging water molecules directly bound to the gadolinium ion. A calibration curve was developed to predict *q*-value based on the solvent-accessible surface area of gadolinium. This predictive method was validated with the following gadolinium crystal structures: (ethylenediaminetetraacetic acid)-gadolinium(III) [Gd(EDTA)] [Templeton, L. K., Templeton, D. H., Zalkin, A., and Ruben, H. W. (1982) Anomalous Scattering by Praseodymium, Samarium, and Gadolinium and Structures of their Thylenediaminetetraacetate (EDTA) Salts. *Acta Crystallogr., Sect. B 38*, 2155], (1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid)-gadolinium(III) [Gd(DOTA)] [Dubost, J.-P., Leger, J.-M., Langlois, M.-H., Meyer, D., and Schaefer, M. (1991) Structure of a Magnetic Resonance Imaging Agent - The Gadolinium-DOTA Complex $C_{16}H_{24}N_4O_8NaGd$, $5H_2O$. *C. R. Acad. Sci., Ser. 2 312*, 349], (diethylenetriaminepentaacetic acid)-gadolinium(III) [Gd(DTPA)] [Stezowski, J. J., and Hoard, J. L. (1984) Heavy Metal Ionophores - Correlations Among Structural Parameters of Complexed Nonpeptide Polyamino Acids. *Isr. J. Chem. 24*, 323], (diethylenepenta-acetato)-gadolinium(III) [Gd(DTPA-BEA)] [Smith, P. H., Brainard, J. R., Morris, D. E., Jarvinen, G. D., and Ryan, R. R. (1989) Solution and Solid-State Characterization of Europium and Gadolinium Schiff-Base Complexes and Assessment of their Potential as Contrast Agents in Magnetic Resonance Imaging. *J. Am. Chem. Soc. 111*, 7437], and (1,7,13-triaza-4,10,16-trioxacyclo-octadecane-*N*,*N*′,*N*″-triacetato)-gadolinium(III) [Gd(TTTA)] [Chen, D., Squattrito, P. J., Martell, A. E., and Clearfield, A. (1990) Synthesis and Crystal Structure of a 9-Coordinate Gadolinium-(III) Complex of 1,7,13-Triaza-4,10,16-Trioxacyclooctadecane-N,N′,N″-Tri-Acetic Acid. *Inorg. Chem. 29*, 4366]. Predicted *q*-values were in complete agreement with experimentally determined *q*-values. A genetic algorithm-based conformational search method was developed to generate valid 3D models for gadolinium chelates. The method was successfully tested on the following gadolinium chelates: Gd(EDTA) (Templeton et al., 1982), Gd(DOTA) (Dubost et al., 1991), Gd(DTPA-BEA) (Smith et al., 1989), Gd(TTTA) (Chen et al., 1990), Gd(triethylene glycol) [Rogers, R. D., Voss, E. J., and Etzenhouser, R. D. (1988) F-Element Crown Ether Complexes. 17. Synthetic and Structural Survey of Lanthanide Chloride Tiethylene Glycol Complexes. *Inorg. Chem. 27*, 533], and Gd(tetraethylene glycol) [Rogers, R. D., Etzenhouser, R. D., Murdoch, J. S., and Reyes, E. (1991) Macrocycle Complexation Chemistry. 35. Survey of the Complexation of the Open-Chain 15-Crown-5 Analogue tetraethylene Glycol with the Lanthanide Chlorides. *Inorg. Chem. 30*, 1445].

INTRODUCTION

The importance of intravenously administered contrast agents for magnetic resonance imaging (MRI) is evidenced by the fact that approximately one-half of all routine clinical MRI procedures involve the use of contrast agents (*8*). Particularly, small water-soluble chelates of Gd(III) such as $[Gd(DTPA)]^{2-}$ and $[Gd(DOTA)]^{-}$ have found widespread clinical application as MRI contrast agents due to their favorable characteristics of high chemical stability, low toxicity, and rapid clearance. The effectiveness of a contrast agent is determined by the ability of the complex to increase the relaxation rate of bulk water protons, or relaxivity in vivo.

For small water soluble polyaminocarboxylate gadolinium chelates at field strengths pertinent to MRI, the magnitude of the relaxivity is determined mainly by four parameters: (1) t_R, the rotational correlation time of the chelate; (2) *r*, the distance between the centers of the gadolinium ion and the protons of the coordinated water molecules; (3) *q*, the number of water molecules bound in the inner coordination sphere of the gadolinium ion; and (4) τ_M, the residence lifetime of water molecules in the inner coordination sphere of the gadolinium ion. For most gadolinium chelates reported in the literature (*9*−*11*), the values of t_R, *r*, and τ_M affect the relaxivity to a minor extent as compared to the value of *q*. Indeed,

previous work has established a linear relationship between integer *q*-value and relaxivity at 1.2 T, a field-strength typical of clinical MRI (*10*).

Due to the toxicity of free lanthanide ions, the biological tolerance of contrast agents is largely determined by the ability of the gadolinium complex to remain intact in vivo. The acute toxicity of a number of polyaminocarboxylate gadolinium complexes has been demonstrated to be inversely proportional to the conditional binding constants of the ligands. Despite a 50-fold range of LD_{50} values for four Gd(III) complexes, all become lethally toxic to mice at dosages where 13−15 mM of Gd(III) is released in vivo (*12*). The authors propose that release of Gd(III) from the complex is responsible for the toxicity and that this appears to be a consequence of Zn(II), Cu(II), and Ca(II) transmetalation in vivo. In general, the stability of metal−ligand complexes increases with the number of potential coordination sites which are occupied.

The goal in designing improved MRI contrast agents is to maximize both the biological tolerance (conditional stability) and efficacy (*q*-value) of the gadolinium chelate. Therefore, predictive methods for determining both conditional stability constants and *q*-value for gadolinium chelates would help facilitate the discovery of improved contrast agents. Previously, molecular mechanics calculations and dynamics simulations, based on the AMBER force field (*13*), were used to examine the structure and stabilities of gadolinium complexes (*14*). However, no predictive methods for the determination the *q*-values has been reported. Herein, we would like to report a computational method to predict the *q*-values and structures of gadolinium chelates for magnetic resonance imaging.

COMPUTATIONAL DETAILS

***q*-Value Calculation and Validation.** The Connolly surface is the area traced out by rolling a defined probe (a sphere of 1.4 Å which represents a water molecule) over the gadolinium ion. A calibration curve for translating calculated Connolly surface area to *q*-value was developed using the crystal structure of $Gd(H_2O)_9$ (*15*). If one water is removed, then there is one vacancy to which a water molecule can bind; in other words, eight of the nine coordination sites are already occupied. This is analogous to a $q = 1$ system where there is space for one solvent water molecule to coordinate to the gadolinium ion, and the rest of the "solvent sites" are involved in complexation to the chelate. Therefore, for $q = 1$, one water is removed from the structure and the Connolly surface area is calculated for the gadolinium using SYBYL software (*16*). There are nine possible ways to remove one water molecule, each of the nine possible Connolly surface areas are calculated, and the average, maximum, and minimum values are recorded. This same procedure was repeated for $q = 0$ to $q = 9$ and the resultant data plotted as a calibration curve, Figure 1. For $q = 2$, 3, 4, 5, 6, 7, and 8, only contiguous waters were removed. This restriction was applied to prevent "partial sites" from being mistakenly counted. For example, if one and a half sites were available on the top of the molecule and half a site was available on the bottom, there would not actually be room for two solvent water molecules to bind since the sites are not contiguous.

Since the structures generated during conformational analysis will be minimized structures, a new calibration curve was developed using the same procedure for the $Gd(H_2O)_9$ crystal structure after minimization. Gadolinium nonahydrate was minimized in SYBYL using the parameters and conditions listed below. The data were plotted as before and the same linear calibration curve was observed.

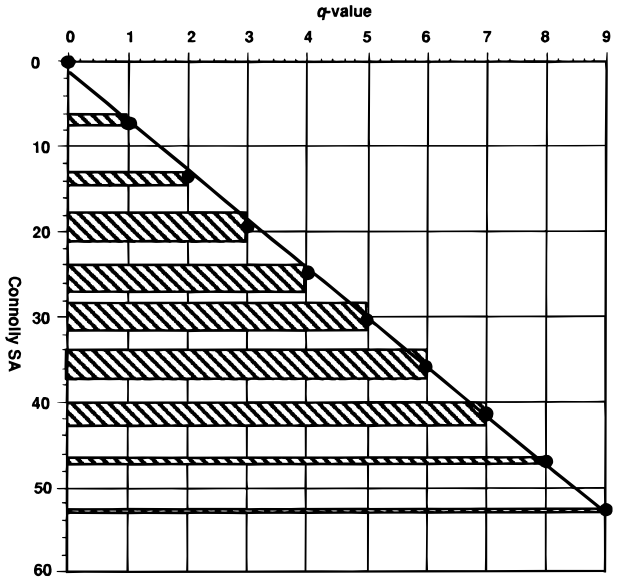

Figure 1. Graph of *q*-value vs calculated Connolly surface area for the crystal structure of $Gd(H_2O)_9$. The dots denote the average value of Connolly surface area for each *q*-value. The shaded bar denotes the data spread between highest and lowest calculated Connolly surface area for each *q*-value. Note no bands overlap.

Gadolinium Parameter Development. The SYBYL force field was extended in this work to include an atom type for Gd(III). The parameters for the remaining atoms are taken directly from the published SYBYL force field (*17*). Since the gadolinium is not covalently bonded to the chelates, only nonbonded parameters needed to be developed. The van der Waals energy term used in the SYBYL force field is as follows:

$$E_{\mathrm{vdw}} = \sum_{\substack{i=1 \\ \text{nonbonded}}}^{\text{Natoms}} \sum_{j>1} E_{ij} \left(1/a_{ij}^{12} - 2/a_{ij}^{6}\right)$$

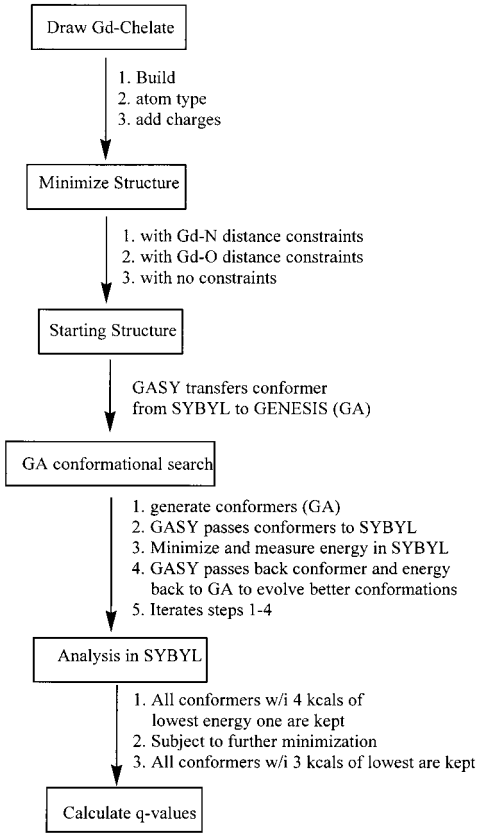
where E_{ij} is the van der Waals constant, a_{ij} equals $r_{ij}/(R_i + R_j)$, r_{ij} is the distance between atoms i and j, R_i is the van der Waals radius of the ith atom, and R_j is the van der Waals radius of the jth atom.

These parameters were developed empirically by varying E_{ij} and R_i for a database of gadolinium complex crystal structures. The optimal parameters being the ones that fit the structural data obtained from the crystal structures.

Crystal structures from the Cambridge Structural Database (CSD) (*18*) were used to construct this database. A search of the CSD resulted in 76 structures containing gadolinium and carbon. Structures were eliminated if they were duplicates, contained more than one gadolinium, were diagnostic imaging agents that would be used later to test these methods, contained uncomplexed gadolinium with the ligand, contained just gadolinium and solvent, or contained other metals as part of the ligand. A total of 59 structures were eliminated, leaving 17 structures in the database.

The database contained the following structures: (18-crown-6)-ethanol-dichloro-gadolinium(III) chloride (*19*),

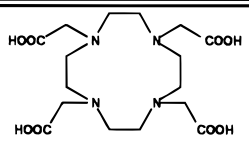
nona-aqua-gadolinium(III) tris(trifluoromethanesulfonate) (*14*), tris(acetylacetonato)-diaqua-gadolinium(III) monohydrate (*20*), tris(acetylacetonato-*O*,*O*′)-bis(acetylacetoniminato)-gadolinium(III) acetylacetonimine solvate (*21*), chloro-diaqua-(*18*−*crown*−*6*)-gadolinium(III) dichloride dihydrate (*22*), bis(η-1,3,5-tri-*tert*-butylbenzene)-gadolinium(0) (*23*), penta-aqua-(triethylene glycol-*O*,*O*′,*O*″,*O*‴)-gadolinium(III) trichloride (6), cis-trichloro-tris(2, 6-dimethyl-4-pyrone)-gadolinium(III) (*24*), aqua-tris(nitrato-*O*,*O*′)-bis[di-isopropyl(1, 2-bis(diethylcarbamoyl)ethyl) phosphonato-*O*]gadolinium(III) (*25*), tris[(3-aza-4-methylhept-4-en-6-on-1-yl)amine-*O*,*O*′,*O*″]-tris(nitrato-*O*,*O*′)-gadolinium(III) (*26*), triaqua-chloro-(tetraethylene glycol)-gadolinium(III) dichloride monohydrate (*7*), [10-(2-((2-hydroxy-1-(hydroxymethyl)ethyl) amino]-1-[(phenylmethoxy)methyl]-2-oxo-ethyl)-1,4,7,10-tetra-azacyclododecane-1,4,7-triacetic acid)-gadolinium(III) trihydrate (*27*), pentasodium tris(oxy-diacetato-*O*,*O*′,*O*″)gadolinium-(III) diperchlorate hexahydrate (*28*), trinitrato-1, 2-bis-(pyridine-2-aldimino)ethane-gadolinium(III) (*29*), acidic gadolinium tetrakis(benzoylacetonate) piperidine (*30*), bis[diaqua-(2-formyl-4-methyl-6-(4-(2-pyridyl)-2-azonia-but-1-enyl)phenolato-*O*,*O*′)-gadolinium(III)] diperchlorate chloride hydrate (*31*), and trichloro-bis(dimethoxyethane-*O*,*O*′)-gadolinium(III) (*32*).

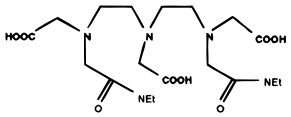


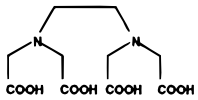
All structures in the database were subjected to the following protocol after extraction from the CSD. The crystal structures were imported into SYBYL, and counterions and water molecules were removed. Atoms were atom typed, and bonding was fixed if necessary. Hydrogens were added and minimized, holding the rest of the molecule fixed (default conditions: simplex method (*33*), 20 steps for any atom with a force above 1000 kcal/mol Å^2 followed by the Powell method of conjugate gradient minimization (*34*) to a convergence 0.05 kcal/molÅ^2 RMS (root-mean-square gradient). Gasteiger charges were calculated setting the charge on gadolinium to +3.0.

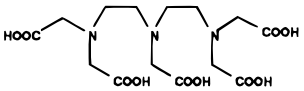
The R_i of Gd was varied from 1.8 to 2.3 Å in increments of 0.1 Å, the database was minimized (default conditions) using the default E_{ij} (van der Waals constant or well depth) value of 0.1. The resulting minimized structures were saved in a new database, and the total RMS deviations (no hydrogen atoms) from original crystal structures were used as a measure of "goodness" of parameter fit. The following four structures were eliminated since the RMS deviation (no hydrogen atoms) was very poor (>1) for all values of R_i: cis-trichloro-tris(2,6-dimethyl-4-pyrone)-gadolinium(III) (*24*), bis(diethylcarbamoyl)ethyl-phosphonato-*O*-gadolinium(III) (*25*), acidic gadolinium tetrakis(benzoylacetonate)piperidine (*30*), and bis[diaqua-(2-formyl-4-methyl-6-(4-(2-pyridyl)-2-azonia-but-1-enyl)phenolato-*O*,*O*′)-gadolinium(III)] diperchlorate chloride hydrate (*31*).

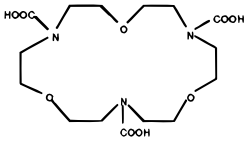
A narrower range of suitable R_i was obtained by graphing the sum of the total RMS deviations (no hydrogen atoms) for each run vs R_i. An approximately parabolic curve was obtained with the best radius range in the well being 1.9−2.1. Using a similar procedure as before, both R_i (1.9−2.1 with increments of 0.05) and E_{ij} (0.001, 0.01, 0.05, 0.1, 0.2, 1.0) were varied. The best parameters found were $R_i = 2.0$ and $E_{ij} = 0.2$.











Genetic Algorithm Conformational Search Method. A flow chart representation of this method is shown in Scheme 1. Initially in SYBYL, the gadolinium chelate is built, then atom typed and charged using Gasteiger charges, setting the charge on Gd to +3.0. To go from a 2D drawing to a reasonable starting gadolinium chelate complex, initial constraints are applied. Distance constraints of 2.6 Å are applied to all gadolinium−nitrogen pairs, and the structure is minimized [Powell method of conjugate gradient minimization (*34*) until a convergence of 0.01 energy gradient tolerance is reached]. Then additional distance constraints of 2.4 Å are added for the gadolinium−oxygen pairs (one constraint for each carboxylate group, arbitrarily picking just one of the oxygens in the COO^- group), and the chelate is minimized. Then all constraints are removed, and the structure is minimized. The structure is output in SYBYL's mol2 format. This conformation is used as the starting structure for the genetic algorithm conformational searching technique described below.

Scheme 1. Flowchart of Gd-Chelate Conformation Generation and *q*-Value Prediction

A genetic algorithm (GA) search method was used to identify favorable binding conformation for the gadolinium ligand system. This search was performed using a hybrid system known as GASY which linked the genetic algorithm package GENESIS (*35*) with the molecular-modeling package SYBYL, hence the name GASY (GA linked through the SYBYL software). The GENESIS package was configured to generate lists of floating point numbers whose values had a possible range of −180 to 180. These lists were passed to SYBYL via named pipes. SYBYL was configured using SYBYL programming language (SPL) procedures to retrieve the sets of floating point numbers from the incoming pipe and interpret them as strings of torsional values. GASY then used the values to set a conformation of the molecular system, minimize the conformation [simplex method (*33*), 20 steps for any atom with a force above 1000 kcal/molÅ^2 followed by the Powell method of conjugate gradient minimization (*34*), 200 steps or a minimum energy change of 0.05kcal/mol], and measure the energy of this binding conformation. The energy value was then passed to the GENESIS program via a second pipe where it was treated as a measure of the fitness of the set of floating point numbers. This completed the evaluation loop and allowed

Table 1. Gd Chelates Used to Test the Predictive Capability of This Method[a]

Gd Chelate	Chelate	Connolly SA	Predicted q-value	Exptl. q-value
DOTA		5.9	1	1
DTPA-BEA		6.1	1	1
EDTA		18.6	3	3
DTPA		6.5	1	1
TTTA		0	0	0

[a] Connolly surface area was calculated for each of these known crystal structures, and the calibration curve shown in Figure 1 was used to predict the *q*-value. The predicted and experimental *q*-values are in agreement.

the GA to evolve better conformations. For cyclic chelates, a bond must be broken before the GA run and then reestablished before the SYBYL minimization and energy evaluation.

The messaging scheme used by GASY was necessary because both programs are designed to be in control of the sequence of operations and there is no easy way to make either program a subprogram of the other. GASY is a general modeling optimization tool. It allows the easy optimization of any number of problems where a string of numbers can be encoded into a molecular system and a fitness evaluation of the resulting system can be performed.

Analysis of Genetic Algorithm Searches. The analysis of the conformations that were generated by the method outlined above was performed within SYBYL using a macro that had been created in SYBYL Programming Language (SPL) (see Scheme 1.). This macro reads a file that was generated by the Genetic Algorithm that contains an ordered list of the values of the torsions of each of the rotatable bonds. All energetically acceptable conformations were defined as those that were less than or equal to the minimum energy found over the entire run, plus 4 kcals. The program creates a table in SYBYL whose rows represent the conformations and whose columns represent a rotatable bond. Atom numbers of the four atoms which define each of the torsions from the GA initialization file are determined. Lastly, the program generates each of the conformations in the 4 kcal set and reports their energies as calculated in the SYBYL package. The resulting conformations are minimized with another SPL and deposited into a SYBYL database along with their corresponding calculated energies. All low-energy structures (within 3 kcal of lowest) are considered valid models, and their *q*-values are calculated using the above-described method. The Connolly surface of the gadolinium for each model is calculated in SYBYL, and the calibration curve is used to convert Connolly surface area to corresponding q-value.

RESULTS AND DISCUSSION

Our hypothesis was that *q*-value would be proportional to the solvent-accessible surface area of the gadolinium ion. Typically, calculated Connolly surface area has been used to estimate the solvent accessible surface area of proteins. Using the crystal structure of gadolinium nonahydrate (*15*), it was shown that a linear correlation exists between calculated Connolly surface area of the gadolinium ion and *q*-value (see Figure 1). This calibration curve was developed by iteratively removing waters from the crystal structure of gadolinium nonahydrate and calculating Connolly surface area. To test the predictive capability of this method, this calibration curve was used to determine the *q*-values of the following gadolinium crystal structures: Gd(EDTA) (*1*), Gd(DOTA) (*2*), Gd(DTPA) (*3*), Gd(DTPA-BEA) (*4*), and Gd(TTTA) (*5*) (see Table 1). The predicted *q*-values were in total agreement with the experimentally determined values (*36*).

To develop this as a tool for novel agent design, where no prior structural information exists, we needed to develop a method to generate valid 3D structures for the gadolinium chelates. Since any computationally generated model would be a minimized structure, the force field used had to be augmented to include gadolinium. Nonbonded force field parameters for Gd(III) were developed empirically within SYBYL. A new calibration curve was developed for minimized structures using the minimized gadolinium nonahydrate crystal structure (vide infra). The predictive capability was again tested using the minimized crystal structures listed above. Again, the predicted *q*-values were in complete agreement with the experimentally determined values (*36*).

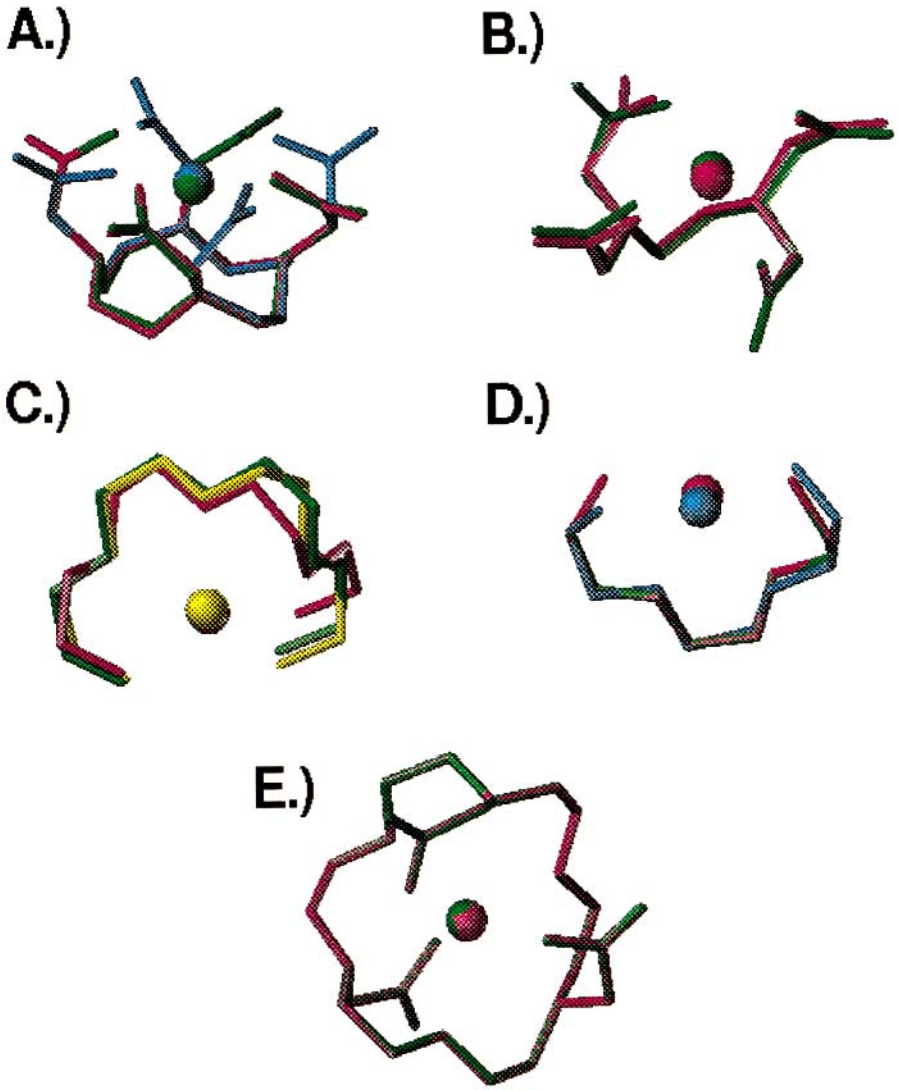


Figure 2. Superposition of minimized crystal structures (green) and the GA generated conformations (magenta) for (A) Gd(DOTA), second unique GA generated conformation shown in blue; (B) Gd(EDTA); (C) Gd(tetraethylene glycol), two crystal structures are reported for this molecule and the second minimized crystal strucure is shown in yellow; (D) Gd(triethylene glycol), the second unique GA generated conformation is shown in blue; (E) Gd(TTTA).

A genetic algorithm based conformational search method (vide infra) was used to generate 3D models for the following chelates: Gd(EDTA) (*1*), Gd(DOTA) (*2*), Gd(DTPA-BEA) (*4*), Gd(TTTA) (*5*), Gd(tetraethylene glycol) (*7*), and Gd(triethylene glycol) (*6*). For Gd(EDTA) and Gd(tetraethylene glycol), one unique low-energy structure was generated (see Figure 2, panels B and C). Two unique equivalent energy structures were generated for Gd(DOTA) and for Gd(triethylene glycol). For Gd(DOTA), one structure is a diastereomer of the minimized crystal structure differing only in the rotation about the $N-CH_2$ bond and the other is the enantiomer of the crystal structure (see Figure 2A). For Gd(triethylene glycol), one structure is the same as the minimized crystal structure and the other is a slightly lower energy structure which is similar in conformation to the minimized crystal structure (see Figure 2D). Two families of structures are generated for Gd(TTTA); one is the same as the minimized crystal structure and the other is the enantiomer of the minimized crystal structure (see Figure 2E). All the GA-generated structures are similar to the minimized crystal structures and have the same *q*-value and number of metal coordinating ligands as the minimized crystal structures. For Gd(DTPA-BEA), two families of structures were generated. Within the families, the structures are very similar and only differ by end methyl rotations. Both structures are similar in energy to the minimized crystal structure, but are inverted at one nitrogen (see Figure 3). These two models still yield the correctly predicted *q*-value and number of metal coordinating ligands and, therefore, are reasonable models to use for design purposes.

Water molecules that exchange rapidly between the inner coordination sphere of the gadolinium ion and the bulk solvent dominate the relaxivity. Despite the fact that our calculations do not take water exchange rates ($1/\tau_M$) into account, the exchange rates for all gadolinium chelates reported thus far are sufficiently rapid to contribute to the relaxivity. In a recent study, the exchange rates [298 K, units of inverse seconds (s^{-1})] ranged from 8.3×10^8 to 4.3×10^5 for a series of gadolinium compounds (*11*). Although this range of exchange rates spans 4 orders of magnitude, the exchange rates are sufficiently rapid to make the value of the relaxivity insensitive to the precise value of the exchange rate for small gadolinium complexes (*37*). Consequently for small gadolinium complexes, the water molecules in the inner coordination sphere may be considered in rapid exchange with the bulk.

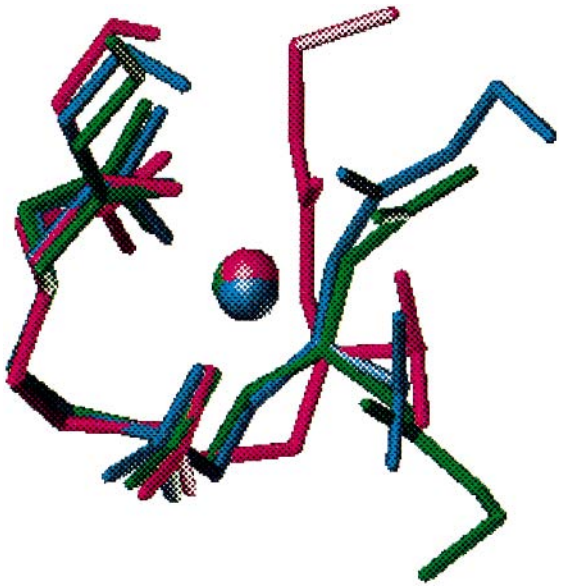

Figure 3. Superposition of minimized crystal structure (green) and the two GA generated conformations (magenta and blue) for Gd(DTPA-BEA).

SUMMARY AND CONCLUSIONS

A quick computational method for predicting integer *q*-value of small molecule gadolinium chelates has been developed. Using the crystal structure of gadolinium nonahydrate, a calibration curve to predict *q*-value from solvent accessible surface area of the gadolinium ion was developed. The calibration curve was tested using the crystal structures of gadolinium chelates obtained from the CSD, thus establishing a linear relationship between the calculated Connolly surface area of the gadolinium ion and experimental *q*-value. Furthermore, a genetic algorithm based protocol which generates valid three-dimensional structures of known gadolinium chelates has been developed. The combination of the genetic algorithm conformational search method and *q*-value calibration curve produce literature consistent *q*-values and structures for selected MRI contrast agents. Use of the described method will help facilitate the discovery of novel MRI contrast agents.

Cellular Uptake of Adamantyl Conjugated Peptide Nucleic Acids

Trine Ljungstrøm, Helle Knudsen, and Peter E. Nielsen*

Center for Biomolecular Recognition, Department of Medical Biochemistry & Genetics, Biochemistry Laboratory B, The Panum Institute, Blegdamsvej 3c, 2200 Copenhagen N, Denmark. Received April 30, 1999; Revised Manuscript Received August 30, 1999

Peptide nucleic acids (PNA) (15-mers) conjugated to adamantyl acetic acid and labeled with fluorescein have been prepared, and their (liposome mediated) uptake in human cells in culture (HeLa, IMR-90 and MDA-MB-453) has been studied by confocal fluorescence microscopy. It is found that adamantyl-PNAs show greatly improved (endosomal) cellular uptake, but that this uptake is dependent on the cell line. Cellular uptake of such lipophilic PNAs is further mediated by cationic liposomes, and in some cases, the intracellular localization is diffuse cytoplasmic or nuclear, again cell-type dependent. The results show that this simple PNA modification can indeed greatly improve cellular uptake, but the effect appears strongly cell-type as well as PNA-sequence dependent.

INTRODUCTION

Short synthetic oligonucleotides as highly specific inhibitors of translation or transcription have shown great promise as antisense (and antigene) gene therapeutic drugs (Agrawal, 1996; Altmann et al., 1996; Sharma and Narayanan 1995; Wagner and Flanagan, 1997; Bennet, 1998). The quest for oligonucleotide analogues and mimics with improved properties in terms of nuclease resistance and target affinity have led to the development of a large number of DNA analogues (Agrawal and Iyer, 1995; De Mesmaeker et al., 1995; Freier and Altmann, 1997).One of the more promising of these mimics is peptide nucleic acid (PNA), which contains a pseudo-peptide backbone composed of uncharged *N*-(2-aminoethyl)glycine units to which the nucleobases are attached via methylene carbonyl linkers (Nielsen et al., 1991; Egholm et al., 1992a,b; Egholm et al., 1993; Hyrup and Nielsen, 1996; Good and Nielsen, 1997). PNA hybridizes with high affinity and sequence selectivity to complementary DNA or RNA oligomers by normal Watson−Crick base pairing (Egholm et al., 1993; Leijon et al., 1994; Brown et al., 1994; Jensen et al., 1997; Eriksson and Nielsen, 1996a,b). Notably, homopyrimidine PNAs binds to sequence complementary targets in double-stranded DNA by forming a strand displacement complex where two PNAs bind to the target strand, forming a triplex, and the nontarget strand is looped out (Cherny et al., 1993; Nielsen et al., 1994a). Such complexes are extremely stable and can efficiently block transcription and replication elongation (Hanvey et al., 1992; Nielsen et al., 1994b; Taylor et al., 1997). Likewise, homopyrimidine PNAs form thermally extremly stable PNA_2−RNA triplexes with targets in RNA (Egholm et al., 1992a,b; Kim et al., 1993). PNA is resistant to degradation by nucleases and proteases and show high stability in cellular extracts (Demidov et al., 1994). They are conveniently synthesized by solid-phase peptide chemistry (Christensen et al., 1995). Taken together, these properties make PNA a promising candidate for development of gene-specific drugs. Indeed, PNA has been shown in vitro to have antisense activity against interleukin-2 receptor α (IL-2Rα) (Hanvey et al., 1992), chloramphenicol acetyltransferase (CAT) (Knudsen and Nielsen, 1996) and promyelocytic leukemia/retinoic acid receptor α (PML/RARα) (Gambacorti-Passerini et al., 1996; Mologni et al., 1998).

Table 1: List of the PNAs Used in the Study[a]

PNA or S-ON	sequence	target
960	Fl-TTT AGC TTC CTT AGC-LysNH_2	CAT
1118	Ada-Fl-TTT AGC TTC CTT AGC-LysNH_2	CAT
1196	Ada-Fl-TTT GGG CGG CAT GAC-LysNH_2	Rb

1401	Ada-Fl-GGT_{Lys} GCT_{Lys} CAC T_{Lys}GC GGC-LysNH_2	Her-2
1402	Fl-GGT_{Lys}GCT_{Lys}CAC T_{Lys}GC GGC-LysNH_2	Her-2
1662	Ada-Fl-ACT TGC GGC TCC GGC C-LysNH_2	Her-2
S-ON	Fl-GGT GCT CAC TGC GGC	Her-2

[a] Ada is adamantyl acetic acid, Fl is fluoresceinated PNA monomer, and T_{Lys} is a thymine PNA monomer with a lysine residue.

However, simple PNAs show very poor cellular uptake when studied in cell culture (Bonham et al., 1995; Gray et al., 1997). Previous experiments with anionic oligonucleotides have shown that their cellular uptake can be greatly improved by covalent attachment of lipophilic groups, such as cholesterol (Letsinger et al., 1989; Stein et al., 1991; Boutorine et al., 1993) or aliphatic chains of different lengths (Kabanov et al., 1990; Saison-Behmoaras et al., 1991; Svinarchuk et al., 1993; Hubus et al., 1995; Mishra et al., 1995). However, the only general solution for delivery of oligonucleotides to cells in culture has been employment of cationic liposomes as vehicles (Bennett et al., 1992; Thierry and Dritschillo, 1992; Zelphati and Szoka, 1996; Wielbo et al., 1997).

Recently, various small peptides have been used to transport PNA into cultured cells. For instance, PNA conjugated to the insulin-like growth factor 1 peptide was reported to be taken up if the cognate receptor was expressed on the cell surface (BALB/c 3T3 cells) (Basu and Wickstrom, 1997). Hybrids between PNAs and cationic peptides, such as the third helix of the homeodomain of Antennapedia, were reported to cross through cell membranes and enter immortal human prostate

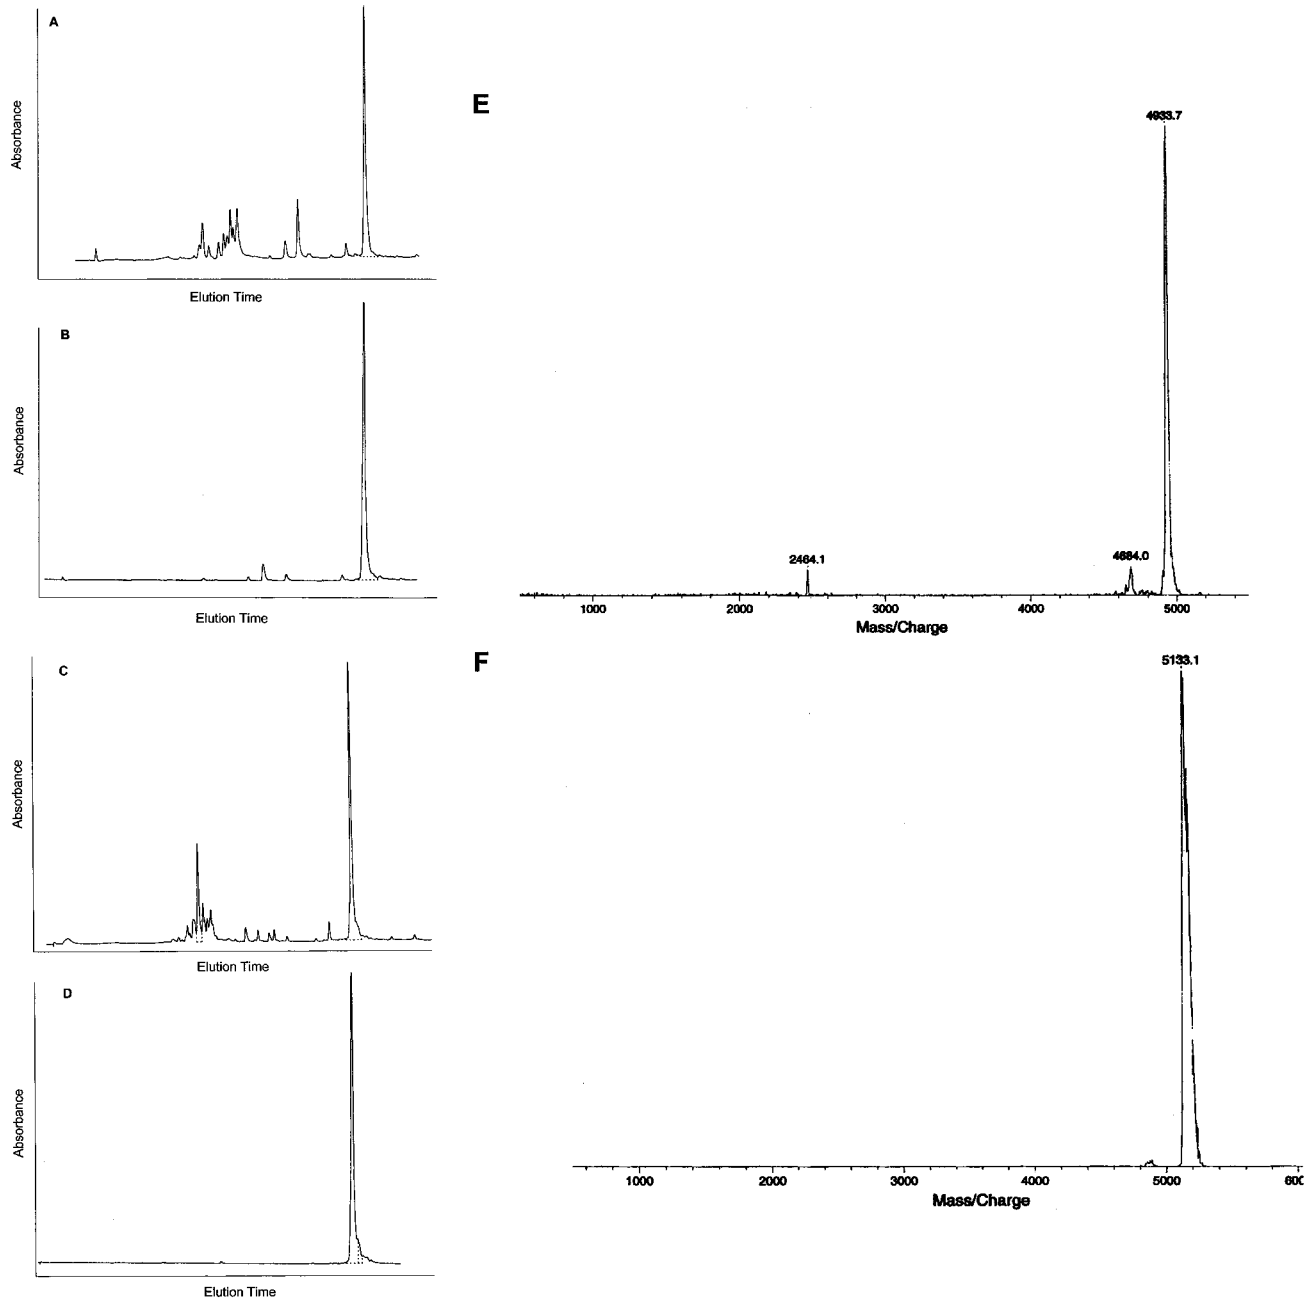

Figure 1. HPLC chromatographs of raw and purified PNA 1253 (A and B, respectively) and 1401 (C and D, respectively). The gradient (35 min) was 0 to 100% (0−30 min, 0 to 50%; 30−33 min, 50%; 33−35 min, 50 to 100%) CH_3CN in H_2O, 0.1% CF_3COOH, and the PNA oligomers eluted at 28 min. MALDI-TOF mass spectra (Kratos Maldi-II) of PNAs 1253 (E) and 1401 (D). The found (and calculated) masses are 4933.7 (4928.8) (PNA1253) and 5133.1 (5141) (PNA1401), respectively. The signal from PNA 1401 was weak and, thus, rather broad and less accurate.

tumor-derived D4145 cells (Simmons et al., 1997). This peptide (or its retro-inverso analogue) was also recently used as a vehicle to carry PNA into mammalian cells (Pooga et al., 1998; Aldrian-Herrada et al., 1998), and in one case, down regulation of an antisense targeted neural receptor was reported using a PNA conjugated to "penetratin" (Pooga et al., 1998).

As PNAs are inherently charge neutral oligomers, these will not spontaneously associate with cationic liposomes as do the anionic oligonucleotides, and liposome delivery of PNAs is therefore impeded by inefficient liposome loading. Others have used cationic oligonucleotides either conjugated to the PNA (Uhlmann et al., 1996) or just complexed by hybridization (Hamilton et al., 1999) to increase the efficiency of liposomal loading. We reasoned that supplying PNAs with a lipophilic tail

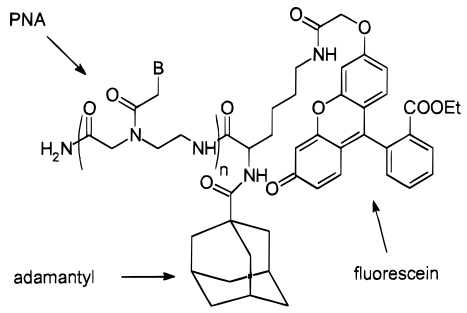

Figure 2. Chemical structure of adamantyl conjugated, fluoresceinated PNA. For regular PNA units R = H and B = adenine, cytosine, guanine or thymine; for T_{lys} modified PNA units R = $-(CH_2)_4-NH_2$ and B = thymine.

should greatly increase their affinity toward liposomes and could even confer spontaneous incorporation upon liposome assembly. Furthermore, such PNA−lipid conjugates could by themselves exhibit improved cellular uptake by initial membrane association and subsequent internalization. We therefore set out to synthesize lipid-PNA conjugates and study their (liposome mediated) cellular uptake.

The cellular uptake of five PNAs was investigated in three different cell lines, HeLa, IMR-90, and MDA-MB-453. Fluorescein-labeled adamantyl-conjugated PNAs were added to cell cultures either alone or in combination with cationic DOPE/DDAB liposomes, and the uptake was observed by fluorescence (confocal) microscopy. We find that the pattern of uptake varies with the type of cells used. Furthermore, the behavior of the PNAs in the cell culture is highly dependent on their sequence as well as the chemical modification.

EXPERIMENTAL PROCEDURES

Synthesis of PNAs and S−ON. PNAs were synthesized and purified as described previously (Christensen et al., 1995). The sequences of the employed PNAs and their gene targets are outlined in Table 1. Conjugation of fatty acids was done using the normal coupling procedure (Christensen et al., 1995). T_{Lys} monomer (D-form) was synthesized and incorporated into PNA oligomers as described (Haaima et al., 1996). As for standard PNA Boc-synthesis, the procedure yielded PNA oligomers of good purity that were further purified by reversed-phase HPLC and characterized by MALDI-TOF mass spectrometry (Figure 1). Typically, the yield of purified PNA was 1−2 μmol from a 10 μmol (50 mg of resin) synthesis. Phosphorothioate oligonucleotides were synthesized by standard procedures and were kindly provided by Dr. Otto Dahl, University of Copenhagen.

Preparation of DOPE/DDAB Liposomes. DOPE/DDAB liposomes were prepared by a modification of the ethanol injection method described by Campbell (Campbell, 1995). Briefly, 13.4 μmol of DOPE (dioleyl-L-α-phosphatidylethanolamine) and 6.6 μmol of DDAB (dimethyldioctadecylammonium bromide) were dissolved in 1 mL of 96% ethanol. Then 40 μL of this solution was combined with 10 μL of a 2.5 mM PNA solution in DMSO. The resulting 50 μL of PNA/lipid mix was added rapidly to 950 μL of sterile distilled water while vortex mixing. The PNA concentration in the liposome solution was thus 25 μM.

Uptake Experiments. The cells were maintained at 37 °C in a humidified atmosphere containing 5% CO_2. The human breast cancer cell line MDA-MB-453 and HeLa cells were grown in RPMI 1640 medium containing Glutamax, penicillin/streptomycin (10 μg/mL), and 10% fetal calf serum. The human fibroblast cell line IMR-90 was grown in DMEM containing the same supplements. On day 0, the cells were plated at the appropriate density in 35 mm dishes containing a glass coverslip. On day 1, the semiconfluent cells were washed twice with Opti-MEM (Life Technologies: modified Eagle medium with L-glutamine, $NaHCO_3$, Hepes, sodium-pyruvate, hypoxanthine, thymidine, trace elements, and growth factors) and given 1 mL of OptiMEM containing either PNA or DNA alone or PNA combined with DOPE/DDAB liposomes or DNA combined with LipofectAMINE. On day 3, the cells were washed three times with PBS and fixed for 15 min on ice in 3% formaldehyde/0.2% glutaraldehyde. The coverslips were then mounted on objective glasses and the cells examined by fluorescence microscopy on a Leitz Diaplan microscope. Micrographs were taken using a Kodak Ektachrome 1600 ASA film. Confocal microscopy was performed on a Nicon DIAPHOT 200 controlled by a Silicon Graphics Computer.

RESULTS AND DISCUSSION

Initially, we synthesized PNAs conjugated to various fatty acids (heptanoic acid, decanoic acid, dodecanoic acid, and adamantyl acetic acid) by coupling of this acid to the terminal amine of a PNA on the solid support using conventional in situ activation, followed by deprotection and cleavage from the solid support by the low/high TFMSA procedure routinely used for PNA synthesis (Christensen et al., 1995). However, upon purification by RP-HPLC, only the heptyl and adamantyl derivatives eluted off the column as sharp peaks, and since these in initial cellular experiments appeared to behave identical, we focused on the adamantyl derivatives which could be purified and handled without special precautions.

Four different 15-mer PNAs (1118, 1196, 1253, and 1662) as listed in Table 1 were conjugated to adamantyl and a fluorescein monomer (Lohse et al., 1997) was included as well as a marker for cellular uptake. Furthermore, a derivative of PNA 1253 containing three T_{Lys}-monomers (having a lysine replacing the glycine in the backbone) was made (PNA 1401) to increase the aqueous solubility of the PNA (Haaima et al., 1996). Finally, control PNAs without adamantyl were made (PNAs 960, 1252, and 1402) as well as a phosphorothioate corresponding to PNAs 1253, 1401, and 1402.

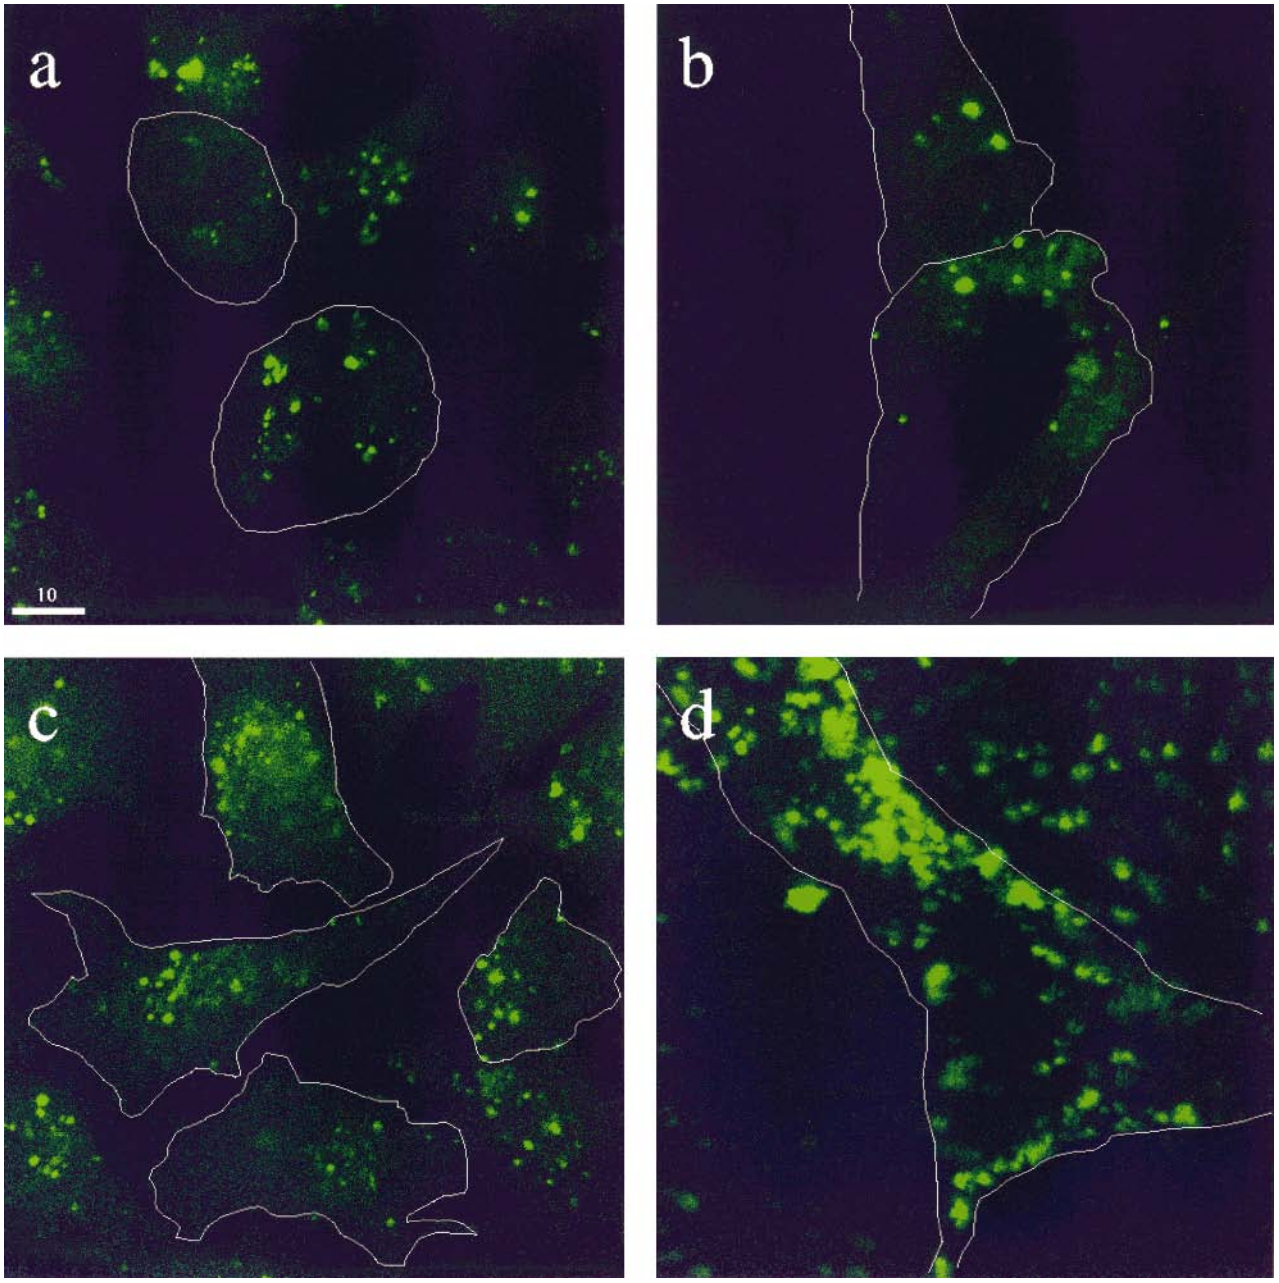

Figure 4. Confocal images of cells incubated overnight with 1 μM fluorescein labeled adamantyl-PNA. (a) HeLa cells incubated with PNA 1118. (b) IMR-90 cells incubated with PNA 1118. (c) HeLa cells incubated with PNA 1196. (d) IMR-90 cells incubated with PNA 1196. The scale-bar is 10 μm. The contour of the cells are indicated by white lines.

Uptake of Adamantyl-Conjugated PNAs. To avoid possible interfering interactions between PNA and serum proteins, the PNAs were added to the cells in serum-free medium. Generally, the uptake was evaluated after an overnight incubation (16−18 h).

Three different monolayer cell lines were used for the uptake studies (HeLa, IMR-90, and MDA-MB-453) and the PNA was delivered either in pure water (added to the serum free medium) or as a liposome preparation (in serum free medium). Selected and representative fluorescence images are presented in Figures3−6 and schematically the results are compiled in Table 2. At first sight, these data may appear confusing since the uptake apart from being strongly influenced by the presence of the lipophilic adamantyl group as well as the use of a cationic liposome vehicle (Figure 3), is also strongly dependent both on the cell type and on the PNA (sequence). Nonetheless, some trends can easily be extracted.

First of all, no significant cellular uptake was found for any of the simple PNAs (960 and 1252) even with the help of liposomes. Furthermore, the attachment of the adamantyl group clearly increased the spontaneous uptake (PNA 1118 and 1196), although PNA 1118 was not taken up by the MDA-MB-453 cells. This uptake appeared, however, exclusively endosomal as concluded from a distinctly punctuated appearance by (confocal) fluorescence microscopy (Figure 4). Employment of cationic liposomes to mediate the uptake of the adamantyl PNAs 1118 and 1196 clearly increased the uptake (Figure 5). However, more interestingly a qualitatively different intracellular distribution of the PNA was obtained at least with some cells. In HeLa cells PNA 1118 showed clear nuclear as well as diffuse cytoplasmic localization (Figure 6a), whereas diffuse cytoplasmic localization was obtained with PNA 1196 in IMR-90 cells (Figure 5b).

PNAs 1253 and 1662, which are both relatively purine (and especially guanine) rich, aggregated easily and,

therefore, could not be handled in terms of cellular uptake experiments. To produce a more water-soluble derivative of PNA 1253, we included three T_{Lys} monomers in the PNA (1401), which introduces three positive charges and which we have previously found to confer significantly increased aqueous solubility (Haaima et al., 1996). As a control, we also tested such a PNA (1402) lacking the adamantyl group. Quite interestingly, membrane association as well as some endosomal uptake was observed with this PNA—in contrast to the normal PNA (1252)—indicating that simply equipping the PNA with positive charges may significantly facilitate cellular uptake. This mechanism could be analogous to that responsible for the effect of, e.g. the Antennapedia peptide which is also cationic, as well as the use as polyethylenimine as carrier in DNA transfection. The introduction of the lysine backbone modification also significantly increased the aqueous solubility of the corresponding adamantyl conjugated PNA (1401) which showed spontaneous endosomal uptake (Figure 6). This uptake was, however, not facilitated further by liposomes. Instead aggregation was observed. Possibly, the positive charges of the PNA are interfering with the incorporation into the also cationic liposomes.

Finally, uptake of the PNAs were compared with the uptake of a phosphorothioate having the same sequence as PNA 1253 (and 1401 and 1402). The phosphorothioate was added to HeLa and IMR-90 cells either alone or combined with commercial liposomes (LipofectAMINE) and to MDA-MB-453 cells combined with LipofectAMINE. The S−ON alone showed clear endosomal uptake in HeLa and IMR-90 cells, whereas in combination with LipofectAMINE strongly fluorescent nuclei were observed in all three cell lines (Figure 7).

Table 2: Summary of Uptake Patterns of the PNAs in the Three Cell Lines Studied

PNA or S-ON	treatment	HeLa	IMR-90	MDA-MB-453

CONCLUSION

The present results clearly demonstrate that conjugation of PNAs to a simple lipophilic ligand, such as an adamantyl group, can confer dramatically increased cellular uptake properties, especially when mediated by cationic liposomes. The results also show that increased cellular uptake may be attained by using a lysine backbone modification. However, the results just as clearly show that the cellular uptake by any of these schemes is highly dependent on the cell-type as well as on the PNA sequence. The limited data, unfortunately, does not yet allow us to deduce guidelines as to which modification to be used with which cells and PNA sequences, but it should eventually be possible to arrive at such more general guidelines. Nonetheless, the adamantyl and backbone lysine modifications represent significant improvements toward more efficient PNA antisense reagents. Naturally, the real test of such PNAs will be antisense efficacy and such experiments are now in progress.

Prolonged Circulating Lives of Single-Chain Fv Proteins Conjugated with Polyethylene Glycol: A Comparison of Conjugation Chemistries and Compounds

L. Stanford Lee,* Charles Conover, Celine Shi, Marc Whitlow,† and David Filpula*

Enzon Inc./SCA Ventures, 20 Kingsbridge Road, Piscataway, New Jersey 08854-3969. Received June 14, 1999; Revised Manuscript Received August 16, 1999

The utility of single-chain Fv proteins as therapeutic agents would be substantially broadened if the circulating lives of these minimal antigen-binding polypeptides were both prolonged and adjustable. Poly(ethylene glycol) (PEG) bioconjugate derivatives of the model single-chain Fv, CC49/218 sFv, were constructed using six different linker chemistries that selectively conjugate either primary amines or carboxylic acid groups. Activated PEG polymers with molecular weights of 2000, 5000, 10 000, 12 000, and 20 000 were included in the sFv bioconjugate evaluation. Additionally, the influence of PEG conjugate geometry in branched PEG strands (U-PEG) and the effect of multimeric PEG-sFv bioconjugates on circulating life and affinity were examined. Although random and extensive PEG polymer conjugations have been achievable in highly active derivatives of the prototypical PEG-enzymes, PEGylation of CC49/218 sFv required stringent adjustment of reaction conditions in order to preserve antigen-binding affinity as measured in either mucin-specific or whole cell immunoassays. Purified bioconjugates with PEG:sFv ratios of 1:1 through 2:1 were identified as promising candidates which exhibit sFv affinity (K_d) values within 2-fold of the unmodified sFv protein. Interestingly, PEG conjugation to carboxylic acid moieties, using a PEG-hydrazide chemistry, achieved significant activity retention in bioconjugates at a higher PEG:sFv ratio (5:1) than with any of the amine-reactive activated PEG polymers. Prolonged circulating life in mice was demonstrated for each of the PEG conjugates. An increase in PEG polymer length was found to be more effective for serum half-life extension than a corresponding increase in total PEG mass. For example, CC49/218 sFv conjugated to either one strand of PEG-20000, or four strands of PEG-5000, displayed about 20- or 14-fold increased serum half-life, respectively, relative to the unmodified sFv. The demonstrated suitability of established random conjugation chemistries for PEGylation of sFv proteins, in conjunction with innovative site-specific conjugation methods, indicates that production of a panoply of sFv proteins with both engineered affinity and tailored circulating life may now be achievable.

INTRODUCTION

The immunoglobulin repertoires in vertebrates consist of antigen-binding domains—the Fv modules—which may be employed within the animal in a limited number of Fc formats corresponding to IgG, IgM, IgA, IgE, and IgD isotypes. The utility of antibody derived therapeutics has been confined by the restrictive circulating lives and associated Fc effector functions of mAbs. It has been the goal of antibody engineers to greatly extend the versatility of antigen-binding proteins by tailoring the binding properties, valency, effector functions, and pharmacokinetic behavior of immunomolecules through protein engineering and bioconjugate strategies. The single gene, single polypeptide design of single-chain Fv proteins provides a minimal antigen-binding format which has been extensively explored by antibody engineers in the past decade (*1*−*3*). Early clinical trials are employing sFv derived therapeutics as immunotoxins, imaging agents, antagonists, targeting agents, and intracellular antigen-binding compounds (*4*−*7*). The clinical versatility and therapeutic efficacy of sFv proteins may be expanded by drug delivery technologies that provide control over the rate at which these small protein compounds are cleared from circulation via renal filtration. The use of very high-affinity human sFv molecules or multivalent/multi-specific formats are promising solutions to this challenge (*8*−*13*). However, to provide a more general approach to controlling the circulating lives of sFv proteins, we wished to investigate the potential of a bioconjugate strategy that is clinically well established for enhancing the efficacy of other protein drugs.

Two FDA licensed therapeutics and several compounds undergoing clinical trials employ PEGylation,[1] the conjugation of compounds with poly(ethylene glycol) polymers, to prolong circulating life and reduce immunogenicity. In general, activated PEG polymers reactive with primary amines have been employed and PEG conjugation of the majority of available lysine residues on enzyme therapeutics such as adenosine deaminase and asparaginase has provided extensively modified derivatives which still maintain specific activities similar to the unmodified enzymes (*14*−*16*). In comparison, PEGylation of cytokines, hormones, and other small protein ligands generally represents a greater challenge in enhancing the clinical potency of the PEG derivatives due to the opposing effects of (1) a reduction in receptor binding affinity versus (2) a prolonged circulating life relative to the unmodified protein (*17*−*23*). The antigen-binding site may constitute about one-third of the Fv

surface area (*24*) and reactive amines or carboxyls are prevalent surface moieties on the hypervariable and framework regions of essentially all Fv sequences (*25*). Consequently, extensive random conjugations may be inactivating either through direct attachments to antigen-binding contact residues or as a result of transient steric hindrance and diffusional constraints from the long polymer strands.

We have previously reported the successful construction of sFv variants with engineered cysteine or N-glycan sites which retain binding activity following site-specific single or multiple PEG attachments (*4*, *26*). However, these structural adjustments are not suitable for all therapeutic sFv applications. In this report, we describe the controlled application of conventional random PEGylation chemistries in production of delimited PEG-CC49/218 sFv compounds which have binding affinities comparable to the parent compound, yet display markedly extended circulating lives that correlate with the mass and length of the attached polymers. We also demonstrate the capacity of homobifunctional PEG polymers to generate multivalent sFv compounds that display increased functional affinity (avidity) and may simulate the long circulating life and multivalency of antibodies.

EXPERIMENTAL PROCEDURES

Materials. The *Escherichia coli* GX9251 expression strain for production of CC49/218 sFv protein has been described (*27*). Precast polyacrylamide slab gels (4−20%) were obtained from Novex (San Diego, CA). Bovine submaxillary mucin type I was purchased from Sigma (St. Louis, MO). Superdex 75 was obtained from Pharmacia Biotech (Piscataway, NJ). POROS HS was purchased from PerSeptive Biosystems (Framingham, MA). Rabbit anti-CC49/218 sFv polyclonal antibody was obtained from HRP (Denver, PA). Mouse anti-CC49/218 polyclonal antibody was supplied by Enzon. PEG-hydrazide hydrochloride (Hz-PEG-5000), PEG-trichlorophenyl carbonate (TPC-PEG-5000), and *N*-hydroxysuccinimide PEG-biotin (NHS-PEG-3400-biotin) were obtained from Shearwater Polymers (Huntsville, AL). Succinimidyl carbonate PEG (SC-PEG), Thiazolidine-2-thione PEG (T-PEG), branched SC-PEG (U-PEG), and bifunctional SC-PEG (BSC-PEG) were synthesized by Enzon as previously reported (*16*, *28*−*30*). Calibrated PEG-protein molecular mass standards were obtained from Enzon.

Purification and Characterization of CC49/218 sFv Protein. The purification of clinical-grade CC49/218 sFv from *E. coli* expression strain GX9251 by refolding and cation-exchange chromatography has been described in detail (*27*). Purified sFv was further characterized by SE-HPLC and RP-HPLC as previously reported (*10*, *27*, *31*). Protein determination employed the BCA (bicinchoninic acid) procedure according to the vendor's instructions (Pierce Chemical Co., Rockford, IL).

Molecular Modeling. The model of 4-4-20/212 sFv was constructed on an Evans & Sutherland PS330 using Frodo, starting from the 4-4-20 Fab structure (PDB entry 1FLR). Poly(ethylene glycol) strands were modeled on surface accessible lysine residues, L112, and H78 (*26*), using the program Add_PEG (written by M. Whitlow). Add_PEG builds the PEG polymer one atom at a time, checking each for unfavorable contacts. Each atom is added using a random procedure that generates trans, gauche+, and gauche− in the ratios of 0.68:0.16:0.16.

Chemical Analysis of PEG-sFv Derivatives. Three methods were employed for determination of the stoichiometry of PEG attachment on sFv proteins. First, the TNBS method of Habeeb (*32*) was performed for quantitation of free primary amines. Second, the molecular mass of individual PEG-sFv compounds was examined by SDS−PAGE and compared to calibrated PEG-protein standards with known PEG:protein stoichiometry. Proteins were electrophoresed on precast 4−20% slab gels and protein bands were visualized with Coomassie brilliant blue G-250. Area quantitation of stained bands was performed using a Molecular Dynamics PD-SI laser scanner. PEGylated polypeptides exhibit reduced mobility on SDS−PAGE compared to unmodified polypeptides of equivalent molecular mass. For example, PEG-sFv molecules containing one PEG-5000 linear unbranched polymer per protein display an increased molecular mass of approximately 10 000 compared to the unmodified sFv. Area quantitation of stained bands was also used to estimate the percentage of each PEG derivative if the conjugation reaction produced multiple fractions. The PEG/sFv stoichiometric values are reported as the average for the integrated distribution. Third, size-exclusion HPLC was performed on selected PEG-sFv samples to analyze the molecular size of the derivatives compared to PEG-proteins with calibrated polymer numbers.

PEG Modification of Primary Amines. The model CC49/218 sFv protein contains 19 primary amine groups including lysines and the N-terminus. The amine-reactive PEG polymers examined in this study included SC-PEG with molecular masses of 2000, 5000, 10 000, 12 000, and 20 000; U-PEG-10000; NHS-PEG-3400-biotin; T-PEG-5000; T-PEG-12000; and TPC-PEG-5000. Chemical conjugation chemistries for these polymers have been published (*16*, *28*−*30*). While phosphate buffers are commonly employed in these protocols, the choice of borate buffers may beneficially influence the PEGylation reaction rates and resulting products. As an example, for derivatives modified with SC-PEG-5000, the CC49/218 sFv (2 mg/mL) in 0.1 M sodium borate buffer, pH 8.0, was reacted with SC-PEG at the designated molar ratios for 1 h at 25 °C. The reaction was quenched by the addition of 50 mM glycine and the product was purified by Superdex 75 SE-HPLC.

PEG Modification of Carboxyl Sites. The CC49/218 sFv protein sequence includes 19 aspartic acid/glutamic acid groups in addition to the carboxyl terminus of the polypeptide. The utility of PEG-hydrazide in selective modification of carbodiimide-activated protein carboxyl groups under acidic conditions has been described (*16*, *33*). CC49/218 sFv protein (2 mg/mL) in 50 mM NaCl was adjusted to pH 4.75 by addition of HCl. PEG-hydrazide powder was added to a final molar excess of 200-fold. The reaction was initiated with the addition of EDC in 100:1

molar quantities relative to the sFv protein. The reaction was allowed to proceed for 45 min, while maintaining the pH (4.75−5.0). The reaction product was chromatographed on size-exclusion−HPLC and high molecular weight fractions were isolated.

Bifunctional PEG Modification of CC49/218 sFv. The homobifunctional activated PEG polymer BSC-PEG-5000, which includes one activated SC group at each of the two polymer termini, was utilized in cross-linking reactions to produce multimeric Fv (mFv). BSC-PEG-5000 (1.89 mg) was dissolved in 0.1 mL of 25 mM Mops (3-[*N*-morpholino]propane-sulfonic acid) buffer, pH 7.3. Within 10 s of dissolution, the PEG solution was added to CC49/218 sFv protein (1.5 mg/mL) in 2 mL of PBS (25 mM sodium phosphate, pH 7.3, 0.15 M NaCl). The mixture was stirred for 1 h at 24 °C. The reaction was terminated by addition of solid guanidine hydrochloride (GuHCl) to a final concentration of 0.6 M. The material was immediately applied to a 2 cm × 60 cm Superdex 75 SE-HPLC column previously equilibrated in 50 mM Tris-HCl, pH 7.3, 1 mM $CaCl_2$, 0.1 mM PMSF (phenylmethanesulfonyl fluoride), 50 mM KCl, and 60 mM GuHCl. Following fractionation of heterogeneous multimers by gel filtration chromatography, monomer, dimer, and trimer fractions were identified from comparisons to calibrated PEG-sFv standards by SDS−PAGE and SE-HPLC.

ELISA for sFv Binding Activity. Immunoassay procedures were performed using modifications of previously published procedures (*10*, *34*−*36*). Bovine submaxillary mucin (1 μg/100 μL well) was used to coat microtiter plate wells (MaxiSorp, Nunc, VWR Scientific, Boston, MA). The purified CC49/218 sFv protein or PEGylated sFv derivatives were diluted serially in PBS containing 1% BSA and incubated in the coated wells at 22° C for 1 h. After the plate had been washed with PBS containing 0.05% Tween 20 (PBS-T), the bound sFv was detected by a 1 h incubation with a secondary anti-CC49/218 sFv rabbit serum (1:2000) followed by a PBS-T wash and a 1 h incubation with an HRP-conjugated goat anti-rabbit serum (1:2000 dilution) at 22 °C. The plates were washed three times with PBS-T. After addition of 50 μL of 3,3′,5,5′-tetramethylbenzidine (TMB) and 50 μL of 1 M H_2SO_4 as described by Harlow and Lane (*34*), the plate was read at 450 nm using a Molecular Devices (Sunnyvale, CA) plate reader.

Competition ELISA. The apparent affinity constants (K_d) of the PEGylated sFv derivatives were determined using biotin-labeled CC49/218 sFv in competition immunoassays as reported previously (*26*, *35*). HRP-conjugated streptavidin (Pierce) was employed as the detection agent.

ELISA for Relative Affinity of Multimeric Fv. The method of Friguet et al. (*36*) was used for comparison of the relative affinities of mFv derivatives. PEGylated CC49/218 sFv compounds were incubated at varied molar ratios with bovine submaxillary mucin in PBS for 24 h at 4° C. ELISA determinations of the unbound and bound sFv fractions were performed as described above.

Circulating Life in Mice. Pharmacokinetics of sFv and PEGylated sFv derivatives were measured in ICR (CD-1) 7−8 week-old mice supplied by Harlan Sprague Dawley (Madison, WI). A single injection (200 μL) with 60 μg of protein of PEG-sFv derivatives was performed via the tail vein. After compound administration, sampling of blood (100 μL) via the recta orbital sinus was undertaken following anesthetization with 0.09% Avertine. In the minimal standard protocol ($N = 6$): three mice were bled at 2 min and 1, 4, and 8 h; three other mice were bled at 15 min, and 2 and 6 h; all six mice were bled at 24 h. Blood was allowed to clot and then processed for serum and immediately frozen. The concentrations of the modified, active sFv were measured by ELISA. The circulatory half-life, area under the curve, and mean residence time for the sFv compounds were calculated using a one-compartment i.v. bolus model (WinNonlin software package, Scientific Consulting, Apex, NC). The correlation between the observed and predicted model time points was ≥95%.

RESULTS AND DISCUSSION

Characterization of Purified CC49/218 sFv. The detailed purification protocol for clinical-grade CC49/218 sFv, which recognizes the human pancarcinoma antigen TAG-72, has been reported (*27*). Vialed CC49/218 sFv protein (*37*) was determined by SDS−PAGE and RP-HPLC to exhibit ≥99% homogeneity. We have previously reported that CC49 sFv with the 18 residue "218" linker maintains a monomeric rather than multimeric structure (*31*). SE-HPLC characterization of CC49/218 sFv demonstrated that multimeric Fv species constitute less than 1% of the freshly purified protein preparation. Mucin-binding activity of the sFv protein was characterized by ELISA and competition ELISA as previously described (*35*) and the apparent dissociation constant, $K_d = 4.5 \times 10^{-9}$ M, was determined as previously reported (*26*).

Molecular Modeling of PEGylated sFv. Covalent attachment of poly(ethylene glycol) polymers is a proven drug delivery strategy which is employed in established FDA-licensed protein therapeutics and several ongoing clinical trials of experimental medicines (*14*, *15*). Initial success in the use of random and extensive PEGylation of enzyme therapeutics having small molecule substrates demonstrated the capacity of many such enzymes to tolerate PEG conjugation on the majority of the surface lysines while maintaining suitable enzymatic specific activity. In contrast to this global conjugation approach for enzymes, a more parsimonious PEGylation strategy is mandated for small protein ligands such as cytokines, hormones, and peptides (*17*, *18*, *22*) by utilizing either site-specific conjugations or controlled and limited conjugations. The goal of these studies is to introduce the benefits of prolonged circulating life and diminished clearance by PEGylation, while maintaining acceptable biological activity for the bioconjugate. As shown in Figure 1, single-chain Fv molecules constitute a family of small proteins with six hypervariable antigen-binding loops (CDRs) within a conserved β-sheet framework architecture. We have shown previously (*4*, *26*) that the use of site-specific sFv conjugations to engineered cysteines or *N*-glycans is a promising approach for selected applications. However, it would also be desirable to develop sFv PEGylation methodologies that employ clinically explored linker chemistries, which also do not require an alteration of the primary sequence of the sFv of interest. Molecular modeling of a representative sFv protein conjugated at two exposed lysines to PEG-12000 polymers is illustrated in Figure 2. The model sFv protein is derived from the available crystal structure of 4-4-20 anti-fluorescein Fab (*26*).

The degree of surface exposure of lysine, aspartic acid, and glutamic acid residues for 34 Fv structures is shown in Table 1. These three amino acid moieties are partially to completely exposed for most Fv residue assignments. About 21% percent of the surface-exposed lysines and 27% of the exposed carboxyls occur within the CDR segments, though not necessarily in antigen contacts. In

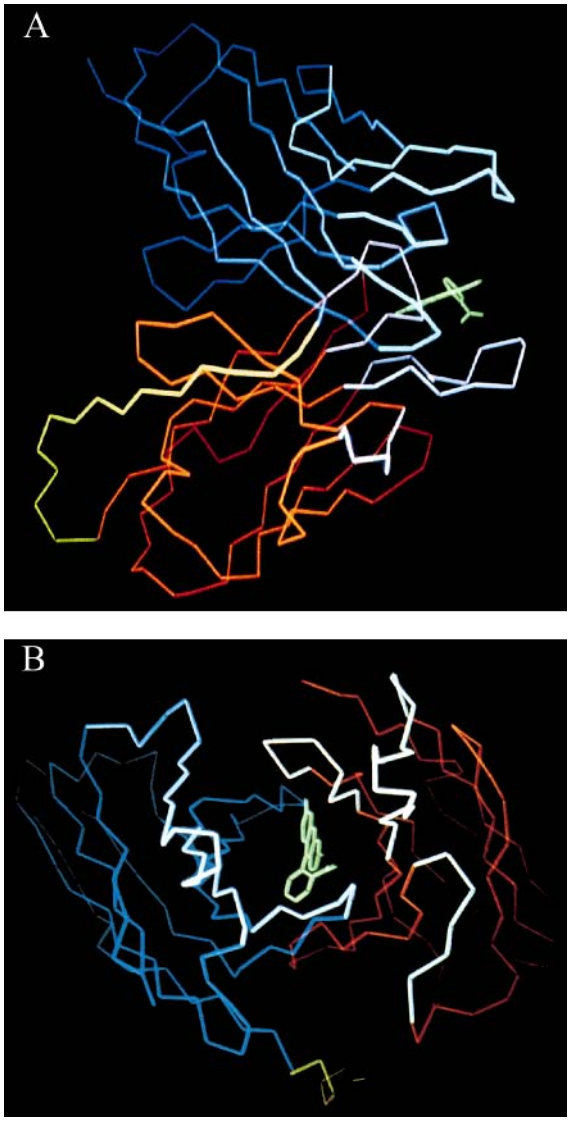

Figure 1. Two views of the V_L-linker-V_H anti-fluorescein 4-4-20/212 sFv model based on the Fab crystal structure. The V_L is shown in red, the V_H in blue, the linker in yellow and the antigen in green. The CDRs have been highlighted in light shades. (A) Antigen-binding site is at right in the α-carbon tracing model. (B) The molecule shown in panel A is rotated 90° on two axes placing the antigen-binding site in the center of the sFv model.

addition, single-chain Fv proteins have an exposed amine at the N-terminus and an exposed carboxyl group at the C-terminus plus additional target residues within the engineered linker peptide (Figure 1). While the correlation of the degree of surface exposure of these residues and their reactivity to conjugation will also be influenced by regional chemical and steric factors, the prevalence and dispersity of these three amino acids on Fv surfaces suggest that optimal PEGylation chemistries for these target residues may need to be carefully tailored for individual sFv. We chose as a model protein, CC49/218 sFv, which was recently investigated clinically as an imaging agent for metastatic colorectal carcinoma (*37*). The sFv exhibited rapid blood and whole body clearance, almost exclusively via renal clearance. As shown in Figure 3, we have chosen a fairly challenging model murine sFv wherein four of the total 18 lysines are within designated CDR regions while five of the total 19 aspartic/glutamic acid residues are within CDR loops. In comparison, the Kabat consensus sequence for a prototypical human V_kI/218/V_HIII sFv contains 11 lysines (two in CDRs) and 17 aspartic/glutamic acids (five in CDRs) if the most commonly occurring amino acids at each position are represented (*25*).

PEGylations of sFv Primary Amines. Two critical parameters, (a) relative binding affinity and (b) circulatory retention in mice, were evaluated for PEGylated sFv compounds using five different activated PEG linker chemistries. In addition, PEGylated sFv conjugates were evaluated by SDS−PAGE, SE-HPLC, and chemical analysis in order to estimate the polymer:protein stoichiometry and heterogeneity of the compounds. The PEGylation reaction conditions (see Experimental Procedures) require an excess of activated PEG relative to sFv protein, and the relative stoichiometry and reaction times were adjusted to optimize the polymer number on the bioconjugate while also maintaining acceptable binding activity. The five amine reactive linker chemistries included succinimidyl carbonate (SC-PEG), thiazolidine-2-thione (T-PEG), *N*-hydroxysuccinimide (NHS-PEG), trichlorophenyl carbonate (TPC-PEG), and branched SC-PEG (U-PEG). Incremental PEG polymer lengths of 2, 5, 12, and 20 kDa were additionally investigated for the SC-PEG linker chemistry. PEGylated sFv proteins were purified by SE-HPLC and cation-exchange chromatography to completely separate bioconjugates from any remaining unmodified sFv protein. Our initial ELISA results indicated that attachment of greater than four PEG polymers per sFv using any of these five methods resulted in diminution of sFv apparent affinity by 30−100-fold (data not shown). Consequently, we focused our attention on the goal of producing minimally PEGylated sFv, which displayed apparent binding affinities within one log value of the unmodified protein. Figure 4 shows an SDS−PAGE analysis of the bioconjugate preparations used in the subsequent ELISA and pharmacokinetic studies. While random conjugation chemistries are expected to produce heterogeneous mixtures of bioconjugates that correspond to differences in the number of modified amines, the overall dispersity in bioconjugate masses under our optimized reaction conditions was relatively limited as seen in Figure 4. For most reactions, the production of a single predominant molecular size of PEG-sFv was observed, which may be accompanied by a subpopulation of bioconjugates of larger molecular size. This simplified the estimation of the average PEG number per sFv protein in the purified preparations. Under the selected reaction conditions, one major molecular mass constituted the majority of the total PEGylated sFv product using all of the amine-reactive PEG polymers except SC-PEG-2000 and SC-PEG-5000. Competition ELISA demonstrated excellent retention of apparent binding affinity (K_d) in representative minimally PEGylated sFv proteins as shown in Table 2. The PEG-20000 sFv bioconjugate exhibited the greatest difference in apparent K_d (7.5×10^{-9}) when compared to the unmodified CC49 sFv (4.5×10^{-9}). We have previously reported an increase in apparent K_d of 2- and 12-fold for glycosylated sFv and multiply PEGylated, glycosylated CC49/218 sFv, respectively (*26*). While identification of the most reactive primary amine sites for each individual sFv protein and for each individual activated PEG polymer would require peptide mapping and other chemical analyses, the demonstrated capability of randomly attaching one or two polymers to active sFv molecules suggests that the lysines within, or very near, the antigen-binding site may not be the most reactive moieties using these reaction conditions.

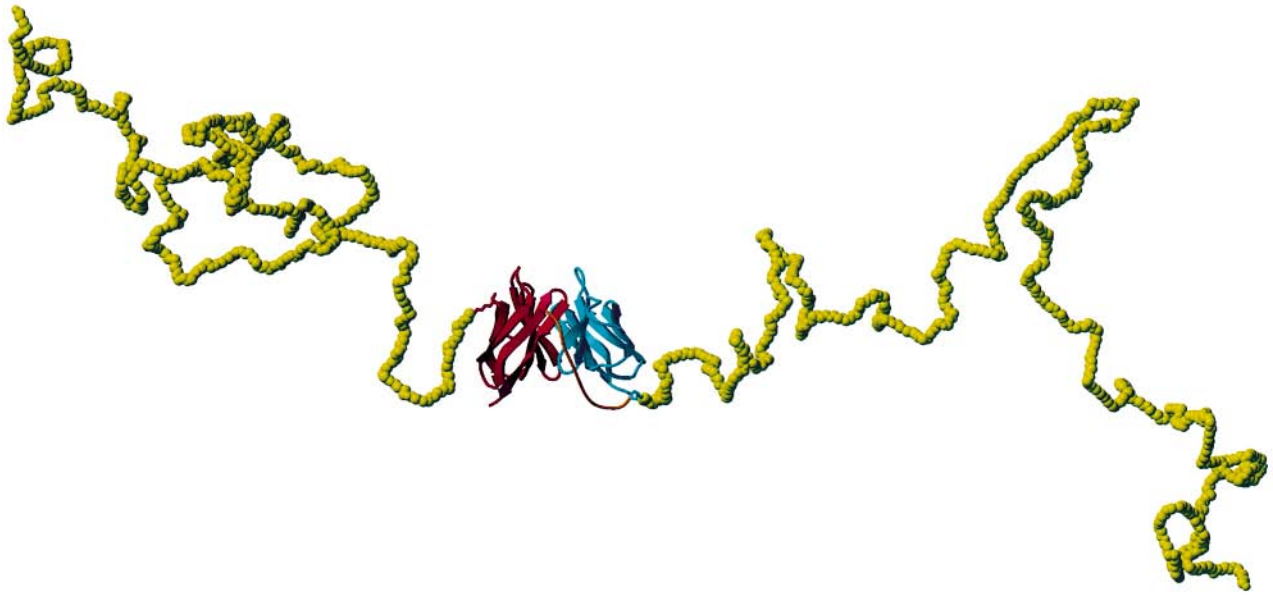

Figure 2. Molecular model of PEGylated V_L-linker-V_H 4-4-20/212 sFv. The PEG-12000 polymers attached to surface lysines L112 (blue) and H78 (red) are shown as yellow CPK models. The 4-4-20/212 sFv is shown as a ribbon diagram, with the light chain in blue; the linker in orange; and the heavy chain in red. The figure was produced using MolScript (45) and Raster3D (46).

Table 1. Exposure Patterns of CDR and Framework Residues in 34 Fv Structures[a]

amino acid	Bu	mB	pB	mE	Ex	totals
CDR residues						
lysine	0	5	13	32	28	78
aspartic acid	14	21	21	28	37	121
glutamic acid	7	6	10	12	8	43
framework residues						
lysine	9	11	39	128	109	296
aspartic acid	59	13	22	45	69	208
glutamic acid	20	4	37	92	85	238
totals	109	60	142	337	336	984

[a] Data adapted from compilation by Padlan (*24*) for 34 human and mouse Fv regions of known three-dimensional structures, which were analyzed for fractional solvent accessibilities of residues within CDR and framework sequences. The five categories of relative solvent exposure are defined from the following range of fractional accessibility values: 0.00−0.20, completely buried (Bu); 0.20−0.40, mostly buried (mB); 0.40−0.60, partly buried/partly exposed (pB); 0.60−0.80, mostly exposed (mE); ≥0.80, completely exposed (Ex).

Figure 3. Amino acid sequence of CC49/218 sFv protein. Lysine (K) residues are indicated (#). The amino acids aspartic acid (D) and glutamic acid (E) are also highlighted (*). CDR sequences are underlined and the 218 linker is in italics.

Carboxyl-Reactive PEGylation and Branched PEG. Charged amino acid residues, including lysine, aspartic acid, and glutamic acid, have a marked tendency to be solvent accessible on protein surfaces (Table 1). Conjugation to carboxylic acid groups of proteins is a less frequently explored approach for production of protein bioconjugates. However, the hydrazide/EDC chemistry described by Zalipsky and colleagues (*16*, *33*) offers a practical method of linking PEG polymers to protein carboxylic sites. For example, this alternate conjugation chemistry has been shown to be superior to amine linkages for PEGylation of brain-derived neurotrophic factor (BDNF) while retaining biological activity (*38*). Maeda and colleagues have also found carboxyl-targeted PEGylation to be the preferred approach for bilirubin oxidase conjugations (*39*). Two significant observations from our investigations of the conjugation reactions of Hz-PEG-5000 with CC49 sFv are as follows: (a) the employment of much higher PEG concentrations in the PEGylation reactions was possible in generation of active PEG-sFv compounds and (b) the retention of antigen-binding activity in PEG-sFv compounds was possible with increased numbers of PEG polymers on the bioconjugates. Specifically, antigen-binding activity was lost by PEGylation of CC49 sFv with a 14-fold or greater molar excess of activated PEG polymer using any of the amine chemistries with straight-chain polymers; whereas the activity was well preserved when the SC-PEG per sFv molar reaction ratio was below 4. An exception to this rule occurred for the branched SC-activated PEG (U-PEG) for which PEG:sFv reaction ratios of 14 produced a predominately monoPEGylated sFv compound (Figure 4, panels C and D) that demonstrated an equivalent apparent affinity when compared to the unmodified sFv. These results illustrate the influence of steric factors in the reaction rates of the polymer conjugation. The development of U-PEG by Greenwald and colleagues (*29*) has provided significant geometric adaptability for PEGylation strategies, and is shown here to substantially modulate the reaction kinetics of conjugation as well.

In contrast to the linear amine-reactive PEG polymers, PEGylation reactions employing a 200-fold molar excess of Hz-PEG-5000 relative to sFv protein were demonstrated to produce active PEG-sFv compounds with an average PEG number of 4.8 (Figure 4D and Table 3). Although this Hz-PEG-sFv preparation displayed a 10−15-fold diminished binding affinity by competition ELISA, the retention of significant antigen-binding activity in

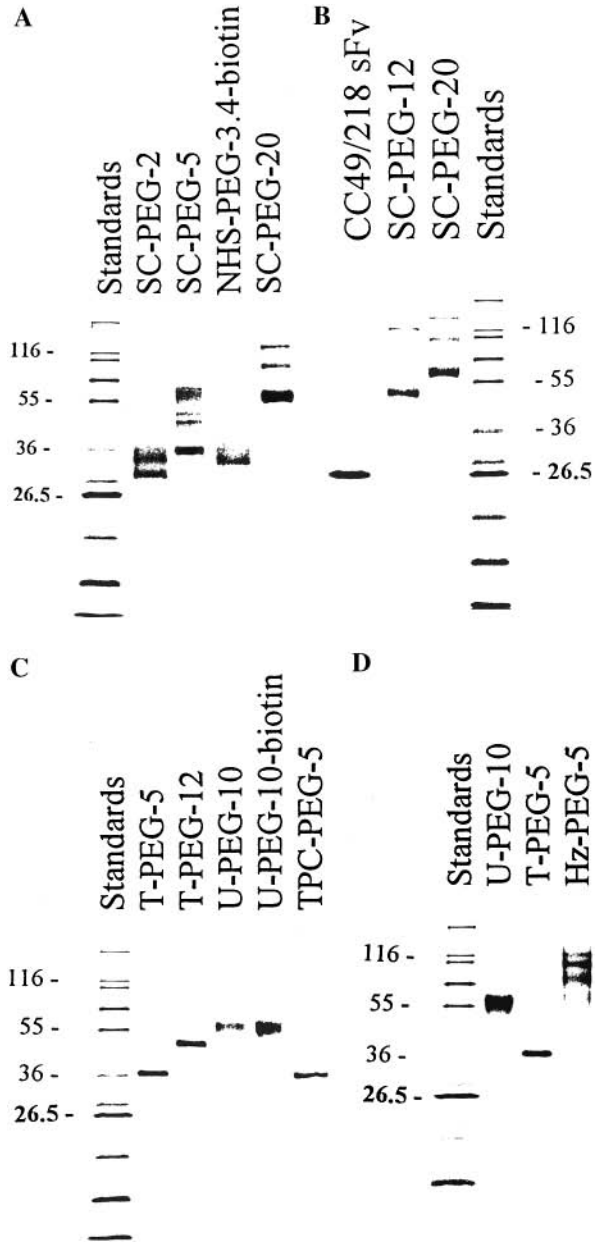

Figure 4. SDS−PAGE analysis of PEGylated CC49/218 sFv formulations. Coomassie blue stained proteins and conjugates were analyzed by 4−20% SDS−PAGE. Highlighted standard markers (kDa × 10^{-3}) within the Novex Mark12 series (Experimental Procedures) are unmodified CC49/218 sFv (26.5); lactate dehydrogenase (36); glutamic dehydrogenase (55); and β-galactosidase (116). (A) SC-PEG-2000, SC-PEG-5000, NHS-PEG-3400-biotin, SC-PEG-20000; (B) CC49/218 sFv, SC-PEG-12000, SC-PEG-20000; (C) T-PEG-5000, T-PEG-12000, U-PEG-10000, U-PEG-10000-biotin, TPC-PEG-5000; (D) U-PEG-10000, T-PEG-5000, Hz-PEG-5000.

Table 2. Dissociation Constants (K_d) of sFv Compounds

sFv formulation	PEG/sFv[a]	K_d (×10^{-9} M)
native CC49/218	0	4.5
SC-PEG-2000	2.1	4.6
NHS-PEG-3400-biotin	2.0	6.1
SC-PEG-12000	1.3	5.8
SC-PEG-20000	1.1	7.5
T-PEG-5000	1.0	7.0

[a] Ratio of PEG polymer per sFv.

this moderately PEGylated sFv provides a very attractive alternative conjugation strategy which may be employed when amine chemistries are not suitable. Remarkably,

Table 3. Pharmacokinetics of sFv and PEG-sFv Conjugates

sFv compd			PEG/	circulating half-life (h)		area under the curve (μg h/mL)		mean residence time (h)	
MW	linker	label	sFv	mean	std error	mean	std error	mean	std error

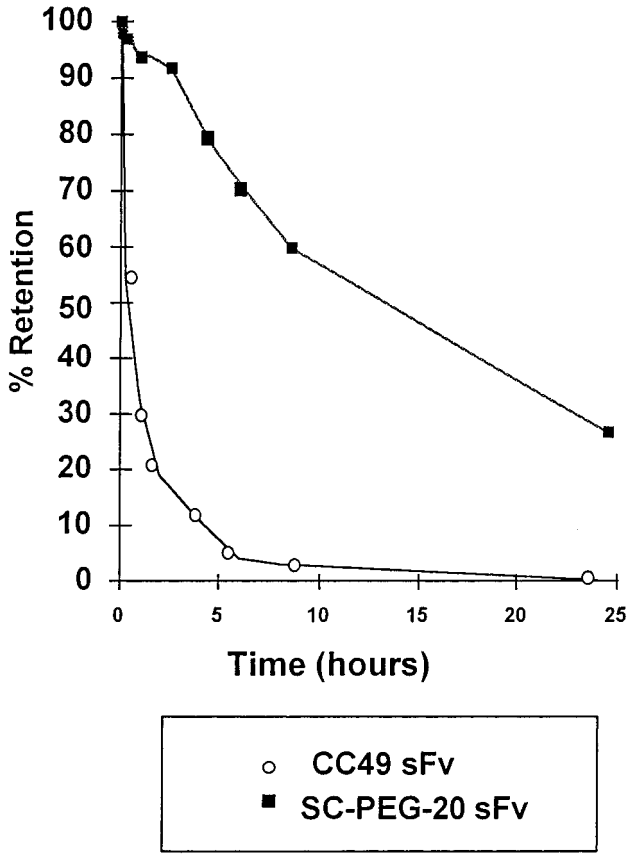

Figure 5. Pharmacokinetics of plasma retention of CC49/218 sFv and SC-PEG-20 conjugate. Plasma retention studies of the unmodified sFv (open circles) and the PEGylated compound (closed boxes) were performed in mice (six per group) as described in Experimental Procedures.

SE-HPLC purified, Hz-PEG-5000-modified sFv compounds with PEG numbers as high as 11 demonstrated detectable antigen-binding activity (data not shown). The observed capacity of carboxyl-directed conjugations of the sFv protein to preserve binding activity at higher PEG numbers plausibly correlates with the locations for the most reactive moieties in this category at sites distal to the CDRs; in this connection, surface exposure of carboxyls is not as predominant as for lysines in Fv structures (Table 1). Ultimately, Hz-PEG polymers of higher molecular weight and/or with branched U-PEG geometry may provide further benefits. Since the V_L and V_H immunoglobulin families have inherent sequence variability, the availability of alternate conjugation

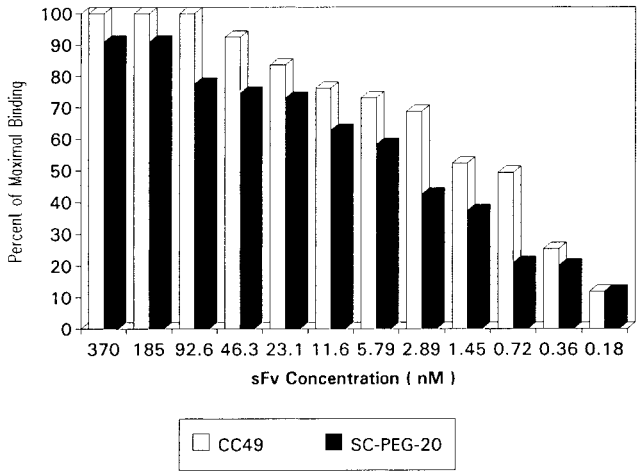

Figure 6. ELISA showing equilibrium binding of CC49/218 sFv (open bars) and SC-PEG-20 conjugate (filled bars) using LS-174-T whole cell preparations. Control compounds (10 mg/mL) BSA and 4-4-20 sFv did not exhibit binding activity. Each starting sFv compound was analyzed in 1:2 serial dilutions.

chemistries provides the antibody engineer with options for construction of individual PEG-sFv immunomolecules. The eventual biochemical characterization of therapeutic PEG-sFv-lead candidates with regard to the specific residue modifications and degree of heterogeneity will provide a more detailed understanding of these bioconjugates.

Circulating Lives of PEGylated sFv. Table 3 presents the pharmacokinetic profiles of 10 PEGylated sFv compounds which differ in linker chemistry, polymer length, and polymer geometry. Included in Table 3 is the estimated stoichiometry (PEG/sFv) in these compounds. Each of these minimally modified preparations demonstrated an average PEG number (n) of $1.0 \leq n \leq 2.1$ except the Hz-PEG-sFv conjugate. Groups of six mice were injected intravenously with unmodified CC49/218 sFv or one of the PEGylated sFv compounds, and circulatory half-life, area under the curve (AUC), and mean residence time were calculated using a one compartment model as described in Experimental Procedures. Unmodified sFv protein cleared rapidly from the plasma with a circulating half-life of 0.7 ± 0.4 h. Renal clearance has previously been established as the predominant, if not exclusive, mechanism responsible for sFv protein elimination (*35*, *37*). All PEGylated sFv compounds demonstrated markedly increased circulating lives which extend the $t_{1/2}$ values from 2.6-fold (T-PEG-5000) up to 20.3-fold (T-PEG-12000). Three significant observations may be drawn from these pharmacokinetic data. First, PEGylated sFv compounds having both similar PEG numbers and polymer sizes also had similar circulating lives.

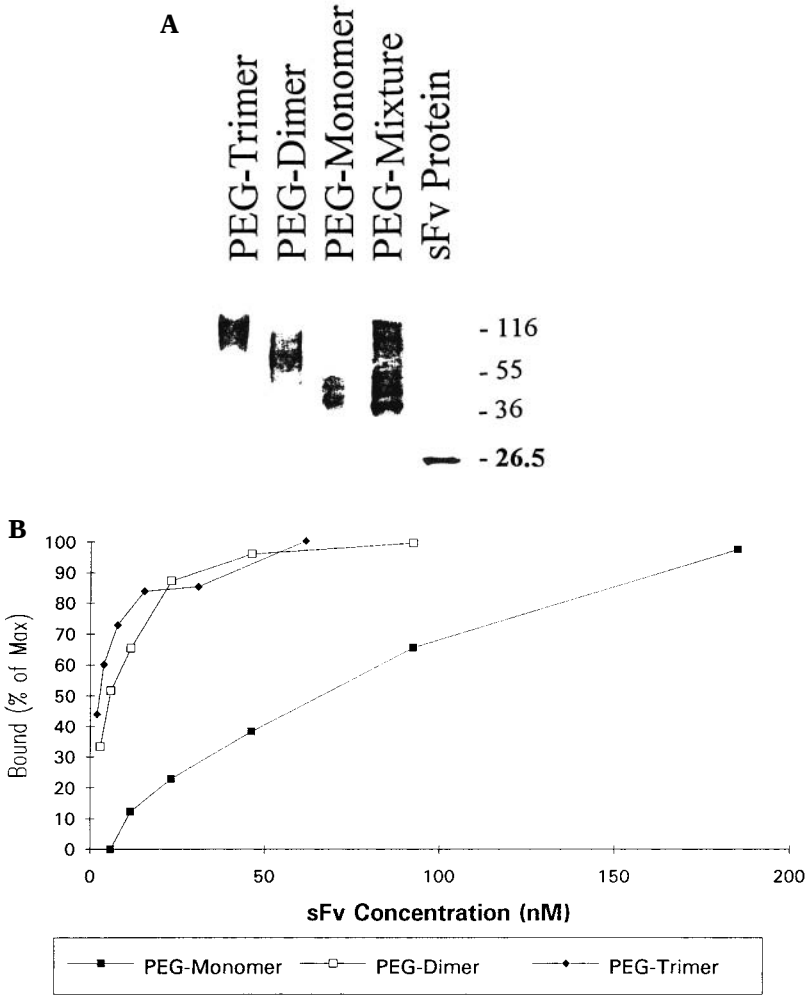

Figure 7. Production and functional affinity of multivalent cross-linked PEG-sFv compounds. (A) Purified CC49/218 sFv compounds corresponding to monomer, dimer, and trimer valencies were generated with homobifunctional cross-linking BSC-PEG-5000 and analyzed on Coomassie blue stained SDS−PAGE 4−20% slab gels. The initial product mixture of the PEGylation reaction is also shown. (B) ELISA of monomer, dimer, and trimer PEG-sFv compounds for mucin-binding activity versus sFv protein concentration.

Second, the employment of PEG polymers of longer lengths extended circulating lives to a greater degree than multiple shorter polymers of equivalent total mass. For example, Hz-PEG-5000-sFv with a PEG number of 4.8 exhibited a $t_{1/2} = 9.8 \pm 1.6$ h, while SC-PEG-20000-sFv with a PEG number of 1.1 demonstrated a $t_{1/2} = 12.8 \pm 0.7$ h. Third, the extension of AUC by as much as 20-fold, such as in the SC-PEG-20000 sFv compound, without substantially compromising sFv antigen-binding activity, bodes well for the potential of PEGylation for systematically extending the bioavailability of sFv protein therapeutics. Figure 5 shows the blood clearance kinetics of the PEG-20000 sFv compound, and Table 2 includes the calculated K_d for this compound for the validated surrogate antigen, bovine submaxillary mucin. As an independent confirmation of binding activity for this compound to the tumor-associated mucin target, a modified ELISA analysis of equilibrium binding using the TAG-72-expressing LS-174-T carcinoma cell line as capture antigen was performed as previously described (*35*). As shown in Figure 6, the PEG-20000-modifed sFv also maintained specific cell-binding activity comparable to the unmodified sFv protein.

In the context of our observations on the benefits of employing PEG polymers of longer length, as opposed to multiple short-chain conjugations, we anticipate that clearance rates for succeeding sFv bioconjugate formulations may be further optimized. The overall selection of PEG modifications will ultimately relate to the individual targeting goal for the sFv, and verification of PEG-sFv efficacy can only be fully validated by in vivo studies. Although the attached polymers may have a temporal influence on the rapid tissue penetration of sFv proteins, the described "enhanced permeability and retention effect" (*40*−*43*) of polymers such as PEG may provide interesting dual targeting modalities utilizing both passive (PEG) and active (sFv) targeting strategies for tumors or other tissues.

PEGylated Multivalent sFv. Multivalency is another intrinsic property of natural human antibodies of any class. Recent success in engineering multivalent and multifunctional forms of sFv proteins (*1*, *9*−*12*, *44*) has established the single-chain Fv format as a comprehensive antibody technology. Conceptually, multivalent Fv may also be engineered through polymer-based bioconjugates, which simulate the functional affinity advantages of multivalency for repetitive epitopes. In a pilot study to evaluate the valency and activity of multimeric PEG-cross-linked sFv proteins, we utilized a bifunctional PEG-5000 polymer having activated SC moieties (BSC-PEG) on both termini of the linear strand (*16*). Our selected reaction conditions did not produce substantial amounts of PEG-sFv monomers, and multimeric PEG-sFv (PEG-mFv) could be readily purified from monomeric sFv forms by Superdex 75 chromatography. As with most homobifunctional reagent linkages, the cross-linked sFv proteins are expected to be heterogeneous with regard to valency (i.e., dimers, trimers, and tetramers) and also with respect to surface linkage sites. However, for antigen-binding molecules such as CC49 sFv which recognizes a repetitive Sialyl-Tn epitope on mucin, a parameter which may be investigated in formulations of cross-linked sFv is the relative degree of functional affinity in these compounds. Two SE-HPLC fractions of PEG-mFv were isolated, which, according to molecular mass estimates, correspond to dimeric and trimeric sFv species. Monomer, dimer, and trimer are defined here as having either one, two, or three sFv proteins, respectively, incorporated in the heterogeneous PEGylated conjugates. Figure 7A shows the SDS−PAGE analysis of these preparations. As described in Experimental Procedures, a solution-binding assay was developed to compare the relative functional affinity of the monomeric SC-PEG-5000 sFv and multimeric PEG-sFv compounds. As shown in Figure 7B, a marked increase in apparent affinity was observed in the PEG-mFv conjugates when compared to the PEG-sFv monomer. A comparable increase in apparent affinity was previously reported in immunoassays of the dimeric CC49 mAb when compared to the monovalent CC49 sFv (*10*, *31*). Further improvements of this approach may be anticipated by employing site-specific heterobifunctional activated PEG polymers of selected length to achieve well-defined cross-linked sFv protein compounds, which may be highly adjustable with respect to the critical circulating life parameters.

In conclusion, we report the applicability of established random PEGylation procedures for generating highly active PEG-sFv compounds exhibiting substantial extensions of circulating lives in mice. The potential to create designed antibody derived drugs with tailored pharmacokinetic properties provides numerous practical applications in immunotherapy.

ACKNOWLEDGMENT

We thank Jeng-Dar Yang, Anna Nepomich, and Maoliang Wang for technical assistance in the ELISA data collection and the purification of bioconjugates. We are also grateful to Jeff McGuire, Jo Bossart, Rich Greenwald, Kwok Shum, and Chyi Lee for support and helpful discussions on PEGylation and pharmacokinetic analysis.

Potentiation of Chlorin e6 Photodynamic Activity in Vitro with Peptide-Based Intracellular Vehicles

Stuart K. Bisland, Devender Singh,† and Jean Gariépy*

Department of Medical Biophysics, University of Toronto and the Division of Molecular and Structural Biology, Ontario Cancer Institute, Princess Margaret Hospital, 610 University Avenue, Toronto, Ontario, Canada M5G 2M9. Received February 23, 1999; Revised Manuscript Received August 20, 1999

Photodynamic therapy (PDT) is a targeted treatment modality where photosensitizers accumulate into cells and are selectively activated by light leading to the production of toxic species and cell death. Focusing the action of photosensitizers to a unique intracellular target may enhance their cytotoxicity. In this study, we demonstrate that the routing of the porphyrin-based photosensitizer chlorin e_6, to the nucleus of cells can significantly alter its toxicity profile. The cellular localization of chlorin e_6 was achieved by coupling the chromophore during solid-phase synthesis to a nucleus-directed linear peptide (Ce6-peptide) or a branched peptide (Ce6-loligomer) composed of eight identical arms displaying the sequence of the Ce6-peptide. These constructs incorporated signals guiding their cytoplasmic uptake and nuclear localization. Ce6-peptide and Ce6-loligomer displayed an enhanced photodynamic activity compared to unconjugated chlorin e_6, lowering the observed CD_{50} values for CHO and RIF-1 cells by 1 or more orders of magnitude. The intracellular accumulation of Ce6-peptide and Ce6-loligomer was assessed by electron and confocal microscopy as well as by flow cytometry. Constructs were internalized by cells within an hour and by 6 h, the release of active oxygen species could be observed within the nucleus of cells pretreated with Ce6-loligomer. These results highlight the utility of designing peptides as vehicles for regulating the intracellular distribution of photosensitizers such as chlorin e_6 in order to maximize their efficacy in PDT.

INTRODUCTION

The dynamic use of light to selectively kill proliferating cells is termed photodynamic therapy (PDT). PDT represents a noninvasive procedure requiring the use of a photosensitizer (a photosensitive compound) to generate cytotoxic oxygen radicals within a diseased tissue. This approach has recently been popularized by the introduction of Photofrin, a porphyrin derivative, presently being evaluated in clinical trials (*1*). Photofrin, a clinically effective first-generation photosensitizer, is characterized by a low absorbance in the red region of the spectrum and displays side effects such as prolonged skin photosensitivity (*2*). Recent animal studies found chlorin e_6, a related porphyrin-based agent, to be a useful photosensitizer in vivo, with low toxicity and preferential tumor localization (*3*−*5*). The efficiency of photosensitizers in situ is ultimately dependent on their selective uptake into tissues and on their cellular accumulation within tissues. This finding is supported by the fact that singlet oxygen ($^1O_2$)-induced photodamage incurred upon porphyrin activation is usually localized to within 0.1 μm of its site of release (*6*). The toxicity of photodynamic drugs could potentially be enhanced by delivering high amounts of a photosensitizer into subcellular organelles such as the nucleus where nucleic acids represent target molecules sensitive to photodamage (*7*). The photodynamic potential of unbound chlorin e_6 is limited as a result of its tendency to localize largely at the plasma membrane (*8*). Bovine serum albumin (BSA) conjugates incorporating chlorin e_6 and nuclear localization sequences have recently been assembled to guide their cellular localization (*11*). These PDT-labeled conjugates have an enhanced phototoxicity in relation to free chlorin e_6 (*9*−*12*). In particular, BSA conjugates incorporating insulin have been reported to target the insulin receptor in an effort to create cell-specific constructs (*11*). The composition of these BSA constructs, however, remains approximate and had to be inferred from the average ratio of each component present in these conjugates as estimated from polyacrylamide gel electrophoresis and by absorbance measurements based on the incorporation of chlorin e_6 molecules (*11*). The engineering and characterization of defined, optimal delivery agents based on the chemical cross-linking of multiple components remain a challenging and difficult task.

Our group has recently designed branched peptides that act as multitasking intracellular vehicles (*13*−*15*). This first generation of vehicles incorporates eight identical peptide arms coding for two functional domains, namely a pentalysine domain acting as a cytoplasmic transport sequence (CTS)[1] and the simian virus SV40 large T antigen nuclear localization signal (NLS) which

guide their nuclear uptake (*13*−*15*). These squid-like, intracellular vehicles are referred to as loligomers (derived from the Latin root *loligo* referring to members of the squid family). This study describes the assembly and application of a nucleus-directed linear peptide and a loligomer incorporating the photosensitizer chlorin e_6. The chromophore was introduced during solid-phase peptide synthesis and the resulting constructs display a photodynamic activity that exceeded the toxicity of free chlorin e_6.

MATERIALS AND METHODS

Synthesis of Chlorin e_6 Peptides and Their Derivatives. Peptides were assembled using *tert*-butoxycarbonyl (t-Boc) chemistry and phenylacetamidomethyl (PAM) resin supports as described elsewhere (*13*, *14*). Chlorin e_6 was coupled to the N-terminus of the peptide and the loligomer by first activating its carboxylic groups with 0.5 molar equivalent of dicyclohexylcarbodiimide and *N*-methyl-2-pyrrolidone at 23 °C for 40 min. The activated chlorin e_6 (4 molar excess in relation to the number of N-terminal amino groups) was then added to the reaction vessel containing the peptide resins. The coupling reaction was left to proceed in the dark for 24 h at room temperature. Both chlorin e_6-containing peptides were desalted using Sephadex G10 (Ce6-peptide) or G25 size-exclusion columns (Ce6-loligomer), respectively. Columns were preequilibrated in phosphate-buffered saline (PBS; pH 7.2). Ce6-peptide was further purified by reversed-phase HPLC (Lichrosorb C_{18}) using a linear gradient of acetonitrile in water (20 to 60%) containing 0.1% (v/v) trifluoroacetic acid. The peptide eluted at 40% acetonitrile:water. The mass of Ce6-peptide was established by ionization mass spectroscopy. (MH+ ion: calculated, 2889; observed, 2888). The amino acid composition of both peptides were confirmed by amino acid analysis. The calculated and expected (parentheses) number of residues comprising each peptide construct are listed in accordance with the three-letter code for each amino acid. Ce6-peptide: Arg, 1.0 (1); Asp, 0.9 (1); Glu, 1.0 (1); Gly, 1.9 (2); Lys, 8.3 (9); Pro, 3.0 (3); Ala, 0.9 (1); Tyr, 1.0 (1); Val, 1.0 (1). Ce6-loligomer: Arg, 8.0 (8); Asp, 6.6 (8); Glu, 9.8 (8); Gly, 19.8 (17); Lys, 81.4 (79); Pro, 22.5 (24); Ala, 8.3 (8); Tyr, 2.4 (1); Val, 8.3 (8). The absorption spectra of either chlorin e_6, Ce6-peptide, or Ce6-loligomer displayed a characteristic Soret band (maximum at ∼401 nm) and Q-band (maxima at 654, 656 and 664 nm), respectively (data not shown). Using chlorin e_6 as a standard, extinction coefficients were calculated at 401 nm [Ce6-peptide (17 000 M^{-1} cm^{-1}) and Ce6-loligomer (129 000 M^{-1} cm^{-1})] and at 664 nm [chlorin e_6 (10 000 M^{-1} cm^{-1}), Ce6-peptide (12 000 M^{-1} cm^{-1}), and Ce6-loligomer (40 000 M^{-1} cm^{-1})]. The calculated number of chlorin e_6 molecules attached to Ce6-loligomer based on amino acid analysis and spectral properties (410 nm) was 7.6 or 0.95 mol of chlorin e_6/mol of loligomer arm (7.6/8). A cysteine residue was included within the C-terminus (analytical arm) of each peptide to allow the attachment of either a maleimido-containing fluorescent probe or a biotin moiety. Texas red or fluorescein were incorporated by dispensing 1 mg of Ce6-peptide or Ce6-loligomer in 1 mL of PBS, pH 7.4 into a glass vial and by adding dropwise a solution of 0.1 mg of either Texas red C_2 maleimide or fluorescein-5-maleimide dissolved in 100 μL of dimethylformamide (Molecular Probes, Eugene, OR). The coupling reactions were left to proceed with constant stirring for 4 h at 4 °C in the dark. The molar ratio of each incorporated fluorochrome was <1. Biotin maleimide (0.5 mg; Molecular Probes) was dissolved in 100 μL of dimethylformamide before being added to a 1 mg solution of either Ce6-peptide or Ce6-loligomer. The pH of the resulting solutions was adjusted to pH 6.5 with 1 M NaOH. The solutions were mixed for 4 h at 4 °C in the dark. Unreacted fluorochrome or biotin reagent was removed by size-exclusion chromatography (as described above). The incorporation of biotin into peptides was established by ELISA using a streptavidin-horseradish peroxidase conjugate, as described elsewhere (*14*). Aliquots of Ce6-peptide and Ce6-loligomer were lyophilized and stored in the dark at −70 °C.

Cell Lines and Cell Cultures. The Chinese hamster ovary (CHO) cell subclone, AUXB1 (*16*), was purchased from the American Type Culture Collection. The radiation-induced fibroblast cell line (RIF-1) was obtained from Dr. Brian Wilson (Ontario Cancer Institute). Cells were grown as monolayers in α-minimal essential medium (α-MEM) supplemented with 10% (v/v) fetal calf serum (FCS; ImmunoCorp., Montreal, Canada), penicillin (1 units/mL) streptomycin (100 μg/mL), and 1 mM glutamine and maintained at 37 °C and 5% CO_2 in a humidified incubator.

Intracellular Uptake. Aliquots of 5×10^5 cells were pipetted into microcentrifuge tubes and suspended in 1 mL of medium containing a noncytotoxic dose (0.01 μM) of either fluorescein-labeled Ce6-peptide (Ce6-peptide-FL5) or Ce6-loligomer (Ce6-loligomer-FL5). Control samples were also prepared which were not exposed to chlorin e_6 and related peptides in order to assess the background level of autofluorescence. The cells were maintained in suspension using a gentle rocking motion and incubated at 37 °C in the dark. At time intervals of 0, 1, 2, 4, 6, and 8 h, samples from each treated cell suspension were placed on ice for 5 min and the cells recovered by centrifugation, washed with PBS (three times), and finally resuspended in aliquots of 0.5 mL of PBS. Cytometric analyses were recorded on a FACScan instrument (Becton Dickinson, San Jose, CA) gating on viable cell populations assessed using 7-amino-actinomycin D (7-AAD; Sigma, St. Louis, MO) (*17*). Samples were prepared in duplicate with 10 000 events recorded for each and experiments repeated 3 or 4 times.

Confocal Microscopy. Aliquots of 5×10^2 cells suspended in 1 mL of medium were plated onto sterile borosilicate coverglass slides (Lab-Tek Nunc, Napierville, IL) and incubated at 37 °C for 16 h to allow time for cells to adhere. Cells were then treated with a nontoxic concentration (0.01 μM) of either fluorescein-labeled Ce6-peptide (Ce6 peptide-FL5) or Ce6-loligomer (Ce6-loligomer-FL5). At selected time intervals, labeled cells were washed five times with sterile PBS to remove any excess construct from the extracellular space and examined by confocal microscopy (Zeiss LSM510 instrument). The signal from chlorin e_6 linked to the N-terminus of our peptide vehicles was observed directly upon UV excitation (Argon laser; Nikon, 364/585 LP filter) while a Nikon 488/520 BP filter was used to visualize the fluorescein signal associated with the C-terminal arm of both peptide constructs.

Electron Microscopy. RIF-1 and CHO cells were harvested from monolayer cultures and dispensed as suspensions (10^6 cells/mL) into medium containing Ce6-peptide-biotin or Ce6-loligomer-biotin (final concentration of biotinylated peptides; 0.01 μM). Cells were incubated at 37 °C without light, and samples collected at 1, 2, 4, 6, or 24 h. Cells were prepared and analyzed using electron microscopy, as previously described (*14*). The accumulation and distribution of gold particles (colloidal gold streptavidin conjugate, 21.7μg/mL; British Biocell

International, Cardiff, U.K.) within cells was quantified using electron micrographs analyzed using a software program (NIH Image; version 1.61). A total of six cells were analyzed for two time points (1 and 6 h) following the exposure of cells to either peptide constructs. Cells were randomly chosen from over 10 electron micrographs.

Photodynamic Treatment. Aliquots of 5×10^3 cells of either CHO or RIF-1 cells suspended in 200 μL growth medium were seeded into wells of blackened 96 well plates with clear bottoms (Corning Costar Corp., Cambridge, MA) and cultured for 6 h at 37 °C in the presence of 5% CO_2. Cells (as quadruplicate cultures) were treated with PBS or increasing concentrations of either chlorin e_6, Ce6-peptide, or Ce6-loligomer followed by light activation treatments. Control samples were also prepared and kept from light. The concentration range of peptides differed for each cell line. CHO cells were treated with chlorin e_6, $(1 \times 10^{-6})-(5 \times 10^{-4})$ M, Ce6-peptide, $(5 \times 10^{-9})-(2 \times 10^{-5})$ M, and Ce6-loligomer, $(2 \times 10^{-11})-(5 \times 10^{-8})$ M, while RIF-1 cells were treated with chlorin e6, $(1 \times 10^{-6})-(5 \times 10^{-4})$ M, Ce6-peptide, $(2 \times 10^{-8})-(1 \times 10^{-4})$ M, and Ce6-loligomer, $(5 \times 10^{-10})-(2 \times 10^{-6})$ M. Wells were irradiated with 664 nm light from above using an optic fiber coupled to a dye laser source (Spectra Physics model 375B), applying a radiant exposure of 12 J/cm^2 at a fluence rate of 20−30 mW/cm^2. The photoinduced thermal effect was measured in individual wells using a thermovision camera. The increase in temperature was found to be less than 3 °C (23.5−26 °C). Once irradiated, cells were incubated with fresh growth medium for an additional 48 h at 37 °C in the dark.

Photoinduced Oxidative Burst. RIF-1 cells (2×10^4 cells) were suspended in 1 mL of growth medium containing 0.01 μM Ce6-loligomer-TxRd and incubated (37 °C, 5% CO_2) for 6 h in the dark and then washed with PBS (three times). Two subsequent incubations were performed. Cells were exposed for 25 min at 37 °C in medium containing 5 μM 5 (and 6)-chloromethyl-2,′7′-dichlorodihydrofluorescein diacetate (CM-H_2 DFDA) followed by a second incubation for 5 min at 23 °C in medium containing 5 μM AcrO. Cells were washed twice with PBS between incubation periods, resuspended in fresh medium, and seeded into chamber slides (Nunc Inc. Naperville, IL). Slides remained at room temperature in the dark until analyzed by confocal microscopy. Single cells were visualized before and after the activation of chlorin e_6 and Ce6-loligomer-TxRd and AcrO signals recorded using a scanning confocal imaging system (Argon-ion laser; 488/514.5 nm; MRC 600, Bio-Rad Laboratories Ltd., Ont., Canada). Both signals were viewed through a ×40/0.55 Nikon water-immersible objective lens. Chlorin e_6 was subsequently activated using a helium cadmium (HeCd) laser (omNichrome series 56). The fluorescence signal from CM-H_2 DFDA was simultaneously recorded using a green filter.

Cell Viability. The toxicity of chlorin e_6, Ce6-peptide, or Ce6-loligomer toward CHO and RIF-1 cells was measured using a tetrazolium salt-based cell viability assay (*18*). Following a 6 h exposure to chlorin e_6 and related peptide constructs, identical groups of cell samples were treated either with light (photoirradiation) or kept in the dark. The assay was performed on cells 48 h after the photoirradiation treatment (±photoirradiation). Cells were incubated in the presence of the tetrazolium salt WST-1 [10 μL/well; 4-[3{4-iodophenyl}-2-{4-nitrophenyl}-2H-5-tetrazolio]-1−3-benzene disulfonate; Boehringer Mannheim, Montreal, Canada] for 1 h, and the resulting orange formazan product was quantified by measuring the optical density of the cell extracts at 450 nm. Percent

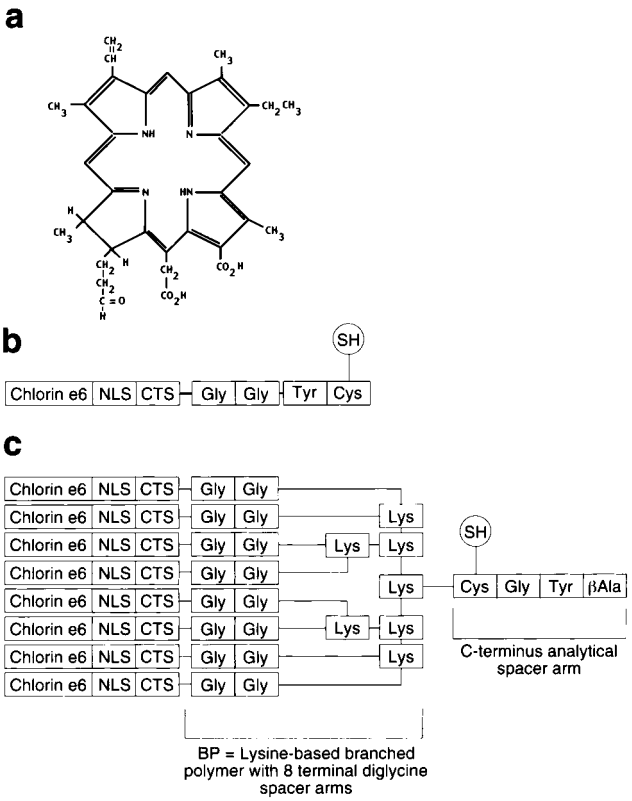

Figure 1. Structures of chlorin e_6-derived constructs. (a) Chlorin e_6 (*8*). (b) Ce6-peptide. The N-terminal region of Ce6-peptide consists of a single chlorin e_6 molecule followed by the simian virus (SV40) large-T-antigen nuclear localization signal residues 124−135 [NLS; A^{124}SV40LTa(124−135), Ala-Pro-Pro-Lys-Lys-Lys-Arg-Lys-Val-Glu-Asp-Pro harboring a threonine to alanine substitution at position 124] and a pentalysine sequence representing a cytoplasmic translocation signal (CTS). This region is linked via a diglycine spacer arm to a C-terminal region (analytical arm) consisting of tyrosine and cysteine residues. (c) Ce6-loligomer. This construct represents a branched version of the Ce6-peptide with eight N-terminal branches linked to a lysine scaffold (BP). The construct incorporates a C-terminal analytical arm also containing a cysteine residue. Each N-terminal arm consists of a chlorin e_6 group, a NLS and a CTS sequence. The unique thiol side chain of the cysteine residue within the C-terminal region of each construct was derivatized with either Texas red, fluorescein or a biotin moiety.

cell viability was defined by the equation

$$[\text{Abs(drug/light)} - \text{Abs(no cells)}/\text{Abs(absence of drug/light)} - \text{Abs(no cells)} \times 100]$$

and represented the average of duplicate cell cultures within a group. Experiments were repeated at least three times. The morphological characteristics of healthy and apoptotic CHO cells were also discerned visually by light microscopy.

RESULTS

Design and Characterization of Chlorin e_6 Conjugates. Chlorin e_6 (Figure 1A) was initially coupled via solid-phase synthesis to a single arm peptide incorporating an homologue of the SV40 large T antigen nuclear localization sequence (NLS; A^{124}SV40LTa(124−135), Ala-Pro-Pro-Lys-Lys-Lys-Arg-Lys-Val-Glu-Asp-Pro) (*19*), a pentalysine cytoplasmic transport sequence (CTS) and a C-terminus analytical arm. Kalderon and co-workers (*19*) had defined residues 127−133 of the SV40 large T antigen as the minimal region responsible for the nuclear import of this protein. It was subsequently shown by one

of us (*20*) as well as others (*21)* that peptides containing the minimal sequences 126−135 or 126−132 could be coupled to carrier proteins and effectively routed to the nucleus of cells. The kinetics of nuclear import with the minimal length peptide 126−135 (*20*) have proven to be comparable to values observed with longer analogues of this NLS domain shown by Rihs and co-workers to cause a 2-fold improvement in nuclear uptake (*22*). Since the length of the NLS sequence incorporated into our peptide and loligomer designs represents an important issue in terms of the limitations of solid-phase peptide synthesis, it was decided that residues 125− 135 of the SV40 large T antigen would be introduced into our constructs. An alanine residue (position 124) was added at the N-terminus to avoid ending the peptide arms with a terminal proline imino group. Alanine was selected over the naturally occuring threonine residue since this latter residue is a site of phosphorylation known to modulate in the level of nuclear import (*23*). As for the cytoplasmic uptake of our constructs, it is well established that most eukaryotic cells tend to harbor a net negative charge on their surface and, as a result, will bind linear chains of polycationic amino acids such as poly(L-lysine). These cationic peptides are rapidly internalized by cells through a process termed adsorptive endocytosis and are able to enhance the cytoplasmic transport of macromolecules such as albumin and horseradish peroxidase (*24*−*27*). A pentalysine sequence (CTS) was thus introduced into each arm of our peptide vehicles as a strategy to have these constructs routed into cells. This design strategy has proven to be an effective approach to import loligomers into cells (*13*−*15*).

A schematic representation of the resulting chlorin e_6-peptide construct (Ce6-peptide) is shown in Figure 1B. The loligomer used in this study (Figure 1C; referred to as Ce6-loligomer) incorporates eight arms containing NLS and CTS domains. The arms are linked to a branched lysine structure using a peptide synthesis strategy developed by Tam (*28*). This branched peptide has been shown in the past to act as a nucleus-directed peptide shuttle (*13, 14*). Three variants of the Ce6-peptide and Ce6-loligomer were created by derivatizing the unique thiol group (cysteine side chain; C-terminus region) with either fluorescein (FL-5), Texas red, or a biotin group. Texas red was introduced for analyzing cellular uptake of constructs by confocal microscopy, while fluorescein derivatives were used for flow cytometry. The biotinylated constructs, Ce6-peptide-biotin and Ce6-loligomer-biotin, were designed for electron microscopic studies.

Intracellular Uptake of Chlorin e_6-Constructs into CHO and RIF-1 Cells. The time-dependent internalization of Ce6-peptide-FL5 and Ce6-loligomer-FL5 (0.01 μM) into CHO and RIF-1 cells at 37 °C is represented by the mean fluorescence intensity for a given cell population. Ce6-peptide-FL5 and Ce6-loligomer-FL5 were initially associated with the cell surface and subsequently internalized at similar rates by both cell lines (Figure 2). The mean fluorescence signal associated with Ce6-peptide-FL5 and Ce6-loligomer-FL5 gradually increases as a function of time reaching a plateau after 6 h. Flow cytometric histograms depicting cell number as a function of fluorescence intensity reveal that all cells show an increase in fluorescence intensity over time (results not shown; see Figure 3), suggesting that the entire cell population is targeted by the constructs.

