Bioconjugate Chemistry

EDITORIAL: What's New

In addition to submitting typed or printed manuscripts, beginning this year authors will be able to submit them electronically via the Web. Instructions are available from the *Bioconjugate Chemistry* home page, <http://pubs.acs.org/BC>. Web submission will significantly reduce the time required for review and publication. The manuscript submission site employs state-of-art security mechanisms to ensure confidentiality.

We welcome the new members of the *Bioconjugate Chemistry* Editorial Advisory Board for 2001:

Dr. Carolyn J. Anderson, Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO

Dr. John E. Shively, Beckman Research Institute of City of Hope, Duarte, CA

Dr. Jens Peter Jacobsen, Department of Chemistry, Odense University, Odense, Denmark

Dr. Kenneth A. Jacobson, LBC, NIDDK, National Institutes of Health, Bethesda, MD

Dr. Kevin G. Rice, College of Pharmacy, University of Michigan, Ann Arbor, MI

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 2000 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the eleventh volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are listed on the following page.

Hemin (Fe^{3+})– and Heme (Fe^{2+})–Smectite Conjugates as a Model of Hemoprotein Based on Spectrophotometry

Tetsuji Itoh, Takuya Yamada, Yoh Kodera, Ayako Matsushima, Misao Hiroto, Katsukiyo Sakurai, Hiroyuki Nishimura, and Yuji Inada*

Toin Human Science and Technology Center, Department of Biomedical Engineering, Toin University of Yokohama, Kurogane-cho, Aoba-ku, Yokohama 225-8502, Japan. Received May 29, 2000

Hemin (Fe^{3+}) was adsorbed onto synthetic smectite (clay mineral) in acetone to form a hemin–smectite conjugate. The hemin–smectite conjugate became soluble in water to form a transparent colloidal solution with a dark brown color. Its absorption spectrum in water showed a sharp Soret band at 398 nm with the molar extinction coefficient as $\epsilon_{398\text{nm}} = 11.6 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$, which is in good agreement with $\epsilon_{398\text{nm}} = (12.2 \pm 3) \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ of monomeric hematin (1). Hemin (Fe^{3+})–smectite conjugate had a peroxidase-like activity in the presence of hydrogen peroxide (a hydrogen acceptor) and guaiacol (a hydrogen donor) in aqueous solution and its activity was higher than that of hematin. Hemin (Fe^{3+})–smectite conjugate in water was reduced by adding sodium dithionite to form a heme (Fe^{2+})–smectite conjugate which is also a transparent colloidal solution in water. Its absorption spectrum in aqueous solution was surprisingly in close agreement with that of oxyhemoglobin. Its peak positions of α , β , and Soret bands were located in only a 9–3 nm shift to shorter wavelengths in comparison with those of oxyhemoglobin. Therefore, heme (Fe^{2+})–smectite conjugate was bound to O_2 to form O_2 –heme (Fe^{2+})–smectite conjugate. The addition of carbon monoxide, CO, to O_2 –heme (Fe^{2+})–smectite conjugate caused the formation of CO–heme (Fe^{2+})–smectite conjugate with a similar absorption spectrum of carboxyhemoglobin (HbCO) accompanied by shifting 8–10 nm to shorter wavelength. Therefore, the transformation of O_2 –heme (Fe^{2+})–smectite conjugate to CO–heme (Fe^{2+})–smectite conjugate was accompanied by shifting of 7, 4, and 3 nm to shorter wavelengths in the α , β , and Soret bands respectively, which are similar to the spectral change from oxyhemoglobin to carboxyhemoglobin. Also the ratio (1:1.6) of the molar extinction coefficient of Soret band of O_2 –heme (Fe^{2+})–smectite conjugate and CO–heme (Fe^{2+})–smectite conjugate was surprisingly agreement with ratio (1:1.5) of oxyhemoglobin and carboxyhemoglobin. The phenomenon shown above was unexpectedly found during the course of study of bioconjugate of a bioactive substance, hemin (Fe^{3+}) or heme (Fe^{2+}), and a clay mineral, smectite, in place of the protein of globin in hemoglobin.

Human hemoglobin with the molecular weight of 64 500 in red blood cells consists of 6% heme and 94% globin and plays, in vivo, an important role in transport of oxygen. In its oxygenation form it is called oxyhemoglobin, HbO_2 ,¹ and when the oxygen is displaced by carbon monoxide, it is called carboxyhemoglobin, HbCO (3). This splendid function depends on the cooperative action of heme and globin protein ($\alpha_2\beta_2$) having a specific conformation composed of primary (α chain, 141 amino acids; β chain, 146 amino acids), secondary (helix content, 70%), tertiary (the steric conformation), and quaternary structures (four subunits) (4, 5). The hemoglobin molecule has a compact spheroidal structure of 6.4 by 5.5 by 5.0 nm in dimension (6). When one of amino acids in hemoglobin molecule is deleted or substituted by another amino acid by mutation, the normal function of hemoglobin can be harmed to form what is called abnormal hemoglobin (7). On the other hand, heme (Fe^{2+}) is a prosthetic group of hemoglobin and is obtained by reducing hematin (Fe^{3+}) in alkali solution by sodium dithionite (Figure 1a) (2). The absorption spectrum of monomeric

hematin in aqueous solution could be measured at pH 6.8 and found to have a sharp Soret band with a molar extinction coefficient as $\epsilon_{398\text{nm}} = (12.2 \pm 3) \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$, as reported by Inada and Shibata (1).

The smectite (hectorite), which was hydrothermally synthesized, had unique physical and chemical properties such as high transparency in water, cation exchange, and the ability to form organic and inorganic interlayer complexes (8, 9). Expandable phyllosilicates have a structure composed of alternating 2:1 layer, which consists of two sheets of linked SiO_4 tetrahedra sandwiching octahedral cations, Mg, between them as shown in Figure 1b. The 2:1 layers which have a net negative charge (layer charge), are loosely tied together by interlayer cations. Water also is present between the layers. The properties of smectite prepared by Torii and Iwasaki (8–10) are as follows: elemental composition Si 8.00, Mg 5.65, Li 0.70, and Na 1.05; transmittance 95% in 1% aqueous solution at 500 nm; and methylene blue absorption 101 milliequiv/100 g which is obtained from Co-op Chemical Co., Ltd (Tokyo, Japan).

Chlorohemin is soluble in dilute potassium hydroxide solution to form hematin. The monomeric hematin molecule is unstable and has a marked tendency to take a polymerized form. The hemin–smectite conjugate was prepared by adding 300 mg of smectite powder to 33 mL

¹ Abbreviations: HbO_2 , oxyhemoglobin; HbCO, carboxyhemoglobin; SME, smectite.

Figure 1. (a) Heme or hemin consists of protoporphyrin being made up of four pyrrole groups and an iron ion. The iron atom in heme or hemin binds to the four nitrogens in the center of the protoporphyrin ring. The iron can form two additional bounds. Their bonding sites are termed the fifth and sixth coordination positions. The iron atoms in the heme can be in the ferrous (Fe^{2+}) or the ferric (Fe^{3+}) oxidation state. (b) The chemical structure of smectite in a crystal state consists of two sheets of linked SiO_4 tetrahedra sandwiching octahedral cation (Mg) between them, and the interlayer. Elemental composition Si 8.00, Mg 5.65, Li 0.70, Na 1.05; transmittance 95% in 1% aqueous solution at 500 nm; and methylene blue absorption 101 milliequiv/100 g.

of acetone solution containing chorohemin (0.85 mg). The suspension was then shaken for 1 h at 25 °C to establish the adsorption equilibrium between hemin and smectite. The hemin (Fe^{3+})-smectite conjugate thus formed was collected by centrifugation and was dried under reduced pressure. The amount of hemin adsorbed onto smectite was spectrophotometrically determined by measuring the absorbance of the supernatant liquid obtained by centrifugation of the sample suspension using the molar extinction coefficient of hematin. The hemin-smectite conjugate, in which amount of hemin (0.2 mg) was adsorbed onto 100 mg of smectite, was dissolved in water to form transparent solution with dark brown color. Absorption spectrum of hemin (Fe^{3+})-smectite conjugate (1.14% in water) shows a sharp Soret band at 398 nm and two peaks at 490 and 610 nm as shown in Figure 2a. And its molar extinction coefficient at 398 nm as $\epsilon_{398\text{nm}} = 11.6 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ was in good agreement with that of monomeric hematin (1). The absorption spectrum of hematin, dashed line in Figure 2a, shows a polymerized form of hematin with a broad Soret band at approximate 360 nm. Figure 2b shows the peroxidase activities of hemin (Fe^{3+})-smectite conjugate (closed circle) and hematin (open circle) against incubation time using hydrogen peroxide (a hydrogen acceptor) and guaiacol (a hydrogen donor) in aqueous solution. The activity of the hemin (Fe^{3+})-smectite conjugate was increased linearly with time, while the activity of hematin was lowered with time. The peroxidase-like activity of the conjugate was well retained at high concentration of H_2O_2 and in high temperature at more than 60 °C in the reaction system in comparison with that of natural peroxidase composed of protein and hemin.

Hemin (Fe^{3+})-smectite conjugate in the thunberg tube was deaerated by successive freeze-pump-thaw cycles and was reduced by the addition of sodium dithionite to form heme (Fe^{2+})-smectite conjugate. Absorption spectrum of heme (Fe^{2+})-smectite conjugate in water is shown by solid line in Figure 3a, which is quite different from that of hemin (Fe^{3+})-smectite conjugate shown by dashed line in Figure 3a. The peak positions of α , β , and Soret bands in heme (Fe^{2+})-smectite conjugate were located at 568, 534, and 411 nm, respectively, which represent an only approximately 9–3 nm shift to shorter wavelengths compared with those of oxyhemoglobin

Figure 2. Absorption spectra of hemin (Fe^{3+})-smectite conjugate and hematin (Fe^{3+}) in water (a) and peroxidase activity of hemin-smectite conjugate in the presence of hydrogen peroxide and guaiacol in aqueous solution (b). (a) The spectrum of hemin (Fe^{3+})-smectite conjugate (17 μM) is shown by solid line with a sharp Soret band at 398 nm. The absorption spectrum of hematin at the same concentration as the hemin (Fe^{3+})-smectite conjugate is shown by dashed line with a broad band at about 360 nm as a Soret band which is a polymerized form of hematin. (b) The peroxidase activity was spectrophotometrically determined by measuring the absorbance at 460 nm caused by the oxidation of guaiacol (0.3 mM) with hydrogen peroxide (3.2 mM) in 3.1 mL of 0.1 M phosphate buffer (pH 7.0) in the presence of hemin-smectite conjugate (8.6 μM) or hematin (8.2 μM). The absorbance at 460 nm was plotted against incubation time (min) at 25 °C.

(Table 1). To confirm the binding of O_2 to heme (Fe^{2+})-smectite conjugate to form O_2 -heme (Fe^{2+})-smectite conjugate, states of heme (Fe^{2+}) and hemin (Fe^{3+}) conjugated with smectite were studied by measuring the ESR spectrum with a Japan Electron Optics Laboratory spectrometer model JES-FA 200 operating at 100 kHz. The ESR spectrum of hemin (Fe^{3+})-smectite conjugate in water showed the concomitant formation of the two high-spin states of ($g = 6.160$) and ($g = 5.865$). On the other hand, heme (Fe^{2+})-smectite conjugate obtained by adding sodium dithionite to hemin (Fe^{3+})-smectite conjugate showed a reduced ESR signal in high-spin state ($g = 6.160$). A similar phenomenon had been observed in transformation of methemoglobin (Fe^{3+}) to oxyhemoglobin (Fe^{2+}) in which ESR spectrum with high-spin state

Table 1. Spectrophotometric Characteristics of Hemin (Fe^{3+})– and Heme(Fe^{2+})–smectite Conjugates in Comparison with Those of Hemi(Fe^{3+}) and Hemo(Fe^{2+}) Proteins^a

compound	oxidation state of Fe	ligands		λ_{max}			ϵ (mM)
		fifth	sixth	α	β	Soret	
O_2 -heme-smectite	Fe^{2+}	(SME	O_2)	568	534	411	93
CO-heme-smectite	Fe^{2+}	(SME	CO)	561	530	408	148
oxyhemoglobin ⁽¹⁾	Fe^{2+}	His	O_2	577	541	414	125
carboxyhemoglobin ⁽³⁾	Fe^{2+}	His	CO	570	538	418	191
hemin-smectite	Fe^{3+}	(SME	Cl^-)	610	490	398	116
monomeric hematin ⁽¹⁾	Fe^{3+}	OH-	H_2O	—	—	398	122
hemoglobin ⁽³⁾	Fe^{3+}	His	H_2O	630	500	406	

^a The absorption spectra of hemin– and heme–smectite conjugates in water, a transparent colloidal solution, was measured with a Shimadzu spectrophotometer MPS-2000 (Kyoto, Japan). Soret (ϵ , mM): the peak position (λ_{max}) of Soret band with molar extinction coefficient (ϵ , mM).

Figure 3. Absorption spectra of O_2 -heme (Fe^{2+})–smectite conjugate (a) and CO-heme (Fe^{2+})–smectite conjugate (b) in water. (a) Spectrum of O_2 -heme (Fe^{2+})–smectite conjugate in water (17 μM) obtained by adding dithionite to hemin (Fe^{3+})–smectite conjugate. The peak positions are located at 568, 534, and 411 nm. (b) Spectrum of CO-heme (Fe^{2+})–smectite conjugate (17 μM) obtained by adding carbon monoxide, CO, to O_2 -heme (Fe^{2+})–smectite conjugate. The absorption bands are at 561, 530, and 408 nm which are located at shorter wavelengths compared with the spectrum of O_2 -heme (Fe^{2+})–smectite conjugate. Dashed lines shown in panels a and b indicate the spectrum of hemin (Fe^{3+})–smectite conjugate having the peak positions of 610 and 490 nm and the Soret band at 398 nm.

($g \approx 6$) of methemoglobin (Fe^{3+}) is hardly detected in oxyhemoglobin (HbO_2) due to diamagnetism (11). It suggests the possibility of heme (Fe^{2+})–smectite conjugate being bound to oxygen to form O_2 -heme (Fe^{2+})–smectite conjugate. Furthermore, the addition of carbon monoxide, CO, to O_2 -heme (Fe^{2+})–smectite conjugate caused the formation of CO-heme (Fe^{2+})–smectite conjugate with the absorption maxima at 561, 530, and 408 nm, which are also similar to carboxyhemoglobin (HbCO) with peak positions at 570, 538, and 418 nm (Figure 3b and Table 1).

It is well-known that oxyhemoglobin changes easily to carboxyhemoglobin (HbCO) in the presence of carbon monoxide, CO, with the spectral change as shown in Table 1. A similar phenomenon was observed in heme (Fe^{2+})–smectite conjugate, in a form of a spectral change of O_2 -heme (Fe^{2+})–smectite to CO-heme (Fe^{2+})–smectite from 568, 534, and 411 nm to 561, 530, and 408 nm, respectively, with a 7–3 nm shift to shorter wavelength as shown in Table 1. The ratio of the molar extinction coefficient of O_2 -heme (Fe^{2+})–smectite conjugate and CO-heme (Fe^{2+})–smectite conjugate was 1:1.6 which is closely agreement with that of oxyhemoglobin and carboxyhemoglobin, 1:1.5 (Table 1). From the results obtained above, it may be concluded that the heme (Fe^{2+})–

smectite conjugate prepared by the above method is bound to an oxygen molecule to form O_2 -heme (Fe^{2+})–smectite conjugate.

It was previously known in a similar line of study conducted extensively by us that conjugate of tetrapyrrole ring including magnesium or chlorophylls adsorbed onto clay minerals such as bentonite and smectite is closely associated with the development of the photochemical function of chlorophylls (10, 12–14). It is well-known that chlorophylls *a* and *b* extracted with organic solvents from fresh green leaves are quite unstable and are rapidly bleached by light-illumination, although chlorophylls bound to protein in chloroplast are quite stable in vivo. In expectation of making chlorophylls much more stable against light, chlorophylls were adsorbed onto clay minerals such as bentonite or smectite in place of protein. Chlorophyll *a*–smectite conjugate was quite photostable, and the absorption maximum of the conjugate approached 678 nm, which is the absorption maximum of intact spinach leaves. And the chlorophyll–smectite conjugate becomes soluble in aqueous solution although chlorophylls are never soluble in water. The conjugate of chlorophyll *a*, poly(vinylpyrrolidone), and smectite had an absorption maximum at 677 nm thus becoming more photostable than chlorophyll–smectite conjugate and catalyzing hydrogen gas evolution by visible light in aqueous solution. The similar line of study was conducted by Wang (15): heme embedded in a hydrophobic matrix of polystyrene and 1-(2-phenylethyl)-imidazole has the ability of O_2 and CO binding.

During the course of the study mentioned above, we happened to prepare hemin (Fe^{3+})– and heme (Fe^{2+})–smectite conjugates in which smectite, soluble in water, was used in place of the protein of globin in hemoglobin. It was unexpected that the heme (Fe^{2+})–smectite conjugate is bound to O_2 and CO in a manner similar to hemoprotein. Soon, bioconjugate compounds of smectite with chlorophylls are expected to make artificial photosynthesis possible and that of smectite with heme serves as an oxygen carrier in place of hemoglobin.

ACKNOWLEDGMENT

The authors are grateful to Dr. Masahiro Kohno, Research and Development Department Analytical Instruments Division, JEOL Ltd., and Dr. Youkoh Kaizu, Professor, Faculty of Science, Department of Chemistry, Tokyo Institute of Technology, for his basic and technical advice in measurement of ESR spectra. We are deeply indebted to professor Saburo Osabe, Tooin University of Yokohama, for his assistance in preparation of the manuscript.

REVIEWS

Bifunctional Chelators for Therapeutic Lanthanide Radiopharmaceuticals

Shuang Liu* and D. Scott Edwards

Medical Imaging Division, DuPont Pharmaceuticals Company, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received June 21, 2000

INTRODUCTION

Therapeutic radiopharmaceuticals are radiolabeled molecules designed to deliver therapeutic doses of ionizing radiation to specific disease sites (1, 2). Therapeutic doses of radiation can be delivered to sites of disease such as cancer in three ways: external beam irradiation, implantable “seeds” or systemic administration. Brachytherapy involves the use of seeds, which are physically placed at the tumor site and will remain there unless they are surgically removed. Brachytherapy plays a vital role in the care of prostate cancer patients. It is only useful for the treatment of accessible tumor mass. The systemic administration of radiopharmaceuticals that are designed for specific localization at tumor sites provides the opportunity for the treatment of disseminated disease (2–7). Most systemically administered therapeutic radiopharmaceuticals are small organic or inorganic compounds with definite composition (4, 5). They can also be macromolecules, such as monoclonal antibodies or antibody fragments labeled with a radionuclide. Ideally, the radiopharmaceutical should localize at the tumor sites in sufficient concentration to deliver a cytotoxic radiation dose to the tumor cells and clear rapidly from the blood and other normal organs to minimize radiation damage to normal tissues.

Radiotherapy has been around for over four decades starting with the use of radioiodine for the treatment of thyroid disorders. The main obstacle to radiotherapy assuming a wider role in clinical practice are the availability of therapeutic isotopes and techniques for their specific localization in diseased tissues. The introduction of [^{111}In]DTPA-octreotide (OctreoScan in Figure 1) for the diagnosis of somatostatin receptor positive tumors has spurred the search for new receptor-based target specific therapeutic radiopharmaceuticals. A number of radiolabeled small peptides (8–33) have been studied for their potential use in tumor therapy. These studies have provided an impetus to research in the production and chemistry of new therapeutic radionuclides (34–37), as well as new bifunctional chelators (BFCs).

Metalloradiopharmaceuticals are pharmaceuticals composed of a metallic radionuclide (e.g., ^{67}Cu , ^{90}Y , $^{99\text{m}}\text{Tc}$, ^{111}In , ^{177}Lu , ^{186}Re , ^{188}Re , and ^{212}Bi). In general, a target-specific metalloradiopharmaceutical (Figure 2) can be divided into four parts: a targeting biomolecule, a linker, a BFC, and a metallic radionuclide. The targeting biomolecules can be macromolecules such as antibodies or antibody

^{111}In -DTPA-Octreotide (OctreoScan®)

Figure 1. Structure of [^{111}In]DTPA-octreotide (OctreoScan).

Figure 2. Schematic presentation of a target-specific metalloradiopharmaceutical. The linker is often used as a pharmacokinetic modifier (PKM).

fragments, or small peptides, peptidomimetics, or non-peptide receptor ligands. Between the targeting biomolecule and the radionuclide is the BFC, one end of which is covalently attached to the targeting molecule either directly or through a linker while the other strongly coordinates to the metallic radionuclide. Selection of a BFC is largely determined by the nature and oxidation state of the metal ion. The linker is often used for modifying the pharmacokinetic properties of the radiopharmaceutical.

The choice of a linker depends on the pharmacokinetic requirements for the radiopharmaceutical. Figure 3 shows several types of linkers (cationic, anionic, neutral or metabolically cleavable). The linker can be a simple hydrocarbon chain to increase lipophilicity, a peptide sequence (such as polyglycine, polyserine, or polyaspartic acid) to improve the hydrophilicity and renal clearance, or a poly(ethyleneglycol) linker to slow extraction by the hepatocytes. It has been reported that linker groups have significant effect on biodistribution of ^{111}In - and $^{99\text{m}}\text{Tc}$ -labeled antibodies (38–40). Metabolizable linkers have been used for ^{111}In -labeled somatostatin analogues (41). A tetrapeptide linker Gly-Gly-Gly-L-(p-NO₂)-Phe-CONH₂ that is cleaved between Gly and Phe residues has been used to modify pharmacokinetics of ^{90}Y -labeled antibodies (42–45). Depending upon the radionuclide and the BFC, linker groups capable of rapid metabolism can increase

^a The specific activity of a radionuclide depends on the source and method of production, as well as the technique of separation. In general, generator-produced radionuclides, such as ⁹⁰Y and ¹⁸⁸Re, have a higher specific activity than those accelerator- or reactor-produced radioisotopes. High specific activity can also be achieved by chemical purification of the desired radionuclide from the parent element after direct (n,γ)-activation of the target.

the clearance of the radiopharmaceutical from the blood via the renal system.

The use of metallic radionuclides offers many opportunities for designing new radiopharmaceuticals by modifying the coordination environment around the metal with a variety of chelators. The coordination chemistry of the metallic radionuclide will determine the geometry and solution stability of the metal chelate. Different metallic radionuclides have their different coordination chemistries, and require BFCs with different donor atoms and ligand frameworks. The metal chelate can significantly impact the tumor uptake and biodistribution of radiopharmaceuticals based on small biomolecules, due to the fact that in many cases the metal chelate contributes greatly to the overall size and molecular weight of the radiopharmaceutical. Therefore, the design and selection of the BFC is very important for the development of a clinically useful therapeutic agent.

Several reviews have appeared recently covering a broad range of topics related to diagnostic and therapeutic radiopharmaceuticals (46–49). This review will focus on the critical aspects to the development of clinically useful agents, the fundamentals of lanthanide chemistry, the design and synthesis of new BFCs for lanthanide radionuclides, and the factors influencing the ⁹⁰Y-labeling of DTPA- and DOTA-conjugated biomolecules (DTPA-BM and DOTA-BM, respectively).

General Considerations for Therapeutic Radiopharmaceuticals. In the development of a new thera-

peutic radiopharmaceutical, several factors need to be considered to satisfy the clinical need and to comply with FDA (Food and Drug Administration) regulations. While tumor imaging relies heavily on a high target-to-background ratio for the best contrast, tumor therapy depends largely on a high concentration of radioactivity in the tumor for a long duration. Thus, the new radiopharmaceutical must have high and fast tumor uptake, high tumor-to-background ratio, long tumor residence time, and fast renal clearance. High tumor uptake and fast renal clearance are particularly important to improve the tumor-to-background ratio and to reduce the radiation burden to other normal organs such as the kidney, liver and bone marrow. The new radiopharmaceutical must have high radiochemical purity (RCP > 90%) and high solution stability. Unlike diagnostic radiopharmaceuticals, which are typically made by radiopharmacists just before injection, therapeutic radiopharmaceuticals have to be manufactured and released under GMP conditions, and then delivered to the clinic. Therefore, the therapeutic radiopharmaceutical must retain its chemical and biological integrity during storage and transportation. This requires that the BFC bind strongly to the radionuclide and form a metal chelate with both thermodynamic stability and kinetic inertness.

Choice of Radionuclides. Table 1 shows some radionuclides potentially useful for radiotherapy. Among them, lanthanide radioisotopes are of particular interest. There are several lanthanide isotopes to choose, including

low-energy β -emitter ^{177}Lu , medium-energy β -emitters, ^{149}Pm and ^{153}Sm , and high-energy β -emitters, ^{166}Ho and ^{90}Y . Yttrium and lanthanide metals share similar coordination chemistry. The chelator technology and their coordination chemistry are well developed and well understood.

Identifying the most appropriate isotope for radiotherapy is often a difficult task and requires weighing a variety of factors (50–52). These include tumor uptake and retention, blood clearance, rate of radiation delivery, half-life and specific activity of the radionuclide, and the feasibility of large-scale production of the radionuclide in an economical fashion. The key point for a therapeutic radiopharmaceutical is to deliver a tumoricidal dose of radiation to the tumor cells while not causing unmanageable side-effects.

The physical half-life of the therapeutic radionuclide should match the biological half-life of the radiopharmaceutical at the tumor site. If the half-life of the radionuclide is too short, most of the dose will have been delivered before the radiopharmaceutical has reached the maximum target/background ratio. In this situation, attaining a sufficient integrated tumor dose for sterilization (>50 Gy) will prove problematic (50–52). On the other hand, too long a half-life would cause unnecessary radiation dose to normal tissues. Ideally, the radionuclide should have a half-life long enough so that a minimal dose rate (>0.4 Gy/h) is achieved and all cells are irradiated during the most radiation sensitive phases of the cell cycle. In addition, the half-life of a radionuclide has to be long enough to allow adequate time for manufacturing, release, and transportation.

Other practical considerations in selecting a radionuclide for a given targeting biomolecule for tumor therapy are availability and quality. The purity has to be sufficient and reproducible, as trace amounts of impurities can affect the radiolabeling and radiochemical purity of the radiopharmaceutical. The target receptor sites in tumors are typically limited in number. This requires that the chosen radionuclide have high specific activity. The specific activity depends primarily on the production method. Trace metal contaminants must be minimized as they often compete with the radionuclide for the BFC and their metal complexes compete for receptor binding with the radiolabeled BFC–BM conjugate.

For tumor therapy, both α - and β -emitters need to be considered. α -Particles are particularly good cytotoxic agents because they dissipate a large amount of energy within one or two cell diameters. Most α -emitters are heavy elements that decay to hazardous daughter products and their penetration range is limited to only 50 μm in tissue (52). The short-range α -emitters are more attractive if the radiopharmaceutical is internalized into tumor cells. Auger electron emitters are shown to be very potent but only if they can cross the cell membrane and come into close proximity with the nucleus, which creates extra challenges for the design of new metalloradiopharmaceuticals. β -Particle emitters have relatively long penetration range (2–12 mm in the tissue) depending the energy level. The long-range penetration is particularly important for solid tumors with high heterogeneity. The β -particle emitters yield a more homogeneous dose distribution even when they are heterogeneously distributed within the target tissue. Depending on the tumor size and location, the choice of the β -emitter may be different. For example, medium- or low-energy β -emitters such as ^{153}Sm and ^{177}Lu are better for smaller metastases while high-energy β -emitters such as ^{90}Y are used for larger tumors.

Figure 4. Ionic radius (Å) for trivalent yttrium and lanthanide metal ions.

Some β -emitters contain a small percentage of γ -emission. There is an ongoing controversy over the use of the γ -emission for dosimetry determination and staging of radiotherapy. Some favor the use of γ -emission for these purposes, and some are strongly against it mainly because of the additional radiation burden to the patient. In general, γ -emission should be avoided in selecting a suitable radionuclide since it is only useful for treatment planning not for treatment monitoring or staging of radiotherapy. There are better tracers or imaging modalities to monitor cancer therapy. For dosimetry determination, one can find a closely related diagnostic surrogate, which shares the similar coordination chemistry to that of the therapeutic radiopharmaceutical. For example, the $^{99\text{m}}\text{Tc}$ complexes are often used for the dosimetry determination of $^{186/188}\text{Re}$ radiopharmaceuticals.

For systemic cancer radiotherapy, ^{90}Y is of particular interest because it is a high-energy pure β -particle emitter. The half-life of 2.7 days is short enough to achieve a critical dose rate and long enough to allow the radiopharmaceutical to be manufactured and delivered for clinic use. For quantitative imaging, the corresponding ^{111}In BFC–BM complex is often utilized as a surrogate to determine the biodistribution and the dosimetry of ^{90}Y BFC–BM (10, 14, 18, 20, 22).

Fundamentals of Yttrium and Lanthanide Chemistry. Yttrium and lanthanide (La to Lu) metals all favor the +3 oxidation state. Due to its similar charge, ionic radii (Figure 4) and coordination chemistry, yttrium is often treated as a “pseudo-lanthanide” metal. In contrast to the d -block transition metals, the $4f$ electrons are inner electrons, shielded from external influences by the overlying $5s^2$, $5p^6$, and $6s^2$ -electron shells. The ligand field effect is relatively weak, and the magnetic properties of the metal ion are not significantly affected by the coordination environment. Since $4f$ electrons are not involved in bonding, the interactions between donor atoms and lanthanide metal ions are predominately ionic.

Metal Ions in Solution. Yttrium and lanthanide metal ions in solution are usually indicated as M^{3+} , as though they were “naked” cations suspended in structureless medium. In fact, they exist in aqueous solution in their complexed forms with a number of bonded water molecules. The number of water molecules bound directly to the metal ion, its coordination number, is very similar to the number of donor atoms found in its metal chelate in the solid state and depends largely on the size of the metal ion. Metal chelate formation involves replacement of the coordinated water molecules by a chelating agent. Due to their large size, the coordination numbers of yttrium and lanthanide ions are typically between 7 and 10. Very few six coordinate species are known while coordination numbers of 8 and 9 are common.

^a Martell, A. E., and Smith, R. M. (1974) *Critical Stability Constants*. Vol. 4, Plenum, New York.

Hydrolysis and Precipitation. One of the characteristics of yttrium and lanthanide metal ions in aqueous solution is their easy precipitation with commonly occurring anions such as hydroxide, phosphate or carbonate. Table 2 lists the solubility constants of lanthanide complex precipitates. Both phosphate and carbonate are able to compete for the metal ions with a BFC-BM conjugate, while the effect of metal hydroxide formation may not play a significant role in the release of the radionuclide from the metalloradiopharmaceutical. This is mainly due to the presence of more phosphate and carbonate anions in the blood circulation. The high affinity of lanthanide metal ions for the phosphate anion may also explain their affinity for localizing in bone (53).

Thermodynamic Stability. For a therapeutic radiopharmaceutical, the concentration in the blood circulation may become so low that dissociation of the radiometal from the metal chelate will eventually become favored, particular in the presence of many native chelators (54, 55). The loss of radiometal from the chelate may result in the accumulation of radioactivity in nontarget organs. It has been reported that ⁹⁰Y and lanthanide isotopes are readily deposited on the bone (53). Therefore, the BFC must form a metal chelate with high thermodynamic stability to retain its integrity in competition with natural chelators, such as transferrin. However, high thermodynamic stability is not the sole requirement because it only reflects the direction, not the rate, of the reaction. As a matter of fact, the solution stability of a metalloradiopharmaceutical in the blood stream is predominantly determined by the kinetic inertness, not the thermodynamic stability, of the metal chelate.

Conditional Stability Constants. The solution behavior of lanthanide radiopharmaceuticals should be considered in the context of pharmacokinetics, protein binding, excretion, and safety. The coordination chemistry of the radionuclide and BFC in the circulation is extremely complicated. There are many factors influencing the dissociation of the radionuclide. These factors include the competition of proton and metal ions such as Ca²⁺, Cu²⁺, Zn²⁺, and Fe³⁺, which are abundant in the blood stream, for the coordinated BFC, hydroxide, phosphate, and native chelators such as amino acids and transferrin for the radionuclide (54, 55). The concentration of Ca²⁺ is as high as 5 mM in the blood stream. Therefore, the conditional stability constant of a metal chelate is more predictive of the solution behavior of the radiopharmaceutical.

The thermodynamic stability constant K_{ML} of a metal complex is defined by Equation 1. [ML] is the concentration of the metal complex, [M] is the concentration of the metal ion, and [L] is the concentration of the polydentate chelator. Considering the factors influencing the stability of the metal complex, the conditional constant K_{con} can be calculated using eq 2. Due to the competition of proton and metal ions in the blood stream, the concentration of the chelator [L_{tot}] can be calculated by eq 3, where K_1 , K_2 , ..., K_n are the stepwise protonation constants of the

ligand while K_{CaL} , K_{CuL} , K_{ZnL} , and K_{FeL} are stability constants of the corresponding Ca²⁺, Cu²⁺, Zn²⁺, and Fe³⁺ complexes, respectively. Due to hydrolysis (hydroxide), formation of precipitate (phosphate), and coordination of the metal ion by native chelators such as amino acids and transferrin (54, 55), the concentration of the metal ion [M_{tot}] has to be calculated using eq 4, where β_1 , β_2 , and β_3 are formation constant of the metal hydroxide, K_{sp} is the solubility constant of the phosphate precipitate, and K_{ML} is the stability constant of the metal complex of any given native chelator.

$$M + L = ML, \text{ where } K_{ML} = [ML]/([M][L]) \quad (\text{formal stability constant}) \quad (1)$$

$$M + L = ML, \text{ where } K_{con} = [ML]/([M]_{tot}[L]_{tot}) \quad (\text{conditional stability constant}) \quad (2)$$

$$[L_{tot}] = [L](1 + K_1[H^+] + K_1K_2[H^+]^2 + \dots K_1K_2\dots K_n[H^+]^n + K_{CaL}[Ca^{2+}] + K_{CuL}[Cu^{2+}] + K_{ZnL}[Zn^{2+}] + K_{FeL}[Fe^{3+}] \dots) = [L]\alpha_L \quad (3)$$

$$[M_{tot}] = [M](1 + \beta_1[OH^-] + \beta_1\beta_2[OH^-]^2 + \beta_1\beta_2\beta_3[OH^-]^3 + K_{sp}^{-1}[PO_4^{3-}] + \dots K_{ML}[L] \dots) = [M]\alpha_M \quad (4)$$

$$K_{con} = [ML]/([M]_{tot}[L]_{tot}) = \frac{[ML][M][L]\alpha_M\alpha_L}{[ML]\alpha_M\alpha_L} = K_{ML}\alpha_M\alpha_L \quad (5)$$

Table 3 shows the conditional stability constants of Gd complexes of various polydentate chelators and the amount of ¹⁵³Gd found in the rodent skeleton at 7 days postinjection for various complexes (56–58). If proton competition is the only factor taken into consideration, the conditional constants of these complexes are calculated according to eq 5. While thermodynamic (K_{ML}) and conditional constant (K_{con}) values for [Gd(EDTA)(H₂O)_n][−] ($K_{con} = 14.9$) and [Gd(DTPA-BMA)(H₂O)][−] ($K_{con} = 14.7$) are comparable (59, 60), the amount of Gd-153 deposited in bone is significantly different (~0.8% ID/g for [¹⁵³Gd(EDTA)(H₂O)_n][−] and 0.03% ID/g for [¹⁵³Gd(DTPA-BMA)(H₂O)][−]). For [Gd(DO3A)(H₂O)], the conditional stability constant is very low due to low denticity; the bone uptake of [¹⁵³Gd(DO3A)(H₂O)] is extremely small (0.03% ID/g) (58). Obviously, thermodynamics alone is not sufficient to explain and predict the biological properties of these complexes.

Kinetic Inertness. The term kinetic inertness refers to the rate of dissociation of the radionuclide from the metalloradiopharmaceutical. As noted in the previous sections, dissociation kinetics plays a significant role for the in vivo stability of a metal chelate. While fast dissociation kinetics are characteristic of metal complexes

Figure 5. Structures of selected acyclic chelators.

of acyclic chelators (Figure 5), an accumulated body of literature has shown that metal complexes containing macrocyclic chelators (Figure 6) are much more kinetically inert (59–66). This has been clearly demonstrated by the extremely high solution stability of ^{90}Y -labeled macrocycles such as DOTA and DOTMP even though the thermodynamic stability constants of $\text{Y}(\text{DOTA})^-$ and $\text{Y}(\text{DOTMP})^-$ are comparable to that of $\text{Y}(\text{DTPA})^{2-}$.

It should be noted that for metalloradiopharmaceuticals containing a macrocyclic chelator such as DOTA as BFC, acid-catalyzed dissociation of radionuclide from the metal chelate should be minimal in the blood circulation, and transmetalation is not anticipated to be an important mechanism for bone marrow toxicity. Recently, McMurry and co-workers studied ^{89}Y -labeled antibodies with a series of backbone-functionalized DTPA BFCs, and found that the acid-catalyzed dissociation is not the dominant pathway for the in vivo release of ^{89}Y (67). There are many receptors in the bone marrow or on the bone surface for the binding of radiolabeled biomolecules. Some small metal chelates of polyaminocarboxylates, such as HEDTA (*N*-hydroxyethylethylenediamine-*N,N',N'*-triacetic acid), often show very high bone uptake (68–71). The accumulation of radioactivity in the bone may not be caused by the loss of radionuclide from its metal chelate. The overwhelming importance on acid-catalyzed dissociation of radionuclide found in the literature is probably a little oversimplified. Biological studies in different animal models still remain the most appropriate method for evaluating the in vivo stability of the radiopharmaceutical.

The choice of kinetic characteristics of the metal chelate of a BFC is also dependent on the pharmacoki-

netics of the radiopharmaceutical. For radiolabeled antibodies, that often have long biological half-lives in the blood stream and at the tumor site, and are often metabolized in the liver, the metal chelate must have extremely high thermodynamic stability and kinetic inertness to withstand the competition from metal ions and native chelators in circulation and to tolerate the hepatobiliary metabolism. For radiolabeled small molecules, the biological half-life in the circulation is normally much shorter than that of radiolabeled antibodies. The requirement of kinetic inertness of the BFC metal chelate may not be as demanding. The main goal in choosing a successful BFC is to minimize the in vivo dissociation of radionuclide from the metal chelate of the radiopharmaceutical.

Basic Requirements for BFC. A BFC usually contains three parts: binding unit, ligand framework, and a conjugation group. There are several requirements for an ideal BFC. The BFC has to be able to withstand radiolysis because a large dose of β -radiation can produce very reactive free radicals and result in a significant amount of decomposition of the metal chelate during the manufacturing process and transportation. The BFC must form a metal chelate with high thermodynamic stability and kinetic inertness at neutral pH in order to keep the metal chelate intact under physiological conditions. Decomposition of the metal chelate produces free lanthanide metal ion, which may deposit on the bone and cause bone marrow toxicity. The BFC must form a metal chelate with a minimum number of isomers. The tumor uptake of a radiopharmaceutical depends not only on the receptor binding affinity of the biomolecule but also on pharmacokinetics, which is determined by the physical

**Figure 6.** Structures of selected macrocyclic chelators.

and chemical properties of both the biomolecule and the metal chelate. Formation of isomers may have a significant impact on the biological properties of the radiopharmaceutical. The BFC must have high hydrophilicity, which helps to improve the blood clearance and renal excretion of both the labeled and unlabeled BFC–BM conjugate. Fast renal clearance of the unlabeled BFC–BM will minimize its competition with the radiolabeled BFC–BM for the receptor. Finally, the conjugation group should be easily attached to the biomolecule.

Denticity Requirement. The most common way to increase the thermodynamic stability and kinetic inertness of a metal complex is to use a polydentate chelator. The denticity requirement of a BFC is largely dependent on the size and coordination geometry preference of the metal ion. Yttrium and lanthanide metal ions are large and need eight to nine donor atoms to complete the coordination sphere and form stable complexes with macrocyclic chelators, such as DOTA and its derivatives. It should be emphasized that the denticity requirement of a BFC for therapeutic lanthanide radiopharmaceuticals is not the same as that for MRI contrast agents. For chelators used in lanthanide MRI contrast agents, they are most likely hepta- or octadentate, leaving at least one site open for water ligand exchange to enhance the water proton relaxation rates. For BFCs in radiopharmaceuticals, higher denticity (9, 10) may provide enhanced thermodynamic stability and the improved kinetic inertness, particularly when extra donors are incorporated into a chelating arm attached to the macrocyclic cyclen framework. By adding extra donor atoms, all coordination sites of the lanthanide metal ion are occupied. Kimura et al. (72) studied the thermodynamic and kinetic properties of lanthanide complexes of a series of polydentate

**Figure 7.** Bonding units for building polydentate chelators.**Figure 8.** Ligand frameworks for polydentate chelators. X and Y represent donating heteroatoms incorporated in the ligand framework.

chelators, including DOTA, PEPA, HEHA, and DTPA. It was found that both PEPA and HEHA form Y^{3+} complexes with less kinetic inertness mainly due to the increased flexibility of the macrocyclic chelator framework. Thus, the design of new BFCs should be focused on those using cyclen as the macrocyclic chelator framework.

Bonding Unit and Donor Atoms. A polydentate chelator is built by the appropriate arrangement of the bonding units on a chelator framework. Figure 8 shows several bidentate bonding units, which are often used for building polydentate chelators. In the last two decades, a large number of chelators have been synthesized and studied for their complexation with various metal ions, including catechols, 8-hydroxyquinoline, aminephenols, hydroxamates, aminocarboxylates, aminophosphonates,

and hydroxypyridinones. In general, chelators with two ligating oxygen atoms (catechols, hydroxypyridinones, and hydroxamates) or aminocarboxylates and aminophosphonates have been more widely studied than the other classes.

Catechol binds strongly to trivalent metals such as Fe^{3+} , In^{3+} , and Ln^{3+} (73–78). However, the pK_a values for the two phenol groups are considered too high (9.2 and 13.0). The competition between the metal ion and protons leads to formation of a range of species at neutral or lower pH values. 8-Hydroxyquinoline possesses a high affinity for trivalent cations, but is not selective, as it also binds to Cu^{2+} tightly (78). Hydroxyquinoline is toxic probably due to its extreme lipophilicity. In addition, hydroxylated aromatics are very susceptible to radiolytic decomposition. Therefore, catechol and 8-hydroxyquinoline bonding units are not suitable as BFCs for therapeutic metalloradiopharmaceuticals.

Hydroxypyridinones have been used as substitutes for catechol in drug design (78–80). Like hydroxamates, the hydroxypyridinones are monobasic and form stable metal complexes with hard trivalent metal ions, such as Fe^{3+} , In^{3+} , and Ln^{3+} . Hydroxy-pyridinones have relatively low pK_a values (5–9). For example, the pK_a for 1-hydroxypyridin-2-one is only 5.8. It forms a highly stable ML_3 complex with Fe^{3+} at pH 3–9. They also have high selectivity for trivalent metal ions. As a result, chelators based on hydroxypyridinones have been used for metal detoxification, and their metal complexes have been studied as diagnostic imaging agents. It is surprising that very little information is available on the use of hydroxypyridinones as BFCs. The utility of hydroxypyridinones as binding units for the development of BFCs may be limited by the lipophilicity imparted by the aromatic ring. The same limitations may also apply to pyridinecarboxylates and imidazolecarboxylates. However, the combination use of hydroxypyridinones, pyridinecarboxylates and imidazolecarboxylates with other more hydrophilic bonding units may prove to be useful in designing new BFCs.

The hydroxamate moiety has been widely found in bacteria and fungi siderophores (78–80). The stability constants for 1:1 ML complexes are much lower than the corresponding values for catechols due to the fact that only one oxygen is protonated ($\text{pK}_a = 9.35$) under physiological conditions. As discussed above, the complex formation with metal ions can be considered as a competition reaction with proton, and consequently the charged 1:1 and 1:2 species dominate under acidic conditions even if an excess of hydroxamate is added. At pH 7.0, the 1:3 complex dominates and the stability is further enhanced in the presence of excess ligand. Although polydentate hydroxamate ligands were reported to form highly stable lanthanide complexes (81), there are very few examples of hydroxamate ligands used as BFCs.

Aminocarboxylate groups have been widely used to build polydentate chelators such as EDTA and DTPA (Figure 5). In general, aminocarboxylate groups possess a high affinity toward large cations, particularly In^{3+} . For lanthanide metal ions, EDTA and DTPA are not large enough to completely envelop the metal ion, leaving the remaining coordination sites occupied by water molecules. It should be noted that EDTA has a high affinity for divalent metal ions such as Zn^{2+} , Ca^{2+} , and Cu^{2+} . As a matter of fact, EDTA has higher affinity for Cu^{2+} than it does for La^{3+} and Gd^{3+} . Thus, they are not specific for lanthanide metals (78, 79). High selectivity of polyaminocarboxylate chelators for lanthanide metal ions can be

achieved by using macrocyclic frameworks with eight to nine donor atoms.

Aminophosphonate groups have been reported to have high affinity for hard cations such as Ca^{2+} . Metal complexes of polyaminophosphonates often localize in bone. Due to their high bone uptake, lanthanide complexes of polyaminophosphonates have been studied as therapeutic radiopharmaceuticals for bone-pain palliation and for the treatment of bone cancer metastasis. The complex [^{153}Sm]EDTMP (Quadramet) has recently been approved by FDA for bone pain palliation (82, 83). The complex [^{166}Ho]DOTMP is under clinical investigation for both bone pain palliation and the treatment of bone metastases (84, 85). In general, aminophosphonates form less stable metal complexes than their aminocarboxylate analogues. For example, EDTMP has lower affinity for La^{3+} than EDTA. The localization of metal complexes of polyaminophosphonates at bone and the resulting bone marrow toxicity makes this class of chelators not suitable as BFCs for the radiolabeling of biomolecules with ^{90}Y and lanthanide radionuclides.

Aminethiols and amidethiols form stable complexes with $[\text{Tc}=\text{O}]^{3+}$ and $[\text{Re}=\text{O}]^{3+}$ cores (86, 87). Depending upon nature of the chelator, the technetium and rhenium complexes of diaminedithiols or diamidedithiols can be cationic, neutral, or anionic. Both diaminedithiols and diamidedithiols have been used in BFCs for the radiolabeling of biomolecules with $^{99\text{m}}\text{Tc}$. Polyaminethiols have also been used for coordination of trivalent “hard” metal ions such as Ga^{3+} , Fe^{3+} , In^{3+} , and Ln^{3+} (88–92). Even though thiolate-S is considered as a “soft” donor, polyaminethiols were found to form very stable Ga^{3+} and In^{3+} complexes. It should be noted that the bonding between the trivalent metal ion and the donor atoms is predominantly ionic. Once the thiolate-S is deprotonated, it becomes anionic. Therefore, it is not surprising that polyaminethiols form very stable complexes with trivalent “hard” metal ions such as Ga^{3+} and In^{3+} (88–92).

Ligand Framework. The ligand framework is the spatial arrangement of the bonding units; several examples are shown in Figure 8. Polydentate ligands (panels B–D in Figure 8) with three-dimensional cavities are of particular interest because of their capability to adopt a preorganized conformation in the uncomplexed form. The higher the degree of preorganization of an uncoordinated ligand, the more stable the metal complex. Preorganization of the ligand framework also improves the kinetic inertness, which, as discussed in previous section, is the determining factor for the release of radionuclide from the metalloradiopharmaceutical.

Preorganization minimizes the freedom of motion of the donor atoms and the ligand framework during the complexation process in such a way that the free ligand has a conformation more similar to that in the complex (93–95). Because of the restricted freedom of motion, the loss of entropy in forming the complex is much less, which leads to the increased thermodynamic stability of the metal chelate. Although preorganization is a concept usually applied to macrocyclic and cryptate metal complexes, it is also of some importance for open-chain chelators. For example, metal complexes of CDTA (trans-cyclohexanediaminetetraacetic acid) are often 2–3 orders of magnitude more stable than those of EDTA (ethylenediaminetetraacetic acid) because of the restricted motion of the iminodiacetic chelating arms in CDTA (95).

It should be noted that preorganization of a polydentate chelator results in not only high thermodynamic stability but also increased kinetic inertness of its metal complex. This has been exemplified by the fact that the

Figure 9. Selected examples of preorganized ligand frameworks.

half-life for $\text{Gd}(\text{DOTA})^-$ in 0.1 M HCl is 60.2 h while the complex $\text{Gd}(\text{DTPA})^{2-}$ having comparable thermodynamic stability decomposes rapidly under acidic conditions ($K_{\text{obs}} = 1.2 \times 10^{-3} \text{ s}^{-1}$; $t_{1/2} \approx 1 \text{ min}$) (61). The highly preorganized macrocyclic framework of DOTA forces the four acetate chelating arms to adopt a conformation that “wraps” the metal ion in an N_4O_4 donor set (96). At the same, it is more difficult for the coordinated acetate to be dissociated from the metal center. Therefore, preorganization should be an important factor in the design of new BFCs for the radiolabeling of biomolecules.

There are several ways to achieve a high degree of preorganization for a polydentate chelator. These include the use of a macrocyclic ligand framework, the use of hydrogen bond(s) to enforce a three-dimensional cavity for metal coordination, and the choice of appropriate chelating arms. Polyaminocarboxylate ligands based on cyclen are known to be well preorganized and form highly stable lanthanide complexes due to the endocyclic orientation of the nitrogen donors. The siderophore enterobactin (Figure 9) forms much more stable Fe^{3+} complex than MECAM because of the cyclic triester ligand framework and hydrogen bonding (97, 98). Tripodal peptides with chiral conformations were found to be stabilized by interstrand hydrogen bonds (99–104). Orvig et al. (105–109) reported a series of tripodal aminephenol ligands and found that hydrogen bonding plays a significant role in the conformation of the uncoordinated ligands. The use of a carbon atom as the bridgehead instead of a tertiary nitrogen atom also limits the motion of the three aminephenol chelating arms (Figure 9). Renaud et al. (110) reported C_3 symmetrical lanthanide podates organized by intramolecular trifurcated hydrogen bonds.

Polyazamacrocycles have been widely used as chelators for a variety of transition metal ions. Macrocyclic BFCs, such as DOTA, are of particular interest for several reasons. The macrocyclic ligand framework is well organized so that they form metal complexes with high thermodynamic stability and kinetic inertness. The pK_a values for the carboxylic groups are in the range 2–5. Lower pK_a values result in less competition from proton, high stability of the metal complex, and minimum acid-assisted demetalation, even under acidic (pH 2) conditions. A functional group for conjugation of a BM can be attached to either one of the four nitrogen donor atoms

Figure 10. Structures of selected acyclic BFCs.

or one of C-atoms of the macrocyclic backbone. The acetate groups attached to the nitrogen donor atoms have low molecular weight and are very hydrophilic. Therefore, the contribution of the BFC to the overall molecular weight of the BFC–BM conjugate is minimized. The high hydrophilicity of the BFC is will favor faster blood clearance for small molecule radiopharmaceuticals, resulting in reduced competition between the labeled and unlabeled BFC–BM in binding to the targeted receptor. If the biomolecule is an antibody or antibody fragment, attachment of the BFC may not have such a dramatic impact on physical and biological properties of the BFC–protein conjugate as it does for small biomolecules.

Synthetic Strategies for DTPA Analogues. EDTA-based BFCs (Figure 10) were first developed by Sunberg and co-workers in the 1970s (111). Krejcarek and Tucker developed an activated DTPA analogue via a mixed anhydride, which can be linked to proteins (112). The cyclic anhydride of DTPA has also been used by many nuclear medicine researchers since (113). These linear BFCs (Figure 10) bond to a variety of metal ions, such as ^{111}In or ^{90}Y , forming thermodynamically stable metal complexes. A major advantage using DTPA analogues as BFCs is fast labeling kinetics, which is extremely important for antibodies and antibody fragments due to their sensitivity toward heating. However, the metal chelates of linear BFCs are often kinetically labile, which is believed to contribute to the loss of radionuclide for the metal chelate and often leads to significant bone marrow toxicity (114–116).

Considerable efforts have been made to produce polyaminocarboxylate BFCs that form complexes with ^{90}Y with improved thermodynamic stability and kinetic inertness (117–121). As a result, several functionalized DTPA analogues (Figure 10) have been developed as BFCs for the radiolabeling of biomolecules. For example, Gansow and co-workers reported the synthesis of 2-(p-

Chart 1. Synthesis of p-SCN-Bz-DTPA

isothiocyano-benzyl)DTPA (1B-DTPA), in which all eight donor atoms are available for metal ion bonding, and the conjugation group is located on the diethylenetriamine backbone (118, 120).

In general, synthesis (Chart 1) of open-chain polyaminocarbonylate BFCs is straightforward. The most important step is the preparation of the functionalized triamine. The alkylation of the triamine can be achieved in one step by reaction with excess bromoacetic acid in the presence of NaOH or in two steps using *tert*-butyl bromoacetate in DMF in the presence of sodium or potassium carbonate. Following the alkylation, the crude product is purified by cation-exchange chromatography. The major advantage of using *tert*-butyl bromoacetate as the alkylating agent is that the polyester intermediate can be easily purified using reversed-phase chromatography. In both cases, the alkylation step and subsequent steps have to be performed in acid-washed glassware or metal-free plasticware to avoid adventitious sequestering of divalent metals, especially calcium.