Visualization of Chlorin e_6-Construct Internalization and Intracellular Distribution. The uptake and distribution of Ce6-loligomer-FL5 into RIF-1 and

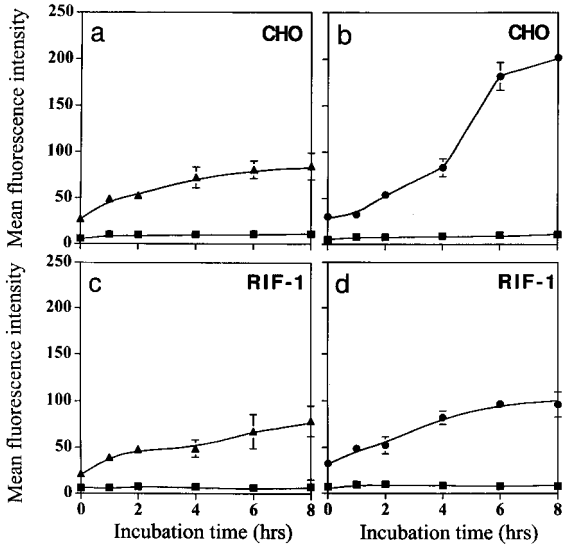

Figure 2. Uptake of chlorin e_6-constructs by CHO cells (panels a and b) and RIF-1 cells (panels c and d) as a function of time. Cells suspensions maintained at 37 °C were exposed to a 0.01 μM solution of either Ce6-peptide-FL5 (▲) or Ce6-loligomer-FL5 (●). Mean fluorescence intensities were recorded by flow cytometry over a period of 8 h. The autofluorescence of cells (■) which had not been exposed to a construct were also analyzed for each experiment.

CHO cell lines was monitored as a function of time by confocal microscopy (Figure 3). The emission fluorescence of conjugated chlorin e_6 was visualized directly (red fluorescence) and shown to colocalize with the fluorescein label attached to the C-terminal arm of the loligomer (green fluorescence). The combination of phase contrast and fluorescence images suggests that all cells import the chlorin e_6 construct, a result confirmed by flow cytometric analyses (not shown). After a 1 h incubation period, Ce6-loligomer-FL5 was mainly localized to the cytoplasm of RIF-1 or CHO cells, with only a small amount observed in the nucleus (Figure 3 panels A and D). By 6 h, the Ce6-loligomer-FL5 construct was clearly visible within the nucleus of RIF-1 and CHO cells (Figure 3, panels B and E) and was still observed at 24 h (Figure 3, panels C and F).

The migration of Ce6-peptide-biotin and Ce6-loligomer-biotin into RIF-1 cells was analyzed by electron microscopy using streptavidin-conjugated gold particles (see Figure 4). Micrographs revealed that while both constructs were initially internalized into RIF-1 cells within endocytic vesicles, their subsequent patterns of cellular distribution clearly differ. Vesicular compartments were saturated with Ce6-peptide-biotin after 1 h of exposing cells to the construct (Figure 4a). At 6 h, Ce6-peptide-biotin remained primarily confined to these vesicles with some of the construct reaching the cytosol (Figure 4c, see arrows). A small fraction of the Ce6-peptide-biotin population was also seen in the nucleus of cells by 24 h (results not shown). In contrast, Ce6-loligomer-biotin accumulates in the nucleus of RIF-1 cells within 6 h of exposure (Figure 4d). In the case of both chlorin e_6 constructs, peptide-loaded vesicles accumulated at the perimeter of the nucleus by 24 h (not shown). Electron microscopy allowed the events leading to cellular uptake to be visualized where small aggregates of Ce6-loligomer-biotin became enveloped by invaginations in the plasma membrane (Figure 5a; see arrow) and vesicles formed within 1 h of being exposed to the construct (Figure 5b). Endocytic vesicles were evident throughout the cytoplasm of cells at differing distances from the nucleus (Figure

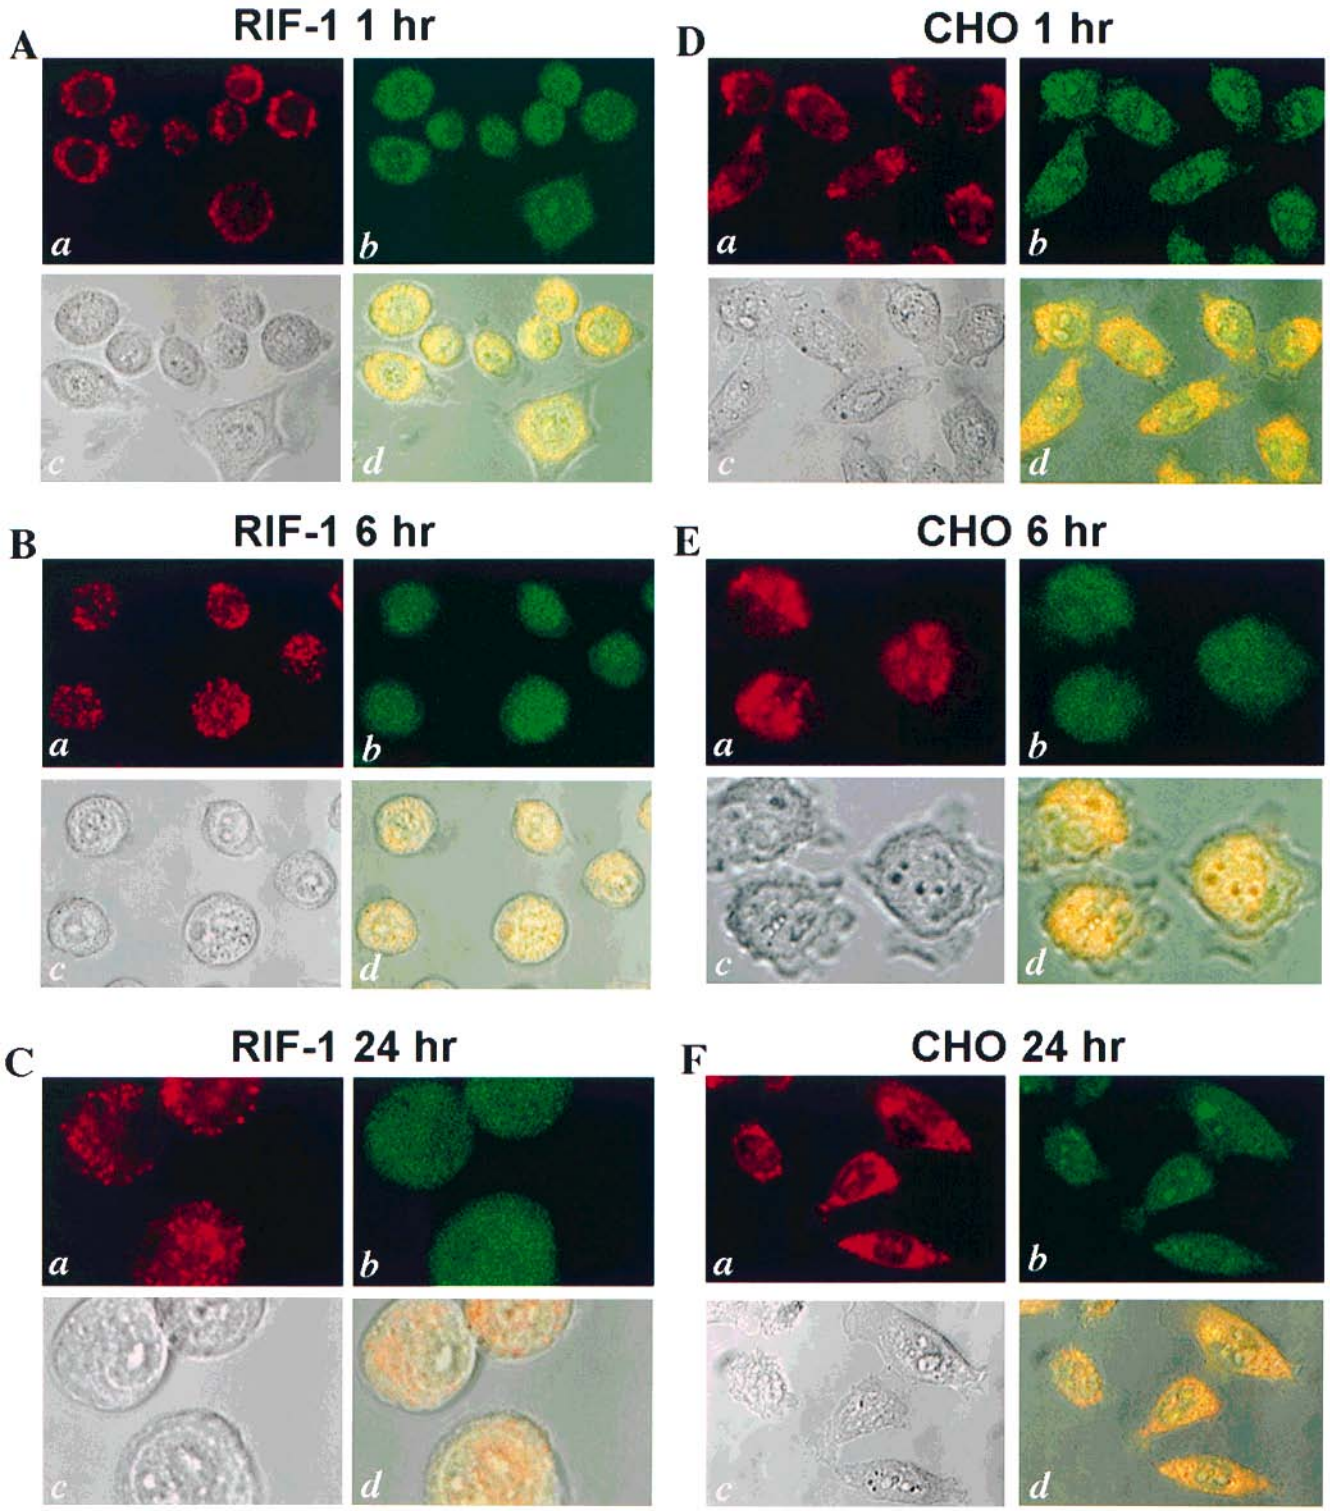

Figure 3. Confocal images of Ce6-loligomer-FL5 (0.01 μM) inside RIF-1 or CHO cells recorded after 1 h (panels A and D), 6 h (panels B and E), or 24 h (panels C and F) of exposure to the construct. Images of fluorescence signals in RIF-1 cells from chlorin e_6 (images labeled *a*) and fluorescein-labeled loligomer (images labeled *b*) indicate that all cells (as shown in the matched phase contrast images labeled *c*) import the construct. Composite images of both fluorescence signals and phase contrast images are presented in panels labeled *d*. The yellow fluorescence in these images emphasizes the comigration of chlorin e_6 (red fluorescence) linked to the loligomer (green fluorescence) over a period of 24 h.

5c). Constructs appear to be released from their endocytic compartments prior to nuclear uptake. A number of steps which characterize the endocytic pathway are shown in Figure 5d. Quantitative analysis of gold particle accumulation provided an estimate of the distribution of each construct within RIF-1 cells. The quantity of gold particles within an individual cell exposed to Ce6-loligomer-biotin or Ce6-peptide-biotin for 1 or 6 h was calculated in terms of gold particles present per square micron (μm^2) unit area (Table 1). Similar analyses were also conducted for cells which had not been exposed to the constructs. Background levels of gold particle accumulation never exceeded 5% of the values obtained for treated cells (data not shown). In RIF-1 cells, Ce6-

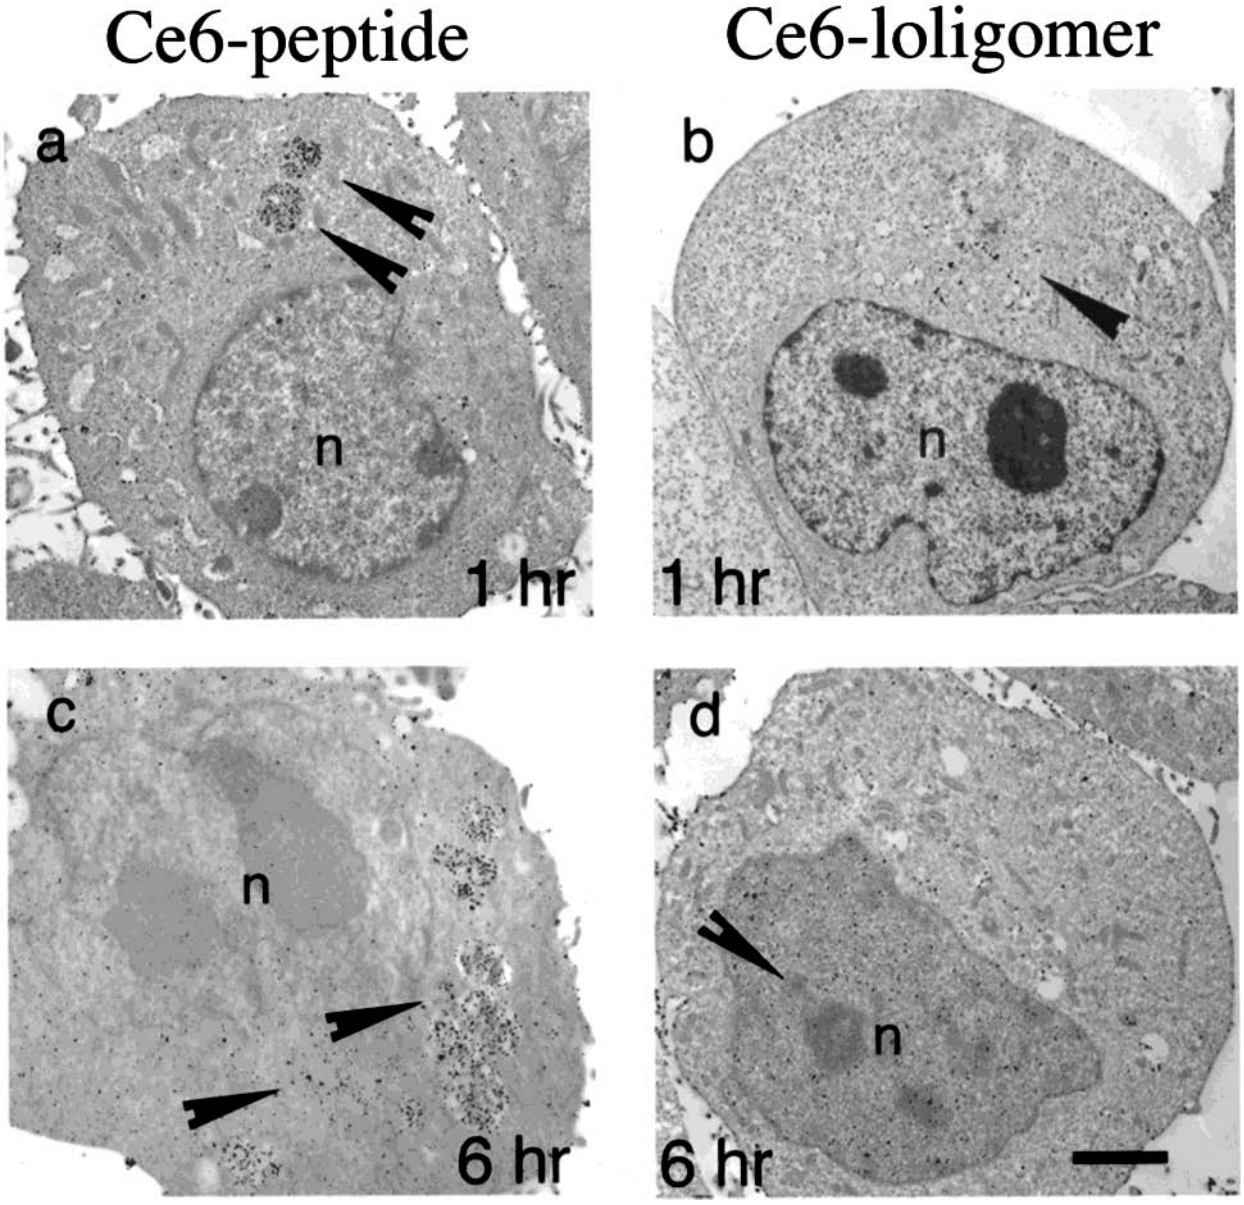

Figure 4. Electron micrographs showing the distribution of Ce6-peptide-biotin (0.1 μM) or Ce6-loligomer-biotin (0.1 μM) inside RIF-1 cells after 1 h (panels a and b) or 6 h (panels c and d) of exposure to either construct. Vesicular compartments containing the construct can be observed within the cytosol of cells by 1 h (panel a; see arrows). By 6 h, Ce6-peptide-biotin is still largely confined to vesicules (panel c), while Ce6-loligomer-biotin accumulates within the nucleus (panel d; see arrow). Scale bar represents 6 μm.

loligomer-biotin accumulated within the nucleus to a greater extent (1.5 times; 19.2 ± 1.9 particles/μm^2) after a 1 h incubation period than Ce6-peptide-biotin (12.4 ± 2.2 particles/μm^2). This difference is further augmented after 6 h where the extent of nuclear uptake by Ce6-loligomer-biotin was >3-fold (3.3 times; 49.9 ± 12.1 particles/μm^2) higher than the level of Ce6-peptide-biotin (15.3 ± 5.4 particles/μm^2). In contrast, the amount of Ce6-loligomer-biotin in the cytoplasm of RIF-1 cells after 1 and 6 h incubations was 0.5 (12.8 ± 1.9 vs 27.9 ± 9.3 particles/μm^2) and 0.7 (46.1 ± 16.4 vs 34.3 ± 4.9particles/μm^2) times that of Ce6-peptide-biotin, respectively. Analysis for individual cells demonstrated that after an incubation period of 1 or 6 h, Ce6-peptide-biotin preferentially localized within the cytoplasm of RIF-1 cells with less than half of the total amount of biotinylated peptide within the cell being present in the nucleus (0.4, 12.4 ± 2.2 vs 27.9 ± 9.3 particles/μm^2, and 0.3, 15.3 ± 5.4 vs 46.1 ± 16.4 particles/μm^2, respectively). Meanwhile, the amount of Ce6-loligomer-biotin within the nucleus of RIF-1 cells was 1.5 times (19.2 ± 1.9 vs 12.8 ± 1.9 particles/μm^2) and 1.4 times (49.9 ± 12.1 vs 34.3 ± 4.9 particles/μm^2) the amount in the cytoplasm after a 1 or 6 h incubation, respectively. These results confirm the enhanced nuclear localization properties of Ce6-loligomer-biotin compared with Ce6-peptide-biotin.

Photodynamic Action of Nucleus-Targeted Chlorin e_6-Peptide Constructs. The viability of CHO and RIF-1 cells was determined as a function of exposure to increasing concentrations of chlorin e_6 or the two peptide constructs using an established cell viability assay (WST-1 tetrazolium salt assay). Dose response curves (Figure 6) indicate that both constructs were moderately cytotoxic toward CHO and RIF-1 cells in the absence of photoirradiation (Figure 6, panels a and b). CD_{50} values determined for chlorin e_6 and the related peptide conjugates following photoirradiation (Figure 6, panels c and d), revealed that the photodynamic activity of Ce6-loligomer against CHO cells (CD_{50}; 20 nM) was 400 times higher than that of chlorin e_6 alone (CD_{50}; 8 μM), whereas the activity of Ce6-peptide (CD_{50}; 200 nM) was 40 times that of chlorin e_6. The photodynamic activity of Ce6-

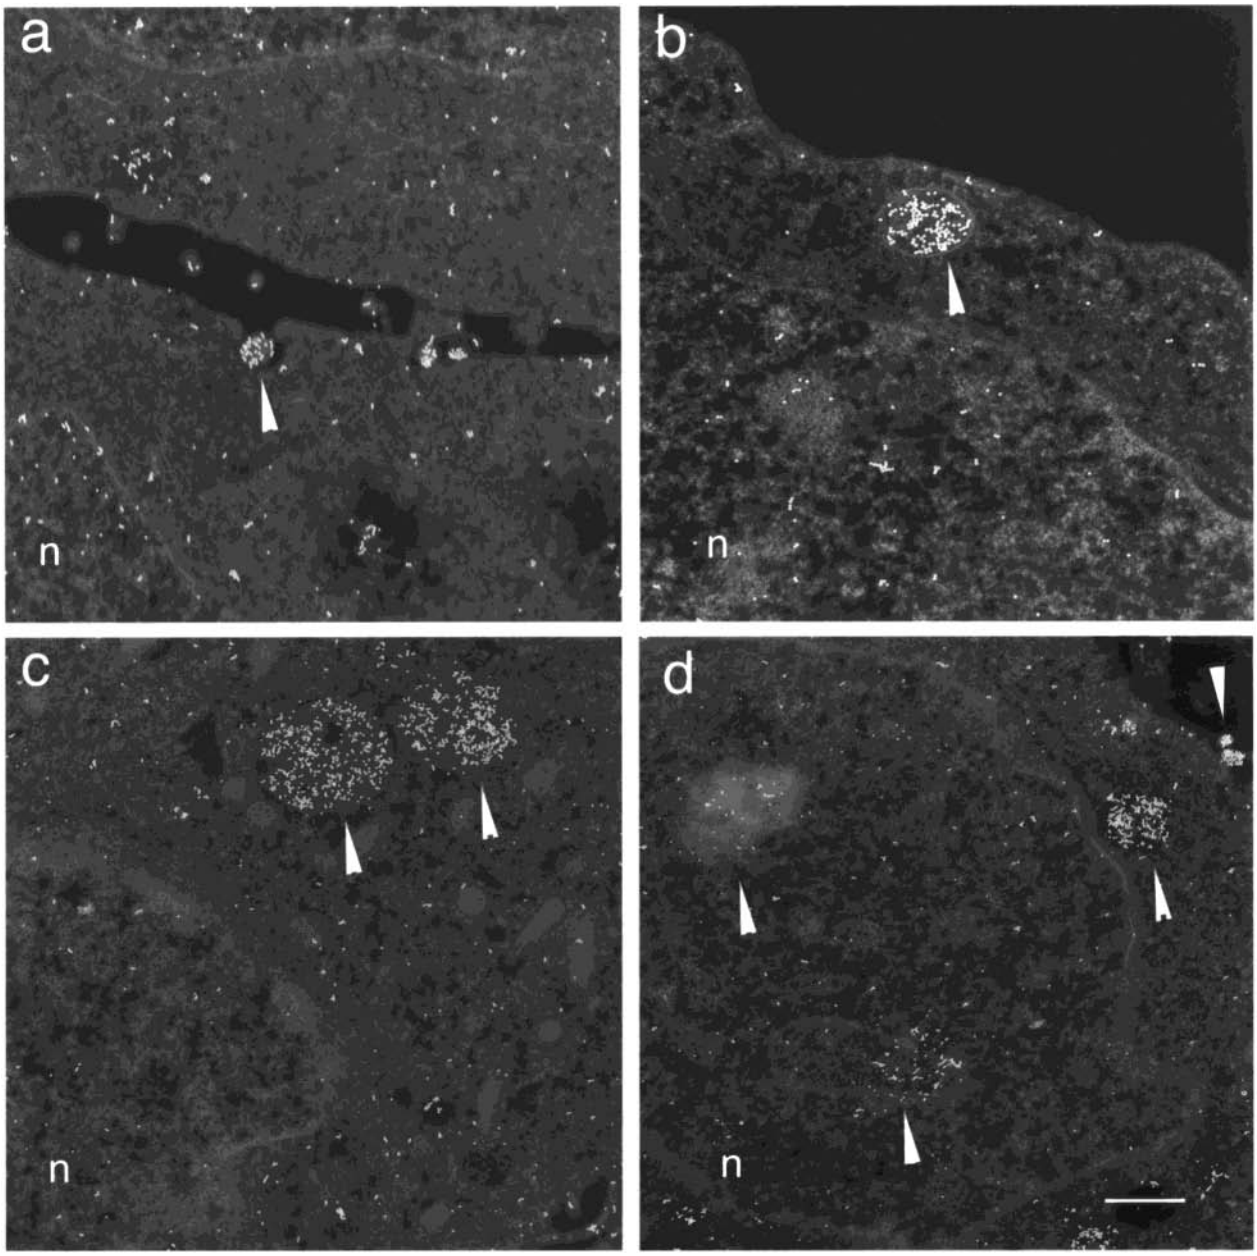

Figure 5. Electron micrographs (negative prints) detailing the endocytic uptake and migration of Ce6-loligomer-biotin (0.1 μM) in RIF-1 cells. The loligomer construct was initially internalized through the plasma membrane by absorptive endocytosis (panel a; arrow) and subsequently encapsulated within a membrane-bound endocytic vesicle (panel b). Within 1 h of exposure to Ce6-loligomer-biotin, RIF-1 cells contained large cytoplasmic vesicles densely packed with gold particle-associated Ce6-loligomer-biotin (panel c). The construct accumulated within regions of the nucleus (n) after 6 h (panel d). Scale bar represents 0.88 μm (panels a and b), 0.94 μm (panel c) or 1.85 μm (panel d).

Table 1. Quantification of Gold Particles in Electron Micrographs of RIF-1 Cells Exposed to Biotinylated Ce6-Peptide and Ce6-Loligomer

peptide construct	biotinylated Ce6−peptide[a]		biotinylated Ce6-loligomer[a]	
time (h)	1	6	1	6
nucleus (N)	12.4 ± 2.2	15.3 ± 5.4	19.2 ± 1.9	49.9 ± 12.1
cytoplasm (C)	27.9 ± 9.3	46.1 ± 16.4	12.8 ± 1.9	34.3 ± 4.9
total cellular uptake ($N + C$)	40.4 ± 11.5	61.4 ± 21.8	32 ± 3.8	84.2 ± 17
N/C ratio	0.4	0.3	1.5	1.4

[a] Biotinylated peptide constructs were labeled with streptavidin-conjugated gold particles. Values are expressed as the number of gold particles per square micron area (μm^2) of cell.

loligomer against RIF-1 cells (CD_{50}; 1.6 μM) was less than that for CHO cells although significantly enhanced (~40-fold) in relation to chlorin e_6 (CD_{50}; 63 μM). The phototoxicity of Ce6-peptide toward RIF-1 cells (CD_{50}; 6.3 μM) as in the case of CHO cells, was less than the effects of Ce6-loligomer and showed a 10-fold killing enhancement relative to chlorin e_6. The enhanced phototoxicity of our Ce6 peptide conjugates thus depends in part on the nature of the cell line targeted.

Generation of Reactive Oxygen Species within the Nucleus of RIF-1 Cells by Chlorin e_6-Loligomer Construct. To establish the precise subcellular sites of photoactivation/photooxidation of chlorin e_6 and to confirm that the conjugation of chlorin e_6 to the loligomer did not interfere with its activity, RIF-1 cells which had previously been treated with Ce6-loligomer-TxRd (0.01 μM) for 6 h were subsequently treated with CM-H_2 DFDA (5 μM). CM-H_2 DFDA passively diffuses into cells, where the acetates are cleaved by intracellular esterases to form reduced 2′,7′-dichlorofluorescin. The subsequent produc-

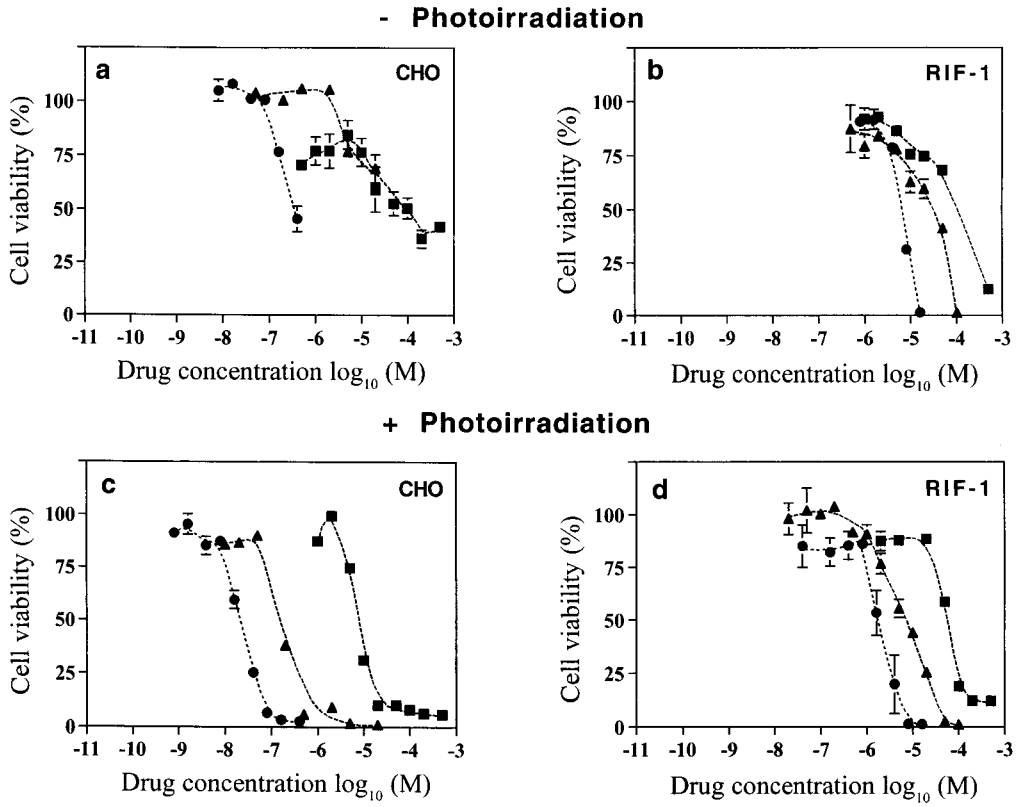

Figure 6. Cell viability curves for CHO and RIF-1 cells incubated (6 h) in the presence of increasing concentrations of chlorin e_6 (■), Ce6-peptide (▲), or Ce6-loligomer (●). Cell viability was determined for cells exposed (+) or not (−) to photoirradiation. Cell viability was reported as the percentage of surviving cells measured using the WST-1 assay (ref *17*; see Materials and Methods). The term drug concentration represents the molar concentration of chlorin e_6 either free or attached to the peptide constructs.

tion of active oxygen species induced by photoirradiation oxidizes 2′,7′-dichlorofluorescin to a highly fluorescent product, dichlorofluorescein (*28*). The thiol-reactive chloromethyl groups of CM-H_2 DFDA potentially interact with intracellular thiols to form adducts that prolong its retention within cells. This event allows the observation of reactive oxygen for several seconds after chlorin e_6 activation (Figure 7). Cells were either treated in the presence (Figure 7f) or absence (Figure 7b) of AcrO (5 μM) to indicate the position of the cell nucleus. The fluorescent signal generated by Ce6-loligomer-TxRd was recorded prior to the activation of chlorin e_6 (Figure 7, panels a and e) as well as after chlorin e_6 activation (Figure 7, panels c and g). CM-H_2 DFDA-associated fluorescence was undetectable prior to the activation of chlorin e_6 (Figure 7, panels b and f). Photoirradiation of the cells and the subsequent activation of intracellular chlorin e_6 resulted in a delay of ∼10−20 s before the generation of reactive oxygen species within RIF-1 cells, an event that was confirmed by a strong fluorescence burst which persisted for 1−2 min. The release of reactive oxygen species colocalizes exactly with the site of Ce6-loligomer accumulation (see Figure 7, panels a and d, or Figure 7, panels e and h). AcrO staining provided evidence of its release in the nucleus of these cells (see Figure 7, panels f and h).

DISCUSSION

Photodynamic therapy has emerged within the past decade as a promising treatment modality for certain malignancies, offering the possibility of guided therapies which restrict phototoxicity to the tumor site. PDT is currently used in the treatment of early and late stage cancers including bladder, esophageal, lung, gastric, and cervical cancers and is either in use or being evaluated in clinical trials for early stage oesophageal and lung cancer (*30*). The phototoxicity of photosensitizers is associated with the production of singlet oxygen species ($^1O_2$), which has a lifetime of several microseconds in aqueous environments and a limited cellular diffusion [∼20 nm (*31*, *32*)]. The sphere of influence of $^1O_2$ is thus very small, and only intracellular regions with both a high $^1O_2$ concentration and a high photosensitizer concentration are susceptible to photooxidative damage. Therefore, the location of the photosensitizer within cells governs the areas subjected to its photodynamic action. Potential targets of $^1O_2$-mediated toxicity include cellular membranes which may undergo lipid peroxidation, protein cross-linking and loss of ionic homeostasis (*33*), lysosomes which can release acidic hydrolases into the cytosol (*34*), mitochondria as well as the endoplasmic reticulum (*35*).$^1O_2$ is also known to cause single-strand breaks and alkali-labile lesions in DNA (*36*) as well as inactivate enzymes involved in DNA repair (*37*). Consequently, the nucleus represents an attractive target for photooxidative damage. Unfortunately, photosensitizers tend to accumulate to the perinuclear region of the cell cytoplasm. As a result, DNA is not usually subjected to photoinduced toxicity. The realization that certain sites within a cell display enhanced sensitivity to photooxidative damage justifies the design of delivery strategies which target photosensitizers to these sensitive sites. One strategy would be to use intracellular vehicles such as linear and branched peptides (*13*−*15*) to shuttle photosensitizers to specific cellular loci. The results of this study demonstrate that peptide constructs can be used to traffic the photodynamic drug chlorin e_6 to the nucleus of cells and, in doing so, can potentiate its cytotoxicity.

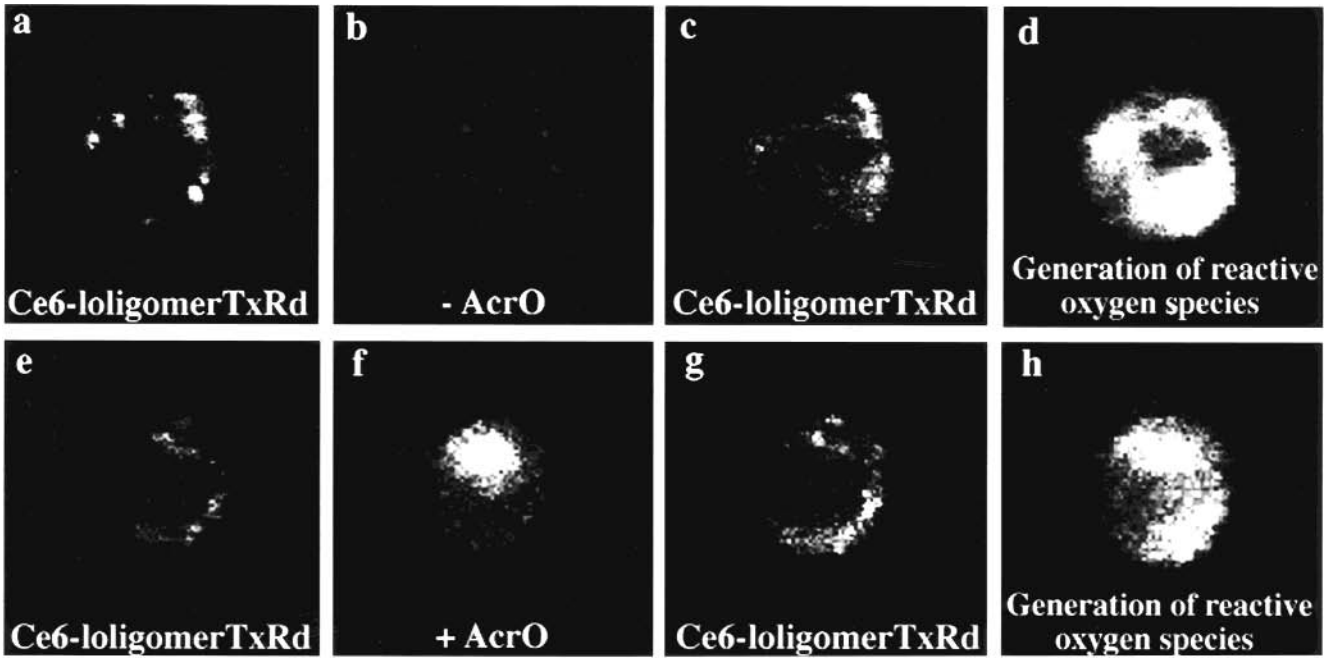

Figure 7. Light activation of chlorin e_6 in RIF-1 cells as monitored by fluorescence microscopy. Photoinduced generation of reactive oxygen species within two individual RIF-1 cells (cell 1, panels a−d; cell 2, panels e−h) following their treatment with Ce6-loligomer-TxRd for 6 h. Panels a, b, e, and f depict fluorescence images recorded prior to light exposure and panels c, d, g, and h are images taken following light activation. Cell 2 was stained with AcrO to identify areas within the cell containing DNA (panel f). CM-H_2-DCFDA was used to visualize the generation of reactive oxygen species in cells following the activation of chlorin e_6 (panels d and h). The fluorescent signal of CM-H_2DCFDA colocalizes with the signal of Ce6-loligomer-TxRd in both cells.

Chlorin e_6 was coupled to either a nucleus-directed loligomer (Ce6-loligomer; Figure 1C) or a peptide corresponding to one arm of this construct (Ce6-peptide; Figure 1B) in an effort to guide the intracellular uptake and nucleus routing of this photosensitizer. The endocytosis and subsequent localization of these constructs within cell nuclei could be visualized using fluorescently tagged constructs with confocal microscopy and by following the migration of biotinylated constructs inside cells using electron microscopy. The time course and extent of intracellular accumulation of fluorescently tagged constructs were also assessed by flow cytometry. Cellular uptake studies were conducted with CHO and RIF-1 cells maintained in suspension.

Loligomers have been shown in the past to be internalized rapidly into eukaryotic cells by absorptive endocytosis, with their maximal uptake occurring between 6 and 8 h of incubation (*13, 14*). In contrast, unconjugated chlorin e_6 is taken up by passive membrane diffusion (*38, 39*). The interaction between photosensitizers and cells is ultimately governed by their chemical properties. Negatively charged hydrophobic photosensitizers such as chlorin e_6 tend to concentrate at the surface of membranes with minimal electrostatic drive to actually traverse them (*7*). In contrast, cationic dyes such as rhodamines and kryptocyanines, are subject to electrochemical gradients which promote their interaction with anionic sites and subsequent translocation across cellular membranes, in particular, across mitochondrial membranes (*40*). Ce6-loligomer and Ce6-peptide were rapidly imported inside CHO cells (Figures 2 and 3). Furthermore, Ce6-peptide uptake into CHO cells was considerably greater than the level of import previously observed for a similar linear peptide which lacked chlorin e_6 (*13*), suggesting a role for the porphyrin group in promoting the internalization of the construct. Another factor which may influence intracellular uptake is the net negative charge of the cell membrane which varies depending on cell type and cell function (*41*).

All cells (CHO and RIF-1) were targeted by the constructs as confirmed by flow cytometry (results not shown) and by confocal microscopy (Figure 3). However, the distribution of biotinylated constructs inside cells as revealed by electron microscopy indicate that nuclear uptake is only significant for the Ce6-loligomer constructs (Figure 4, panels c and d). Electron microscopy also provided evidence suggesting that biotinylated variants of both peptide (Figure 4, panels a and c) and loligomer (Figure 4, panels b and d) constructs enter the cytosol of target cells in a similar fashion. To reach the cell nucleus, these constructs must first escape their vesicular compartments with their NLS sequences still intact (*13−15*). The precise mechanism underlying this translocation event of constructs across endosomal membranes is presently unknown. Zauner et al. (*42*) suggested that polylysine may under certain circumstances promote lysis of internal vesicles. The distribution of biotinylated Ce6-peptide and Ce6-loligomer constructs inside cells was monitored with colloidal gold particles conjugated to steptavidin. The constructs were released from endocytic vesicles into the cytoplasm and subsequently routed to the nucleus (Figure 5). Dual labeling of loligomers with distinct fluorochromes attached to the N-terminus and C-terminus arms have indicated that both probes remain at least partly associated following their release from vesicular compartments (Sheldon and Gariépy, unpublished results) and that 80% of the intracellular pool of loligomer is retained within CHO cells (*14*). These results suggest that the degradation of signals on loligomers is not extensive within the time scale of our measurements (hours) and that cycling of such constructs back to the cell surface does not represent a dominant cellular pathway. This result was confirmed in the present study where the fluorescence signal associated with both chlorin e_6 linked to the N-terminus and a fluorescein label attached to the C-terminal end of Ce6-loligomer-FL5 were shown to co-localize in cells over a period of at least 24 h (Figure 3). The branching design of loligomers with

multiple SV40 NLS sequences was also shown to enhance nuclear localization (ref *13*; see also Figures 3−5 and Table 1). The quantitation of gold particles present in the cytosol and nucleus of RIF-1 cells indicated that the amount of Ce6-loligomer in their nuclei at 6 h was more than three times that of Ce6-peptide (Table 1). Once inside the nucleus, biotinylated loligomer constructs appear to localize in areas of high DNA content. It has previously been documented that cationic photosensitizers (e.g., methylene blue) have a greater affinity for nucleic acid interactions compared with noncationic photosensitizers (*43*).

The incorporation of eight chlorin e_6 molecules into a single loligomer construct (Ce6-loligomer) was found to enhance its toxicity by 400-fold in CHO cells and by 40-fold in RIF-1 cells when compared on a mole-to-mole basis with chlorin e_6 alone (Figure 6). Similarly, the phototoxicity of the single arm construct Ce6-peptide, although modest in relation to Ce6-loligomer, was greater than the toxicity level observed for chlorin e_6. A comparison of CD_{50} values for Ce6-loligomer with values obtained for loligomer without the photosensitizer (*14*) reveals a shift in CD_{50} values of almost 4 log units. These results point out that the level of enhanced phototoxicity observed using our chlorin e_6-containing peptide constructs is dependent on the cell line targeted. The present study supports results published recently by Akhlynina et al. (*11*) describing the construction and delivery of macromolecular conjugates composed of insulin, chlorin e_6, and NLS peptides chemically cross-linked to bovine serum albumin into cells. The insulin-containing BSA constructs were shown to enhance the photodynamic activity of chlorin e_6 by >2000-fold. A comparison of the levels of enhancement in phototoxicity observed between our compounds and these BSA conjugates is difficult to establish since the basal toxicity of the insulin-containing BSA constructs in the absence of photoirradiation was not reported and the cell lines tested by Akhlynina's group were different from the ones used in our studies. The BSA conjugates incorporating insulin do target the insulin receptor and as such may represent constructs affording a more guided delivery. However, this past study did not provide phototoxicity data of these constructs toward a control cell line that did not express the insulin receptor. Akhlynina et al. (*11*) suggested that the enhanced PDT activity of their constructs could be partly linked to the number of NLS peptides attached to the conjugates, rather than the number of chlorin e_6 molecules. In the present study, the introduction of multiple NLS sequences in the structure of Ce6-loligomer also resulted in the enhanced nuclear localization potential and cytotoxicity profile of this construct in relation to Ce6-peptide. From the perspective of designing intracellular vehicles, the simplicity and directed assembly of Ce6-peptide and Ce6-loligomer can be contrasted with the preparation of the reported BSA conjugates (*11*). More precisely, the average ratio of components in these BSA conjugates had to be inferred from molecular weight estimates derived from polyacrylamide gel electrophoresis and optical density measurements of chlorin e_6. The present study demonstrates that peptide-based vehicles such as Ce6-peptide and Ce6-loligomer represent simple and easily constructed synthetic assemblies able to deliver PDT agents into specific areas of a cell which display heightened photosensitivity in order to improve the photodynamic efficiency of these agents.

The mechanism of Ce6-loligomer-mediated toxicity was shown to involve the generation of reactive oxygen species, confirming that the activation of chlorin e_6 is not hindered upon its attachment to the loligomer (Figure 7). Although it was demonstrated that Ce6-loligomer reaches the cytosol and accumulates in the nucleus of CHO and RIF-1 cells (Figures 3−5 and Table 1), it remains unclear if the enhanced phototoxicity observed is predominantly due to singlet oxygen events occurring in the nucleus of cells as a result of nuclear localization or a simple consequence of the improved cellular uptake of chlorin e_6 when attached to this peptide construct. The sites of production of reactive singlet oxygen species as reported using CM-H2-DFDA (Figure 7) suggest a diffuse distribution of the reactive $^1O_2$ species throughout the cytosol and nucleus of RIF-1 cells. Preliminary results from flow cytometry studies also confirmed that PDT-induced cell death following treatment with uncoupled chlorin e_6 or related constructs occurred via an apoptotic pathway for CHO and RIF-1 cell lines (results not shown). Morphological signs of apoptotic cell death were apparent as cytoplasmic blebbing and shrunken nuclei.

In summary, the cytotoxicity of photosensitizers such as chlorin e_6, in the context of photodynamic therapy, is dependent on the intracellular localization of these agents. The incorporation of chlorin e_6 into peptide-based intracellular vehicles will dictate its toxicity. In particular, the routing of chlorin e_6 to the cytoplasm and nucleus of CHO and RIF-1 cells using intracellular peptide shuttles can alter its phototoxicity.

ACKNOWLEDGMENT

The authors thank Drs. Lothar Lilge and Eric LaCasse for their assistance with experimental apparatus and protocol, Battista Calvieri, Steven Doyle, and Trudy Franklin for their kind help with electron and confocal microscopy, Juliet Sheldon for her technical assistance in operating the flow cytometer and Jim Ferguson for synthesizing peptides. This work was supported by a grant from the National Cancer Institute of Canada with funds from the Canadian Cancer Society.

Polyelectrolyte Vectors for Gene Delivery: Influence of Cationic Polymer on Biophysical Properties of Complexes Formed with DNA

Margreet A. Wolfert, Philip R. Dash, Ola Nazarova,† David Oupicky,† Leonard W. Seymour,* Sarah Smart, Jiri Strohalm,† and Karel Ulbrich†

CRC Institute for Cancer Studies, University of Birmingham, B15 2TA, U.K., and Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, Prague 6, The Czech Republic. Received March 2, 1999; Revised Manuscript Received August 13, 1999

Cationic polymer/DNA complexes are widely used for gene delivery, although the influence of the cationic polymer on the biophysical properties of the resulting complex is poorly understood. Here, several series of cationic polymers have been used to evaluate the influence of structural parameters on properties of DNA complexes. Parameters studied included the length of side chain, charge type (primary versus tertiary and quaternary), polymer molecular weight, and charge spacing along the polymer backbone. Cationic polymers with short side chains (such as polyvinylamine) formed small complexes, resistant to destabilization by polyanions, with low surface charge, limited transfection activity, and efficient intranuclear transcription. Conversely, cationic polymers with long side chains (e.g., poly[methacryloyl-Gly-Gly-NH-$(CH_2)_6$-NH_2)] showed inefficient complex formation, high positive surface charge, and better transfection activity. The effects of molecular weight varied between polymers, for example, low molecular weight poly(L-lysine) produced relatively small complexes, whereas low molecular weight poly[2-(trimethylammonio)ethyl methacrylate chloride] produced large aggregates. Polymers containing quaternary ammonium groups showed efficient complex formation but poor transfection. Finally, spreading charges widely on the polymer structure inhibited their ability to condense DNA. In summary, to achieve small, stable complexes, the use of cationic polymers with short side chains bearing primary amino groups is suggested.

INTRODUCTION

The successful application of gene therapy can lead in principle to significant improvements in the treatment of several diseases (*1*). However, studies to date have highlighted the difficulty of achieving efficient transfection of target cells and tissues, both in vitro and in vivo. Indeed, inadequate transgene expression currently comprises a major factor limiting therapeutic application of sophisticated molecular treatment strategies (*2, 3*). Most existing gene delivery vectors are relatively inefficient when applied in vivo, requiring administration directly to the target tissue to attain useful levels of therapeutic gene expression (*4*). For useful deployment of gene therapy protocols, there is an urgent need for development of more efficient and biocompatible vectors (*5*). Ideally, these should ideally be capable of remote targeting and efficient transfection of specific cells and tissues following intravenous injection (*6*).

We are developing novel vectors for gene delivery based on self-assembly of DNA with synthetic polymers. Although the final vectors are expected to contain several functional groups, the core of the complex will be formed by binding and condensation of DNA expression plasmids by cationic polymers, producing discrete polyelectrolyte particles (*7, 8*). There are several biophysical requirements of such polyelectrolyte particles. Chief among these are requirements that the particles should be small, to facilitate good biodistribution and extravasation properties (*9*), and also be capable of undergoing efficient transcription following arrival in the nucleus of the target cell (*10*). In addition, resistance of complexes to destabilization by serum proteins is desirable, since there is increasing evidence that the rapid clearance of such polyelectrolyte complexes from the circulation follows their interaction with serum proteins (*11*).

The principles of particle formation following cooperative binding of polycations to DNA have been widely studied, although several details of the process remain to be elucidated (*12*−*16*). Most of the work performed so far on formation of interpolyelectrolyte complexes has made use of the simple cationic polymer poly(L-lysine) (pLL), and there has been very little systematic study of the influence of polycation structure on self-assembly with DNA and the properties of the resulting complexes.

In this study, we have examined a range of synthetic linear cationic polymers, selected to permit systematic evaluation of the influence of individual parameters on the biophysical properties of complexes formed by self-assembly with DNA. Specific molecular parameters selected for study are the distance of cationic charge from polymer backbone (length of side chain), order of cationic charge, influence of charge density along the polymer backbone, and polycation molecular weight. The ability of the cationic polymers to bind and condense DNA into particles has been assessed using gel electrophoresis and fluorescence inhibition assays. Physical properties of the particles formed have been characterized using atomic force microscopy (AFM)[1] and ζ-potential (a measurement of charge at the surface of the particle). Their stability has been assessed using a polyanion-disruption assay, and finally, their biological properties have been assessed

by monitoring transfection of cells in vitro and measuring transcriptional activity directly following microinjection into the nucleus of Xenopus oocytes. In this way, we aim to identify molecular parameters of cationic polymers influencing properties of the complexes formed with DNA, providing information that should allow us to begin the design and development of polyelectrolyte complexes with properties selected for specific applications.

EXPERIMENTAL PROCEDURES

DNA Purchase and Preparation. A circular 6 kb expression vector containing a CMV promoter-driven β-galactosidase reporter and ampicillin resistance was used for the atomic force microscopy, electrophoresis, and all studies of biological properties. This was prepared by growth in *Escherichia coli* DH5α and purified by standard technology. Following the final ethanol precipitation, the purity of the DNA was checked by agarose gel electrophoresis. The ethidium bromide fluorescence quenching and ζ-potential assays were performed using calf thymus DNA (Sigma Chemical Co.), with average molecular size determined to be 8 kb. For calculation of the N-to-P ratio of polyelectrolyte complexes, a mass per charge of 325 Da was used for DNA.

Cationic Polymers Studied. The polymers described below were purchased or synthesized for systematic examination of the influence of individual parameters on the properties of complexes formed by self-assembly with DNA. Chemical structures of all cationic polymers examined are shown in Figure 1.

(1) Influence of Length of Side Chain Bearing Cationic Residue. Several poly-(methacrylate)-based homopolymers with differing side chains bearing primary amino groups were synthesized as described below. These were poly[methacryloyl-Gly-Gly-NH-$(CH_2)_6$-NH_2] hydrochloride (pMADGHDA.HCl), mass per primary amino group, 334.6 Da; poly[methacryloyl-Gly-NH-$(CH_2)_2$-NH_2] hydrochloride (pMAGEDA.HCl), mass per primary amino group, 221.6 Da, and poly[methacryloyl-NH-$(CH_2)_2$-NH_2] hydrochloride (pMAEDA.HCl), mass per primary amino group, 164.5 Da, together with poly(L-lysine) hydrobromide (pLL.HBr), mass per primary amino group, 209 Da; poly(allylamine) hydrochloride (pAA.HCl), mass per primary amino group, 57 Da; and poly(vinylamine) hydrochloride (pVA.HCl), mass per primary amino group, 79 Da. They were allowed to form complexes with DNA, using cationic polymer preparations of roughly similar molecular weight distribution in each case, and properties of the resulting complexes were determined and compared as described below.

(2) Primary, Tertiary, and Quaternary Amino Groups. The influence of order of cationic charge on the properties of complexes formed with DNA was examined. The tertiary amino group-containing polymer poly(2-dimethylaminoethyl methacrylamide) (in free base form, pDMAEMam, mass per amino group 157 Da) was synthesized and properties of its DNA complexes were compared with those of the quaternized ester poly[2-(trimethylammonio)ethyl methacrylate chloride] (pTMAEM.Cl, mass per charge 208 Da) and also with those formed by polymers bearing primary amino groups, mentioned above.

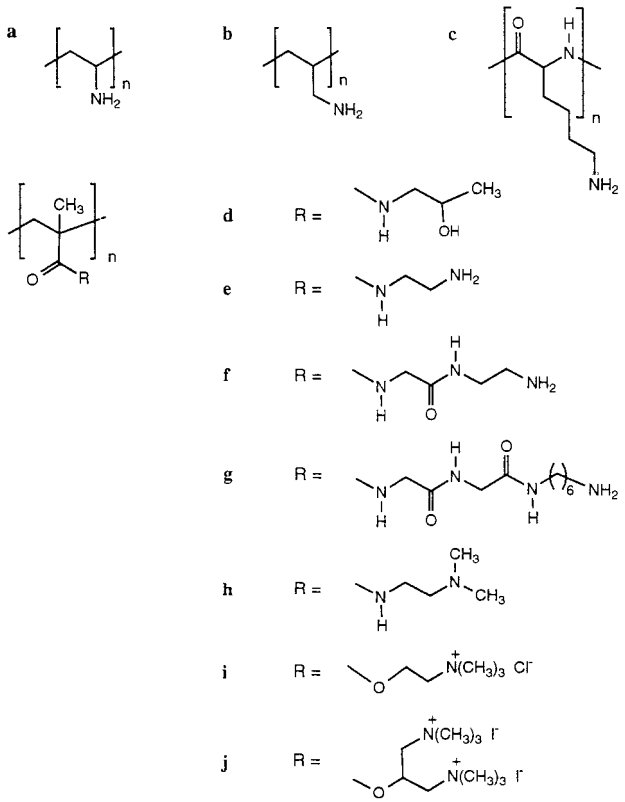

Figure 1. Structure of synthetic polymers used in this study. For simplicity, primary cationic monomers are shown as free bases. Panels a–c represent simple monomers as follows: a, pVA; b, pAA; c, pLL. Panels d–j show the side chains based on the methacrylate backbone shown, as follows: d, pHPMA; e, pMAEDA; f, pMAGEDA; g, pMADGHDA; h, pDMAEMam; i, pTMAEM.Cl; j, pBTMAIP.I_2. Systematic names, together with full details of molecular weight averages, counterions, etc., are given in the text.

(3) Influence of Charge Spacing along the Polymer Chain. Charge spacing was varied by synthesising statistical copolymers containing *N*-(2-hydroxypropyl)-methacrylamide (HPMA) and 2-(trimethylammonio)ethyl methacrylate chloride (TMAEM.Cl), with TMAEM.Cl present at monomer ratios of 5, 15, 50, 75, and 100 mol %, masses per charge 2925, 1019, 351, 255, and 208 Da, respectively. In addition, poly[1,3-bis-(trimethylammonio)isopropyl methacrylate iodide] (pBTMAIPM.I_2), which bears two cationic groups per monomer, was examined. It had a mass per charge of 249 Da.

(4) Influence of Molecular Weight or Degree of Polymerization. Several families of polymers were compared to evaluate the influence of molecular weight on properties of complexes formed with DNA. pLL.HBr was purchased with weight average molecular masses, 4, 10, 24, 54, and 224 kDa (manufacturer's specifications). Several polymers were synthesized (described below), including pTMAEM.Cl, weight average molecular masses, 5, 8, 21, 34, and 413 kDa; pMADGHDA.HCl, weight average molecular masses, 38, 74, and 330 kDa; pMAGEDA.HCl, weight average molecular masses, 29, 82, and 323 kDa; and pMAEDA.HCl, weight average molecular masses 19

[1] Abbreviations: HPMA, (2-hydroxypropyl)methacrylamide; pMADGHDA.HCl, poly[methacryloyl-Gly-Gly-NH-$(CH_2)_6$-NH_2] hydrochloride; pMAGEDA.HCl, poly[methacryloyl-Gly-NH-$(CH_2)_2$-NH_2] hydrochloride; pMAEDA.HCl, poly[methacryloyl-NH-$(CH_2)_2$-NH_2] hydrochloride; pLL.HBr, poly(L-lysine) hydrobromide; pAA.HCl, poly(allylamine) hydrochloride; pVA.HCl, poly(vinylamine) hydrochloride; pDMAEMam, poly(2-dimethylaminoethyl methacrylamide); pTMAEM.Cl, poly[2-(trimethylammonio)ethyl methacrylate chloride]; pBTMAIPM.I_2, poly[1,3-bis-(trimethylammonio)isopropyl methacrylate iodide]; DCC, *N*,*N*′-dicyclohexylcarbodiimide; AIBN, azobisisobutyronitrile; IVA, 4,4′-azobis(4-cyanovaleric acid); DMSO, dimethyl sulfoxide; DMF, *N*,*N*-dimethyl formamide; BOC, di-*tert*-butyl dicarbonate; pVFA, poly(*N*-vinylformamide).

and 42 kDa. Degrees of polymerization (DPn) are given in Table 1.

Chemicals. 1-Amino-2-propanol, methacryloyl chloride (freshly distilled), glycine, glycylglycine, 4-nitrophenol, *N*,*N*′-dicyclohexylcarbodiimide (DCC), azobisisobutyronitrile (AIBN), 4,4′-azobis(4-cyanovaleric acid) (IVA), 3-mercaptopropionic acid, cysteamine, cysteamine hydrochloride, *N*,*N*-dimethyl ethylenediamine, 1,2-diaminoethane, di-*tert*-butyl dicarbonate, *N*-BOC-1,6-diaminohexane hydrochloride, 4-(dimethylamino)pyridine, tetramethylammonium chloride, dimethyl sulfoxide (DMSO), *N*,*N*-dimethyl formamide (DMF), trifluoracetic acid, and triethylamine were from Fluka A.G., Switzerland. *N*-Vinylformamide was from Aldrich, Germany, and poly(L-aspartic acid, sodium salt) and pLL.HBr preparations were from Sigma, U.K. Solvents (all used after distillation) and other chemicals were of analytical grade quality, Lachema Brno, Czech Republic.

Synthesis of Cationic Polymers. Cationic monomers and polymers were synthesized as described below. In each case, the composition of the monomers was checked by elemental analysis prior to polymerization and found to be within 0.5% of the theoretical values. In most cases, ^{1}H NMR was used as an additional technique to characterize the monomers and some of the polymers. In addition, the polymer products were routinely characterized by GPC for weight and number average molecular weights. The polydispersity of most of the polycations was about 1.8.

Poly[*N*′-{2-[(*tert*-butyloxycarbonyl) amino]ethyl}-methacryl amide] [MA-NH-$(CH_2)_2$-NH-BOC] was prepared as follows. A solution of di-*tert*-butyl dicarbonate (2.45 g, 0.011 mol) in dioxane (30 mL) was added dropwise to a solution of 1,2-diamino-ethane (5.25 g, 0.087 mol) in dioxane (30 mL). The mixture was stirred for 22 h at room temperature. The dioxane was evaporated in vacuo and the crude product triturated with 50 mL of water. The insoluble bis-substituted diamine was removed by filtration. The filtrate was extracted three times with methylene chloride (150 mL), the organic layer was separated and the solution was dried over Na_2SO_4. Methylene chloride was evaporated, and the yield of oily BOC-NH-$(CH_2)_2$-NH_2 was 1.29 g (72%). Contamination of the product with free diamine was checked by TLC, but none could be determined. The oily product was used for the synthesis of MA-Gly-NH-$(CH_2)_2$-NH-BOC and MA-NH-$(CH_2)_2$-NH-BOC without further purification.

N-BOC-1,2-diamino-ethane (1 g, 0.00625 mol) and triethylamine (5.5 mL) were dissolved in 50 mL of freshly distilled chloroform. The mixture was cooled to −5 °C and methacryloyl chloride (0.68 g, 0.0065 mol) was added dropwise under stirring within 3 h. Reaction mixture was extracted four times with 20 mL of water and then a chloroform layer was dried with Na_2SO_4. Chloroform was evaporated, and after trituration in diethyl ether, the yellow crude product was obtained. This product was purified by recrystallization from the benzene−hexane mixture and characterized by elemental analysis and ^{1}H NMR ($CDCl_3$). Yield was 1.2 g (81%). Melting point: 73−76 °C. The monomer and initiator of polymerization (AIBN) were dissolved in methanol to form a solution containing 7−30 wt % of monomer and 0.1−2 wt % of AIBN related to polymerization mixture. The solution was introduced into an ampule and bubbled through with nitrogen. The ampule was sealed, and polymerization was carried out at 50 or 60 °C for 24 h. The polymer was precipitated into diethyl ether and reprecipitated from methanol into diethyl ether. The precipitated polymer was filtered off, washed with diethyl ether, and dried in vacuo. Molecular weight of polymers was controlled by varying the monomer concentration, the initiator concentration, or the temperature. BOC protecting group was removed by dissolution of the polymer in a solution of dry hydrochloric acid in methanol (15 wt % of HCl in methanol and 20 wt % of polymer in solution) and stirring for 1 h. The deprotected polymer was diluted with methanol, evaporated in vacuo to remove the excess of hydrochloric acid, and precipitated into diethyl ether. The precipitated polymer was filtered off, washed with diethyl ether and dried in vacuo. The quantitative removal of the protecting BOC groups was confirmed by the absence of the BOC signal (1.4 ppm) in the ^{1}H NMR spectrum of the polymer.

Poly[*N*′-{2-[(*tert*-butyloxycarbonyl)amino]ethyl}-methacryloylglycinamide] [MA-Gly-NH-$(CH_2)_2$-NH-BOC] was prepared as follows: BOC-NH-$(CH_2)_2$-NH_2 (1.1 g, 0.0068 mol) was dissolved in 2 mL of DMSO. MA-Gly-ONp (1.6 g, 0.0061 mol) was dissolved in 3.5 mL of DMSO and added dropwise to the solution of amine. Reaction mixture was stirred for 2 h at room temperature. DMSO was evaporated in vacuo (bp 55 °C) and an oily residue was dissolved in 50 mL of chloroform. An organic layer was extracted three times with 20 mL of distilled water. Organic layer was dried over Na_2SO_4. Chloroform was evaporated, and MA-Gly-NH-$(CH_2)_2$-NH-BOC was crystallized from ethyl acetate. Melting point: 136−38 °C. Polymerization and deprotection of the amino group were carried out according to the polymerization of MA-NH-$(CH_2)_2$-NH-BOC with subsequent deprotection of the BOC-containing polymer and NMR check of the BOC group removal.

Poly[*N*′-{(6-*tert*-butyloxycarbonyl)amino]hexyl}-methacryloylglycylglycin amide] [MA-GlyGly-NH-$(CH_2)_6$-NH-BOC] was prepared as follows. MA-GlyGly-ONp (3 g, 0.0093 mol) and *N*-BOC-1,6-diamino-hexane hydrochloride were dissolved in 15 mL of DMF. Triethylamine (1.3 mL) was added in three portions, and reaction mixture was stirred 24 h at room temperature. The precipitated triethylamine hydrochloride was filtered off, and the filtrate was evaporated in vacuo to dryness. A crude product was dissolved in chloroform and extracted three times with 15 mL of water. An organic layer was dried with Na_2SO_4 and evaporated in vacuo. The product was crystallized from a chloroform−diethyl ether mixture. Melting point: 122−124 °C. Yield was 1.98 g (54%). Polymerization and deprotection of the amino group were carried out according to the polymerization of MA-NH-$(CH_2)_2$-NH-BOC with subsequent deprotection of the BOC-containing polymer and NMR check of the BOC group removal.

DMAEMam was prepared as follows. *N*,*N*-Dimethyl ethylenediamine (8.22 g, 0.093 mol) was diluted with 30 mL of dichlormethane, and the solution was cooled to −15 °C. The solution of methacryloyl chloride (5.0 g, 0.047 mol) in dichloromethane (5 mL) was added dropwise under stirring within 2 h. The precipitate (*N*,*N*-dimethylethylenediamine hydrochloride) was filtered off, and dichlormethane was evaporated from the reaction mixture. The product was purified by rectification at reduced pressure. Polymerization of DMAEMam was carried out according to the polymerization of MA-NH-$(CH_2)_2$-NH-BOC. Briefly, a polymerization mixture consisting of 13 wt % methanol solution containing 0.6 wt % AIBN was introduced into an ampule and bubbled through with nitrogen. The ampule was sealed and polymerization was carried out at 60 °C for 20 h. A mixture of acetone and

diethyl ether was used for deprotection and reprecipitation of the polymer.

pTMAEM.Cl was prepared as follows. TMAEM.Cl was prepared by quaternization of 75 g dimethylaminoethyl methacrylate with gaseous methyl chloride in 200 mL of acetone in the presence of 5 mL of *N,N*-dimethylformamide at room temperature. The crystalline precipitate was isolated by filtration, washed three times with acetone, and dried in vacuo. Melting point: 174 °C. Polymerization was carried out as described elsewhere (*17*).

pBTMAIPM.I_2 was prepared by radical polymerization of 1,3-bis-(trimethylammonio)isopropyl methacrylate iodide (10 wt %) in DMF using IVA (0.3%) as initiator. Polymerization was carried out at 70 °C for 40 h in a sealed ampule under nitrogen atmosphere. The polymer was precipitated into dry acetone-diethyl ether mixture, washed with dry acetone, and dried in a vacuum.

pVA.HCl was prepared by alkaline hydrolysis of poly(*N*-vinylformamide) (pVFA). pVFA was prepared by radical precipitation polymerization of 4 g of *N*-vinylformamide dissolved in methanol, using 0.38 g of initiator (AIBN) and 2-mercaptoethanol as a chain transfer agent for regulation of molecular weight. Polymerization was carried out at 60 °C for 24 h. Precipitated polymer was washed with methanol, dissolved in 28 mL of NaOH (1.7 M), and hydrolyzed at 80 °C for 6 h. The polymer solution was acidified by concentrated HCl solution. Precipitated pVA.HCl was washed with methanol, acetone, and dried in vacuo.

Synthesis of statistical copolymers of TMAEM.Cl with HPMA. HPMA was prepared by the reaction of methacryloyl chloride with 1-amino-2-propanol, as described earlier (*18*). Copolymers were prepared by radical copolymerization of TMAEM.Cl with HPMA in methanol using AIBN as initiator. Monomers in various molar ratio (25−95% HPMA) were dissolved in methanol to obtain 20 wt % solution. Concentration of AIBN was 0.6 wt %, polymerization temperature 60 °C, and polymerization time 24 h. Polymerization was conducted in sealed ampules under nitrogen atmosphere. Copolymers were isolated by precipitation into diethyl ether−acetone and purified on GPC (Sephadex LH-20, methanol). The composition of copolymers was calculated using data of elemental analysis (chlorine content).

The molecular weight distribution (weight average molecular weight M_w and polydispersity M_w/M_n) of cationic polymers was determined either by FPLC on Sepharose 12 using 0.25 M sodium acetate buffer, pH 6.6, containing 0.5 M NaCl and 0.028 M tetramethylammonium chloride, or using Catsec 300 column (Micra Scientific) with an aqueous solution of $NaNO_3$ (0.2 M, adjusted to pH 2 using trifluoroacetic acid) as mobile phase. The columns were calibrated with fractionated low-polydispersity polyHPMA standards with molecular weights in a range 18000−300000 g/mol. The molecular weights of polyHPMA standards were determined by static laser light scattering. Weight average of molecular weight (M_w) of selected polycations was determined using light scattering (Fica 40).

Formation of Cationic Polymer/DNA Complexes. The conditions of complex formation were standardized to permit comparison of different properties. DNA was dissolved in water at 20 μg/mL, and then cationic polymers were added in a small volume of concentrated (5 mg/mL) solution in water. Samples were mixed very gently and then allowed to stand for at least 1 h at room temperature before more thorough mixing. To permit comparison of different cationic polymers, containing amino groups with different pK_a values, complexes were formed at defined molar ratios of highly charged amino groups to DNA phosphate (N-to-P ratios), and no correction was made for different levels of protonation.

Inhibition of Ethidium Bromide/DNA Fluorescence by Cationic Polymers. Decreased ethidium bromide-DNA fluorescence can be used to indicate condensation of the DNA (*13*). The influence of N-to-P ratio on DNA condensation by each polymer was determined by loss of ethidium bromide fluorescence in aqueous solution using a fluorimeter ($\lambda_{ex} = 366$ nm, $\lambda_{em} = 590$ nm). DNA (20 μg/mL) was incubated in water in the presence of ethidium bromide (400 ng/mL) before sequential addition of small volumes of the cationic polymer (5 mg/mL), each addition accounting for increased N-to-P ratio of 0.1. The parameters deduced for each interaction were the N-to-P ratio of polymer causing 50% fall in measured fluorescence (IF_{50}) and the lowest fluorescence level achieved at any N-to-P ratio (Min F), expressed as a % the fluorescence of equivalent free DNA.

Ethidium Bromide/DNA Fluorescence Restoration by Poly(L-aspartic acid). Polyelectrolyte complexes containing 20 μg/mL DNA were formed at an N-to-P ratio of 2 in the presence of ethidium bromide (400 ng/mL). Poly(L-aspartic acid) was then added in sequential aliquot portions in water. After each addition, solutions were mixed and ethidium bromide/DNA fluorescence was monitored as above. Poly(L-aspartic acid) was added in small portions until fluorescence was restored to 50% of its original value (the RFI_{50} concentration; Figure 3).

Agarose Gel Electrophoresis. Polymer/DNA complexes in water were electrophoresed on agarose gel (0.8% w/v) (BRL) for 45 min at 90 V. Ethidium bromide was included in the gel to show the location of DNA using a UV transilluminator.

Atomic Force Microscopy (AFM). Samples containing complexes in water (1−2 μL) with final DNA concentration of 20 μg/mL were deposited onto the center of a freshly split untreated mica disk (Agar Scientific). Following adsorption for 1−2 min at room temperature, excess fluid was taken off by absorption onto filter paper. The mica surface was dried at room temperature before imaging using an AFM-2, part of the NanoScope II system (Digital Instruments). A 200 μm long Si_3N_4 cantilever with a spring constant of 0.12 N/m and a D scanner head (AFM 351) with 12 μm scan range were used. The image mode was set to constant force mode, hence the images obtained are height images of the sample surface. The scanning speed varied between 2.48 and 8.68 Hz.

Analysis of ζ-Potential. The surface charge of the polymer/DNA complexes was assessed by using a Zetamaster system (Malvern Instruments). The system was routinely calibrated using a −55 mV standard. Experimental samples (5 mL) contained a final calf thymus DNA concentration of 20 μg/mL and were measured 5 times for 30 s at 1000 Hz with zero field correction.

Microinjection of DNA Complexes into *Xenopus oocytes*. Reporter gene activity was determined following injection of polymer/DNA complexes directly into the nucleus of Xenopus oocytes. Mature female frogs were killed by benzocaine overdose, and oocytes were individually examined in a Petri dish containing Modified Barth's Solution (MBS, pH 7.6). Only oocytes at developmental stage IV were used, and complexes were microinjected using a Drummond Auto Oocyte Injector (Drummond Scientific Company). The injection volume was 13.8 nL/oocyte and DNA concentration 22 pg/nL (either free DNA

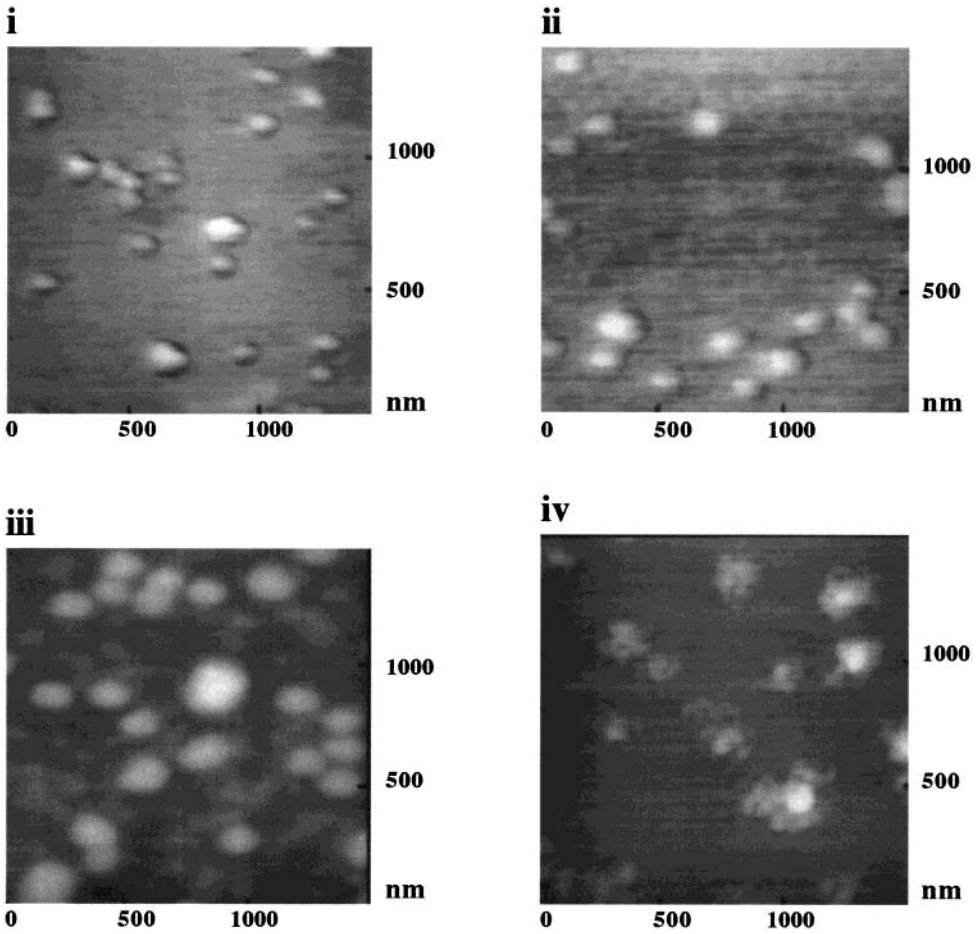

Figure 2. Influence of side-chain length on structure of complexes formed with DNA, viewed by AFM. Polymer/DNA complexes were formed at an N-to-P ratio of 2.0. The images show conjugates formed using (i) pAA.HCl (54 700 Mw; DPn 960), (ii) pMAEDA.HCl (41 900 Mw; DPn 255), (iii) pMAGEDA.HCl (82 000 Mw; DPn 370), and (iv) pMADGHDA.HCl (73 700 Mw; DPn 220). The height of the AFM image is represented by a graded black-white scale, with white indicating a height of 30 nm above the mica surface. The *x* and *y* dimensions are scaled as shown. The images are typical of the results of multiple evaluations performed on separate days.

or as polymer/DNA complexes). Oocytes were maintained in MBS for a further 48 h in small Petri dishes at 18−20 °C (individually grouped for specific studies), at which time healthy looking oocytes were pooled together (10 oocytes/mL) in lysis solution (100 mM potassium phosphate, 0.2% vol/vol Triton X-100, and 1 mM dithithreitol, pH 7.8). Oocytes were lysed by pipetting them up and down, and samples were centrifuged at 13 000 rpm (MicroCentaur, 10 min). The clear supernatant (20 μL) was then assayed for β-galactosidase activity by Galactolight, as described below.

Efficiency of Transfection in Vitro. Polymer/DNA complexes were prepared in water at an N-to-P ratio of 2 and with a DNA concentration of 20 μg/mL. Complexes were added to 293 cells and incubated for 4 h at a final DNA concentration of 2.6 μg/mL in serum-free medium containing chloroquine (100 μM). Cells were washed after exposure and reincubated in the presence of serum (10%). After 48 h, medium was removed from the culture and the cells were washed once with PBS (100 μL). Aliquots of lysis buffer (100 mM potassium phosphate, pH 7.8, and 0.2% Triton X-100) (100 μL) were added, and the plates were left for 40 min at room temperature until the lysis was complete. After centrifugation, the cell lysates were assayed for gene expression and total protein content (see below).

Evaluation of Gene Expression. Total β-galactosidase activity was quantified using the chemiluminescent reporter assay system Galacto-Light Plus (Tropix, Cam-

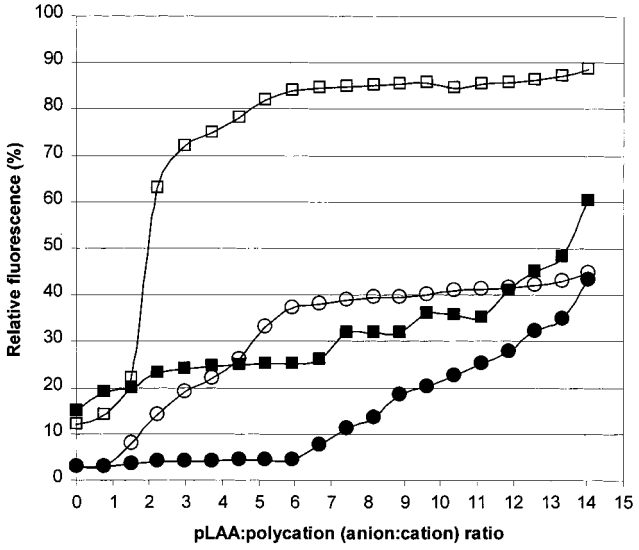

Figure 3. Restoration of ethidium bromide/DNA fluorescence by addition of poly(L-aspartic acid) to preformed polymer/DNA complexes. Complexes were formed at an N-to-P ratio of 2.0, in the presence of ethidium bromide (400 ng/mL), and allowed to stabilize for 2 h, and then poly(L-aspartic acid) was added in small portions, with fluorescence determined at λ_{ex} 366 and λ_{em} 590 nm. The behavior of DNA complexes formed with pVA.HCl [60 000 Mw, DPn 760 (●)], pAA.HCl [54 000 Mw, DPn 960 (○)], pMAEDA,HCl [41 900 Mw, DPn 255 (■)], and pMAGEDA.HCl [82 000 Mw, DPn 370 (□)] is shown.

bridge, U.K.). Cell lysates were diluted 1:1 with lysis buffer containing 2 mM dithiothreitol. After centrifugation, 50 μL of the supernatant was then added to 200 μL of chemiluminescent substrate solution (Galacton-Plus in 100 mM sodium phosphate, pH 8.0, and 1 mM magnesium chloride). After incubation for 1 h, 300 μL of luminescence accelerator reagent was added, and the sample was assayed on a monolight luminometer (Lumat LB9501, Berthold) by counting emitted light units for 10 s. Transfection was quantified as β-galactosidase activity measured per μg of protein (light units/μg). The total protein content was measured in the absence of dithiothreitol using the bicinchonninic acid (BCA) assay for protein.

RESULTS

Influence of Length of Polycation Side Chain on Properties of Complexes Formed with DNA. Different distance of cationic charge from the polymer backbone had an important influence on the properties of complexes formed with DNA. Polymers with charges close to the backbone (e.g., pVA.HCl) showed generally efficient condensation, with relatively low values of IF_{50} and Min F (Table 1). Conversely, polymers with long lateral side chains (e.g., pMADGHDA.HCl) showed poor condensation. It is important throughout these studies comparing different side chains to consider the influence of DPn, since polymers based on small monomers have more charges per polymer of the same molecular weight compared with polymers based on larger monomers. However, even bearing this in mind, it is clear that polymers with long side chains tend to be less efficient at condensing DNA than polymers with short side chains (Table 1). Nonetheless, the influence of side-chain length is not simple as some polymers with intermediate length side chains, such as pLL.HBr, also achieved efficient DNA condensation judged by inhibition of ethidium bromide/DNA fluorescence.

AFM was used to measure sizes of polymer/DNA complexes. However, pVA.HCl/DNA complexes tended to flocculate in water, particularly with lower molecular weight pVA.HCl, and no AFM images were possible. pAA.HCl and cationic polymers with side chains of intermediate length produced discrete, well-defined complexes with DNA, typical diameter about 100 nm. DNA complexes produced with cationic polymers with long side chains (pMADGHDA.HCl) were often loose with structural irregularities, and there was still DNA protruding from the complexes even several hours following initial mixing of pMADGHDA.HCl with DNA (Figure 2).

The influence of side-chain length was also evident when complexes were subject to interaction with pLAA, and restoration of ethidium bromide/DNA fluorescence was monitored. Although complexes based on all other polymers showed fluorescence restoration (RFI_{50}) at concentrations of pLAA less than 60 μg/mL (a molar ratio of aspartic acid to cation of 3.5), those based on polymers with shortest side chains (pVA.HCl and pAA.HCl) showed much greater resistance to pLAA, pVA.HCl achieving RFI_{50} values even over 400 μg/mL (aspartic acid/cation ratios over 20; Table 1 and Figure 3). This does not appear to be strongly influenced by the DPn and may reflect high stability of DNA complexes formed with cationic polymers such as pAA.HCl and pVA.HCl.

When the surface charge of complexes was monitored (using N-to-P ratio of 2.0), DNA complexes formed with pVA.HCl or pAA.HCl were found to have ζ-potentials of approximately zero (Table 1), perhaps contributing to the tendency of pVA.HCl complexes to flocculate in water. Comparing complexes formed with medium molecular mass (40−80 kDa) cationic polymers, most of the cationic polymers with medium or long pendent side chains produced positive ζ-potential values, for example, pMADGHDA.HCl, 36 mV; pLL.HBr, 36 mV; pTMAEM.Cl, 9 mV. Although it is intuitively attractive to consider that longer side chains may result in a surface layer of nonneutralized positive charges, any such proposal is compromised by the low value of ζ-potential (1 mV) produced by pMAGEDA.HCl and the higher value (14 mV) produced by the shorter side chain pMAEDA.HCl.

DNA complexes formed using the short side-chain PVA.HCl gave no significant spontaneous transfection when applied to 293 cells in vitro, and pAA.HCl also produced only slight increases compared with DNA alone. Complexes based on all the other nonquaternized cationic homopolymers examined produced higher levels of gene expression, and this may relate to the known positive ζ-potential of the latter complexes, possibly mediating greater membrane adsorption. Complexes formed using pMADGHDA.HCl, known from AFM studies to be incompletely condensed, also mediated high levels of transgene expression, similar to the levels achieved using high molecular weight pLL.HBr (Table 1).

Following direct inoculation into Xenopus *oocytes*, complexes based on most homopolymers produced levels of gene expression comparable to that following injection of free DNA. pAA.HCl and pVA.HCl complexes showed over 60% expression, suggesting that despite their high stability to polyanions they are still suitable for intranuclear transcription. The only indication of the influence of side-chain length was from the long side-chain pMADGHDA.HCl polymer, which gave relatively low gene expression (25%) (Table 1).

Influence of Charge Strength on Properties of Complexes Formed with DNA. Comparison of similar molecular weight poly(methacrylamide)-based polymers containing primary (pMAEDA.HCl), tertiary (pDMAEMam), or quaternary (pTMAEM.Cl) amino groups permitted examination of the influence of these different types of charge on properties of complexes formed with DNA.

Quaternary charged pTMAEM.Cl was relatively efficient at DNA condensation, achieving low IF_{50} values (Table 1). In contrast, the tertiary amino-based pDMAEMam was very poor at DNA condensation, and failed to decrease ethidium bromide/DNA fluorescence to 50% of the starting value even at N-to-P ratios of 4.0. This poor ability of pDMAEMam to form complexes with DNA was probably due to its presence in free base form, leading to lower levels of protonation in water than with the other cationic polymers which were salts.

When poly(L-aspartic acid) was added to complexes to restore fluorescence of ethidium bromide/DNA, complexes based on pTMAEM.Cl/DNA required greater levels of poly(L-aspartic acid) than DNA complexes formed using methacrylate polymers containing primary amino groups (Table 1). AFM showed no obvious differences between DNA complexes formed using methacrylate-based polymers of different order of charge, with all polymers capable of producing discrete complexes of about 100 nm diameter. Similarly, there were no trends in ζ-potential determined for the complexes, except that DNA complexes formed with the tertiary amino-containing pDMAEMam displayed negative values of ζ-potential (Table 1).

Spontaneous transfection of 293 cells in vitro could be achieved to levels of about 10^5 l.u./μg protein by DNA

complexes formed using the methacrylate based primary amino polymer pMAEDA.HCl, and also by the tertiary amino pDMAEMam. These levels were comparable with those achieved using pLL.HBr. Complexes based on quaternary pTMAEM.Cl, however, showed much lower levels of spontaneous transfection, achieving maximal levels of 10^3 l.u./μg protein. This was only marginally increased compared with the intrinsic transfection activity of free DNA. Following direct intranuclear injection in Xenopus oocytes, complexes based on primary amino-bearing pMAEDA.HCl showed transgene expression at a level of 77% that of the equivalent dose of free DNA. pDMAEMam/DNA complexes achieved 71%, and pTMAEM.Cl/DNA complexes 40%. However, the 2-fold decreased intranuclear activity of the quaternary pTMAEM.Cl-based complexes is not sufficient to explain their very low levels of spontaneous cell transfection, suggesting that cellular transfection by pTMAEM.Cl/DNA complexes may be subject to particular problems of gaining access to the cytoplasm or nucleus (Table 1).

Influence of Charge Spacing along Polymer Backbone on Properties of Complexes Formed with DNA. A series of random copolymers of TMAEM.Cl and HPMA permitted examination of the influence of charge spacing on the properties of complexes formed with DNA. To permit comparison, all copolymers were used at standard concentrations of charge, which for some materials (particularly the 5% TMAEM.Cl copolymer) necessitated use of very high total concentrations of copolymer. Copolymers containing 50% pHPMA were unable to mediate 50% inhibition of ethidium bromide/DNA fluorescence at any N-to-P ratio examined (Figure 4a). Interestingly, agarose gel electrophoresis showed that all random copolymers, including the material containing 95% HPMA (where each positively charged TMAEM.Cl group is surrounded by an average 19 noncharged HPMA groups) was capable of binding DNA and mediating a gel-shift assay (Figure 4b). At N-to-P ratio of 1.0, there was still some electrophoretic mobility of DNA condensed with the 5% TMAEM.Cl copolymer, although at N-to-P ratio of 2.0, this had disappeared. In addition, fluorescence of DNA complexes retained in the wells was lower using polymers with greater TMAEM.Cl content, corresponding with data in Figure 4a, and suggesting formation of tighter complexes. AFM analysis showed that the higher charge density cationic polymers was capable of forming discrete complexes, while copolymers containing 50% or less TMAEM.Cl produced images of extended structures, probably representing DNA/cationic polymer complexes which are not subject to charge neutralization-driven particle self-assembly (Figure 5).

Measurement of ζ-potential also showed that every copolymer was capable of binding DNA, with all ζ-potentials measured in the range 10−50 mV, compared with the ζ-potential of free DNA (−80 mV, approximately). Although all copolymer complexes showed some activity in spontaneous transfection of 293 cells, levels were very low compared with pLL.HBr/DNA complexes, similar to the level achieved using complexes formed using pTMAEM.Cl homopolymer. After direct intranuclear injection to Xenopus oocytes, copolymer/DNA complexes showed low levels of gene expression (14−30% of DNA control), although again this is comparable with the activity of pTMAEM.Cl/DNA complexes (Table 1).

pBTMAIPM.I_2 is a polymer bearing two quaternary positive charges per methacrylate-based monomer, and hence the charge density of the polymer is relatively high. Properties of the complexes formed between pBTMAIPM.I_2 and DNA were very similar to pTMAEM/DNA complexes, showing similar condensation parameters and poor ability to transfect cells despite positive surface charge. This may reflect the poor transcriptional ability of pBTMAIPM.I_2/DNA complexes observed following intranuclear injection, similar to that observed for complexes based on high molecular weight pTMAEM.Cl.

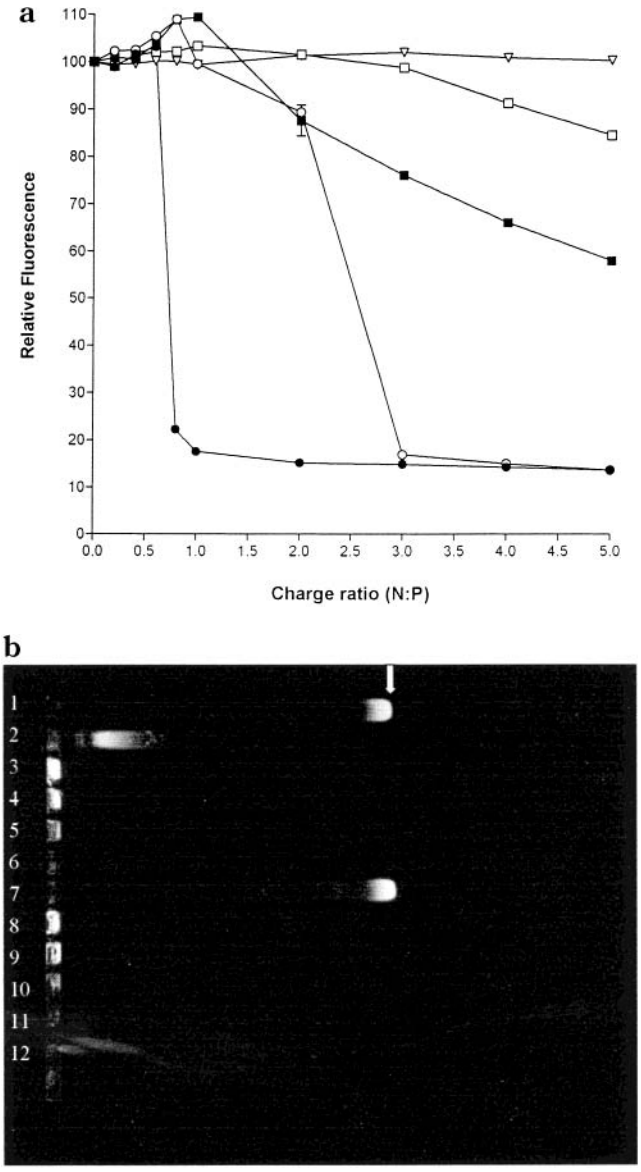

Figure 4. Assessment of DNA condensation by TMAEM.Cl-*co*-HPMA random copolymers. (a) Fluorescence of ethidium bromide allowed to integrate into the DNA before addition of the cationic polymers, as described in the text. The lines represent sequential addition of copolymers of different composition: 100 mol % TMAEM.Cl (Mw 21 240; DPn 102; ●), 75 mol % TMAEM.Cl (Mw 16 000; DPn 63; ○), 50 mol % TMAEM.Cl (Mw 13 000, DPn 37; ■), 15 mol % TMAEM.Cl (Mw 41 000, DPn 40; □), 5 mol % TMAEM.Cl (Mw 35 000, DPn 12, ▽). (b) Agarose gel shift assay. Complexes were formed by addition of precise amounts of TMAEM.Cl-*co*-HPMA random copolymers to DNA. After 2 h, samples were analyzed by agarose gel electrophoresis, with ethidium bromide present in the gel to permit visualization of DNA. Samples applied are as follows: lanes 1 and 7, free DNA; lanes 2 and 8, 5 mol % TMAEM.Cl (Mw 35 000); lanes 3 and 9, 15 mol % TMAEM.Cl (Mw 41 000); lanes 4 and 10, 50 mol % TMAEM.Cl (Mw 13 000); lanes 5 and 11, 75 mol % TMAEM.Cl (Mw 16 000); lanes 6 and 12, 100 moly TMAEM.Cl (Mw 34 150). Complexes were formed at an N-to-P ratio of 1.0 (lanes 2−6) or 2.0 (lanes 8−12). The gel was photographed using a UV transilluminator, and the arrow marks the position of free DNA running into the gel.

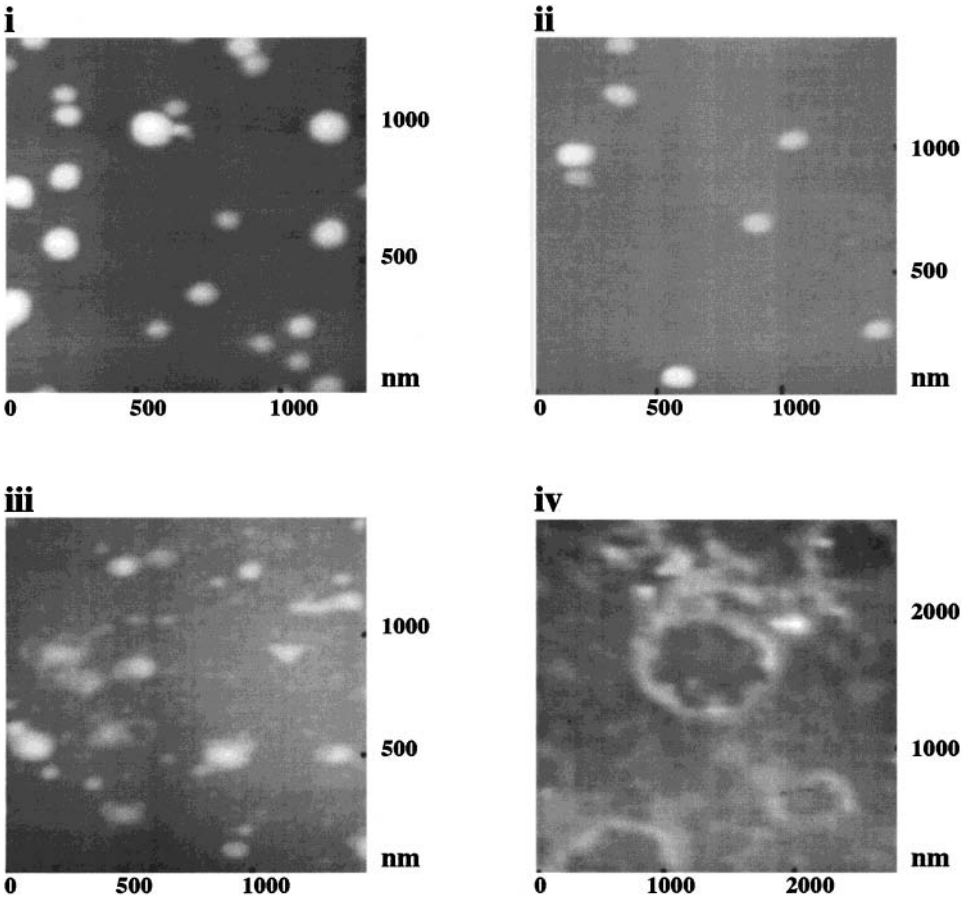

Figure 5. Influence of charge spacing in TMAEM.Cl-*co*-HPMA random copolymers on complexes formed with DNA, visualized by AFM. Complexes were formed at an N-to-P ratio of 2.0. The images show conjugates formed using (i) 100 mol % TMAEM.Cl (Mw 21 240), (ii) 75 mol % TMAEM.Cl (Mw 16 000), (iii) 50 mol % TMAEM.Cl (Mw 13 000), and (iv) 15 mol % TMAEM.Cl (Mw 41 000). The height of the AFM image is represented by a graded black-white scale, with white indicating a height of 30 nm above the mica surface. The *x* and *y* dimensions are scaled as shown. The images are typical of the results of multiple evaluations performed on separate days.

Influence of Cationic Polymer Molecular Weight or DPn on Properties of Complexes Formed with DNA. Self-assembly of cationic polymers with DNA, measured by inhibition of ethidium bromide/DNA fluorescence, showed molecular weight (or DPn) effects that varied from polymer to polymer. The simplest methacrylate-based polymer, pMAEDA.HCl, showed much better DNA condensation using a higher molecular weight preparation, achieving lower values of IF_{50} and Min F. Similar results were obtained using the longer side chain pMAGEDA.HCl. With the quaternary pTMAEM.Cl, no real effects of molecular weight were seen, and all polymer fractions showed similar condensation abilities. In contrast, pLL.HBr showed clear effects of molecular mass, with medium molecular mass pLL (24 kDa) mediating more efficient condensation of DNA than high or low molecular mass preparations.

Sizes of complexes formed by self-assembly with DNA, measured by AFM, showed molecular weight influences that varied between polymers. There were no reproducible effects for the polymer pMAEDA.HCl, although pMAGEDA.HCl and pMADGHDA.HCl both seemed to give better defined complexes at higher molecular weight, with lower molecular weight preparations yielding more extended structures. pTMAEM.Cl showed a clear effect of molecular weight, with complexes based on low molecular weight polymer showing a larger size, probably due to aggregation. pLL.HBr also showed a clear molecular weight effect that was effectively the opposite, namely significantly smaller complexes formed using lower molecular weight polycation. This phenomenon has been observed before (*7*).

ζ-Potential of complexes formed between DNA and polycations showed no trends with molecular weight for any of the cationic polymers examined except pLL.HBr. In the case of pLL.HBr, low molecular weight polycations yielded lower values of ζ-potential, with pLL.HBr 4 kDa showing a relatively low positive value (16 mV). Smaller preparations (e.g. pLL.HBr 1 kDa) showed further decreased ζ-potential, perhaps reflecting incomplete condensation, but also a tendency to flocculate.

Following microinjection of complexes into the nucleus of Xenopus oocytes, complexes based on high molecular weight pTMAEM.Cl showed much lower levels of gene expression than even those based on midrange pTMAEM.Cl. This may reflect relatively high stability of these complexes and protection of DNA from polymerase enzymes, or could reflect other effects, possibly toxicological, of this high molecular weight polycation. Complexes based on pLL.HBr show no such effects of molecular weight, with even complexes based on very high molecular weight pLL.HBr showing roughly the same levels of transcription as all other pLL.HBr/DNA complexes. This was in sharp contrast to the levels of gene expression achieved by simple transfection, where the use of complexes based on high molecular weight pLL.HBr achieved much greater levels of gene expression (Figure 6). The other polymers examined also showed the same trend in transfection, with complexes based on larger polymers mediating higher levels of transgene expres-

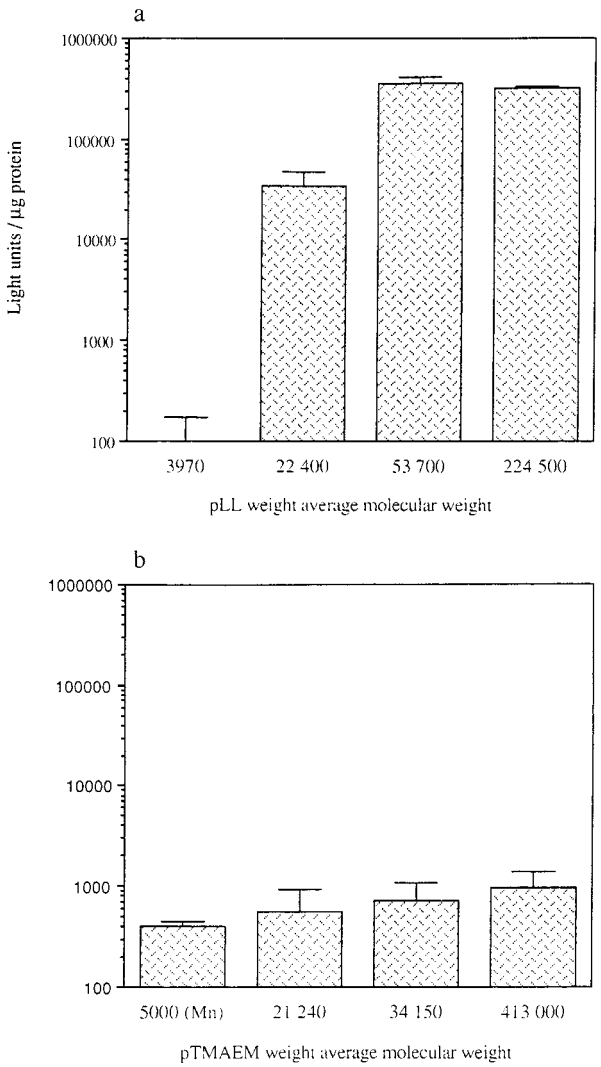

Figure 6. Influence of molecular weight of cationic polymers on transfection activity against 293 cells. (a) Influence of molecular weight of pLL.HBr, while panel b shows the influence of molecular weight of pTMAEM.Cl. Complexes were formed, cells were transfected, and expression of the β-galactosidase gene delivered was assayed as described in the text.

sion, although the effect was not always statistically significant.

DISCUSSION

Several techniques have been employed in this study to characterize the biological and physical properties of complexes formed spontaneously between cationic polymers and DNA. Some of the techniques are still under development, however, and results must be interpreted cautiously. For example, it is not clear whether loss of ethidium bromide/DNA fluorescence upon complex formation (*13*, *19*) results from expulsion or quenching of the fluorophore, and in the case of expulsion, whether the motive force is physical compression or electrostatic repulsion of the ethidium bromide from the complex.

Subject to these qualifications, the techniques employed have yielded considerable information on the interaction of cationic polymers with DNA. Considering first the influence of side-chain length, polymers studied with long side chains (e.g., pMADGHDA.HCl) were incapable of efficient complex formation with DNA. The resulting complexes maintained considerable residual fluorescence and high ζ-potential and showed loops of nonincorporated DNA protruding from the structure when viewed by AFM. They did show considerable transfection activity, however, despite poor gene expression following direct intranuclear injection. At the other extreme were complexes formed using pVA.HCl and pAA.HCl, both with very short side chains. These polymers were efficient at complex formation, yielding complexes that displayed little residual fluorescence and no appreciable surface charge. They appeared to form complexes efficiently with DNA, showing remarkable stability to subsequent polyanion-mediated disruption. Efficient charge neutralization may also explain their lack of surface charge, which probably underlies their tendency to aggregate. Their low transfection activity may also reflect their low surface charge, but their ability to undergo efficient intranuclear transcription is perhaps surprising in light of their stability to polyanions. The ability of cells to transcribe DNA bound even relatively firmly to cationic polymers may increase the opportunities for design of complexes combining good extracellular stability with efficient transcription following arrival within the nucleus (*20*).

The next parameter studied in depth was the influence of cationic charge strength, using primary, tertiary, or quaternary amino groups, on the properties of complexes formed with DNA. Quaternary amino groups (pTMAEM.Cl) seemed to form complexes relatively efficiently with DNA, perhaps reflecting a stronger bond than with primary amino groups. Perhaps the most striking observation was the very poor transfection activity associated with the quaternarized polycation, pTMAEM.Cl, being 10−100-fold less active than complexes based on most other cationic polymers. It did undergo reasonably efficient intranuclear transcription, however, (except at high molecular weights) and the reason for its poor transfection activity may involve relatively poor access to the nucleus. Complexes formed using cationic polymers with pK_a values in the endosomal range [e.g. poly(ethylene imine), Starburst dendrimers] are thought to mediate selective membrane activity on the endosome, perhaps via the so-called proton sponge mechanism (*21*), and this leads to extremely high transfectional activity. Hence, it seems possible that the complete absence of pH responsiveness in the quaternized polycation may restrict its ability to enter the cytoplasm/nucleus of target cells.

The tertiary amine-containing pDMAEMam was less effective at DNA condensation in water, probably reflecting low protonation of its free base form, and complexes displayed a low ζ-potential (−15 mV). However, AFM showed that discrete complexes were formed and there was efficient transcription following their injection into the nuclei of Xenopus oocytes. These complexes also demonstrated reasonably high levels of transfection of 293 cells in vitro, compatible with the suggestions of good transfection activity associated with polymers with pK_a in the endosomal range (*21*, outlined above). It should be noted that the pDMAEMam polymer is based on a methacrylamide backbone, while most of the other polymers are methacrylate-based; however, this difference is thought unlikely to affect properties of the complexes formed. Indeed, the corresponding methacrylate-based polymer has been studied in great detail (*22*), and high molecular weight forms are reported to have particularly good activity as in vitro transfection agents (*23*).

The influence of the density of positive charge along the cationic polymer on the properties of complexes formed with DNA was examined by comparing pTMAEM.Cl with pBTMAIPM.I_2, which bears two quater-

nary ammonio groups per monomer. Properties of complexes were remarkably similar, suggesting that a high density of positive charges does not adversely affect the interaction with DNA, although neither were any significant benefits observed. The effect of charge dilution was addressed by spreading out the positive charges using random copolymers containing TMAEM.Cl and HPMA as monomers. All copolymers were capable of binding DNA, according to ζ-potential and effects on electrophoretic mobility of the DNA, although copolymers with greater than 50% TMAEM.Cl content were not capable of forming particulate complexes, judged by AFM. Hence, it seems likely that these copolymers cannot drive hydrophobic self-assembly of polymer/DNA complexes even at charge neutrality; instead they form extended structures which can even display greater ethidium bromide/DNA fluorescence than untreated DNA controls (Figure 4a). It seems likely that the effects noted using these copolymers are mediated more by the presence of the hydrophilic HPMA component than directly by the spreading of the positive charges.

In terms of biological activity, complexes based on the random copolymers showed low levels of transfection similar to the parent pTMAEM.Cl quaternary homopolymer. However, they also showed particularly poor ability to undergo transcription following intranuclear injection. Although the reasons for this are not clear, it may involve steric protection of the DNA from polymerases by the presence of the hydrophilic polymer.

Finally, the influence of cationic polymer molecular weight average on properties of complexes formed with DNA has been examined. With DNA complexes based on pLL.HBr, polycation molecular weight is known to influence several properties (*7*). For example, complexes based on larger pLL.HBr are significantly bigger, more resistant to disruption by poly(L-aspartic acid), show a higher ζ-potential and are more active in transfecting cells (Figure 6). One explanation may be that, during complex formation, binding of small pLL.HBr to DNA is essentially reversible and leads to formation of thermodynamically stable complexes based on single DNA molecules. Such small complexes are efficiently charge neutralized and can often flocculate. Binding of larger pLL.HBr can be irreversible, however, and often proceeds inefficiently due to the inability of the polyelectrolytes to rearrange themselves. This leads to regions of excess positive charge, cross-linking of DNA molecules, and eventually to formation of complexes which are stable kinetically but thermodynamically locked in an unstable configuration. However, despite the simplicity of this hypothesis, it remains unsubstantiated when the same principles do not seem to govern self-assembly of DNA with other polymers such as pTMAEM.Cl.

There were some indications of effects of molecular weight on transfection activity against 293 cells for many of the polymers examined in this study, including pVA.HCl, pLL.HBr, pMAEDA.HCl, pMAGEDA.HCl, and pTMAEM.Cl. With these polymers, DNA complexes formed with higher molecular weight cationic polymer preparations often showed greater expression of reporter genes. This was generally parallel with increased cytotoxicity of preparations based on larger cationic polymers, and it is not clear whether the cationic polymer which is free in solution at these N-to-P ratios is exerting an important effect in either cytotoxicity or transfection.

The observations made in this study permit us to begin identifying parameters of cationic polymers that may affect the properties of the complexes they form with DNA. Many people working in this field are searching for complexes with improved transfectional activity. It is clear from the above that polymer/DNA complexes formed using high molecular weight polymers are generally more transfection active, although the involvement of quaternary charges may lead to less efficient passage through the target cell to the nucleus.

In contrast, targeted gene delivery for systemic application requires DNA complexes that are stable in the circulation, small enough to undergo extravasation into target tissues, able to recognize and enter target cells, including translocation into the nucleus, and suitable for efficient transcription within the nucleus of the target cell. One key issue is stability of complexes in the plasma, where they may interact with many different biological components (*24*−*27*). This area is the subject of several related studies, and at present, it is uncertain whether all of these requirements can be fulfilled by a simple self-assembling polycation/DNA system. We are therefore presently developing means of postassembly modification of complexes to mediate some of the objectives specified, using the self-assembling system as the core of the final complex (*27*−*29*). Chief requirements of the core complex are therefore small size, formation of monodisperse complexes, and the ability to permit efficient transcription within the nucleus of target cells. Consideration of the information generated in this analysis leads us to believe that the most appropriate complexes will be based on cationic polymers with a high charge density, containing nonquaternary amino groups, short side chains, and medium-to-low molecular weight distribution.

Received April 20, 1999; Revised Manuscript Received August 5, 1999

The synthesis of oligonucleotides carrying nuclear localization peptide sequences is described using two strategies: first, oligonucleotides carrying a thiol group at the 5′ end were reacted with maleimido peptides; second, peptide and oligonucleotide were prepared stepwise on the same support, yielding oligonucleotide-3′-peptide conjugates. This second approach was thoroughly studied. Using amino acids and small peptides as model compounds, some side reactions were analyzed, detected, and minimized. Oligonucleotides complementary to Ha-*ras* gene and carrying nuclear localization peptides at the 3′ and 5′ ends were prepared. Melting temperature studies showed that duplexes containing nuclear localization peptides were more stable than duplexes with unmodified oligonucleotides. Moreover, oligonucleotide−peptide conjugates maintain a good mismatch discrimination when they bind to their target RNA.

INTRODUCTION

A large interest in oligonucleotide−peptide conjugates has arised. These conjugates are chimeric molecules constituted by oligonucleotides connected to peptide sequences and they are produced to add some of the biological and/or biophysical properties of peptides to synthetic oligonucleotides. They were first used to introduce multiple nonradioactive labels (Haralambidis et al., 1987, 1990) and as artificial sequence-specific nucleases (Corey and Schultz, 1987). Later, they were used as antisense oligonucleotides (Crooke and LeBleu, 1994). Conjugation of oligonucleotides to polylysine (Lamaitre et al., 1987), basic (Vivès and LeBleu, 1997), hydrophobic (Juby et al., 1991), fusogenic (Bongartz et al., 1994; Soukchareun et al., 1995), and signal peptides (Arar et al., 1993; Ede et al., 1994; Reed et al., 1995; Zanta et al., 1999) and penetratin (Allinquant et al., 1995) has been performed in order to increase the cellular uptake or the intracellular delivery of antisense oligonucleotides. Moreover, binding oligonucleotides to certain peptide sequences improves the binding to complementary DNA (Tung et al., 1996), the hybridization speed (Corey, 1995), the binding to RNA (Tung et al., 1995) and proteins (Lin et al., 1995), and the resistance to nucleases (Robles et al., 1997). Finally, peptide sequences have been used for encoded combinatorial libraries (Tetzlaff et al., 1998).

Two strategies can be followed to synthesize oligonucleotide−peptide hybrids. In the postsynthetic conjugation approach, the two moieties are independently prepared and thiols and maleimido groups are especially incorporated to link both molecules (Eritja et al., 1991a; Arar et al., 1993; Ede et al., 1994). In the stepwise approach, oligonucleotide−peptide conjugates are prepared by stepwise addition of amino acids and nucleobases in solid phase on the same solid support (de la Torre et al., 1994; Bergmann and Bannwarth, 1995; Soukchareun et al., 1995; Robles et al., 1997). In this case, the problem to be solved is the incompatibility of the standard schemes of protection. For example, at the end of the solid-phase peptide synthesis, a treatment with acid is usually required and can provoke partial depurination of DNA. In the synthesis of oligonucleotide 3′-peptides, this effect could be prevented using Boc-protected amino acids with Fm or Fmoc groups for the protection of side chains, a base-labile linker, and standard phosphoramidites (de la Torre et al., 1994; Bergmann and Bannwarth, 1995; Soukchareun et al., 1995; Robles et al., 1997). Moreover, protected peptide fragments (Peyrottes et al., 1998) and protected oligonucleotide (McMinn and Greenberg, 1998, 1999) fragments have been used.

In the present communication, we describe the synthesis of oligonucleotides carrying nuclear localization peptide sequences following two strategies and the binding properties of these conjugates. Our target oligonucleotide sequence is the dodecamer R5, complementary to a mutated Ha-*ras* oncogene (Duroux et al., 1995). The specific binding to mutated mRNA and not to the wild-type sequence accounts for the antiproliferative activity of R5 (Duroux et al., 1995). Thus, the discriminatory properties of the conjugates were analyzed.

zoyl-Ala-Ala-Pro-Lys-Lys-Lys-Arg-Lys-Val-$CONH_2$) was prepared on polystyrene supports using Fmoc amino acids, as described in Eritja et al. (1991a). Other peptide sequences were synthesized in a homemade manual synthesizer using PEG-PS functionalized with amino groups (PerSeptive Biosystems) as starting solid support. The NPE[1] handle 2,4,5-trichlorophenyl 4-hydroxyethyl-3-nitrobenzoate [3-fold excess, Eritja et al. (1991b)] was anchored in excellent yields to the amino-PEG-PS resin when HOBt was added (3-fold excess) using DMF as solvent. The Fm handle (Rabanal et al., 1992) was coupled to the amino-PEG-PS resin following Rabanal et al. (1995). The C-terminal-protected Boc amino acid derivative (5 equiv) was reacted with the hydroxyethyl group of the NPE and Fm resins with DCC (5 equiv), DMAP (0.5 equiv) and DMF as solvent. After 2 h of coupling, unreacted hydroxyl groups were acetylated with 10% acetic anhydride in pyridine. The aminohexyl handle MMT-NH-hexyl hemisuccinate (Will et al., 1995) was coupled to the amino-PEG-PS following Gupta et al. (1995). The elongation of peptide chains was performed in DMF using 5-fold excess of amino acid Boc-protected and 5-fold excess of PyBOP for 1 h. The peptide sequences were (A) Gln-Ala-[Lys(Fmoc)]$_4$-Leu-Asp(Fm)-Lys(Fmoc) and (B) Ala-[Lys(Fmoc)]$_4$-Leu-Asp(Fm)-Lys(Fmoc). For the incorporation of Boc-Gln-OH, DIPCI and HOBt (5-fold excess) were used to avoid the formation of the nitrile.

Synthesis and Solid-Phase Coupling of the Spacer. *p*-Nitrophenyl 6-(4,4′-dimethoxytrityloxy)hexanoate was prepared as has been described for the hydroxybutyrate derivative (Haralambidis et al., 1990).

The Boc-peptide supports described above were treated with 50% TFA in DCM to remove the Boc protecting group of the last amino acid and were neutralized (5% DIEA in DCM). The resulting resins were swelled in DMF for 10 min, and then 5-fold excess of spacer dissolved in DMF was added. After 2 h, the support was washed with DMF five times, twice with DCM and once with MeOH. Finally, it was dried and stored for further use in oligonucleotide synthesis. Small aliquots of the supports carrying the peptide and the spacer were detritylated and treated with concentrated ammonia at 55 °C overnight. The resulting products were purified by reversed-phase HPLC, and the major products were collected and analyzed by MALDI-TOF mass spectrometry: HO-spacer-$AK_4LDK-CONH-(CH_2)_6$-OH, MS (MALDI-TOF) [M] = 1171.6 g/mol (M= 1171.4 g/mol calculated for $C_{55}H_{106}N_{14}O_{13}$); HO-spacer-$QAK_4LDK-CONH-(CH_2)_6$-OH, MS (MALDI-TOF) [M] = 1299.7 g/mol (M= 1299.5 g/mol calculated for $C_{60}H_{114}N_{16}O_{15}$).

Synthesis and Purification of Oligonucleotide−Peptide Conjugates. The conjugate carrying the SV40 nuclear localization sequence was prepared by conjugation of maleimido-benzoyl-Ala-Ala-Pro-Lys-Lys-Lys-Arg-Lys-Val-$CONH_2$ with 5′-thiolhexyl phosphate-CACCGACGGCGC (Eritja et al., 1991a). The thiol group at the 5′ end of the oligonucleotide was incorporated by addition of the available (Glen Research) phosphoramidite of DMT-protected bis-(6-hydroxyhexyl) disulfide. The oligonucleotide was deprotected with a solution (1 mL) of 0.1 M DTT in concentrated ammonia at 55 °C overnight as described in Gottschling et al. (1998). The desired product was characterized by amino acid analysis and enzymatic digestion. VKRKKKPAA-maleimidobenzoyl-hexylthio-CACCGACGGCGC. Amino acid analysis: Arg 1.22 (1), Ala 1.81 (2), Pro 1.04 (1), Val 1.00 (1), Lys 3.89 (4). Enzymatic analysis: dC 5.6 (6), dG 4.0 (4), dA 2.3 (2). Yield (1 μmol scale synthesis): 14 OD units at 260 nm.

The conjugates with the nucleoplasmine nuclear localization sequence were synthesized following a stepwise method. The sequences were (I) 5′ T_5-spacer-QAK_4LDK, (II) 5′ T_5-spacer-AK_4LDK, (III) 5′ CAC CGA CGG CGC-spacer-QAK_4LDK, and (IV) 5′ CAC CGA CGG CGC-spacer-AK_4LDK. Oligonucleotides were synthesized by a DNA synthesizer (Applied Biosystems 392) using standard 2-cyanoethyl phosphoramidites on 1 μmol scale. The phosphoramidites were dissolved in dry DCM (0.1 M), and a modified cycle was used. Coupling time was increased to 5 min, capping and oxidation times to 1 min, and detritylation time to 2 min (4 × 30 s). The last DMT-protecting group was not removed. The average coupling yield was >98%/step. The solid supports containing the oligonucleotide−peptide conjugates were washed with acetonitrile, treated with a 0.5 M DBU solution in acetonitrile for 5 min, washed with acetonitrile and dried. The resulting supports were finally treated with concentrated aqueous ammonia-dioxane 10:1 overnight at 55 °C. After filtration of the solid supports, the solutions were evaporated to dryness, the residues dissolved in water, and the hybrids purified using a standard two-step HPLC purification. HPLC conditions were as follows: column, Nucleosil 120-10 C_{18} (250 × 4 mm); 20 min linear gradient from 15 to 80% B and 5 min 80% B (DMT on conditions); 20 min linear gradient from 0 to 60% B (DMT off conditions); flow rate 1 mL/min; mobile phase A was 20 mM TEAA in water and B (1:1) acetonitrile: water. In the first step, truncated sequences were separated from the product containing DMT, and in the second step the desired conjugates were isolated after removal of the DMT with 80% acetic acid. Characterization of the conjugates was made by amino acid analysis after 6 N HCl hydrolysis and nucleoside analysis after enzyme digestion. Moreover, the purified products were analyzed by electrospray and MALDI-TOF mass spectrometry: T_5-spacer-$AK_4LDK-CONH-(CH_2)_6$-OH, MS (MALDI-TOF) [M] = 2692.3 g/mol (M= 2692.2 g/mol calculated for $C_{105}H_{171}N_{24}O_{48}P_5$); T_5-spacer-$QAK_4LDK-CONH-(CH_2)_6$-OH, MS (MALDI-TOF) [M] = 2820.3 g/mol (M = 2820.3 g/mol calculated for $C_{110}H_{179}N_{26}O_{50}P_5$); R5 dodecamer-spacer-$AK_4LDK-CONH-(CH_2)_6$-OH, MS (electrospray) [M] = 4848.5 g/mol (M= 4851.3 g/mol calculated for $C_{169}H_{252}N_{62}O_{83}P_{12}$); R5 dodecamer-spacer-$QAK_4LDK-CONH-(CH_2)_6$-OH, MS (electrospray) [M] = 4979.0 g/mol (M= 4979.4 g/mol calculated for $C_{174}H_{260}N_{64}O_{85}P_{12}$). Amino acid analysis of the R5 dodecamer-spacer-$QAK_4LDK-CONH-(CH_2)_6$-OH: Leu 1.00 (1), Asp 1.07 (1), Glu 1.23 (1), Lys 5.48 (5), Ala 0.86 (1). Nucleoside composition for R5 dodecamer-spacer-$QAK_4LDK-CONH-(CH_2)_6$-OH: dC 5.5 (6), dG 4.0 (4), dA 2.2 (2). The average yield of the R5 dodecamer conjugates synthesis (1 μmol scale synthesis) was 12 OD units at 260 nm.

Mass Spectrometry Analysis. Mass measurements were performed on a Bruker REFLEX MALDI time-of-

flight mass spectrometer (Bruker-Franzen, Bremen, Germany) using α-cyano-4-hydroxy-cinnamic acid as matrix and the fast evaporation technique for sample preparation (Jensen et al., 1997).

Alternatively, the samples were dissolved in 50% acetonitrile and analyzed by nano electrospray on a triple quadrupole mass spectrometer on negative mode (API III, PE-Sciex, Ontario, Canada).

Evaluation of the Optical Purity of the Amino Acids. Boc amino acids were anchored on NPE-PEG-PS as described above. After removal of the Boc-protecting group, resins were treated with concentrated aqueous ammonia-dioxane 10:1 and left overnight at 50 °C. After filtration of the solid supports, the solutions were evaporated to dryness. A total of 0.2 mL of the residue was dissolved in 0.1 M $NaHCO_3$ and added to 0.2 mL of 1-fluoro-2,4-dinitrophenyl-5-L-alanine amide (FDAA) 10 mM in acetone freshly prepared. The mixture was kept for 1 h at 40 °C with frequent shaking. After cooling, 0.2 mL of 0.2 N HCl was added, and the resulting solution was analyzed by HPLC on a Nucleosil 120-10 C_{18} column (250 × 4 mm) using a 30 min gradient from 10 to100% B at a flow rate of 1 mL/min, detection at $\lambda = 340$ nm. The mobile phase A was 20 mM TEAA in water and B acetonitrile:water (1:1). Standards were prepared following the same procedure using commercially available unprotected amino acids in L- and D-form. The amino acids studied were Phe, Leu, Val, and the dipeptide Gly-Val.

Carboxylic Acid versus Carboxamide Formation during Treatment of NPE and Fm Solid Supports with Ammonia. To study the formation of carboxylic acid and/or amide at the C-terminal position of peptides when NPE and Fm supports were used, model pentapeptides (H-Tyr-Gly-Gly-Phe-Leu-OH and H-Tyr-Gly-Gly-Phe-Leu-NH_2) were prepared following standard Fmoc methodology. The same sequence (H−Phe-Gly-Gly-Phe-Leu) was assembled on PEG-PS supports carrying the NPE and Fm linkers using Boc amino acids as described above. Aliquots of the peptide supports were treated with several solutions: (a) concentrated ammonia at 55 °C, (b) 20% piperidine in DMF at room temperature, and (c) 0.1 M tetrabutylammonium fluoride in tetrahydrofuran at room temperature. At different times, the supports were filtered out and the resulting solutions were evaporated to dryness. The residues were dissolved in water and analyzed by HPLC using the same conditions as for the racemization studies. The retention time of H-Tyr-Gly-Gly-Phe-Leu-OH was 20 min and the peptide amide eluted at 24 min.

Stability of the Side Chain of Trifunctional Amino Acids during Oligonucleotide Synthesis Conditions. Dipeptides Boc-Gln-Phe, Boc-Asp(Fm)-Phe, and Boc-Lys(Fmoc)-Phe were synthesized on PEG-PS supports with the AmHex linker as described above. Aliquots of these supports were treated for 1 h at room temperature with the following solutions: (a) a 1:1 mixture of the oligonucleotide synthesis capping solutions [Cap A, acetic anhydride/lutidine/tetrahydrofuran (1:1:8) and Cap B: 0.1M *N*-methylimidazole in tetrahydrofuran]; (b) 0.05 M iodine solution in tetrahydrofuran, H_2O/pyridine (7:2:1); and (c) a 1:1 mixture of 0.1 M solution of A phosphoramidite in acetonitrile and 0.4 M tetrazol in acetonitrile. Thereafter, the supports were washed with acetonitrile, treated with a 0.5 M DBU solution in acetonitrile for 5 min, washed again with acetonitrile, and dried. The resulting supports were finally treated with concentrated ammonia at 55 °C overnight. The supernatants were concentrated to dryness and the residues were analyzed by HPLC and mass spectrometry. The desired dipeptide was obtained and no side products were found. Boc-Gln-Phe-CONH-$(CH_2)_6$-OH MS (electrospray) [M + H] = 493.4 g/mol (M = 492.6 g/mol calculated for $C_{25}H_{40}N_4O_6$); Boc-Asp-Phe-CONH-$(CH_2)_6$-OH MS (electrospray) [M] = 479.3 g/mol (M = 479.5 g/mol calculated for $C_{24}H_{37}N_3O_7$); Boc-Lys-Phe-CONH-$(CH_2)_6$-OH MS (electrospray) [M+H] = 493.5 g/mol (M= 492.6 g/mol calculated for $C_{26}H_{44}N_4O_5$).

Melting Studies. Melting experiments were carried out by mixing equimolar amounts of two dodecamer strands dissolved in a solution containing 0.15 M NaCl and 0.05 N Tris-HCl buffer, pH 7.5. Duplexes were annealed by slow cooling from 80 to 4 °C. UV absorption spectra and melting curves (absorbance vs temperature) were recorded in 1 cm path-length cells using a Varian Cary 13 spectrophotometer with a temperature controller and a programmed increase of 0.5 °C/min. Melts were run on duplex concentrations of 4 μM at 260 nm.

Binding of Oligonucleotide−Peptide Conjugates to Ha-*ras* RNA (Gel Shift Assay). 27-mer RNA (4 nM) carrying the sequence complementary to the R5 dodecamer (5′ GUG GUG GGC GCC GUC GGU GUG GGC AAG 3′) and wild-type RNA sequence (5′ GUG GUG GGC GCC GGC GGU GUG GGC AAG 3′) were radioactively labeled and incubated with unlabeled oligonucleotides in a buffer containing 40 mM Tris (pH 7.9) and 100 mM KCl. After preincubation for 15 min at 37 °C, glycerol loading buffer (80% glycerol, 0.1% xylene cyanol, 0.1% bromophenol blue) was added, and samples were electrophoresed on a 15% native polyacrylamide gel at 37 °C, using 0.05 M Tris-borate (pH 9). Hybridization to the 5′-end-labeled 27 mer (^{32}P) RNA was analyzed by quantitation of gel shifts using particle detection (Phosphorimager). The fraction of duplex is the ratio of particle counts of the double-stranded oligonucleotide−RNA complex (arrow) referred to the total (single and double stranded).

RESULTS

Synthesis of Oligonucleotide−Peptide Conjugates Using the Postsynthetic Conjugation Approach. Two types of oligonucleotide−peptide conjugates were prepared. The conjugate carrying the SV40 nuclear localization sequence was synthesized by conjugation of maleimido-benzoyl-AAPKKKRKV-$CONH_2$ with 5′-thiol-hexyl phosphate-CACCGACGGCGC, as described in Eritja et al. (1991a) (see Figure 1). The thiol group at the 5′ end of the oligonucleotide was incorporated by addition of a phosphoramidite derivative of bis-(6-hydroxyhexyl) disulfide. The maleimido peptide carrying the SV40 nuclear localization sequence (maleimidobenzoyl-AAPKKKRKV-$CONH_2$) was prepared on polystyrene supports using Fmoc amino acids (Eritja et al., 1991a).