Synthetic Strategies for Macrocyclic BFCs. Macrocyclic compounds, $(XCH_2CH_2)_n$ ($X = O, NH$, and S ; n

$= 4, 5$, and 6), have been known for many years. It was not until 1967, however, that crown ether chemistry was really born when Pederson (122) first reported the synthesis and unique cation complexing properties of a number of macrocyclic compounds. Since that time, a number of macrocyclic chelators with a variety of donor atoms have been prepared and investigated for the coordination chemistry with metal ions. Among various macrocyclic chelators, tetraazamacrocycles and their N- or C-substituted derivatives (Figure 11) are of particular interest as BFCs because of the high thermodynamic stability and kinetic inertness of their metal complexes (123–127). Due to large body of literature in this area, it is very difficult to cover all the procedures for synthesis of these macrocycles. In the following section, we will focus on syntheses of some selected tetraazamacrocycles and their N- and C-substituted derivatives.

Richman–Atkins Method. In 1974, Richman and Atkins (128) first reported the synthesis of polyazamacrocycles (Chart 2) by reacting tosylated polyamines with respective dihalogeno or ditosyl fragments in the presence of a base, such as NaH, in DMF at elevated temperatures. This method has been used to produce a variety of tri-, tetra-, penta-, and hexaazamacrocycles. It remains one of the most prevalent synthetic methods for C-functionalized tetraazamacrocycles. When sodium was replaced by tetramethylammonium cation, the yield decreased. It has been suggested that the large tosyl groups tend to restrict free rotation in the starting materials. As a consequence, there is a small internal entropy loss on cyclization, allowing for macrocyclization to occur in good yield (50–80%) even when no apparent preorganization is involved by a template ion. This approach does not require high dilution conditions. Rather concentrated solutions of reactants appear to give the best yields. The yields are solvent-dependent; DMF has always been the solvent of choice and should be dried carefully prior to use (128, 129).

There is usually more than one synthetic route (Chart 2) to produce the same macrocycle. It has been suggested that the use of precursors of similar length is needed for high yields in the cyclization step (122, 128). It seems that the relative stability, solubility, and water-sensitivity of different tosylates and sulfonamides salts are the most significant factors affecting the yield. The choice of preparative method usually depends on the availability

**Figure 11.** Structures of selected macrocyclic BFCs.

Chart 2. Richman-Atkins Method for the Synthesis of Tetraazamacrocycles**Chart 3. Weisman's Method for the Synthesis of Cyclen****Chart 4. Schiff Base Method for the Synthesis of Cyclen**

and ease of preparation of the precursor diols, amine diols, and polyamines.

Weisman's Methods for the Synthesis of Cyclen.

Weisman and Reed (130) recently reported a two-step synthesis of cyclen from triethylenetetraamine and dithiooxamide (Chart 3). This synthetic route is much easier to carry out, and also avoids the use of transition metal templates and the use of a large volume of dry DMF solvent. The starting materials are cheaper and readily available from commercial sources. The overall yield of cyclen is 57% at 100 mg to 5 g scale. Similar approaches (Chart 4) have also been disclosed recently using triethylenetetraamine and glyoxal. In all the cases, cyclen can be prepared in high yield and high quality (131, 132).

N-Functionalized Tetraazamacrocycles. Functionalization of tetraazamacrocycles is much more complicated than that of open-chain triamines. The most widely

Chart 5. N-Alkylation of Tetraazamacrocycles

used method is the alkylation of secondary amine-nitrogen atoms (133–140). However, the resulting product is often a mixture of macrocycles with variable number of substituents depending upon reaction conditions (such as solvent, pH, reaction time, and heating temperature) and the relative ratio of alkylating agent and the tetraazamacrocycle. Chart 5 shows synthesis of some examples of N-functionalized tetraazamacrocycles.

The alkylation (Chart 5) of a tetraazamacrocycle can be achieved by reacting with excess alkyl bromide in an aprotic solvent in the presence of base (e.g., Et_3N). For example, DOTA can be prepared in two steps by reacting with excess *tert*-butyl bromoacetate in DMF in the presence of potassium carbonate or triethylamine. The tetrabutyl ester of DOTA is then hydrolyzed with anhydrous TFA or a mixture of TFA and dichloromethane to give the crude product, which is then purified by cation-exchange chromatography. The advantage of using *tert*-butyl bromoacetate as the alkylating agent is that the tetrabutyl ester can be easily purified using reverse phase chromatography. An important intermediate in the reaction mixture is DO3A-(OEt)₃, which can be selectively prepared by adjusting the relative ratio of cyclen and ethyl bromoacetate (140).

Chart 9. Meares Peptide Method for the Synthesis of *p*-NO₂-BzDOTA

can be easily reduced with excess borane (BH₃) to afford the macrocyclic tetraamine: 6-(4-nitrobenzyl)-1,4,8,11-tetraazacyclotetradecane. Reaction of the macrocyclic tetraamine with bromoacetic acid in the presence of NaOH gives the product: 6-(4-nitrobenzyl)-1,4,8,11-tetraazacyclotetradecane-*N,N',N'',N'''*-tetraacetic acid. The nitro group is then converted to an amino group for conjugation of biomolecules (152, 153).

Meares and co-workers (154) also reported a synthetic route involving formation of a linear tetrapeptide, reduction of the peptide bonds and intramolecular tosylamide ring closure (Chart 9). In this approach, the amino acid starting materials are readily available. The use of amino acids also allows one to vary the side chains. Racemization is unlikely under the conditions involved in the synthesis. Because of Meares' pioneering efforts in this area, many macrocyclic BFCs have been synthesized and studied for their use in the radiolabeling of biomolecules.

Parker and co-workers used the similar approach to prepare a series of C-substituted macrocyclic tetraamines for the radiolabeling of antibodies (155–157). Kimura and co-workers (66) also used the peptide approach to prepare C-functionalized BFCs (Chart 10). First, a dilute solution of diethyl aminomalonate hydrochloride and linear tetraamine in methanol was refluxed for 3 days to give the dioxoaza cyclic amine in ~30% yield. Reduction of the dioxoaza amine with BH₃–THF afforded the corresponding macrocyclic amine, which was then allowed to react with 4-nitro-benzaldehyde in the presence of NaBH₃CN to afford 4-nitrobenzylamino-substituted TRITA or TETA. Moreau and co-workers (158) also used this approach to synthesize 6-(4-aminobenzyl)-1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (H₂NBn-TETA).

McMurphy and co-workers (159) used the peptide approach (Chart 11) to prepare the 12-membered tetraaza macrocycle, 2-(4-nitrobenzyl)-1,4,7,10-tetraazacyclododecane, and its N-substituted analogue, 2-(4-nitrobenzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid. The reaction of 4-nitrobenzyl-ethylenediamine with carbamate-protected amino disuccinimido ester under high-dilution conditions afforded the diamide in ~40% yield. The ready availability of carbamate-protected amino diesters from the corresponding aminoacetic acids, as well as the substituted diamine, makes this an efficient route for the construction of C-functionalized tetraaza macrocycles. Deprotection of the Boc groups was achieved by stirring the macrocycle in anhydrous HCl(g)/dioxane.

Chart 10. Kimura Peptide Method for the Synthesis of Tetraazamacrocycles

Reduction of the macrocyclic diamide produces the corresponding macrocyclic tetraamine. The 12-membered macrocyclic tetraamine was also prepared by an independent route employing the same cyclization chemistry but with a different diamine starting material (Chart 11). The cyclic diaminediamide was reduced with excess borane (BH₃) to produce the macrocyclic tetraamine, 2-(4-nitrobenzyl)-1,4,7,10-tetraazacyclotetradecane. Alkylation of the macrocyclic tetraamine to form the corresponding aminocarboxylate was accomplished in one step by using bromoacetic acid (pH 8.5) or in two steps by using *tert*-butyl bromoacetate (Na₂CO₃/DMF) followed by deprotection with TFA.

Mishra and co-workers (160) recently reported a new approach for the synthesis of 2-(4-nitrobenzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (Chart 12). This approach is a combination of the Richman-Atkins' method and peptide method. Reaction of 4-nitrobenzylethylenediamine with *N,N'*-bis(bromoacetyl)-ethylenediamine in the presence of cesium carbonate afforded the diamide in ~40% yield. High dilution conditions were not required for the reaction. The cyclic diaminediamide was easily reduced with excess borane (BH₃) to afford the corresponding macrocyclic tetraamine, 2-(4-nitrobenzyl)-1,4,7,10-tetraazacyclotetradecane. Reaction of the macrocyclic tetraamine with bromoacetic acid in the presence of a base afforded 6-(4-nitrobenzyl)-1,4,8,11-tetraazacyclotetradecane-*N,N',N'',N'''*-tetraacetic acid. The crude product was purified using a reverse phase HPLC method.

Isomerism of Lanthanide Chelates. Stereochemical nonrigidity is characteristic of metal complexes with coordination number of 7 or greater; there is very little energy barrier between different coordination geometries. However, the use of a polydentate chelator makes it difficult for different isomers to interconvert. As a result, it is not uncommon that metal complexes with coordination number of 7 or greater show isomerism both in the solid state and in solution.

In the past decade, many acyclic and macrocyclic BFCs have been used for the radiolabeling of antibodies and peptides. Very little information is available on isomerism of the metal chelate. In many cases, ITLC is the only analytical tool for the final product analysis. Radio-HPLC chromatograms are not presented nor are the HPLC

Chart 11. McMurtry Method for the Synthesis of *p*-SCN-Bz-DOTA**Chart 12. Mishra Peptide Method for the Synthesis of *p*-NH₂-Bz-DOTA**

methods used for the characterization of the radiolabeled biomolecule. Therefore, it is not surprising that there has been no detailed discussion about isomerism and the impact of isomerism on the biological properties of the radiolabeled biomolecule.

For radiolabeled antibodies, the attachment of the BFC and the radionuclide does not disturb the tertiary structure of the polypeptide; thereby, the biological and receptor binding properties are not significantly affected. For small biomolecules, however, the metal chelate (radionuclide and BFC) contributes greatly to the overall size and molecular weight of the radiopharmaceutical. Isomerism may have a significant impact on the biological performance (receptor binding and biodistribution) since the distribution of the radiopharmaceutical is dependent on the physical and chemical properties of both the biomolecule and the metal chelate.

Solid state structures provide a wealth of information about the coordination chemistry of a specific chelating system. However, the solution structure may be different from the solid state structure because of possible dissociation of certain donor atom or due to the coordination of water molecules. The isomerism observed in the solid state structure may not be seen in solution due to interconversion of isomers or fluxionality of the ligand framework. On other occasions, only one isomeric form is found in the solid state due to the crystal packing effect, and more isomers are observed in solution. Thus, it is imperative to confirm the solution structure in order to understand the biological properties of a metalloradiopharmaceutical. Recently, Caravan et al. (60) has reviewed extensively both the solid state and solution structures of lanthanide complexes of various acyclic and macrocyclic chelators. In this review, we only discuss some specific topics associated with the isomerism of lanthanide complexes of bifunctional polyaminocarboxylate chelators.

Inversion at the Coordinated Nitrogen. The pyramidal environment at coordinated amine-nitrogen atoms has been conclusively established by X-ray methods (161). Rapid inversion at monodentate amine nitrogen atoms is very common (Chart 13). Once the nitrogen atom in a polydentate chelator is bonded to the metal ion, the inversion becomes more difficult and involves dissociation and reformation of the coordination bond. Therefore, coordination of amine-nitrogen often results in formation of isomers in yttrium and lanthanide complexes of polyaminocarboxylate chelators. For example, DTPA, DTPA-MA, and DTPA-BMA contain three amine-nitrogen donors. In principle, this will result in formation of eight possible isomers. In solid state, only some of them were observed by X-ray crystallography (162–169). In solution, all eight isomers have been observed by NMR at low temperature (162–172). Some of them interconvert via a partial dissociation at elevated

Chart 13. Inversion at the Coordinated and Uncoordinated Amine-Nitrogen

temperatures. For example, the proton NMR spectra of the Pr^{3+} and Eu^{3+} complexes of DTPA show that at room temperature there are only two main isomers (Figure 12), which undergo rapid exchange in solution at tempera-

tures higher than 95°C (162, 163). For the Lu^{3+} chelate of DTPA-BMA, however, the temperature for rapid exchange of two isomers is lower (85°C), reflecting the weak bonding of carbonyl-oxygen as compared to carboxylate-oxygen donors (171, 172). The major feature of the exchange process involves the shuffling of coordinated acetate, accompanied by a flip of the backbone ethylene bridges between staggered conformations.

If the biomolecule in DTPA-monoamide is stereochemically pure, the yttrium complex will have the same number of isomers as the Y-DTPA complex. Recently, we used a reversed-phase HPLC method to characterize two DTPA-peptide conjugates (SQ169 and SQ170) (173). It was found that the ^{90}Y complex, RP762 (Figure 13), shows two radiometric peaks (Figure 14), suggesting that there are two detectable isomeric forms (A and B) in solution at room temperature. The formation of RP762 at room temperature is almost instantaneous, and the initial peak ratio is 50:50. The peak ratio changes over time until the equilibrium is reached with the peak

**Figure 12.** Two major isomers for lanthanide complexes of DTPA.**Figure 13.** Structures of two ^{90}Y -labeled vitronectin receptor antagonists: RP762 (top) and RP763 (bottom).

Figure 14. Typical radio-HPLC chromatograms of RP762 (top) and RP763 (bottom). The y-axis represents the signal intensity while the x-axis indicates retention time of a radiolabeled compound (data from ref 173).

A/peak B ratio of 48:52. The rate of interconversion is slow at room temperature. At a higher temperature (54 °C), the rate of interconversion is accelerated, and it took about 6.5 h for peak A to reach the 48:52 (peak A/peak B) ratio. However, it took a much longer time (>7.5 h) for peak B to reach the equilibrium, suggesting that isomer B is thermodynamically more stable. Both peak A and peak B remained stable in the HPLC mobile phase (containing ~10% acetonitrile) at 54 °C for more than 6 h, suggesting that interconversion of these two isomers is intramolecular.

A slightly different mobile phase was used to analyze RP763 (Figure 13) due to its higher lipophilicity (173). RP763 shows only one broad peak with the half-width of ~3 min (Figure 14). There are two possibilities for the large half-width of the peak. The first possibility is that the peak is a combination of several unresolved peaks. If that were true, it would have been possible to separate them using a long gradient method or isocratic chromatographic conditions. We tried several different gradients, and found that RP763 always show one broad peak with different half-widths depending upon the HPLC chromatographic conditions. The second possibility is that there is a rapid interconversion between different isomers at room temperature.

In general, the lanthanide complexes of DTPA analogues assume distorted tricapped trigonal prism (TTP) geometries. In the TTP arrangement, the neutral donor atoms with longer bond length will prefer to occupy face capping position rather than a prismatic corner. However, since it is not possible for all three amine-nitrogen donors to occupy capping positions, the central nitrogen

Chart 14. Eight Possible Isomers of the Complex Y(DTPA-Monoamide)

atom tends to occupy a prismatic corner (Figure 12) while the two terminal amine-nitrogen atoms occupy capping positions. Because of distortion, the actual coordination geometry is, in most cases, between TTP and monocapped square antiprism (CSAP).

^1H and ^{13}C NMR studies of lanthanide complexes of DTPA and DTPA-bisamide derivatives have revealed a rapid interconversion of two wrapping isomers (Figure 12). It has been proposed that the rapid exchange process involves "wagging" of the diethylenetriamine backbone and shuffling of coordinated acetate groups. Inversion at the coordinated nitrogen atoms has been excluded due to the fact that the ^1H signals of methylene hydrogens of the acetate and acetamide groups remains as AB quartets even at 85 °C (165, 166). This strongly suggests that the energy barrier for the inversion at coordinated amine-nitrogen donors is much higher than that for interconversion of two "wrapping isomers".

It should be noted that the concentration of the lanthanide complexes for NMR studies ranged from 0.05 to 0.2 M. Dissociation of acetate-oxygen and amine-nitrogen donors is not significant. At the tracer level, however, the concentration of RP762 in the collected HPLC mobile phase is only $\sim 10^{-10}$ M. At this concentration, it is quite possible for acetate-oxygen, carbonyl-oxygen, and amine-nitrogen donors to become dissociated. Partial dissociation of these donor atoms makes the interconversion between "wrapping isomers" much easier. That may account for the different solution characteristics of lanthanide complexes of DTPA-MA and DTPA-BA at different concentration levels.

Among eight possible isomers of Y(DTPA-monoamide) (Chart 14), four of them are enantiomers. If one assumes

Chart 15. Eight Possible Isomers of the Complex Y(DTPA-Bisamide)

that the rapid interconversion occurs between “wrapping isomers” at room temperature, isomer **1** is readily converted to **1'** via “shuffling” of the two NO₂ donor sets and “wagging” of the diethylenetriamine backbone. The same is true for **2** to **2'**. Since **1'/2** and **2'/1** are the two enantiomer pairs, these four isomers are not separable by radio-HPLC, and are expected to appear as single peak while the remaining four isomers (**3**, **3'**, **4**, and **4'**) as another single peak in the HPLC chromatogram. This is completely consistent with the presence of two radiometric peaks in the HPLC chromatogram of RP762 (Figure 14).

It should be noted that the relative orientation of the acetamide group to the acetate arm at the central nitrogen atom is different (cis and trans, respectively) in isomers **1** and **4** (Chart 14). The same is true for isomers **1'** and **4'**, **2** and **3**, **2'** and **3'**. For cis and trans isomers to interconvert, inversion at the terminal amine-nitrogen atoms has to occur. This suggests that the NO₂ donor set have to be dissociated and accompanied by a rapid “umbrella-type” inversion at the nitrogen atom. That explains the fact that both radiometric peaks of RP762 interconvert and the rate of interconversion is temperature dependent. Since RP762 remains stable for at least 6 h at 54 °C without a significant decomposition, it is reasonable to assume that the remaining part of the DTPA-monoamide conjugate remains firmly bonded to Y(III) when one of the two NO₂ donor sets undergoes a rapid “umbrella-type” inversion at the terminal nitrogen atom.

SQ170 is a DTPA-bisamide and bonds to yttrium(III) as an octadentate chelator using two carbonyl-oxygen, three amine-nitrogen, and three acetate-oxygen donor

**Figure 15.** Four possible isomers of lanthanide complexes of DOTA.

atoms. Due to the chirality of the three coordinated amine-nitrogen atoms, DTPA-bisamide forms Y(III) complexes with eight isomers (four pairs of enantiomers in Chart 15). Compared to acetate-oxygen, the carbonyl-oxygen is a weak donor for yttrium(III). Thus, it is easier for the two NO₂ donor sets to be dissociated in solution, which results in faster interconversion between “wrapping isomers” and inversion at coordinated amine-nitrogen atoms. As a result, RP763 shows only one broad radiometric peak in its HPLC chromatogram (Figure 14).

Chiral Centers at Carbon Atoms. Substitution at carbon atoms of the chelator backbone or acetate chelating arms results in formation of more isomers due to the presence of stereogenic carbon at the point of substitution. For example, BOPTA has a benzyloxymethyl (BOM) group at one acetate group, which in combination with three prochiral amine-nitrogen atoms are expected to form 16 possible stereoisomers for lanthanide complexes (174). The introduction of chiral centers of equal configuration (*RRRR* or *SSSS*) to one or all four acetate arms of DOTA results in four pairs of diastereomers upon chelation to lanthanide metals. Two isomers were also observed for the *RRRR*-DOTMA by the proton NMR and high-resolution luminescence of the Eu³⁺ complex. A rapid exchange process between the two isomers was established by ¹H EXSY (175).

DOTA and Its Derivatives. In the solid state, lanthanide complexes of DOTA are often nine-coordinate with four amine-nitrogen and four carboxylate-oxygen atoms arranged in a square antiprismatic geometry and the monodentate water-O capping the face of the four carboxylate-oxygen donors (176–182). In principle, there are four possible isomers (panels A–D in Figure 15) for lanthanide metal complexes of DOTA. Isomers A and B are enantiomers and indistinguishable by NMR. Isomers C and D represent the other pair of enantiomers. Isomers A and B are close to square prismatic with the acetate arms in a different layout and the cyclododecane ring conformation being identical to those of C and D. Interconversion within each enantiomeric pair (A ↔ B or C ↔ D) occurs through inversion of the ethylenic groups and

Figure 16. Room temperature ^1H NMR spectra of complexes Y(DOTA-MBA) (top) and Y(DOTA-BA) in 90% D_2O .

concerted or stepwise rotation of the acetate arms (180). This process is easily observed in the VT ^{13}C NMR spectra since it results in the equilibration at high temperatures of the two distinct resonances for the ethylenic carbons. On the other hand, the exchange between diastereomers may take place either by rotation of the acetate arms while maintaining the same conformation of the macrocyclic ring or by inversion of the ethylenic groups without changing the orientation of the acetate arms.

Recently, we prepared two model compounds, Y(DOTA-MBA) (MBA = methyl-benzylamine) and Y(DOTA-BA) (BA = benzylamine), for the radiolabeled DOTA-BM conjugates (183). Theoretically, DOTA-MBA should form lanthanide complexes with four possible isomers. Unlike those of lanthanide DOTA complexes, these four possible isomers are no longer enantiomers but diastereomers, which are expected to show distinctive NMR spectra. The lack of axial symmetry removes the signal degeneracy in the NMR spectra, and a large number of resonance signals are expected for each isomer. However, the ^1H (Figure 16) and ^{13}C NMR data show clearly that the complex Y(DOTA-MBA) exists predominantly as one isomer in solution. There are some small satellite peaks on either the right or left side of each main peak, suggesting that there may be a minor isomer for Y(DOTA-MBA). The percentage of the minor isomer is so low that it is barely detectable by both ^1H and ^{13}C NMR. For the complex Y(DOTA-BA), we were supposed to observe only one pair of enantiomers as demonstrated by the ^1H NMR (Figure 16) since the complex does not contain any chiral centers. We also prepared the corresponding ^{90}Y complexes, $^{90}\text{Y}(\text{DOTA-MBA})$ and $^{90}\text{Y}(\text{DOTA-BA})$. Using a reversed phase HPLC method (183), we found that both complexes showed only one radiometric peak in their radio-HPLC chromatograms (Figure 17). This is completely consistent with results obtained by ^1H and ^{13}C NMR and suggests that both complexes exist in solution as only one predominant isomer.

Introduction of a substituent at the ethylenic carbon or one of the four acetate arms will result in an extra chiral center and double the number of isomers. For example, DOTA-pNB has a *p*-nitrophenyl substituent attached to one of the four acetate arms (184). Theoretically, it should form lanthanide complexes with eight possible isomers. However, an NMR study shows that the complex $\text{La}(\text{DOTA-pNB})^-$ exists in solution as only one isomer while complexes $\text{Ho}(\text{DOTA-pNB})^-$ and $\text{Ho}(\text{DOTA-pNB})^-$ exist in two isomeric forms with a relative ratio of 88:12 for $\text{Ho}(\text{DOTA-pNB})^-$ and ~3:1 for $\text{Yb}(\text{DOTA-pNB})^-$. The relative ratio of the two isomers for the lanthanide complexes of DOTA and DOTA-pNB varies

Figure 17. Typical radio-HPLC chromatograms of ^{90}Y -DOTA-MBA (top) and ^{90}Y -DOTA-BA (bottom). The y-axis represents the signal intensity while the x-axis indicates retention time of a radiolabeled compound (data from ref 183).

from metal to metal. There is not a general trend among the lanthanide metals.

DOTP and DOTMP Analogues. Like DOTA, DOTP, and DOTMP also form highly stable lanthanide complexes in which the phosphonate and phosphinate chelating groups are orientated clockwise or counterclockwise. The phosphonate- or phosphinate-P atom is chiral. The coordination of four pendant chelating arms results in a chiral center at each phosphorus. Six diastereomers are possible, RRRR, RRRS, RRSS, RSRS, RSSS, and SSSS, each having two possible wrapping isomers resulting in six enantiomer pairs (185). ^{19}F NMR spectra of the lanthanide complexes of fluorinated phosphonate ester, F-DOTPM, revealed up to 16 resolved ^{19}F NMR resonance signals, consistent with formation of all six possible diastereomers (186). In contrast, the ^1H NMR spectra of Y^{3+} , Yb^{3+} , and Eu^{3+} complexes of the tetraphosphinate DOTBzP showed only one species in solution, with no fluxional behavior observed over a temperature range of 5–80 $^\circ\text{C}$ (187).

Attachment Position of Biomolecules. Generally, there are three possible approaches to attach a biomolecule to DOTA. In the first approach, the attachment is at one of the carbon atoms of the macrocyclic chelator backbone (Figure 18). In principle, this will result in formation of eight possible isomers when it is coordinated to the lanthanide metal. In the second approach, the linker is attached to one of four acetate chelating arms. This may also result in formation of eight possible isomers when it is bonded to the metal center. In both cases, the conjugation of the biomolecule does not lead to a significant change in the thermodynamic stability and kinetic inertness of the metal complex as compared to those of the DOTA complex. In the third approach, the biomolecule is conjugated to one of the four acetate groups via a CO-NH amide bond. Compared to the carboxylate-oxygen, the carbonyl-oxygen is a relatively weak donor for yttrium and lanthanide metal ions. This is consistent with the lower thermodynamic stability of

Figure 18. Three possible approaches to attach a biomolecule to a DOTA chelator.

the lanthanide complex (e.g., $K_{Y-DOTA-monoamide} \approx 21.8$; $K_{Y-DOTA} = 23.5$) (60, 188). However, the kinetic inertness of the lanthanide complex remains relatively unchanged as evidenced by the high solution stability of radiolabeled DOTA-BM conjugates.

Conjugation Groups. In the last two decades, a number of conjugation techniques have been developed for modification of proteins, DNA, and other biologically active molecules. There are many conjugation groups useful for attachment of a BFC to a biomolecule. These include the activated disulfide, diazobenzene, acid chloride or anhydride, bromo- or iodoacetamide, isothiocyanate, *N*-hydroxysuccinimide (NHS) ester, aldehyde/ketone, and maleimide. These conjugation groups are electrophiles, which require a nucleophile functionality in the biomolecule. In some instances, the biomolecule of interest contains only electrophilic functionality (e.g., the carboxylic acid), further synthetic elaboration is needed. In these cases, a bis-nucleophilic reagent, such as ethylenediamine or propylenediamine, is often used to convert the electrophilic functionality into a nucleophilic group. These reactive groups, whether they are naturally part of the biomolecule or are artificially introduced, can serve as "handles" for conjugation of a BFC. The selection of the conjugation group is largely dependent on the nature of the handle on the biomolecule. Very often the handle is a primary amine or a thiol group. The functional groups reactive toward primary amines include DTPA dianhydride, NHS-activated esters, isothiocyanates, and aldehyde/ketone, while maleimide is very reactive to the thiol functionality.

DTPA Anhydride. A major advantage of using DTPA as BFC is that DTPA dianhydride is commercially available and reacts readily with primary amines to form the DTPA-biomolecule conjugate. The reaction can be performed in both aqueous and nonaqueous media. There are two possible products: DTPA-monoamide and DTPA-bisamide (Chart 16). The cross-linking between two macromolecules (antibodies and antibody fragments) is disadvantageous, and may have dramatic impact of the biological and immunogenic properties of the DTPA-biomolecule conjugate. For small biomolecules, however, the cross-linking may prove to be beneficial for the improved receptor binding kinetics because simultaneous binding of two biomolecules on adjacent receptor sites will result in a slow dissociation of the receptor ligand. Asymmetric anhydrides of DTPA and DOTA have also been used for the synthesis of the corresponding bioconjugates (188, 189). However, the yield is often very low.

The NHS-activated esters (Chart 16) have intermediate reactivity toward amines, with high selectivity for aliphatic amines. The optimum pH for reaction in aqueous systems is 8.0–9.0. Virtually any molecule that contains a carboxylic group can be converted into its NHS ester, making NHS-activated ester groups among the

Chart 16. Several Important Conjugation Groups

most powerful and the most commonly used conjugation groups for antibodies and their fragments. Water-soluble NHS-activated ester has also been used for conjugation of biomolecules to DOTA (190, 191).

Like NHS esters, isothiocyanates (Chart 16) are amine-reactive groups with an intermediate reactivity, and form thiourea bonds with primary amines of proteins or peptides. They are somewhat more stable in water than the NHS esters and react with amines in aqueous solution optimally at pH 9.0–9.5. Isothiocyanates may not be suitable for modifying proteins that are sensitive to alkaline pH conditions. Aromatic isothiocyanates have been used for conjugation of biomolecules to DTPA and DOTA analogues (117, 154, 192, 193).

Aldehydes and ketones (Chart 16) can react with primary and secondary amines to form Schiff bases. A Schiff base is a relatively labile bond that is readily reversed by hydrolysis in aqueous solution. The formation of Schiff bases is enhanced at basic pH, but they are not completely stable. A number of reducing agents can be used to convert the Schiff base C=N bond into an alkylamine linkage, which is highly stable under both acidic and basic conditions. Virtually any molecule that

Chart 17. Two Radiolabeling Approaches

contains an aldehyde or ketone group can be converted into its Schiff base form. The aldehyde conjugation group has been used for radiolabeling of antibodies and antibody fragments. However, the aldehyde and ketone conjugation groups have not been widely used for conjugation of small biomolecules.

Maleimide (Chart 16) is a thiol-reactive group (191) and reacts selectively with a thiol from an antibody to form a thioether bond without any interference from histidine and other reactive groups. The optimum pH for the reaction is near 7.0. At pH higher than 8.0, maleimides may hydrolyze to form nonreactive maleamic acids. Since many small biomolecules contain no thiol functionality, the use of maleimide as a conjugation group is in some way limited.

Radiolabeling Approaches. The choice of radiolabeling approach depends on the type of biomolecules to be labeled and the purpose of the study. In general, there are two approaches (the prelabeling approach and the postlabeling approach) useful for the radioabeling of biomolecules with lanthanide radionuclides. In the post-labeling approach (Chart 17), a BFC is first attached to the biomolecule either directly or via a linker to form the BFC-BM conjugate. The radiolabeling can be accomplished simply by reacting the BFC-BM with radiometal chloride in a buffer solution in the presence of weak chelating agent (such as citrate), if necessary. DTPA-BM conjugates can be readily radiolabeled within 10 min at room temperature and pH 5–7. The high radiolabeling efficiency (fast and high yield labeling) can be attributed to the linear chelator backbone of DTPA analogues. The labeling kinetics of DOTA-BM conjugates is usually slow. In this case, higher pH and elevated temperature are often needed to achieve fast labeling and high radiolabeling yield. The postlabeling approach is particularly useful for biomolecules that are not sensitive to the sometimes forcing conditions used in the chelation step. For biomolecules, which are sensitive to heating, the prelabeling approach might be the best alternative.

The prelabeling approach (Chart 17) involves formation of the metal complex with a BFC, and conjugation of the M-BFC complex to a biomolecule in a separate step on the tracer level (43). In this approach, the chemistry is

well defined, and the biomolecule is not exposed to the harsh conditions used in the chelation step. For research purposes, this approach is very useful to demonstrate the proof of principle in a short period of time. However, this approach is too complex and time-consuming for routine clinical use. It is also not practical for large-scale production since it involves two steps of chromatographic separation of ^{90}Y -labeled molecules at the tracer level.

Quality Control of the ^{90}Y -Labeled Biomolecules. Before discussing details of ^{90}Y -labeling of biomolecules, it is very important to clarify a misconception on two commonly used terms: radiolabeling yield and radiochemical purity (RCP). In a radiolabeled "kit" mixture, there are a number of possible ^{90}Y -containing species: [^{90}Y]acetate if acetate is used as a buffering agent, [^{90}Y]colloid formed during the radiolabeling, the [^{90}Y]BFC-BM complex, and other impurities. Radiolabeling yield is a term to describe the overall percentage of ^{90}Y -labeled species except [^{90}Y]colloid and [^{90}Y]acetate. Radiochemical purity is the fraction of the total radioactivity in the desired chemical form of a radiopharmaceutical. Radioimpurities arise either from BFC-containing organic impurities or decomposition of the [^{90}Y]BFC-BM complex during the radiolabeling process. If there are no other ^{90}Y -species (such as [^{90}Y]acetate, [^{90}Y]colloid, and ^{90}Y -impurities) formed, the radiochemical purity is the radiolabeling yield of a radiopharmaceutical. However, in most cases, the radiochemical purity of a radiopharmaceutical is *always lower than* its radiolabeling yield.

TLC/ITLC is the most frequently used procedure for the quality control of ^{90}Y -labeled biomolecules. It is simple and quick, usually taking only 5–15 min to complete the whole procedure. Ideally, one TLC paper strip or plate is needed for the separation of [^{90}Y]acetate, [^{90}Y]colloid, and the [^{90}Y]BFC-BM complex. The mobile phase is often comprised of an organic solvent (acetone, ethanol, acetonitrile, methyl ethyl ketone or isopropyl alcohol) and a buffer. The [^{90}Y]colloid and [^{90}Y]acetate remain at the origin and the [^{90}Y]BFC-BM complex migrates to the solvent front. It should be noted that TLC methods typically give only the radiolabeling yield. Rarely can they provide the radiochemical purity (RCP) data for the [^{90}Y]BFC-BM complex, and is not suitable for separation of different isomeric forms.

For the past decade, HPLC has become a routine technique for quality control of various radiopharmaceuticals. The advantage of radio-HPLC is its capability to determine the RCP for the [^{90}Y]BFC-BM complex, and to separate different ^{90}Y species in the kit. It is also a very powerful tool for separation of different isomers such as epimers and diastereomers. The separation of optical isomers requires the use of chiral chromatographic conditions (chiral column or chiral mobile phase). However, radio-HPLC also has its limitations. For example, it cannot be used for the assessment of the amount of [^{90}Y]colloid in the radiolabeled kit. Therefore, a TLC method is needed in combination with radio-HPLC to assess both the radiolabeling yield and the radiochemical purity of the ^{90}Y -labeled biomolecule. In addition, a 4 mM DTPA solution (pH 4–5) is often recommended for accurate determination of unchelated ^{90}Y during the standard quality control by HPLC (17). If DTPA is not used, the unchelated ^{90}Y will be readily bound to the column; thereby giving a false indication of the radiochemical purity of the radiopharmaceutical.

It is very important to emphasize that a single peak in the HPLC chromatogram does not mean that there is only one ^{90}Y -species. This is particularly true when the

chromatographic conditions are not optimized. Different chromatographic conditions (such as an isocratic mobile phase or a long and slow gradient mobile phase) are strongly recommended to confirm that the single peak observed in the HPLC chromatogram is really one peak and that there are no other radioimpurities or isomeric forms coeluting with the ^{90}Y -BFC-BM complex.

^{90}Y -Labeling of DTPA-BM Conjugates. As discussed in the previous section, a major advantage of using DTPA analogues as BFCs is fast radiolabeling kinetics under mild conditions. Stimmel et al. studied the ^{90}Y -chelation properties of a series of DOTA and DTPA analogues (194, 195). It was found that the ^{90}Y -chelation efficiency of acyclic chelators (DTPA, nitro-CHX-A-DTPA, nitro-MX-DTPA, and TMT-amine) was much higher than that of macrocyclic chelators, and that trace metal (Ca^{2+} , Fe^{2+} , and Zn^{2+}) contamination had minimal effect on the radiolabeling. The DTPA-BM conjugates can be readily radiolabeled under mild conditions (room temperature and pH 4–7). We studied the ^{90}Y -chelation properties of a DTPA-conjugated cyclic peptide (SQ169), and found that higher pH gives faster radiolabeling kinetics (173). High yield labeling (RCP > 95%) can be readily achieved by reacting 2 μg of SQ169 with 20 mCi of $^{90}\text{YCl}_3$ in the 0.5 M ammonium acetate buffer (pH 8.0). The SQ169:Y ratio is $\sim 4:1$ under these conditions, and chelation is almost instantaneous at room temperature.

^{90}Y -Labeling of DOTA-BM Conjugates. The labeling kinetics of DOTA-BM conjugate is usually slow, and much more dependent on the radiolabeling conditions (195–198). There are many factors influencing the radiolabeling yield. These include the amount of DOTA-BM conjugate, the pH in the reaction mixture, temperature and heating time, buffer agent and buffer concentration, stabilization agent and its concentration, and the presence of other trace metal contaminants, such as Fe^{3+} and Zn^{2+} .

Metal Ion Contamination. Unlike that of acyclic chelators (DTPA, nitro-CHX-A-DTPA, nitro-MX-DTPA, and TMT-amine), the ^{90}Y -chelation efficiency of macrocyclic chelators (nitro-DOTA, nitro-TRITA, and nitro-PADOTA) diminished when the concentration of trace metal contaminants (Ca^{2+} , Fe^{2+} , and Zn^{2+}) was increased (194, 195). Table 4 shows the maximum limits of trace metal contaminants (as of production date) in the ^{90}Y -stock solution from NEN (New England Nuclear) and

Table 5. Half-Times for the ^{90}Y -Labeling of DOTA-MoAb Immunoconjugate in 0.5 M Ammonium Acetate Buffer under Perspective Radiopharmacy Labeling Conditions^a

pH value	half-time (min)	pH value	half-time (min)
4.5	46–410	7.5	0.28–2.5
5.5	4.3–38	8.5	0.06–0.53
6.5	4.2–37

stability constants of their corresponding DOTA complexes (199–203). Most of the trace metals (Al, Ca, Ce, Co, Cr, Cu, Fe, La, Ni, Pb, Zn, and Zr) in the ^{90}Y -stock solution have the potential to influence the ^{90}Y -labeling efficiency of a DOTA-based BFC. The actual metal contaminant concentration may not be as high as specified by the manufacturer; but results from our lab clearly showed that the concentration of total trace metal contaminants in the ^{90}Y -DOTA-BM reaction mixture is much higher than that of ^{90}Y . It is strongly recommended that the trace metal contamination be minimized during the radiolabeling.

BFC-BM Conjugate Concentration. Radiolabeling efficiency is a term often used to describe the ability of a chelator to form its radiometal complex at a low concentration under mild conditions. The radiolabeling efficiency of a macrocyclic chelator is largely dependent upon radiolabeling conditions (the concentration of trace metal contaminants, pH, heating temperature, and reaction time). It was reported that the radiolabeling efficiency of DOTA analogues was maximal only when the chelator-to-radiometal ratio was greater than 3 (194, 195). It should be noted that the radiolabeling yields and radiochemical purity reported in these studies were determined by only ITLC not a combination of radio-HPLC and ITLC. *The bonding of the radiometal to the BFC does not mean that the desired radiometal complex is formed.* Giving the fact that the radionuclide solution is often contaminated with other trace metals at higher concentrations than that of the radiometal, the data reported for the radiolabeling efficiency of macrocyclic chelators should be used with caution.

Heating Temperature and Reaction Time. Room temperature labeling offers advantages over heating at 100 °C; but it often requires much longer reaction time and a higher concentration of the DOTA-BM conjugate in the reaction mixture to complete the radiolabeling (RCP > 90%). Under the same radiolabeling conditions, higher temperature and longer heating time usually gives better radiolabeling yield provided that the biomolecule is not subjected to thermal decomposition. It has been reported that the rate of ^{90}Y -chelation could be significantly enhanced by increasing temperature from 22 °C to 37 °C (204). For a DOTA-BM conjugate, heating at 100 °C for a short period of time (5–10 min) is preferred to avoid extensive radiolysis during radiolabeling, particularly when a large amount of ^{90}Y (100–200 mCi) is used for radiolabeling.

Buffering Agent and Its Concentration. The choice of a buffering agent depends on the optimum pH value for complexation. Ammonium acetate and ammonium citrate are preferred buffering agents to avoid any competition from other metals with ^{90}Y and to stabilize the Y^{3+} cation by forming a weak ^{90}Y -acetate or ^{90}Y -citrate complex. The buffering agent concentration is normally 0.1–0.5 M. It was reported that the 0.5 M ammonium acetate buffer (pH 7.0–7.5) is ideal for the

Figure 19. Possible structures of yttrium complexes $\text{YH}_2(\text{DOTA})^+$, $\text{YH}(\text{DOTA})$, and $\text{Y}(\text{DOTA})^-$.

radiolabeling of DOTA-conjugated biomolecules (204). The use of phosphate and carbonate/bicarbonate should be avoided since both phosphate and carbonate readily form a precipitate with Y^{3+} .

Meares and co-workers (204) recently reported optimized conditions for ^{90}Y -chelation of DOTA-immunoconjugates. It was found that the pH of the reaction mixture has a dramatic impact on the rate of chelation. For example, the time required to chelate 94% of ^{90}Y was 17–148 min at pH 6.5, but it was only 1–10 min at pH 7.5 when the concentration of DOTA conjugate was 97–870 μM and ^{90}Y concentration was in the range of 0.83–6.1 μM .

DOTA and its derivatives tend to exist in solution as their zwitterion forms (198–209), and the conformation of the chelator is determined by the degree of protonation of DOTA. For example, the predominant form at pH 3.6–5.0 is $\text{H}_3(\text{DOTA})^-$ while DOTA exists primarily (90%) as $\text{H}_2(\text{DOTA})^{2-}$ at pH 6.0–7.0. The formation of $\text{Y}(\text{DOTA})^-$ complexes proceeds via two intermediate complexes: $\text{YH}_2(\text{DOTA})^+$ and $\text{YH}(\text{DOTA})$. The rate-limiting step is proton transfer from $\text{YH}(\text{DOTA})$ to form the eight-coordinated complex $\text{Y}(\text{DOTA})^-$ since it requires a significant rearrangement of the macrocyclic ring (210), including rotation of C–C and C–N bonds and inversion of the N-atom. Once the proton is removed, chelation of the remaining three N-atoms will be fast. Thus, higher pH results in faster complexation rate.

Different deprotonated intermediates of DOTA form $\text{Y}(\text{III})$ complexes with different structures (210). It has been suggested that in the doubly protonated complex $\text{YH}_2(\text{DOTA})^+$ (Figure 19), $\text{Y}(\text{III})$ is located outside the cage composed of carboxylate-oxygens and ring nitrogen and is coordinated solely by four carboxylate-oxygens. Upon removal of one proton from the ring nitrogen to form $\text{YH}(\text{DOTA})$, the $\text{Y}(\text{III})$ moves toward the ring to become five-coordinated to the four carboxylate oxygens and the one ring nitrogen. Because of static interaction, the N-atom bonding to the metal is most likely to be the one trans to the protonated N-atom. With the removal of the last proton, the expected eight-coordinated complex $\text{Y}(\text{DOTA})^-$ is formed in a square prismatic coordination geometry.

CONCLUSIONS

A target-specific metalloradiopharmaceutical usually contains a targeting biomolecule, a linker, a BFC, and a metallic radionuclide. The targeting biomolecule is only one part of the whole molecule, and the discovery of a new class of biomolecules is just the beginning of the whole drug development process. The development of an efficient BFC and new radiolabeling technologies is equally important. For the receptor-based therapeutic radiopharmaceuticals, it is very important to remember

that the receptor population is often limited. The use of a large amount of unlabeled BFC–BM conjugate may block the binding of the radiolabeled BFC–BM conjugate at the receptor sites. Therefore, the BFC must have very high labeling efficiency (fast and high-yield labeling) and form metal complexes with high specific activity.

The choice of BFC is largely dependent upon the nature and oxidation state of the metal ion and requires a good understanding of the coordination chemistry of any given radiometal. Among various radionuclides, yttrium is of particular importance due to its chemical and nuclear characteristics. The solution stability of a radiopharmaceutical depends on the thermodynamic stability and more importantly the kinetic inertness of the metal chelate. Thus, DOTA derivatives are often used as BFCs for the ^{90}Y -labeling of small biomolecules.

Many acyclic and macrocyclic bifunctional chelators (BFCs) have been synthesized and used for the radiolabeling of antibodies and small peptides. Although formation of isomers in yttrium and lanthanide complexes of DTPA analogues has been studied by various NMR methods, very little attention is paid to the isomerism of the metal chelate (radionuclide and BFC) in radiolabeled DTPA- and DOTA-biomolecule conjugates at the tracer level. For radiolabeled antibodies, the attachment of the BFC and the radionuclide may not have a significant impact on their biological properties due to the fact that the metal chelate is only a small part of the radiolabeled protein. For small biomolecules, however, the metal chelate contributes greatly to the overall size and molecular weight of the radiopharmaceutical. Isomerism may have significant impact on the biological performance (receptor binding and biodistribution). Therefore, it is very important to develop appropriate analytical methods and to study the possible isomerism in the metal chelate in order to understand the biological properties of a new metalloradiopharmaceutical.

A major advantage of using DTPA analogues as BFCs is fast radiolabeling kinetics under mild conditions. However, the kinetic lability of their metal chelates may prove to be problematic when they are used as BFCs for biomolecules having a long blood retention and slow blood clearance. The labeling kinetics of DOTA-based BFCs is usually slow, and much more dependent on the radiolabeling conditions, including the BFC–BM concentration, pH, reaction temperature and heating time, buffer agent and buffer concentration, and presence of other metal ions, such as Fe^{3+} and Zn^{2+} . The ultimate goal is to prepare a therapeutic radiopharmaceutical under the optimized radiolabeling conditions and to retain its chemical and biological integrity during release and transportation.

BIFUNCTIONAL CHELATORS FOR THERAPEUTIC LANTHANIDE RADIOPHARMACEUTICALS

The authors sincerely apologize to Dr. Garry E. Kiefer and co-workers for the oversight of their US patent no. 5587451, which was inadvertently omitted in reference to Chart 4 of this manuscript. US patent no. 6013793 disclosed the routes showing condensation of triethylene-tetraamine (TETA) with glyoxal, followed by oxidation with bromine and formation of a dicationic intermediate. In contrast, the monocationic intermediate depicted in Chart 4 is obtained from the condensation of TETA with dimethylformamide dimethyl acetal as described in US patent no. 5587451.

of potential cancer therapeutics. Until recently, most of the efforts to develop drugs to reduce the activity of oncogenic Ras proteins has focused on the inhibition of protein farnesyltransferase (PFTase). However, PFTase inhibitors may have limited utility against many cancers since some Ras proteins, including oncogenic forms of Ki4B-Ras are geranylgeranylated in a compensatory manner when farnesylation is blocked by inhibition of PFTase (6). Inhibition of Ca_{1a_2}X prenyl protease will disrupt the processing of both types of prenylated Ras proteins and could provide another approach to reducing the activity of oncogenic Ras.

Ca_{1a_2}X prenyl protease (7) activity has been studied in yeast (8, 9), rat (10), and bovine (11) membrane preparations. The rat and bovine enzymes were partially purified (11–13). Prenylated tri-C(farnesyl) a_{1a_2} and tetra-C(farnesyl) a_{1a_2}X peptides are substrates for proteolysis. Recently, the yeast and human genes for Rce1p were expressed in Sf9 insect cells by infection with a recombinant baculovirus (14). The yeast gene was also expressed in a protease-deficient strain of *Saccharomyces cerevisiae*. Biochemical and site-directed mutagenesis studies suggest that yRce1p is a cysteine protease (15).

A variety of assays have been developed for the enzyme. These include HPLC detection of a radioactive cysteine product, a fluorometric HPLC assay (16), and a coupled proteolysis/methylation assay (8, 9, 14). Liu et al. recently reported an assay that relies on the strong affinity of avidin for biotin (17). We were attracted to this assay since it does not require a chromatographic separation or use of a coupling enzyme, is sensitive, and has potential for development as a high throughput system. The peptide synthesized by Liu et al. consisted of a C(S-farnesyl)-VI-[^3H]S tetrapeptide attached to biotin by a hydrophobic spacer. Their synthesis combined a solid-phase assembly of a biotinylated CVI tripeptide with solution phase additions of the farnesyl moiety [^3H]serine. HPLC purifications were required to purify material following each solution phase step. We encountered considerable difficulties with insoluble intermediates and low yields when attempting to adapt these protocols to our system and decided to develop a solid-phase approach for the entire synthesis on a resin whose chemistry was compatible with acid sensitive side chains. In addition, the hydrophobic linker was replaced by a PEG-linker to improve overall solubility of the biotinylated substrate used in the coupling reaction. We now describe the solid-phase synthesis of a radiolabeled, biotinylated, and farnesylated Ca_{1a_2}X peptide and its use to assay for Ca_{1a_2}X proteolytic activity in membranes enriched with recombinant yRce1p.

EXPERIMENTAL PROCEDURES

Amino acids, commercially available *N*-BOC protected amino acids, farnesyl bromide, di-*tert*-butyl dicarbonate, *N,N'*-dicyclohexylcarbodiimide, and *N*-hydroxybenzotriazole, and other chemicals were purchased from Aldrich Chemical Co. Polystyrene resin was purchased from BioRad. [^{14}C]-L-Alanine was obtained from NEN DuPont Corp. Biochemical reagents were purchased from Gibco or Sigma. Kaiser's benzophenone oxime resin was synthesized by the method of DeGrado and Kaiser (18). Avidin resin was purchased from Pierce. THF was dried and distilled from sodium benzophenone. CH_2Cl_2 was distilled from CaH_2 . DMF was vacuum distilled from CaH_2 . Analytical thin-layer chromatography was carried out on either E. Merck or Whatman precoated silica gel

60 (0.2 mm, aluminum support) TLC plates. Preparative TLC was carried out using E. Merck silica gel 60 glass backed TLC plates. C_{18} reverse phase HPLC was carried out using a Vydac Protein and Peptide column with monitoring at 214 nm. Solvents for C_{18} HPLC were a gradient of acetonitrile and water containing 0.1% v/v TFA.

^1H , ^{13}C , and DEPT NMR spectra were obtained using a UNITY Varian 300 MHz NMR and were referenced to either TMS or the residual NMR solvent signal for d_6 -DMSO at 2.50 ppm for ^1H or 39.5 ppm for ^{13}C . Optical rotations were obtained in spectral grade solvents. Infrared spectra were obtained as thin films on NaCl plates. FABMS (positive or negative ion) were obtained from the Mass Spectrometry Service Center in the Chemistry Department. MALDI spectra were provided by the Mass Spectral facility in the Department of Medicinal Chemistry.

Syntheses. *N-tert*-Butoxycarbonyl-L-Valinyl-L-Isoleucinyl Kaiser's Oxime Ester Resin (2). To a solution of *N*-BOC-L-isoleucine (1.64 g, 7.11 mmol) and HOBt (0.96 g, 7.11 mmol) in 20 mL of anhydrous THF at 0 °C under nitrogen was added dropwise DCC (1.47 g, 7.11 mmol) in 10 mL of anhydrous THF. The mixture was stirred for 3 h while it was allowed to warm to room temperature. Dicyclohexylurea was removed by filtration through a plug of Celite, and the plug was washed with ice-cold THF. Solvent was removed at reduced pressure to give L-isoleucine active ester.

The isoleucine active ester was dissolved in 100 mL of anhydrous CH_2Cl_2 and added to 10.0 g of Kaiser's resin. Anhydrous triethylamine (0.91 mL, 6.52 mmol) was added, and the mixture rotated under N_2 overnight. The resin was collected by suction filtration on a medium porosity sintered glass funnel and washed with the following standard protocol: (1) four 100 mL portions of CH_2Cl_2 ; (2) four 100 mL portions of DMF; (3) four 100 mL portions of 2-propanol; and (4) four 100 mL portions of CH_2Cl_2 . The resin was dried overnight under high vacuum.

N-BOC-L-valine (1.54 g, 7.11 mmol) was converted to the HOBt active ester as described previously for *N*-BOC-L-isoleucine. The active ester was isolated as described above.

N-BOC-L-isoleucinyl Kaiser's oxime resin was added to 160 mL of anhydrous CH_2Cl_2 . TFA (40 mL) was added and the suspension rotated for 1 h under nitrogen. The resin was collected by suction on a medium porosity sintered glass funnel, washed with four 100 mL portions of CH_2Cl_2 and added to a solution of L-valine active ester in 100 mL of anhydrous CH_2Cl_2 . Anhydrous triethylamine (2.0 mL, 14.2 mmol) was added, and the suspension was rotated overnight under N_2 . The resin was collected by suction on a sintered glass funnel and washed with the four solvent protocol as described above. The resin was dried under high vacuum overnight to afford 11.32 g of a tan solid.

(*S*-(*E,E*-Farnesyl)-L-cysteinyl)-L-valinyl-L-isoleucinyl Kaiser's Oxime Ester Resin Trifluoroacetate Salt (3). A suspension of *N*-(triphenylmethyl)-(*S*-(*E,E*-farnesyl)-L-cysteine) (4.48 g, 7.89 mmol) (19), HOBt (1.07 g, 7.89 mmol), and 30 mL of anhydrous THF was cooled to 0 °C under N_2 . DCC (1.63 g, 7.89 mmol) in 30 mL of anhydrous THF was slowly added dropwise. The reaction mixture was stirred for 24 h while slowly warming to room temperature. Dicyclohexylurea was removed by filtration through a plug of Celite, and the Celite was washed with 25 mL of ice-cold THF. Solvent was removed in vacuo to afford the *N*-trityl active ester as a thick oil.

A slurry of 10.10 g of *N*-BOC-L-valinyl-L-isoleucinyl Kaiser's oxime ester resin, 100 mL of anhydrous CH_2Cl_2 and 25 mL of TFA were rotated under N_2 for 1.5 h. The resin was collected by suction filtration and washed with four 100 mL portions of CH_2Cl_2 . The deprotected resin was added to a solution of the *N*-trityl active ester in 100 mL of anhydrous CH_2Cl_2 and anhydrous triethylamine (2.2 mL, 15.78 mmol). The suspension was rotated under nitrogen for 24 h. The resin was collected on a sintered glass funnel, washed with the four solvent wash protocol, and dried overnight under high vacuum to afford 10.24 g of a tan solid.

The *N*-trityl Kaiser's oxime ester resin (9.45 g) was suspended in 100 mL of anhydrous CH_2Cl_2 . Ethylmethyl sulfide (5.52 mL, 61 mmol) was added by syringe to scavenge advantageous cations, followed by 1.18 mL (15.3 mmol) of TFA. The resin was rotated for 30 min, collected by suction, washed by mixing with four 125 mL portions of CH_2Cl_2 , and dried in vacuo for 15 min to give the TFA salt of Kaiser's resin **3**.