Preliminary Studies on the Synthesis of Oligonucleotide−Peptide Conjugates Using the Stepwise Approach. Oligonucleotide−peptide conjugates carrying the nucleoplasmine nuclear localization sequence (QAKKKKLDK) were synthesized by the stepwise approach. Polyethylenglycol-polystyrene (PEG-PS) was selected as solid support since it gave the best results for the coupling of both amino acids and nucleoside phosphoramidites (de la Torre et al., 1994). Figure 2 shows the pathway followed to synthesize oligonucleotide−peptide conjugates on the same support (de la Torre et al., 1994). To avoid the use of strong acids in the presence of the oligonucleotide, the peptide part was first synthesized using the acid-labile Boc group to protect the α-amino function. The protective groups of the side

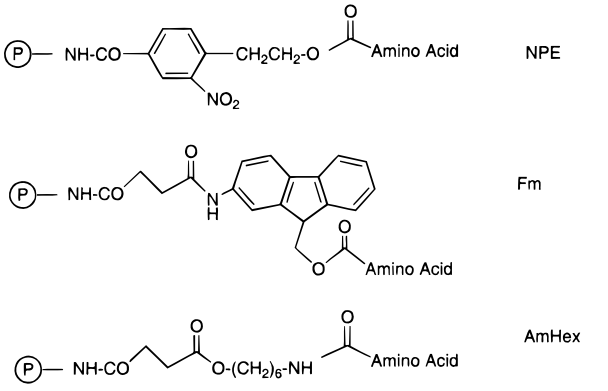

Figure 3. Base labile linker molecules used to connect the first amino acid to the solid support. P, polymer [poly(ethylene glycol)-polystyrene]; NPE, 2-(2-nitrophenyl)ethyl linker; Fm, fluorenylmethyl linker; AmHex, 6-aminohexylsuccinyl linker.

chain of the amino acids (Fmoc for Lys and Fm for Asp) and the linker of the first amino acid to the support were base labile so that they would be removed at the same time as the protective groups of the nucleobases. To that end, three base-labile linkers (see Figure 3) were examined: the 2-(2-nitrophenyl)ethyl (NPE, Eritja et al., 1991b), the fluorenylmethyl [Fm, Rabanal et al. (1992, 1995)], and the 6-aminohexylsuccinyl [AmHex, Will et al. (1995)]. The linkage between the amino acid and the NPE and the Fm linkers is excised by strong bases such

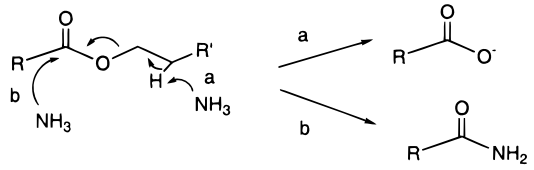

Figure 4. Ammonolysis of 2-substituted ethyl esters: Nucleophillic attack versus β-elimination mechanisms yielding peptides with carboxylic acid or carboxamide group at the C-terminus.

as piperidine or DBU following a β-elimination reaction which releases the free carboxylic function of the amino acid or peptide. In the AmHex linker, the excised bond is a succinyl ester which yields the amino acid or peptide with an aminohexylamide group at the C-terminal. Prior to the synthesis of oligonucleotide−peptide conjugates, racemization of the C-terminal amino acid was studied.

Racemization Studies on the C-Terminal Amino Acid in Base Deprotection Conditions. The synthetic protocol implies the use of basic conditions in the removal of the protective groups. Oligonucleotides are usually treated with concentrated aqueous ammonia for 16 h at 55 °C. To check the stability of the peptide part in such conditions, several amino acids and a dipeptide were attached to the support and analyzed after ammonia treatment. The possible racemization of the C-terminal amino acid due to the anchoring method or the cleavage conditions was carefully studied.

Boc-valine, Boc-leucine, and Boc-phenylalanine were incorporated to the NPE support (Albericio et al., 1991). After removal of the Boc group, the amino acyl-NPE supports were treated with concentrated ammonia. The resulting amino acids were reacted with Marfey's reagent (Adamson et al., 1992) to obtain the diastereoisomers, which were analyzed by HPLC. The free L-amino acids were obtained and no racemization was found (detection limit 0.1%), in agreement with Bray et al., who showed that there was no racemization when deblocking peptides with ammonia vapors (Bray et al., 1994). Moreover, the dipeptide Gly-L-Val was prepared on the NPE-resin, the support was treated with concentrated ammonia, and the product was reacted with Marfey's reagent. Likewise, no racemization was found, but a second product, thought to be, the dipeptideamide (Gly-L-Val-NH_2), was detected. This side product coeluted with a synthetic sample of the peptide amide. In addition to the expected β-elimination reaction of the ester, there was direct nucleophillic attack of ammonia to the ester, which resulted in the formation of the amide (Figure 4).

Carboxylic Acid vs Carboxamide Formation during Deprotection. The sequence H-Tyr-Gly-Gly-Phe-Leu (Leu-enkephaline) was selected in order to study this reaction and, therefore, synthesized on NPE and Fm handles. Independently, H-Tyr-Gly-Gly-Phe-Leu-OH and H-Tyr-

Gly-Gly-Phe-Leu-NH_2, used as controls, were synthesized following conventional solid-phase peptide protocols. Aliquots of the pentapeptide-NPE and Fm supports were treated with concentrated ammonia, 20% piperidine in DMF, and 0.1 M tetrabutylammonium fluoride. The resulting solutions were analyzed by HPLC. When concentrated ammonia at 55 °C was used, the ratio carboxylic acid:carboxamide was 50:50 on the NPE support and 75:25 on the Fm support. When 20% piperidine in DMF and 0.1 M tetrabutylammonium fluoride in tetrahydrofuran were used, only the carboxylic acid was found. In the deprotection of larger molecules, such as oligonucleotide−peptide conjugates, treatments with piperidine and, especially, fluoride were less efficient than treatment with ammonia. These results are not consistent with those described by Robles et al. (1997), who found that in fluoride solutions, oligonucleotide−peptide conjugates were released. Here, poly(ethylene glycol)-polystyrene was used as solid support, whereas Robles et al. (1997) used polystyrene. Therefore, poly(ethylene glycol) may inhibit the fluoride-catalyzed reaction. As poly(ethylene glycol) improves the coupling of phosphoramidites (de la Torre et al., 1994), we focused on the linker AmHex (Figure 3), which has been used in the synthesis of peptide nucleic acid chimeras on poly(ethylene glycol)-polystyrene supports (Will et al., 1995). The succinate bond is easily cleaved by concentrated ammonia, yielding the peptide with the *N*-(6-hydroxyhexyl)amide group at the C-terminus. This linker also allows the removal of the Fm (Asp), Fmoc (Lys), and cyanoethyl (phosphate) groups with a nonnucleophillic base (such as DBU) before ammonia deprotection. At this stage, a DBU treatment will minimize or prevent the formation of Asn from Asp(Fm) and the alkylation of lysine residues by the acrylonitrile formed during the phosphate deprotection described by Tetzlaff (Tetzlaff et al., 1998).

Stability of the Side Chains of Trifunctional Amino Acids in Oligonucleotide Synthesis Conditions. The stability of the peptide moiety in oligonucleotide synthesis conditions was also studied. Hydrophobic amino acids are stable in oligonucleotide synthesis conditions (Soukchareun et al., 1995; Robles et al., 1997; Tetzlaff et al., 1998), but to our knowledge, the behavior of trifunctional amino acids has not been thoroughly studied. To test the stability of the trifunctional amino acids belonging to the nucleoplasmine sequence, Boc-[Gln, Asp(Fm) and Lys(Fmoc)]-Phe dipeptides were prepared on PEG-PS supports with the AmHex linker. The Boc-dipeptide supports were treated with oligonucleotide synthesis reagents such as capping (acetic anhydride, *N*-methylimidazol), oxidation (iodine), and coupling (phosphoramidite and tetrazol) solutions for 1 h at room temperature. After DBU treatment and ammonia deprotection, the products were analyzed by HPLC and mass spectrometry. Only the expected dipeptides were found. To determine whether activated phosphoramidites can react with peptide bonds and/or with the primary amide group of Gln., aliquots treated with phosphoramidite and tetrazole were also treated with iodine and 2% trichloroacetic acid in DCM between the phosphoramidite treatment and deprotection. A small amount of phosphoramidite may react with peptides, as, after treatment with 2% trichloroacetic acid, a red solution was observed. The amount of DMT released from the peptide supports was 12, 15, and 14% for Boc-Lys(Fmoc)-Phe, Boc-Asp(Fm)-Phe, and Boc-Gln-Phe, respectively. No extra peak was observed on HPLC or MS analysis. Thus, the small amount of phosphoramidite addition on the peptide supports does not yield detectable side products.

Synthesis of the Oligonucleotide−Peptide Conjugates Using the Stepwise Approach. The following molecules were prepared: (I) 5′ TTTTT-spacer-Gln-Ala-Lys-Lys-Lys-Lys-Leu-Asp-Lys, (II) 5′ TTTTT-spacer-Ala-Lys-Lys-Lys-Lys-Leu-Asp-Lys, (III) 5′ CACCGACGGCGC-spacer-Gln-Ala-Lys-Lys-Lys-Lys-Leu-Asp-Lys, and (IV) 5′ CACCGACGGCGC-spacer-Ala-Lys-Lys-Lys-Lys-Leu-Asp-Lys. The pentanucleotide sequence was used to find the optimal coupling conditions. The dodecamer sequence is complementary to the mutated Ha-*ras* oncogene. The peptide sequence is the nuclear localization sequence found in nucleoplasmine. In one set of experiments (II and IV), the last glutamine was not included so that the influence of unprotected glutamine in the purity of the oligonucleotide−peptide conjugates could be studied. Although our results on model dipeptides (see above) indicated that there were no side-reactions on glutamine, the formation of N-acyl phosphoramidates has been described as side reaction of glutamine and chlorophosphines (Robles et al., 1995). First, peptide sequences were prepared on the PEG-PS support containing the aminohexyl linker (AmHex, Figure 3). Once the peptide was synthesized, a spacer molecule was added to connect the oligonucleotide by conversion of the last amino group of the peptide into an hydroxyl group protected with a DMT group. For this purpose, we used the active ester of the *O*-DMT protected derivative of the 6-hydroxy hexanoic acid [Figure 2, Haralambidis et al. (1990)]. After the addition of the linker, oligonucleotide synthesis was studied in the pentathymidine sequence I. Unexpectedly, the addition of the phosphoramidites was strongly influenced by the solvent used during the coupling reaction. We tried different combinations of acetonitrile, pyridine, DMF, and DCM. The highest coupling efficiencies (<98%) were reached when DMT-T phosphoramidite was dissolved in DCM and tetrazol was dissolved in acetonitrile or THF. We used acetonitrile for dissolving tetrazol and DCM for dissolving phosphoramidites as tetrazol dissolved in acetonitrile is available and thus, the only change required was to dissolve phosphoramidites in dry DCM instead of dry acetonitrile. From the results obtained in the manual synthesis, a new cycle for the automatic synthesizer was developed for 1 μmol scale. The following changes were applied: coupling time was increased from 25 s to 5 min; capping and oxidation times were increased to 1 min; detritylation was increased to 2 min (4 × 30 s). The detritylation rate with PEG-PS was clearly lower than with CPG because of the polyethylenglycol matrix. After these changes, the coupling yield was similar to the one found in standard conditions. For cleavage and deprotection, two consecutive treatments were applied: first a 0.5 M DBU solution in acetonitrile for 5 min and second, concentrate aqueous ammonia-dioxane 10:1 at 55 °C overnight. Oligonucleotide−peptide conjugates (I−IV) were separated from truncated sequences as DMT protected compounds (Figure 5a). After removing the DMT group with 80% acetic acid, a major product was obtained (Figure 5b) that was characterized by (i) amino acid analysis after hydrolysis 6 N HCl, (ii) nucleoside analysis after digestion with snake venom phosphodiesterase and alkaline phosphatase, and (iii) mass spectrometry (MALDI-TOF, electrospray). By mass spectroscopy, the pentanucleotides I and II were easily characterized by MALDI-TOF, whereas dodecamers III and IV only gave the correct mass on electrospray (Figure 5c). The MALDI-TOF spectra of dodecamers III and IV gave a mass corresponding to the peptide part, the spacer and a phosphate (data not shown), which was not found by electrospray. During the acquisition of the MALDI-

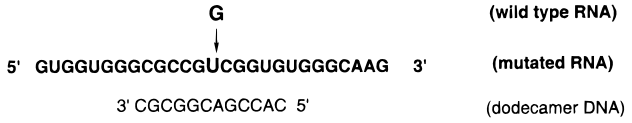

Figure 6. Sequence of 27-mer RNA and dodecamer R5.

TOF mass spectra, the phosphate bond between oligonucleotide and peptide breaks and the peptide fragment is easier to detect than the conjugate. As for pentamers I and II and dodecamers III and IV, no differences were observed, and we concluded that the presence of unprotected glutamine does not affect the purity of the oligonucleotide−peptide conjugates. Average yield for the stepwise synthesis of the R5 dodecamer conjugates was 12 OD units at 260 nm (1 μmol scale synthesis). Using the postsynthetic approach 14 OD units of the conjugate (1 μmol synthesis) were obtained.

Properties of Oligonucleotide−Peptide Conjugates. Hybridization of oligonucleotide−peptide conjugates to their complementary DNA sequence was evaluated spectrophotometrically. Melting temperatures (Tm) of dodecamer duplexes at 0.15 M NaCl, 0.05 M Tris·HCl, pH 7.5, 1 mM EDTA were as follows: unmodified R5 dodecamer (5′ CACCGACGGCGC3′) with its complementray strand (5′GCGCCGTCGGTG3′), 61.5 °C; 5′-peptide (VKRKKKPAA-R5 dodecamer), 63.5 °C; 3′-peptide (R5 dodecamer- AKKKKLDK), 62.6 °C; 3′-peptide (R5 dodecamer-QAKKKKLDK), 63.6 °C. All the oligonucleotide−peptide conjugates carrying nuclear localization sequences show a slightly higher melting temperature. The higher stability, related to the presence of positive charges of lysine and arginine side chains in the peptides, is in agreement with data on conjugates carrying basic amino acids (Eritja et al., 1991; Harrison and Balasubramanian, 1998; Zhu et al., 1993).

Binding of peptide modified dodecamers to their target RNA was analyzed by gel shift experiments. Target RNA (27 mer, Figure 6) carrying the Ha-*ras* sequence complementary to the dodecamers was radioactively labeled and incubated with dodecamers carrying the SV40 (5′-peptide) and nucleoplasmine (3′-peptide) sequences. Single-stranded RNA and dodecamer−RNA complexes were separated by polyacrylamide native gel electrophoresis (see Figure 7). One or two bands with less mobility revealed that there had been duplex formation. Double bands (especially with the 5′-peptide) indicated the presence of RNA: dodecamer−peptide complexes with different mobility. We have compared the affinity of dodecamers for the mutated Ha-*ras* and for the wild-type Ha-*ras* gene to analyze the mismatch discrimination of oligonucleotide−peptide conjugates. The dodecamer R5 is a perfect match to mutated RNA (A·U) but contains a mismatch to wild-type RNA (A·G misspair). Titration curves of unmodified and peptide-modified dodecamers with both mutated and wild type 27-mer RNA were performed (data not shown). The concentration of antisense oligonucleotide (μM) required to complex 50% of the target RNA is shown in Table 1. Peptide-modified dodecamers elicit approximately 10-fold less affinity for target RNA than the unmodified dodecamer but oligonucleotide−peptide conjugates discriminate mutated RNA from wild-type RNA.

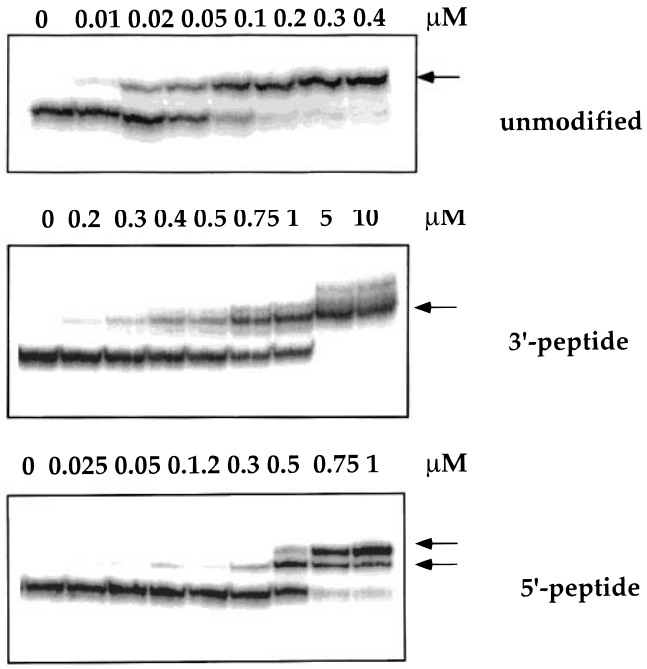

Figure 7. Binding of oligonucleotide−peptide conjugates carrying nuclear localization sequences to target 27-mer RNA by gel-shift experiments (see conditions in Experimental Section). The arrows show the position of the complex between the RNA target and the conjugate.

Table 1. Concentration of Oligonucleotide (μM) Required to Complex 50% of the RNA Target (4 nM)[a]

modification	RNA 27-mer (mutated)	RNA 27-mer (wild-type)
no	0.07	>10
5′-peptide	0.5	7.2
3′-peptide	0.7	9

[a] In the modification column: no = unmodified R5 dodecamer, 5′-peptide = VKRKKKPAA-R5 dodecamer and 3′-peptide = R5 dodecamer-QAKKKKLDK.

DISCUSSION

There is a growing interest in oligonucleotide−peptide conjugates, due to their potential use as oligonucleotide probes and antisense inhibitors of gene expression. The incorporation of peptide sequences opens the possibility of enhancing some of the biophysical and biological properties of oligonucleotides. Signal sequences (Arar et al., 1993), penetratin (Allinquant et al., 1995), and fusogenic peptides (Bongartz et al., 1994) are among the most interesting peptide sequences introduced into oligonucleotides because of their biological properties.

The aim of this study is the synthesis of oligonucleotide−peptide conjugates carrying nuclear localization sequences. Previously, oligonucleotide−peptide conjugates carrying nuclear localization sequences were found, inactive, in the freshwater ciliate *Paremecium* (Reed, 1995). Recently, it has been shown that a single nuclear localization signal sequence in a 3.3 kbp luciferase gene induces a strong transfection enhancement (Zanta, 1999). We studied the effect of the peptide sequence upon the binding properties of oligonucleotides, especially in mismatch discrimination.

Nuclear localization sequences are rich on basic amino acids, especially lysine, that may hinder the synthesis of oligonucleotide−peptide conjugates (Tetzlaff et al., 1998). For the synthesis of the conjugates, we used two approaches. First, we prepared the oligonucleotide and the peptide on separate supports following well-known methods. A thiol group was introduced at the 5′ end of the oligonucleotide and a maleimido group at the *N*-terminal position of the peptide to ensure the formation of a defined oligonucleotide−peptide conjugate (Eritja et al., 1991; Arar et al., 1993; Ede et al., 1994). Such conjugates carry the peptide moiety at the 5′ end of the oligonucleotide, which is attached to the N-terminal residue of the peptide. Likewise, other conjugates can be prepared by changing the position of the thiol and the maleimido group. Nevertheless, the most common connection between peptide and oligonucleotide in the postsynthetic conjugation approach is the N-terminus → 5′ end connection since the connecting molecules are coupled at the end of the synthesis preventing the exposure of the connecting molecules to peptide and oligonucleotide synthesis conditions. Most of the oligonucleotide−peptide conjugates described in the literature are prepared following the postsynthetic conjugation approach, which allows the use of standard conditions in the assembly of both polymers.

The synthesis of oligonucleotide−peptide conjugates following the stepwise approach is an attractive choice in the large-scale production of conjugates. In this approach, the building blocks are not the standard Boc/Bzl or Fmoc/*t*Bu-protected amino acids and the connection between peptide and oligonucleotide is N-terminus to the 3′ end because of the normal C → N and 3′ → 5′ sense of synthesis. It is also easier to assemble first the peptide using Boc chemistry without the oligonucleotide since oligonucleotides can undergo depurination during the TFA treatments needed for the removal of the Boc group. To avoid further acid treatments in the presence of oligonucleotides, the side chains of the amino acids are protected with base-labile groups. Whether the conditions used during oligonucleotide synthesis and deprotection provoke side reactions in the peptide part was also studied. To that end, we used model compounds and exhaustive characterization to analyze the possibility of racemization and the modification of the side chain of trifunctional amino acids in synthesis and deprotection conditions. The use of a special 6-aminohexyl linked prevented the formation of a mixture of products containing carboxylic acid/carboxamide at the C-terminus. This side reaction may also take place on Fm protected Asp and Glu. Moreover, alkylation of lysine residues by acrylonitrile (Telzlaff, 1998) is avoided by a two-step deprotection protocol that removes acrylonitrile before ammonia treatment, but does not prevent small amounts of several products eluting near the desired product (see Figure 5b). Nevertheless, these products can be easily separated from the desired compound. In agreement with several authors (Bermann and Bannwarth 1995, Souckchareun et al., 1995; Robles et al., 1997), we found that both postsynthetic conjugation and stepwise approaches produce the desired oligonucleotide−peptide conjugates with similar yields and purity.

All oligonucleotide−peptide conjugates carrying nuclear localization sequences hybridized with complementary sequences with a slightly higher stability than unmodified sequences. This is in agreement with the results obtained with conjugates carrying basic amino acids (Harrison and Balasubramanian, 1998; Zhu et al., 1993). On the contrary, the binding of conjugates carrying nuclear localization sequences to the target 27-mer RNA was 10-fold less efficient (see Table 1) and several complexes were found. This indicates that melting studies, although they are needed to screen high-affinity compounds, cannot be used for predicting RNA binding because of the secondary structure of RNA. To understand the binding of oligonucleotide analogues to their target RNA, further structural studies ahould be carried out. However, and despite the less efficient binding, conjugates carrying the nuclear localization sequence discriminate single-mutated RNA from wild-type RNA.

CONCLUSION

In summary, we showed that oligonucleotide−peptide conjugates carrying nuclear localization peptides can be synthesized using either a postsynthetic conjugation or a stepwise approach. These conjugates show a slightly higher affinity to complementary DNA but a lower affinity to target RNA than ummodified oligonucleotides, although they maintain a good mismatch discrimination.

Polymerization of Diaspirin Cross-Linked Hemoglobin (DCLHb) with Water-Soluble, Nonimmunogenic Polyamide Cross-Linking Agents

Ton T. Hai,* David E. Pereira, Deanna J. Nelson,† Ana Srnak, and James Catarello

Corporate Research and Technical Services, Baxter Healthcare Corporation, 25212 West State Route 120, Round Lake, Illinois 60073-9799 . Received April 28, 1999; Revised Manuscript Received August 17, 1999

Diaspirin cross-linked hemoglobin (DCLHb), a human hemoglobin that is intramolecularly cross-linked between the α chains (lysine $99_{\alpha1}$−lysine $99_{\alpha2}$), was polymerized with a number of water-soluble, nonimmunogenic polyamide cross-linking agents. The degree of polymerization and the oxygen-carrying capacity depended upon the polyamide reagent, the starting concentration of DCLHb, the molar ratio of the polyamide reagent to DCLHb used, the reaction pH, and whether oxy- or deoxy-DCLHb was used in the polymerization reaction.

INTRODUCTION

It is generally accepted in the blood substitutes community that increasing the size of hemoglobin by polymerization or surface modification offers the benefits of reduced renal clearance, reduced rate of metabolism, and increased duration in the vascular circulation (*1*−*3*). Historically, this was accomplished by using reagents such as glutaraldehyde (*4*), poly(ethylene glycol) (*5*), or dextran (*6, 7*). The polymerized products were mixtures of hemoglobin, oligomers of hemoglobin, and polymers of hemoglobin having a spectrum of sizes and molecular weights. If a product in a specific size range was desired, it had to be separated from the bulk product mixture by chromatographic or ultrafiltration methods.

Because the separation of such product mixtures into the various size ranges on a commercial scale is technically difficult, time consuming, and costly, our goal was to control the product composition of hemoglobin polymerization using water-soluble, nonimmunogenic polyamide cross-linking agents (*8, 9*). These novel cross-linking agents were used to effect the polymerization of diaspirin cross-linked hemoglobin (DCLHb), a human hemoglobin that is intramolecularly cross-linked between the α chains (lysine $99_{\alpha1}$−lysine $99_{\alpha2}$) (*10, 11*). The goal of the research was to obtain a polymerized DCLHb (poly-DCLHb) product that would meet the following requirements (a) The polyDCLHb would be an oxygen-delivering solution suitable for large-volume infusions. (b) It would have a longer half-life in the systemic circulation as oxyhemoglobin than DCLHb. (c) It would have an enhanced safety profile relative to DCLHb. (d) It would have a stability profile at least equivalent to that of DCLHb.

Objectives a−c appeared to be related to the size of the polyDCLHb. We recognized that, in general, larger hemoglobins are retained longer in the vascular system. Moreover, we also recognized those polyhemoglobin molecules that are too large are prone to aggregation and/or precipitation. With this in mind, polyDCLHb synthesis was directed to obtain a polymerized DCLHb product having hemoglobin molecules with molecular mass in the range 130000−260000 Da (equivalent to dimers to tetramers of DCLHb).

To this end, we have tried various synthetic approaches in an attempt to produce a polyDCLHb solution that contained neither residual DCLHb nor high molecular mass polymer (defined as any product having a molecular mass exceeding the exclusion limit of 1×10^6 Da of a TSK G4000SW column). These experiments included the assessment of a spectrum of polyamide reagents with varying molecular masses and terminal reactive functional groups, using various concentrations of DCLHb, varying the number of molar equivalents of the polyamide reagent, and altering the reaction pH.

EXPERIMENTAL PROCEDURES

General. Diaspirin cross-linked hemoglobin (DCLHb), Plasma Lyte A, and Lactated Ringer's irrigation solution were obtained from Baxter Healthcare Corporation, Deerfield, IL. The polyamide cross-linking agents were prepared as previously described (*8*). All other commercial reagents were of the highest purity available. All solvents used were of HPLC grade.

Analytical Methods. Analytical RP-HPLC was carried out on a Vydac Protein C_4 column (5 μm, 4.6 × 250 mm). The mobile phase was delivered at 1 mL/min as a linear gradient of B (CH_3CN:H_2O:TFA, 60:40:0.1, by volume) in A (CH_3CN:H_2O:TFA, 20:80:0.1, by volume) as follows: (1) 50% B to 55% B over 20 min, (2) 55% B to 75% B over 10 min, and (3) 75% B to 85% B over 10 min. Analytes were detected by measuring the absorbance at 220 nm.

Size-exclusion chromatography (SEC) was performed using TSK G4000SW and TSK G3000SW columns (7.5 × 300 mm, TosoHaas) connected in series. Analytes were eluted with a binary mobile phase (50 mM phosphate, pH 6.5/2-propanol, 9:1 by volume) delivered at a flow rate of 1 mL/min. Analytes were detected by measuring the absorbance at 280 nm.

Oxygen equilibrium curves were recorded by reoxygenation of nitrogen equilibrated deoxyhemoglobin in 0.1 M Bis-Tris buffer (pH 7.4 at 37 °C) in the spectral cuvette of a Hemox Analyzer (TCS Medical Products Co., Huntington Valley, PA). The oxygen pressure at which

hemoglobin is half saturated (P_{50}) and the subunit cooperativity (n_{40-60}) were calculated from the oxygen equilibrium curves.

The concentrations of oxy-, deoxy-, and methemoglobin were calculated from their absorbances at three wavelengths (630, 576, and 560 nm) and the reported molar extinction coefficients (*12*). Total hemoglobin concentration was calculated by summation of the concentrations of these components, and percent methemoglobin (MetHb) was calculated as its portion of the total hemoglobin concentration. The number of reactive thiols on the polyDCLHb molecules was determined by the method of Neis et al. (*13*).

Polymerization of DCLHb with Activated Esters (1a, 1b, and 2a Reagents). *Method 1.* DCLHb polymerizations with activated esters of the polyamides were completed as follows. A solution of DCLHb in 0.1 M Hepes, pH 7, or DCLHb in Lactated Ringer's solution was deoxygenated by successive vacuum/nitrogen cycles at room temperature for 1.5 h. In some experiments, 15 molar equivalents of sodium tripolyphosphate (STP) were added to facilitate hemoglobin deoxygenation. A solution of the activated ester in deoxygenated water was added quickly to the deoxyDCLHb solution, and the resulting reaction solution was stirred at room temperature under nitrogen. The course of the reaction was monitored by SEC. When a suitable SEC profile was observed or the reaction was complete (the point at which the SEC profile no longer changed), the reaction mixture was cooled to 5 °C, and a solution of 1 M *N*-acetyl-L-cysteine (NAC), pH 9, was added (i.e., NAC/**1a**, **1b,** or **2a** molar ratio of 4:1). The solution was stirred at 5 °C under nitrogen overnight, and then the solution was dialyzed against Lactated Ringer's solution to give the final product.

Method 2. A solution of the **1a**, **1b**, or **2a** in cold, sterile water was added through a 0.2 μm pore-size filter to a deoxygenated DCLHb solution in 0.1 M Hepes, pH 8 at 5 °C. In some experiments, 15 molar equivalents of sodium tripolyphosphate were added to facilitate the hemoglobin deoxygenation. After the addition of the polyamide solution, the reaction mixture was stirred at 5 °C under nitrogen, and the course of the polymerization was monitored by SEC. When the reaction was complete, the polyDCLHb solution was reoxygenated, concentrated to 7−7.5 g/dL, and diafiltered into PlasmaLyte A solution.

Effects of DCLHb Concentration. Polymerizations of DCLHb with **1a** (MW 4200) were completed under the conditions described in method 1. In these reactions, the DCLHb concentration was varied from 3 to 15 g/dL, and the effects of DCLHb concentration on the degree of polymerization were monitored by SEC. The experimental data are summarized in Table 1 and Figure 2.

Effects of Increased Polyamide Molecular Mass. Polymerizations of DCLHb (15 g/dL) with **1a** (MW 4200) and **1a** (MW 7600) were completed as described in method 1. The polymerization was complete in about 1 h for **1a** (MW 7600) and in about 4 h for **1a** (MW 4200). The experimental data are summarized in Supporting Information, Table S-1, and Figure 3.

Effects of Changes in Reaction pH. The polymerization of DCLHb in 0.1 M Hepes, pH 8, or in 0.1 M borate buffer, pH 9, with **1a** (MW 5600) or **1b** (MW 5200) was performed as follows. A solution of DCLHb (3 g/dL) in 0.1 M borate buffer, pH 9, containing 15 equiv of STP was deoxygenated by vacuum/nitrogen cycles at room temperature for 1.5 h. The deoxygenated hemoglobin solution was cooled to 5 °C, and a deoxygenated solution of **1a** (MW 5600) or **1b** (MW 5200) in deoxygenated water was added. The solution was stirred at 5 °C under nitrogen, and the reaction was monitored by SEC. The polymerization was complete in about 3.0 h. The reaction mixture was dialyzed against PlasmaLyte A solution to give the final product. The experimental results are summarized in Supporting Information, Table S-2.

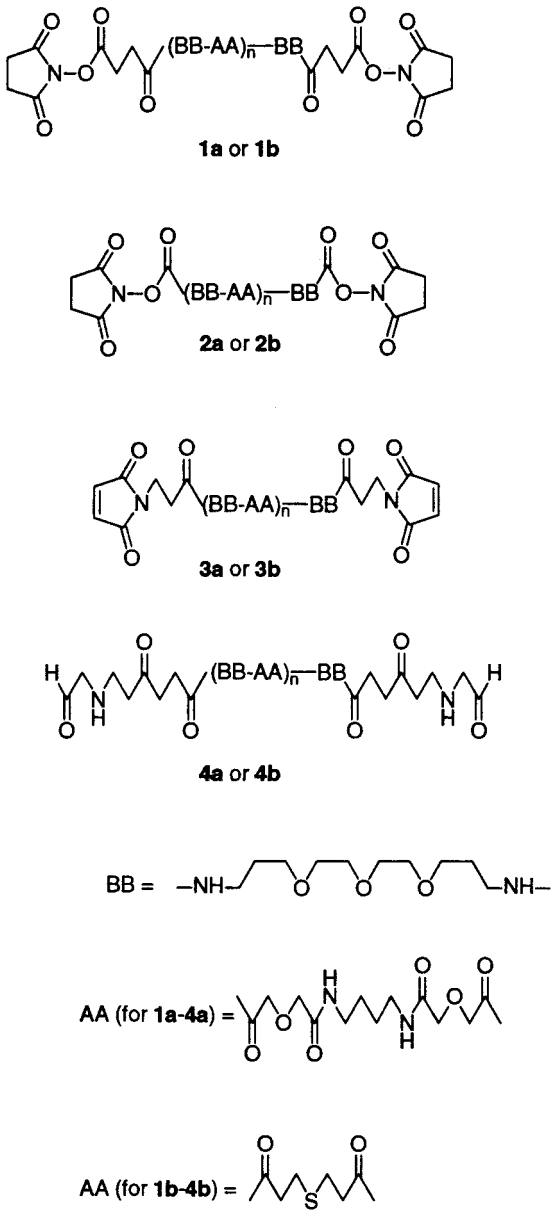

Figure 1. Polyamide reagent structures.

Polymerization of DCLHb with Maleimides [3a (MW 4080)]. A solution of DCLHb (20 g/dL) was deoxygenated by successive vacuum/nitrogen cycles for 1.5 h at room temperature. A solution of the maleimide-terminated polyamide reagent **3a** (MW 4080) in deoxygenated water was added immediately to the deoxy-DCLHb solution, and the reaction mixture was stirred at room temperature under nitrogen. The course of the reaction was followed by SEC. After 15 h, the reaction was complete. The reaction mixture was cooled to 5 °C and a solution of 1 M *N*-acetyl-L-cysteine, pH 9 [molar ratio NAC to **3a** (MW 4080) of 5] was added. The solution was stirred at 5 °C under nitrogen overnight and then dialyzed against Lactated Ringer's solution to give the final product. The experimental data are presented in Supporting Information, Table S-3.

Polymerization of DCLHb with Aldehydes (4a). A solution of DCLHb (15 g/dL) in 0.1 M Hepes, pH 7,

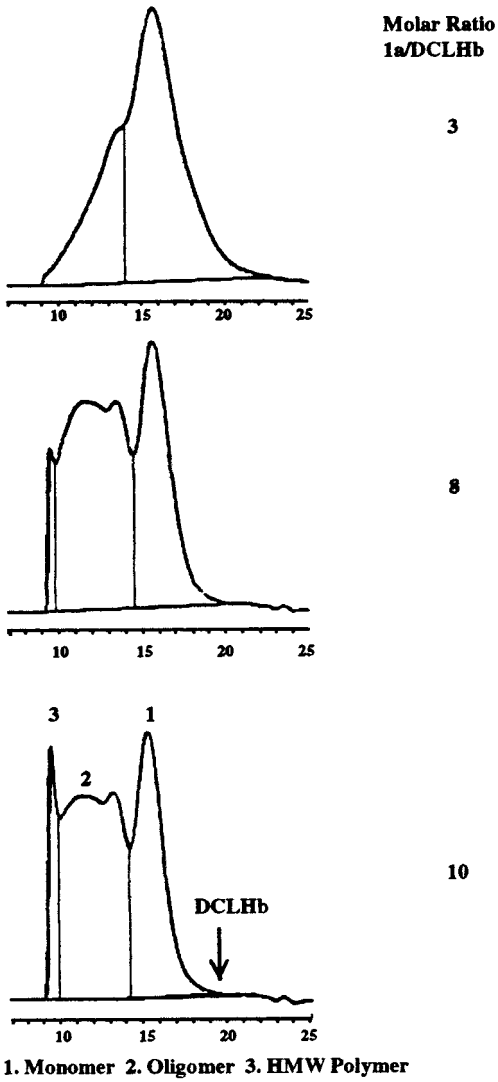

Figure 2. SEC profiles of **1a** (MW 4200) polymerized DCLHb.

was deoxygenated by successive vacuum/nitrogen cycles for 1.5 h at room temperature. A solution of **4a** (MW 4000) and a reducing agent (in a molar ratio of reducing agent to **4a** of 10) was added. When sodium borohydride was used as the reducing agent, it was added after 20 h to allow time for imine formation and to avoid reducing the aldehyde groups of **4a**. After 24 h, the reaction mixture was cooled to 5 °C, and 1.0 M glycine, pH 9 (molar ratio of glycine to **4a** of 4), and 1.0 M NAC, pH 9 (molar ratio NAC to DCLHb of 8), were added to quench the polymerization and to reduce methemoglobin, respectively. The solution was stirred under nitrogen at 5 °C overnight and then dialyzed against Lactated Ringer's solution to give the final products. The experimental results are summarized in Supporting Information, Table S-3.

Effects of Polymerization with OxyDCLHb. A solution of oxy- or deoxy-DCLHb in 0.1 M Hepes, pH 8, in the presence of 15 molar equivalents of STP was employed. The reactions were generally conducted as described in method 1. Experimental results are summarized in Supporting Information, Table S-4.

RESULTS AND DISCUSSION

Polymerization of DCLHb with Polyamide Cross-Linking Agents. All of the polyamide cross-linking agents employed in these studies were bifunctional reagents. The activated bis(*N*-oxysuccinimidyl) diesters **1a** and **1b** can react with the ϵ-amino groups of lysine residues or the N-terminal amino groups of hemoglobin to form amide linkages between the polyamide and the protein. Maleimide derivatives, such as **3a** and **3b**, can react with lysine or cysteine residues of hemoglobin to form C−N and C−S linkages, respectively. **2a** and **2b** (that contain succinimidyl-N-oxycarbonyl end groups) can react with lysine residues or the N-terminal amino groups of hemoglobin to form urea linkages. The polyamide bis(aldehyde) **4a** and **4b** can polymerize DCLHb via reductive amination reactions, to yield DCLHb molecules linked by covalent C−N bonds.

If both reactive end groups of a polyamide react with different DCLHb molecules, an intermolecularly cross-linked polyDCLHb is produced, and the SEC retention time is decreased. In contrast, if only one reactive terminus reacts with a DCLHb molecule and the other reactive terminus is deactivated (i.e., via hydrolysis), surface modification of DCLHb will result. As is true of a polyDCLHb, the SEC retention time of a surface-modified DCLHb is decreased, but not as greatly as when DCLHb is polymerized.

Historically, the size of hemoglobin derivatives has been assessed using size-exclusion chromatography (SEC). A series of protein standards having known molecular weights typically are used to calibrate the chromatographic conditions, so that retention times may be correlated with the molecular weight. A shortcoming of this relationship is that its rigor depends on the similarity of the test articles to the protein standards. The polyDCLHb derivatives we have evaluated have been modified using polyamides that both modify the surface and polymerize the protein. This type of modification renders them different from the protein standards. Therefore, the chromatographic retention time does reflect the relative size of the polyDCLHb molecules being separated, but it cannot be used to vigorously establish molecular weights.

The targeted polymerized DCLHb product would be devoid of monomer (DCLHb) and high molecular mass polymers (defined as products having with molecular masses that exceed the exclusion limit of 1×10^6 Da a of TSK G4000SW column). With this objective in mind, the molecular mass of the polyamide, the polyamide reactive end groups, the DCLHb concentration, the number of molar equivalents of polyamide used (relative to DCLHb), and the reaction pH were varied. In addition to these reaction parameters, the effects of sodium tripolyphosphate (STP) on the polymerization of DCLHb were studied. In general, the methemoglobin content increased from 3 to 10% during the polymerization reaction. Methemoglobin is the oxidized form (Fe^{2+} to Fe^{3+}) of hemoglobin and is nonfunctional, that is, does not transport oxygen. Therefore, to minimize the methemoglobin content of the polyDCLHb molecules, *N*-acetyl L-cysteine was added to the deoxygenated product. The reduction of methemoglobin was allowed to take place over a 12−24 h period prior to product workup.

The effects of the DCLHb concentration on the course of polymerization were studied using **1a** (MW 4200) (Table 1 and Figure 2). In general, polymerization of DCLHb with this polyamide gave a product mixture having a SEC profile consisting of three peaks. These peaks were identified as "monomer" (DCLHb and surfaced modified DCLHb), "oligomers" of DCLHb, and "high molecular weight (HMW) polymers" of DCLHb that eluted in the excluded volume of the column.

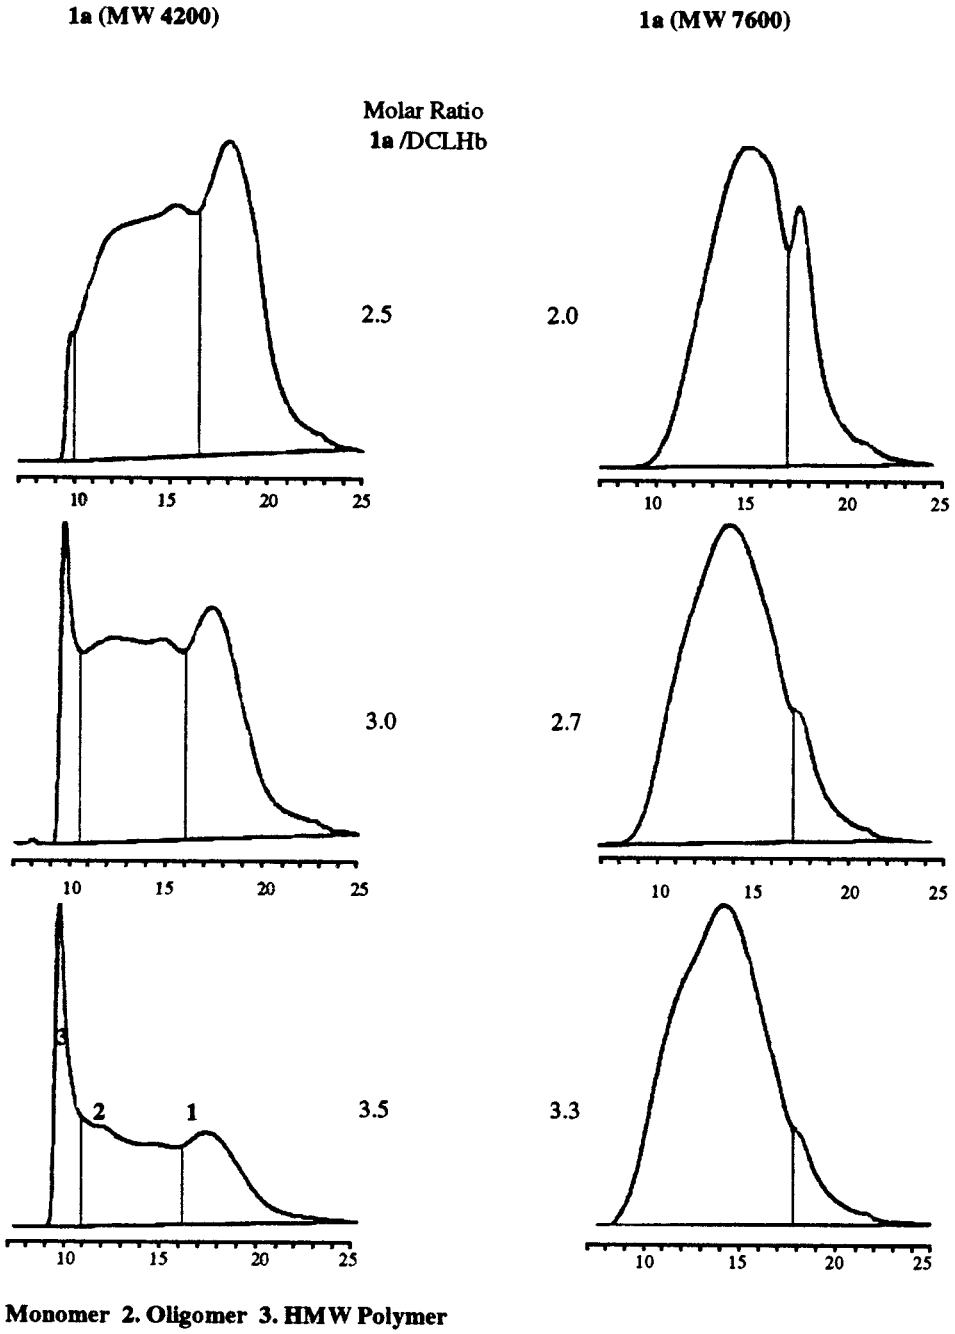

Figure 3. Comparison of the SEC profiles of **1a** (MW 4200) and **1a** (MW 7600) polymerized DCLHb.

As expected, the data indicate that high DCLHb concentrations favor the formation of polymeric products, even when low molar ratios of the cross-linker to DCLHb were used. Thus, when the DCLHb concentration was 15 g/dL, the use of 3 molar equivalents of **1a** (MW 4200) gave a product in which 60% of the DCLHb had been polymerized. In contrast, when the DCLHb concentration was 6 or 3 g/dL, the use of 3 molar equivalents of **1a** (MW 4200) gave only 37 and 22% polymerized hemoglobin, respectively.

The polymerization of DCLHb at higher DCLHb concentrations was difficult to control. The use of 2.5 molar equivalents of **1a** (MW 4200) and a DCLHb concentration of 15 g/dL yielded a product mixture containing 2% of the undesired HMW polymers. The data are presented in Table 1. If the number of molar equivalents of the cross-linker was increased in an attempt to increase the extent of polymerization, the percentage of undesired HMW polymers increased rapidly. However, if the DCLHb concentration was 3 g/dL (the lowest concentration that is practical for commercial manufacture), as many as 7 molar equivalents of **1a** (MW 4200) could be used for polymerization. These conditions provided a product that was 50% polymerized and contained no HMW polymers. Moreover, the shift in retention times of the monomers indicated that the product was extensively surface modified. Surface modification of DCLHb may enhance the longevity in the systemic circulation and the biocompatibility of the polyDCLHb. Thus, the degree of polymerization and product composition could be controlled by altering the concentration of DCLHb and the molar ratio of the polyamide reagent to DCLHb.

The molecular mass of the polyamide reagent played a key role in maximizing the efficiency of the polymerization reaction. DCLHb is a globular protein having a diameter of about 60 Å. Because of this relative bulki-

[a] Number in parentheses is the elution time in minutes of the corresponding peak maximum.

ness, a longer chain polyamide would be expected to facilitate intermolecular linking of DCLHb molecules; thus, the efficiency of polymerization was expected to increase with the chain length of the cross-linker. This was indeed the case. A comparison of the extent of DCLHb polymerization with **1a** (MW 4200) and (the longer) **1a** (MW 7600) shows that as much as 90% polymerization could be obtained with **1a** (MW 7600). Moreover, no HMW polymers formed when the higher molecular weight (longer chain) **1a** (MW 7600) was used (Table S-1). Thus, a shorter chain cross-linking agent is more useful for surface modification and polymerizing DCLHb, while a polyamide with a longer chain provides a higher degree of polymerization**.** Representative SEC profiles are shown in Figure 3.

The polyamide cross-linking agents **1a** and **1b** contain reactive end groups that can be hydrolyzed; therefore, the reaction pH can affect the extent of polymerization. In a solution that contains DCLHb, the reagents **1a** or **1b** can react either with the amino groups on DCLHb to form amide bonds or can be hydrolyzed by water to carboxylic acids that can no longer react with DCLHb. Therefore, if one of the end groups of the polyamide reagent reacts with DCLHb via aminolysis and the end group under goes hydrolysis, surface modification of DCLHb will result. Thus, the reaction of a **1a** or **1b** derivative with DCLHb affords a mixture of polyDCLHb and surface-modified DCLHb molecules in which the ratio of polymerized to surface-modified DCLHb molecules is dependent on the relative rates of aminolysis and hydrolysis of the activated end groups of the polyamides. Because the nucleophilicity of the amino groups of DCLHb depends on their lack of protonation, the rate of aminolysis will depend on the buffer pH.

The effect of the buffer pH on the degree of polymerization was evaluated by performing DCLHb polymerizations at pH 8 (0.1 M Hepes) and pH 9 (0.1 M borate) and comparing the product profiles. The product distribution of the polymerization of deoxyDCLHb (3 g/dL) at 5 °C in 0.1 M Hepes, pH 8, or 0.1 M borate, pH 9, containing 15 molar equivalents of STP were compared using both **1b** (MW 5200) and **1a** (MW 5600). The data presented in Table S-2 illustrate several points. First, using the same Polyamide/DCLHb molar ratio, reactions performed at pH 9 gave polyDCLHb containing less surface-modified DCLHb (monomer) and more oligomers than those performed at pH 8. For example, at pH 8, polymerization of DCLHb (3 g/dL) with 3.5 molar equivalents of **1b** yielded a product mixture containing 8% surface modified DCLHb and 90% oligomers, about 1/4 of which were the higher molecular weight Oligomer II fraction, defined as molecules with peak maxima having retention times of 11.0−14.7 min. At pH 9, oligomerization was almost quantitative; the corresponding product mixture contained at most traces of surface-modified DCLHb, and approximately a third was the Oligomer II fraction.

Similar results were obtained with **1a** (MW 5600). For example, with a **1a**/DCLHb molar ratio of 3, at pH 8, polymerization with **1a** (MW 5600) yielded a product mixture containing 10% surface-modified DCLHb and 90% oligomers, about 1/3 of which were the higher molecular weight Oligomer II fraction. In contrast, at pH 9, the corresponding product mixture contained 5% surface-modified DCLHb and 95% oligomers, approximately half of which are the Oligomer II fraction. Second, similar polyDCLHb profiles could be obtained by using lower polyamide/DCLHb molar ratios if the reaction was performed at pH 9 rather than at pH 8. For example, the polyDCLHb obtained from **1b** (MW5200) at pH 9 using a 3:1 molar ratio of **1b**/DCLHb had a similar SEC profile to that obtained at pH 8 using a 3.5:1 molar ratio of **1b**/DCLHb. Finally, the P_{50} and n values of Poly-DCLHb derived from **1b** were not extensively affected by the reaction pH.

The effect that competitive hydrolysis of a reactive end group of a polyamide has on the extent of polymerization was demonstrated by the comparison of the polymerization of DCLHb with **1a** (MW 4200) (a cross-linking agent subject to hydrolysis) with the polymerization observed using **3a** (MW 4080), a maleimide-terminated cross-linker of comparable length that will not hydrolyze under the reaction conditions. The reactions of the two cross-linkers were similar in two respects: (a) the yield of the oligomer increased with the number of molar equivalents of cross-linker used and (b) the elution times of the monomer decreased with the number of molar equivalents of cross-linker used, indicating that surface modification of DCLHb had occurred. The data are presented in Tables S-2 and S-3.

The reactions of these two cross-linkers also differed in two other respects. First, the RP-HPLC profiles (Figure 4) suggest that **3a** (MW 4080) reacted specifically with DCLHb. A new peak, the β_1 peak, was detected at all ratios of **3a** (MW 4080) tested. Maleimide reagents, such as **3a**, are expected to bind specifically to cysteine-β 93 residues, and this modification would shift the retention time of the β-subunit. Specific reaction of the β-chain was also supported by the decrease in titratable thiol residues (Figure 5); about 65 and 90% of the titratable thiol groups are modified when 1 and 2 equiv of **3a** (MW 4080) are used, respectively. Second, thiol modification by **3a** (MW 4080) resulted in a decrease in the P_{50} values of the polymerized products to 18−20 mmHg, whereas modification by **1a** did not effect the P_{50} values under similar reaction conditions. A decrease in the P_{50} value is an expected consequence of cysteine-β 93 modification (*14*, *15*).

Finally, the effectiveness of two other types of polyamide cross-linking agents was assessed. DCLHb was polymerized with **4a** (MW 4000), a polyamide containing aldehyde end groups, via reductive amination. The reductive amination reactions were performed in 0.1 M Hepes, pH 7.0, in the presence of either sodium cyanoborohydride, borane-pyridine, sodium borohydride, or borane-dimethylamine. The data are presented in Table S-3. Unexpectedly, we found that reduction of the imine with borane-dimethylamine or sodium borohydride did not produce polyDCLHb, although other investigators have reported that these are useful reducing agents for reductive amination reactions (*16*). In contrast, when either sodium cyanoborohydride or borane-pyridine was used, **4a** (MW4000) provided both surface-modified and polymerized DCLHb, although the efficiency of the latter was modest. Under the best conditions found, the polymerized products still contain 38−48% of modified

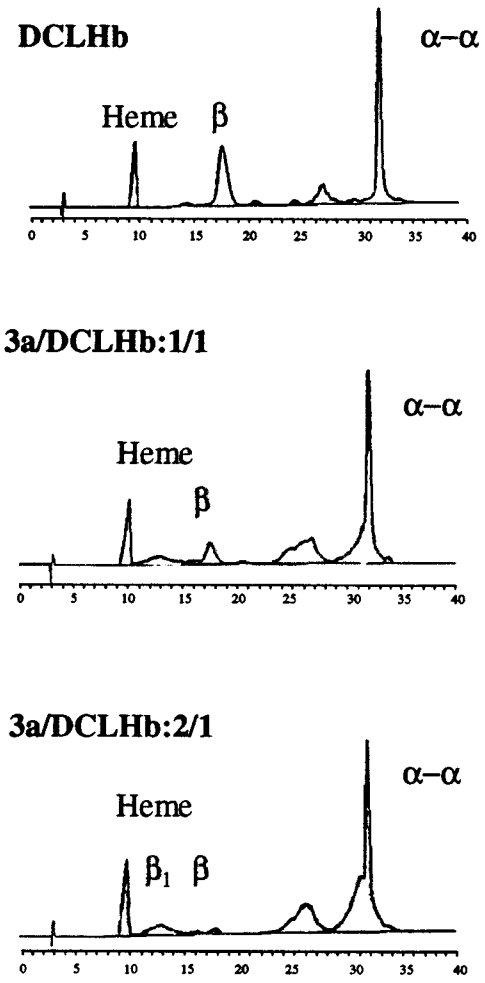

Figure 4. Reversed-phase HPLC profiles of **3a** (MW 4800) polymerized DCLHb.

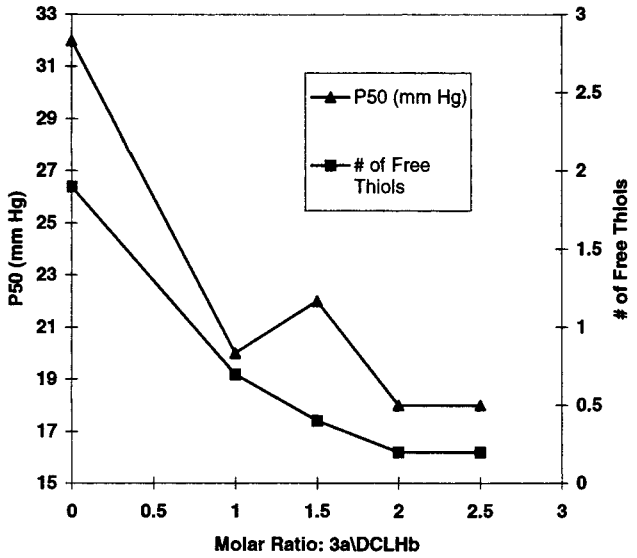

Figure 5. Relationship between the number of free thiols and the P_{50} value of **3a** polymerized DCLHb.

monomer. Reduction with borane-pyridine produced a polyDCLHb having values of P_{50} and n in the range 33−36 mmHg and 1.9−2.1, respectively. Thus, the polymerization of DCLHb by reductive amination maintained the P_{50} value and cooperativity of DCLHb.

DCLHb was also polymerized with **2a** (MW 2800) and **2a** (MW 5600), polyamides having succinimidyl-*N*-oxy-

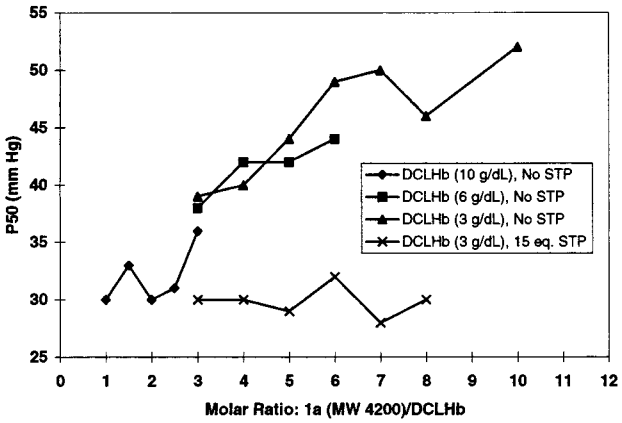

Figure 6. Relationship between the P_{50} value of polymerized DCLHb and the concentration of DCLHb.

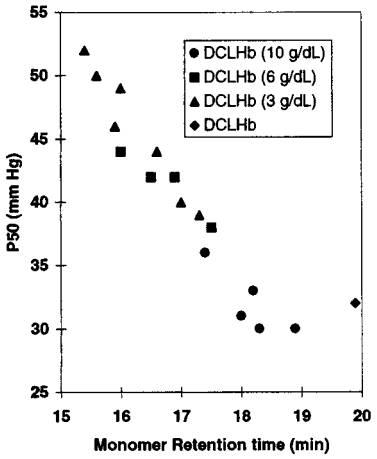

Figure 7. Relationship between the P_{50} value and the retention time of the monomer peak of **1a** (MW 4200) polymerized DCLHb.

carbonyl (activated urethane) termini. In each case, a 3 g/dL deoxyDCLHb solution in 0.1 M Hepes, pH 8, was allowed to react at 5 °C. Six molar equivalents of **2a** (MW 2800) and 4 molar equivalents of the longer **2a** (MW 5600) were used in the respective polymerizations. Both polyDCLHbs had acceptable SEC profiles and appeared to be suitable for additional biological screening. However, the SEC profiles changed during refrigerated storage of the products, suggesting that the resulting urea linkages were unstable.

Controlling the Oxygen-Binding Characteristics of the PolyDCLHbs. Three means for controlling the oxygen-binding characteristics of the polyDCLHb products were studied. First, the polymerization reaction was performed in the presence of STP. Under these conditions, the P_{50} of the product was maintained in the range 27−36 mmHg, the same range as that of DCLHb. However in the absence of STP, the P_{50} of the product was dependent upon the starting concentration of DCLHb used in the polymerization and the molar equivalents of the polyamide reagent used. The data are presented in Figure 6. For each concentration of DCLHb used, the P_{50} increased with an increase in the molar equivalents of the polyamide used in the reaction. The highest P_{50} values were obtained with dilute starting concentrations of DCLHb. It was also noted, as the graph in Figure 7 illustrates, that there is an approximately linear relationship between the P_{50} value of the polyDCLHb solution and the SEC retention time of the monomer. The data suggest that an increase in the extent of surface modification of DCLHb correlates with an increase in the P_{50} value of the polymerized product.

A comparison of the SEC profiles of the polymerized products indicates that STP has no detectable effect on the product composition despite the effect on the P_{50} value. Since STP is known to bind to hemoglobin at the 2,3-diphosphoglycerate (DPG) binding site (*17*, *18*), one reasonable interpretation of this observation is that the presence of STP in the DPG-binding site protects the amino acid residues in that region from modification by **1a** (MW 4200).

Altering the reactive end group provided a second means for controlling the oxygen-binding characteristics of the polyDCLHb products. A P_{50} value of about 20 mmHg and a decrease of the cooperativity value to 1.7 (n_{40-60}) were obtained by polymerization with a polyamide containing a maleimide end group such as **3a** (MW 4080). As shown in Figure 5**,** the alkylation of the thiols of cys β93 has a profound effect on the oxygen binding characteristics of the polymerized products.

Last, the oxygen-binding characteristics of the poly-DCLHb products could be modified by polymerization of either oxyDCLHb or deoxyDCLHb. Other investigators have shown that polymerization in the T-conformation of hemoglobin (deoxyHb) or in the R-conformation (oxyHb) yields polymerized hemoglobins that are partially locked in the T- or R-conformation, respectively (*2*). The oxygen affinity of a polyHb prepared from a T-state Hb is expected to be different from that prepared from a R-state Hb. To demonstrate that this also applied to the polyamide-polymerized DCLHb, deoxyDCLHb (3 g/dL or 6 g/dL) or oxyDCLHb (3 g/dL or 6 g/dL) in 0.1 M Hepes, pH 8, was polymerized with **1a** (MW 5600) in the presence of 15 molar equivalents of STP at 5 °C. In general, SEC profiles of the polyDCLHbs produced under these conditions gave four SEC bands: monomer band, oligomer I band (defined as molecules having peak maxima with retention times of 15.2−17.2 min), oligomer II band (defined as molecules having peak maxima with retention times of 11.0−14.7 min), and HMW polymer band (defined as molecules having molecular sizes exceeding the exclusion limit of the columns) (see Table S-4). When oxyDCLHb was polymerized with **1a** (MW 5600), the polyDCLHb products had P_{50} and n values in the range of 18−27 mmHg and 1.5−2.3 (n_{40-60}), respectively. In contrast, when deoxyDCLHb was polymerized, these values were in the range of 23−36 mmHg and 1.8−2.5(n_{40-60}), respectively.

In summary, we have demonstrated the ability to control the polymerization of DCLHb and the oxygen-binding properties of the polyDCLHb product. This was accomplished by either altering the polyamide cross-linking reagent, the reaction pH, the DCLHb concentration, the molar equivalents of the polyamide reagent, or by conducting the polymerization with either oxy- or deoxyDCLHb.

Supporting Information Available: Data describing the polymerized DCLHb products are presented in Tables S-1−S-4. This material is available free of charge via the Internet at http://pubs.acs.org.

Synthesis of Biotinylated Glycoconjugates and Their Use in a Novel ELISA for Direct Comparison of HIV-1 Gp120 Recognition of GalCer and Related Carbohydrate Analogues

Katherine D. McReynolds, Michael J. Hadd, and Jacquelyn Gervay-Hague*

The University of Arizona, Department of Chemistry, Tucson, Arizona 85721. Received April 28, 1999; Revised Manuscript Received September 16, 1999

As part of our program directed toward the design and synthesis of high-affinity ligands for the GalCer-binding site on the HIV cell surface glycoprotein, gp120, we required a reliable method for qualitatively assessing relative binding affinities for related analogues. Due to the hydrophilic nature of these synthetic conjugates, difficulties were encountered with typical ELISA methods, which rely upon hydrophobic interactions to anchor the ligand to a microtiter plate. Other types of assays were also problematic due to nonspecific binding of gp120. Therefore, we developed a general method for plating water-soluble ligands on microtiter plates using biotin/NeutrAvidin recognition for adhesion. A water-soluble GalCer analogue was prepared by conjugating psychosine to biotin using a novel tetraethylene glycol linker. In a similar manner, LacCer and GlcCer analogues were prepared and these conjugates were plated into microtiter wells containing NeutrAvidin. Unoccupied sites were blocked using biotin functionalized as a primary amide. Gp120 binding to galactosyl sphingosine, GalSph (**19**), GlcSph (**22**), and LacSph (**23**) conjugates was assessed through incubation with recombinant HRP-gp120. It was determined that LacSph has the strongest interaction with gp120. The binding affinities of GalSph and GlcSph were similar to each other and less strong than LacSph. These data contradict earlier studies where HPTLC showed that LacCer and GlcCer do not significantly bind gp120. They also contradict liposome-based assays that reported psychosine is not recognized by gp120. The extent of plating for each biotinylated molecule was quantified using HRP-biotin, allowing direct comparison of ligand plating efficiencies for the first time. Several other synthetic biotin conjugates were prepared and tested, demonstrating the feasibility of performing ELISA on water-soluble ligands.

INTRODUCTION

HIV entry into host cells is a complex process. The primary mode of host cell recognition and infection involves the CD4 receptor on the surface of helper T cells and is mediated by the viral envelope glycoproteins, gp120 and gp41. In 1991, Harouse and co-workers reported that there is an alternate mode of viral entry, based upon the susceptibility of CD4 negative cell lines to infectivity (*1*). Instead of using CD4 as a receptor, gp120 is able to recognize and bind a glycolipid, galactosyl ceramide (GalCer, **1**), and infect cells that do not express CD4. GalCer is present on the surfaces of neuronal and glial cells in the brain, in addition to some colorectal cell lines, vaginal epithelial cells, and primary macrophages (*2*). The ability of HIV to infect these CD4-negative cell lines represents a possible mode of infection through sexual transmission.

A primary goal of our research is to develop target-specific drug delivery systems that prevent HIV entry into both CD4-positive and CD4-negative host cells. As a part of this program, we are developing new carbohydrate-based drug candidates designed to block the GalCer-binding domain. Our design process requires a functional screening assay to determine the extent to which these water-soluble compounds bind to gp120 in comparison to GalCer. Although several binding studies of GalCer analogues have been reported, there are contradicting conclusions (vide infra). This is partly due to the fact that, until this report, there was not a uniform method available for directly comparing the binding of new synthetic conjugates to gp120 in the same assay.

Harouse and co-workers utilized high-performance thin-layer chromatography (HPTLC) to determine that GalCer is a receptor for gp120 (*1*). In their study, glycolipids such as GalCer (**1**), GalCer sulfatide (GalS (**2**)), psychosine (**3**), glucosyl ceramide (GlcCer (**4**)), lactosyl ceramide (LacCer (**5**)), and ceramide (**6**) and a mixture of neutral glycolipids from human erythrocytes including ceramide, trihexose, and globoside were plated on HPTLC plates (Figure 1). After separation and washing, the plates were incubated with ^{125}I-labeled recombinant gp120, then washed and counted. Upon development, it was found that gp120 bound only to GalCer (**1**) and GalS (**2**). A second experiment confirmed that antibodies against GalCer inhibited both the infectivity of susceptible cell lines and internalization of the virus. Table 1 summarizes the binding profiles of several bioconjugates compared to GalCer (*3*).

Interestingly, similar studies by Latov et al. utilizing ELISA, an immunospot assay on nitrocellulose, and HPTLC contradict the results by Harouse and co-workers (*4*). Specifically, Latov determined that GalS bound to gp120, but GalCer did not, in both an immunospot assay and ELISA. However, in HPTLC, GalCer was found to bind. They attributed this discrepancy to a lower specificity of the TLC assay because the binding on the plates can be altered by the polyisobutyl methacrylate coating.

Binding studies were also performed using liposomes doped with glycoconjugates (*5*). Mixtures of phosphatidyl ethanolamine (PE), phosphatidyl choline (PC), cholesterol, and various glycosphingolipids (GalCer, GalS, psychosine, GlcCer, LacCer, and sphingomyelin) were

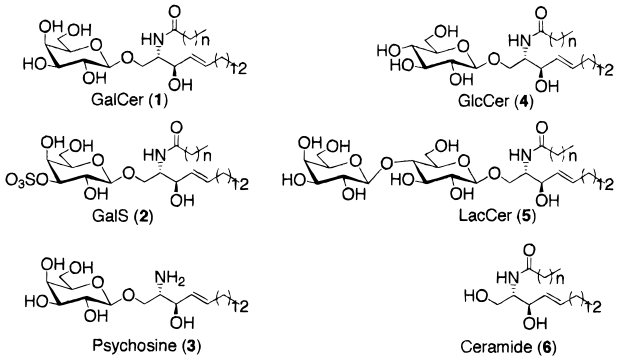

Figure 1. Representative bioconjugates assayed for HIV-1 gp120 affinity using various techniques.

Table 1. Assays of Various Bioconjugates Affinity for HIV-1 gp120 Using HPTLC and Doped-Liposomes

bioconjugate	percent binding (HLTLC) (*1*)	percent Gp120 bound (liposomes) (*4*)
GalCer (**1**)	100	95
GalS (**2**)	109 ± 11	30−60
psychosine (**3**)	95 ± 14	<5
GlcCer (**4**)	5 ± 2	25−55
LacCer (**5**)	19 ± 2	60−90
ceramide (**6**)	9 ± 3	not assayed

used to make liposomes. The assay consisted of incubating gp120 with the liposomes, then allowing binding to occur before a series of steps were performed to isolate the bound gp120-liposomal components. The isolated media was subjected to SDS−PAGE electrophoresis and Western blotting to detect the presence of gp120. Using this methodology, the researchers determined that GalS (**2**), GlcCer (**4**), and LacCer (**5**) have significant activity, while psychosine (**3**) does not (Table 1).

Because the presentation geometry of the ligands may differ dramatically between the aforementioned assays, drawing conclusions about relative binding affinities from comparative data is problematic. To enable the direct comparison of several different carbohydrate analogues, we developed a new ELISA wherein various ligands are conjugated to a water-soluble linker possessing a biotin moiety. These conjugates are then irreversibly adhered to NeutrAvidin-coated microtiter plates, ensuring that all ligands are bound in a similar manner and allowing direct comparison of binding affinity data.

Utilization of the water-soluble chemical linker is a critical factor in this ELISA. There are commercially available biotin linkers that can be conjugated to various ligands, however, they are typically comprised of hydrophobic caproic acid segments (*6*). In addition to creating solubility problems in plating, our studies showed that the commercial hydrophobic linkers obscured important interactions between gp120 and carbohydrate analogues through nonspecific binding. Both of these problems are alleviated with hydrophilic linkers. We have synthesized a water-soluble linker with bifunctionality bearing amino and carboxylic acid termini. The amino side is used for biotinylation, and the carboxylic acid is used to covalently attach carbohydrates with amine functionality. Both the linker and carbohydrate are hydrophilic. The linker can thus effectively extend the carbohydrate out into solution, maximizing the carbohydrate/protein interaction. Although the use of biotin/streptavidin for carbohydrate assays has been reported (*7*), to our knowledge, this is the first report of a water-soluble chemical linker for use in gp120 binding ELISA (*8*). We have also developed a unique method for quantifying the plating efficiency of individual ligands. This report focuses on the synthetic preparation of various bioconjugates and the determination of their binding affinity for recombinant HRP-gp120 using a novel ELISA construct. This assay provides a powerful tool for studying the binding of hydrophilic carbohydrate-based ligands.

EXPERIMENTAL SECTION

General Procedures. All materials were obtained from commercial sources and used without additional purification, unless otherwise noted. Solvents were all distilled prior to use as reaction media. All glassware utilized in water-sensitive reactions was flame-dried before use. ^{1}H NMR spectra were recorded at 250 or 500 MHz on Bruker superconducting FT spectrometers. ^{13}C NMR spectra were recorded at 62.5 or 125 MHz and were proton decoupled. All spectra are reported as ppm downfield of tetramethylsilane.

***tert*-Butyl-4,7,10-trioxadodecyl-12-*p*-toluenesulfonate (8).** A total of 2.0 g (7.19 mmol) **7** (prepared by the method of Seitz and Kunz) (*9*) was weighed directly into an oven-dried flask. The flask was placed in an ice bath upon addition of 40 mL of pyridine, and the solution was allowed to cool to 0 °C under argon gas. A total of 2.74 g (14.38 mmol) of purified TsCl (recrystallized from petroleum ether) was added, and the reaction was stirred under argon from 0 °C to room temperature for 4.5 h. The reaction was quenched by the addition of 80 mL of deionized H_2O and extracted three times with ethyl acetate. The combined organic layers were washed with brine and dried over anhydrous sodium sulfate. Purification of the crude product was achieved by silica gel chromatography with 9:1 toluene/acetone. A total of 2.42 g (75%) of a clear yellow oil was obtained. ^{1}H NMR (250 MHz, $CDCl_3$) δ 1.51 (s, 9H), 2.51−2.59 (m, 5H), 3.64−3.66 (app d, 8H, J = 3.0), 3.76 (app q, 4H, J = 6.6, 13.0), 4.22 (t, 2H, J = 4.3), 7.42 (d, 2H, J = 8.1), 7.86 (d, 2H, J = 8.2). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ 21.56, 28.02, 36.19, 66.80, 68.57, 69.27, 70.27, 70.44, 70.63, 80.35, 127.89, 129.81, 132.91, 144.78, 170.79. High-resolution mass spectrum (FAB^+) calcd for $C_{20}H_{33}SO_8$ $(MH)^+$: 433.1896. Found: 433.1895.

***tert*-Butyl-12-azido-4,7,10-trioxadodecylate (9).** A total of 2.12 g (4.91 mmol) of compound **8** was transferred to a flask as a solution in dichloromethane, then evaporated and weighed. A total of 29.5 mL of DMF was added to a flask under argon and stirred. A total of 958 mg (14.73 mmol) of NaN_3 was added, and the reaction was stirred at room temperature under argon for 1.5 h. The reaction was quenched by the addition of 50 mL of deionized H_2O and extracted three times with diethyl ether. The combined organic layers were washed with brine and dried over anhydrous sodium sulfate. Purification of the crude product was achieved by silica gel chromatography using 3:1 hexanes/ethyl acetate. A total of 1.35 g (91%) of a clear, colorless oil was obtained. The product contained a slight impurity by TLC. ^{1}H NMR revealed that the product was ~95% pure. IR (thin film) 2978, 2864, 2104, 1719 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$) δ 1.39 (s, 9H), 2.45 (t, 2H, J = 6.6), 3.33 (t, 2H, J = 5.0), 3.54−3.68 (m, 12H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ 27.89, 36.09, 50.48, 66.70, 69.88, 70.20, 70.41, 70.49, 70.56, 80.17, 170.64. High-resolution mass spectrum (FAB^+) calcd for $C_{13}H_{26}N_3O_5$ $(MH)^+$: 304.1872. Found: 304.1865.

***tert*-Butyl-12-amino-4,7,10-trioxadodecylate (10).** A total of THF was added to a flask containing 539 mg (1.78 mmol) of compound **9**. 64.1 mL (3.56 mmol) of deionized H_2O was added, followed by 512 mg (1.95

mmol) of triphenylphosphine (*10*). The reaction was stirred at room temperature for 80 h, and then evaporated. A solution of 1:1 ether/petroleum ether was added to the flask, then placed on ice (*11*). The solution was filtered through Celite, then filter paper, to remove the precipitated triphenylphosphine oxide. The filtrate was then evaporated. Purification of the crude product was achieved by silica gel chromatography with 90:10:0.1 chloroform/methanol/triethylamine. A total of 405 mg (82%) of a clear yellow oil was obtained. ^{1}H NMR (250 MHz, $CDCl_3$) δ 1.37 (s, 9H), 2.43 (t, 2H, $J = 6.5$), 2.80 (t, 2H, $J = 5.1$), 3.45 (t, 2H, $J = 5.2$), 3.56 (s, 8H), 3.64 (t, 2H, $J = 6.5$). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ 28.09, 36.25, 41.72, 66.89, 70.27, 70.38, 70.51, 70.57, 73.23, 80.47, 170.8. High-resolution mass spectrum (FAB^+) calcd for $C_{13}H_{28}NO_5$ $(MH)^+$: 278.1967. Found: 278.1960.

D-Biotin-*tert*-butyl-12-amido-4,7,10-trioxadodecylate (12). A total of 205 mg (0.74 mmol) of compound **10** was transferred to the reaction flask as a solution in dichloromethane, then evaporated and weighed. A total of 11.6 mL of DMF was added, followed by 309 μL (2.22 mmol) of TEA, with the flask under nitrogen. The solution was stirred, and 290 mg (0.74 mmol) of D-biotin-2,3,5,6-tetrafluorobenzoate (**11**) was added. The reaction was stirred at room temperature, under nitrogen, for 24 h, then evaporated. The resultant crude product was purified using silica gel chromatography with a gradient of 16:1 to 8:1 chloroform/methanol. A total of 369 mg (99%) of a clear amorphous solid was obtained. ^{1}H NMR (250 MHz, $CDCl_3$) δ 1.38 (app s, 11H), 1.46−1.75 (m, 4H), 2.16 (t, 2H, $J = 7.2$), 2.43 (t, 2H, $J = 6.4$), 2.67 (d, 1H, $J = 13.7$), 2.83 (dd, 1H, $J = 4.5, 12.9$), 3.07 (app d, 1H, $J = 4.4$), 3.36 (app t, 2H, $J = 4.6$), 3.50 (app t, 2H, $J = 5.1$), 3.55 (app s, 8H), 3.64 (app t, 2H, $J = 6.5$), 4.25 (m, 1H), 4.43 (m, 1H), 6.02 (s, 1H), 6.87 (m, 2H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ 25.79, 28.28, 28.40, 36.15, 36.41, 39.33, 40.72, 55.81, 60.42, 61.96, 67.07, 70.15, 70.29, 70.56, 80.80, 164.2, 171.1, 173.58. High-resolution mass spectrum (FAB^+) calcd for $C_{23}H_{42}N_3SO_7$ $(MH)^+$: 504.2743. Found: 504.2754.

D-Biotin-12-amido-4,7,10-trioxadodecanoic acid (13). Reagent K (*12*) was prepared in a separate glass-stoppered flask and contained the following: 1.65 mL of TFA (85% v/v), 100 μL of thioanisole (5% v/v), 50 μL of 1,2-ethanedithiol (2.5% v/v), 100 μL of deionized H_2O (5% v/v), and a small amount of phenol (~5% w/v). A total of 42.4 mg (0.079 mmol) of compound **12** was transferred to the reaction flask as a solution in dichloromethane, then evaporated and weighed. Reagent K was transferred to the reaction flask, stoppered with glass, stirred at room temperature for 1.5 h, then evaporated. Purification of the crude acid was achieved using silica gel chromatography with a gradient of chloroform/methanol/glacial acetic acid from 20:1:0.1 to 8:1:0.1. A total of 31 mg (89%) of a powdery white solid was obtained. ^{1}H NMR (250 MHz, DMSO-d_6) δ 1.23−1.62 (m, 6H), 2.06 (t, 2H, $J = 7.1$), 2.43 (t, 2H, $J = 6.2$), 2.57 (d, 1H, $J = 12.4$), 2.81 (dd, 1H, $J = 5.1, 12.4$), 3.05−3.14 (m, 1H), 3.18 (app t, 2H, $J = 5.5$), 3.38 (t, 2H), $J = 6.0$), 3.49 (s, 8H), 3.59 (t, 2H, $J = 6.3$), 4.13 (m, 1H), 4.30 (m, 1H), 6.38 (s, 1H), 6.44 (s, 1H), 7.85 (t, 1H, $J = 5.5$). ^{13}C NMR (62.5 MHz, DMSO-d_6) δ 25.28, 28.05, 28.21, 34.79, 35.10, 38.46, 55.44, 59.10, 59.21, 60.95, 61.05, 66.29, 69.18, 69.58, 69.65, 69.72, 162.75, 172.15, 172.79. High-resolution mass spectrum (FAB^+) calcd for $C_{19}H_{34}N_3SO_7$ $(MH)^+$: 448.2117. Found: 448.2117.

D-Biotin-12-amido-4,7,10,-trioxadodecyl-1-(2,3,5,6-tetrafluoro)benzoate (14). A total of 13.6 mg (0.03 mmol) of compound **13** was transferred to the reaction flask as a solution in dichloromethane, then evaporated and weighed. Next, 272 μL of 70 °C DMF was added to the flask under argon. This was then allowed to cool to room temperature, followed by the addition of 8.5 μL (0.061 mmol) of TEA and 15.7 μL (0.091 mmol) of 2,3,5,6-tetrafluorophenyl trifluoroacetate (prepared by the method of Gamper et al.) (*13*). Upon the addition of the last reagent, opaque white fumes filled the flask. These fumes dissipated with time. The reaction was stirred at room temperature under argon overnight, then evaporated. The crude product was purified using silica gel chromatography in 12:1 chloroform/methanol. A total of 15 mg (86%) of pure compound was obtained as a clear yellow amorphous solid. ^{1}H NMR (250 MHz, DMSO-d_6) δ 1.14−1.64 (m, 6H), 2.05 (t, 2H, $J = 7.2$), 2.57 (d, 1H, $J = 12.5$), 2.81 (dd, 1H, $J = 5.0, 12.4$), 3.02 (app t, 2H, $J = 5.9$), 3.07−3.20 (m, 2H), 3.38 (t, 2H, $J = 6.0$), 3.50−3.61 (m, 9H), 3.77 (t, 2H, $J = 5.9$), 4.12 (m, 1H), 4.29 (m, 1H), 6.38 (s, 1H), 6.44 (s, 1H), 7.85 (t, 1H, $J = 6.2$), 7.95 (m, 1H). ^{13}C NMR (62.5 MHz, DMSO-d_6) δ 25.27, 28.05, 28.20, 34.02, 35.10, 38.44, 55.43, 59.21, 61.05, 65.61, 69.18, 69.56, 69.71, 69.75, 69.83, 104.11, 104.48, 104.86, 162.73, 167.95, 172.13. High-resolution mass spectrum (FAB^+) calcd for $C_{25}H_{34}N_3F_4SO_7$ $(MH)^+$: 596.2054. Found: 596.2054.

D-Biotinamide (15). A total of 21.2 mg (0.054 mmol) of D-biotin-1-(2,3,5,6-tetrafluoro)benzoate (compound **11**) was dissolved in 2.0 mL of THF. NH_3(g) was then bubbled into the reaction solution for 30 min. After the NH_3(g) was removed, the reaction was stirred for an additional 15 min before evaporating. A total of 15.4 mg of crude product was obtained. This was used without further purification. ^{1}H NMR (500 MHz, DMSO-d_6) δ 1.28−1.35 (m, 2H), 1.42−1.49 (m, 3H), 1.58−1.63 (m, 1H), 2.03 (t, 2H, $J = 7.4$), 2.57 (d, 1H, $J = 12.4$), 2.82 (dd, 1H, $J = 5.1, 12.4$), 3.10 (m, 1H), 4.13 (m, 1H), 4.30 (m, 1H), 6.35 (s, 1H), 6.43 (s, 1H), 6.69 (s, 1H), 7.23 (s, 1H). ^{13}C NMR (125 MHz, DMSO-d_6) δ 25.07, 28.05, 28.24, 34.90, 40.01, 55.41, 59.17, 61.03, 162.69, 174.21. High-resolution mass spectrum (FAB^+) calcd for $C_{10}H_{18}N_3SO_2$ $(MH)^+$: 244.1120. Found: 244.1127.

D-Biotin-12-amido-4,7,10-trioxadodecyl Cyclohexylamide (16). A total of 10 mg (0.0168 mmol) of compound **14** was dissolved in 400 μL of DMF. Next, 8 μL (0.057 mmol) of TEA was added, followed by 3.8 μL (0.034 mmol) of cyclohexylamine. The reaction mixture was stirred at room temperature under nitrogen overnight, then evaporated. The crude compound was purified by silica gel chromatography using a gradient from 95:5 to 8:2 chloroform/methanol. A total of 8.2 mg (92%) of a clear yellow amorphous solid was obtained. ^{1}H NMR (250 MHz, $CDCl_3$) δ 1.05−1.48 (m, 7H), 1.56−1.69 (m, 7H), 1.83−1.88 (m, 2H), 2.21 (t, 2H, $J = 7.5$), 2.42 (t, 2H, $J = 5.9$), 2.72 (d, 1H, $J = 12.6$), 2.88 (dd, 1H, $J = 4.7, 12.8$), 3.12 (app q, 1H, $J = 7.1, 11.4$), 3.39−3.46 (m, 2H), 3.54 (t, 2H, $J = 4.8$), 3.61 (s, 8H), 3.72 (app t, 3H, $J = 5.9$), 4.30 (m, 1H), 4.48 (m, 1H), 5.44 (s, 1H), 6.29 (d, 1H, $J = 7.7$), 6.43 (s, 1H), 6.75 (app t, 1H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ 25.04, 25.79, 28.30, 29.90, 33.27, 36.11, 37.37, 39.34, 40.74, 48.22, 55.75, 60.39, 62.00, 67.75, 70.20, 70.28, 70.49, 70.60, 77.43, 164.03, 170.66, 173.50. High-resolution mass spectrum (FAB^+), calcd for $C_{25}H_{45}N_4SO_6$ $(MH)^+$: 529.3060. Found: 529.3078.

D-Biotin-12-amido-4,7,10-trioxadodecyl Sphingosinamide (18). A total of 5 mg (0.017 mmol) of D-sphingosine (**17**) (Avanti Polar Lipids, Inc.) was dissolved in 266 μL of DMF. Next, 7.1 μL (0.051 mmol) of TEA was added, followed by 11.1 mg (0.019 mmol) of compound **14**. The reaction was stirred at room-temperature

overnight under argon, then evaporated. The crude product was purified using silica gel chromatography in 9:1 chloroform/methanol. A total of 12 mg (100%) of an off-white powder was obtained. ^{1}H NMR indicated the presence of a minor impurity. ^{1}H NMR (250 MHz, DMSO-d_6) δ 0.85 (m, 5H), 1.14−1.59 (m, 39H), 1.94 (m, 2H), 2.06 (t, 2H, J = 7.4), 2.32 (t, 2H, J = 6.6), 2.57 (d, 1H, J = 12.7), 2.81 (dd, 1H, J = 5.0, 14.9), 3.09−3.21 (m, 5H), 3.33−3.65 (m, 17H), 3.87 (m, 1H), 4.12 (m, 1H), 4.49 (t, 1H, J = 7.7), 4.83 (d, 1H, J = 5.4), 5.34−5.60 (m, 2H), 6.37 (s, 1H), 6.44 (s, 1H), 7.54 (d, 1H, J = 8.7), 7.86 (t, 1H, J = 5.3). ^{13}C NMR NMR (62.5 MHz, DMSO-d_6) δ 13.97, 22.11, 25.26, 28.04, 28.20, 28.60, 28.72, 28.83, 28.99, 29.07, 31.31, 31.73, 35.09, 36.18, 55.43, 59.19, 60.31, 61.03, 66.97, 69.19, 69.52, 69.56, 69.72, 71.19, 130.81, 131.24, 162.71, 169.90, 172.12. High-resolution mass spectrum (FAB$^+$), calcd for $C_{37}H_{69}N_4SO_8$ $(MH)^+$: 729.4836. Found: 729.4814.

D-Biotin-12-amido-4,7,10-trioxadodecyl Psychosinamide (19). A total of 9 mg (0.015 mmol) of compound **14** was dissolved in dichloromethane, transferred to reaction flask, then evaporated and weighed. A total of 356 μL of DMF was then added to the reaction flask, followed by 7.1 μL (0.051 mmol) of TEA. Psychosine (**3**) (Sigma) (7.6 mg, 0.016 mmol) was added next. The reaction was stirred at room temperature under argon overnight, then evaporated. The purification method was the same as that for compound **18**. A total of 10 mg (74%) of a pale yellow amorphous solid was obtained. ^{1}H NMR (500 MHz, DMSO-d_6) δ 0.85 (t, 4H, J = 6.6), 1.15−1.31 (m, 27H), 1.40−1.56 (m, 4H), 1.58−1.65 (m, 1H), 1.95 (app. d, 2H, J = 7.0), 2.06 (t, 2H, J = 7.4), 2.32 (m, 2H), 2.57 (d, 1H, J = 12.4), 2.82 (dd, 1H, J = 5.0, 12.5), 3.09 (m, 1H), 3.18 (app. q, 2H, J = 5.8, 11.6), 3.26−3.62 (m, 39H, incl. HOD), 3.78 (m, 1H), 3.93 (m, 2H), 4.03 (d, 1H, J = 7.2), 4.12 (m, 1H), 4.30 (m, 1H), 4.36 (d, 1H, J = 4.5), 4.56 (app. t, 1H, J = 5.7), 4.71 (d, 1H, J = 5.3), 4.87 (m, 2H), 5.39 (dd, 1H, J = 6.9, 15.4), 5.55 (m, 1H), 6.35 (s, 1H), 6.41 (s, 1H), 7.62 (d, 1H, J = 9.0), 7.83 (t, 1H, J = 5.5). ^{13}C NMR (125 MHz, DMSO-d_6) δ 13.91, 22.05, 25.21, 28.00, 28.15, 28.58, 28.66, 28.78, 28.94, 28.97, 29.02, 31.25, 31.67, 35.06, 36.19, 38.40, 40.01, 53.19, 55.37, 59.16, 60.37, 61.00, 66.86, 68.04, 68.50, 69.15, 69.46, 69.52, 69.69, 70.61, 70.73, 72.20, 73.12, 75.20, 104.30, 131.12, 131.28, 162.66, 169.75, 172.09. High-resolution mass spectrum (FAB$^+$) calcd for $C_{43}H_{79}N_4SO_{13}$ $(MH)^+$: 891.5364. Found: 891.5351.

2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosyl-(1→1)-(2S,3R,4E)-3-hydroxy-2-*N*-(12-D-biotinamide-4,7,10-trioxadodecyl)-sphingenine (20). 1-Hydroxy-2,3,4,6-tetra-*O*-acetyl-D-glucopyranose was prepared by method of Flandor et al. (*14*), starting with 1,2,3,4,6-penta-*O*-acetyl-β-D-glucopyranose (Aldrich). A 74% yield resulted after purification of the crude product by silica gel chromatography. This product was converted to the α-trichloroacetimidate, utilizing a procedure by Schmidt and co-worker (*15*). A 48% yield of the α-anomer was obtained after silica gel chromatography. The spectral data for both of the above precursors matches that of the literature precedence. The α-trichloroacetimidate-derivatized glucose was weighed dry into the reaction flask (19 mg, 0.038 mmol), as was compound **18** (35 mg, 0.048 mmol). These constituents were dissolved in 1.20 mL of 1,2-dichloroethane and stirred over AW-300 powdered molecular sieves at −10 °C. $BF_3{\cdot}Et_2O$ (9.7 μL, 0.077 mmol) was introduced last and the reaction stirred at 0 °C. After 16 h, an additional equivalent of $BF_3{\cdot}Et_2O$ was added. At 22 h, the reaction mixture was filtered through Celite, then washed with saturated $NaHCO_3$, followed by water. The organic layer was dried over anhydrous $MgSO_4$, filtered, then evaporated. The crude product was purified by silica gel chromatography in 9:1 chloroform/methanol. A total of 9.6 mg (24%) of an amorphous light yellow solid resulted. ^{1}H NMR (500 MHz, $CDCl_3$) δ 0.85 (t, 3H, J = 7.1), 1.23 (app s, 22H), 1.44 (m, 2H), 1.67 (m, 5H), 2.00 (m, 17H), 2.20 (t, 2H, J = 7.4), 2.46 (m, 2H), 2.73 (d, 1H, J = 12.7), 2.88 (dd, 1H, J = 4.9, 12.8), 3.13 (app q, 1H, J = 7.1, 11.9), 3.41 (app s, 2H), 3.53 (t, 2H, J = 5.0), 3.59−3.73 (m, 15H), 3.97−4.05 (m, 2H), 4.10 (app d, 1H, J = 2.3), 4.13 (m, 1H), 4.24 (dd, 1H, J = 4.7, 12.2), 4.30 (m, 1H), 4.46−4.48 (m, 2H), 4.94 (q, 1H, J = 8.1, 9.4), 5.04 (t, 1H, J = 9.5), 5.17 (app s, 2H), 5.44 (dd, 1H, J = 6.3, 15.4), 5.70 (m, 1H), 6.14 (s, 1H), 6.70 (t, 1H, J = 5.4), 6.78 (d, 1H, J = 7.8). ^{13}C NMR (125 MHz, $CDCl_3$) δ 14.32, 20.80, 20.92, 20.93, 22.89, 25.75, 28.29, 28.36, 29.49, 29.53, 29.56, 29.69, 29.75, 29.87, 29.88, 29.91, 32.13, 32.60, 36.05, 37.24, 39.36, 40.70, 53.59, 55.69, 60.37, 62.02, 62.09, 67.49, 68.60, 68.65, 70.19, 70.27, 70.50, 70.62, 71.50, 72.12, 72.83, 72.95, 100.94, 128.71, 133.99, 163.83, 169.66, 169.84, 170.34, 170.86, 171.87, 173.49. High-resolution mass spectrum (FAB$^+$) calcd for $C_{51}H_{87}N_4SO_{17}$ $(MH)^+$: 1059.5787. Found: 1059.5801.

2,3,4,6-Tetra-*O*-acetyl-β-D-galactopyranosyl-(1→4)-*O*-(2,3,6-tri-*O*-acetyl-β-D-glucopyranosyl)−(1→ 1)−(2S,3R,4E)-3-hydroxy-2-*N*-(12-D-biotinamide-4,7,10-trioxadodecyl)-sphingenine (21). The reducing end 1-hydroxy derivative of hepta-*O*-acetyl lactose was prepared using the techniques of Flandor et al. (*14*), starting with octa-*O*-acetyl lactose (Aldrich). An 80% yield resulted upon purification by column chromatography. This product was subsequently converted to the α-trichloroacetimidate utilizing a procedure by Schmidt and coworker (*15*). Silica gel chromatography of the crude product yielded 42% of the desired α-trichloroacetimidate. This α-trichloroacetimidate-derivatized lactose was weighed into a reaction flask dry (25 mg, 0.033 mmol), along with compound **18** (26 mg, 0.036 mmol). These components were dissolved in 1.03 mL of 1,2-dichloroethane and stirred over AW-300 powdered molecular sieves at −10 °C. $BF_3{\cdot}Et_2O$ (8.4 μl, 0.066 mmol) was introduced last, and the reaction was stirred overnight at 0 °C. At this time, an additional equivalent of $BF_3{\cdot}Et_2O$ was added, and the reaction stirred at between 5 and 10 °C. After 48 h, the reaction solution was filtered through Celite and evaporated. The crude product was purified by column chromatography using a gradient from 15:1 to 12:1 chloroform/methanol. An amorphous yellowish solid resulted (5.4 mg, 12%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 0.85 (t, 3H, J = 6.9), 1.23 (app s, 22H), 1.43 (m, 2H), 1.53−1.68 (m, 5H), 1.95−2.12 (m, 23H), 2.20 (t, 2H, J = 7.4), 2.46 (t, 2H, J = 5.9), 2.72 (d, 1H, J = 12.7), 2.89 (dd, 1H, J = 4.8, 12.6), 3.13 (app q, 1H, J = 7.1, 11.9), 3.41 (app t, 2H, J = 5.1), 3.53 (app t, 2H, J = 4.8), 3.62 (s, 5H), 3.61−3.79 (m, 22H), 3.86 (m, 1H), 3.95 (app dd, 1H, J = 5.6, 10.6), 4.00−4.16 (m, 6H), 4.30 (m, 1H), 4.43−4.52 (m, 5H), 4.85 (app t, 1H), 4.95 (dd, 1H, J = 3.4, 10.4), 5.07 (dd, 1H, J = 7.9, 10.3), 5.16 (t, 1H, J = 9.1), 5.20 (app s, 1H), 5.32 (d, 1H, J = 11.2), 5.43 (dd, 1H, J = 6.5, 15.4), 5.69 (dt, 1H, J = 6.9, 15.4), 6.04 (s, 1H), 6.70 (d, 2H, J = 7.7). ^{13}C NMR (125 MHz, $CDCl_3$) δ 14.31, 20.84, 20.85, 20.95, 21.00, 21.05, 22.89, 25.72, 28.27, 28.33, 29.50, 29.53, 29.56, 29.69, 29.75, 29.87, 29.91, 32.12, 32.61, 36.01, 37.20, 39.34, 40.71, 53.57, 55.67, 60.35, 60.99, 61.99, 62.14, 66.85, 67.49, 68.71, 69.33, 70.19, 70.24, 70.49, 70.58, 70.60, 70.88, 71.17, 71.84, 72.83, 72.87, 72.99, 76.40, 100.76, 101.25, 128.65, 134.05, 163.73, 169.28, 169.87, 170.08, 170.26, 170.32, 170.56, 170.68, 171.82, 173.48. ***β*-D-Glucopyranosyl-(1→1)−(2S,3R,4E)-3-hydroxy-2-*N*-(12-D-biotinamide-4,7,10-trioxadodecyl)-sphingenine (22).** A total of 9.6 mg (0.009 mmol) of compound **20** was dissolved in 1 mL of methanol, and a catalytic quantity of sodium methoxide (Avocado) was added. The reaction was allowed to stir at room temperature for 1 day. After TLC in 9:1 chloroform/methanol indicated that reaction was complete, Dowex H$^+$ resin was added and the solution stirred for 45 min until the pH was neutral. The solution was filtered through glass paper and evaporated. The compound was then taken up into a small quantity of water and freeze-dried. A total of 6.3 mg (78%) of an off-white fluffy solid resulted. ^{1}H NMR (500 MHz, 4:1 $CDCl_3$/MeOD mixture, using internal $CDCl_3$ as a reference) δ 0.72 (t, 3H, $J = 6.7$), 1.10 (s, 22H), 1.28 (m, 2H), 1.43−1.58 (m, 6H), 1.87 (m, 3H), 2.07 (t, 3H, $J = 7.3$), 2.33 (t, 2H, $J = 5.8$), 2.58 (d, 1H, $J = 12.8$), 2.77 (dd, 1H, $J = 4.9, 12.8$), 3.01 (app q, 1H), 3.09−3.14 (m, 2H), 3.20−3.31 (m, 6H, includes MeOD signal), 3.40 (t, 2H, $J = 4.9$), 3.47−3.60 (m, 14H), 3.70 (app d, 2H), 3.87 (br s, 1H), 4.11 (d, 1H, $J = 7.7$), 4.16 (m, 1H), 4.35 (dd, 1H, $J = 4.9, 7.5$), 5.31 (dd, 1H, $J = 7.1, 15.3$), 5.55 (m, 1H). ^{13}C NMR NMR (125 MHz, 4:1 $CDCl_3$/MeOD mixture, using internal $CDCl_3$ as a reference) δ 13.94, 22.61, 25.45, 28.07, 28.34, 29.25, 29.28, 29.30, 29.50, 29.60, 29.64, 31.87, 32.35, 35.62, 36.57, 39.10, 40.28, 53.50, 55.58, 60.16, 61.47, 61.93, 67.21, 68.46, 69.78, 69.86, 69.94, 70.05, 70.14, 70.26, 72.17, 73.53, 76.17, 76.26, 103.21, 128.92, 134.05, 164.27, 172.17, 174.40. High-resolution mass spectrum (FAB$^+$) calcd for $C_{43}H_{78}N_4SO_{14}Na$ (MNa)$^+$: 913.5184. Found: 913.5156.

***β*-D-Galactopyranosyl-(1→4)-*O*-(*β*-D-glucopyranosyl)−(1→1)−(2S,3R,4E)-3-hydroxy-2-*N*-(12-D-biotinamide-4,7,10-trioxadodecyl)-sphingenine (23).** A total of 13.4 mg (0.010 mmol) of compound **21** was dissolved in 2 mL of methanol and a catalytic quantity of sodium methoxide (Avocado) was added. The reaction was allowed to stir overnight at room temperature. At this time, TLC in 12:1 chloroform/methanol indicated a complete reaction. Dowex H$^+$ resin was added to the reaction solution, and stirring was continued until neutral pH was achieved. The solution was filtered through glass paper and evaporated. The residue was dissolved in a small quantity of water, then freeze-dried. A total of 9.9 mg (94%) of an off-white fluffy solid resulted. ^{1}H NMR (500 MHz, 4:1 $CDCl_3$/MeOD mixture, using internal $CDCl_3$ as a reference) δ 0.73 (t, 3H, $J = 6.8$), 1.11 (s, 22H), 1.29 (m, 3H), 1.43−1.60 (m, 5H), 1.87 (app q, 2H, $J = 7.0, 14.2$), 2.07 (t, 2H, $J = 7.6$), 2.33 (t, 2H, $J = 6.1$), 2.59 (d, 1H, $J = 12.8$), 2.77 (dd, 1H, $J = 5.0, 12.9$), 3.02 (m, 1H), 3.16−3.26 (m, 5H, includes MeOD signal), 3.35−3.50 (m, 18H), 3.53−3.62 (m, 3H), 3.67−3.76 (m, 4H), 3.87 (m, 1H), 3.98 (app dd, 1H), 4.14 (d, 1H, $J = 7.8$), 4.17 (m, 1H), 4.21 (d, 1H, $J = 7.8$), 4.36 (app q, 1H, $J = 4.9, 7.8$), 5.31 (dd, 1H, $J = 7.0, 15.3$), 5.55 (dt, 1H, $J = 6.8, 15.1$). ^{13}C NMR (125 MHz, 4:1 $CDCl_3$/MeOD mixture, using internal $CDCl_3$ as a reference) δ 13.95, 22.62, 25.50, 28.12, 28.42, 29.27, 29.30, 29.50, 29.61, 29.65, 31.87, 32.35, 35.68, 36.56, 39.11, 40.28, 53.41, 55.63, 60.17, 60.88, 61.57, 61.97, 67.18, 68.53, 69.12, 69.71, 69.85, 69.96, 70.118, 70.29, 71.04, 72.11, 73.21, 73.42, 74.66, 74.97, 75.41, 79.58, 103.08, 103.71, 128.99, 134.06, 164.28, 172.11, 174.41. High-resolution mass spectrum (FAB$^+$) calcd for $C_{49}H_{89}N_4SO_{18}$ (MH)$^+$: 1053.5893. Found: 1053.5885.

1-(Trichloroacetamide)-2-(2,3,4,6-tetra-*O*-acetyl-*β*-D-galactopyranoside)-ethanolamine (25). To a solution of 1,2,3,4,6-penta-*O*-acetyl-galactopyanoside (300 mg, 0.77 mmol) in 3 mL of dichloromethane with 3 Å molecular sieves was added iodotrimethylsilane (120 μL, 0.85 mmol). This solution was allowed to stand at room temperature for 1 h. The solvent was then removed in vacuo, and 2 mL of toluene was added and again removed in vacuo. A solution of the trichloroacetamide of ethanolamine (238 mg, 1.15 mmol) was added as a solution in 4 mL of acetonitrile and refluxed for 3 h. Sodium bicarbonate (70 mg) was then added and the solvent was removed in vacuo. The resultant oil was subjected to column chromatography (2:1 hexanes:ethyl acetate) twice to yield 26 mg (6%) of the target compound. ^{1}H NMR (250 MHz, $CDCl_3$) δ 1.96 (s, 3H), 2.02 (s, 3H), 2.03 (s, 3H), 2.13 (s, 3H), 3.42−3.63 (m 2H), 3.72−3.80 (m, 1H), 3.88−3.96 (m, 2H), 4.05−4.13 (m, 2H), 4.49 (d, 1H, $J = 7.9$ Hz), 4.99 (dd, 1H, $J = 10.5, 4.20$ Hz), 5.17 (dd, 1H, $J = 10.5, 7.8$ Hz), 5.37 (dd, 1H, $J = 3.3, 1.0$ Hz); ^{13}C NMR (62.5 MHz, $CDCl_3$) δ 20.5, 20.6, 20.8, 41.2, 61.3, 66.9, 67.3, 68.7, 70.7, 70.9, 101.0, 170.0, 170.1, 170.3. High-resolution mass spectrum (FAB$^+$) calcd for $C_{18}H_{25}NO_{11}Cl_3$: 536.0493 (MH)$^+$. Found: 536.0474. $[\alpha]_D = +12.0$ ($c = 0.04$ $CDCl_3$).

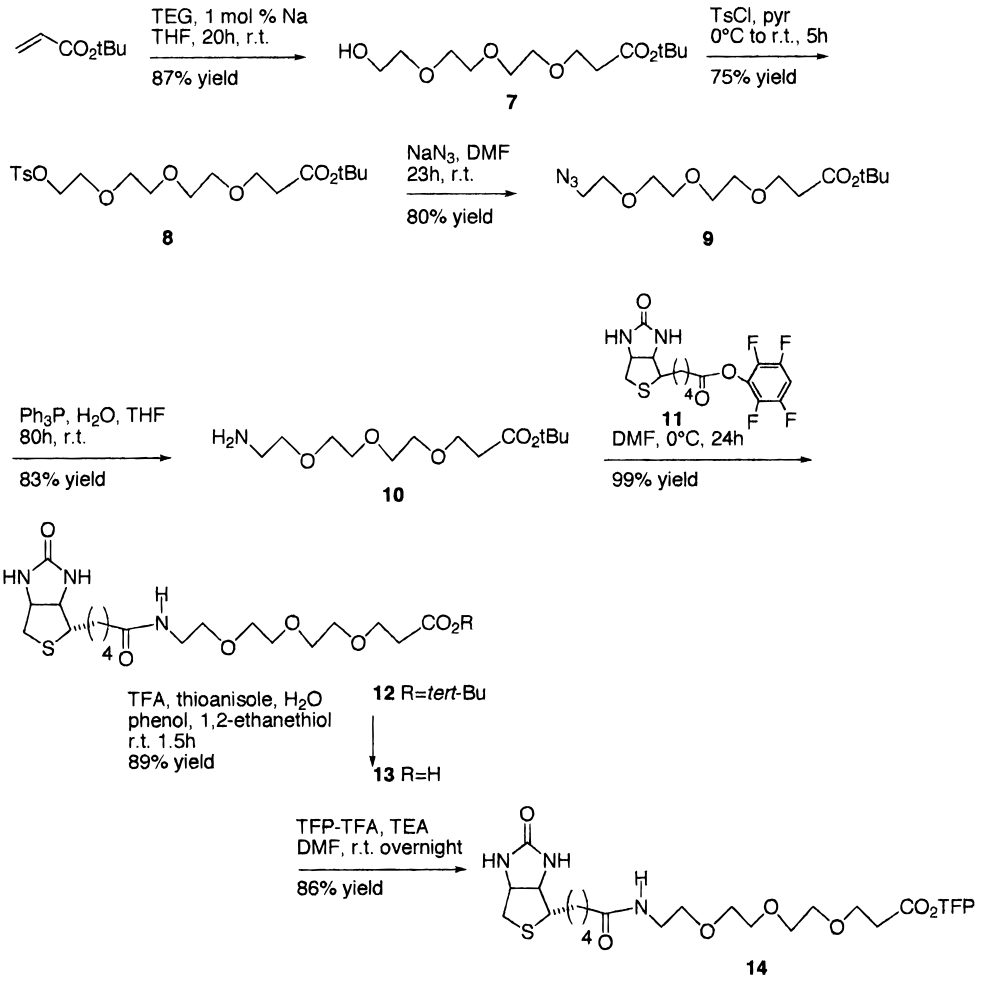
1-(Trichloroacetamide)-2-(2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranoside)-ethanolamine (27a/b). To a solution of 1,2,3,4,6-penta-*O*-acetyl-glucopyanoside (400 mg, 1.02 mmol) in 3 mL of acetonitrile was added iodotrimethylsilane (120 μL, 0.85 mmol). This solution was allowed to stand at room temperature for 20 min. The solvent was removed in vacuo, and 2 mL of toluene was added and again removed in vacuo. A solution of the trichloroacetamide of ethanolamine (317 mg, 1.53 mmol) was added as a solution in 4 mL of acetonitrile and refluxed for 2.5 h. Diisopropylethylamine (500 μL) was then added, the solution filtered, and the solvent then removed in vacuo. Acetic anhydride (5 mL) was then added followed by diisopropylethylamine (500 mL) and a catalytic amount of DMAP. The solution was stirred for 20 min, and then the solvent was removed in vacuo. The resulting oil was subjected to column chromatography (2:1 hexanes: ethyl acetate) to yield 160 mg (29%) of a 2:1 β: α ratio of glycosides. This mixture was carried forward without further purification. High-resolution mass spectrum (FAB$^+$) calcd for $C_{18}H_{25}NO_{11}Cl_3$: 536.0493 (MH)$^+$. Found: 536.0512.

Deacetylation Conditions (28, 29a/b). The above glycosides (Compounds **25** and **27a/b**) were dissolved in methanol and a catalytic amount of sodium methoxide was added. The solution was stirred overnight. Dowex H$^+$ resin was added, the solution filtered, and the solvent then removed in vacuo. This yielded the fully deprotected 1-ethanolamine-2-*β*-D-galactopyranoside (**28**) and 1-ethanolamine-2-α/*β*-D-glucopyranoside (**29a/b**).

D-Biotin-12-amido-4,7,10-trioxadodecyl-1-(2-*β*-D-galactopyranosyl)-ethanolamide (30). A total of 4.0 mg (0.018 mmol) of 1-ethanolamine-2-*β*-D-galactopyranoside (compound **28**) was dissolved in methanol and transferred to the reaction flask, then evaporated and weighed. Next, 187 μL of DMF and 4.9 μL (0.035 mmol) of TEA were added. This was followed by the addition of 7 mg (0.012 mmol) of compound **14** to the reaction mixture as a solution in dichloromethane. The reaction was stirred overnight at room temperature under nitrogen and then evaporated. The crude product was dissolved in 2 mL of 0.03 M ammonium bicarbonate buffer and purified by low-pressure chromatography in a 1.5 × 50 cm column packed with Biogel P-2. The product was detected at 222 nm via the use of an Isco V3 UV−vis detector. A total of 6 mg (73%) of a light yellow grainy powder resulted. ^{1}H NMR (500 MHz, DMSO-d_6)

δ 1.20−1.35 (m, 2H), 1.40−1.52 (m, 3H), 1.55−1.65 (m, 1H), 2.06 (t, 2H, J = 7.3), 2.32 (t, 2H, J = 6.4), 2.57 (d, 1H, J = 12.4), 2.82 (dd, 1H, J = 5.1, 12.4), 3.09 (m, 1H), 3.17−3.62 (m, 28H, incl. HOD), 3.69 (m, 1H), 4.07 (d, 1H, J = 7.0), 4.13 (m, 1H), 4.30 (m, 1H), 6.36 (s, 1H), 6.42 (s, 1H), 7.85 (m, 2H). ^{13}C NMR (125 MHz, DMSO-d_6) δ 25.24, 28.02, 28.18, 35.08, 36.04, 38.43, 38.73, 55.41, 59.18, 60.44, 61.03, 66.76, 67.74, 68.10, 69.15, 69.55, 70.55, 73.24, 75.23, 103.73, 162.71, 170.14, 172.14. High-resolution mass spectrum (FAB$^+$) calcd for $C_{27}H_{49}N_4SO_{12}$ $(MH)^+$: 653.3068. Found: 653.3081.

D-Biotin-12-amido-4,7,10-trioxadodecyl-1-(2-α/β-D-glucopyranosyl)-ethanolamide (31a/b). 1-Ethanolamine-2-α/β-D-glucopyranosyl ethanolamine (compound **29a/b**) was dissolved in enough methanol to yield a 10 mg/mL solution. Some of this volume was transferred to the reaction flask, then evaporated and weighed (24.5 mg, 0.103 mmol). Compound **29a/b** was then dissolved in 532 μL of DMF, followed by the addition of 14.2 μL TEA (0.102 mmol). Compound **14** was then introduced to reaction flask as a solid. The reaction was stirred at room-temperature overnight under argon, then evaporated. The crude product was purified in the manner described for compound **30**. A total of 15.8 mg (72%) of a light yellow grainy powder was obtained. The ratio of α- to β-anomers was found to be roughly 12:1 by ^{1}H NMR. ^{1}H NMR (250 MHz, DMSO-d_6) δ 1.22−1.67 (m, 6H), 2.06 (t, 2H, J = 6.6), 2.24−2.36 (m, 2H), 1.53 (app s, 1H), 2.82 (dd, 1H, J = 5.2, 12.8), 2.93−3.78 (m, 38H, incl. HOD), 4.12 (m, 2H), 4.30 (m, 1H), 4.57 (m, 1H), 4.99 (br. s, 2H), 6.37 (s, 1H), 6.44 (s, 1H), 6.82 (s, 1H), 7.10 (br. s, 2H), 7.30 (s, 1H), 7.86 (app s, 2H). ^{13}C NMR (62.5 MHz, DMSO-d_6) δ 22.60, 25.26, 28.04, 28.20, 35.09, 35.84, 36.04, 55.43, 59.19, 60.92, 61.04, 66.77, 67.99, 69.17, 69.51, 69.56, 69.71, 70.03, 73.44, 76.51, 76.88, 98.82, 103.14, 162.73, 170.18, 172.16, 172.25. High-resolution mass spectrum (FAB$^+$) calcd for $C_{27}H_{49}N_4SO_{12}$ $(MH)^+$: 653.3068. Found: 653.3050.



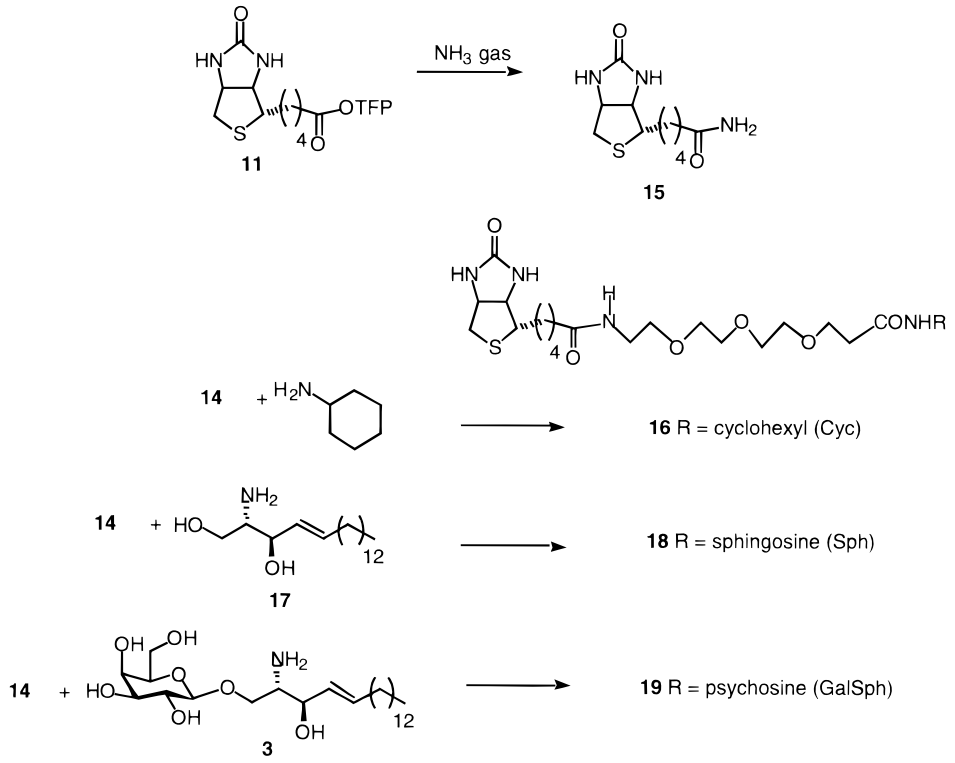
ELISA Ligand Dilutions. Freeze-dried biotinylated analytes (compounds **12**, **15**, **16**, **18**, **19**, **22**, **23**, **30**, **31a/b**) were weighed out to the tenth of a microgram using a Cahn 21 Automatic Electrobalance. Stock solutions of these compounds were prepared at 1 mg/mL concentrations in 20% DMSO/80% PBS buffer. DMSO was first added, and the compounds allowed to fully dissolve prior to addition of PBS buffer. The solutions were thoroughly mixed prior to further dilution in PBS for assaying, and they were stored at −20 °C between uses. The dilution concentration of all compounds utilized in the assays was 20 μg/mL, unless otherwise noted.

Testing of Blocking Reagents. Compounds **12**, **15**, and **16** were evaluated as potential blocking reagents for ELISA using NeutrAvidin coated 8-well strip plates (Pierce). Each compound was plated into four wells each at a volume of 150 μL and incubated for 1 h at 25 °C at 1000 rpm on a Jitterbug microplate incubator (Boekel). An additional eight wells were incubated in this step with 150 μL/well of PBS buffer. After the incubation, the wells were rinsed 3 × 200 μL of PBS. Next, all wells, with the exception of four PBS-incubated wells of the first incubation, were incubated with 100 μL each of a 1:4000 dilution of HRP-biotin (Pierce Biochemicals) for 1 h at 25 °C and 1000 rpm. The four wells without HRP-biotin were incubated with 100 μL each of PBS and would serve as the TMB blank. The wells were rinsed as before. A TMB (3,3′,5,5′-tetramethylbenzidine, Sigma) solution was prepared (1 mg of TMB in 500 μL of DMSO and 9.5 mL of 0.05 M phosphate-citrate buffer with sodium perborate). The TMB solution was added to each well, including the blanks, at a volume of 100 μL/well. The plate was immediately read on a Bio-Rad model 550 microplate reader every minute for 20 min at 630 nm, with a reference wavelength of 490 nm, and 5 s of shaking between each reading. All wells for each analyte were averaged, and had the TMB blank automatically subtracted through the use of the Bio-Rad Microplate Manager software package. The standard deviations for all data points were determined using Excel. The four wells containing only HRP-biotin at its absorbance maximum served as a 100% measure of the sites filled by HRP-biotin. All other blocking reagent wells were compared to the HRP-biotin wells at the same reference point. Upon the basis of these results, the percentage of NeutrAvidin sites filled was determined for each compound. The results given for this assay are representative of several trials performed.

Plating Efficiency Assay. The plating efficiency of each compound (see ELISA Ligand Dilutions) was tested to ensure comparable coverage on NeutrAvidin-coated eight-well strip plates (Pierce Biochemicals). In this assay, each compound was plated into two wells at 150 μL each and incubated for 4 h at 25 °C and 1000 rpm in a Jitterbug microplate incubator (Boekel). Two blank wells were incubated with 150 μL of PBS, and four wells were incubated with 150 μL of PBS each for HRP-biotin determination in the second incubation. After four h, each well was rinsed 3 × 200 μL of PBS. Next, a 1:4000 dilution of HRP−biotin was added to all wells excluding the blanks in 100 μL quantities. The blank wells were incubated with 100 μL of PBS. The second incubation was for one h at 25 °C and 1000 rpm. After the incubation, the wells were rinsed as before. A TMB (3,3′,5,5′-tetramethylbenzidine, Sigma) solution was prepared (1 mg of TMB in 500 μL of DMSO and 9.5 mL of 0.05 M phosphate-citrate buffer with sodium perborate). The TMB solution was added to each well, including the blanks, at a volume of 100 μL/well. The plate was immediately read on a Bio-Rad model 550 microplate reader every min for 20 min at 630 nm, with a reference wavelength of 490 nm and 5 s of shaking between each reading. All wells for each analyte were averaged and had the TMB blank automatically subtracted through the use of the Bio-Rad Microplate Manager software package. The standard deviations for all data points were determined using Excel. The four wells containing only HRP-biotin at its absorbance maximum served as a 100% measure of the sites filled by HRP-biotin. All other analyte wells were compared to the HRP-biotin wells at the same reference point. Upon the basis of these results, the percentage of NeutrAvidin sites filled was determined for each compound. The results given for this assay are representative of multiple assay trials.

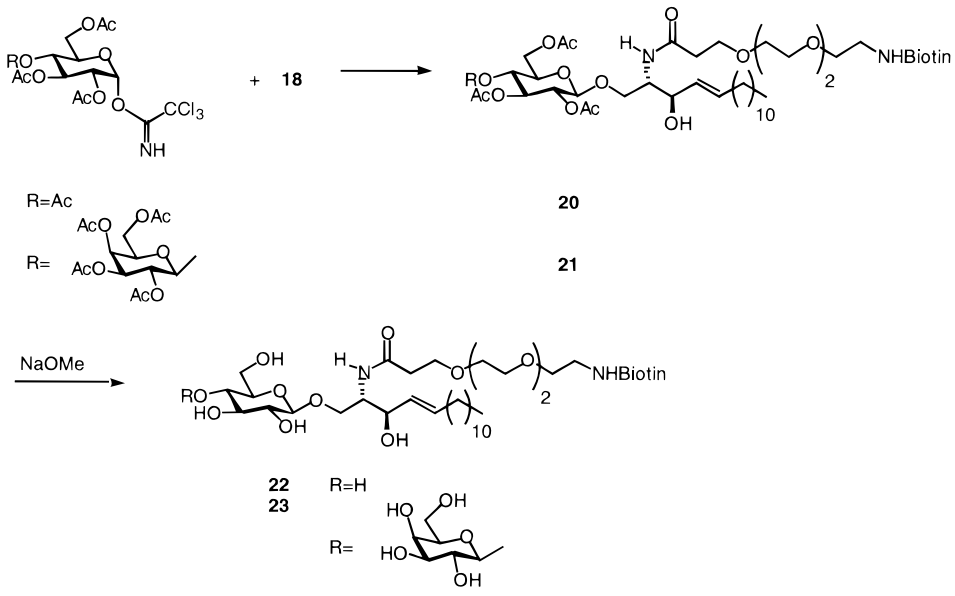
ELISA Assay. The compounds (see ELISA Ligand Dilutions) were plated in 150 μL volumes into four wells each of NeutrAvidin-coated eight-well strip plates (Pierce Biochemicals). The plate was incubated for 4 h at 25 °C and 1000 rpm on a Jitterbug microplate incubator (Boekel). An additional four wells each of both a TMB blank (see Plating Efficiency Assay) and a gp120 blank were incubated with 150 μL of PBS in this incubation. Following the first incubation, the wells were rinsed 3 × 200 μL of PBS. Next, 150 μL/well, excluding the TMB and gp120 wells, of compound **15** was incubated for 1 h at 25 °C and 1000 rpm, to ensure that all remaining open NeutrAvidin sites were blocked. The TMB and gp120 wells were incubated instead with 150 μL of PBS, as before. After the second incubation, the wells were rinsed as in the first incubation. The third incubation comprised

Scheme 1



of adding 100 μL of a 1:4 dilution (from a 500 μL vial containing 0.333 μg of gp120) of gp120-HRP (Intracel) into every well, except the TMB wells. The TMB wells were incubated with 100 μL of PBS each. The incubation was for 1 h at 25 °C at 1000 rpm. The wells were then rinsed with 5 × 200 μL of PBS. A solution of TMB reagent (1 mg tablet) was prepared in 500 μL of DMSO and 9.5 mL of phosphate-citrate buffer containing sodium perborate. A total of 100 μL of the TMB reagent was added to each well. The plate absorbances were read every min for 20 min at a test wavelength of 630 nm, a reference wavelength of 490 nm, with a 5 s shake between each reading, on a Bio-Rad model 550 microplate reader. All wells for each analyte were averaged and had the TMB blank automatically subtracted through the use of the Bio-Rad Microplate Manager software package. The standard deviations for all values were determined using Excel. The wells containing only gp120 served as a measure of nonspecific binding interactions between the glycoprotein and the plate and were minimal. This assay was repeated several times, with a representative experiment reported. The error bars reflect the standard deviation between these experiments.

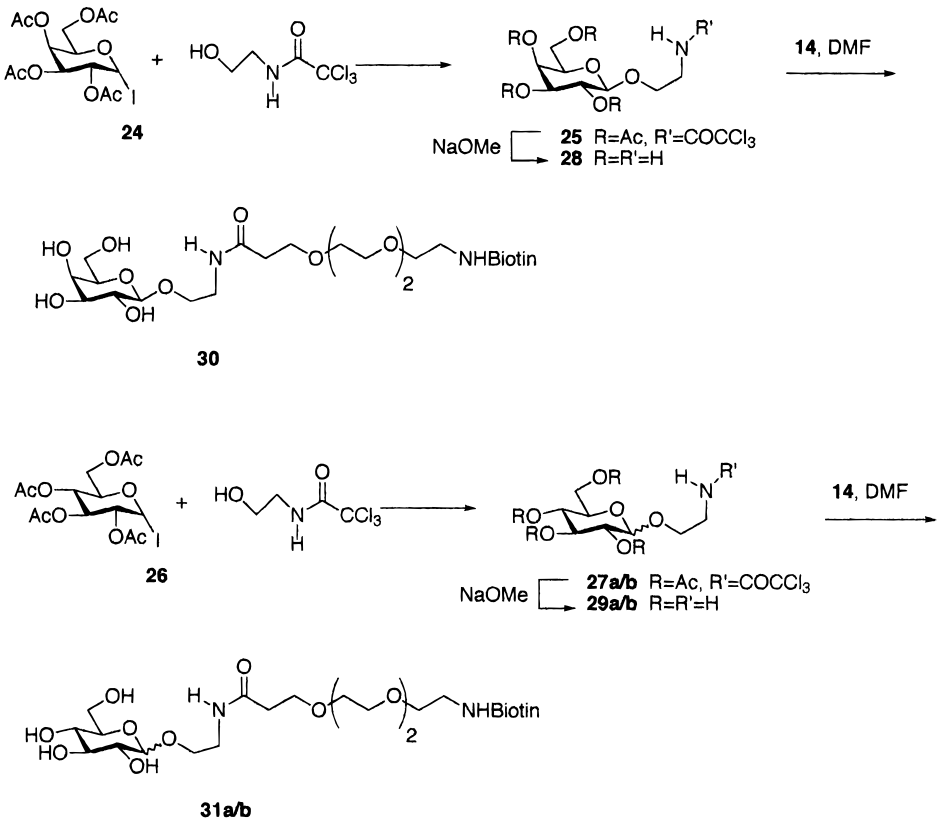
RESULTS



The water-soluble linker was prepared by reacting *tert*-butyl acrylate with tetraethylene glycol (TEG) in the presence of sodium to give **7** (Scheme 1) (*9*). Conversion of the primary alcohol to an azide was accomplished by tosylation (**8**) with subsequent azide displacement to give **9**. Direct incorporation of the azide under Mitsunobu conditions (***16***) was also possible; however, the yield was not as high as the two-step approach. Azide reduction under Staudinger conditions provided the amine **10 (***10*), which was reacted with the tetrafluorophenyl ester of biotin (compound **11**) (*17*) to give **12** in 99% yield. The *tert*-butyl ester was removed under the action of trifluoroacetic acid (TFA) in the presence of thioanisole, 1,2-ethanedithiol, water, and phenol to prevent degradation of the biotin thioether (*12*). The acid (compound **13**) was activated by reaction with tetrafluorophenyl trifluoroacetate (*13*) to give the activated water-soluble linker **14**. Several ligands containing amine functionalities were conjugated to **14** providing a panel of ligands for subsequent ELISA screening.

A simple amide analogue of biotin was prepared by reacting **11** with ammonia to give **15** (Scheme 2). A cyclohexyl analogue, **16**, was prepared by reacting **14** with cyclohexylamine. Sphingosine (**17**) was reacted with **14** to give Sph (**18**), which is a semi-water-soluble analogue of ceramide. In a similar fashion, reaction of **14** with psychosine (**3**) afforded a hydrophilic derivative of GalCer (GalSph, **19**). Synthesis of the GlcSph (**22**) and LacSph (**23**) analogues was more involved since the sphingosine derivatives of Glc and Lac were not commercially available (Scheme 3). Nonetheless, sufficient quantities of these compounds were prepared through reaction of the corresponding peracetylated trichloroacetimidates (*15*) with **18** according to the method of Ogawa (*18*), to give the conjugates **20** and **21**, which when deprotected, afforded **22** and **23**.