N-(13-Amino-4,7,10-trioxatridecanyl)biotinamide (**4**) was synthesized by the method of Wilbur et al. (20).

(*N*-(13-*N*-Succinimidyl-4,7,10-trioxatridecanyl)biotinamide-(2,3,5,6-tetrafluorophenyl Active Ester) (**5**). To a solution of 1.0 g (2.24 mmol) of **4** and 0.25 g (2.46 mmol) of succinic anhydride in 20 mL of anhydrous DMF under N_2 , 0.35 mL (2.46 mmol) of anhydrous triethylamine was added by syringe. The reaction was stirred for 16 h before the DMF was removed in vacuo at 40 °C. The residue was dissolved with vigorous stirring in 25 mL of 1 M acetic acid and 25 mL of *n*-butanol. The mixture was extracted with two 25 mL portions of *n*-butanol, and the pooled organic phases were evaporated in vacuo. The residue was repeatedly evaporated from 25 mL portions of CHCl_3 to afford a white solid. The solid was purified by silica column chromatography upon elution with 1:5 MeOH: CHCl_3 , followed by 1:5 MeOH: CHCl_3 containing 5% v/v acetic acid. Fractions that were homogeneous by silica TLC (1:5 MeOH: CHCl_3 containing 5% v/v acetic acid) were pooled and concentrated in vacuo to afford 1.01 g (82%) of a white solid; ^1H NMR (300 MHz, DMSO) δ 1.20–1.34 (m, 2 H), 1.40–1.68 (m, 6 H), 2.04 (t, 2 H, biotin CH_2CO), 2.28 (t, 2 H, succinimidyl CH_2), 2.40 (t, 2 H, succinimidyl CH_2), 2.55 (d, 1 H), 2.73–2.89 (m, 1 H), 3.03–3.12 (m, 5 H), 3.38 (t, 4 H), 3.42–3.52 (m, 8 H), 4.09–4.15 (m, 1 H), 4.28–4.32 (m, 1 H), 6.38 (s, 1 H, biotin NH), 6.46 (s, 1 H, biotin NH), 7.76 (t, 1 H, NH), 7.82 (t, 1 H, NH); ^{13}C NMR (75 MHz, DMSO) δ 173.96, 171.94, 170.87, 162.78, 69.79, 69.56, 68.12, 68.06, 61.07, 59.08, 59.22, 55.47, 39.89, 35.82, 35.74, 35.23, 30.04, 29.43, 29.37, 29.24, 28.26, 28.07, 25.34 ppm. Positive ion FABMS: calcd for $\text{C}_{24}\text{H}_{43}\text{N}_4\text{O}_8\text{S}$ ($\text{M} + \text{H}$) 547; found ($\text{M} + \text{H}$) m/z 547.

To a solution of 1.67 g (3.05 mmol) of *N*-(13-*N*-succinimidyl-4,7,10-trioxatridecanyl)biotinamide and 0.86 mL (6.11 mmol) of anhydrous triethylamine in 32 mL of anhydrous DMF was added dropwise a solution of 1.20 g (4.58 mmol) of 2,3,5,6-tetrafluorophenyltrifluoroacetate (**21**) in 5 mL of anhydrous DMF. The reaction was stirred for 1 h under N_2 . DMF was removed in vacuo with a water bath at ≤ 50 °C to afford a pale yellow oil. Diethyl ether (200 mL) was added with stirring under N_2 . Slowly, over 30 min a white solid formed on the walls of the flask. The ether was removed by suction using a pipet, and a second 200 mL portion of diethyl ether was added. The suspension was stirred for 30 min, and the ether was removed as before. The white solid was dried under high vacuum for 30 min and used immediately.

(1-*N*-Biotinyl-(13-*N*-(succinimidyl-(*S*-(*E*,*E*-farnesyl)-L-cysteinyl)-L-valinyl-L-isoleucinyl)-4,7,10-trioxatridecanediamine) Kaiser's Resin Oxime Ester (**6**). To resin **3** (9.45 g) and newly synthesized tetrafluorophenyl active ester of *N*-(13-*N*-succinimidyl-4,7,10-trioxatridecanyl)biotinamide **5** was added 60 mL of DMF and 60 mL of CH_2Cl_2 , followed by dropwise addition of 1.75 mL (12.51 mmol) of anhydrous triethylamine. The suspension was rotated under N_2 for 48 h.

The slurry was collected on a sintered glass funnel and washed with the four solvent protocol described previously. The resin was dried under high vacuum for 18 h to afford 9.79 g of a tan solid.

(1-*N*-Biotinyl-(13-*N*-succinimidyl-(*S*-(*E*,*E*-farnesyl)-L-cysteinyl)-L-valinyl-L-isoleucinyl-L-alaninyl)-4,7,10-trioxatridecanediamine) Benzyl Ester (**8**). To a suspension of 0.50 g of (1-*N*-biotinyl-(13-*N*-(succinimidyl-(*S*-(*E*,*E*-farnesyl)-L-cysteinyl)-L-valinyl-L-isoleucinyl)-4,7,10-trioxatridecanediamine), Kaiser's resin **6**, were added 0.33 g (0.97 mmol) of L-alanine benzyl ester tosylate and 5 mL of anhydrous CH_2Cl_2 . Glacial acetic acid (56 μL , 0.97 mmol) and anhydrous triethylamine (136 μL , 0.97 mmol) were added. The flask was rotated under N_2 for 24 h.

The resin slurry was poured into a sintered glass funnel that contained 20 mL of 2-propanol and was washed with five 40 mL portions of CHCl_3 and 2-propanol. The CHCl_3 /2-propanol filtrate was concentrated in vacuo and redissolved in 45 mL of CHCl_3 . The solution was washed with 15 mL of saturated NaHCO_3 solution and two 15 mL portions of 1 M acetic acid. The organic layer was dried over anhydrous MgSO_4 , and the solvent was removed at reduced pressure. The last traces of acetic acid were removed by high vacuum overnight.

The residue (0.14 g) was dissolved in CHCl_3 and applied to two preparative silica gel thin-layer chromatography plates. The plates were eluted with 1:10 MeOH: CHCl_3 . The UV active band at $R_f = 0.24$ was removed by scraping and eluted from the silica with a total of 200 mL of 1:5 MeOH: CHCl_3 . Solvent was removed in vacuo to afford **8** (0.11 g, 26% overall) as a white solid; HPLC analysis was performed on a Vydac C_{18} reverse phase column with detection at 214 nm and elution with acetonitrile:water containing 0.1% TFA. The gradient profile was 45% acetonitrile:55% water to 80% acetonitrile:20% water over 20 min. The retention time of **8** under these conditions was 14.82 min. ^1H NMR (300 MHz, DMSO) δ 0.70–0.82 (m, 12 H, valine and isoleucine CH_3), 0.97–1.09 (m, 2 H), 1.27 (d, 3 H, $J = 7.2$ Hz, alanine CH_3), 1.30–1.70 (m, 10 H), 1.54 (s, 6 H, farnesyl CH_3), 1.60 (s, 3 H, farnesyl CH_3), 1.62 (s, 3 H, farnesyl CH_3), 1.86–2.10 (m, 10 H, biotin CH_2CO and farnesyl allylic CH_2), 2.24–2.40 (m, 4 H, succinimidyl CH_2), 2.56 (d, 2 H, $J = 12.3$ Hz, CH_2S), 2.70–2.85 (m, 2 H, SCH_2), 3.00–3.18 (m, 7 H), 3.37 (t, 4 H, $J = 6.3$ Hz, PEG CH_2), 3.42–3.52 (m, 8 H, PEG CH_2), 4.09–4.22 (m, 3 H, cysteine, valine, and isoleucine CH), 4.25–4.34 (m, 2 H, biotin CH), 4.45 (q, 1 H, $J = 7.8$ and 8.1 Hz, alanine CH), 5.00–5.10 (m, 4 H, farnesyl olefinic and benzylic CH_2), 5.15 (t, 1 H, $J = 7.8$ and 8.1 Hz, farnesyl olefinic), 6.47 (br s, 2 H, biotin NH), 7.33 (s, 5 H, aromatic H), 7.71 (d, 1 H, $J = 8.7$ Hz, NH), 7.77 (t, 1 H, $J = 5.4$ Hz, PEG NH), 7.86 (t, 1 H, $J = 5.4$ Hz, PEG NH), 7.89 (d, 1 H, $J = 9.0$ Hz, NH), 8.21 (d, 1 H, $J = 8.1$ Hz, NH), 8.38 (d, 1 H, $J = 6.6$ Hz, NH); ^{13}C NMR (75 MHz, DMSO) δ 172.20, 171.92, 171.64, 171.20, 170.65, 170.42, 170.38, 162.76, 138.30, 135.95, 134.55, 130.65, 128.38, 127.99, 127.75, 124.13, 123.68, 120.27, 69.79, 69.57, 68.12, 65.85, 61.07, 59.23, 57.83, 56.36, 55.47, 52.55, 47.66, 39.88,

39.12, 36.69, 35.85, 35.72, 35.22, 32.69, 30.82, 30.40, 29.43, 29.36, 28.96, 28.25, 28.06, 26.20, 25.93, 25.51, 25.34, 24.18, 19.18, 18.09, 17.56, 16.81, 15.80, 15.07, 10.94 ppm. Positive ion FABMS: calcd for $C_{65}H_{103}N_8O_{12}S_2$ (M + H) 1228; found (M + H) m/z 1228.

1-N-Biotinyl-(13-N-succinimidyl-(S-(E,E-farnesyl)-L-cysteiny)-L-valinyl-L-isoleucinyl-L-alanine))-4,7,10-trioxatridecanediamine (1). To 0.11 g (0.088 mmol) of benzyl ester **8** in 2.2 mL of dry THF was added 0.45 mL (0.110 mmol) of 0.25 M KOH. The mixture was stirred under N_2 for 24 h. TLC analysis on silica gel (1:10 MeOH:CHCl₃) showed the presence of a small amount of starting benzyl ester. A 0.17 mL (0.042 mmol) portion of 0.25 M KOH was added, and the mixture stirred for 4 h. TLC analysis showed no benzyl ester. Solvent was removed at reduced pressure and distilled deionized water (10 mL) was added. The solution was extracted with 40 mL of diethyl ether; the aqueous layer was acidified with 20 mL of 1 M acetic acid, and the resulting milky suspension was extracted with three 20 mL portions of water saturated *n*-butanol. The extracts were combined and the *n*-butanol was removed in vacuo with a water bath at $\leq 40^\circ C$. The residue was dissolved in 1:5 MeOH:CHCl₃ and transferred to a tared flask. Solvent was removed in vacuo to give 0.092 g of a white solid. HPLC analysis as described above gave a retention time of 10.20 min for **1**. The material was purified by silica column chromatography upon elution with 1:5 MeOH:CHCl₃ containing 5% v/v acetic acid. Homogeneous fractions were pooled, and the solvent removed in vacuo to give 0.072 g (72%) of **1** as a white solid, $[\alpha]_D^{20} = -3.80$ (1:5 MeOH:CHCl₃ containing 5.0% v/v glacial acetic acid, $c = 5.0$); IR TF (NaCl) 3353, 3211, 3082, 2961, 2930, 2869, 1707, 1633, 1549, 1454, 1385, 1222, 1115, 755, 709 cm⁻¹; TLC, $R_f = 0.57$ using 1:5 MeOH:CHCl₃ with 5.0% v/v glacial acetic acid on silica; ¹H NMR (300 MHz, DMSO) δ 0.70–0.84 (m, 12 H, valine and isoleucine CH₃), 0.94–1.12 (m, 2 H), 1.16–1.30 (m, 3 H, alanine CH₃), 1.32–1.74 (m, 10 H), 1.51 (s, 6 H, farnesyl CH₃), 1.57 (s, 3 H, farnesyl CH₃), 1.59 (s, 3 H, farnesyl CH₃), 1.84–2.06 (m, 10 H, biotin CH₂CO and farnesyl allylic CH₂), 2.20–2.40 (m, 4 H, succinimidyl CH₂), 2.53 (d, 2 H, $J = 12.3$ Hz, CH₂S), 2.66–2.84 (m, 2 H, S CH₂), 2.94–3.16 (m, 7 H), 3.34 (t, 4 H, $J = 6.3$ Hz, PEG CH₂), 3.38–3.52 (m, 8 H, PEG CH₂), 4.00–4.20 (m, 4 H, cysteine, valine, isoleucine CH, and biotin CH), 4.25–4.34 (m, 1 H, biotin CH), 4.41 (q, 1 H, $J = 7.5$ and 8.1 Hz, alanine CH), 4.96–5.08 (m, 2 H, farnesyl olefinic), 5.12 (t, 1 H, $J = 7.5$ Hz, farnesyl olefinic), 6.35 (s, 1 H, biotin NH), 6.43 (s, 1 H, biotin NH), 7.60–7.96 (m, 4 H, NH), 8.00–8.10 (m, 1 H, NH), 8.17 (d, 1 H, $J = 7.5$ Hz, NH); ¹³C NMR (75 MHz, DMSO) δ 173.92 (carbonyl), 171.90 (carbonyl), 171.60 (carbonyl), 171.18 (carbonyl), 170.40 (carbonyl), 162.76 (urea carbonyl), 138.30 (quaternary), 134.55 (quaternary), 130.65 (quaternary), 124.13 (CH), 123.68 (CH), 120.26 (CH), 69.78 (CH₂), 69.56 (CH₂), 68.10 (CH₂), 61.06 (CH), 59.21 (CH), 57.81 (CH), 56.48 (CH), 55.46 (CH), 52.53 (CH), 47.60 (CH), 39.88 (CH₂), 39.22 (CH₂), 39.12 (CH₂), 36.67 (CH), 35.84 (CH₂), 35.72 (CH₂), 35.22 (CH₂), 32.70 (CH₂), 30.81 (CH₂), 30.41 (CH), 29.42 (CH₂), 29.35 (CH₂), 28.94 (CH₂), 28.24 (CH₂), 28.05 (CH₂), 26.19 (CH₂), 25.93 (CH₂), 25.52 (CH₃), 25.33 (CH₂), 24.16 (CH₂), 19.20 (CH₃), 18.08 (CH₃), 17.57 (CH₃), 17.18 (CH₃), 15.80 (CH₃), 15.21 (CH₃), 11.01 (CH₃) ppm; negative FABMS (glycerol/25 mM NH₄HCO₃): calcd m/z 1135.3 (M – H); found m/z 1135.4 (M – H). The derived isotopic pattern for the M–H signal was found to be identical to the theoretical spectrum: 1135 (100.00%), 1136 (66.87%), 1137 (37.69%), 1138 (16.71%), 1139 (7.87%); MALDI mass spectroscopy: calcd

for $C_{56}H_{97}N_8O_{12}S_2$ (M + H) 1137.6667, found 1137.6810 (4%); calcd for (M + Na) 1159.6487, found 1159.6715 (59%); calcd for (M + K) 1175.6226, found 1175.6484 (37%).

Synthesis of [¹⁴C]1**.** A solution of 116 μ L (3 μ mol, 5 mg/mL) *p*-toluenesulfonic acid in anhydrous THF was evaporated to dryness before 5.0 mL of [¹⁴C]-L-alanine (2.9 μ mol, 0.5 mCi, 174.6 mCi/mmol) in 2:98 ethanol:water was added by syringe. Two 1.0 mL portions of 2:98 ethanol:water were used to rinse the syringe. The solution was flash frozen in a dry-ice/acetone bath and lyophilized to give [¹⁴C]-L-alanine tosylate.

Spectral grade methanol (250 μ L) was added to the residue followed by 30 μ L of 2 M thionyl chloride in anhydrous CH₂Cl₂. The mixture was stirred 4 h at which time 250 μ L of spectral grade methanol and 30 μ L of thionyl chloride/CH₂Cl₂ solution were added. The mixture was stirred for 18 h before addition of third portion of 30 μ L of thionyl chloride/CH₂Cl₂ solution. The reaction was stirred for 2 h before the solvent was removed with a stream of argon. The flask was placed under high vacuum for 15 min.

To [¹⁴C]-L-alanine methyl ester tosylate and 0.020 g of (1-N-biotinyl-(13-N-succinimidyl-(S-(E,E-farnesyl)-L-cysteiny)-L-valinyl-L-isoleucinyl)-4,7,10-trioxatridecanediamine) Kaiser's resin **6** were added a stock solution of glacial acetic acid (5.8 μ mol) in CH₂Cl₂ (200 μ L) and triethylamine (5.8 μ mol) in CH₂Cl₂ (200 μ L). The slurry was vigorously stirred for 96 h. The suspension was filtered through a Pasteur pipet/cotton plug. The resin was washed with four 1.0 mL portions of CHCl₃, three 1.0 mL portions of 2-propanol, and five 1.0 mL portions of 1:5 MeOH:CHCl₃. Solvent was removed from the filtrate with a gentle stream of argon.

The residue was dissolved in a minimal amount of 1:5 MeOH:CHCl₃ and applied to an analytical Merck glass-backed silica gel 60 thin-layer chromatography plate. The plate was eluted with 1:5 MeOH:CHCl₃ containing 5% v/v acetic acid. A faint UV-positive band of R_f value 0.68–0.80 was carefully removed by scraping, and the silica was placed in a Pasteur pipet plugged with cotton. The silica was eluted with twelve 1.0 mL portions of 1:5 MeOH:CHCl₃ containing 0.5% v/v acetic acid. Solvent was removed with a gentle stream of argon followed by high vacuum to remove final traces of acetic acid.

To the residue were added 200 μ L of THF and 200 μ L of 50 mM aqueous KOH. The progress of the reaction was monitored by silica TLC (1:5 MeOH:CHCl₃ containing 5% v/v acetic acid). Two hundred microliter portions of 50 mM aqueous KOH were added every 15 min until TLC analysis indicated the starting methyl ester had been saponified. Acetic acid (50 μ L, 1 M) was added. Solvent was removed with a gentle stream of argon, followed by high vacuum to removed traces of acetic acid and water. DMF (500 μ L) was added, and the solution was divided into portions, which were stored at $-80^\circ C$. The overall radiochemical yield was 45% from [¹⁴C]-L-alanine.

Growth of JDY101/pJel- α Rcemyc (15). Following the procedure of Worland and Wang (22), single colonies from freshly streaked plates were used to inoculate 10 mL cultures of synthetic minimal media lacking uracil and supplemented with 2% (w/v) glucose to repress PGAL1. Cultures were grown to late log phase, and a 3 mL portion was used to inoculate 300 mL of synthetic minimal media lacking uracil and supplemented with 3% (w/v) glycerol and 2% (w/v) lactic acid. The cultures were grown at $30^\circ C$ for 20–24 h (OD₆₀₀ = 0.5–0.7). Galactose was added to a final concentration of 2%, and the cells

were grown for an additional 6 h. Cells were pelleted by centrifugation at 5000*g* for 15 min, washed with cold sterile water, and stored at -80 °C.

Preparation of Membrane Fractions. Alkaline carbonate-leached membranes (AC-P139) were prepared according to the procedure of Ashby and Rine (9), with slight modifications. Briefly, 4 mL of frozen cell paste was thawed on ice and resuspended in 8 mL of SST buffer (0.3 M sorbitol, 0.1 M NaCl, 10 mM Tris-HCl, pH 7.4, 5 mM EDTA, pH 8, 1 mM PMSF, 0.5 mM 1,10-phenanthroline). Acid washed glass beads (212–300 μm) were added (8 mL), and the suspension chilled on ice for 5 min prior to vortexing at maximum setting for 1 min and then chilled on ice for 1 min. The vortex-chilling cycle was repeated 10 times. The cellular lysate was clarified by centrifugation at 3500*g* for 15 min at 4 °C. The centrifugation was repeated for the supernatant. The final 3500*g* supernatant was transferred to ultracentrifuge tubes, mixed with 1/10 volume of 2 M Na_2CO_3 , pH 11.5, and spun at 139000*g* (40 000 rpm, TY65 rotor) for 1 h at 2 °C. The P139 pellet was gently washed twice with cold SST buffer (8 mL), resuspended in 8 mL of cold SST buffer with a Dounce homogenizer. The sample was spun again at 139000*g* for 1 h at 2 °C. The pellet was washed as before and was resuspended in 2 mL of cold SST buffer. The AC-P139 membrane preparation was divided into portions, quickly frozen in dry-ice/acetone, and stored at –80 °C.

Protease Assays. *Biotin/Avidin-Binding Assay.* Assays (50 μ L) contained AC-P139 membranes (1–5 μ g) and 1-*N*-biotinyl-(13-*N*-succinimidyl-(*S*-(*E*,*E*-farnesyl)-L-cysteinyl)-L-valinyl-L-isoleucinyl-L-alanine)-4,7,10-trioxatridecanediamine ([^{14} C]1) in 100 mM Tris, pH 7.4, 0.5 mM 1,10-phenanthroline, and 1 mM PMSF. Reactions were initiated by the addition of [^{14} C]1 in 2.5 μ L of DMF. After incubation for 15–30 min at 37 $^{\circ}$ C, the enzyme was inactivated by heating at 80 $^{\circ}$ C for 5 min. The incubation mixtures were briefly cooled on ice, avidin resin (150 μ L, Pierce) was added, and the material was allowed to stand at room temperature for 15 min with frequent mixing. Assay buffer (150 μ L) was added, the tubes were centrifuged for 1 min, and radioactivity in 200 μ L of supernatant was measured.

Radioactive HPLC Assay to Confirm Endo-Protease Activity. Assays (50 μ L) contained AC-P139 membranes (1–100 μ g) and [^{14} C]**1** in 100 mM Tris, pH 7.4, 0.5 mM 1,10-phenanthroline, and 1 mM PMSF. Reactions were initiated by the addition of [^{14} C]**1**. Incubation proceeded for 15–30 min at 37 $^{\circ}$ C followed by termination in boiling water for 5 min. Assay tubes were briefly centrifuged, and the supernatants were transferred to fresh tubes. Avidin resin (150 μ L) was added and the tubes were allowed to stand at room temperature for 15 min with frequent mixing. Assay buffer (150 μ L) containing a mixture of cold A, I-A, and V-I-A was added, and the tubes were centrifuged for 1 min. A 200 μ L portion of the peptide/reaction mixture was transferred to fresh tubes and an additional 150 μ L of the mixture containing cold peptide was added. These samples were frozen at -80° C until HPLC analysis. Samples were analyzed on a 4.6 $\times$ 250 mm Vydac reversed phase C₁₈ column with isocratic elution using 3.5% acetonitrile/0.06% TFA. After the first min, 1 min fractions were collected, added to 10 mL of scintillation cocktail, and counted.

RESULTS AND DISCUSSION

Synthesis of Nonradioactive and Radiolabeled Biotinylated Farnesylated Tetrapeptide 1. Biotin-

Scheme 2. Synthesis of S-Farnesylated Kaiser's Resin^a

^a Reagents: (a) TFA in CH₂Cl₂, 1.5 h; (b) *N*-trityl-(*S*-farnesyl)-L-cysteine, THF, DCC, HOBT, 0 °C; (c) Et₃N, CH₂Cl₂; (d) wash protocol, dried in vacuo; (e) 2.5 equiv of TFA, 10 equiv of EtSMe, CH₂Cl₂.

ylated **1** was synthesized using solid-phase methods based on Kaiser's oxime resin (*18*) as outlined in Schemes 2, 3, and 4. This approach allowed us to take advantage of solid-phase chemistry to assemble the entire biotinylated, farnesylated, radiolabeled tetrapeptide and to introduce the radioactive unit near the end of the synthetic sequence. The reactions needed to assemble and cleave the peptide from the resin are compatible with the sensitive isoprenoid group attached to the cysteine residue.

Kaiser's benzophenone oxime resin was synthesized on a 100 g scale using the method of DeGrado and Kaiser (18). *N*-BOC-L-valinyl-L-isoleucinyl resin **2** was produced by a standard sequence using HOBt/DCC activation and TFA mediated *N*-BOC deprotection steps. As outlined in Scheme 2, *N*-BOC-L-valinyl-L-isoleucinyl resin **2** was deprotected using TFA and then allowed to react with the HOBt-derived active ester of *N*-triphenylmethyl-S-(*E,E*-farnesyl)-L-cysteine. A standard wash protocol of four 100 mL portions of CH₂Cl₂, four 100 mL portions of DMF, four 100 mL portions of 2-propanol, and finally four 100 mL portions of CH₂Cl₂ was used after all peptide or linker coupling steps. After drying in vacuo, the *N*-trityl resin was suspended in CH₂Cl₂ containing ethylmethyl sulfide as a cation scavenger and deprotected with TFA. The TFA salt of the resin **3** was used immediately in the next step.

Attempts using solution phase chemistry to attach biotin to farnesylated cysteine by an L-alanine linker were unsatisfactory. Although coupling between biotin-L-alanine and S-(*E,E*-farnesyl)-L-cysteine esters appeared to proceed as judged by TLC, the product formed an intractable gel in all solvents we studied, including DMSO-*d*₆, typically used for NMR spectra. Lui et al. (17) had reported a similar synthesis; however, in their case the cysteine was not farnesylated, and the isoprenoid moiety was added in an additional step near the end of the synthesis. To avoid problems with solubility, a PEG linker (20) was used to tether biotin to the tetrapeptide (Scheme 3). The biotinylated-PEG linker (**4**) was synthesized as described by Wilbur et al. (20). The free amine of **4** was converted to the succinate half-amide, and the free carboxylate group was activated using 2,3,5,6-tetrafluorophenyltrifluoroacetate (21). This activating agent was particularly useful, since the biotinylated

Scheme 3. Synthesis of Biotinylated Linker^a

^a Reagents: (a) succinic anhydride, DMF, Et₃N; (b) 2,3,5,6-tetrafluorophenyltrifluoroacetate, DMF, Et₃N.

active ester could easily be purified by precipitation using diethyl ether to remove excess activating agent and triethylamine salts. Active ester **5** was isolated by ether precipitation, dried in vacuo, and used immediately in the next step.

The final reactions for syntheses of both the nonradioactive and radiolabeled forms of the biotinylated sub-

strate **1** are shown in Scheme 4. The TFA salt of the farnesylated tripeptide resin **3** and the biotinylated tetrafluorophenyl active ester **5** were successfully coupled to give the biotinylated farnesylated Kaiser's oxime ester resin **6**. Resin **6** was used to synthesize both the non-radioactive substrate **1** and radioactive [¹⁴C]**1**. The final peptides were cleaved from the resin as also outlined in Scheme 4. The coupling procedures for radioactive and nonradioactive peptides differed slightly with respect to the type of alanine ester used. Initially, L-alanine benzyl ester was used for the nonradioactive synthesis, to take advantage of the UV-active benzyl group during purification. Accordingly, biotinylated farnesylated Kaiser's oxime ester resin **6** was treated with L-alanine benzyl ester tosylate **7** (R = Bz) to give **8** (R = Bz) in 26% yield overall from Kaiser's oxime resin. Saponification of **8** (R = Bz) with aqueous KOH in THF gave nonradioactive **1** in 72% yield.

Methyl ester [¹⁴C]**7** (R = CH₃) was used to synthesize [¹⁴C]**1**. Initial attempts to esterify L-alanine as a benzyl ester on a scale compatible with the synthesis of radioisotopes gave unsatisfactory yields. Accordingly, [¹⁴C]-L-alanine was esterified using *p*-toluenesulfonic acid and thionyl chloride in methanol to afford the tosylate salt of [¹⁴C]**7** (R = CH₃). [¹⁴C]**7** (R = CH₃) was coupled to

Scheme 4. Synthesis, Radiosubstrate Cleavage, and Saponification^a

^a Reagents: (a) 1:1 DMF:CH₂Cl₂, Et₃N; (b) 1.05 equiv of *p*-TsOH, (c) (1) BzOH, PhH, reflux; (2) MeOH, SOCl₂; (d) HOAc, Et₃N, CH₂Cl₂; (e) KOH, THF.

Figure 1. $\text{Ca}_{1.2}\text{X}$ endoprotease activity increases with increasing amounts of alkaline carbonate leached membranes. $[\text{C}^{14}]\text{1}$ ($25\text{ }\mu\text{M}$) was incubated with yRce1p membranes ($0.1\text{--}1.0\text{ }\mu\text{g}$ of protein) at $37\text{ }^{\circ}\text{C}$ for 15 min. The reaction was stopped and the mixture was treated with avidin resin as described in the Experimental Section.

biotinylated farnesylated **6** using conditions similar to those for unlabeled material, followed by aqueous work-up, to afford $[\text{C}^{14}]\text{8}$ ($\text{R} = \text{CH}_3$). The tetrapeptide was purified easily by analytical TLC to remove any unreacted radioactive methyl ester in order to minimize any radioactive contaminants that would contribute to a higher background in the enzymatic assay. The methyl ester was saponified to afford $[\text{C}^{14}]\text{1}$ in an overall radiochemical yield of 45% for the coupling and hydrolysis steps. This material comigrated with unlabeled **1** on reverse-phase HPLC.

Endoprotease Assays. yRce1 activity was measured by release of the radioactive C-terminal tripeptide from $[\text{C}^{14}]\text{1}$ using biotin/avidin binding to separate the radioactive product and substrate. The assay involved incubation of $[\text{C}^{14}]\text{1}$ with yRce1p membranes (15) followed by heat inactivation. Unreacted substrate was separated from the VIA fragment by incubation of the reaction mixture with avidin resin at room temperature. The resin was pelleted by centrifugation, and the radioactivity of $\text{VI}[\text{C}^{14}]\text{A}$ in the supernatant was measured by liquid scintillation counting. A proportional increase in protease activity was observed upon incubation of a saturating concentration of $[\text{C}^{14}]\text{1}$ with increasing amounts of membranes (Figure 1). At saturating substrate concentrations ($>25\text{ }\mu\text{M}$), it was necessary to use $150\text{ }\mu\text{L}$ of avidin resin in order to achieve 10:1 signal-to-noise. Incubation of the assay mixture with avidin resin for 15 min with frequent mixing was sufficient to remove radioactive substrate.

Steady-state kinetic constants were determined for membrane-bound yRce1p. A plot of initial velocity versus $[\text{C}^{14}]\text{1}$ is shown in Figure 2. The experimental data were fit to the Michaelis–Menten equation to give $K_M = 1.3 \pm 0.3\text{ }\mu\text{M}$ and $V_{\text{Max}} = 46.1 \pm 2.7\text{ nmol min}^{-1}\text{ mg}^{-1}$. Addition of biotin and the PEG linker to the farnesylated tetrapeptide apparently had a minimal impact on the ability of yRce1p to hydrolyze the substrate. A K_M of $2.8\text{ }\mu\text{M}$ was obtained with membranes from native yeast using the peptide substrate KWDP(farnesyl)CV-[4,5- ^3H]**1A** (9). In addition, a non-hydrolyzable inhibitor of mammalian $\text{Ca}_{1.2}\text{X}$ endoproteases reported by Ma et al. (23), inhibited membrane-bound recombinant yRce1p with an $\text{IC}_{50} = 103 \pm 9\text{ nM}$ (data not shown).

Although alanine and the IA dipeptide are potential radioactive products from $[\text{C}^{14}]\text{1}$ by nonspecific proteolysis by Rce1p or contaminating proteases in the crude membrane preparation, analysis of the reaction mixture by

Figure 2. A plot of the initial velocity for proteolysis versus $[\text{C}^{14}]\text{1}$ concentration. yRce1p membranes ($0.29\text{ }\mu\text{g}$) were incubated with $[\text{C}^{14}]\text{1}$ for 15–30 min at $37\text{ }^{\circ}\text{C}$. $\text{VI}[\text{C}^{14}]\text{A}$ was separated from unreacted substrate with avidin resin and counted as described in the Experimental Section.

Figure 3. Reversed-phase HPLC analysis of the products from farnesylated peptide, $[\text{C}^{14}]\text{1}$ upon incubation with yRce1p. Yeast membranes ($5\text{--}20\text{ }\mu\text{g}$ of protein) were incubated with $50\text{ }\mu\text{M}$ $[\text{C}^{14}]\text{1}$ for 45 min at $37\text{ }^{\circ}\text{C}$. The reactions were stopped by boiling for 5 min and were treated with avidin resin as described in the Experimental Section. Cold A, IA, and VIA were added to the nonbiotinylated products. The mixture was analyzed by HPLC on a C_{18} reversed-phase column as described in the Experimental section. Fractions were collected in 1 min intervals. Detection of the cold standards was monitored at 214 nm .

reversed phase HPLC confirmed that $\text{VI}[\text{C}^{14}]\text{A}$ was the only radioactive product. After incubating $[\text{C}^{14}]\text{1}$ with Rce1p under standard assay conditions, the avidin-treated supernatant was mixed with cold A, IA, and VIA, and the mixture was analyzed by HPLC to give the results shown in Figure 3. The large peak of radioactivity coeluted with VIA, and no significant radioactivity above background was detected with the fractions correspond-

ing to alanine (Figure 3A). In contrast, prolonged incubation with membranes prepared from a yeast strain deficient in Rce1p activity (15) showed no radioactivity coeluting with VIA and only a small amount of radioactivity coeluting with alanine. A similar profile was seen when no membranes were added. The peak coeluting with VIA decreased when the RPI inhibitor was added to the assay (Figure 3B). In contrast, membranes isolated from rat liver produced tripeptide VI-[³H]S, dipeptide I-[³H]S, and, in some cases, [³H]S (17). The smaller radioactive fragments, released from substrate and the tripeptide product by contaminating protease activities, limited the utility of the assay to precisely measure the activity of the Ras and a-mating factor proteases. Our recombinant membrane preparations were essentially free of activities that compete with yRce1p for the substrate. [¹⁴C]1 and recombinant yRce1p were recently used to assess the sensitivity of the enzyme to metal ion chelators, heavy metals, and a variety of protease inhibitors (15) and to screen a library of *N*-acetyl-S-(*E,E*-farnesyl) Ca₁a₂X tetrapeptides (24).

Spacers separate biotin from bulky groups elsewhere in the molecule that can interfere with its binding avidin and streptavidin (25) and help maintain strong biotin/avidin binding (20). We used a commercially available water soluble spacer, 4,7,10-trioxa-1,13-tridecanediamine and a succinic diamide unit to link biotin to the farnesylated Ca₁a₂X peptide. The PEG spacer improved the solubility of the biotinylated prenyl Ca₁a₂X peptide in common organic solvents and greatly facilitated its synthesis and ease of handling. The tetrafluorophenyl active ester used to couple the biotinylated-PEG linker to the resin bound tripeptide proved to be ideal. The ester was easy to prepare, easy to purify by ether precipitation, and coupled smoothly to resin-bound peptide in good yield.

A completely solid-phase method based on Kaiser's resin provides several advantages over previously reported syntheses of compounds of this kind. Acid-sensitive groups such as the farnesyl and geranylgeranyl moieties found in prenylated proteins can be introduced regiospecifically as modified amino acids (i.e., *S*-farnesyl cysteine) during the peptide elongation process. The mild conditions used to cleave the peptide from the resin are ideal for preserving acid-sensitive side chains. Since the nucleophile employed to cleave the peptide becomes the *N*-terminal amino acid in the released peptide, radiolabel can be introduced into the final product at a late stage in the synthesis in a manner that minimizes the handling of radioactive materials. The high specific activity of [¹⁴C]1, and corresponding high sensitivity of the assay, has proved to be useful for screening and characterization of inhibitors for Ca₁a₂X proteases.

ACKNOWLEDGMENT

We would like to thank Dr. Lance Steward for helpful discussions and Dr. Elliott Rachlin of the University of Utah, Department of Chemistry, Mass Spectral Facility, for mass spectral determinations. This work was supported by Acacia Biosciences and a University of Utah SEED Grant.

Received April 19, 2000; Revised Manuscript Received October 15, 2000

We present the synthesis and characterization of the somatostatin receptor-specific peptide $\text{H}_2\text{N}(\text{D-Phe})\text{-cyclo}[\text{Cys-Phe}(\text{D-Trp})\text{-Lys-Thr-Cys}]\text{-Thr-OH}$, which is labeled with a carboxylated indodicarbo- and an indotricarbocyanine dye at the N-terminal amino group. The preparation was performed by automated solid-phase synthesis, with subsequent attachment of the cyanine dye and cleavage of the entire conjugate from the resin. The compounds display high molar absorbance and fluorescence quantum yields typical for cyanine dyes and are thus suitable receptor-targeted contrast agents for molecular optical imaging. The ability of these agents to target the somatostatin receptor was demonstrated by flow cytometry in vitro, in which the indotricarbocyanine conjugate led to elevated cell-associated fluorescence on somatostatin receptor-expressing tumor cells. In contrast, the corresponding linearized derivative of the sequence $\text{H}_2\text{N}(\text{D-Phe})\text{-Met-Phe}(\text{D-Trp})\text{-Lys-Thr-Met-Thr-OH}$ produced only minimal cell fluorescence, hence confirming the specificity of the cyclic somatostatin analogue. Intracellular localization could be visualized by near-infrared (NIR) fluorescence microscopy. In conclusion, receptor-specific peptides are promising tools for designing site-directed optical contrast agents for use in molecular optical imaging.

INTRODUCTION

Neuropeptides and their pharmacologically optimized analogues have a unique clinical potential as carrier molecules for diagnostic and therapeutic substances. Based on the observation that many human tumors overexpress receptors for neuropeptides (1, 2), new diagnostic methods have been developed that detect and localize tumors using radiolabeled neuropeptides (3, 4). The clinical diagnostic value of receptor scintigraphy has been demonstrated by the use of [^{111}In]DTPA-octreotide (Pentetreotide, OctreoScan), a radiodiagnostic agent with high binding affinity for somatostatin receptors (5).

To date, five different somatostatin receptor subtypes have been cloned and functionally characterized (6). These receptor subtypes mediate the many physiological effects of somatostatin, for example the regulation of hormone release (7, 8). They are present in both normal (6) and tumor tissues of the central nervous system and peripheral areas including the gastroenteropancreatic system (9, 10). In vitro studies have shown that the majority of these tumors, particularly neuroendocrine tumors, preferentially express the somatostatin receptor subtype 2 (9, 11). This represents the molecular basis for therapeutic and diagnostic applications of somatostatin analogues, such as octreotide.

Octreotide, a synthetic octapeptide with improved metabolic stability and high binding affinity for the somatostatin receptor subtypes 2 and 5, was first used for the symptomatic treatment of patients with neuroendocrine tumors (12). The high density of somatostatin receptor subtype 2 in neuroendocrine tumors has led to the development of octreotide scintigraphy (5). In vivo visualization of somatostatin receptor positive tumors using [^{111}In]DTPA-octreotide, is based on the binding, internalization, and retention of the radioligand in intracellular compartments such as endosomes or lysosomes (13, 14).

The emerging field of biomedical optical imaging (15) has awakened a great deal of interest in developing optical contrast agents capable of engendering disease-specific optical signals within the tissue (16). The detection of site-specific fluorescence provides a notable alternative to radioactive imaging methods, as tissue is relatively transparent for near-infrared light (700–900 nm) (15). Cyanine dyes have proven to be promising contrast agents for the in vivo fluorescence demarcation of tumors (17, 18) and have been successfully applied as fluorescent labels for target-specific carriers (19, 20).

We report on the synthesis and the photophysical and biological properties of novel fluorescently labeled somatostatin receptor-specific peptides of the sequence $\text{H}_2\text{N}(\text{D-Phe})\text{-cyclo}[\text{Cys-Phe}(\text{D-Trp})\text{-Lys-Thr-Cys}]\text{-Thr-OH}$, which are labeled with a carboxylated indodicarbo- or indotricarbocyanine dye at the N-terminal amino group. The compounds represent fluorescent analogues of pentetreotide ([^{111}In]DTPA-cyclo[Cys-Phe(D-Trp)-Lys-Thr-Cys]-Thr(ol)). Using the cyanine-labeled peptides, we intend to show that the advantages of low molecular weight

peptides are of practical use for other diagnostic techniques and permit the development of site-directed fluorescent *in vivo* contrast agents.

For this purpose, we have synthesized and characterized two monocarboxylated cyanine dyes of different absorption wavelengths employing a carboxylic acid group that permits covalent attachment to peptides during solid-phase preparation. We describe results from the solid-phase synthetic preparation of the two cyanine-labeled octreotide-analogue peptide conjugates **1** and **2** (Figure 1). Results from studies on cellular uptake *in vitro* demonstrate that low molecular weight peptides, structurally based on somatostatin, enable receptor-mediated intracellular delivery of optical probes.

EXPERIMENTAL PROCEDURES

Synthesis of Cyanine Dyes. *Chemicals and Analysis.* 1-(4-Sulfobutyl)-2,3,3-trimethyl-3H-indolenin (**5**) and 5-carboxy-1-(4-sulfobutyl)-2,3,3-trimethyl-3H-indolenin (**6**) were synthesized as described in the literature (21, 22). Glutaconic aldehyde dianilide hydrochloride was purchased from Lancaster Synthesis (Mühlheim, Germany). All other reagents and solvents were purchased from Sigma-Aldrich Co. Reactions were monitored by reversed phase TLC (RP-18 plates) with water/methanol (1:2). Purification of the synthesized dyes was performed by reversed phase chromatography on an MPLC (Kronwald, Sinsheim, Germany) with RP-18 material (Euoprep 60–30 C-18, 60 Å, 30 μ m, Knauer) using water/methanol as eluant. The synthesized dyes were characterized by ^1H NMR and mass spectroscopy. The ^1H NMR spectra were recorded in CD_3OD with a Bruker AC400 (400 MHz). The mass spectra were obtained with a ZAB-E spectrometer (Fisons Scientific Equipment, Loughborough, UK). Measured mass/charge ratios (m/z) and proton shifts (δ) are listed for each compound.

Bis-1,1'-(4-sulfobutyl)indodicarbocyanine-5-carboxylic Acid, Sodium Salt (7). A mixture of **5** (1 g, 3.4 mmol) and malonaldehyde-bis(phenylimine) monohydrochloride (0.78 g, 3.0 mmol) in 12 mL of acetic anhydride was stirred for 30 min at 120 $^\circ\text{C}$. After cooling to room temperature, **6** (1.2 g, 3.6 mmol), sodium acetate (1.0 g, 12 mmol), 12 mL of acetic anhydride, and 5 mL of acetic acid were added. The resultant mixture was heated to 120 $^\circ\text{C}$ under vigorous stirring, cooled to room temperature, and poured into 150 mL of diethyl ether. The precipitate was collected by filtration and then purified by reversed phase chromatography (Euoprep 60–30 C-18, 60 Å, 30 μ m, Knauer; eluents water/methanol 9:1 to 1:1) yielding 1.3 g (72%) **7** as a blue lyophilisate.

^1H NMR: δ 1.75 (s, 12H, $4 \times \text{CH}_3$), 2.0 (m, 8H, $2 \times \text{CH}_2\text{CH}_2\text{CH}_2\text{SO}_3^-$), 2.9 (t, 4H, $2 \times \text{CH}_2\text{SO}_3^-$), 4.1, 4.2 (2t,

4H, $2 \times >\text{NCH}_2$), 6.3, 6.45 (2d, 2H, $\alpha\text{-H}$, $\alpha'\text{-H}$), 6.7 (t, 1H, $\gamma\text{-H}$), 7.3 (dd, 2H, $5'\text{-H}$, $6'\text{-H}$), 7.4 (m, 2H, $4'\text{-H}$, $7'\text{-H}$), 7.5 (d, 1H, 7-H), 8.05 (s, 1H, 4-H), 8.1 (d, 1H, 6-H), 8.2, 8.3 (2dd, 2H, $\beta\text{-H}$, $\beta'\text{-H}$). FAB-MS: 715 [35, (M + Na) $^+$], 693 [70, (M + H) $^+$], 671 [35, (M + 2H-Na) $^+$], 91 (100).

Bis-1,1'-(4-sulfobutyl)indotricarbocyanine-5-carboxylic acid, sodium salt (8). The synthesis and product isolation were performed as described for **7** using glutaconic aldehyde dianilide hydrochloride (0.86 g, 3.0 mmol) with **5** (1 g, 3.4 mmol), **6** (1.2 g, 3.6 mmol), and sodium acetate (1.0 g, 12 mmol), yielding 1.5 g (80%) **8** as a blue lyophilisate. ^1H NMR: δ 1.6, 1.65 (2s, 12H, $4 \times \text{CH}_3$), 1.7–1.9 (m, 8H, $2 \times \text{CH}_2\text{CH}_2\text{CH}_2\text{SO}_3^-$), 2.55 (t, 4H, $2 \times \text{CH}_2\text{SO}_3^-$), 3.95, 4.2 (2 t, 4H, $2 \times >\text{NCH}_2$), 6.25 (d, 1H, $\alpha'\text{-H}$), 6.55 (dd, 1H, $\gamma'\text{-H}$), 6.65 (dd, 1H, $\gamma\text{-H}$), 6.7 (d, 1H, $\alpha\text{-H}$), 7.25 (d, 1H, 7-H), 7.35, 7.45 (2t, 2H, $5'\text{-H}$, $6'\text{-H}$), 7.6, 7.65 (2d, 2H, $4'\text{-H}$, $7'\text{-H}$), 7.75 (m, 2H, $\delta\text{-H}$, $\beta'\text{-H}$), 7.9 (d, 1H, 6-H), 7.95 (s, 1H, 4-H), 8.0 (dd, 1H, $\beta\text{-H}$). FAB-MS: 719 [12, (M + H) $^+$], 697 [25, (M + 2H-Na) $^+$], 135 (100).

Synthesis of Dye–Peptide Conjugates. *Chemicals, Equipment, and Analysis.* Fmoc-protected amino acids were purchased from Orpegen (Heidelberg, Germany) and Nova Biochem GmbH (Bad Soden, Germany) and used with the following side-chain protecting groups: *tert*-butoxycarbonyl (Boc) for Lys and Trp, *tert*-butyl ether for Thr, and Trityl (trt) for Cys. Dimethylformamide (DMF) and acetonitrile were purchased from Proligo GmbH (Hamburg, Germany), and piperidine and diisopropyl ethylamine from Sigma-Aldrich Co. Peptide resins were obtained from Rapp Polymere GmbH (Tübingen, Germany). Assembly of the protected peptide chain was carried out using the stepwise solid-phase method on an automated peptide synthesizer (433A, Perkin-Elmer GmbH, Überlingen, Germany). The mass spectra (MALDI-TOF) were recorded on an Compact Maldi II spectrometer (Shimadzu, Japan). Analytical HPLC analysis was performed using a Nucleosil 300 C18 column (5 μ m particle size; 125 $\times$ 4.6 mm); gradient: 10% B to 100% B for 45 min [(A) 1000 mL of water, 2 mL of TFA; (B) 500 mL of acetonitrile, 100 mL of water, 1 mL of TFA].

Synthesis of Dye–Peptide Conjugates 1 and 2. The peptide sequence (D-Phe)-Cys-(D-Trp)-Lys-Thr-Cys-Thr-OH was built up by Fmoc chemistry using 2-(1H-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) as the activating agent and 20% piperidine in DMF for deprotection of the Fmoc groups.

In the last step of the synthesis, **7** or **8** were coupled for 18 h on resin in DMF using HBTU, diisopropyl ethylamine (preactivation with 1.1 equiv of HBTU for 15 min). After completion, the resin was washed with DMF and methylene chloride, dried, and then treated with 10 mL of a mixture containing 90% trifluoroacetic acid (TFA), 5% water, and 5% triisopropylsilane. TFA was removed under vacuum and the crude peptide precipitated with diethyl ether. Cys–Cys cyclization was achieved by dissolving the crude peptide in dimethyl sulfoxide (DMSO)/water (15:85), adjusting the pH to 7.5, and stirring the mixture for 18 h. After completion (HPLC control) the peptide solution was lyophilized twice to remove the DMSO. The crude, cyclized peptide was purified by reversed-phase HPLC on a VYDAC C18 column (40 $\times$ 300 mm, 1520 μ m, 300 Å) at a flow rate of 100 mL/min using an acetonitrile gradient of 30% B to 80% B for 50 min [(A) 1000 mL of water, 2 mL of TFA; (B) 500 mL of acetonitrile, 100 mL of water, 1 mL of TFA]. The fractions were analyzed by HPLC. The purified fraction containing the desired product was collected,

freeze-dried, and analyzed by mass spectrometry (MALDI-TOF). (1) Calcd 1705, found 1699; (2) calcd 1731, found 1726.

Synthesis of Control Dye–Peptide Conjugates 3 and 4. The synthesis of the control peptide sequence (D-Phe)-Met-Phe-(D-Trp)-Lys-Thr-Met-Thr-COOH and the conjugation of dyes 7 and 8 were performed analogously. The crude product was directly subjected to chromatographic purification as described above. MALDI-TOF. (3) Calcd 1734, found 1730; (4) calcd 1760, found 1756.

Photophysical Characterization. Absorption measurements were performed with a Lambda 2 photometer (Perkin-Elmer GmbH, Überlingen, Germany). Fluorescence properties were measured in phosphate-buffered saline (PBS) and bovine plasma with a SPEX Fluorolog fluorometer (Instruments S. A. GmbH, Grassbrunn, Germany) (single excitation and emission monochromator, 350 W xenon lamp, PM Hamamatsu R928) with 2 μ M dye solutions in front-face mode. The solutions of the indodicarbocyanine peptides 1 and 3 were excited at 590 nm, those of the indotricarbocyanine peptide conjugates 2 and 4 at 690 nm. To determine fluorescence quantum yields (QY's), the lamp and photomultiplier were calibrated with respect to their spectral sensitivity. The quantum yields obtained are based on the standards indocyanine green (ICG) in DMSO ($\Phi = 0.13$) and NK1967 in DMSO ($\Phi = 0.28$) (23).

Cell Culture Experiments. The cellular uptake of 2 and 4 was examined by fluorescence microscopy and flow cytometry using somatostatin receptor subtype 2 transfected RIN38 tumor cells (RIN38 SSTR2 cells) (24). RIN38 cells were cultured following standard procedures (RPMI 1640 medium; Life Technologies GmbH, Eggenstein, Germany) and using 5% fetal bovine serum and 5% newborn calf serum supplemented with Geneticin (200 μ g/L).

In preparation for flow cytometry, 1×10^5 RIN38 SSTR2 cells were cultured on 24-well microtiter plates for 3 days. Cells were incubated in 300 μ L of buffer containing 50 mM Tris/HCl, pH 7.5, 5 mM MgCl_2 , 1 mM CaCl_2 , 100 mM NaCl, 4% BSA (incubation buffer) in the presence of 100 nM cyanine dye-labeled peptides for 1 h at 37 $^\circ\text{C}$. After incubation, the medium was removed and the cells were washed twice with PBS. The cells were then incubated with 200 μ L of a 0.25% trypsin solution in PBS for 2 min at room temperature. The cell suspension was transferred to a 5 mL polystyrene tube (Becton Dickinson, Heidelberg, Germany) and centrifuged for 5 min at 4 $^\circ\text{C}$ and 400g. The supernatant was removed and the cells were resuspended in 300 μ L of CellFIX (Becton Dickinson, Heidelberg, Germany). FACS analysis was performed using a FACSCalibe flow cytometer (Becton Dickinson, Heidelberg, Germany) with a red laser diode (~ 635 nm) for excitation and FL3 optics for detection. Cell-associated fluorescence was recorded within a defined cell population until the event of 10 000 cells was reached.

For fluorescence microscopic studies RIN38 SSTR2 cells were cultured on cover slides (22 $\times$ 22 mm). After 24 h the cover slides were transferred to a six-well macro plate (Greiner GmbH, Frickenhausen, Germany) containing 0.5 mL of incubation buffer (see above). Peptide conjugate 2 or 4 was added at a final concentration of 1 μ M, and incubation was carried out for 1 h at 4 $^\circ\text{C}$. After incubation, the cells were washed twice in 2 mL of cold PBS, and 0.5 mL of prewarmed incubation buffer was added. The cells were incubated at 37 $^\circ\text{C}$ in the absence of peptides for a further 1 and 60 min. The cells were fixed by the addition of 2 mL of 0.1% CellFIX (Becton

Figure 2. Scheme showing the preparation of the monocarboxylated indodicarbo- (7) and indotricarbocyanine (8), and the structures of the resulting peptide conjugates 1–4.

Dickinson, Heidelberg, Germany) per well for 15 min at room temperature. Cover slides were mounted for microscopic analysis using Roti Histokit (Carl Roth GmbH, Karlsruhe, Germany). The fluorescence signal of the cells was recorded using an Axiovert 135 fluorescence microscope (Carl Zeiss Jena GmbH, Göttingen, Germany) equipped with a Cy 7 filter set (Exciter, HQ 710/75; Emitter, HQ 810/90; Beam splitter, Q750LP). An AttoArc HBO 100 W microscopic illuminator (Carl Zeiss Jena GmbH, Göttingen, Germany) was used as a light source for fluorescence excitation. Images were taken using a thermoelectrically cooled charge-coupled device (CCD) (Micromax, model RTE/CCD-576, Princeton Instruments Inc., Trenton, NJ) and analyzed using WinView Software version 1.6.2 (Princeton Instruments Inc., Trenton, NJ).

RESULTS AND DISCUSSION

Synthesis of Cyanine Dye–Peptide Conjugates.

To enable a directed and uniform labeling of peptides, we synthesized two cyanine dyes bearing a carboxylic acid group as activatable moiety for further linkage. In contrast to dyes described in the literature (25–27), the carboxylic acid group is positioned at one of the benzoic rings of the chromophore, thus resulting in nonsymmetrically substituted compounds with a benzoic acid-like element. The synthesis is easily performed starting from the indolenins 5 (21) and 6 (22), giving bis-1,1'-(4-sulfobutyl)indodicarbocyanine-5-carboxylic acid (7) and bis-1,1'-(4-sulfobutyl)indotricarbocyanine-5-carboxylic acid (8) in 72 and 80% yields, respectively, after chromatographic purification. This synthesis is illustrated in Figure 2. The performance of the reactions allowed the suppression of the formation of the corresponding symmetric byproducts, which were estimated (TLC; data not shown) to be less than 20% in the crude product.

Figure 3. Reversed-phase HPLC chromatograms of **1** (A) and **2** (B). Conditions are stated in the text.

^a Solvent PBS. ^b Fluorescence quantum yields based on ICG as standard (QY = 0.13 in DMSO). ^c Excited at 605 nm. ^d Excited at 685 nm.

The somatostatin receptor-specific peptide sequence (D-Phe)-Cys-Phe-(D-Trp)-Lys-Thr-Cys-Thr-OH was generated by automated solid-phase synthesis using Fmoc chemistry. For N-terminal dye attachment at the resin, **7** and **8** were readily activated using HBTU as activating agent followed by incubation with the dye reaction mixture for 18 h. TFA cleavage of protecting groups and liberation of the conjugate from the resin was possible without noticeable decomposition of the chromophore, so that conjugates **1** and **2** were assessable in good purity (above 95%) after HPLC. In Figure 3 typical chromatograms of these compounds are depicted.

The control peptides, for which we expected a significantly decreased receptor affinity, were obtained by synthesizing the corresponding noncyclic peptides of the sequence (D-Phe)-Met-Phe-(D-Trp)-Lys-Thr-Met-Thr-OH with the two cysteins replaced by methionin. Dye coupling in an analogous manner led to the conjugates **3** and **4**.

Absorption and Fluorescence Properties. We studied the absorption and fluorescence properties of the conjugates and determined the absorption and fluorescence maxima, as well as the molar extinction and fluorescence quantum yields in comparison to the free dyes **7** and **8**.

Carbocyanine dyes are known to have high molar extinction coefficients with ϵ -values between 100 000 and 250 000 L mol⁻¹ cm⁻¹ being less affected by the chemical environment. However, fluorescence is known to be considerably quenched for certain compounds when the dye is attached to biomolecules. A general observation for cyanine dyes is that quenching of fluorescence is

Figure 4. Normalized absorbance (—) and fluorescence emission (---) spectra of **1** (A) and **2** (B) in PBS (pH 7.4). Concentration, 2 μ M.

Figure 5. FACS analysis of RIN38 SSTR2 cells after incubation with free dye **8**, indotricarbocyanine dye-peptide conjugate **2**, and the corresponding linear conjugate **4**. The inserted picture represents a FACS plot of the cell population typically used. Fluorescence was recorded for 10 000 cells of the defined gate.

accompanied by deformation of the spectral absorbance profile, with the shorter-wavelength dimer shoulder being more pronounced compared with the monomer peak (28).

Nevertheless, the absorption and fluorescence emission characteristics of the synthesized dye-peptide conjugates are similar to those of the free dyes, as is apparent from the data in Table 1. The molar extinction coefficients of the conjugates exhibit decreased values of around 110 000–180 000 L mol⁻¹ cm⁻¹ compared with those of the free dyes. Within both the indodicarbocyanine (compounds **1**, **3**, and **7**) and indotricarbocyanine groups (compounds **2**, **4**, and **8**) the noncyclic conjugates (**3** and **4**) tended to have higher extinction coefficients than the cyclic conjugates **1** and **2**. In Figure 4 the absorption

Figure 6. Bright field (left row) and corresponding NIR fluorescence images (right row) of RIN38 SSTR2 cells after 1 and 60 min of incubation in the presence of 1 μ M **2** (set A) and 1 μ M **4** (set B) at 37 °C. The fluorescence image after 60 min at 37 °C for **4** (B) was scaled to a smaller signal range to visualize the poor cell-associated intensity.

spectra and fluorescence emission spectra measured in PBS as solvent are displayed for **1** and **2**. Both the absorbance and the fluorescence spectra are typical in shape compared to known indodi- or indotricarbocyanine-based chromophores (25–27). Only the indotricarbocyanine conjugate **2** showed a more pronounced dimer shoulder (690 nm), indicating that the compound exhibits a greater tendency to form aggregates.

Fluorescence quantum yields (QY) for the indodicarbocyanines **1**, **3**, and **7** were in the range of 30%, whereas the indotricarbocyanines **2**, **4**, and **8** displayed values of about 10% (Table 1).

No remarkable deviations in fluorescence quantum yields were observed in either group, suggesting that the degree of aggregate formation, as supported by the absorbance profile for conjugate **2**, does not influence the fluorescence properties of the dyes when conjugated to the peptide. It has to be underlined, that the extent of

aggregate formation cannot be extracted from the data described herein. Hence, further studies directly analyzing the aggregation behavior are needed.

Cell Culture Studies on Cellular Uptake. To study cellular uptake by means of an overall fluorescence signal derived from a defined population of tumor cells, we used the method of flow cytometry and compared the indotricarbocyanine peptide conjugate **2** with the control conjugate **4** as well as with the free label **8**. Tumor cells were incubated for 1 h at a probe concentration of 100 nM. The mean fluorescence signals obtained from the trypsinated and fixed cell population are displayed in Figure 5. The fluorescence intensity derived from **2** is about 5-fold above that from **4** and 40-fold above the signal generated by autofluorescence or by incubation with the free dye **8**. The data indicate that the underlying binding mechanism of **2** to the cells is a specific receptor–ligand interaction.

To consolidate receptor-mediated internalization into the cell, we performed NIR microscopic studies. Figure 6 shows fluorescence microscopic images of RIN38 SSTR2 tumor cells incubated with **2** (1 μ M) at two different time points as well as the corresponding bright field images. After 7 min, the fluorescence signal is distributed over the whole cell and most likely associated with the plasma membrane, whereas after 30 min of incubation the fluorescence was observed in the perinuclear region and disappeared almost completely from the membrane. The appearance of small fluorescent spots suggests that **2** is localized within intravesicular compartments. Consistent with the results from flow cytometry, only negligible perinuclear signals were detectable after 60 min of incubation at 37 °C using the control probe **4** (Figure 6B), again underlining receptor specificity of **2**.

The receptor affinities (IC_{50} values) of these optical probes remain to be investigated by an appropriate competition assay. Additionally, an important aspect of such compounds is their ability to fluorescently delineate tumors in vivo after systemic administration. This is currently being explored by fluorescence imaging in tumor-bearing animals.

CONCLUSION

We have demonstrated that an octreotide-derived peptide can be conjugated to near-infrared absorbing and fluorescing cyanine dyes, and that the resulting compounds maintain their photophysical properties. Through flow cytometry and fluorescence microscopy using tumor cells we showed that the conjugates specifically bind the somatostatin receptor and are internalized into intracellular compartments.

The developed peptide conjugates structurally related to [^{111}In]DTPA-octreotide exemplify the strength of low molecular weight peptide probes as vehicles for receptor-targeted optical imaging. This principle may be utilized for other clinically more relevant receptor–ligand systems, thus broadening the spectrum of applications for contrast-enhanced optical imaging.

Fluorescence-Labeled Octapeptides as Substrates for Histone Deacetylase

Katharina Hoffmann,[†] Richard M. Söll,[‡] Annette G. Beck-Sickinger,[‡] and Manfred Jung^{*,†}

Department of Pharmaceutical Chemistry, Westfälische Wilhelms-Universität Münster, Hittorfstrasse 58-62, 48149 Münster, Germany and Institute of Biochemistry, University of Leipzig, Talstrasse 33, D 04103 Leipzig, Germany. Received May 9, 2000; Revised Manuscript Received September 15, 2000

The determination of histone deacetylase (HDAC) activity and the screening of potential inhibitors is gaining increasing importance due to the involvement of HDAC in transcription regulation. The level of histone acetylation can be modulated by HDAC inhibitors resulting in differentiation and/or apoptosis in cancer cells. We have previously reported the development of a nonisotopic assay for HDAC using a fluorescent derivative of ϵ -acetyl lysine. Here we report fluorescein-labeled octapeptides which are substrates for HDAC that bear closer resemblance to the native substrate. HPLC with fluorescence detection is successfully applied to the analysis of the time- and site-dependent deacetylation. LC-MS analyses are used to confirm the findings. The observed selectivity toward one of two possible deacetylation sites might result from steric hindrance by the label but the methodology presented here could be applied to similar larger peptides which might be improved tools to characterize HDAC site selectivity in vitro.

1. INTRODUCTION

The reversible acetylation of lysine residues near the N-termini of nucleosomal histones by histone deacetylases (HDACs) and histone acetyltransferases (HATs) regulates chromatin structure and transcriptional activity. The importance of the level of histone-acetylation for basic cellular functions such as DNA-replication, transcription, differentiation, and apoptosis is highlighted by a increasing number of experimental studies (1, 2). Most important, HDACs and HATs usually are recruited by other proteins in suppressing or activating transcriptional activity with HDACs usually being co-suppressors and HATs acting as co-activators (3–7). In several cases, deregulated histone acetylation has been correlated with malignant disease, and interactions of HDAC with cancer-related proteins such as mutated retinoic acid receptors PML-RAR α and PLZF-RAR α in acute promyelocytic leukemia (APL) have been identified as the basis of the disease on a molecular level (8, 9). Therefore, HDAC inhibitors are an attractive target for drug discovery and valuable tools for studying the impact of chromatin acetylation on gene regulation. One way toward a better understanding of the function of various deacetylases is the analysis of their reactivity in terms of time- and substrate-dependent turnover. This may also lead to the design of new inhibitors.

The natural substrate, acetylated histones (10), or synthetic oligopeptides which consist of 8 (11) or 24 (12) amino acids, have traditionally been used in activity and inhibition assays. The latter are derived from sequences from the N-termini of histones. In either case, the substrate is labeled with [³H]acetic acid and the liberation of tritiated acid is quantitated by scintillation

counting or a scintillation proximity assay (13). Thus, there are problems with the exposure of operating personnel and the disposal of radioactive waste. The labeled histones are obtained by a procedure involving treatment of chickens with phenylhydrazine over several days and the sacrifice of the animals is unavoidable. The acetylation degree of the prelabeled histones is difficult to standardize resulting in varying substrate properties. There is also a cell-based screening assay that relies on antibody-mediated detection of H4-hyperacetylation (14). The analysis of HDAC-site-selectivity in substrates with multiple lysines has so far been restricted to histones and requires gel electrophoresis and the use of several specific antibodies (15). Our studies deal with the development of fluorescence-based in vitro assays for the characterization of HDAC reactivity and its inhibition. We have previously reported on the first nonradioactive HDAC in vitro screening assay that relies on the use of a fluorescent cumarin-labeled acetyl-lysine **1** (see Figure 1). It can be used to analyze HDAC-activity in protein purification and for the screening of new inhibitors (16, 17) and has become commercially available.

In this report, we describe the enzymatic conversion of an octapeptide **2a** upon incubation with rat liver HDAC. It contains two acetyl-lysine residues and is labeled with fluorescein carboxylic acid at the N-terminus (see Figure 1) and we apply HPLC and fluorescence detection to the question of deacetylation-site preference. One of the lysines is deacetylated readily by a rat liver HDAC whereas only little of the bis-deacetylation product **2d** can be found.

2. EXPERIMENTAL PROCEDURES

2.1. Chemicals. Trichostatin A was purchased from Wako. 5-Aminofluorescein was obtained from Sigma, *tert*-butyl alcohol, 4(5)-carboxyfluorescein, *N,N*-dimethylformamide (DMF), 1-hydroxybenzotriazole, thioanisole, and trifluoroacetic acid from Fluka (Buchs, Switzerland). Fmoc-amino acids were obtained from Alexis (Läufelfin-

gen, Switzerland) and 4-(2',4'-dimethoxyphenyl)-Fmoc-aminomethyl)phenoxy (Rink amide) resin from NovaBiochem (Läufelfingen, Switzerland). Diisopropylcarbodiimide and thiocresol were obtained from Aldrich (Buchs, Switzerland), and diethyl ether and acetonitrile from Romil (Cambridge, England). ^3H -Labeled histones were a gift from Prof. Dr. P. Loidl (University of Innsbruck).

2.2. Octapeptides. Peptides were built up by Fmoc-strategy on a Rink amide resin by using a robot system (Syro, MultiSynTech, Bochum) as described previously (18). Trt side-chain protection was used for His, Boc for Lys, and 2,2,5,7,8-pentamethyl-6-chromansulfonyl for Arg. Acetylated Lys was incorporated directly. The peptides were subsequently labeled at the N-terminus with 4(5)-carboxy-fluorescein prior to cleavage from the resin using a 10-fold excess of the acid, diisopropylcarbodiimide, and 1-hydroxybenzotriazol (all 0.25 mM in DMF) at 25 °C in DMF (30 min) (19). They were cleaved with trifluoroacetic acid/thioanisole/thiocresol (20:1:1; v/v) within 3 h, precipitated and washed with cold diethyl ether, collected by centrifugation and lyophilized from water/*tert*-butyl alcohol (3:1).

Cleavage products were investigated by reversed-phase HPLC (Merck-Hitachi, Darmstadt, Germany) on a Nucleosil RP-18 (5 μm) column (125 $\times$ 3 mm, Macherey and Nagel) at a flow rate of 0.6 mL/min. Absorbance was measured at 220 and 437 nm. The solvent system consisted of 0.1% trifluoroacetic acid in water (A) and 0.1% trifluoroacetic acid in acetonitrile (B). A linear gradient from 5 to 55% B in 30 min was applied. Furthermore, the peptides were analyzed by electrospray mass spectrometry (MS) (SSQ710, Finnigan, San Jose, CA). The following analytical data were obtained: (**2a**) HPLC retention time, 14.7 min; MS, $M_{\text{experimental}} = 1392.3$ amu and $M_{\text{theoretical}} = 1392.5$ amu; (**2b**) HPLC retention time, 13.6 min; MS, $M_{\text{experimental}} = 1350.4$ amu and $M_{\text{theoretical}} = 1350.5$ amu; (**2c**) HPLC retention time, 13.8 min; MS, $M_{\text{experimental}} = 1350.3$ amu and $M_{\text{theoretical}} = 1350.5$ amu; (**2d**): HPLC retention time, 13.0 min; MS, $M_{\text{experimental}} = 1308.3$ amu and $M_{\text{theoretical}} = 1308.5$ amu.

2.3. Fluorescence Spectra and Chromatography. Fluorescence spectra of **2** were recorded in a mixture of solvents C and D (80 + 20, v/v, see below) on a Shimadzu RF-540, and the strongest maxima (excitation 475 nm, emission 520 nm) were used for detection in HPLC.

A Shimadzu RF 535 was used as fluorescence detector for HPLC ($\lambda_{\text{ex}} = 475$ nm, $\lambda_{\text{em}} = 520$ nm). A Nucleosil RP-18, 3 μm , 125 $\times$ 4 mm (Macherey-Nagel) was used for analysis of the incubation experiments and a column from the same brand (10 μm , 2 $\times$ 4 mm) served as guard column. The eluent consisted of solvent C (doubly distilled water with 0.06% v/v trifluoroacetic acid) and solvent D (acetonitrile/doubly distilled water 80/20 v/v). A gradient was run increasing the percentage of D from 20% (0 min) to 28% (50 min) and decreasing it back to 20% (70 min) with a flow of 0.8 mL/min. Retention times of the substrates were 26.84/29.33 min (**2a**), 14.69/15.60 min (**2b**), 17.07/19.63 min (**2c**), 7.82/9.03 min (**2d**), and 23.82 min for the internal standard (5-aminofluorescein).

2.4. Enzyme and Radioactive Assay. A partially purified rat liver histone deacetylase was used for the incubation experiments. It is prepared via separation on Q-sepharose big beads (Pharmacia) with an increased gradient of NaCl. The detailed procedure is described elsewhere (17). Radioactive assays were performed as described (20) previously. Shortly, 100 μL of rat enzyme preparation (at 37 °C) were incubated (30 min) with 10 μL of total [^3H]acetate prelabeled chicken reticulocyte histones (1 mg/mL). Reaction was stopped by addition of 36 μL of stop solution (1 M HCl/0.4 M acetate) and 800 μL of ethyl acetate. After centrifugation (10000g, 5 min) an aliquot of 600 μL of the upper phase was counted for radioactivity in 3 mL of liquid scintillation cocktail. **2a** showed no inhibition of HDAC at 80 μM .

2.5. Stock Solutions, Incubation, and Sample Preparation. For qualitative analysis, small amounts of the peptides were dissolved in water. The solutions are stable at -20 °C for about 2 weeks. For the quantitative measurements, solutions of the peptides in water were prepared in the following concentrations (mg/mL): 3.540 (**2a**), 9.740 (**2c**), and 9.469 (**2d**). As the peptides contain between 25 and 30% of salt, a salt content of 25% was assumed for all compounds and accordingly corrected concentrations were used for all calculations. **2b** was not used for quantitative analysis as it is not formed upon incubation. The concentration of the internal standard stock solution was 5.021 mg/mL.

For the calibration, different aliquots of **2a**, **2c**, and **2d** were added to 110 μL of incubation buffer [15 mM tris-HCl, pH 7.9; 0.25 mM EDTA; 10 mM NaCl; 10% (v/v) glycerol; 10 mM 2-mercaptoethanol]. A total of 1.5 μL of internal standard solution was added, and incubation buffer was added to a final volume of 120 μL . The reaction was stopped immediately (200 μL stop solution) and vortexed (2 min). 200 μL of solvent C were added and the mixture was vortexed again (2 min). After centrifugation (10 000 rpm, 5 min) an aliquot was taken from the supernatant. A total of 20 μL was injected in the HPLC system via autosampler ($n = 2$). Linear regression provided the following equations: $f(x) = 0.00783 + 0.02242x$, $r = 0.9992$ (**2a**); $f(x) = 0.01474 + 0.02188x$, $r = 0.9997$ (**2c**); $f(x) = -0.09928 + 0.02512x$, $r = 0.9978$ (**2d**).

For the time-dependent analysis of conversion of **2a**, 15 parallel reactions were set up as above. The mixture was incubated on ice for 15 min and at 37 °C afterward. The reaction was stopped and the samples were prepared as above after 1, 2, 3, 4, 6, 8, 10, 12, 14, 18, 22, 24, 36, and 42 h ($n = 3$, except for $t > 18$ h, $n = 2$).

2.6. Mass Spectrometry. A Finnigan LCQ mass spectrometer with an electrospray interface was used for LC-MS coupling analyses. For identification of the incubation products, the column and solvent conditions were used as above (injection volume was changed to 50 μL), and the elution was monitored by UV detection (210 nm). Full-Scan and Zoom-Scan modes were used for analysis of the MS pattern of the standards and the incubation reactions (12 and 20 h). Spiking of the incubation

Figure 2. HPLC chromatograms of a standard mixture of **2a–d** and internal standard (IS) (left) and a mixture after incubation with rat liver HDAC for 20 h (right).

reactions with the standards did not lead to other signals. Solutions without substrates or enzyme did not result in signals in the observed range nor in peaks monitored at 210 nm with similar retention times.

RESULTS

The peptides **2** were built up by Fmoc-strategy on a Rink amide resin by using a robot system and subsequently labeled with 4(5)-carboxy-fluorescein prior to cleavage from the resin. The latter reagent had been previously proven to be superior to established derivatization reagents 4(5)-fluoresceinisothiocyanate and 4(5)-carboxyfluorescein-*N*-succinimidylester (19). The labeled peptides were obtained in amounts of 5–10 mg.

A chromatographic system for the separation of the peptides **2a–d** had to be established. Especially the separation of the two mono-acetylated species **2b** and **2c** proved to be difficult. We succeeded applying a system with an increasing gradient of trifluoroacetic acid in water/acetonitrile and the use of a 3 μ m RP-material was crucial to the success. Each of the peptides is showing two peaks due to the isomerism in the commercial starting material used for the labeling procedure. It was not necessary to separate the respective isomers but all eight peptides could be discriminated with the gradient method. Throughout all experiments, there was no indication for a preference of the enzyme for one of the fluorescein isomers. To increase the accuracy and precision of the system, an internal standard was sought and 5-aminofluorescein proved to be suitable. Figure 2 is showing a standard chromatograph of the peptides **2a–d** and the internal standard (IS). We then subjected the peptide **2a** to incubation with a partially purified rat liver HDAC. At first only the mono-deacetylation product **2c** could be detected, while after 3 h also some bis-deacetylation product **2d** was monitored. There was no indication for formation of the mono-deacetylation product **2b** even after 20 h (see Figure 2).

The identity of the incubation products with the synthetic metabolites was not only demonstrated by coelution. LC-MS analyses were performed with the standards and incubation mixtures after 12, 20, and 30 h proved identity of the compounds. Table 1 is showing selected observed mass peaks for a standard mixture and a 30 h incubation mixture obtained by LC-MS coupling. Zoom scan analyses ascertained that monitored signals are indeed $(M + n)/z$ ($n = z = 2$ or 3) peaks for the intact peptides (i.e., protonated species of the highly basic compounds) and not peaks resulting from degradation of the octapeptides by potential residual proteolytic activity in the partially purified rat liver preparation. Spiking of the incubation mixtures with the synthetic

Table 1. LC-MS Signals for Octapeptides **2**

		standard mixture			30 h incubation mixture		
compd	Mr	t_R	$[M + 2]$	$[M + 3]$	t_R	$[M + 2]$	$[M + 3]$
		(min)	$z = 2$	$z = 3$	(min)	$z = 2$	$z = 3$
2a	1392.5	27.06	697.0	465.1	28.05	697.0	465.1
2a	1392.5	26.53	697.0	465.1	25.29	696.9	465.0
2c	1350.5	18.92	675.9	451.1	18.93	675.8	451.0
2c	1350.5	16.81	676.0	451.0	16.69	675.9	451.1
2d	1308.5	10.37	<i>a</i>	437.1	10.20	<i>a</i>	437.1
2d	1308.5	9.44	<i>a</i>	437.1	9.60	<i>a</i>	437.1

a Not observed.

reference materials did not lead to any new signals in the time range monitored. Analysis of samples without the substrate **2a** or solvent blanks did not result in any signals with respective MS signals nor registration of peaks with the retention times of the standards with fluorescence or UV (210 nm) detection.

For quantitative analysis calibrations with standard samples were performed for the substrate **2a** and the two deacetylation products **2c** and **2d**. Figure 3 is showing the calibration curves for the respective peptides. No calibration was performed for **2b** as it is not formed upon incubation with rat liver HDAC.

To monitor the exact time course of the deacetylation reaction we set up 15 parallel experiments in which the enzyme incubation was terminated after increasing periods of time. The results are depicted in Figure 4.

The total area under the curve (AUC) is obtained by multiplying the starting concentration of **2a** and the total incubation time of 42 h and equals 3328.678 h μ mol/L. The measured AUC-values for the three peptides are 384.496 ± 24.163 h μ mol/L (**2a**), 2267.858 ± 140.571 h μ mol/L (**2c**), and 684.861 ± 33.868 h μ mol/L (**2d**). The AUC values in relation to the total AUC are $11.6 \pm 0.7\%$ (**2a**), $68.1 \pm 4.2\%$ (**2c**), and $20.6 \pm 1.0\%$ (**2d**). This adds up to $100.3 \pm 5.9\%$. No additional peaks at 520 nm nor at 210 nm (UV detection) were detected in the time frame of 70 min. Thus, remaining **2a** and all of its biotransformation products are quantitated by the presented method.

DISCUSSION

Fluorescein-labeled octapeptide **2a** is a substrate for histone deacetylase that is gradually deacetylated at the acetyl-lysine near its C-terminus and eventually formation of some bis-deacetylation product **2d** can be observed. This pattern of reactivity may be due to steric hindrance by the N-terminal label but as some deacetylation near the label is monitored this might be an indication for a deacetylation-site preference. Our studies show for the first time that HPLC-chromatography in combination with fluorescence detection and mass spectroscopy is a powerful tool to address questions of regioselective deacetylation in HDAC substrates with several acetyl-lysine residues in-vitro. They may serve as a model for similarly labeled larger peptides that are known to be substrates of histone deacetylase (12) and might not suffer from steric constraint by the label. Similar investigations have just recently been presented with a 20mer-peptide fragment from the N-terminus of histone H3 and the histone acetyltransferase PCAF (p300/CBP-associated factor) (21). Here MALDI/TOF analysis of tryptic digests of the peptidic substrate was used to identify the single acetylation site. Deacetylation site preferences are important for the characterization of various deacetylases and might have an impact on the design of substrate-analogues as HDAC inhibitors. Finally, due to its excitation wavelength of 475 nm our

substrate **2a** can be used for applications that are not amenable to the existing coumarin-derived substrate, e.g., fluorescence correlation spectroscopy.

Recognition of Novel Lipopolypeptides with Many Pendent Sugar Residues by Lectin[†]

Hiromi Kitano,* Yusuke Sumi, and Koji Tagawa

Department of Chemical and Biochemical Engineering, Toyama University, Toyama 930-8555, Japan.
Received May 9, 2000; Revised Manuscript Received September 12, 2000

A lipid–polypeptide conjugate (lipo-polypeptide) was obtained by the ring-opening polycondensation of *N*- ϵ -Z-L-lysine *N*-carboxyanhydride (NCA) using 3-aminopropyl dioctadecylamine as initiator and subsequent deprotection. Maltose lactone was coupled with the lipo-polypeptide to give novel amphiphiles which carried many maltoamide residues as pendent groups. The sugar group-carrying amphiphiles incorporated in phospholipid liposomes were recognized by a lectin from *Canavalia ensiformis* (Con A), which was proven by the increase in turbidity of the liposome suspension after mixing with the lectin. The recognition was largely affected by the degree of polymerization of lysine residues and the surface density of the amphiphile in the liposomes. The association constant (K_{ass}) of Con A with maltoamide residues on the liposome was much larger than those for small molecular weight sugars due to the “cluster effect”.

INTRODUCTION

Devices used in drug delivery systems are composed of various components which are designed for targeting, encapsulation, slow release, reduction of immunogenicity, and pharmacological activity, etc. (1). We have been interested in preparation of various liposome-forming hybrid materials having pH- or temperature-responsiveness using a lipophilic radical initiator or lipophilic chain transfer reagent (2, 3), respectively. Copolymerization of polymerizable lipid with pH-responsive vinyl monomer was also carried out to obtain pH-responsive hybrid amphiphiles (4). These materials would be promising candidates as a component in drug delivery systems.

Meanwhile, it has been revealed that oligosaccharides are important mediators for a large number of biological processes, such as cell–cell recognition and adhesion, hormone–cell recognition, and viral or bacterial adhesion to host cells (5–9). Therefore, various diseases and infections can be pharmacologically treated by the administration of molecules which mimic endogenous oligosaccharides or can block the recognition or adhesion processes (9).

We have pointed out that amphiphiles with many pendent sugar residues in their hydrophilic headgroups can be effectively recognized by the sugar binding protein, lectin (10–15). For the preparation of the sugar-carrying amphiphiles (so-called “glycolipids”), the lipophilic radical initiator mentioned above (2) has been mainly used.

In this report, we prepared amphiphilic compounds which have a lipid group, polypeptide chain, and many pendent sugar groups. These compounds can be named “chimeric” amphiphiles because of their hybrid structures. We investigated recognition of the amphiphilic compounds incorporated in phospholipid liposomes by a

lectin Concanavalin A (Con A)¹ from *Canavalia ensiformis*. The effects of the length and surface density of the polypeptide (poly-L-lysine in this work) above the liposome surface on the recognition by the lectin were examined.

EXPERIMENTAL PROCEDURES

Materials. 3-Aminopropyl dioctadecylamine (DODAAM, Scheme 1) was prepared by the Michael addition of dioctadecylamine (DODA, Fluka, Switzerland) to acrylonitrile at 80 °C and subsequent reduction with LiAlH₄ in dry tetrahydrofuran (16). Maltose lactone was prepared by the oxidation of maltose with iodine, and subsequent lactonization with cation-exchange resins (Amberlite IR-120 B, H⁺-form) and silver carbonate as previously reported (11, 17, 18). Concanavalin A (Con A) from *C. ensiformis*, L- α -dimyristoyl phosphatidylcholine (DMPC), and *N,N'*- α,ϵ -dicarbobenzoxy-L-lysine (di-Z-L-Lys) were from Sigma. Other reagents were commercially

available. A Milli-Q grade water was used for preparation of sample solutions.

Preparation of NCA of ϵ -Z-L-Lysine (*N*- ϵ -Z-L-Lys NCA). Di-Z-L-Lys (4.01 g, 13 mmol) was incubated with phosphorus pentachloride (PCl_5 , 2.41 g) in a dry 1,4-dioxane-ether mixture (10 mL + 15 mL) for 30 min in ice as reported previously (19). The solution mixture was evaporated, and washed with acetonitrile. The solid product was recrystallized from ethyl acetate-*n*-hexane, and dried in vacuo (*N*- ϵ -Z-L-Lys NCA, 2.88 g, 97% yield). IR (KBr): N-H (NCA, Z), ν 3341 cm^{-1} ; C=O (NCA), ν 1814, 1774 cm^{-1} ; C=O (Z), ν 1690 cm^{-1} ; N-H (NCA, Z), δ 1533 cm^{-1} ; CH_2 , ν_{as} 2939 cm^{-1} ; CH_2 , ν_{s} 2866 cm^{-1} ; C(=O)-O, ν 1258 cm^{-1} . Anal. calcd for $\text{C}_{15}\text{H}_{18}\text{N}_2\text{O}_5$: C, 58.82; H, 5.92; N, 9.15. Found: C, 59.05; H, 6.04; N, 9.09.

Preparation of Lipid-Poly(L-Lysine) Conjugate (DODA-PLL, Scheme 2). 3-Aminopropyl dioctadecylamine (20 mg, 34.5 μmol) and *N*- ϵ -Z-L-lysine NCA (0.424 g, 1.4 mmol) were dissolved in dry chloroform (15 mL). After passing N_2 gas for 5 min, the solution mixture was incubated for 24 h at room temperature and afterward refluxed at 60 $^\circ\text{C}$ for 4 days. The solution mixture was condensed by evaporation and purified by washing with ether (0.224 g, 59% yield). The degree of polymerization (DP) of L-lysine residue was estimated to be 25.3 by NMR and elemental analysis. ^1H NMR (400 MHz, CDCl_3): δ 0.88 (t, 6H, CH_3 -), 3.10 (m, 50.6H, $-\text{CH}_2-\text{NH}-\text{Z}$), 4.99 (s, 50.6H, $-\text{O}-\text{CH}_2-\text{C}_6\text{H}_5$), 7.23 (m, 126.5H, $-\text{C}_6\text{H}_5$). Anal. calcd for $\text{C}_{39}\text{H}_{82}\text{N}_2-(\text{C}_{14}\text{H}_{18}\text{N}_2\text{O}_3)_{25.3}$: C, 65.45; H, 7.51; N, 10.21. Found: C, 66.01; H, 7.54; N, 9.61.

The Z groups in the lipid obtained were cleaved with a CF_3COOH (1.40 mL)-*m*-cresol (0.24 mL)-trimethylsilyl trifluoromethanesulfonate (0.40 mL) mixture in ice for 2 h, while N_2 gas was passed through the reaction mixture (20). After evaporation, the oily mixture was dispersed in ether, and the precipitates recovered by decantation were dispersed in water by vortexing. The pH value of the dispersion mixture was adjusted to 5.6 with N/10 HCl and NaOH solutions, and the dispersion was dialyzed (molecular cutoff of the dialysis tube, 1000; Por CE membrane, Spectrum Medical Industries, Houston, TX) against pure water for 7 days. The dispersion was finally lyophilized (DODA-PLL, 0.104 g, 20% yield). ^1H NMR (400 MHz, D_2O): δ 0.61 (t, 6H, CH_3 -), 2.97 (m, 47.8H, $-\text{CH}_2-\text{NH}_2$), 4.30 [m, 23.9H, $-(\text{C}=\text{O})-\text{CH}(\text{NH})-\text{CH}_2-$]. The degree of polymerization (DP) of DODA-PLL became slightly smaller during the deprotection process (25.3 $\rightarrow$ 23.9) due to the partial cleavage of the peptide chain.

Scheme 3. Preparation of Chimeric Compound Which Carries Sugar, Polypeptide, and Lipid Moieties**Preparation of Sugar-Carrying Amphiphile**

(Scheme 3). DODA-PLL (50 mg) and maltose lactone (0.202 g, 0.6 mmol) were dissolved in a water-*N,N*-dimethylformamide mixture (2 mL + 15 mL) in a test tube. Pyridine (50 μL) was added, and the reaction mixture was incubated for 8 days at 70 $^\circ\text{C}$. After evaporation of the solvent, the maltoamide-carrying amphiphile was dissolved in water and purified by ultrafiltration (membrane, Amicon YM-3; molecular cutoff, 3000). The amphiphile, which had been dispersed in water by a vortex mixer and subsequently by an ultrasonifier (Astrason W-385, Heat Systems-Ultrasonics, Inc., NY) for 3 min, was finally lyophilized (21.6 mg, DODA-PLL-Mal-3). IR (KBr): O-H (maltoamide residue), ν 3358 cm^{-1} ; C=O (secondary amide), ν 1609 cm^{-1} ; C=O (tertiary amide), ν 1652 cm^{-1} ; N-H (secondary amide), δ 1540 cm^{-1} ; CH_2 , ν_{as} 2928 cm^{-1} ; CH_2 , ν_{s} 2853 cm^{-1} . The degree of substitution (DS) of the sugar residue was determined as 10.0 by H_2SO_4 -phenol method (21). The degree of polymerization (DP) of amphiphiles estimated by NMR was approximately consistent with that by elemental analyses. Anal. calcd for $\text{C}_{39}\text{H}_{82}\text{N}_2(\text{C}_6\text{H}_{12}\text{N}_2\text{O}_{13.9}(\text{C}_{18}\text{H}_{32}\text{N}_2\text{O}_{12})_{10.0}(\text{CF}_3\text{COOH})_{14.9})$: C, 45.63; H, 6.73; N, 7.98. Found: C, 47.06; H, 7.00; N, 7.55.

By changing the ratio of DODAAM and *N*- ϵ -Z-L-lysine NCA, maltoamide-carrying lipo-polypeptides of smaller degree of polymerization were prepared. Because of the difficulty to purify amphiphilic compounds, the yields of sugar-carrying lipids were in general very low (Table 1).

Acetylation of Lysine Residue in DODA-PLL-Mal.

DODA-PLL-Mal-1 (DP = 5, DS = 4.1, 49.8 mg, 30 μmol) was incubated with acetic acid (0.60 mL, 10 mmol) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (20.4 mg, 0.1 mmol) in water at pH 5.0 for 1 h in ice, and afterward at room temperature for 24 h. The solution mixture was purified by ultrafiltration (membrane, Amicon YM-1; molecular cutoff, 1000), and finally lyophilized (26.5 mg, 49.8% yield). The average degree of acetylation of α - and ϵ -amino groups retained in the poly-L-lysine moiety (DP = 5, DS = 4.1) was estimated to be 1.5 by 1,3,5-trinitrobenzenesulfonic acid method (22).

Preparation of Sugar-Carrying Polypeptide. Poly-(L-lysine) hydrobromide salt (DP = 18, 201 mg, 0.96 mequiv) and maltose lactone (811 mg, 2.4 mmol) were dissolved in a water-*N,N*-dimethylformamide-dimethyl sulfoxide mixture (15 mL + 20 mL + 3 mL) in a round-bottomed flask. The reaction mixture was incubated with

Table 1. Preparation of Sugar-Carrying Amphiphiles

amphiphile	DODA-PLL (g)	DP ^a	sugar lactone (g)	solvent (mL)	product (mg) [% yield]	DS ^b

anion-exchange resins (Amberlite IRA 96SB) for 10 days at 70 °C. After filtration of the resins and subsequent evaporation of the solvent, the maltoamide-carrying polypeptide (PLL-Mal) was purified by ultrafiltration (membrane, Amicon YM-1), and finally lyophilized (65.3 mg, 28% yield). The degree of substitution (DS) of the sugar residue was determined as 10.2 by the H₂SO₄-phenol method (21).

Preparation of Liposome. DMPC (16 mg) was dissolved in CHCl₃ (1 mL) in a small round-bottomed flask, and the solvent was evaporated. The thin lipid membrane formed was dispersed into a *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) buffer (pH 8.2, 10 mM) in which the sugar-carrying lipid had been dispersed beforehand using a vortex mixer at 60 °C. The dispersion was further ultrasonified for 3 min while N₂ gas was passed through the suspension.

Dynamic Light Scattering Method. Hydrodynamic diameter of liposomes composed of various molar ratios of sugar-carrying lipid and DMPC was determined by the dynamic light scattering method (DLS-7000, Otsuka Electronics, Hirakata, Japan; light source, He-Ne laser 632.8 nm).

Turbidity Measurements. The dispersion of sugar-carrying liposome (0.5 mL) was quickly mixed with a solution of lectin (0.5 mL) using a polyethylene mixing rod in a quartz cell. The lectin-induced agglutination of the liposomes was followed by the increase in decadic absorbance at 350 nm using a UV-vis spectrophotometer (Ubest-35, Japan Spectroscopic Co., Tokyo, Japan). The observation cell was thermostated by a Peltier device. The uncertainties of the rate of turbidity change were within 10%.

Association Constants for Con A to Sugar-Carrying Liposomes. The association constant, K_{ass} , between Con A (L) and the sugar-carrying amphiphile (S) (eq 1) was determined by the Scatchard plot (23).

The ratio of the concentration of free Con A to that of the complex with Con A is given by the eq 2.

$$[L \cdot S]/[L] = K_{\text{ass}}([S]_0 - [L \cdot S]) \quad (2)$$

where $[L \cdot S]$ and $[L]$ refer to the concentration of bound Con A and that of free Con A, respectively, and $[S]_0$ refers to the total concentration of sugar residues. A plot of $[L \cdot S]/[L]$ versus $[L \cdot S]$ should ideally give a straight line with a slope $-K_{\text{ass}}$. The association constant obtained from the plot was expressed in inverse molarity (M⁻¹), assuming a molecular weight of 25 583 for four subunits in the Con A molecules (24).

The sugar-carrying liposome suspension in a test tube (1 mL) was incubated with various concentrations of Con A (1 mL) at 25 °C for 3 h. The Con A bound to the liposome (actually the aggregates of liposomes cross-linked by Con A molecules) was removed with a syringe

filter (Millipore Millex-GV; pore size, 0.22 μm), and the absorbance of the filtrate at 280 nm was measured. Although the filter of low protein binding was used to remove the liposome-Con A aggregates, free Con A was observed to adsorb to the filter a little. Therefore, we at first estimated the relationship between the absorption of filtrate (2 mL) at 280 nm vs the concentration of free Con A before the filtration, and the amount of Con A bound to the liposome was calculated with the help of this calibration curve. The association constant, K_{ass} , between the water-soluble linear polymer and Con A was determined in the same way as the sugar-carrying liposome system.

In the binding experiment of maltose to Con A, a mixture of Con A and maltose dissolved in the HEPES buffer was dialyzed against the same buffer at 25 °C for 24 h using a seamless cellulose membrane (molecular cutoff, 13 000; Wako Pure Chemicals, Osaka, Japan). The concentration of nonbound maltose outside of the membrane was determined by the H₂SO₄-phenol method, and the K_{ass} value for the maltose-Con A system was estimated.

RESULTS AND DISCUSSION

Recognition of Sugar Residues on Liposomes by Lectin. Using the dynamic light-scattering method, diameter of the liposomes composed of DODA-PLL-Mal-3 (DP = 24, DS = 10) and L-α-dimyristoyl phosphatidylcholine (DMPC) was estimated to be 130 nm on average. The diameter of other liposomes was approximately the same value. Turbidity of maltoamide-carrying liposomes (DODA-PLL-Mal-3, DP = 24) at 350 nm was rapidly increased by the addition of lectin (Con A), whereas the glycolipid with a smaller degree of polymerization (DP = 5, 9) showed a slower turbidity change (Figure 1). The rate of turbidity increase was increased with the concentration of Con A, and after passing the maximum, gradually decreased. Similar phenomena were often observed in the lectin-glycolipid-carrying liposome systems (25), lectin-cell systems (26), and antigen-antibody systems (27).

In the presence of methyl α-D-mannopyranoside (Me-Man), which is known to strongly bind to Con A (28), this turbidity increase was largely decelerated, whereas the addition of mannose and glucose decreased the rate of turbidity change less significantly (Figure 2). Furthermore, the addition of MeMan to the suspension of maltoamide-carrying liposome-Con A aggregates induced the prompt reduction of turbidity (Figure 2, inset). In addition, there was no nonspecific lectin-mediated aggregation of DMPC liposomes nor self-aggregation of maltoamide-carrying liposomes (data not shown). These results strongly support that the turbidity change is due to the specific recognition of maltoamide residues (in other words, α-glucoside residues) on the liposomes by Con A, and subsequent aggregation of the liposomes mediated by the tetrameric lectin molecules.

Figure 1. Effect of Con A concentration on the rate of turbidity change at 350 nm after the addition of Con A into the liposome suspension at 25 °C. (○) DODA-PLL-Mal-1 (DP = 5); (●) DODA-PLL-Mal-2 (DP = 9); (■) DODA-PLL-Mal-3 (DP = 24). Content of glycolipid = 2.7 mol %. [liposome] = 0.05 mg/mL.

Figure 2. Inhibitory effect of monosaccharides on the rate of turbidity change at 350 nm in the agglutination of sugar-carrying liposomes by Con A. (○) Glucose; (●) mannose; (■) MeMan. Content of DODA-PLL-Mal-3 (DP = 24) = 2.7 mol %. [liposome] = 0.05 mg/mL. (Inset) Time course of turbidity changes at 350 nm after addition of Con A at 25 °C. [DMPC/DODA-PLL-Mal-3] = 0.05 mg/mL. [Con A] = 0.5 mg/mL. MeMan (final concentration, 4 mM) was added at the arrow.

The glycolipid prepared in this work had unmodified ϵ -amino and α -amino groups (at the end of the polypeptide), and these amino groups might increase the hydrophilicity of the sugar-carrying polypeptide chain. There have been many reports that hydrophobic aglycon promotes the recognition of sugars by lectin (29). Actually, by the acetylation of free amino groups, the rate of turbidity change was largely increased as indicated in Figure 3. Furthermore, the inhibitory effect of MeMan on the aggregation of the maltoamide-carrying liposome was affected by the degree of substitution (DS): The more the DS, the more resistant in the agglutinability to the presence of MeMan (data not shown).

Figure 4 shows the effect of weight percent of glycolipid (DODA-PLL-Mal-3, DP = 24, DS = 10) on the rate of turbidity change. There was a prompt increase in the rate of turbidity change at a low content of maltoamide-carrying lipid (1.2 mol %). The presence of threshold value in 5 mol % of lactosyl-ceramide in liposomes at the lectin-induced aggregation was previously reported (25).

Figure 3. Effect of acetylation of amino groups in the glycolipid on the rate of turbidity change at 350 nm after the addition of Con A into the liposome suspension at 25 °C. (○) DODA-PLL-Mal-1 (DP = 5, DS = 4.1); (●) DODA-PLL-Mal-1 (DP = 5, DS = 4.1, two-thirds of unreacted amino groups were acetylated). [liposome] = 0.05 mg/mL.

Figure 4. Effect of glycolipid content in the liposome on the rate of turbidity change at 350 nm after the addition of Con A into the liposome suspension at 25 °C. Glycolipid, DODA-PLL-Mal-3. [Con A] = 1 mg/mL. [lipid] = 0.05 mg/mL.

In the case of DODA-PLL-Mal-3 (DS = 10) liposome system, however, the rate of turbidity increase at the very small weight percent was significant, because many sugar residues were present in a polar head region of one lipid molecule, which made it not so largely necessary for the lectin to bind to plural number of sugar lipids on each liposome to bring about the stable aggregation, and consequently, induced the agglutinability of the lectin at the low content of the glycolipid.

Association Constants for Con A to Maltoamide-Carrying Amphiphiles. The association constant (K_{ass}) for Con A with various kinds of sugar derivatives obtained by the Scatchard plot is shown in Table 2. The K_{ass} value for DODA-PLL-Mal-3 was much larger than those of methyl α -D-manopyranoside (MeMan), methyl α -D-glucopyranoside (MeGlc), and maltose, and similar to the value of a branched pentasaccharide (30) shown in the table. The K_{ass} value for the sugar-carrying polypeptide (PLL-Mal) was also much larger than those for small molecular weight sugars. These results clearly

Table 2. Association Constants (K_{ass}) for the Complexation of Con A with Sugar-Carrying Amphiphile and Sugar Derivatives at 25 °C

amphiphile or sugar derivatives	K_{ass} ($\times 10^3 \text{ M}^{-1}$) ^a
DODA-PLL-Mal-3 (DP = 24)	1300
PLL-Mal (DP = 18)	170
methyl α -D-glucopyranoside (MeGlc) ^b	1.96
methyl α -D-mannopyranoside (MeMan) ^b	8.2
maltose	1.2 ^c
(GlcNAc(β -1,2)-Man) ₂ -(α -1,6, α -1,3)Man-OH) ^b	1400

^a In the 10 mM HEPES buffer (pH 8.2) containing 0.1 mM CaCl₂ and 0.1 mM MnCl₂. ^b Reference 30. ^c In ref 30, $1.31 \times 10^3 \text{ M}^{-1}$.

show that sugar residues incorporated in the polymer chain as pendent groups enhance appreciably the affinity for Con A compared with mono- and disaccharides. This is due to the so-called "cluster effect" which enhances the apparent affinity of cluster glycosides toward lectins without significantly changing the sugar concentration (31).

As shown in the table, the K_{ass} value for PLL-Mal was about 1/8 of the DODA-PLL-Mal-3 liposome system. This is probably because sugar-carrying polymer chains stretching from the liposome surface are more advantageous to fix Con A molecules rigidly than the sugar-carrying polymer chain in solution phase. Previously we examined recognition of mannose residue at lipid bilayer-liquid interfaces (14), and observed that the affinity of Con A for the amphiphiles which carried many pendent mannose residues was much higher (10^4 times at the most) than that for MeMan. In addition, we examined catalytic behavior of galactose oxidase at lipid bilayer-liquid interfaces (12, 13) and observed that the affinity of galactose oxidase for the amphiphiles carrying many pendent galactose residues was much higher (10^4 times and 10^2 times at the most) than those for various galactose derivatives with low molecular weight, and those for galactose-carrying water-soluble polymers, respectively. These results might be interpreted by the two-dimensional "cluster effect" in the reaction of glycosides with lectins and other sugar-binding proteins on membrane surfaces.

The number of amino acids and sugar residues in the sugar-carrying lipo-polypeptide can be controlled by the concentration ratio of the initiator (3-aminopropyl diocadecylamine) and lysine NCA, and that of amino group in the lipo-polypeptide and sugar lactone (maltose lactone, lactose lactone (11), and other sugar lactones) at the modification, respectively. Therefore, the compounds prepared here have a possibility to be used as a tool for drug delivery system to cells with sugar-binding receptors (hepatocytes, for example).

ACKNOWLEDGMENT

New PEGs for Peptide and Protein Modification, Suitable for Identification of the PEGylation Site

F. M. Veronese,^{*,‡} B. Saccà,[‡] P. Polverino de Laureto,[‡] M. Sergi,[‡] P. Caliceti,[‡] O. Schiavon,[‡] and P. Orsolini[§]

Department of Pharmaceutical Sciences (CNR, Center for Chemical Investigation of Drugs), University of Padova, Via Marzolo 5, 35131 Padova, Italy, and DEBIOPHARM s.a. Martigny, Switzerland. Received June 1, 2000; Revised Manuscript Received October 6, 2000

New PEG derivatives were studied for peptide and protein modification, based upon an amino acid arm, Met-Nle or Met- β Ala, activated as succinimidyl ester. PEG-Met-Nle-OSu or PEG-Met- β Ala-OSu react with amino groups in protein-yielding conjugates with stable amide bond. From these conjugates PEG may be removed by BrCN treatment, leaving Nle or β Ala as reporter amino acid, at the site where PEG was bound. The conjugation of PEG and its removal by BrCN treatment was assessed on a partial sequence of glucagone and on lysozyme as model peptide or protein. Furthermore, insulin, a protein with three potential sites of PEGylation, was modified by PEG-Met-Nle, and the PEG isomers were separated by HPLC. After removal of PEG, as reported above, the sites of PEGylation were identified by characterization of the two insulin chains obtained after reduction and carboxymethylation. Mass spectrometry, amino acid analysis and Edman sequence, could reveal the position of the reporter norleucine that corresponds to the position of PEG binding.

INTRODUCTION

The identification of the PEGylation sites in the primary sequence of peptides and proteins remains an open problem in the characterization of conjugates. This information may be of help to design reaction conditions more suitable to direct PEG toward residues not involved in binding with substrates, ligands, or receptors; furthermore, it is important for characterization of the conjugates as required by FDA.

Indeed, for short peptides, Edman degradation may be sufficient to identify the PEGylation site since the conjugated amino acid appears as a gap in the sequence. This was the case encountered in our laboratory to establish the position of PEG isomers in the 29 amino acid sequence of growth hormone releasing factor (1). However, this procedure is no longer feasible in large peptides and proteins, where a previous enzymatic cleavage must be carried out to get shorter sequence, as was the case of growth hormone or G-CSF (2). In such case, the conjugate was hydrolyzed by trypsin and the site of PEGylation stated on the basis of the missing tryptic peptides (due to PEGylation) in comparison with those obtained from the native protein. Although successful, this method cannot be considered of general suitability, since it is based on a negative information: a missing peptide may come also from incomplete hydrolysis that may occur close to a PEGylated lysine. Despite of their limitations these methods were successfully employed in the characterization of α -interferon also, where only monopegylated isomers, purified by ion exchange chromatography were obtained (3).

A further approach to the problem is based on the use of PEG with a hydrolyzable succinic acid ester arm

between polymer and protein. In this case, a mild basic cleavage removes PEG from the protein, leaving succinic acid bound to the protein as a reporter group. This labeled protein, after being digested with a proteolytic enzyme, is subjected to peptide fractionation and the succinylated peptides identified by Maldi mass spectrometry (4). This original procedure overcomes also the problem of the difficult fractionation of PEGylated peptides due to the hindrance of the polymer, although a limit still remains, i.e., the easy in vivo release of PEG from these conjugates at the level of the labile ester bond (5).

As a contribution to this problem, we describe here a procedure that overcomes the limits of the negative information of one method, the instability of the conjugates obtained with the succinimidyl arm, as well as the general problem connected with the difficult fractionation of PEGylated peptides or proteins. The method is based on the use of PEG-Met-Nle-OSu or PEG-Met- β Ala-OSu for protein modification. The PEG conjugates so obtained are stable in blood stream, but allow the in vitro cleavage at the methionine bond by BrCN, leaving Nle or β Ala bound to protein molecule as reporter group of the PEGylation site (see Figure 1). The peptide or protein, now devoid of PEG hindrance, may undergo any enzymatic and chemical treatment, or chromatographic fractionation, while the presence of the reporter is revealed by amino acid analysis, mass spectroscopy, or Edman degradation.

EXPERIMENTAL PROCEDURES

Methoxypoly(ethylene glycol) (MW 5000) (PEG) was purchased from Shearwater Polymer (Huntsville, AL), PEG-*p*-nitrophenyl carbonate was prepared according to a method previously reported (6), and bovine insulin, methionine, *p*-nitrophenylchloroformate, DL-norleucine methyl ester (Nle-OMe), β -alanine (β Ala), 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide metho-*p*-toluene-sul-

Figure 1. Conjugation of PEG-Met-Nle-OSu or PEG-Met- β Ala-OSu to a protein amino group and its removal by BrCN treatment.

fonate (CMC), and 1-hydroxybenzotriazole (HOBt) were purchased from Sigma (St. Louis, MO). Triethylamine (TEA), *N*-hydroxysuccinimide (HOSu), 1,4-dithio-L-threitol (DTT) and lysozyme from egg white were purchased from Fluka Chemie. Trinitrobenzenesulfonic acid (TNBS) was purchased from Aldrich (Milwaukee, WI), iodoacetamide from Merck (Rahway, NJ), and cyanogen bromide (BrCN) from Pharmacia (Uppsala, SW). The nonapeptide partial sequence of glucagons was from our laboratory.

Proton NMR spectroscopy was performed with a Varian Gemini 200 MHz instrument. Ultraviolet spectroscopy was performed with a Perkin-Elmer λ 5 instrument. Ultrafiltration was performed with an Amicon system and YM3 membrane (cut off 3000 Da). Ionic exchange chromatography was performed on a Pharmacia LKB system using a QAE-Sephadex A50 column. Reversed-phase chromatography was performed with a Shimadzu analytical and semipreparative HPLC system, using a Vydac 218TP54 and Vydac 218TP1022 column, respectively, with UV detector. Gel filtration chromatography was performed on a Pharmacia FPLC system, using a Superose 12TM column and an UV detector. Amino acid analyses were carried out after hydrolysis with HCl in vapor phase and derivatization with phenyl isothiocyanate (Fluka Chemie) (7) using a HPLC column Macherey-Nagel Nucleosil 120-5 C18. Maldi mass spectroscopy was performed in a Kratos Kompact MALDI 1 V5.2.0 instrument. Trinitrobenzenesulfonate (TNBS) was used as reagent for quantitative amino groups determinations following the procedure described by Habeeb (8). PEG content was evaluated colorimetrically using the iodine assay (9).