Scheme 2



Scheme 3

To probe the importance of the sphingosine component, simple amino analogues of Glc and Gal were prepared (Scheme 4). Reaction of 2,3,4,6-tetra-*O*-acetyl galactosyl iodide **24** with 2-*N*-trichloroacetyl ethanol gave **25**. In a similar fashion, the glucosyl iodide **26** was reacted with 2-*N*-trichloroacetyl ethanol to give an inseparable mixture of anomers **27a/b**. These analogues were deprotected to give GalEA **28** and GlcEA **29a/b**. Subsequent conjugation to **14** afforded the water-s**o**luble Gal and Glc ethanolamine derivatives (WSGalEA, **30**) and (WSGlcEA, **31a**/**b**), respectively. Filling the maximum number of NeutrAvidin binding sites is essential and is done to ensure minimization of nonspecific gp120 binding. We had previously determined that common blocking agents, such as Tween and BSA, led to significant interference due to nonspecific binding of gp120. A series of ELISA were performed in order to determine which of the ligands would best serve as blocking agents. The simple biotin amide **15**, cyclohexyl amide **16**, and *tert*-butyl ester **12** conjugates were screened. Compound **15** was thought to be a good choice as a blocking reagent because of its small size, increased hydrophilicity over biotin, and the lack of an interfering anionic functionality, known to bind the V3 loop region of gp120. Compounds **12** and **16** were tested as blocking reagents because of the presence of the hydrophilic linker that would resemble the analyte ligand and possibly plate more favorably than compound **15**. Compounds **12** and **16** were also tested because of their inability to bind gp120. The extent of blocking was determined by incubating the blocked wells with HRP-biotin. The magnitude of HRP-biotin plating can be monitored by colorimetric measurements, where the

Scheme 4

amount bound is directly proportional to increased absorbance. An efficient blocking agent would prevent HRP-biotin from binding to the plate and result in lower absorbance readings. As can be seen in Figure 2, the simple amide (**15**) was most effective at preventing HRP-biotin binding and was therefore used as the blocking agent in all subsequent assays.

The efficiency of plating for each bioconjugate could be determined by first incubating the microtiter plate with the analyte, followed by incubation with HRP-biotin. NeutrAvidin sites left unoccupied by ligand become saturated with HRP-biotin, analogous to the situation given in the blocking reagent assays. The efficiency of plating is shown in Table 2. Using the maximum absorbance value generated by filling all available NeutrAvidin sites with HRP-biotin as our 100% estimate, relative measurements of the percentage of sites filled by each ligand were generated at the same reference point. It was critical to ensure that all ligands filled approximately the same number of protein sites in the well. If they did not, the gp120 binding events could not be attributed solely to differences in affinity for each bioconjugate, but instead might be a consequence of variable plating efficiency. Table 2 illustrates that all of the bioconjugates tested fill 75−93% of the NeutrAvidin sites available, when compared to the 100% HRP-biotin value. The standard deviations for each data point in four separate experiments were calculated as a measure of the error for each ligand. These plating efficiencies were used to normalize the data obtained from subsequent ELISA with recombinant HRP gp120.

After the best blocking agent and the efficiency of plating were determined, the panel of ligands was subjected to screening with recombinant HRPgp120. The proof of the ELISA validity as a new method to test hydrophilic compounds for gp120 binding was evidenced by the results of the known positive GalCer analogue,

The error was calculated from the standard deviation in data from four different experiments. These data are representative of multiple trials.

test reagent because it had a six-membered ring, much like a carbohydrate. It was suspected that it would not bind to gp120 because it lacks the carbohydrate component present in GalCer. As shown in Figure 3, GalSph, (**19**) did have significant binding to gp120, whereas **16** showed only background levels of gp120 binding activity. GalSph (**19**) and GlcSph (**22**) had similar binding affinities for gp120, while the binding affinity of LacSph (**23**) was higher. These observations contradict previously reported results, where GalCer binds with the highest affinity and GlcCer and LacCer do not bind at all. (*1*,*2*,*3*)

DISCUSSION

There are a number of possible explanations for the similar binding profiles of GalSph and GlcSph, and enhanced binding of LacSph. One possibility is that the monosaccharides are not spatially far enough away from the lipid-linker portion of the molecule and interfere with full protein interaction, while the disaccharide is further removed. It may also be that the presentation geometries of the monosaccharides versus the disaccharide are significantly different, affecting the protein-binding event. A third possibility is that gp120 recognition of cell-surface glycoconjugates is mediated by a combination of hydrophobic and hydrophilic interactions and LacSph (**23**) may fulfill the requirements better than GlcSph (**22**) and GalSph (**19**). We are currently investigating these possibilities.

Interestingly, we have found that Sph (**18**) interacts moderately well with gp120, suggesting that the lipid component is important, as had been demonstrated in earlier work (*19*). The WSGalEA (**30**) and WSGlcEA (**31a/b**) ligands do not bind gp120, indicating that while the carbohydrate component is important, it is not sufficient to achieve full gp120 binding. Perhaps, the lipid portion of the glycoconjugate forms the first contact point with gp120 and the second interaction with the carbohydrate affords strength and specificity to the interaction. Alternatively, the lipid/gp120 interaction could cause a conformational change in the protein, facilitating access to the binding region for the carbohydrate.

In summary, we have prepared water-soluble analogues of GalCer, GlcCer, and LacCer and determined their relative binding affinities for recombinant HIV-1 gp120 using a novel ELISA construct. To our knowledge, this ELISA is the only known method to directly compare gp120 recognition of various bioconjugates that yields both consistent and reproducible results. The assay has the added advantage that the analyte plating efficiency can be determined, which is not possible with the existing lipid-based assays. This assay is a powerful screening tool for obtaining qualitative binding measurements. To obtain accurate binding affinities, more sensitive techniques will be required. The hydrophilic nature of the reported synthetic bioconjugates may uniquely position us to study their binding using biosensors, where both on and off rates, as well as quantitative binding affinities, could be measured.

ACKNOWLEDGMENT

We are indebted to Dr. Arpad Somogyi, director of the UA Mass Spectrometry Facility. Financial support for this research was gratefully received from NIH (AI40359-02), Eli Lilly, Alfred P. Sloan Foundation, and The National Science Foundation Early Career Award (CHE9623583). Surface Plasmon Resonance (SPR) as a Tool for Antibody Conjugate Analysis

Maciej Adamczyk,* Phillip G. Mattingly, Kevin Shreder, and Zhiguang Yu

Abbott Laboratories, Diagnostics Division, Department of Chemistry D9NM, Building AP 20, 100 Abbott Park Road, Abbott Park, Illinois, 60064-6016. Received May 20, 1999; Revised Manuscript Received August 12, 1999

Surface plasmon resonance (SPR) analysis was used to assess the immunoreactivity of anti-biotin (**4**) and anti-fluorescein (**5**) monoclonal antibody after conjugation with the *N*-hydroxysuccinimide ester of acridinium-9-carboxamide **1**. Only minor changes in the apparent equilibrium dissociation constants of the antibody conjugates for their ligands resulted from the conjugation process. However, comparison of the initial binding rate of the conjugates with their ligands with those of the unmodified antibodies over a range of concentrations showed that the antibody conjugates were partially inactivated. The anti-fluorescein conjugates retained at least 90% of their immunoreactivity over the range of modification tested, while anti-biotin conjugates showed a progressive loss of reactivity with increased substitution by the label.

INTRODUCTION

Surface plasmon resonance (SPR) is a phenomenon that is measured by the change in the refractive index at a surface as a function of the mass of the material bound to the surface. As commercialized on the BIAcore instrument, SPR allows for the real-time measurement of the kinetics of noncovalent interactions between a ligand and a binding partner (*1*−*3*). We have recently highlighted surface plasmon resonance on the BIAcore system as a valuable tool that can be used to characterize immunoreagents utilized in immunoassays (*4*−*8*). The previous reports have detailed the utility of SPR in evaluating how the structural variations in a library of small molecule haptens affected the kinetics and thermodynamics of binding to anti-hapten antibodies or Fab fragments. In one study, each analogue in the library was immobilized on a separate biosensor chip and evaluated individually with the antibody or Fab (*7*). The association and dissociation rates for each analogue were determined from the generated sensorgrams, and the affinity constants were calculated and compared. In this *direct* SPR method, it was necessary to optimize the surface density of the ligand at a low level on the biosensor chip to *minimize* rebinding events and mass transport limitations. Other studies have taken a different approach in which a single biosensor was used to determine the affinity constants of each member of the library with the Fab in solution at equilibrium (*5*, *8*). The technique is based on the observation that under mass transport limited conditions the initial binding rate of the antibody with the biosensor is proportional to the concentration of the antibody and independent of the affinity of the antibody for the ligand on the biosensor chip (*9*). Plotting initial binding rate versus antibody concentration produces a calibration curve from which concentrations of free antibody in an unknown sample at equilibrium can be determined. For this experiment, the surface density of the ligand on the biosensor must be *high* enough to *ensure* mass transport limited kinetics.

Both types of studies were particularly applicable to characterizing the reagents used in assay formats in which the antibody would be unmodified by labeling or immobilization. It is often the case, however, that the antibody component of the immunoassay is modified by conjugation to a detectable tag, ligand, or solid support [see, for example, Abraham et al. (*10*)]. SPR has only recently been reported to study the effect of the biotinylation of anti-LH mAbs on binding to LH in an immunometric format (*11*). The degree of biotinylation of the mAbs was not determined, but the authors offered the qualitative observation that the conjugation procedure had a marked effect on the sensor-bound antibody binding to LH. In general, chemical modifications to any antibody may vary from lot to lot and unpredictably change the conjugate's binding properties with the analyte ligand, which in turn would affect assay performance. SPR provides a convenient tool for assessing the changes in antibody binding characteristics in a reproducible, automated fashion using a minimal amount of the antibody conjugate.

In this report, a series of conjugates between anti-biotin (**4**) and anti-fluorescein (**5**) monoclonal antibodies and a new chemiluminescent *N*-sulfonylacridinium-9-carboxamide derivative (**1**) was prepared and evaluated by SPR on the BIAcore system using the solution competition method.

MATERIALS AND METHODS

Anti-biotin (**4**, IgG2a) and anti-fluorescein (**5**, IgG1) monoclonal antibodies, obtained from the Abbott cell culture facility (Abbott Laboratories, Abbott Park, IL), were dialyzed exhaustively against PBS (100 mM sodium phosphate and 150 mM sodium chloride, pH 7.2) using a 10 000 MW cutoff membrane dialysis cassette (Slide-A-Lyzer, Pierce Chemical Co., Rockford, IL). The acridinium-9-carboxamide label **1** (*12*, *13*) and *O*-(6-fluoresceinylmethyl)hydroxylamine **2** (6-OFMHA) (*14*, *15*) were prepared as previously described. 5-(Biotinamido)pentylamine **3** was obtained from Pierce Chemical Co. UV−vis spectroscopy was performed on a Beckman DU 640 spectrophotometer (Fullerton, CA). Preparative HPLC

was performed using a Waters (Milford, MA) 600E system controller and pumps and a model 486 tunable absorbance detector set to 280 nm. Surface plasmon resonance measurements were carried out at 25 °C on a BIAcore 2000 (BIAcore, Inc., Piscataway, NJ) automated system using research-grade CM-5 four-channel sensor chips. Reagents for the BIAcore instrument consisted of HBS running buffer [10 mM Hepes (pH 7.4), 150 mM NaCl, 3.4 mM EDTA, and 0.05% surfactant P-20], a biosensor chip activation kit containing *N*-hydroxysuccinimide (0.5 M, NHS), *N*-ethyl-*N*′-(3-dimethylaminopropyl)carbodiimide hydrochloride (0.2 M, EDC), and a capping solution of ethanolamine hydrochloride (1 M, pH 8.5), all from BIAcore, Inc.

Preparation of Antibody-acridinium-9-carboxamide Conjugates. *General Procedure.* To each antibody (3.0 mg mAb in 1.4 mL of PBS, pH 8.0) was added (a) 4, (b) 8, or (c) 16 molar equivalents of the acridinium-9-carboxamide active ester **1** (Figure 1) in DMF (0.2 mL). Upon addition, the solutions were rapidly vortexed then allowed to stand for 18 h in the dark. Each reaction was purified by preparative HPLC using a Bio-Rad (Hercules, CA) SEC-250-5 gel permeation chromatography column eluting with PBS [pH 6.3, containing CHAPS (0.1%), 1.0 mL/min] and subsequently stored at 2−8 °C in the dark. Labeled antibody ($R_t \approx 8.3$ min) and unconjugated acridinium-9-carboxamide label ($R_t = 11.1$ min) were readily separated under these conditions.

The concentration of antibody conjugate was determined by UV−vis spectroscopy using the following formula:

$$[\text{conjugate}] = [A_{280} - (A_{369}/4.1)]/\epsilon_{280}$$

where A_{280} and A_{369} are the absorbance readings of the acridinium-9-carboxamide-antibody conjugates at the corresponding wavelengths; 4.1 is the A_{369}/A_{280} of the free carboxylic acid form of **1**, and ϵ_{280} (210 000 M^{-1} cm^{-1}) is the extinction coefficient of the IgG antibody at 280 nm. The ratio of acridinium label to antibody (**r**) conjugate was determined by UV−vis spectroscopy using the following formula:

$$r = \frac{A_{369}/\epsilon_{369}}{[A_{280} - (A_{369}/4.1)]/\epsilon_{280}}$$

where ϵ_{369} (14 700 M^{-1} cm^{-1}) is the extinction coefficient of the label free carboxylic acid form of **1** at 369 nm. For the acridinium-9-carboxamide-anti-biotin conjugates **4a**−**c**, label-to-antibody ratios of 2.1, 4.0, and 7.5 were obtained, respectively. For the acridinium-9-carboxamide-anti-fluorescein conjugates **5a**−**c**, label-to-antibody ratios of 2.2, 3.6, and 7.4 were obtained, respectively.

Preparation of Biotin and Fluorescein Biosensors. Biosensors were prepared under the conditions listed in Table 1. In general, CM-5 chips were equilibrated with running buffer (10 μL/min), then activated with NHS/EDC. A solution of 5-(biotinamido)pentylamine (**3**) or 6-OFMHA (**2**) was injected over the cell. Reactive sites remaining on the biosensor chip were blocked with ethanolamine (70 μL, 1.0 M). The binding capacities of the resulting biosensors were estimated using unlabeled anti-biotin mAb (**4**) or unlabeled anti-fluorescein mAb (**5**). Control surfaces for each sensor were generated at the same conditions, omitting the ligand immobilization step.

Antibody Conjugate Analysis by the Solution Competition Method. *(A) Calibration Curve.* Stock solutions of the native antibodies (**4** and **5**) and antibody conjugates (**4a**−**c** and **5a**−**c**) in PBS were serially diluted into HBS buffer to obtain 11 solutions in concentrations ranging 2−22 nM. The diluted solutions of known concentration were injected over the corresponding biosensors (5 μL/min, 2.0 min). The biotin biosensor was regenerated after each run with formic acid (1.0 M, 1 min), then guanidine·HCl (6.0 M, 1 min; 1.5 M, 1 min). The fluorescein biosensor surface was regenerated by consecutive pulses of guanidine·HCl (6.0 M, 2 × 1 min; 1.5 M, 1 min). The initial binding rate was obtained from each sensorgram by linear fitting of a 15 s window, starting 20 s after injection. Calibration curves were generated for either the native antibodies or their conjugates by plotting the initial binding rate vs antibody (or conjugate) concentration.

(B) Determination of Apparent Solution Equilibrium Dissociation Constants (K_D). 5-(Biotinamido)pentylamine (**3**) and 6-OFMHA (**2**) were each serially diluted with HBS buffer to give 11 solutions ranging 8−100 nM for **3** and 40−1000 nM for **2**. Stock solutions of the native antibodies (**4** and **5**) and antibody conjugates (**4a**−**c** and **5a**−**c**) in PBS buffer were diluted into HBS buffer to obtain 40 nM solutions. Each ligand solution was mixed with the corresponding antibody or conjugate solution (1:1 v/v). Once equilibration was reached after 1 h at ambient temperature, the concentration of free antibody or antibody conjugate in each sample was assayed using a biosensor chip and the corresponding calibration curve. Nonlinear least-squares regression analysis supplied with the BIAevaluation software (version 3.0) was used to fit a plot of the concentrations of free antibody versus the concentrations of the competitor and determine the apparent solution affinity. The formula used in the software is shown below:

$$A_{\text{Free}} = (A_T - L_T - K_D)/2 + [(A_T + L_T + K_D)^2/4 - L_T A_T]^{1/2}$$

where A_{Free} is the concentration of free antibody in equilibrated solution with the competitor ligand, A_T is the total concentration of antibody, L_T is the total concentration of ligand, and K_D is the apparent equilibrium dissociation constant for the binding between the ligand and the antibody.

Determination of Retained Antibody Conjugate Activity. Solutions of antibody conjugates (**4a**−**c** and

Table 1. Experimental Conditions for the Preparation and Regeneration of Biotin and Fluorescein Biosensors

5a−**c**) ranging 2−22 nM were injected over the corresponding biosensors (5 μL/min), and the initial binding rate was determined from each sensorgram. The activity of each conjugate (**4a**−**c** and **5a**−**c**) was compared to the unmodified antibody (**4** or **5**, respectively) using the formula

$$\% \text{ active antibody conjugate} = k/k_0$$

k_0 is the slope in the calibration curve of the unmodified antibody (**4** or **5**) and k is the slope observed for the antibody conjugates (**4a-c** and **5a-c)**.

RESULTS

Preparation of Antibody-acridinium-9-carboxamide Conjugates. The antibodies **4** and **5** were conjugated with the acridinium-9-carboxamide active ester **1** at three stoichiometries (4:1, 8:1, and 16:1) in buffer/DMF (7:1, pH 8.0). The antibodies and labeling reagent were completely soluble during the course of the reaction and throughout purification. Purification of the conjugates by gel permeation chromatography removed unreacted or hydrolyzed **1**. The efficiency of the coupling reaction between both antibodies and the active ester **1** ranged from 53 to 47% based on incorporated **1**. There was no significant difference in the coupling efficiency between the three stoichiometries.

Preparation of Biosensors. *Anti-Biotin mAb Sensor.* Biotin containing a pentanediamine linker (**3**) was immobilized on a NHS/EDC-activated carboxymethylated dextran surface of a CM-5 sensor chip to afford a biosensor. Using a ligand concentration of 10 mM for 10 min produced a biosensor with an anti-biotin antibody (**4**) binding capacity of 11 000 RU (Table 1).

Anti-Fluorescein mAb Sensor. Immobilization of 5(6)-fluoresceinamine, 4′-aminomethylfluorescein or 5(6)-aminomethylfluorescein (data not shown) under the conditions that were successful for the biotin series, proved to be insufficient to generate the ligand density necessary to achieve mass transport limitation. It was reasoned that at pH 8 the negatively charged fluorescein molecule is electrostatically repulsed from the carboxylated sensor surface. 6-OFMHA (**2**) was immobilized on the sensor chip under acidic conditions that circumvented this problem. Thus, a 1 mM solution of **2** buffered at pH 5.5 reacted with the activated CM-5 chip over 20 min to afford a suitable ligand surface with a binding capacity for anti-fluorescein mAb **5** of 30 000 RU (Table 1).

Mass transport limited conditions were reached when biotin and fluorescein surfaces were prepared to have antibody capacities of 11 000 and 30 000 resonance units (RU), respectively. Injection of native antibodies on sensor chips with slightly less antibody capacities yielded the same initial binding rates, which confirmed that mass transport limited conditions had been reached. Fluorescein surfaces were regenerated by two consecutive pulses of 6.0 M guanidine·HCl and one pulse of 1.5 M guanidine·HCl, each lasting for 1.0 min. In contrast, regeneration of biotin surfaces was found to be more difficult. To clean the latter surface thoroughly, a 1 min pulse of 1.0 M formic acid was needed prior to washing the surface with 6.0 and 1.5 M guanidine·HCl (Table 1).

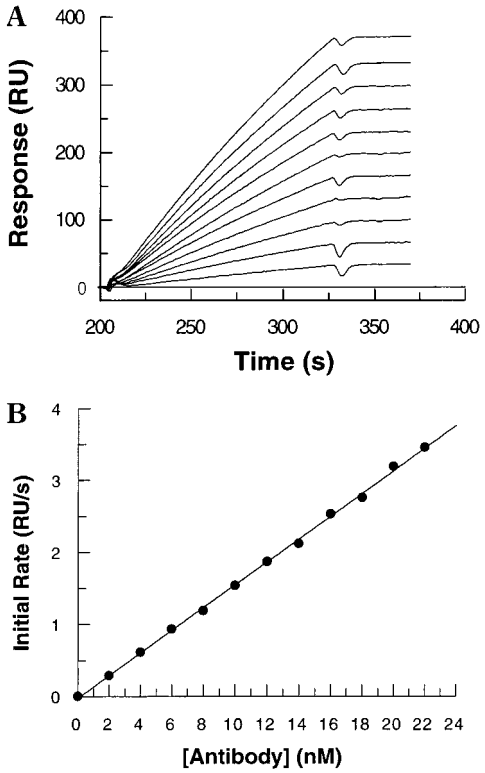

Figure 2. Calibration curve for anti-biotin mAb **4.** (A) Sensorgrams (**4,** 2−22 nM). (B) The initial rate at each concentration was calculated using a 15 s window, starting 20 s after the injection.

Antibody Conjugate Analysis by the Solution Competition Method. The required calibration curves of initial binding rate vs antibody (or conjugate) concentration were constructed using the corresponding biotin or fluorescein biosensors. Thus, the sensorgrams obtained for different concentrations of anti-biotin mAb (**4**) under mass transport limiting conditions are typical (Figure 2A). Both the initial binding rates and the total response units obtained during the binding phase of the sensorgrams increase proportionally to the increase in binding protein concentration within the range examined (2−22 nM). The initial binding rate for each concentration of **4** was obtained by analyzing the sensorgram over a 15 s window beginning 20 s postinjection. Data from the first 20 s of each sensorgram was omitted due to sample dispersion effects at the start of injections. A plot of initial binding rate versus concentration of **4** yielded the calibration curve (Figure 2B).

To determine the apparent solution equilibrium dissociation constant of anti-biotin antibody **4** with biotin ligand **3**, a stock solution of **3** was serially diluted into HBS buffer to obtain solutions ranging 6.6−67 nM. These diluted ligand solutions were mixed with the anti-biotin antibody **4** (40 nM) in equal volumes. After equilibrium

was reached (>1 h), the resulting solutions were injected over the biotin surface to produce the sensorgrams shown in Figure 3A. The initial slope of each sensorgram was converted to concentration of free native antibody based on the calibration curve. The apparent equilibrium dissociation constant of anti-biotin antibody **4** with ligand **3** was determined after plotting the free concentrations of antibody vs concentrations of the ligand **3** (Figure 3B) using BIAevaluation 3.0 software. Conjugates **4a**−**c** were evaluated analogously using the corresponding calibration curves. Apparent equilibrium dissociation constants of anti-fluorescein mAb **5** and its acridinium-9-carboxamide conjugates (**5a-c**) were measured in a similar fashion using solutions of 6-OFMHA (**2**), ranging from 40 to 1000 nM as the competing ligand.

Table 2 shows the apparent equilibrium dissociation constants of anti-biotin antibody **4**, anti-fluorescein antibody **5**, and their acridinium-9-carboxamide conjugates at different labeling ratios. Within a set, the affinities were very similar. For **4** and **4a**−**c**, the apparent equilibrium dissociation constants ranged 5.2−6.4 nM. For **5** and **5a**−**c**, the apparent equilibrium dissociation constants ranged 72−81 nM.

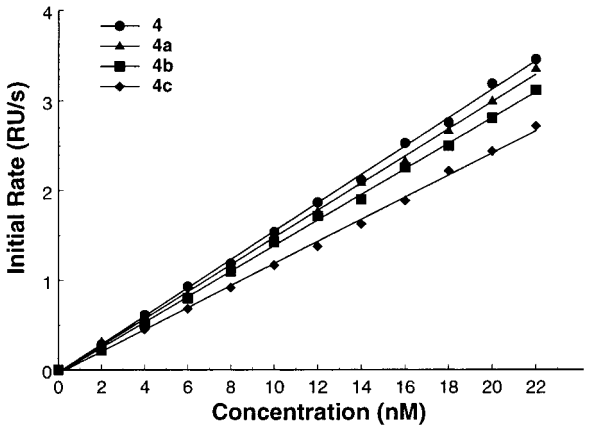

Figure 4. Comparison of the calibration curves of anti-biotin mAb **4** and conjugates **4a**−**c**.

Determination of Retained Antibody Conjugate Activity. To evaluate the extent to which the conjugation procedure deactivated the antibodies **4** and **5**, conjugates **4a**−**c** and **5a**−**c** (2−22 nM) were injected over the corresponding ligand-bearing biosensors under mass transfer limiting conditions. Plotting the initial binding rate from the resulting sensorgrams versus the concentration of the antibody (conjugate) produced a series of calibration curves (Figure 4). The slope (k) of the calibration curve of each conjugate was compared to the slope (k_0) of the native antibody and the ratio was taken as a measure of the immunoreactive fraction of the conjugate. As shown in Table 2, relatively little anti-fluorescein antibody was deactivated during the conjugation process. Even at a high loading ratio of acridinium to anti-fluorescein antibody (7.4:1), more than 90% of the antibody retains activity similar to the native antibody. By contrast, a larger percentage of the anti-biotin conjugates lost their binding ability at higher label-to-antibody ratios. Approximately 23% of the anti-biotin conjugates were effectively inactive when the coupling ratio of acridinium to antibody reached 7.5.

DISCUSSION

There are several advantages to using SPR as a technique to characterize antibody conjugates. First, with the advent of commercially available instrumentation, characterization of the binding parameters of antibody conjugates can be performed in an automated and reproducible fashion. Because antigen bearing sensor chips can be regenerated and reused, a single and controllable surface can be created to test the binding parameters among different lots of antibody conjugates. This advantage can be especially useful when comparing antibodies utilized in different diagnostic platforms. Second, SPR is an efficient method of analysis. Real-time monitoring of the antibody-binding event eliminates time-consuming secondary methods (e.g., enzyme or colorimetric based assays) to detect the bound antibody. Dangerous radioactivity, as might be used in immunoassay-based analyses, is also avoided. Because SPR instrumentation is accompanied by software capable of commanding automated routines, once the immobilization of ligand to a sensor chip has been optimized, samples can be analyzed in a high-throughput manner within minutes for a typical antibody. Third, the quantity of materials needed is minimal using SPR analysis. For each passover, the amount of antibody required ranges from roughly 0.0005 to 0.05 mg, depending on the nature of the antibody. This minimal amount of material allows

for multiple runs to be performed within an experiment or over time without the large expenditure of conjugate. If an antibody lot is destined for commercial development, the nonconsumptive nature of the method is a plus for both reasons of production and cost.

As in any analysis of antibody binding, the bivalency of the antibody must be considered in determining true equilibrium affinity or dissociation constants. Often the study can be simplified by preparing monovalent Fab fragments of the antibody (*7*). This alternative is not practical in the evaluation of antibody conjugates that will be used as such in an assay. The added manipulation to form and purify the Fab fragment may itself alter the binding properties of the protein. In previous studies using the BIAcore, it has been shown that the binding data obtained from intact antibodies actually fits the equation for a one to one binding interaction better than the equation that takes bivalency into consideration (*9*). The binding constants from both equations were quite close in that case.

The present study utilizes Karlsson's simplified model to determine apparent equilibrium dissociation constants useful in the comparison of the relative avidity of antibodies covalently modified with a low molecular weight label. For the two antibodies studied here, SPR analysis demonstrated that conjugation with a chemiluminescent acridinium label did not significantly affect the antibody conjugates' ability to bind ligand in solution (Table 2). With these data alone, one would conclude that the immunoreactivity of the conjugate was not compromised during the conjugation procedure. However, comparison of the calibration curves generated for each conjugate with those of the native antibodies revealed a discrepancy.

In the anti-biotin mAb series (Figure 4), the calibration curve of each conjugate differed from the unmodified antibody by showing a progressively shallower slope that correlated with the degree of hapten substitution. Conjugate **4c** had a slope that was 23% less than the unmodified **4**. In the anti-fluorescein mAb series, this effect was much less pronounced; the most highly substituted anti-fluorescein conjugate, **5c** was still within 10% of the native mAb. Under the mass transport limiting conditions of these experiments, the initial binding rate depends only on the concentration of the antibody (conjugate), the bivalency of the antibody is not an issue. The initial rates were calculated for the antibody and conjugates at the same protein concentrations, thus, the calibration curves should be nearly identical. Any deviation could be due to inactivation of some percentage of the conjugate during the conjugation process. Because the apparent equilibrium dissociation constants within a set of conjugates and their parent antibody were similar, the deactivation of the conjugates appears to be an all-or-nothing effect; conjugation either completely disrupts binding or does not change the affinity of the antibody. In addition, anti-fluorescein antibody was clearly less sensitive to the process of label conjugation than the anti-biotin antibody. For the anti-biotin antibody, this difference may point to a higher susceptibility of key residues in the CDR to acylation by the label, a lowered resistance to denaturation imposed by the covalent attachment of the label, or a combination of both.

The use of the BIAcore instrument to measure active protein concentration is not new. Indeed, Karlsson et al. have measured the concentration of active, unmodified antibodies under mass transport limiting conditions (*16*). They observed that the initial rate versus antibody concentration calibration curves to be identical for a variety of IgGs (monoclonal, monoclonal mixtures, and polyclonal) and thus valid as a general method with the caveat that the association rate of the antibodies had to be at or above 10^5 M^{-1} s^{-1}. Others have modified the procedure to measure the concentration of lower affinity, unmodified binding proteins under partial mass transport limiting conditions (*17*, *18*). Neither group had exploited their methods to characterize antibodies that have been covalently modified.

In summary, our past studies have shown that SPR can be useful in determining the optimal structure of small molecule ligands for binding to a given antibody whether the ligand is in solution or bound to a solid support (*4*−*8*). While that was a significant advance in the design of immunoassay components, it also set the basis for monitoring lot to lot variations in the binding properties of the antibody. Until now, SPR had not been used to systematically examine the affect of covalent modification on antibody immunoreactivity. The present study demonstrated that random coupling of the activated ester of acridinium-9-carboxamide **1** to anti-biotin (**4**) and anti-fluorescein (**5**) monoclonal antibodies was chemically efficient based on UV analysis. Surface plasmon resonance of the purified conjugates indicated only minor variations in the apparent equilibrium dissociation constants of these antibody conjugates as a result of the conjugation process, which was a welcome result. In addition, and more importantly, SPR provided a means of detecting the ratio of active to inactive antibody-conjugate present in the preparation. While the anti-fluorescein conjugates retained at least 90% of their immunoreactivity over the extent of modification tested, anti-biotin conjugates showed a progressive loss of reactivity. The ultimate goal is to match the conjugation procedure to the antibody to minimize losses of immunoreactive conjugate. The reasons for the loss of active antibody is, of course, still speculation, but SPR proved to be a very convenient method for observing the effect.

New Cyclization Reaction at the Amino Terminus of Peptides and Proteins

Keith Rose,*,† Jianhua Chen,† Marina Dragovic,† Weiguang Zeng,† Damien Jeannerat,‡ Philippe Kamalaprija,‡ and Ulrich Burger‡

Department of Medical Biochemistry, University Medical Center and Department of Organic Chemistry, University of Geneva, CH-1211 Geneva 4, Switzerland. Received May 20, 1999; Revised Manuscript Received September 8, 1999

Mild oxidation with periodate of the 1-amino-2-ol moiety of N-terminal seryl or threonyl peptides and proteins leads to a terminal aldehyde function O=CH−CO− which usually may be exploited for bioconjugate formation (e.g., via oximation with an O-alkyl hydroxylamine). We report that, when followed by a prolyl residue, the O=CH−CO− group can undergo a rapid cyclization and dehydration reaction through nucleophilic attack by the amide nitrogen of the third amino acid residue of the chain. We have characterized the resulting heterocycle, which is stable in aqueous acid, by mass spectrometry and NMR. Quantitative oximation can nevertheless be achieved in such cases by performing a one-pot oxidation-oximation without isolation of the intermediate aldehyde, as is demonstrated with cholera toxin B subunit.

INTRODUCTION

The oxidation by periodate of N-terminal 1,2-amino alcohols Ser (R = CH_2OH) or Thr [R = $CH(OH)CH_3$] residues NH_2−CHR−CO− of a polypeptide to an aldehyde function O=CH−CO− has been known for many years (*1*). More recently, this mild oxidation reaction has been exploited for the synthesis of bioconjugates through formation of hydrazone, thiazolidine, or oxime (−ON=CH−CO-) bonds (e.g., refs *2*−*8*). Usually, the polypeptide aldehyde is stable in aqueous solution at pH values between 2 and 5 and may be lyophilized and stored as a powder at −20 °C (*4*). In some cases, however, the aldehyde can undergo side reactions. For example, formation of a 1,3,4-oxadiazolino peptide containing two peptide aldehyde units has been observed during attempted hydrazone formation (*9*).

We have observed that some polypeptides and proteins, including Cholera toxin B subunit (CTB), undergo rapid and quantitative oxidation to yield a compound which may be isolated and has the mass calculated for the expected O=CH−CO-polypeptide species, but oximation occurs very slowly indeed (half time estimated in weeks under conditions where normally the half time is of the order of very few minutes). The first protein which gave such difficulties was a β-lactamase (*5*), and in that case, the problem was solved by careful optimization of the conditions of oxidation of the N-terminus and storage of the aldehyde, but such an approach was not successful with CTB. We were able to reproduce the phenomenon of oxidation followed by very slow oximation using a small synthetic peptide consisting of the first six residues of the β-lactamase, Thr-Pro-Val-Ser-Glu-Lys-amide. In this article, we show that, when followed by a prolyl residue, the O=CH−CO− group formed by oxidation of N-terminal Ser or Thr can undergo a rapid cyclization and dehydration reaction through nucleophilic attack by the amide nitrogen of the third amino acid residue of the chain. The resulting heterocycle, which is stable in aqueous acid, was characterized by mass spectrometry and NMR. To achieve quantitative oximation in such cases, we developed a one-pot oxidation-oximation without isolation of the intermediate aldehyde and demonstrate here with CTB that it is possible to prepare in good yield a hybrid construct of which 60% of the mass is the B subunit and 40% is totally synthetic. CTB conjugates are potentially useful as vaccines: CTB can supply T helper epitopes and, if the construct assembles as its noncovalent pentamer, such constructs would be expected to elicit a mucosal immune response (e.g., refs *10* and *11*).

EXPERIMENTAL PROCEDURES

Materials. Synthetic peptides were prepared using Boc chemistry on a model 430A synthesizer (Applied Biosystems Inc.) modified according to Kent (*12*). ^{15}N (99 atom %) N^t-Boc-L-valine was purchased from Isotec. Methylbenzhydrylamine resin (NovaBiochem, Switzerland) was used to obtain peptide amides directly upon cleavage with HF. Synthetic peptides were purified by high-pressure liquid chromatography (HPLC), acetonitrile was removed by rotary evaporation at room temperature, and product was recovered by lyophilization. Purified peptides gave a single peak on analytical HPLC and the expected mass spectrum. The aminooxyacetyl peptide NH_2OCH_2CO-Gly_3[Lys(Ser)]$_5$Gly-OH was prepared as previously described (*13*). Cholera toxin B subunit (CTB, Inaba strain) was obtained from the Swiss Serum and Vaccine Institute, Berne, Switzerland. Sodium metaperiodate and guanidine hydrochloride (MicroSelect grade) were purchased from Fluka, Buchs, Switzerland. Boc-aminooxyacetic acid was from Calbiochem-NovaBiochem, Läufelfingen, Switzerland.

Chromatography. High-pressure liquid chromatography was performed using a column of Nucleosil 300A 5 μm C_8 (Macherey Nagel, Oensingen, Switzerland), 250

× 4 mm id for analytical work (0.6 mL/min, 2 mL loop) and a radial compression system (210 × 25 mm id, Nova-Pak HR 60A 6 μm C_{18}, 20 mL/min, 50 mL loop) for preparative work, monitoring at 214 or 229 nm for analytical or preparative work, respectively. Linear gradients were established between solvent A [1 g of trifluoroacetic acid (TFA) added to 1 L of HPLC grade water and then vacuum filtered and degassed] and solvent B (1 g of TFA added to 100 mL of water, brought to 1 L with gradient grade acetonitrile then vacuum filtered and degassed). Gel filtration was performed on a Superdex 75 HR 10/30 column (Pharmacia, Uppsala, Sweden) at a flow rate of 0.4 mL/min using 0.25 M phosphate buffer, pH 7.0 (counterion sodium), which was 1 mM in EDTA, monitoring at 280 nm.

Mass Spectrometry. Spectra were obtained using electrospray ionization on either a Trio 2000 (infused at 2 μL/min) or Platform II instrument (infused at 7 μL/min); both machines were from Micromass, Altrincham, U.K. Samples of synthetic peptides were dissolved in water/acetonitrile 1:1 by volume, whereas protein samples were dissolved in water/acetonitrile/acetic acid (49.5:49.5:1 by volume).

NMR spectroscopy (*14*) was performed on a Bruker AMX-2−600 spectrometer operating at 14.1 T. Peptide samples were dissolved in D_2O at pD 4.7 (DCl). After acquisition of all data, samples were reanalyzed by HPLC to check for possible decomposition. Two-dimensional experiments were performed at 298 K. $^1H/^1H$-DQF−COSY spectra were acquired using 512 × 16K data points and a spectral width of 12 ppm in both dimensions. A shifted sine bell function was applied to the indirectly detected dimension during data processing. The heteronuclear HSQC (*15*−*17*) and HMBC experiments (*18*−*19*) were performed with 128 × 4K data points and spectral widths of 90 × 10.69 ppm in the carbon and proton dimension, respectively. Folded signals could easily be identified as such. For the processing, sine bells were applied in both dimensions.

Oxidation of TPVSEK-amide. To a solution of purified hexapeptide amide (17.6 mg, 26.8 μmol of peptide, 28 mL of water, 2.8 mL of 10% ammonium bicarbonate solution) was added 5.6 mL of sodium metaperiodate solution (0.184 g/L in water, 4.8 μmol) with vortex mixing. As soon as possible, the reaction was quenched by mixing in 5.6 mL of ethyleneglycol (10 M in water) and injecting the reaction mixture onto preparative HPLC. After a 5 min isocratic period, a linear gradient of 1% B/min was established. Once the three components had eluted (within 30 min), the column was washed briefly at 50% B then reequilibrated at 100% A. Organic solvent was removed by rotary evaporation at room temperature and product recovered by lyophilization. From 85 mg of peptide, we isolated 39 mg of peak 1, 4.6 mg of peak 2 and 4.6 mg of peak 3.

Oximation of Oxidized TPVSEK-amide. For the study at pH 4.6, the buffer was 0.1 M acetate, counterion sodium. In separate experiments, both forms of the oxidized hexapeptide amide (peaks 2 and 3, 0.3 mg in 60 μL buffer) were treated with aminooxyacetic acid (60 μL, 5 mM in buffer). For the study at pH 7.0, a phosphate buffer was used (0.1 M, counterion sodium) in place of acetate. The oximation reactions were monitored by HPLC, injecting 10 μL volumes with a gradient from 0 to 35% B over 30 min.

Oxidation and Oximation of CTB. CTB was supplied as a lyophilized powder in the presence of buffer salts, including Tris which might be expected to react with periodate. Vial contents (1 mg of protein) were therefore dissolved in 1 mL of water, and the protein was isolated by gel filtration as the noncovalent pentamer. The protein was concentrated by ultrafiltration (Centricon, Amicon, Beverly, MA, 10000 molecular weight cutoff, precentrifuged twice with 1 mL of phosphate chromatography buffer to remove glycerol which interferes with the oxidation step) to 400 μL. Methionine (50 μL, 0.2 M in the phosphate buffer) was added to protect against thioether oxidation, then oxidation of the N-terminal Thr residue was initiated by addition of sodium periodate (25 μL, 40 mM in the phosphate buffer). After 5 min in the dark, excess periodate was quenched with ethyleneglycol (60 μL, 0.5 M in water), then 4 min later, 27.8 mg of aminooxyacetyl peptide NH_2OCH_2CO-$Gly_3[Lys(Ser)]_5$Gly-OH was added, followed by 50 μL of acetic acid. An aliquot (15 μL) was removed for HPLC and mass spectrometric analysis after 30 min, whereupon the sample was placed at −20 °C overnight. The next day, 500 mg of guanidine hydrochloride was added and the protein oxime isolated by gel filtration and ultrafiltration to a volume of about 400 μL. Oxidation of the Ser residues on the Lys side chains of the peptide attached to CTB was achieved by adding methionine (150 μL, 0.2 M in phosphate buffer) followed by periodate (62.5 μL, 80 mM in phosphate buffer). After 5 min in the dark, the reaction was quenched with 1,3-diamino-2-propanol (Fluka, 300 μL, 0.5 M in water adjusted to pH 7.8 with acetic acid). Four minutes later, 500 mg of guanidine hydrochloride was added, and the oxidized protein isolated again by gel filtration and concentrated by ultrafiltration to about 400 μL. A second 400 μL sample (from a separate experiment) was pooled at this stage. To the pool (800 μL), aminooxyacetyl peptide CH_3CO-$DC(CH_2CONH_2)$-TLIDALLGDPHK$(COCH_2ONH_2)$-NH_2 was added (5.7 mg), and the solution made 4% in acetic acid. For every microliter of this solution, 1 mg of guanidine hydrochloride was added and the oximation left overnight. Final product was isolated by semipreparative HPLC (1 mg after lyophilization) and characterized by mass spectrometry.

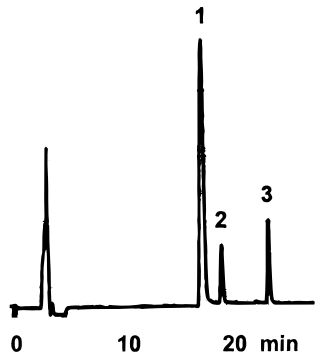

Figure 1. Preparative HPLC chromatogram of the oxidation of TPVSEK-amide with a limited quantity of periodate. After a 5 min isocratic period at 100% A, a gradient of 1%/min solvent B was applied, monitoring at 229 nm. Mass spectrometry and NMR identified components as peak 1, unmodified peptide; peak 2, hydrated glyoxylyl peptide $(HO)_2CHCO$−PVSEK-amide; peak 3, cyclic isomer of the expected O=CHCO−PVSEK-amide.

RESULTS AND DISCUSSION

Oxidation of TPVSEK-amide. To study the rapid oxidation of the terminal 1-amino-2-ol moiety of **1**, oxidation with periodate was performed with limiting amounts of periodate and a reaction time of a few seconds (to allow mixing). This allowed isolation of three components by HPLC (Figure 1). Peak 1 was identified by retention time and mass spectrum as unreacted starting

peptide (abundant signal at *m/z* 660.0 corresponding to the protonated molecular ion, most intense peak at *m/z* 330.9, the doubly protonated molecule, data not shown). Peak 2 gave a mass spectrum with signals at *m/z* 614.5, 632.5, and 654.4. The most intense peak *m/z* 632.5 corresponds to the hydrated form of the aldehyde, $(HO)_2CHCO-$PVSEK-amide (**2**) with one proton, and *m/z* 654.4 corresponds to sodium cationization of the same species. The small signal at *m/z* 614.5 in the spectrum of peak 2 became the most intense peak in the spectrum of peak 3, where it was accompanied by *m/z* 636.6. These two signals correspond to O=CHCO−PVSEK-amide (i.e., the aldehyde) with one proton and with one sodium ion, respectively, although we show below that peak 3 is actually a cyclic isomer (**3**) of the aldehyde. Peak 2 material, upon storage in aqueous solution at pH 4.6 (sodium acetate buffer), was found by HPLC and mass spectrometry to transform to peak 3 material over a number of days, but was more stable in 0.1% TFA at pH 2 (not shown). Thus, the signal at *m/z* 614.5 in the spectrum of Peak 2 material could be due to dehydration of the hydrate within the mass spectrometer to give either the aldehyde itself or its isomer (**3**). Peaks 1, 2, and 3 were found to be stable for days in aqueous solution at pH 2 at room temperature, and for months as lyophilized powders at −20 °C (not shown).

Oximation of oxidized TPVSEK-amide (peaks 2 and 3) was studied at pH 4.6 and pH 7.0. It has previously been shown that oximation proceeds faster at lower pH, and very slowly indeed at neutral pH (*7*). Oximation of peak 2 (the hydrated aldehyde) with aminooxyacetic acid at pH 4.6 was found to proceed extremely rapidly. Figure 2a shows almost quantitative reaction after 130 min: reaction halftime was approximately 10 min judging by earlier time points (not shown). The expected oxime product was identified by mass spectrometry through its protonated molecular ion at *m/z* 687.7. A trace of peak 3 material is also formed, which elutes 2 min after the oxime (ox). Oximation of peak 3 (which has the mass of the aldehyde) proceeded extremely slowly at pH 4.6, with very little product formed after 130 min (Figure 2b). The oxime was nevertheless being formed (it elutes 2 min earlier than peak 3 and is just visible in Figure 2b), and it represented about 12% after 35 h (product confirmed by mass spectrometry, not shown).

At pH 7.0, almost exactly the same chromatograms were obtained during oximation of peak 2 (Figure 2c) and peak 3 (Figure 2d). After 10 min, both showed presence of peak 2 and peak 3, with virtually no oxime product. At this pH, peaks 2 and 3 clearly interconvert rapidly: equilibrium is almost attained after 10 min, but not quite since we notice that Figure 2c is slightly richer in the starting peak 2 whereas Figure 2d is still slightly richer in the starting peak 3. In both cases, oxime formation proceeded very slowly, reaching about 30% after 10 h (not shown). Thus, although oximation proceeded very slowly at pH 7.0 for both peaks 2 and 3, it nonetheless proceeded more rapidly than for peak 3 at pH 4.6 (but much less rapidly than for peak 2 at pH 4.6).

These results were difficult to understand. For years it has been known that small aliphatic aldehydes (such as heptanal), many peptides and proteins carrying a O=CH−CO−NH−CHR−CO− group (where R is the side chain of a genetically coded amino acid), many polypeptides carrying a $-NHCH_2CH=O$ group, and many peptides carrying a O=CH−CO− group attached to the side chain of Lys undergo rapid and almost quantitative oximation at mildly acid pH. In the case of the oxidized small synthetic peptide TPVSEK-amide, the hydrated aldehyde (peak 2) was able to undergo rapid oximation at pH 4.6, but the apparent aldehyde (peak 3) was not. This led us to investigate by NMR spectroscopy the structure of peaks 1, 2, and 3.

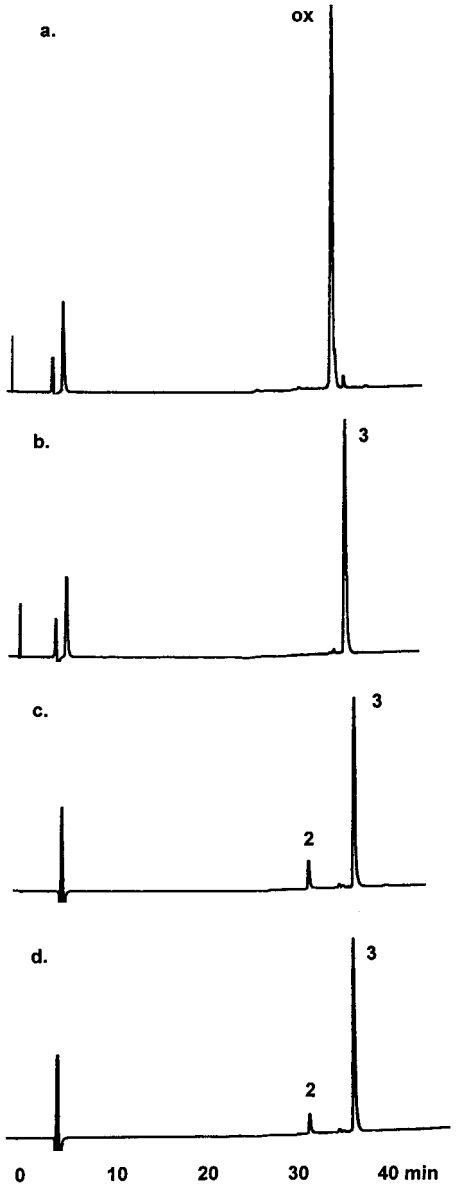

Figure 2. Analytical HPLC chromatograms of oximation reactions of peaks 2 and 3 of Figure 1. Remaining material is labeled 2 or 3, accordingly. Oxime product (ox) was identified by mass spectrometry. After a 5 min isocratic period at 100% A, a gradient of 1.17%/min solvent B was applied, monitoring at 214 nm. (a) Peak 2, pH 4.6, 130 min. (b) Peak 3, pH 4.6, 130 min. (c) Peak 2, pH 7, 10 min. (d) Peak 3, pH 7, 10 min.

NMR Analysis. The $^1H/^1H$-DQF−COSY spectra of compounds **1**, **2**, and **3** allowed assignment of all resonances of hydrogen atoms bound to carbon (*14*). Since the amino acid residues differ all in their spin systems, the assignment was straightforward and unambiguous. Data for ^1H chemical shifts are compiled in Table 1.

Comparison of the ^1H-spectra of **1** and **2** immediately confirmed the Thr residue as the site of oxidative cleavage. The three signals of Thr of **1** are missing in compound **2** and are replaced by a singlet at δ (ppm) 5.58. This is the resonance of the H−C(2) proton of the newly formed dihydroxyacetyl residue [the former H−C(α) of Thr]. That we were dealing with a hydrated aldehyde was corroborated by an HSQC-experiment (*15*−*17*) which correlates this proton to a ^{13}C signal at δ (ppm) 86.0 via

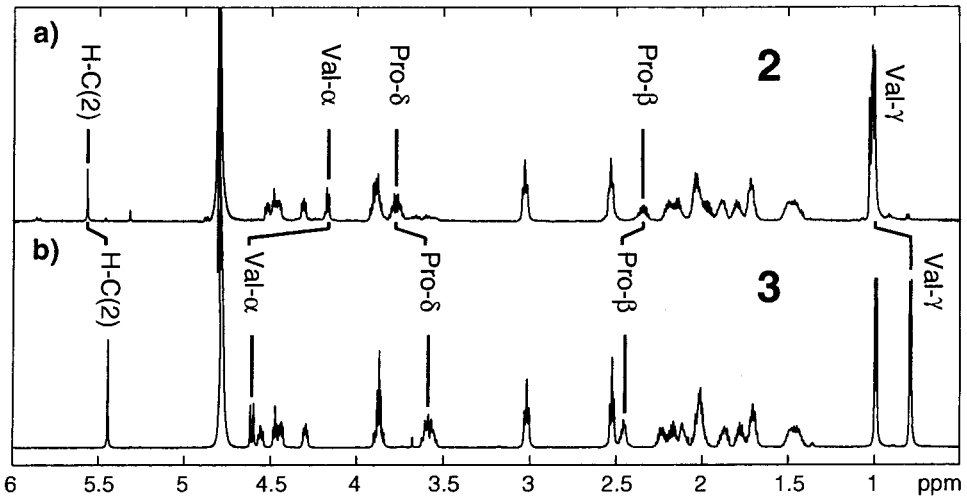

Figure 3. ^{1}H NMR spectra recorded at 600 MHz in D_2O of (a) compound **2** and (b) compound **3**, with assignment of those resonances which change significantly upon cyclization.

[a] Dihydroxyacetate for **2**, and H−C(2) of the new six-membered heterocycle for **3**.

^1J scalar coupling. The ^{1}H chemical shifts of the remaining five residues (Pro, Val, Ser, Glu, and Lys-amide) show a remarkable similarity between compounds **1** and **2**. Clearly, these amino acid residues were not altered.

However, when comparing compounds **2** and **3** (Table 1 and Figure 3), it was evident that the dehydration reaction resulted in significant changes of the Pro and Val resonances. One of the methyl groups of Val had undergone an upfield shift of 0.2 ppm, whereas H−C(α) of Val changed from 4.17 to 4.63. A significant change (5.58 → 5.46) was observed also for the H−C(2) resonance of the oxidized residue. The signals of the three remaining amino acid residues Ser, Glu, and Lys-amide are almost identical for **2** and **3**. These findings clearly show that only Val and Pro sense the new molecular environment in **3**. Bond formation between the nitrogen atom of Val and C(2) of the oxidized residue, i.e. the disguised aldehyde, best accounts for our observations (Scheme 1).

The conclusions found strong support by a HMBC experiment (*18, 19*), which unveiled scalar ^{1}H/^{13}C coupling between H−C(α) of Val and C(2) of the oxidized residue. The absolute value of this $^3J_{C/H}$ coupling is 4.6 Hz. The existence of the crucial C(2)−$N_{(Val)}$ bond was

eventually ascertained by specific ^{15}N-labeling of compound **3** in the $N_{(Val)}$ position. The ^{13}C NMR spectrum of this labeled material [$^{15}N_{(Val)}$-**3**] shows $^1J_{C/N}$ coupling for three carbon atoms, which are C(2) [at δ = 79.9, $^1J_{C/N}$ = 7.6 Hz], $C(\alpha)_{(Val)}$ [at δ = 64.4, $^1J_{C/N}$ = 8.4 Hz], and $CO_{(Pro)}$ [at δ = 175.9, $^1J_{C/N}$ = 12.8 Hz]. In addition, $^{15}N_{(Val)}$ couples

over two bonds with $C(\alpha)_{(Pro)}$ [at $\delta = 61.58$, $^2J_{C/N} = 5.4$ Hz]. These values are close to what is expected for **3** (*20*), and they leave no doubt that $N_{(Val)}$ is bound to three carbon atoms. The ring closure creates, with high stereoselectivity, a new center of chirality. We see a single epimer of **3**. The absolute configuration at H−C(2), however, is unknown.

The cyclization process **2** → **3** is entropically favored by the rigidity of the proline ring, which keeps the two reacting centers in proximity. This propensity to cyclize is probably responsible for the difficulty sometimes encountered to oximate a polypeptide which, by mass spectrometry, has the mass of the aldehyde. All of our difficult oximations have involved X-Pro sequences, where X is Thr or Ser (Table 2, where only a small selection of easily oximated polypeptides is shown).

Studying "glyoxylyl-Pro-Ile-Val-amide" made by treatment of diisopropylthioacetyl peptide with N-bromosuccinimide and isolation under acidic conditions, Qasmi et al. (*21*) found the mass of the aldehyde form (which is the same as that of the cyclic form) by isobutane CI mass spectrometry, but found evidence by NMR (in DMSO) and FAB mass spectrometry (thioglycerol matrix) that the polypeptide can also exist in hydrated form, as we found for our synthetic peptide. By proton NMR, they found no aldehydic proton at all for "glyoxylyl-Pro-Ile-Val-amide", but found a singlet at δ(ppm) 9.2−9.3 integrating 0.5 H for the aldehyde proton of "glyoxylyl-Phe-Pro-Ile-Val-amide" and "glyoxylyl-Asn-Phe-Pro-Ile-Val-amide".

Oxidation of CTB and oximation with the carrier molecule $NH_2OCH_2CO\text{-}Gly_3[Lys(Ser)]_5Gly\text{-}OH$ under the "one-pot" conditions described led to quantitative conversion (Figure 4a) to the expected oxime $CTB{=}NOCH_2CO\text{-}Gly_3[Lys(Ser)]_5Gly\text{-}OH$: relative molecular mass found by electrospray ionization mass spectrometry, 12 938 Da (theoretical mass, 12 937 Da). CTB normally exists as a noncovalent pentamer, but treatment with acid and organic solvents leads to the monomeric form exclusively. Oxidation of the side-chain Ser residues of the ligated carrier molecule followed by isolation of the oxidized protein possessing five aldehyde groups and oximation with the peptide $CH_3CO\text{-}DC(CH_2CONH_2)TLIDALLGDPH{-}K(COCH_2ONH_2)\text{-}NH_2$ (NH_2OCH_2CO-peptide) yielded 1 mg of product from 2 mg of starting CTB. Characterization by mass spectrometry showed this product (relative molecular mass, 21 102 Da, theoretical mass, 21 101 Da) to be the expected branched hybrid $CTB{=}NOCH_2CO\text{-}Gly_3[Lys(COCH{=}NOCH_2CO\text{-peptide})]_5Gly\text{-}OH$.

A similar product was made earlier (*22*) using the "one-pot" conditions and different form of the peptide, $CH_3CO\text{-}DC(SCH_2CH_2NHCOCH_2ONH_2)TLID\text{-}ALLGDPH{-}NH_2$. At that time, we did not know why it was necessary to use "one-pot" conditions for the first oximation step, while it was possible to isolate the oxidized protein prior to the second oximation step. By performing the "one-pot" oxidation-oximation at pH 6.5 instead of 7.0, and quenching after 2 min, it was possible to isolate four components from the reaction mixture (Figure 4b). Mass spectrometry identified peaks 1−4: peak 1 was the expected oxime (found, 12 938; calcd, 12 937); peak 2 was unoxidized CTB (found, 11 602; calcd, 11 604); peak 3 was hydrated glyoxylyl CTB $(HO)_2CHCO{-}CTB$ (found, 11 580; calcd, 11 577); and peak 4 had the mass expected for "glyoxylyl-CTB" but was most probably the cyclic isomer; found, 11 558; calcd, 11 559. Incubation of peak 3 material with $NH_2OCH_2CO\text{-}Gly_3[Lys(Ser)]_5Gly\text{-}OH$ led to formation of peak 1 material (oxime), while oximation of peak 4 material failed. Use of methanol, which leads to hemiacetal formation, in place of acetonitrile as cosolvent for electrospray ionization shifted the mass of peak 3 to, found, 11 589 and, calcd, 11591, but did not shift the other masses, in particular that of peak 4, providing further evidence of lack of a free aldehyde moiety for peak 4. Taken together with the mass spectrometric and NMR results obtained with the model peptide, it would seem that cyclization of glyoxylyl-Pro polypeptides to a cyclic isomer which oximate with difficulty may also occur with proteins.

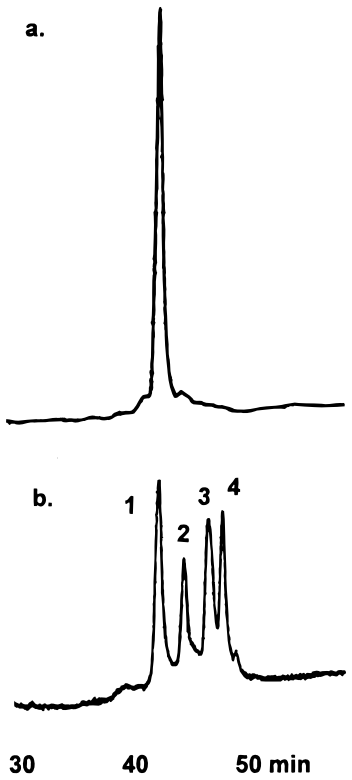

Figure 4. Analytical HPLC chromatograms of oximation reactions of oxidized CTB with $NH_2OCH_2CO\text{-}Gly_3[Lys(Ser)]_5\text{-}Gly\text{-}OH$. Compounds were identified by mass spectrometry. After a 5 min isocratic period at 35% B, a gradient of 0.2%/min solvent B was applied, monitoring at 214 nm. (a) "One-pot" oxidation-oximation under optimized conditions, showing quantitative conversion to the oxime. (b) "One-pot" reaction at suboptimal pH and time.

CONCLUSIONS

It is generally an advantage to isolate an oxidized (glyoxylyl-) polypeptide prior to oximation to avoid the necessity to use an excess of aminooxy component over the aldehydes coproduced during the oxidation reaction (formaldehyde from Ser, acetaldehyde from Thr, and formaldehyde from oxidation of the quenching agent ethyleneglycol). However, particularly when the N-ter-

minal Ser/Thr residue to be oxidized is followed by Pro, we recommend "one-pot" oxidation-oximation to avoid possible formation of the cyclic isomer of the aldehyde described here.

We have not studied the biological properties of the heterocyclic isomer of the aldehyde. It might be interesting as a scaffold for combinatorial chemistry of small (or even protein-sized) molecules, or for other purposes.

ACKNOWLEDGMENT

We are indebted to the Swiss National Science Foundation (Grants 31-50826.97 and 20-52905.97) and the Schmidheiny Foundation. We thank Marie-Laure Curchod, Irène Rossitto-Borlat, and Pierre-Olivier Regamey for expert technical assistance. The allocation of spectrometer time in the regional high-field NMR facilities in Lausanne-Dorigny is also gratefully acknowledged.

Surface Membrane Biotinylation Efficiently Mediates the Endocytosis of Avidin Bioconjugates into Nucleated Cells

Urszula Wojda, Paul Goldsmith,† and Jeffery L. Miller*

Laboratory of Chemical Biology, Building 10, Room 9N308, National Institute of Diabetes and Digestive and Kidney Diseases and Metabolic Disease Branch, National Institutes of Health, 9000 Rockville Pike, Bethesda, Maryland 20892. Received May 21, 1999; Revised Manuscript Received August 3, 1999

Here we demonstrate that biotin covalently attached to cell surface obligates existing receptors to endocytose avidin bioconjugates into nucleated cells. Incubation of fluorescein-labeled avidin with biotinylated cell lines resulted in uniform and rapid surface attachment and endocytosis compared with no detectable association of the avidin-conjugated dye with unbiotinylated cells. Uptake was detected within minutes with efficiencies approaching 100% in cell lines and freshly obtained peripheral blood mononuclear cells. After 24 h, avidin was barely detectable on the surface of the nucleated cells. In marked contrast, fluorescent avidin remained exclusively on the external membrane of erythrocytes after 24 h. To investigate biotin-mediated endocytosis for the delivery of DNA, we prepared polyethylenimine−avidin (PEI−avidin) conjugates. Surface biotinylation significantly increased the transfection efficiencies of PEI−avidin condensed plasmid DNA coding green fluorescent protein (GFP) to the level of transferrin-receptor targeted gene delivery (15−20% GFP positive cells in culture after 48 h). The increase in transfection efficiency was blocked by the addition of free avidin or biotin to the culture medium. Biotin covalently bound to cell surface membrane proteins efficiently mediates the entry of avidin bioconjugates into nucleated cells.

INTRODUCTION

Endocytosis describes the processes whereby eukaryotic cells internalize a wide range of extracellular materials including nutrients and toxins (*1*). Receptor-mediated endocytosis involves the attachment of extracellular molecules (ligands) to specified molecules (receptors) present on cell membranes and transport of those receptor−ligand complexes to the cell interior. The ligands are either then recycled to the cell surface, degraded within lysosomal compartments, or escape degradation and enter the cytoplasm. The endocytic process is responsible for a vast array of beneficial processes ranging from surface ligand clearance to nutrient uptake. In addition, some toxins and viruses require receptor-mediated endocytosis in order to access to the interior of cells (*2*, *3*).

Several factors determine the specificity and efficiency with which ligands present within the extracellular space enter cells after binding to cell surface receptors. The absolute number of receptors expressed on the cell surface largely determines the quantity of specific ligands permitted to enter individual cells. For instance, iron uptake is regulated by the number of transferrin receptors available on the cell surface (*4*). When cells proliferate, more transferrin receptors are expressed on the cell surface to enhance iron uptake. In the case of proliferating erythroid cells, exceedingly high levels of transferrin receptors are present due to the requirement of iron for hemoglobin synthesis, but the number of receptors decreases as iron requirements decrease and the cells mature (*4*). The affinity with which ligands bind to their receptors may also regulate entry into cells. Although receptors for interleukin-2 (IL-2R) exist in three forms: low, intermediate, and high affinity, only the high affinity form permits selective binding and uptake of the IL-2R targeted bioconjugates into cells (*5*). The entry of folic acid into cells is regulated both by the expression level of folate-binding receptors and the affinity of folate for those receptors (*6*).

It is well-known that conjugation of a receptor-specific ligand with molecules normally restricted to the extracellular space leads to their endocytosis into cells expressing the corresponding ligand-specific receptor. Examples include folate and transferrin conjugated to fluorescent dyes (*7*, *8*). Similarly, binding of specific monoclonal antibodies with affinities for individual cell surface receptors may result in their endocytosis (*9*). However, it remains unclear whether the modification of disparate receptors on the cell membrane by covalently bound molecules [defined here as receptor-adaptor(s)] is sufficient to mediate the endocytosis of adaptor-specific ligands. To test this hypothesis, biotin was covalently attached to proteins on the cell membranes to increase specifically the affinity of those biotin-modified proteins for avidin-containing molecules. Biotin was an ideal adaptor due to its small size, low toxicity in vivo (*10*, *11*) and the well recognized affinity of biotin for avidin (*12*). Remarkably, surface biotinylation resulted in fluorescein-tagged avidin entry into nearly 100% of cultured and primary cells tested compared with no detectable uptake by unbiotinylated cells. No evidence of exocytosis, surface recycling of the fluorescent probe, or growth inhibition was noted. A comparison of biotinylated-receptor and transferrin-receptor targeted polyethylenimine−DNA bioconjugates revealed equivalent transfection efficiencies. These data suggest that molecules covalently attached to proteins expressed on the cell membrane may be

generally useful for mediating the endocytosis of ligands normally confined to the extracellular space.

EXPERIMENTAL PROCEDURES

Cells, Antibodies, and Plasmid DNA. K562 human chronic myelogenous leukemia, the human acute Jurkat T cell leukemia (clone E6-1), and HEL erythroleukemia cell lines were obtained from American Type Culture Collection and cultured in the recommended media supplemented with 10% fetal bovine serum (FBS; Biofluids, Rockville, MD) and with 25 μg/mL gentamicin (Life Technologies, Gaithesburg, MD). Primary hematopoietic cells were obtained from donated blood. Mononucleated cells and enucleated erythrocytes were isolated using Lymphocyte Separation Media (ICN Biomedicals, Aurora, OH) according to the manufacturer's protocol. Primary cells expressing transferrin receptor at high levels were obtained by flow cytometry (*13*). Staining of 10^5 K562 cells with mouse anti-avidin-FITC monoclonal antibody (clone WC19.10, IgG1, Sigma, St. Louis, MO) and control IgG1-FITC (Immunotech, Westbrook, ME) was performed by incubation with 4 μL of antibody in 100 μL of PBS for 30 min at 4 °C. The plasmid pGT encoding for green fluorescence protein was prepared and purified as described elsewhere (*14*). Briefly, pGT was subcloned from the 780 base pairs DNA *Eco*RI/*Not*I fragment encoding eGFP from pEGFP−N1 (Clontech, Palo Alto, CA) inserted into the pGreenLantern-1 vector (Life Technologies, Gaithersburg, MD) digested with *Eco*RI and *Not*I. All chemicals were purchased from Sigma (St. Louis, MO) unless otherwise stated in the text.

Biotinylation and Avidin−FITC Addition. Biotinylation of all cells was performed as follows: 10^6 cells were incubated in a final concentration of 0.5 ng of sulfo-NHS-biotin/cell (Pierce, Rockford, IL) in PBS for 30 min at 4 °C and washed twice with PBS. Avidin or avidin conjugated with fluorescein isothiocyanate (Av-FITC, 0.1 ng/cell) was incubated with the cells in 1 mL of PBS. In the time-course studies, cells labeled with Av-FITC were incubated at 37 °C, and at each time-point, cells were collected, fixed with 2% *p*-formaldehyde, and analyzed by flow cytometry and fluorescence microscopy.

Preparation of PEI−Avidin (PA) Conjugates. Polyethylenimine (PEI; Fluka, Switzerland) of MW 800 kDa was prepared as a 5% w/v hydrochloride salt solution (800 μL of commercial PEI, 7 mL of water, 200 μL of 36% hydrochloric acid). The pH of prepared PEI was 9.2, and the reagent was stored at 25 °C until used in conjugate preparation. Each avidin sample was prepared by dissolving 20 mg of lyophilized avidin in 2 mL of PBS, pH 7.4. To each sample of dissolved avidin was added 218 μL of 20 mg/mL sodium periodate solution, and the sample was wrapped with foil and incubated for 60 min at 25 °C. Since avidin is glycosylated, sodium periodate oxidation allows the introduction of aldehyde residues onto carbohydrates. Next the aldehyde residues can react with amine groups of PEI (Schiff base formation and reductive amination in the coupling buffer). Sodium periodate was dissolved in water (20 mg/mL) and stored at 25 °C protected from light. The reaction was quenched with glycerol followed by gel filtration on Sephadex G-25 superfine (PD10 Pharmacia) column. The resulting 3.5 mL fractions containing protein in PBS, pH 7.4, were used for conjugation with PEI. PEI was added to the avidin fractions at four different molar ratios: (A) 1: 2 (120 mg of PEI in 2.4 mL), (B) 1: 4 (60 mg of PEI in 1.2 mL), (C) 1: 8 (30 mg of PEI in 0.6 mL), and (D) 1: 16 (15 mg of PEI in 0.3 mL). The samples were mixed vigorously for 1 h at 25 °C, and 1 mL of coupling buffer (20 mM Na_3PO_4, pH 7.5, 0.2 M NaCl, and 3 mg/mL $NaCNBH_3$) was added to each sample followed by 1 h incubation. The addition of the coupling buffer was repeated twice at 1 h intervals with a total of 3 mL of coupling buffer added to each sample prior to overnight incubation. Glycine in molar excess quenched the avidin for 1 h at 25 °C. A 10 mm × 100 mm Macro-Prep High S support (Bio-Rad, Hercules, CA) cation-exchange column equilibrated at 20 mM Hepes, pH 7.5, containing 0.5 M NaCl was used to fractionate the samples with the 0.5−3 M NaCl gradient in 20 mM Hepes, pH 7.5, using Gilson HPLC system equipped with protein detection system at 280 and 214 nm. Some protein was eluted in the flow through. The main conjugate fraction of each sample was eluted between 1.3 and 3.0 M salt, pooled, concentrated to 6 mL by ultrafiltration, and dialyzed overnight against 3 × 1 L of PBS, pH 7.4. The avidin content of each conjugate preparation was determined at 280 nm and PEI content by ninhydrin assay (NIN-SOL ninhydrin reagent from Pierce) at 570 nm. The conjugate reactions yielded the following products: (A) 31.2 mg of PEI conjugated to 5.2 mg avidin at the molar ratio of 1:2.0, (B) 12 mg of PEI conjugated to 4.36 mg avidin at the molar ratio of 1:4.36 (PA4), (C) 3.32 mg of PEI conjugated to 2.30 mg of avidin at the molar ratio of 1:8.31 (PA8), and (D) 1.05 mg of PEI conjugated to 1.35 mg of avidin at a molar ratio of 1:15.46 (PA16). The overall yield of these conjugates based on PEI was (A) 26.0%, (B) 20.0%, (C) 11.7%, and (D) 7.0%; based on avidin, the yield was (A) 26.0%, (B) 21.8%, (C) 11.5%, and (D) 6.8%. The conjugates were aliquoted and stored at −80 °C. Gel retardation assay of the PEI conjugates was performed in 1.2% agarose gels as previously described (*15*).

Transfection of Cells. Transfection complexes of DNA with PEI or PEI−avidin (PA) conjugates were prepared as follows. Plasmid DNA was added and mixed gently with PEI or PA conjugates in PBS, in a total volume of 0.5 mL. PEI−DNA or PA−DNA complexes were formed at various molar ratios of PEI nitrogen to DNA phosphate (N:P) as indicated further in the text. Different N:P ratios were prepared by titrating DNA concentrations at a constant PEI concentration or by titrating PEI with the amount of DNA held constant. After 30 min of incubation in 25 °C, 0.5 mL of transfection mixture was added to the cells in 1.5 mL culture medium containing 10% FBS and gently mixed. Cells were biotinylated before transfection using standard procedure at 4 °C and washed with cold PBS. All transfections were performed in 24 well plates (Costar, Cambridge, MA) with 5 × 10^5 cells/well. After 4 h of incubation with the transfection complexes, 1 mL of fresh culture media containing 15% FBS was added to each well. Transfection was assessed based on GFP expression by fluorescence microscopy and flow cytometry 48 h later.

Transfection using Transferrin−PEI (TfPEI Kit, Bender MedSystems, Vienna, Austria) and with DMRIE-C Reagent (GIBCO BRL, Life Technologies, Grand Island, NY) was done according to manufacturer's instructions.

Flow Cytometry and Fluorescence Microscopy. Flow cytometry analyses were performed using an EPICS ELITE ESP flow cytometer (Coulter, Hialeah, FL). In each experiment, 10 000 cells were analyzed using argon laser excitation and 525 nm versus 575 nm band-pass emission filters for fluorescein (FITC), green fluorescent protein (GFP), and phycoerythrin (PE) detection. Fluo-

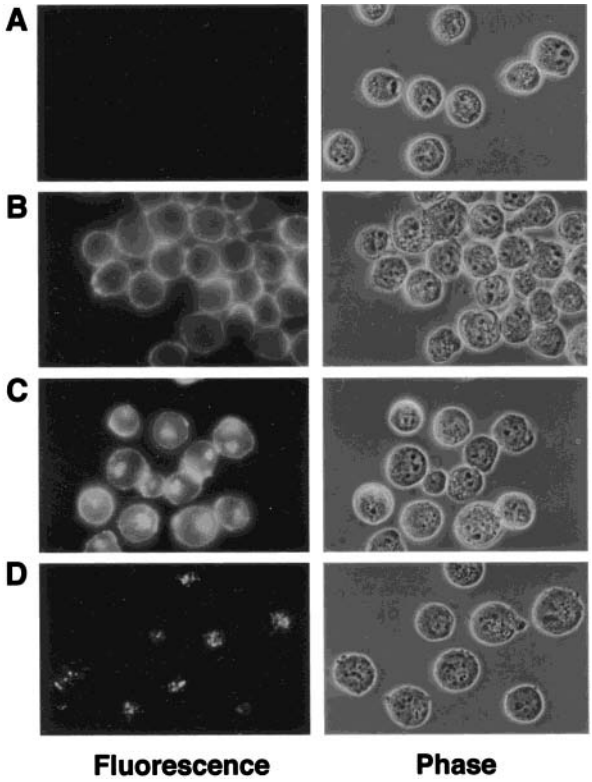

Figure 1. Addition of avidin-FITC to biotinylated K562 cells. Matching fluorescence (left panels) and phase (right panels) microscopy images of biotinylated cells incubated at 37 °C after addition of fluorescent avidin are shown (100× objective). Untreated biotinylated cells (A), and cells treated with avidin-FITC and observed immediately (B), after 30 min (C), and after 24 h (D) were compared. Each experiment was repeated several times with similar results.

rescence microscopy of cells was carried out using an Axiophot microscope and standard filter sets (Zeiss, Germany).

RESULTS

Entry of Fluorescein-Labeled Avidin into Cultured Cell Lines and Primary Hematopoietic Cells. Fluorescein-labeled avidin (Av-FITC) was used to examine kinetics of binding and possible internalization of avidin into biotinylated K562 leukemia cells. Untreated K562 cells showed very little autofluorescence or nonspecific binding of Av-FITC as assessed by flow cytometry and fluorescence microscopy (Figure 1A). When Av-FITC was added to biotinylated K562 cells, 100% of cells became fluorescently labeled. Av-FITC was well dispersed on the cell surfaces with several areas of increased fluorescence (Figure 1B). After 30 min, fluorescein was detected inside endosomal compartments in all the cells (Figure 1C). The fluorescence gradually shifted from the cell surface to the cell interior within the next 24 h as demonstrated by comparing the fluorescence and phase images of the same microscopic field (Figure 1D). Once endocytosed, the fluorescein remained inside the cells without evidence of recycling to the cell surface, and no exocytosis of fluorescent complexes was detected. Other biotinylated cell lines including HEL and Jurkat cells exhibited a nearly identical pattern and time-course of Av-FITC endocytosis under the same conditions, and no internalization was observed when the cells were incubated at 4 °C.

In the absence of biotinylation, incubation of freshly isolated peripheral blood cells with Av-FITC did not increase their fluorescence to detectable levels (Figure 2A). We next biotinylated separate pools of erythrocytes and mononuclear cells and examined Av-FITC uptake in those cells. Immediately upon the addition of Av-FITC and after 24 h, 100% of the biotinylated erythrocytes exhibited intense fluorescence evenly distributed only on their surfaces (Figure 2B). Unlike erythrocytes, after 24 h, the pattern of fluorescence among the biotinylated mononuclear peripheral blood cells was similar to that observed in cell lines with nearly 100% of nucleated cells internalizing the fluorescent label (compare Figure 2C and Figure 1D). A comparison of brightfield and fluorescent views of individual cells (Figure 2, bottom panels) revealed a punctuate cytoplasmic distribution consistent with endosomal localization of the fluorescein. The flourescent label was also retained at a low level on the plasma membrane of several nucleated blood cells compared with no surface label retained on the K562 cells after 24 h (Figure 1D).

Flow cytometry was used to examine whether avidin cross-linking affected the rate of avidin and biotin clearance from the cell surface or the growth of those cells. Untagged avidin was added to biotinylated cells at time = 0 and fluorescent anti-avidin antibodies were used to measure the amount of avidin remaining on the surface over time. The surface level decreased by 20% within 15 min, and only 50% of avidin-bound biotin remained after 2 h (Figure 3A, dotted line). In contrast, biotin was cleared from the cell surface at a much slower rate in the absence of avidin cross-linking (Figure 3A, solid line). Biotin-mediated endocytosis of the avidin caused no significant decrease in cell growth as measured by cell counts (Figure 3B), and no change in cell viability was detected by dye exclusion.

PEI−Avidin Conjugates Condense DNA and Transfect Biotinylated Hematopoietic Cells. We chose the model of DNA transfection to study the biotin-mediated endocytosis of more complex avidin bioconjugates designed for the delivery of biologically active molecules to the nucleus. Polyethylenimine (PEI), a DNA condensing agent that may enhance endosomal escape, was conjugated with avidin. Green fluorescent protein (GFP) encoded plasmid DNA provided a specific marker of endosomal escape and trafficking of plasmid DNA to the nuclear compartment. Another advantage of this transfection model for our study was the low transfection efficiency of PEI−DNA among hematopoietic cells unless the PEI−DNA complexes were delivered by receptor-mediated endocytosis (*15*). Four PEI−avidin conjugates were prepared with increasing content of avidin as described in the Experimental Procedures. PA2, PA4, PA8, and PA16 define conjugates with avidin to PEI molar ratios of 2, 4, 8, and 16, respectively. The gel retardation assay showed a similar profile of cationic binding for PEI and the PEI−avidin conjugates as a function of PEI nitrogen:DNA phosphate (N:P) molar ratios. Consistent with the p*K* profile of PEI, approximately one of six nitrogen atoms in PEI is protonated at physiological pH (*16*). Our gel retardation assay demonstrated that cationic binding of PEI or PEI−avidin completely neutralized the anionic charge of plasmid DNA and prevented electrophoretic mobility at N:P ratios above 3.

Gene-transfer efficiencies of PEI−avidin conjugates were measured in K562 cells by flow cytometry. GFP-expressing cells were defined as those cells having a fluorescence at levels at least 2 standard deviations above the negative control. Optimization of transfecting conditions was performed based on avidin content in the

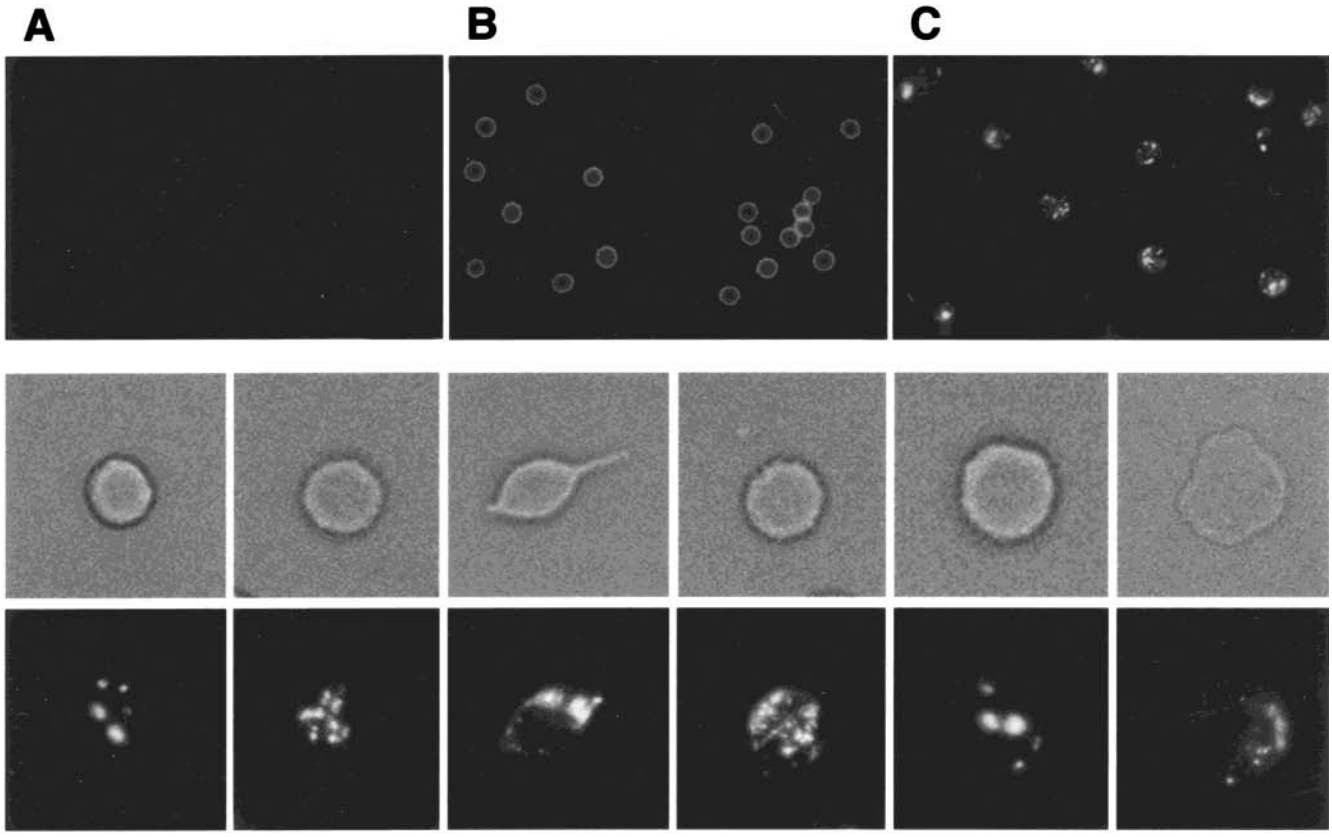

Figure 2. Examination of human peripheral blood cells. Cells were obtained from blood donations, biotinylated, and photographed 24 h after addition of avidin-FITC. Upper three panels show fluorescence microscopy of unbiotinylated, unseparated peripheral blood cells (A), biotinylated erythrocytes (B), and biotinylated mononuclear cells (C). (Lower panels) Enlargement of six individual mononuclear cells are shown in matching brightfield and fluorescent views for comparison.

conjugate, molar ratio of PEI nitrogen to DNA phosphate (N:P), cell number, and serum content. A comparison of gene-transfer efficiencies among the four conjugates was then performed. PA4 conjugates had the highest transfection efficiency when compared with PA2, PA8, and PA16 (Figure 4A). PA4 conjugates were most efficient at a N:P ratio of 6.4 (Figure 4B). At higher N:P ratios, increased cell toxicity was noted as a function of cation excess as reported elsewhere (*15, 16*). Reducing the amount of PA4−DNA added to cells resulted in a linear reduction in the transfection efficiency as measured by the percentage of cells expressing GFP after 48 h.

To determine the relative efficiency of biotin-mediated endocytosis for DNA transfection among hematopoietic cells, PA4 transfection efficiency was compared with unconjugated PEI and transferrin−PEI bioconjugates, as well as a lipid-based reagent DMRIE-C (Figure 5). Transfection of the cell lines with PA4 and trasferrin−PEI resulted in a significant increase in GFP expression when compared to PEI alone and a severalfold increase in transfection efficiency in comparison to lipid-based DMRIE-C. Incorporation of avidin into PEI significantly increased the transfection efficiency on biotinylated K562, Jurkat, and HEL cells to the level achieved with transferrin−PEI (15−20%). A significant increase in biotin-targeted transfection efficiency was detected among HEL cells (20 ± 1.9% PA4 versus 11.8 ± 1.0% transferrin−PEI). In contrast to the malignant cells, significant transfection of terminally differentiated or proliferating hematopoietic cells expressing the transferrin receptor at high levels was not demonstrable with any of the vectors (Figure 5, striped; dotted bars).

PEI−Avidin Mediated Gene Transfer into Biotinylated Cells Is Blocked by Free Avidin or Biotin. Free avidin or biotin was added to PA4 transfection mixtures in order to determine if PEI−avidin-mediated gene transfer required specific binding to the biotin-modified receptors. After formation of PA4−DNA complexes, 0.5 mg/mL biotin was added to the transfection mixture and incubated for 30 min. Alternatively, 10 μg/mL free avidin was added to the biotinylated cells before the addition of PA4−DNA complexes. As shown in Figure 6, free biotin or avidin significantly blocked PA4-mediated gene transfer in all the cell lines examined.

DISCUSSION

One mechanism cells use to determine which molecules are endocytosed is the expression of high-affinity receptors on their external membranes. In this way, nutrients such as iron, folic acid, and lipoproteins enter cells to meet metabolic needs while other molecules not useful to the cell are excluded. When a single receptor binds one or more ligands, the number of binding sites per receptor and the number of receptors per cell is limited in order to regulated ligand entry (*17, 18*). Receptor-binding specificity also plays a large role in restricting the tropism of several viruses (*19*). Here we have demonstrated that covalently added adaptor molecules can modify the cell surface in order to specifically mediate the endocytosis of extracellular elements. We used biotin as a receptor-adaptor due to the well-recognized interaction of biotin with avidin and the lack of avidin-specific receptors on human cells. The covalent addition of a sulfo-*N*-hydroxysuccinimide (sulfo-NHS) group to biotin permits conjugation to free amine groups, primarily the epsilon amine group of lysine residue in proteins. The receptor-mediated nature of avidin endocytosis was confirmed by the ability of free avidin or biotin to block

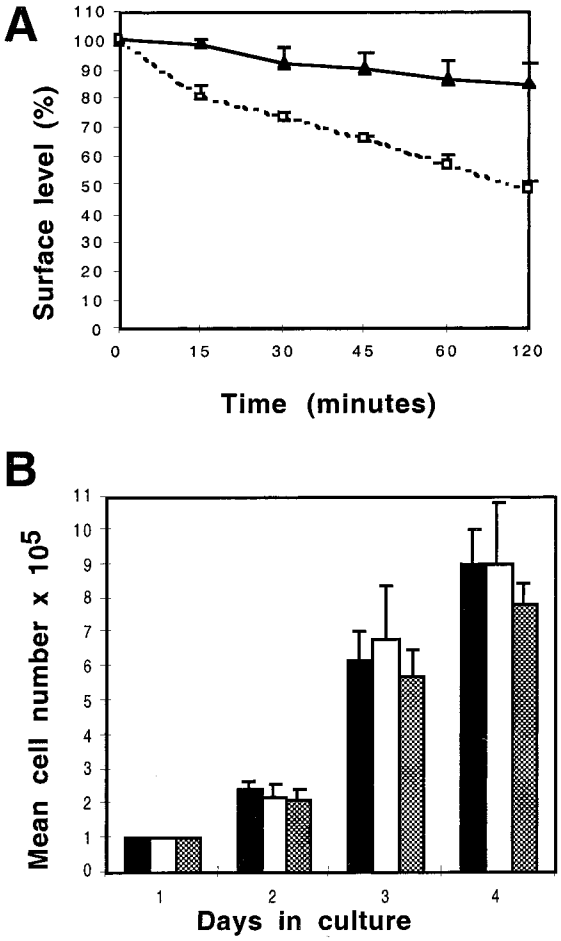

Figure 3. Kinetics of biotin and avidin clearance and cell growth before and after avidin addition. (A) Flow cytometry was used to measure the clearance of avidin and biotin from the cell surface. (solid line) K562 cells were biotinylated and the amount of biotin remaining on the cell surface was measured by relative fluorescence after the addition of avidin-FITC. (dotted line) Unlabeled avidin was added to biotinylated K562 cells at time = 0 and the clearance of avidin was measured using anti-avidin antibodies. The data points show the mean fluorescence values ± standard deviation of triplicate experiments with time = 0 representing 100%. (B) Following biotinylation and incubation with avidin-FITC, cell growth was measured on 3 successive days. Numbers of cells are means of triplicate experiments with standard deviation bars. (solid bars) control K562 cells, (open bars) biotinylated K562 cells, (hashed bars) biotinylated K562 cells incubated with avidin.

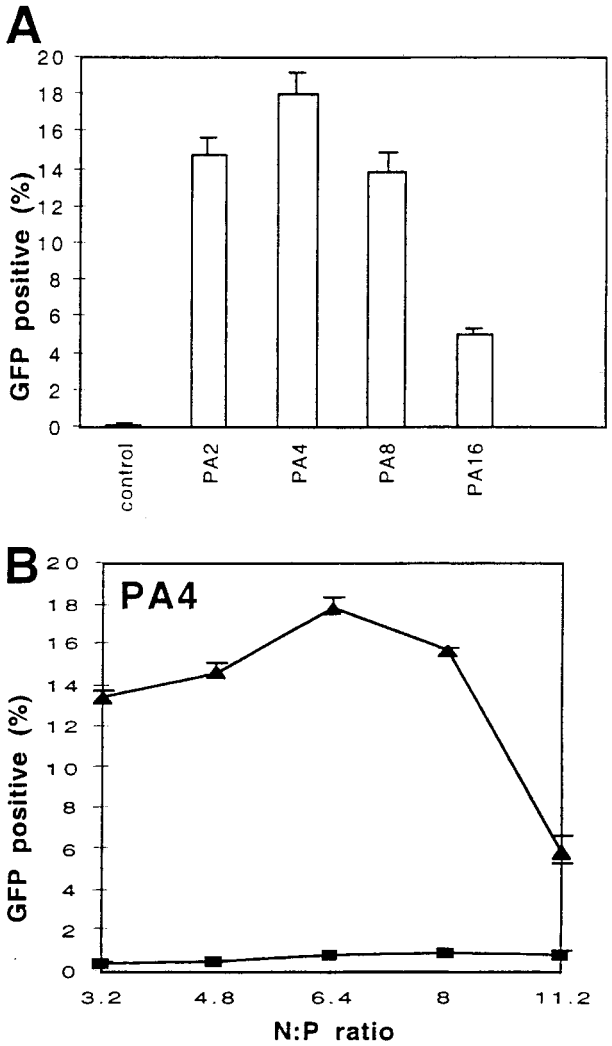

Figure 4. Transfection efficiency of PEI−avidin conjugate variants. (A) Transfection efficiency of PEI−avidin (PA) conjugates at increasing molar ratios of avidin: PA2, PA4, PA8, and PA16. (B) efficiency of PA4 in function of N:P ratio. PA4 was tested on biotinylated K562 cells (triangles) and compared to experiment with PEI alone on K562 cells (squares). The same experiment was performed for all PA conjugates. PEI or PA conjugates were mixed with 10 μg of DNA (pGT) in 0.5 mL of PBS at a growing N:P ratios as indicated on the figure and added to 5×10^5 cells/well in 1.5 mL culture medium (DMEM containing 10% serum), in a 24 well plate. After 4 h, 1 mL of DMEM containing 15% FBS was added to the cells. Flow cytometry was used to determine the percentage of cells expressing GFP 48 h after transfection. Values are shown as means ± standard deviation of triplicate transfections.

the process. The nonspecificity of the biotinylation reaction for free amines on the cell surface additionally suggests that membrane elements not classically associated with endocytosis may be adapted for this purpose. Avidin and biotin have been used extensively in the design of bioconjugates due to their remarkable affinity ($K_a = 10^{15}$ M^{-1}), low cost, and availability (*20*). Surface biotinylation of human red blood cells has been used in humans as an alternative to ^{51}Cr in labeling studies (*21*). Biotinylation has little effect on the stability of red blood cells in vivo, and surface biotinylation rarely modifies their antigenicity as measured by serological assays (*22*). However, internalization of the biotin molecules is prevented by the inability of erythrocytes to endocytose their membrane (*23*) (Figure 2B). The addition of avidin to biotinylated red blood cells also increases their immunogenicity due to their inability to clear bound avidin from the surface (*24*). In marked contrast with erythrocytes, nucleated cells rapidly endocytose the surface avidin as demonstrated here.

The dissociation constant of avidin−biotin is several powers of magnitude higher than that of naturally occurring receptor ligand pairs even at very low pH (*25*). Due to the high affinity and stability of the avidin−biotin bond, we expected a significant portion of the endocytosed avidin to be continuously recycled to the cell surface. However, within the limits of detection, the surface staining pattern of fluorescent avidin suggests most of the avidin was removed from the cell surface within 24 h (Figures 1 and 2).These findings probably reflect the ability of nucleated cells to redirect cross-linked receptors from the recycling pathway to the lysosomal compartment. This redirection away from recycling pathways and lysosomal retention of multivalent ligands has been demonstrated in the case of homodimerric cross-linking of Fc receptors (*26*) as well as oligomerization of transferrin receptors (*27*). The tetravalency of avidin for biotin

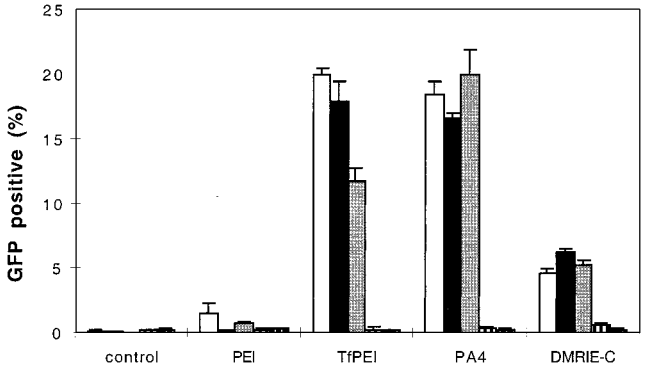

Figure 5. Comparison of PEI−avidin transfection efficiency in hematopoietic cells with other transfection reagents. Transfection efficiency using PEI, Transferrin−PEI, PEI−avidin (PA4), or DMRI-C with pGT plasmid was compared under similar conditions in K562 cells (open bars), Jurkat cells (solid bars), HEL cells (dashed bars), primary mononucleated cells from buffy coat (striped bars) and in proliferating primary erythroid cells demonstrating extremely high level transferrin receptor expression (dotted bars). Efficiency is represented as percentages of GFP expressing cells assessed by flow cytometry from three independent experiments done in duplicate.

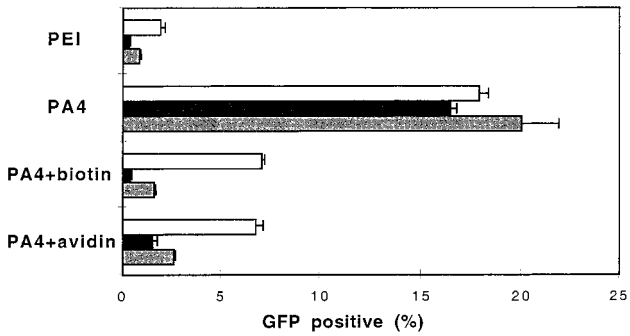

Figure 6. Transfection efficiency of PEI−avidin in biotinylated cells in the presence of excess free biotin or avidin. A total of 8 μg of PEI alone or in PEI−avidin (PA4) complexed with 10 μg of pGT (N:P ratio = 6.4) with and without addition of free biotin or avidin was used to transfect biotinylated K562 cells (open bars), Jurkat cells (solid bars) and HEL cells (dashed bars). Additional biotin was added to 0.5 mg/mL final concentration to preformed PEI−DNA or PA4−DNA complexes, the mixture was incubated for 30 min at 25 °C and used to transfect cells in the medium supplemented with 0.5 mg/mL biotin. Avidin was added to the 10 μg/mL concentration to cells in media and incubated for 30 min at 25 °C before transfection with PEI−DNA or PA4−DNA containing 10 μg/mL avidin. Forty-eight hours later, the percentage of GFP expressing cells was assessed by flow cytometry and is shown as means of triplicate studies ± standard deviation.

results in the clustering of biotinylated proteins on the cell surface (*28*). Therefore, trafficking of avidin−biotin protein complexes to lysosomal compartments may serve as a default pathway for the clearance of irreversibly clustered proteins from the cell surface. Endocytosis triggered by cross-linking of membrane domains containing glycosylphosphatidyinisitol-anchored receptors may also be involved in this process (*29*). Our study has not determined whether specific endocytic elements, such as clathrin, or specific signaling cascades are required for biotin-mediated endocytosis to occur.

In addition to the study of endocytosis itself, receptor adaptation on nucleated cells may be useful for targeting bioconjugates into cells. Immense efforts have recently been directed toward increasing the efficiency of gene transfer and other technologies by targeting membrane components classically associated with receptor-mediated endocytosis. Among nonviral vectors, folate-targeted conjugates (*30*), transferrin conjugates (*15*), galactose conjugates (*31, 32*), conjugates with integrin binding motifs (*33*), and antibody-coupled conjugates (*34*) have been developed for this purpose. Despite recent advances in targeting strategies, transfection of targeted nonviral vectors generally does not result in high-level gene expression in a majority of cells**.** Our data suggest the generally low transfection efficiency in this setting may be due to cell type specific barriers that are postendocytotic and not specifically related to the cell cycle. Additional explanations include the low sensitivity of GFP as a marker of gene transfection (*35*), and the physical state of the DNA−bioconjugate complexes (*32*). In the peripheral blood mononuclear cells studied here, little is known about the catabolism of transferred plasmid DNA, cytoplasmic trafficking after endosomal release, or nuclear localization. Despite the low level of effective gene transfer in these cells, the extremely high efficiency of biotin-mediated endocytosis in primary cells suggests receptor adaptation may prove useful for the entry of other therapeutic bioconjugates or the targeted clearance of extracellular toxins. Conceptually, receptor-adaptation should provide a generic means for delivering bioconjugates across tissue and species boundaries.

ACKNOWLEDGMENT

We thank Dr. A. Schechter for critical reading of the manuscript, Dr. A. Gubin for his assistance in the preparation of plasmid DNA, and J. Muthoni Njoroge for technical assistance with flow cytometry.

Rapid Esterification of Nucleosides to Solid-Phase Supports for Oligonucleotide Synthesis Using Uronium and Phosphonium Coupling Reagents

Richard T. Pon,*,† Shuyuan Yu,† and Yogesh S. Sanghvi‡

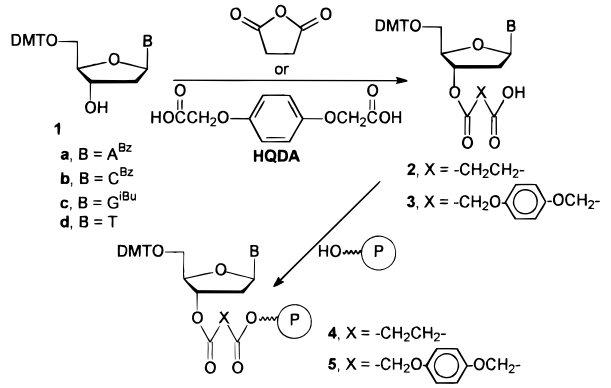
Department of Molecular Biology and Biochemistry, University of Calgary, 3350 Hospital Drive N.W., Calgary, Alberta, Canada T2N 4N1, and Isis Pharmaceuticals, Development Chemistry Department, 2280 Faraday Avenue, Carlsbad, California 92008. Received May 24, 1999; Revised Manuscript Received August 4, 1999

Nucleosides can be esterified to solid-phase supports using uronium or phosphonium coupling reagents and a coupling additive, such as 1-hydroxybenzotriazole (HOBT), 7-aza-1-hydroxybenzotriazole (HOAT), *N*-methylimidazole (NMI), or 4-(dimethylamino)pyridine (DMAP). However, DMAP was far superior to other additives and high nucleoside loadings (up to 60 μmol/g) and rapid coupling reactions ($\leq$10 min) were possible. Hydroxyl-derivatized CPG was attached to nucleosides with 3′-succinyl or 3′-hydroquinone-*O*,*O*′-diacetic acid (HQDA or *Q-Linker*) carboxyl groups through a *primary* ester linkage. Alternatively, supports derivatized with succinic acid or the *Q-Linker* were attached directly to the 3′-OH group of nucleosides through a *secondary* ester linkage. Uronium reagents (HATU or HBTU) gave the best results with the HQDA linker arm, while the bromophosphonium (BrOP or PyBrOP) reagents were best with the succinyl linker arm. In all cases, the coupling reactions were much faster than previous methods using carbodiimide coupling reagents. The ease and speed of the reaction make this support derivatization procedure suitable for automated in situ couplings on DNA synthesizers.

INTRODUCTION

We have introduced a new dicarboxylic acid linker arm (*1*), hydroquinone-*O*,*O*′-diacetic acid (HQDA[1] or *Q-Linker*), which allows oligodeoxynucleotides to be cleaved from the support approximately 30 times faster than a traditional succinic acid linker arm (i.e., 2 min vs 60 min). We have also developed very fast ($\leq$60 s) and efficient (only 0.05 mmol of nucleoside required/g of support) coupling procedures for attaching the first nucleoside to amino derivatized solid-phase supports (*2*). Recently, we have used these improvements to recycle and reuse hydroxyl derivatized solid-phase supports multiple times, without having to remove the support from the synthesis column (*3, 4*).

The support recycling required *ester* attachments, which were more easily cleaved than the usual *amide* linkages. Coupling through ester linkages is also important when cellulose (*5, 6*), soluble poly(ethylene glycol) (*7*), poly(ethylene glycol)-polystyrene (*8, 9*), oxime (*10*), photolabile (*11*−*13*), or other hydroxyl (*14*) supports are used. There has also been interest in ester linkages for the synthesis of alcohol peptides (*15*−*17*), depsipeptides (*18, 19*), oligonucleotide−peptides (*20*), and combinatorial libraries (*21*). Unfortunately, the reduced nucleophilicity of hydroxyl groups relative to amino groups makes coupling through ester linkages more difficult, and so the coupling reactions are longer and often produce lower support loadings. This problem becomes even more pronounced when coupling must be made through a secondary alcohol (*22, 23*) such as the 3′-OH group in nucleosides. Therefore, we wanted to find coupling conditions which would form the required ester linkages faster and more efficiently than the carbodiimide coupling reagents previously used (*22*−*27*).



We investigated a number of commonly used uronium and phosphonium coupling reagents. These reagents have become very popular for peptide (*28, 29*) and PNA synthesis (*30*−*32*) because they are stable, nonhygroscopic, and easy to handle. Similar amide linkage formation in oligonucleotide synthesis has also been performed (*33*−*36*). Recently, PyBOP[1] and photolabile protecting groups have allowed functionalization of oligonucleotides while still immobilized on the support (*37*). Various phosphonium salt reagents have also been used to activate phosphate (*38*), phosphonate (*39, 40*) and phosphorothioate/dithioate compounds (*41, 42*). However,

ester bond formation using these reagents has not been as common. BOP and PyBOP have been used to prepare primary, secondary, *tert*-butyl, or cyclic esters of amino acids (*43*−*45*), and 2,2,2-trihaloethyl esters have been converted into other esters by phosphonium salts generated in situ (*46*). Occasionally, HATU (*47*), HBTU (*48*), and TBTU (*49*) have also been used to attach amino acids to hydroxyl resins for peptide or PNA synthesis.

In this report, we describe conditions for efficient and rapid coupling of nucleosides, via succinyl or hydroquinone-*O*,*O*′-diacetyl ester linkages, to solid-phase supports using a number of commonly available uronium and phosphonium coupling reagents in acetonitrile solution. Conditions for coupling through both primary (Scheme 1) and secondary ester linkages (Scheme 2) have been developed using 1 equiv of DMAP as a coupling additive. These esterification reactions are much faster (1−60 min) than previous ester coupling reactions (*22, 23, 43*−*49*), yield excellent nucleoside loadings (up to ∼60 μmol/g), and can be readily implemented on automated DNA synthesizers.

MATERIALS AND METHODS

Materials and General Methods. LCAA-CPG (120−200 mesh, 500 Å, 90−120 μmol/g NH_2 groups) was obtained from CPG Inc. (Lincoln Park, NJ). Hydroxyl-CPG (*4*) and succinyl-CPG (*22*) were prepared as previously described. HBTU and HOBT were from Quantum Biotechnologies (Montreal, PQ, Canada), HATU and HOAT were from Perseptive Biosystems (Framingham, MA), BOP and HBPyU were from Sigma Chemical (St. Louis, MO), PyBOP, PyBrOP, TNTU, and TPTU were from Chem-Impex Intl. (Wood Dale, IL), BrOP and HBPipU were from Fluka Chemie (Buchs, Switzerland), and TOTU was from Aldrich Chemicals (Milwaukee, WI).

Caution. Precautions must be taken to avoid skin exposure to any coupling reagent since allergic sensitivity may develop in users.

[a] Nucleosides **2a**−**c**, coupling reagents, and coupling additives were used at a concentration of 0.05 M in acetonitrile with a wait step of 600 s during the coupling reaction. [b] Nucleoside **2d** required 1:1 acetonitrile/dichloromethane for solubility. [c] Loading determinations by trityl assay are ±5%.

Nucleoside-3′-*O*-succinates were purchased from Sigma Chemical and nucleoside-3′-*O*-hydroquinone-*O*,*O*′-diacetic acid hemiesters were prepared as previously described (*1*) and used as a mixture of both hemi- and diesters. DIEA was distilled and stored over molecular sieves and acetonitrile was freshly distilled from CaH_2. Quantitative analysis of dimethoxytrityl colors was performed using 5% dichloroacetic acid/1,2-dichloroethane (±5% accuracy). Synthesis, cleavage, and deprotection of trial oligonucleotides (data not shown) proceeded without modification.

Primary Esterification. OH-CPG (0.5 g), nucleoside **2** or **3** (0.1 mmol), HBTU (0.1 mmol), and coupling additive (DMAP, HOBT, HOAT, or NMI, 0.1 mmol) were combined in a septum-sealed 10 mL vial. DIEA (3 mmol, 520 μL) and acetonitrile (2.48 mL) were added, via syringe, and the reaction shaken at room temperature. Aliquots (∼10−20 mg) were removed at various intervals, washed with CH_2Cl_2, MeOH, and CH_2Cl_2, dried, and the progress of the reaction was determined by trityl analysis (*27*). The CPG was filtered off and washed with CH_2Cl_2, MeOH, and CH_2Cl_2. The results for nucleosides **2a**−**d**, using HBTU/HOBT and coupling times of either 10, 30, or 60 min were, for **2a**, 7, 14, and 20; for **2b**, 6, 12, and 16; for **2c**, 10, 20, and 22; and for **2d**, 13, 28, and 40 μmol/g. Other coupling results are shown in Figures 1 and 2.

Automated primary esterification reactions (see Table 1) were performed on a PE Biosystems 394 DNA synthesizer as previously described for primary amide coupling reactions (*2*). However, OH-CPG was used instead of LCAA-CPG, equal nucleoside and coupling reagents concentrations (0.05−2 M as described in the discussion), a 5 min capping step was included to acetylate unreacted hydroxyl groups on the support, and in the case of nucleoside **2d**, 1:1 acetonitrile/CH_2Cl_2 was required for solubility.

Preparation of HQDA-CPG 7. LCAA-CPG (1.0 g), HQDA (0.4 mmol, 90 mg), DMAP (0.38 mmol, 46 mg), and HBTU (0.38 mmol, 144 mg) were combined in a glass screw capped vial or flask and then DIEA (0.8 mmol, 140 μL) and acetonitrile (10 mL) were added via syringe. The reaction was shaken at room temperature (2 h). The support was filtered off and washed with acetonitrile, MeOH, and finally CH_2Cl_2. After drying, the amount of

[a] Loading determinations by trityl assay are ±5%. [b] 0.05 M **1d** and DIEA solution was used with 0.05 M coupling reagent/DMAP solution. [c] The carboxyl loadings of the succinylated **6** and *Q-Linker* **7** supports were respectively, 90 and 40 μmol/g.

HQDA on the support (~40 μmol/g) was determined by derivatizing a small aliquot with *N*-monomethoxytrityl-6-amino-1-hexanol (*1*) followed by trityl analysis.

Secondary Esterification. 5′-Dimethoxytritylthymidine **1d** (0.1 mmol, 54 mg), HATU or HBTU (0.1 mmol), DMAP (12 mg), and carboxyl-CPG **6** or **7** (0.25 g) were combined in a 4 mL glass vial. Acetonitrile (1 mL) was added and the mixture shaken at room temperature. Aliquots (~10−20 mg) were removed at various intervals, washed with CH_2Cl_2, MeOH, and CH_2Cl_2, dried, and the progress of the reaction was determined by trityl analysis. The loadings obtained on succinylated support **6** after coupling times of 5, 15, 30, and 60 min were HATU/DMAP, 34, 47, 53, and 63; HBTU/DMAP, 45, 51, 61, and 59 μmol/g. The loading obtained on the *Q-Linker* support **7** after 2 h was 43 μmol/g.

The above reaction was also performed with succinylated support **6** using one-half the amount of nucleoside, and HATU/DMAP or HBTU/DMAP. The loadings obtained after coupling times of 5, 15, 30, and 60 min were, for HATU/DMAP, 17, 21, 22, and 23 and, for HBTU/DMAP, 15, 17, 18, and 19 μmol/g.

Automated secondary esterification reactions were performed as above, except a 0.05 M solution of **1d** and DIEA was used as the nucleoside reagent and carboxyl-CPG supports **6** and **7** were used instead of OH-CPG (see Table 2).

RESULTS AND DISCUSSION

Coupling through Primary Ester Linkages. The hydroxyl-derivatized solid-phase support (OH-CPG) was prepared from long-chain alkylamine controlled pore glass (LCAA-CPG), succinic anhydride, and 6-aminohexan-1-ol as previously described (*4*). Although, our initial experiments with this support, *Q-Linker* nucleosides **3a**−**d,** and an HBTU/HOBT coupling reagent were satisfactory, we found that this method did not work well with the 3′-O-succinylated nucleosides **2a**−**d**. For example, the *Q-Linker* nucleosides gave loadings of 30−50 μmol/g while the 3′-O-succinylated nucleosides produced only 6−13 μmol/g during a 10 min long coupling reaction.

Then we used DMAP as an additive, instead of HOBT, to improve coupling performance. A catalytic amount of DMAP is commonly used with carbodiimide coupling reagents (*22*−*27*), and recently, we found that DMAP greatly increases the speed and efficiency of amide formation with uronium or phosphonium coupling reagents (*2*). However, there have only been a few other reports of DMAP used with uronium (*47*−*50*) or phosphonium (*46*, *51*) coupling reagents. This is because DMAP is known to cause racemization during long amino acid couplings (*52*) as well as partial loss of base-sensitive Fmoc protecting groups (*45*). However, in oligonucleotide synthesis, these concerns are not an issue. Instead, it is important that the reagents not cause base modifications, such as those previously reported with sulfonic acid coupling reagents (*53*, *54*) or acetic anhydride/DMAP capping reagents (*55*). Although, only the first nucleoside and not subsequent bases are exposed to the uronium/phosphonium salt and DMAP coupling conditions, we looked for base modifications by treating nucleoside samples (**1c**−**d** or **3c**−**d)** with an excess (2 equiv) of coupling reagent (HBTU, BrOP, or PyBrOP) and DMAP in either the presence or absence of phenoxyacetic acid (2 equiv). Phosphorothioate oligonucleotide 20-mers made from supports derivatized with the HBTU/DMAP reagent were also analyzed by CE, AX-HPLC, and MS (*3*). In both cases, no unexpected products were detected (results not shown). It is also noteworthy that no base modifications have been reported in any previous applications of uronium or phosphonium coupling reagents in oligonucleotide synthesis (*33*−*35*, *38*, *40*−*42*) or PNA synthesis (*30*−*32*, *47*).

To evaluate the effect of DMAP as an additive, identical coupling reactions using the succinylated nucleosides **2a** and **2d** were setup with HBTU solutions (0.033 M) containing either HOBT or DMAP and samples were removed for trityl analysis at various times. In both cases, the DMAP coupling reactions were much better than the HOBT reactions (Figure 1a). The nucleoside

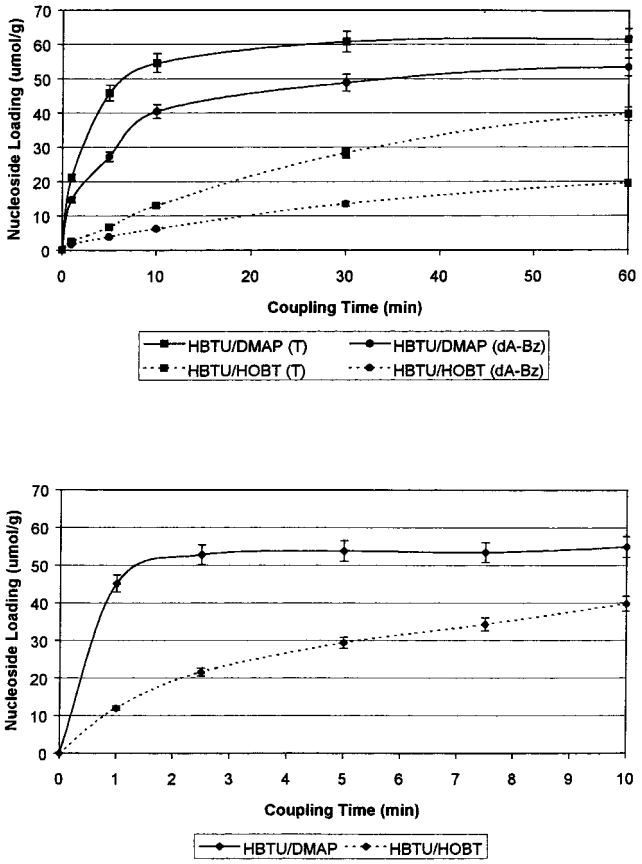

Figure 1. Comparison of HOBT (1 equiv) and DMAP (1 equiv) as additives in the coupling of nucleoside-3′-carboxylates to OH-CPG through primary ester linkages. 0.2 mmol/g of nucleoside and coupling reagent were used at a concentration of 0.033 M. (a) Nucleosides **2a** and **2d** with a 3′-succinyl linker arm. (b) Nucleoside **3d** with a 3′-HQDA linker arm.

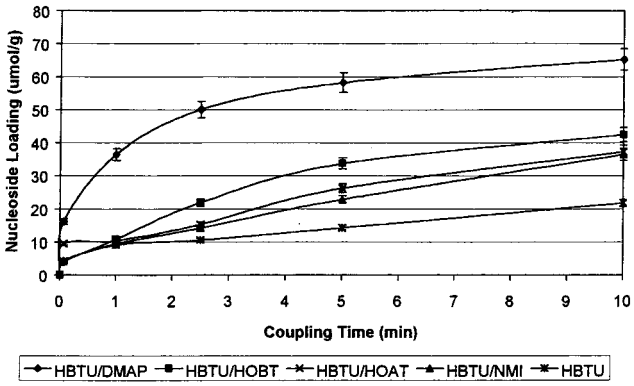

Figure 2. Comparison of different coupling additives in the coupling of 0.1 M nucleoside-3′-*O*-HQDA **3d** through a primary ester linkage to OH-CPG by HBTU.

loadings obtained with DMAP were 1.5−2 times greater than with HOBT and these loadings were obtained in only 10 min instead of 60 min.

A similar experiment with the *Q-Linker* nucleoside **3d** was also performed (Figure 1b). In this case, the *Q-Linker* nucleoside reacted much faster than the succinylated nucleosides using either HOBT or DMAP. However, the DMAP reaction was still much better. For example, after only a 1 min coupling, the respective loadings for the HOBT and DMAP reactions were 12 and 45 μmol/g.

The rapid couplings observed were ideal for implementation on an automated DNA synthesizer. Automation allows different coupling reagents and additives to be easily compared under identical conditions and allows inexpensive underivatized supports to be used for oligonucleotide synthesis (*2*). Therefore, an automated PE Biosystems 394 DNA synthesizer was programmed to fill a synthesis column with a mixture of nucleoside and coupling reagent solutions (4.0 s), wait a defined time for coupling (60−600 s), acetylate unreacted hydroxyl groups (300 s), and then continue with oligonucleotide synthesis. The nucleoside loading was determined by measurement of the trityl color released during detritylation (*27*).

In the first set of automated coupling experiments, the effect of different additives on the esterification of the *Q-Linker* nucleoside **3d** to OH-CPG using HBTU was investigated. Five identical sets of experiments were performed using either 0.1 M HBTU, HBTU/DMAP (1:1), HBTU/NMI (1:1) HBTU/HOBT/DIEA (1:1:1), or HBTU/HOAT/DIEA (1:1:1) and coupling times of up to 10 min. The results (Figure 2) showed that HBTU alone could produce some esterification (22 μmol/g) to the *Q-Linker* after 10 min. However, inclusion of 1 equiv of either NMI, HOAT, or HOBT with the HBTU almost doubled the nucleoside loading (37−42 μmol/g) within the same coupling time. However, a remarkable increase in the speed and amount of esterification was obtained when DMAP was used. Approximately the same nucleoside loading (37 μmol/g) was obtained using DMAP for 1 min, as produced in 10 min with either NMI, HOAT, or HOBT. Coupling for 10 min with DMAP produced more than three times the loading (65 μmol/g) as HBTU alone and ∼1.5 times the loading of the other three additives.

In a second set of experiments, the coupling efficiency of the four *Q-Linker* nucleosides **3a**−**d** with either 0.075 M HBTU/DMAP or 0.2 M HBTU/HOBT was compared (10 min coupling in each case). The average loading for the four nucleosides using 0.075 M HBTU/DMAP was 66 μmol/g, while the average loading using 0.2 M HBTU/HOBT was only 46 μmol/g. Therefore, even with more than twice the reagent concentration, the HBTU/HOBT coupling reagent was less satisfactory than HBTU/DMAP.

Coupling experiments were also performed with 0.075 M solutions of *Q-Linker* nucleoside **3d**, DMAP, and either HATU, HBTU, BrOP, or PyBrOP. These experiments showed that the uronium reagents were slightly better (69−71 μmol/g) than the bromophosphonium reagents (53−56 μmol/g) when used with a *Q-Linker* nucleoside.

Finally, the automated primary esterification experiments were performed using OH-CPG, and 0.05 M solutions of 3′-succinylated nucleosides **2a**−**d**, DMAP, and 11 coupling reagents (Table 1). When the results for the 3′-succinylated nucleoside **2a** were compared, the best coupling reagents were the bromophosphonium reagents BrOP and PyBrOP. These two reagents produced significantly higher nucleoside loadings (47−57 μmol/g) than the other coupling reagents, and the order of esterification efficiency was BrOP > PyBrOP > HATU > TOTU > BOP > HBTU > HBPipU ≈ HBPyU ≈ PyBOP ≫ TNTU ≈ TPTU. The only unsatisfactory results (2 μmol/g) were obtained using the last two reagents. Similar results were also obtained with nucleosides **2b**,**c** and HATU/DMAP or HBTU/DMAP. Poorer results were obtained with succinylated thymidine nucleoside **2d**, possibly because a 1:1 mixture of acetonitrile/dichloromethane instead of acetonitrile was required for solubility.

Coupling through Secondary Ester Linkages. We also investigated a scheme, which did not require prior synthesis of a separate nucleoside-3′-O-carboxylate (i.e., **2** or **3**) for each base. In this strategy, the dicarboxylic acid linker was first added to the support to produce carboxylic acid derivatized supports **6** and **7** (Scheme 2). The carboxyl supports were then coupled to a nucleoside's 3′-OH position via a secondary ester linkage. This strategy has three important advantages. First, the cost of nucleosides with free 3′-OH groups is less than the cost of nucleosides with 3′-carboxyl groups. Second, nucleosides, which may be rare or very expensive, do not need to be converted into 3′-carboxylic acid derivatives before being attached to the support. Finally, the strategy uses readily available amino-derivatized supports, instead of hydroxyl supports, as the starting materials. However, esterification to a secondary hydroxyl group is more difficult, and long coupling times (24 h) are required if carbodiimide coupling reagents (*22*, *23*) are used. Therefore, we were very interested to know if our faster coupling conditions could be used to improve this approach.

Succinylated-CPG **6** (90 μmol/g) was prepared from LCAA-CPG and succinic anhydride, (*22*) and HQDA-CPG **7** (40−45 μmol/g) was prepared by coupling HQDA to LCAA-CPG using HBTU/DMAP. Although, the carboxyl loading of support **7** was not as high as support **6**, the loading was still satisfactory for most purposes.

Nucleoside coupling was performed by shaking succinylated-CPG support **6** with either HATU/DMAP or HBTU/DMAP and either 0.2 or 0.4 mmol of nucleoside **1d** (0.05 and 0.1 M respectively) per gram of support. Unreacted carboxyl groups on the support were not blocked since carboxyl sites do not interfere with subsequent phosphoramidite synthesis (*56*). These initial experiments showed that nucleoside loadings within the range most commonly used (∼20−50 μmol/g) could be obtained within 15−30 min. A similar experiment, with HQDA-CPG **7** resulted in all the carboxyl groups (∼40 μmol/g) being derivatized with nucleoside **1d**. Thus, both the HATU/DMAP and HBTU/DMAP reagents were sig-

nificantly faster than the previously used carbodiimide reagents (*22, 23*).

Next, we adapted this coupling procedure to run on our automated DNA synthesizer. We examined coupling of 0.05 M **1d** to supports **6** or **7** using either BrOP, PyBrOP, HATU, HBTU or TOTU, and DMAP. Loadings were determined after coupling times of either 60, 150, 300, or 600 s **(**Table 2). Nucleoside loadings within the ideal range ~30−40 μmol/g were obtained on succinylated support **6** using either BrOP/DMAP or PyBrOP/DMAP and coupling times of 150−600 s. The nucleoside loadings obtained on the *Q-Linker* support **7** were lower (20−25 μmol/g), probably due to the lower (~40 μmol/g) carboxylic acid loading of the support, but still useful. Also, the uronium coupling reagents were more satisfactory for coupling to the *Q-Linker* than the bromophosphonium reagents. Finally, it should be noted that the thymidine compound **1d** with a free 3′-OH group was much more soluble than the thymidine compound **2d** with a 3′-succinyl group and so there were no solubility problems with any of the four 3′-OH nucleosides **1a**−**d**.

The above method is well-suited for automation on high-throughput oligonucleotide synthesizers (*57*) because the reagents are inexpensive, easy to handle, stable in solution, and fast enough to allow nucleoside attachment in about the same time period as a typical phosphoramidite coupling cycle. In particular, the cost savings obtained by using less expensive 3′-OH nucleosides and carboxyl derivatized supports is a significant improvement to our previous proposal to use nucleoside-3′-carboxylates and amino supports (*2*).

We believe that using automated on-line nucleoside attachment through amide or ester linkages is superior to adding the first base as a phosphoramidite derivative, as proposed for other "universal" supports (*58*−*60*). This is because our approach eliminates the need for either additional reagents or deprotection time to 3′-dephosphorylate the final product. There is also no possibility of 3′-phosphorylated impurities contaminating the final product if 3′-dephosphorylation is incomplete. Indeed, when the linker arm is the *Q-Linker*, the products can be very quickly removed (2 min) from the support with the desired 3′-OH terminus. Although, base deprotection must still be performed by conventional means, this can be done away from the synthesizer and the solid-phase support. This allows equipment to be reused sooner, allows easy separation of the final product from the support, and reduces any contamination from the support (i.e., dissolved silica).

In conclusion, we have found that uronium or phosphonium salt coupling reagents used with 1 equiv of DMAP are very efficient coupling reagents for both ester and amide couplings. The coupling reactions are very fast and both primary and secondary hydroxyl groups can form ester linkages to supports in 10 min or less. Esterification was obtained with a number of different reagents; however, the best reagents differed with the linker arm used. With the *Q-Linker*, the best results were obtained with uronium coupling reagents, while the best results with the succinyl linker were obtained with bromophosphonium reagents. Primary ester linkages, used to couple nucleoside-3′-carboxylates to OH-CPG, are best when short coupling times, high nucleoside loadings, and only the four common bases are required, i.e., the large-scale synthesis of antisense oligonucleotides (*3*). On the other hand, secondary ester couplings, used to attach nucleosides with free 3′-OH groups to carboxyl derivatized supports, are more suitable when the cost of the nucleosides is a concern, i.e., high volume, small-scale synthesis or use of rare or modified nucleosides.

Although our work has only used these conditions for coupling nucleosides to solid-phase supports, ester formation is of general synthetic interest. We hope the utility of the above coupling conditions will encourage others to use these reagents in the synthesis of other bioconjugates or combinatorial products.

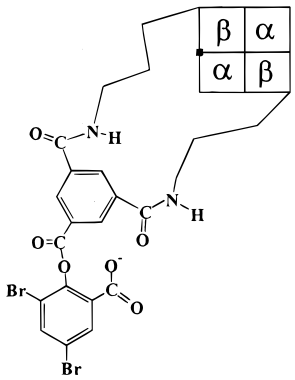
Molecular Necklaces. Cross-Linking Hemoglobin with Reagents Containing Covalently Attached Ligands

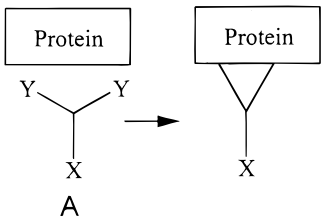
Sanda Crapatureanu, Ruxandra Serbanescu, Sharon Bisley Brevitt, and Ronald Kluger*

Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 3H6.
Received May 27, 1999; Revised Manuscript Received August 13, 1999



Hemoglobin can be cross-linked and converted to a bioconjugate in one step by a "molecular necklace", a reagent that contains two reacting sites and a pendant ligand. The compound to be conjugated is activated as an electrophile. The activated material is then combined with a reagent (3-aminoisophthalic acid) that contains a nucleophilic (amino) site and two latent (carboxyl) sites. The latent sites of the product are activated as 3,5-dibromosalicylates to produce the cross-linker. Illustrative examples of cross-linking are presented with pendant biotin [bis(3,5-dibromosalicyl) *N*-biotinyl-5-aminoisophthalate] and pendant *N*-trifluoroacetyl-L-isoleucylglycine [bis(3,5-dibromosalicyl) *N*-(*N*-trifluoroacetyl-L-isoleucylglycyl)-5-aminoisophthalate)]. The resulting modified hemoglobins contain two principal types of cross-link: (β-Lys-82−β'-Lys-82) and (α-Lys-99−α'-Lys-99). The functional properties of the modified hemoglobin containing biotin in a (β-Lys-82−β'-Lys-82) cross-link are (pH 7.4, 55 μM heme, 25 °C, 0.1 M chloride, and 50 mM Bis-Tris) $P_{50} = 4.9$ Torr, $n_{50} = 3.0$, values which are approximately the same as for native hemoglobin. The results of affinity chromatography of the biotinylated cross-linked hemoglobin using a column of immobilized avidin indicate that the pendant biotin is much less accessible than free biotin. We suggest that the results are consistent with the pendant species being strongly attracted into the hemoglobin environment.