Synthesis of PEG-methionine-norleucine-hydroxysuccinimidylester (PEG-Met-Nle-OSu) and of PEG-methionine- β -alanine-hydroxysuccinimidylester (PEG-Met- β Ala-OSu). (1) *PEG-Met-Nle-OSu*. PEG-*p*-nitrophenyl carbonate (5 g; 0.97 mmol) was added in small portions to 724 mg (4.8 mmol; 5 equiv) of methionine dissolved in 10 mL of a 50% acetonitrile solution in water and brought to pH 8 with 676 μ L (4.8 mmol; 5 equiv) of triethylamine. After overnight stirring, acetonitrile was removed under reduced pressure and the pH of the reaction mixture was adjusted to 3 using solid citric acid. *p*-Nitrophenol was removed by ether extraction while the product was extracted several times with chloroform. The pooled organic fractions were dried, the volume was reduced to a few milliliters, and the product, precipitated by adding 300 mL of dry diethyl ether, was collected by filtration. For further purification the product was dissolved with acidified water, extracted with chloroform and precipitated by diethyl ether. The yield of the reaction, evaluated by 0.01 N NaOH titration, was almost quantitative. ^1H NMR (chloroform-*d*, 2000 MHz): δ 3.61 (s, PEG backbone -OCH₂-); 3.41 (s, 3H, PEG CH₃O-); 2.55

(t, 2H, Met γ CH₂); 2.07 (s, 3H, Met CH₃). In the following step 523 mg (2.888 mmol; 4 equiv) of norleucine methyl ester and a equimolecular amount of triethylamine (401 μ L) were added to a solution of 10 mL of anhydrous dichloromethane, containing 3.71 g (0.72 mmol) of PEG-Met-OH and mixed at 0 °C with 305 mg (0.72 mmol; 1 equiv) of 1-cyclohexyl-3-(2-morpholino ethyl) carbodiimide metho-*p*-toluene-sulfonate (CMC) and 97 mg (0.72 mmol; 1 equiv) of 1-hydroxybenzotriazole (HOBt). After stirring for 3 days at room temperature, the ureic derivative of CMC was filtered off, the mixture was dropped into 250 mL of dry diethyl ether, and the precipitate collected by filtration and dried. The product was further purified by ionic-exchange chromatography on a QAE Sephadex A50 column, eluted with water followed by 10 mM NaCl. The fractions containing the PEG-dipeptide were collected and lyophilized (yield: 93%). ^1H NMR (chloroform-*d*, 200 MHz): δ 3.70 (s, 3H, OMe CH₃); 3.61 (s, PEG backbone -OCH₂-); 3.41 (s, 3H, PEG CH₃O-); 2.55 (t, 2H, Met γ CH₂); 2.07 (s, 3H, Met CH₃); 1.32 (m, 4H, Nle γ e δ CH₂); 0.88 (t, 3H, Nle CH₃). In the last step, PEG-Met-Nle-OMe (1.41 g; 0.26 mmol) was stirred overnight at room temperature in a solution of methanol (5 mL) containing 20 equiv of 0.1 N NaOH (5.3 mL). The pH of the mixture was brought to 2 using 1 N HCl, and the product extracted with chloroform. The collected organic fractions were dried over anhydrous sodium sulfate, concentrated to a small volume under reduced pressure, and the product, precipitated by addition of dry diethyl ether, was filtered and dried. PEG-Met-Nle-OH was further purified by ionic-exchange chromatography on a QAE Sephadex A50 column, eluted first with water and then with a water solution of 10 mM NaCl. The fractions containing the sodium salt of the PEG-dipeptide were pooled, concentrated, and extracted by chloroform after acidification of the water solution. The purified product was finally obtained by precipitation with dry diethyl ether. Yield, calculated by 0.01 N NaOH titration, was 67%. ^1H NMR (chloroform-*d*, 200 MHz): δ 3.61 (s, PEG backbone -OCH₂-); 3.41 (s, 3H, PEG CH₃O-); 2.55 (t, 2H, Met γ CH₂); 2.07 (s, 3H, Met CH₃); 1.32 (m, 4H, Nle γ e δ CH₂); 0.88 (t, 3H, Nle CH₃).

The 1:1:1 ratio among the integration value of methoxy protons of PEG, methoxy protons of methionine and norleucine demonstrates the correct composition of the product and the complete derivatization of PEG.

The identity of the product was also demonstrated by amino acid analysis following acid hydrolysis (Lys 1.01, Met 0.9, Nle 1.0). In this case, PEG content was evaluated by iodine assay (9). For a mole of PEG (MW 5000) methionine and norleucine corresponded to 0.95 and 1.01 mol, respectively.

For PEG-Met-Nle-OH activation, the product (600 mg 0.11 mmol) was dissolved in 5 mL of dichloromethane, and hydroxy-succinimide (104 mg 0.9 mmol) and DCCI (185 mg, 0.9 mmol) were added. The reaction mixture was left to react for 24 h, and the product, precipitated by ethyl ether, collected by filtration and dried. The activation degree, expressed as percentage of -OSu for PEG-Met-Nleu, was over 95% in three different preparations. The activation degree was determined by the amino groups modification of glycine-glycine as substrate using TNBS for residual NH₂ groups evaluation (10).

(2) *PEG-Met- β Ala-OSu*. This product was prepared according to a procedure different from that followed for the nor-leucine derivative preparation, namely PEG activated as *p*-nitrophenylchloroformate was reacted with H-Met- β Ala-OMe and the product, after alkaline hydrolysis, activated as hydroxysuccinimidylester.

Table 1. Characterization of the Nonapeptide Derived from a Glucagon Sequence Following PEGylation with PEG-Met- β Ala-OSu and Removal of the PEG Chain by BrCN Treatment

	elution volume from HPLC ^a (min)	molecule mass ^b (Da)	Met mol/peptide ^c	β Ala mol/peptide ^c
free monopeptide	16.4	1091.1	0	-
PEGylated form	36.3	11090.0	2	2
following BrCN treatment	16.8	1317.4	0	2

^a A Vydac 218TP54 reverse phase HPLC column was used. ^b The mass was evaluated by Maldi mass spectroscopy. ^c Values obtained by amino acid analysis after acid hydrolysis. These nominal values were calculated from the following amino acid analyses: For PEGylated form, Thr, 0.81; Ser, 1.81; Arg, 1.08; Tyr, 1.77; Leu, 1.03; Arg, 1.02; Met, 1.75; β Ala, 2.20. For the BrCN treated product, Thr, 0.78; Ser, 1.75; Arg, 1.01; Tyr, 1.82; Leu, 0.98; β Ala, 1.04.

The dipeptide was synthesized from BOC-Met-OH (0.7 g, 2.9 mmol) and β -Ala-OMe (0.618 g, 4.4 mmol) in the presence of EDC (0.566 g, 2.9 mmol) and HOBt (0.399 g, 2.9 mmol) in 5 mg of dichloromethane. After extraction with basic and acid aqueous solution, the organic phase has been dried by Na_2SO_4 and evaporated.

¹H NMR (chloroform-*d*, 200 MHz): δ 1.5 (s, 9 H, BOC); 1.9 (m, 2H, $-\text{CH}_2-\text{CH}_2-\text{S}-\text{CH}_3$); 3.7 (s, 3 H, $-\text{S}-\text{CH}_3$); 2.5 (m, 4 H, $-\text{S}-\text{CH}_2 + \beta\text{Ala}-\text{CH}_2-\text{CO}$); 3.5 (m, $-\text{NH}-\text{CH}_2-\beta\text{Ala}$); 3.7 (s, 3 H, $-\text{COOCH}_3$); 4.2 (m, 1 H, $-\text{CH}-$); 5.25 (d, 1 H, BOCNH); 6.75 (t, 1 H, $-\text{NH}-\text{CO}$). The deprotection has been accomplished by stirring the product in a mixture of 2.5 TFA and 2.5 mL of dichloromethane. H-Met- β Ala-OMe was recovered by ether precipitation. ¹H NMR (chloroform-*d*, 200 MHz): 2.1 (s, 3 H, $-\text{S}-\text{CH}_3$); 2.15 (m, 2 H, $\text{CH}_2-\text{CH}_2-\text{S}-\text{CH}_3$); 2.6 (m, 4 H, $-\text{S}-\text{CH}_2 + \beta\text{Ala}-\text{CH}_2-\text{CO}$); 7.6 (t, 1 H, $\text{NH}-\text{CO}$); 7.9 (bs, 2 H, NH_2). The product was coupled to PEG-*p*-nitrophenylchloroformate, the methylester removed and the carboxylic group activated by OSu as previously reported for PEG-Met-Nle-OSu.

The amino acid analysis after acid hydrolysis and PEG evaluation carried out by colorimetric assay demonstrated the identity of the compound. For a mole of PEG (5000 MW), methionine and β -alanine were found to be 0.97 and 1.04, respectively. The activation degree was found to be over 97% in different preparations.

PEG Conjugation, Followed by Its Removal, to a Nonapeptide, Lysozyme, and Insulin. (a) *PEG Conjugation and Removal from H-Thr-Ser-Arg-Tyr-Ser-Lys-Tyr-Leu-Asp-OH*. A total of 41 mg (4.0 μmol) of MPEG-Met- β Ala-OSu was added, in small aliquots, to 0.9 mg (0.8 μmol) of the nonapeptide dissolved in 1 mL of DMSO, at pH 8 with TEA (nonapeptide: MPEG-Met-Nle-OSu molar ratio = 1:5). After 3 days of stirring at room temperature, the pH of the reaction mixture was adjusted to 3 with 1 N HCl, and the product was extracted several times by chloroform. The chloroform was anhydriified with dry Na_2SO_4 and concentrated to dryness. The collected conjugate was further purified by means of a Shimadzu semipreparative HPLC system, using a reversed-phase Vydac 218TP54 column (C18 bonded phase, 0.46×25 cm i.d., $5 \mu\text{m}$ particle diameter). A linear gradient of aqueous 0.05% trifluoroacetic acid and 0.05% trifluoroacetic acid in acetonitrile was used and the fractions of the unique peak revealed by absorption at 280 nm and by iodine assay were pooled and concentrated to dryness. The PEGylation was verified by the disappearance of reactivity of the peptide amino groups and by the presence of two β Ala and Met residues revealed by amino acid analysis after acid hydrolysis (see Table 1). For the removal of bound PEG, 1 mg (85.2 μmol) of PEG-Met- β Ala-nonapeptide was treated with 100 equiv of BrCN in aqueous 70% formic acid (11). After 24 h standing at room temperature, the mixture was poured into 10 vol of water and lyophilized; this procedure was repeated twice. The product was fractionated by a Shi-

madzu analytical HPLC system, using a reversed-phase Vydac 218TP54 column (C18 bonded-phase, 0.46×25 cm i.d., $5 \mu\text{m}$ particle diameter). The eluent was a linear gradient of aqueous 0.05% trifluoroacetic acid and 0.05% trifluoroacetic acid in acetonitrile.

(b) *PEG Conjugation and Removal from Lysozyme*. A total of 42.2 mg (7.8 μmol) of mPEG-Met-Nle-OSu was added, in small aliquots while stirring, to 3.75 mg (0.26 μmol) of lysozyme from egg white dissolved in 1 mL of 0.2 M borate buffer, pH 8.5. The molar ratio of lysozyme amino groups to mPEG was 1:5. After 30 min of stirring at room temperature, the conjugate was purified by means of a semipreparative FPLC system, using a gel filtration Superose 12TM column (1.5×25 cm) eluted with 0.01 M phosphate buffer and 0.15 M NaCl, pH 7.2. The fractions were analyzed for lysozyme elution by absorption at 280 nm and iodine assay for PEG elution. The fractions containing the modified lysozyme were collected and concentrated to a small volume by ultrafiltration with an Amicon system using a YM3 membrane (cut off 3000 Da). The concentrated solution was diluted with water and ultrafiltered. This procedure was repeated and the product was finally lyophilized. For PEG removal, 0.04 μmol of modified lysozyme was treated with 600 equiv of BrCN in aqueous 70% formic acid and left stirring for 24 h at room temperature. The mixture was poured into 50 mL of water and lyophilized; the procedure was repeated twice. The product obtained was analyzed by gel filtration column by a FPLC system as above, to compare the chromatography profiles.

(c) *Insulin Modification by PEG-Met-Nle-OSu Followed by Removal of PEG and Identification of the Sites of PEGylation*. PEG-Met-Nle-OSu was added to 7 mg (1 μmol) of bovine insulin dissolved in 1 mL of DMSO until a 3:1 PEG: insulin molar ratio was reached. The mixture was left stirring for 5 h at room temperature. The conjugate was purified by means of a Shimadzu preparative HPLC system, using a reversed-phase Vydac 218TP1022 column (C18 bonded phase, 2.2×25 cm i.d., $10 \mu\text{m}$ particle diameter) and a linear gradient of aqueous 0.05% trifluoroacetic acid and 0.05% trifluoroacetic acid in acetonitrile, monitoring the absorption at 226 nm wavelength. Three peak fractions of conjugated insulin were collected (at 21.867, 23.275, and 24.158 min of elution) and lyophilized. The product of each peak, called insulin A, insulin B, and insulin C, were separately treated with BrCN in aqueous 70% formic acid to remove PEG. The molar ratio between insulin and BrCN was 1 to 200. After 24 h stirring at room temperature, the mixture was poured into 10 vol of water and freeze-dried; the procedure was repeated twice. The obtained products were analyzed and purified by means of a Shimadzu analytical HPLC system, using a reversed-phase Vydac 218TP54 column (C18 bonded phase, 0.46×25 cm i.d., $5 \mu\text{m}$ particle diameter) with a linear gradient of aqueous 0.05% trifluoroacetic acid and 0.05% trifluoroacetic acid

Figure 2. ^1H NMR spectrum (CDCl_3 , 200 MHz) of mPEG-Met-Nle-OH.

in acetonitrile. To determine the position of PEG in the insulin chains, the disulfide bonds were reduced and carboxymethylated. To this aim, 500 μg (0.08 μmol) of each Nle-insulin sample, obtained from PEG-Met-Nle-insulin A, B, and C after BrCN treatment, were dissolved in 250 μL of Tris-HCl buffer, pH 7.5, containing 2 mM EDTA and 6 M Gdn-HCl; 3.8 mg of 1,4-dithio-L-threitol were added, and the mixture was left standing for 2 h at 37 $^\circ\text{C}$. Finally, 9.2 mg of iodoacetamide were added and the mixture was left for 1 h at 37 $^\circ\text{C}$. The solutions were lyophilized, and the products fractionated by means of a Shimadzu semipreparative HPLC system, using a reversed-phase Vydac 218TP54 column as described above. The eluted products monitored by absorption at 226 nm wavelength revealed in all the samples the presence of two main peaks, corresponding to the reduced carboxymethylated α and β chains, respectively. The two polypeptides were separated, recovered, and analyzed by amino acid analysis, mass spectrometry and eventually Edman degradation (12).

RESULTS

Synthesis of PEG-Met-Nle-OSu and PEG-Met- β Ala-OSu. The synthesis of the two new PEG derivatives may be carried out by sequential amino acid addition to PEG according to the polymer supported liquid-phase synthesis procedure (13) or by the linkage of PEG to the dipeptide, followed by the carboxylic groups activation. Here the first method was employed for PEG-Met-Nle, while the second for PEG-Met- β Ala preparation. The identity of the polymer derivatives was verified qualitatively and quantitatively by ^1H NMR spectroscopy (see Figure 2 for PEG-Met-Nle-OH) and by evaluation of the three components: PEG by iodine assay, methionine and nor-leucine (14) or β -alanine by amino acid analysis after acid hydrolysis.

Using glycyl-glycine as model (10), it was verified the degree of activation as hydroxysuccinimidylester. It also demonstrated that the rate of aminolysis of OSu of these

new PEG derivatives was the same of the known simple PEG-Nle-OSu (14).

Protein and Peptide Conjugation with the New PEG-Derivatives Followed by PEG Removal by BrCN. The peptide and protein conjugation of the new PEG-peptide arms, activated as succinimidyl ester, followed by deblocking by BrCN treatment, was verified using three different models: a nonapeptide, the small protein insulin and the 12 kDa protein lysozyme.

(A) The nonapeptide H-Thr-Ser-Arg-Tyr-Ser-Lys-Tyr-Leu-Asp-OH, a partial sequence of glucagon, was chosen since it presents two reactive amino groups. Following treatment with PEG-Met- β Ala-OSu, 5 kDa, the mass of the nonapeptide, evaluated by Maldi mass spectrometry, increased from the 1091.11 kDa of the free peptide to a value of about 11410 kDa. The mass spectrometry peak was broad (spectrum not shown) due to the known polydispersity of PEG. The increase in mass, of approximately 10 kDa, corresponds to the conjugation of two PEG-Met- β Ala chains and is accompanied by the disappearance of amino group reactivity, demonstrated by TNBS reaction 12. Contemporaneously an increase in reversed-phase HPLC elution volume from 16.4 to 36.3 mL was found. Following BrCN treatment, a sharp peak with a mass of 1233.26 kDa, corresponding to the nonapeptide mass plus two β Ala residues could be observed by mass spectrometry. At the same time the HPLC elution dropped to 16.8 mL, a volume close to that of the free nonapeptide (16.4 mL). Furthermore the amino acid analysis showed the presence of two β Ala residues per peptide molecule and no trace of methionine. These values are summarized in Table 1.

(B) Figure 3 reports the elution from a GPC column of three lysozyme species: native, PEGylated and after BrCN treatment. The PEGylated lysozyme (b) was eluted by gel filtration chromatography at the 12 mL, much ahead of the native enzyme, 18 mL, (a) due to its large increase in mass. Six PEG chains were bound as revealed by mass spectrometry, amino acid analysis following acid

Figure 3. Elution peaks of lysozyme (a), PEGylated lysozyme (b) and the conjugation product after PEG removal by BrCN treatment (c), from a GPC column.

hydrolysis, and amino groups titration by TNBS. The sample obtained after deblocking with BrCN. Nle conjugated lysozyme (c), was eluted 17.8 mL a volume close to that of the native protein (18 mL). The small difference in elution being related to the difference in mass of the two species: 14 388 kDa of native lysozyme, as compared to 15 066 kDa of lysozyme plus the six nor-leucine residues as confirmed by amino acid analysis.

The data regarding a small peptide or a model protein, reported in A and B, are in favor of the possibility to link these novel PEGs to polypeptides as well as of their quantitative removal by BrCN treatment, leaving Nle or β Ala as reporter amino acids bound to the starting molecule.

Localization of Conjugation Site in PEGylated Insulin. Insulin was the third polypeptide model chosen to test the suitability of the proposed methodology, because in this case different PEGylated isomers may be obtained in the conjugation reaction. Figure 4b, shows that when insulin is PEGylated in dimethyl sulfoxide at a 1 to 1 molar ratio of polymer to insulin available amino group, three conjugation products are obtained. They are eluted later as compared to native insulin (18.3 mL, see Figure 4a) since the presence of PEG. Colorimetric amino group titration and amino acid analysis following acid hydrolysis on the basis of methionine and nor-leucine presence, demonstrated that peak A (eluted at 21.9 min) corresponds to mono-PEGylated insulin. Peak B (eluted at 23.3 min) corresponds to an insulin species with two PEG molecules bound. The third peak C (eluted at 24.1 min) is the three-PEGylated product (see Figure 4b).

This last product (c) being modified at all available insulin amino groups (Gly 1 of α chain, Phe 1 and Lys

29 of β chain), did not need further studies for its characterization.

As shown in Figure 5a, when the mono-PEGylated product (peak A of Figure 4) was treated with BrCN, HPLC fractionation yielded a single peak that, by mass spectrometry, showed a mass of 5845.32 Da, corresponding to the mass of one insulin plus 1 residue of norleucine (expected value 5846.68 Da, see Figure 5b). The elution from HPLC, 18.4 mL (see Figure 5a) is close to that of native insulin, 18.3 mL (see Figure 4a), the difference is due to the fact the two products differ for only one amino acid (Nle).

To identify the position of PEGylation, the two insulin chains were separated by reduction followed by carboxymethylation. It was found that only the heavy chain was PEGylated, showing a mass of 3629.81 Da (the expected mass of β chain plus 1 Nle residue is 3627.59 Da, Figure 6).

To identify whether the PEGylation was at Phe 1 or at Lys 29, one step of Edman was carried out. Mass spectrometry demonstrated the release of one phenylalanine and one norleucine residue (expected mass 3367.22, found 3369.23) (see Figure 7). This demonstrated that the α amino group of phenylalanine was free (Phe was in fact released by Edman) and consequently that PEG was bound to ϵ -lysine (to note that Nle also was released by CNBr from the Nle- ϵ -Lys bond).

The di-PEGylated insulin, corresponding to the major peak B of Figure 4, was also purified to homogeneity and PEG was removed (see Figure 8a). The dePEGylated product yielded a mass of 5954.09 that corresponds to insulin plus 2 Nle residues (see Figure 8b, expected value 5959.86). After reduction and carboxymethylation, the two chains were separated by HPLC. They were identified by mass spectrometry: one showed a mass of 3628.95 Da, already found in the peak A of Figure 4, corresponding to mono-PEGylation; the second, of 2689.06 Da (see Figure 9) corresponds instead to a mono-PEGylated light chain (expected value 2681.18).

While for the α chain there is only one position of PEGylation at the level of glycine in position 1 of the peptide, for the β chain two positions are possible, as described above. One step of Edman degradation showed that the α amino group was free since phenylalanine was released demonstrating that the PEG binding involved lysine 29, as for the previous peak B of insulin.

From these experiments, it was therefore possible to assign the position of PEGylation to the mixture of products obtained in insulin conjugation. It was contemporaneously possible to demonstrate that, under these conditions of reaction, the order of reaction is lysine 29 of β chain (the one always found), followed by glycine 1 of α chain, being phenylalanine 1 of β chain the less reactive. These results are in agreement with the known properties of insulin residues in which the low reactivity of Phe 1 of α chain is ascribed to its pK_a (15, 16). Extensive PEGylation of this residue was obtained only by a previous protection by BOC of the other two more reactive amino groups (17–19).

CONCLUSIONS

The data obtained using a nonapeptide, insulin and lysozyme as models, strongly support the use of PEG with Met-X as peptide arm for the modification of proteins. Convenient X are amino acids non natural or non frequent in proteins, norleucine and β -alanine standing as the preferred ones.

This functionalized polymers present unique advantages for the analytical characterization of PEG conju-

Figure 4. (a) Elution pattern from reversed-phase column of insulin and (b) of the reaction mixture of insulin conjugation with PEG-Met-Nle-OSu. Peaks A, B, and C correspond to insulin with 1, 2, and 3 PEG chains bound per insulin molecule.

Figure 5. (a) Elution pattern of mono-PEGylated insulin, corresponding to peak A of Figure 4, following purification and treatment with BrCN to release PEG, to leave the reporter Nle only bound to the peptide; (b) mass spectrum of the Nle insulin reported in panel a. gates, since the hindered PEG may be specifically removed by BrCN treatment leaving bound norleucine or β -alanine as reporter group bound to the proteins. These

de-PEGylated proteins are more easily fractionated in their constituent isomers of the PEG containing products, since their lower hindrance. This is an important aspect

Figure 6. Mass spectrum of the reduced carboxymethylated insulin heavy chain carrying one norleucine residue. The sample comes from the peak A of Figure 4 after purification, dePEGylation (see Figure 5a) and separation of the chains. Found: 3629.81 Da. Expected: 3627.59 Da.

because it is known that PEGylation yields heterogeneous mixture, that only in few lucky cases may be separated.

Furthermore the proteins, devoid of PEG, may undergo any chemical or enzymatic cleavage needed for sequence evaluation and the labeled peptides are easily identified

Figure 8. (a) Elution pattern of di-PEGylated insulin, corresponding to peak B of Figure 4, following treatment with BrCN to release PEG. (b) Mass spectrum of Nle insulin reported in panel a, showing that two Nle residues are bound to the protein. Found: 5954.09 Da. Expected: 5959.86 Da.

on the basis of norleucine or β -alanine detectable by amino acid analysis or mass spectrometry. In this respect norleucine appears ideal as reporter residue in mass spectrometry analysis for its higher molecular weight. β -Alanine is less convenient in this respect, but it

presents the advantage, over norleucine, of not being released by Edman degradation, thereby allowing its localization in a peptide where multiple lysine residues are present (20).

The BrCN based removal of PEG offers an additional

advantage for the identification of the site of PEGylation. As well-known BrCN, in the same step of dePEGylation, cleaves also the protein at the level of methionine, if present in the primary sequence, yielding shorter peptides where the reporter groups may be directly identified. This peptide cleavage did not take place in our models nonapeptide or in insulin, both devoid of methionine. In lysozyme, on the other hand, the cleavage took place, but the peptides remained still linked together by disulfide bridges.

To verify the suitability of these new PEGs for a therapeutic application of their protein conjugates, studies to evaluate the stability in blood of PEG-Met-Nle and PEG-Met- β Ala conjugates are presently under way, and will be reported separately.

Reaction of Nitric Oxide with Synthetic Hemoprotein, Human Serum Albumin Incorporating Tetraphenylporphinatoiron(II) Derivatives

Teruyuki Komatsu, Yasuko Matsukawa, and Eishun Tsuchida*

Department of Polymer Chemistry, Advanced Research Institute for Science & Engineering, Waseda University, Tokyo 169-8555, Japan. Received June 13, 2000; Revised Manuscript Received September 5, 2000

The reaction of nitric oxide (NO) with a synthetic hemoprotein, the recombinant human serum albumin (rHSA) incorporating *eight* tetraphenylporphinatoiron(II) derivatives bearing a covalently linked axial base (FeP) [rHSA-FeP], has been investigated. The UV–vis absorption spectrum of the phosphate buffer solution (pH 7.3) of rHSA-FeP showed maxima at 425 and 546 nm upon the addition of NO. The carbonyl rHSA-FeP, in which FePs are six-coordinate CO-adducts, also moved to the same species after bubbling with NO gas. ESR spectroscopy revealed that the incorporated FePs in the albumin formed six-coordinate nitrosyl complexes; the proximal imidazole moiety does not dissociate from the central iron when NO binds to the trans side. The NO-binding affinity of rHSA-FeP ($P_{1/2}^{\text{NO}}$, 1.7×10^{-6} Torr, pH 7.3, 298 K) was significantly lower than that of FeP itself ($P_{1/2}^{\text{NO}}$, 1.8×10^{-8} Torr in toluene). Kinetically, this arises from the decreased association rate constant ($k_{\text{on}}^{\text{NO}}$, $8.9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1} \rightarrow 1.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$). Since NO-association is diffusion controlled, incorporation of the synthetic heme into the albumin matrix appears to restrict the NO access to the central iron(II).

INTRODUCTION

Several types of hemoglobin (Hb)-based O_2 -carriers are currently being studied in clinical trials (Chang, 1997; Tsuchida, 1998). Administration of these cell-free Hbs as red cell substitutes, however, often induces acute increases in systemic blood pressure by vasoconstriction (Keipert et al., 1993; Moisan et al., 1998; Schultz et al., 1993). This side effect is now recognized to be due to the fact that small Hb molecules extravasate through the vascular endothelium and react with the endothelial-derived relaxation factor (EDRF), *namely nitric oxide* (NO), thus inhibiting its vasorelaxing action. On the other hand, we have recently found that the recombinant human serum albumin (rHSA) incorporating a tetraphenylporphinatoiron(II) derivative with a covalently linked proximal base, 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxy-methyl]-*meso*-tetrakis($\alpha,\alpha,\alpha,\alpha$ -*o*-pivalamido)phenylporphinatoiron(II) (FeP) [rHSA-FeP], can reversibly bind and release dioxygen (O_2) under physiological conditions (in aqueous media, pH 7.3, 37 °C) like Hb and myoglobin (Mb) (Komatsu et al., 1999; Tsuchida et al., 1997, 1999; 2000). A maximum of eight FeP molecules are included inside the albumin structure by hydrophobic interaction, and the O_2 -binding affinity satisfies the initial clinical requirements for an artificial red cell. On the basis of laser flash photolysis experiments, the two-phase kinetics of CO- and O_2 -binding to rHSA-FeP was also carefully studied related to the molecular environment around each FeP in the albumin (Komatsu et al., 2000a). However, to date, much less is known for the reaction of NO to rHSA-FeP. One can anticipate that the injection of this cell-free type O_2 -carrier into the blood vessels may induce unfavorable hypertension, if its NO-binding af-

finity is enough high to react with 1 μM NO in the endothelium cells (Malinski et al., 1996). Hence, it is an urgent necessity to elucidate the NO-binding properties of this albumin-heme hybrid.

On the other hand, from the viewpoint of coordination chemistry, a considerable number of studies have been made on the nitrosyl hemoproteins and synthetic porphyrinatoirons, because NO shows a unique negative trans effect, which is quite different from the other gaseous ligand such as carbon monoxide (CO) and O_2 (Hoffman et al., 1978; Hoshino et al., 1989; Nasri et al., 1997; Moore et al., 1976; Rose et al., 1983; Shimizu et al., 1984; Traylor et al., 1992). The most significant difference is that the axial base coordination to the Fe(II)porphyrin is weakened upon the addition of NO; this often leads to a rupture in the iron(II)–imidazole bond. On the contrary, we have shown that covalently attaching the proximal imidazole directly to the porphyrin periphery provides an incredibly large equilibrium constant for the imidazole bonding and prevents the *base-off* reaction when NO is bound to the trans side. Indeed, the FeP formed a six-coordinate nitrosyl complex in toluene at 298 K (Komatsu et al., 2000b).

Six-coordinate nitrosyl FeP

This paper describes for the first time the formation of the six-coordinate nitrosyl complex of FeP in rHSA and the equilibrium and kinetic parameters for NO-binding to this albumin-heme hybrid, rHSA-FeP.

EXPERIMENTAL PROCEDURES

Materials and Preparation of rHSA-FeP Solution. 2-[8-{*N*-(2-Methylimidazolyl)}octanoyloxymethyl]-*meso*-tetrakis($\alpha,\alpha,\alpha,\alpha$ -*p*-ivalamidophenyl)porphinatoiron(II) (FeP) was synthesized as previously described (Tsuchida et al., 1995). A recombinant human serum albumin (rHSA; 25 wt %) was obtained from the WelFide Corporation. The rHSA-FeP solutions [FeP/rHSA = 8 mol/mol; [FeP] = 20 μ M to 1 mM, in 33 mM phosphate buffer, pH 7.3] were prepared according to our previously reported procedure (Tsuchida et al., 1999). The nitric oxide (NO) gas cylinders (1% and 5 ppm) were purchased from Takachiho Chemical Industry Co., Ltd.

Nitrosylation of FeP. (a) *In Toluene Solution.* The iron(III) complex of FeP in toluene was reduced by a heterogeneous two-phase system using aqueous dithionite under an argon atmosphere (Tsuchida et al., 1995). After removing the water phase and dehydration with anhydrous Na_2SO_4 , the UV-vis absorption spectrum [λ_{max} = 440, 541, 559, 608(sh) nm] showed the formation of the five-*N*-coordinated high-spin Fe(II) complex. The UV-vis absorption measurements were performed using a Shimadzu V-570 spectrometer within the range of 350–700 nm. The FeP concentrations of 20 μ M were normally used. Five parts per million NO in N_2 was then bubbled through the solution until the spectrum reached equilibrium. To remove the higher oxides, NO was successively passed through the gas-washing bottles filled with solid KOH and phosphate buffer solution (pH 7.3), respectively, in turn prior to use. A double stopcock was equipped on the quartz cuvette as a barrier to the O_2 diffusion.

(b) *In Aqueous Solution.* The aqueous solution of rHSA incorporating the carbonyl FePs [rHSA-FeP, FeP/rHSA = 8 mol/mol; [FeP] = 20 μ M] was prepared according to our previously reported procedures (Tsuchida et al., 1999). For the UV-vis absorption spectroscopy, we used special glassware, consisting of a two-neck round flask (normally 50 mL) with one neck having a double-stopcock on the top, and the other with the quartz cuvette. CO was gently bubbled through the sample in the flask in which a magnetic stirring bar was continuously stirred to avoid O_2 contamination. One percent NO in N_2 was then introduced into the solution through a stainless steel needle. Three hours of bubbling was normally required to obtain a constant absorbance at room temperature. Bubbling occasionally resulted in the denaturation of rHSA-FeP, but a low flow rate tends to prevent this. After the solution was transferred to the cuvette, the UV-vis absorption measurements were carried out.

NO-Binding Affinity. For determination of the NO-binding affinity (partial pressure at half NO-binding to FeP, $P_{1/2}^{\text{NO}} = 1/K^{\text{NO}}$), we used the ligand exchange method of Romberg and Kassner, which requires titration of the six-coordinate carbonyl complex with NO (Romberg et al., 1977).

The partition coefficient between NO and CO, $N (=K^{\text{CO,NO}})$ is defined by the equation

$$N = \frac{[\text{FeP(NO)}]P^{\text{CO}}}{[\text{FeP(CO)}]P^{\text{NO}}} \quad (2)$$

where P^{CO} and P^{NO} correspond to the partial pressure of CO and NO. When the concentration of the nitrosyl complex becomes 50%, N is equal to $P_{1/2}^{\text{CO}}/P_{1/2}^{\text{NO}}$. The equilibrium constants are written as

$$K^{\text{NO}} = K^{\text{CO}}K^{\text{CO,NO}} \quad (3)$$

This equation can be expressed in terms of $P_{1/2}$ and N :

$$P_{1/2}^{\text{NO}} = \frac{P_{1/2}^{\text{CO}}}{N} \quad (4)$$

Consequently, the $P_{1/2}^{\text{NO}}$ was calculated from $P_{1/2}^{\text{CO}}$ and the N value determined spectrophotometrically. In the case of rHSA-FeP, however, reproduction of the spectral changes was not constant and had a relatively large error, due to protein denaturation by the long gas bubbling in the solution. Therefore, the $P_{1/2}^{\text{NO}}$ of rHSA-FeP was eventually determined by $k_{\text{on}}^{\text{NO}}/k_{\text{off}}^{\text{NO}}$ (vide infra). A KOFLOC Gas Blender GB-3C was used to prepare the CO/NO gas for the desired partial pressure. The obtained gas was passed through the KOH and water columns before bubbling the solution as already described for elimination of the small amount of higher oxides. The concentrations of NO and CO in toluene and the phosphate buffer were calculated from their partial pressures and the solubilities (NO, 11 mM; CO, 7.41 mM in toluene; and NO, 2 mM; CO, 0.94 mM in water) at 1 atm and 298 K.

ESR Measurements. ESR measurements at the X-band frequency were performed using a JEOL JES-RE2X spectrometer with 100 kHz field modulation at 298 and 77 K. A JEOL ES-SCXA frequency meter calibrated the magnetic field, and the field corrections for the samples were made with MnO_2 . The nitrosyl FeP concentration in toluene or in aqueous rHSA solutions was approximately 1 mM. After confirming the visible absorption spectra, which show the formation of the nitrosyl complex, the samples were carefully transferred to an ESR tube equipped with the double stopcock on the top.

Association and Dissociation Rate Constants. The bindings of gaseous ligands to FeP were expressed by

where L is NO, CO, or O_2 . The association rate constant of NO ($k_{\text{on}}^{\text{NO}}$) was obtained from the rebinding kinetics following NO-photodissociation after the laser flash photolysis [Continuum Surelight I-10 (Nd:YAG laser SHG: 532 nm, 6 ns pulse width)]. The Xenon lamp (150 W) was used as the monitoring light source. The time dependence of the absorption changes accompanied the NO-recombination were detected by a Hamamatsu Photonics R636 photomultiplier, and the relaxation curves were analyzed by the second-order kinetics (Hoshino et al., 1989), affording the association rate constants ($k_{\text{on}}^{\text{NO}}$). The sample cuvette ([FeP] = 20 μ M) was placed in a thermostated holder and the temperature was maintained at 298 K.

On the other hand, studies of the dissociation of NO from rHSA-FeP were accomplished by diluting a nitrosyl rHSA-FeP solution (Moore et al., 1976). The NO-dissociation reaction was initiated by mixing of a CO-saturated aqueous dithionite solution with the nitrosyl rHSA-FeP solution (1/2 v/v). The absorption change at 428 nm was continuously measured for 10^4 s, and its relaxation was analyzed by first-order kinetics. The absorption at infinite time was calculated from the FeP concentration and the extinction coefficient at 428 nm.

RESULTS AND DISCUSSION

Nitrosylation of rHSA-FeP. Upon the addition of NO (5 ppm in N_2) through the toluene solution of the five-coordinate FeP or six-coordinate carbonyl FeP, the UV-vis absorption spectrum immediately changed to the corresponding NO-adduct [$\lambda_{\max} = 415, 479(\text{sh}), 542$, and 610 nm]. The ESR and IR spectroscopies exhibited the formation of the six-coordinate nitrosyl complex in which the intramolecularly bound 2-methylimidazole does not dissociate from the central iron (Komatsu et al., 2000b). We have concluded that covalently attaching the imidazolyl group directly to the porphyrin periphery inhibits the proximal base elimination, which is triggered by the NO-binding to the trans side. The NO gas (1% in N_2) was then exposed to the phosphate buffer solution (pH 7.3) of rHSA-FeP. The UV-vis absorption spectrum showed maxima at 425 and 546 nm (Figure 1). The carbonyl rHSA-FeP, in which the incorporated FePs are six-coordinated carbonyl complex, also moved slowly to the same species after bubbling the NO gas. Further addition of the 100% CO gas to these solutions led to the spectral

changes in the carbonyl complexes ($\lambda_{\max} = 428, 541$ nm), indicating that (i) the nitrosylation of FeP is reversible and (ii) the central iron was not oxidized during the reaction. ESR spectroscopy was again employed to confirm the coordination structure of this nitrosyl rHSA-FeP. The absorption curve of the frozen solution at 77 K showed the characteristic shape of rhombic symmetry around the paramagnetic center and very similar to those of the nitrosyl Hb and Mb (Figure 2) (Yonetani et al., 1972). The obtained g values (g_1, g_{II-1}, g_3) are also in good agreement with those of the six-coordinate nitrosyl Hb, Mb, as well as FeP (Table 1) (Yonetani et al., 1972; Yoshimura, 1991). It is well-known that an ESR spectrum of the nitrosyl Hb is sensitive to the experimental conditions (pH, presence of IHP, etc.), especially, the spectral pattern directly correlates with the rupture of the iron(II)–imidazole bonding which is often seen during the nitrosylation of the T-state Hb (Scholler et al., 1979). If the imidazolyl moiety is dissociated from the central iron(II) of the FeP, the spectrum of the five-coordinate nitrosyl complexes become a sharp intense triplet associated with g_3 . However, this was not observed. On the basis of these findings, it can be concluded that FeP forms the six-coordinate nitrosyl complex with an intramolecularly bound 2-methylimidazolylalkyl arm in the albumin structure, as in the toluene solution.

NO-Binding Parameters of rHSA-FeP. The NO-binding affinity ($P_{1/2}^{\text{NO}}$) of Fe(II)porphyrin is usually determined by the ligand-exchange procedure, which requires the titration with NO of the carbonyl complex (Romberg et al., 1977). During the measurements of the toluene solution of FeP, the isosbestic points were clearly observed in the visible absorption spectra during the titration (not shown). In the case of the aqueous solution of rHSA-FeP, however, reproductions of the spectral changes were not obtained due to the partial denaturation of the albumin by the long gas bubbling into the solution. Therefore, the $P_{1/2}^{\text{NO}}$ of rHSA-FeP was finally calculated using the ratio of the association and dissociation rate constants of NO: $k_{\text{on}}^{\text{NO}}/k_{\text{off}}^{\text{NO}}$ (1.7×10^{-6} Torr), which was significantly lower than that of FeP itself ($P_{1/2}^{\text{NO}} = 1.8 \times 10^{-8}$ Torr in toluene).

The NO-association rate constants ($k_{\text{on}}^{\text{NO}}$) of rHSA-FeP can be obtained by laser flash photolysis techniques. The time dependence of the absorption decay at 445 nm after the laser flash irradiation showed second-order kinetics, which was independent of the monitoring wavelength and the laser pulse intensity (Figure 3). The $k_{\text{on}}^{\text{NO}}$ was determined to be $1.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$. Regarding the CO- and O_2 -rebinding to rHSA-FeP, the kinetics are composed of three phases, in which the long-lived biphasic decay corresponds to the direct recombination of CO and O_2 (Komatsu et al., 2000a). Two of the eight binding sites of FeP in rHSA are estimated to be the *slow sites* for the CO- and O_2 -associations, which is probably due to the steric restriction by the amino acid residues of the protein

interior. In contrast to these results, the kinetics of the NO-rebinding to rHSA-FeP displayed a monophasic decay, which can be fitted to a simple second-order equation (Figure 3 inset). On the other hand, the dissociation rate constant ($k_{\text{off}}^{\text{NO}}$) of NO was determined by the diluting method of a nitrosyl rHSA-FeP solution with sodium dithionite ($\text{Na}_2\text{S}_2\text{O}_4$) (Moore et al., 1976). The addition of excess CO to the dissociation mixture yields a single-exponential process that is substantially independent of the FeP and $\text{Na}_2\text{S}_2\text{O}_4$ concentrations (Figure 4). The obtained NO-binding parameters of rHSA-FeP are summarized in Table 2. Kinetically, the low NO-binding affinity of rHSA-FeP compared to that of FeP arises from the decreased association rate constant. It

has been widely recognized that the NO-binding to Fe-(II)porphyrin and natural hemoproteins are diffusion controlled (Hoshino et al., 1989; Rose et al., 1983; Traylor et al., 1992). In fact, the $k_{\text{on}}^{\text{NO}}$ value of FeP in toluene ($8.9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) approaches the value for a diffusion controlled reaction ($\sim 4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) (Amdur et al., 1966), and Hb and Mb have identical $k_{\text{on}}^{\text{NO}}$ values (approximately $1.7 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$), which are 10-fold lower than that of the naked protoheme-imidazole [Fe(II)-protoporphyrin(1-methylimidazole)] (Rose et al., 1983). Interestingly, a similar decrease is observed in our synthetic hemoproteins, i.e., incorporation of FeP into the albumin matrix restricts the NO access to the central iron which led to 60-fold reduction in its NO-association rate.

In conclusion, synthetic hemoprotein, rHSA-FeP, forms a nitrosyl adduct upon addition of NO at ambient temperature, in which FePs are six-coordinate nitrosyl complexes with a proximal imidazole. The NO-binding affinity of rHSA-FeP at pH 7.3 was significantly lower than that of FeP itself, which is mainly due to the decreased association rate constant. This result demonstrates that incorporation of FePs into the albumin structure retards NO association to the central iron as similarly observed in Hb and Mb. As a red cell substitute, the NO-binding affinity of rHSA-FeP is still 9-fold higher compared to the Hbs. Consequently, there is a concern that an infusion of this cell-free type O_2 -carrier into the blood streams may induce the hypertensive effect. However, the preliminary experiments on the responses to administration of rHSA-FeP solution into anesthetized rats showed negligibly small increases in the systemic blood pressure. For this reason, it is noteworthy that the permeability of serum albumin through the muscle capillary pores is less than 1/100 that of Hb, because of its negative charges on the molecular surface ($\text{pI} = 4.8$) (Guyton, 1986). We now expect that rHSA-FeP can circulate in the blood vessels for a relatively longer time without extravasation, due to the electrostatic repulsion between the albumin and the surface of the glomerular basement membrane. If this is true, the albumin based O_2 -carrier may become a promising material as a new type of red cell substitute. To obtain insight into this hypothesis, further in vivo experimental study is now in progress.

A New Approach to the Synthesis of APTRA Indicators

Pieter A. Otten, Robert E. London, and Louis A. Levy*

National Institute of Environmental Health Sciences, Laboratory of Structural Biology, P.O. Box 12233, MR-01, Research Triangle Park, North Carolina 27709. Received June 13, 2000;
Revised Manuscript Received November 5, 2000

We have devised a general synthesis of Mg^{2+} indicators which is based on the aminophenol triacetic acid (APTRA) structure. The key step is a palladium-catalyzed coupling reaction of a precursor of the APTRA ligand with a fluorescent group. This strategy resulted in new ratioable fluorescent APTRA indicators and the finding that the fluorescence response of these indicators is different for Mg^{2+} and Ca^{2+} in some cases. We believe that this represents a generally useful approach for combining fluorophore and chelator functionalities.

INTRODUCTION

Fluorescent probes have proven to be valuable tools for the determination of the concentration of free metal ions in the cell cytosol (1) and have provided important insight into the function of these ions. As an analytical methodology, fluorescence spectroscopy is an attractive technique as it is very sensitive and only minute intracellular amounts of the indicator are necessary to obtain good signal-to-noise ratios. Intracellular loading of a fluorescent probe leaves the cells intact (in contrast to atomic absorption spectroscopy), thereby allowing one to study the functioning cell. Fluorescent probes can be used to study whole cell populations, single cells, or even subcellular domains. Time dependent changes in intracellular ion distribution can be studied with high spatial and temporal resolution. Fluorescent indicators can also be used in conjunction with flow cytometry to sort cells on the basis of their free metal content or other properties.

Magnesium, the most abundant divalent metal ion in tissues, participates in a broad range of biochemical and regulatory processes. Magnesium ions are involved in many important functions in the cell such as enzyme activity, the conformation of DNA, ion transport through the cell membrane, the maintenance of cell shape, and in signaling pathways (2). Magnesium ions are essential cofactors for most of the ATP-dependent phosphorylation reactions which take place in the cell. Furthermore, the distribution of cytosolic magnesium and subcellular magnesium appears to be important in cell cycle control and regulation of cell differentiation (3).

Mag-fura-2 (1) [also known as FURAPTRA (4)], Mag-fura-5 (1), and Mag-indo (1) are three, widely used, commercially available, fluorescent probes for magnesium. A literature search revealed that in the period 1997–1998, over 40 papers have described the use of these indicators. In some recent literature examples, fluorescent indicators have been used to study the mechanism of Mg^{2+} transport across the cell membrane (5–8); to determine the influence of hormones on Mg^{2+} regulation in the cell (9–12); and in the investigation of this ion's role in the fructose-induced activation of

glycogen phosphorylase (13). The use of Mag-fura 2 has revealed the high levels of cytosolic free Mg^{2+} in platelets of patients with essential hypertension (14) and vasospastic angina (15).

An important and desirable feature of Mag-furas and Mag-indo is that they are ratioable indicators. Upon binding Mg^{2+} , the excitation maximum (of all three indicators) and the emission maximum (Mag-indo) of the indicator-cation complex display a significant wavelength shift relative to the free indicator (1, 4, 16–18). This allows the ion concentration to be measured as a function of the ratio of the fluorescence at two different wavelengths, preferably the fluorescence maxima of both species (16). By using a ratioable fluorophore, the measurements of Mg^{2+} are not influenced by variations in the efficiency of the instrument and the dye concentration in the cell (18). Other commercially available fluorescent probes (1), Magnesium Green, Magnesium Orange, and Mag-Fura Red, are not ratioable but have excitation wavelengths in the visible region thereby eliminating the interference from the fluorescence of intracellular chromophores (18).

The chelating moiety of the magnesium probes is based on the aminophenol triacetic acid (APTRA) structure, which was developed for this purpose by Levy et al. (19). At physiological pH, the deprotonated carboxylate groups, the anilino nitrogen atom, and the ether oxygen are all available for complexation (19). The dissociation constants (K_D^{Mg}), determined in vitro, of APTRA indicators fall in the low millimolar range [1.0–3.9 mM at physiological pH (1)]. These values correspond well with the low and submillimolar levels of cytosolic free Mg^{2+} (2), and thus, one can make use of the optimum sensitivity of the fluorophores. Care must be taken in using in vitro determined K_D^{Mg} values as recent publications on the in vivo calibration of APTRA-type indicators, reported higher K_D^{Mg} values [5.2 mM for Mag-indo (20) and 5.4 mM for Mag-fura-2 (21)]. It should also be noted that APTRA chelators have a higher affinity for Ca^{2+} than for Mg^{2+} ; the K_D^{Ca} values were found to be around 30 μM . However, these values are 2 orders of magnitude higher than basal, free Ca^{2+} levels (17), and calcium, found at levels of about 100 nM, does not interfere with magnesium measurements under normal conditions. However, APTRA indicators also have been used as low affinity

Scheme 1. Retrosynthetic Approach to an APTRA Indicator

Ca^{2+} indicators (22–24). In addition, APTRA-type fluorophores can be applied to measure Zn^{2+} and Cd^{2+} (1). Recently, Prodi et al. has reported a nonratioable fluorescent 1,10-diaza-18-crown-6 with a higher affinity for Mg^{2+} over Ca^{2+} (25).

For the chelator to have fluorescent properties, the APTRA unit is connected to a reporter group, preferably a polyaromatic group, or the APTRA chelator may be incorporated as part of a polyaromatic structure. The development of new fluorescent magnesium indicators has been limited because of the lack of an efficient and general synthesis of these compounds. The present approach of a unique synthesis for each candidate is unattractive because the fluorescent response of an indicator upon metal complexation is unpredictable. From a retrosynthetic perspective, a general approach to the synthesis of new APTRA fluorophores would employ in one step, the joining of an APTRA chelator, or some precursor thereof, with a fluorescent group. The method of choice for the formation of such a carbon–carbon bond between two aryl groups is a palladium catalyzed coupling reaction (26). A coupling reaction, catalyzed by an appropriate palladium catalyst, between triflate **1** ($\text{X} = \text{OTf}$) and an organometallic reaction partner **2**, carrying the fluorescent group, would give the basic structure of a new fluorophore (Scheme 1). Further elaboration of the obtained protected nitrophenol through established chemistry would afford the desired APTRA indicator.

Using the strategy described above, we have synthesized three new fluorescent APTRA chelators carrying a naphth-1-yl, a naphth-2-yl, and a benzo[*b*]fur-2-yl substituent. The fluorescent response of these three fluorophores was found to depend strongly on the nature of the polyaromatic group and on whether the chelated ion is Mg^{2+} or Ca^{2+} .

EXPERIMENTAL PROCEDURES

General Remarks. Tetrahydrofuran (THF) was dried and distilled (Na/benzophenone) prior to use. Dimethylformamide (DMF) was dried over freshly activated (300 °C) molecular sieves (4 Å) and acetonitrile was distilled from P_2O_5 . NaI was dried at 100 °C in vacuo. Ethyl acetate, hexane, diethyl ether, and all other commercially available chemicals were used as received. After extractive workup, the combined organic phases were dried over MgSO_4 . Water used in the UV and fluorescence experiments was filtered through a Hydro Picopure2 filter. Thin-layer chromatography was carried out on Sigma-Aldrich TLC Plates. Chromatographic purifications were done by flash chromatography using Merck Silica Gel, grade 9385, 230–400 mesh, 60 Å. Melting points were measured on a Fisher-Johns melting point apparatus and are uncorrected. ^1H NMR spectra and ^{13}C NMR spectra were recorded on a Nicolet NT 360 MHz NMR Spectrometer and a Varian UNITY plus 400 MHz NMR Spectrometer. Chemical shifts are reported in parts per million (δ), using TMS as an internal standard, and signals are

expressed as an s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), or br (broad). UV spectra were recorded with a Beckman DU 640 Spectrophotometer using Fisherbrand semimicro quartz cells (Fisher Scientific). Fluorescence measurements were recorded with an Aminco-Bowman Series 2 Spectrometer using quartz fluorimeter cuvettes from Sigma.

2-Benzyloxy-4-fluoro-nitrobenzene (4). To a suspension of K_2CO_3 (5.18 g, 38 mmol) in 15 mL of DMF was added 2-nitro-5-fluorophenol (**3**) (3.93 g, 28 mmol) in one portion at room temperature. After gas evolution ceased, the temperature of the bright orange reaction mixture was raised to 70 °C and a solution of benzyl bromide (3.25 mL, 28 mmol) in 10 mL of DMF was added rapidly. After 4 h, TLC (10% EtOAc in hexane) indicated complete conversion of the starting material. The reaction mixture was poured into water and extracted three times with Et_2O . The combined organic layers were washed twice with water. Evaporation of the solvent in vacuo gave a viscous yellow oil (5.96 g, 95%) which slowly solidified at room temperature, mp 58–60 °C. ^1H NMR (CDCl_3) δ 5.22 (s, 2H), 6.72 (ddd, 1H, $J = 2.6$ Hz, $J = 7.0$ Hz, $J = 9.1$ Hz), 6.82 (dd, 1H, $J = 2.6$ Hz, $J = 10.2$ Hz), 7.32–7.48 (m, 5H), 7.95 (dd, 1H, $J = 5.9$ Hz, $J = 10.2$ Hz). ^{13}C NMR (CDCl_3) δ 72.52, 103.88 (d, $J = 26$ Hz), 108.70 (d, $J = 24$ Hz), 128.02, 129.10, 129.22, 129.52, 129.88, 135.87.

3-Benzyloxy-4-nitrophenol (5). To a solution of **4** (4.36 g, 17 mmol) in 50 mL of DMSO was added 11 mL of a 20% NaOH solution which resulted in a mildly exothermic reaction. The orange reaction mixture was stirred overnight and TLC (10% EtOAc in hexane) indicated complete consumption of the starting material. The reaction mixture was poured into 250 mL of water containing 5 mL of concentrated HCl and extracted three times with Et_2O . The combined organic layers were washed two times with water. Evaporation of the solvent gave **5** as a yellow solid (4.04 g, 95%), mp 134–6 °C. ^1H NMR (CDCl_3) δ 5.21 (s, 2H), 6.44 (dd, 1H, $J = 2.6$ Hz, $J = 9.0$ Hz), 6.55 (d, 1H, $J = 2.2$ Hz), 7.22–7.40 (m, 5H), 7.95 (d, 1H, $J = 9.2$ Hz). ^{13}C NMR (CDCl_3) δ 72.00, 102.34, 107.66, 126.94, 128.23, 128.42, 128.71, 135.49, 154.84, 160.97. One quaternary carbon not observed.

2-Benzyloxy-4-(trifluoromethyl)sulfonyl-nitrobenzene (1). A solution of **5** (3.92 g, 16 mmol) in a mixture of 25 mL CH_2Cl_2 , distilled from CaH_2 , and 10 mL of pyridine was cooled with an ice-bath. Over a period of 1 h, a solution of trifluoromethanesulfonic anhydride (5 g, 18 mmol) in 15 mL of CH_2Cl_2 was added. The reaction mixture was allowed to warm to room temperature and stirring was continued overnight. Subsequently, 25 mL of water and 100 mL of CH_2Cl_2 was added. The organic layer was separated and washed twice with 10% HCl. The organic layer was then washed twice with water. Evaporation of the solvent resulted in a yellow oil which was further purified by flash chromatography (30% EtOAc in hexane) to give a pale yellow oil which slowly solidified upon standing at room temperature (4.87 g, 80%), mp 56–8 °C. ^1H NMR (CDCl_3) δ 5.25 (s, 2H), 6.96 (dd, 1H, $J = 2.6$ Hz, $J = 8.9$ Hz), 7.03 (d, 1H, $J = 2.4$ Hz), 7.30–7.50 (m, 5H), 7.96 (d, 1H, $J = 9.1$ Hz). ^{13}C NMR (CDCl_3) δ 72.18, 109.00, 113.26, 118.66 (q, $J = 320$ Hz), 127.14, 127.19, 128.66, 128.84, 134.30, 139.64, 151.97, 153.21.

2-[3-Benzyloxy-4-nitrophenyl]benzo[*b*]furane (7a). A 50 mL three-necked, round-bottomed flask, well-purged with argon, was charged with **1** (1.31 g, 3.70 mmol), benzo[*b*]furan-2-boronic acid (**6a**) (470 mg, 3.0 mmol), $\text{Pd}[\text{P}(\text{C}_6\text{H}_5)_3]_4$ (20 mg, 0.017 mmol), 1 M Na_2CO_3 (5 mL) and

10 mL of DME. The reaction mixture was heated for 4.5 h at 80 °C, cooled, poured into water and extracted three times with CH_2Cl_2 . Evaporation of the solvent gave an orange solid which was crystallized twice from benzene to give **7a** as bright yellow crystals (782 mg, 75%), mp 137–9 °C. ^1H NMR (CDCl_3) δ 5.37 (s, 2H), 7.20–7.70 (m, 12H), 7.99 (d, 1H, J = 8.5 Hz), ^{13}C NMR (CDCl_3) δ 71.77, 104.72, 111.42, 117.03, 121.53, 123.51, 125.65, 126.39, 126.46, 127.18, 128.31, 128.72, 135.52, 135.99, 152.73, 153.32, 155.39. One quaternary carbon not observed. MS: (m/z) 345.0994, required for $\text{C}_{21}\text{H}_{15}\text{NO}_4$ 345.1001.

1-[3-Benzyloxy-4-nitrophenyl]naphthalene (7b).

In a manner similar to the preparation of **7a**, compound **7b** was prepared and isolated pure (91%) as a white powder by flash chromatography (10% EtOAc in hexane), mp 115–8 °C. ^1H NMR (CDCl_3) δ 5.28 (s, 2H), 7.18 (dd, 1H, J = 1.7 Hz, J = 8.1 Hz), 7.30–7.50 (m, 6H), 7.50–7.60 (m, 2H), 7.69 (d, 1H, J = 8.8 Hz), 7.93 (d, 1H, J = 8.1 Hz), 7.94 (d, 1H, J = 8.1 Hz), 8.02 (d, 1H, J = 8.1 Hz). ^{13}C NMR (CDCl_3) δ 71.42, 117.23, 122.33, 125.13, 125.19, 125.62, 126.11, 126.67, 126.76, 127.05, 128.17, 128.46, 128.67, 128.81, 130.97, 133.83, 135.53, 137.95, 147.12, 151.66. MS: (m/z) 355.1233; required for $\text{C}_{23}\text{H}_{17}\text{NO}_3$, 355.1208.

2-[3-Benzyloxy-4-nitrophenyl]naphthalene (7c).

In a manner similar to the preparation of **7a**, compound **7c** was prepared and isolated pure (92%) as an off-white powder by flash chromatography (10% EtOAc in hexane), mp 114–6 °C. ^1H NMR (CDCl_3) δ 5.36 (s, 2H), 7.30–7.46 (m, 5H), 7.50–7.58 (m, 4H), 7.64 (dd, J = 9 Hz, J = 1.5 Hz), 7.84–8.08 (m, 5H). ^{13}C NMR (CDCl_3) δ 71.71, 114.54, 119.69, 124.83, 126.27, 126.59, 126.76, 126.79, 127.15, 127.70, 128.26, 128.34, 128.71, 128.87, 133.28, 133.48, 135.67, 136.38, 139.26, 147.39, 152.44. MS: (m/z) 355.1196; required for $\text{C}_{23}\text{H}_{17}\text{NO}_3$, 355.1208.

2-(3-Hydroxy-4-aminophenyl)benzo[b]furan-*N,N*,*O*-triacetic acid trimethylester (9a). Compound **7a** (345 mg, 1.00 mmol) and 100 mg of 5% Pd on C were suspended in 25 mL of ethanol. This reaction mixture was hydrogenolyzed over 16 h in a Parr apparatus at an initial H_2 pressure of 30 psi. The reaction mixture was filtered and the solvent evaporated in vacuo. TLC (50% EtOAc in hexane) indicated complete consumption of the starting material and ^1H NMR of the crude product confirmed complete removal of the benzyl group. The crude aminophenol **8a** was dissolved in 10 mL of acetonitrile and transferred to a 100 mL oven-dried, three-necked, round-bottomed flask, equipped with a stirring bar and oven-dried condenser and charged with NaI (1.0 g, 6.7 mmol), Proton Sponge (1.7 g, 7.9 mmol), and methyl bromoacetate (1.0 mL, 10 mmol). The reaction mixture was refluxed for 16 h under an argon atmosphere, allowed to cool to room temperature, and poured into 200 mL of Et_2O . The resulting white suspension was filtered and the filtrate was washed with 50 mL portions of buffer (pH 2, Hydriion), until the aqueous layer remained acidic. The ether layer was dried, filtered and 5 g of silica gel was added. After evaporation of the solvent, the silica gel was loaded on a pre-packed column (33% EtOAc in hexane). Triester **9a** was obtained as a colorless oil (210 mg, 47% overall). ^1H NMR (CDCl_3) δ 3.75 (s, 6H), 3.82 (s, 3H), 4.26 (s, 4H), 4.76 (s, 2H), 6.87 (s, 1H), 6.92 (d, 1H, J = 8.5 Hz), 7.20–7.28 (m, 2H), 7.30 (d, 1H, J = 1.5 Hz), 7.42 (dd, 1H, J = 1.8 Hz, J = 8.2 Hz), 7.49 (d, 1H, J = 8.2 Hz), 7.54 (d, 1H, J = 8.7 Hz). ^{13}C NMR (CDCl_3) δ 51.70, 52.07, 53.82, 66.56, 100.29, 110.96, 111.88, 119.80, 119.85, 120.59, 122.84, 123.87, 124.84, 129.40, 140.07, 149.67, 154.75, 155.60, 168.98, 171.35. MS: (m/z) 441.1400; required for $\text{C}_{23}\text{H}_{23}\text{NO}_3$, 441.1424.

1-(3-Hydroxy-4-aminophenyl)naphthalene-*N,N*,*O*-triacetic Acid Trimethylester (9b). In a manner similar to the preparation of **9a**, compound **9b** was obtained as a colorless oil (64% overall yield) by flash chromatography (25% EtOAc in hexane). ^1H NMR (CDCl_3) δ 3.76 (s, 3H), 3.77 (s, 6H), 4.30 (s, 4H), 4.68 (s, 2H), 6.93 (d, 1H, J = 2.0 Hz), 6.98 (d, 1H, J = 8.4 Hz), 7.07 (dd, 1H, J = 2.0 Hz, J = 8.4 Hz), 7.37 (dd, 1H, J = 0.8 Hz, J = 7.0 Hz), 7.41 (ddd, 1H, J = 1.6 Hz, J = 6.8 Hz, J = 8.4 Hz), 7.45–7.50 (m, 2H), 7.82 (d, 1H, J = 8.0 Hz), 7.88 (d, 1H, J = 8.8 Hz), 7.91 (d, 1H, J = 8.8 Hz). ^{13}C NMR (CDCl_3) δ 52.89, 53.16, 54.69, 67.13, 117.47, 120.36, 125.27, 126.40, 126.81, 127.02, 127.07, 127.83, 128.54, 129.30, 132.67, 134.86, 135.87, 139.72, 140.61, 150.12, 170.22, 172.89. MS: (m/z) 451.1621; required for $\text{C}_{25}\text{H}_{23}\text{NO}_7$, 451.1631.

2-(3-Hydroxy-4-aminophenyl)naphthalene-*N,N*,*O*-triacetic Acid Trimethylester (9c). In a manner similar to the preparation of **9a**, compound **9c** was obtained as a colorless oil (51% overall yield) by flash chromatography (25% EtOAc in hexane). ^1H NMR (CDCl_3) δ 3.75 (s, 6H), 3.81 (s, 3H), 4.27 (s, 4H), 4.77 (s, 2H), 7.00 (d, 1H, J = 8.0 Hz), 7.18 (d, 1H, J = 2.0 Hz), 7.31 (dd, 1H, J = 2.0 Hz, J = 8.0 Hz), 7.43–7.51 (m, 2H), 7.65 (dd, 1H, J = 2.0 Hz, J = 8.4 Hz), 7.85 (dd, 1H, J = 9.6 Hz, J = 9.6 Hz), 7.87 (d, 1H, J = 8.8 Hz), 7.93 (s, 1H). ^{13}C NMR (CDCl_3) δ 52.90, 53.24, 54.68, 67.50, 115.34, 121.08, 122.79, 126.19, 126.34, 126.85, 127.36, 128.68, 129.13, 129.45, 133.50, 134.71, 136.55, 138.85, 140.06, 150.89, 170.50, 172.73. MS: (m/z) 451.1618, required for $\text{C}_{25}\text{H}_{23}\text{NO}_7$, 451.1631.

2-(3-Hydroxy-4-aminophenyl)benzo[b]furan-*N,N*,*O*-triacetic Acid (10a). In a 25 mL round-bottomed flask, equipped with a condenser, triester **9a** (60 mg, 0.17 mmol) was suspended in a mixture of 2 mL of methanol and 2 mL of 1 M NaOH. The reaction mixture was refluxed for 4 h and allowed to cool to room temperature. The solvent was evaporated in vacuo and the remaining solid material was dissolved in 2 mL of water to give a clear yellow solution. The aqueous solution was cooled with a ice-bath and acidified with 1 M HCl to pH 3. Stirring was continued for 15 min. The precipitate was collected by filtration and dried in vacuo over P_2O_5 to give 50 mg (89%) of an off-white powder which decomposes above 240 °C. ^1H NMR ($\text{DMSO}-d_6$) δ 3.53 (s, 4 H), 4.17 (s, 3 H), 6.73 (d, 1H, J = 8.4 Hz), 6.76 (s, 1H), 6.90 (d, 1H, J = 1.7 Hz), 7.02–7.10 (m, 3H), 7.28 (d, 1H, J = 8.0 Hz), 7.37 (d, 1H, J = 7.0 Hz). ^{13}C NMR [D_2O (1.0 mL and 50 μL of 40% NaOD)] δ 57.78, 68.67, 100.85, 110.44, 111.94, 118.81, 119.31, 121.86, 123.36, 124.15, 125.03, 130.38, 150.39, 155.27, 156.91, 178.12, 180.42.

1-(3-Hydroxy-4-aminophenyl)naphthalene-*N,N*,*O*-triacetic acid (10b). In a manner similar to the preparation of **10a**, triacid **10b** was obtained as an off-white powder (57%), which decomposes above 230 °C. ^1H NMR [D_2O (1.0 mL, and 50 μL of 40% NaOD)] δ 3.68 (s, 4H), 4.33 (s, 2H), 6.83 (d, 1H, J = 8.3 Hz), 6.95 (s, 1H), 7.08 (d, 1H, J = 7.7 Hz), 7.30–7.48 (m, 2H), 7.55 (d, 1H, J = 8.0 Hz), 7.60–7.80 (m, 3H), 7.83 (s, 1H). ^{13}C NMR [D_2O (1.0 mL and 50 μL of 40% NaOD)] δ 58.13, 68.54, 112.50, 119.65, 121.01, 125.42, 126.00, 127.09, 127.62, 128.59, 129.05, 129.47, 133.07, 134.74, 138.34, 140.55, 150.93, 171.97, 180.33.

2-(3-Hydroxy-4-aminophenyl)naphthalene-*N,N*,*O*-triacetic acid (10c). In a manner similar to the preparation of **10a**, triacid **10c** was obtained as a slightly pink powder (49%), which decomposes above 250 °C. ^1H NMR [D_2O (1.0 mL, and 50 μL of 40% NaOD)] δ 3.86 (s, 4H), 4.44 (s, 2H), 6.87 (s, 1H), 6.92 (d, 1H, J = 8.42 Hz), 6.99

Table 1. Spectroscopic Data and K_D Values of Indicators 10a–c

compd	abs. max (nm)	Mg^{2+}			Ca^{2+}		
		λ_{emiss} (nm) ^b	λ_{excit} (nm) ^{b,c}	K_D (mM)	λ_{emiss} (nm)	λ_{excit} (nm) ^{b,c}	K_D (μ M)

^a Absorption maximum of the free indicator. ^b An arrow denotes a shift of the fluorescence maximum upon ion complexation. ^c The emission wavelength used is given in brackets.

(d, 1H, $J = 7.7$ Hz), 7.40–7.58 (m, 4H), 7.87 (d, $J = 8.05$, 1H), 7.90–8.02 (m, 2H). ^{13}C NMR [D_2O (1.0 mL and 50 μ L of 40% NaOD)] δ 57.91, 68.51, 115.75, 118.88, 123.81, 126.77, 126.84, 127.22, 127.49, 127.92, 128.44, 129.37, 132.04, 134.06, 134.62, 140.22, 140.53, 150.33, 178.05, 180.61.

Fluorescence Measurements. The buffered solutions used in all experiments contained 120 mM KCl, 20 mM NaCl, and 15 mM Tris and were brought to pH 7.20 with concentrated HCl. Using sonication, a stock solution of indicator **10b** was prepared by dissolving 3.2 mg (7.8 μ mol, 1.6 mM) in 5 mL of buffer. To record a UV spectrum, the stock solution of **10b** was diluted 40 times (25 μ L in 975 μ L of buffer). For the fluorescence titration experiments, 25 μ L of stock solution was diluted 100 times (to 16 μ M) with 2475 μ L of buffer. A fluorescence emission and a fluorescence excitation spectrum were recorded (for excitation and emission wavelengths, see Table 1). To 2475 μ L of 500 mM $MgCl_2$ solution was added 25 μ L of stock solution of the indicator. To the solution of the free indicator, increasing amounts of the $MgCl_2$ /indicator solution (5, 10, 20, 40, 80, and 160 μ L) were added and after each titration step, a fluorescence emission and a fluorescence excitation spectrum were recorded. In the case of a fluorescence titration with $CaCl_2$, a 1 mM solution was used and portions of 5, 10, 20, 40, 80, 160, 320, and 320 μ L of the $CaCl_2$ /indicator solution were added. Using this procedure, fluorescence titrations of indicators **10a**, and **10c** were performed with stock solutions of these indicators of 0.81 and 0.54 mM, respectively.

The corresponding dissociation constants (K_D^{Mg} and K_D^{Ca}) were determined from the fluorescence/titration experiments as follows. In the case of Mg^{2+} , the free Mg^{2+} concentration, $[Mg^{2+}]$, was approximated by the total Mg^{2+} added, since the correction for bound Mg^{2+} is minimal. The data were fit to a straight line according to

$$[Mg^{2+}] = K_D^{Mg} \left[\frac{(F - F_0)}{(F_{sat} - F)} \right] \quad (1)$$

where F is the fluorescence at a given wavelength (preferably the fluorescence maximum) and at a given $[Mg^{2+}]$, and F_0 and F_{sat} are the fluorescence values for zero and saturating Mg^{2+} . For a ratioable indicator, with fluorescence maxima at λ_1 and λ_2 for the free and metal-bound indicator, respectively, the data were fit to a straight line applying the following equation:

$$[Mg^{2+}] = K_D^{Mg} \left[\frac{(R - R_0)}{(R_{sat} - R)} \right] \left(\frac{F_{0,\lambda_2}}{F_{sat,\lambda_2}} \right) \quad (2)$$

where R is the ratio of the fluorescence values at λ_1 and λ_2 at a given $[Mg^{2+}]$, R_0 and R_{sat} are the ratios at zero and saturating Mg^{2+} , and F_{0,λ_2} and F_{sat,λ_2} represent the fluorescence values of the free and saturated indicator at λ_2 .

Scheme 2. Synthesis of Triflate 1

Scheme 3. Suzuki Coupling of 1

Scheme 4. Completion of the APTRA Synthesis

Since for Ca^{2+} binding, the Ca^{2+} dissociation constant, K_D^{Ca} , is of the same order of magnitude as the indicator concentration, the data were analyzed using a two parameter fit using Mathematica to fit a nonlinear function according to

$$F_{obs} = F_F(1 - p_B) + F_B p_B \quad (3)$$

where F_{obs} is the observed intensity of the fluorescence at the measured wavelength, F_F and F_B are the indicator fluorescence values of the uncomplexed and Ca^{2+} -complexed forms, and p_B the fraction of indicator bound to Ca^{2+} . The latter were calculated from the equilibrium equation assuming 1:1 binding stoichiometry:

$$p_B = \frac{Ca - I}{I_0} \quad (4)$$

leading to

Figure 1. Fluorescent responses of compound 10b to Mg^{2+} and Ca^{2+} . (A) Emission spectra as a function of $[\text{Mg}^{2+}]$ (in mM), excitation at 310 nm; (B) emission spectra as a function of $[\text{Ca}^{2+}]$ (in μM), excitation at 310 nm; (C) Excitation spectra as a function of $[\text{Mg}^{2+}]$ (in mM), emission measured at 499 nm; (D) Excitation spectra as a function of $[\text{Ca}^{2+}]$ (in μM), emission measured at 499 nm. Spectra obtained at 20 °C.

$$p_B = (I_0 + K_D^{\text{Ca}} + [\text{Ca}^{2+}] - \sqrt{(I_0 + K_D^{\text{Ca}} + [\text{Ca}^{2+}])^2 - 4I_0[\text{Ca}^{2+}]})/2 \quad (5)$$

where I_0 is the total indicator concentration, the two parameters to be fit are the fluorescence of the Ca^{2+} -indicator complex, F_B , and the Ca^{2+} -indicator dissociation constant, K_D^{Ca} . The value of F_F is obtained directly from the spectrum of the sample in the absence of added calcium.

SYNTHESIS

Triflate **1** was obtained in three steps (Scheme 2) starting from commercially available 2-nitro-5-fluorophenol **3**. The starting phenol **3** was protected as its benzyl ether **4** by a reaction with benzyl bromide in DMF/ K_2CO_3 . The crude benzyl ether proved to be sufficiently pure for further manipulation. The key step in the synthesis of **1** stems from the realization that the electron-poor aromatic ring of compound **4** readily un-

Figure 2. Fluorescent excitation spectra for compound 10c. (A) as a function of $[Mg^{2+}]$ (in mM), emission measured at 498 nm; (B) as a function of $[Ca^{2+}]$ (in μM), emission measured at 498 nm. Spectra obtained at 20 °C.

dergoes a nucleophilic aromatic substitution at the carbon bound to fluorine. Thus, when **4** was subjected to NaOH in DMSO/H₂O at room temperature, the fluorine substituent was replaced by a hydroxyl group to give phenol **5** in quantitative yield. Phenol **5** is then converted to the triflate **1** in good yield. Protection of the phenol **3** as its benzyl ether serves two purposes. First, it prevents deprotonation of the phenol which would prevent the substitution reaction from taking place. Second, it allows a regioselective preparation of triflate **1** via the newly created hydroxyl group *para* to the nitro substituent of **4**.

Standard conditions for the Suzuki-coupling reaction (Scheme 3) of boronic acids **6a–c** with triflate **1** were employed (27). It was found that using the weaker base NaHCO₃ instead of Na₂CO₃ did not result in conversion of **1**. Consumption of **1** was complete after several hours at 80 °C in all cases studied. The coupling products were obtained pure and in excellent yields after extractive workup, followed by flash chromatography. The highly crystalline nature of benzo[*b*]fur-2-yl derivative **7a** allowed its purification by crystallization from benzene.

Reduction of the nitro group and deprotection of the adjacent benzyl ether of compounds **7a–c**, was accomplished in one step by palladium-catalyzed hydrogenation and debenzylation in ethanol. The ¹H NMR spectrum of the crude products showed that complete reduction/deprotection was achieved after 16 h. The use of ethyl acetate, although a better solvent, led to incomplete removal of the benzyl ether. The crude aminophenol derivatives **8a–d** were found to be sufficiently pure for further manipulation. Alkylation of aminophenols **8a–d** with methyl bromoacetate was achieved in refluxing acetonitrile in the presence of Proton Sponge and sodium iodide. After extractive workup and flash chromatography the corresponding triesters **9a–d** were obtained in good overall yields (Scheme 4). It was found that the use of carefully dried acetonitrile and the use of NaI (to form, in situ, the more reactive methyl iodoacetate) were necessary for success of this reaction.

The triesters were readily saponified in refluxing aqueous MeOH/NaOH. After acidic workup, tri-acids **10a–c**, R²=H were isolated in a pure state by filtration.

FLUORESCENCE

The emission and excitation fluorescence spectra of **10a–c** were recorded using 5.4–16 μM solutions of the chelator, buffered at pH 7.2. The solutions also contained 120 mM KCl and 20 mM NaCl to mimic the ionic strength of the intracellular milieu. These solutions were titrated with stock solutions of MgCl₂ or CaCl₂ containing an equimolar concentration of the APTRA chelator to cancel out dilution effects during the titration. After each titration step, both the emission and excitation fluorescence spectra were recorded.

The dissociation constants of indicators **10a–c** for Mg²⁺ were determined as originally described by Grynkiewicz et al. (18). It should be noted that the micromolar range concentrations of the APTRA indicators used here are of the same order of magnitude as the expected *K_D*s for Ca²⁺. We found that when using APTRA concentrations in the nanomolar range for the fluorescence titrations with Ca²⁺, the likely presence of trace metal impurities in the materials used caused nonreproducible fluorescent responses. We therefore chose to apply higher indicator concentrations to minimize the influence of trace metal impurities on the total fluorescence. That the problem was with the adventitious trace metals was confirmed by the fact that addition of EGTA—to capture trace metal impurities—to micromolar solutions of the free indicator did not change the fluorescence intensities. The *K_D* values for Ca²⁺ were determined by applying a nonlinear least-squares module of Mathematica (see Experimental Procedures). Table 1 shows the results of the spectral analysis of indicators **10a–c**. Because of the buffering effect of the indicator on the Ca²⁺ concentration, it is not possible to compare changes in the fluorescence intensities to those observed with Mg²⁺.

RESULTS

Indicator **10a** proved to be a nonratioable fluorescent indicator for Mg^{2+} and Ca^{2+} . The change in fluorescent response to increasing Mg^{2+} concentrations of APTRA chelator **10a**, carrying a benzo[*b*]fur-2-yl group, is small. Upon saturation of the chelator with Mg^{2+} , the fluorescence emission intensity increases 25%. In addition, a small shift of the emission maximum from 407 to 416 nm is observed. The change in fluorescence response to increasing Ca^{2+} concentrations is similar. When saturated with Mg^{2+} , the fluorescence excitation maximum of **10a** at 340 nm displays an overall decrease of its intensity. In addition, a shift of the excitation fluorescence maximum to 328 nm from 340 nm is observed. An identical shift of the excitation fluorescence maximum of **10a** upon an increase of the Ca^{2+} concentration was found.

Figures 1 and 2 show the titration/fluorescence spectra of compounds **10b** and **10c** with Mg^{2+} and Ca^{2+} . The emission fluorescence spectrum of naphth-1-yl-substituted APTRA ligand **10b** shows two maxima at 358 and 499 nm (Figure 1A). Saturation of the chelator with Mg^{2+} results in an increase of the fluorescence intensities at both wavelengths; a 7-fold increase at 358 nm and a 1.8-fold increase at 499 nm are observed. No shifts of either emission maxima were found. Titration of **10b** with Ca^{2+} resulted in a different response in its fluorescence spectrum (Figure 1B). The fluorescence intensity at 362 nm increased, as was observed with Mg^{2+} , but the fluorescence intensity at 500 nm was found to decrease upon increasing Ca^{2+} concentration. An isosbestic point was found at 400 nm. Thus, APTRA chelator **10b** is a ratioable indicator for Ca^{2+} . Titration of **10b** with Mg^{2+} and measurement of its fluorescence excitation spectra shows that this APTRA derivative can be used as a ratioable indicator (Figure 1C). The excitation fluorescence at 325 nm (emission observed at 499 nm), corresponding to the free chelator, decreases upon complexation whereas a peak at 295 nm of the Mg^{2+} complex appears and increases in intensity upon further titration. An isoexcitation point was observed at 318 nm. In contrast, upon titration with Ca^{2+} , the fluorescence excitation spectrum displayed a different behavior. Again, the intensity of the excitation fluorescence at 325 nm decreases with increasing Ca^{2+} concentration (emission observed at 499 nm), while there is a very small increase in intensity of the excitation fluorescence at lower wavelengths (Figure 1D), in contrast with the case of a titration with Mg^{2+} (Figure 1C). This difference between the responses of the fluorescence excitation of **10b** could allow one to make a distinction between changes in Mg^{2+} or Ca^{2+} levels in the cell. In the latter case, a change in fluorescence excitation at 325 nm will not be accompanied by a change in fluorescence at 295 nm.

In contrast to the naphth-1-yl-substituted APTRA chelator, the naphth-2-yl-substituted derivative **10c** shows only one maximum in its emission spectrum at 498 nm. Upon saturation of the chelator with Mg^{2+} , the fluorescence intensity does not change significantly; a shift of fluorescence maximum to 482 nm being observed. Saturation of **10c** with Ca^{2+} results in a reduction of the fluorescence intensity at 498 nm. Titration of **10c** with Mg^{2+} and recording the excitation fluorescence spectra shows that this chelator possesses the spectral characteristics required for a ratioable indicator (Figure 2A). The fluorescence excitation at 328 nm (emission observed at 498 nm) decreases upon increasing Mg^{2+} concentration, whereas the fluorescence at 305 nm increases. An isoexcitation point is found at 313 nm. Titration of **10c**

with Ca^{2+} only results in a decrease of the fluorescence at 328 nm (emission observed at 498 nm), but no response of the fluorescence was observed at lower wavelengths (Figure 2B). Thus, chelator **10c** could also be useful to distinguish changes of intracellular Mg^{2+} levels from "calcium spikes" in the cell.

CONCLUSIONS

The palladium catalyzed coupling reaction has proven to be a useful tool for the synthesis of new fluorescent APTRA indicators. Triflate **1** could be readily coupled with polyaromatic organoboron species and the resulting coupling products could then be easily carried on to the desired APTRA derivatives in good overall yields. The fluorescent response of the indicators on complexation of Mg^{2+} and Ca^{2+} depends greatly on the nature of the polyaromatic group coupled to the chelating APTRA moiety. Benzo[*b*]fur-2-yl-substituted ligand **10a** was found to be a nonratioable indicator for both Mg^{2+} and Ca^{2+} . However, the APTRA-ligand substituted with a naphth-1-yl or a naphth-2-yl group did result in the discovery of two new ratioable fluorescent indicators for Mg^{2+} . Indicators **10b** and **10c** showed an appreciable spectral shift of 30 and 23 nm, respectively in their fluorescent excitation spectra upon complexation of Mg^{2+} and with useful dissociation constants. Thus, these new ratioable indicators may be expected to find use in studying intracellular Mg^{2+} levels by fluorescence microscopy/imaging techniques.

We also found that the nature of the fluorescent response of indicators **10b** and **10c** depends strongly on the metal ion. This is most notable for indicators **10b** and **10c**. When titrated with Mg^{2+} , both indicators displayed the desired ratioable characteristics in their excitation fluorescence spectra. On the other hand, the excitation fluorescence spectra showed only a decrease of the fluorescence intensity upon increasing Ca^{2+} levels. This observation is important because corrections made for (high intracellular levels of) Ca^{2+} when measuring intracellular Mg^{2+} are often based on the assumption that the fluorescent response of an indicator to both metal ions is identical (13).

The dissociation constants for Mg^{2+} found for all three indicators **10a-c**, ranging from 1.8 mM to 2.3 mM, are similar to the values reported for Mag-indo and Mag-fura (1). Analysis of the Ca^{2+} fluorescence/titration data via a two parameter nonlinear fit resulted in K_D^{Ca} values for indicators **10a-c** (70, 17, and 28 μM) which correspond very well with the values found for the commercially available APTRA indicators. The lower Ca^{2+} affinity found for benzo[*b*]fur-2-yl substituted indicator **10a** may be explained by the stronger electron-withdrawing character of this hetero-aromatic system compared to a naphthyl group.

Isomerism and Solution Dynamics of ^{90}Y -Labeled DTPA–Biomolecule Conjugates

Shuang Liu,* Eric Cheung, Milind Rajopadhye, Neal E. Williams, Kirsten L. Overoye, and D. Scott Edwards

Medical Imaging Division, DuPont Pharmaceuticals Company, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received June 23, 2000; Revised Manuscript Received October 18, 2000

This report describes the synthesis of two DTPA-conjugated cyclic peptides, cyclo(Arg-Gly-Asp-D-Phe-Lys)DTPA (SQ169) and [cyclo(Arg-Gly-Asp-D-Phe-Lys)]₂DTPA (SQ170), and a chromatographic study of their ^{90}Y complexes (RP762 and RP763, respectively). The goal is to study the solution structure and the possible isomerism of ^{90}Y -labeled DTPA–biomolecule conjugates at the tracer level ($\sim 10^{-10}$ M). RP762 was prepared in high radiochemical purity (RCP > 95%) by reacting 2 μg of SQ169 with 20 mCi of $^{90}\text{YCl}_3$ (corresponding to a SQ169:Y ratio of $\sim 4:1$) in the 0.5 M ammonium acetate buffer (pH 8.0) at room temperature. RP763 was prepared in a similar fashion using SQ170. In both cases, the ^{90}Y -chelation was instantaneous. By a reversed-phase HPLC method, it was found that RP762 exists in solution as a mixture of two *detectable* isomers (most likely cis and trans isomers), which interconvert at room temperature. The interconversion of different isomeric forms of RP762 involves a rapid exchange of “wrapping isomers” via the “wagging” of the diethylenetriamine backbone, “shuffling” of the two NO_2 donor sets, and inversion at the terminal amine-nitrogen atom. The inversion at a terminal nitrogen atom requires simultaneous dissociation of the NO_2 donor set. For RP763, the interconversion of different isomers is much faster than that for RP762 due to the weak bonding of two carbonyl-oxygen donors. Therefore, RP763 shows only one broad radiometric peak in its HPLC chromatogram. The rapid interconversion of different isomers is intramolecular via a partial dissociative mechanism. The results obtained in this study are consistent with the lack of kinetic inertness of ^{90}Y - and ^{111}In -labeled DTPA–biomolecule conjugates. Thus, the design of new BFCs should be focused on those which form lanthanide complexes with high thermodynamic stability and more importantly kinetic inertness.

INTRODUCTION

In the past decade, many acyclic and macrocyclic bifunctional chelators (BFCs) have been synthesized and used for the radiolabeling of antibodies and peptides (1–24). Although formation of isomers in yttrium and lanthanide complexes of DTPA analogues has been studied by various NMR methods, very little information is available on isomerism of the radiolabeled DTPA–biomolecule conjugates at the tracer level. In many cases, TLC is the only tool for analysis of the final product. Radio-HPLC chromatograms are not presented nor is the HPLC method for the characterization of the radiolabeled biomolecule. It is not surprising that there has been no detailed discussion about isomerism and the impact on the biological properties of the radiolabeled DTPA–biomolecule conjugates.

Recently, Caravan and co-workers (25) extensively reviewed both the solid state and solution structures of lanthanide complexes of various acyclic and macrocyclic chelators. Solid state structures provide a wealth of information about the coordination chemistry of a specific chelating system. However, the solution structure may be different from the solid state structure because of possible dissociation of certain donor atom(s) or the coordination of water molecules. The isomerism observed in the solid state structure may not be seen in solution

due to interconversion of isomers or fluxionality of the ligand framework. On other occasions, only one isomeric form is found in the solid state, and more isomers are observed in solution. Thus, it is imperative to study the possible isomerism in the metal chelate, particularly at the tracer level, to understand the biological properties of a new metalloradiopharmaceutical.

For radiolabeled antibodies, the attachment of the BFC and the radionuclide normally does not disturb the tertiary structure of the polypeptide; thereby the biological and receptor binding properties are not significantly affected. For small biomolecules, however, the metal chelate (radionuclide and BFC) contributes greatly to the overall size and molecular weight of the radiopharmaceutical. Isomerism may have significant impact on the biological performance (receptor binding and biodistribution) since the distribution of the radiopharmaceutical is dependent on the physical and chemical properties of both the biomolecule and the metal chelate.

In this report, we describe the synthesis of two DTPA-conjugated cyclic peptides (SQ169 and SQ170) and a chromatographic study of their ^{90}Y complexes (RP762 and RP763 in Figure 1). The purpose of the study is to obtain a sufficient understanding of the solution structure of these complexes, and to explore the possible isomerism in ^{90}Y -labeled DTPA–biomolecule conjugates (DTPA–monoamide and DTPA–bisamide) at the tracer level ($\sim 10^{-10}$ M), the kinetics for the formation of isomers, and the dynamics of interconversion between different isomeric forms.

EXPERIMENTAL SECTION

Materials. Acetic acid (ultrapure), ammonium hydroxide (ultrapure), and diethylenetriaminepentaacetic acid cyclic dianhydride were purchased from either Aldrich or Sigma Chemical Co. and were used as received. ⁹⁰YCl₃ (in 0.05 N HCl) was purchased from New England Nuclear, N. Billerica, MA. The cyclic pentapeptide, cyclo(Arg-Gly-Asp-D-Phe-Lys), as its trifluoroacetic acid (TFA) salt was prepared according to the literature method (26).

Synthesis of Cyclo(Arg-Gly-Asp-D-Phe-Lys)DTPA (SQ169) and [Cyclo(Arg-Gly-Asp-D-Phe-Lys)]₂DTPA (SQ170). To a solution of cyclo(Arg-Gly-Asp-D-Phe-Lys)·2TFA (0.050 g, 0.060 mmol) in DMF (2 mL) was added triethylamine (41.9 μ L, 0.30 mmol). This solution was added dropwise over 4 h to a solution of diethylenetriaminepentaacetic dianhydride (0.107 g, 0.30 mmol) in DMF (2 mL) and dimethyl sulfoxide (2 mL). The reaction mixture was stirred for 16 h, and was then concentrated to give an oily residue, which was purified using a preparative HPLC method, which used a Rainin Rabbit HPLC system, a Knauer VWM UV-vis detector (λ = 230 nm), and a Vydac C₁₈ preparative column (21.2 mm $\times$ 25 cm). The flow rate was 15 mL/min with the mobile phase starting from 98% solvent A (0.1% TFA in H₂O) and 2% solvent B (0.1%TFA in ACN/H₂O = 9:1) to 63.2% solvent A and 36.8% solvent B at 16 min. The two peaks at 12 and 15 min were collected separately. LC-MS data showed that the peak at 12 min was from SQ169 and the peak at 15 min was from SQ170. After lyophilization, SQ169 was obtained in 46% yield (30 mg) and SQ170 in 21% yield (21.5 mg). ES-MS for SQ169: *m/z* 977.5 (M-H)⁻ (C₄₁H₆₂N₁₂O₁₆). ES-MS for SQ170: *m/z* 1562.8 (M-H)⁻ (C₆₈H₁₀₁N₂₁O₂₂).

General Procedure for Synthesis of RP762 and RP763. To a lead-shielded clean 5 mL vial containing 2–100 μ g of SQ169 or SQ170 in 1 mL of 0.5 M ammonium acetate buffer (pH 8.0) was added 10–20 μ L of ⁹⁰YCl₃ stock solution (~20 mCi) in 0.05 N HCl. The reaction mixture was allowed to stand at room temperature for 20 min. A sample of the resulting solution was diluted 20-fold with saline and then analyzed by HPLC (Gradient A for RP762 and Gradient B for RP763) and by ITLC.

The HPLC method used a HP-1100 HPLC system with a UV-vis detector (λ = 215 nm), an IN-US radio-detector, and a Zorbax C₁₈ column (4.6 mm $\times$ 250 mm, 80 Å pore size). The flow rate was 1 mL/min with a gradient mobile phase. For RP762, the gradient was 100% solvent A (95:5 mixture of 25 mM ammonium acetate buffer, pH 6.8, and acetonitrile) to 95% A and 5% solvent B (50:50 mixture of 25 mM ammonium acetate buffer, pH 6.8, and acetonitrile) at 8 min and to 90% of solvent A and 10% solvent B at 24 min. For RP763, the gradient was 85% solvent A and 15% solvent B to 80% of solvent A and 20% solvent B at 18 min. The ITLC method used Gelman Sciences silica gel ITLC paper strips and 1:1 mixture of acetone and saline as eluant. By this method, RP762 and RP763 migrate to the solvent front while [⁹⁰Y]colloid and [⁹⁰Y]acetate remain at the origin.

Interconversion of the Two Isomers of RP762. To a shielded clean 5 mL vial containing 20 μ g of SQ169 or SQ170 in 1 mL of 0.5 M ammonium acetate buffer (pH 8.0) was added 20 μ L of ⁹⁰YCl₃ stock solution (~20 mCi) in 0.05 N HCl. The reaction mixture was allowed to stand at room temperature for 20 min. The two peaks at 16.8 and 20.9 min were separated by HPLC, and were collected into separate 10 mL round-bottom flasks. The activity concentration of two collections (peak A and peak B) was about 0.5 mCi/mL. Each collected fraction was dispensed into two separate vials: one was kept at room temperature while the other was kept in a 54 °C water bath. Samples of these solutions were analyzed by HPLC every 30 min for 6 h.

⁹⁰Y-Chelation Efficiency of SQ169. To a lead-shielded clean 5 mL vial containing 2, 25, 50, and 100 μ g of SQ169 in 1 mL of 0.5 M ammonium acetate buffer (pH 8.0) was added 20 μ L of ⁹⁰YCl₃ stock solution (~20 mCi) in 0.05 N HCl. The reaction mixture was allowed to stand at room temperature for 30 min. A sample of the resulting solution was diluted 20-fold with saline, and then analyzed by HPLC (Gradient A) and by ITLC. The RCP was corrected by subtracting the percentage of [⁹⁰Y]-colloid and [⁹⁰Y]acetate obtained by ITLC from the yield obtained by HPLC.

Synthesis of [⁸⁹Y]RP762 for LC-MS and HPLC Concordance Experiment. To a clean 5 mL vial containing 0.5 mg of SQ169 in 0.5 mL of 0.5 M ammonium acetate buffer (pH 8.0) was added 0.2 mL of the Y(NO₃)₃·6H₂O solution (10 mg/mL in 0.5 M ammonium acetate buffer, pH 8.0). The reaction mixture was allowed to stand at room temperature for 30 min. A sample of the resulting solution was analyzed by LC-MS. No further purification was performed for the LC-MS analysis and the HPLC concordance experiment. The LC-MS spectra were collected using a HP1100 LC/MSD system with API-electrospray interface. The LC-MS method used a Zorbax C₁₈ column (4.6 mm $\times$ 150 mm, 3.5 μ m particle size) at a flow rate of 1 mL/min and a gradient mobile phase starting from 92% Solvent A (10 mM ammonium acetate buffer, pH 7.0) and 8% Solvent B (methanol) to 100% B at 23 min. The MSD parameters are found in Table 1.

RESULTS AND DISCUSSION

The pyramidal environment at coordinated amine-nitrogen atoms has been conclusively established by X-ray methods (27). Rapid inversion (Chart 1) at the amine nitrogen atoms is common. However, once the nitrogen atom in a polydentate chelator is bonded to the metal ion, the inversion becomes more difficult and

Chart 1. Inversion at the Coordinated and Uncoordinated Amine-Nitrogen.

involves dissociation and reformation of the coordination bond (Chart 1). Therefore, coordination of a polydentate chelator containing amine-nitrogen donor atoms often results in formation of isomers in its yttrium and lanthanide complexes. For example, DTPA, DTPA-MA (MA = monoamide), and DTPA-BA (BA = bisamide) contain three amine-nitrogen donors. In principle, this will result in formation of eight possible isomers once they are coordinated to a metal ion. In the solid state, only some of them were observed by X-ray crystallography (27–31). In solution, however, all eight isomers of lanthanide complexes have been observed by NMR at low temperature (32–39). Some of them interconvert via a partial dissociation at elevated temperatures. For example, the proton NMR spectra of the Pr^{3+} and Eu^{3+} complexes of DTPA show that at room temperature there are only two main isomers (Figure 2), which undergo rapid exchange in solution at temperatures higher than 95 °C (32–34). For the Lu^{3+} chelate of DTPA-BMA, however, the temperature for the rapid exchange is lower (85 °C), reflecting the weak bonding of carbonyl-oxygen as compared to carboxylate-oxygen donors (35–39). The major feature of the exchange process involves the shuffling of coordinated acetate accompanied by a flip of the backbone ethylene bridges between staggered conformations. This results in a change in helicity of the complex and leads to the equilibration of acetate arms. Inversion at the coordinated nitrogen atoms has been excluded based on ^1H NMR data (35). In all the cases, the concentration of the lanthanide complexes studied by NMR ranged from 0.05 to 0.20 M.

^{90}Y -labeled DTPA-biomolecule conjugates (DTPA-MA and DTPA-BA) are often prepared at low concentration (2–20 mCi/mL corresponding to 4×10^{-9} to 4×10^{-8} M). For HPLC analysis, the amount of injected radioactivity is even lower (1.0 μL corresponding to about 1 μCi). The actual complex concentration in the mobile phase is only $\sim 10^{-15}$ M. Because of this concentration difference, these lanthanide complexes may have different solution characteristics at the tracer level. The purpose of the study is to obtain a sufficient understanding of the solution structure and isomerism of the ^{90}Y -labeled DTPA-

peptide conjugates at the tracer level, and the dynamics of interconversion between different isomeric forms.

Synthesis of SQ169 and SQ170. The DTPA conjugates (SQ169 and SQ170) were prepared according to Chart 2 by reacting DTPA with the cyclic pentapeptide, cyclo(Arg-Gly-Asp-D-Phe-Lys)·2TFA, in a mixture of DMF and DMSO. SQ169 and SQ170 were isolated as their TFA salts, and were repurified by HPLC before being used for radiolabeling.

Synthesis of RP762 and RP763. RP762 was prepared (Chart 2) by reacting SQ169 with $^{90}\text{YCl}_3$ in the 0.5 M ammonium acetate buffer (pH 8.0) at room temperature. The pH is very important for high yield radiolabeling. A higher pH usually gives better radiolabeling yield. Using 0.5 M ammonium acetate buffer (pH 8.0), RP762 could be prepared in high yield (RCP > 95%) by reacting 2 μg of SQ169 with 20 mCi of $^{90}\text{YCl}_3$ corresponding to a SQ169:Y ratio of $\sim 4:1$. RP763 was prepared in a similar fashion using SQ170 substituting for SQ169. In both cases, the ^{90}Y -chelation was instantaneous. This is consistent with the results reported in the literature (40, 41).

HPLC Characterization of RP762. For the past decade, HPLC has become a routine technique for quality control of various radiopharmaceuticals. The advantage of radio-HPLC is its capability to determine the RCP for a specific radiopharmaceutical, and to separate different radiolabeled species in the reaction mixture. It is also a very powerful tool for separation of different isomers such as diastereomers. In this study, we used a reversed-phase HPLC method to analyze reaction mixtures containing RP762. Figure 3 shows typical radio-HPLC chromatogram of RP762. Two radiometric peaks at 16.8 and 20.9 min were detected and there are no other radio-impurities. We also tried several other reversed-phase HPLC methods. In all the cases, RP762 shows only two radiometric peaks, suggesting that the HPLC method is specific. The presence of the two peaks in the HPLC chromatogram also suggests that RP762 exists as two detectable isomers in solution.

It is interesting to note that the peak ratio of peak A and peak B changes over time until the equilibrium is reached. For example, the peak ratio at $t = 0$ h was 50:50 while it was about 48:52 at 12 h and remained relatively constant from that time. This observation suggests that there is a slow conversion from peak A to peak B at room temperature, and the formation of the different isomeric forms is probably kinetically controlled. Since the ^{90}Y -chelation was instantaneous under the conditions described in the experimental, it is not surprising that these isomers were formed at the same time with equal population at the early stage.

We also studied the conversion rate of HPLC purified peak A and peak B. First, RP762 was prepared using 20 mCi of ^{90}Y , and the isomers at 16.8 and 20.9 min were collected into two separate 5 mL vials. The two vials were either kept at room temperature or placed in a water bath at 54 °C. Samples of the collected fractions (activity concentration = 0.5 mCi/mL) were analyzed by the HPLC over 6 h. It was found that the rate of interconversion between these two peaks is very slow at room temperature (Figure 4). That may explain why it takes almost 24 h for these isomers to reach the equilibrium. At a higher temperature (54 °C), the rate of interconversion between different isomers of RP762 is accelerated (Figure 5), and it took about 6.5 h for peak A to reach the 48:52 (peak A/peak B) ratio. However, it took a much longer time (>7 h) for peak B to reach the equilibrium, suggesting that peak B is thermodynamically more stable. It is

Figure 2. Proposed mechanism for the interconversion between the two wrapping isomers of lanthanide DTPA complexes.

Chart 2. DTPA Conjugation and ^{90}Y -Chelation.

very important to note that both peak A and peak B remained stable in the HPLC mobile phase (containing 10% acetonitrile) at 54 °C for more than 6 h. There is no significant decomposition of the metal chelate, suggesting that interconversion between these isomeric forms is intramolecular.

HPLC Concordance Experiment. We performed a HPLC concordance experiment using RP762 and [^{89}Y]-RP762. [^{89}Y]-RP762 was prepared by reacting SQ169 with yttrium(III) nitrate in 0.5 M ammonium acetate buffer (pH 8.0), and was analyzed without further purification using identical chromatographic conditions to those for RP762. Figure 6 shows HPLC chromatograms of RP762 (top) and [^{89}Y]-RP762 (bottom). It is quite clear that the same complexes were prepared at the tracer (^{90}Y) and macroscopic (^{89}Y) levels. We used LC-MS to determine the composition of [^{89}Y]-RP762. The two peaks of [^{89}Y]-RP762 show identical fragmentation patterns and the same molecular ions at m/z 1065.2 for $(\text{M} + \text{H})^+$ and 533.3 for $(\text{M} + 2\text{H})^{2+}$ (Figure 7). This provides direct evidence to support the conclusion that the two peaks in the radio-

Figure 3. Typical radio-HPLC chromatograms for RP762 (top) and RP763 (bottom).

HPLC chromatogram of RP762 are indeed due to the resolution of two isomers.

HPLC Characterization of RP763. We used a slightly different mobile phase when analyzing RP763 by radio-HPLC due to its higher lipophilicity. Figure 3 shows a typical radio-HPLC chromatogram for RP763. In contrast to RP762, RP763 shows only one broad peak with the half-width of ~3 min. There are no other radio-impurities in the HPLC chromatogram. In general, there are two possibilities for the large half-width of the peak.

Figure 4. Interconversion kinetics of the two isomers of RP762 at room temperature.

The first possibility is that the peak at ~15 min is a combination of several unresolved peaks from different isomers. If that were true, it should have been possible to separate them using long gradient or isocratic chromatographic conditions. We tried several different gradients, and found that RP763 always shows one broad peak with different half-widths depending upon the HPLC chromatographic conditions. The second possibility is that there is a rapid interconversion between different isomers at room temperature under the conditions used in this study.

In general, the lanthanide complexes of DTPA analogues assume distorted tricapped trigonal prism (TTP) geometries. In the TTP arrangement, the neutral donor atoms with longer bond lengths will prefer to occupy face capping positions rather than a prismatic corner. However, since it is not possible for all three amine-nitrogen donors to occupy capping positions, the central nitrogen atom tends to occupy a prismatic corner (Figure 2) while the two terminal amine-nitrogen atoms occupy capping positions. Because of distortion, the actual coordination geometry is, in most cases, between TTP and monocapped square antiprism (CSAP).

SQ169 is a DTPA-monoamide and bonds to yttrium(III) with one carbonyl-oxygen, three amine-nitrogen, and four acetate-oxygen donor atoms. Theoretically, there are eight possible isomers (four pairs of enantiomers in Chart 3) due to the chirality of three coordinated nitrogen donors. If the biomolecule in the DTPA-peptide conjugate is stereochemically pure, it will form an yttrium

Figure 5. Interconversion kinetics of the two isomers of RP762 at 55 °C.

complex with the same number of isomers as that of the Y-DTPA complex. Previously, ^1H and ^{13}C NMR studies of lanthanide complexes of DTPA and DTPA-bisamide derivatives have revealed a rapid interconversion of two wrapping isomers (26, 32–39). It has been proposed that the rapid exchange process involves “wagging” of the diethylenetriamine backbone and shuffling of coordinated acetate groups. Inversion at the coordinated nitrogen atoms has been excluded due to the fact that the ^1H signals of methylene-hydrogens of the acetate and acetamide groups remain as AB quartets even at 85 °C (34). This strongly suggests that the energy barriers for the inversion at the coordinated amine-nitrogen donors is much higher than that for the rapid interconversion of “wrapping isomers”.

It should be noted that the concentration of the lanthanide complexes for NMR studies ranged from 0.05 to 0.2 M. At this concentration, the dissociation of acetate-oxygen and amine-nitrogen donors is not significant. At the tracer level, however, the concentration of RP762 in the HPLC mobile phase is only $\sim 10^{-10}$ M. At this concentration, it is quite possible for acetate-oxygen, carbonyl-oxygen and amine-nitrogen donors to become dissociated due to the competition from acetate anions in the mobile phase. Partial dissociation of these donor atoms makes the interconversion between “wrapping isomers” much easier. That may account for the different solution characteristics of lanthanide complexes of DTPA-MA and DTPA-BA at different concentration levels.

MSD1 SPC, time = 19.32:20.47, API-ES, Positive, Max = 15431

Figure 7. LC-MS spectra of the two isomers of RP762.

RP762 has four possible pairs of enantiomers, which are not separable by the HPLC methods described in this

Chart 3. Eight Isomers of the Complex Y(DTPA-MA).

study. If one assumes that the rapid interconversion occurs between “wrapping isomers” at room temperature, isomer **1** is readily converted to **1'** via “shuffling” of the two NO₂ donor sets and “wagging” of the diethylenetriamine backbone. The same is true for **2** and **2'**. Since **1** and **2** are the two enantiomer pairs, these four isomers are not separable by radio-HPLC, and are expected to appear as single peak while the remaining four isomers (**3**, **3'**, **4**, and **4'**) as another peak in the HPLC chromatogram. This is completely consistent with the presence of two radiometric peaks in the HPLC chromatogram of RP762 (Figure 3).

It should be noted that the relative orientation of the acetamide group to the acetate arm at the central nitrogen atom is different (cis and trans, respectively) in isomers **1** and **4** (Chart 3). The same is true for isomers **1'** and **4'**, **2** and **3**, **2'** and **3'**. For cis and trans isomers to interconvert, inversion at the terminal amine-nitrogen atoms has to occur. This suggests that the NO₂ donor set have to be dissociated and accompanied by a rapid “umbrella-type” inversion at the nitrogen atom. That explains the fact that both radiometric peaks of RP762 interconvert and the rate of interconversion is temperature dependent. Since RP762 remains stable for at least 6 h at 54 °C without a significant decomposition, it is reasonable to assume that the remaining part of the DTPA-monoamide conjugate remains firmly bonded to Y(III) when one of the two NO₂ donor sets undergoes a rapid “umbrella-type” inversion at the terminal nitrogen atom.

SQ170 is a DTPA-BA and bonds to yttrium(III) as an octadentate chelator using two carbonyl-oxygen, three amine-nitrogen, and three acetate-oxygen donor atoms. Like DTPA-MA, DTPA-BA forms a Y(III) complex with

Chart 4. Eight Isomers of the Complex Y(DTPA-BA).

eight isomers (Chart 4) due to the chirality of the three coordinated amine-nitrogen atoms. Compared to acetate-oxygen, the carbonyl-oxygen is a weak donor for yttrium(III). Thus, it is easier for the two NO_2 donor sets to be dissociated in solution, which results in faster interconversion between "wrapping isomers" and inversion at coordinated amine-nitrogen atoms. As a result, RP763 shows only one broad radiometric peak in its HPLC chromatogram (Figure 3).

CONCLUSION

In this study, we presented synthesis and characterization of two DTPA-peptide conjugates (SQ169 and SQ170) and the corresponding ^{90}Y complexes (RP762 and RP763, respectively). By a reversed-phase HPLC method, we found that the ^{90}Y -labeled DTPA-monoamide conjugate exists in solution as a mixture of two detectable isomers (cis and trans isomers), which interconvert at room temperature under the chromatographic conditions described in this study. The interconversion of different isomeric forms of RP762 involves a rapid exchange of "wrapping isomers" via the "wagging" of the diethylenetriamine backbone, "shuffling" of the two NO_2 donor sets, and inversion at the terminal amine-nitrogen atom. For the ^{90}Y -labeled DTPA-BA conjugate (RP763), the interconversion of different isomers (particularly cis-cis, cis-trans, trans-cis, and trans-trans isomers) is much faster than that for RP762 due to the weak bonding of two carbonyl-oxygen donors; thereby RP763 shows one broad radiometric peak in its HPLC chromatogram.