INTRODUCTION

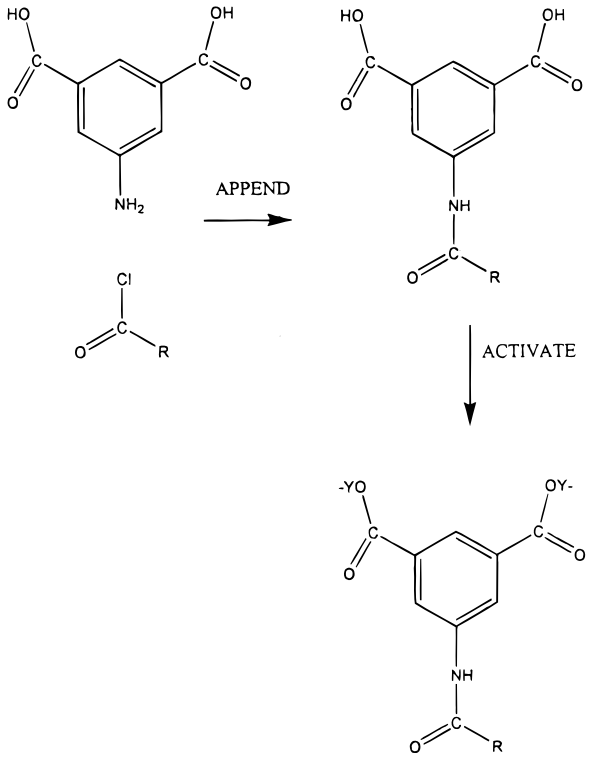


Human hemoglobin contains four subunits ($\alpha\alpha\beta\beta$) that dissociate spontaneously into $\alpha\beta$ dimers (*1*). The hemoglobin contained in red cell substitutes (for use in transfusions) must be altered to prevent its dissociation into dimers in order to avoid excretion via the kidney (*2*, *3*). Appropriate chemical cross-linking can prevent dissociation of the tetramer and has been used to create a wide variety of red cell substitutes. Site-directed reagents introduce cross-links and produce altered hemoglobins with defined structures (*4*−*7*).

The chemical alteration of hemoglobin that introduces a cross-link has potential utility beyond producing red cell substitutes: the entity created in the cross-link can serve as a site for tethering species with useful functions. In one potential application, the conjugated species can combine the properties of a red cell substitute with those of a drug-delivery agent (*8*−*10*). This complements an approach in which conjugation is achieved by de novo synthesis of mutants of hemoglobin containing additional cysteines that serve as linking points (*11*).

The existing method for producing conjugates on a cross-link (*9*) uses a trifunctional reagent [trimesyl tris(3,5-dibromosalicylate), TTDS], in which only two sites react with hemoglobin. The third site is available for addition to the resulting cross-linked hemoglobin. A schematic diagram of the cross-linked hemoglobin resulting from the reaction with TTDS is shown below. Substitution of the dibromosalicylate ester creates a novel adduct with a nucleophile.

Hydrolysis of the ester derived from TTDS in the cross-linked protein will compete with the desired substitution reaction that is used to produce a bioconjugate, reducing the potential yield of conjugated protein. Since hydrolysis and the desired ester substitutions compete in the necessarily aqueous medium, it is not likely that hydrolysis can be suppressed once the cross-linked ester has formed. An alternative approach can avoid the competition: form the bioconjugate with the reagent prior to cross-linking the protein. Such a reagent can be visualized as a "molecular necklace" with the bioconjugate materials contained in the unreactive portion of the cross-linking reagent. In the schematic diagram below, molecular necklace "A" has a pendant species "X" and two sites "Y" that react with the protein.



A

We have developed an efficient general route to produce compounds with the properties of "A". First, the compound to be conjugated (X) is activated as an elec-

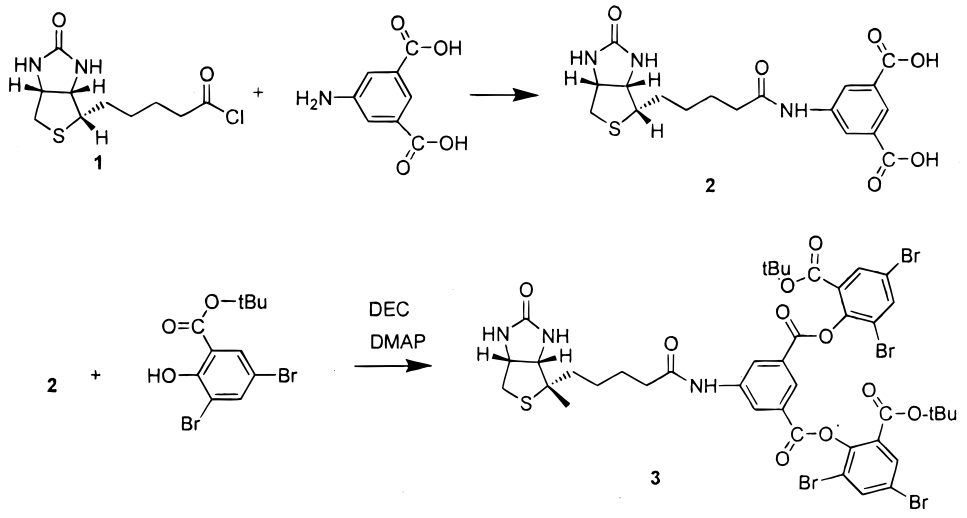
Scheme 1

trophile. The activated material is then combined with a reagent that contains a nucleophilic site and two latent sites. The latent sites of the product are activated to produce the molecular necklace cross-linker. The general strategy is exemplified in Scheme 1, where the pendant ligand is added as an acid chloride and the carboxyls are activated as "OY-", which is an anionic ester group.



We illustrate the method by creating a cross-linking reagent with two examples of pendants, biotin (an affinity group) and a peptide, *N*-trifluoroacetyl-L-isoleucylglycine (for drug delivery or receptor activation). These react directly with hemoglobin, converting it into a cross-linked bioconjugated species.

EXPERIMENTAL PROCEDURES

Materials. D-Biotin, *N*-t-Boc-Ile-Gly, *N*-t-Boc-L-Phe, avidin, 3,5-dibromosalicylic acid, and 5-aminoisophthalic acid were obtained from commercial sources and used directly. Solutions of trypsin and endoproteinase Glu-C were freshly prepared. Human hemoglobin A was obtained in the carbonmonoxy form from Hemosol, Inc. All other materials were of the highest grade commercially available. The identity and purity of newly synthesized materials was assessed by NMR spectroscopy, mass spectrometry, infrared spectroscopy and thin-layer chromatography. Proton NMR spectra were recorded at 200 and 300 MHz. Carbon NMR and fluorine NMR spectra were recorded on multinuclear spectrometers whose proton resonance is 500 and 400 MHz. Melting points are uncorrected. Oxygen-binding analysis followed the automated method described originally by Imai (*12*−*14*). We developed a computer interface and program that enabled the data to be collected in an MS-DOS computer environment.

The structures of compounds in the descriptions of syntheses are numbered in Scheme 2. The synthesis of bis (3,5-dibromosalicyl) *N*-biotinyl-5-aminoisophthalate (**3**) involves addition of amino-isophthalic acid to the acid chloride of biotin (**1**) to form the dicarboxylic acid (**2**) followed by activation of the diacid to the bis-dibromosalicylate (**3**). Biotin (1.07 g, 4.38 mmol) was dissolved in 20 mL of distilled thionyl chloride at room temperature and stirred until it dissolved. After 20 min, excess thionyl chloride was distilled away. The residue, the acid chloride of biotin (**1**), was dried in vacuo. 5-Aminoisopthalic acid (0.99 g, 5.5 mmol) was dissolved in 25 mL of anhydrous *N*,*N*-dimethylacetamide and stirred for 20 min under nitrogen. 4-(Dimethylamino)pyridine (7.1×10^{-3} g, 0.58 mmol) was added to this solution and stirred until all material dissolved. The solution was cooled to 0 °C and then added to a solution of the biotin acid chloride. The reaction mixture was stirred at room temperature for 14 h. A light brown precipitate formed and was collected on a filter. The solid was dissolved in DMF and precipitated with water. This was collected by filtration, washed with hot methanol, and dried under vacuum (0.700 g, 1.72 mmol) to give bis(3,5-dibromosalicyl)-*N*-biotinyl-5-aminoisophthalate: mp 220−221 °C (decomposed); IR (KBr, cm^{-1}) 3391 (m), 2922 (m), 1696 (s), 1452 (m), 758 (m), 697 (s); ^{1}NMR (DMSO-d_6) δ 10.23(s, 1H, NH), 8.42(s, 2H, ArH), 8.12 (s, 1H, ArH), 6.43 (s, 1H, NH), 6.35 (s, 1H, NH), 4.25−4.29 (m, 1H), 4.11−4.15 (m, 1H), 3.10−3.12 (m, 1H), 2.77−2.80 (m, 1H), 2.58 (s, 1H), 2.32 (s, 2H), 1.34−1.61 (m, 6H); ^{13}C NMR (DMS0-d_6) δ 25.01, 28.11, 28.21, 36.26, 40.10, 55. 41, 59.20, 61.05, 123.4, 124.3,

Scheme 2

131.6, 139.9, 162.7, 166.5, 171.7; MS parent peak (CI) calcd, 407.4; found, 408 (MH^+).

Bis((1-*tert*-butoxycarbonyl)-3,5-dibromosalicyl) *N*-Biotinyl-5-amino-isophthalate (3). *N*-Biotinyl-5-aminoisophthalic acid (0.18 g, 0.43 mmol), *tert*-butyl 3,5-dibromosalicylate (0.340 g, 0.97 mmol), 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (0.334 g, 1.74 mmol), and 4-(dimethylamino)pyridine (0.0250 g, 0.200 mmol) were dissolved in 15 mL of anhydrous DMF and stirred at 4 °C for 20 h. The precipitated byproduct was removed by filtration. The filtrate was diluted with water and ethyl acetate. The aqueous layer was extracted several times with ethyl acetate. The organic layers were pooled, washed with water, saturated sodium bicarbonate, and water. The pooled organic extracts were dried over anhydrous magnesium sulfate and evaporated under vacuum (off-white solid). The product was purified by flash chromatography (silica gel 60; eluent, acetone). The product, bis((1-*tert*-butoxycarbonyl)-3,5-dibromosalicyl) *N*-biotinyl-5-amino-isophthalate was isolated, 0.19 g, 0.17 mmol: ^{1}H NMR (DMSO-d_6) δ 10.6 (s, 1H, NH), 8.83 (d, J = 1.5, 2H, ArH), 8.48 (t, J = 1.5, 1H, ArH), 8.35 (d, J = 2.4, 2H, ArH), 8.03 (d, J = 2.4, 2H, ArH), 6.46 (s, 1H, NH), 6.38 (s, 1H, NH), 4.31−4.27 (m, 1H), 4.15−4.12 (m, 1H), 3.13−3.10 (m, 1H), 2.79 (dd, J = 5, 1H), 2.58 (d, J = 12.3, 1H), 2.38 (t, J = 7.35, 1H), 1.66−1.59 (m, 1H), 1.31 (s, 18 H); ^{13}C (DMSO-d_6) δ 172.2, 162.7, 162.1, 161.5, 145.6, 141.1, 138.8, 133.0, 129.4, 128.6, 125.0, 124.9, 119.6, 119.1, 83.1, 61.0, 59.2,55.4, 40.0, 36.3, 28.2, 28.1, 24.8.

Bis(3,5-dibromosalicyl) *N*-Biotinyl-5-aminoisophthalate (4). Bis((1-*tert*-butoxycarbonyl)-3,5-dibromosalicyl) *N*-biotinyl-5-aminoisophthalate (0.18 g, 0.17 mmol) was dissolved in 15 mL of anhydrous trifluoroacetic acid (0 °C) and stirred 10 min at 0 °C, then for 30 min at room temperature. Diethyl ether was added to induce crystallization. The solution was left for 1 h at 4 °C. The resulting solid was collected by filtration, washed with diethyl ether, and dried under vacuum (0.16 g, 0.17 mmol): mp 235−236 °C (dec); IR (KBr, cm^{-1}) 3368 (m), 3025 (m), 2921 (s), 1708 (s), 1452 (s), 1198 (s), 697 (s); ^{1}H NMR (DMSO-d_6) δ 10.56 (s, 1H, NH), 8.77 (s, 2H, ArH), 8.41 (s, 1H, ArH), 8.34 (d, J = 2.1, 2H, ArH), 8.10 (d, J = 2.1, 2H, ArH), 6.47 (s, 1H, NH), 6.38 (s, 1H, NH), 4.31−4.27 (m, 1H), 4.15−4.10 (m,1H), 3.24−3.11 (m, 1H), 2.80 (dd, J = 5,1H), 2.58 (d, J = 12.6, 1H), 2.37 (t, J = 7.2, 2H), 1.65−1.40 (m, 6H); ^{13} C NMR (DMS0-d_6) δ 24.92, 28.15, 28.25, 36.34, 55.43, 59.26, 61.10, 119.36, 119.54, 124.8, 127.6, 129.5, 133.5, 139.05, 139.70, 140.90, 162.4, 162.8, 163.53. MS(ESI) calcd, 963.29; found: 963.4.

Bis(3,5-dibromosalicyl) *N*-(*N*-trifluoroacetyl-L-isoleucylglycyl)-5-aminoisophthalate (8). *N*-(*N*-*tert*-butyloxycarbonyl-L-isoleucylglycyl)-5-aminoisophthalic Acid Dimethyl Ester (5). *N*-t-Boc-Ile-Gly (2.88 g, 9.97 mmol), dimethyl 5-amino-isophthalate (2.11 g, 10.1 mmol) and 4-(dimethylamino)pyridine (0.125 g, 1.03 mmol) were dissolved in 60 mL of anhydrous DMF under nitrogen. DCC (2.05 g, 9.94 mmol) was dissolved in 30 mL of anhydrous DMF and added dropwise to the first solution. The reaction mixture was stirred for 3 days at room temperature under dry nitrogen. The precipitated *N*,*N*-dicyclohexylurea was removed by filtration. Ethyl acetate and water were added to the filtrate and the layers were separated. The aqueous layer was extracted three times with ethyl acetate. The organic layers were pooled, filtered to remove additional precipitate, and washed with 2 M hydrochloric acid (1.2 L), saturated salt solution (500 mL), saturated sodium bicarbonate solution (700 mL), and again with saturated salt solution (250 mL). The ethyl acetate solution was dried over magnesium sulfate, filtered, and concentrated under reduced pressure. The mixture was kept at 4 °C for 24 h. The resulting yellow precipitate was collected by filtration, washed with hexane, and dried under vaccuum (1.75 g, 3.65 mmol): mp 124−125 °C; IR (KBr) 3307 (m), 2967 (m), 1730 (s), 1555 (s), 1515 (s), 14 440 (s), 1343 (s), 1250 (s), 1168 (s), 1009 (m), 758 (s); ^{1}H NMR (DMSO-d_6) δ 10.2 (s, 1H, NH), 8.48 (d, J = 1.2, 2H, ArH), 8.34 (t, J = 5.4, 1H, NH), 8.14 (t, J = 1.5, 1H, ArH), 6.94 (d, J = 8.1, 1H, NH), 3.91−3.83 (m, 3H, masked), 3.87 (s, 6H), 1.71−1.69 (m, 2H), 1.35 (s, 9H), 1.16−1.11 (m, 1H), 0.86−0.78 (m, 6H); ^{13}C NMR (DMSO-d_6) δ 172.00 (s), 168.33 (s), 165.18 (s), 155.70 (s), 139.62 (s), 130.70 (s), 124.1 (s), 123.5 (s), 78.20 (s), 58.99 (s), 52.50 (s), 42.73 (s), 36.24 (s), 28.11 (s), 24.50 (s), 15.34 (s), 11.00 (s); MS (ESI) calcd, 479.5; found, 480.4 (MH^+).

***N*-[*N*-*tert*-butyloxycarbonyl-L-isoleucylglycyl]-5-aminoisophthalic Acid (6).** *N*-[*N*-*tert*-butyloxycarbonyl-L-isoleucylglycyl]-5-aminoisophthalic acid dimethyl ester (1.75 g, 3.65 mmol) was dissolved in 100 mL of methanol, 20 mL of 6 N sodium hydroxide was added, and the reaction mixture stirred under nitrogen for 2 h. After addition of water and 50 mL of 2 N HCl to the reaction mixture, a white precipitate formed, which was filtered, washed with water, and dried under vacuum (1.58 g, 3.50 mmol): mp 215−216 °C; IR (KBr, cm^{-1}) 3329 (m, br), 2970 (m), 1699 (s), 1558 (m), 1252 (m), 667 (w); ^{1}H NMR (DMSO-d_6) δ 10.15 (s, NH), 8.43 (d, J = 1.5, 2H, ArH), 8.33 (t, J = 5.7, 1H), 8.15 (t, J = 1.5, 1H, ArH), 6.90 (d, J = 8.1,1H, NH), 3.90−3.80 (m, 3H), 1.70−1.68 (m, 2H), 1.35 (s, 9H), 1.14−1.09 (m, 1H), 0.86−0.78 (m, 6H); ^{13}C NMR (DMSO-d_6) δ 172.04 (s), 168.24 (s), 166.45 (s), 155.74 (s), 139.35 (s), 131.87 (s), 124.69 (s), 123.56 (s), 78.24 (s), 59.04 (s), 42.78 (s), 36.31 (s), 28.20 (s), 24.57 (s), 15.40 (s), 11.07 (s); MS(ESI) calcd, 451.45; found, 452.4 (MH^+).

Bis((1-*tert*-butoxycarbonyl)-3,5-dibromosalicyl) *N*-[*N*-*tert*-butyloxycarbonyl-L-isoleucylglycyl]-5-aminoisophthalate (7). *N*-[*N*-*tert*-butyloxycarbonyl-L-isoleucyl-glycyl]-5-aminoisophthalic acid (1.58 g, 3.50 mmol), 4-(dimethylamino)pyridine (0.085 g, 0.7 mmol), and *tert*-butyl-3,5-dibromosalycilate (2.46 g, 7.00 mmol) were dissolved in 300 mL of anhydrous THF and cooled in an ice bath. 1-(3-dimethyl-aminopropyl)-3-ethylcarbodiimide hydrochloride (2.4 equiv, 1.61 g, 8.40 mmol) was dissolved in dry dichloromethane and added via a syringe, under nitrogen, dropwise to the solution. After stirring the mixture at 0 °C for 5 min and at room temperature for 48 h, the solvent was evaporated and the solid dissolved in ethyl acetate. The solution was washed successively with saturated sodium bicarbonate and water, evaporated under reduced pressure. The white solid product was used directly (1.40 g, 1.25 mmol).

Bis(3,5-dibromosalicyl) *N*-(*N*-trifluoroacetyl-L-isoleucylglycyl)-5-aminoisophthalate (8). Bis((1-*tertert*-butoxycarbonyl)-3,5-dibromosalicyl) *N*-[*N*-*tert*-butyloxycarbonyl-L-isoleucylglycyl]-5-aminoisophthalate (1.40 g, 1.25 mmol) was dissolved in a mixture of trifluoroacetic acid and trifluoroacetic acid anhydride and stirred under nitrogen at room temperature for 2 h. The solvent was removed under vacuum, leaving a clear oil as a residue. Addition of ether resulted in the formation of a white precipitate, which was filtered and identified as a decomposition product. Adding hexane to the filtrate precipitated the desired compound. The solid was collected by filtration and dried under vacuum (0.411 g, 0.410 mmol): mp 170−172 °C, IR (KBr, cm^{-1}) 3350 (m, br), 2923 (m), 1718 (s), 1558 (s), 1452 (s), 1199 (s), 697 (s);

Cross-Linking Procedures. Reactions were conducted in solutions of deoxyhemoglobin, which was prepared from carbonmonoxyhemoglobin. Stock solutions of carbonmonoxyhemoglobin (1.0 mL, 1.23 mM) in 50 mM bis-tris (pH 6.9) were passed through a Sephadex G-25 column at 4 °C equilibrated with 0.1 M sodium borate buffer (pH 9). Carbonmonoxyhemoglobin was converted to oxyhemoglobin by photoirradiation in a rotating flask under a stream of humidified oxygen for 3 h at 0 °C (*14*). Oxyhemoglobin was converted to deoxyhemoglobin by continuously flowing wet nitrogen through the rotating flask for 3 h at 37 °C. The cross-linking reagent (2 mol/mol of hemoglobin) was dissolved in 0.2−0.3 mL of peroxide-free dioxane and 0.3 mL of 0.1 M sodium borate buffer (pH 9). The reaction solution was deoxygenated under a stream of nitrogen for 1 h and then added to the hemoglobin solution via a syringe. The reaction mixture was kept rotating at 37° under slowly flowing nitrogen to maintain the hemoglobin in the deoxy state. The reaction was monitored by C-4 reversed-phase HPLC. The reaction was stopped when no more α- or β-chain modification was observed. At the end of the reaction period, the flask was cooled on ice, flushed with carbon monoxide, and passed through a Sephadex G-25 column equilibrated with 0.1 M borate buffer (pH 9) in order to remove unreacted cross-linking reagent.

Structural Characterization of Modified Hemoglobins. Chromatographic Analysis. Modified globin chains were identified by analytical reversed-phase HPLC (*15*) using a 330 Å pore size C-4 Vydac column (250 × 4.6 mm). The materials were then separated by preparative reversed-phase HPLC using the same column packing (250 × 12 mm). Developers contained 0.1% trifluoroacetic acid and gradients of acetonitrile in water from 20 to 60%. The effluent was monitored for absorbance at 220 nm. Analysis of the reaction mixture and isolation of modified hemoglobins was accomplished by analytical and semipreparative anion-exchange HPLC using a Synchropak AX-300 column (analytical, 250 × 4.5 mm; semipreparative, 250 × 10 mm) and a POROS column (from Perseptive Biosystems: 7000 Å pore, 10 μm particle). Developers for the AX-300 column contained 15 mM Tris, (pH 8) and gradients of sodium acetate in water starting at 10 mM and ending at 150 mM. The flow rate was 1 mL/min for the analytical analysis and 4 mL/min for the semipreparative separation. For the analysis using the POROS column, a pH gradient from pH 8.5 to 6.5 was used. The effluent was monitored at 420 nm.

Peptide fragments were separated by reversed-phase HPLC using a C-18 Vydac column (93 × 4.7 mm; 330 Å pore, 5 μm particle), with developers containing 0.1% trifluoroacetic acid. Gradients of acetonitrile in water ranged from 0 to 100%, pumped at 1 mL/min. The effluent was monitored at 220 and 280 nm (*14*).

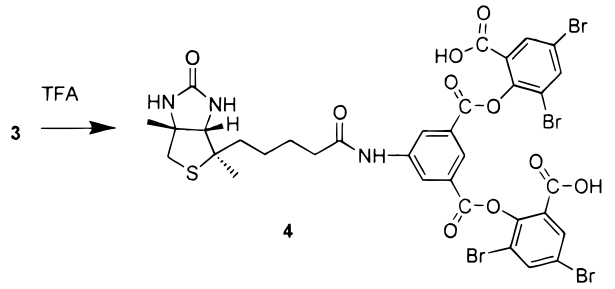
The presence of cross-links between globin chains can be established by molecular mass bands that are multiples those of the 16 kDa monomers in SDS−PAGE (*16*). Polyacrylamide gels (12%) were run in a dual-slab cell apparatus at 200 mV. Prior to electrophoresis, the protein sample was dissolved in 0.5 M tris-HCl, pH 6.8, which contained 0.05% bromophenol blue, 4% v/v β-mercaptoethanol, 2% SDS, and 10% v/v glycerol. The sample was kept for 5 min in boiling water to denature it. Approximately 10 μg of protein was applied to each lane of the gel and subjected to electrophoresis for 35 min. Unmodified hemoglobin and molecular weight standards were used to estimate the molecular weight of the resulting bands after fixation followed by staining with Coomassie Brilliant Blue R.

The molecular masses of cross-linked hemoglobins were determined precisely by electrospray ionization mass spectrometry, coupled to reversed-phase HPLC, as described previously (*17*). Standard masses were taken from literature compilations (*18*).

Separation of peptides from tryptic digestion of partially acylated globin chains reveals the site of amide modification by comparison with the intensity of peaks of tryptic peptides from native globin chains (*14*). Native and cross-linked α and β chains were separated and collected using the reversed-phase HPLC procedure outlined above. Organic developers were evaporated under reduced pressure and water removed by lyophilization. The globin chains were then dissolved in 8 M urea to help denature the protein and promote complete hydrolysis. They were kept for 2 h at room temperature. The solution was diluted to 2 M urea with, pH 8.5, 0.8 M bicarbonate. Freshly prepared TPCK-treated trypsin solution (2 mg/mL, 4% of mass of total protein) was added and the digestion continued for 24 h at room temperature. The tryptic hydrolysate was heated in boiling water for 2 min and diluted to 1 M urea with 0.8 M bicarbonate buffer (pH 8.5). A solution of endoproteinase Glu-C (1 mg/mL, 2% of mass of total protein) was added and the mixture digested for 72 h at room temperature. The sample was clarified by filtration through a 0.45-μm filter before injection onto the C-18 reversed-phase HPLC column. Peptide fragments were separated according to the procedure described above. The modified peaks were identified by peptide pattern analysis. The tryptic-Glu-C peptide maps of modified α and β subunits were analyzed by comparison with the peptide maps of unmodified α and β subunits and by comparison with published standards (*14*).

Quantitative Affinity Chromatography. 4-Nitrophenyl chloroformate was use to activate Sepharose CL-4B. All steps in the activation procedure were performed in an ice bath according to the reported procedure (*19*). Sepharose Cl-4B (50 mL) was washed in batches through a sintered glass funnel with increasing concentrations of acetone in water, starting at 0% and ending at 100% absolute acetone. To the washed Sepharose gel, an acetone solution (50 mL) containing 4-nitrophenyl chloroformate (0.3 mmol/mL) was added. To this suspension, 50 mL of an acetone solution containing 4-dimethylaminopyridine (0.35 mmol/mL) was added dropwise with stirring, and the resin was stirred for 90 min. The activated Sepharose was then washed exhaustively with acetone (500 mL), acetone-2-propanol (1:1) (200 mL), 2-propanol (200 mL), 2-propanol-water (1:1) (200 mL), and distilled water until the solution remained clear in the presence of 0.2 N sodium hydroxide. The activated resin (0.737 mmol 4-nitrophenol/g resin) was dried by lyophilization and stored at 4 °C.

Avidin (3.8 mg) was dissolved in 6 mL of 0.1 M sodium bicarbonate (pH 8.5). To this solution, 2.73 g of activated Sepharose was added, and the reaction mixture stirred



for 1 h at room temperature then overnight at 4 °C (*20*). The resin was then washed successively with water, 0.2 M acetic acid, water, and 0.01 M sodium hydroxide, followed by distilled water, 0.1 M sodium bicarbonate, and phosphate-buffered saline (PBS), pH 7.4. The immobilized avidin was stored at 4 °C in PBS.

Circular dichroism (CD) spectra of the native and modified hemoglobins were recorded on a Jasco J-710 instrument between 200 and 280 nm in, pH 9, 0.003 M sodium borate buffer. Circular dichroism (CD) spectra were recorded on a Jasco J-710 system between 200 and 280 nm (hemoglobin concentration 0.3 mM in sodium borate buffer, pH 9).

RESULTS AND DISCUSSION

We have been able to produce cross-linking reagents with appended molecules by a process that first adds the appendage to the amino group of amino isophthalic acid. We then activate the carboxylic acid groups by converting them to reactive esters. The resulting material has the potential to attach the pendant ligand while linking between two sites on the protein, functioning as a "molecular necklace". Producing the cross-linking reagent in this manner avoids hydrolysis of the activated ester, which occurs if the ester group is appended to the protein. The reaction sequence is presented in Scheme 2. Bis(3,5-dibromosalicyl) *N*-biotinyl-5-aminoisophthalate (DBBA, **4**) is a conjugation agent that adds a pendant molecule of biotin in the cross-linking process.

Addition of 5-aminoisophthalic acid to biotin acid chloride (**1**) gives *N*-biotinyl-5-aminoisophthalic acid (**2**). This is coupled with the substituted salicylate to give bis-[(1-*tert*-butoxycarbonyl)-3,5-dibromosalicyl] *N*-biotinyl-5-aminoisophthalate (**3**). Removal of the *tert*-butyl groups

gives the biotin-substituted cross-linker, bis(3,5-dibromosalicyl) *N*-biotinyl-5-aminoisophthalate (**4**, DBBA).

We used an analogous route to prepare a cross-linker with a pendant dipeptide derivative. The preparation of bis(3,5-dibromosalicyl) *N*-[*N*-trifluoroacetyl-L-isoleucylglycyl]-5-aminoisophthalate (DBTIA, **8**) is presented in Scheme 3. *N*-[*N*-*tert*-butyloxycarbonyl-L-isoleucylglycyl]-5-amino-isophthalic acid dimethyl ester (**5**) was prepared by coupling of *N*-t-Boc-Ile-Gly with dimethyl 5-aminoisophthalate. The diester was hydrolyzed to the diacid (**6**). This was coupled with the substituted salicylate to give the *tert*-butyl 3,5-dibromosalicylate ester (**7**). Removal of the *tert*-butyl group with trifluoroacetic acid and formation of trifluoroacetyl derivative of the terminal amino group with trifluoroacetic anhydride in a single step gave DBTIA (**8**).

In our experience, hemoglobin reacts with cross-linking reagents most readily and completely in its deoxy form (*21*). This is also the case with the reagents in the present study. Carbonmonoxyhemoglobin reacted very slowly with DBBA (pH 9, 37 °C). The reagent was much more reactive toward deoxyhemoglobin under the same conditions: combining 1 equiv of hemoglobin with 2 equiv of the reagent led to more than 75% conversion in 3 h. The solution contained two principal products. The larger fraction was the material cross-linked in the β subunits ($\alpha\alpha\beta82-82\beta'$), from acylation of the ϵ-amino groups of Lys-82 of each of the β subunits. The other major product is cross-linked between the ϵ-amino groups of Lys-99 of each of the α subunits ($\beta\beta\alpha99-99\alpha'$) (Figure 1). Increasing the reaction time to 14 h led to over 95% acylation of hemoglobin, with an increase in the extent of inter-α cross-linking and almost no further reaction of the β subunits. The details of the analysis follow.

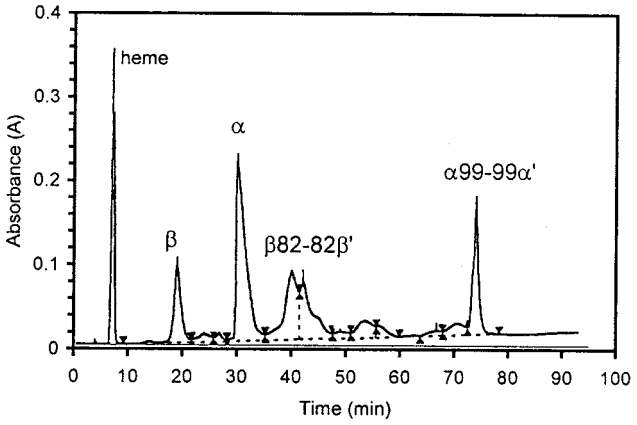


Figure 1. Globin chain separation after reaction of deoxyhemoglobin with DBBA (pH 9, 37 °C, 3 h).

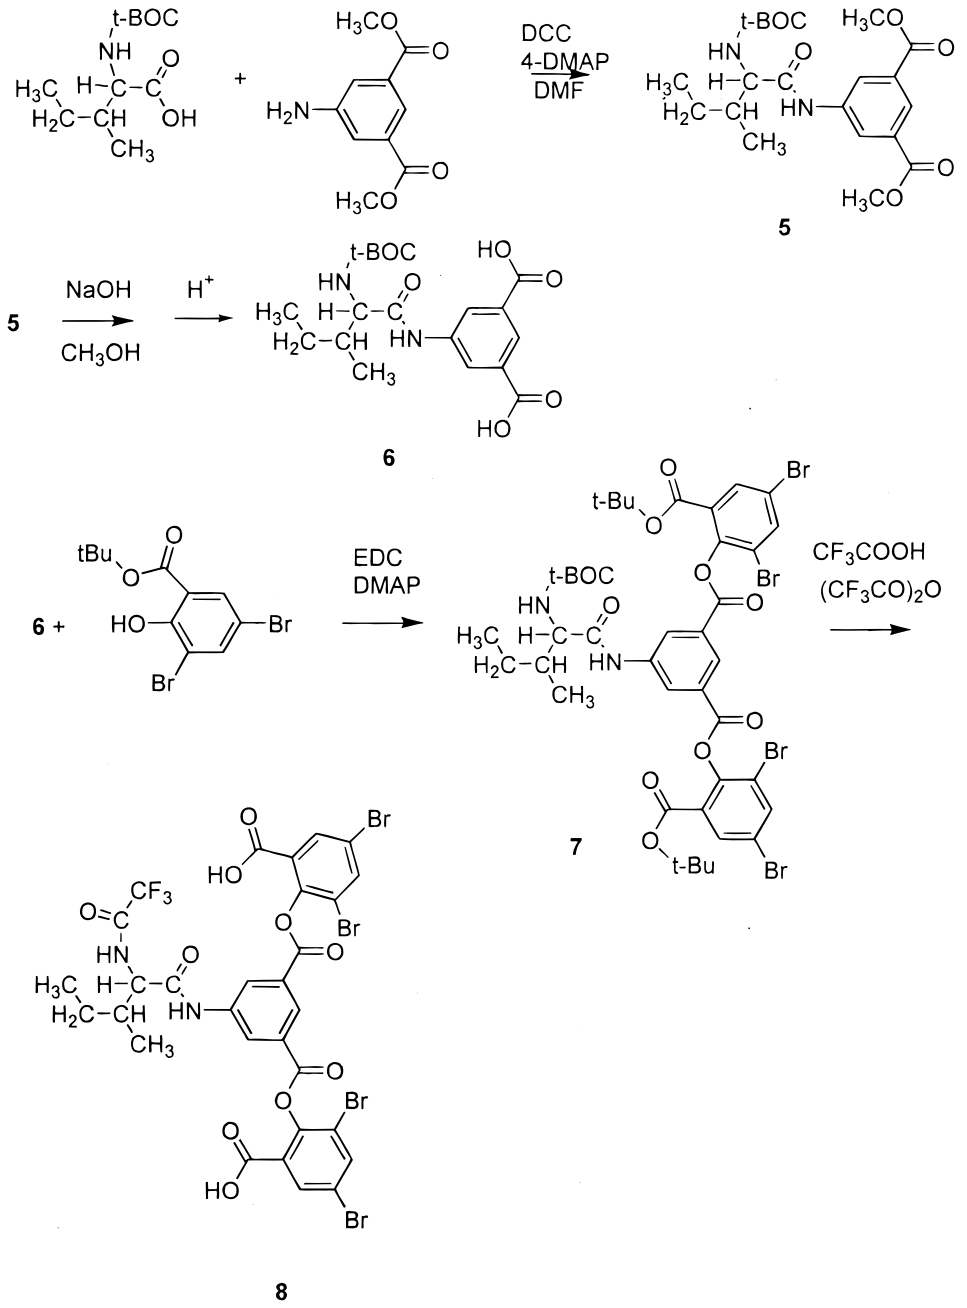

Product Structures. Products were analyzed as previously described (22). The C-4 reversed-phase HPLC chromatogram (Figure 1) has peaks for two cross-linked hemoglobin chains along with the peaks coincident with those of the native protein (heme, α and β subunits). The relative areas of the unreacted α and β chains compared to those from unreacted hemoglobin indicates that the chemical modification takes place predominantly in the β chains.

SDS−PAGE of the globin chains indicated the presence of covalent cross-links with 32 kDa bands corresponding to linked dimers from 16 kDa monomers. The mass of each globin chain was determined by HPLC-MS. The first major modified globin ($\beta82-82\beta'$ in Figure 1) has a mass of 32 093 Da, consistent with an inter-β cross-linked dimer containing *N*-biotinyl-5-aminoisophthalate (calculated mass, 32 093 Da). The second major modified globin ($\alpha99-99\alpha'$ in Figure 1) has a mass of 32 615 Da, consistent with an $\alpha-\alpha$ dimer containing *N*-biotinyl-5-aminoisophthalate (calculated mass, 32 619 Da). Two distinct peaks eluting at 43 and 45 min could not be distinguished by their molecular weight and peptide pattern analysis. Their different chromatographic behavior suggests that these could be stereoisomers, differing in the orientation of the biotin derivative with respect to the protein.

The intermediate chromatographic zones correspond to cross-linked globins having a second molecule of cross-linker attached to a third site with or without one leaving group hydrolyzed, as suggested by their HPLC-MS analysis. Since they made up only a small percentage of the other two products, they were not further analyzed.

The anion-exchange HPLC chromatogram of the reaction products is shown in Figure 2. The peaks were identified by comparison with the chromatogram of native hemoglobin run under the same conditions, separation of the main fractions, purification by chromatography on a POROS column and globin chain separation

Scheme 3

on a C-4 reversed-phase column of the purified hemoglobins. Retention times of globin chains separated on C-4 reversed-phase column from the purified hemoglobins were compared with those from the reaction mixture for which HPLC-MS analysis was performed. Peak A is unmodified hemoglobin. Peak B is the inter-α cross-linked hemoglobin. Regions C and D correspond to the $\alpha\alpha\beta 82-82\beta'$ hemoglobin conjugate. The inter-β cross-linked hemoglobin fraction (peak C) was concentrated and used for functional studies. Its C-4 chromatogram (Figure 3) indicates the presence of the heme, the α monomer and the $\beta-\beta'$ cross-linked dimer. Region E contains a mixture of modified hemoglobins corresponding to the minor globins in the C-4 chromatogram (Figure 2).

To determine the site of modification of the protein chain, the cross-linked dimers (peaks $\beta 82-82\beta'$ and $\alpha 99-99\alpha'$ in 1) were separated on a C-4 column and digested with trypsin followed by endoproteinase Glu-C. Peptide peaks were identified by comparison with the peptide pattern of the digest of native α and β globins. The patterns of tryptic peptides eluting at 43 and 45 min (Figure 1) are identical to one another (Figures 4 and 5). The peptide maps are characteristic of the β chain of human hemoglobin (*14*) with the exception of the absence of βT-9 and βT-10a′ peptide fragments and the presence of additional peaks at 93.8 and 94.3 min. These results are consistent with the selective acylation of the β-Lys-82. The peptide pattern for the peak eluting at 75 min in the C-4 chromatogram (Figure 1) is missing the αT-11 and αT-12 peak (Figure 6). A large peak elutes at 111.8 min. These results suggest the formation of an amide bond between the α-Lys-99 (on the C-terminus of αT-11) on each α subunit and the cross-linker. This newly formed amide bond prevents trypsin from hydrolyzing the peptide bond between αT-11 and αT-12 peptide fragments. These peptide pattern data along with the molecular masses determined experimentally by HPLC-MS

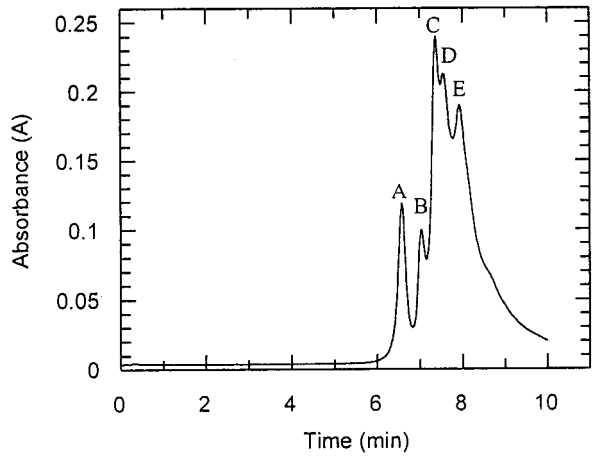

Figure 2. Anion-exchange HPLC profile on a POROS column for the reaction of DBBA with deoxyhemoglobin (37 °C, pH 9, sodium borate buffer, 3 h).

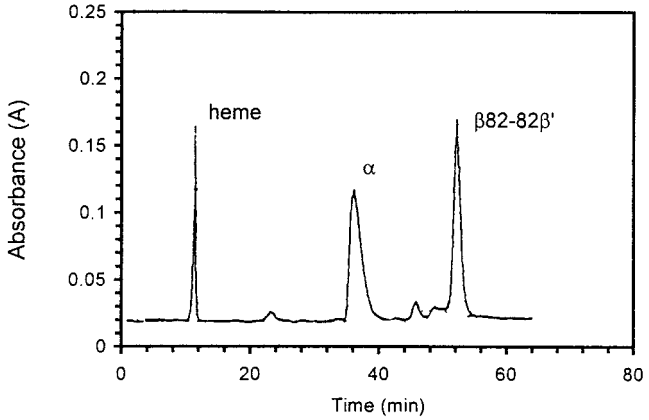

Figure 3. Globin chain separation on a C-4 column of the inter-β cross-linked Hb (peak C in Figure 2) purified on an AX-300 column.

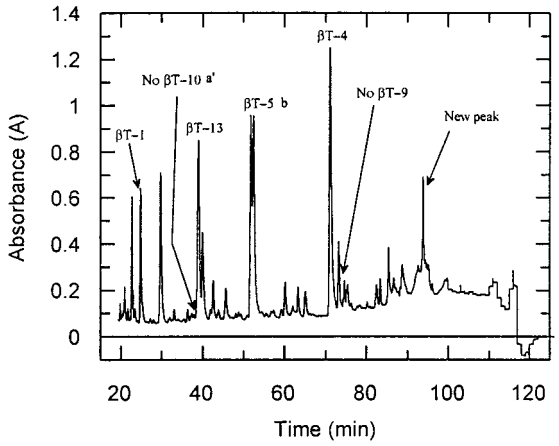

Figure 4. C-18 reversed-phase HPLC chromatogram of the β82−82β' globin dimer (peak eluting at 43 min in the C-4 chromatogram), after trypsin/Glu-C digestion, monitored at 200 nm.

for the globin dimers indicate that two β and two α chains are cross-linked by a *N*-biotinyl-5-aminoisophthalate moiety.

Affinity Chromatography of Cross-Linked Biotinylated Hemoglobin. Quantitative measurements of the accessibility to avidin on the column of biotin conjugated to hemoglobin followed the procedures described by Wilchek (*23*). The hemoglobin−biotin conjugate was applied to the avidin Sepharose column and

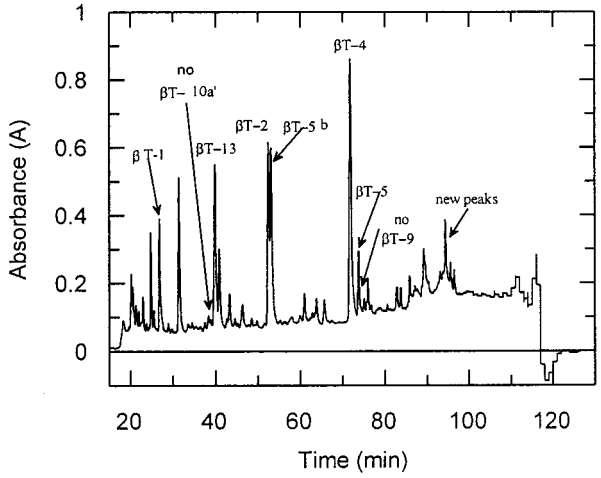

Figure 5. C-18 reversed-phase HPLC chromatogram of the β82−82β' globin dimer, after trypsin/Glu-C digestion, monitored at 200 nm.

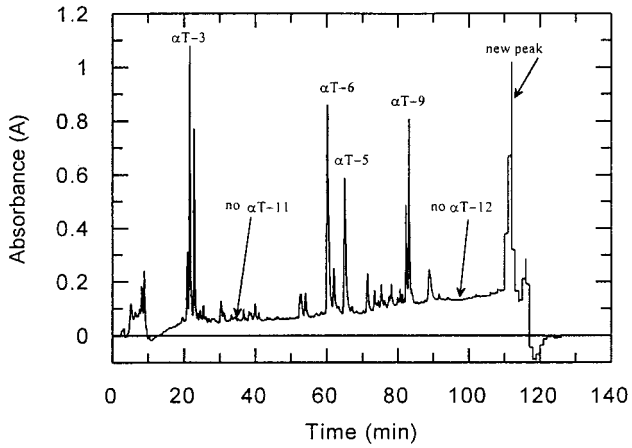

Figure 6. Tryptic digest separation on C-18 reversed-phase HPLC from cross-linked α99−99α′ globin dimer (obtained from reversed-phase HPLC of globin chains), monitored at 200 nm..

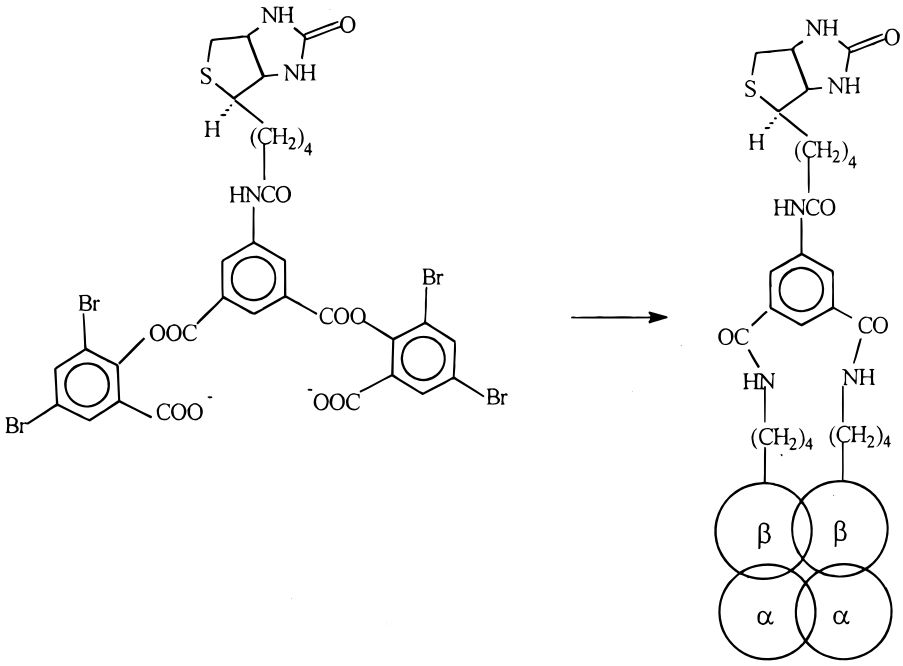
eluted with PBS, pH 7.4 (~4 mg avidin on the column; avidin:biotinylated hemoglobin 2:1, M:M).The column was eluted until absorbance at 420 nm was minimal. The ratio of absorption from hemoglobin (all as conjugate) in the effluent to absorption of total hemoglobin conjugate that had been applied was used to calculate the amount retained on the column:



$$Hb_{total} - Hb_{effluent}/Hb_{total} = (A_{420applied} - A_{420effluent}/A_{420applied}) \times 100\%$$

These measurements indicate that only 17% of the modified hemoglobin adheres to the avidin column (which binds free biotin quantitatively) (*24*). It is likely that because of the relatively short tether, only part of the biotin species extends beyond the hemoglobin to which it is attached.

Reaction of hemoglobin with DBTIA. The materials, method, and analytical procedures are the same as for cross-linking hemoglobin with DBBA with a 2-fold molar excess of reagent to protein. The reaction was stopped after 3 h. C-4 HPLC analysis of the reaction mixture indicated formation of a reaction mixture in which the β-globin chains are all reacted while the α chains are mostly unreacted (Figure 7).

The material in each peak was identified by comparing the chromatogram with that for native protein combined

Scheme 4

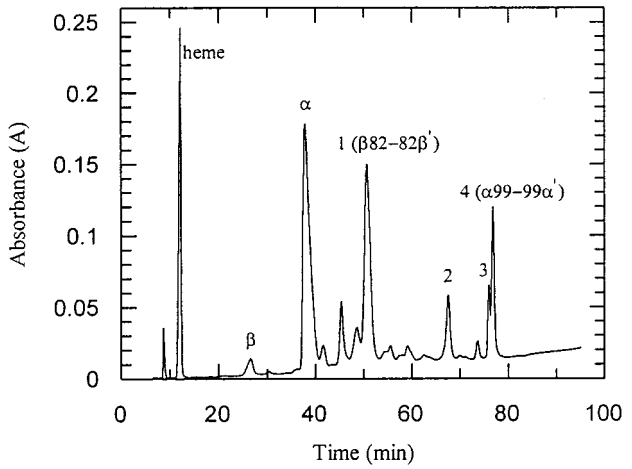


Figure 7. C-4 reversed phase HPLC chromatogram of separated subunits from the reaction of deoxyhemoglobin with DBTIA (pH 9, 37 °C, 3 h).

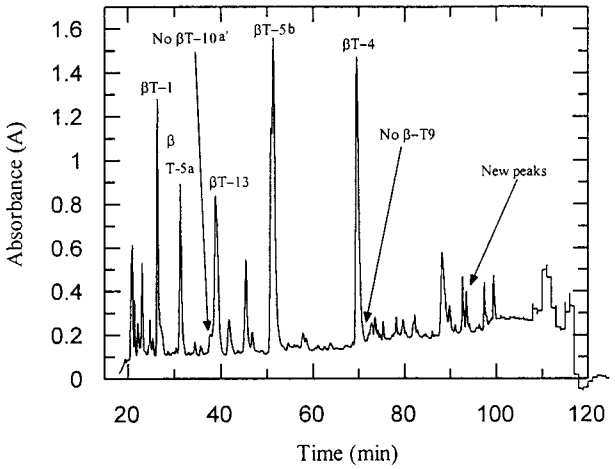

Figure 8. Tryptic-Glu-C peptide map of DBTIA-cross-linked β-chains (peak 1 in Figure 7).

with MS (ESI) analysis. The peaks designated "α" and "β" in Figure 7 are those of native globin chains. Peak 1 corresponds to a $\beta-\beta'$ dimer cross-linked by the isoleucylglycyl-5-aminoisophthalate (calculated, 32 133; found, 32 138). The molecular weight for the species in peak 2 is in the range expected for a $\beta-\beta$ cross-linked dimer that has a second molecule of cross-linker attached as a monoamine to the protein, with the second ester intact. This dimer is cross-linked between the same residues as 1, based on the peptide pattern analysis. The experimental mass for peak 3 is consistent with that of the α globin chain to with the reagent as a monoamide with the remaining ester intact (calculated, 15 832; found, 15 839). Peak 4 corresponds to an α−α cross-linked dimer (calculated, 30 661; found, 30 665). The reaction mixture was also analyzed by anion-exchange chromatography, which separates hemoglobin tetramers and modified tetramers, giving results consistent with the HPLC analysis.

To determine the site of modification of the protein chain, the cross-linked dimers (peaks 1, 2, and 4 in Figure 7) were collected and digested with trypsin followed by endoproteinase Glu-C. The peptide maps of native α and β chains obtained by C-18 reversed-phase HPLC were compared to those for the modified chains in order to identify the site of modification.

In the C-18 reversed-phase HPLC of peaks 1 and 2, the peptide fragments βT-9 and βT-10a′ are not present and new peaks elute at approximately 85−100 min (Figures 8 and 9). These two peptide fragments result from cleavage adjacent to Lys-82. In both chromatograms, the fragment β T-1 is unmodified. These results suggest that only the ϵ-amino groups of the β-Lys-82 residues have been blocked, the β-Val-1 residue [the amino group that is also modified by other reagents (*25*)] remaining unmodified. This is consistent with the formation of a bis-amide cross-link between the ϵ-amino group of the Lys-82 residue of one β chain and the ϵ-amino group of the Lys-82 residue of the other β chain. The peptide pattern for peak 4 in the C-4 chromatogram (Figure 7) is missing the αT-11 and the αT-12 peaks (Figure 10). These results, combined with the mass spectral data, suggest that a bis-amide cross-link between the ϵ-amino groups of two α-Lys-99 (the C-terminus of αT-11) has formed selectively.

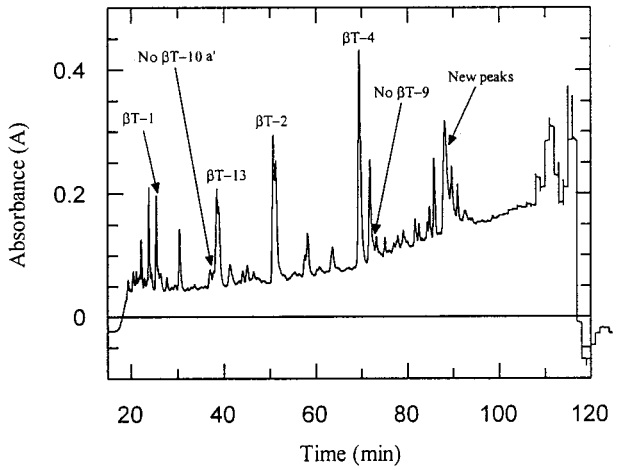

Figure 9. Tryptic-Glu-C peptide map of DBTIA-cross-linked β chains (peak 2 in Figure 7).

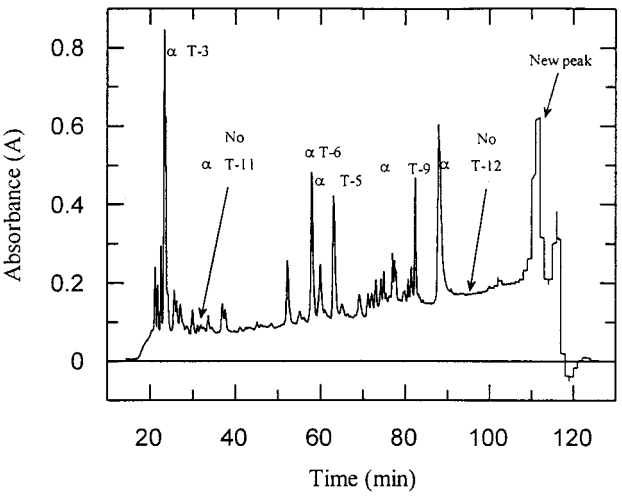

Figure 10. Tryptic-Glu-C peptide map of DBTIA-cross-linked α chains (peak 4 in Figure 7).

Table 1. Product Distributions (relative percentages ot total eluted) from Reaction of Deoxyhemoglobin with DBBA and with DBTIA (pH 9, 3 h: based on reversed phase HPLC analysis)

reagent	β82-X-82β'	α99-X-99α′	unreacted β	unreacted α
DBBA	21	10	7.4	23
DBTIA	14.3	4.9	0.7	13

On the basis of the structural analysis and quantitative measurement of products, we determined the yield of modified hemoglobin obtained in the reactions. The results are summarized in Table 1. The cross-linked hemoglobins are produced in sufficient yields to permit isolation of reasonable amounts of bioconjugates. The process is not efficient in terms of use of hemoglobin, but it does produce stable, modified species that are easily isolated. We made no attempt to optimize the process by varying reaction conditions.

The oxygen-binding properties of the biotinylated cross-linked hemoglobin [β82-(aminoisophthalylbiotintyl)-82β' (DBBA-Hb] were determined by a modification of the Imai method (*12*, *14*). The oxygen affinity (P_{50} = 5.0; pH 7.4, 25 °C, 0.1 M chloride and 50 mM bis-tris) is very close to that of native hemoglobin (P_{50} = 4.9) (*25*), and full cooperativity is maintained (n_{50} = 3.1). Previous work has established a linear correlation between the length of the cross-link span and the oxygen affinity of the hemoglobin conjugate (for common sites of modification) (*22*, *26*). The oxygen-binding properties of the DBBA-Hb conjugate fit this correlation for a span of ∼7 Å between the ϵ amino groups of the linked lysines (β82-X-82β'), the span of the isophthalyl cross-link. The cross-link is located on the 2-fold rotation axis of hemoglobin and does not introduce asymmetric distortion into the tetramer. Physical studies have shown that this cross-linking causes symmetrical perturbations in the structure of the protein (*27*), and related crystal structures show the retained symmetry (*28*). Thus, it is likely that the β82−82β' cross-link preserves the quaternary structure of the protein. The CD spectrum of the modified protein is essentially superimposable on that of the native protein, indicating that the modification does not alter the basic structure of the protein.

We have used sequential activation to produce the cross-linking reagents with pendant ligands. The ligand to be appended is activated to react with the amino group of 3-amino-isophthalic acid to form an amide. The two carboxylic acid groups are then activated as 3,5-dibromosalicylates to react with the protein. The reagents that we have produced, DBBA and DBTIA, have their reactive sites in the isophthalyl geometry that with other reagents produces a cross-link selectively between β-Lys-82 residues of hemoglobin. The data in Table 1 show that DBBA and DBTIA also give significant amounts of products with α-Lys-99-α′-Lys-99 connections as well as the expected β-Lys-82 products. Walder has shown that for reactions with fumaryl bis (3,5-dibromosalicylate), the α-Lys-99 amino groups are normally reactive if the β-Lys-82 sites are blocked (*29*). Thus, we propose that reaction at the α-Ly-99 probably occurs because a molecule of the reagent binds between the β subunits without reacting, directing a second reagent to the alternative site between the α subunits. A schematic representation of the primary cross-linking reaction leading to the product with biotin appended is shown in Scheme 4.

CONCLUSION

The procedures we have developed establish that molecular necklaces convert hemoglobin directly into cross-linked bioconjugates. Our method involves sequential activation, avoiding competition with hydrolysis in the final products. The method is general and should be applicable to generating a wide range of bioconjugates.

New Class of Polymers for the Delivery of Macromolecular Therapeutics

Hector Gonzalez,† Sue Jean Hwang,† and M. E. Davis*

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received June 9, 1999; Revised Manuscript Received August 6, 1999

Cationic polymers show promise for the in vitro and in vivo delivery of macromolecular therapeutics. Known cationic polymers, e.g., poly(L)lysine (PLL) and polyethylenimine (PEI), have been employed in native and modified forms for the delivery of plasmid DNA (pDNA) and reveal varying levels of toxicity. Here, we report the preparation of a new class of cationic polymers that are specifically designed to deliver macromolecular therapeutics. Linear, cationic, β-cyclodextrin (β-CD)-containing polymers (CD-polymers) are synthesized by copolymerizing difunctionalized β-CD monomers (AA) with other difunctionalized comonomers (BB) such that an AABBAABB product is formed. The β-CD polymers are able to bind ~5 kbp pDNA above polymer to DNA (+/−) charge ratios of 1.5, compact the bound pDNA into particles of approximately 100−150 nm in size at charge ratios above 5+/−, and transfect cultured cells at charge ratios above 10+/−. In vitro transfections with the new β-CD-polymers are comparable to the best results obtained in our hands with PEI and Lipofectamine. Some cell line-dependent toxicities are observed for serum-free transfections; however, no toxicity is revealed at charge ratios as high as 70+/− in transfections conducted in 10% serum. Single IV and IP doses as high as 200 mg/kg in mice showed no mortalities.

INTRODUCTION

Methodologies currently under investigation for the in vivo delivery of macromolecular therapeutics, e.g., proteins, oligonucleotides, ribozymes, plasmid DNA, etc., include both viral and nonviral constructs. Viral transfection systems can produce efficient expression of transgenes within cells of interest. However, they have several disadvantages, e.g., adenoviruses have high immunogenicity, retroviruses produce random genomic integration, and both vectors have severely limiting capacities for the size of a foreign transgene. Additionally, scaled-up manufacture of replication-deficient viral constructs in the absence of recovered replication-competency is problematic (*1*). In contrast, nonviral transfection systems have low immunogenicity and the capacity to handle larger sizes of DNA than viruses and are amenable to large-scale manufacture. A recent review has appeared on nonviral gene delivery constructs (*2*). Despite the advantages of nonviral delivery systems, they reveal numerous problems such as substantially less gene expression than viral vectors and toxicity.

The goal of our work was to synthesize new nonviral vectors for the delivery of therapeutic macromolecules. Our approach was to construct a completely new family of materials specifically prepared for this application. We chose to work with polymeric materials and attempted to address the issue of toxicity. To this end, we synthesized a new class of cyclodextrin-containing polymers in the hope of creating a relatively nontoxic vector for the delivery of macromolecules since numerous cyclodextrins are known to have low toxicity (*3*).

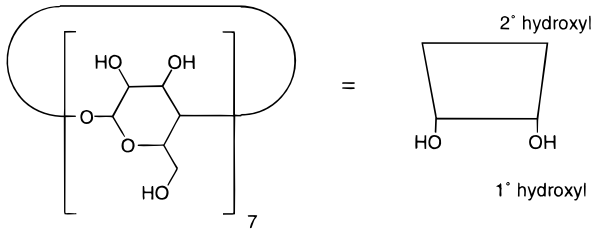

Figure 1. Schematic of β-cyclodextrin.

Cyclodextrins (CDs) are cup-shaped molecules formed by cyclic oligomers of glucose (see Figure 1). Cyclodextrins comprised of 6, 7, and 8 glucose units are called α-, β-, and γ-cyclodextrins, respectively. The three-dimensional structure of CDs is such that the cavity is relatively hydrophobic when compared to the exterior and thus can be used to imbibe hydrophobic compounds to form host−guest complexes. The ability of CDs to form inclusion complexes has been exploited in CD drug formulations throughout the world (including the U.S.; the first drug formulation to contain a CD, Sporanox, was approved by the FDA in 1997). Because of this, it is known that CDs have relatively low toxicity and lack immunogenicity (*3*). The question addressed here is whether these desirable features can be maintained in polymeric form in order to deliver macromolecules.

In this paper, the synthesis and characterization of a new family of β-CD-containing polymers is presented. Numerous polymers have been prepared (*4*), and here we provide several representative examples. It is shown that these polymers can bind and condense pDNA and transfect cells with a low level of toxicity.

MATERIALS AND METHODS

Monomers. 6A,6D-Dideoxy-6A,6D-diamino-β-cyclodextrin (**1**, Figure 2) and 6A,6D-dideoxy-6A,6D-di(2-

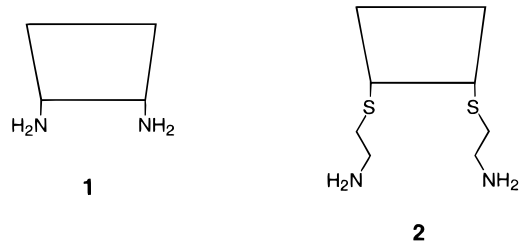

Figure 2. β-Cyclodextrin comonomers.

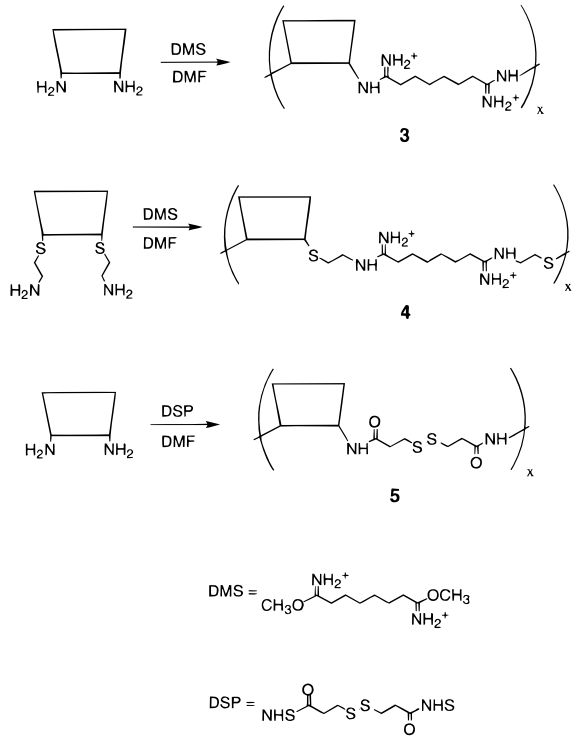

Figure 3. Schematic of β-cyclodextrin polymer (**3**−**5**) syntheses.

aminoethanethio)-β-cyclodextrin (**2**, Figure 2) were synthesized according to literature procedures (*4*) and had satisfactory NMR, mass spectral, and elemental analyses. All reagents were purchased from the Aldrich Chemical Co. (Milwaukee, WI) and used as received except for dimethylsuberimidate·2HCl (DMS) and dithiobis(succinimidyl propionate) (DSP), which were purchased from Pierce Chemical Co. (Rockford, IL), and used as received. The degree of hydration of the cyclodextrin samples was determined by measuring the weight loss on a TA Instruments TGA 951 thermogravimetric analyzer operating from 25 to 140 °C at a 5 °C/min heating rate.

Polymers Containing β-Cyclodextrin (3−5). β-CD copolymers **3**-**5** were prepared by the polymerization of a difunctionalized β-CD (AA) monomer with a difunctionalized comonomer (BB) to give an AABBAABB product (Figure 3). One procedure to form **4** is provided below. Additional synthetic methodologies can be found elsewhere (*4*). An 8 mL vial was charged with a solution of the bis(hydrogen carbonate) salt of 6A,6D-dideoxy-6A,-6D-di(2-aminoethanethio)-β-cyclodextrin hexahydrate (184.6 mg, 1.36×10^{-4} mol) dissolved in 0.5 M Na_2CO_3. DMS (37.0 mg, 1.36×10^{-4} mol) was added, and the solution was centrifuged briefly to dissolve the components. The resulting mixture was stirred at 25 °C for 15 h. The mixture was then diluted with ca. 10 mL of water and the pH brought to 4 with 10% HCl. This material was then dialyzed against a Spectra/Por 7 MWCO 3500 dialysis membrane (Spectrum, Houston, TX) in dH_2O for 24 h. The dialyzed solution was lyophilized to dryness yielding 51 mg (24%) of a white amorphous solid. Calcd for $C_{54}H_{94}N_4Cl_2O_{33}S_2 \cdot 7H_2O$: C, 40.83; H, 6.85; N, 3.53. Found: C, 40.77; H, 6.52; N, 3.46. ^{1}H NMR (500 MHz, D_2O) δ 1.39 (br, 4H), 1.69 (br, 4H), 2.49 (br, 4H), 2.92 (br, 4H), 3.16 (br, 4H), 3.5−4.0 (m, 42H), 5.05 (m, 7H). ^{13}C NMR (125 MHz, D_2O) δ 27.5, 28.6, 31.5, 33.8, 39.6, 42.6, 61.6, 73.2, 74.2, 82.7, 85.2, 103.2, 169.4. IR (KBr) 1652 (C═N).

Light Scattering and Molecular Weight Determination. The specific refractive index increment, d*n*/d*c*, was measured in 0.3 M NaCl using a Waters 2410 differential refractive index detector at a flow rate of 1.0 mL/min. The value of d*n*/d*c* for **4** in 0.3 M NaCl at λ = 930 nm and 25 °C was 0.155 mL/g. Polymer samples were then analyzed on a Hitachi D6000 HPLC system equipped with a ERC-7512 RI detector, a Precision Detectors PD2020/DLS light scattering detector and a Progel-TSK G2000 SWXL column using 0.3 M NaCl as eluant at a 0.7 mL/min flow rate. The weight average molecular weight, M_w, was determined to be 8800, with a polydispersity index, M_w/M_n of 1.10.

Cell Lines and Cell Culture. BHK-21 cells were purchased from ATCC (Rockville, MD) and maintained in Dulbecco's Modified Eagle Medium supplemented with 10% fetal bovine serum (FBS), 100 units/mL penicillin, 100 μg/mL streptomycin, and 0.25 μg/mL amphotericin. CHO-K1 cells were purchased from ATCC and maintained in Ham's F-12 medium with the above listed supplements. All cells were cultured at 37 °C in a 5% CO_2 humidified atmosphere and passaged every 4−5 days. Media and supplements were purchased from Gibco BRL (Gaithersberg, MD).

Plasmids. pGL3-Control Vector (pGL3-CV) plasmid, which contains the luciferase gene under the control of the SV40 promoter, was purchased from Promega (Madison, WI). Plasmids were amplified by *Escherichia coli* strain DH5α and purified using Qiagen's Endotoxin-free Megaprep Kit (Valencia, CA).

Preparation of DNA−Polymer Complexes and DNA Gel Retardation Assay. One microgram of pGL3-CV (0.1 μg/μL in distilled water) was mixed with an equal volume of polymer (10 μL in distilled water) at the appropriate charge ratios. After a 15−30 min incubation, the samples were pipetted with 1 μL of loading buffer into wells of a 0.6% agarose gel containing 6 μg of ethidium bromide/100 mL of TAE buffer (40 mM Tris-acetate, 1 mM EDTA) and electrophoresed.

Solid-Phase DNA Binding Assay. A 5′-amino-modified 50-mer oligonucleotide (5′-amino-AAA ACT GCT TAC CAG GGA TTT CAG TGC ATG TAC ACG TTC GTC ACA TCT CA-3′, "NMODSOL") and its complementary oligonucleotide ("COMPSOL") were synthesized by the Biopolymer Synthesis and Analysis Research Center at Caltech (Pasadena, CA). NMODSOL was covalently coupled to magnetic porous glass (MPG) supports according to manufacturer's instructions (Solid-Phase Oligo COUPLE-IT Kit, CPG. Inc, Lincoln Park, NJ). UV absorption analysis revealed successful coupling of 190 μg of oligo to 10 mg of MPG particles. The complementary oligo, COMPSOL, was then annealed to the coupled strand by heating a solution of COMPSOL in 45 mM NaCl with the MPG-coupled oligo in boiling water for 2 min and then allowing the solution to slowly cool to room temperature. UV analysis confirmed successful annealing of the complementary strand.

Primary amine-containing compounds to be analyzed for DNA-binding capability were added at a 1:5 (+/−) charge ratio in 1 mL of distilled water to the MPG-

supported DNA (dsDNA-MPG) and incubated with gentle rotation for 2 h. The particles were magnetically separated and the supernatant removed. Unbound molecules remaining in the supernatant were quantified by amine reaction with TNBS at pH 8.5 (*6*) and compared to amine quantification of the solution before exposure to dsDNA-MPG to determine extent of DNA binding.

Cell Transfections and Luciferase Assay. BHK-21 cells were plated at 60 000 cells/well in 24-well plates 24 h before transfection. Immediately prior to transfection, cells were rinsed once with PBS (pH 7.4) and 200 μL of Optimem (Gibco), for serum-free transfections, or complete media, for transfections in 10% serum, was added to each well. Polymer **4**−DNA complexes were prepared as described above. Lipofectamine (Gibco) and Superfect (Qiagen) complexes were prepared according to manufacturers' instructions. PEI (branched 25 kDa, Sigma) and polylysine (35 kDa, Sigma) complexes were prepared as described above, except in 150 mM NaCl at pH 7.0 instead of distilled water. Thirty minutes was allowed for complex formation before addition to cells. After 5 h, 800 μL of appropriate media with 10% FBS were added to cells. Twenty-four hours after transfection, the media in each well was replaced with 1 mL of culture media/well. After another 24 h, media was removed by aspiration, and cells were washed twice with PBS (pH 7.4) and lysed by one freeze−thaw cycle in 50 μL Cell Culture Lysis Buffer (Promega, Madison, WI). Cell lysates were analyzed for luciferase activity with Promega's luciferase assay reagent and for vector toxicity as described below. Light units were integrated over 10 s in duplicate with a luminometer (Monolight 2010, Analytical Luminescence Laboratory, San Diego, CA).

Toxicity. The amount of protein in cell lysates obtained 48 h after transfection was used as a measure of cell viability. Protein levels of transfected cells were determined by Bio-Rad's DC protein assay (Hercules, CA) and normalized with protein levels of cells transfected with naked DNA. A protein standard curve was run with various concentrations of bovine IgG (Biorad) in Cell Culture Lysis Buffer.

Physicochemical Characteristics of Polymer−DNA Composites. *Transmission Electron Microscopy.* Polymer−DNA complexes were prepared at different charge ratios as described above for the gel retardation assay. After 1 h of incubation, five microliters of sample was applied in duplicate to 400-mesh carbon-coated copper grids for 45 s, after which excess liquid was removed by blotting with filter paper. The 400-mesh carbon-coated copper grids were glow-discharged immediately prior to sample loading. One set of samples was then rotary shadowed at a 6° angle with a 3 cm tungsten wire while the duplicate set was negatively stained with 2% uranyl acetate for 45 s before blotting. Images were recorded using a Philips 201 electron microscope operated at 80 kV.

Dynamic Light Scattering (DLS) and ζ-Potential. For determination of particle size and charge, 2 μg of pGL-CV3 (0.1 μg/μL in dH_2O) was mixed with an equal volume of polymer (20 μL in dH_2O) and allowed to stand for 30 min before diluting with H_2O to a final volume of 1.3 mL for measurements. Particle size and ζ-potential of the complexes were measured using a ZetaPals dynamic light scattering detector (Brookhaven Instruments Corporation, Holtsville, NY). Three measurements were taken for each sample and data reported as average size and ζ-potential.

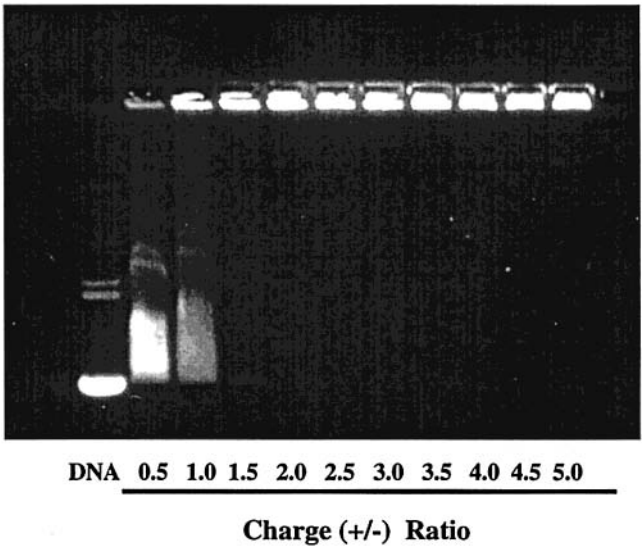

Figure 4. Determination of β-CD polymer **4**−DNA charge ratio necessary for complex formation by DNA retardation. DNA is visualized by ethidium bromide.

RESULTS

Binding of Functionalized CD Monomers 1 and 2 to DNA. DNA is not retarded in the electrophoresis assay by contact with the functionalized CD monomers **1** and **2** (data not shown), and this is most likely due to weak binding interactions that are disrupted by the presence of salts. Therefore, a solid-phase DNA-binding assay conducted in deionized water was developed as described in Materials and Methods. Using this assay, the CD-monomer **1** does not bind to DNA (0% binding), possibly due to the steric hindrance of the bulky cyclodextrin cups that are in very close proximity to the positive charge center. To test this hypothesis, **2** was prepared to specifically remove the amine further from the CD. CD-monomer **2** readily binds to DNA, with 88% binding. This binding compares favorably to other short polycations, such as spermine (19% binding).

DNA Binding of CD-Polymer. Although CD monomer **2** is not able to bind to DNA in the presence of salt, polymer **4** is able to completely bind DNA above polymer to DNA charge ratios of 1.5, as shown by DNA gel retardation (Figure 4). Binding is observed for complex formation in dH_2O, 150 mM NaCl, and complete media (data not shown). Polymer **3** does not bind to DNA even at polymer to DNA charge ratios as high as 50 (data not shown) and is likely due to the same reasons as mentioned previously with compound **1**.

In Vitro Transfection and Toxicity of DNA Complexes. One microgram of pGL3-CV, encoding for the luciferase gene under the control of the SV40 promoter, was complexed with **4** at various charge ratios in 10% serum and serum-free conditions and added to BHK−21 and CHO-K1 cells plated in 24-well plates. Transfection efficiencies of these complexes were determined by assaying for luciferase protein activity and reported in relative light units (RLU) per milligram of total cell protein. Luciferase protein activity in BHK-21 cells transfected in serum-free conditions reached a stable maximum at 30+/− with $\sim 1 \times 10^9$ RLU/mg of protein. The presence of 10% serum in the transfection media decreased luciferase activity at all charge ratios (Figure 5a). With CHO-K1 cells, increasing charge ratio also enhanced the transfection for all conditions tested. Ad-

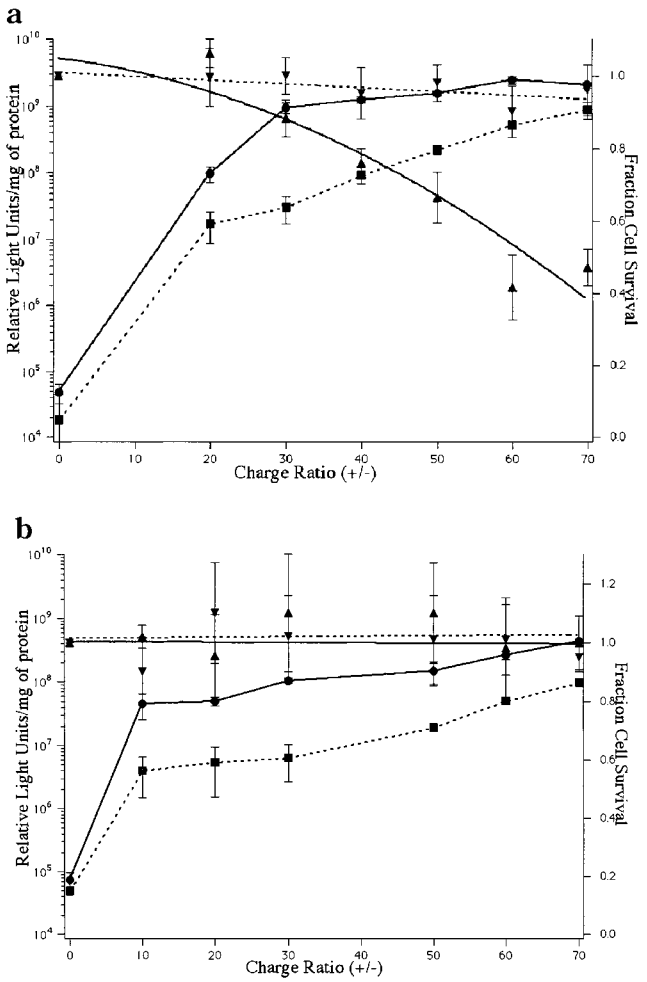

Figure 5. The effect of β-CD polymer **4** to DNA charge ratio and serum conditions on transfection efficiency (● and ■) and cell survival (▼ and ▲) in BHK-21 (a) and CHO-K1 (b) cells. Results from transfections in 10% serum and serum-free media are shown with the dotted and solid lines, respectively. Data are reported as the mean ± SD of three samples. Toxicity data are presented as best fit lines.

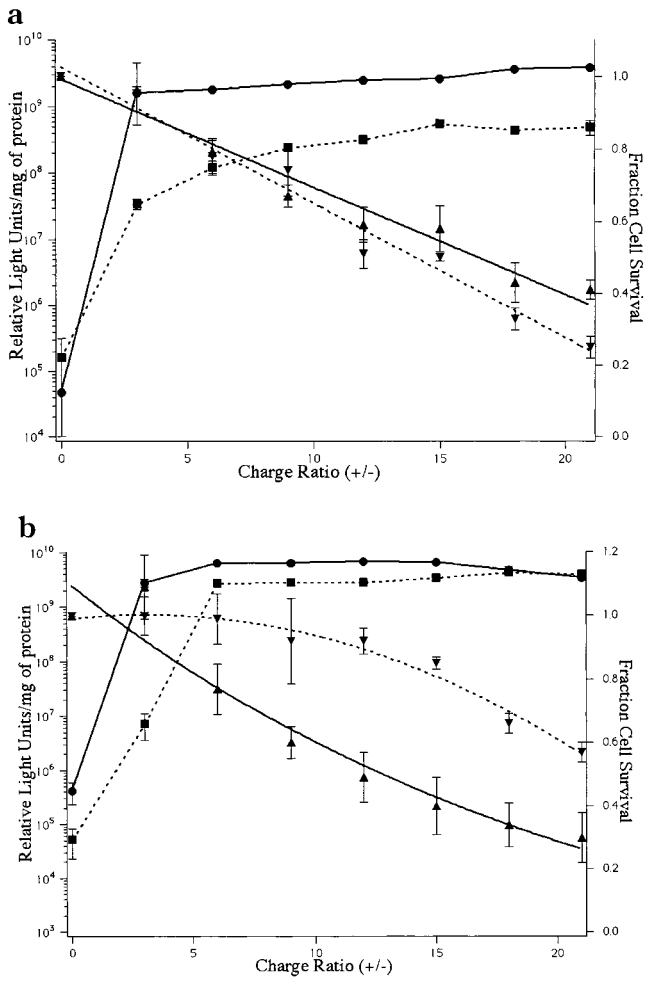

Figure 6. The effect of PEI to DNA charge ratio and serum conditions on transfection efficiency (● and ■) and cell survival (▼ and ▲) in BHK-21 (a) and CHO-K1 (b) cells. Results from transfections in 10% serum and serum-free media are shown with the dotted and solid lines, respectively. Data are reported as the mean ± SD of three samples. Toxicity data are presented as best fit lines.

ditionally, transfection in serum decreased light units by an order of magnitude (Figure 5b). The toxicity of the β-CD polymer to cells was measured by determining total cellular protein in the wells 48 h after transfection. Polymer **4** showed toxicity only to BHK-21 cells for transfections in the absence of serum. Toxicity was minimized with the presence of 10% serum during transfection (Figure 5a). No noticeable toxicity was observed from transfections to CHO-K1 cells (Figure 5b).

pGL3-CV was complexed with various commercially available transfection agents and exposed to BHK-21 and CHO-K1 cells under the same protocol as used with **4** for comparison. The transfection and toxicity results for PEI (branched 25 kDa) are shown in Figure 6. Maximum transfection was obtained at a charge ratio of 3+/− for BHK-21 cells and 6+/− for CHO-K1 cells. The presence of 10% serum decreased transfection efficiencies in both cell lines, although more dramatically for BHK-21 cells. Concentration-dependent toxicity was observed for both cell lines regardless of serum conditions.

pGL3-CV transfected with **4** gave RLUs that are 2 orders of magnitude higher than transfection with Superfect and on the same order of magnitude as transfection with PEI and Lipofectamine (Figure 7a). The toxicity of the vectors at conditions for maximum transfection are shown in Figure 7b. While transfection with some of the vectors resulted in less than 60% cell survival in one or both of the cell lines tested, transfection with **4** showed low toxicity.

Particle Characterization. Previously, it has been reported that negative staining with uranyl acetate may affect DNA condensation (*7*, *8*). Here, samples for electron microscopy were prepared by both rotary shadowing and negative staining. Electron microscopy of rotary-shadowed **4**−DNA samples showed discrete particles around 100−150 nm in diameter; however, these samples did not appear focused due to low electron density. Negatively stained samples revealed uniform structures at charge ratios of 5+/− and above (Figure 8), as observed by Tang et al. (*7*), that were not present in samples without polymer addition.

Particle size was also confirmed by dynamic light scattering and surface charge of the particles was determined by ζ-potential measurements (Figure 9a). Particle charge increased with increasing polymer addition, reaching neutrality between polymer to DNA charge ratios of 1 and 2. ζ-Potential of the particles approached +32 mV as charge ratios increased. Polymer **4** begins to condense DNA at a charge ratio of 1+/−, although the particles have a net negative charge. When the charge ratio is

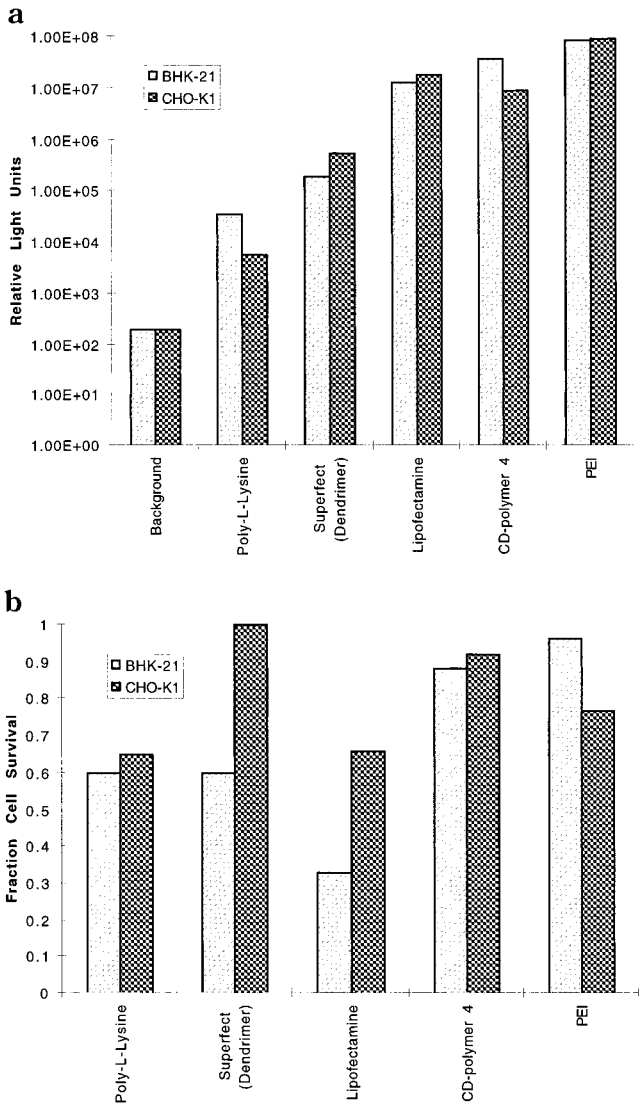

Figure 7. (a) Comparison of transfection efficiency of various nonviral vectors with BHK-21 cells. Cells were transfected with a range of vector/DNA charge ratios and starting cell densities for all vectors in serum-free media. The value reported here is obtained from the optimum transfection conditions found for each vector. (b) Comparison of the toxicities of various nonviral vectors to BHK-21 and CHO-K1 cells. Percent survival was determined by a modified Lowry protein assay at serum-free conditions giving the maximum transfection for each nonviral vector.

increased to 2+/−, the particles are near neutrality (ζ-potential = +5.8 mV) and particle aggregation occurs. The **4**−DNA particle diameter remains relatively constant at 150−180 nm above charge ratios of 10+/−. The particle size measured by DLS is slightly higher than that observed by TEM because the DLS measures the hydrodynamic diameter. Particles formed in water remained stable for several hours. Addition of 150 mM salt to the particles results in extensive aggregation that begins almost immediately. These results are consistent with those observed for peptide−DNA complexes (*9*).

A similar ζ-potential and particle diameter profile is observed for PEI−DNA complexes (Figure 9b). PEI begins to condense DNA at 1+/−. Neutral particles are formed around a charge ratio of 1.5+/− (+1.5 mV) as demonstrated by the aggregation of particles at this charge ratio. PEI also forms particles with pDNA of ca. 150 nm in diameter above charge ratios of 3+/−. The ζ-potential of the particles increases with charge ratio, reaching +40 mV at 21+/−.

DISCUSSION

The polyamidine-CD copolymer **4** prepared here is obtained with an overall yield of 24%. This yield is comparable to other synthetic, sugar-containing cationic polymers that are prepared via an AABB-type polymerization (*10*). The molecular weight, as determined by light scattering, was ca. 8800. This molecular weight corresponds to a degree of polymerization of 6, and an end-group analysis by ^{13}C NMR spectroscopy is consistent with this degree of polymerization. Polymers with pendent cyclodextrins of equivalent molecular weight have been prepared (*11*), but those reported here are the first to have the cyclodextrin as a part of the polymer backbone. Polymer **4** is found to be highly water soluble; solutions of at least 0.4 M concentration can be prepared. Thus, we were able to successfully incorporate a rather insoluble β-cyclodextrin moeity (1.6 mM) in a water-soluble polymer formulation.

The cationic nature of **4** allows for complexation to DNA. Plank et al. report that a minimum chain length of six to eight cationic amino acids is required to compact DNA into structures active in receptor-mediated gene delivery (*9*). Polymer **4** contains an average of 12 cationic charges and is able to condense plasmid DNA into discrete particles of 150 nm size in dH_2O. Although **4**−DNA particles aggregate under physiological salt conditions, there are methods of inhibiting particle aggregation by PEGylation (*12*) and we are currently exploring these and other techniques for preparing particle formulations that would be stable at physiological conditions.

The **4**−DNA complexes are also able to efficiently transfect cells in vitro. Transfection is observed for particles formed at and above +/− ratios of 10, which corresponds to an average ζ-potential of at least +24 mV. Increasing +/− ratios also increases transfection efficiency. Thus, particles are probably transfecting cells by proteoglycan-mediated entry (*13*). The presence of 10% serum during transfection decreases transfection efficiency in both BHK-21 and CHO-K1 cell lines.

Although positively charged **4**−DNA complexes of 150 nm diameter are formed by charge ratios of 5+/− (Figure 9a), transfection efficiencies continue to improve with increasing charge ratios despite little change in particle size and charge (Figure 5). It is possible that increasing the polymer to DNA ratio only serves to increase the concentration of free polymer in solution, which may in turn aid transfection by affecting the integrity of the cell membrane. To test this possibility, plasmid DNA was complexed with PEI under low charge ratio conditions which allow for complete DNA binding, but negligible transfection. Polymer **4** was then added to the transfection mixture at charge ratios up to 50+/−. Because PEI essentially binds irreversibly to pDNA, increases in transfection efficiency could be attributed to the effects of free **4** in the media. Instead, transfection efficiencies remained slightly above baseline at all concentrations of **4**. These results indicate that the increasing ratios of **4** to DNA aid transfection by affecting the properties of the **4**−DNA complexes. The nature of these phenomena are currently under investigation.

Initial trafficking studies with fluorescently labeled DNA (Gene Therapy Systems, San Diego, CA) show successful penetration of nearly 100% of cells; however, most of the complexes appear trapped in intracellular

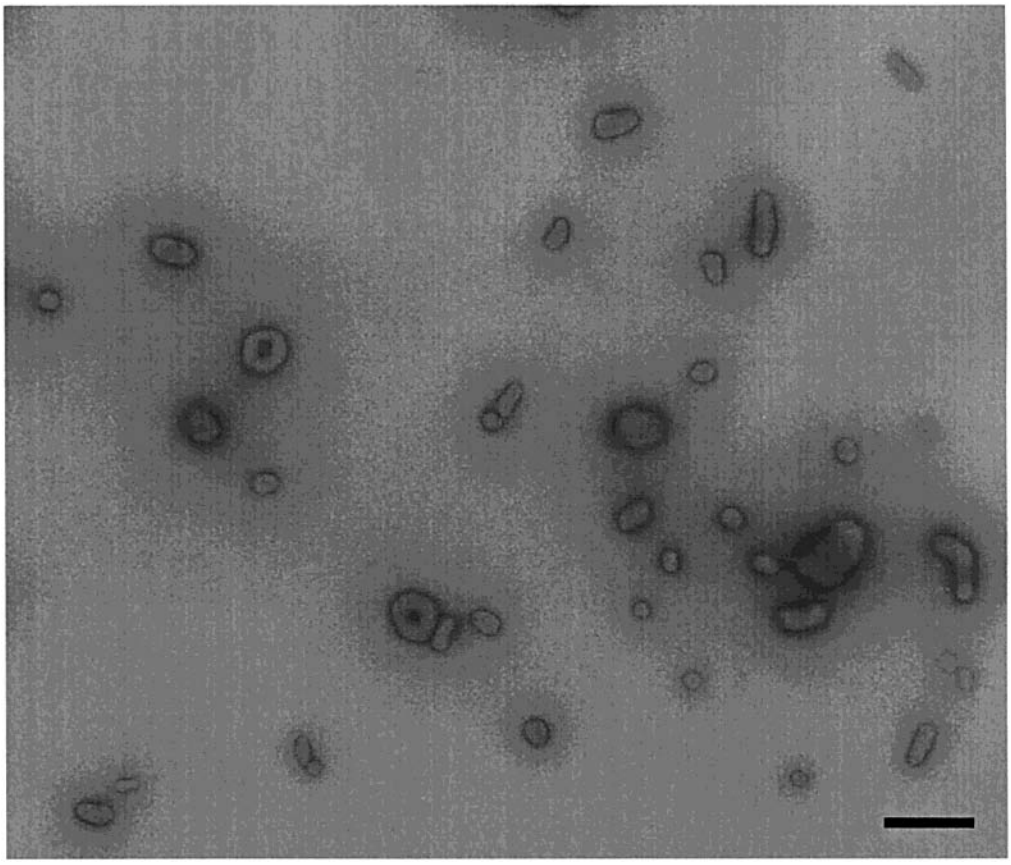

Figure 8. Electron micrographs of negatively stained complexes of polymer **4** complexed with DNA at 30+/− charge ratio in distilled water. Bar represents 200 nm.

vesicles, even 24 h after initial cell contact. The high percentage of cell transfection followed by subsequent vesicular entrapment has also been reported in lipid-based systems (*14*). Transfections at various charge ratios were, therefore, conducted in the presence of 25 μM chloroquine, an agent which delays lysosomal degradation of the pDNA by buffering the endosomal pH (*15*). The addition of chloroquine enhanced transfection efficiencies by over 2 orders of magnitude (an increase from 1×10^8 RLU/mg of protein to 7×10^{10} RLU/mg of protein at 20+/−). The transfection efficiency in the presence of chloroquine was also dependent on the polymer to DNA charge ratio; as seen before, increasing the polymer concentration also increases transfection efficiency. The transfection enhancement due to chloroquine addition confirms particle entry by endocytosis and the lack of efficient endosomal release. Nevertheless, the **4**−DNA complexes show transfection efficiencies comparable to vectors with endosome-escape mechanisms: PEI, that is speculated to act as a "proton sponge" to release complexes from endosomes by osmotic pressure (*16, 17*), and lipofectamine, which supposedly releases DNA by destabilizing endosomal membranes (*18*).

The cyclodextrin-based polymer **4** provides for efficient in vitro transfection of cells while remaining nontoxic under most conditions. Most cationic materials, such as lipid-based vectors and dendrimers have revealed some toxicity in in vitro studies (*17*). Polymer **4** showed toxicity to BHK-21 cells at increasing charge ratios in serum-free media (Figure 5a). However, no toxicity is observed with 10% serum for BHK-21 and CHO-K1 cell lines (Figure 5b), and in serum-free conditions for CHO-K1 cells, even up to charge ratios of 200+/− (data not shown).

Cytotoxicity of individual cyclodextrins is dependent upon type, e.g., α, β, and γ, and functionalization, e.g., native vs hydroxypropylated (*19*). Cyclodextrins can produce cell membrane solubilization by complexation with membrane components such as cholesterol (*19*). To test whether observed toxicity with **4** is from the polycationic nature of the polymer or from the cyclodextrin itself, BHK-21 and CHO-K1 cells were contacted with polymer **5** (no cationic charge), β-CD, and comonomer **2**. No toxicity was observed at β-CD monomer concentrations or monomer concentrations of **5** up to 700 μM, which is equivalent to the monomer concentration of **4** used for transfections at 200+/−. Finally, the cells were contacted with difunctionalized monomer DMS at concentrations up to 700 μM. Because DMS is a membrane permeable molecule, it is possible that the cell toxicity noted at high polymer concentrations is caused by the DMS end groups of the polymers. However, no cell toxicity was seen at the tested concentrations. These results indicate that the toxicity of **4** in BHK-21 cells is likely due to the polycationic nature of the polymer.

Preliminary in vivo toxicity studies have also been consistent with the in vitro findings. Single intravenous and intraperitoneal injections in mice of a cyclodextrin polymer similar to **4** at concentrations up to 200 mg/kg showed no mortalities. Macroscopic examinations at necropsy revealed no evidence of damage 5 days after polymer administration. For comparison, 22 kDa linear PEI has a LD_{50} of approximately 30 mg/kg in the presence of 5 mg/kg pDNA in mice (*20*) and a PEG-terminated copolymer of D-lysine/D-serine is lethal to mice within 30 min of i.v. administration at 200 mg/kg (*21*).

β-Cyclodextrin containing cationic polymers were synthesized in an effort to develop a delivery vehicle that would be nontoxic and would condense DNA to particles sufficiently small to enable efficient transfection. The polyamidine polymer **4** satisfies these criteria.

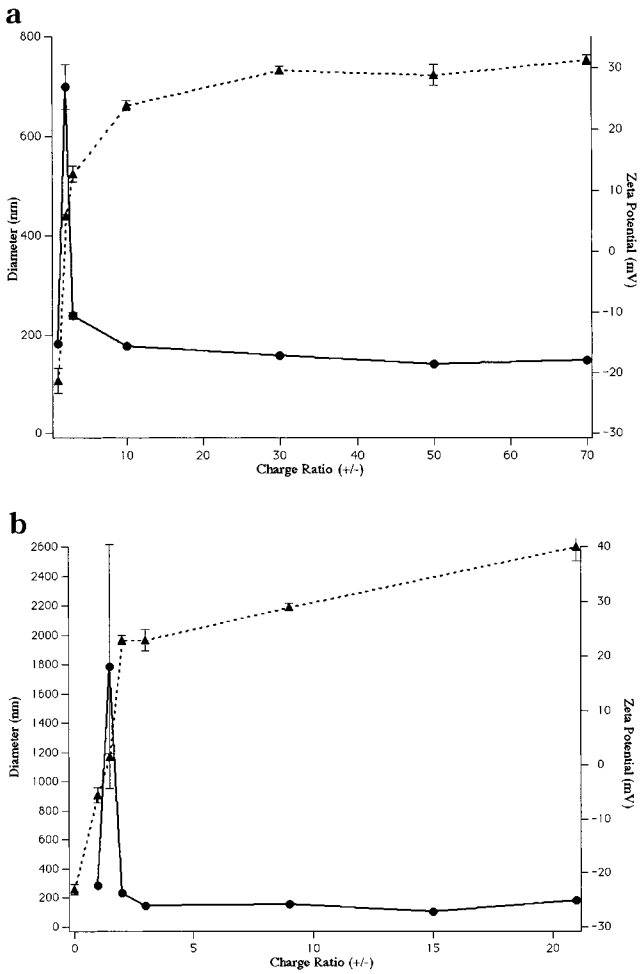

Figure 9. The effect of polymer **4** to DNA (a) and PEI to DNA (b) charge ratio on particle size (●), as determined by dynamic light scattering, and particle charge (▲), as estimated by ζ-potential measurements.

Multicomponent DNA Carrier with a Vesicular Stomatitis Virus G-Peptide Greatly Enhances Liver-Targeted Gene Expression in Mice†

Martin J. Schuster, George Y. Wu, Cherie M. Walton, and Catherine H. Wu*

Department of Medicine, Division of Gastroenterology-Hepatology, University of Connecticut School of Medicine, Farmington, Connecticut 06030. Received June 9, 1999; Revised Manuscript Received September 10, 1999

Genes can be targeted to hepatocytes in vitro and in vivo by the use of asialoorosomucoid−polylysine conjugates. After systemic application, this nonviral vector is recognized by highly selective asialoglycoprotein (AsGP) receptors on the sinusoidal liver cell membrane and is taken up via receptor-mediated endocytosis. As most of the DNA is rapidly transferred to lysosomes where it is degraded, transfection efficiency is low and gene expression transient. To address this problem, we incorporated a pH-dependent synthetic hemolytic peptide derived of the G-protein of Vesicular Stomatitis Virus (VSV) into the gene transfer system, to increase endosomal escape of internalized DNA. The multicomponent carrier binds DNA in a nondamaging way, is still recognized by the AsGP receptor, and is targeted to the liver in vivo. Injection of DNA complexes containing a luciferase marker gene resulted in luciferase expression of 29 000 pg/g liver which corresponded to an increase of a factor of 10^3 overexpression after injection of DNA complexes without endosomolytic peptide. Furthermore, the amount of intact transgene within isolated liver cell nuclei was increased by a factor of 10^1−10^2 by the use of the multicomponent carriers. These results demonstrate that incorporation of a hemolytic peptide into a nonviral vector can greatly increase gene expression while retaining cell type targetability in vivo.

We have shown previously that DNA can be delivered specifically to the liver based on the presence of receptors on hepatocytes that recognize galactose-terminal (asialo)-glycoproteins (AsGP).[1] Binding of the soluble DNA−protein complex by the AsGP receptor results in internalization of the ligand into the endosomal compartment and ultimately degradation in lysosomes. In early studies, this strategy was used to deliver foreign genes to hepatocytes in vitro (*1*) as well as in vivo (*2*), resulting in short term, low level gene expression. Targeted transfer to hepatocytes by this technology was successfully applied to temporarily correct metabolic defects in animal models of human disease (*3*, *4*).

Subsequent experiments were performed to prolong the duration as well as to increase the efficiency of targeted gene expression. Partial hepatectomy immediately after intravenous injection of the complex resulted in extended persistence and expression of the transgene (*5*, *6*). The majority of the persisting DNA was shown to exist in cytoplasmic vesicles for many weeks (*7*, *8*). Disruption of the microtubule network, which is required for the translocation of endosomes to lysosomes (*9*) was shown to be responsible for this effect (*4*).

To circumvent the natural degradative process, in a noninvasive manner, we sought to imitate survival techniques of natural pathogens. We noted that vesicular stomatitis virus (VSV) has evolved a mechanism for survival that depends on release from endocytotic vesicles after cell entry. Membrane fusion is mediated by the VSV glycoprotein (G-protein) in a pH-dependent manner. After internalization within endosomes, the decrease in pH triggers a conformational change in the G-protein which results in insertion into the endosomal membrane and release of the virus from the endosome. It was demonstrated that G-protein-mediated fusion depends on an internal domain (*10*, *11*) as well as membrane anchoring (*12*) of the protein. A synthetic peptide corresponding to the amino-terminal 25 amino acids of VSV G-protein has been shown to be hemolytic at pH 5, but inactive at physiological pH, and thought to be the fusogenic domain (*13*, *14*). Although this peptide was later proven to be dispensable for G-protein membrane fusion (*15*), its properties appeared favorable for achieving release of endosomal contents following receptor mediated endocytosis.

In the following report, we demonstrate for the first time, that a hemolytic peptide corresponding to the amino-terminal 25 amino acids of the VSV G-protein (VSVG) increases the efficiency of receptor-mediated gene transfer in vivo. We found that this carrier was still highly liver selective and greatly enhanced receptor-mediated gene expression in vivo.

MATERIALS AND METHODS

Animals. Balb C female mice (∼20 g body weight) were obtained from Charles River Laboratory, Wilmington, MA, housed under controlled conditions of temperature and humidity, and fed normal chow ad libitum. All experimental procedures were performed in accordance with protocols approved by our Institutional Animal Care Committee.

Materials. A 878 bp *Bgl*II−*Hin*dIII fragment of pRc-CMV (Invitrogen, Carlsbad, CA) containing CMV immediate-early gene enhancer-promoter sequences was cloned into the *Bgl*II−*Hin*dIII sites of pGL3-Basic (Promega, Madison, WI) to create pGL3CMVluc. pEGFP-C1 was obtained from Clontech (Palo Alto, CA). Plasmid DNA was prepared as described previously (*16*). All chemicals used were of analytical grade (Sigma, St. Louis, MO), if not mentioned otherwise. DNA-modifying enzymes were obtained from Life Technologies (Gaithersburg, MD).

Preparation of DNA Carriers. Asialoorosomucoid (AsOR) was produced by acid hydrolysis (*17*) of orosomucoid isolated from pooled human serum (American Red Cross) (*18*) and covalently linked to L-lysine methyl ester (lysine-OMe) using 1-ethyl-3(3-dimethylaminopropyl) carbodiimide (EDC, Pierce, Rockford, IL) to incorporate positive charges for DNA binding. Ten milligrams of AsOR was dissolved in 1 mL of water and filtered through a 0.45 μm syringe-tip filter (Acrodisc, Gelman Sciences, Ann Arbor, MI). Fifty milligrams of lysine-OMe was dissolved in 1 mL of water and added to the AsOR, and the pH adjusted to 6.5 using NaOH at 0.1 N. To this mixture was added 4 mg of EDC, dissolved in 1 mL of water and incubated with stirring at 37 °C for 5 h, followed by dialysis of the reaction mixture through membranes with 12−14 kDa exclusion limits (Spectra/Por, Spectrum Medical Industries, Houston, TX) against 20 L of water at 4 °C for 24 h. The dialyzate was lyophilized and then redissolved in 0.15 M NaCl (10 mg/mL), filtered through a 0.45 μm syringe-tip filter, and applied on a Waters HPLC system using a Shodex KW-804 column (300 × 8 mm, Waters Corporation, Milford, MA). Samples of 250 μL were injected and eluted with 0.15 M NaCl at a flow rate of 0.12 mL/min. Samples 0.6 mL each were collected, and absorption was monitored at 280 nm. Samples of the two peaks in the effluent were analyzed by 12% SDS−PAGE. The second peak was used for further conjugation and corresponding samples were lyophilized.

Purified conjugates were hydrolyzed in constant boiling HCl and submitted for amino acid analysis to determine the ratios of components present. The total number of lysine residues minus the lysine residues expected from AsOR alone provided quantitation of the amount of lysine-OMe present. The number of aspartic acid residues was used to determine the amount of AsOR in each conjugate, and a lysine-OMe to AsOR molar ratio was calculated.

VSVG peptide (KFTIVFPHNQKGNWKNVPSNYHY-CP) was obtained from Immune Response Corporation (Carlsbad, CA) and shown to be hemolytic in a pH-dependent manner as described previously (*13*, *14*). The cysteine residue was used to couple peptides to AsOR-lysine-OMe with *N*-succinimidyl 3-(2-pyridyldithio) propionate (SPDP, Pierce). Five milligrams of purified AsOR-lysine-OMe was dissolved in 1 mL of PBS (pH 7.4), and 0.18 mL of freshly prepared SPDP (3.1 mg/mL in DMSO) was added to give a 30-fold molar excess of SPDP over AsOR-lysine-OMe. The mixture was incubated with stirring for 1 h at 25 °C. The reaction mixture was then dialyzed in membranes with 12−14 kDa exclusion limits against 20 L of water for 24 h at 4 °C and lyophilized. To remove any free SPDP, the conjugate was dissolved in water and applied to a Sephadex G25 column (Amersham Pharmacia Biotech, Piscataway, NJ), followed by elution with water. The eluate was checked for absorption at 280 nm and lyophilized. To determine the molar ratio of AsOR-lysine-OMe to SPDP, the absorption at 343 nm was measured with and without reduction using dithiothreitol (DTT) as described previously (*19*). To activate the sulfhydryl group, VSVG peptide was dissolved in PBS and incubated with a 10-fold molar excess of DTT for 60 min at 25 °C. Excess DTT was separated by HPLC using an Aquapore Cation Exchange CX-300 column (250 × 10 mm, Rainin Instrument) and elution with 0.3 M NaCl at a flow rate of 1 mL/min. VSVG was then conjugated to AsOR-lysine-OMe-SPDP. Two milligrams of AsOR-lysine-OMe-SPDP and 10 mg of activated VSVG peptide were each dissolved in 1 mL of water. VSVG was added in a 20-fold molar excess over AsOR to the conjugate. NaCl at 1.5 M was added to make a final concentration of 0.15 M, and the reaction mixture was passed through a 0.45 μm syringe-tip filter and incubated on a nutator at 25 °C for 18 h, followed by lyophilization. Five milligram samples were then dissolved in 0.5 mL of water, applied to a Sephadex G25 column, and eluted with water. The eluate was monitored for its absorbance at 280 nm, and the first peak was collected. The conjugates were analyzed on a 12% SDS−polyacrylamide gel with and without the addition of DTT as described previously (*19*). Amino acid analysis was performed to permit calculation of the molar ratio of VSVG to AsOR from tyrosine (present in AsOR and VSVG) and glutamic acid (present only in AsOR) content. AsOR-polylysine (26 kDa) was prepared as described (*2*), using poly-L-lysine, 26 kDa.

Formation of Protein Conjugate−DNA Complexes. Ethidium bromide exclusion was used to determine the DNA-binding capacity of protein conjugates. Sixty micrograms of pGL3CMVluc was dissolved in 2.5 mL of 0.15 M NaCl containing 2.5 μM ethidium bromide. Conjugates (0.6 mg/mL) were dissolved in 0.15 M NaCl and added in 50 μL increments to the DNA solution, while fluorescence was measured with excitation at 260 nm and emission at 591 nm on a fluorimeter. The minimum amount of protein conjugate resulting in maximum ethidium bromide exclusion was selected, and DNA complexation was confirmed by agarose gel retardation as described previously (*1*). DNA−protein conjugate complexes for injection were made starting with 40 μg/mL of DNA in 0.15 M NaCl. While continuously vortexing, 25 μL aliquots of protein conjugate were added over 30 min at 25 °C, followed by incubation for 30 min at 25 °C. Absorption was measured at 260, 340, and 400 nm to detect complexes. The purified products were filtered through a 0.22 μm syringe top filter (Gelman Sciences). Recovery of filtered complexes was measured by absorption at 260 nm and brought to a concentration of 10 μg with respect to DNA in 0.5 mL by adding sterile 0.15 M NaCl.

Dissociability and Stability of DNA−Protein Conjugate Complexes. To investigate dissociability, DNA was complexed with either AsOR-lysine-OMe, AsOR-lysine-OMe-VSVG, or AsOR-polylysine as described above and mixed with equal amounts of either 0.15 M NaCl, 8 M urea, or 0.15 M NaCl containing 200 units of heparin and incubated at 37 °C. Aliquots were withdrawn at 0, 10, and 30 min, respectively, transferred on ice, and analyzed on a 0.8% agarose gel containing 0.5 μg/mL EtBr. To determine if DNA complexed by protein conjugates were protected from degradation by serum nucleases, DNA complexes were incubated at 37 °C in the presence of 0.33 milliunits of DNase I (Boehringer Mannheim). Aliquots were withdrawn after 0, 2, 5, 10, and 30 min, respectively, and reactions stopped by adding Na_2EDTA up to 12.5 mM, followed by heat inactivation for 20 min at 75 °C. To release DNA from protein conjugates, 200 units of heparin (for AsOR-polylysine, AsOR-lysine-OMe) or an equal volume of 8 M urea (for

AsOR-lysine-OMe-VSVG) were added. Finally, all samples were analyzed on a 0.8% agarose gel containing 0.5 μg/mL EtBr. Following electrophoresis, DNA was visualized by UV transillumination (302 nm).

Organ Distribution of AsOR-Lysine-OMe-VSVG Conjugates. To determine whether the multicomponent carrier retained its ability to be recognized by hepatocyte AsGP receptors in vivo, conjugates were iodinated as described (*20*). Two micrograms of [^{125}I]AsOR-lysine-OMe-VSVG or AsOR-lysine-OMe-[^{125}I]VSVG with a specific activity of 10^6 cpm/μg, respectively, was injected intravenously into tail veins of mice. Animals were sacrificed after 10 min, and ^{125}I content of various organs was determined using a γ counter. Experiments were performed in triplicate, and results were expressed as means ± SEM. To determine whether the organ distribution of the radiolabeled carrier corresponded to luciferase expression found in the solid organs, liver, spleen, kidneys, and lungs were removed 24 h after injection, homogenized, and assayed for luciferase expression.

Assay for Targeted Gene Expression. Complexes containing 10 μg of pGL3CMVluc in 0.5 mL of 0.15 M NaCl were passed through 0.2 μm syringe-tip filters and immediately injected into the tail veins of mice over the course of 10−30 s. After 24 h and after 7 days, animals were sacrificed, and livers removed, washed with ice-cold PBS, and weighed. A liver section (~100 mg) was removed, weighed, and homogenized in lysis buffer (100 mg/mL, Luciferase Assay System, Promega), and liver luciferase activity determined by luminometry. A standard curve for luciferase using firefly luciferase (Analytical Luminescence Laboratory, Ann Arbor, MI) was performed along with the test samples. For each experiment, injections were performed under identical conditions in three animals in parallel, using free DNA, or DNA complexed by AsOR-lysine-OMe, AsOR-polylysine, or AsOR-lysine-OMe-VSVG, respectively. All experiments were performed at least in triplicate, and results were expressed as means ± SEM in units of picograms of luciferase per gram of liver tissue (1 pg corresponds to 200 000 LU/30 s). The remaining liver tissue was used for isolation of liver cell nuclei. Competition experiments were performed using AsOR or orosomucoid (OR) and mixed with the DNA−protein conjugates complexes in 100-fold molar excess immediately before injection.

To determine whether an adverse immune response could occur due to antigenicity of complexes, second injections of the identical complexes were performed 1 week after the first. Targeted gene expression was evaluated as described above for animals that received only single injections.

To determine the efficiency of liver cell transduction, immunohistochemical analysis for luciferase protein was performed 24 h after injection of DNA complexed with AsOR-lysine-OMe-VSVG. Animals were sacrificed, and livers were removed and frozen in Tissue Freezing Medium (Triangle Biomedical Medium, Durham, NC). Cryosections were fixed with 4% *p*-formaldehyde, incubated for 30 min with blocking solution (5% dry milk, 150 mM NaCl, 10 mM Tris Cl, pH 7.5, and 0.5% Tween 20), followed by incubation with anti-luciferase antibody (1:500, polyclonal, Cortex Biochemicals, San Leandro, CA) for 2 h, followed by washing and incubation with anti-rabbit-IgG Texas Red (1:5000, Amersham) for 30 min. Following treatment with antifade (Dabco, Sigma), samples were subjected to fluorescence laser scanning microscopy (Zeiss CLSM, Germany). For direct detection of green fluorescent protein (GFP) in liver sections from mice injected with pEGFP-C1 complexed with multicomponent carrier, cryosections were fixed with 4% *p*-formaldehyde, treated with antifade, and subjected to fluorescence laser scanning microscopy.

Assay for Acute Liver Toxicity. To investigate whether injection of DNA complexed by AsOR lysine-OMe-VSVG conjugates led to liver cell damage, blood samples were collected from the retroorbital plexus 24 h after injection, and serum was subjected to ALT analysis (kinetic ALT kit, Sigma). Liver sections were stained with H and E and examined by light microscopy to determine signs of liver cell necrosis or cellular infiltration.

Isolation of Nuclei and Extraction of Episomal DNA. Twenty four hours after injection of complexed DNA in the mice, livers were removed and homogenized in 4 mL of buffer (sucrose at 0.32 M, $CaCl_2$ at 3 mM, magnesium acetate at 2 mM, Na_2EDTA at 0.1 mM, Tris HCl, pH 8.0, at 10 mM, DTT at 1 mM, and NP40 at 0.5%) using a Dounce Tissue Grinder (Kontes) and applying five strokes with a loose, and then a tight-fitting pestle. The homogenate was loaded on a gradient consisting of four layers with 1.0, 1.4, 1.6, and 1.8 M sucrose, respectively, in buffer 2 (magnesium acetate at 5 mM, Na_2EDTA at 0.1 mM, Tris HCl, pH 8.0, at 10 mM, and DTT at 1 mM) and centrifuged for 40 min, 34000*g* at 4 °C (Beckmann SW28 rotor). The nuclei containing pellet was resuspended in 1 mL of buffer 1 (without NP40) and pelleted again by low-speed centrifugation (750*g*, 2 min). Finally, nuclei were resuspended in 1 mL of TE50/10 (Tris HCl, pH 7.5, at 50 mM and Na_2EDTA at 10 mM) and lysed with 1.5 mL of lysis buffer (SDS at 1% and NaOH at 0.2 N). To obtain episomal DNA, a modified Hirt extraction was performed by adding 1.25 mL of 3−5 M potassium acetate. After incubation for 15 min on ice, the precipitate was pelleted and the supernatant was extracted with phenol/chloroform. Following precipitation with ethanol, samples were resuspended in 100 μL of TE (Tris HCl, pH 7.5, at 10 mM and Na_2EDTA at 1 mM) and subjected to PCR analysis.

Semiquantitative PCR of Full-Length Luciferase Gene. A semiquantitative PCR assay was performed as described (*21*) to determine the amount of intact luciferase cDNA in isolated nuclei. Primers used were S1 (5′-3′) cat aaa gaa agg ccc ggc gcc att and AS1 caa aca caa ctc ctc cgc gca act, resulting in the amplification of a 1538 bp fragment, corresponding to nt 105−1642 of pGL3-Basic and comprising 93% of the luciferase coding sequence. As a competitive internal standard, a plasmid pLUC−*Kpn*I was constructed containing the 1538 bp luciferase PCR fragment cloned into pGEM-T vector (Promega) with an additional *Kpn*I restriction site at position 595 (with respect to the PCR product). The new *Kpn*I site was created by PCR site-directed mutagenesis, using S2 (5′-3′) ctg gat cta ctg ggg tac cta agg gtg tg and AS2 cac acc ctt agg tac ccc agt aga tcc ag as primers. After *Kpn*I digestion of PCR samples, PCR products generated from target sequences (1538 bp) or internal standard (596/942 bp), respectively, could be discriminated.

DNA amplification experiments were carried out with 2.5 units of Taq polymerase/reaction and 1.5 mM $MgCl_2$. A hot start protocol was used with annealing at 60 °C (45 s), elongation at 72 °C (3 min), and denaturation at 94 °C (45 s) for 35 cycles, followed by a final elongation at 72 °C for 10 min. For each sample of episomal DNA extracted from one animal, eight PCR reactions were performed in parallel, containing 5 μL of sample as template and an increasing amount (0−250 fg) of internal standard pLuc−*Kpn*I as competitive template. Fifteen microliters of each reaction was digested with *Kpn*I and loaded onto a 0.8% agarose gel containing 0.5 μg/mL EtBr

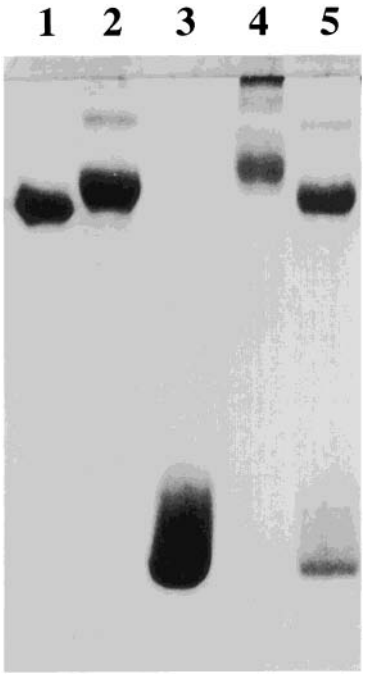

Figure 1. SDS−PAGE of AsOR-lysine-OMe-VSVG. Conjugates were analyzed with or without the addition of DTT to reduce disulfide bonds between peptides and AsOR-lysine-OMe. Lane 1, AsOR; lane 2, AsOR-lysine-OMe; lane 3, VSVG peptide (25 aa); lane 4, AsOR-lysine-OMe-VSVG; lane 5, AsOR-lysine-OMe-VSVG plus DTT.

and subjected to electrophoresis. DNA was visualized by UV transillumination (302 nm), and the intensity of bands was measured using IPLab Gel software. The PCR reaction with equal density of bands generated from internal standard and target sequences was used to calculate the relative increase of the amount of transgene in the isolated nuclei. Assays were performed in parallel for mice injected with either DNA alone or DNA complexed with AsOR-polylysine or AsOR-lysine-OMe-VSVG.

RESULTS

After covalently linking lysine-OMe to AsOR and purification by HPLC, the effluent fractions showed two peaks regarding absorbance at 280 nm. Analysis by SDS−PAGE demonstrated that the first peak contained aggregates and the second peak, which was used for further conjugation, was mostly monomeric conjugate. The molar ratio between linked lysine-OMe residues and AsOR was calculated to be 8:1 based on amino acid analysis of the purified material. AsOR-lysine-OMe migrated slightly slower on a 12% SDS−polyacrylamide gel compared to AsOR (Figure 1, lane 1 and 2). After conjugation of AsOR-lysine-OMe with SPDP and analysis of the product after reduction with DTT, the molar ratio of SPDP to AsOR-lysine-OMe was calculated to be 22−24:1. Conjugates of AsOR-lysine-OMe with VSVG were analyzed on a 12% SDS polyacrylamide gel and showed a single band that had no detectable free VSVG (Figure 1, lane 4). That the VSVG peptide was indeed linked by disulfide bonds was shown by reduction of the conjugates with DTT which resulted in the appearance of free peptide at the appropriate location (Figure 1, lane 5). On the basis of amino acid analysis, the ratio of AsOR:VSVG was calculated to be 1:8. The average minimum amount of conjugate resulting in maximum EtBr exclusion was approximately 1.6 μg/μg of DNA, with some variation between different batches. Binding of the DNA was confirmed by complete retardation on an agarose gel (Figure 2A), and complexes composed of this ratio were used in all subsequent experiments.

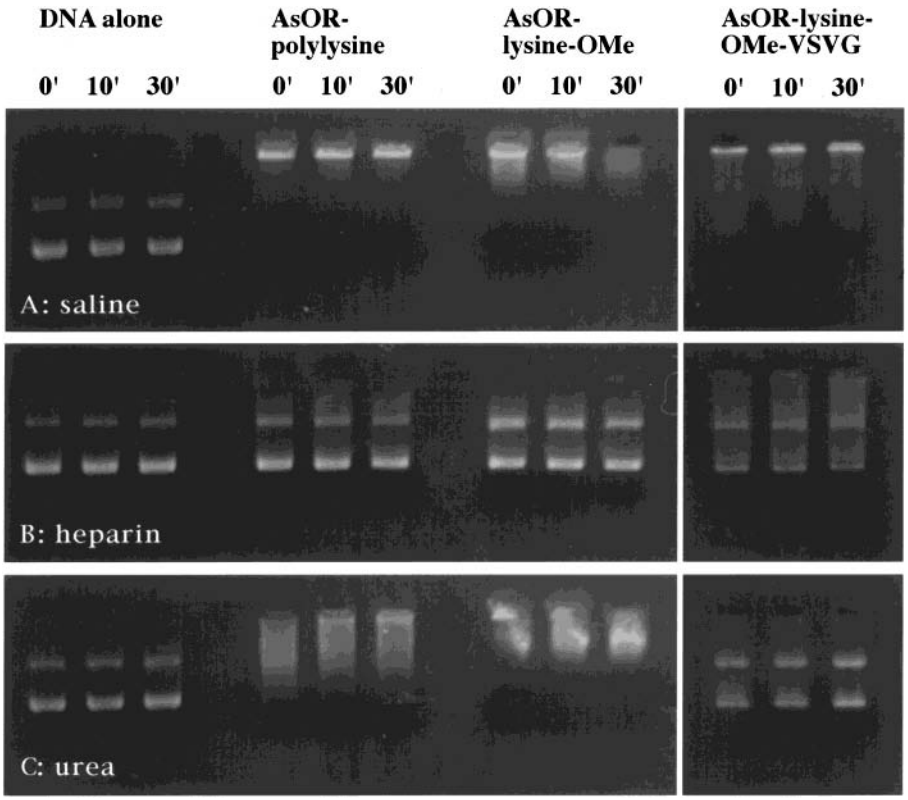

Figure 2. Agarose gel electrophoresis of DNA−protein conjugate complexes. Complexes were formed as described in the text containing 1 μg of DNA and incubated at 37 °C for the indicated time. (A) Incubation in saline; (B) Incubation with heparin; (C) Incubation with urea. Samples were analyzed on a 0.8% agarose gel containing 0.5 μg/mL EtBr and DNA was visualized by UV transillumination.

Table 1. Distribution of Radioactivity after Injection of ^{125}I-Labeled Protein Conjugates and Luciferase Expression in Different Organs[a]

organs	fraction of injected counts (%)			luciferase (pg/g tissue); pCMVluc AsOR-lysine-OMe-VSVG
	[^{125}I]AsOR (ref *2*)	[^{125}I]AsOR-lysine-OMe-VSVG	AsOR-lysine-OMe-[^{125}I]VSVG	
blood	8.5 ± 1.0	13.3 ± 4.1	12.3 ± 3.5	ND
liver	89 ± 3.5	78.6 ± 10.1	79 ± 8.0	15 351 ± 484
heart	0.1 ± 0.1	0.6 ± 0.4	0.7 ± 0.4	ND
spleen	0.5 ± 0.1	0.6 ± 0.3	2.7 ± 1.2	11.6 ± 6.2
lung	1.6 ± 0.1	5.1 ± 5.4	6.1 ± 4.4	9.7 ± 2.5
kidney	0.2 ± 0.1	1.9 ± 0.6	1.4 ± 0.9	11.3 ± 4.3

[a] Two micrograms of [^{125}I]AsOR, [^{125}I]AsOR-lysine-OMe-VSVG, or AsOR-lysine-OMe-[^{125}I]VSVG with a specific activity of 10^6 cpm/μg, respectively, was injected intravenously into mice. Animals were sacrificed after 10 min, and ^{125}I content of the organs was determined using a γ counter. Luciferase activity is shown in units of picograms per gram tissue 24 h after mice were injected with 10 μg of DNA complexed by AsOR-lysine-OMe-VSVG. Experiments were performed in triplicate, and results were expressed as means ± SEM (1 pg corresponds to 200 000 LU/30 s). ND, not done.

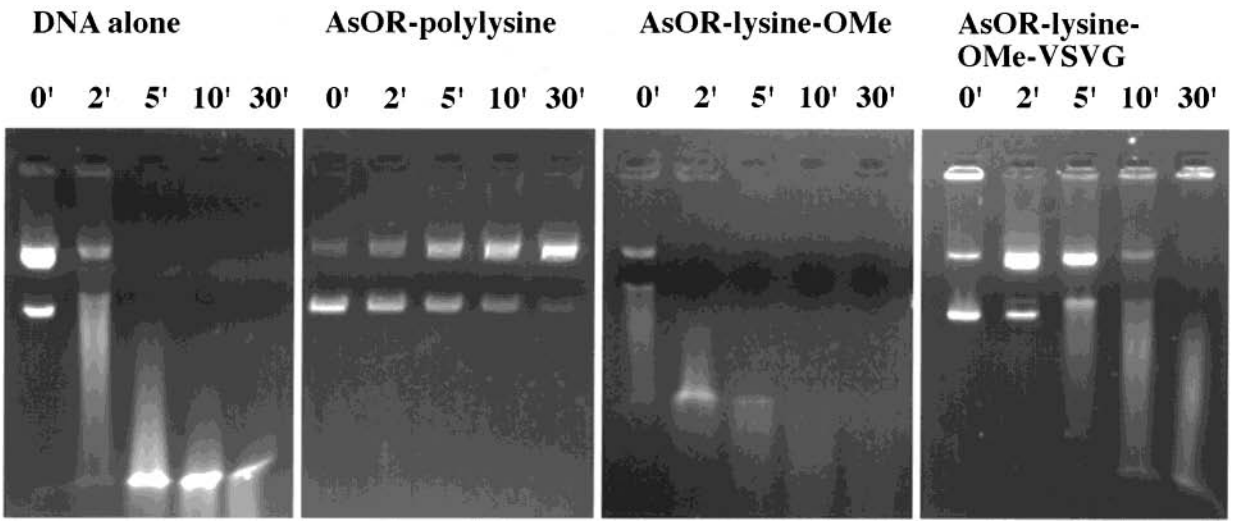

Figure 3. Protection of DNA complexed by protein conjugates against degradation. Complexes were formed as described in the text containing 1 μg of DNA and incubated at 37 °C in the presence of DNase I for the indicated time. After aliquots were withdrawn, reactions were stopped by adding Na_2EDTA up to 12.5 mM, followed by heat inactivation for 20 min at 75 °C. To release DNA from protein conjugates, 200 units of heparin (AsOR-polylysine, AsOR-lysine-OMe) or an equal volume of 8 M urea (AsOR-lysine-OMe-VSVG) was added. Samples were analyzed on a 0.8% agarose gel containing 0.5 μg/mL EtBr and DNA was visualized by UV transillumination.

The organ distribution of radioactivity after intravenous injection of iodinated AsOR-lysine-OMe-VSVG into mice showed a slight difference compared to the organ distribution of iodinated AsOR alone (*2*). When either AsOR or VSVG peptide was labeled with ^{125}I, about 80% of recovered radioactivity was found in the liver, while about 12−13% was still in the circulation (Table 1). An average of 96 ± 2% of total radioactivity injected was recovered. In accordance with the distribution of radioactivity, no substantial luciferase activity was detected in solid organs other than the liver (Table 1).

Dissociability of DNA from protein conjugates showed a notable difference between AsOR-polylysine, AsOR-lysine-OMe, and AsOR-lysine-OMe-VSVG conjugates. When incubated in the presence of heparin, DNA was dissociated from AsOR-polylysine conjugates completely, while DNA was only slightly released from AsOR-lysine-OMe-VSVG conjugates (Figure 2B). When incubated in the presence of 4 M urea, DNA was dissociated completely from the latter conjugate, but not from AsOR-lysine-OMe or AsOR-polylysine (Figure 2C). These differences suggest that interactions in addition to electrostatic ones between DNA and protein conjugates are likely involved with AsOR-lysine-OMe-VSVG conjugates. Figure 2 shows that DNA−protein conjugate complexes were stable when incubated at 37 °C in normal saline over 30 min, and DNA was completely retarded after agarose gel electrophoresis (Figure 2A). Incubation of AsOR-lysine-OMe-VSVG complexes in the presence of DNase I showed greater protection of DNA against degradation over 5 min, compared to DNA alone which was already completely degraded in the same incubation period (Figure 3). AsOR-polylysine provided greater protection to complexed DNA over 30 min, compared to AsOR-lysine-OMe (lacking VSVG peptide), which had no obvious protective effect (Figure 3).

Liver luciferase activity determined by luminometry performed 24 h after injection of pGL3CMVluc in the form of complexes is shown in Table 2. Luciferase activity after injection of DNA complexed with multicomponent protein conjugates was, on average, 3 orders of magnitude higher than luciferase activity after injection of AsOR-polylysine-DNA complexes containing the same amount of DNA, and more than 4 orders of magnitude increased over gene expression after injection of free DNA. Expression from multicomponent complexes was 99% blocked by competition with a 100-fold molar excess of AsOR, but essentially unaffected by coadministration of a 100-fold molar excess of OR, which has an identical amino acid sequence, but lacks exposed terminal galactose residues and, therefore, is not a ligand for the AsGP receptor (Table 2). The duration of gene expression was short, with only 1.0 ± 0.9% (n = 3) of luciferase activity remaining after 1 week. A second injection of DNA complexed by AsOR lysine-OMe-VSVG in the same animal, 1 week after the first injection, resulted in

Table 2. Luciferase Activity in Liver Tissue 24 h after Mice Were Injected with 10 μg of DNA Either Alone or Complexed by Protein Conjugates[a]

	luciferase (pg/g liver)				competition[c] (% inhibition)	
injection	mean	minimum	maximum	fold increase[b]	AsOR	OR
DNA alone	2.2 ± 1.9	0.1	5.5	NA	ND	ND
AsOR-lysine-OMe	2.2 ± 2.0	0.2	8.0	1.0	ND	ND
AsOR-polylysine	12.2 ± 11.4	0.7	29.7	11.1	ND	ND
AsOR-lysine-OMe-VSVG	29 000 ± 28 000	522	79 600	18 000	99.2 ± 0.9	3.0 ± 3.1

[a] For each experiment, injections were performed under identical conditions in three animals in parallel, using free DNA or DNA complexed by AsOR-lysine-OMe, AsOR-polylysine, or AsOR-lysine-OMe-VSVG, respectively. A standard curve for luciferase using firefly luciferase was performed along with the test samples. All experiments were performed at least in triplicate, and results were expressed as means ± SEM in units of picograms of luciferase per gram of liver tissue (1 pg corresponds to 200 000 LU/30 s). NA, not applicable. ND, not done. [b]Fold increase gives the average increase compared to the expression of luciferase after injection of free DNA. [c]Competition experiments were performed using AsOR or OR, mixed with the DNA−protein complexes in 100-fold molar excess immediately before injection. Results are shown as percent inhibition.

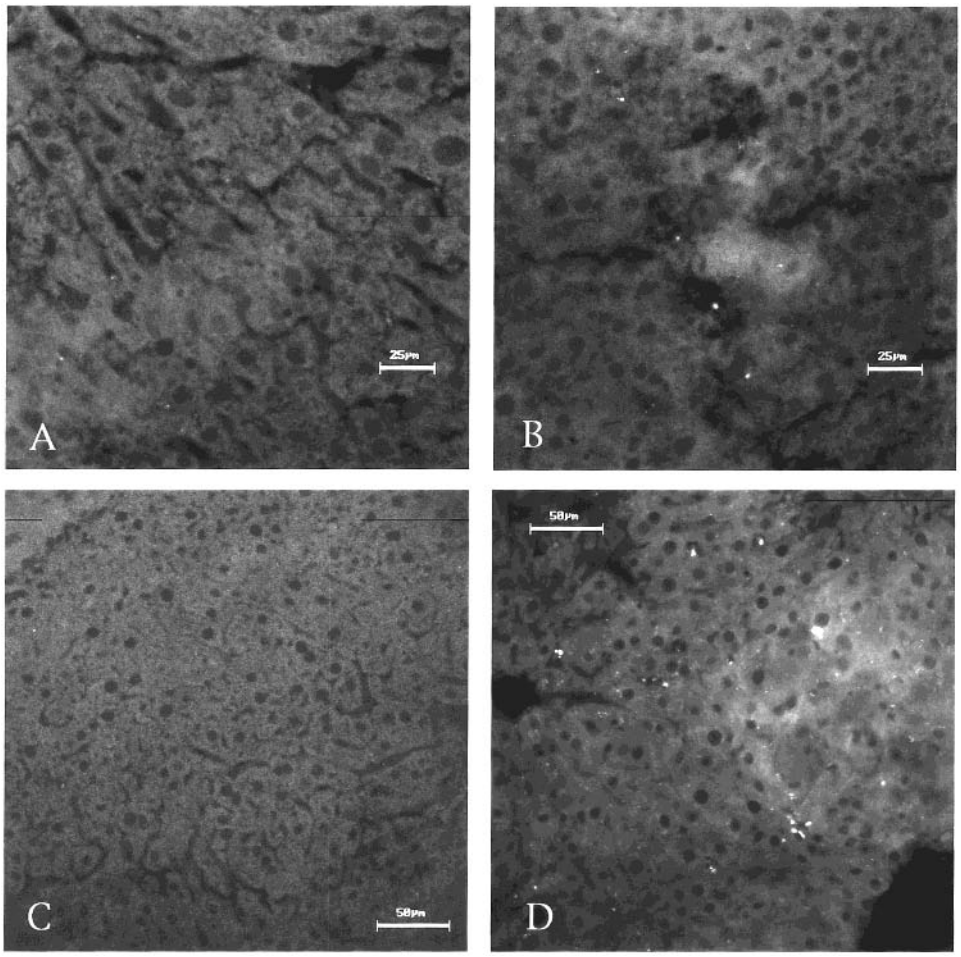

Figure 4. Immunohistochemical analyses of liver sections for luciferase gene expression (panels A and B) and green fluorescent protein gene expression (GFP, panels C and D). Twenty-four hours after injection of DNA (pCMVluc, panels A and B or pEGFP-C1, panels C and D) either alone (panels A and C), or complexed with AsOR-lysine-OMe-VSVG (panels B and D), animals were sacrificed and cryosections of the liver fixed, and treated as described in the the Materials and Methods. Representative sections of the liver are shown. Panels A and B show analyses of Texas Red signal for luciferase, and panels C and D show analyses for GFP expression.

luciferase expression of the same magnitude as the first injection (7695 ± 1777 pg of luciferase/g of liver, $n = 3$).

Immunohistochemical analysis of liver sections using anti-luciferase antibodies and laser scanning fluorescence microscopy showed a transfection efficiency of about 1.0% of cells. A representative section is shown in Figure 4B. Direct fluorescence analysis after delivery of a green fluorescent protein expression vector confirmed these results (Figure 4D). Animals injected with DNA alone, showed no expression of luciferase or GFP (Figure 4, panels A and C).

Injected animals showed no signs of acute toxicity, as shown by normal serum ALT values, and normal liver histology in H and E stained liver sections (data not shown).

The transgene could not be demonstrated in the episomal fraction of nuclear DNA 24 h after injection by Southern Blot analysis. However, semiquantitative competitive PCR assay, of which Figure 5 is a representative of six separate experiments, clearly demonstrated the presence of intact luciferase gene in liver cell nuclei after delivery by the various protein conjugates. The amount of DNA was approximately 1−2 orders of magnitude larger after injection of the multicomponent conjugate (panel D), compared to injection of the same amount of DNA in the form of AsOR−polylysine complexes (panel

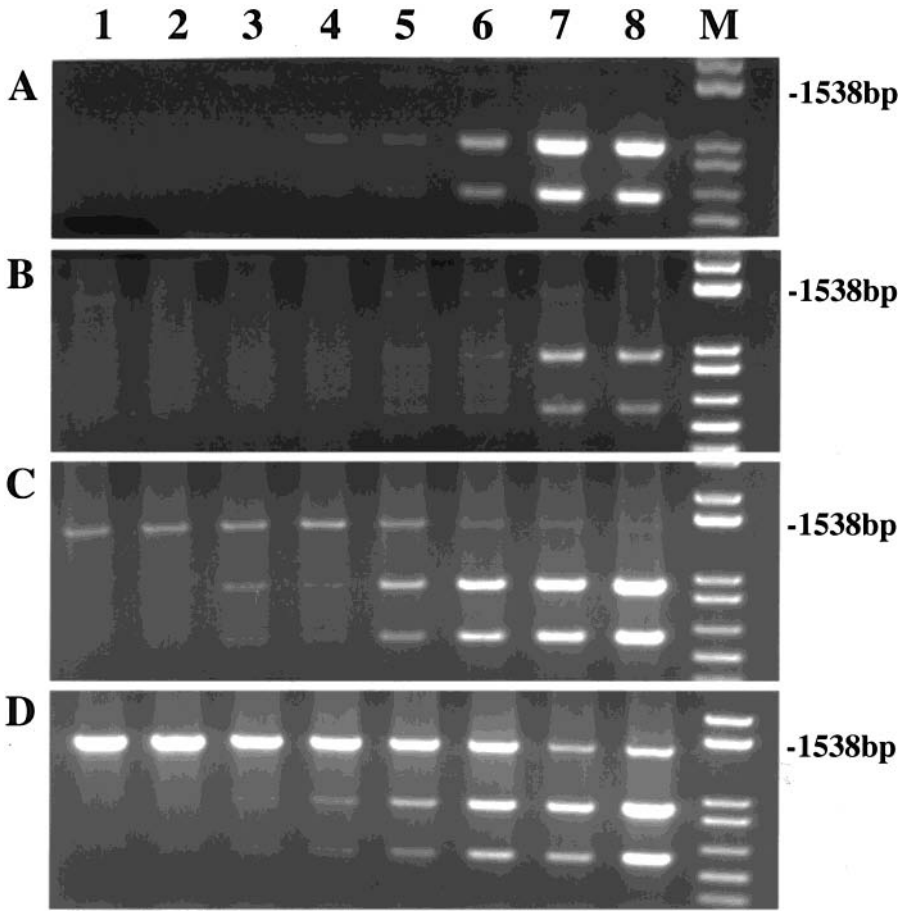

Figure 5. Semiquantitative competitive PCR analysis of episomal DNA extracted from isolated liver cell nuclei 24 h after injection of free DNA or DNA complexed with the various protein conjugates. (A) Negative control; (B) free DNA; (C) AsOR-polylysine; (D) AsOR-lysine-OMe-VSVG. Each PCR reaction contained the same amount of extracted episomal DNA (5 μL of a total of 100 μL) and an increasing amount of competitive template from lane 1 to lane 8 of 0, 0.25, 1.25, 2.5, 12.5, 25, 125, and 250 fg, respectively. After digestion with *Kpn*I, the PCR product amplified from wild-type luciferase DNA appeared as a band at 1538 bp. The PCR product amplified from competitive template sequences appeared as bands at 596 and 942 bp, respectively.

C). There was no intact luciferase gene present after injection of DNA alone (panel B).

DISCUSSION

In contrast to viral vectors, synthetic vectors resemble classical pharmaceutical agents in which defined compounds are produced by chemical means. A broad spectrum of genes in the form of plasmid DNA has been delivered to a large variety of cells by receptor-mediated endocytosis using nonviral vectors (*22*). So far, only a few studies have used this technique to successfully deliver polynucleic acids in vivo to the liver (*2*−*8*, *23*−*25*) and other organs (*26*−*29*). When linked to a target cell-specific ligand, the DNA is cointernalized by the target cell into the endosomal compartment, from which release is required into the cytoplasm in order to escape degradation in the lysosome. While disruption of the microtubular network, either through partial hepatectomy (*6*) or by administration of colchicine (*4*), has been used to increase and prolong gene expression, these methods are not likely to be practical clinically. In the current study, a DNA-binding component composed of lysine-OMe, and AsOR was used instead of polylysine for several reasons. First, it combines the cell-targeting component and DNA-binding component in a single molecule. Negatively charged amino acids on AsOR that react with lysine-OMe are converted into positively charged residues. For each lysine-OMe linked, there is a net increase of two positive charges per residue. Second, the dissociability of conjugate from DNA once inside the cells was hypothesized to be likely improved with a DNA carrier having dispersed positive charges rather than the concentrated multiple positive charges of polylysine-based carriers. Finally, it was possible that reproducibility of synthesis of conjugates might be improved by avoiding commercial polylysines that have substantial heterogeneity of chain length within the same batch, and especially from batch to batch (*30*).

Many viruses have evolved mechanisms to escape the degradative endosomal-lysosomal pathway. We and others have taken advantage of the endosomolytic property of whole viruses such as adenoviruses (*31*−*37*), rhinoviruses (*38*), or short synthetic fusogenic peptides derived from Influenza Virus hemagglutinin (*39*−*42*) to enhance DNA escape from endocytotic vesicles and augment gene expression after receptor-mediated gene transfer in vitro. The coadministration of endosomolytic viral particles, like adenoviruses, showed impressive enhancement of gene expression in vitro (*35*). Direct linkage between viral particle and the receptor ligand, substantially increased gene expression (*33*, *36*). The addition of VSVG protein partially purified from VSV-infected cells to cationic lipids enhanced gene transfer in vitro by a factor of 10 (*43*). The attachment of virus-derived or synthetic endosomolytic peptides to polylysine-based nonviral vectors has also been shown to be feasible in increasing gene expression in different cell types in vitro (*39*−*42*). However, until now, it has not been shown that viral peptides

can increase receptor-mediated gene delivery in vivo. While the incorporation of VSVG peptides into the DNA carrier was designed to enhance endosomal escape, the data on DNA stability of the complex suggest that the addition of the peptide also had the unexpected effect of increasing resistance to nuclease degradation compared to the AsOR-lysine-OMe parent conjugate, Figure 2. As there has not been described any inherent nuclease inhibitory activity for VSVG peptide, it is likely that the protective effect is related to the relative inaccessibility of the DNA when in the form of AsOR-lysine-OMe-VSVG complexes.

There was considerable variability in the liver assays particularly in Table 2. Different batches of conjugate were used for Table 1 and Table 2 experiments, which could account for the differences in the results between the values in the tables and the variability. As a result, there was no significant difference between the liver value in Table 1 (15 351 ± 484) and Table 2 (29 000 ± 28 000). Similarly, while the mean level of expression on reinjection was only approximately 25% (7695 ± 1777) of the initial value, because of the variability, this difference also did not reach statistical significance at the 0.05 level.

Our results demonstrate that it is possible to link a hemolytic peptide to nonviral vectors while retaining receptor recognition and internalization of the ligand. The present study demonstrates that this results in a large increase of gene expression and a higher amount of the intact transgene inside the liver cell nuclei. While increasing the level, the duration of gene expression was not extended and lasted not longer than 7 days. DNA delivered by asialoglycoprotein-targeting to the liver has been shown previously to remain episomal (*44*). The incorporation of the VSV peptide would not be expected to change the episomal status of the targeted DNA, and so an increase the duration of gene expression was not expected.

Although the data do not directly prove the mechanism of increased gene expression, the results are consistent with an improved endosomal release of delivered DNA by documented pH-dependent hemolytic properties of the VSVG peptide. Regarding the magnitude of increase of reporter gene expression, our results are in accordance with previously reported in vitro studies (*31*, *35*, *39*). The difference between the increase of nuclear transgene by a factor of 10^1-10^2 and the increase of gene expression can be explained by the fact that a single mRNA is translated into multiple copies of corresponding protein. In agreement with the pH-dependent hemolytic activity of the VSVG peptide (*13*, *14*), we neither observed physical distress in injected animals nor noticed any signs of hemolysis. Accordingly, neither elevations of serum ALT levels nor signs of liver cell necrosis or cellular infiltrates at the light microscopic level were found.

In conclusion, our results demonstrate, that DNA can be targeted to the liver in vivo using a multicomponent carrier. The protein conjugate−DNA complexes are taken up by receptor-mediated endocytosis via the AsGP receptor. The incorporation of a hemolytic peptide derived from VSV G-protein into an AsOR-based nonviral vector greatly increases gene expression in vivo. This concept could be extended to other DNA carriers based on other targeting ligands, which may permit enhanced DNA delivery and gene expression to a variety of nonhepatocytic cells.

ACKNOWLEDGMENT

We thank Dr. Ellen Carmichael for helpful advice. The technical assistance of Peili Zhan and the secretarial assistance of Mrs. Martha Schwartz is gratefully acknowledged. Comparison of Recombinant and Synthetically Formed Monoclonal Antibody-β-Lactamase Conjugates for Anticancer Prodrug Activation

David E. Kerr,[†] Vivekananda M. Vrudhula,[‡] Håkan P. Svensson,[§] Nathan O. Siemers,[||] and Peter D. Senter*

Bristol-Myers Squibb Pharmaceutical Research Institute, Seattle, Washington 98121. Received June 11, 1999; Revised Manuscript Received August 3, 1999

Conjugates of the L49 monoclonal antibody (binds to the p97 antigen on melanomas and carcinomas) were formed by attaching Enterobacter cloacae β-lactamase (bL) to the L49-Fab′ fragment using a heterobifunctional cross-linking reagent or by linking the enzyme to L49-sFv using DNA recombinant technology. The conjugates thus formed, L49-Fab′-bL and L49-sFv-bL, were designed to activate cephalosporin containing anticancer prodrugs at the surfaces of antigen positive tumor cells. Results from in vitro experiments using two lung carcinoma cell lines demonstrated that the conjugates were equally active in effecting the release of phenylenediamine mustard from the cephalosporin nitrogen mustard prodrug CCM. While treatment with either of the conjugates combined with the maximum tolerated doses of CCM led to cures of established SN12P renal cell carcinoma tumors in nude mice, only the L49-sFv-bL conjugate maintained its ability to do so at 1/4 the maximum tolerated dose of CCM. L49-sFv-bL was also superior to L49-Fab′-bL in the 1934J renal cell carcinoma tumor model and was shown to be quite active in two in vivo models of human lung carcinoma. These results demonstrate that the recombinant fusion protein leads to more pronounced therapeutic windows than the chemical conjugate and is active in an array of human tumor models.

INTRODUCTION

The use of antibody−enzyme conjugates for the activation of anticancer prodrugs has been the subject of a great deal of investigation (reviewed in refs *1*−*4*). This targeting strategy, commonly referred to as antibody-dependent enzyme prodrug therapy (ADEPT), is a form of pretargeting that involves two separate steps to achieve therapeutic efficacy. Initially, a nontoxic monoclonal antibody-enzyme (mAb−enzyme) conjugate is administered that diffuses into solid tumor masses and binds to cell-surface antigens. Once sufficiently high tumor to nontumor ratios are achieved, a relatively nontoxic prodrug is injected. Upon contact with the targeted enzyme, the prodrug is catalytically converted into a cytotoxic drug. There are now many examples demonstrating that this drug-targeting strategy results in high intratumoral drug concentrations, pronounced antitumor activities at well tolerated doses, and to positive responses in early clinical trials (*1*−*4*).

Several enzymes have been utilized for targeted prodrug activation (reviewed in refs *1*−*3*). We (*5*−*11*) and others (*12, 13*) have focused on the use of Enterbacter cloacae β-lactamase (bL) as an activating enzyme, due to its high specific activities on an array of cephalosporin containing anticancer prodrugs. Conjugates were formed by linking bL to the L49 and 96.5 mAbs (*9*−*11*) which recognize distinct epitopes on the p97 melanotransferrin antigen, present on the surfaces of most human melanoma tumors and on some carcinomas (*10, 14*). One of the advantages in using bL for prodrug activation is that there is no known human counterpart that can catalyze cephalosporin β-lactam hydrolysis. Consequently, the conjugated enzyme is the principal source of prodrug activation.

Therapy experiments in mice with melanoma xenografts have demonstrated that pronounced antitumor activities, including cures and complete regressions of established tumors, were obtained using the combination of 96.5-Fab′-bL with CCM (Figure 1), a prodrug from which phenylenediamine mustard (PDM) is released upon hydrolysis of the β-lactam bond (*9*). The prodrug in these experiments was injected 3 days post conjugate treatment, a period of time that allowed most of the nontargeted enzyme to clear from the systemic circulation. On the basis of these results, a recombinant L49-sFv-bL fusion protein was prepared and expressed in *Escherichia coli* (*11*). In contrast to the chemically produced L49-Fab′-bL conjugate, the fusion protein underwent very rapid intratumoral uptake and systemic clearance. It was therefore possible to safely administer the prodrug 12 h after conjugate administration, leading to pronounced therapeutic efficacy.

Although several mAb−enzyme fusion proteins have now been described for anticancer prodrug activation (*8, 11, 15*−*19*), their effects relative to chemically produced conjugates have not been reported. In this paper, we

compare the antitumor activities obtained when L49-Fab′-bL/CCM and L49-sFv-bL/CCM combinations are administered in mice with renal cell carcinoma xenografts. We show that the fusion protein leads to better therapeutic windows in two renal cell carcinoma models. In addition, we demonstrate that the combination of the fusion protein with CCM is effective, both in vitro and in vivo, in treating models of p97 antigen positive human lung adenocarcinomas.

MATERIALS AND METHODS

Cell Lines and Reagents. The 3713 and 3754 lung carcinoma cell lines were developed at Bristol-Myers Squibb (Seattle, WA) from tumor biopsies obtained from patients with lung carcinoma. The SN12P and 1934J renal cell carcinoma lines have been reported earlier (*10*). The mAb L49 (IgG_1) binds to melanotransferrin (p97), a human melanoma associated antigen that is also expressed on a number of carcinomas (*10, 14*). P1.17 (IgG_{2a}) is a mouse myeloma protein that was used as a nonbinding control. L49-Fab′-bL was prepared as described earlier for other mAb−Fab′-bL conjugates (*20*). Briefly, the Fab'_2 fragment of the L49 mAb was reduced with dithiothreitol and combined with maleimide-substituted bL. The conjugate was subjected to purification on a boronic acid affinity column (hydrophilic type L), followed by gel filtration on Sepahacryl S-300. L49-sFv-bL, containing the r2-1 bL mutant (*21*), was expressed in *E. coli* and purified as reported earlier (*11*). Purification involved a combination of affinity chromatographic steps, first using immobilized p97, followed by immobilized boronic acid. PDM and CCM were synthesized as reported earlier (*5*).

Cell-Surface Expression of the p97 Antigen. The expression of melanotransferrin on SN12P and 1934J cells has been described previously (*10*). Fluorescein conjugates of L49 and P1.17 were used to assess antigen expression on the lung carcinoma cell lines. Cells were detached from monolayer cultures with trypsin, incubated in culture media with mAb−fluorescein conjugates at 10 μg/mL, washed, then subjected to fluorescence activated cell sorter analysis (FACScan, Becton-Dickinson). The L49/P1.17 binding ratios were determined from the ratios of the mean fluorescence intensities after incubation with the respective mAb−fluorescein conjugates.

In Vitro Cytotoxicity. A total of 3713 and 3754 lung adenocarcinoma cells were plated into 96-well microtiter plates (10^4 cells/well in 0.1 mL of IMDM with 10% fetal bovine serum, 0.06 mg/mL penicillin, and 0.1 mg/mL streptomycin) and allowed to adhere overnight. For blocking experiments, the cells were incubated with unconjugated whole L49 at 1 μM for 30 min prior to treatment with the L49 conjugates. The cells were then exposed to the L49-bL conjugates at 10 nM. After 30 min at 4 °C, the plates were washed three times with antibiotic free RPMI 1640 medium with 10% fetal bovine serum, and then various amounts of CCM were added. CCM and PDM were also added to cells that were not treated with the conjugates. After 1 h at 37 °C, the cells were washed with IMDM and incubated for approximately 18 h. The cells were then pulsed for 12 h with [^{3}H]thymidine (1 μCi/well) at 37 °C, detached by freezing and thawing, and were harvested onto glass fiber filter mats using a 96-well cell harvester. Radioactivity was counted using a β-plate counter.

In Vivo Therapy Experiments. Athymic nude mice from Harlan Sprague/Dawley (10 weeks old) were implanted with subcutaneous 3713 or 3754 tumors, and therapy experiments started 35 days later when tumors reached approximately 120 mm^3. Tumors from in vivo passages 3−8 were used. Groups of five mice were injected with L49-sFv-bL iv at 1 mg/kg (10 mL/kg in PBS). This was followed 15−18 h later by iv CCM treatment at various concentrations (10 mL/kg in 0.12 M sodium bicarbonate with 10% DMSO). Control mice were either untreated, or received iv PDM (10 mL/kg in saline) at the doses specified in the figures. This was repeated weekly for a total of three rounds. Tumor volume was computed using the following formula: 1/2[longest dimension × perpendicular dimension^2]. Mice were removed from the study before their tumor volumes reached 2000 mm^3, at which point the average tumor sizes from the remaining mice were no longer plotted. Maximum tolerated doses led to less than 20% sustained (≥2 weeks) weight loss, led to no treatment related deaths, and were within 50% of the dose where such events took place.

For the renal cell carcinoma experiments, mice (five per group) bearing subcutaneous 1934J or SN12P tumors were treated with 1.4 mg/kg L49-Fab′-bL or with 1.0 mg/kg L49-sFv-bL. The prodrug CCM was administered 3 days post-L49-Fab′-bL and 1 day post-L49-sFv-bL. Treatments were administered weekly for a total of three rounds.

RESULTS

Expression of the p97 Antigen on Carcinoma Cell Lines. The L49 mAb (IgG_1) has previously been shown to bind to the p97 melanotransferrin antigen with subnanomolar affinity (*11*) Almost all human melanomas tested have been reported to be strongly p97 positive (*14*). Antibodies against the p97 antigen also react with some carcinomas, although the antigen tends to be expressed at lower levels compared to melanomas (*10, 14*). The presence of the p97 antigen on a panel of 13 lung carcinoma cell lines was determined by fluorescence-activated cell sorter analysis using the L49 mAb conjugated to fluorescein. Binding was compared to that of P1.17-fluorescein, a nonbinding control conjugate. As shown in Table 1, most of the lung cell lines expressed the p97 antigen. Using a ratio of 1.3 as a cutoff for positive binding (*10*), 10 of the 13 lung carcinoma cell lines were p97 antigen positive. The average binding ratio among the positive cell lines was 3.0 ± 1.4, indicating generally low levels of p97 antigen expression. For comparison, the binding ratios for renal cell carcinoma and melanoma cell lines are shown, since L49-bL/CCM combinations have demonstrated pronounced in vivo

Table 1. L49 Binding to Cell Lines Relative to the Nonbinding P1.17 Control

cell line	tumor type	binding ratio[a]
2981	lung adenocarcinoma	1.5
2987	lung adenocarcinoma	1.0
3697	lung adenocarcinoma	1.1
3713	lung adenocarcinoma	4.9
3754	lung adenocarcinoma	4.4
3766	lung adenocarcinoma	1.0
3776	lung adenocarcinoma	1.5
3896	lung adenocarcinoma	1.6
3963	lung adenocarcinoma	3.5
4013	lung adenocarcinoma	2.2
4015	lung adenocarcinoma	2.7
4023	lung adenocarcinoma	5.0
4026	lung adenocarcinoma	2.5
3677	melanoma	4.2
SN12P	renal cell carcinoma	35[b]
1934J	renal cell carcinoma	1.8[b]

[a] Cells were incubated with L49-fluorescein or P1.17-fluorescein at 10 μg/mL, washed, and analyzed on a fluorescence activated cell sorter. Binding ratios are the ratios of mean fluorescence intensities of L49-fluorescein to P1.17-fluorescein. A ratio of greater than 1.3 is considered p97 antigen positive. [b] From ref *10*.

activities in these tumor models (*8*−*11*). A total of 7 of 13 of the lung carcinomas express relatively higher levels of the p97 antigen than the 1934J renal cell carcinoma, a tumor that underwent regression upon treatment with L49-sFv-bL/CCM.

In Vitro Studies. The L49-Fab′-bL conjugate was prepared according to previously described methods (*10*) by combining sulfhydryl-containing L49 Fab′, derived from reduction of L49 Fab'_2, with maleimide-substituted bL. After purification, SDS−PAGE analysis revealed a major protein band at approximately 90 kDa, and several minor bands at higher and lower molecular masses (*10*). The L49-sFv-bL fusion protein was expressed in *E. coli* and purified by affinity chromatography (*11*). In contrast to the chemically formed conjugate, the fusion protein was homogeneous according to SDS−PAGE analysis, and had a molecular mass of approximately 63 kDa (*11*). Both of these conjugates retained the enzymatic and binding activities of the proteins from which they were derived (*10*, *11*). The equilibrium dissociation constants (K_D) for the L49-Fab′-bL and L49-sFv-bL conjugates were 1.3 and 1.0 nM, respectively (*11*).

The cytotoxic activities of L49-Fab′-bL and L49-sFv-bL in combination with CCM were determined on the p97 positive 3713 and 3754 lung adenocarcinoma cell lines. The cells were exposed to the conjugates, washed to remove unbound material, and treated with varying concentrations of CCM. Cytotoxic activity was determined by measuring the incorporation of [^{3}H]thymidine into DNA relative to untreated cells. On 3713 cells, PDM was approximately 40 times more cytotoxic than the prodrug CCM (Figure 2, panels A and B). The L49-Fab′-bL and L49-sFv-bL conjugates both effectively activated the prodrug, leading to cytotoxicities that were equivalent to PDM. Prodrug activation by the conjugates was immunologically specific, since much lower levels of cytotoxic activity was obtained on cells that were saturated with unconjugated L49 prior to treatment with the conjugate/CCM combinations. Similar trends were obtained with the 3754 cells, but the differences in CCM and PDM cytotoxicity were only about 10-fold (Figure 2, panels C and D). These in vitro experiments demonstrate that L49-Fab′-bL and L49-sFv-bL bind equally well to the p97 antigen and are indistinguishable in their abilities to induce CCM activation on antigen positive cells.

In Vivo Therapeutic Activity. The relative antitumor activities of the L49-Fab′-bL and L49-sFv-bL conjugates in combination with CCM were compared in two models of human renal cell carcinoma. The tumors were implanted subcutaneously, and treatment was initiated at a point when they were well established (approximately 200 mm^3) and growing. The conjugates were injected iv at 1.0 mg/kg for L49-sFv-bL and 1.4 mg/kg for L49-Fab′-bL, and CCM was injected iv 24 and 72 h post-L49-sFv-bL and L49-Fab′-bL administration, respectively. These doses and schedules were considered nearly optimal, based on previously published in vivo efficacy and pharmacokinetic data (*7*−*13*), and led to comparable intratumoral conjugate levels (*11*). The intervals between conjugates and prodrug administrations were chosen since they allow sufficient time for the conjugates to localize in tumors and clear from the systemic circulation. This treatment protocol was repeated weekly for a total of three rounds of therapy. The therapeutic effects were compared to those of PDM at its maximum tolerated dose.

Treatment with either L49-sFv-bL (Figure 3A) or L49-Fab′-bL (Figure 3B) led to cures of all the SN12P tumors when combined with maximum tolerated doses (defined in Materials and Methods) of CCM. Most likely, the reason that more CCM could be administered to L49-sFv-bL (240 mg/kg/injection)- compared to L49-Fab′-bL (180 mg/kg/injection)-treated mice was that at the time of prodrug administration there were lower concentrations of the fusion protein compared to the chemical conjugate in the serum (*11*). Differences between the conjugates were evident when CCM was injected at levels significantly below the respective maximum tolerated doses. The antitumor effects of the L49-sFv-bL/CCM combination were maintained at 1/4 the maximum tolerated dose of CCM (60 mg/kg/injection), while this amount of CCM in L49-Fab′-bL treated mice (1/3 the maximum tolerated dose) resulted only in a delay of tumor outgrowth. PDM at the maximum tolerated dose had no antitumor activity.

Similar experiments were conducted in mice with 1934J renal cell carcinoma xenografts (Figure 3, panels C and D). This tumor model has previously been shown to have 1/4 the total p97 antigens/cell compared to SN12P, and accumulation of L49-Fab′-bL very poor (*10*). L49-sFv-bL treatment led to slightly better therapeutic efficacy than L49-Fab′-bL when each was combined with CCM. Cures were obtained at both 180 mg/kg CCM (two of five animals) and 120 mg/kg CCM (one of five animals) in the L49-sFv-bL treated mice, while all of the tumors in mice receiving L49-Fab′-bL/CCM eventually progressed. Again, PDM had no therapeutic activity.

The in vivo therapy results suggest that L49-sFv-bL effects a higher degree of intratumoral CCM activation compared to the chemical conjugate. To extend its utility, we explored the activities of L49-sFv-bL/CCM combinations in mice with p97 positive lung adenocarcinomas. Complete regressions and long-term growth delays were obtained in L49-sFv-bL/CCM treated animals bearing subcutaneous 3713 (Figure 4A) and 3754 (Figure 4B) tumors. The dosing regimens were well below the maximum tolerated doses, since there were no signs of toxicity or weight loss during and after treatment. The 3713 tumor model was insensitive to treatment with the maximum tolerated dose of PDM (3 mg/kg/injection), while 3754 tumor growth (maximum tolerated dose of

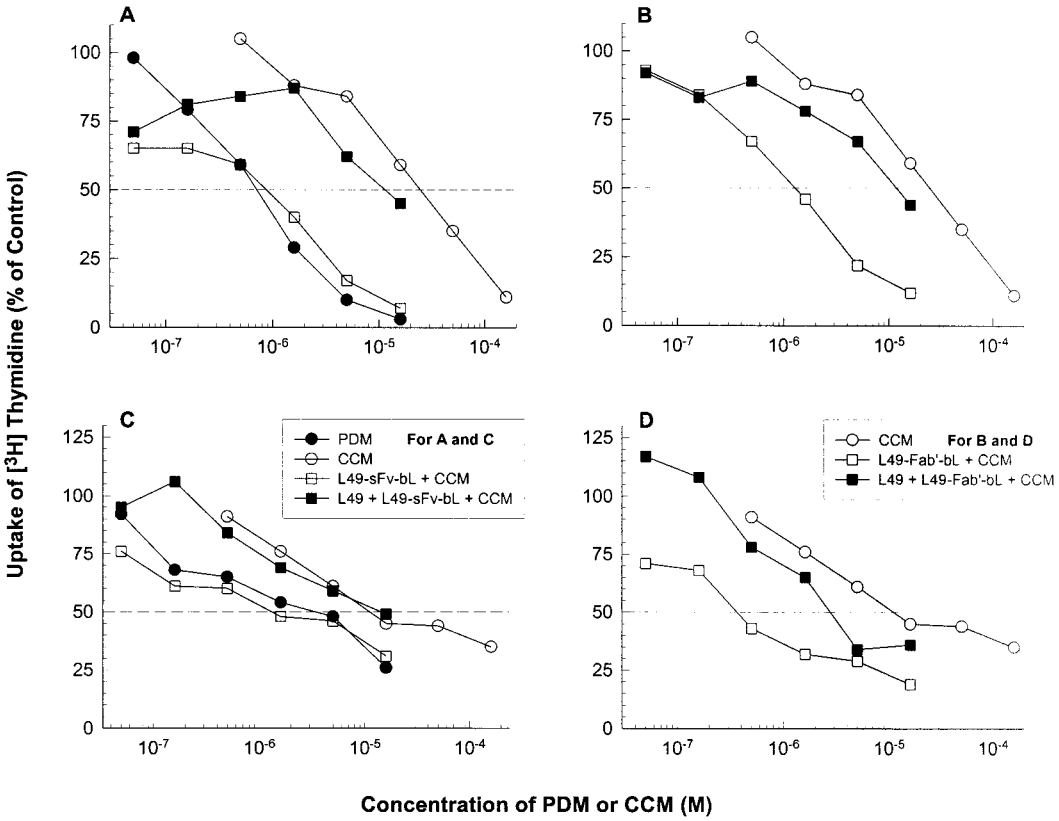

Figure 2. Cytotoxic effects of mAb−bL + CCM combinations on 3713 (A and B) 3754 and (C and D) human lung carcinomas. The cells were incubated with the mAb−bL conjugates, washed, and treated with CCM for 1 h. The effects were compared to cells treated with CCM or PDM for 1 h without prior conjugate exposure and to cells that were treated with saturating amounts of unconjugated L49 prior to conjugate treatment. The samples were run in triplicate, and the standard deviations were less than 10%.

PDM was 4 mg/kg/injection) was stable for 8 weeks before eventually growing out. The basis for this difference is unclear, but may be due to increased tolerance of PDM in mice with 3754 compared to 3713 tumor implants. These results provide the first evidence that L49-sFv-bL in combination with CCM may be efficacious for treating lung adenocarcinomas.

DISCUSSION

A number of recombinant mAb−enzyme fusion proteins are being explored and developed as tools in diagnostics and therapy. In contrast to nearly all chemically formed conjugates, such fusion proteins are molecularly defined, and after purification can consist of single molecular entities. An additional advantage in using recombinant technology for fusion protein production is the ease with which specific amino acid substitutions can be introduced in order to customize the proteins for their intended applications. A few examples of mAb−enzyme fusion proteins include mAb−alkaline phosphatase conjugates for immunoassays (*22*), mAb−toxin (*23*−*25*), and mAb−ribonuclease (*26*) conjugates for cancer and mAb−tissue plasminogen activator conjugates for dissolving blood clots (*27*). There are also several examples of recombinant mAb−enzyme fusion proteins for the activation of anticancer prodrugs. The first example, a mAb−β-glucuronidase conjugate, was reported by Bosslet and co-workers (*15*). A related molecule has since been reported by Haisma and co-workers that recognizes the CD20 antigen on lymphomas (*16*). Carter and co-workers have reported the development of a disulfide stabilized anti-p185HER2−Fv-*E. coli* bL conjugate for the activation of paclitaxel and doxorubicin prodrugs (*17, 18*). Our work with recombinant mAb−enzyme fusion proteins began with L6-*Bacillus cereus* bL for the activation of a doxorubicin prodrug (*19*) and has since shifted toward the construction of the L49-sFv-bL conjugate described here and elsewhere (*11*). The particular bL used was from *Enterobacter cloacae* but incorporated some mutations in one of the loops to enhance its ability to hydrolyze the β-lactams of nitrocefin and a doxorubicin prodrug (*21*). The L49 mAb was selected because of its ability to bind with high affinity to human melanomas and carcinomas (*10, 11*).

Prior to the studies reported here, there have been no published comparisons of chemical conjugates and recombinant fusion proteins for prodrug activation. Results from the in vitro studies shown in Figure 2 fail to distinguish between L49-Fab′-bL and L49-sFv-bL, which is not surprising since they have similar binding and enzymatic characteristics (*11*). In contrast, the in vivo studies show that L49-sFv-bL leads to better therapeutic efficacy compared to L49-Fab′-bL when each conjugate was combined with suboptimal doses of CCM (Figure 3). This is most likely due to differences in conjugate biodistribution at the time of prodrug administration. A detailed pharmacokinetic study in mice with subcutaneous melanoma tumors demonstrated that L49-sFv-bL treatment resulted in a tumor/blood ratio of 105 within 24 h of administration (*11*). Nontarget tissues took up very small amounts of the fusion protein. In contrast, specific intratumoral uptake of the L49-Fab′-bL chemical conjugate was not nearly as pronounced. L49-Fab′-bL cleared quite slowly from the blood, and reached a 5.6 tumor/blood ratio 72 h post conjugate administration. From these data, it can be predicted that fusion protein treatment leads to higher intratumoral drug concentrations compared to the chemically formed conjugate, since

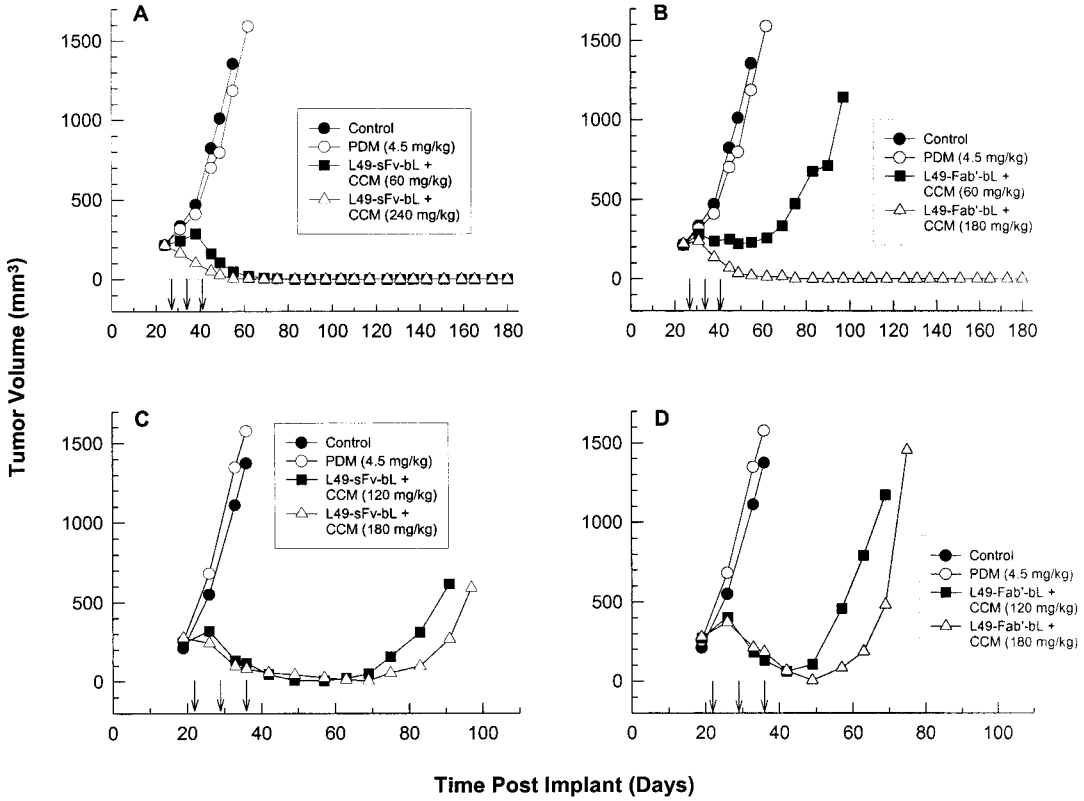

Figure 3. Therapeutic effects of L49-bL/CCM combinations in nude mice with SN12P (A and B) and 1934J (C and D) subcutaneous tumor xenografts. The L49-sFv-bL and L49-Fab′-bL conjugates were injected intravenously at 1.0 and 1.4 mg/kg/injection, respectively. CCM was administered intravenously 24 h after L49-sFv-bL and 3 days after L49-Fab′-bL on the days indicated by the arrows. The effects were compared to those of the maximum tolerated dose of PDM, which was administered on the days indicated by the arrows.

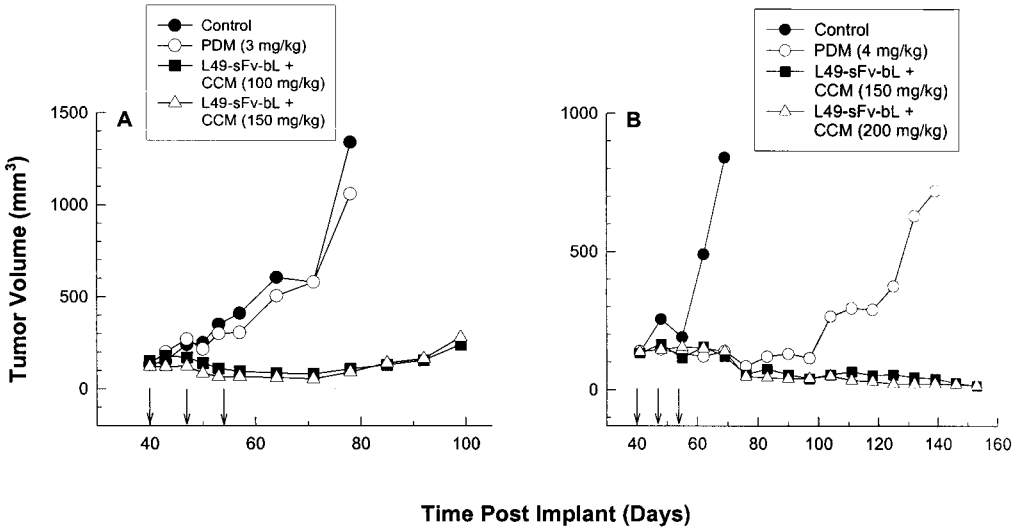

Figure 4. Therapeutic effects of L49-sFv-bL/CCM combinations in nude mice with (A) 3713 and (B) 3754 lung adenocarcinoma tumors. L49-sFv-bL was injected intravenously (1.0 mg/kg/injection). CCM, or PDM in previously untreated mice, was administered at the maximum tolerated dose intravenously 24 h later on the days indicated by the arrows.

more of the prodrug is activated in the tumor rather than in the blood. This might account for the improved activities of the fusion protein when the prodrug is administered well below the maximum tolerated dose. As with other mAb−enzyme/prodrug combinations (*7*, *28*−*30*), the intratumoral drug concentrations obtained are likely to be higher than that achieved from systemic drug administration.

In conclusion, the L49-sFv-bL fusion protein presents advantages over the chemically produced conjugate since it is more homogeneous in composition and leads to better therapeutic efficacy. It is significant that pronounced effects are obtained in lung tumor models that have low levels of antigen expression. The activities of the L49-sFv-bL/prodrug combinations in models of human melanoma (*8*, *11*), renal cell carcinoma (*10*; Figure 3), and lung adenocarcinoma (Figure 4) provide a compelling basis for clinical development.

ACKNOWLEDGMENT

We wish to thank Karl Erik and Ingegerd Hellström for their support throughout the course of this research and Joseph Francisco for his useful comments on the manuscript.

Fluorescent Neoglycoproteins: Antibody-Aminodextran-Phycobiliprotein Conjugates

Olavi Siiman,*,† Julie Wilkinson,† Alexander Burshteyn,‡ Patricia Roth,† and Stephen Ledis†

Advanced Technology, and Reagents Applications & Development, Beckman Coulter, Inc., 11800 SW 147th Avenue, Miami, Florida 33196-2500. Received June 14, 1999; Revised Manuscript Received September 15, 1999

New, highly amino-substituted dextran or aminodextran (hereafter denoted Amdex) of various sizes between about 20 and 1000 kDa molecular mass and degrees of amino-substitution between 7 and 40% were prepared and characterized by elemental analyses and polyacrylamide gel electrophoresis. These aminodextrans together with others commercially available were shown by static light scattering, viscosity, and refractive index measurements to adopt a globular structure in aqueous salt solutions. Antibody and fluorescent protein dye, phycoerythrin, or its tandems with cyanin 5.1 and TEXAS RED, were covalently conjugated to the aminodextrans. The conjugates contained multiple dye molecules and were shown by dynamic light scattering and scanning electron microscopy to assume either globular structure or aggregates thereof. Streptavidin could be substituted for antibody to prepare streptavidin−aminodextran−PE conjugates, which were then used with biotinylated antibody to label subpopulations of white blood cells. The conjugates yielded up to 20-fold amplification of fluorescence intensity over direct antibody−dye conjugates in labeling white blood cells for flow cytometry.

INTRODUCTION

Water-soluble polysaccharides such as dextrans have enjoyed widespread use in the preparation of neoglycoproteins, the synthetic analogues of glycoproteins, as reviewed in ref *1*. Dextrans and other polysaccharides are inert to most direct reactions with proteins, and must be chemically activated to allow conjugation to proteins. The use of antibody-dextran-type substances as carriers for drugs, toxins, photoprobes, etc. has been previously described for ternary conjugates of antibody−polyaldehyde dextran−methotrexate (*2*), antibody−aminodextran−chlorin (*3*), and antibody−dextran hydrazide−Sn(IV) chlorin (*4*). Other conjugated and dextran-crosslinked species have been described in several texts and review articles (*5*−*9*). One of the primary methods of preparing protein−dextran conjugates first involves preparation of "aminodextran". Common practice for the introduction of amine groups at random positions in dextran has been to first cleave the sugar rings with periodate to form polyaldehyde−dextran. The second step is to react the cleaved rings with a diamine such as ethylenediamine or 1,3-diaminopropane to form a Schiffs' base, which is then stabilized by reduction with sodium borohydride. The "aminodextran" compounds as described in the literature cited above were not well characterized. Typically, they were not isolated as solid compounds and, thus, were not characterized by elemental analyses and average molecular mass determinations. Further, the periodate oxidation−diamine method of preparing aminodextrans was restricted to a low percentage of amino groups per molecule. The percentage was less than 4−5%. Higher degrees of amine substitution were not possible under the usual conditions because high diamine concentrations caused extensive aminolysis of the glucosidic linkages between the sugar rings in dextran which resulted in very low molecular mass fragments. As a result, the yields were low and decreased drastically as higher degrees of amine substitution were pursued.

An alternative method of producing aminodextrans without opening glucopyranose rings involves carboxymethylation of sugar residue hydroxyl groups by chloroacetic acid, followed by carbodiimide coupling of a diamine such as ethylenediamine. This method (*10*−*11*) has been used to produce an aminodextran having about one amine group per 67 glucose residues, which is then used to prepare anti-Ig antibody−aminodextran conjugates for use in inducing B cell activation and proliferation.

Other methods of preparing protein−dextran conjugates include the direct reaction of protein with polyaldehyde−dextran (*2*), the reaction of an oxidized oligosaccharide moiety in a monoclonal antibody (MCA) with dextran hydrazide (*4*), the coupling with cyanogen-bromide-activated dextran (*12*), the spontaneous Maillard reaction in controlled dry heating between the ϵ-amino groups in proteins and the reducing-end carbonyl groups in polysaccharides (*13*), and the selective reductive amination of the single terminal aldehyde group of dextran (*14*).

Protein−dextran conjugates possess certain advantageous properties. It has been shown that enzymes possess enhanced thermal stability, when they have been immobilized by covalent attachment to polymers. Examples include glucoamylase on various periodate oxidized polysaccharides (*15*, *16*) and trypsin on cyanogen-bromide-activated dextran (*12*). Other noted effects of protein conjugation to polysaccharides were improved emulsifying properties (*17*), improved solubility of insoluble gluten (*18*), enhanced antioxidant effect of ovalbumin (*19*), and broadened bactericidal effect of lysozyme (*20*). Our own work has been focused on the synthesis of new, highly substituted (7−40%) aminodextrans and their use as (1)

conjugates with anti-CD3 monoclonal antibody (*21*) for the activation and proliferation of T cells; (2) a locus for nucleation and growth of magnetic metal oxide (*22*) particles and luminescent II−VI metal sulfide semiconductor[1] nanoparticles; (3) a locus for nucleation and growth, and a reducing agent for preparation of colloidal metal particles (*23*−*24*); and (4) coatings (*25*, *26*) for colloidal particles.

Nevertheless, amplification of fluorescence by this method has not hithertofore been part of this success. Amplification of light signals for detection of species present in very low concentrations has been achieved in other ways, such as when enhanced light emission (*27*, *28*) was observed by indirect fluorescence staining of cell receptor sites with multiple layers of phycoerythrin−streptavidin attached to biotinylated antibody at cell receptor sites. However, enhanced light-induced photochemistry (*3*) was used in excitation of chlorin e_6 coupled through dextran to anti-T-cell monoclonal antibody to enhance singlet oxygen production. The common feature in these studies was the required increase in the number of probe molecules per targeted site.

This method applied to fluorescence amplification in organic dyes of low molecular mass does not work well. In one attempt, ca. 1978, described in refs *29* and *30*) at amplification of fluorescence signals, large numbers (several hundred) of fluorescein molecules were attached to a synthetic polymer, polyethylenimine, which was then conjugated with antibody. Since fluorescence emission from fluorescein molecules was quenched under these circumstances due to short nearest neighbor distances between fluorophores on the same polymer molecule, lack of control over fluorophore spatial orientation, and lack of control over the structure of the resultant conjugate, the method did not work. More than 100 fluorescent dextrans consisting of soluble dextrans (10−2000 kDa) conjugated with various fluorescent dyes such as fluorescein, dansyl, rhodamine, and TEXAS RED are commercially available (*31*). The degrees of substitution are 1−2 dyes/dextran of 10 kDa, 2−4 dyes/dextran of 40 kDa, 3−6 dyes/dextran of 70 kDa, ∼64 dyes/dextran of 500 kDa, and ∼134 dyes/dextran of 2000 kDa. Higher degrees of substitution than these may lead to quenching and nonspecific interactions. Most of the listed dextran conjugates are also available as so-called "lysine-fixable", i.e., have incorporated lysine residues, which can be used for further reaction such as covalent attachment of antibody molecules. Fluorescein isothiocyanate (FITC) derivatives of dextran and poly-L-lysine are also commercially available from sources such as Sigma Chemical Co. with degrees of substitution ranging 0.003−0.020 mol of FITC/mol of glucose and 0.003−0.01 mol of FITC/mol of lysyl residue. For the largest molecular mass dextran of 2000 kDa that is listed, 33−222 FITC molecules/molecule of dextran would be available. For a 70 kDa poly-L-lysine molecule, up to 5.5 FITCs are available. One molecule of phycoerythrin (PE) (*32*), however, contains 34 individual chromophoric groups, each of which exhibits about the same fluorescent intensity as one FITC unit. PE, isolated from phycobilisomes, the main light-harvesting pigment complexes in prokaryotes such as red algae and cyanobacteria, utilizes linear tetrapyrroles as chromophoric groups and is among the brightest fluorescent dyes currently available. On a molar basis, one molecule of PE has a fluorescence yield that is equivalent to at least 30 fluorescein or 100 rhodamine molecules at comparable wavelengths. Thus, the largest molecular mass FITC−dextran conjugate with the greatest degree of FITC substitution has the potential to yield a fluorescence enhancement factor of 222/30 = 7.4 over a single PE molecule. With so many FITC units per dextran carrier and a broad distribution in the molecular mass of each dextran, it would be difficult to synthetically mimic the monodisperse population of fluorescent groups that occurs naturally in molecules of PE. The spread in fluorescent intensities from one molecule of FITC−dextran complex to another will offset the large enhancement factor that may be numerically anticipated. No enhancement factor greater than one, relative to PE fluorescence, has hithertofore been reported for the above FITC derivatives of dextran or poly-L-lysine, and no direct fluorescent stain which has a net fluorescence intensity greater than a single PE molecule is currently known.

In phycoerythrin (PE) (*32*), there is a monodisperse population of fluorescent bilin groups naturally embedded in a protein through biosynthesis. PE exhibits maximal absorbance and fluorescence without susceptibility to either internal or external fluorescence quenching so that attachment of two or more PE molecules to a polymeric carrier should not quench PE fluorescence. The net fluorescence intensity from a PE−polymer complex should be the sum of fluorescence intensities from individual PE molecules. Only a single PE molecule (270 kDa) can normally be directly conjugated to an IgG antibody (160 kDa) and still retain antibody specificity (*33*, *34*). Polymeric carrier molecules such as aminodextran of sufficiently large molecular weight can accommodate multiple antibody molecules. Our previous experience, described in ref *21* in conjugating anti-CD3 (T3) monoclonal antibody to aminodextran (1×-Amdex, ∼1000 kDa, 7% diamine substitution; 5×-Amdex, ∼350 kDa, 25% diamine substitution) under saturating conditions of antibody on dextran gave a CD3 antibody:aminodextran molar ratio in the conjugates of 37:1 for CD3-1×-Amdex and 20:1 for CD3-5×-Amdex, thus showing that aminodextran can be effectively loaded with many large protein molecules. Similar methods can be used to prepare protein−aminodextran conjugates with two or more protein molecules per aminodextran molecule, the protein being of one type or several different types. Herein, we describe the preparation of such conjugates for immunofluorescent labeling applications in which one protein would be PE and the other would be an antibody. Aminodextrans and the ternary conjugates were characterized by light scattering and scanning electron microscopy (SEM). Triple detector (light scattering, viscosity, and refractive index) measurements for all aminodextrans derived from linear, water-soluble dextran showed that the product aminodextrans were also linear, even though analytical evidence for branching through intermolecular cross-linking was suggested for some preparations of highly substituted aminodextran. Previous work in the high-resolution transmission electron microscopy (TEM) of antibodies, polysaccharides, and phycobilisomes and their component pigments has revealed the ultrastructure of antibody shape, the branching of polysaccharide chains in proteoglycans (*35*, *36*), and the shape and size of R-phycoerythrin (*32*). Herein, moderate resolution SEM is used to determine the shape and size of ternary conjugates of MCA and PE with aminodextrans.

Enhanced phycoerythrin fluorescence intensities per marker in labeling white blood cells were obtained by substituting the direct conjugates with aminodextran-cross-linked conjugates, which results have been reported

[1] Matijevic, E., Sondi, I., Koester, S., and Siiman, O., unpublished results.

by us in meeting proceedings, and in issued and pending patents (*37*−*39*). The amplification of fluorescence was initially demonstrated for marked cells which usually showed dim fluorescence intensity (*37*, *38*) when their receptors for monoclonal antibodies (BB27, IL12Rβ.44, and BY55) were saturated with direct antibody−PE conjugates and their fluorescence intensity was measured by flow cytometry. PE-tandem dye molecules that can be excited with the same laser line, 488.0 nm Ar^+, as PE, were also incorporated into cross-linked conjugates to offer a set of six different markers using three colors, two intensity per color. One tandem dye is PC5 (PE-Cy5, phycoerythrin-cyanin 5.1) (*40, 41*), and a second tandem dye is ECD (phycoerythrin-TEXAS RED) (*42*, *43*). This allowed multiplex labeling (*39*) of cells for analysis of mixed cell populations by flow cytometry.

EXPERIMENTAL PROCEDURES

Materials. Dextran, T-2M, produced by *Leuconostoc mesenteroides*, strain B-512, was obtained from the Sigma Chemical Co., St. Louis, MO, as were other chemicals related to the preparation of aminodextrans. All inorganic chemicals were of reagent grade and were not further purified. Dextran, amino, nominally of 2 MDa M_r (molecular mass, was purchased from Molecular Probes, Inc., Eugene, OR, abbreviated as Amdex-M.P. Analytical data for lot 6551−3: 130 amines/mol. Measurement of the molecular mass of this lot of aminodextran by the Viscotek Corp. (Houston, TX) triple detection system (vide infra) gave ∼3 MDa. Therefore, there are (3 000 000 g/mol)/(162.1 g/mol glucose monomer) = 18 507 glucose units/dextran molecule or 130/18 507 = 0.007 02, i.e., ∼1/140 degree of substitution with single amine group per reacted glucose unit. The degree of substitution unless otherwise noted is defined as the total number of amino groups (primary and secondary) per monomeric glucose unit in the aminodextran molecule.

R-PE (catalog no. PB31), extracted and purified from red algae, was obtained from Prozyme, Inc., San Leandro, CA. Sulfosuccinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (sulfo-SMCC) was a Pierce product while 2-iminothiolane hydrochloride, L-cysteine, free base, and iodoacetamide were from Sigma. Column packing materials, G-25 or G-50 Sephadex and Bio-Gel A-5m and A-15m, were products of Pharmacia Biotech and Bio-Rad Laboratories, respectively. Phosphate-buffered saline, 1× PBS, pH 7.1−7.3, and conductivity, 13500−15500 $\mu\Omega^{-1}$ cm^{-1}, was prepared by dilution with distilled water from a 20× PBS stock solution, which contains 26.9 g dm^{-3} of K_2HPO_4, 6.4 g dm^{-3} of KH_2PO_4, and 170.0 g dm^{-3} of NaCl.

Desalting and purification of aminodextrans was carried out with hollow fiber (polysulfone, 9.9 ft^2 membrane surface area, 1 mm diameter fibers) cartridges, A/G Technology Corp. model UFP-5-E-35 (5 kDa MWCO) or model UFP-30-E-35 (30 kDa MWCO), with tubing adaptor kit, KA12-3P. Lyophilization of the final washed aminodextrans was accomplished with an FTS Systems, Inc. model TDS-00030-A, Dura-Dry microprocessor-controlled freeze-drier.

The CD4 antibody [CD4 clone SFCI12T4D11 (IgG1)] and CD8β antibody [CD8β clone 2ST8.5H7(IgG2a)] are products of Coulter Corp., Miami, FL. Anti-CD4-FITC, -PE, and -ECD are products of Coulter Corp. Streptavidin (catalog no. 15532-039) was obtained from Gibco Life Technologies, Inc., Gaithersburg, MD. Avidin, NeutraLite, R-phycoerythrin conjugate (catalog no. A-2660) was obtained from Molecular Probes, Inc.

Preparation of Aminodextrans. Aminodextrans were obtained commercially or were prepared by the following procedures. In a standard preparation of 1×-Amdex, 8.56 g of $NaIO_4$ in 100 mL of distilled water (DW) was added dropwise to 80 g of dextran (2 MDa) in 600 mL of DW over about 10 min with vigorous stirring, after which the mixture was stirred at room temperature for 3 h. The resulting viscous reaction mixture was then diluted to 2 L with DW and desalted using a hollow fiber cartridge and about 18−22 L of DW to obtain a solution having a final pH of 6.0−6.5. To the final, 800 mL volume of washed, oxidized dextran solution was slowly added 80 mL of colorless, liquid 1,3-diaminopropane (DAP) over about 10 min at room temperature. The resulting mixture was stirred for 3 h. Then, 3.2 g of $NaBH_4$ in 40 mL of 1 mM aqueous NaOH was added to the aminodextran reaction mixture over about 5 min with stirring. The resulting mixture was stirred for 1 h and then desalted using a 5 kDa MW cutoff hollow fiber cartridge and about 20−25 L of DW to reduce the specific conductance to about 3−4 $\mu\Omega^{-1}$ cm^{-1} and the pH to 6.0−6.5. The final volume of aminodextran solution was 400 mL. This solution was passed through a 0.2 μm sterile cellulose acetate filter unit and then freeze-dried to obtain 48 g of flaky, pale yellow solid, a 52% yield. Elemental analysis observed: C, 42.53; H, 6.52; N, 1.01; O (by difference), 49.94. Elemental analysis calcd for $C_{49}H_{84}NO_{40}\cdot 3H_2O$: C, 42.61; H, 6.57; N, 1.01; O, 49.81. The empirical formula $C_{49}H_{90}NO_{43}$ is very similar to the formula based on 31 units of glucose, 1 unit of fully diamine substituted sugar ring, and three units of water. The degree of substitution in dextran by diamine was 1/32. Other runs varied between 1/28 and 1/45 degree of substitution. Similar results were obtained for aminodextrans prepared from dextrans having average M_r of 10 kDa to 2 MDa with 1×−5×-diaminopropane substitution. Modifications were made to periodate oxidation, diamine addition, and borohydride reduction reactions. The first modification was to use only a 10% excess of diamine over the stoichiometric 2:1 diamine:periodate molar ratio previously used. Second, the diamine addition reaction was conducted at a temperature in the range of 5−10 °C. Third, the diamine addition reaction was spectroscopically monitored in the near-UV region for Schiffs' base formation, which was deemed completed when successive spectral analyses indicated a plateau was reached. These modifications reduced depolymerization and thus gave higher yield of product. Elemental analyses for 5×-Amdex, lot −11, which was prepared at a 500 g dextran scale and gave the best yield of conjugates were C , 44.45%; H, 7.20%; N, 3.79%, O (by difference), 44.56%. The empirical formula was $C_{13.7}H_{26.4}O_{10.3}N$, which is similar to the formula $C_{13}H_{24}O_9N\cdot H_2O$ based on 5 units of glucose/1 unit of 1.5 diaminopropane-substituted sugar ring ($C_{9.5}H_{21}O_2N_3$), or a degree of substitution in dextran of 1/6. Similar results were obtained for 5×-Amdex, lot −69 prepared at a 300 g dextran scale. High diamine concentrations caused depolymerization and thus gave significantly lower molecular weight aminodextrans than the starting dextran. β-Elimination and thereby depolymerization (*44*) has been previously noted in various oxidation reactions of cellulose and starch. The periodate oxidation of glucose units in dextran was shown (*45*, *46*) to release one mole of formic acid per mole of reacted glucose unit by 95% of the anhydroglucose residues. Thus, the overall redox equation requires 2 mol of periodate/1 mol of glucose unit or 2 mol of aldehyde for complete reaction. However, in 5×-Amdex preparations, 2 mol of periodate/5 mol of glucose units were used so

that the theoretical degree of substitution is 1/5. Thus, the maximum degree of substitution of dextran with DAP is also 1/5.

Partially cross-linked 5×-Amdex was prepared by a modified procedure. Dextran, T-2M, 500 g was blended in 4 L of DW to dissolve all solid. A solution of 267.5 g of sodium m-periodate in 2 L of DW was added to the dextran solution over a 5−15 min period using vigorous stirring. The reaction mixture was stirred for 4 h, over which 5−6 L of DW further was added to reduce the viscosity of the solution. The reaction mixture was then desalted using about 100 L of distilled water to obtain 6−9 L of washed, oxidized dextran solution having a specific conductance of about 6−20 $\mu\Omega^{-1}$ cm^{-1} and pH of 6.5−7.0. Then, the first portion of DAP, 70 mL of pure liquid, was added over about 5 min to the desalted, oxidized dextran solution. The resulting solution immediately began to show formation of a gel, which persisted for another 5−10 min before redissolving as a yellow solution. The reaction mixture was then put on an ice bath to maintain a reaction temperature of 8−10 °C and stirred vigorously before a second portion of 70 mL of DAP was added over a period of 5 min. After an additional 10 min of stirring, the third and final 70 mL portion of DAP was added to the reaction mixture. The total DAP addition and reaction time was 45 min. Then, 70 g of sodium borohydride in 700 mL of 1 mM aqueous KOH solution were added to the reaction mixture at 8−10 °C over about 10−15 min with overhead stirring. The reaction mixture was stirred for an additional 2 h until the yellow Schiffs' base color had disappeared. The reaction mixture was then desalted using a 5 kDa MW cutoff hollow fiber cartridge and about 80 L of DW to produce about 1.6 L of aminodextran solution having a specific conductance of 10−20 $\mu\Omega^{-1}$ cm^{-1} and pH of 7.0−8.0. The aminodextran solution was filtered through a 1.6 μm glass filter and lyophilized for a minimum of 72 h to produce 75−90 g (15−18% yield) of flaky, white to pale yellow crystals. Analyses for 5×-Amdex, lot 1−5, which gave a good yield of conjugates were C = 41.38%, H = 7.81%, N = 4.15%, O = 45.64%, I = 97 ppm, B = 590 ppm. The empirical formula was $C_{11.6}H_{26.1}O_{9.6}N$, which is similar to the formula $C_{11.2}H_{20.3}O_{7.3}N{\cdot}2H_2O$ based on 4 units of glucose/one unit of 1.5 diaminopropane-substituted sugar ring. Thus, the degree of diamine substitution in dextran was 1/5. Similar procedures were used in the preparation of 5×-Amdex, lot 2−2, except 1/3 x DAP was added in two portions and a 30 kDa MW cutoff hollow fiber cartridge was used for desalting to give a product which analyzed as C, 40.44%; H, 7.75%; N, 3.48%; O, 48.48% with a degree of substitution of 1/8.

Some 5×-Amdex lots require further description. The reaction mixture of the 5×-Amdex, lot 11−6, after addition of DAP and sodium borohydride, was adjusted to pH 8.5 with aqueous hydrochloric acid. It was then desalted, concentrated, and freeze-dried in the previously described manner. Elemental analyses for 5×-Amdex, lot 11−6, were C, 39.72%; H, 7.77%; N, 4.44%; Cl, 2.81%; O (by difference), 45.26%. The empirical formula based on actual analyses was $C_{10.4}H_{24.3}O_{8.9}NCl_{0.25}$. The chloride analysis showed that one of four total amine (primary and secondary) groups had a chloride counterion. As shown in the following section describing results of electrophoretic light-scattering experiments on suspensions of polystyrene latex beads coated with DAP or aminodextran, only primary amine groups are protonated near neutral pH to which the reaction mixture was desalted prior to lyophilization, this implies that 50% of the diaminopropane groups in aminodextran are bridging or cross-linking groups between dextran chains. A portion of the lyophilized aminodextran hydrochloride was dissolved in DW and deionized in batchwise fashion with mixed bed (H^+, OH^- form), Bio-Rad AG 501-X8 resin, until the specific conductivity of the supernatant was minimized. The resin was removed by filtration of the suspension through rayon cloth, and the aminodextran (∼50 mg/mL) in the filtrate was fractionated by precipitation with acetone (0−43% cut). The solid precipitate was washed with acetone and dried in a vacuum desiccator under silica gel. Elemental analyses of this deionized and fractionated material gave C, 45.55%; H, 7.03%; N, 3.82%; Cl < 0.5%, O (by difference), 43.60%, showing that chloride ion had been removed.

DELSA Results for DAP- and Amdex-Coated Polystyrene Latex Beads. 1,3-Diaminopropane (DAP) in aqueous solution is reported (*47*) to show acid dissociation constants, pK_{a1} = 10.94 and pK_{a2} = 9.03 at 10 °C. When either one of the primary amine groups of DAP is converted to a secondary amine in DAP derivatives, the pK_a of the secondary amine is expected to drop significantly. This was borne out when protonation of primary and secondary amines of DAP derivatives was observed (*48*) in Coulter DELSA (Doppler Electrophoretic Light Scattering Analyzer) 440 experiments with DAP−PS and 1×-Amdex-polystyrene (PS) latex beads dispersed in aqueous media. Multiangle Doppler electrophoretic light scattering measurements have been reviewed (*49*). Mobility versus pH data were obtained for PS aldehyde/sulfate beads, nominally of 2.0 μm diameter from Interfacial Dynamics Corp., and the same beads coated covalently with DAP or 1xAmdex at pH ∼10, followed by reduction of the Schiffs' base with sodium borohydride, and washing of the beads by centrifugation at 3000−4000*g*, discarding the supernatant, and redispersion of the residue in an equal volume of distilled water. The chemistry that was used in converting aldehyde PS beads to DAP−PS beads was the same as that used in the conversion of oxidized dextran to aminodextran. Note that any unreacted aldehyde in the reaction with DAP is converted to alcohol by borohydride reduction. Bead suspensions, 4 or 1% w/v solids, were diluted about 1000-fold with 0.01 M aqueous sodium nitrate solution, and pH was adjusted with either 0.1 M aqueous sodium hydroxide or 0.1 M aqueous sulfuric acid solutions.

The mobility of DAP−PS beads shows a relatively flat, −0.275 to −0.92 cm^2/V s, dependence from pH 7 to 9; but, a relatively steep rise from −0.275 to +4.87 cm^2/V s between pH 7.0 and 5.6. Raw PS aldehyde/sulfate beads show a highly negative mobility of −6.6 to −6.0 cm^2/V s between pH 9.9 and 5.6, and then a slight rise to −4.4 cm^2/V s at pH 4.3. The data for DAP−PS beads indicate nearly complete compensation of the negative sulfate group charge by protonated primary amine groups in the pH 9 to 7 range, and further protonation of secondary amine at acidic pH less than 7. A similar trend is observed in electrophoretic mobilities of 1×-Amdex-PS beads. An almost flat mobility versus pH dependence of −1.161 to −1.083 cm^2/V s from pH 7 to 9, but a rise from −1.161 to +0.567 cm^2/V s was observed between pH 7.0 and 5.6. 1×-Amdex-coated PS beads show less compensation for the negative sulfate charge due to less than saturation coverage of the bead surface by amine groups of the polymeric diaminopropane-dextran derivative and correspondingly fewer secondary amine groups protonated at acidic pH less than 7.

Preparation of Buffer-Exchanged Phycoerythrin (PE). In one run, four 2.5 mL portions of 20 mg/mL Prozyme PE concentrate (in 60% ammonium sulfate, 50

mM phosphate, and 5 mM sodium azide) were each pipetted into four 50 mL polypropylene centrifuge tubes. A total of 25 mL of PE storage buffer (50 mM phosphate and 2 mM EDTA, pH 7.0) was added to each of the four tubes. The tubes and contents were roller mixed for 30 min and then centrifuged for 30 min in a Beckman J6-B centrifuge at 3200 rpm. Residues were discarded. Supernatants were retained, and concentrated in CentriPrep-30 tubes (Amicon) by multiple centrifugations for about 20min each at 2000 rpm. The final 1−2 mL of PE concentrate was applied to the top of a 60 mL of G-50 Sephadex column, equilibrated, and eluted with PE storage buffer. The middle fraction, about 4 mL of total volume, was collected and retained. Absorbance readings for a 50-fold diluted sample at 565 nm gave a PE concentration in the concentrate of 35.050 mg/mL and a yield of 140.2 mg of PE. Further concentration of this fraction to 1−2 mL total volume gave a PE concentrate of 104.7 mg/mL.

Preparation of Antibody−Phycobiliprotein Conjugates. Direct monoclonal antibody (MCA)-fluorochrome (PE, PC5, and ECD) conjugates are commercially available for most antibodies from Coulter Corporation or Immunotech, as prepared by established procedures of conjugation reactions of 2-iminothiolane (IT) activated PE (or PC5; ECD) with sulfo-SMCC activated antibody or sulfo-SMCC activated PE (or PC5; ECD) with DTT (dithiothreitol) reduced antibody. The molar ratio of MCA:fluorochrome in these conjugates is about 1:1. Conjugation of IgG monoclonal antibody to PC5 was accomplished by sulfosuccinimidyl 4-[*N*-maleimidomethyl] cyclohexane-1-carboxylate (sulfo-SMCC) activation of PC5 and activation of antibody by reduction of disulfide bonds in the hinge region with DTT. As an example, a 100-fold dilution of the CD8β Antibody-PC5 conjugate pooled sample gave an $A_{565.5} = 0.4809$, yielding 20.31 mg of total PC5 in the CD8β−PC5 conjugate, and an $A_{280} = 0.1513$, giving 21.90 mg of total CD8β antibody in the CD8β−PC5 conjugate. The molar ratio of PC5/CD8β is, therefore, 0.618. A corrected *F*/*P* ratio based on the formula, MCA:PC5 = $[A_{280}/A_{565.5}$ (conjugate) − $A_{280}/A_{565.5}$ (dye)] × 8.77, is 0.864. Similar methods were used to prepare an CD4−ECD conjugate having an *F*/*P* ratio of 0.96.

Preparation of Antibody−Aminodextran−Phycobiliprotein Conjugates. The procedure was similar to the one previously (*21*) used to prepare conjugates of anti-CD3 antibody with aminodextran, either 1×-Amdex or 5×-Amdex. However, in the present work two different proteins, one, an iminothiolane-activated monoclonal antibody and the other, an iminothiolane-activated fluorescent protein, PE, PC5, or ECD, were conjugated simultaneously to the sulfosuccinimidyl 4-[*N*-maleimidomethyl] cyclohexane-1-carboxylate (sulfo-SMCC)-activated aminodextran. The IT to MCA and IT to PE (PC5 and ECD) molar ratios were maximized at 15 and 22.5, respectively, so as not to interfere with MCA activity (*7*) or with PE (PC5 and ECD) fluorescence intensity. Trials were typically done for new proteins at molar ratios of 7.5, 15, and 22.5. This is in accord with the exposure of CDR (complementary-determining or hypervariable region) and framework (or nonhypervariable region) residues in 34 human and murine antigen-binding regions of known three-dimensional structure (*50*). In 34 CDRs, of 78 total lys residues with an amine group which can react with IT, 60 are exposed to give an average of 2 exposed Lys/antibody, and of 3 total Cys residues, 0 are exposed, and 1 is partly buried. In 34 framework regions, of 296 total Lys residues, 237 are exposed to give an average of 7 exposed Lys/antibody, and of 136 total Cys residues, 0 are exposed, all are buried. Thus, the tested range 7.5−22.5 in IT:MCA molar ratio covers the maximum of about 9 Lys residues that can react with IT.

R-PE was further purified by centrifugation to remove high MW aggregates, followed by buffer exchange on G-50 Sephadex and concentration. Three protocols were used as follows.

(i) For 1×-Amdex conjugates, the molar ratio of reactants that were used was 4:1:4 = Dye:MCA:Amdex or the weight ratio was 25.713:4.287:10 = Dye:MCA:Amdex at the 10 mg Amdex scale.

(ii) For Amdex−Molecular Probes (hereafter denoted as Amdex or Amdex-M.P.), 50% less weight of dye, and MCA relative to Amdex was used so that molar ratio was 16:4:1 = Dye:MCA:Amdex and weight ratio was 12.856: 2.143:10 = Dye:MCA:Amdex at 10 mg Amdex scale.

(iii) For 5×-Amdex, the same dye:MCA:Amdex weight ratios as previously listed and as used in 1×-Amdex trials were adopted, but the molar ratio was 4:1:15 = Dye:MCA: Amdex.

Described below is the preparative procedure for Amdex-M.P.-cross-linked CD8β−PC5.

CD8β Antibody−Amdex−PC5 Conjugates. Conjugation was carried out with 50% less weight of dye and antibody relative to aminodextran so that molar ratio was 16:4:1 = PC5:CD8β antibody:Amdex and weight ratio was 12.856:2.143:10 at the 10 mg Amdex scale.

1. Activation of Aminodextran with sulfo-SMCC. A total of 0.340 mL of a 29.412 mg/mL solution of Amdex in distilled water, to which 0.018 mL of 20× PBS buffer solution was added to make a 1× PBS solution, was activated with 0.180 mL of 10 mg/mL sulfo-SMCC solution in 1× PBS, to which was added 0.462 mL of 1× PBS solution to make a total Amdex concentration of 10 mg/mL. The mixture was roller mixed for about 1 h at room temperature. After the mixing was completed, the reaction mixture was immediately applied to the top of a 60 mL (1.7 cm × 28 cm) G-50 Sephadex column equilibrated with 1× PBS. The sample was eluted using 1× PBS and collected in about 2 mL fractions. Fractions of the first band absorbing at 280 nm contained the high molecular weight activated Amdex as was verified by Tyndall scatter with a focused visible light beam (model 650, Cambridge Instruments, Inc., Buffalo, NY). These fractions were pooled to give about 5.8 mL of total sulfo-SMCC-activated Amdex.

2. Activation of Antibody. CD8β monoclonal antibody was activated by the addition of 0.033 mL of a 2 mg/mL solution of iminothiolane in 1× PBS and 0.219 mL of 1× PBS to 0.081 mL of CD8β concentrate (61.67 mg/mL). The resulting solution which had an antibody concentration of 15 mg/mL and an iminothiolane molar concentration 15-fold larger was mixed at ambient temperature for about 1 h. The reaction mixture was then chromatographed on a 60 mL (1.7 cm × 28 cm) G-50 Sephadex column equilibrated with 1× PBS, and the sample was eluted using 1× PBS. The first band peak fraction yielded about 4.2 mL of 1.113 mg/mL antibody solution, which contained a total of 4.67 mg of IT-CD8β antibody derivative.

3. Activation of PC5. PC5 was activated by the addition of 0.097 mL of a 2 mg/mL solution of iminothiolane in 1× PBS and 0.098 mL of 1× PBS to 0.179 mL of PC5 concentrate (83.625 mg/mL). The resulting solution which had a PC5 concentration of 40 mg/mL and an iminothiolane molar concentration 22.5-fold larger was mixed at room temperature for about 1 h. The reaction mixture

was then applied to the top of a 60 mL (1.7 cm × 28 cm) G-50 Sephadex column equilibrated with 1× PBS and the sample was eluted with 1× PBS. The first band peak fraction gave about 3.9 mL of 3.35 mg/mL PC5 at an A_{565}/A_{280} ratio of 6.2394, which contained a total of 13.065 mg of IT-PC5.

4. Conjugation of IT-CD8β and IT-PC5 to sulfo-SMCC-Amdex. For a 15 mg total protein, 10 mg Amdex weight ratio, 1.926 mL of 1.113 mg/mL IT-CD8β solution (about 2.143 mg antibody) was first mixed with 3.839 mL of 3.35 mg/mL IT-PC5 solution (about 12.86 mg IT-PC5), to which was added 5.8 mL of sulfo-SMCC−Amdex solution (about 10 mg Amdex), and the entire mixture was roller mixed overnight for 16−24 h.

After the mixing was completed, the total volume of the mixture was determined, and 0.120 times this volume of 5 mg/mL L-cysteine in 1× PBS was added to each conjugation mixture. The L-cysteine containing mixtures were then mixed for an additional 15 min to effect blocking of any unreacted sulfo-SMCC moieties. Last, 20 mg/mL iodoacetamide in 1× PBS in the amount of 0.120 times the total mixture volume and 1 M borate buffer solution, pH 9.8, in the amount of 0.020 times the total mixture volume were added to each mixture. The resulting mixtures were mixed for about 30 min to block any unreacted sulfhydryl groups.

5. Purification of CD8β-Amdex-PC5 conjugates. The total volume of conjugation mixture was reduced to about 2.5 mL by centrifuging an Amicon Centri-Prep 30 tube containing the sample for about 20 min at 2000 rpm using a refrigerated Beckman J-6B centrifuge. The sample was placed on the top of a Bio-Gel A-15m agarose column (2.5 cm × 48 cm) equilibrated with 1× PBS and chromatographed using 1× PBS as eluant. Eluant fractions of about 3.6 mL volume were collected using a Pharmacia LKB FRAC-100 collector operating in the drop collection mode. The fractions were monitored using a LKB 2138 Uvicord S monitor operating at 280 nm. The first narrow, intense band eluted from the column contained the CD8β−aminodextran−PC5 conjugate. A lower intensity shoulder of less than one-third the intensity of the first peak contained ∼1:1 PC5:aminodextran conjugate and excess PC5. A medium-to-low intensity well-separated third band was attributed to the low molecular weight excess blocking reagents.

The fractions collected for the CD8β−Amdex−PC5 conjugate were analyzed spectrophotometrically at 565.5 and 280 nm using a 1 mm path-length cell. The concentration of PC5 in mg/mL in the conjugate was derived from the absorbance at 565.5 nm by using the formula $A_{565.5}$/8.167. Data for fractions 19−24 under the first narrow peak gave 4.241 mg of total PC5 in the conjugate. Since 12.86 mg of IT-PC5 was used in conjugation, the yield was 33.32%.

6. Estimation of Molecular Masses of Antibody-Aminodextran-PE Conjugates. Blue dextran (Sigma, T-2M) was applied to an A-15m column that was used to purify the antibody−aminodextran−PE conjugates, eluted from the column with 1× PBS, monitored by A_{280}, and collected at the same drop count of 120 drops/fraction. The first narrow peak (about fraction 20) in the elution profile of antibody−aminodextran−dye conjugates occurred in the same fraction as the first narrow peak in the elution profile of blue dextran. Therefore, we estimate the conjugates to have a similar molecular mass of about 2 000 000 Da.

Trials with 5×-Amdex were run at a 4:1:15 molar ratio of Dye:MCA:Amdex or weight ratio of 25.713:4.287:10 at a 10 mg 5×-Amdex scale. Procedures for other aminodextrans were similar to the ones described above for Amdex-M.P., i.e., activation ratios were the same but amounts were doubled to reflect the 2× greater amount of dye and antibody. In trial 1 for CD8β antibody-5×-Amdex (lot −11)-PC5, purification of the conjugation mixture on Bio-Gel A-15m was carried out with collection of eluant fractions of 1.8 mL volume. A chromatogram showing the A_{280} versus fraction number recording is displayed in Figure 1. Data for fractions 36−46 under the first narrow peak containing the conjugate are listed in Table 1. The active CD8β antibody concentration was determined by an ELISA assay (*51*) for IgG1 antibody; however, assay results appeared to show interference from nonantibody parts of the conjugate. Thus, A_{280} values corrected for the PC5 contribution were used to obtain antibody concentrations. In another trial for CD8β antibody-5×-Amdex (lot 1−5)-PC5, the conjugation mixture gave an intense first band off the Bio-Gel A-15m column but the yield was low since the bulk of the blue−purple conjugate aggregated with the gel at the top of the column and could not be eluted. Fractions 20−25 collected at 3.6 mL/fraction gave 4.831 mg of conjugate, an 18.78% yield based on 25.724 mg of IT-PC5 used in the conjugation.

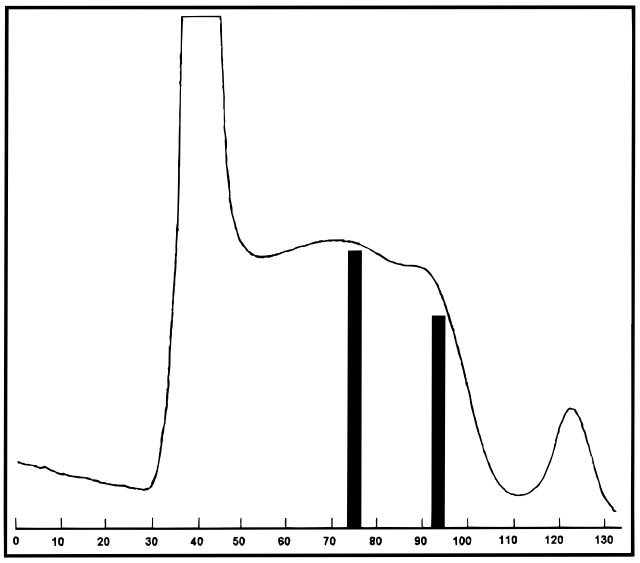

Figure 1. A_{280} versus fraction number trace for 2 mL of concentrate of CD8β−5×-Amdex−PC5 conjugate on Bio-Gel A 15 m column of 2.5 × 48 cm size. Run conditions: 1 mm/min chart speed; ∼1.3 mL/min elution with 1× PBS; 0−1 absorbance unit scale. Positions of A_{280} maxima for either PC5 or CD8β antibody alone on the column are indicated with bars in fractions 74−76, and 92−94, respectively.

Table 1. Fractionation Data for Trial 1, CD8β−5×-Amdex−PC5 Conjugate.

fraction	$A_{565.5}$	A_{280}	$A_{565.5}/A_{280}$	PC5 (mg/mL)	CD8β (mg/mL)
36	0.0891	0.0344	2.59	0.109	0.193
37	0.2661	0.0959	2.77	0.326	0.507
38	0.7280	0.2450	2.97	0.891	1.212
39	1.1681	0.3744	3.12	1.430	1.758
40	1.1810	0.3646	3.24	1.446	1.639
41	0.8906	0.2648	3.36	1.090	1.134
42	0.5169	0.1452	3.56	0.633	0.573
43	0.2720	0.0715	3.81	0.333	0.252
44	0.1637	0.0397	4.13	0.200	0.118
45	0.1160	0.0260	4.46	0.142	0.063
46	0.0915	0.0191	4.79	0.112	0.035

$A_{565.5}$ and A_{280} are absorbances measured at 565.5 and 280 nm with a 1 mm path length cell.

Table 2. Triple Detector System Data for Dextran and Various Aminodextrans.

sample	concentration (mg/mL)	d*n*/d*c* (mL/g)	M_w (kDa)	η (dL/g)	R_g (nm)	L (nm)	R_h (nm)
1. 5X-Amdex, lot −11	0.860	0.155	414	0.262	15.6	38.2	10.4

Dextran (*63*)			500				22.5

CD4 Antibody−Amdex−ECD Conjugate. The procedures were the same as those outlined for the preparation of the anti-CD8β−Amdex−PC5 conjugate in Section II, except anti-CD4 antibody was activated with IT and used in the conjugation instead of CD8β antibody, and the tandem PE-Texas red or ECD fluorescent dye (*41, 42*) was used instead of PC5. In trial 2, IT-ECD (12.856 mg) and IT-CD4 (2.143 mg) were mixed with sulfo-SMCC−Amdex (10 mg) at concentrations of 1.10, 0.184, and 0.857 mg/mL, respectively, during conjugation. The IT-ECD ($A_{565.5}/A_{280}$) ratio was 5.424. The conjugation mixture was concentrated to about 1.5 mL and applied to the top of an A-15m column. Data for fractions 20−26, collected at about 3.6 mL/fraction under the first narrow peak in trial 2, gave 5.756 mg of total ECD in the conjugate. Since 12.858 mg of IT-ECD was used in conjugation, the yield was 44.77%.

CD4 Antibody−Amdex−PE Conjugates. Again, the procedures were the same as those outlined for the CD8β−Amdex−PC5 conjugate in section 2, except CD4 antibody of the IgG class and PE were activated with IT and used in the conjugation instead of CD8β antibody and PC5. In trial 3, the reactants, 3.896 mL of 3.30 mg/mL IT-PE (12.856 mg), were first mixed with 4.75 mL of sulfo-SMCC−Amdex (10 mg) solution, to which were then added 3.058 mL of 0.701 mg/mL IT-CD4 (2.143 mg). The IT-PE (A_{565}/A_{280}) ratio was 5.800. The conjugation mixture was concentrated to about 1.0 mL and applied to the top of an A-15m column. Data for fractions 18−24 collected at 3.6 mL/fraction under the first narrow peak in trial 3 gave 4.957 mg of total PE in the conjugate. Since 12.856 mg of IT-PE was used in conjugation, the yield was 38.56%.

Streptavidin−Amdex−PE Conjugates. The procedures were similar to those already described for CD8β−Amdex−PC5 and CD8β−5×-Amdex−PC5, except streptavidin was substituted for CD8β antibody and PE was substituted for PC5. To obtain concentrations of IT-streptavidin in milligrams per milliliter, the A_{280} values in two runs were divided by 2.5 [approximately the M_r ratio of IgG antibody/streptavidin = 160000/60000 Da = 2.67] in the 9−11 run and 3.0 in the 9−15 run. In both trials, 10 mg of Amdex (~30 mg/mL in 1× PBS) was activated with 0.180 mL of 10 mg/mL sulfo-SMCC, and the three purified fractions showing the most Tyndall scatter were pooled to give about 5−9 mL of sulfo-SMCC−Amdex solution. In run 9−11, 8.806 mg of IT-PE (8.30 mg/mL) and 2.143 mg IT-streptavidin (1.940 mg/mL) were mixed with 9 mL of sulfo-SMCC−Amdex−M.P., and 17.613 mg of IT-PE and 4.287 mg of IT-streptavidin were mixed with 9 mL of sulfo-SMCC−5×-Amdex (lot −11) overnight for 21 h. In run 9−15, 12.856 mg of IT-PE (8.85 mg/mL) and 2.143 mg of IT-streptavidin (1.202 mg/mL) were mixed with 8 mL of sulfo-SMCC−Amdex−M.P.; and 25.713 mg IT-PE and 4.287 mg IT-streptavidin were mixed with 5 mL of sulfo-SMCC−5×-Amdex (lot −11) overnight for 20 h. Blocking with L-cysteine free base and iodoacetamide was done for each run in the same way as previous conjugations. The concentrated reaction mixtures of about 1 mL of total volume were each individually purified on a Bio-Gel A-15m column. Fractions (about 3.6 mL) of the first band, peaking in protein and PE concentrations at fraction 21 for the Amdex-M.P. conjugate and at fraction 22 for the 5×-Amdex conjugate, were retained.

Triple Detector System Measurements. The Viscotek Corp. (Houston, TX) system consists of a model T-60 differential viscometer/light-scattering dual detector and a model LR40 differential laser refractometer with a 670 nm diode laser source. The principles of the method and analyses have been described (*52*). The responses of the three primary detectors are as follows: light scattering, $M(\mathrm{d}n/\mathrm{d}c)^2 \times c$; viscometer, ηc; refractometer, $\mathrm{d}n/\mathrm{d}c \times c$. Right-angle light-scattering gives the molecular weight when combined with viscometry detection. The 90° LS is corrected for angular dissymmetry using the Debye equation, together with the molecular size information provided by the viscometer. Viscometry yields the molecular density, which is related to conformation and branching. The refractometer measures sample concentration, providing a direct determination of the refractive index increment, d*n*/d*c*, of the polymer sample. The hydrodynamic volume of a polymer molecule in solution, related to the cube of its radius of gyration, R_g, is directly proportional to the intrinsic viscosity (η) and the weight average molecular weight (M_w), divided by Avogadro's number. The accuracy of R_g values determined by the triple detector system is claimed to be within 0.5 nm.

RESULTS

Light Scattering, Viscosity, Refractive Index Measurements. Molecular data for 11 samples, one dextran and 10 aminodextrans, determined from duplicate batch analyses by the triple detector system are summarized in Table 2. The samples were run at a concentration of 0.7−3.5 mg/mL in 0.2 M aqueous sodium nitrate solution through a column consisting of a 50 ft coil of 0.01 in. i.d. stainless steel tubing without any column packing in batch mode. Some lots of solid aminodextran resisted dissolution and needed a more extensive protocol to afford complete dissolution. Two dissolution protocols were followed: (1) by minimum heating at ~70−80 °C for 5−10 min for samples 1, 3, 5, 6, and 8; (2) by first soaking at

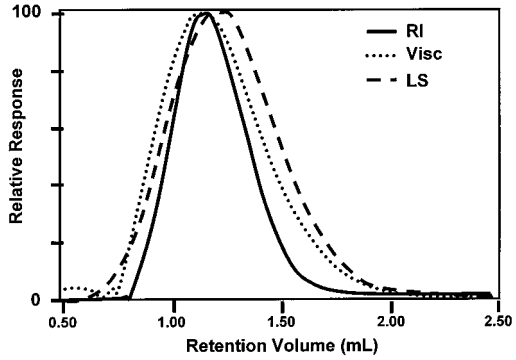

Figure 2. Triple chromatogram of Amdex-M.P. Run conditions: solvent, 0.05 M aqueous sodium sulfate; flow rate, 0.5 mL/min; injection volume, 50 μL; column temperature, ambient; concentration, 0.1 mg/mL. Traces of curves on RHS are for refractive index (RI), viscosity (Visc), and light scattering (LS) in order from left to right.

room temperature for 1−2 h and then heating at ∼70−80 °C for 30 min for samples 2, 4, 7, 9, 10, and 11. The latter dissolution protocol gave reproducible results. Comparison of relative responses of viscosity and light scattering versus retention time within each sample showed that peak positions and band shapes were similar to each other as shown for Amdex-M.P. in Figure 2, implying little or no branching in the dextran and aminodextran chains. Lots of 5×-Amdex prepared by the same 500 g dextran scale, the same molar ratio of DAP-to-sodium periodate, and the same mode of DAP addition in three equal portions consistently gave molecular mass figures in the 25−45 kDa range.

SDS−PAGE Gel Electrophoreses. SDS−PAGE of aminodextrans was run at 400 V (65 V h) on the Pharmacia Phast system, using a 4 to 15 gel gradient for the 30−300 kDa molecular mass range and SDS buffer strips. The use of this system for aminodextrans is made possible by the protonation and, thus, charging of primary amine groups at pH 8.1 of SDS buffer strips and the selective electrostatic interaction between negatively charged sulfonate groups of the widely used Coomassie blue stain (*53, 54*) and protonated, primary amine groups of aminodextrans. Electrophoresis, applied to the study of synthetic polyelectrolytes, has been shown (*55*) to provide a more detailed molecular mass distribution than size-exclusion chromatography. We obtained an accurate measure of the size distribution in aminodextrans from the spread of bands in the electrophoretograms. Both dissolution protocols 1 and 2 were used to prepare 1 mg/mL Amdex solutions in 1× PBS buffer, each mixed 1:1 with SDS buffer, which were then run together with a high molecular mass (200, 116, 97, 66, and 45 kDa) standards sample. Gel electrophoresis bands stained with Coomassie blue for the two runs are shown in Figure 3. All the aminodextrans showed well-stained SDS−PAGE gels, indicating the presence of abundant primary amine groups. Molecular weight ranges for the aminodextrans were estimated from the range of the heaviest blue stain in each lane of the gel referenced to the relatively narrow band positions of five standards in the same gel. The 5×-Amdex lots 1−5, 2−2, −11, and 11−6 and 1×-Amdex lot −75 gave molecular mass ranges of about 30−75, 60−190, 50−150, 35−250, and 150−250 kDa, respectively, for protocol 1 dissolution, and about 30−75, 55−175, 40−90, 30−110, and 150−250 kDa, respectively, for protocol 2 dissolution. The 5×-Amdex lots showed the largest change to lower molecular mass fragments with the more extensive protocol 2 dissolution procedure. Also, the 5×-Amdex lot 2−2, which was purified with a 30 kDa M_r cutoff membrane, showed a significantly higher starting M_r range than other 5×-Amdex lots which were purified with a 5 kDa M_r cutoff hollow fiber cartridge. Thus, other higher MWCO (100, 300, and 500 kDa) membranes that are available can be used to obtain narrower and higher size distributions of aminodextrans where they are required. The average molecular masses obtained from the triple detector system measurements, and the molecular mass ranges obtained from electrophoresis for 1×- and 5×-Amdex samples, both show the extensive depolymerization of dextran starting material (2−3 MDa) that occurred during the aminodextran preparation by the periodate oxidation-diamine addition route.

Dynamic Light Scattering. Hydrodynamic radii, R_h, were obtained from photon correlation spectroscopy (PCS), also known as quasi-elastic light-scattering (QELS), measurements (*56, 57*) on the COULTER N4MD analyzer. The N4MD contains a correlator and microprocessor which converts autocorrelator results using Provencher's program CONTIN to an intensity distribution. A second microprocessor then converts the intensity distribution by the exact Mie theory to give mass average molecular mass. Solutions of either PE, PC5, or ECD as well as their antibody−aminodextran−dye conjugates were measured at concentrations of 5 mg/mL or less in 1× PBS buffer, pH 7.2, with 632.8 nm He/Ne laser excitation. Measurements for freshly buffer-exchanged and purified PE at a concentration of 1.5 mg/mL in 50 mM phosphate, 2 mM EDTA buffer at pH 7.0 gave a mean diameter of 32.7 nm. The scattering angle was 22.8° instead of 90° to improve the intensity of scattered light by a factor of about 16, since PE is small and a poor scatterer which absorbs part of the incident laser light at 632.8 nm. PCS analyses of the peak chromatographic fraction for all three PE, PC5, and ECD conjugates with anti-CD4−Amdex-M.P. in 1× PBS gave the same mean diameter of 146 nm.

Scanning Electron Microscopy. More direct evidence for the structure of the conjugates was obtained from scanning electron microscope (SEM) photos taken with a Philips model XL40-FEG instrument. Samples were prepared by filtering about 0.5 mL of conjugate at 0.4 mg/mL in 1× PBS, pH 7.2, through an 0.2 μm polycarbonate membrane filter (Poretics Corp., Livermore, CA) and drying the filter in air in a sterile Petri dish for 3−4 h to overnight. Portions of the sample on the filter were cut and attached to double-sided carbon tape on an aluminum stub. All samples were gold-sputter-coated with a Cressington Model 108 auto coater at a 25 sec argon gas plasma cycle time and 7.5 cm platform-to-target distance for a thickness of 15−25 nm. Figure 4 shows images of four conjugate samples prepared in the above way for SEM. Note the globular shape of the conjugates, some of which are located inside the 0.2 μm pores of the membrane while others were retained on the surface of the filter. Hydrated samples, as shown in Figures 5 and 6 for CD4−Amdex-M.P.-PE (fraction 20) and CD8β−Amdex−M.P.−PC5 (fraction 19) conjugates, respectively, were measured within 1 day of sample preparation. This is necessary for retention of globular structure, especially for smaller conjugates with 5×- and 1×-Amdex; otherwise, the structures collapsed to varying degrees. The range of mean diameters from SEM photos is included in Table 3.

Flow Cytometry. CD8β−PC5 and fractions of CD8β−5×-Amdex−PC5 conjugates from trial 1 were titered with 3−0.5 μg of antibody in the conjugate per tube. Amounts

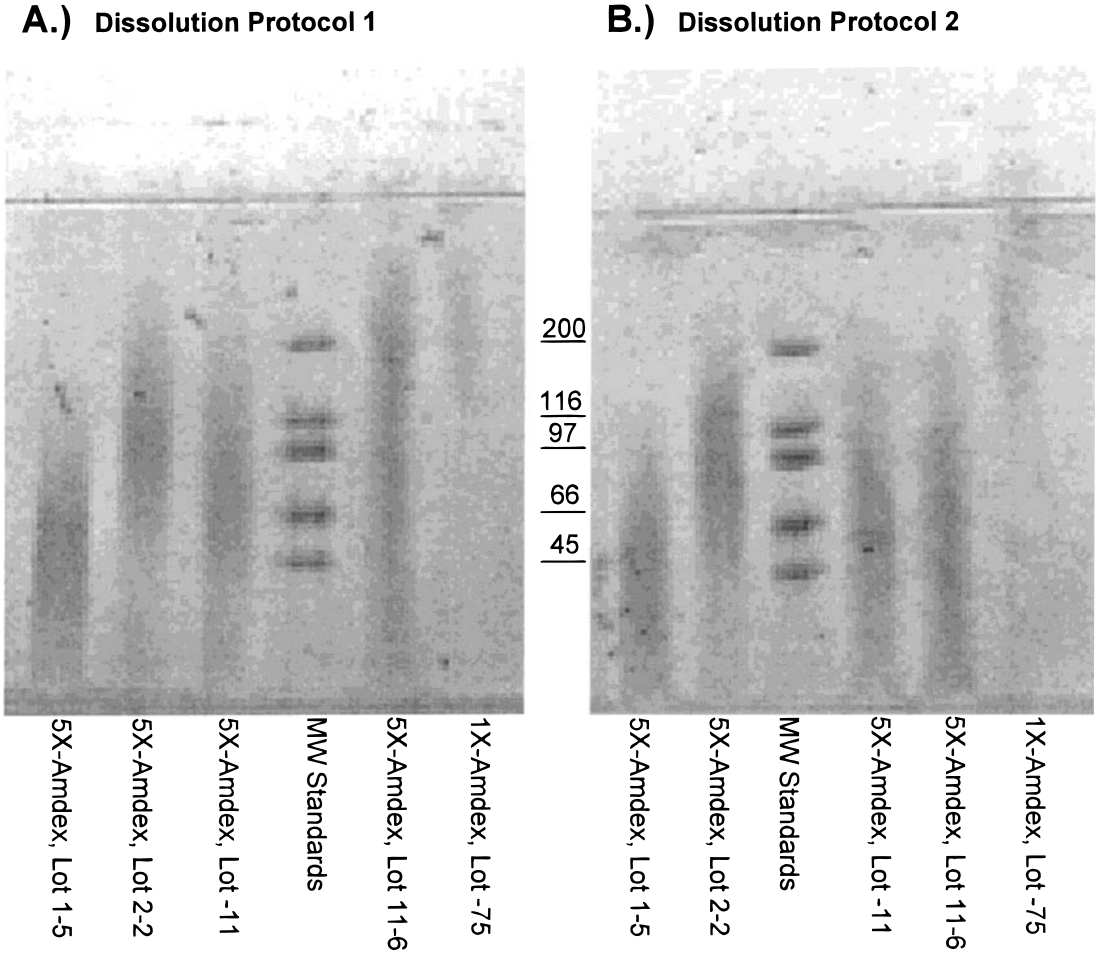

Figure 3. SDS−PAGE results for various aminodextran lots dissolved in 1× PBS buffer solution: (A) protocol 1 dissolution; (B) protocol 2 dissolution.

of antibody for the titers were determined from corrected A_{280} values for the conjugates. Dilutions were added to 100 μL of whole blood and incubated for 60 min at room temperature. For analysis on a flow cytometer (COULTER EPICS 4-color XL-MCL), the blood mixtures were lysed and quenched using the COULTER ImmunoPrep reagent system on the COULTER Q-Prep workstation, washed once with 1× PBS (addition of 2 mL of 1× PBS, centrifugation at 500 g for 5min, discarding supernatant), and the cell pellet was resuspended in 1 mL of 1× PBS. The lymphocyte cell population was distinguished with forward light scatter vs 90° light scatter, electronically gated, and displayed on single parameter histograms [*y*-axis = number of fluorescent events (count); *x*-axis = fluorescence intensity]. Flow cytometer instrument settings were adjusted to display the nonstaining negative lymphocyte subpopulation only within the first decade on the 4-decade log scale for fluorescence intensity. Figure 7 shows the ability of CD8β−5×-Amdex−PC5 conjugate as a fluorescent marker containing more than two PC5 molecules per dextran molecule, to enhance the mean channel PC5 fluorescence intensity (MFI) of the positive cell population over that obtained with the direct CD8β−PC5 conjugate which contains only 0.86 PC5/antibody. The histograms show that the cross-linked conjugate has 3.5-fold higher fluorescence intensity on CD8β+ lymphocytes. In another run, it was found that the mean channel fluorescence intensity of labeled T cells could be enhanced up to 8-fold by examining various fractions of trial 1, CD8β−5×-Amdex−PC5 conjugate as the fluorescent marker. Titers of the control, CD8β−PC5, and the sample, CD8β−5×-Amdex−PC5, with the same instrument settings were run and the results, mean channel PC5 fluorescence intensities and MFI ratios, sample fraction-to-control at same titers, are presented in Table 4 for another donor. MFI ratios corrected for the *F*/*P* ratio, 0.860, of the control, direct CD8β−PC5 conjugate, were about 16−17% higher than values listed in Table 4.

CD4−ECD and a single pooled sample of CD4−5×-Amdex−ECD conjugates were titered with 0.5−0.015 μg (based on the corrected A_{280} value for each conjugate) per tube in the same way as in the previous example. The results are shown in Figure 8 for the positive population mean channel ECD fluorescence intensities (MFI) for the $CD4^+$ lymphocytes with the direct and cross-linked antibody-ECD conjugates. The MFI ratios, maximizing at 9.7 were calculated from the mean channel positions of each 5×-Amdex sample compared to the saturating bottle product dose of CD4−ECD (0.5 μg). Using the *F*/*P* ratio of 0.96 for the CD4−ECD conjugate, the corresponding maximum MFI ratio is 10.1.

CD4 antibody conjugates were prepared to obtain an enhanced fluorescence standard with a narrow distribution of fluorescence intensities for positive lymphocytes. To 100 μL of whole blood from a single normal blood donor, 0.5 μg each of the CD4-PE control conjugate and the CD4−5×-Amdex−PE fraction samples were added and mixed for 30 min at room temperature. Concentrations of CD4 antibody in the conjugates were based on corrected A_{280} values. The samples were prepared for flow cytometric analyses (FCM) as before. The amplification

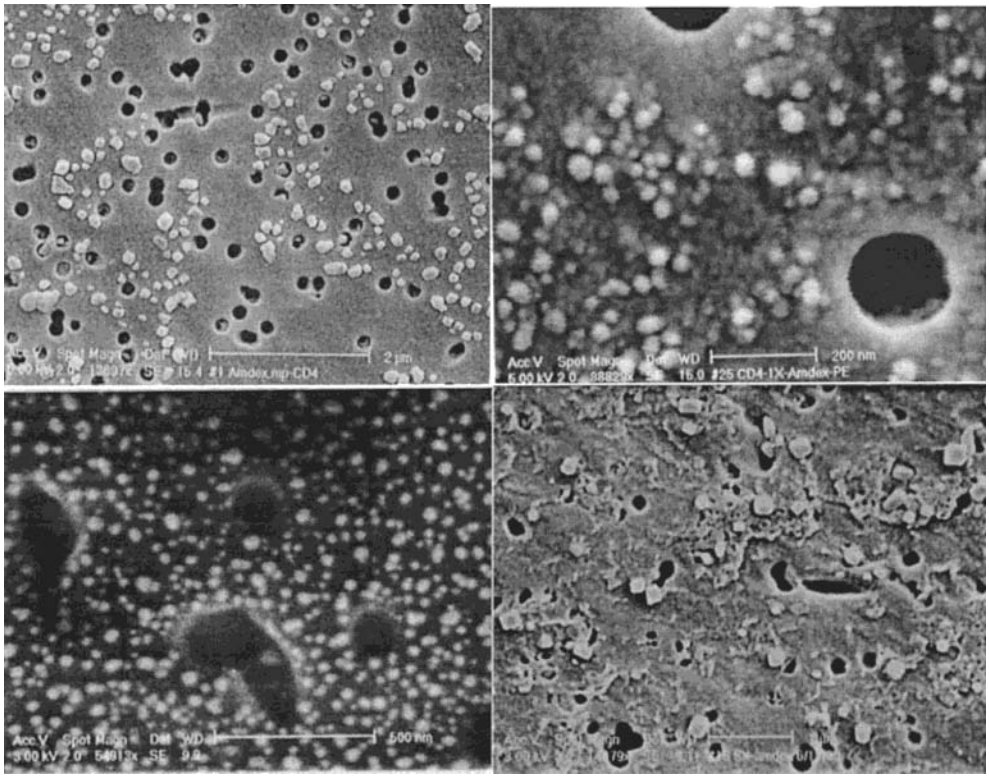

Figure 4. Scanning Electron Micrographs of CD4−Amdex, M.P.-PE, top, left; CD4-5×-Amdex(lot 1−5)-PE, bottom, left; CD4-1×-Amdex(lot−75), top, right; and CD8β−5×-Amdex(lot−11)-PC5 conjugates. The instrument was operated with the secondary emission detector and 3−5 kV electron beam intensity. Magnification was 13697×, 54913×, 88829×, and 14479×, respectively, on original photo, but should otherwise be determined from bar length.

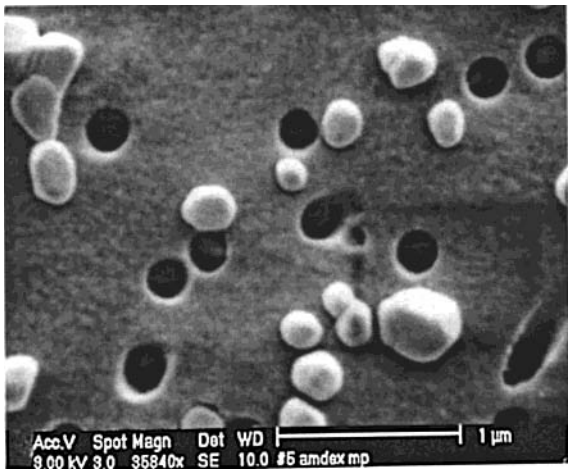

Figure 5. Scanning electron micrograph of CD4−Amdex, M.P.-PE conjugate, pooled and concentrated fractions 19 and 20.

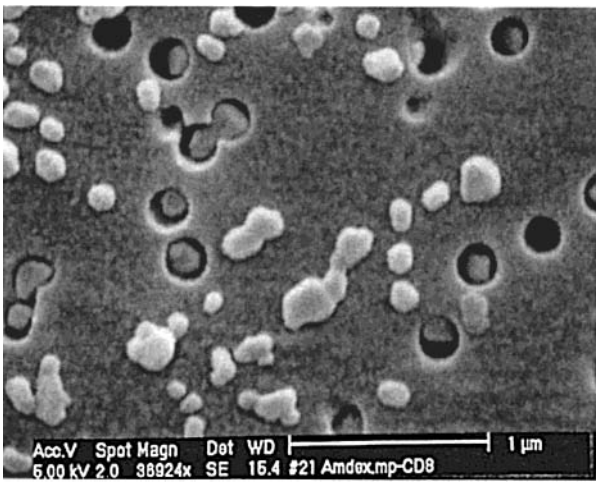

Figure 6. Scanning electron micrograph of CD8β−Amdex, M.P.-PC5 conjugate, fraction 19.

of the mean channel PE fluorescence intensities relative to the control, obtained at the same instrument settings, is shown in Table 5. The maximum positive amplification ratio was 4.7; however, the negative population of MFI was also amplified, although not to the same extent. The signal-to-noise (S/N) amplification, which encompasses both the positive and negative amplification ratios, was approximately 2.0. Both the amplified and nonamplified CD4 antibodies detected similar percentages of $CD4^+$ and $CD4^-$ lymphocytes.

Maximum amplification ratios of 8.5, 4.2, and 2.2 occurred in the CD4,PE; CD4,ECD; and CD8β,PC5 conjugates with Amdex-M.P. (fractions 19, 21, and 19, respectively) as shown in Tables 6-8. These fractions coincided with the lower fraction side (higher molecular mass) of the first intense band observed in chromatography of conjugation mixtures. The CD4−Amdex−PE conjugate demonstrated the highest amplification ratio ever obtained for a CD4, PE conjugate with any lot of aminodextran. Also, this ECD conjugate is the first one to show excellent yield in the first band as well as the highest amplification ratio of any ECD conjugate. Also notable in Tables 6−8 is that the Amdex M.P. gives low negative amplification ratio values, and thus higher S/N amplification ratios, as compared to the 5×-Amdex values in Table 5.

A degree of substitution of ~1/140 with a single amino group per reacted glucose unit was shown to be sufficient to obtain MCA−Amdex−PE (PC5, ECD) conjugates in good yields. For CD4−Amdex−PE conjugates, Amdex-M.P. has provided the highest amplification of fluorescence intensity over that obtained with direct CD4−PE

Table 3. Mean Diameters of PE and Its Conjugates and Molar Ratios of PE:Aminodextran

species	mean diameter by QELS (nm)	SEM diameter range (nm)	MW (kDa)	mole fraction [PE/(PE + Ab)]	PE/Amdex by packing	PE/Amdex by MW	PE/Amdex by flow cytometry

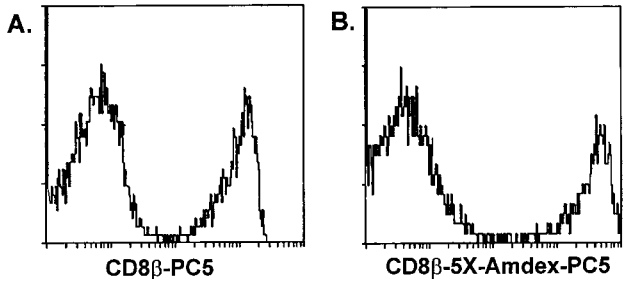

Figure 7. Flow cytometric histograms of CD8β−PC5 and CD8β−5×-Amdex−PC5 conjugates mixed with whole blood. 100 μL of whole blood from a normal donor was stained with 10 μL (2.5 μg) of CD8β monoclonal antibody either as (A) a CD8β−PC5 or (B) a CD8β−5×-Amdex−PC5 conjugate. The fluorescence intensity of a light scatter-gated lymphocyte sub-population is displayed as histograms where the *y*-axis represents the number of fluorescent events (count), and the *x*-axis shows fluorescence intensity. The nonstaining negative cell population is seen in the left quarter of the histogram.

conjugate in labeling CD4+ cells in whole blood. Flow cytometry histograms of the number of fluorescence events versus mean channel fluorescence intensity are shown in Figure 9 for CD4-PE versus various CD4−Amdex−PE-labeled lymphocytes of the same blood donor. Good separation between the direct conjugate and each Amdex-cross-linked conjugate was obtained. Also, no interference from CD4 negative populations ever was observed. Similar histograms for CD4−ECD versus CD4−Amdex−ECD are shown in Figure 10.

A graph comparing CD4,PE with carriers of various molecular masses is shown in Figure 11, and shows the direct, linear proportionality between amplified fluorescence intensity and molecular mass of carrier only for the direct conjugate and conjugates with 1×-Amdex and Amdex-M.P.

Both cross-linked, 5×-Amdex conjugates with CD4 antibody and PE show much higher amplification than predicted from the linear plot in Figure 11 for linear chain aminodextrans of low degree of amino substitution

0.5	53	485	9.7

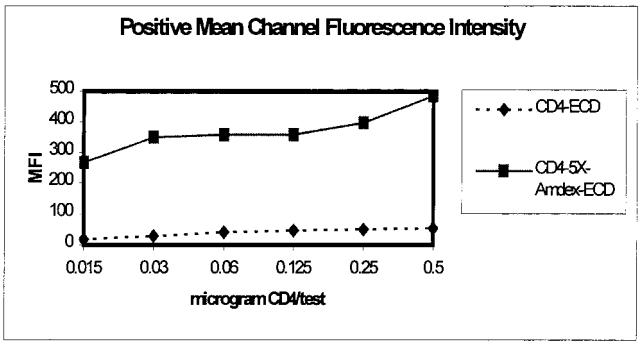

Figure 8. Flow cytometric results in tabulated and graphical form: positive population mean fluorescence intensity (MFI) data for direct CD4−ECD and CD4-5×-Amdex−ECD conjugates mixed with 100 μL whole blood at various titers of 0.015−0.5 μg of CD4.

and for the direct conjugate. Possibly, a more globular structure and higher degree of amino substitution in 5×-Amdex, albeit cross-linked, allows formation of multiply cross-linked complexes of the type -Amdex−MCA, PE−Amdex-, which, as a single unit in binding to antigenic sites on biological cells can yield greater amplification of fluorescence intensity. The broad range of yields of MCA−5×-Amdex−PE, PC5, or ECD conjugates and their much greater sensitivity to the nature of the antibody that was used in the conjugations, point to the formation of multimeric complexes.

Furthermore, several trials with aminodextran-cross-linked conjugates, streptavidin−Amdex−PE and streptavidin−5×-Amdex−PE, were used as indirect secondary reagents with biotinylated CD4 primary antibody to label and analyze for CD4+ cells in whole blood by flow cytometry. Titers between 0.25 and 5.0 μg of protein in the peak fraction 21 of lot 9−15, streptavidin−Amdex−PE conjugate with 100 μL of whole blood (previously stained with biotinylated CD4 antibody and washed once), were lysed, quenched, washed, and analyzed. These are shown in the overlaid histograms of Figure 12A. A plateau indicating saturation of CD4+ receptors in the sample was reached in mean channel fluorescence intensity at a titer of 2.5 μg. The Figure 12 histograms for different fractions of conjugates containing either (B) Amdex-M.P. or (C) 5×-Amdex, lot −11, showed that all fractions were equally good at providing fluorescence intensity, i.e., within each series of fractions the number of PE molecules per conjugate molecule was about the same. When compared against trials with 2.5 μg amounts

of avidin in the direct conjugate, avidin, NeutraLite −PE, the streptavidin−Amdex−PE conjugates gave about 8−11-fold greater fluorescence intensity from labeled CD4+ lymphocytes as shown in Figure 13 for four runs.

DISCUSSION

Data from Table 2 were further used to construct a Mark−Houwink plot of log(η) versus log(M_w), shown in Figure 14. Linear regression analysis for all data gave a correlation coefficient of 0.976 and a slope of 0.451. The slope corresponds to the exponent in the equation, $[\eta] = KM^a$, where K is the proportionality constant. In the above samples, the value of the exponent is very similar to the $a = 0.50$ btained (*58*) for linear dextran (20−100 kDa) in water at 25° C. This value of the exponent has been established for linear, flexible polymers under "theta" temperature or solvent conditions, whereas the branched fraction of dextran of 800 kDa in water at 25° C gave $a = 0.20$. A similar plot of log(R_g) versus log(M_w) for all data gave a correlation coefficient of 0.998 and a

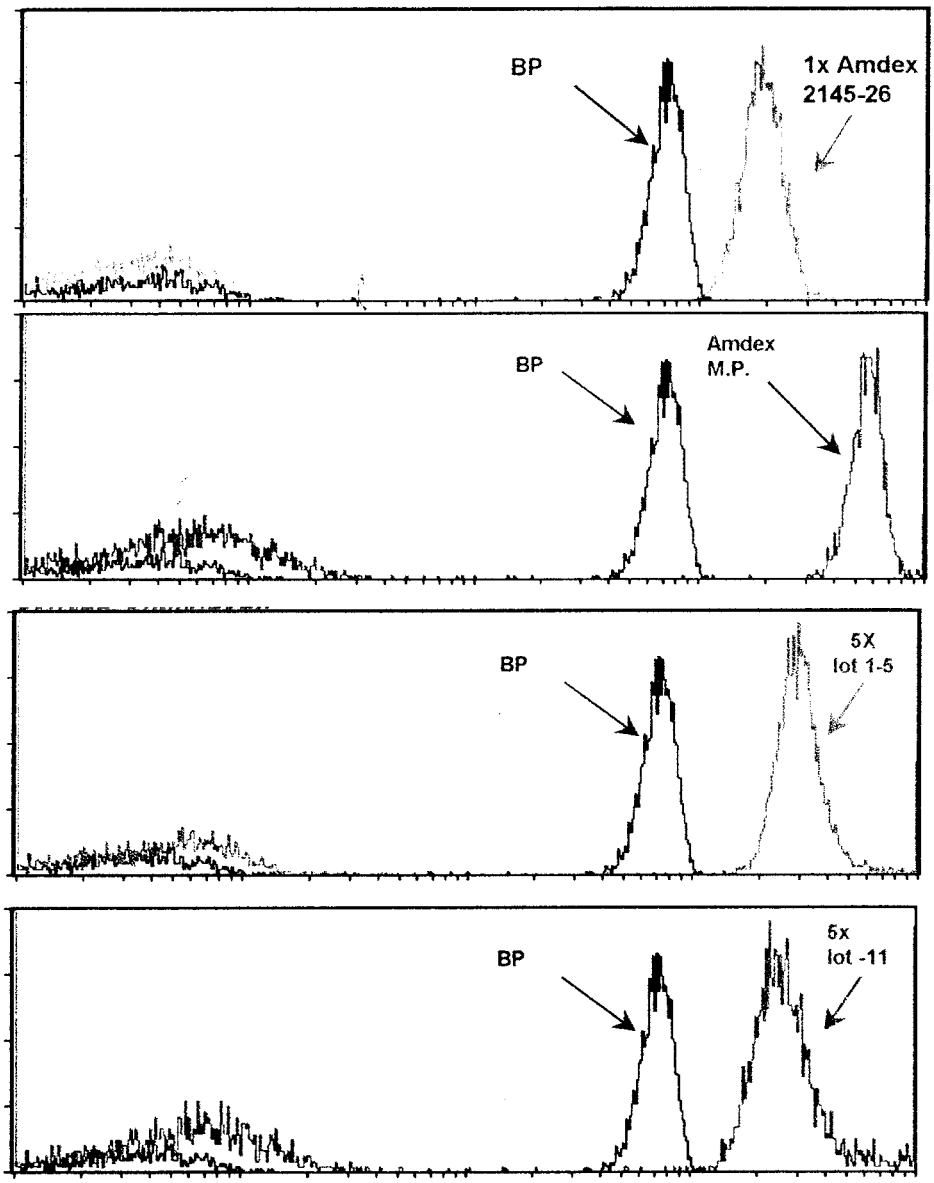

Figure 9. Comparison of flow cytometric histograms of direct CD4-PE and various CD4−Amdex−PE conjugates, 1X = 1×-Amdex, Amdex M.P., and two lots of 5×-Amdex, mixed with 100 μL of whole blood. The fluorescence intensity of a light scatter-gated lymphocyte subpopulation is displayed as histograms where the *y*-axis represents the number of fluorescent events (count), and the *x*-axis shows fluorescence intensity. The nonstaining negative cell population is seen in the left quarter of the histogram.

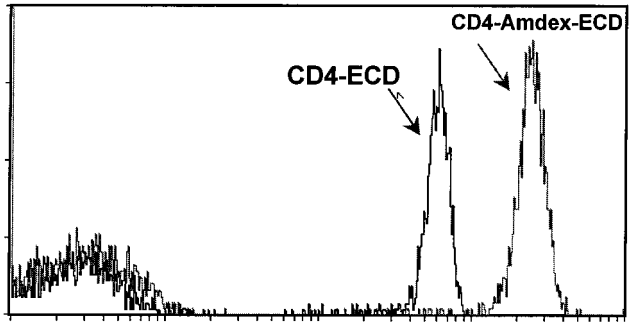

Figure 10. Comparison of flow cytometric histograms of direct CD4−ECD and CD4−Amdex, M.P.-ECD conjugates mixed with 100 μL of whole blood. The fluorescence intensity of a light scatter-gated lymphocyte subpopulation is displayed as histograms where the *y*-axis represents the number of fluorescent events (count), and the *x*-axis shows fluorescence intensity. The nonstaining negative cell population is seen in the left quarter of the histogram.