The results obtained from this study have significant implications for ^{90}Y -labeled DTPA-biomolecule conjugates. The ^{90}Y -labeled DTPA-biomolecule conjugate exists in solution as a mixture of eight possible isomers,

some of which undergo rapid interconversion at room temperature. Therefore, the presence of different isomeric forms may not impose a significant problem with respect to the difference in biological properties of these isomers. The most critical issue using DTPA as a BFC is its low kinetic inertness. When the two isomers of RP762 were separated by HPLC, the HPLC mobile phase did not contain any significant amount of trace metal ion. The rapid interconversion of different isomers is purely intramolecular. Once the ^{90}Y -labeled DTPA-biomolecule conjugate is injected into a biological system, the presence of biologically important metal ions such as Ca^{2+} , Cu^{2+} , Fe^{2+} , and Zn^{2+} , is expected to have a significant impact on the biological fate of the ^{90}Y -labeled DTPA-biomolecule conjugate. These metal ions can compete with ^{90}Y for the DTPA-biomolecule conjugate due to their high concentration. Once ^{90}Y is dissociated from the DTPA-biomolecule conjugate, it will most likely deposit in bone. It is not surprising that many ^{90}Y - and ^{111}In -labeled DTPA-biomolecule conjugates often show high bone activity. Thus, the design of new BFCs should be focused on those which form lanthanide complexes with high thermodynamic stability and more importantly kinetic inertness.

Histidylated Polylysine as DNA Vector: Elevation of the Imidazole Protonation and Reduced Cellular Uptake without Change in the Polyfection Efficiency of Serum Stabilized Negative Polyplexes

Mahajoub Bello Roufaï and Patrick Midoux*

Centre de Biophysique Moléculaire CNRS UPR 4301 affiliated to the University of Orléans and to INSERM, 45071 Orléans Cedex 02, France. Received June 28, 2000; Revised Manuscript Received October 14, 2000

We have reported that polylysine substituted with histidyl residues (His) was suited to make complexes with plasmid DNA (pDNA) and to transfect cells *in vitro* in the presence of serum. The present study was performed to determine whether the acetylation of the α -amino group of histidyl residues (AcHis) had an influence on the size and the charge of polyplexes and on their transfection efficiency. We found that the presence of free α -amino groups allowed the formation of smaller polyplexes but did not modify the ζ potential of +17 mV. At a physiological salt concentration, the adsorption of many serum proteins on His- and AcHis-polyplexes reduced their size below 100 nm, inhibited their aggregation, and reversed their ζ potential to –25 mV. The acetylation of the α -amino groups reduced slightly the adsorption of serum proteins. The presence of the α -amino groups increased the pK of the imidazole protonation of histidine bound to polylysine from pH 5.8 to 6.9; in addition, the protonation was further elevated in the presence of pDNA. Serum stabilized negative histidylated polyplexes were less taken up by cells but their transfection efficiency did not decrease; depending on the cell line, His-polyplexes were more efficient than AcHis-polyplexes. The results indicate that (i) the α -amino groups of histidyl residues bound to polylysine favorably influence the size and the transfection efficiency of polyplexes, (ii) the α -amino groups also elevate the imidazole protonation of His-polyplexes, which is suited to destabilize the membrane of early endocytic vesicles in order to favor pDNA delivery in the cytosol, and (iii) the absorption of selective serum proteins on His-polyplexes could be a way for *in vivo* gene targeting.

INTRODUCTION

Soluble interpolyelectrolyte complexes (termed polyplexes) (1) formed between a plasmid DNA (pDNA) and a cationic polymer are a promising approach for a nonviral gene delivery (for reviews, see refs 2 and 3). Their self-assembly in an aqueous solution results from a cooperative system between the polyanionic phosphate backbone of nucleic acids and the positive charge of amino groups of the cationic polymers via electrostatic bonds. Such electrostatic interactions allow pDNA condensation in morphologically variable polyplexes depending on the polymer structure (4). To be efficient, polyplexes must have the capacity (i) to enter into cells of interest, (ii) to transfer a great number of copies into the cytosol in a sufficient number of cells, and (iii) to transport a great number of copies into the cell nucleus. Polylysine and ligand-substituted polylysine are widely used to condense pDNA in toroid particles and short rods that are taken up by cells via nonspecific and receptor-mediated endocytosis, respectively. Polyplexes must escape the endocytic pathway and pDNA reach the cytosol. This is favored by using chloroquine (5–7) glycerol (8) or acidic dependent fusogenic peptides (6, 9–14).

Recently, we have reported that partially histidylated polylysine complexed with pDNA actively transfect cells in culture in the presence of serum and in the absence of chloroquine or a fusogenic peptide (15). We found that the transfection efficiency into cystic fibrosis airway

epithelial cell lines was as great as that obtained with polyethylenimine or lipofectamine as pDNA vectors (16). It was shown with polylysine and polyethylenimine that the polymer/DNA ratio, the chemical substitution of the cationic polymer and conditions of the polyplexes formation largely influenced the morphology, the size, the charge as well as the transfection efficiency of polyplexes (4, 17–22).

This paper was focused on a comparative study of polyplexes made with polylysine substituted with either histidyl or *N*-acetyl-histidyl residues in order to evaluate the influence of the α -amino substitution on the transfection efficiency. The size and the charge of both polyplexes were determined as a function of the DNA/polymer ratio, the salt concentration, the pH medium and the amount of serum. Histidylated polylysines which were designed to favor pDNA delivery into the cytosol after the uptake of polyplexes by the cells, contain several imidazoles which can induce membrane destabilization after their protonation in an acidic medium. We have determined the pH of the protonation of imidazole in both polymers as well as in polyplexes and showed that the protonation of His-polyplexes¹ can occur in the lumen of early endocytic vesicles.

MATERIALS AND METHODS

Chemicals. Chemicals, unless otherwise stated, were purchased from Sigma-Aldrich (St Quentin Fallavier, France). Poly(L-lysine) and HBr (degree of polymerization = 190, Bachem, Bubendorf, Switzerland) were changed in polylysine *p*-toluenesulfonate salt as previously described (23).

Histidylated Polylysine (His₁₀₉-pLK). Polylysine *p*-toluenesulfonate salt (50 mg; 0.87 μ mol) in 3 mL of DMSO was reacted for 15 h at 20 °C in the presence of diisopropylethylamine (DIEA) (23 μ L; 143.5 μ mol) with the *N*-succinimidyl derivative of BocHis(Boc)-OH (25.5 mg; 56.5 μ mol) (Bachem). The *N*-protecting Boc groups of histidyl residues were removed by acidic treatment by adding H₂O/trifluoroacetic acid mixture (1:1; v:v) for 12 h at 20 °C. Water and trifluoroacetic acid were removed under reduced pressure. Histidylated polylysine was precipitated by adding 10 vol of 2-propanol and collected by centrifugation (1800*g* for 15 min). The pellet was washed with 2-propanol, collected by centrifugation, solubilized in distilled water, and freeze-dried.

***N*-Acetyl-histidylated Polylysine (AcHis₁₀₀-pLK).** Polylysine *p*-toluenesulfonate salt (50 mg; 0.87 μ mol) in 3 mL of DMSO was reacted in the presence of DIEA (60 μ L; 344 μ mol) for 24 h at 20 °C with *N*-acetyl-His-OH (18.8 mg; 0.96 μ mol) in the presence of 84.5 mg of BOP (1.92 μ mol). The polymer was precipitated by adding 10 vol of 2-propanol and collected by centrifugation (1800*g* for 15 min). The pellet was washed with 2-propanol, collected by centrifugation, solubilized in distilled water, and freeze-dried.

Determination of the Histidyl Polylysine Substitution Level. The average number of histidyl residues (*x*) bound per pLK molecule was determined by ¹H NMR spectroscopy at 300 MHz in D₂O according to $x = 6(h_{8.7}/h_{Lys})DP$, where $h_{8.7}$ was the value of the integration of the signal at 8.7 ppm corresponding to the proton (C2-H) of histidyl as well as of *N*-acetylhistidyl residues and h_{Lys} was the value of the integration, in the range 1.3–1.9 ppm, corresponding to the six methylene protons (β,γ,δ) of lysyl residues and DP was the degree of polymerization of pLK.

Fluoresceinylated Polymers. His₁₀₉-pLK and AcHis₁₀₀-pLK (5 mg in 0.5 mL of DMSO) were reacted for 6 h at 20 °C with 5 equiv of FITC (Molecular Probes, Eugene, OR) in the presence of DIEA (2.3 μ L; 14.3 μ mol). Fluoresceinylated polymers were purified by precipitation in 10 vol of 2-propanol and spun down by centrifugation (800*g*, 10 min). Pellets were washed three times with 5 vol of 2-propanol in order to remove unreacted FITC. The absence of FITC was checked by silica thin-layer chromatography with a chloroform/methanol/water (6:6:1; v:v:v) mixture as solvent.

Plasmids. pSV2Luc (5.0 kb) plasmid was an expression vector encoding the firefly luciferase gene under the control of the SV40 T large antigen promoter (24). pUT650 plasmid (5.15 kb) (CAYLA, Toulouse France) was an expression vector encoding the firefly gene under the control of the human cytomegalovirus promoter.

Polyplexes Formation. A polymer in a total volume of 30 μ L of distilled water containing 5% (w/v) glucose unless otherwise stated was mixed with 10 μ g of pDNA in 70 μ L of distilled water containing 5% (w/v) glucose. The mixture was kept 30 min at 20 °C to allow the formation of polyplexes.

ζ Potential Measurement. The global surface charge of polyplexes was measured by electrophoretic mobility

using a ZetaSizer 3000 (Malvern Instruments, Orsay, France) with the following parameters: viscosity, 0.89 cP; dielectric constant, 79; temperature, 25 °C; Smoluchowsky constant $F(ka)$, 1.50; maximum voltage of the current, 15 V. The system was routinely calibrated using a -50 ± 5 mV standard dts 5050 from Malvern. The measurement was performed five times for 30 s with zero field correction in aqueous dep cell on 1.1 mL samples containing a final DNA concentration of 10 μ g/mL.

Size Measurement. Polyplexes size was determined by quasi-elastic laser light scattering (QELS) using a ZetaSizer 3000 with a sample refractive index of 1.59; viscosity, 0.89 cP. The system was routinely calibrated using a 220 nm standard dts 5050 from Malvern. For serum free polyplexes, measurements were performed 10 times for 12 s on 1 mL of sample. The size corresponds to an average size calculated by using the cumulant analysis mode.

Imidazole Protonation of Histidylated Polymers. The protonation of the imidazole of histidine free base (5 mg/mL) and of histidylated polymers (10 mg/mL) was assessed by measuring the chemical shift of the C2-H of histidyl residues versus the pH medium by using ¹H NMR spectroscopy in D₂O at 300 MHz. Chemical shifts were determined downfield the HDO peak at 4.75 ppm used as the internal standard.

Effect of Serum on the ζ Potential of Polyplexes. Polyplexes prepared as described above were diluted in 1 mL of 5 mM Hepes buffer, pH 7.4, containing 10 or 20% of 0.2 μ m filtered fetal bovine serum (FBS, Gibco, Renfrewshire, U.K.). After 30 min, the solution was loaded on 50% (w/v) simple sucrose cushion and centrifuged at 4 °C for 4 h at 30 000 rpm in a Beckman Ultracentrifuge SW40Ti rotor. The supernatant was carefully removed and the pellet containing polyplexes was resuspended in 200 μ L of distilled water. An agarose gel electrophoresis of the suspension showed that more than 90% of polyplexes was in the pellet. ζ -Potential measurement was performed as described above after dilution in 1 mL of distilled water.

Cells and Cell Culture. Human hepatocarcinoma cells (HepG2 cells, ATCC HB 8056, Rockville, MA) were cultured in Eagle's minimal essential medium (MEM, Gibco) with 10% heat inactivated FBS. The immortalized human tracheal epithelial cell line (Σ CFTE29o- cells) was from a cystic fibrosis patient homozygous for the Δ F508 mutation and was kindly given by D. C. Gruenert (Cardio-vascular Research Institute, San Francisco, CA). Σ CFTE29o- cells were plated on tissue culture plasticware coated with fibronectin, collagen, and bovine serum albumin and grown in MEM supplemented with 10% non de complemented FBS (25). All culture media were supplemented with 2 mM L-glutamax (Gibco) and antibiotics (100 units/mL penicillin and 100 μ g/mL streptomycin from Gibco). Cells were grown at 37 °C in a humidified atmosphere containing 5% CO₂ and 95% air. Cells were harvested by treatment with PET (PBS with 0.02% (w/v) EDTA and 2.5 μ g/mL trypsin) at 37 °C for 5 min. Cells were mycoplasma free as evidence by bis-benzimidazole (Hoechst 33258) (26).

Uptake of Histidylated Polyplexes. HepG2 and Σ CFTE29o- cells (4×10^5 cells) were incubated for 3 h at 37 °C in the presence of fluorescein-labeled polyplexes at 10 μ g/mL pDNA made with either *F*-His₁₀₉-pLK (30 μ g) or *F*-AcHis₁₀₉-pLK (40 μ g) and chased 1 h in the presence of the respective unlabeled polyplexes at the same concentration. Cells were washed three time with PBS, trypsinized for 5 min at 37 °C and suspended in cold PBS. The cell-associated fluorescence was analyzed

¹ Abbreviations: AcHis, *N*-acetyl-histidyl residue; BOP, benzotriazol-1-yl-oxy-tris-(dimethylamino) phosphonium hexafluorophosphate; EDTA, ethylenediaminetetracetic acid; FITC, fluorescein isothiocyanate isomer I; *F*-, fluorescein-labeled; His, histidyl residue; MEBS, 1 mM 3-[*N*-morpholino] propane sulfonic acid, 0.1 mM EDTA, 10 mM NaCl; PBS, phosphate-buffered saline; pLK, poly-L-lysine; QELS, quasi-elastic laser light scattering; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis.

using a FACSort flow cytometer (Becton Dickinson, Grenoble, France) before and after a postincubation for 15 min at 4 °C in the presence of 50 μ M monensin (27, 28). Data were analyzed using Cell Quest Software (Becton Dickinson).

Polyfection and Luciferase Assay. Two days prior the transfection, cells were seeded at 2×10^5 cells per 4 cm² in a 12 wells plate and incubated at 37 °C in a humidified atmosphere (5% CO₂). The polyplexes were prepared as described above in 100 μ L of water containing 5% (w/v) glucose and then diluted with 900 μ L of culture medium containing either 0, 10, or 20% FBS. Cells were then incubated at 37 °C in 5% CO₂ with polyplexes. After 4 h, the medium containing polyplexes was removed and replaced by culture medium containing 10% FBS without polyplexes. Luciferase gene expression was measured at 72 h by monitoring the luminescence activity according to De Wet et al. (29). The medium was discarded, and cells were washed three times with PBS. The homogenization buffer (200 μ L of 8 mM MgCl₂, 1 mM DTT, 1 mM EDTA, 1% Triton $\times$ 100, 15% glycerol, 25 mM Tris-phosphate buffer, pH 7.8) was poured into each well. After 15 min at 20 °C, the solution was recovered and spun down (5 min at 800 g). Ninety five μ L of a 2 mM ATP solution in the homogenization buffer without Triton $\times$ 100 was added to 60 μ L of supernatant and the solution was shaken with a vortex. The luminescence was recorded for 4 s in a Lumat LB 9501 luminometer (Berthold, Wildbach, Germany) upon addition of 150 μ L of a 167 mM luciferin solution in water. Measurements were done in duplicate. The luciferase activity was expressed as the number of relative light units (RLU) per cell. The number of RLU of 1 pg/mL of luciferase was 2000 under these conditions.

RESULTS

Polyplexes Formation. The condensation of pDNA in the presence of histidylated polylysines at low salt concentration was assessed by agarose gel electrophoresis, ζ potential and size measurements of polyplexes. The migration in the agarose gel showed that 10 μ g of pDNA mixed with 30 μ g of His₁₀₉-pLK or 30 μ g of AcHis₁₀₀-pLK was completely retarded and thus all the plasmid was complexed whereas pDNA was completely retarded with 10 μ g of pLK (Figure 1). At pH 7.4, polyplexes made with 30 μ g of His₁₀₉-pLK and 10 μ g of pDNA at a N:P of 3.4 (ratio of lysyl ϵ -amino plus histidyl α -amino groups to pDNA phosphates) were positively charged and exhibited a ζ potential of $+18 \pm 2$ mV (Table 1). Increasing the amount of polymer did not increase the ζ potential. Polyplexes made with 30 μ g of polylysine at the same N:P of 3.4 (ratio of lysyl ϵ -amino groups to pDNA phosphates) exhibited a similar ζ potential ($+17$ mV) which increased to $+22 \pm 3$ mV with 40 μ g of pLK. Polyplexes made with 40 μ g of AcHis₁₀₀-pLK (N:P, lysyl ϵ -amino groups to DNA phosphates ratio of 2.3) exhibited a ζ potential of $+14 \pm 3$ mV close to that of polyplexes made with His₁₀₉-pLK at a N:P of 3.4 (Table 1). QELS measurements showed that polyplexes made with His₁₀₉-pLK gave homogeneous particles of mean diameter 110 ± 15 nm under maximal condensation which were slightly bigger than those made with pLK (Table 1). AcHis₁₀₀-pLK formed larger polyplexes (165 ± 15 nm) than His₁₀₉-pLK indicating that with the latter the α -amino groups interacted with pDNA phosphates and induced a better condensation. These results indicated that 10 μ g of pDNA was completely condensed and saturated with 30 μ g of His₁₀₉-pLK. In water, the presence of histidyl as well as *N*-acetyl-histidyl residues on

Figure 1. Agarose gel electrophoresis of polyplexes. Various amounts of cationic polymer expressed in micrograms per milliliter (μ g/mL) were mixed with 10 μ g of plasmid in 60 μ L of distilled water. After 30 min incubation at 20 °C, 20 μ L of each sample was analyzed by electrophoresis for 2 h under 80 V/cm, through a 0.6% agarose gel containing ethidium bromide (1 μ g/mL of gel) in Tris-borate-EDTA buffer (95 mM Tris, 89 mM boric acid, and 2.5 mM EDTA), pH 8.6.

polylysine increased 2-fold the global charge of polyplexes ($+33$ mV). The enhancement of the ζ potential due to the presence of protonated imidazoles shows that protonated imidazoles do not interact with pDNA phosphates probably because of their distance between the polymer backbone.

Effect of the Salt Concentration on the Polyplexes Size. We have investigated the influence of the salt concentration on the size of histidylated polyplexes because it is known that at physiological salt concentration (i.e., 0.15 M NaCl) pLK/DNA complexes form aggregates. QELS measurements showed that in distilled water and water containing 5% glucose, the size of polyplexes was 120 ± 10 and 105 ± 15 nm, respectively (Figure 2). Small polyplexes of 100 nm were also obtained after dilution in MEBS, pH 7.2, or 5 mM Hepes, pH 7.0. However, aggregates appeared as soon as the salt concentration was 25 mM NaCl and large aggregates of 800 nm were formed at 0.15 M NaCl. Large aggregates were also observed when the polyplexes were prepared at physiological salt concentration in 0.15 M NaCl serum-free medium.

Table 1. Size and ζ Potential of Histidylated Polyplexes^a

	polymer/pDNA weight ratio ($\mu\text{g}/\mu\text{g}$)					
	ζ potential (mV)			size (nm)		
	2	3	4	2	3	4
His ₁₀₉ -pLK	+17.5 $\pm$ 3 (+32)*	+18 $\pm$ 2 (+33)	+17 $\pm$ 3 (+34)	140 $\pm$ 10	110 $\pm$ 10	110 $\pm$ 10
AcHis ₁₀₀ -pLK	-18 $\pm$ 2 (+32)	-5 $\pm$ 3 (+34)	+14 $\pm$ 3 (+37)	179 $\pm$ 10	170 $\pm$ 10	165 $\pm$ 15
pLK	+10 $\pm$ 3 (+12)	+17 $\pm$ 3 (+18)	+22 $\pm$ 3 (+22)	100 $\pm$ 10	100 $\pm$ 10	90 $\pm$ 10

^a Polyplexes were prepared by mixing 10 μg of pDNA with different amounts of cationic polymers in 100 μL of water containing 5% (w/v) glucose. The mixture was kept for 30 min at 20 $^{\circ}\text{C}$ and diluted with 900 μL of either 5 mM Hepes buffer, pH 7.4, or (*) water containing 5% glucose. Size and ζ potential measurements were performed by using the ZetaSizer 3000.

Figure 2. Effect of the salt concentration on the polyplexes size. pDNA/His-pLK polyplexes (10/30; $\mu\text{g}/\mu\text{g}$) were prepared in 100 μL of distilled water. After 30 min at 20 $^{\circ}\text{C}$, they were diluted with 900 μL of either distilled water, water containing 5% glucose and various NaCl concentration, serum-free MEM or other buffers. Polyplexes size was then determined after 1 h by QELS measurements with the ZetaSizer 3000.

Effect of Serum on the Size and the Charge of Polyplexes. As shown above, the size of polyplexes grown up rapidly in the absence of serum and formed aggregates of 1–3 μm within 30 min (Figure 3). In contrast, the size of polyplexes was stabilized at 250 ± 10 and at 100 ± 10 nm when polyplexes prepared at low salt concentration were diluted 10 times in 0.15 M NaCl buffer containing 1 and 10% serum, respectively (Figure 3). The hydrodynamic diameter of polyplexes was further reduced to 70 ± 5 and 50 ± 5 nm in the presence of 20 and 50% serum, respectively. This inhibition of the aggregation and the reduction of the size of polyplexes in the presence of serum was also observed with AcHis-polyplexes but their size reached only 90 ± 10 nm in the presence of 50% serum (Figure 3). These data indicate that serum anionic components bind to the surface of cationic polyplexes and prevent hydrophobic contacts between the particles and/or modify the global surface charge allowing repulsion between particles. First of all, we found that the size of polyplexes decreased and reached a minimum of 375 nm in the presence of 10 mg/mL serum albumin a protein present in large quantity in the serum (Figure 3, inset). The size was bigger than that obtained in the presence of serum suggesting that other proteins interacted with polyplexes to form particles of 70 nm. Then, we have performed SDS-PAGE analysis of polyplexes after incubation in the presence of bovine fetal serum and isolation by ultracentrifugation

Figure 3. Influence of fetal bovine serum (FBS) on the polyplexes size. pDNA/His₁₀₉-pLK (10/30; $\mu\text{g}/\mu\text{g}$) and pDNA/AcHis₁₀₀-pLK (10/40 $\mu\text{g}/\mu\text{g}$) polyplexes were prepared in 100 μL of H₂O 5% glucose. After 30 min at 20 $^{\circ}\text{C}$, they were diluted with 900 μL of 0.15 M NaCl 5 mM Hepes buffer, pH 7.4 containing various amounts of FBS and the solution was kept 1 h at 20 $^{\circ}\text{C}$. QELS measurements were performed upon 10 times dilution of polyplexes at a final serum concentration less than 2.5% (v/v) in order to prevent any significant light scattering signal coming from serum components. (Inset) Influence of bovine serum albumin (BSA) on the polyplexes size. pDNA/His₁₀₉pLK polyplexes were diluted 10 times in 0.15 M NaCl 5 mM Hepes buffer, pH 7.5, containing various amount of BSA.

on sucrose cushion. We found that several major serum proteins of 66 (probably serum albumin), 59, 52, 45, and 27 kDa molecular mass (Figure 4, lane j) were associated with both histidylated polyplexes (Figure 4, lanes d–g). In addition, there were several other proteins with high, medium (between 30 and 45 kDa) and low (10, 14, and 16 kDa) molecular mass present in low quantity in the serum that were more strongly associated with His-polyplexes (Figure 4, lanes d and e). The acetylation of the α -amino group of histidyl residues reduced drastically the binding of all serum proteins (Figure 4, lanes f and g).

The global surface charge of polyplexes incubated with 10 and 20% serum was also investigated after their isolation by ultracentrifugation on sucrose cushion. His- and AcHis-polyplexes exhibited a negative ζ potential of -25 and -15 mV, respectively (Figure 5).

Influence of pH Medium on Polyplexes Size. The size of His-polyplexes increased from 230 nm at pH 7.5 to 350–430 nm at pH 9.5 due to a decrease of the interactions between His-pLK and pDNA after deprotonation of α -amino groups (pK close to pH 7.0) when the pH of the medium was above 7.5 giving less condensed polyplexes (Figure 6). The size decreased to 100 nm at

Figure 4. SDS-PAGE analysis of serum proteins bound to His- and AcHis-polyplexes. Polyplexes containing 10 $\mu\text{g/mL}$ pDNA in 100 μL of H_2O 5% glucose were diluted in 5 mM Hepes buffer, pH 7.4, containing filtered bovine fetal serum. After 30 min, polyplexes were isolated by ultracentrifugation on 50% (w/v) sucrose cushion and analyzed under SDS-PAGE with visualization by a silver staining. (Lane a) Molecular weight markers; (lane b) 100 times diluted filtered bovine fetal serum; (lane c) His-polyplexes without serum; (lane d) His-polyplexes with 10% serum; (lane e) His-polyplexes with 20% serum; (lane f) AcHis-polyplexes with 10% serum; (lane g) AcHis-polyplexes with 20% serum; (lane h) histidylated polylysine; (lane i) plasmid DNA; (lane j) serum without polyplexes.

Figure 5. Influence of serum on polyplexes charge. (Dark bar) pDNA/His₁₀₉-pLK and (shaded bar) pDNA/AcHis₁₀₉-pLK complexes were prepared in 100 μL of H_2O . After 30 min at 20 $^{\circ}\text{C}$, polyplexes were diluted in 900 μL of 5 mM Hepes buffer, pH 7.4, in the absence or the presence of bovine fetal serum and the solution kept 30 min at 20 $^{\circ}\text{C}$. Polyplexes were then isolated by ultracentrifugation on 50% (w/v) sucrose cushion. ζ potential measurements were performed on resuspended polyplexes.

pH 6.5 and remained stable at lower pH when the α -amino groups were protonated. In contrast, the size of AcHis-polyplexes (165 nm) did not depend on the pH of the medium.

Imidazole Protonation. The protonation of the imidazole in His₁₀₉-pLK, AcHis₁₀₀-pLK and histidine free base

Figure 6. Influence of pH medium on the polyplexes size. pDNA (10 μg) was complexed with either (dark barr) His₁₀₉-pLK (30 μg) or (shaded barr) AcHis₁₀₀-pLK (40 μg) for 30 min in 100 μL of 5 mM Hepes buffer, pH 7.4, and diluted 10 times in 5 mM Hepes buffer, pH 7.4. The pH medium was then adjusted under pH meter by adding aliquots of either a 0.1 M HCl or a 0.1 M NaOH solution and the size of polyplexes was measured.

Figure 7. Imidazole protonation in histidylated polylysines. The chemical shifts of imidazole C2-H of either ($\circ$) His-pLK, (∇) AcHis-pLK, or ($\bullet$) histidine reflecting the charge state of the imidazole ring was measured by ^1H NMR spectroscopy in D_2O at 300 MHz as a function of the pH medium. Chemical shifts were determined downfield from the HDO peak at 4.75 ppm used as the internal standard.

was determined by ^1H NMR spectroscopy by monitoring the C2-H peak position versus the pH medium reflecting the charge state of the imidazole ring (30). The pK of the imidazole in histidine free base, His₁₀₉-pLK, and AcHis₁₀₀-pLK was found to be 5.8, 6.9, and 6.0, respectively (Figure 7). The protonation of the imidazole of a *N*-acetyl-histidyl residue bound to polylysine had a pK similar to that of histidine free base. In contrast, the protonation occurred at a 1.1 pH unit higher than in histidine free base when the α -amino groups were free.

The imidazole protonation was also investigated in polyplexes by measuring their ζ potential at various pH. Measurements were performed with polyplexes made with both histidylated polylysines but only data from ζ potential values of those made with AcHis₁₀₀-pLK were used to evidence the protonation of the imidazole. The ζ potential values of polyplexes made with His₁₀₉-pLK did not only correspond to the imidazole protonation but also to that of the α -amino group which occurs between pH 7.0 and 6.5. The ζ potential of AcHis-polyplexes increased

^a Mean of the cell-associated fluorescence (arbitrary units) measured by flow cytometry before (-Mo) and after (+Mo) a posttreatment with monensin. The cell-associated fluorescence was expressed relative to that of cells incubated with His₁₀₉-pLK/pDNA polyplexes.

^b Luciferase activity was expressed as the relative light unit (RLU) per cell.

Figure 8. Imidazole protonation in *N*-acetyl-histidylated polyplexes. pDNA (10 μ g) was complexed with AcHis₁₀₉-pLK (40 μ g) in 200 μ L of 5 mM Hepes buffer, pH 7.4, the solution kept 30 min at 20 °C and then diluted 10 times in 5 mM Hepes buffer pH 7.4. The pH was adjusted under pH meter by adding aliquots of either a 0.1 M HCl or 0.1 M NaOH solution and the ζ potential of polyplexes was measured.

from +5 to +40 mV when the pH decreased from pH 7.5 to 5.0 as a consequence of the protonation of the imidazole (Figure 8). In polyplexes, the pK of the imidazole was estimated to 6.5 which was slightly higher than that found for the polymer in the absence of plasmid (pK = 6.0) (Figure 7).

Uptake of Histidylated Polyplexes. HepG2 and Σ CFTE290- cells were incubated with pDNA complexed with either *F*-His-pLK or *F*-AcHis-pLK. After 3 h, the medium was removed and cells were chased 1 h in the presence of unlabeled polyplexes. The cell-associated fluorescence was then analyzed by flow cytometry after a postincubation with the proton/sodium ionophore monensin to evidence the uptake of polyplexes. Monensin induces neutralization of acidic compartments and restores the fluorescence of fluorescein quenched in an acidic medium such as in endosomes and lysosomes (27, 28). The fluorescence intensity of both cell lines incubated in the absence of serum with His-polyplexes and AcHis-polyplexes was 2–3-fold higher in average than that of cells incubated in the presence of serum (Table 2). This showed that polyplexes aggregates generated in the absence of serum were more associated with the cells than the 100 nm stabilized polyplexes in the presence of serum. Indeed, the number of polyplexes molecules was increased on the surface of adherent cells because the aggregates sedimented rapidly in serum-free medium; in addition, their positive ζ potential favored their binding to sulfated proteoglycans of the plasma membrane. Conversely, the binding and the uptake by the cells of small polyplexes which exhibited a negative ζ potential were reduced in the presence of serum (Table 2). AcHis-

polyplexes were more associated with both cell lines than His-polyplexes probably because their size was bigger and their sedimentation faster than His-polyplexes. After a posttreatment with monensin, the cell-associated fluorescence of Σ CFTE290- cells incubated with both polyplexes increased 2-fold showing that some polyplexes were internalized in acidic compartments (Table 2). The cell-associated fluorescence of HepG2 cells incubated with *F*-AcHis-polyplexes was 5–7.8-fold higher after monensin posttreatment. This indicated that these polyplexes were internalized in more acidic compartments than in Σ CFTE290- cells or that a greater amount of polyplexes were internalized in the same compartments as in Σ CFTE290- cells.

Polyfection with Histidylated Polyplexes. The luciferase activity into the cell lines transfected with both histidylated polyplexes was similar in the absence of serum, but the luciferase activity was 2-fold greater in Σ CFTE290- cells (Table 2). The luciferase activity into Σ CFTE290- cells transfected with His-polyplexes in the presence of serum was 2-fold greater than that obtained in the absence of serum; it was also 4–5-fold greater than into cells transfected with AcHis-polyplexes (Table 2). This indicates that small polyplexes are more efficient in transfecting cells and that pDNA condensation is likely to play a role in the uptake and the intracellular processing of polyplexes which could depend on the cell type. Indeed, the luciferase activity into HepG2 cells transfected with both histidylated polyplexes was similar and did not depend on the presence of serum (Table 2).

DISCUSSION

The assembly of pDNA with histidylated polylysine at low ionic strength via both lysyl ϵ -amino and histidyl α -amino groups, gave homogeneous small particles with a positive ζ potential. As reported for polylysine and polyethylenimine (17–22), histidylated polyplexes showed high tendency to aggregate in 0.15 M NaCl and serum-free medium. In contrast, the polyplexes particles remained stable and kept a small size in 10% serum supplemented medium. This is due to the adsorption of serum proteins on the polyplexes surface which then prevents hydrophobic particle/particle interactions. Beside the major proteins of the serum including serum albumin, several other proteins with low molecular masses and molecular masses ranging between 30 and 45 kDa difficult to identify were strongly associated with His-polyplexes. They might be proteins with acidic pI such as α 1-fetoprotein (66 kDa), α 1-acid glycoprotein (41 kDa), apolipoproteins (A-I, 30 kDa; E, 34 kDa; A-II, 8.5 kDa) and α 1-microglobulin (31 kDa). The binding of these serum proteins probably occurred via interactions with protonated imidazole of His-polyplexes. Indeed, in agreement with the respective protonation of imidazole, their

binding at pH 7.4 on AcHis-polyplexes was reduced because the number of protonated imidazole in AcHis-polyplexes was lower than in His-polyplexes. While the ζ potential of both polyplexes was similar, a different distribution of the charge on the surface of polyplexes could also explain a decrease of the binding of serum proteins on AcHis-polyplexes. By using the same protocol but with plasma which instead of serum contains high molecular weight proteins of the coagulation cascade, pLK/DNA complexes were found to bind proteins with molecular masses of 66 (probably serum albumin) and 120 kDa (31, 32). Polyplexes with polyethylenimine were found to bind high molecular mass plasma proteins (up to 150 kDa) such as IgM, fibronectin, fibrinogen, complement C3 and albumin, but in this case the isolation of polyplexes was carried out by filtration (33).

In addition to the inhibition of the polyplexes aggregation, the binding of serum proteins lead to polyplexes with a net negative ζ potential (-25 mV). This reversion of the global charge of polyplexes decreased their uptake by the cells but did not decrease their transfection efficiency; it even increased 2-fold for Σ CFTE29o- cells. This suggests that a preincubation of polyplexes in autologous serum could be a way to decrease the non-specific cell binding via the negatively charged sulfated proteoglycans (34) and might be suited to overcome the activation of the alternative complement pathway by cationic particles (35). Identification of serum proteins that bind strongly to His-polyplexes could be useful for *in vivo* gene targeting.

Histidylated polylysines contain several protonable imidazoles which are supposed to induce membrane destabilization after protonation in an acidic medium. The protonation of the imidazoles appears more sensitive to the presence of the α -amino group of the histidyl residues than that of the ϵ -amino group of the lysyl residues on the polymer. The protonation of 50% of the imidazoles of His-pLK occurs at pH 6.9 whereas that of AcHis-pLK occurs at pH 6.0. The imidazole protonation is also modified when the polymer is complexed with pDNA; in AcHis-polyplexes it occurs at pH 6.5, at a 0.5 pH unit higher than in AcHis-pLK. This elevation of the pK is consistent with that reported for polyhistidine/DNA complexes (36) and for Poly(Lys,His) copolymer/DNA complexes (37). In the latter protonated imidazoles were found to interact with DNA phosphates. Therefore, the imidazole protonation of histidylated polyplexes can surely occur in endocytic vesicles following acidification of their lumen from pH 7.4 to 6.0 and can allow the destabilization of vesicles to deliver pDNA into the cytosol. However, the mechanism leading to pDNA delivery into the cytosol in the presence of His-pLK is not yet known. Membrane could be disrupted via a direct interactions of His-pLK as for H5WYG peptide (14). This peptide (GLFHAIAHFIHGGWHGLIHGWYG) containing five histidines permeabilizes the plasma membrane of cells at pH 6.1 with a midpoint at pH 6.8. The involvement of the imidazole protonation in the pDNA delivery in the cytosol is also supported by confocal microscopy data showing that histidylated oligolysines induce a cytosolic delivery of antisense oligonucleotides after their uptake by cells via acidic vesicles (38). In addition, the effect of H5WYG, histidylated oligolysines and histidylated polylysines are inhibited in the presence bafilomycin A1 an inhibitor of the ATPase proton pump of endosomes. However, the imidazole protonation of histidylated polyplexes could also buffer the lumen of vesicles containing polyplexes and induce swelling and

destabilization of vesicles as for chloroquine and polyethylenimine.

In conclusion, this study shows that the presence of free α -amino group on the histidyl residues on His-pLK allows the formation of small and soluble polyplexes. It shifts the imidazole protonation up to a neutral pH which is in favor for a destabilization of very early endocytic vesicles. The adsorption of serum proteins especially on His-polyplexes which (i) renders the particles negatively charged, (ii) reduces their nonspecific binding on the cells, (iii) stabilizes particles with a small size, and (iv) does not affect their transfection efficiency, points out that selective proteins recognized by a given cell type could be used for *in vivo* gene targeting.

ACKNOWLEDGMENT

We thank Brigitte Guérin for her skillful assistance in cell culture and plasmid preparation; Henri Labbé and Anita Caille for their skillful assistance in NMR spectroscopy; Nadège Piclin for her technical help in size measurements. Received June 30, 2000; Revised Manuscript Received October 9, 2000

Two novel macromolecular MRI contrast agents based upon generation-6 polyamidoamine dendrimers (G6) of presumed similar molecular size, but of different molecular weight, were compared in terms of their blood retention, tissue distribution, and renal excretion. Two G6s with either ammonia core (G6A) or with ethylenediamine core (G6E), which possessed 192 and 256 exterior primary amino groups, respectively, were used. These dendrimers were reacted with 2-(*p*-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M). The G6–1B4M conjugates were reacted with ¹⁵³Gd for studying biodistribution and blood clearance or Gd(III) for the MRI study. 3D-micro-MR angiography of the mice were taken with injection of 0.033 mmol of Gd/kg of G6A–(1B4M-Gd)₁₉₂ or G6E–(1B4M-Gd)₂₅₆ using a 1.5-T superconductive MRI unit. Although numerous fine vessels of ~100 μm diameter were visualized on subtracted 3D-MR-angiography with both G6A–(1B4M-Gd)₁₉₂ and G6E–(1B4M-Gd)₂₅₆, ¹⁵³Gd-labeled saturated G6E–(1B4M)₂₅₆ remained in the blood significantly more than ¹⁵³Gd-labeled saturated G6A–(1B4M)₁₉₂ at later than 15 min postinjection (*p* < 0.01). In addition, G6E–(1B4M-Gd)₂₅₆ visualized these finer vessels longer than G6A–(1B4M-Gd)₁₉₂. The G6A–(1B4M-Gd)₁₉₂ showed higher signal intensity in the kidney on the dynamic MR images and brighter kidney images than G6E–(1B4M-Gd)₂₅₆. In conclusion, the G6A–(1B4M-Gd)₁₉₂ was observed to go through glomerular filtration more efficiently than G6E–(1B4M-Gd)₂₅₆ resulting faster clearance from the blood and higher renal accumulation, even though both of G6–1B4M conjugates have almost similar molecular size and same chemical structure. In terms of the ability of intravascular contrast agents, G6E–(1B4M-Gd)₂₅₆ was better due to more Gd(III) atoms per molecule and longer retention in the circulation than G6A–(1B4M-Gd)₁₉₂.

INTRODUCTION

The starburst polyamidoamine (PAMAM)¹ dendrimers are a new class of highly branched spherical polymers that are highly soluble in aqueous solution and have a unique surface of primary amino groups (1, 2). Compared with many other types of dendritic macromolecules that recently have been synthesized, PAMAM dendrimers are the only class of macromolecules that are undispersed and show high positive charge densities restricted to the surface of the molecule (3). The defined structure and large number of available surface amino groups of PAMAM dendrimers have led to their use as substrates for the attachment of many chelating agents to single

antibody molecule (2, 4–6) and in the preparation of novel MRI contrast agents (7, 8).

Two types of macromolecular contrast agents for MRI have been reported. One was albumin conjugated with diethylenetriaminepentaacetic acid (DTPA) [albumin-(DTPA-Gd)_{30–34}], originally described by Ogan et al. (9). The other was fundamentally a polyamine conjugated with multiple chelates [DTPA derivatives or 1,4,7,10-tetraazacyclododecanetetraacetic acid (DOTA) derivatives]. Although polylysine has been used for the core of contrast agents among the various polyamines (10, 11), PAMAM dendrimers have recently been preferred as an alternative to polylysine (10–12). Wiener et al. and we reported the preferable use of generation-6 PAMAM dendrimers (G6) with ammonia core (G6A) conjugated with DTPA derivative as an intravascular macromolecular MR contrast agent (7, 13). G6 with an ethylenediamine core (G6E) have almost similar molecular size and possesses more amines than G6A (256 for G6E compared with 192 for G6A) (Figure 1). Therefore, G6E fully conjugated with DTPA can potentially complex and sequester 1.33 times as many metal atoms as G6A.

In this study, the *in vivo* pharmacokinetics of ¹⁵³Gd-labeled G6E–(1B4M)_x were evaluated in the mice and compared with those of ¹⁵³Gd-labeled G6A–(1B4M)_x. In addition, the differences between G6E–(1B4M-Gd)₂₅₆

and G6A-(1B4M-Gd)₁₉₂ as MR contrast agents were evaluated.

EXPERIMENTAL PROCEDURES

PAMAM Dendrimers. The generation-6 PAMAM dendrimer with an ammonia core (G6A) (Polysciences, Warrington, PA) that possesses 192 amino groups and has a molecular mass of 43 451 Da and the generation-6 PAMAM dendrimer (G6E) (Aldrich Chemical Co., Milwaukee, WI) with an ethylenediamine core that possesses 256 reactive amino groups and has a molecular mass of 57 991 Da were used.

Conjugation of Chelates to G6 Dendrimers. The dendrimers were concentrated to ~5 mg/mL and diafiltered against 0.1 M phosphate buffer at pH 9. The G6A and G6E dendrimers were reacted with a 192 or a 256-fold molar excess of 2-(*p*-isothiocyanatobenzyl)-6-methyldiethylenetriaminepentaacetic acid (1B4M) at 40 °C, respectively, and maintained at pH 9 with 1 M NaOH for 24 h. Another additional equal amount of the 1B4M was added to each after 24 h as a solid. The resulting preparations were purified by diafiltration using a Centricon 30 (Amicon Co., Beverly, MA) for either G6A or G6E. This resulted in 99.2 ± 1.1 and 99.8 ± 1.5% of the amine groups on the G6A and G6E dendrimers reacting with the 1B4M for four different preparations of each core, respectively, as determined by ¹¹¹In (Medipysics, Takarazuka, Japan) labeling of the reacted samples as previously described (14). In brief, ~500 000 cpm of ¹¹¹In acetate was added to ~100 µg/10 µL of the conjugate samples before diafiltration and incubated in 0.2 M acetate buffer for 15 min at room temperature. Then, the bound fractions to the conjugates and free 1B4M were separated using a PD-10 column (Pharmacia) and counted. After which, the numbers of 1B4M chelates bound to both G6A and G6E were calculated, respectively, from the count of the radioactivity in the bound fraction to the conjugates.

To evaluate the effect of fully saturating the amino groups on the surface of G6s with 1B4M chelates on their biodistribution properties, G6A and G6E were each reacted with a 4-fold molar excess of 1B4M under the same conditions described above. Finally, after purification as related above we isolated the G6A-1B4M₂ and G6E-1B4M₂ conjugates. Assaying again by ¹¹¹In confirmed saturation of the surface of the dendrimers with the 1B4M chelating agent.

Radiolabeling of G6-1B4Ms. Carrier-free ¹⁵³GdCl₃ was purchased from NEN DuPont (Boston, MA) and ~750 µg (1 µmol) of each G6-1B4M conjugate was reacted with 20 µCi of ¹⁵³Gd citrate in 0.3 M citrate buffer at pH 5 for 30 min at room temperature. To remove any nonincorporated free radiometal, 10 µL of 0.5 M EDTA

(Nakarai, Tokyo, Japan) was added and the product was purified by PD-10 column (Pharmacia, Uppsala, Sweden), which was eluted with PBS, (pH 7.4). The resulting purified materials were referred to as "unsaturated" because on the average they had one radiometal (¹⁵³Gd) per total molecule.

To evaluate the effect on biodistribution by saturation of the 1B4M chelating agents with metals, the prepared G6-1B4M conjugates were each saturated with nonradioactive gadolinium. The preparation method was the same as described above, except that a 3-fold molar excess of nonradioactive Gd(III) citrate (Nakarai, Tokyo, Japan) (3 µmol) to conjugated 1B4M was added to the reaction mixture and incubated for 1 h before addition of EDTA and subsequent column purification. The radiolabeling yields were 95–97% and from ~40%, respectively, for the unsaturated and saturated preparations.

Preparation of Contrast Agent for MRI with nonRadioactive Gd(III). Approximately ~3 mg of each G6-1B4M conjugate (containing 4 µmol of 1B4M) were mixed with 6 µmol of nonradioactive Gd(III) citrate in 0.3 M citrate buffer for 2 h at 40 °C. The excess Gd in each preparation was removed by diafiltration using the Centricon 30 (Amicon Co.) for G6A and G6E while simultaneously changing the buffer to 0.05 M PBS. The purified samples were diluted to 0.5 mL with 0.05 M PBS and 100 µL was used as the MRI contrast agent per mouse. A replacement assay for three different preparations of each conjugate using ¹⁵³Gd determined that 81.9 ± 1.9 and 82.5 ± 1.8% of the 1B4M on the G6D-1B4M conjugates were indeed chelating Gd(III) atoms, respectively. In brief, ~100 000 cpm of ¹⁵³Gd was added with 0.1 µmol of nonradioactive Gd(III) to 5 µL of the injected samples and incubated in 0.5 M citrate buffer for 2 h at 40 °C, after which the bound and unbound fractions to the conjugates were separated using a PD-10 column (Pharmacia) and counted. After which, the number of Gd atoms replaced from the gadolinium citrate to 1B4M was calculated from the count of the radioactivity in the bound fraction. Then, the number of available 1B4M chelates for binding Gd atoms on the conjugates was calculated.

Biodistribution of ¹⁵³Gd-Labeled G6-1B4Ms. Six groups of nude mice (*n* = 4 in each group) were each injected with one of the following preparations: 0.8 µCi/200 µL of ¹⁵³Gd-labeled unsaturated G6A-(1B4M)₁₉₂ or G6E-(1B4M)₂₅₆; 0.5 µCi/200 µL of ¹⁵³Gd-labeled saturated G6A-(1B4M)₁₉₂ or G6E-(1B4M)₂₅₆; 0.5 µCi/200 µL of ¹⁵³Gd-labeled saturated G6A-(1B4M)₂ or G6E-(1B4M)₂. All studies were approved by the Animal Care Committee of Kyoto University. The mice were euthanized 15 min after the injection of ¹⁵³Gd-labeled preparation. Biodistribution studies were carried out, and the data were expressed as the percent injected dose per gram (% ID/g) of tissue and blood-to-normal tissue ratio. The blood was drawn (~0.7 mL) by the cardiac puncture. In the case of bone, the bone marrow was included.

Blood Clearance of ¹⁵³Gd-Labeled Saturated G6-1B4Ms. Two groups of nude mice (*n* = 4 in each group) were carefully injected with 3.5 µCi/200 µL of ¹⁵³Gd-labeled saturated G6A-(1B4M)₁₉₂ or G6E-(1B4M)₂₅₆ from the proximal portion of the left tail vein without any subcutaneous leakage. All mice received a small cut on their distal or middle portion of the right tail vein and blood samples were collected with a 5-µL micropipet 2, 6, 15, 30, 60, 120, and 240 min postinjection of ¹⁵³Gd-labeled preparations. The data were expressed as the

Figure 2. Biodistribution of ^{153}Gd -labeled unsaturated or saturated preparations of G6A [G6A-(1B4M-Gd)₂ (■), G6A-(1B4M)₁₉₂-Gd (cross-hatched bar), or G6A-(1B4M-Gd)₁₉₂ (□)] (a) and ^{153}Gd -labeled unsaturated or saturated preparations of G6E [G6E-(1B4M-Gd)₂ (■), G6E-(1B4M)₂₅₆-Gd (cross-hatched bar), or G6E-(1B4M-Gd)₂₅₆ (□)] (b) in normal nude mouse at 15 min after injection. The data are expressed as the mean percentages of injected dose per gram of normal tissues and standard deviation ($n = 4$ or 5). The asterisks indicate significant differences ($p < 0.01$) compared with G6A.

Figure 3. Blood clearance of ^{153}Gd -labeled saturated G6A-(1B4M-Gd)₁₉₂ (open circle) or G6E-(1B4M-Gd)₂₅₆ (closed circle) in normal nude mouse 2, 6, 15, 30, 60, 120, and 240 min postinjection. The data are expressed as the mean percentages of injected dose per gram of blood and standard deviation ($n = 4$). The asterisks indicate significant differences ($p < 0.01$) compared with G6A.

percent injected dose per gram (% ID/g) of blood, and then the data of each mouse were fitted by the single-exponential curve, and the half-life of each preparation from the blood was calculated.

Excretion and Body Retention of ^{153}Gd -Labeled Saturated G6D-1B4M Conjugates. Two groups of nude mice ($n = 3$ in each group) were injected with 2 $\mu\text{Ci}/200 \mu\text{L}$ of either ^{153}Gd -labeled saturated G6A-(1B4M)₁₉₂ or G6E-(1B4M)₂₅₆. The mice were put in a metabolic cage for 2 days and their urine and feces were serially collected 3, 10, 24, and 48 h postinjection. The mice were euthanized and the amount of ^{153}Gd in the carcass was measured. The data were expressed as percentage of injected dose (% ID).

Figure 4. Urinary (circle) and fecal (square) excretion of ^{153}Gd -labeled G6A-(1B4M-Gd)₁₉₂ (open circle/square), or G6E-(1B4M-Gd)₂₅₆ (closed circle/square). The data are expressed as the mean percentages of injected dose of three mice, which put in a metabolic cage together.

3D-micro-MR Angiography of Mice. MR angiography of the mice were taken with injection of 0.033 mmol of Gd/kg of G6D-A-(1B4M-Gd)₁₉₂ (175 kDa) or G6D-E-(1B4M-Gd)₂₅₆ (240 kDa) using a 1.5-T superconductive magnet unit (Signa, General Electric Medical System, Milwaukee, WI). Six female 8 week-old balb/c nu/nu mice of 18–21 g body weight in each group were used and each contrast agent was prepared at least four separate times for these imaging studies. All images were obtained with dual phased-array 3-in. round surface coils fixed at 3-cm intervals by an in-house constructed mouse and coil holder. The mice were anesthetized with 1.15 mg of sodium pentobarbital (Dainabot, Osaka, Japan) and placed at the center of the coils. The 3D-fast spoiled gradient echo (FSPGR; TR/TE 150/4.2; flip angle 60°; scan time 1 min, 48 s) with chemical fat-suppression

Figure 5. Plots of the signal intensity in the left ventricle of the heart (a), the cortex (b) and medulla (c) of the kidney, the inferior vena cava (d), the liver (e), and the muscle (f) obtained from the contrast-enhanced dynamic MRI of mice with 0.033 mmol/Kg of G6A-(1B4M-Gd)₁₉₂ (open circle) or G6E-(1B4M-Gd)₂₅₆ (closed circle). The single and double asterisks indicate significant differences ($p < 0.01$ and $p < 0.05$, respectively).

technique were used for all mice from 0 to 14 min after injection of the contrast agents for all mice. The coronal images were reconstructed with 2-mm section thickness without gaps. The FOV was 8×6 cm and the size of matrix was 256×192 . The regions of interest were set to be the ventricles, inferior vena cava, the cortex and medulla of the kidney, and other organs and analyzed the time-intensity curve. In addition, the slice data were processed subtracting from postcontrast images to pre-contrast images and constructing into 3D images with the maximum intensity projection (MIP) method using

a work station (Advantage Windows, General Electric Medical System).

Statistical Analysis. Statistical analysis was performed using either student-*t* test or the one-way analysis of variance (ANOVA), with pair wise comparison using the Bonferroni method (Sigmastat, Jandel Scientific, San Rafael, CA).

RESULTS

Biodistribution of ¹⁵³Gd-Labeled G6-1B4Ms. Saturated G6E vs G6A. The ¹⁵³Gd-labeled saturated G6E-

Figure 6. The values of the enhancement effects ratio in the cortex (a) and the medulla (b) of kidney, the liver (c), and the muscle (d) to the blood in the left ventricle of the heart were plotted. (enhancement effects ratio) = $\{[(\text{the postcontrast signal intensity of the organs}) - (\text{the precontrast signal intensity of the organs})] / [(\text{the postcontrast signal intensity of the left ventricle}) - (\text{the precontrast signal intensity of the left ventricle})]\}$. The single and double asterisks indicate significant differences ($p < 0.01$ and $p < 0.05$, respectively).

(1B4M)₂₅₆ ($32.4 \pm 0.6\%$ ID/g) remained in the blood significantly more than the ^{153}Gd -labeled saturated G6A-(1B4M)₁₉₂ ($24.2 \pm 1.1\%$ ID/g) ($p < 0.01$) and accumulated significantly less in the liver (17.1 ± 1.2 vs $28.9 \pm 1.2\%$ ID/g) and in the kidney (13.6 ± 0.5 vs $17.8 \pm 0.4\%$ ID/g) than all other preparations ($p < 0.01$) (Figure 2).