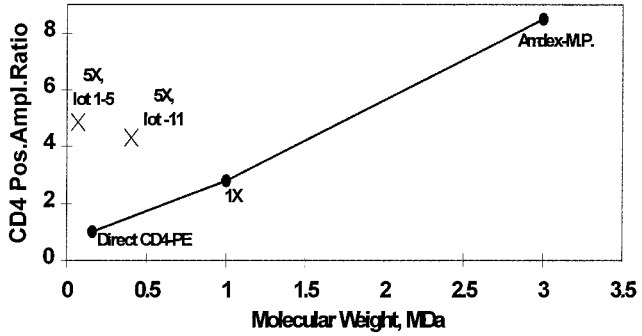

Figure 11. Graph of the positive amplification ratio [MFI (CD4−Amdex−PE)/MFI (CD4-PE)] for CD4 conjugates labeling CD4 positive lymphocytes in whole blood versus molecular mass for various aminodextrans.

slope of 0.481. We conclude, therefore, that the aminodextrans behave in aqueous sodium nitrate solution as flexible, linear chains arranged in a more relaxed, globular structure than the compact globular structures assumed by typical proteins. The positive charges of primary amino groups in 5×-Amdex are not sufficient to

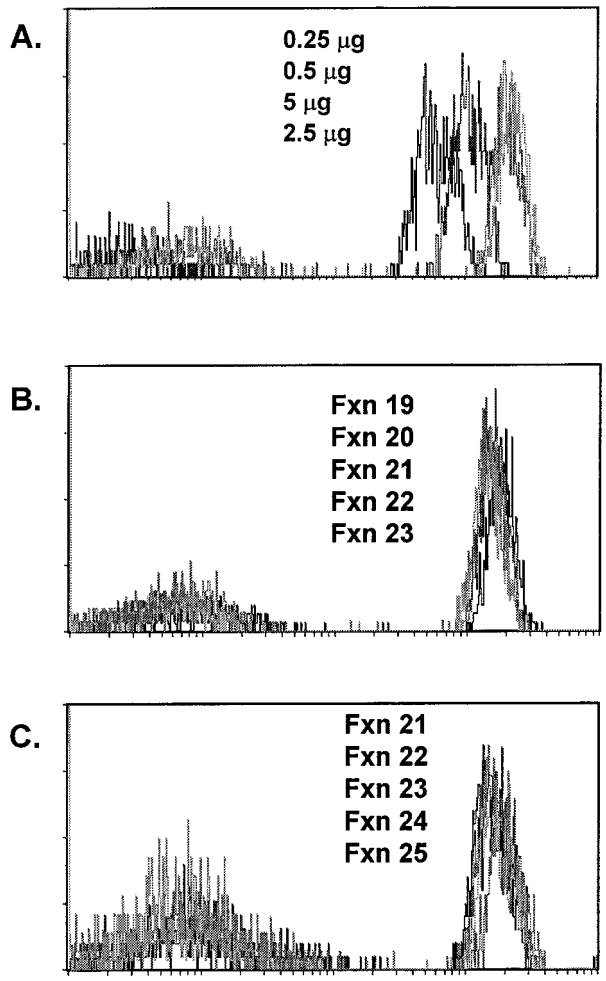

Figure 12. Flow cytometric histograms of streptavidin−Amdex−PE conjugates mixed with 100 μL of whole blood pretreated with biotinylated CD4 antibody. (A) Amdex, M.P. conjugate, lot 9−15, fraction 21 mixed in titers of 0.25, 0.5, 2.5, and 5 μg of protein. (B) Amdex, M.P. conjugate, lot 9−11, fractions 19, 20, 21, 22, and 23, all mixed individually at 2.5 μg of streptavidin. (C) 5×-Amdex conjugate, lot 9−15, fractions 21, 22, 23, 24, and 25, all mixed individually at 2.5 μg of streptavidin. The fluorescence intensity of a light scatter-gated lymphocyte subpopulation is displayed as histograms where the *y*-axis represents the number of fluorescent events (count), and the *x*-axis shows fluorescence intensity. The nonstaining negative cell population is seen in the left quarter of the histogram.

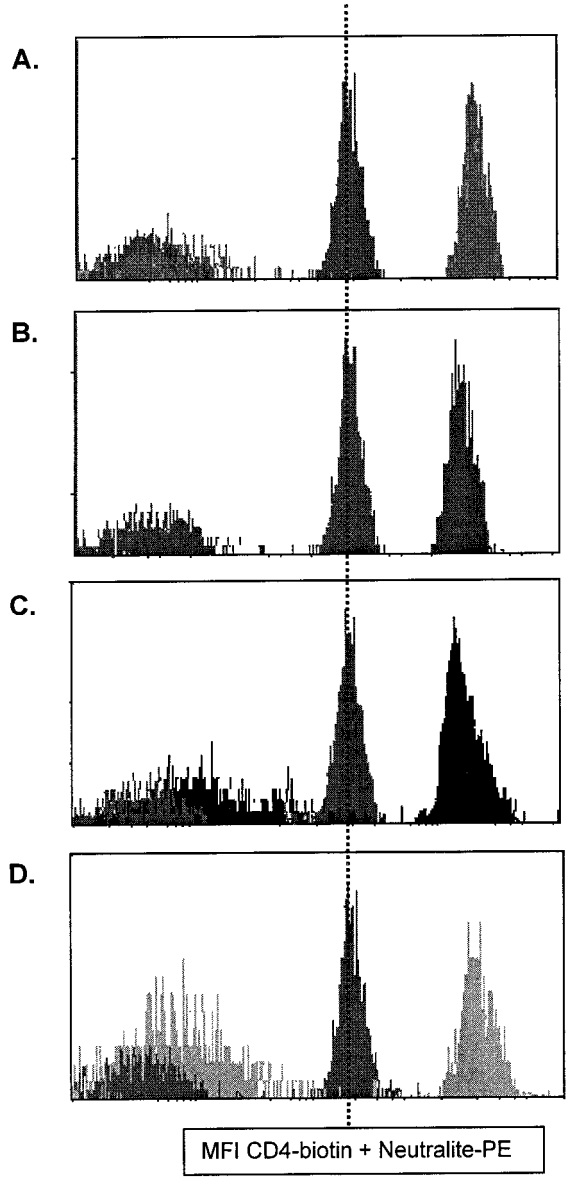

Figure 13. Comparison of flow cytometric histograms for avidin, NeutraLite-PE conjugate (vertical dotted line) and streptavidin−Amdex−PE conjugates, both individually mixed with 100 μL of whole blood pretreated with biotinylated CD4 antibody. (A) Amdex, M.P. conjugate, lot 9−15, fraction 21; (B) Amdex, M.P. conjugate, lot 9−11, fraction 21; (C) 5×-Amdex conjugate, lot 9−11, fraction 25; (D) 5×-Amdex conjugate, lot 9−15, fraction 26. Each sample contained 2.5 μg of avidin or streptavidin. The fluorescence intensity of a light scatter-gated lymphocyte sub-population is displayed as histograms where the *y*-axis represents the number of fluorescent events (count), and the *x*-axis shows fluorescence intensity. The nonstaining negative cell population is seen in the left quarter of the histogram.

force aminodextrans to assume an extended, straight chain structure.

The radius of gyration for a randomly coiled, linear, polymer molecule has been derived from random walk statistics as $R_g^2 = 1/6\ nl^2$, where n is the number of statistical segments in the polymer chain and l is the length of each statistical segment. Also, the mean square end-to-end distance, L^2, in a random coil is given by $L^2 = nl^2$, (*59*). Thus, the R_g and mass average molecular mass values obtained from light scatter and viscosity, and elemental analyses (empirical formulas and degree of substitution) can be used to calculate L and other parameters. Values of R_h, the hydrodynamic radius, were calculated from R_g values by using the relationship, $R_h = 0.665R_g$, derived for random polymer coils. Statistical segment lengths were 7.5−9.0 Å for the aminodextrans, compared to the length of a single unit of 1,6-linked glucose reported (*60*) as about 8 Å long. Free rotation about the methylene group between residues of 1,6-glucosyl units in aminodextran also confers extra flexibility on the polymer chain in contrast to the rigidity of the chain of 1,4-glucosyl units in cellulose nitrate in which glucose residues are joined only by an ether linkage. Light-scattering results and a Zimm plot for cellulose nitrate in acetone (*61, 62*) gave $M_w = 400$ kDa, a statistical segment length of 35 Å or about seven 1,4-glucosyl units, and a root-mean-square end-to-end distance, L, of 1500 Å. The longer statistical segment length and high L value confirm that cellulose nitrate has an unusually stiff and extended structure. The above data for randomly coiled polymer, dextran and aminodextrans, have shown them to assume much more tightly coiled and compact structures. Previous studies of dextran of molecular mass greater than 2000 Da also indicated a

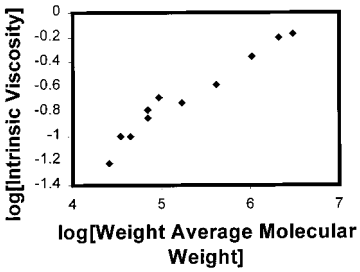

Figure 14. Mark−Houwink plot of log[intrinsic viscosity, η] versus log[molecular weight, M_w] for various aminodextrans and dextran as compiled in Table 2.

globular structure (*60*, *63*) in contrast to the open, extended structures of fiber and extracellular matrix polysaccharides such as cellulose (*61*, *62*) and proteoglycans (*35*, *36*). Dextran prepared by freeze fixation and detected by electron microscopy (*63*) showed dextran globules. Direct observation (*60*) of the polymerization reaction to form dextran in the cell of a light-scattering instrument followed by construction of Zimm plots for dextran solutions showed uniform spheres of 75−85 nm radii of gyration for molecular masses of 64−105 MDa; however, the process of purification of these high molecular mass dextrans invariably gave products insoluble in aqueous media. These results have made it easier to structurally visualize the formation of protein, antibody, and phycobiliprotein, conjugates of aminodextrans by constructing a working model of a central, loose, globular aminodextran core surrounded by a shell of protein molecules.

A direct proportionality between the total accessible surface area and molecular mass has been proposed (*64*) for large protein molecules. If this relationship, $4\pi R_h^2 \propto M$, is applied to the dextran and aminodextran data of Table 2 using the surface area of a sphere of radius R_h in angstroms, we find that $4\pi R_h^2 = 0.366$ M on the average for 11 measurements. This suggests that the total accessible surface area, $4\pi R_h^2/0.366$, of aminodextrans in random coil configurations is about 2.7 times greater than the surface area of a sphere of the same size. This figure is higher than the one for proteins for which the accessible surface area is quoted (*64*) as being nearly two times greater than that expected for a sphere of the same size.

In most 5×-Amdex samples, the average molecular mass determined from the triple detector system measurements fell in the middle of the range shown by SDS−PAGE results, even though the position of species in electrophoretograms depends strictly on their charge-to-size ratio. Two factors may have contributed to the high, apparent 150−250 kDa molecular range for 1×-Amdex. First, the molecular mass standards were globular proteins, which are more compact than aminodextrans of the same molecular mass, having a relatively open chain, random coil structure. The gel will be more effective in separating aminodextrans of somewhat lower molecular mass as compared with proteins. Second, aminodextrans of higher positive charge such as 5×-Amdex will travel more quickly through the gel compared to aminodextrans of low positive charge such as 1×-Amdex.

Several mechanisms for depolymerization of dextran dialdehyde by strongly alkaline media may be proposed. The mechanisms involve either of two acidic hydrogen atoms in the periodate cleaved, dialdehyde units of dextran dialdehyde polymer as shown in Figure 15 for each of the acidic hydrogen sites. Mechanism 1, β-carbonyl elimination, appears to be the more favored (*65*, *66*) one because of the presence of a carbonyl in β-position to a C-atom involved in the glycosidic linkage, which yields a conjugated C=O, C=C structure in the product.

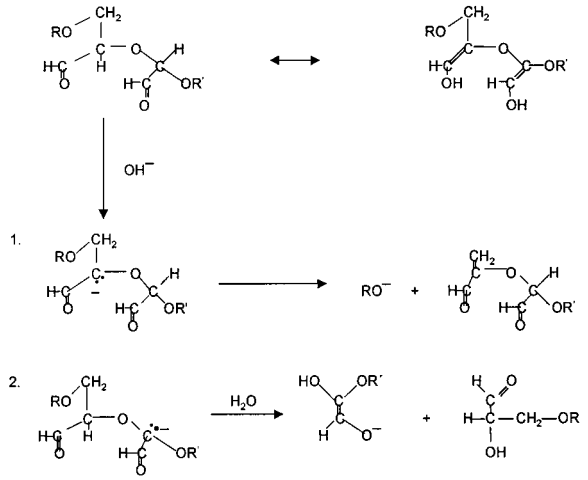

Figure 15. Schematic of the depolymerization mechanisms for dextran dialdehyde.

Mean hydrodynamic diameters of PE and conjugates were measured by PCS. Molar ratios, PE/Amdex, were obtained in three different ways (two, by model calculations, and one, from flow cytometry measurements): (1) by calculating the number of hard spheres of PE that can be arranged in a closest packed array around a hard sphere of aminodextran, i.e., surface area of sphere of aminodextran, $4\pi R_h^2$, divided by $d^2(\text{PE}) \times \sqrt{3}/2$, and then multiplying by the mole fraction of PE; (2) by subtracting the molecular mass of one aminodextran molecule from the molecular mass ($=4\pi R_h^2$) of the conjugate, then, dividing by the average of the molecular masses of IgG antibody (160 kDa) and PE (270 kDa), and finally multiplying by the mole fraction of PE; and (3) by taking the ratio of mean channel fluorescence intensity of the CD4−aminodextran−PE conjugate to the mean channel fluorescence intensity of the direct CD4−PE conjugate, both measured by flow cytometry at saturation of the receptor sites on the targeted CD4+ lymphocytes in whole blood.

Molecular masses (M) of the corresponding PE conjugates listed in Table 3 were calculated from hydrodynamic diameters determined from PCS measurements by assuming the relationship, $4\pi R_h^2 = M$ with radius R_h in angstroms, for large protein molecules (*64*). Estimates of the PE/Amdex ratios by packing and by molecular mass differ most widely from each other for 5×-Amdex conjugates. When the PE/Amdex ratio was less than 1 or close to 1 as with 5×-Amdex and 1×-Amdex conjugates, the size of the Amdex molecule was smaller than the size of either PE or antibody molecule. In these cases, the smaller Amdex (25−94 kDa) molecules will tend to pack around a larger, central PE (270 kDa) or antibody (160 kDa) molecule. Further, amplification factors exceed packing limits around a single, unassociated 5×-Amdex molecule for the CD4−5×-Amdex−PE conjugates and, thus, suggest that more than one 5×-Amdex molecule is part of the conjugate. This allows a network of 5×-Amdex−MCA, PE−5×-Amdex to form and contain additional PE molecules. The most consistent amplification ratios were obtained in conjugates with Amdex-M.P., which has a low degree of amine substitution and very large size.

The main criteria for success in obtaining good yields of antibody, fluorescent dye conjugates with aminodex-

tran, that produce large enhancements in fluorescence intensity of targeted cells appear to be the following: (1) use of the highest molecular mass possible for the aminodextran carrier while still retaining solubility in aqueous media; (2) a low degree of amine substitution (1/140) in dextran of 3 MDa still allows conjugation of antibody and phycobiliproteins; however, the percentage of saturation coverage of the aminodextran carrier may be low; (3) more highly substituted 5×-Amdex (1/5 to 1/8) allows a greater packing density of protein, and also the possibility of network structures containing even more aminodextran and phycobiliprotein.

With the advances now being made in microfluidics *(67*−*69)*, it will soon be possible to use these large conjugates to perform fluorescence-activated sorting of targeted molecules instead of just micron size objects such as biological cells and particles. Development of new detection and sequencing methods for nucleic acids could arise from using polymeric carriers such as aminodextrans with conjugated oligo and fluorescent dye.

New Donor−Acceptor Pair for Fluorescent Immunoassays by Energy Transfer

Uwe Schobel,[†] Hans-Joachim Egelhaaf,[†] Andreas Brecht,[‡] Dieter Oelkrug,[†] and Günter Gauglitz*[,†]

Institute of Physical and Theoretical Chemistry, Auf der Morgenstelle 8, D-72076 Tübingen, Germany, DC-LCPPM, EPFL, CH-1014 Lausanne-Ecublens, Suisse. Received June 12, 1999; Revised Manuscript Received August 4, 1999

A novel Förster donor−acceptor dye pair for an immunoassay based on resonance energy transfer (RET) is characterized with respect to its photophysical properties. As donor and acceptor, we chose the long-wavelength excitable cyanine dyes Cy5 and Cy5.5, respectively. Due to the perfect spectral overlap, an exceptionally high R_0 value of 68.7 Å is obtained in solution. For biochemical applications, antibodies (IgG) are labeled with Cy5, while a tracer for competitive binding is synthesized by labeling bovine serum albumin (BSA) with an analyte derivative and Cy5.5. Binding the dyes to proteins at a low dye/protein ratio increases the fluorescence lifetimes and quantum yields, leading to an enhanced R_0 value of 85.2 Å. At higher dye/protein ratios, the formation of nonfluorescent dimeric species causes a decrease in the fluorescence lifetime and quantum yield due to RET from monomeric dyes to dimers within one protein molecule. The Förster distances could be calculated using the dimer absorption spectra to 83.9 and 83.6 Å for Cy5 and Cy5.5, respectively. Upon binding of the Cy5-labeled IgG to the tracer, efficient quenching of Cy5 fluorescence is observed. Steady-state and time-resolved measurements reveal that approximately 50% of the quenching results in Förster-type RET, while the residual quenching effect is caused by static quenching processes. The applicability of this dye pair is demonstrated in a homogeneous competitive immunoassay for the pesticide simazine.

INTRODUCTION

Immunoassays relying on fluorescence detection (fluoroimmunoassays, FIA) are known to be highly sensitive. They have the potential to replace the radioimmunoassay (RIA) technique (*1*) if the background signal arising from fluorescence of the biological matrix and light scattering can be effectively reduced (*2*−*4*). Two different approaches have been applied to minimize the background: (i) time-resolved fluorescent techniques (*5*−*9*) and (ii) methods using far-red excitable fluorescent dyes (*10*). The second approach takes advantage of reduced light scattering at longer wavelengths, and minimal tissue absorbance and autofluorescence, particularly above 600 nm (*10*, *11*). For excitation in the far-red wavelength region, inexpensive semiconductor laser diodes are available. Several classes of polymethine cyanine dyes, which are excitable in the far-red (635−1100 nm), including heptamethine cyanine dyes (*12*−*14*), squarine cyanine dyes (*15*), and sulfoindocyanine dyes (*16*−*21*), have been developed. Many of these have been successfully used as labels for analyte derivatives and/or antibodies in FIA-based applications (*22*−*25*). However, these dyes are known to aggregate (dimer formation) (*26*−*30*), particularly when present at high concentrations on protein surfaces. This leads to a drastic reduction in fluorescence intensity, since the dimers are essentially nonfluorescent. An accurate adjustment of the labeling ratio is therefore indispensable.

Several photophyiscal parameters of the labels are employed as observables in FIA to monitor the binding of the participating compounds, e.g., fluorescence polarization (*31*), fluorescence quenching (*32*, *33*) and enhancement (*34*), and resonant energy transfer (RET) (*35*). Among these FIA techniques, RET is the most versatile because of its little interference with different sample matrixes and the simple read-out technique (*36*). The efficiency of the RET process scales with the inverse 6th power of the distance R between the chromophores. The distances between donor and acceptor at which 50% of the excitation energy of the donor is transferred to the acceptor is the so-called Förster distance R_0. Typical R_0 distances are between 20 and 60 Å. So far, only four D−A pairs have been described with R_0 values between 60 and 70 Å (*37*). To achieve high-energy transfer efficiencies and thus high-intensity modulations in immunoassay-based applications, large R_0 values of the employed donor−acceptor pair are required.

In this paper, we present a new donor−acceptor pair with an exceptionally high R_0 value, comprising two commercially available long-wavelength excitable sulfoindocyanine dyes Cy5 and Cy5.5. The photophysical properties of the free and protein-bound dyes are determined. The effect of dimer formation of the protein-bound dyes on mean fluorescence lifetimes and quantum yields is investigated. To determine quantitatively the dependence of fluorescence intensity on the ratio of monomeric to dimeric dyes, the pure dimeric spectra are calculated. A homogeneous competitive RET immunoassay was set up with the optimized system. The fluorescence intensity modulation is investigated in detail, and the applicability of this immunoassay for the detection of the pesticide simazine is demonstrated.

EXPERIMENTAL PROCEDURES

N-Hydroxysuccinimidyl (NHS) esters of Cy5 (monofunctional) and Cy5.5 (bisfunctional) were purchased

from Amersham Life Science, Braunschweig/Germany. The triazine derivative 4-chloro-6-(isopropylamino)-1,3,5-triazine-2-(6'-amino)caproic acid (atrazine caproic acid, ACA) was synthesized and purified as described in ref *38*. Polyclonal anti-simazine antibody (IgG) was received as a present from Dr. Ram Abuknesha, GEC London. Solvents of analytical grade, Sephadex G-25 columns and all other common chemicals and biochemicals were purchased from Sigma Chemical Co., Deisenhofen/Germany and Fluka, Neu-Ulm/Germany.

Absorption spectra were recorded on a Perkin-Elmer λ 2 spectrophotometer. Fluorescence excitation and emission spectra were obtained with a Perkin-Elmer LS-50 B luminescence spectrometer equipped with a red-sensitive photomultiplier R928. Polarization spectra and anisotropies were determined using a Spex Fluorolog 222 spectrofluorometer. Fluorescence lifetimes were determined with a Spex Fluorolog 112. Single photon counting equipment was from EG & G ORTEC. The light source was a Hamamatsu laser diode at 653 nm. The emission was detected through a 670 nm cut-on filter. The emission monochromator was set to 680 and 705 nm for recording the decay of Cy5 and Cy5.5, respectively.

Fluorescence anisotropies r were calculated using the following equation:

$$r = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} \tag{1}$$

where $I_{\parallel}$ and $I_{\perp}$ are the intensities observed parallel and perpendicular, respectively, to the axis of the vertically polarized excitation light (*39*). The excitation wavelength was set to the wavelength with the largest r_0 value in the excitation polarization spectra. To consider the effect of rotational diffusion on fluorescence anisotropies, we determined the rotational correlation time τ_R, which is given by the Perrin equation:

$$\tau_R = \frac{\tau}{(r_0/r) - 1} \tag{2}$$

where τ is the fluorescence lifetime and r_0 the anisotropy in the absence of depolarizing processes.

Time-resolved decays of fluorescence intensities $I(t)$ were fitted as a sum of exponentials

$$I(t) = \sum_i \alpha_i e^{-t/\tau_i} \tag{3}$$

where τ_i is the decay time and α_i the corresponding preexponential factor. The values of the parameters τ_i and α_i were determined using least-squares analysis software. Equation 3 was also used for fitting time-resolved fluorescence decays of protein-bound dyes which are additionally deactivated by RET. The assumption involved herein is that donor and acceptor are rather separated by a fixed distance than being randomly distributed. This situation is frequently encountered for labeled proteins (*39*).

The mean lifetime $\bar{\tau}$ was calculated according to

$$\bar{\tau} = \sum_i \alpha_i \tau_i^2 / \sum_i \alpha_i \tau_i \tag{4}$$

The Förster distance R_0 (*37*) was calculated using

$$R_0^6 = \frac{9000(\ln 10)\kappa^2 \phi_D J}{128\pi^5 n^4 N_{AV}} \tag{5}$$

Table 1. Molar Ratio of Reactive Dye and Protein Used in the Labeling Procedure in Comparison with the Obtained Dye/Protein Ratio of the Conjugates

protein	reactive dye	[reactive dye]/[protein] ratio	[attached dye]/[protein] ratio
IgG	Cy5-NHS	5	0.8
IgG	Cy5-NHS	20	3.7
IgG	Cy5-NHS	25	4.5
IgG	Cy5-NHS	35	8.7
BSA	Cy5.5-NHS	10	1.6
BSA	Cy5.5-NHS	20	2.9

where κ^2 is the orientation factor, ϕ_D is the donor quantum yield in the absence of acceptor molecules, J is the overlap integral, n is the refractive index of the medium, and N_{AV} is Avogadro's number. For the orientation factor κ^2, the average value of 2/3 for randomly oriented donors and acceptors in solution was assumed. The index of refraction n in PBS was assumed to be 1.33. The overlap integral J is defined as

$$J = \frac{\int \epsilon_A(\lambda) f_D(\lambda) \lambda^4 \, d\lambda}{\int f_D(\lambda) \, d\lambda} \tag{6}$$

where $f_D(\lambda)$ is the donor emission spectrum and $\epsilon_A(\lambda)$ is the extinction coefficient of the acceptor.

The fluorescence quantum yields ϕ_F(conjugate) of Cy5 monomers in the IgG−Cy5 conjugate (1:3.7) and Cy5.5 monomers in the BSA−Cy5.5 conjugate (1:1.6) were determined according to

$$\phi_F(\text{conjugate}) = \phi_F(\text{dye}) \frac{\tau_F(\text{conjugate})}{\tau_F(\text{dye})} \tag{7}$$

where ϕ_F(dye) is the fluorescence quantum yield of the free dye in solution and τ_F(conjugate) and τ_F(dye) are the experimental fluorescence lifetimes of the conjugate and of the corresponding dye, respectively.

The quantum yields of the IgG−Cy5 conjugates (1:0.8, 1:4.5, and 1:8.7) and BSA−Cy5.5 conjugate (1:2.9) were determined relative to the fluorescence quantum yields of the conjugates determined above by correcting the contribution of the nonfluorescent dimeric species to the absorbance at the excitation wavelength 649 nm and integration of the corrected emission spectra.

ACA−*N*-Hydroxysuccinimide Ester. A total of 3.76 mg (18 μmol) of dicyclohexylcarbodiimide (DCC) was added to a solution of 5 mg (16.5 μmol) of ACA and 2.1 mg (18 μmol) of *N*-hydroxysuccinimide (NHS) in 200 μL of absolute *N*,*N*-dimethylformamide (DMF) kept on ice. The mixture was stirred for 6 h at room temperature, filtered, and then used directly (without further purification) for conjugation to proteins.

Labeling of IgG and BSA with the Dyes. A total of 20 μL of reactive dye (for molar ratios see Table 1) in absolute DMF was added to a solution of 500 μg of protein (3.3 nmol of IgG or 7.2 nmol of BSA) in 250 μL of 0.1 M sodium carbonate-bicarbonate buffer, pH 9.7, and mixed thoroughly by gentle vortexing. The reaction was incubated at room temperature for 30 min. Unconjugated dye was separated from protein−dye conjugate by gel permeation chromatography over Sephadex G-25 using phosphate-buffered saline (PBS, 10 mM potassium dihydrogenphosphate, 150 mM sodium chloride, pH 7.4) as eluent. The dye-to-protein ratio was determined spectrophotometrically by measuring the absorbance at 653 nm (Cy5) or 681 nm (Cy5.5) and 278 nm (protein) in PBS: DMF (1:1, v/v) (*15*) and inserting the measured values

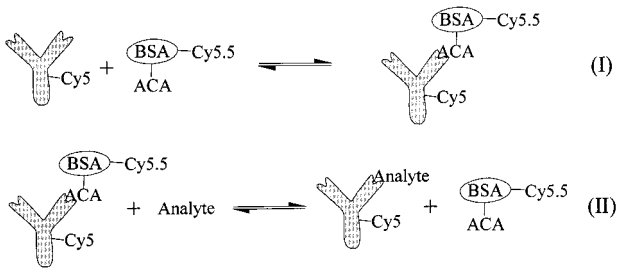

Figure 1. Schematic description of the competitive RET immunoassay. At low analyte concentrations (reaction I) the ACA-BSA-Cy5.5 conjugate is preferably bound to the antibody, at high analyte concentrations (reaction II) the ACA-BSA-Cy5.5 conjugate is displaced from the antibody binding sites.

into equation

$$[\text{attached dye}]/[\text{protein}] = \frac{A_{\text{dye}}\epsilon_{\text{protein}}}{(A_{278} - XA_{\text{dye}})\epsilon_{\text{dye}}} \quad (8)$$

The molar extinction coefficients of Cy5 and Cy5.5 (ϵ_{dye}) were assumed to be equal to their values in PBS (ϵ = 250 000 M^{-1} cm^{-1} and ϵ = 190 000 M^{-1} cm^{-1}, respectively), and the extinction coefficients of IgG and BSA ($\epsilon_{\text{protein}}$) were taken to be 201 700 M^{-1} cm^{-1} and 45 540 M^{-1} cm^{-1}, respectively. The factor X in the denominator accounts for dye absorption at 278 nm, which is 5 and 13% of the absorption of Cy5 (18) and Cy5.5 (20) at their maximum absorption (A_{dye}). The dye/protein ratios obtained are given in Table 1.

Labeling of BSA–Cy5.5 (1:1.6) Conjugate with ACA–NHS. A solution of 45 μg (150 nmol) of ACA–NHS in absolute DMF was added to a solution of 400 μg (5.8 nmol) of BSA–Cy5.5 conjugate in 250 μL of 0.1 M sodium carbonate-bicarbonate buffer, pH 9.7, and mixed thoroughly by gentle vortexing. The reaction condition and duration as well as the purification of the conjugate were the same as described above. The ACA concentration of the conjugates was determined by means of reflectometric interference spectroscopy (RIfS) (*40*). The ACA/BSA ratio was found to be 3.6:1, corresponding to a labeling efficiency of 15%.

RET Immunoassay. The principle of the competitive RET immunoassay is illustrated in Figure 1. The antibody (anti-simazine) was labeled with the donor Cy5 (IgG–Cy5). An analyte derivative (ACA) and the acceptor Cy5.5 were covalently linked by using bovine serum albumin (BSA) as carrier protein (ACA-BSA-Cy5.5). The immunoassay was performed by adding first 50 μL of IgG–Cy5 conjugate and then 50 μL of ACA-BSA-Cy5.5 conjugate to 400 μL standard solutions of simazine. The conjugates were dissolved in PBS, pH 7.4, containing 100 μg/mL chicken egg albumin (OVA) as background protein. The simazine standard solutions were diluted in PBS from a stock solution of c(simazine) = 1 mg/mL in DMF. After the addition of each conjugate, the solution was incubated for 10 min at 20 °C. After equilibration, the fluorescence intensity at 667 nm was measured. At low analyte concentrations the ACA-BSA-Cy5.5 conjugate is preferably bound to the antibody binding sites (reaction I). Due to the close proximity of Cy5.5 and Cy5 in the antigen–antibody complex, the IgG–Cy5 fluorescence is quenched by energy transfer. Higher analyte concentrations (reaction II) leads to a decreased occupation of the antibody binding sites by the ACA-BSA-Cy5.5 conjugate. This results in an increased IgG–Cy5 fluorescence.

The calibration curve was fitted to a four-parameter logistic equation according to the following formula (*41*):

$$y = \frac{A - B}{[1 + (x/C)^D]} + B \quad (9)$$

where y is the fluorescence intensity, x is the concentration of analyte, A and B are the upper and lower asymptotes, respectively, C is the concentration producing 50% of the maximal fluorescence intensity, and D is the slope at the inflection point of the sigmoidal curve.

RESULTS AND DISCUSSION

Photophysical Properties of the Free and Protein-Bound Dyes. The chemical structures of the sulfoindocyanine dyes Cy5 (donor) and Cy5.5 (acceptor) are shown in Figure 2. The absorption and fluorescence spectra of the two dyes are shown in Figure 3. There is an almost perfect spectral overlap between the Cy5 emission and the Cy5.5 absorption. The Förster distance (R_0) calculated for energy transfer from Cy5 to Cy5.5 (see eqs 5 and 6) is 68.7 Å, inserting a fluorescence quantum yield of $\phi_F^{Cy5} = 0.27$ for the donor (see Table 3) and an extinction coefficient of $\epsilon_{676nm}^{Cy5.5} = 190\,000$ M^{-1} cm^{-1} for the acceptor. The photophysical properties including absorption and emission maxima, extinction coefficients, fluorescence lifetimes, and rotational correlation times of the dyes are summarized in Table 2.

The photophysical properties of the IgG–Cy5 and BSA–Cy5.5 conjugates are also given in Table 2. The increase of the rotational correlation time τ_r indicates that the dyes are covalently attached to the proteins. Due to the higher polarizability of the environment, the absorption maxima shift toward longer wavelengths by 2 and 5 nm for Cy5 and Cy5.5, respectively. The fluorescence maxima of the conjugates are red-shifted by 2 and 10 nm.

Dimer Formation. The absorption spectra of the IgG–Cy5 and BSA–Cy5.5 conjugates (see Table 1) are shown in Figure 4A and Figure 5A, respectively. With increasing dye/protein ratio, the extinction coefficient of the absorption maximum is reduced and a new band appears, which is blue-shifted by 46 nm (Cy5) and 50 nm (Cy5.5), respectively. In addition, two isosbestic points appear, indicating that two colored species are in equilibrium. This effect is caused by attractive interactions between adjacent dye molecules, leading to the formation of dimeric species (*28*) at higher dye/protein ratios. The aggregated portion of the dyes in the conjugates is almost completely converted to the monomeric form by adding DMF to PBS solution of the conjugates (1:1, v/v) (*15*). Thus, the spectral positions of the isosbestic points could be determined accurately.

The fluorescence excitation spectra of these conjugates are superimposable on the monomer absorption spectra (see Figure 4A and Figure 5A). This indicates that the dimers are essentially nonfluorescent.

To calculate the proportion of the dimeric species on the protein conjugates, the molar extinction coefficients of the pure dimers at a given wavelength must be known. The dimer spectra can be calculated by applying the law of mass action to the monomer ⇌ dimer equilibrium of the free dyes in solution (*42*). If the fraction of the total molar concentration c of the dye in solution present as dimer is α, the association constant is

$$K = \frac{c_d}{{c_m}^2} = \frac{\alpha}{2(1 - \alpha)^2 c} \quad (10)$$

where c_d and c_m are the concentrations of the dimeric and monomeric dyes, respectively. In Figure 4B and Figure

Table 2. Photophysical Properties of the Unbound and Protein-Bound Cy5 and Cy5.5 in PBS[a]

	Cy5	Cy5.5	IgG-Cy5	ACA-BSA-Cy5.5
λ_{max}(abs)[b] (nm)	647	676	649	681
λ_{max}(em)[b] (nm)	665	693	667	703
ϵ (L/mol cm)[b]	250 000[c]	190 000[d]	250 000	190 000
τ_1 (ns)	0.94	0.99	1.01 (0.12)[e]	1.17 (0.16)[f]
τ_2 (ns)			1.88 (0.1)[e]	1.94 (0.09)[f]
$\bar{\tau}$ (ns)			1.54[e]	1.53[f]
τ_r[b]	0.47	0.84	1.08[e]	1.27[f]

[a] The α_i values of the fitted fluorescence lifetimes τ_i are given in the brackets after the lifetimes. [b] Phosphate-buffered saline (PBS), [c] Values adopted from ref *18*. [d] Values adopted from ref *20*. [e] Values determined for IgG-Cy5 (1:3.7). [f] Values determined for ACA-BSA-Cy5.5 (3.6:1:1.6). The experimental error of τ and τ_r is typically ±5 and ±7%, respectively.

5B the absorption spectra of the pure monomeric dyes and the spectra of a 1×10^{-3} M and a 1×10^{-2} M solution of the dyes in PBS are shown together with the calculated dimeric spectra. Upon dimer formation, the main absorption band is split into two bands, one of high intensity at the high-frequency side of the monomeric maximum, and the other of lower intensity at the low-frequency side of the monomeric maximum. This splitting of the excited electronic state of the monomer into two states upon dimer formation is due to the interaction of obliquely oriented transition dipole moments, as explained by the exciton model (*29*).

Table 3. Quantum Yields of the Free and Protein-Bound Cy5 and Cy5.5 in PBS

	monomer (%)	ϕ_F[b]
Cy5	100	0.27[c]
IgG-Cy5 (1:0.8)	90	0.88
IgG-Cy5 (1:3.7)	74	0.44
IgG-Cy5 (1:4.5)	69	0.40
IgG-Cy5 (1:8.7)	52	0.14
Cy5.5	100	0.23[d]
BSA-Cy5.5 (1:1.6)	84	0.36
BSA-Cy5.5 (1:2.9)	76	0.21

[a] In the first column the percentage of monomer dye molecules present on the proteins are given. [b] Phosphate-buffered saline (PBS), [c] Value adopted from ref *18*. [d] Value adopted from ref *20*. The experimental error of ϕ_F is typically ±5%.

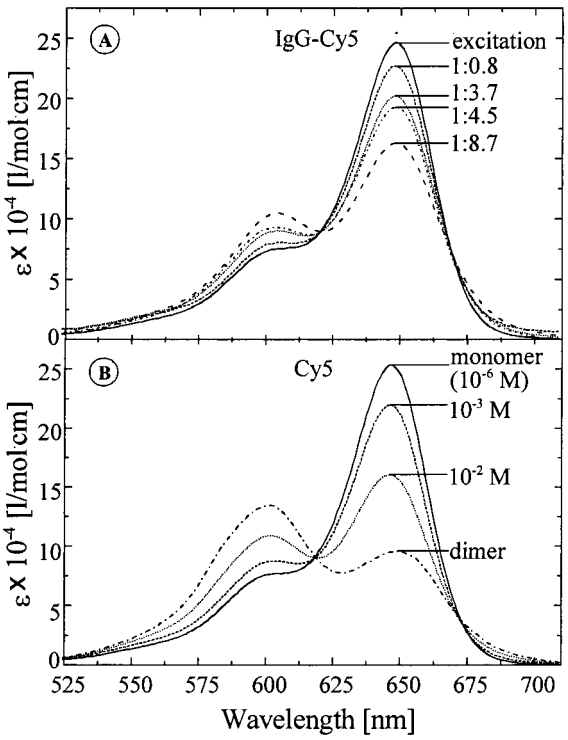

Figure 4. (A) Fluorescence excitation spectrum of the antibody conjugates in comparison with their absorption spectra in PBS. (B) Absorption spectra of different concentrations of the unbound Cy5 dye in PBS solution. The absorption spectrum of the monomer Cy5 dye is superimposable to its fluorescence excitation spectrum.

Using the dimeric spectra, we were able to calculate the monomer/dimer ratios of the employed protein conjugates. Table 3 shows the data obtained for the IgG−Cy5 as well as for the BSA−Cy5.5 conjugates. With increasing numbers of Cy5 and Cy5.5 molecules attached to the IgG (0.8−8.7) and BSA (1.6−2.9), the relative amounts of monomers are reduced from 0.9 to 0.52 and from 0.84 to 0.76.

Quantum Yields and Fluorescence Lifetimes. With the knowledge of the monomer/dimer ratio of the employed protein conjugates, it was possible to determine the fluorescence quantum yields of the protein-bound monomeric dyes. At low Cy5/IgG ratios, an enhancement of the fluorescence quantum yield of the monomeric Cy5, compared to that in solution, is observed (see Table 3).

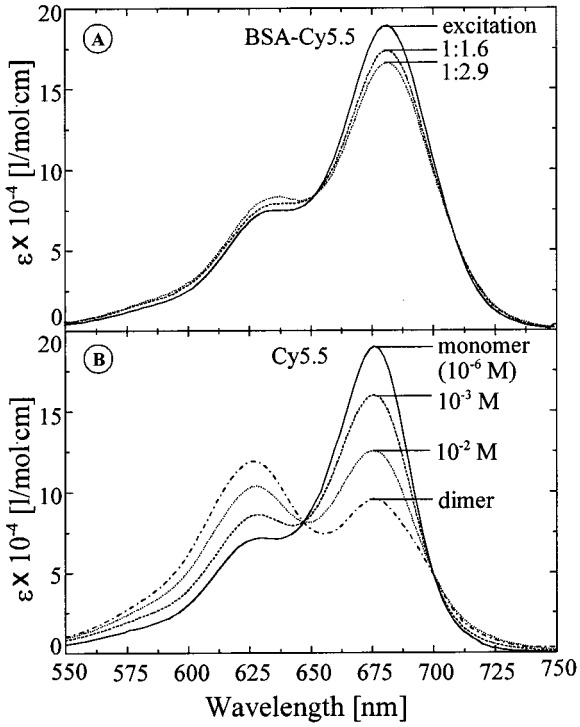

Figure 5. (A) Fluorescence excitation spectrum of the BSA conjugates in comparison with their absorption spectra in PBS. (B) Absorption spectra of different concentrations of the unbound Cy5.5 dye in PBS solution. The absorption spectrum of the monomer Cy5.5 dye is superimposable to its fluorescence excitation spectrum.

This enhancement, which goes along with the increase of the Cy5 fluorescence lifetime, is most likely due to the restricted torsional motion about the central methine bridge, a result obtained also for other cyanine dyes (*43*–*46*).

With increasing Cy5/IgG ratios, a decrease of the quantum yield is obtained. This decrease is due to RET from the fluorescent monomeric dye to increasing numbers of nonfluorescent dimer molecules on the antibody. The calculated Förster distance is $R_0 = 83.9$ Å, which results in very efficient fluorescence quenching by RET, if a radius of a spherical antibody molecule of approximately 6 nm is assumed. The maximum of fluorescence intensity per labeled antibody can be derived by multiplying the fluorescence quantum yield of Cy5 monomer with the number of monomeric Cy5 on the antibody. With rising Cy5/IgG ratios, the fluorescence increases, reaching a maximum at a Cy5/IgG ratio of approximately 4. At higher Cy5/IgG ratios, fluorescence quenching by RET begins to dominate, resulting in decreasing fluorescence intensity. This result is in good agreement with the value obtained in an earlier report (*19*) for a similar carboxymethylindocyanine dye (Cy5.12).

The fluorescence quantum yield for Cy5.5 shows a behavior similar to that of Cy5. An enhancement is observed when bound to BSA (Cy5.5/BSA ratio 1.6:1) (see Table 3), whereas a higher Cy5.5/BSA ratio (2.9:1) leads to a decrease in fluorescence quantum yield. The Förster distance for RET from the fluorescent monomeric Cy5.5 to nonfluorescent dimer molecules on the BSA is calculated to $R_0 = 83.6$ Å. Very efficient fluorescence quenching by RET results, if a radius of a spherical BSA molecule of approximately 3 nm is assumed.

Energy Transfer in the Antigen–Antibody Complex. The Förster distances for energy transfer from IgG–Cy5 (labeling ratio 1:3.7) to the BSA bound Cy5.5

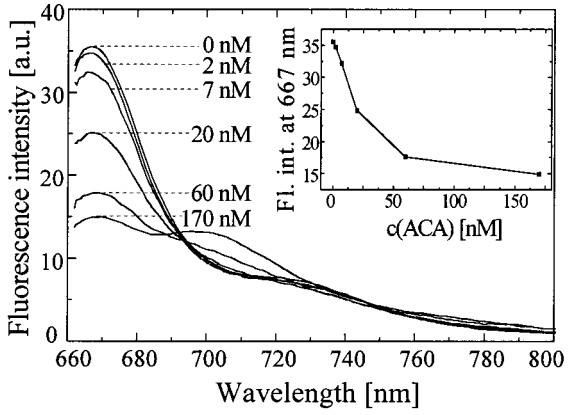

Figure 6. Titration of 67 nM IgG–Cy5 (1:3.7) with increasing amounts of ACA-BSA-Cy5.5 (3.6:1:1.6) [c(ACA) = 0–170 nM]. The quenching of the fluorescence signal of IgG–Cy5 [c(ACA) = 0 nM] amounts to 65% [c(ACA) = 170 nM].

monomers and dimers are calculated using the data in Table 2 and Table 3. Exceptionally high values of $R_0 = 75.9$ Å and $R_0 = 77.8$ Å are obtained for the monomeric and dimeric Cy5.5, respectively. This is the consequence of the increased overlap integral and the high fluorescence quantum yield of the fluorescent monomeric Cy5 compared to the free dyes in solution.

Emission spectra of 67 nM IgG–Cy5 (1:3.7) are shown in Figure 6. Additions of 0–170 nM ACA-BSA-Cy5.5 (3.6:1:1.6) (see Figure 1, reaction I) lead to a progressive decrease in the steady-state intensity of Cy5 emission (see inset of Figure 6). At 170 nM ACA-BSA-Cy5.5, a maximum quenching of the IgG–Cy5 fluorescence is achieved. The total quenching of IgG–Cy5 fluorescence (ΔI^{Cy5}_{quench}), calculated as the difference of the fluorescence intensities of IgG–Cy5 in absence (I_F^{Cy5}) and in the presence of 170 nM ACA-BSA-Cy5.5, equals to

$$\Delta I^{Cy5}_{quench} = 0.65 I_F^{Cy5} \tag{11}$$

In the following, we will show that two mechanisms are involved in the quenching of the IgG–Cy5 fluorescence in the antigen–antibody complex: (i) quenching due to RET from Cy5 to Cy5.5 and (ii) static quenching due to the close proximity of Cy5 and Cy5.5. Figure 7 shows the analysis of the quenching process. Negative values represent decrease of fluorescence intensity whereas increase of fluorescence intensity is plotted on the positive *y*-axis.

The fraction of fluorescence intensity of IgG–Cy5 which is quenched due to RET from Cy5 to Cy5.5 (ΔI^{Cy5}_{RET}) and thus leads to sensitized fluorescence of Cy5.5 ($\Delta I^{Cy5.5}_{RET}$) is given by

$$\Delta I^{Cy5}_{RET} = \Delta I^{Cy5.5}_{RET} \frac{\phi_F^{Cy5}}{\phi_F^{Cy5.5}} \tag{12}$$

and equals to

$$\Delta I^{Cy5}_{RET} = 0.53 \Delta I^{Cy5}_{quench} \tag{13}$$

$\Delta I^{Cy5.5}_{RET}$ has been corrected for directly excited fluorescence contributions, ϕ_F^{Cy5} is the fluorescence quantum yield of IgG bound monomeric Cy5, and $\phi_F^{Cy5.5}$ is the mean fluorescence quantum yield of BSA bound Cy5.5. To confirm the contribution of RET to the quenching process in the antigen–antibody complex, the IgG–Cy5

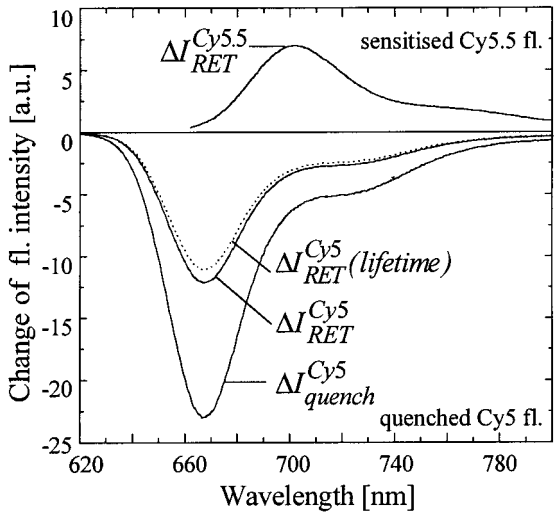

Figure 7. Plots of the sensitized ACA-BSA-Cy5.5 fluorescence (positive *y*-axis) and the quenching of IgG−Cy5 fluorescence (negative *y*-axis) which can be attributed to different quenching processes of IgG−Cy5 in the antigen−antibody complex. For details see text.

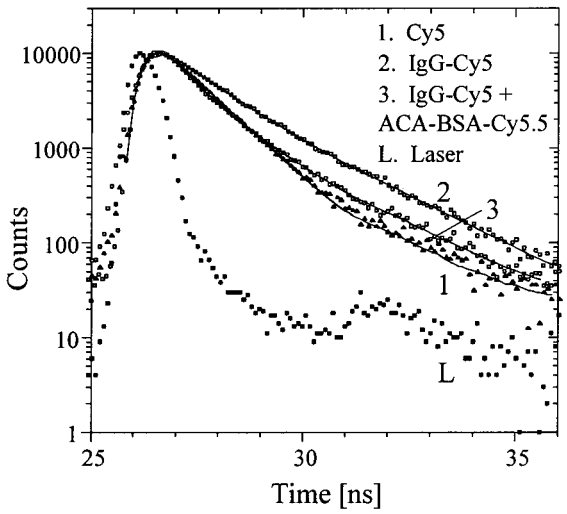

Figure 8. Fluorescence intensity decay of unbound Cy5 (1), 67 nM IgG−Cy5 in absence (2) and presence (3) of 170 nM ACA-BSA-Cy5.5.

fluorescence intensity decays were measured. Figure 8 shows the increase of the mean fluorescence lifetime of Cy5 upon binding to the antibody from 0.94 to 1.54 ns (see also Table 2) and the decrease of the mean fluorescence lifetime of Cy5 in the antigen−antibody complex from 1.54 to 1.06 ns, as it is expected for RET. From this it follows that a fraction of 0.31 of the donor excitation energy is deactivated by RET. The integral emission which corresponds to this quenching [ΔI_{RET}^{Cy5}(lifetime)] is also shown in Figure 7 (dashed line). It equals to

$$\Delta I_{RET}^{Cy5}(\text{lifetime}) = 0.48\Delta I_{quench}^{Cy5} \qquad (14)$$

The discrepancy between the fraction of fluorescence quenching by RET, which is derived from the steady-state (0.53) and the lifetime measurements (0.48), is within experimental error. Using the data from Table 3 the fraction of RET from IgG−Cy5 to the BSA bound Cy5.5 monomers and dimers can be calculated to $0.44\Delta I_{quench}^{Cy5}$ and $0.09\Delta I_{quench}^{Cy5}$, respectively. Table 4 summarizes the characteristical parameters which describe the energy transfer process, i.e., the Förster distance R_0,

Table 4. Analysis of Energy Transfer from IgG−Cy5 to ACA-BSA-Cy5.5

τ_D (ns)[a]	τ_{DA} (ns)[b]	R_0 (Å)	E_{RET}[c]	k_{RET} (1/s)[d]	R (Å)[e]
1.54	1.06	75.9	0.31	3×10^8	86.7

[a] Mean fluorescence lifetime of the donor in absence of the acceptor. [b] Mean fluorescence lifetime of the donor in the presence of the acceptor. [c] Efficiency of energy transfer. [d] Rate of energy transfer. [e] Average distance between the fluorophores.

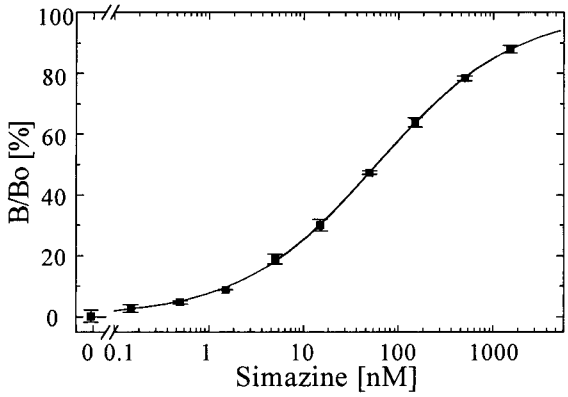

Figure 9. Calibration curve of simazine using an antibody concentration of 3 nM (450 ng/mL) and an ACA-BSA-Cy5.5 concentration of 10 nM (3 μg/L). Error bars are the standard errors of the mean from three replicate analyses.

the efficiency of energy transfer E_{RET}, the rate of energy transfer k_{RET} and the distance between the fluorophores R (*37*).

The fraction of the IgG−Cy5 quenching, which could not be ascribed to RET processes must be assigned to static quenching (ΔI_{static}^{Cy5})

$$\Delta I_{static}^{Cy5} = \Delta I_{quench}^{Cy5} - \Delta I_{RET}^{Cy5}(\text{lifetime}) = 0.47\Delta I_{quench}^{Cy5} \qquad (15)$$

The high fraction of static fluorescence quenching (47%) not resulting in sensitized acceptor fluorescence is favorable for energy-transfer immunoassays, because the signal modulation of Cy5 is enhanced.

Competitive Immunoassay. With the system described above, a competitive immunoassay for the analyte simazine has been performed (see Figure 1). The antibody concentration used was 3 nM (450 ng/mL). The ACA-BSA-Cy5.5 concentration was optimized by titration, to obtain the maximum quenching of the IgG−Cy5 fluorescence and thus a great dynamic range of the calibration curve. At a concentration of 10 nM (3 μg/L) ACA-BSA-Cy5.5, a quenching of 47.2% was achieved. A typical calibration curve for simazine, using these concentrations, is shown in Figure 9. The coefficients of variation are between 0.5 and 2%, the test midpoint is at 50 nM (10 μg/L) simazine, and the working range, defined as 10−90% B/B_0, is from 1.5 nM (0.3 μg/L) to 1000 nM (200 μg/L) simazine. The EU drinking water limit for a single pesticide of 0.1 μg/L cannot be achieved in this first assay. With further optimizations of the competitive analyte derivative with regard to the affinity of the antibody, the test midpoint and the limit of detection can be improved.

ACKNOWLEDGMENT

Design of Dendritic Macromolecules Containing Folate or Methotrexate Residues

Kenji Kono,‡ Mingjun Liu, and Jean M. J. Fréchet*

Department of Chemistry, University of California, Berkeley, California 94720-1460. Received June 18, 1999; Revised Manuscript Received September 20, 1999

Polyether dendritic compounds bearing folate residues on their surface were prepared as model drug carriers with potential tumor cell specificity. Starting from ester-terminated polyether dendrimers, hydrazide groups were easily introduced to the surface of the dendrimers by reaction with hydrazine. Folate residues were then conjugated to the hydrazide chain ends of the dendrimers by direct condensation with folic acid in the presence of a condensing agent or by reaction with an active ester derivative of folic acid. Essentially complete functionalization of the terminal hydrazide groups was achieved for both the first and the second generation dendrimers with four and eight hydrazide groups. For the G-2 dendrimer with 16 hydrazide groups, an average number of only 12.6 folate residues were attached to each dendrimer. The conjugates are soluble in aqueous medium above pH 7.4. In addition, a similar conjugation of the antitumor drug methotrexate to the dendrimer was also investigated. Once optimized, these molecules may form the basis for a novel family of multivalent drug carriers.

Dendrimers are unique synthetic macromolecules that have attracted much interest due to their unique structures and properties since their introduction in the mid-1980s. Their highly branched and well-defined structure, globular shape, and controlled surface functionality are some of the important characteristics of dendrimers (*1*−*3*). While applications of dendrimers have been explored in a very broad range of fields, their use in drug delivery systems has remained largely unexplored.

The functional groups present at the surface of dendrimers have been utilized for the conjugation of various biologically active molecules. For example, antibody (*4*−*6*) and sugar moieties (*7*, *8*) have been conjugated to the chain ends of poly(amidoamine) dendrimers, and these modifications have afforded dendrimers that may possess site-specific properties via antibody−antigen binding or via interactions between sugars and their receptors on cell surfaces.

The interior of dendrimers has also been shown to be capable of encapsulating guest molecules. Meijer and coworkers have reported that guest molecules, such as Rose Bengal, may be physically entrapped into the internal "cavity" of high generation poly(propylene imine) dendrimers when an amino acid derivative was used to cap each end group of the dendrimer (*9*). Because the amino acid derivative used was bulky, sterically crowded, and subject to hydrogen bonding, the entrapped guest molecules could not diffuse out of the dense packed shell of the dendrimer into the surrounding solution. Yet another strategy for the encapsulation of guest molecules in dendrimers makes use of hydrophobic interactions. Thus, Newkome et al. have prepared dendritic macromolecules with hydrophobic interior and hydrophilic chain ends (*10*), and these molecules were shown to behave as unimolecular micelles capable of solubilizing various hydrophobic compounds in aqueous solution (*11*).

In early work, we have also reported that simple and well-characterized poly(aryl ether) dendrimers bearing carboxylic groups as chain ends were able to solubilize pyrene in water (*12*). More recently, we have explored the possibility of using more appropriately designed dendritic unimolecular micelles as drug delivery agents, and the result showed that ca. 11 wt % of a hydrophobic drug such as indomethacin could be easily entrapped inside the hydrophobic interior of dendritic micelles and released slowly into buffer solution (*13*, *14*). Another, yet less explored (*15*, *16*), approach to the use of dendrimers in drug delivery is to attach drug molecules to the chain ends of the dendrimers; therefore, a high concentration of drug may be carried by a simple well-defined molecule. If an appropriate ligand is conjugated to one of the terminal groups of the dendrimers, a targeting feature may eventually be added to these dendrimer−drug conjugates.

It is known that a membrane-associated folate receptor, folate binding protein, is overexpressed on the surface of a variety of human tumor cells (*17*−*19*). When folic acid molecules are covalently linked to proteins, the folate−protein conjugates are internalized into cells via receptor-mediated endocytosis (*20*). Therefore, folate has been used as a ligand for the targeting of proteins (*21*), liposomes (*22*, *23*), and other molecules (*24*, *25*) to tumor cells that express the folate-binding proteins. The folic acid molecule (see Figure 1) possesses two carboxyl groups, termed α- and γ-, and the latter exhibits a much higher reactivity in a carbodiimide-mediated coupling to amino groups (*26*). In addition, folate linked via its γ-carboxyl group retains a strong affinity toward its receptor (*26*).

In this study, we have designed and synthesized dendritic molecules containing folate residues as models

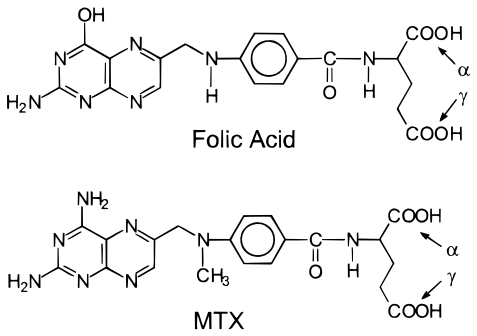

Figure 1. Structure of folic acid and MTX.

for drug carriers with tumor cell specificity. The synthesis is started from readily accessed ester-terminated dendrimers. After conversion of the ester groups to hydrazide groups, conjugation of folic acid to the dendrimers was accomplished by coupling the carboxylic groups of folic acid to the hydrazide groups of the dendrimers. The conjugation of methotrexate (MTX) (see Figure 1), an anti-cancer drug which has a structure similar to that of folic acid, to the dendrimer was also investigated.

EXPERIMENTAL PROCEDURES

General Methods. Folic acid and methotrexate (MTX) were purchased from Sigma. Poly(ethylene glycol) (PEG) monomethyl ether (M_n = 2000) was obtained from Shearwater Polymers, Inc. Other materials were obtained from Aldrich and used without further purification unless otherwise stated. DMSO was distilled under vacuum. ^{1}H NMR spectra were recorded on a Bruker AMX-300 (300 Hz) spectrometer and the solvent signals were used as the standard. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectra were recorded on a Voyager-DE PerSeptive Biosystems in a positive ion mode using 2,5-dihydroxybenzoic acid as the matrix.

Synthesis of Hydrazide-Terminated Dendritic Compounds. Diethyl isophthalate-terminated polyether dendrimers were synthesized according to the published procedure of Leon et al. (*27*). Hydrazide-terminated polyether dendrimers were prepared by reaction of ester-terminated dendritic precursors with hydrazine.

$(H_2NHNCO)_4$-[G-1]-OH (1). To a solution of $(EtO_2C)_4$-[G-1]-OH (0.50 g, 0.90 mmol) in DMF (10 mL) was added hydrazine (anhydrous, 1.5 mL), and the solution was stirred at 60 °C for 2 days under N_2 atmosphere. Methanol (50 mL) was added to the reaction mixture, and the white precipitate was collected by filtration. The crude product was redissolved in DMF and precipitated by addition of methanol. The precipitate was collected and dried under vacuum. Yield: 0.38 g, 84%. ^{1}H NMR δ 4.44 (s, 2 H, benzylic *H*), 4.53 (s, 8 H, NH_2), 5.15 (s, 5 H, benzylic *H* + O*H*), 6.59 (s, 1 H, aromatic *H*), 6.63 (s, 2 H, aromatic *H*), 8.00 (s, 4 H, aromatic *H*), 8.19 (s, 2 H, aromatic *H*), 9.84 (s, 4 H, CON*H*).

$(H_2NHNCO)_8$-[G-2]-OH (2). This was prepared via the same procedure from $(EtO_2C)_8$-[G-2]-OH and hydrazine. Yield: 66%. ^{1}H NMR δ 4.30−4.70 (m, 18 H, benzylic *H* and NH_2), 4.90−5.30 (m, 13 H, benzylic *H* + O*H*), 6.50−6.80 (m, 9 H, aromatic *H*), 8.01 (s, 8 H, aromatic *H*), 8.20 (s, 4 H, aromatic *H*), 9.84 (s, 8 H, CON*H*).

{$(H_2NHNCO)_8$-[G-2]}$_2$-[C] (3). This was prepared via the same procedure (except DMSO used as solvent instead of DMF) from {$(EtO_2C)_8$-[G-2]}$_2$-[C] and hydrazine. Yield: 94%. ^{1}H NMR δ 4.51 (s, 32 H, NH_2), 5.01 (s, 12 H, benzylic *H*), 5.14 (s, 16 H, benzylic *H*), 6.60−6.80 (m, 18 H, aromatic *H*), 7.00 (d, 4 H, J = 8.7 Hz, aromatic *H*), 7.46 (d, 4 H, J = 8.7 Hz, aromatic *H*), 7.98 (s, 16 H, aromatic *H*), 8.16 (s, 8 H, aromatic *H*), 9.79 (s, 16 H, CON*H*).

Conjugation of Folic Acid to Hydrazide-Terminated Dendritic Macromolecules. *Direct Condensation*. To a solution of folic acid (0.28 g, 0.63 mmol) and triethylamine (0.27 mL) dissolved in DMSO (10 mL) were added 1-hydroxybenzotriazole (0.19 g, 1.41 mmol) and EDC (0.27 g, 1.41 mmol), and the solution was stirred for 1 h at room temperature. Then, $(H_2NHNCO)_4$-[G-1]-OH **1** (0.040 g, 0.072 mmol) in DMSO (2 mL) was added and the mixture was stirred for 2 days at room temperature. Acetone was added to the reaction mixture, and a yellow precipitate formed. The precipitate was collected by filtration and dried under vacuum. The crude product was dissolved in water, and the pH was adjusted to ca. 9 using 1 N NaOH(aq) solution. The solution was loaded to a Sephadex G-25 column (40 cm × 2.5 cm) using water as effluent. Fractions containing the conjugate were collected, and the pH of the solution was adjusted to ca. 3 using 1 N HCl. The product precipitated out and was collected by filtration. The product was washed with water and dried under vacuum. Yield: 0.14 g.

Active Ester Method. The active ester of folic acid was prepared via the method reported by Lee and Low (*22*). To a solution of folic acid (0.30 g, 0.68 mmol) and triethylamine (0.10 g, 1.0 mmol) dissolved in DMSO (10 mL) was added DCC (0.14 g, 0.68 mmol), and the solution was stirred for 1 h at room temperature. Then, *N*-hydroxysuccinimide (0.12 g, 1.0 mmol) was added, and the mixture was stirred overnight at room temperature. The reaction mixture was filtered and the filtrate was precipitated into ether. The active ester of folic acid was collected by filtration, washed with dry THF, and dried under vacuum.

The active ester of folic acid was dissolved in DMSO (25 mg/mL), and the hydrazide-terminated dendrimers dissolved in DMSO (10 mg/mL) was added. The solution was stirred for 5 days (for **1** and **2**) and 10 days (for **3**) at room temperature. Acetone was added to the reaction mixture, and a yellow precipitate formed. The precipitate was collected by filtration and dried under vacuum. The product was purified using a Sephadex G-25 column as described above.

Conjugation of MTX to Hydrazide-Terminated Dendritic Macromolecule. To a solution of MTX (0.072 g) and triethylamine (0.050 mL) dissolved in DMSO (6 mL) was added DCC (0.066 g), and the mixture was stirred for 1 h at room temperature. Then, $(H_2NHNCO)_8$-[G-2]-OH (0.020 g) in DMSO (1 mL) was added, and the resulting mixture was stirred for 2 days. Ether was added to the reaction mixture, and a yellow precipitate formed. The precipitate was collected by filtration and dried under vacuum. The product was purified using a Sephadex G-25 column as described above. Yield: 0.028 g.

Synthesis of $(EtO_2C)_8$-[G-2]-PEG. To a dispersion of NaH (0.105 g) in dry THF (5 mL) was added PEG monomethyl ether (1.46 g) dissolved in THF (15 mL) dropwise at room temperature, and the solution was stirred for 2 h. Then, $(EtO_2C)_8$-[G-2]-Br (1.12 g) dissolved in THF (15 mL) was added and the reaction mixture was stirred for 2 h. The reaction mixture was filtered and the

[1] Abbreviation: MTX, methotrexate; MALDI-TOF, matrix-assisted laser desorption ionization time-of-flight; DCC, *N*,*N*′-dicyclohexylcarbodiimide; EDC, 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide, PEG, poly(ethylene glycol).

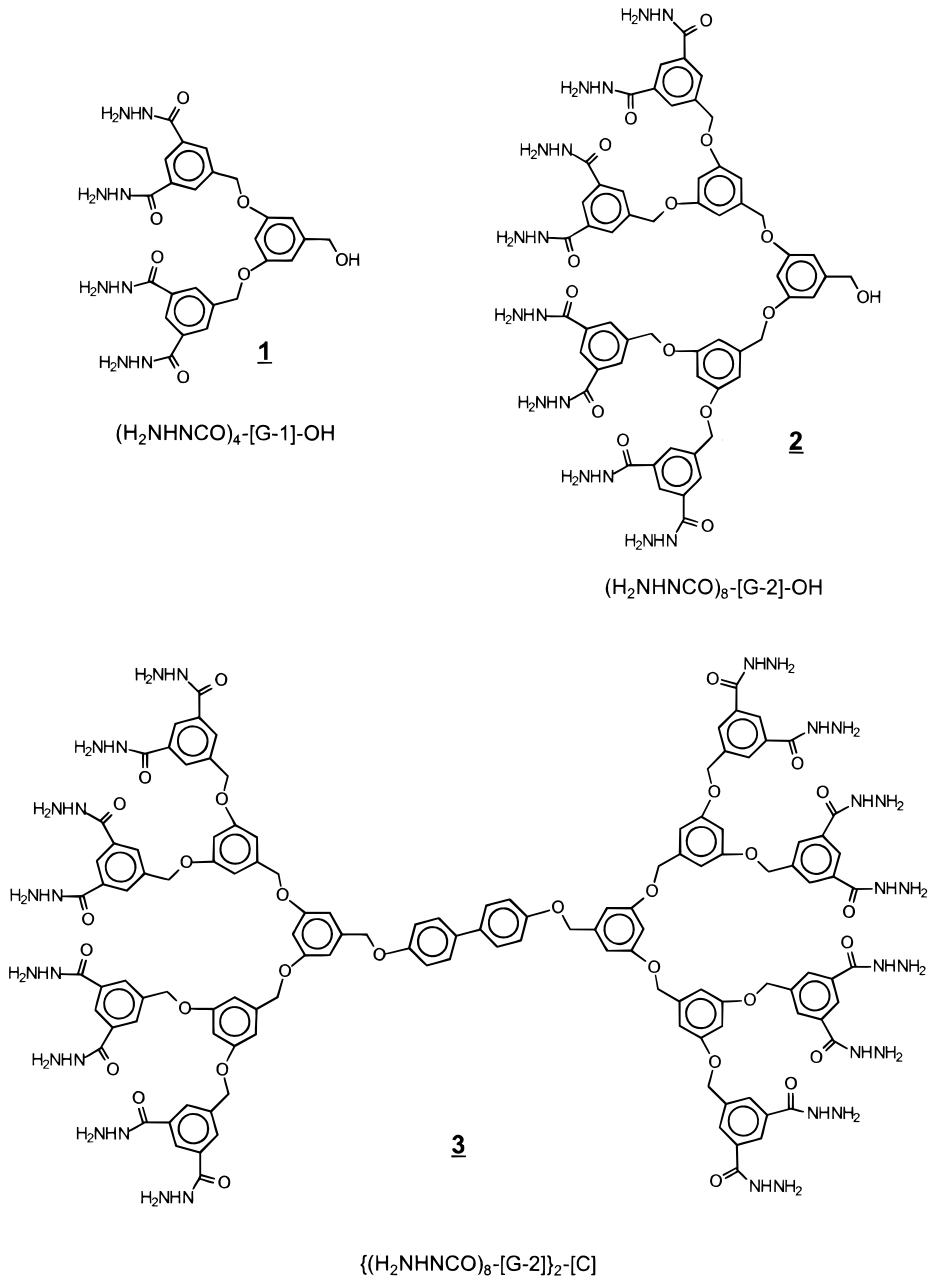

Figure 2. Structure of the hydrazide-terminated dendrimers.

crude product was precipitated by addition of ether to the filtrate. The crude product was loaded to silica gel column and washed with 15% THF/CH_2Cl_2. The eluent was changed to CH_2Cl_2, then 5% methanol/CH_2Cl_2. The product $(EtO_2C)_8$-[G-2]-PEG was eluted using 5% methanol/CH_2Cl_2. Yield: 0.58 g.

Synthesis of $(H_2NHNCO)_8$-[G-2]-PEG. $(EtO_2C)_8$-[G-2]-PEG (0.13 g) and hydrazine (2 mL) in DMSO (3 mL) were heated at 40 °C for 3 days. The product was precipitated by adding ether to the reaction mixture. The precipitate was dissolved in methanol, reprecipitated into ether, and dried under vacuum. Yield: 0.10 g.

Synthesis of Folate-[G-2]-PEG Conjugate. $(H_2NHNCO)_8$-[G-2]-PEG (0.040 g) was allowed to react with folic acid (0.132 g) in the presence of EDC (0.058 g) and triethylamine (0.092 mL) in DMSO (10 mL) for 4 days as described above. The conjugate was precipitated by addition of ether, collected by filtration, and purified using a Sephadex G-25 column eluted with water. Yield: 0.080 g.

Water-Solubility Measurement. The water solubility of the folate−dendrimer conjugates was examined by measuring the turbidity of their aqueous solutions. The conjugate sample (1.2 mg) was dissolved in 10 mM phosphate buffer solution containing 140 mM NaCl (3 mL) under an alkaline condition (pH 9−11). The pH of the solution was adjusted to a given value by the addition of 1 N HCl, and the optical density of the solution was measured using a spectrophotometer (JASCO V-560).

RESULTS AND DISCUSSION

1. Synthesis of Hydrazide-Terminated Dendritic Compounds. The selection of the functional groups used for conjugation of folic acid onto the dendrimer surface is important. In this work, we chose hydrazide groups because of their easy synthesis and high reactivity toward coupling with folic acid. Small dendritic polyvalent hydrazides have previously been used as cross-linkers for the preparation of hydrogels of hyaluronic acid (*28*). Starting from ester-terminated dendrimers, hydrazide

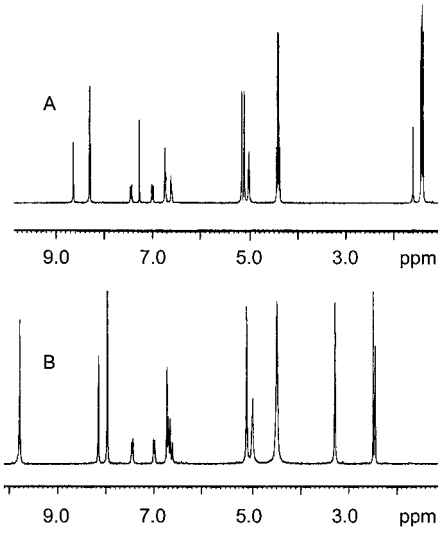

Figure 3. ^{1}H NMR spectra for the ester-terminated (A) and the hydrazide-terminated (B) $[G\text{-}2]_2$-[C] dendrimers.

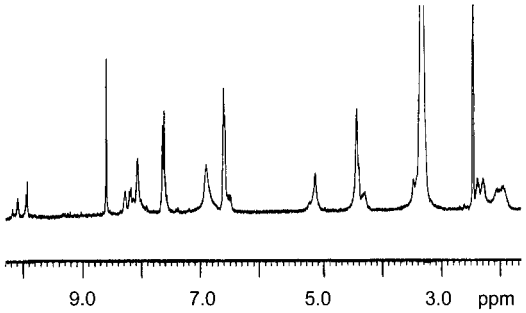
groups could easily be introduced onto dendrimers by reaction with hydrazine. We prepared three different hydrazide-terminated dendritic compounds with 4, 8, and 16 hydrazide groups. Figure 2 shows the structure of the hydrazide-terminated dendritic compounds used in this work for the construction of conjugates. Characterization by ^{1}H NMR confirmed the complete transformation of ester groups to hydrazide groups. Figure 3 shows the ^{1}H NMR spectra for the precursor dendrimer $\{(EtO_2C)_8\text{-}[G\text{-}2]\}_2$-[C] and the corresponding hydrazide derivative $\{(H_2NHNCO)_8\text{-}[G\text{-}2]\}_2$-[C]. Signals for ethyl groups appear at 1.42 and 4.42 ppm in the spectrum for the ester-terminated dendrimer. In contrast, these signals disappeared completely after reaction with hydrazine, and a new signal corresponding to the protons from the hydrazide groups appeared at 4.50 and 9.78 ppm. The same changes in ^{1}H NMR spectra were also observed in the transformation of the precursor dendrimers, $(EtO_2C)_4$-[G-1]-OH and $(EtO_2C)_8$-[G-2]-OH, into the corresponding hydrazides, $(H_2NHNCO)_4$-[G-1]-OH and $(H_2NHNCO)_8$-[G-2]-OH.

2. Conjugation of Folic Acid to Dendrimers. Conjugation of folic acid to $(H_2NHNCO)_4$-[G-1]-OH was carried out via condensation between the γ carboxyl group of folic acid and the hydrazide groups of the dendrimer. Two methods were tested for this condensation (Scheme 1): direct condensation in the presence of the carbodiimide condensing agent EDC and reaction of the hydrazide groups with the active ester of folic acid as previously reported (*21*−*23*, *26*).



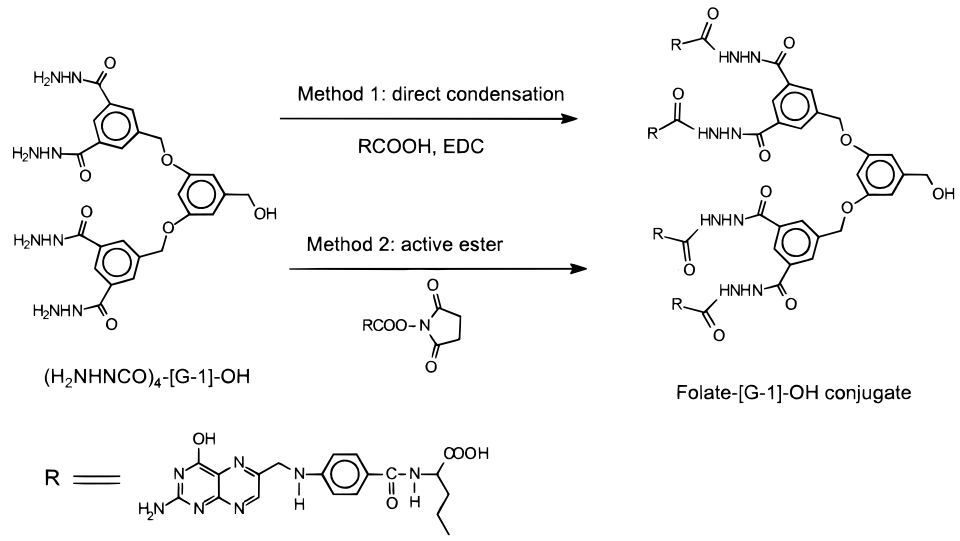


Figure 4. ^{1}H NMR spectrum for the folate-[G-1]-OH conjugate in DMSO-d_6.

The conjugates were characterized by ^{1}H NMR spectroscopy as shown in Figure 4. It is apparent that the spectrum of the conjugate contains signals originating from both folic acid and the dendrimer. From the integral ratio of the signal at 8.64 ppm, which corresponds to the proton at the 7-position of the pterin ring, to the signal at 5.15 ppm, which corresponds to the benzylic proton from the dendritic moiety, the average number of folate residues in the conjugate can be evaluated. By using excess of active ester of folic acid with the G-1 dendrimer, an average number of 3.6 folate molecules became attached to the dendrimer. However, when the conjugate was prepared via direct condensation, the average number of folate molecules per conjugate was 3.0. The lower number of folate per conjugate may be the result of reaction between the two carboxyl groups of one folic acid molecule and two hydrazide groups. Such coupling is possible since each of the two carboxyl groups of folic acid may be activated by EDC. After attachment of folic acid to the dendrimer by coupling between one carboxyl group and one hydrazide group, the other carboxyl group may react with second hydrazide groups on the same dendrimer, leading to a macrocyclic structure. Thus, the possibility of attachment of a folate residue via two hydrazide groups may be higher for the conjugation method involving carbodiimide-mediated direct conden-

Scheme 1

Table 1. Syntheses of Folate-[G-2]-OH and Folate-[G-2]2-[C] Conjugates

conjugate	the ratio of folic acid/ dendrimer in reaction mixture	folate residues per conjugate
folate-[G-2]-OH	8.0	3.2
	15.2	7.3
	24.0	8.2
folate-[G-2]2-[C]	48.0	12.6

sation. Therefore, the active ester method was used in the construction of all of the conjugates described in this work.

The folate-[G-1]-OH conjugate was further characterized using MALDI-TOF mass spectrometry. Figure 5 depicts the MALDI-TOF mass spectrum for the conjugate prepared via the active ester method. The spectrum shows strong peaks at 2268 and 2247, which correspond to the $[M + Na]^+$ ion and the $[M + H]^+$ ion of the conjugate with four folate residues, respectively. In addition, relatively small peaks were observed at 1850 and 1826 corresponding to the $[M + Na]^+$ ion and the $[M + H]^+$ ion of the conjugate with three folate residues.

Conjugation of folic acid to $(H_2NHNCO)_8$-[G-2]-OH and $\{(H_2NHNCO)_8$-[G-2]$\}_2$-[C] using the active ester method was also examined. Preparation conditions and the average number of folate residues per conjugate are listed in Table 1. For folate-[G-2]-OH conjugate, the average number of folates per conjugate increases as the folic acid/ dendrimer ratio in the reaction mixture increases. Essentially complete functionalization of the hydrazide groups was achieved when 3 equiv of folic acid active ester were used for each hydrazide group. However, in the case of $\{(H_2NHNCO)_8$-[G-2]$\}_2$-[C] dendrimer with 16 hydrazide groups, only an average of 12.6 folate residues were found to be attached to the dendrimer even after 10 days of reaction. When the same reaction was carried out for 5 days, only 10.0 folate residues could be attached to the dendrimer. These findings suggest that the terminal hydrazide groups of the $\{(H_2NHNCO)_8$-[G-2]$\}_2$-[C] dendrimer are somewhat less accessible than those of the $(H_2NHNCO)_8$-[G-2]-OH, perhaps as a result of the increased steric congestion on the dendrimer surface, or due to reason intrinsic to this demanding carbodiimide-mediated coupling.

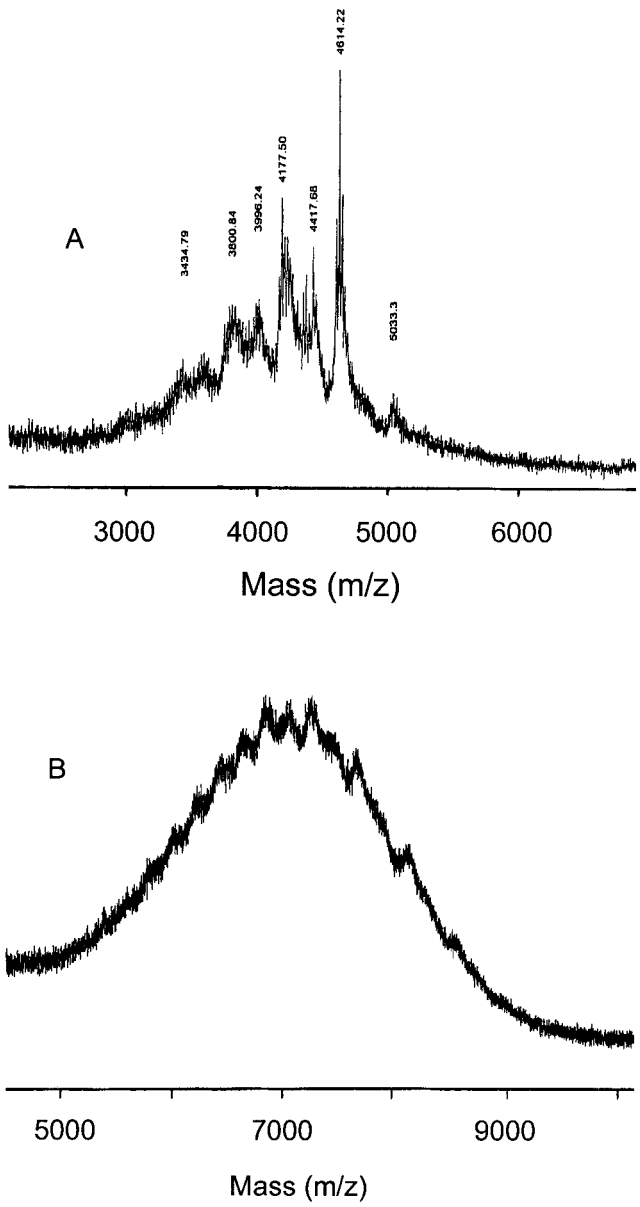

Figure 6. MALDI-TOF mass spectra for the folate-[G-2]-OH conjugate (A) and the folate-$[G-2]_2$-[C] conjugate (B).

The molecular weight of the conjugates was investigated by MALDI-TOF mass spectrometry. For the folate-[G-2]-OH conjugate (Figure 6A), strong peaks are observed at a mass of 4614, which corresponds to the $[M + Na]^+$ ion of the conjugate with eight folate residues. Also, several peaks were observed around 4177 that correspond to the conjugate with seven folate residues. The existence of peaks between those for conjugates with seven and eight folate residues suggests the occurrence of fragmentation of the conjugate residues during measurement. It has been reported that folate residues fragment readily with formation of pteridinyl radicals with a molecular mass of 176 Da (*26*). Therefore, peaks observed around 4417 are likely due to the molecular ions and Na adducts of the fragments of conjugates with eight folate residues that have lost a single pteridinyl radical. It is not unlikely that this kind of fragmentation could occur during the MALDI-TOF measurement since higher power is frequently used for such high MW compounds. Small peaks around 5033 correspond to the conjugate containing eight

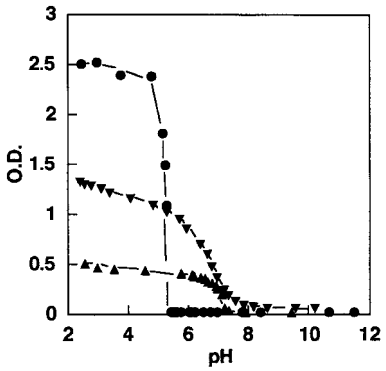

Figure 7. Turbidity of solutions of the folate-[G-2]-OH conjugate (▲); the folate-$[G\text{-}2]_2$-[C] conjugate (▼); and pure folic acid (●) in 10 mM phosphate-buffered solutions containing 140 mM NaCl at varying pH values. The ordinate shows the optical density of the solution at 550 nm.

folate residue at the chain ends plus one folate residue at the focal point. The MALDI-TOF spectrum for the folate-$[G\text{-}2]_2$-[C] conjugate with 12.6 folate residues as measured by NMR analysis is shown in Figure 6B. The conjugate gave a broad peak centered at a mass of 7100 that corresponds to a conjugate with an average of 10.7 folate residues.

3. Water Solubility of the Folate−Dendrimer Conjugates. Since the folate−dendrimer conjugates have carboxyl groups on their surface, they are expected to be soluble in water under conditions where these groups are charged. Thus, pH dependence of the water solubility of the conjugates was examined. Figure 7 shows the turbidity of the solutions of the conjugates and folic acid at varying pH values. The solution of folic acid was not turbid under either neutral or alkaline conditions. However, its turbidity increased drastically near pH 5.4, indicating precipitation of the folic acid. Potentiometric titration of an aqueous solution of folic acid at pH 8.3 using 10 mM HCl showed that 2 equiv of HCl was consumed to neutralize the folate anion near pH 5.4, indicating that both the α- and the γ-carboxyl groups of folic acid were neutralized at this pH value where precipitation is expected to take place. For the folate-[G-2]-OH conjugate, the solution was completely clear under alkaline conditions, showing that the conjugate is soluble in water under such conditions. However, an increase in turbidity was observed near pH 7.4. Similarly, an increase in turbidity was also seen for the solution of folate-$[G\text{-}2]_2$-[C] conjugate at the same pH. Agarose gel electrophoresis analysis of the folate-$[G\text{-}2]_2$-[C] conjugate showed that the conjugate was negatively charged at pH 8.0. Therefore, it is considered that these conjugates indeed acquired water solubility as a result of the presence of a negative charge on the remaining carboxylate group of the folate residues. Protonation of these carboxylate groups results in the precipitation of the conjugates. Precipitation of these conjugates took place at higher pH than observed for free folic acid, probably due to the hydrophobic nature of the dendritic moieties.

4. Conjugation of MTX. Because methotrexate (MTX), a widely used antitumor drug, is structurally similar to folic acid, coupling of MTX to the dendritic macromolecules is expected to occur through the same process. Conjugation of MTX to synthetic polymers has already been attempted and the MTX−polymer conjugates have shown antitumor activity or cell growth inhibitory activity (*29*, *30*). The conjugation of MTX to hydrazide terminated dendrimer $(H_2NHNCO)_8$-[G-2]-OH was examined briefly to demonstrate its feasibility. Using an

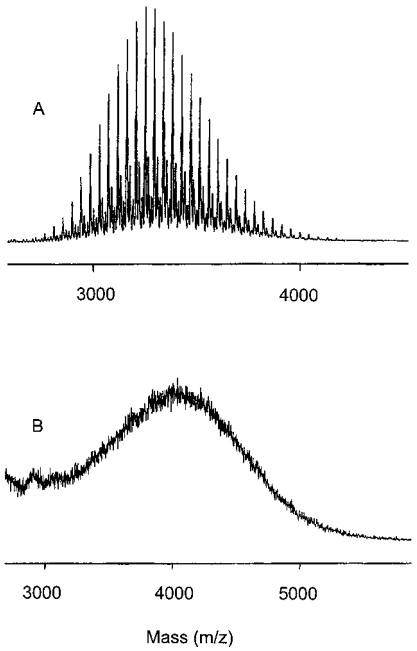

Figure 8. MALDI-TOF spectra of the ester-terminated [G-2]-PEG (A) and the folate-[G-2]-PEG conjugate (B).

MTX/dendrimer (mole/mole) ratio of 10.4, the ^{1}H NMR of the product showed that an average of 4.7 MTX residues/conjugate was bound.

5. Folate-dendron-PEG Conjugates. The G-2 dendron $(EtO_2C)_8$-[G-2]-OH possesses one hydroxyl group at the focal point, and this group may be used for the attachment of another molecule. This might be a targeting moiety or a solubilizing group. In a first exploration, we examined the introduction of a PEG chain at the focal point of the dendrimer since this PEG chain is expected to modify the behavior of the conjugate in the body and increase the overall water solubility of the conjugate (*31*, *32*). The hybrid molecule $(EtO_2C)_8$-[G-2]-PEG was prepared via a Williamson ether synthesis involving $(EtO_2C)_8$-[G-2]-Br and a PEG monomethyl ether with Mn 2000 and a polydispersity of 1.01. Figure 8A shows the MALDI-TOF spectrum of the resulting $(EtO_2C)_8$-[G-2]-PEG. A series of peaks centered at 3294 were observed. These correspond to the hybrid molecule with a PEG chain of MW 1968. The mass difference between two adjacent peaks in the MALDI spectrum is 44, which is the mass of one oxyethylene repeating unit. Unfortunately, the PEG sample is not monodisperse and its effect on broadening the dispersity of the dendrimer is quite significant. The hydrazide derivative of the hybrid and its subsequent folate conjugate were prepared via the same procedure as described above without optimization for complete coupling. The MALDI-TOF spectrum of the folate-[G-2]-PEG conjugate shown in Figure 8B consists of a broad peak centered at 4000, which corresponds to the conjugate with two folate residues only. This result demonstrates that the hydrazide groups of the dendrimer-PEG hybrid are still reactive and available for conjugation, although their reactivity appears to be reduced by the introduction of PEG chain. Further studies with optimized dendritic structure will focus on increased functionalization of such hybrid structures.

CONCLUSION

Our work has shown that folate residues could easily be conjugated to the chain ends of a hydrazide-terminated polyether dendrimer. The folate−dendrimer conju-

gates were soluble in phosphate buffer solution at physiological pH. The folate−dendrimer conjugates possess hydrophobic interior and hence might be useful to entrap hydrophobic drugs. Because these molecules have folate residues on their surface, they are expected to exhibit a strong affinity for tumor cells that overexpress folate receptor on the cell surface. Thus, these types of conjugates may potentially be useful as drug carriers with targeting specificity. In addition, the anticancer drug MTX has been successfully attached to a dendrimer. Although the toxicology of the polyether dendrimers remains to be clarified, these molecules or analogues thereof based on more biocompatible dendritic building blocks may be used in the design of a sophisticated type of multivalent drug carriers. Interactions of the conjugates with cells are currently under investigation.

Synthesis of Metallointercalator−DNA Conjugates on a Solid Support

R. Erik Holmlin, Peter J. Dandliker,† and Jacqueline K. Barton*

Division of Chemistry and Chemical Engineering, California Institiute of Technology, Pasadena, California 91125. Received June 21, 1999; Revised Manuscript Received August 26, 1999

Metallointercalator−DNA conjugates were prepared by amide bond formation between active esters on the nonintercalating ligands of transition metal complexes and primary amines presented at the 5′ or the 3′ termini of oligonucleotides attached to solid supports. The conjugates were liberated from the support by aminolysis and purified by HPLC on C18 or C4 stationary phases, which separates the two diastereomeric forms of the conjugates containing either the Λ or the Δ enantiomer of the octahedral metal complex. The coupling reaction proceeds with ∼75% conversion of the amino-terminated oligonucleotide into the conjugate; the isolated yield is ∼200 nmol for syntheses initiated on DNA-synthesis columns with a loading of 2 μmol. The conjugates were characterized by ultraviolet−visible and circular dichorism absorption spectroscopy, electrospray ionization mass spectrometry, enzymatic digestion, and polyacrylamide gel electrophoresis (PAGE). Oligonucleotides bearing $[Rh(phi)_2(bpy')]^{3+}$ (phi = 9,10-phenanthrene quinone diimine; bpy′ = 4-butyric acid-4′-methyl bipyridyl) form 1:1 duplexes with the complementary strand, and the electrophoretic mobility under nondenaturating PAGE of duplexes containing Δ-Rh is notably different from duplexes containing Λ-Rh. High-resolution PAGE of DNA photocleavage reactions initiated by irradiation of the tethered Rh complexes reveal intercalation of the complex only near the tethered end of the duplex. Analogous DNA-binding properties were observed with $[Rh(phi)_2(bpy')]^{3+}$ tethered to the 3′ terminus. By combining the 3′ and 5′ modification strategies, a mixed-metal DNA conjugate containing both $[Os(phen)(bpy')(Me_2\text{-}dppz)]^{2+}$ (Me_2-dppz = 7,8-dimethyldipyridophenazine) on the 3′ terminus and $[Rh(phi)_2(bpy')]^{3+}$ on the 5′ terminus was prepared and isolated. Taken together, these strategies for preparing metallointercalator−DNA conjugates offer a useful approach to generate chemical assemblies to probe long-range DNA-mediated charge transfer where the redox initiator is confined to and intercalated in a well-defined binding site.

INTRODUCTION

Investigations of long-range electron transfer (ET) reactions mediated by the stacked, heterocyclic bases of DNA are important to fundamental studies of ET, as well as the complete biochemical characterization of the genetic material. In our laboratories we employ transition metal complexes that bind to DNA by intercalation, metallointercalators, with well-defined redox properties to probe DNA-mediated electron transfer (*1*). Here we describe synthetic methods to prepare oligonucleotide conjugates in which a metallointercalator, $[Rh(phi)_2(bpy')]^{3+}$ (Figure 1; phi = 9,10-phenanthrene quinone diimine; bpy′ = 4-butyric acid-4′-methyl bipyridyl), is attached covalently to DNA at either the 5′ or 3′ terminus while the assembly is immobilized on a solid support.

Photoinduced ET between metallointercalators bound to DNA is remarkably fast and efficient (*2*−*5*). In titrations of electron acceptor (Δ-$[Rh(phi)_2(bpy)]^{3+}$) into solutions of electron donor (Δ-$[M(phen)_2(dppz)]^{2+}$) bound to DNA, 50% of the donors were quenched by just 1 equiv of Δ-$[Rh(phi)_2(bpy)]^{3+}$ on a time scale of <30 ps when the average donor−acceptor separation is 25 base pairs. These observations suggested that the DNA base stack could facilitate efficient ET over large separations of donor and acceptor. We (*2*) and others (*6*, *7*) also considered the possiblity that the metal complexes might preferentially intercalate in adjacent sites throughout the titration, which would result in only one donor−acceptor separation and explain the observation of a rate of recombination that was independent of the loading of acceptor on the helix.

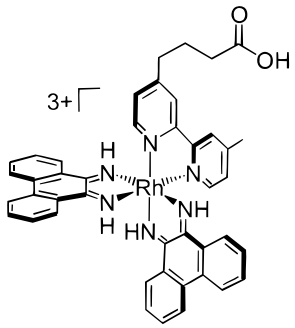

Figure 1. Schematic illustration of Δ-$[Rh(phi)_2(bpy')]^{3+}$.

In studies of oxidative damage to DNA at the 5′-guanine (G) of 5′-GG-3′ sequences, as well as oxidative repair of thymine dimer lesions in duplex DNA, we were unable to correlate the site of the chemical reaction on DNA with the site of intercalation by the metallointercalator (*8*, *9*). These observations again suggested the possiblity that the DNA base stack might facilitate electron transfer over long range.

To address unambiguously the question of whether long-range ET can occur on the DNA double helix, we

sought to prepare DNA assemblies by covalently attaching the reactants to the terminus of oligonucleotides so as to confine intercalated donors and acceptors to well-defined binding sites. Murphy et al. tethered $[Ru(phen')_2(dppz)]^{2+}$ (phen′ = 5-amidoglutaricacid-1,10-phenanthroline) and Δ-$[Rh(phi)_2(phen')]^{3+}$ to opposite ends of a 15 bp duplex, and found that 100% of the ruthenium luminescence was quenched by the rhodium complex on a subnanosecond time scale (*10*). However, the synthetic methods used to generate these materials proved to be irreproducible and tedious, which impeded the systematic study of these assemblies. Other laboratories have now also developed methods to functionalize oligonucleotides with ruthenium complexes using solid-phase synthesis (*11*−*14*). These strategies have largely focused on the construction of ruthenium-modified nucleoside phosphoramidites for incorporation into oligonucleotides using automated techniques. While these methods offer the versality of incorporating a metal complex at any site along the oligonucleotide (*11*−*18*), methods of postmodification on the resin become valuable when the metallating species contains more sensitive functionality. In the particular applications we have been interested in addressing, we have, moreover, wanted to focus on modifying oligonucleotides with intercalators tethered to oligonucleotide termini, with tethers of sufficient length to ensure proper stacking in the helix. Therefore, we have developed a convenient and efficient strategy that permits the covalent attachment of a metallointercalator to an oligonucleotide either at the 3′ or 5′ terminus while the oligomer is attached to the solid support. This methodology allows the characterization of DNA-mediated ET reactions in molecular assemblies with well-defined separations beteween reactants.

EXPERIMENTAL SECTION

Materials. Solvents used in coupling chemistry were anhydrous (Fluka over molecular sieves). DNA synthesis reagents were supplied by Glen Research and chemicals for heterogeneous coupling reactions were obtained from Fluka, Aldrich, and Sigma and used as received.

Unmodified Oligonucleotides. Unmodified (native) oligonucleotides were prepared by the phosphoramidite method (*19*) on an ABI 394 DNA synthesizer. Purification was carried out on the 5′-DMT oligonucleotide by RP HPLC (C18; ammonium acetate/acetonitrile). The DMT group was removed by treatment with 400 μL of 80% (v/v) glacial acetic acid in water for 20 min, followed by precipitation by anhydrous ethanol. The alcoholic acid was removed under reduced pressure, and the 5′-OH strand purified a second time by RP HPLC.

Metal Complexes. $[Rh(phi)_2(bpy')]Cl_3$ and $[Os(phen)(bpy')(Me_2\text{-}dppz)]Cl_2$ (Me2-dppz = 7,8-dimethyldipyridophenazine) were synthesized as described previously (*20*, *21*).

Preparation of Conjugates: Aminoalkylation of the 5′ Terminus. This procedure followed closely the method of Wachter, with slight modification (*22*). The desired oligonucleotide was synthesized by automated DNA synthesis using the phosphoramidite approach (*19*) on CPG resin with 2000 Å pores (Glen Research). The synthesizer was programmed to leave the oligonucleotide on the resin with the DMT group off of the 5′ terminus. The DNA-coated beads (2 × 1 μmol loading) were removed from the synthesis columns and added to a 2.5 cm × 10 cm glass cylinder fitted with a course glass frit and stopcock at the bottom.

The oligonucleotide on the resin was washed three times with 3 mL of dry dioxane (Fluka; over molecular sieves), and a solution of carbonyl diimidazole (CDI) (Sigma) in dry dioxane (50 mg/1 mL) was added to the beads in the cylindrical reaction vessel. The suspension was agitated by bubbling dry Ar(g) through the glass frit. After 30 min of agitation the CDI solution was removed and the resin was washed five times with 3 mL of dry dioxane.

A solution of diaminononane in 9:1 dioxane/water (32 mg/1 mL) was added to the functionalized DNA on the resin and the suspension was agitated as above for 25 min. If this reaction proceeds for too long, the amino linker will hydrolyze the DNA from the resin. At the conclusion of the reaction time, the aminononane solution was washed from the resin and the beads were washed with excess dioxane and methanol. The methanol will dissolve unreacted diaminononane. At this point, the linker has been installed and the resin may be stored or reacted further.

Coupling $[Rh(phi)_2(bpy')]^{3+}$ to 5′-Aminoalkylated DNA on CPG. $[Rh(phi)_2(bpy')]Cl_3$ (10 mg) and *N*,*N*,*N*′,*N*′-tetramethyl-*O*-(*N*-succinimidyl)uronium tetrafluoroborate (TSTU) (8 mg; Aldrich) were dissolved in 0.5 mL of 1:1:1 $CH_3OH/CH_2Cl_2/CH_3CN$ along with *N*,*N*-diisopropyl ethylamine (DIEA) (6 μL) and stirred at ambient temperature for 1 h. The complete activation of the carboxylate was confirmed by thin-layer chromatography (TLC) on alumina (CH_3OH), where the R_f for the ester is much greater than the R_f for the acid. This solution of $[Rh(phi)_2(bpy')]^{3+}$-NHS ester was added to the DNA (aminoalkylated) coated beads in a 5 mL round-bottom (rb) flask (after wetting them with 1:1:1 $CH_3OH/CH_2Cl_2/CH_3CN$ and draining the excess solvent). DIEA (20 μL) was added and the resulting slurry was stirred for 12 h to effect coupling.

Liberating the Conjugate from the CPG Beads. Following the coupling reaction, the solution of metal complex was washed away from the beads on a glass frit, and the beads were washed with excess CH_3OH, CH_2Cl_2, and CH_3CN. At this stage, the beads are colored orange and the intensity of the color is strongly solvatochromic. The color appears darkest in CH_2Cl_2.

The beads were transferred into a 1.7 mL Eppendorf tube and combined with ∼500 μL of concentrated (37%) NH_3 (aq). The mixture was agitated to wet the beads and then incubated at 60 °C for 6 h. After 1 h of incubation, the solution is colored red and the intensity of color on the beads is reduced.

After 6 h of incubation, the mixture was cooled to room temperature (very important) and filtered on a centrifuge filter (nylon; Rainin). The ammonia solution was removed in vacuo on a speed vac evaporator.

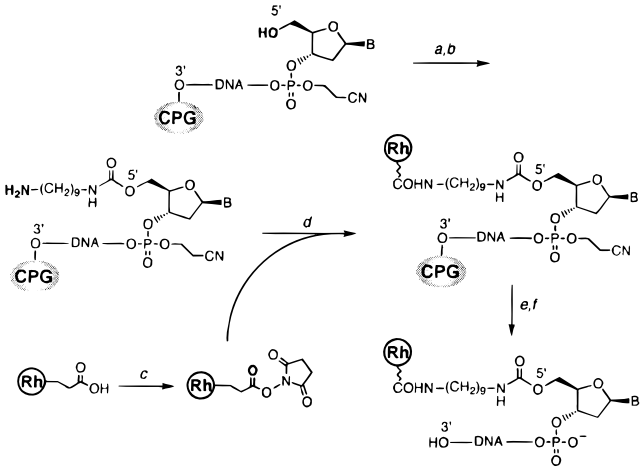
After the sample was dried, it was redissolved in water (330 μL) and filtered to remove insoluble materials. The mixture was purified by reversed-phase HPLC on C4 or C18 stationary phases using 50 mM ammonium acetate (pH ∼6)/CH_3CN as the mobile phase. The extinction coefficient for Rh-modified oligonucleotides is taken as $1.9 \times 10^4\ M^{-1}\ cm^{-1}$ at 390 nm.

Synthesis of 3′-Rh-Modified Conjugates. CPG resin (Glen Research) functionalized with a hydroxyaminoalkyl linker protected at the amine with an Fmoc and at the hydroxyl group with DMT was used for DNA synthesis. A "dummy" base was incorporated at the 3′ terminus of the sequence so the DNA synthesizer would remove the DMT from the linker and build the DNA strand from that branching point. The DNA synthesizer was programmed to leave the oligonucleotide on the resin with the 5′ DMT group intact.

After the DNA synthesis was complete, the Fmoc was selectively removed by treatment of the beads with a solution of piperidine (20% v/v) in DMF (*23*) under Ar(g) for 30 min. The DMF solution was washed away from the beads, and the resin was transferred to a 5 mL round-bottom flask. A solution of $[Rh(phi)_2(bpy')]^{3+}$-NHS ester was added to the beads along with DIEA (20 μL), and the mixture was stirred for 12 h to effect coupling. For this procedure, we increased the concentration of the solution of NHS ester by reducing the volume to 250 μL and using the same amount of reagents. This modification of the procedure is necessary to accommodate the linker buried in the CPG and the fact that we are using 500 Å beads, which are smaller.

After the coupling reaction, we removed the DMT group before cleaving the conjugate from the resin by treatment with trichloroacetic acid in dichloromethane for 18 s on the DNA synthesizer. The conjugate was then liberated from the beads and purified as described above. In general, these conjugates are more hydrophilic than the 5′-modified analogues owing to an extra phosphate in the linker.

Synthesis of 3′,5′-bis-Heterometalated Oligonucleotides. A metal complex was introduced onto the 3′ terminus of an oligonucleotide using the procedure described above. After removing the DMT protecting group from the 5′-terminal hydroxyl by treatment with trichloroacetic acid in CH_2Cl_2, the oligonucleotide was 5′-aminoalkylated according to the standard procedure, and a second metallointercalator was coupled onto the 5′ terminus as described for singly modified strands. Liberation and purification procedures were the same as for the singly metalated DNA, however, higher concentrations of acetonitrile in the mobile phase were required to elute the product.



Methods. ESI data for oligonucleotides were provided by UC Riverside. CD spectroscopy was carried out on a Jasco 2500 spectrometer using 20 μM samples. Polyacrylamide gel electrophoresis (PAGE) and photocleavage assays were carried out using the methods described previously (*20*, *24*, *25*).

Enzymatic Digestion of Oligonucleotides. An aqueous solution of oligonucleotide containing ~1 nmol of strand was added to 10 μL of 1.0 M $MgCl_2$(aq), 10 μL of AP buffer (10× supplied with enzyme), 3 μL of SVP (Sigma), 3 μL of AP (Boehrringer Mannheim), and water in a 1.7 mL Eppendorf tube to give a volume of 100 μL. The cocktail was incubated at 37 °C for ~8 h.

Following incubation, the mixture was filtered on nylon (0.4 μm) centrifuge filters and analyzed by RP HPLC on a 100 Å, analytical (C18) column. The mobile phase consisted of 50 mM ammonium acetate, pH 5.5, and acetonitrile. The gradient started at 0% acetonitrile and went to 5% acetonitrile over 25 min. Some analyses required that the column be heated to 40 °C. The nucleotides elute from the column in the following order: 1-C, 2-G, 3-T, 4-A, as confirmed by co-injection of standard solutions.

The area under each peak (observation at 260 nm) was normalized to the extinction coefficient of the base (dC = 7.3 $mM^{-1}\,cm^{-1}$, dG = 11.7 $mM^{-1}\,cm^{-1}$, dT = 6.7 $mM^{-1}\,cm^{-1}$, dA = 15.0 $mM^{-1}\,cm^{-1}$; Glen Research). The fraction of normalized area for a given base was then multiplied by the total number of bases to indicate the number of that component present in the mixture. In general, we find the results for dG and dT to be slightly high (~10%; independent of the conjugation chemistry) and the results for dA to be slightly low, which probably reflects some error in the extinction coefficients used in the calculations.

[a] Reagents: (a) CDI, dioxane, 30 min, rt; (b) $H_2N(CH_2)_9NH_2$, dioxane/H_2O (9:1), 25 min, rt; (c) TSTU, DIEA, CH_3OH, CH_3CN, CH_2Cl_2 (1:1:1), rt, 1 h; (d) heterogeneous coupling, DIEA, rt, 12 h; (e) NH_3(aq), 60 °C, 6 h. [b]Abbreviations: CPG = controlled pore glass; Rh = $[Rh(phi)_2(bpy')]^{3+}$.

Hybridization of Complementary Oligonucleotides to Form Duplexes. Complementary DNA strands were dissolved in 5 mM sodium-phosphate buffer and 50 mM NaCl, pH 7.0, in a 1:1 ratio at the desired concentration. The sample was heated to 90 °C for 5 min and cooled to ambient temperature (20 °C) with a linear gradient over 180 min.

RESULTS AND DISCUSSION

Synthesis and Characterization of Oligonucleotide Conjugates with $[Rh(phi)_2(bpy')]^{3+}$ Attached to the 5′-Terminus. Several methods permit the synthesis of oligonucleotides with molecular probes attached to the terminal, 5′ hydroxyl (*26*, *27*). These strategies typically rely on amide bond formation between an activated carboxylate on the probe, and an amino-terminated linker attached to the oligonucleotide. We initiated our studies with $[Rh(phi)_2(bpy')]^{3+}$ (Figure 1) as a suitable complex for these studies since the nonintercalating ligand bears the carboxylate to be used in conjugation, which should preserve the DNA-binding properties of the intercalator.

(A) Synthetic Strategy. Scheme 1 outlines the multistep, hetereogeneous coupling method we developed to tether $[Rh(phi)_2(bpy')]^{3+}$ to the 5′ terminus of oligonucleotides. In this approach, the DNA is attached to the controlled pore glass (CPG) bead used for automated DNA synthesis. There are three principal advantages to this solid-phase approach. (i) Each reaction may be driven to completion by employing an excess of reagents since any unreacted material is simply washed away. (ii) The phosphate moieties of the DNA backbone are all protected as cyanoethyl esters so the oligonucleotide is uncharged and well solvated by organic solvents. (iii) The exocyclic amines on the DNA bases are masked with acyl protective groups. Thus, for our purposes, the only reactive functionality is the 5′-OH.

We employed the method of Wachter et al. (*22*) to introduce a flexible alkyl linker onto the 5′-OH through a carbamate linkage. This reaction proceeds in >85%

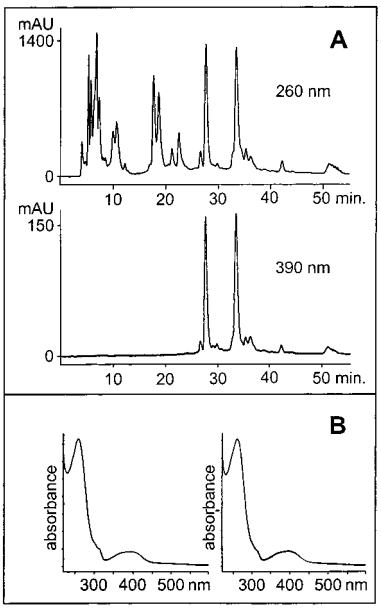

Figure 2. HPLC chromatogram of an Rh−DNA conjugate reaction mixture before purification (upper panel). UV−vis absorption spectra of the two rhodium-containing fractions at elution times of 28 min (left) and 34 min (right) (lower panel). The sequence of the oligonucleotide was as follows: 5′-Rh-ACG ATA TAC TAA CGT-3′.

yield and can be followed by reversed-phase HPLC (Supporting Information). At this stage, the oligonucleotide is poised for reaction with an electrophile.

We exploited simple, high-yield amide bond formation to tether the metal complex to the functionalized oligonucleotide on the solid support. The carboxylate of $[Rh(phi)_2(bpy')]^{3+}$ was converted to the NHS ester by treatment with TSTU. TSTU was used to synthesize an active ester with a derivative of $[Ru(phen)_3]^{2+}$ for conjugation to amino-modified DNA in solution (*28*−*30*), and in our work we favored TSTU because we could follow the activation of the carboxylate by TLC, and isolate the NHS ester for characterization. A matrix-assisted laser-desorption mass spectrum of the NHS ester of $[Rh(phi)_2(bpy')]^{3+}$ is provided in the Supporting Information.

We executed the coupling reaction by combining the solution of the NHS ester of $[Rh(phi)_2(bpy')]^{3+}$ (without isolation) and the CPG beads coated with the amino-modified DNA and stirring the slurry overnight. Owing to the tendency of the conjugate attached to the bead to be well solvated by organic solvents, we observed significant solvatochromism in the coloration of the CPG beads after the coupling reaction, which is consistent with incorporation of the transition metal chomophore.

The final step in this procedure is to liberate simultaneously the conjugate from the bead and remove the protecting groups by treatment with aqueous ammonia. The conjugates are purified by reversed-phase HPLC under the same conditions employed for purification of unmodified oligonucleotides. We estimate the yield of the coupling step to be ∼75% by comparing the amount of amino-modified DNA present (relative to the unmodified strand as an internal standard) before and after coupling. A similar procedure was employed to attach a metallointercalator containing ruthenium to the 5′ terminus of oligonucleotides in a study of long-range oxidative damage to guanine in DNA duplexes (*9*).

(B) Isolation of of 5′-Rh-Modified Oligonucleotides by HPLC. Figure 2 shows a typical chromatogram of an unpurified reaction mixture for the synthesis

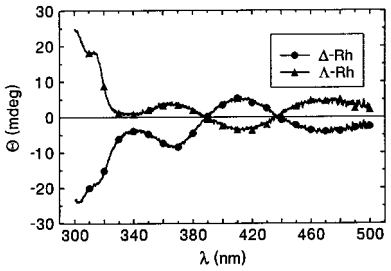

Figure 3. Circular dichroism of the two rhodium-containing products (Δ-Rh-151, Λ-Rh-151) isolated from the reaction mixture shown in Figure 2.

of 5′-Rh-modified DNA monitored at two wavelengths: 260 nm where everything in the mixture absorbs and 390 nm where only the rhodium complex absorbs. This reaction yields two products that contain rhodium. Owing to the hydrophobicity added by the metallointercalator, the conjugates elute with later retention times compared to the unmodified DNA, which simplifies their purification.

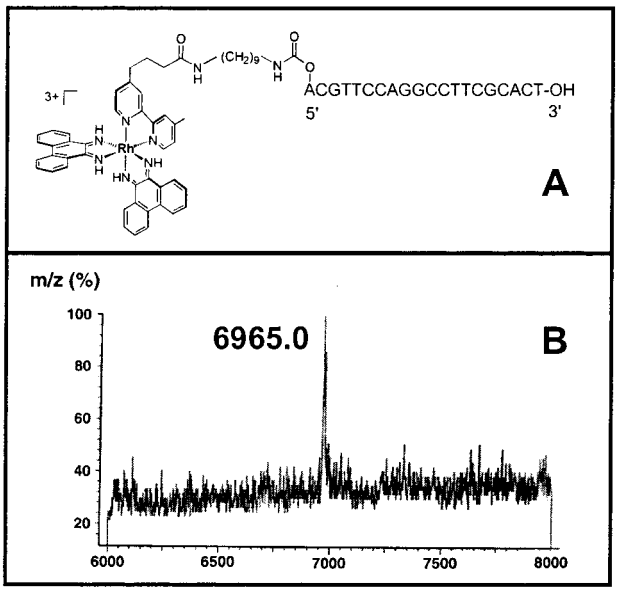
The absorption spectra of the two rhodium-containing products (Figure 2) are identical and consistent with expectation for Rh-modified DNA. The intense absorption centered at 260 nm reflects the contribution of the DNA bases, while the absorption centered at 390 nm corresponds to absorption of the metal complex. The transition centered at 390 nm is hypochromic compared to that for the metal complex free in solution. Such hypochromicity for the conjugate indicates that the metal complex interacts preferentially with the bases of the single-stranded DNA (*20*, *24*).

The HPLC chromatogram in this figure reveals several side products that do not contain a rhodium complex. Since we find that the amounts of these species vary considerably from one synthesis to the next, we suggest that they likely reflect side products and failed sequences in the DNA synthesis. It is important to note that the relative amount of these products is somewhat exaggerated by the fact that the Rh-modified DNA elutes as two peaks, so the relative height of the product peak is reduced by a factor of 2 while the height of the peaks due to the side products are constant.

(C) Circular Dichroism Spectroscopy of Rh-Modified DNA. To answer the question of why two products with identical absorption spectra are formed, we measured the circular dichroism (CD) spectra of each species (Figure 3). On the basis of the equal and opposite relationship of the spectra in this region where the metal complex absorbs and by comparison to CD spectra for the enantiomers of the parent $[Rh(phi)_2(bpy)]^{3+}$, we concluded that into one product we had incorporated the Δ enantiomer of $[Rh(phi)_2(bpy')]^{3+}$, while we introduced Λ-$[Rh(phi)_2(bpy')]^{3+}$ into the other. Remarkably, achiral HPLC was the only purification method required to separate these two diastereomeric Rh-DNA conjugates. Moreover, neither diastereomer was formed preferentially.

(D) Electrospray Ionization Mass Spectrometry of Rh−DNA Conjugates. We used electrospray ionization (ESI) MS to measure the mass of Rh-modified oligonucleotides. ESI MS can be used to confirm not only that the conjugate is intact, but also it confirms that all of the protecting groups have been eliminated (*31*).

Figure 4 shows the ESI MS of $[Rh(phi)_2(bpy')]^{3+}$ attached by a diaminononane linker to the 5′-hydroxyl of a 20 nt oligonucleotide. The data shown is a deconvoluted spectrum constructed from mass:charge (*m*/*z*) data for several charge states (*31*). The calculated mass for the



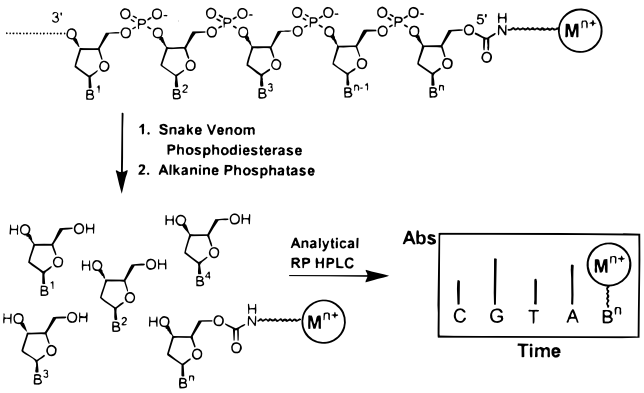


Figure 4. Electrospray ionization (ESI) mass spectrum of $[Rh(phi)_2(bpy')]^{3+}$ tethered to a 20-mer oligonucleotide. The calculated mass for this conjugate is 6964.8 amu and the observed mass is 6965.0.

Scheme 2. Schematic Illustration of the Enzymatic Digestion of Oligonucleotides by Snake Venom Phosphodiesterase To Give Nucleotide Monophosphates (NMPs)[a]

[a] Hydrolysis of NMPs by alkaline phosphatase gives the nucleotides. The 5′-terminal base remains attached to the metallointercalator because the enzymes do not hydrolyze the carbamate linkage. The products are separated by HPLC and the numbers of each base are counted.

conjugate is 6964.8, and the observed mass is 6965.0. From this spectrum we can say (i) the product is the desired conjugate and (ii) all of the protecting groups are remove upon treatment with aqueous ammonia without degredation of the metal complex or the DNA.

(E) Enzymatic Digestion of Rh-Modified DNA to Establish Base Content. To establish that covalent modification occurred at the targeted terminus as designed, we determined the base content of Rh-modified DNA and compared the results to data for unmodified DNA. The premise of this assay, outlined in Scheme 2, is to detect the modification of the 5′-terminal base. The oligonucleotide is treated with a cocktail of snake venom phosphodiesterase (SVP) and alkaline phosphatase (AP) (*32*). SVP cleaves the phosphodiester bonds of the oligonucleotide to release the nucleotide monophosphates (NMPs). AP then hydrolyzes the NMPs to give the neutral nucleotides, which are significantly more amenable to chromatographic separation. The reaction mixture is then analyzed by reversed-phase HPLC. Since the enzymes do not recognize the carbamate linkage that joins the nucleotide and the metal complex through an aliphatic linker, the modified DNA will appear to have lost one base in the HPLC analysis.

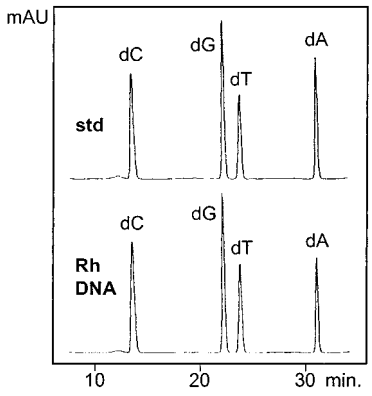

Figure 5. HPLC chromatograms monitored at 260 nm of the enzymatic digestion of an unmodified 14-mer (top) and a Rh-modified 14-mer (bottom). The area under the peak for dA is clearly reduced in the data for the conjugate. This loss of dA is consistent with the coupling of the metallointercalator to the 5′ terminus of this oligonucleotide.

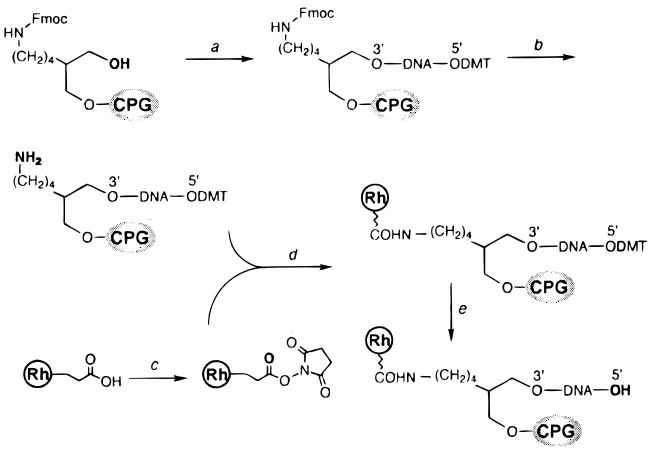

Figure 5 shows the results of the digestion of two oligonucleotides: an unmodified 14-mer and the corresponding Rh-modified 14-mer. For this conjugate, the rhodium complex is attached to a deoxyadenosine (dA). The quantity of each base, determined by integration of the chromatograms, is consistent with expectation based on the known sequence. The area under the peak corresponding to dA is clearly diminished for the conjugate compared to the unmodified strand. These results establish that the conjugation reaction is selective for the 5′ terminus and that no other bases are modified. Following the digestion, the metal complex attached to the 5′ terminal nucleoside adsorbs to the filter before analysis and therefore does not appear in the chromatogram in Figure 5.

Synthesis of Rh-Modified Oligonucleotides with the Metallointercaltor Attached to the 3′ Terminus. To generalize our method of generating metallointercalator−DNA conjugates, we developed a procedure to modify the 3′ terminus of oligonucleotides (Scheme 3). As with conjugation to the 5′-hydroxyl, this approach relies on derivatization of the strand on the CPG resin.

A commercially available CPG bead functionalized with a hydroxy aminoalkane masked with Fmoc and dimethoxy trityl (DMT) protecting groups was used as the support for automated DNA synthesis. Following selective removal of the DMT group, the DNA was synthesized by the standard phosphoramidite approach to give an oligonucleotide functionalized at the 3′ terminus with an Fmoc protected, alkylamine while the assembly remains attached to the solid support.

The amine is selectively unmasked by treatment with piperidine in DMF without affecting the protecting groups on the DNA bases or backbone (*23*). The oligonucleotide is then coupled to the NHS ester of $[Rh(phi)_2(bpy')]^{3+}$ as described for the 5′-modification strategy. Before removing the product from the bead, the DMT protecting group is removed from the 5′-hydroxyl by treatment with trichloroacetic acid in acetonitrile. Oligonucleotide conjugates prepared by this procedure are also purified by HPLC and can be resolved into the Δ- and Λ-rhodium-containing diastereomers (*33*).

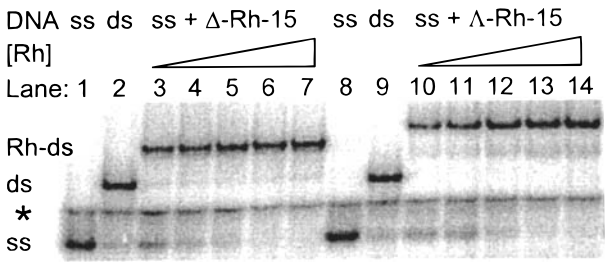

Figure 6. Nondenaturing polyacrylamide (20%) gel for following the hybridization of ^{32}P-end-labeled complement to Rh-modified DNA. Contents of lanes: (1) labeled complement (single stranded); (2) unmodified duplex (complement plus rhodium strand; 1:1); (3−7) labeled complement (8 μM) plus increasing concentrations of Δ-Rh-DNA (6, 7, 8, 9, 10 μM). Lanes 8−14 are the same as 1−7, with Λ-Rh substituted for the Δ isomer.

Characterization of Rh-Modified DNA Duplexes. (A) Monitoring the Hybridization of Rh-Modified Oligonucleotides to Their Complements by PAGE. We followed the hybridization of ^{32}P-end-labeled DNA to Rh-modified DNA on nondenaturing polyacrylamide gels (free of urea). Owing to the stiffness of duplex DNA relative to single strands, the duplexes are retarded relative to single stranded DNAs under electrophoresis on polyacrylamide gels.

Figure 6 illustrates a typical hybridization experiment for Λ-Rh-DNA and Δ-Rh-DNA (*25*). The first lane of each titration contains only the ^{32}P-end-labeled complement of the Rh-modified strand ([^{32}P]Rh-DNA-C). The second lane contains [^{32}P]Rh-DNA-C hybridized to 1 equiv of the unmodified rhodium strand. As expected for the formation of a 1:1 complex, a new band appears in the gel retarded relative to the single strand and there is no [^{32}P]-Rh-DNA-C remaining. The next five lanes contain [^{32}P]-Rh-DNA-C (8 μM) and increasing concentrations of Rh-DNA (6, 7, 8, 9, and 10 μM). As in the case of the unmodified duplex, a new band appears near the top of the gel. The intensity of this band increases with Rh-DNA until it reaches saturation at 8 μM. Similarly, the band for [^{32}P]Rh-DNA-C decreases in intensity until disappearing from the gel when the sample is fully duplexed. There is an exogenous source of radioactivity present at equal levels in the sample that is present in all lanes and migrates just above the single strand.

It is noteworthy that the Rh-modified duplexes migrate above the unmodified duplex. Such an observation is consistent with the positively charged metal complex reducing the total negative charge of the assembly and diminishing its attraction to the positive pole of the gel (*25*).

Upon comparison of migration profiles of the Δ and Λ-Rh-modified duplexes, the diastereomer containing Λ-Rh moves slower on the gel than the diastereomer containing Δ-Rh. Owing to the symmetry matching of the right-handed DNA duplex with the right-handed Δ-Rh, we expect the complex to be intercalated more deeply into the duplex than the Λ-isomer (*34*). The migration behavior observed in the gels is consistent with this notion, since a more compact structure should be less hindered by the gel, as is the duplex bearing Δ-$[Rh(phi)_2(bpy')]^{3+}$. In the lanes for duplexes with Δ-Rh, there is a faint band that migrates just ahead of the major band for the double-stranded conjugates; this species may reflect a small population of assemblies where the complex is intercalated at a site other than the predominant binding site. These experiments demonstrate that the presence of the rhodium complex does not preclude the stoichiometric formation of duplexes, and that the association of the Λ enantiomer of the metallointercalator with the duplex is different from the interactions of the Δ enantiomer.

(B) Establishing the Intercalation Site by Photocleavage in Rh-Modified DNA Duplexes. To apply Rh-modified oligonucleotides in studies of long-range charge transfer in DNA, it is critical that we know the site at which the reactants are bound to the DNA. Upon photoactivation with UV light ($\lambda \approx 313$ nm) in the presence of DNA, phi complexes of Rh(III) may abstract a hydrogen atom from the sugar residue at the base step of intercalation (*20*), which leads to direct strand scission and marks the site of intercalation. The products of the photochemical reaction with ^{32}P-labeled DNA are separated by PAGE and visualized by phosphorimagery (*25*). This experiment provides single-base resolution of the site of cleavage and permits the determination of the molecular distances that separate electron donors and acceptors during charge-transfer experiments.

Figure 7 shows the polyacrylamide gel used to reveal the site of intercalation in rhodium-modified DNA duplexes as a function of the length of the linker and the binding site. To clarify these results, the data are summarized schematically in Figure 8.

We examined photocleavage by the Δ and Λ enantiomers of $[Rh(phi)_2(bpy')]^{3+}$ tethered by diaminononane (C9) or diaminohexane (C6) linkers to a 15 base pair (bp) duplex (lanes 4−7; Figure 7). In lanes 8−11, the Rh-modified strand contains 16 nt, but it is hybridized to the 15 nt complement used for duplexes in lanes 4−7. This hybrid duplex has a thymine that extends the effective length of the linker joining the duplex and the C9 or C6 tether. These reactions were also compared to photocleavage by the parent complex $[Rh(phi)_2(dmb)]^{3+}$ (dmb = 4,4′-dimethyl bipyridine) bound noncovalently to the unmodified duplexes (lane 14). For the samples where the complex was bound noncovalently, the cleavage is distributed fairly evenly throughout the duplex, with some specificity for binding between the 5′-G(3) and 5′-A(4), as designed. In fact, the 5′-ACGA-3′ sequence was chosen to accommodate the tethered complex since this is a preferred binding sight of $[Rh(phi)_2(dmb)]^{3+}$. Cleavage by the tethered complex is only observed near the end of

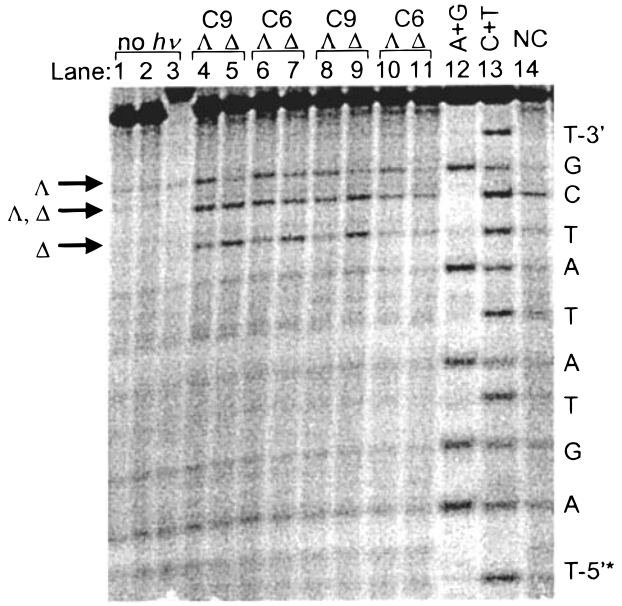

Figure 7. Phosphorimagery results depicting the products of the direct photocleavage of Rh-modified duplexes upon irradiation at 313 nm for 8 min. A schematic representation of these results is shown in Figure 8. The experiment measures the site of intercalation as a function of configuration about the metal center, linker length, and base sequence for a series of rhodium−DNA conjugates. All samples were 8 μM in duplex in 5 mM Na_3PO_4 and 50 mM NaCl, pH 7.0. The contents of each lane are as follows: **1**−**3**, 15 bp duplex, 16/15-mer hybrid duplex, 16 bp, duplex, respectively, no irradiation (dark control); **4**, **5**, Λ-Rh-15 bp duplex, and Δ-Rh-15 bp duplex with C9 linker; **6**, **7**, Λ-Rh-15 bp duplex, and Δ-Rh-15 bp duplex with C6 linker; **8**, **9**, Λ-Rh-16/15 hybrid duplex, and Δ-Rh-16/15 hybrid duplex with C9 linker; **10**, **11**, Λ-Rh-16/15 hybrid duplex, and Δ-Rh-16/15 hybrid duplex with C6 linker; **12**, **13**, Maxam−Gilbert sequencing lanes for 15-mer (A + G, 12; C + T, 13); **14**, Δ-$[Rh(phi)_2(dmb)]^{3+}$ bound noncovalently to 15 bp duplex.

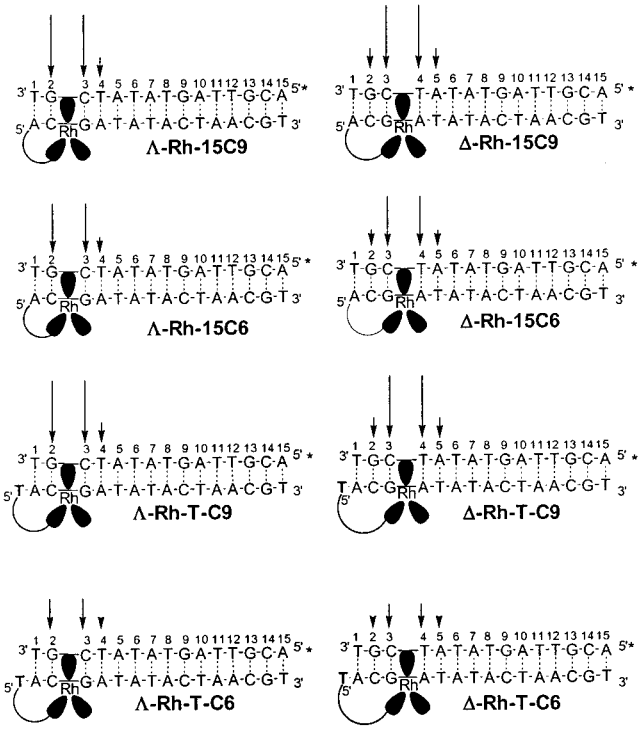

Figure 8. Summary of photocleavage of a 15 bp duplex by $[Rh(phi)_2(bpy')]^{3+}$ tethered to the 5′-ACGA terminus as indicated. The columns correspond to lane numbers in Figure 7 as follows: (left column, top to bottom) lane 4, lane 6, lane 8, lane 10; (right column, top to bottom) lane 5, lane 7, lane 9, lane 11. Arrows represent sites of cleavage and their height represents relative cleavage intensity.

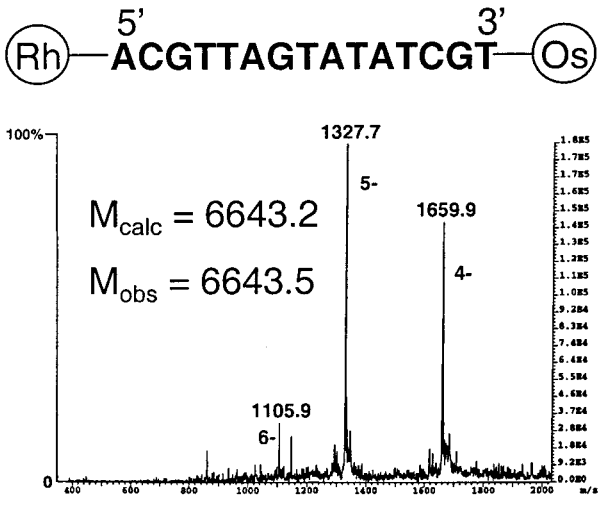

Figure 9. ESI mass spectrum of a 3′,5′-bis-heterometalated oligonucleotide. The calculated mass for the fully protonated species is M_{calc} = 6643.2. According to the distributions of ions present in the mass spectrum, the mass of the ion plus the appropriate number of hydrogens to achieve the targeted charge, leads to a mass of M_{obs} = 6643.5. This remarkable accuracy confirms that the material is the desired compound, and that all protecting groups have been removed.

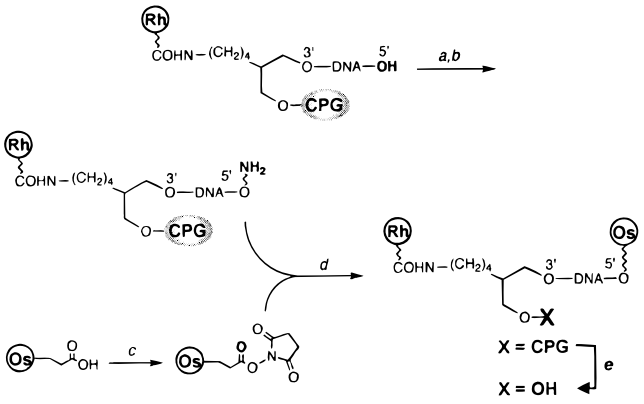

the duplex to which the metallointercalator is confined by the linker.

For modified duplexes bearing the C9 or C6 linkers, the Λ isomer binds primarily two bases in from the 5′-terminus and the Δ isomer binds three bases from the terminus. This observation has been made repeatedly for rhodium complexes tethered to the sequence 5′-ACGA-(T). In quantitative comparisons of cleavage intensities, it is apparent that there is a diminution in the amount of cleavage with the C6 linker, suggesting that this linker might not be long enough to permit efficient access of the preferred binding site. The presence of the overhanging thymine in the hybrid duplexes (Rh-16-mer hybridized to a 15 nt complement) does not seem to affect the site of intercalation, but the cleavage intensity does appear to decrease.

Synthesis of 3′,5′-bis-Hetereometalated Oligonucleotides. Scheme 3 outlines the preparation of oligonucleotides with a metallointercalator attached to the 3′-hydroxyl group. Over the course of these reactions, the 5′-hydroxyl is protected as the DMT ether (*19*). The last steps in that procedure involve deprotection of the 5′-hydroxyl group and liberation of the conjugate from the resin. We recognized that if we unmasked the 5′-hydroxyl of the 3′-modified oligonucleotide, left on the resin, we would be free to functionalize the 5′-hydroxyl as well (*26*, *27*). We could synthesize oligonucleotides that contain an electron donor, for example, at one terminus and an electron acceptor at the other.

We developed the strategy in Scheme 4, which permits the synthesis of so-called 3′,5′-bis-heterometalated oligonucleotides. The first phase of the synthesis consists of incorporating a metallointercalator onto the hydroxy aminoalkyl linker tethered to the 3′ terminus of the oligonucleotide according to the procedure developed for preparing 3′-modified DNA. Next, the DMT protecting group is removed from the 5′ hydroxyl by treatment with trichloroacetic acid in CH_2Cl_2. After coupling the appropriate diaminoalkyl linker to the 5′ hydroxyl, the second metallointercalator is coupled to the free amine

Scheme 4. Synthesis of 3′,5′-bis-Heterometallated Oligonucleotides on a Solid Support[a,b]

[a] Reagents: (a) CDI, dioxane, 30 min, rt; (b) $H_2N(CH_2)_9NH_2$, dioxane/H_2O (9:1), 25 min, rt; (c) TSTU, DIEA, CH_3OH, CH_3CN, CH_2Cl_2 (1:1:1), rt, 1 h; (d) heterogeneous coupling, DIEA, rt, 12 h; (e) NH_3(aq), 60 °C, 6 h. [b] Abbreviations: CPG = controlled pore glass; Os = $[Os(phen)(bpy')(Me_2\text{-}dppz)]^{2+}$.

according to the procedure established for modification of the 5′ terminus. Finally, the whole assembly is liberated from the conjugate and deprotected by treatment with NH_3(aq), and isolated by HPLC.

We executed this procedure to validate our method and isolated one major product. It is important to note that using racemic mixtures of each metallointercalator gives rise to eight possible isomers of the 3′,5′-bis-heterometalated oligonucleotide. The ESI MS of the product isolated in this reaction is shown in Figure 9. This methodology will be important in the application of DNA-mediated electron transfer for metallointercalator-DNA conjugates in sensing technology.

SUMMARY AND CONCLUSIONS

We have established methods to prepare oligonucleotides bearing metallointercalators on either the 5′, 3′, or both 5′ and 3′ termini. The procedures are based on a solid-phase approach in that the conjugates are prepared while the oligonucleotide is immobilized on the CPG bead used in automated DNA synthesis. This approach is attractive for three reasons: (i) excess reagents that drive reactions to completion can be easily washed away from the solid support following reactions; (ii) the phosphate groups are protected so the oligonucleotide is uncharged and well solvated; and (iii) all exocyclic amines on the DNA bases are protected so the only reactive functionality present is the desired point of attachment.

These protocols all provide a means to synthesize, in high, reproducible yields, a variety of conjugates that vary in the DNA sequence of the oligonucleotide as well as the length of the linker used to join the two species. We employed several methods to characterize the materials and establish the chemical composition of the conjugates as well as their ability to form duplexes with their complementary strands and the site of intercalation for the metallointercalator.

The methodology described in this paper has now been employed to prepare metallointercalator−DNA conjugates for investigations of the fundamental properties of DNA as a medium for charge transfer. Rh-modified oligonucleotides have been employed to demonstrate long-range oxidative DNA damage to 5′-GG-3′ sites (*8*), as well as to examine the effect of intervening bulges in the base stack (*35*). We have used Rh-modified DNA to effect the long-range repair of thymine-dimer lesions in DNA (*33*), and to compare long-range charge-transfer reactions in duplexes with 5′-GG-3′ and thymine dimer sites to those with either 5′-GG-3′ or thymine dimers (*36*). This work established for the first time that DNA damage and repair chemistry can be initiated from a remote site. Rh-DNA conjugates have also been useful, along with ethidium-modified DNA to characterize DNA-mediated electron-transfer chemistry using photophysical techniques (*37*). For future applications, these conjugates, including the 3′,5′-bis-heterometalated oligonucleotides, may provide the basis for developing novel DNA-based sensor technologies based on charge-transfer reactions involving the DNA base stack.

ACKNOWLEDGMENT

We are grateful to the NIH for their financial support. We also thank the Parsons Foundation (R.E.H.) and the Damon-Runyon Walter Winchell Cancer Fund (P.J.D.) for fellowship support.

Figure S1. (**A**) Schematic illustration of the N-hydroxysuccinimidyl (NHS) ester of $[Rh(phi)_2(bpy')]^{3+}$. (**B**) Matrix assisted laser desorption ionization (MALDI) time of flight (TOF) mass spectrum of $[Rh(phi)_2(bpy'\text{-}NHS)]^{3+}$.

Figure S2. HPLC chromatograms of an unmodified (upper trace) and an aminoalkylated (lower trace) 15-mer monitored at 260 nm. HPLC Conditions: C18 stationary phase; 50 mM ammonium acetate, pH 6.5/acetonitrile mobile phase; 0-15 % acetonitrile in 30 min. The aminoalkylated DNA shows a later retention time, consistent with increased hydrophobicity introduced by the linker.

Figure S3. HPLC chromatograms for the 3',5'-*bis*-heterometallated oligonucleotide pictured in Figure 9 monitored at 260 nm (top), 390 nm (middle), and 470 (nm) bottom. The 3',5'-*bis*-heterometallated oligonucleotide is the major product, and all eight diastereomers of this material coelute. HPLC Conditions: C18 stationary phase; 50 mM ammonium acetate, pH 6.5/acetonitrile mobile phase; 0-50 % acetonitrile in 75 min.

Synthesis and Biological Activity of Ribose-5′-Carbamate Derivatives of Vitamin B_{12}

J. F. McEwan,* H. S. Veitch, and G. J. Russell-Jones

Biotech Australia Pty Ltd., P.O. Box 20, Roseville, NSW 2069, Australia. Received June 23, 1999; Revised Manuscript Received August 23, 1999

Twelve biologically active derivatives of vitamin B_{12} (cyanocobalamin) have been synthesized in which spacers were attached to the ribose-5′-hydroxyl group of vitamin B_{12}. Their potential to act as oral delivery agents for proteins, nanospheres, or immunogens using the vitamin B_{12} uptake system was evaluated by determining their affinity for intrinsic factor (IF) and non-IF. The ribose-5′-hydroxyl group of vitamin B_{12} was activated through the use of 1,1′-carbonyldiimidazole (CDI), 1,1′-carbonyldi-(1,2,4-triazole) (CDT), or di(1-benzotriazolyl) carbonate (DBTC). Subsequent addition of an aminoalkane, diaminoalkane, or alkane diacid dihydrazide gave rise to vitamin B_{12} derivatives suitable for attachment to various proteins, peptides, or nanospheres to enable oral delivery utilizing the vitamin B_{12} uptake system. The ribose-5′-carbamate derivatives were found to possess similar affinity for intrinsic factor as that of the *e*-monocarboxylic acid of vitamin B_{12}. The affinity for non-IF was similar to cyanocobalamin or even higher for some of the smaller derivatives. Polysciences nanoparticles derivatized with vitamin B_{12} 5′-carbamate adipic dihydrazide into CaCo-2 cells showed significantly higher levels of transport of the particles, when compared to unmodified particles.

INTRODUCTION

The vitamin B_{12} uptake system possesses enormous potential as an absorption enhancing mechanism for orally administered proteins, peptides, and immunogens (*1*). Oral delivery of proteins, peptides, and immunogens is very inefficient due to the impenetrable barrier composed of the cells of the intestinal epithelium and because of proteolysis within the stomach and small intestine. Recent experiments on oral protein delivery have focused on the use of carrier molecules, such as lectins, bile salts, or vitamin B_{12} **1**, which are conjugated to the drug of choice, to utilize the receptor mediated endocytosis of the carrier molecule to provide co-absorption of the drug (*2*). Thus, Russell-Jones and co-workers have utilized this methodology in the generation of orally active conjugates of granulocyte colony stimulating factor (G-CSF), erythropoietin (EPO) (*3*), and luteinizing hormone releasing hormone (LHRH) (*4*) with vitamin B_{12}. Thus, intraduodenal infusion of the VB_{12}-G-CSF conjugates in rats resulted in highly elevated plasma levels of the conjugated protein (299 ± 160 ng/mL) as compared to nonconjugated G-CSF (1.94 ± 1.94 pg/ mL) (*5*). Similarly, the quantity of EPO reaching the systemic circulation when administered as a VB_{12} conjugate was 4-fold greater than the nonconjugated EPO. Conjugation to VB_{12} also seemed to reduce the susceptibility for proteolysis. Oral administration to rats of low doses of a D-Lys_6-ethylamide analogue of LHRH had no effect on serum LH levels, whereas administration of a conjugate with VB_{12} resulted in 20−45% systemic bioavailability, depending on the spacer used (*4*).

The above three examples all involved the attachment of spacers to the vitamin B_{12} *e*-monoacid. This molecule possesses 10-fold higher affinity for intrinsic factor (IF) and for transcobalamin II (TCII) than the alternative *b*- and *d*-monoacids (*6*). There are several other sites on vitamin B_{12} that are suitable for modification to form bioconjugates (*6*). The most readily derivatized position on vitamin B_{12} is the Co metal center; however, the bond so formed is photolabile (*7*, *8*). Conjugation can also occur through the 5′- and 2′-hydroxyl groups on the ribose moiety, the phosphate group, or through the use of appropriately substituted benzimidazoles. The work described herein concentrates on conjugation with the 5′-hydroxyl group of the ribose moiety.

Previous studies have examined the attack by the 5′-hydroxyl group on an acid anhydride, namely succinic anhydride (*9*) or glutaric anhydride (*10*), to provide a four or five carbon spacer possessing carboxylic acid functionality. While these derivatives were obtained in high yield, the methodology employed necessarily limits this procedure to the few anhydrides available. The route followed in this work examines the preactivation of the 5′-hydroxyl group on the ribose by the use of a reagent such as 1,1′-carbonyldiimidazole (CDI), 1,1′-carbonyldi(1,2,4-triazole) (CDT), or di(1-benzotriazolyl) carbonate (DBTC) followed by attack of a nucleophile to furnish the desired spacer. In particular, aminoalkanes, diaminoalkanes, and alkane diacid dihydrazides were employed as nucleophiles. Upon derivatization of the 5′-hydroxyl group, VB_{12} has been shown to retain most of its binding affinity for transcobalamin II (TCII) (*6*) whereas a marked decrease in affinity for diol dehydrase has been observed (*9*, *11*). Also, the 5′-succinic acid derivative did not inhibit the uptake of [^{13}H]cyanocobalamin by *Escherichia coli* (*9*). This work examines the binding affinity of the 5′-carbamate derivatives for non-IF (haptocorrin) (*12*) and IF and also the uptake and transport of nanoparticles, modified with various derivatives, by CaCo-2 cells.

EXPERIMENTAL PROCEDURES

Melting points were determined using an Electrothermal melting point apparatus and are uncorrected. Mass

spectra were recorded on a Mat LCQ detector using ESI with water/methanol (1:1) as solvent at 5 kV and a capillary temperature of 200 °C. Thin layer chromatography (TLC) was carried out on Merck precoated aluminum sheets coated with 0.2 mm silica gel 60 F_{254} and flash chromatography on Merck silica gel 60 (230−400 mesh ASTM). High-performance liquid chromatography (HPLC) was performed using Waters and Associates HPLC instrumentation fitted with a Waters μBondapak C18 column for **2**, **3**, and **7**−**15** and a Vydac 214TP C4 column for **4**, **5,** and **6**. All VB_{12} derivatives were purified to >95% purity as determined by analytical HPLC using a Waters 991 photodiode array detector. Products were eluted, after loading at 5% MeCN containing 0.1% TFA, using a gradient system at 1 mL/min comprising linear gradients to 18% MeCN at 2 min, 28% MeCN at 8.5 min, and 100% MeCN at 13 min.

General Procedure for Preparation of Alkane Derivatives. Solid 1,1′-carbonyldiimidazole (CDI, 260 mg) was added to cyanocobalamin (1.0 g, 0.74 mmol) previously dissolved in dimethyl sulfoxide (12 mL) at 30 °C, and the mixture was stirred for 25 min. Alkylamine (2.7 mmol) was added in one portion and stirring continued for a further for 24 h at room temperature. The mixture was extracted with phenol/dichloromethane (1:1, 2 × 20 mL) and back extracted with water (2 × 20 mL from 1:4 phenol/dichloromethane). The mixture was purified by phenyl sepharose (50 g) column chromatography, eluting the unmodified VB_{12} with 25% ethanol and the product with 60% ethanol. The solvent was removed at reduced pressure and the residue was sonicated for 5 min in acetone (50 mL). The mixture was filtered and the solid washed with acetone and air-dried.

Hexylamine derivative (**2**): yield, 60%; mp 213-215 °C (dec); MS (ESI) mass calcd for $C_{70}H_{101}N_{15}O_{15}CoP$ 1482, found 1505 $(M + Na)^+$; UV (H_2O) λ_{361} ($\epsilon = 10\,500$), HPLC retention time 16.0 min.

Dodecylamine derivative (**3**): yield, 52%; mp 215−218 °C (dec); MS (ESI) mass calcd for $C_{76}H_{113}N_{15}O_{15}CoP$ 1566, found 1589 $(M + Na)^+$; UV (H_2O) λ_{361} ($\epsilon = 16\,900$), HPLC retention time 19.6 min.

Tetradecylamine derivative (**4**): yield, 46%; mp 228−233 °C (dec); MS (ESI) mass calcd for $C_{78}H_{119}N_{15}O_{15}CoP$ 1595, found 1618 $(M + Na)^+$; UV (H_2O) λ_{361} ($\epsilon = 13\,000$), HPLC retention time 18.0 min.

Hexadecylamine derivative (**5**): yield, 48%; mp 223−227 °C (dec); MS (ESI) mass calcd for $C_{80}H_{121}N_{15}O_{15}CoP$ 1623, found 1646 $(M + Na)^+$; UV (H_2O) λ_{361} ($\epsilon = 20\,000$), HPLC retention time 18.4 min.

Octadecylamine derivative (**6**): yield, 66%; mp 220−223 °C (dec); MS (ESI) mass calcd for $C_{82}H_{125}N_{15}O_{15}CoP$ 1651, found 1674 $(M + Na)^+$; UV (H_2O) λ_{361} ($\epsilon = 17\,500$), HPLC retention time 18.8 min.

General Procedure for Preparation of Aminoalkane Derivatives. Solid 1,1′-carbonyldiimidazole (CDI, 260 mg) was added to cyanocobalamin (1.0 g, 0.74 mmol) previously dissolved in dimethyl sulfoxide (12 mL) at 30 °C, and the mixture stirred for 25 min. Diaminoalkane (2.7 mmol) was added in one portion, and the mixture stirred for 24 h at room temperature. The mixture was poured into ethyl acetate (30 mL) and left to stand. The supernatant was decanted and the residue sonicated for 5 min in acetone (50 mL). The resultant precipitate was filtered, and the solid washed with acetone. The product was purified by column chromatography (2-propanol 45%, *n*-butanol 30%, ammonia 2%, water 25%) then lyophilyzed.

1,2-Diaminoethane derivative (**7**): yield, 63%; mp 206−210 °C (dec); TLC (^{i}PrOH 30/*n*-BuOH 45/H_2O 25/NH_4OH 2) $R_f = 0.22$; MS (ESI) mass calcd for $C_{66}H_{94}N_{16}O_{15}CoP$ 1441, found 1441 $(M)^+$; UV (H_2O) λ_{361} ($\epsilon = 19\,900$), HPLC retention time 14.7 min.

1,4-Diaminobutane derivative (**8**): yield, 70%; mp 242−244 °C (dec); TLC (^{i}PrOH 30/*n*-BuOH 45/H_2O 25/NH_4OH 2) $R_f = 0.08$; MS (ESI) mass calcd for $C_{68}H_{98}N_{16}O_{15}CoP$ 1469, found 1469 $(M)^+$; UV (H_2O) λ_{361} ($\epsilon = 15\,500$), HPLC retention time 14.9 min.

1,6-Diaminohexane derivative (**9**): yield, 98%; mp 230−233 °C (dec); TLC (^{i}PrOH 30/*n*-BuOH 45/H_2O 25/NH_4OH 2) $R_f = 0.11$; MS (ESI) mass calcd for $C_{70}H_{102}N_{16}O_{15}CoP$ 1497, found 1497 $(M)^+$; UV (H_2O) λ_{361} ($\epsilon = 17\,000$), HPLC retention time 15.4 min.

1,12-Diaminododecane derivative (**10**): yield, 68%; mp 156−158 °C (dec); TLC (^{i}PrOH 30/*n*-BuOH 45/H_2O 25/NH_4OH 2) $R_f = 0.27$; MS (ESI) mass calcd for $C_{76}H_{114}N_{16}O_{15}CoP$ 1581, found 1581 $(M)^+$; UV (H_2O) λ_{361} ($\epsilon = 33\,000$), HPLC retention time 18.4 min.

General Procedure for Preparation of Hydrazidyl Derivatives. Solid 1,1′-carbonyldi(1,2,4-triazole) (CDT, 90 mg) was added to a solution of cyanocobalamin (500 mg, 0.37 mmol) in dimethyl sulfoxide (6 mL) at 30 °C, and the mixture stirred for 25 min. Acid dihydrazide (0.74 mmol) was added in one portion followed by triethylamine (100 μL), and the mixture stirred for a further 24 h at room temperature. The mixture was poured into ethyl acetate (30 mL) and left to stand. The supernatant was poured off and the residue sonicated for 5 min in acetone (20 mL). The mixture was filtered and the solid washed with acetone. The product was purified by RP HPLC then lyophilized.

Succinic dihydrazide derivative (**11**): yield, 68%; mp 206−208 °C (dec); TLC (^{i}PrOH 30/*n*-BuOH 45/H_2O 25/NH_4OH 2) $R_f = 0.36$; MS (ESI) mass calcd for $C_{68}H_{96}N_{18}O_{17}CoP$ 1581, found 1581 $(M)^+$; UV (H_2O) λ_{361} ($\epsilon = 15\,700$), HPLC retention time 11.8 min.

Adipic dihydrazide derivative (**12**): yield, 73%; mp 208−210 °C (dec); TLC (^{i}PrOH 30/*n*-BuOH 45/H_2O 25/NH_4OH 2) $R_f = 0.33$; MS (ESI) mass calcd for $C_{70}H_{100}N_{18}O_{17}CoP$ 1555, found 1555 $(M)^+$; UV (H_2O) λ_{361} ($\epsilon = 21\,100$), HPLC retention time 14.3 min.

Preparation of Gly Acid Derivative. Cyanocobalamin (1.0 g, 0.74 mmol) and 1,1′-carbonyldiimidazole (CDI, 260 mg) were added sequentially to dimethyl sulfoxide (12 mL) at 30 °C, and the mixture was stirred for 25 min. OMe-Gly (2.7 mmol) was added in one portion followed by triethylamine (200 μL), and the mixture stirred for 24 h at room temperature. The mixture was poured into ethyl acetate (30 mL) and left to stand. The supernatant was poured off, and the residue sonicated for 5 min in acetone (50 mL). The mixture was filtered, and the solid **13** washed with acetone. The residue was then dissolved in 0.1 M NaOH solution and stirred for 30 min. The crude acid was then purified on Dowex 1 × 4 resin eluting with 2% acetic acid.

Gly-acid derivative (**14**): yield, 95%; mp 239−242 °C (dec); TLC (^{i}PrOH 30/*n*-BuOH 45/H_2O 25/NH_4OH 2) $R_f = 0.41$; MS (ESI) mass calcd for $C_{66}H_{90}N_{15}O_{17}CoP$ 1456, found 1456 $(M)^+$; UV (H_2O) λ_{361} ($\epsilon = 19\,800$), HPLC retention time 15.3 min.

Binding of Cobalamin Derivatives with IF and Non-IF. A stock solution of [^{57}Co]VB_{12} was prepared containing 1 ng of [^{57}Co]VB_{12} and 250 ng of cold VB_{12} in 25 mL buffer (1 mg/mL BSA in 0.1 M potassium phosphate buffer, pH 7.5). A total of 100 μL of dilutions of cobalamin, or cobalamin analogues (in 10-fold dilutions from 10 μg to 0.1 ng) were added to 100 μL aliquots of [^{57}Co]VB_{12} solution. A total of 100 μL of a 10 IU/mL solution of porcine intrinsic factor (Sigma) was added and

the tubes incubated for 20 min. A total of 200 μL of a charcoal suspension (2.5% charcoal/0.5% BSA/pH 7.5) was then added, and the tubes were vortexed and centrifuged at 5000 rpm for 5 min. The amount of radioactivity in each fraction was determined in a γ-counter, and the 50% binding inhibition values were calculated for each derivative. A similar procedure was used for the non-IF binding study, in which non-IF (porcine gastric mucosa, Sigma) was substituted for IF in the above method.

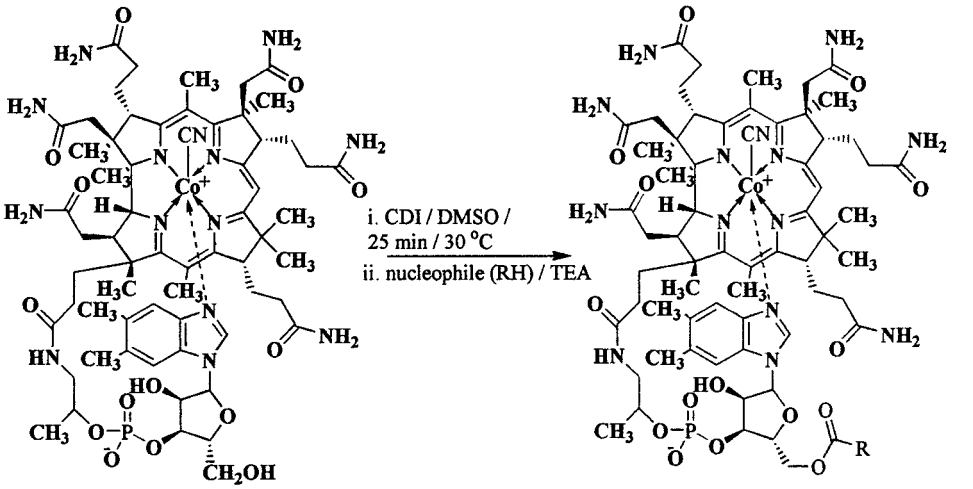
Polysciences Particle Derivatives. To 1 mL of Polysciences YG 50 nm particles (25 mg/mL) was added adipic dihydrazide cobalamin derivative (10 mg) followed by 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDAC, 16 mg), and the mixture was stirred for 4 h. Glycine (100 mg) in 1 mL of 50 mM sodium carbonate solution was added, and the mixture stirred overnight. The nanoparticles were precipitated using 1.0 M $CaCl_2$ (300 μL) followed by centrifugation at 10 K for 5 min. The final pellet was resuspended in 1 M EDTA (1 mL) and rewashed three times. The pellet was resuspended in 1 M EDTA (1 mL) and dialyzed vs water overnight.

Cell Transport Studies. The Caco-2 cell line was obtained from the American Type Culture Collection. Cells were grown in Dulbecco's modified Eagle's medium (DMEM) containing 4.5 g/L glucose and 10% foetal bovine serum in an atmosphere of 5% CO_2. For transport experiments, cells were grown in T75 flasks until 80−100% confluent. Following washing with PBS, adherent cells were removed by treatment with 10 μg/mL trypsin in 10 mM EDTA. Cells were immediately diluted 15-fold into fresh culture medium and counted. Cultures were seeded at $(0.5-1.0) \times 10^5$ cells/mL in 24 well/plate transwells (Costar) and grown for 12−24 days. Costar transwells had a membrane insert size of 6.5 mm and a pore size of 0.4 μM, with an apical chamber volume of 0.25 mL and a basal chamber volume of 1 mL. Cells generally reached confluence within 10 days. Transepithelial resistance (TEER) measurements were made of monolayers and only cultures with greater than 250 ohms/cm^2 were used for experimentation. Prior to nanoparticle experiments, all cell cultures were checked for VB_{12} transport.

[^{57}Co]VB_{12} uptake experiments were conducted on 18−19 day old cultures. Briefly, medium was removed from both the apical and basal chamber, and then 1 mL of medium was added to the basolateral chambers. Cells in the apical chamber were washed once with PBS and a solution containing 2 μL of [^{57}Co]VB_{12}, 1 ng of cold VB_{12}, and 2 IU of IF in medium was added per apical well (250 μL). Cells were incubated overnight at 37 °C, and then apical and basal medium was removed and counted. Cells were washed once with PBS and fresh medium was added to the apical and basolateral wells. Cells were incubated overnight and the medium again removed and counted.

Preparation of VB_{12}-Modified Polysciences Nanoparticles. Fluorescent YG nanoparticles were obtained from Polysciences. These nanoparticles contain a fluorescein-like fluorophore and have surface carboxylic acids groups suitable for chemical modification and VB_{12}-derivatization. Unwashed Polysciences nanoparticles were modified with VB_{12} by activation with EDAC in the presence of **12** or an adipic dihydrazide derivative of eVB_{12} (*5*). Following derivatization, unreacted, EDAC-modified carboxyl groups were blocked by incubation with 50 mg/mL glycine in 0.1 M carbonate buffer, pH 9.5. Nanoparticles were washed 5 times by precipitation with 0.1 M $CaCl_2$, centrifugation (5′, 5K), and resuspension in 50 mM EDTA. After the fifth wash, the particles were dialyzed extensively against distilled water. Particles were analyzed for VB_{12} loading using visible absorption spectroscopy. Adipic eVB_{12} particles were coated at 11.5 μg of VB_{12}/mg particle and adipic 5′-VB_{12} particles were coated at 7.8 μg VB_{12}/mg particle.

Binding/Uptake and Transport of Nanoparticles by Caco-2 Cells. Apical and basal chambers of Caco-2 cell cultures (22−24 day old) which were shown to be positive for [^{57}Co]VB_{12} transport were washed once with buffer (PBS) and the basolateral wells were refed with 1 mL of complete medium. Dilutions of fluorescent Polysciences nanoparticles (0.25 mL) were added to the apical chamber of triplicate wells, and the cultures were incubated at 37 °C overnight. VB_{12}-coated particles, prepared as described previously, were then added to the wells.



Following overnight incubation, apical and basal medium was removed from the wells and the cells washed with PBS (three times). The apical and basal chambers were assayed for bound, internalized, membrane associated, and transported fluorescence. Bound fluorescence was assessed by measuring the fluorescence release following incubation of the cultures with 5 mM EDTA, pH 5.0, for 15 min to release receptor-bound IF−VB_{12} or IF−VB_{12} nanoparticle complexes. Internalized fluorescence was determined following EDTA treatment (surface bound) and lysis of the cells by incubation with a solution of 2% SDS and 50 mM EDTA, pH 8.0, for ≥30 min at room temperature. Finally, the membrane inserts were excised from the transwell, and the fluorescence associated with the filter was assessed by lysis of the nanoparticles with 50% acetone to release the entrapped fluorochrome. All samples were adjusted to pH 8.0 with 1 M Tris·HCl, pH 9.0, prior to fluorescence measurement. Fluorescence was measured on a Bio-Tek Instruments Microplate Fluorescence Reader (FL500) at Ex_{485nm} and Em_{530nm} for YG nanoparticles. Data are expressed as the percentage of the total fluorescence added to the wells.

RESULTS AND DISCUSSION

Preparation of Cobalamin Derivatives. It was found that derivatives of vitamin B_{12} could readily be formed by first activating the ribose-5′-hydroxyl group using 1,1′-carbonyldiimidazole (CDI), 1,1′-carbonyldi-(1,2,4-triazole) (CDT), or di(1-benzotriazolyl) carbonate (DBTC) in dimethyl sulfoxide followed by addition of a nucleophile (Scheme 1). Use of hexylamine as nucleophile afforded **2** in 28% with DBTC, in 42% with CDI, and in 95% with CDT. Although CDT was found to be the most effective activating reagent, the cheaper CDI gave satisfactory yields of most derivatives made.

This functionalization of vitamin B_{12} is particularly useful in that a large variety of nucleophiles can potentially be employed to furnish novel cobalamin derivatives. In this work, alkylamines, diaminoalkanes, and acid dihydrazides were used as nucleophiles to provide a carbamate linkage to the cobalamin. Carbamates are only poorly cleaved by esterases; thus, the derivatives are stable in vivo. They are also suitable for oral delivery of drugs/proteins as the carbamate functionality is not cleaved in the stomach, being stable at pH 1 (>99% stability at 5 h). The derivatives are not stable, however, in a basic environment above pH 12 (71% stability at pH 13 after 2 h, compared with >98% stability at pH 12 after 5 h). We envisage that a carbonate linkage would be suitable in instances where a cleavable linkage is required as carbonates are more rapidly hydrolyzed by esterases and analogous carbonates could be prepared using the carbamate methodology developed here.

Competitive Binding with IF and Non-IF. The cobalamin derivatives were evaluated for their binding to IF and non-IF in a competitive assay that measures the binding relative to cyanocobalamin. For use of the derivatives as oral delivery agents of proteins, peptides, and nanospheres, a high affinity for IF and non-IF is essential. A higher affinity for IF than the more commonly applied *e*-VB_{12} monoacid (30% or 3.3 pmol) would be desirable. The results of the binding studies are given in Figures 1−3 and summarized in Tables 1 and 2.

The smaller derivatives can be seen to retain much of the binding affinity for IF, particularly the 1,2-diaminoethane (45% or 2.2 pmol) and adipic dihydrazide (48% or 2.1 pmol) derivatives. A trend is observed in the alkylamine derivative series in that binding affinity decreases with increasing chain length. Nevertheless, high affinity is conserved until alkyl chains greater than C12 (dodecylamine) are used and the reduced IF affinity with longer chain length is most likely an artifact of the increased hydrophobicity. This is indicated by high IF affinities for lengthy conjugates determined in previous work (*3*). These levels of IF binding are similar in most cases to the *e*-monoacid cobalamin derivative (3.3 pmol) and are significantly higher than the *b*-monoacid (∼1% or ∼100 pmol) or the *d*-monoacid (∼0.1% or ∼1000 pmol).

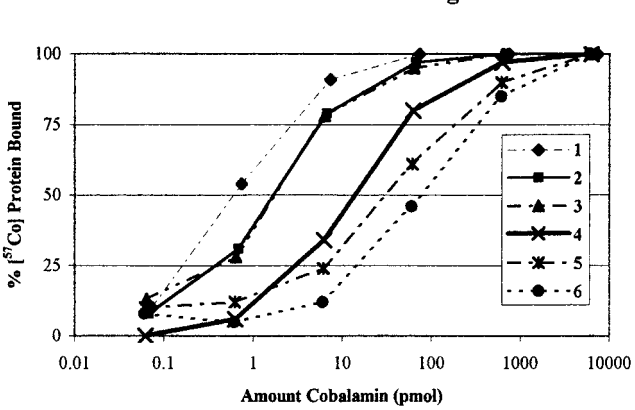

Figure 1. IF binding curve for alkylamine derivatives **2**−**6**. To obtain the data, a quantity of IF that would bind approximately 1 pmol of VB_{12} was mixed with 1 pmol of [^{57}Co]-VB_{12} and 0.01−10000 pmol of unmodified VB_{12} or VB_{12} derivative. The mixture was diluted with BSA/phosphate buffer and incubated at room temperature for 20 min. Free VB_{12} was adsorbed onto BSA-coated charcoal, and the protein-bound radioactivity in the supernatant fraction was measured.

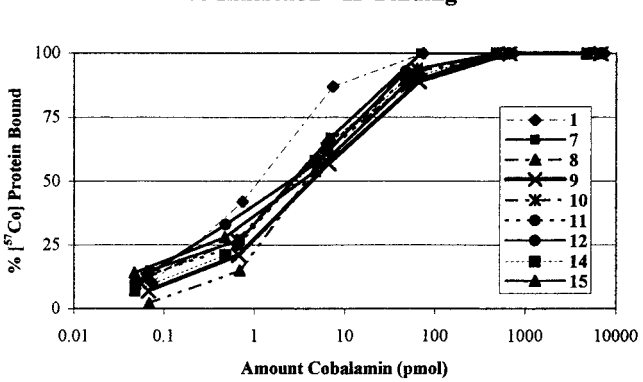

Figure 2. IF binding curve for cobalamin derivatives **7**−**15**. To obtain the data, a quantity of IF that would bind approximately 1 pmol of VB_{12} was mixed with 1 pmol of [^{57}Co]-VB_{12} and 0.01−10000 pmol of unmodified VB_{12} or VB_{12} derivative. The mixture was diluted with BSA/phosphate buffer and incubated at room temperature for 20 min. Free VB_{12} was adsorbed onto BSA-coated charcoal, and the protein-bound radioactivity in the supernatant fraction was measured.

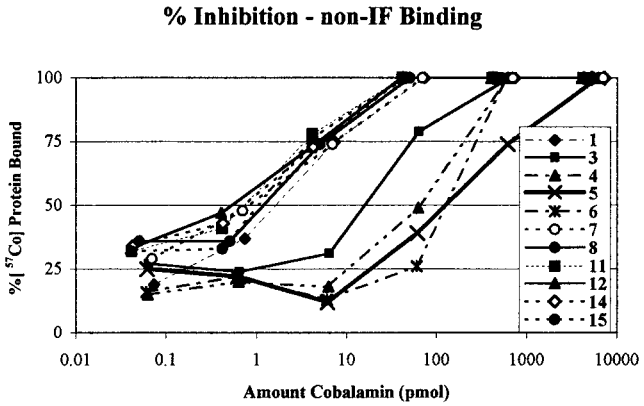

Figure 3. non-IF binding curve for cobalamin derivatives. To obtain the data, a quantity of non-IF that would bind approximately 1 pmol of VB_{12} was mixed with 1 pmol of [^{57}Co]-VB_{12} and 0.01−10000 pmol of unmodified VB_{12} or VB_{12} derivative. The mixture was diluted with BSA/phosphate buffer and incubated at room temperature for 20 min. Free VB_{12} was adsorbed onto BSA-coated charcoal, and the protein-bound radioactivity in the supernatant fraction was measured.

Table 1. Binding of VB_{12} Derivatives with IF Relative to Cyanocobalamin

derivative	50% binding inhibition for [^{57}Co]VB_{12}[a]	% relative IF binding[b]
1	1	100
2	2.8	36
3	2.9	34
4	22	4.5

7	2.2	45
8	3.3	30
9	3.8	26
10	2.3	43
11	2.4	42
12	2.1	48
14	2.5	40
15	2.8	36

[a] The binding inhibition quantity is that amount (pmol) of cobalamin derivative required to inhibit by 50% the binding of 1 pmol of [^{57}Co]VB_{12}. [b]The relative IF binding value (percent) is obtained by dividing 100 by the 50% binding inhibition quantity.

Table 2. Binding of VB_{12} Derivatives with Non-IF Relative to Cyanocobalamin

derivative	50% binding inhibition for [^{57}Co]VB_{12}[a]	% relative non-IF binding[b]
1	1	100
3	10	10
4	42	2.4
5	83	1.2
6	84	1.2
7	0.78	128
8	0.9	111
11	0.72	139
12	0.54	185
14	0.75	133
15	0.9	111

[a] The binding inhibition quantity is that amount (pmol) of cobalamin derivative required to inhibit by 50% the binding of 1 pmol of [^{57}Co]VB_{12}. [b]The relative Non-IF binding value (percent) is obtained by dividing 100 by the 50% binding inhibition quantity.

Since the yield of *e*-monoacid is low (∼6%), we therefore suggest that the ribose-5′-carbamate derivatives of cobalamin should be used for the production of bioconjugates for oral delivery in preference to a monoacid derivative.

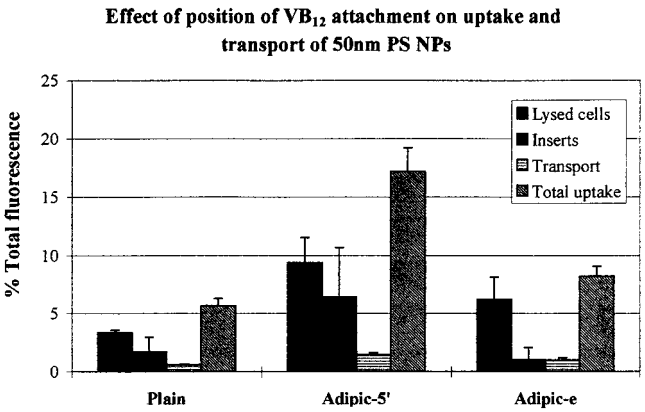

Figure 4. Uptake and transport of cobalamin derivatives in Caco-2 cells. To obtain the data, 625 μg of Polysciences nanoparticles coated with 625 ng VB_{12} were added to a monolayer of Caco-2 cells in 12 mm COSTAR Transwells (0.3 μm pore size) in triplicate. Cells were incubated with the particles overnight. The apical solution was removed, and the cell layer washed with PBS. The cell layer was lysed with SDS, and the inserts excised. The amount of nanoparticles present in the lysed cell layer, the inserts, and the basal chamber was determined by fluorescence measurement. Total uptake was calculated as the sum of all internalized and transported material.

Further, the shorter derivatives prepared possessed similar or even greater affinity for non-IF compared with cyanocobalamin, although the longer chain alkylamine derivatives again showed reduced affinity with increasing chain length.

Cell Transport Studies. In the cell transport studies, adipic acid dihydrazide derivatives of cobalamin were attached to 50 nm Polysciences particles using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDAC) in water. The transport of the particles across Caco-2 cells was then investigated (Figure 4). Surface modification of the particles with either the 5′-O-adipic dihydrazide or the *e*-monoacid adipic dihydrazide cobalamin derivatives significantly enhanced transport of the nanoparticles when compared with the unmodified particles. The adipic dihydrazide-5′-O derivative was approximately twice as effective as the corresponding *e*-monoacid adipic dihydrazide derivative even though the particles had a lower degree of substitution.

SUMMARY

Twelve novel ribose-5′-O derivatives of vitamin B_{12} have been prepared and their bioactivity measured. The derivatives were obtained by activation of the hydroxyl group with CDI, CDT, or DBTC in moderate to high yield, with CDT giving the highest yield. This method of derivatization of cobalamin provides higher yields and greater scope than the traditional monoacid methodology. Furthermore, the 5′-O derivatives had similar or higher affinity for IF and non-IF compared with the corresponding *e*-monoacid derivatives.

Attachment of 5′-O-adipic dihydrazidyl cobalamin to 50 nm Polysciences nanoparticles dramatically enhanced uptake of the nanoparticles relative to unmodified particles. Use of 5′-O-adipic dihydrazidyl cobalamin as delivery agent for nanoparticles resulted in twice the level of transport as the use of the *e*-adipic dihydrazidyl cobalamin derivative.

Following this initial investigation, we intend to couple cobalamin to nanoparticles and peptides using various linkers on the 5′-OH position and investigate the oral activity of the resultant bioconjugates. Overall it appears that the employment of 5′-OH derivatives of cobalamin

in the preparation of bioconjugates provides a viable route to the successful oral delivery of proteins and peptides.

ACKNOWLEDGMENT

We would like to acknowledge Adventis Research & Technology for their financial support for these studies.

TECHNICAL NOTES

Preparation and Characterization of Domoic Acid−Protein Conjugates Using Small Amount of Toxin in a Reversed Micellar Medium: Application in a Competitive Enzyme-Linked Immunosorbent Assay

Philippe Branaa,[†] Jérôme Naar,[†] Mireille Chinain,[†] and Serge Pauillac*[,†,‡]

Unité d'Océanographie Médicale, Institut de Recherches Médicales Louis Malardé, PO Box 30, Papeete, Tahiti, French Polynesia, Unité d'Immunocytochimie, CNRS URA 359, Département d'Immunologie, Institut Pasteur, Paris, France. Received April 12, 1999; Revised Manuscript Received August 4, 1999

With the aim of producing novel antibodies to domoic acid (DA), an original, rapid, and simple procedure for preparing minute amount of hapten−protein conjugates was developed. The amide-bond-generating mixed anhydride method of Erlanger was performed using 0.32−0.64 μmol of DA in a reversed micellar medium allowing strong carrier haptenization as determined by spectrophotometric measurement. Bovine serum albumin (BSA) and ovalbumin (OVA) conjugates were, respectively, used for immunization of BALB/c mice and antibody screening by enzyme-linked immunosorbent assay (ELISA). Specific polyclonal antibodies were produced upon multiple injections of $(DA)_{17}$−BSA conjugate administered by three different routes: (i) intraperitoneal (i.p.), (ii) intraperitoneal + subcutaneous (i.p. + s.c.), (iii) footpad (f.p.). The i.p. route induced antisera of higher titer (1:350000) than did the other protocols (approximately 1:72900) and was selected throughout further experiments. Using a competitive ELISA format with a peroxidase immunoconjugate and a chromogenic substrate, no significant cross-reactivity was observed with glutamic acid, aspartic acid and kainic acid (KA), a structural analogue of DA. The sensitivity of this assay could be enhanced by 1 order of magnitude by using a β-galactosidase immunoconjugate with a fluorogenic substrate while preserving DA specificity. The calculated dissociation constant (K_D) for the interaction of the antibodies with free DA was 5×10^{-7} M (chromogenic assay) and 5×10^{-8} M (fluorogenic assay). Using the optimized assay the limit of detection (LOD) and the limit of quantitation (LOQ) in the ELISA buffer were 1.4 and 3 ng/mL, respectively. Moreover this assay was found applicable for measuring DA levels in spiked mussel extracts precleaned through a solid-phase extraction column, as a very good correlation ($r^2 = 0.96$) was observed between the actual amounts of DA added and amounts detected by ELISA. Thus, accurate determinations of DA in clean extracts could be achieved between 2 and 180 ng/mL in spiked samples which corresponds to 0.02−1.8 μg/g of original mussel tissue. Owing to the regulation limits of 20 μg DA/g of shellfish tissue, these extraction and assay procedures should provide a useful complement to the standard HPLC analytical technique currently employed in monitoring DA in shellfish tissue.

INTRODUCTION

Domoic acid (DA),[1] a naturally occurring amino acid produced by the marine diatom *Pseudonitzschia pungens*, is the most potent compound of a group of structurally related neurotoxins collectively referred to as kainoids after the name of the original member of the group, kainic acid (KA), isolated from the red macroalga *Digenea simplex* (Murakami et al., 1953). Since the first outbreak of food poisoning that occurred in Canada in 1987, DA has been found to accumulate in edible shellfish (Wright et al., 1989; Iverson et al., 1989; Quilliam and Wright, 1989), causing upon ingestion a human syndrome called Amnesic Shellfish Poisoning (ASP). The clinical picture is characterized by a gastrointestinal distress, followed by neurological symptoms such as headache, confusion, disorientation, and severe deficits in short-term memory (Teitelbaum et al., 1990; Perl et al., 1990). At the molecular level, kainoids have been found to exert

membrane depolarizing and neurodegenerative properties via the glutamatergic kainate receptor (Debonnel et al., 1989; Stewart et al., 1990).

Due to public health requirements and seafood industries interests, DA detection has been developed using the mouse bioassay (Iverson et al., 1989) and more specific assays based upon either instrumental method (gas or liquid chromatography coupled or not to mass spectrometry and capillary electrophoresis), or pharmacological and immunochemical techniques [see, for review, Wright and Quilliam (1995)]. Human toxicological data collected from the 1987 ASP Canadian incident have led to the establishment of generally admitted DA regulatory limits of 20 μg/g shellfish tissue. These safe limits, lower than the sensitivity of the mouse bioassay (Grimmelt et al., 1990), together with ethical and practical issues, contribute to exclude its routine use. Indeed routine monitoring of shellfish extracts requires high throughput sample screening with great specificity and sensitivity combined with simplicity, all requirements that only meet with automated binding assays or enzyme-linked immunosorbent assays (ELISA). However, in their present form, the disadvantage of receptor-binding assays is the use of radioactive tracers which imposes the purchase of expensive radiolabeled compounds and necessitates the disposal of radioactive waste. Although specific polyclonal antibodies have been produced (Newsome et al., 1991; Smith and Kitts, 1994, 1995; Osada et al., 1995; Garthwaite et al., 1998), until now there is no fully validated screening immunoassay commercially available for shellfish naturally contaminated with DA. Therefore, immunochemical techniques are to be most actively pursued in order to design a laboratory antibody-based assay that could be scaled up to fit the requirement of a routine cost-effective mass screening of shellfish prior to consumption.

This work describes the production of novel antibodies to DA using fully characterized DA−carrier conjugates obtained by a rapid and simple procedure we have recently designed (Pauillac et al., 1998). This paper is the first to document the production of antibodies to DA using very tiny amount of haptenic material (100−200 μg) in a reversed micellar medium. A preliminary application of these antibodies to competitive ELISA provides the basis to the development of a rapid, simple, specific, and sensitive assay for DA contaminated shellfish.

MATERIALS AND METHODS

Preparation of Conjugates. All chemical reagents, unless otherwise stated, were purchased from Sigma Chemicals Co. (St. Louis, MO). High-quality grade solvents obtained from Prolabo (France) were dried according to standard procedures.

Conjugates were prepared according to a modified version of the mixed anhydride coupling method of Erlanger et al. (1957) as recently described by Pauillac et al. (1998). Briefly, 0.321 or 0.642 μmol of DA were dissolved in 20 μL of dry dimethylsulfoxyde (DMSO), and then a 10-fold molar excess of tributylamine and isobutyl chlorocarbonate was added. The formation of the mixed anhydride was allowed to proceed for 30 min at room temperature. The reaction was monitored by thin-layer chromatography (TLC) run on silica gel 60 F_{254}-precoated plastic foils from Merck (Darmstadt, Germany) using CH_2Cl_2-MeOH (95:5) as developing solvent. UV illumination of the chromatogram showed conversion of DA, which remains at the origin ($R_f \approx 0$), to the mixed anhydride ($R_f = 0.77$) to an extent greater than 95%. The conjugation of activated DA to carriers was carried out in the system of reversed micelles of aerosol OT [AOT or sodium bis(2-ethylhexyl) sulfosuccinate] in heptane (Kabanov et al. 1989; Yatsimirskaya et al., 1993) with relevant modifications for miniaturization purpose and high haptenization yield (Pauillac et al., 1998). Three carriers were used throughout: bovine serum albumin (BSA), ovalbumin (OVA), and poly-DL-lysine (PL, average mol wt 77 000) providing an initial hapten/protein molar ratio around 100.

Control experiments run in parallel, consisting in carrier alone and carrier mixed with non-activated DA, were incubated in the reversed micellar medium under identical conditions.

All carriers in the vials (assay and control) were recovered by acetone precipitation. The precipitates were finally resuspended in 1 mL of distilled water, filter sterilized (0.22 μm), dispensed into sterile tubes, then freeze-dried overnight. Tubes were generally stored at −20 °C until use but some of them were kept at room temperature for subsequent analysis.

Conjugates Analysis. For analytical purpose, carriers from control and assay were resuspended in 1 mL of PBS. Carrier haptenization was assessed spectrophotometrically through a 1 cm light path quartz cuvette with a dual beam spectrophotometer (UV 160A, Shimadzu, Japan). Absorption spectra of all samples were recorded between 200 and 300 nm using a 1:3 (BSA and OVA conjugates) or 1:2 (PL conjugates) dilution in PBS. Concentrations of hapten (read at $\lambda_{max} = 242$ nm) and protein carriers (read at $\lambda_{max} = 280$ nm) were determined according to either standard curves with linear regression in the range 0−20 μg/mL of DA or previously reported extinction coefficients (DA, $\epsilon = 83.83$ mg^{-1} cm^2; BSA, $\epsilon = 0.66$ mg^{-1} cm^2; OVA, $\epsilon = 0.735$ mg^{-1} cm^2). After molar conversion, the degree of hapten conjugation was expressed by the hapten/carrier ratio of the samples, i.e., epitope density of the conjugates. For these calculations, total PL content was considered assuming complete recovery of the conjugate.

Mice Immunization. Three groups of two female BALB/c mice (6−8 weeks of age) were immunized by three different routes: intraperitoneal (i.p.), intraperitoneal + subcutaneous (i.p. + s.c.), and footpad (f.p.). All six animals received a total of six injections of 50 μg $(DA)_{17}$−BSA conjugate emulsified in 100 μL of PBS/adjuvant mixture (1:1). The first injection was made in Freund's complete adjuvant (FCA), and the following in Freund's incomplete adjuvant (FIA) at 3−4 week intervals. Mice were sequentially bled from the retroorbital venous system and pooled sera from each group were tested for anti-DA antibody activity.

Enzyme Immunoassays. The following buffers were used throughout ELISA experiments: phosphate-buffered saline (PBS, 0.01 M KH_2PO_4/K_2HPO_4−150 mM NaCl, pH 7.2) for coating, 5% skim milk powder in PBS as blocking buffer (PBS-M), PBS containing 0.1% Tween 20 (PBS-T) for washing steps, and this latter buffer supplemented with 1% skim milk powder and 1% BSA (PBS-TMB) for dilution of reagents (sera, immunochemicals, or DA standards). All immunochemical reagents, unless otherwise stated, were purchased from Boehringer Mannheim (Indianapolis, IN).

Flat-bottomed polystyrene 96-well Maxisorp Immunoplates (Nunc, Roskilde, Denmark) were coated with 100 μL of $(DA)_{10}$−OVA conjugate (20 ng/mL−1 μg/mL) in PBS by incubation for 1 h at 37 °C then overnight at 4 °C. They were then washed five times with PBS, and the

remaining active sites were blocked by addition of 250 μL of PBS-M. All subsequent incubation steps, unless otherwise stated, were carried out 1 h at 37 °C in precoated plates, which were thoroughly washed with PBS-T after each step.

Kinetics Experiments. For kinetics experiments, pooled sera collected at the indicated time from each 2-mice immunization group were diluted 1:2500 and applied to the plates at 100 μL/well. Bound antibodies were revealed by incubation with 100 μL of goat anti-mouse IgG peroxidase conjugate (GAM-PO) diluted 1:3000 followed by the addition of 100 μL of *o*-phenylenediamine (OPD) as a commercial substrate solution (FAST OPD, Sigma). After 30 min at 37 °C, the enzymatic reaction was terminated by adding 50 μL of 2 M H_2SO_4 and the absorbance at 492 nm was measured using a Multiskan Plus Titerteck (Flow Laboratories, Puteaux, France).

Titration Experiments. For titration experiments, serially diluted pooled immune sera collected after the last boost or control sera (1:300−1:1968300 dilutions) were applied to the plates at 100 μL/well. Bound antibodies were revealed by the successive incubations with GAM-PO and OPD, and the enzymatic reaction terminated as described above after 10 min at 37 °C.

Competitive Experiments. Competitive experiments were conducted using pooled sera collected one week after the last boost from mice immunized according to the i.p. protocol. Pooled sera (1:350000 final dilution) were first preincubated overnight at +4 °C with an equal volume of various concentrations of inhibitors (DA, KA, glutamic acid, and aspartic acid). Samples of these mixtures were transferred (100 μL/well) onto DA-OVA-precoated plates (250 ng/mL). After incubation and washing steps, the antibodies associated with the plates were revealed as described above. In another set of experiments, coating concentration was reduced to 20 ng/mL and bound antibodies were revealed using a fluorescence-based amplification signal by the successive addition of goat anti-mouse IgG−β-galactosidase conjugate (GAM−βGZ; 1:4000 dilution) and 4-methyl umbelliferyl β-D-galactoside (4-MUG) at saturation in 0.1 M phosphate buffer, pH 7.2. Following a 30 min incubation, fluorogenic substrate change was measured using a Dynatech Microfluor Reader with excitation at 365 nm and emission at 450 nm. Recorded values are expressed as relative fluorescence units.

Using both amplification systems, the signals obtained in the presence of various inhibitor concentrations and without inhibitor (maximal signal) are referred to as B and B_o, respectively. The limit of detection (LOD) of each format assay was therefore calculated assuming a decrease of 3 standard deviations from the mean value of B_o is significant ($n = 12$). Standard curves were generated by plotting the percentage of maximal signal (% B/B_o) against the log of free DA concentrations, using the four parameter logistic fitting model provided by the MultiCalc package program (EG & G−Wallac). The limit of quantitation (LOQ) was defined as the DA concentration necessary to produce a 80% decrease in B_o (IC_{80}).

Finally, the dissociation constant (K_D) of mice antibodies binding to DA was estimated by calculating the slope of the regression line obtained using the simplified mathematical equation of Klotz (1953) proposed by Friguet et al. (1985).

Measurement of DA Levels in Rapid Mussel Extracts. Rapid extraction of blue mussels (*Mytilus edulis*) was performed according to the method developed by Quilliam et al. (1998). Briefly 4 g of uncontaminated mussels was mixed with 16 mL of MeOH−H_2O (1:1) and homogenized thoroughly using a Brinkman Polytron. Particulate material was eliminated by centrifugation at 5000*g* for 10 min and the supernatant filtered through a dry methanol-compatible 0.5 μm filter unit. Five milliliter samples (1 g tissue equivalent) of this clear supernatant were either used without additional treatment (crude extract) or precleaned by passing it through a strong anion-exchange solid-phase extraction column (Supelclean LC−SAX, Supelco Inc., Bellefonte, PA). Following several washing steps, putative DA was eluted from the column using MeOH/H_2O/HCOOH (75:23:2). These precleaned extracts were evaporated to dryness under nitrogen atmosphere then reconstituted in 5 mL of MeCN/H_2O (1:9). Finally, 1 mL of this suspension (0.2 g tissue equivalent) and 1 mL of crude extract (0.2 g tissue equivalent) were spiked with 4 μg of DA analytical standard (DACS-1C, NRC−CNRC, Institute for Marine Biosciences, Halifax, Canada) to generate concentrations ranging from 4000 to 2 ng/mL by serial dilutions in MeCN/H_2O (1:9). The same dilutions of DA analytical standard were directly prepared in MeCN/H_2O (1:9) to serve as calibration solutions. These spiked samples or calibration solutions were mixed with an equal volume of pooled mice immune sera (1:400000 final dilution) and incubated overnight at +4 °C. DA levels were determined in triplicate 50 μL volumes of these mixtures, using the competitive ELISA format and the optimized fluorogenic amplification system as described above.

RESULTS AND DISCUSSION

Preparation and Analysis of the Conjugates. Conjugates were prepared in a reversed micellar medium according to the procedure described in the Materials and Methods. Their recovery and substitution ratio were carefully checked spectrophotometrically by incorporating controls in which carriers have been incubated under identical conditions with nonactivated hapten. DA is a chromophore with a unique absorption peak at 242 nm and a molecular extinction coefficient of 83.83 mg^{-1} cm^2 at pH 7 (Falk et al., 1989); therefore, proteins (BSA and OVA) but not the polyamino acid (PL) could be also estimated in the conjugates by UV absorbance at 280 nm (aromatic amino acids).

Consistent with former experiments (Pauillac et al., 1998), carrier protein recovery in control and assay tubes was found to be greater than 95%, hence, the whole carrier content (proteins or PL) was taken into account in the calculation of the hapten/carrier molar ratio (i.e., epitope density) of the samples. Another clue is provided by the demonstration that differential absorption spectra of the conjugates and carriers recovered from control experiments were quite similar to those of the free hapten (data not shown). Using a 100:1 hapten to carrier initial molar ratio, the epitope density of OVA, BSA, and PL conjugates was estimated to be around 10, 20, and 30, respectively. For these calculations the assumption was made that the extinction coefficient of DA is not altered by the conjugation process. This technique proceeding in a reversed micellar medium was initially set up for lipophilic carboxylic haptens (Pauillac et al., 1998) but proved to be likewise valuable for hydrophilic haptens (water solubility of DA is 7.6 mg/mL according to Falk et al., 1991). Compared to relatively high hapten quantities (1−12.4 mg of DA) used in previous studies (Newsome et al., 1991; Smith and Kitts, 1994, 1995; Garthwaite et al., 1998), a significant improvement in preparation of well-defined DA−protein conjugates was achieved by our method. Starting from 200 μg of DA, 435 μg of

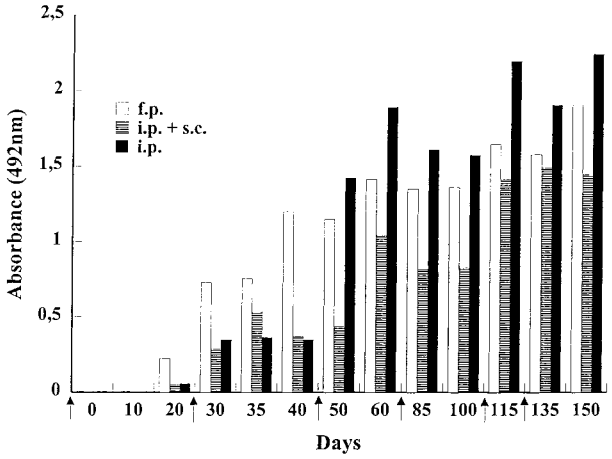

Figure 1. Kinetics of anti-DA antibodies production. Pooled sera from each group were diluted 1:2500 in PBS-TMB and tested for their reactivity onto microtiter plates coated with 1 μg/mL of $(DA)_{10}$−OVA conjugate in PBS. The reaction was developed following the successive incubations with GAM-PO and OPD. Each bar represents the mean of triplicate assays, which varied by no more than 5%. Mice immunization groups: f.p. (open bars), i.p.+ s.c.(hatched bars) and i.p.(black bars). Arrows indicate priming and subsequent boosts.

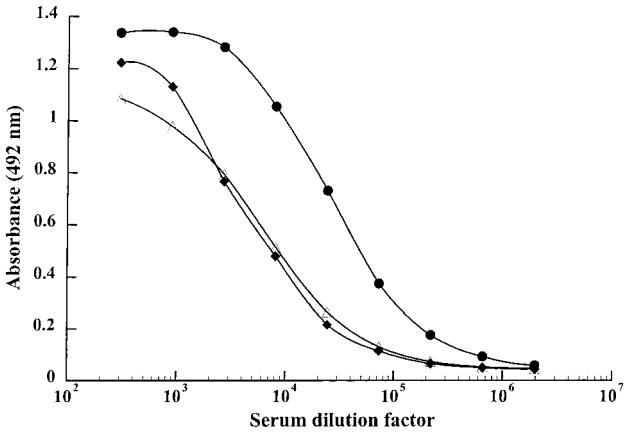

Figure 2. Titration of pooled mice antisera. Pooled sera were serially diluted (1:300−1:1968300) in PBS-TMB and added onto microtiter plates coated with 1 μg/mL of $(DA)_{10}$−OVA conjugate in PBS. The reaction was developed following the successive incubations with GAM-PO and OPD. Mice immunization groups: i.p. (●), i.p.+ s.c. (△), and f.p. (◆). Each value represents the mean of triplicate assays, which varied by no more than 5%.

DA−BSA conjugates were obtained from which 300 μg (six injections of 50 μg) were injected per mouse.

Comparison between the Three Different Routes of Immunization. To investigate the best immunization schedule, three groups of two mice were given a total of six injections of $(DA)_{17}$−BSA conjugates administered via three different routes (i.p., i.p. + s.c., and f.p.). Throughout experiments, mice injected by either route displayed no ill effects or symptoms typical of ASP. Animals were sequentially bled and their sera pooled according to the route of immunization. For each group, anti-DA antibodies production was tested by indirect ELISA using $(DA)_{10}$−OVA conjugate as target antigen. All preimmune sera were totally negative against a panel of coating antigens including the homologous (BSA) and heterologous (OVA) native carriers used (data not shown).

That all mice developed specific immune response upon immunization was clearly demonstrated by the antibody kinetics and level achieved but differences were observed according to the immunization schedule (Figure 1). For instance, the f.p. immunized group responded earlier (as soon as 3 weeks after priming), with a prolonged elevated antibody level attained approximately 3 weeks after the first boost. Consequently subsequent booster injections showed no clear efficacy on further antibody production. In contrast, a secondary immune response of normal magnitude and kinetics could be generated in the i.p. + s.c. and i.p. immunized groups after each injection, especially when the antibody levels had sufficiently decreased before. Nevertheless, the i.p. immunized group always exhibited a stronger specific response, whereas the i.p. + s.c. group tended to catch up with the f.p. one along the time course. These observations were later confirmed by titration experiments (Figure 2). Again, it can be seen that all pooled antisera dilutions exhibited DA specificity, and lower antibody concentrations yielded signals similar to background level (control without antibody). Moreover, it was observed that cross-absorbing anti-DA-BSA antisera with 1% BSA (PBS-TMB diluent buffer) completely neutralized the anti-carrier activity in the sera (data not shown). Therefore, titers estimated by the maximum serum dilution that allowed a 3-fold signal to target antigen, as compared to background level, were found to be 1:350000 for the i.p. mice group and around 1:72900 for the ip. + s.c. and f.p. groups. Consequently, all further reported ELISA experiments were conducted using pooled sera from the last bleeding of i.p. immunized mice.

It is noteworthy that $(DA)_{30}$−PL when used as target antigen yielded a high background noise and nonreproducible results.

Competitive Inhibition of Pooled Mice Antisera Binding to DA-OVA. To further assess the specificity of these anti-DA antibodies, competitive ELISA experiments were performed using various inhibitors (DA, KA, glutamic acid, and aspartic acid). The high specificity of anti-DA antibodies was again clearly demonstrated as all the other free haptens were essentially unrecognized in the concentration range 30−1000 μg/mL (data not shown). Figure 3 illustrates standard curves obtained by plotting the percentage of maximal signal (% B/B_o) against the log of free DA concentrations. These experiments also contributed to compare two amplification signals. The overall sensitivity of the GAM-βGZ/MUG (fluorogenic) amplification system over the GAM-PO/OPD (chromogenic) system is evident from the binding parameters of the standard curves. The working range covered by these assays was 3−245 ng/mL and 58−1437 ng/mL, respectively. Assuming that a difference of 3 standard deviations (n = 12) from the mean signal without inhibitor (B_o) is significant, the LOD of these assays was 1.4 ng/mL and 27 ng/mL using the fluorogenic and the chromogenic amplification systems, respectively. Finally, as can be expected, the K_D for the interaction of the antibodies with free DA was found to be lower using the fluorogenic assay (5×10^{-8} M) than the chromogenic one (5×10^{-7} M).

In the process of the analysis of sera from i.p. immunized mice, two antibody subpopulations were disclosed, which is in good agreement with an earlier observation (Nieto et al., 1984) that decreasing the coating antigen or/and antibody concentrations allowed different antibody subpopulations with increased affinities to be selected.

Recovery of DA from Spiked Samples. The optimized competitive fluorogenic assay has been used to measure DA levels in rapid mussels extracts spiked with DA calibration standards. The effect of matrixes was

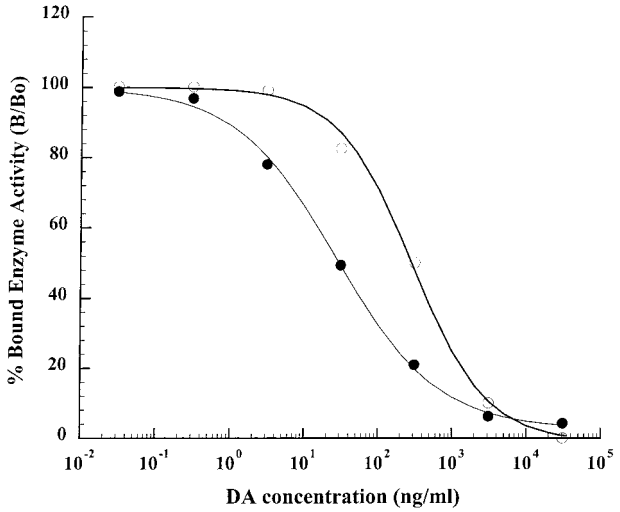

Figure 3. Competitive inhibition of pooled mice antisera binding to DA-OVA coated plates by free DA. $(DA)_{10}$−OVA coating concentration was 250 ng/mL and 20 ng/mL for the chromogenic and fluorogenic assays, respectively. The final antiserum dilution (i.p.-immunized group) was 1:350000 in PBS-TMB. The reaction was developed following the successive incubations of either GAM-PO and OPD (○) or GAM-βGZ and MUG (●) as reported in the Materials and Methods. Each value represents the mean of triplicate assays, which varied by no more than 5%.

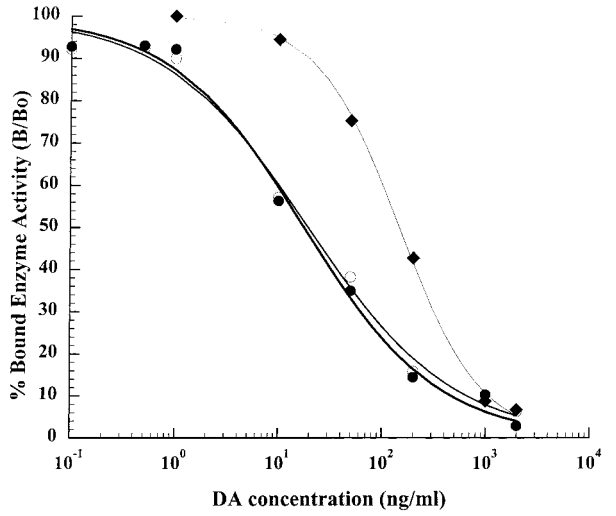

Figure 4. Effect of different biological matrixes on the DA calibration curve using the optimized ELISA format. See legend of Figure 3 for experimental conditions running the fluorogenic amplification system. DA calibration curves prepared in diluent buffer (●), in spiked mussel extracts: crude (◆) and pre-cleaned (○). Each value represents the mean of triplicate assays, which varied by no more than 3%.

investigated by comparing standard calibration curve obtained in diluent buffer with DA recovery from spiked mussel extracts (crude or precleaned). No significant matrix effect was observed for the precleaned extracts ($r^2 = 0.96$), as shown in Figure 4, whereas the use of crude extracts caused negative interferences (i.e., DA is less available for antibody interaction). Consequently, accurate determinations of DA in precleaned extracts could be achieved between 2 and 180 ng/mL in spiked samples, which corresponds to 0.02−1.8 μg/g of original mussel tissue. Owing to the regulation limits of 20 μg of DA/g of shellfish tissue, these extraction and assay procedures should provide a useful complement to the standard HPLC analytical technique currently employed in monitoring DA in shellfish tissue.

An Improved Method for the Microscale Preparation and Characterization of Hapten−Protein Conjugates: The Use of Cholesterol as a Model for Nonchromophore Hydroxylated Haptens

Jérôme Naar,[†] Philippe Branaa,[†] Mireille Chinain,[†] and Serge Pauillac*[,†,‡]

Unité d'Océanographie Médicale, Institut de Recherches Médicales Louis Malardé, P.O Box 30, Papeete, Tahiti, French Polynesia. Received April 12, 1999; Revised Manuscript Received August 3, 1999

A minute amount (0.446 μmol) of cholesterol (Chol) was converted into an hemisuccinate derivative (Chol HS) using an excess of succinic anhydride. The optimal conditions for synthesis of Chol HS were explored by checkerboard experiments in which various succinic anhydride/Chol molar ratios ranging from 5:1 to 30:1 were assayed over a wide temperature range (50−85 °C) and for various incubation times (3−8 h). Total conversion was obtained at the higher reagent ratios, temperatures, and incubation times. Subsequently, this carboxylic derivative was first covalently linked to bovine serum albumin (BSA) then to various proteins (casein, ovalbumin, and hemocyanins) or to a synthetic homopolymer (poly-DL-Lysine) via a modified version of the mixed anhydride method of Erlanger, performed in a reversed micellar medium. The assessment of the number of haptenic groups per mole of BSA (epitope density) was achieved chromatographically by two methods according to a Chol standard curve established at 207 nm with linearity in the range 0−50 μg. These procedures involving an alkaline hydrolysis of a sample of either the conjugate (direct method) or the unreacted Chol HS (indirect method) yielded an acceptable level of agreement and concordant results in all cases. The influence of the activated hapten/BSA molar ratio on the coupling efficiency was investigated by the direct method within the range 10:1 to 250:1. Using the optimal conditions determined for Chol HS synthesis (a molar reagent ratio of 30:1 with incubation at 65 °C for 6 h) and for BSA haptenation (a 100-fold molar excess of activated hapten, with a carrier stock concentration of 5 mg/mL), epitope density of the conjugates lied between 23 and 27. By reacting the same amount of activated hapten (∼216 μg) with identical amounts of various carriers (300 μg), conjugation efficiency was found similar on a microgram of Chol bound per milligram of carrier basis. This simple and reproducible conjugation and analysis procedures should provide a general method applicable to poorly available and weakly immunogenic haptens bearing hydroxyl groups such as polyether-type marine toxins.

INTRODUCTION

Despite occasional reports that conjugates of cholesterol (Chol)[1] can be immunogenic (Bailey et al., 1964; Klopstock et al., 1964; Hara et al., 1979), Chol has long been considered as a poorly immunogenic hapten due to its ubiquitous distribution in the animal kingdom and important biological role. Nevertheless, specific antibodies have been generated using Chol-loaded liposomes containing lipid A as an adjuvant (Swartz et al., 1988). More recently, i.p. injections of silicone oil also have been found to induce specific antibodies through recruitment and adsorption of Chol at the injection site and potent immunostimulant properties (Alving et al., 1996). From all of these previous studies it can be concluded that production of antibodies to Chol may be readily achieved by utilizing a powerful adjuvant and/or a suitable Chol-carrier conjugate to help antigen presentation and recognition by the immune system. With the aim of developing new antibodies against lipophilic hydroxylated haptens such as polyether-type marine toxins [see, for review, Yasumoto and Murata (1993)], we have used Chol as a molecular model to investigate an improved method for the microscale preparation and characterization of hapten−protein conjugates. This choice was made considering Chol is a biologically relevant lipid hapten, is commercially available and inexpensive, possesses a unique secondary hydroxyl group, and has no useful absorption band suitable for detection, except the common absorption peak around 210 nm exhibited by most organic compounds.

In a preceding report (Pauillac et al., 1998), we have described a miniaturized procedure for the conjugation of lipophilic carboxylic haptens to carrier molecules and the production of specific antibodies. The key processes in this synthesis were an effective adaptation of the mixed anhydride method (Erlanger et al., 1957) and some relevant modifications of the reversed micellar system (Kabanov et al. 1989; Yatsimirskaya et al., 1993) for miniaturization purpose and high haptenization yield. In this previous study conducted with chromophoric carboxylic haptens, conjugate analysis could be readily performed spectrophotometrically.

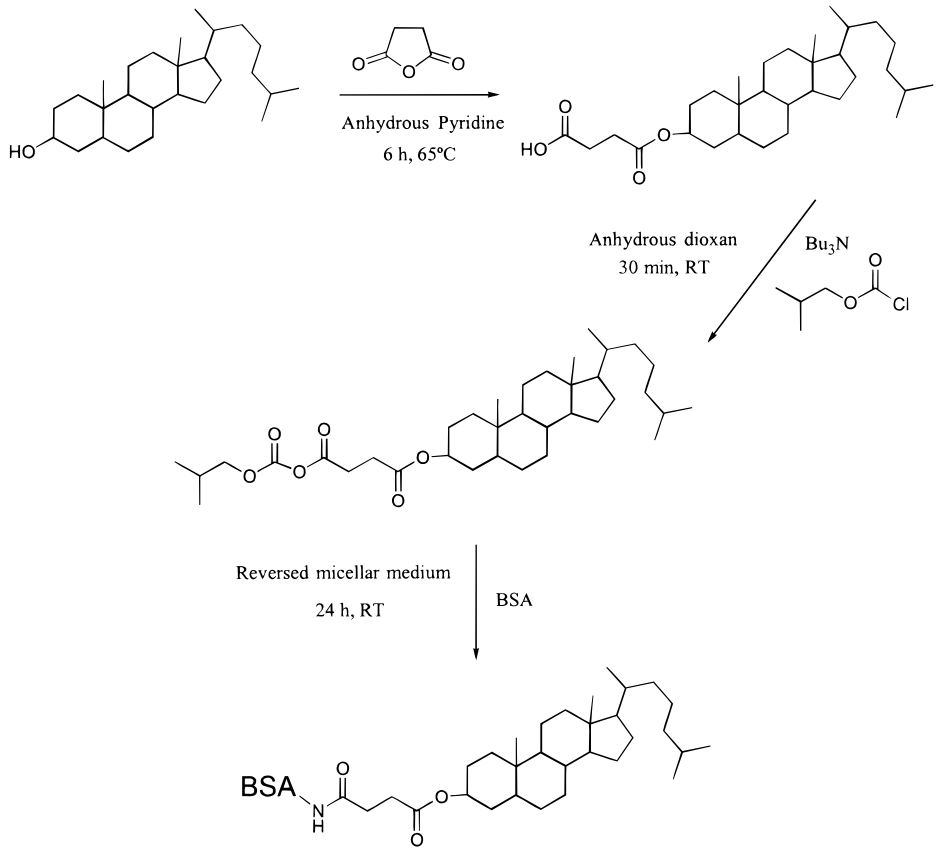

Figure 1. Chemical coupling of cholesterol to BSA in the reversed micellar medium.

Because Chol is a steroid with unique secondary hydroxyl group, the present paper deals first with the microscale preparation of a cholesterol hemisuccinate derivative (Chol HS) and its subsequent conjugation to carrier molecules in the reversed micellar medium, with emphasis on the elucidation of optimal conditions for both synthetic steps. Second, considering previous demonstrations that both the nature of the carrier protein (Fasciglione et al., 1996) and the epitope density of the conjugates (Klaus and Cross, 1974; Erlanger, 1980; Cooper et al., 1993, 1994) can greatly influence the induction of specific antibodies (amount, class, and affinity), the conjugation efficiency to various carrier proteins and a synthetic poly-amino acid has also been chromatographically evaluated. Conjugates immunogenicity has not been tested in this study.

MATERIALS AND METHODS

All chemical reagents, unless otherwise stated, were purchased from Sigma Chemicals Co (St. Louis, MO). High quality grade solvents from Prolabo (France) were dried according to standard procedures. Thin layer chromatograms (TLC) were run on silica gel 60 precoated aluminum foils from Merck (Darmstadt, Germany).

Synthesis and Purification of Cholesterol Hemisuccinate. The optimal conditions for synthesis of Chol HS were explored by checkerboard experiments in which various succinic anhydride/cholesterol molar ratios ranging from 5:1 to 30:1 were assayed over a wide temperature range (50−85 °C) for various incubation times (3−8 h). All reactions proceeding in a sealed vial, the most efficient condition, are described hereafter.

A 30-fold molar excess of succinic anhydride solubilized in 50 μL of anhydrous pyridine was added to 172 μg (0.446 μmol) of crystalline cholesterol in the internal cone of a 1 mL small reaction vial (Pierce, Rockford, IL). The vial was sealed and heated for 6 h at 65 °C, and the solvent evaporated under a stream of nitrogen. Finally, the residue was redissolved in 200 μL of CH_2Cl_2/MeOH (99:1) and succinylation was checked by TLC using CH_2Cl_2/MeOH (95:5) as developing solvent and 30% aqueous sulfuric acid as spray reagent. By heating, Chol and its derivative (Chol HS) appeared as pink spots with R_f values of 0.57 and 0.32, respectively.

Chol HS was purified by rapid chromatography technique on a Sep-Pak Plus silica gel cartridge (Waters-Millipore, Milford, MA) fitted with a 10 mL Luer-tipped syringe and conditioned with 5 mL of CH_2Cl_2. The 200 μL reaction mixture was loaded onto the cartridge, the vial was rinsed with 100 μL of CH_2Cl_2/MeOH (99:1) which was let to pass through the cartridge, and 5 mL of CH_2Cl_2 was added to induce sample stacking then elution was performed using a stepwise gradient beginning with 10 mL CH_2Cl_2-MeOH (90:10) and ending with 5 mL MeOH. The flow rate was maintained around 3 mL/min and 1 mL fractions were collected. Chol HS eluted in tubes 2−4 (10% MeOH) with a yield >95% whereas succinic anhydride was found in the pure MeOH fractions (tubes 12−14). Therefore, subsequent calculations were made on the basis of full recovery.

Preparation of Cholesterol−BSA Conjugates. Conjugates were prepared according to a modified version of the mixed anhydride coupling method of Erlanger et al. (1957) performed in a reversed micellar medium (Pauillac et al., 1998). The synthetic steps are outlined in Figure 1.

Following the rapid chromatographic procedure, fractions containing Chol HS were combined and dried under nitrogen atmosphere in a 1 mL small reaction vial. To this dry derivative, a 10-fold molar excess of tributyl-

amine (V_m = 254.94 μL/mmol) and isobutyl chlorocarbonate (V_m = 131.325 μL/mmol) were added as 1/12th dilutions in dry peroxide-free dioxane to provide a final volume of approximately 20 μL of reaction mixture. The tightly sealed vial was placed onto a mechanical stirrer, and the formation of the mixed anhydride was allowed to proceed for 30 min at room temperature. The reaction was monitored by TLC as described above. Sulfuric acid spraying and heating of the chromatogram showed conversion of Chol HS (R_f = 0.32) to the mixed anhydride (R_f = 0.96) to an extent greater than 95%. The conjugation of activated Chol HS to carriers, was carried out in the system of reversed micelles of aerosol OT [AOT or sodium bis(2-ethylhexyl) sulfosuccinate] in heptane (Kabanov et al. 1989; Yatsimirskaya et al., 1993) with relevant modifications for miniaturization purpose and high haptenization yield (Pauillac et al., 1998). Six carriers were used throughout: bovine serum albumin (BSA), ovalbumin (OVA), casein (CAS), poly-DL-Lysine (PL, average mol wt 77000), keyhole limpet, and *Limulus polyphemus* hemocyanins (KLH and LH, respectively).

During these experiments various activated hapten/carrier molar ratios were assayed in the range 10−250 using commercial Chol HS.

A typical experiment performed at room temperature with two BSA concentrations is described. Four volumes of a 0.5 M solution of AOT in heptane were added to 1 vol of BSA at 5 or 7.5 mg/mL in 0.1 M borate buffer, pH 10.2, under vigorous shaking. The formation of reversed micelles was achieved when the solution turned completely clear. Immediately after, volumes of these BSA micellar solutions corresponding to 300 μg (0.004 41 μmol) were poured into the vials containing the activated hapten and the mixtures were again vigorously shaken, providing for each reaction a hapten/protein molar ratio around 100:1. After a slight and transient turbidity was observed, the reactions were allowed to proceed overnight at room temperature.

Control experiments run in parallel, consisting in BSA alone and BSA mixed with nonactivated Chol HS, were incubated in the reversed micellar medium under identical conditions.

All proteins in the vials (assay and control) were precipitated 20 min at −20 °C in acetone (3 vol), and the whole content was transferred into 5 mL of borosilicate glass test tubes for centrifugation (6000*g* at +4 °C for 15 min). The resultants pellets were redissolved in PBS (250 μL at +4 °C), precipitated again, then thoroughly washed three times with cold acetone (−20 °C) to remove unbound Chol HS. The precipitates were generally resuspended in 1.2 mL of distilled water, filter sterilized, dispensed into 6 aliquots of 200 μL, freeze-dried overnight and stored at −20 °C until use. However, depending upon expected conjugation efficiency, either the whole conjugate (300 μg in 300 μL of distilled water) or a 200 μL aliquot (50 μg) and the pooled acetone supernatants were saved for analysis (see below**)**. Other fully characterized conjugates of Chol with OVA, CAS, PL, KLH, and LH were also obtained according to this procedure: 1 mg/mL of micellar carrier solutions were prepared and incubated with activated or nonactivated hapten under identical conditions as for BSA.

Characterization of Cholesterol−BSA Conjugates. Carrier haptenization was assessed chromatographically by two methods, both involving an alkaline hydrolysis of a sample of either the conjugate (direct method) or the unreacted Chol HS in the acetone phase (indirect method). Chol qualitative and quantitative analyses were performed using an HPLC system (Kontron Instrument, France) equipped with a UV monitor set at 207 nm and a chromatointegrator for calculation of peak areas (PA). The column was a 4.6 mm id × 150 mm Develosil ODS-HG-5 reversed-phase (Normora Chemical, Japan), and separation was carried out under isocratic conditions with pure MeOH at a flow rate of 1 mL/min. Chol content of each sample was determined according to a calibration curve with linear regression in the range 0−50 μg (150 μL/injection), obtained by serial dilutions of a stock solution of crystalline Chol in CH_2Cl_2/MeOH (1:99). After molar conversion, the epitope density of the conjugates (n) was expressed by the hapten/carrier ratio of the samples. For these calculations, according to previous results (Pauillac et al., 1998) the recovery of the conjugates was considered total.

Direct Method. A 200 μL aqueous sample containing 50 μg of Chol−BSA conjugate or the whole conjugate (300 μg in 300 μL distilled water) was mixed with 3 vol of 28% aqueous ammonia, and the mixture was allowed to stand overnight at room temperature. Afterward, the hydrolysis mixture was freeze-dried and the residue was extracted three times with 1 mL of CH_2Cl_2/anhydrous MeOH (20:80). The pooled organic fractions were evaporated under a stream of nitrogen, and the residue was redissolved in 150 μL of CH_2Cl_2/MeOH (1:99) and analyzed by HPLC as described above.

Indirect Method. The pooled acetone supernatant recovered from conjugate precipitation was evaporated to dryness, and the residue redissolved in 200 μL of CH_2Cl_2. Unreacted Chol HS was purified on a Sep-Pak Plus silica gel cartridge as described above. In this case, elution was performed using a stepwise gradient beginning with 10 mL of CH_2Cl_2/MeOH (97.5:2.5) and ending with 5 mL of MeOH. Again the flow rate was maintained around 3 mL/min and 1 mL fractions were collected. Chol HS eluted first (tubes 3−8) whereas AOT was found in the pure MeOH fractions (tubes 12−14). Chol HS containing fractions were combined, evaporated to dryness and redissolved in 200 μL of CH_2Cl_2/MeOH (5:95). Alkaline hydrolysis, freeze-drying, extraction, and solvent evaporation procedures were performed as described for the direct method. Finally, the residue was redissolved in 400 μL of CH_2Cl_2/MeOH (1:99), and a 100 μL sample was subjected to HPLC analysis as described above.

RESULTS

Chol-carrier conjugates were prepared in a reversed micellar medium according to the procedure described in Materials and Methods (Figure 1). Optimal conditions for their preparation were established at each step of the two stages involved. Their recovery and substitution ratio were carefully checked by incorporating controls in which carriers have been incubated in the same conditions with nonactivated hapten. The epitope density of the conjugates (*n*) was expressed by their hapten/carrier molar ratio considering a total recovery of the conjugates.

Chromatographic Quantitation of Cholesterol. Chol is a monohydroxylated, lipid-soluble compound with no characteristic peak absorption with respect to proteins, therefore a reversed-phase HPLC method employing UV detection at 207 nm has been set up for its quantitation (150 μL/sample run). Figure 2A illustrates a chromatogram obtained by injecting 25 μg of Chol, which eluted with a retention time (RT) varying from 9.6 to 10.13 min depending upon the ambient temperature. To assess the linearity of this method, a calibration curve with a working range of 0−50 μg was obtained by plotting peak areas (PA) expressed in millivolt minutes versus

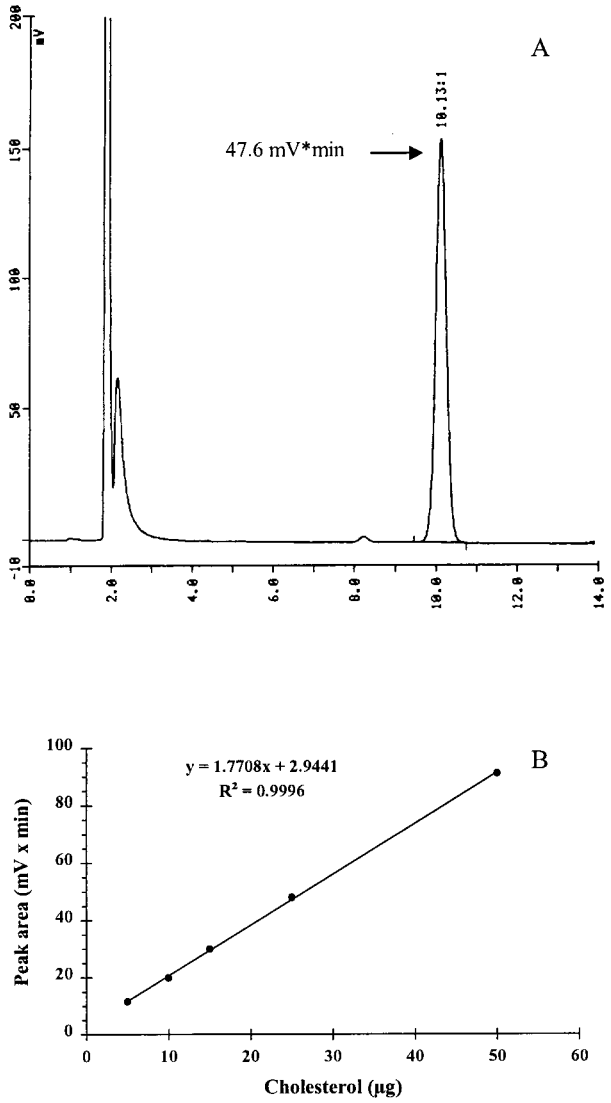

Figure 2. Chromatographic quantitation of cholesterol. chromatogram on a Develosil ODS-HG-5 reverse-phase column. Mobile phase 100% MeOH; flow rate 1 mL/min; detection UV at 207 nm; sample 25 μg of Chol applied in 150 μL of CH_2Cl_2/MeOH (1:99); Retention time, RT = 10.13 min; peak area, PA = 47.6 mV × min. Calibration curve. Increasing amounts of cholesterol solubilized in 150 μL of CH_2Cl_2/MeOH (1:99) were subjected to HPLC analysis. Corresponding peak areas (PA) are plotted versus amounts of injected sample. Values are the mean of two independent experiments (error bars are omitted because of symbol overlapping).

corresponding Chol amounts in micrograms (Figure 2B). All reported values are the means of two series of data obtained separately. The adequacy and high accuracy of this dosage is deduced from the value of the correlation coefficient which was very close to 1.

Optimization of the Succinylation Process. To optimize the succinylation process, the reaction was performed for 3−8 h at different temperatures (50−85 °C), using various succinic anhydride/Chol molar ratios (5:1 to 30:1). Regarding incubation time, in most cases it was found that 6 h was a good compromise because the reaction no longer progressed after this period. The reactions were monitored by TLC and accurately quantified by HPLC using an aliquot or the whole reaction mixture to evaluate remaining Chol amount. Appropriate factors were applied to restore the true value in the original reaction and a subtraction was made on a molar

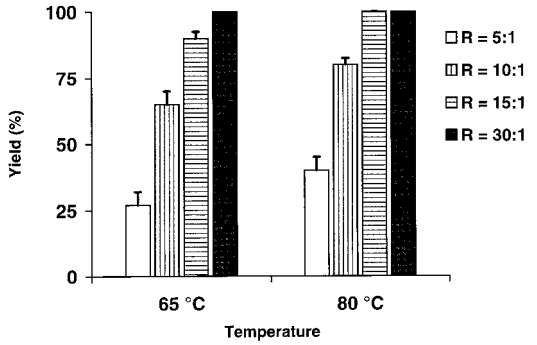

Figure 3. Determination of the optimal conditions for Chol HS synthesis. Effect of two temperatures (65 and 80 °C) and influence of the succinic anhydride/Chol molar ratio (5:1 to 30:1).

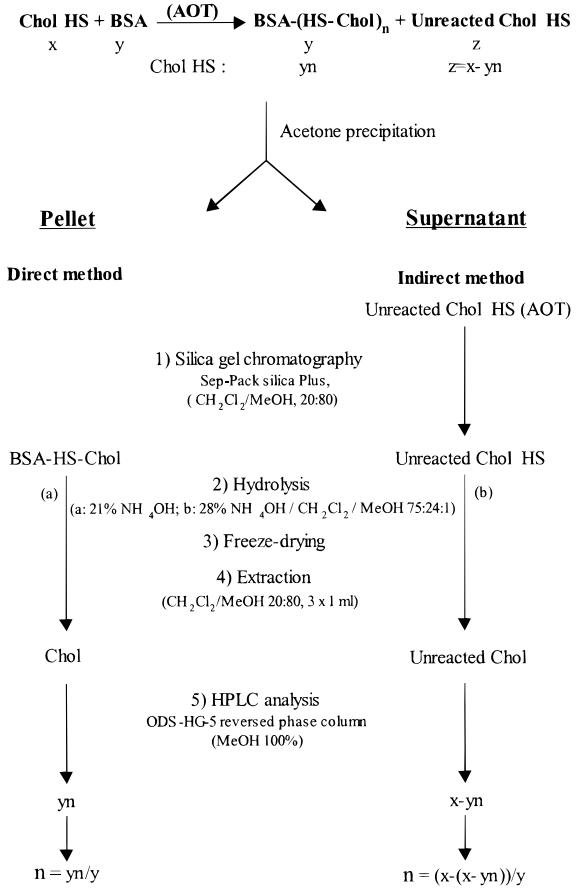

Figure 4. Outline of the two methods for the analysis of Chol-BSA conjugates. x and y are the number of moles of reagents and products; n (normal letter or subscript) is the number of haptenic residues per mole of BSA (epitope density). Calculations are made assuming a total recovery of the protein. The direct method determines bound Chol in the conjugate whereas the indirect method evaluates unreacted Chol in the acetone supernatant (other details in the text).

basis to estimate the amount of Chol HS synthesized. Reaction yield expressed as percentage of the molar ratio of Chol HS per total Chol are reported in Figure 3 for two temperatures (65 and 80 °C). These results clearly indicate that the yield is dependent upon the reagent ratio at both temperatures. However, at 80 °C, maximal yield (100%) can be reached with a 2-fold lower reagent ratio (15:1) compared to 30:1 necessary at 65 °C, thus highlighting also the temperature dependence of the reaction. In addition, temperatures below 60 °C were not favorable to provide yields greater than 40%, and the

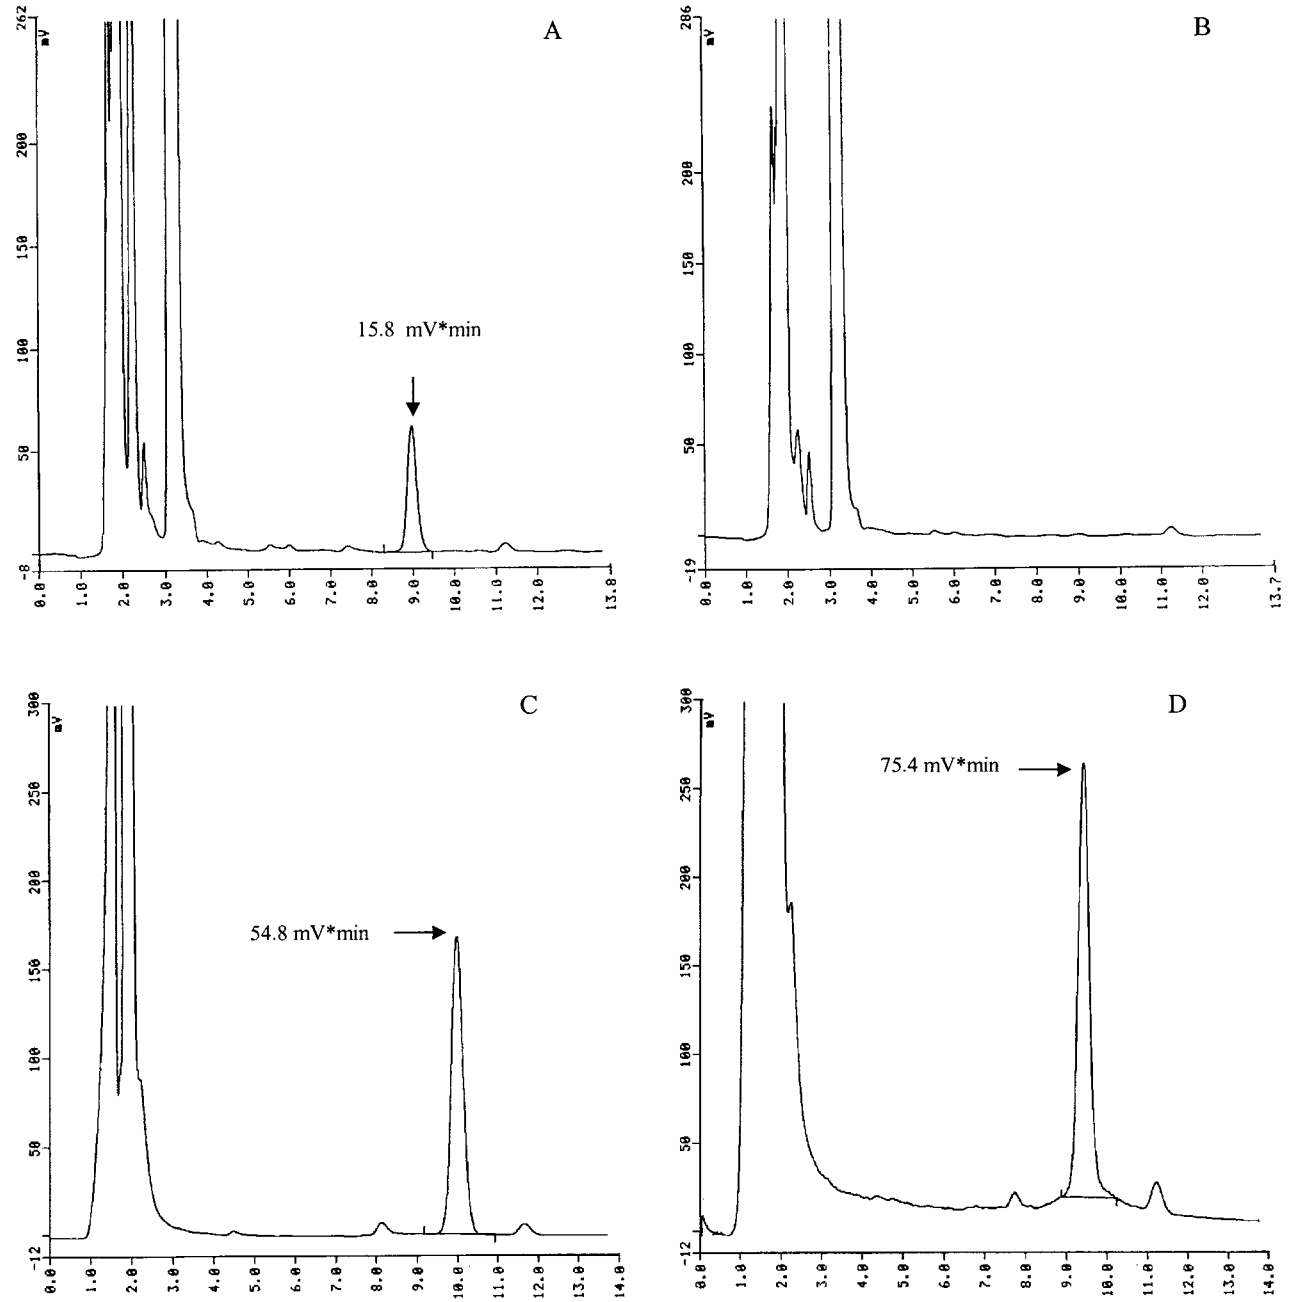

Figure 5. Chromatographic determination of the epitope density of Chol-BSA conjugates. BSA (300 μg) was reacted with either activated or nonactivated Chol HS in a 100-fold molar excess of hapten. Bound and unreacted Chol were evaluated chromatographically from an aliquot of the conjugate and the acetone supernatant, respectively (see Figure 4). Direct method (one-sixth of the original sample): (A) Chol-BSA conjugate; (B) control. Indirect method (one-fourth of the original sample): (C) Chol-BSA conjugate; (D) control.

influence of the reagent ratio was minimized in this temperature range (data not shown). Consequently, optimal conditions for this reaction were set at 65 °C for 6 h with a 30:1 molar reagent ratio.

Analysis of the Conjugates. Haptenation of the chemically activated Chol derivative (Chol HS) by the modified mixed anhydride method in the reversed micellar medium (Pauillac et al., 1998) yielded densely coated BSA carrier protein as revealed by chromatographic determination of bound Chol (direct method) or unreacted Chol HS (indirect method). These two methods are outlined in Figure 4 with the rationale for the determination of conjugates epitope density (n). Figure 5 illustrates these methods by chromatograms obtained with the same Chol-BSA conjugate and its control experiment (300 μg of BSA incubated under identical conditions with either 216.48 μg of activated or nonactivated Chol HS, respectively).

Using the direct method, the PA obtained for the conjugate sample (Figure 5A) corresponded to 7.26 μg of bound Chol (43.6 μg or 0.1127 μmol in the original reaction). Hence, n was found to be 26. It is noteworthy that no Chol was detected in control samples (Figure 5B) even up to a 500-fold molar excess of nonactivated Chol HS (data not shown).

By the indirect method, the PA obtained from the conjugate sample (Figure 5C) corresponds to 29.27 μg of unreacted Chol (117.08 μg in the original reaction). Considering the PA obtained from control sample (Figure 5D) equivalent to 40.93 μg of unreacted Chol, the maximum amount that could be recovered in the original reaction is 163.72 μg. Therefore, a good estimation of

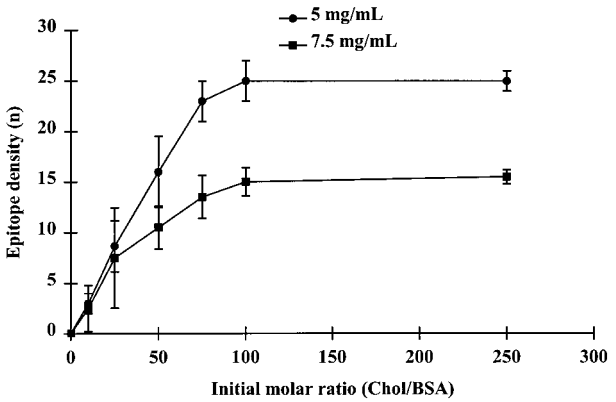

Figure 6. Optimization of cholesterol coupling to BSA. Dependency on hapten/protein molar ratio and influence of the concentration of the BSA stock solution (5 and 7.5 mg/mL). BSA (300 μg) was reacted with activated Chol HS in various molar excess (0−250). After purification, conjugates were solubilized in distilled water then analyzed for their epitope density according to the direct method.

Table 1. Determination of the Epitope Density of Various Chol-Carrier Conjugates

		conjugation efficiency	
carrier	mol wt	μg of Chol/ mg of carrier	n^b
BSA	68000	142	25
OVA	45000	125	14
KLH	ND[a]	112	ND
LH	ND[a]	139	ND
PL	70000	119	21
Casein	23000	151	9

[a] Not determined for the nonhomogeneous hemocyanins. [b] Epitope density, each value represents the average determination from three independent reactions, which varied by no more than 8% (direct method).

bound Chol in the conjugate is 46.64 μg (163.72−117.08), which gave $n = 27$. This value is very similar to that determined by the direct method (*26*). The adequacy and concordance of the direct and indirect method was further assessed by dual analyses of three BSA conjugates obtained using various hapten/carrier molar ratios. In all cases, the indirect method exhibited no more than 10% increase in *n* compared to the direct method and increase of bound Chol rigorously paralleled the decrease of unreacted Chol (data not shown).

Optimization of the Conjugates Preparation. Experiences aiming to investigate the influence of carrier concentration were designed using two BSA stock solutions (5 and 7.5 mg/mL) keeping the same hapten/carrier molar ratio. For convenience, these experiments were conducted using a commercial Chol HS activated at three concentrations (10, 20, and 40 mg/mL in dioxane), to keep approximately the same volume for the reaction mixtures. As shown in Figure 6, at the two stock BSA concentrations tested, the coupling rate is strongly dependent on the hapten/protein molar ratio up to a value of 100:1 but a plateau is eventually reached, indicating that conjugation no longer occurred for greater ratio values. Within the investigated reagent ratio range, the overall coupling efficiency of the assay using 5 mg/mL over the one using 7.5 mg/mL is clearly demonstrated. Maximal binding of Chol to BSA ($n \approx 25$) occurs using a 100-fold molar excess activated Chol HS with a 5 mg/mL protein stock concentration. Taking into account the above results, the optimized procedure was applied to the other carrier molecules and *n* was determined using the direct method (Table 1). For comparison purpose, the same amount of carrier (300 μg) was reacted with either activated or nonactivated Chol HS (∼216 μg), each value represents the average determination from three independent reactions, which varied by no more than 8%. Although *n* lies between 9 and 25, these results clearly show that conjugation efficiency is identical on a microgram of Chol bound per milligram of carrier basis.

DISCUSSION

To establish immunological reagents for the quantitation of haptens, there is a strict need for conjugation to appropriate carriers for preparing satisfactory material for immunization and antibody screening. Dealing with mice immunization, various immunogenic carriers have been successfully used; among them, BSA was the most widely assayed for many reasons. BSA is inexpensive and readily available, contains 60 amino groups of which ∼35 are exposed to the surface of the molecule under physiological conditions, in addition, this protein proved to be heterologous enough to provoke adequate mice immune response in most cases.

A simple conjugation reaction consists of a mixture of the protein, the hapten, and a coupling reagent in such a way that the yield of conjugate is maximal. Nevertheless, conjugation must not alter the antigenic properties of the hapten. To this goal, other practical aspects appear uppermost relevant, as the purity and concentration of the components, products yield, and finally conjugate recovery. Since all these critical factors can individually have a profound effect on the success of the procedure, optimal coupling conditions must be carefully checked.

Haptens bearing nonreadily reactive functional groups must be converted into more reactive derivatives using adequate chemical reagents (Erlanger, 1973, 1980; Wong, 1993). When hydroxyl groups are available, hemisuccinate derivatives are generally produced in the presence of an excess of succinic anhydride in pyridine, linkage to the amino groups of the carrier is subsequently accomplished through a reagent-mediated carboxyl activation. This process has the advantage of introducing a four-carbon spacer arm which exposes the hapten from the surface of the carrier, thus favoring its presentation and recognition by the immune system. However, it has been previously demonstrated that increasing the length of the chemical spacer can severely affect the production of hapten-specific antibodies (Beckett et al., 1978) since, as an artifact, it can also be part of the epitope recognized by the induced antibodies (Weyrer et al., 1990).

In this study, minute amount (0.446 μmol) of Chol was first entirely converted into an hemisuccinate (Chol HS), then the recently described conjugation technique proceeding in a reversed micellar medium (Pauillac et al., 1998) was successfully adapted to this carboxylic derivative as a one-pot synthesis method.

Because the degree of conjugation or epitope density is an essential attribute of a conjugate either as an immunogen (Klaus and Cross, 1974; Erlanger, 1980; Cooper et al., 1993, 1994) or a target antigen (Vyjayanthi et al., 1995), its assessment must be correctly addressed. For these reasons investigations were previously aimed (i) at the study of complete conjugate recovery (Pauillac et al., 1998) and (ii) at accurate determination of Chol on a reversed-phase HPLC column according to a calibration curve. The assessment of the Chol content of the conjugates either by the direct or indirect method gave consistent results. In the direct method, where covalently linked Chol is released by alkaline hydrolysis, corre-

sponding PA was linearly related to sample contents and a simple multiplication by 6 gave the Chol content in the whole conjugates. In the indirect method which measures unbound Chol, a 4-fold factor was applied to restore the true value in the whole supernatant and a subtraction from the total unreacted Chol recovered from control experiments was made to estimate bound Chol in the whole conjugates.

By reacting the same amount of activated hapten (~216 μg) with identical amounts of various carriers (300 μg), epitope density of the conjugates lied between 9 and 25, but on a microgram *o*f Chol bound per milligram of carrier basis, conjugation efficiency was identical. These values were found to fall within the optimal range to ensure hapten-specific antibody production (Erlanger, 1980).

As a matter of fact, using this procedure, PbTx-3 (400 μg; 0.446 μmol)—a member of the brevetoxin polyether-type toxins (Baden, 1989)—was totally converted into an hemisuccinate derivative (PbTx-3 HS) and covalently linked to BSA and OVA. Following mice immunization with $(PbTx\text{-}3)_{18}$—BSA conjugate, highly specific antibodies have been produced as revealed by ELISA on $(PbTx\text{-}3)_{10}$—OVA-coated plates (Naar et al., unpublished results).

In this study dealing with Chol, a hydroxylated lipid-soluble hapten, four major improvements have been achieved in the process of conjugates preparation and analysis: (1) Chol HS was produced with a 100% yield with as little as 172 μg of starting material; (2) the mixed anhydride method of Erlanger was successfully adapted to such minute hapten quantities with a moderate hapten/carrier molar ratio of 100:1; (3) quantitation of both bound Chol and unreacted Chol HS was accurately performed chromatographically; (4) no radioactive probe was required to monitor antigen preparation.

In conclusion, this simple conjugation procedure appears most valuable for poorly available and weakly immunogen haptens bearing hydroxyl groups such as polyether-type marine toxins through the specific induction of high-affinity antibodies.

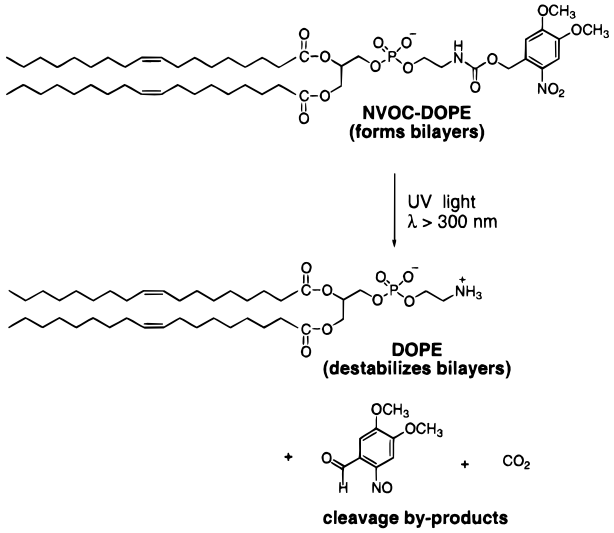
Synthesis and Characterization of NVOC-DOPE, a Caged Photoactivatable Derivative of Dioleoylphosphatidylethanolamine

Zhi-Yi Zhang and Bradley D. Smith*



Department of Chemistry and Biochemistry, 251 Nieuwland Science Hall, University of Notre Dame, Notre Dame, Indiana 46556-5670. Received June 23, 1999; Revised Manuscript Received September 9, 1999

A caged, photocleavable derivative of dioleoylphosphatidylethanolamine (DOPE) called NVOC-DOPE was prepared by reaction of DOPE with 6-nitroveratryloxycarbonyl chloride. In contrast to egg phosphatidylethanolamine (EPE), NVOC-DOPE or its 1:1 mixture with EPE forms liposomes at both pH 7.4 and 5.0. Photolysis ($\lambda > 300$ nm) of aqueous liposomal dispersions of NVOC-DOPE at pH 9.0, 7.4, or 5.0 results in complete conversion to DOPE and subsequent release of entrapped calcein dye. The temporal and spatial control associated with the photorelease technique suggests that NVOC-DOPE can be used to study a range of important dynamic membrane processes such as membrane fusion and the action of membrane-associated enzymes.

INTRODUCTION

The presence of nonbilayer-forming lipids, such as phosphatidylethanolamine (PE), is known to activate important biological membrane processes such as bilayer fusion (Kinnunen, 1996b; Siegel, 1999) and the action of membrane-associated enzymes (Hunter et al., 1999; Kinnunen, 1996a; Stubbs and Slater, 1996; Williams, 1998). These dynamic supramolecular events are spatially localized and short-lived, which makes them hard to observe and characterize by physical methods (Chanturiya et al., 1997; Siegel and Epand, 1997; Siegel et al., 1994; Walter and Siegel, 1993). Thus, there is a need to develop triggered, biophysical characterization methods that have a short time frame. A classical photochemical approach is to synthesize an inert "caged" precursor of the active compound and use flash photolysis to rapidly release the compound in a spatially controlled manner (Adams and Tsien, 1993; Corrie and Trentham, 1993). Here we describe a caged version of 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) called NVOC-DOPE and show that it is able to form stable liposomes. Upon irradiation, NVOC-DOPE is rapidly converted to DOPE (Scheme 1), which induces bilayer instability and liposome leakage.

Scheme 1

EXPERIMENTAL PROCEDURES

Reagents. 1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) and egg phosphatidylethanolamine (EPE) were purchased from Avanti. Calcein, dithiothreitol (DTT), and 6-nitroveratryloxycarbonyl chloride (NVOC−Chloride, or 4,5-dimethoxy-2-nitrobenzyl chloroformate) were purchased from Aldrich.

Synthesis of NVOC-DOPE. DOPE (100 mg, 134 μmol) and 6-nitroveratryloxycarbonyl chloride (1.5 molar equivalents) were mixed in dry methylene chloride in the presence of triethylamine (4.0 molar equivalents). The mixture was stirred at 40 °C for 12 h under nitrogen in the dark. The reaction mixture was cooled to room temperature and washed successively with cold solutions of 4% Na_2CO_3, H_2O, 5% HCl, and H_2O. The organic layer was dried with Mg_2SO_4, and then evaporated. The residue was purified by column chromatography (silica gel) using $CHCl_3$ and subsequently $CH_3OH-CHCl_3$ (1:4, v/v) as eluant to give NVOC-DOPE as a yellow wax: yield 75%. ^{1}H NMR (300 MHz, CD_3OD) 7.74 (s, 1H), 7.20 (s, 1H), 5.46 (s, 2H), 5.34 (t, $J = 5.0$ Hz, 4H), 5.19 (m, 1H), 4.40 (dd, $J = 11.7$, 3.3 Hz, 1H), 4.15 (q, $J = 6.2$ Hz, 1H), 4.00−3.91 (m, 10H), 3.39 (t, $J = 5.4$ Hz, 2H), 2.33−2.26 (m, 4H), 2.02 (d, $J = 5.4$, 8H), 1.58 (m, 4H), 1.30 (m, 40H), 0.90 (t, $J = 6.6$ Hz, 6H) ppm; IR ($CHCl_3$ solution deposited on a NaCl plate) 1738, 1715, 1651, 1609, 1518 cm^{-1}; HRMS (FAB) observed *m/z* 1026.5579, calcd for $C_{51}H_{85}O_{14}N_2PNa_2$ [M + 2Na − 2H] 1026.5534; TLC $R_f = 0.37$ (silica gel/$CH_3OH-CHCl_3$, 1:4, v/v).

Liposome Preparation. A chloroform solution containing an appropriate amount of lipid was evaporated using a rotary evaporator (<30 °C), and the lipid film dried under vacuum for at least 1 h. The liposomes were dispersed in a solution of 50 mM calcein in either pH 5.0 buffer (100 mM NaCl/50 mM sodium acetate), pH 7.4 buffer [100 mM NaCl/5 mM *N*-tris(hydroxymethyl)-methyl-2-aminoethanesulfonic acid], or pH 9.0 buffer (100

Published on Web 10/26/1999

mM NaCl/50 mM sodium carbonate) with the aid of vortex mixer. Pyrex glass beads were added before vortexing to facilitate removal of the lipid film from the sides of the flask (final lipid concentration: 10 mM). The resulting opaque dispersion was frozen in an ethanol/dry ice bath and then allowed to thaw in a water bath at 35−40 °C. This freeze−thaw cycle was repeated 10 times. The resulting mixture was extruded, at room temperature, 29 times through a 19 mm polycarbonate filter (Nucleopore) with 100 nm diameter pores using a hand-held Basic LiposoFast device purchased from Avestin. Untrapped calcein was separated by dialysis against isoosmotic buffer.

Photoinduced Calcein Release. A solution of NVOC-DOPE (300 μM, 300 μL) was placed in a 1 mL glass cuvette situated 20 cm from the output lens of a 150 W Xe lamp (filter cut off λ < 300 nm). The temperature was controlled by a thermostated cell holder. After irradiation, a 30 μL aliquot was diluted to 3.0 mL with isoosmotic buffer. The fluorescence intensity was measured at 25 °C. Excitation was set at 490 nm and fluorescence emission was measured at 520 nm. The fluorescence corresponding to 100% leakage was determined after addition of 75 μL of Triton X-100 (20% w/v). The fluorescence intensity for 100% leakage of a control dark sample was measured after liposome lysis with Triton. The percent leakage of calcein was calculated as $\{[I_t - (I_{100}/I_{100}^{dark})I_0]/[1.025\ I_{100} - (I_{100}/I_{100}^{dark})I_0]\} \times 100\%$ (Bondurant and O'Brien, 1998).

Extent of NVOC-DOPE Cleavage in Calcein-Filled Liposomes. The calcein loaded liposomes (300 μM, 300 μL) were lysed with excess ethanol. After removal of solvents and drying under vacuum, 3 mL of $CHCl_3$ was added to take up the lipids. The solution was passed through a 0.8 μm filter to remove the calcein particles and the absence of calcein was confirmed by UV. The extent of photoconversion was calculated from the decrease in absorbance at 350 nm and confirmed by TLC (silica gel; $CHCl_3$:CH_3OH:H_2O, 80:20:1; R_f NVOC-DOPE = 0.56, R_f DOPE = 0.46).

RESULTS AND DISCUSSION

PE does not form a bilayer membrane at physiological pH, but instead adopts inverse cubic and inverse hexagonal structures (Cullis and De Kruijff, 1976; Litzinger and Huang, 1992). Conversely, N-acylated PEs are negatively charged phospholipids and can form kinetically stable liposomes (Domingo et al., 1995; Shangguan et al., 1998). Triggered liposomal systems have been reported with chemically cleavable N-acyl PEs (Kirpotin et al., 1996; Pak et al., 1998), but to our knowledge there is no published example of a photocleavable N-acyl PE; however, polar lipids with caged headgroups (Tuchinsky and Zehavi, 1998) and hydrocarbon tails (Kusumi et al., 1989) are known. NVOC-DOPE is prepared in one step by reaction of DOPE with 6-nitroveratryloxycarbonyl chloride. After purification; NVOC-DOPE is stable to low-temperature storage in the dark. In contrast to pure DOPE, large unilamellar vesicles (LUVs) composed solely of NVOC-DOPE or a 1:1 mixture of EPE/NVOC-DOPE can be prepared at pH 7.4 or 5.0. Liposomes are not readily formed at neutral pH using a 7:3 mixture of EPE/NVOC-DOPE.

The photocleavage of NVOC-DOPE occurs readily in organic solvent, but an isosbestic point is not observed in the UV spectrum (Figure 1). Most likely, the released DOPE condenses with the 3,4-dimethoxy-2-nitrosobenzaldehyde byproduct, which is a common concern with this photocleavage method (Corrie and Trentham, 1993). The side reaction is not observed in aqueous solution, where reasonably concentrated aqueous dispersions of NVOC-DOPE LUVs (300 μM) at pH 9.0, 7.4, or 5.0 are completely converted to DOPE after irradiation with a 500 W Hg lamp (λ < 300 nm) for 4 min. TLC analysis shows that DOPE is liberated in a stoichiometric amount and that the presence of dithiothreitol, which acts as scavenger of 3,4-dimethoxy-2-nitrosobenzaldehyde (Corrie and Trentham, 1993), has no effect on the photocleavage reaction. A dynamic light scattering analysis of the NVOC-DOPE LUVs at pH 5 before photolysis indicated a mean size of 116 ± 47 nm. After photolysis, the dispersion was slightly turbid, and dynamic light scattering indicated a mean size of 495 ± 191 nm. Thus, concomitant with the photoconversion to DOPE, the vesicles undergo fusion and/or aggregation to form larger particles.

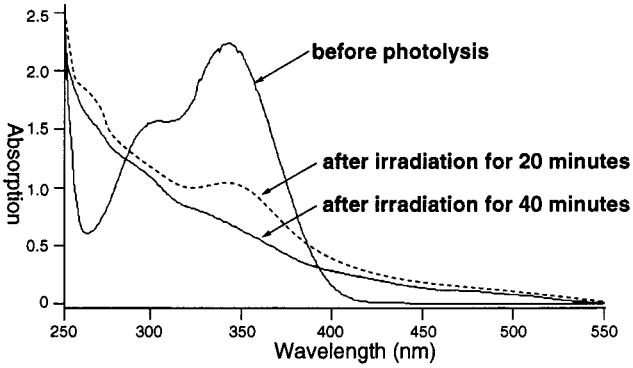

Figure 1. Absorption spectrum of NVOC-DOPE (300 μM) in chloroform.

Calcein leakage experiments show that increasing the fraction of DOPE in the liposomes by photolysis of NVOC-DOPE leads to liposome disruption. The fluorescence assay is hindered by two technical difficulties, the strongly absorbing calcein inhibits the photolysis of NVOC-DOPE, and the calcein emission is decreased due to photobleaching. For example, irradiation of calcein-containing LUVs made from 1:1 EPE/NVOC-DOPE with a 500 W Hg lamp results in rapid and complete leakage of all the calcein, but calcein photobleaching is extensive (~50%). Clearer mechanistic insight was gained using a less intense 150 W Xe lamp that required a longer irradiation time to complete the photocleavage, but produced a much smaller amount of calcein photobleaching and a slower leakage rate. As shown in Figure 2, a 20 min irradiation was needed to convert 90% of the NVOC-DOPE to DOPE, and the amount of escaped calcein initially increased in a slow, linear fashion. Initial calcein leakage rates were measured as a function of temperature, pH, and concentration. The results (Table 1) indicate that photoinduced leakage from 1:1 EPE/NVOC-DOPE LUVs increases with temperature (compare entries 1, 3, and 5), acidity (compare entries 3 and 7), and liposome concentration (compare entries 3 and 8). These trends are in agreement with previous studies of leakage from PE-containing liposomes (Litzinger and Huang, 1992) and show that leakage is promoted by experimental conditions that increase the amount of liposome-liposome contact.

In conclusion, caged derivatives of DOPE, such as NVOC-DOPE reported here, are likely to be useful as photochemical triggers of a range of dynamic membrane processes, especially membrane fusion and the action of

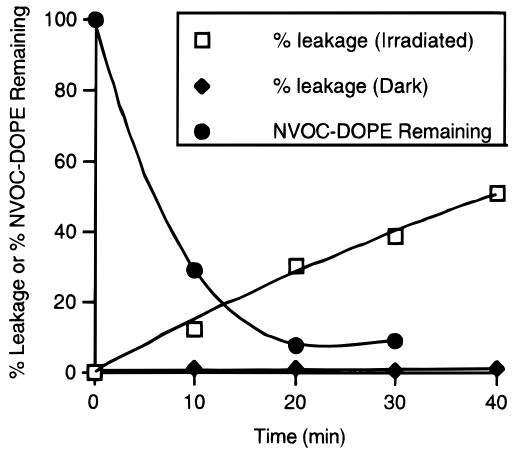

Figure 2. Photocleavage of NVOC-DOPE and calcein release from 1:1 EPE/NVOC-DOPE liposomes (300 μM) at pH 5 and 37 °C, upon irradiation with 150 W lamp.

Table 1. Photoinduced Calcein Leakage from 1:1 EPE/ NVOC-DOPE Liposomes[a]

entry	lipid concentrated (μM)	pH	temp (°C)	light (λ > 300 nm)	leakage rate[a] (% per min)
1	300	5.0	25	UV	0.65
2	300	5.0	25	dark	0
3	300	5.0	37	UV	1.5
4	300	5.0	37	dark	0.05
5	300	5.0	50	UV	2
6	300	5.0	50	dark	0.15
7	300	6.9	37	UV	0.9
8	100	5.0	37	UV	0.8

membrane-associated enzymes. They can be employed in studies that require rapid, spatially controlled activation or where mechanical mixing is impractical. A technical drawback with NVOC-DOPE is that the UV light required to induce cleavage may interfere with some of the optical assays used to monitor the subsequent membrane process. The recent introduction of photolabile protecting groups that can be cleaved by two photon IR radiation, however, suggests that this potential problem can be overcome (Furata et al., 1999). Finally, we note that the development of photoactive liposomes for drug or reagent delivery is an active research area (Bondurant and O'Brien, 1998; Wymer et al., 1998) and that "caged" liposomes may be useful as general, triggered-release capsules for solutes (e.g., inorganic ions, peptides, and enzymes, etc.) that are difficult to modify by chemical methods (Morgan et al., 1995a,b).