Saturated G6E/G6A vs Unsaturated G6E/G6A. Both ^{153}Gd -labeled unsaturated G6-(1B4M)_x preparations accumulated significantly more in the liver (51.6 ± 2.4 and $57.2 \pm 1.2\%$ ID/g for G6E and G6A) and less in the blood (0.4 ± 0.1 and $0.3 \pm 0.1\%$ ID/g for G6E and G6A) than the saturated preparations ($p < 0.01$) (Figure 2).

G6-(1B4M)₂ Preparation. Both ^{153}Gd -labeled saturated G6-(1B4M)₂ preparations which have much smaller molecular masses (60 and 45 kDa for G6E and G6A), accumulated significantly less in the liver (24.4 ± 0.5 and $25.7 \pm 0.9\%$ ID/g for G6E and G6A) and more in the kidney (59.8 ± 0.5 and $78.7 \pm 2.7\%$ ID/g for G6E and G6A) than both the ^{153}Gd -labeled unsaturated and saturated G6E-(1B4M)₂₅₆ and ^{153}Gd -labeled G6A-(1B4M)₁₉₂ ($p < 0.01$) (Figure 2). In this case, ^{153}Gd -labeled saturated G6E-(1B4M)₂ accumulated significantly less in the kidney than ^{153}Gd -labeled saturated G6A-(1B4M)₂ ($p < 0.01$).

Blood Clearance of ^{153}Gd -Labeled Saturated G6-1B4Ms. The blood retention of ^{153}Gd -labeled G6E-(1B4M)₂₅₆ was significantly greater than that of ^{153}Gd -labeled G6A-(1B4M)₁₉₂ at all time points later than 15 min postinjection (Figure 3; $p < 0.01$). The blood half-life of the ^{153}Gd -labeled saturated PAMAM-1B4Ms was

132 ± 29 and 51 ± 17 min for G6E-(1B4M-Gd)₂₅₆ and G6A-(1B4M-Gd)₁₉₂, respectively.

Excretion and Body Retention of ^{153}Gd -Labeled Saturated G6D-1B4M Conjugates. The cumulative urinary excretion of ^{153}Gd -labeled G6E-(1B4M)₂₅₆ (6.0% ID) was less than that of ^{153}Gd -labeled G6A-(1B4M)₁₉₂ (8.5% ID) within 48 h postinjection (Figure 4). The cumulative fecal excretion of ^{153}Gd -labeled G6E-(1B4M)₂₅₆ (3.4% ID) was more than that of ^{153}Gd -labeled G6A-(1B4M)₁₉₂ (1.9% ID) within 48 h postinjection (Figure 4). The whole body retention of ^{153}Gd -labeled G6E-(1B4M)₂₅₆ and ^{153}Gd -labeled G6A-(1B4M)₁₉₂ was 80.9 ± 2.8 and $79.7 \pm 3.2\%$ ID 48 h postinjection, respectively ($p = 0.6$).

3D-micro-MR Angiography of Mice. G6E-(1B4M-Gd)₂₅₆ showed slightly higher signal intensity in the left ventricle of the heart and the inferior vena cava at some of the later time points and significantly lower signal intensity than G6A-(1B4M-Gd)₁₉₂ in the both cortex and medulla of the kidney at all time points that were examined ($p < 0.01$; Figure 5). No significant difference in the signal intensity was observed in the liver and the muscle. Therefore, left ventricle/kidney signal intensity ratio of G6E-(1B4M-Gd)₂₅₆ was significantly lower than that of G6A-(1B4M-Gd)₁₉₂ ($p < 0.01$; Figure 6).

The subtraction MR-angiography with G6A-(1B4M-Gd)₁₉₂ showed apparently brighter kidneys on both early and delayed images (Figure 7).

Figure 7. A pair of the whole body 3D-micro-subtraction-MR-angiography of a mouse, which were constructed with the MIP method with immediately after (left) and 8 min after (right) injection of 0.033 mmol/kg of G6A-(1B4M-Gd)₁₉₂ (a) or G6E-(1B4M-Gd)₂₅₆ (b) are shown. The brighter kidney was shown on panel a than on panel b. The scale shown at the bottom indicates 1 cm.

DISCUSSION

The difference in molecular diameter between G6E-(1B4M-Gd)₂₅₆ and G6A-(1B4M-Gd)₁₉₂ was theoretically expected to be very small because the only difference between those molecules were the core portions (ammonia versus ethylenediamine). Both of these molecules were expected then to have arms of the same length and thus similar spherical shape. When the 1B4M was conjugated with all amino-groups on the surface of the

molecule, the chemical properties of both molecules were then expected to remain similar. However, not only G6E-(1B4M-Gd)₂₅₆ versus G6A-(1B4M-Gd)₁₉₂, but also G6E-(1B4M-Gd)₂ versus G6A-(1B4M-Gd)₂, showed different pharmacokinetics in vivo, especially in the kidney (glomerular filtration). The G6A was predicted to have sparser arms than G6E simply on a numerical basis. Therefore, we speculated that G6A-(1B4M-Gd)₁₉₂ would be more flexible for changing shape than G6E-(1B4M-Gd)₂₅₆,

resulting in increasing the possibility to pass through glomerular filtration.

In the previous and current studies, supporting data was obtained to explain that not only the molecular weight, but also the size and shape of the molecule is an important contributing criteria for glomerular filtration (13). In brief, a hypothesis that the PAMAM-(1B4M-Gd)_x might be filtered through the glomerulus more readily than a nonspherical protein with a comparable molecular weight was formed. Previous results indicated that the G5A-(1B4M-Gd)₉₆ (88 kDa) was partially filtered through the glomerulus, even though G5A-(1B4M-Gd)₉₆ had a greater molecular mass than albumin, thus supporting this hypothesis. In addition, although G4E-(1B4M-Gd)₆₄ (57 kDa) had greater molecular mass and smaller molecular size than G6A-(1B4M-Gd)₂ (45 kDa), the G4E-(1B4M-Gd)₆₄ was significantly filtered more from the glomerulus than G6A-(1B4M-Gd)₂. From these results, not only molecular mass, but also shape, size or charge of the molecule affects the glomerular filtration of these molecules.

A second aspect of this study was that differences in the surface charge density of these molecules might also be an important criteria influencing both clearance rate and route. G6E should have higher surface density charge than G6A simply due to the greater number of 1B4Ms on the exterior of a similar size spherical surface. We have previously reported that the charge of two molecules of similar molecular size, ranging from 40 to 70 kDa, can strongly affect their glomerular filtration (15). However, in this case, this explanation would not be appropriate. The unsaturated G6E-(1B4M-Gd)₂₅₆, which possesses a greater negative charge and G6E-(1B4M-Gd)₂, which has a greater positive charge, both exhibited lower renal accumulation than their respective G6A counterparts. The differences in glomerular filtration influenced the blood clearance rate for both molecules as well, which was reflected in their ability to function as macromolecular intravascular MR contrast agent.

Macromolecular contrast agents for magnetic resonance imaging (MRI) have been reported to be excellent methods to evaluate microvasculature and histological capillary density in tumor tissues (16, 17). Although postcontrast signal changes in the tumors have shown better correlation with histological capillary mass, only in our previous report was the intratumoral microvasculature directly evaluated with MRI using macromolecular MR contrast agents (Kobayashi et al. in submission to *Magn. Reson. Med.*)

In terms of prolongation of contrast-enhancement and large number of Gd(III) atoms containing in a molecule, G6E-(1B4M-Gd)₂₅₆ is superior to G6A-(1B4M-Gd)₁₉₂. Additionally, when using the G6A-(1B4M-Gd)₁₉₂ to visualize microvasculature clearly, the dose of Gd(III) atoms could be decreased to 33% of the current clinical dose for Gd-DTPA (13). Thus, use of G6E-(1B4M-Gd)₂₅₆ would possibly decrease the dose of Gd(III) minimizing toxicity.

In conclusion, G6E-(1B4M-Gd)₂₅₆ demonstrated longer blood retention and lower renal accumulation than the G6A-(1B4M-Gd)₁₉₂, although both of these molecules were expected to theoretically have approximately the same molecular diameter. G6E-(1B4M-Gd)₂₅₆ may be a potential candidate as an intravascular MR contrast agent with a maximum number of Gd(III) atoms and minimal size so as not to be excreted through the kidney and perform as a superior contrast agent for vascular imaging.

New Cationic Liposomes for Gene Transfer into Mammalian Cells with High Efficiency and Low Toxicity

Joon Sig Choi, Eun Jung Lee, Hyung Suk Jang, and Jong Sang Park*

School of Chemistry & Molecular Engineering, Seoul National University, San 56-1, Shillim-dong, Kwanak-ku, Seoul, 151-742, Korea. July 10, 2000

Novel cationic amphiphiles, based on hydrophobic cholesterol linked to L-lysineamide or L-ornithineamide, were designed and tested as nonviral gene transfer vectors. Each amide form of amino acid was conjugated to cholesterol by a carbamate ester bond to facilitate efficient degradation in animal cells. Cytotoxicity tests were performed for some cell lines. The transfection efficiency of the amphiphiles on different cell lines was evaluated as a liposomal solution in the presence of the fusogenic helper lipid, dioleoyl phosphatidylethanolamine (DOPE). The efficiency was also compared with other generally used gene carriers, such as lipofectin, 3 β [N-(N'-N'-dimethylaminoethane)-carbamoyl] cholesterol (DC-Chol) liposome, and polyethylenimine (PEI).

INTRODUCTION

Gene therapy is generally considered as a promising approach not only in the treatment of diseases with genetic defects but also in the development of strategies for treatment and prevention of chronic diseases such as cancer, cardiovascular diseases, and rheumatoid arthritis. Intensive investigation has been conducted during the past decade into methods for transferring genes to cells (1–4). The methods used so far make use of either viral systems (retroviruses or adenoviruses) or nonviral systems (polymers, electroporation, calcium-phosphate precipitation, peptides, and liposomes). Even though some viral systems showed remarkable levels of expression, they are limited for general use in vivo due to their low capacity for large-sized therapeutic genes as well as short and long-term risks such as generation of host immune responses and the possibility of inserted genes combining with endogenous viruses or activation of oncogenes (2, 4).

Consequently, there has been increasing attention focused on the development of safe and efficient nonviral gene transfer vectors (5), which are either polycationic polymers or cationic lipids. Polycationic polymers, e.g., poly-L-lysine, poly-L-ornithine, and polyethylenimine (6, 7), that could interact with DNA forming polyionic complexes, have been introduced for gene delivery. Various cationic lipids have also been proven to form lipoplexes with DNA and induce efficient transfection of a large number of eukaryotic cells (5, 8, 9). Among such kinds of synthetic vectors, cationic lipids are attractive and widely used because it is possible to design and synthesize various kinds of derivatives that are outstanding in the aspects of transfection efficiency, biodegradability, and low toxicity (10). Some cationic lipids are commercially available, and several lipids have already been used in the clinical setting. Among them, cationic cholesterol derivatives are known to be very useful for their high transfection efficiency and low toxicity (11–17). However, there are still many issues to be tackled

such as the gene transfer potency, the half-life in the blood stream, and the biocompatibility deserving less cytotoxicity.

In light of the above considerations, we have prepared and described in this paper new promising DNA delivery agents composed of L-lysineamide, L-ornithineamide and cholesterol, which are designed to be readily susceptible to metabolic degradation after incorporation into animal cells. 3 β [L-lysineamide-carbamoyl] cholesterol (K-Chol)¹ and 3 β [L-ornithineamide-carbamoyl] cholesterol (O-Chol) were synthesized by the solid-phase synthesis method which has several advantages such as simplification of reaction procedures, easy separation of the supported products, and possibility of application to automatic systems.

It was demonstrated that the newly designed cationic cholesterol derivatives were less toxic and more efficient in transfection than lipofectin and DC-Chol. The results for the biocompatible lipids suggest their potential use as general reagents for transfection of mammalian cells and in vivo applications for gene therapy.

MATERIALS AND METHODS

Materials. N- α -Fmoc-N- ϵ -tBOC-L-lysine, N- α -Fmoc-N- ϵ -tBOC-L-ornithine, N-hydroxybenzotriazole (HOBt), and 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) were purchased from AnaSpec, Inc. (San Jose, CA), and cholesteryl chloroformate, N,N-diisopropylethylamine (DIPEA), N,N-dimethylformamide (DMF), piperidine, dichloromethane, and polyethylenimine (PEI, 25 kDa) were from Aldrich (St. Louis, MO). N-[2-Hydroxyethyl]piperazine-N'-[2-ethanesulfonic acid] (HEPES), ethidium bromide (EtBr), o-nitrophenyl- β -D-galactopyranoside (ONPG), 1,2-dioleoyl-sn-glycero-3-phosphatidylethanolamine (DOPE), and 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl tetrazolium bromide (MTT) were purchased from Sigma (St. Louis, MO). Rink amide

resin was from Novabiochem (San Diego, CA). Fetal bovine serum (FBS), Dulbecco's modified Eagle's medium (DMEM), and Dulbecco's phosphate-buffered saline (DPBS) were purchased from GIBCO (Gaithersburg, MD). Minimal essential medium (MEM) was from Hyclone (Logan, UT). 5× Reporter lysis buffer, lipofectin, and pSV- β -gal plasmid (EMBL accession no. X65335) were all purchased from Promega (Madison, WI). DC-Chol was synthesized according to Gao and Huang (12).

Synthesis of K-Chol and O-Chol. As shown in Scheme 1, L-lysine was attached to the rink amide resin by using fluoren-9-ylmethoxycarbonyl (Fmoc) chemistry (18, 19). Coupling of amino acid to the resin was performed with 6 equiv of HOBt, HBTU, *N*- α -Fmoc-N- ϵ -tBOC-L-lysine (AnaSpec, Inc., San Jose, CA), and DIPEA, respectively, in anhydrous DMF. Piperidine (30%) was used for deprotection of the Fmoc group of lysine. Cholesteryl chloroformate was added to the resin-bound lysine (6 equiv, DCM, 25 °C, 4 h). The progress of each reaction was monitored by ninhydrin test until completion. After treating TFA (50:50 TFA-DCM v/v, 4 °C, 1.5 h), the final product was precipitated in ethyl ether and washed with excess ether. The product was solubilized in water and collected by freeze-drying yielding colorless powder (85% yield based on the initial loading level of rink amide resin). The compound gave a single spot on a TLC plate (ethyl acetate:*n*-butanol:acetic acid:H₂O = 2:1:1:1 v/v/v/v, *R_f* = 0.7). ¹H NMR, (300 MHz, *d*₆-DMSO) δ (ppm) 0.65–2.26 (m, skeleton of cholesterol, -(CH₂)₃- of Lys), 2.75 (br, s, ϵ -CH₂ of Lys), 4.3 (br, s, α -CH of Lys) 7.2 (br, -NH₂ of Lys) 7.7 (br, -CO-NH- of Lys). Matrix-assisted laser desorption ionization time-of-flight (MALDI TOF) mass spectra, *m/z* 576 [M + Na]⁺. The product was resuspended in water and stored in refrigerator before use. The compound was stable in aqueous solution over 6 months at 4 °C.

The overall synthesis scheme for O-Chol was the same as described above. *N*- α -Fmoc-N- ϵ -tBOC-L-ornithine was used for the preparation of O-Chol. The compound also gave a single spot on a TLC plate (*R_f* = 0.63). ¹H NMR (300 MHz, *d*₆-DMSO) δ (ppm) 0.65–2.26 (m, skeleton of cholesterol, -(CH₂)₂- of Orn), 2.75 (br, s, -CH₂ of Orn),

4.3 (br, s, -CH of Orn) 7.2 (br, -NH₂ of Orn) 7.7 (br, -CO-NH- of Orn). MS (MALDI) *m/z* 560.2 [M + Na]⁺.

Liposome Preparation. DOPE in chloroform was evaporated under a stream of N₂ gas and further dried under vacuum. Each cationic lipid solubilized in water was added to the dried DOPE and vortex mixed (weight ratio of cationic lipid: DOPE = 1:1). After overnight incubation at 4 °C for hydration, the mixture was sonicated using a bath-type sonicator. The shape and size distribution of the liposome was determined by atomic force microscopy as described below.

Plasmid Preparation. Plasmid pSV- β -gal, where the β -galactosidase reporter gene is expressed was amplified in *Escherichia coli* and prepared as described previously (20).

Agarose Gel Electrophoresis. Lipoplexes were formed at different charge ratios between K-Chol and pSV- β -gal plasmid by incubation in serum-free DMEM at room temperature for 30 min. Each sample was then analyzed by electrophoresis on a 0.7% agarose gel containing ethidium bromide (0.5 μ g/mL of gel).

Atomic Force Microscopy. Atomic force microscopy (Nanoscope IIIa system, Digital Instruments, Inc., Santa Barbara, CA) was used for imaging the shape and particle size of the liposomes and liposome-DNA complexes, as previously reported (21). Briefly, 2 μ L aliquots of either liposome solution or aqueous liposome-DNA complex solutions were loaded onto the center of a freshly split mica disk. The charge ratio of liposome/DNA was set to 1.7, at which the transfection efficiency was optimal. After adsorption for 1–2 min at room temperature, excess complex solution was removed by absorption onto filter paper and the mica surface was further dried at room temperature before imaging. The image mode was set to tapping mode and the average scanning speed was 5 Hz.

Cell Culture. Human embryonic kidney 293 and mouse embryonic fibroblast NIH3T3 cells (ATCC, Rockville, MD) were grown in DMEM with 10% FBS. Human liver carcinoma HepG2 cells (Korean Cell Line Bank) were propagated in MEM supplemented with 10% FBS. All cells were routinely maintained on plastic tissue culture dishes (Falcon) at 37 °C in a humidified 5% CO₂/95% air containing atmosphere.

Determination of Cell Toxicity. Each of the cell lines was seeded in 96 well plates (1–2 $\times$ 10⁴ cells/well) and incubated for 1 day prior to experiment. Lipofectin, PEI, and cationic liposomes were introduced to the cells and incubated for 48 h. The cytotoxicity was determined by comparing the amount of MTT reduced by the cells treated with carriers to that reduced by control cells (22).

Transfection Procedures. For transfection, (1–1.5) $\times$ 10⁵ cells/well were seeded in 24 well plates 1 day prior to transfection experiments, and grown in the appropriate medium with 10% FBS. The cell lines were 60–70% confluent at the time of transfection. Complexes were prepared by mixing each reagent with plasmid DNA (2.0 μ g/well) in FBS-free medium. Each complex solution was further incubated for 30 min at room temperature and added to the cells. Transfection was performed in serum-free medium for 4 h. Each medium was replaced with a fresh complete medium and gene expression was assayed 48 h post-transfection. Control transfections were performed by using DC-Chol liposome and commercially available transfection reagents, such as lipofectin and PEI.

Transfection Assay. The expressed β -galactosidase activity was measured by a standard method as recommended by the manufacturer (23). Briefly, each cell in

Figure 1. The structures of the cationic lipids. (A) DOTMA (lipofectin). (B) DC-Chol. (C) K-Chol. (D) O-Chol.

the 24 well plates was washed with DPBS and lysed with Reporter lysis buffer. The cell lysates were analyzed using the colorimetric ONPG assay in a 96-well plate format. The protein concentration was determined by the Pierce Micro BCA Protein Assay Reagent Kit, using BSA as standard. β -Galactosidase activity is expressed in total milliunits per mg of protein. One milliunit is defined as the amount of β -galactosidase that hydrolyzes 1 nmol of ONPG/min at pH 7.5 at 37 °C.

RESULTS AND DISCUSSION

Syntheses and Features of K-Chol and O-Chol.

The cationic lipids, K-Chol and O-Chol, were prepared in good yields by the solid-phase synthesis method and their structures are presented in Figure 1. The amphiphiles are composed of naturally occurring lipid and amino acid that could be metabolized after administration into animal cells. The amphiphiles are structurally related to the various cationic cholesterol derivatives previously reported, such as ChoSC or ChoTB (11), DC-Chol (12), spermine-cholesterol (13), cholesteryl-spermidine (14), BGSC or BGTC (15), and some DC-Chol derivatives (16, 17). As the primary amino group is abundant in poly-L-lysine and PEI, which are generally used in polymer-mediated gene transfer, that of lysinamide or ornithinamide is considered to be capable of interacting electrostatically with polyphosphate anions of plasmid DNA. The amphiphiles contain a carbamate ester bond that could be efficiently degraded in the cells (12).

Charge Ratio-Dependent Complex Formation and Transfection Activity. To assess the complex formation of K-Chol with DNA, agarose gel electrophoresis of cationic lipid:DNA complexes was performed at various charge ratios. As shown in Figure 2A, plasmid DNA became completely saturated at a charge ratio of around 2 ($\pm$). In addition, some completely retarded

Figure 2. (A) Agarose gel retardation of K-Chol/DNA complexes as a function of cationic lipid to plasmid DNA charge ratio. pSV- β -gal plasmid DNA (1.0 μ g) only (lane 1), charge ratio of K-Chol/DNA = 0.2, 0.3, 0.6, 1.7, and 2.8 (lanes 2, 3, 4, 5, and 6, respectively). (B) β -Galactosidase expression as a function of the mean ionic charge ratio of the lipid/DNA complexes (ϵ -NH₃⁺ group of the cationic lipid to DNA phosphate anion). HepG2 cells were transfected at a fixed amount of DNA (2.0 μ g/well) with various amounts of cationic liposome. Data are shown as mean $\pm$ SD ($n = 3$).

complexes were observed at charge ratios even below 1, which indicates that the mode of K-Chol binding to DNA is cooperative (24).

The results shown in Figure 2B demonstrate the dose dependent transfection activity of K-Chol and O-Chol liposomes for HepG2 cells, with an optimal charge ratio of 1.7 ($\pm$). It was apparent that the transfection efficiency showed a bell-shape dependence on the liposome concentration. Low transfection efficiency at charge ratios below 1 is generally presumed to be due to reduced cell membrane binding, and decreased efficiency at high charge ratios seems to be due to the toxicity of the cationic lipid (15).

AFM Images of the Liposomes and the Liposome-Plasmid DNA Complexes. To examine the shape and size distribution of liposomes and liposome-DNA complexes, atomic force microscopy was introduced. As shown in Figure 3, panels A and B, K-Chol/DOPE liposome gave small vesicles with a diameter of 40–110 nm and O-Chol/DOPE liposome was somewhat larger in size, ranging from ca. 60 to 150 nm. When these liposomes were complexed with plasmid DNA, larger heterogeneous particles were observed and their shapes varied from spherical vesicles to amorphous aggregates (Figure 3, panels C and E). Uncomplexed free liposomes were also observed. As for K-Chol/DOPE-DNA complexes, the particles were 0.3–0.6 μ m in size and O-Chol/DOPE-DNA complexes gave larger particles in the range 0.4–1.2 μ m. As presented in Figure 3, panels C and E, fiberlike structures were also observed surrounding spherical vesicle-like structures. Some sections of Figure 3, panels C and E, are enlarged and presented in panels

Figure 3. AFM images of liposomes and liposome-DNA complexes. (A) K-Chol/DOPE liposome; (B) O-Chol/DOPE liposome; (C), (D) K-Chol/DOPE liposome-DNA complex; (E), (F) O-Chol/DOPE liposome-DNA complex. The white color indicates a height in excess of the designated *nm* above the mica surface. The *x* and *y* dimensions are scaled as shown.

D and F, respectively. These complexes showed aggregates connected in rows by fibrous structures, and this result conforms to previous electron microscopy studies that have reported large aggregates surrounded by thin fibers (25). Even though the structure and location of complexed DNA could not be definitely distinguished in the presented images, the fibrous structures are presumed to result from the interaction of DNA with the cationic liposomes.

Effects of the Liposomes on the Viability of Cells.

The cytotoxicity of our cationic liposomes was compared with that of lipofectin, DC-Chol liposome, and PEI, all are widely used as gene transfer reagents. As shown in Figure 4, the viability of the cells decreased abruptly accordingly as the amount of PEI or lipofectin increased. Cationic cholesterol liposomes showed a lower toxicity level for 293 cells compared to lipofectin and PEI (Figure 4A). In the case of NIH3T3 cells, toxicity was also observed for all the reagents at concentrations much higher than those required for optimal transfection, even though K-Chol and O-Chol liposomes showed much

reduced toxicity toward the cells at the same concentration ranges (Figure 4B). For HepG2 cells, K-Chol and O-Chol liposomes were noticeably less toxic to the cells than other reagents (Figure 4C). The IC_{50} values of the transfection reagents are shown in Table 1.

An important feature of our cationic liposomes is their relatively low toxicity toward the cells at concentrations required for optimal transfection, for cytotoxicity is one of the major hurdles in the application of many cationic amphiphiles. The toxicity of some of the commercially available cationic lipids and synthetic polycationic polymers, such as lipofectin and PEI, has been attributed to their nonnatural, nonbiodegradable nature.

Transfection Efficiency on Different Cell Lines.

To investigate the effectiveness of K-Chol and O-Chol for in vitro transfection of mammalian cells, we performed in vitro transfection tests with some cell lines routinely used in laboratories. It already has been shown that some cell types, especially NIH3T3 cells, are not susceptible to transfection with lipofectin (8, 26, 27) or DC-Chol (27). It was therefore of interest to examine the versatility in

Figure 4. Effect of PEI, lipofectin, DC-Chol/DOPE, K-Chol/DOPE, and O-Chol/DOPE liposome on the cell viability. Relative cell viability was calculated, assuming the absorbance at 570 nm of intact control cells to be 100%. (A) 293 cells. (B) NIH3T3 cells. (C) HepG2 cells. Each data point is the average $\pm$ SD of three different measurements.

transfection efficacy of K-Chol and O-Chol liposomes. To determine the efficiency of the liposomes, they were compared directly with PEI, lipofectin and DC-Chol liposome on the three cell lines. The amounts of lipofectin and DC-Chol liposome were adjusted to the optimum transfection condition. PEI (25 kDa) is known to have the greatest transfection efficiency among PEI derivatives (7, 28). In this experiment, PEI was also tested and

Table 1. Comparison of Cytotoxicity for Different Transfection Reagents^a

transfection reagents	IC ₅₀ (μ g/mL)		
	293	NIH3T3	HepG2
polyethylenimine	9.45	<4.54	14.7
lipofectin	35.5	17.9	21.2
DC-Chol/DOPE	ND	17.2	15.5
K-Chol/DOPE	57.5	21.9	39.2
O-Chol/DOPE	ND	40.9	ND

^a The concentration in which relative viability reached 50% comparing to the control was determined as IC₅₀. When the viability did not reach to the half value even the concentration was over 60 μ g/mL, it was represented as ND (not determined).

Figure 5. Transfection activity of PEI, lipofectin, DC-Chol/DOPE, K-Chol/DOPE, and O-Chol/DOPE liposome. Each value is the mean $\pm$ SD of three different experiments.

used at its optimal condition as previously reported (29, 30). As shown in Figure 5, PEI and O-Chol liposome were the most effective carriers in transfection efficiency for all cells at the routine transfection condition, i.e., for 4 h transfection in the serum free medium. In addition, NIH3T3 and HepG2 cells, which were somewhat refractory to transfection with lipofectin and DC-Chol liposome, displayed high transfection susceptibility toward K-Chol and O-Chol liposome. Our cationic liposomes were more effective than lipofectin and DC-Chol liposome in transfection efficacy for all the cell lines tested. Moreover, the efficiency of O-Chol liposome-mediated transfection was remarkable and was comparable to that of PEI reagent.

In conclusion, we have described the development of some novel cholesterol-based amphiphiles, which were named as K-Chol and O-Chol, respectively. These cationic liposomes self-assembled with plasmid DNA and displayed a relatively high efficient capability to transfect some mammalian cells in vitro. Their transfection efficiency with relatively low cytotoxicity and ease of preparation would make them further promising candidates for general gene therapy experiments both in vitro and in vivo.

Highly Fluorinated Lipospermines for Gene Transfer: Synthesis and Evaluation of Their in Vitro Transfection Efficiency

Jérôme Gaucheron, Catherine Santaella,[†] and Pierre Vierling*

Laboratoire de Chimie Bio-Organique, UMR 6001 CNRS, Université de Nice Sophia-Antipolis, Faculté des Sciences, 06108 Nice Cédex 2, France. Received July 26, 2000; Revised Manuscript Received September 15, 2000

Fluorinated double-chain lipospermines (one or both of these chains being ended by a highly fluorinated tail of various length) which are close analogues of DOGS (Transfectam) were designed as synthetic vectors for gene delivery. For *N/P* ratios (*N* = number of amine functions of the lipid; *P* = number of DNA phosphates) from 0.8 to 10, these lipospermines condensed DNA, with or without the use of DOPE, to form fluorinated lipoplexes. The efficiency of the fluorinated lipoplexes to transfect lung epithelial A549 cells was significantly higher than that of the DOGS lipoplexes. No specific cell toxicity was evidenced for the fluorinated lipoplexes as compared to that of the DOGS ones. The palette of structural elements explored allowed to determine those required for efficient transfection, highlighting the importance of highly fluorinated chains, the unique properties of unsaturated double-chain lipids and of the use of DOPE as helper lipid on transfection.

INTRODUCTION

Gene transfer has become an increasingly important technique and powerful research tool for gene therapy which is applicable to inherited deficiency diseases (cystic fibrosis, dystrophies, haemophilias, ...) as well as to acquired diseases (cancer, AIDS, multiple sclerosis, ...). Successful gene therapy depends on the efficient delivery of genetic material to cells and its effective expression within these cells.

Synthetic nonviral gene transfer vectors have gained wide acceptance over the past decade. Until now, a large variety of (poly)cationic lipids, liposomes, and (lipo)-polymers, eventually associated to molecular conjugates for improving cell targeting, cytoplasmatic delivery and/or nuclear transport, have been tested, in vitro and/or in vivo, as gene delivery systems (Felgner et al., 1987; Remy et al., 1998; Gao and Huang, 1991, 1993; Byk et al., 1998; Miller, 1998; and references therein). These (poly)cationic systems are capable of condensing or compacting DNA into small-sized complexes (e.g., lipoplexes or polyplexes). Although at present, the in vivo expression levels of such "artificial viruses" are lower than for viral vectors and duration of gene expression is relatively short, the former systems present several advantages with respect to low-cost and large-scale production, safety, cell targeting, lower immunogenicity, and capacity to deliver large fragments of DNA.

Several studies have shown that the transfer efficiency of the DNA complexes, and subsequent DNA expression, especially in vivo, vary in function, among others, of the cationic components, the size of the complexes, their stability in biological fluids and their interactions with the cell membranes. Little is also known concerning the intracellular traffick of DNA to the nucleus, and the ongoing research remains highly empirical. Conse-

Figure 1. Chemical structure and code name of the fluorinated and reference lipospermines described in this study.

quently, there is a need to develop new compounds, especially (poly)cationic compounds, with characteristics and properties that are substantially different from those already described. Lipopolyamines with highly fluorinated hydrophobic and lipophobic chains belong potentially to this class of components. It was shown indeed that liposomes made from highly fluorinated lipids offer some of the specific features that make up the uniqueness of fluorinated material, including their unique high hydrophobic and lipophobic character (Vierling et al., 1995). Such "fluorinated" liposomes demonstrated meaningfully improved physicochemical and biological properties as compared to conventional liposomes, including increased stability in biological fluids (Vierling et al., 1995; Gadras et al., 1999; and references therein), extended in vivo blood circulation times comparable to those of some stealth liposomes (Vierling et al., 1995; Santaella et al., 1993).

We report herein on the synthesis of a series of new highly fluorinated lipopolyamines (Figure 1) and on their abilities of compacting and transferring DNA into cells as well as on their cellular compatibility. These compounds are close analogues of DOGS or Transfectam which is, among the cationic lipids tested so far, one of the most efficient synthetic gene transfer agent (Remy et al., 1998, 1994).

The synthesis of a fluorinated analogue of DOGS (e.g., [F4C11][F8C2]-GS in Scheme 1) was described in the

past by some of us (Remy et al., 1994). Although [F4C11]-[F8C2]-GS and DOGS demonstrated similar transfection properties of NIH-3T3 murine fibroblasts with a chloramphenicol-acetyltransferase reporter plasmid, it has proven to be difficult to formulate lipoplexes with this fluorinated lipospermine, owing to its high degree of fluorination.

We have now extended this series to new fluorinated lipopolyamines. Several studies have shown a close correlation of the transfection capability with hydrophobicity and/or physical state of the bilayers that theoretically the lipids form. A modular molecular structure was therefore selected for these fluorinated lipospermines in order to explore the influence of the fluorocarbon moiety on lipoplex formulation, transfection ability and cell viability. Their framework consists of a spermine moiety connected to a hydrophobic part, which includes two saturated (e.g., **DFnCm-GS** and **[FnCm][Cm']-GS**), or unsaturated hydrophobic chains (e.g., **DFnEm-GS** and **[FnEm][Cm']-GS**), one (e.g., **[FnCm][Cm']-GS** and **[FnEm][Cm']-GS**) or both (e.g., **DFnCm-GS** and **DFnEm-GS**) being ended by a highly fluorinated tail of variable length ($n = 4$ or 6). This is also aimed at modulating the hydrophobic/lipophobic character and consequently the biological properties (biodistribution, bioavailability, in vivo fate) of the "fluorinated" lipoplexes that they are able to form with DNA. As the use of DOPE as co-lipid was found to enhance the transfection activity of DOGS (Thierry et al., 1997), we report also on the transfection efficacy of the fluorinated lipospermines used in conjunction with DOPE. Such an approach was further worth to be tested, as we show very recently, and in parallel to this study, that the formulation of "fluorinated" lipoplexes with a fluorinated analogue of DOPE and a conventional (nonfluorinated) lipopolyamine led to a significant in vitro and in vivo transfection improvement (Boussif et al., 2000).

EXPERIMENTAL PROCEDURES

General Experimental and Analytical Conditions. Most of the reactions were performed in anhydrous solvents under dry and oxygen-free nitrogen. Anhydrous solvents were prepared by standard methods. The purifications by column chromatography were carried out using silica gel 60 (Merck, 70–230 mesh) and chloroform (CHCl_3), dichloromethane (CH_2Cl_2), methanol (MeOH), or mixtures thereof as indicated. Unless noted otherwise, the ratios describing the composition of solvent mixtures represent relative volume. Advancing of the reaction was followed by thin-layer chromatography (TLC) on silica plates F_{254} (Merck). The following developing systems were used: UV light, KMnO_4 , $\text{H}_2\text{SO}_4/\text{EtOH}$, Dragendorff reagent (Sigma), ninhydrin reagent (Sigma).

The perfluoroalkylated acid chlorides were synthesized according to Santaella et al. (1991). The perfluoroalkyl iodides were purified over neutral alumina before use. DOGS (or Transfectam) was prepared as described in Remy et al. (1994). DOPE was purchased from Sigma. All other organic chemicals were from Aldrich, Fluka or Novabiochem.

IR spectra were recorded using a Bruker FT-ITS 45 spectrometer. Liquids were analyzed as thin film between two KBr blocks. ^1H , ^{13}C and ^{19}F NMR spectra were recorded at 200, 50.3, and 188.3 MHz, respectively, on a Bruker AC-200. Chemical shifts were measured relative to CHCl_3 (δ 7.27 ppm) or CH_3OD (δ 3.35 ppm) for ^1H , relative to CDCl_3 (δ 76.9 ppm) for ^{13}C and expressed indirectly in relation to TMS, and relative to CCl_3F as internal reference for ^{19}F . The following abbreviations are

used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). Chemical shifts are expressed in parts per million (ppm) and listed as follows: (multiplicity, coupling, integration, and attribution). Elemental analyses were carried out by the Service Central de Microanalyses du CNRS.

Synthesis of the di-11-(F-alkyl)-undec-10-enylamines, 2a,b. Di-undec-10-enylamine 1. Cyanamide (0.34 g, 0.8 mmol; Fluka) was added to a stirred 50% aqueous sodium hydroxide (6 mL) at room temperature. Aliquot 336 (50 mg; Fluka) and 11-bromo-1-undecene (4.7 g, 20 mmol; Fluka) were added, and the resulting mixture was stirred at 80 °C for 2 h, then extracted with CH_2Cl_2 . The organic extract was washed with water, dried, and evaporated. The residue was chromatographed twice on silica gel (CH_2Cl_2 /hexane, 8/2) to afford 1.3 g (3.8 mmol, 47%) of di-undec-10-enylcyanamide. TLC (CH_2Cl_2 , H_2SO_4): $R_f = 0.70$. ^1H NMR (CDCl_3): δ 1.18–1.45 (s large, 24H, $(\text{CH}_2)_6(\text{CH}_2)_2\text{N}$); 1.52–1.70 (m, 4H, $\text{CH}_2\text{CH}_2\text{N}$); 1.94–2.08 (m, 4H, $=\text{CHCH}_2$); 2.93 (t, $^3J = 7.2$ Hz, 4H, CH_2N); 4.88–5.09 (m, 2H, $\text{CH}_2=$); 5.70–5.95 (m, 1H, $=\text{CH}$). ^{13}C NMR (CDCl_3): δ 26.5, 27.7, 28.9, 29.1, 29.2, 29.4 ($(\text{CH}_2)_7\text{CH}_2\text{N}$); 33.8 ($=\text{CHCH}_2$); 51.5 (CH_2N); 114.2 ($\text{CH}_2=$); 117.8 (CN); 139.1 ($=\text{CH}$). A solution of di-undec-10-enylcyanamide (1.3 g, 3.8 mmol) in 10 mL of concentrated H_2SO_4 was refluxed for 24 h. After cooling to room temperature, the solution was brought to pH 12 with 1 M NaOH, then extracted with CH_2Cl_2 . The organic phase was then washed with H_2O until neutrality, dried and evaporated. The residue was purified by silica gel chromatography (CH_2Cl_2 /MeOH from 100/0 to 95/5) to afford 1.05 g (3.3 mmol, 86%) of **1**. TLC (CH_2Cl_2 /MeOH 9/1, ninhydrine): $R_f = 0.63$. ^1H NMR (CDCl_3): δ 1.12–1.41 (s large, 24H, $(\text{CH}_2)_6(\text{CH}_2)_2\text{N}$); 1.48–1.72 (m, 4H, $\text{CH}_2\text{CH}_2\text{N}$); 1.87–2.04 (m, 4H, $=\text{CHCH}_2$); 2.66 (t, $^3J = 7.6$ Hz, 4H, CH_2N); 4.88–5.09 (m, 2H, $\text{CH}_2=$); 5.70–5.95 (m, 1H, $=\text{CH}$); 5.91–6.14 (s large, 1H, NH). ^{13}C NMR (CDCl_3): δ 27.2, 28.1, 28.9, 29.1, 29.3, 29.4, 29.5 ($(\text{CH}_2)_7\text{CH}_2\text{N}$); 33.8 ($=\text{CHCH}_2$); 49.0 (CH_2N); 114.2 ($\text{CH}_2=$); 139.1 ($=\text{CH}$).

Di-11-(F-butyl)-undec-10-enylamine 2a. A solution of **1** (0.5 g, 1.56 mmol), perfluorobutyl iodide (6.8 g, 19.7 mmol), 2-aminoethanol (0.6 mL; Fluka), and CuCl (0.2 g) in *t*-BuOH (3 mL) was stirred under reflux during 2 days. After extraction with CH_2Cl_2 , the combined organic phases were washed, dried, and evaporated and the residue purified by silica gel chromatography (CH_2Cl_2 /MeOH 100/0 to 95/5) to afford 380 mg of **2a** as a pale yellow oil (0.5 mmol, 33%). TLC (CH_2Cl_2 /MeOH 9/1, ninhydrine): $R_f = 0.54$. ^1H NMR (CDCl_3): δ 1.18–1.50 (s large, 24H, $(\text{CH}_2)_6(\text{CH}_2)_2\text{N}$); 1.50–1.70 (m, 4H, $\text{CH}_2\text{CH}_2\text{N}$); 2.09–2.49 (m, 4H, $=\text{CHCH}_2$); 2.66 (t, $^3J = 7.6$ Hz, 4H, CH_2N); 5.39–5.72 (m, 1H, $\text{CF}_2\text{CH} = \text{CH}$); 6.30–6.52 (m, 1H, $\text{CF}_2\text{CH} = \text{CH}$). ^{13}C NMR (CDCl_3): δ 27.2, 27.9, 28.5, 29.2, 29.4 ($(\text{CH}_2)_7\text{CH}_2\text{N}$); 32.0 ($=\text{CHCH}_2$); 49.4 (CH_2N); 116.7 (t, $^2J_{\text{CF}} = 23$ Hz, $\text{CF}_2\text{CH} = \text{CH}$); 143.3 (t, $^3J_{\text{CF}} = 9$ Hz, $\text{CF}_2\text{CH} = \text{CH}$). ^{19}F NMR (CDCl_3): δ -81.5 (3F, CF_3); -107.2 (~0.2F, CF_2CH , Z); -111.9 (~1.8F, CF_2CH , E); -125.0 (2F, $\text{CF}_3\text{CF}_2\text{CF}_2$); -126.1 (2F, CF_3CF_2).

Di-11-(F-hexyl)-undec-10-enylamine, 2b. The same process as described for **2a**, when applied to **1** and perfluorohexyl iodide, afforded **2b** (69%) as a pale yellow oil. TLC (CH_2Cl_2 /MeOH 95/5, ninhydrine): $R_f = 0.48$. ^1H and ^{13}C NMR (CDCl_3) identical to those of **2a**. ^{19}F NMR (CDCl_3): δ -81.5 (3F, CF_3); -107.2 (~0.2F, CF_2CH , Z); -111.9 (~1.8F, CF_2CH , E); -122.3, -123.6, -124.2 (2F, 2F, 2F, $\text{CF}_3\text{CF}_2(\text{CF}_2)_3$); -126.8 (2F, CF_3CF_2).

Note: both **2a** and **2b** consist in a mixture of *E/E*, *E/Z*, and *Z/Z* isomers, as shown by ^{19}F NMR (*E/Z* +

Z/Z representing $\leq 10\%$). They are also accompanied by the $\text{CF}_2\text{-CH}_2\text{-CH=CH-}$ isomers (less than 5%; see text).

Synthesis of the di-11-(F-alkyl)-undecylamines 3a,b. The synthesis of di-11-(F-butyl)-undecylamine and di-11-(F-hexyl)-undecylamine has been performed by condensation of the respective 11-(F-alkyl)undecanoyl chloride and 11-(F-alkyl)undecylamine, then reduction of the amide thus obtained with LiAlH_4 (50–70% overall yields) according to Remy et al. (1994).

Di-11-(F-butyl)-undecylamine, 3a and di-11-(F-hexyl)-undecylamine, 3b (white powder). TLC ($\text{CHCl}_3/\text{MeOH}$ 95/5, ninhydrine): $R_f = 0.28$ and $R_f = 0.62$, respectively. These two derivatives display identical ^1H and ^{13}C NMR spectra. ^1H NMR (CDCl_3): δ 1.15–1.35 (s large, 28H, $\text{CF}_2(\text{CH}_2)_2(\text{CH}_2)_7$); 1.30–1.70 (m, 8H, $\text{CF}_2\text{-CH}_2\text{CH}_2$, $\text{CH}_2\text{CH}_2\text{NH}$); 1.98 (tt, $^3J = 7.5$ Hz, $^3J_{\text{HF}} 18.8$ Hz, 4H, CF_2CH_2); 2.50 (t, $^3J = 7.5$ Hz, 4H, CH_2NH). ^{13}C NMR (CDCl_3): δ 20.2 (t, $^3J_{\text{CF}} = 4$ Hz, $\text{CF}_2\text{CH}_2\text{CH}_2$); 27.5 ($\text{CH}_2\text{CH}_2\text{NH}$); 29.2, 29.3, 29.5, 29.6, 30.3 ($\text{CF}_2(\text{CH}_2)_2\text{-(CH}_2)_7$); 31.0 (t, $^2J_{\text{CF}} = 22$ Hz, CF_2CH_2); 50.3 (CH_2NH). ^{19}F NMR (CDCl_3) of **3a**: δ -81.3 (3F, CF_3); -115.1 (2F, CF_2CH_2); -124.9 (2F, $\text{CF}_3\text{CF}_2\text{CF}_2$); -126.5 (2F, CF_3CF_2). ^{19}F NMR (CDCl_3) of **3b**: δ -81.3 (3F, CF_3); -114.9 (2F, CF_2CH_2); -122.4, -123.4, -124.1 (6F, $\text{CF}_3\text{CF}_2(\text{CF}_2)_3$); -126.6 (2F, 2F, 2F, CF_3CF_2).

Synthesis of N-Tetradecyl-11-(F-alkyl)undec-10-enamine, 4a,b. N-Tetradecyl-undec-10-enamine. The procedure described elsewhere (Remy et al., 1994) when applied to undec-10-enoyl chloride and tetradecanamine afforded N-tetradecyl-undec-10-enamide (white powder, 99%). ^1H NMR (CDCl_3): δ 0.88 (t, $^3J = 6.5$ Hz, 3H, CH_3); 1.14–1.43 (s large, 32H, $(\text{CH}_2)_5(\text{CH}_2)_2\text{C(O)N(H)(CH}_2)_2\text{-(CH}_2)_{11}$); 1.43–1.71 (m, 4H, $\text{CH}_2\text{CH}_2\text{C(O)NHCH}_2\text{CH}_2$); 1.97–2.11 (m, 2H, $=\text{CHCH}_2$); 2.16 (t, $^3J = 7.5$ Hz, 2H, CH_2CO); 3.18–3.32 (m, 2H, CH_2NH); 4.87, 4.94 (m, 2H, $\text{CH}_2=$); 5.75 (m, 1H, $=\text{CH}$); 5.35–5.55 (s large, 1H, NH). ^{13}C NMR (CDCl_3): δ 14.1 (CH_3); 22.7, (CH_3CH_2); 25.9, 27.0, 28.9, 29.1, 29.4, 29.6, 29.7 ($(\text{CH}_2)_6\text{CH}_2\text{C(O)NHCH}_2\text{-(CH}_2)_{10}$); 32.0 ($\text{CH}_3\text{CH}_2\text{CH}_2$); 33.8 ($=\text{CHCH}_2$); 37.0, 39.5 ($\text{CH}_2\text{C(O)NHCH}_2$); 114.2 ($=\text{CH}_2$); 139.2 (CH=); 173.0 (CO).

N-Tetradecyl-11-(F-butyl)undec-10-enamine, 4a. Reduction of N-tetradecyl-undec-10-enamide with LiAlH_4 as described in Remy et al. (1994) gave N-tetradecyl-undec-10-enamine as a white powder (96%). TLC ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 92/8, ninhydrine): $R_f = 0.52$. ^1H NMR (CDCl_3): δ 0.88 (t, $^3J = 6.5$ Hz, 3H, CH_3); 1.20–1.38 (s large, 34H, $(\text{CH}_2)_6(\text{CH}_2)_2\text{N(H)(CH}_2)_2(\text{CH}_2)_{11}$); 1.38–1.56 (m, 4H, $\text{CH}_2\text{-CH}_2\text{N}$); 1.96–2.12 (m, 2H, $=\text{CHCH}_2$); 2.58 (t, $^3J = 7.1$ Hz, 4H, CH_2N); 4.87, 4.94 (m, 2H, $\text{CH}_2=\text{CH}$); 5.75 (m, 1H, $\text{CH}_2=\text{CH}$). ^{13}C NMR (CDCl_3): δ 14.1 (CH_3); 22.7 ($\text{CH}_3\text{N(H)}$); 27.5, 29.0, 29.1, 29.4, 29.5, 29.7, 30.3 ($(\text{CH}_2)_7\text{-CH}_2\text{N(H)CH}_2(\text{CH}_2)_{10}$); 32.0 ($\text{CH}_3\text{CH}_2\text{CH}_2$); 33.8 ($=\text{CHCH}_2$); 50.2 (CH_2N); 114.2 ($=\text{CH}_2$); 139.2 (CH=). Then, the same process as described for the synthesis of **2a**, when applied to N-tetradecyl-undec-10-enamine and perfluorobutyl iodide, afforded **4a** as a yellow oil (58%); TLC ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 9/1, ninhydrine): $R_f = 0.63$. ^1H NMR (CDCl_3): δ 0.88 (t, $^3J = 6.5$ Hz, 3H, CH_3); 1.20–1.38 (s large, 34H, $(\text{CH}_2)_6(\text{CH}_2)_2\text{NH(CH}_2)_2(\text{CH}_2)_{11}$); 1.38–1.56 (m, 4H, $\text{CH}_2\text{-CH}_2\text{N}$); 2.10–2.28 (m, 2H, $=\text{CHCH}_2$); 2.58 (t, $^3J = 7.1$ Hz, 4H, CH_2N); 5.44–5.71 (m, 1H, $\text{CF}_2\text{CH=}$); 6.27–6.48 (m, 1H, $\text{CF}_2\text{CH=CH}$). ^{13}C NMR (CDCl_3): δ 14.1 (CH_3); 22.7 (CH_3CH_2); 27.5, 29.0, 29.1, 29.4, 29.5, 29.7, 30.3 ($(\text{CH}_2)_7\text{-CH}_2\text{N(H)CH}_2(\text{CH}_2)_{10}$); 32.0, 32.1 ($\text{CH}_3\text{CH}_2\text{CH}_2$, $=\text{CHCH}_2$); 50.2 (CH_2N); 116.7 (t, $^2J_{\text{CF}} = 23$ Hz, $\text{CF}_2\text{CH=}$); 143.0 (t, $^3J_{\text{CF}} = 9$ Hz, $\text{CF}_2\text{CH=CH}$). ^{19}F NMR (CDCl_3) identical to that of **2a**.

N-Tetradecyl-11-(F-hexyl)undec-10-enamine, 4b. The same process as described for the synthesis of **2a**, when applied to N-tetradecyl-undec-10-enamine and perfluorohexyl iodide, afforded **4b** as a yellow oil (45%). TLC ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 9/1, ninhydrine): $R_f = 0.66$. ^1H and ^{13}C NMR (CDCl_3) identical to those of **4a**, respectively. ^{19}F NMR (CDCl_3): identical to that of **2b**.

Note: both **4a** and **4b** consist into a mixture of the E- and Z-isomers, the E-isomer representing $\sim 90\%$. They are also accompanied by the $\text{CF}_2\text{-CH}_2\text{-CH=CH-}$ isomers (less than 3%, see text).

Synthesis of the Unsaturated [DFnE11]-GlyNH₂ and [FnE11][C14]-GlyNH₂ Glycinamines. The synthesis of these derivatives has been performed from their respective perfluoroalkylated amines **2a,b** or **4a,b** and benzyloxycarbonylglycine p-nitrophenyl ester (Z-Gly-ONP, Novabiochem) using the procedure described in ref 10 (yields ranging from 50 to 80%), followed by the Z-deprotection in the [DFnE11]-GlyNH-Z or [FnE11]-[C14]-GlyNH-Z derivatives thus obtained. This deprotection was achieved with 40–80% yields, by placing these Z-derivatives in a 30% HBr/AcOH solution for 1 h. After extraction with CH_2Cl_2 , the organic phase was washed with 1 M NaOH, dried and evaporated. The residue was chromatographed on silica gel ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 100/0 to 95/5) to afford the respective [DFnE11]-GlyNH₂ or [FnE11][C14]-GlyNH₂ glycinamines as colorless liquids.

N',N'-di-11-(F-butyl)-(resp. F-hexyl)-undec-10-enyl-N-benzyloxycarbonyl-glycinamine, DF4E11-GlyNH-Z (resp. DF6E11-GlyNH-Z). TLC ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 99/1, UV and ninhydrine): $R_f = 0.83$ and 0.86, respectively. These two derivatives display identical ^1H and ^{13}C NMR spectra. ^1H NMR (CDCl_3): δ 1.09–1.41 (s large, 24H, $(\text{CH}_2)_6(\text{CH}_2)_2\text{N}$); 1.41–1.70 (m, 4H, $\text{CH}_2\text{-CH}_2\text{N}$); 1.96–2.41 (m, 4H, $=\text{CHCH}_2$); 3.17, 3.33 (t, $^3J = 7.6$ Hz, 4H, CH_2N); 4.06 (d, $^3J = 4.0$ Hz, 2H, CH_2NH); 5.15 (s, 2H, CH_2Ph); 5.48–5.76 (m, 1H, $\text{CF}_2\text{CH=}$); 5.81–5.93 (m, 1H, NH); 6.30–6.55 (m, 1H, $\text{CF}_2\text{CH=CH}$); 7.20–7.35 (m, 5H, Ph). ^{13}C NMR (CDCl_3): δ 26.9, 27.0, 27.6, 28.0, 28.8, 28.9, 29.2, 29.3, 29.4 ($(\text{CH}_2)_7\text{CH}_2\text{N}$); 32.0 ($=\text{CHCH}_2$); 42.7 (CH_2NH); 46.3, 47.0 (CH_2N); 66.9 ($\text{CH}_2\text{-Ph}$); 117.0 (t, $^2J_{\text{CF}} = 23$ Hz, $\text{CF}_2\text{CH=CH}$); 128.1, 128.2, 136.7 (Ph); 143.4 (t, $^3J_{\text{CF}} = 9$ Hz, $\text{CF}_2\text{CH=CH}$); 156.4 (NHCO); 167.5 (COCH_2). ^{19}F NMR (CDCl_3) identical to that of **2a** and **2b**, respectively.

N'-[11-(F-butyl)-(resp. F-hexyl)-undec-10-enyl]-N'-tetradecyl-N-benzyloxy-carbonyl-glycinamine, [F4E11][C14]-GlyNH-Z (resp. [F6E11][C14]-GlyNH-Z). TLC ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 99/1, UV and ninhydrine): $R_f = 0.38$ and 0.43, respectively. These two derivatives display identical ^1H and ^{13}C NMR spectra. ^1H NMR (CDCl_3): δ 0.88 (t, $^3J_{\text{HH}} = 6.5$ Hz, 3H, CH_3); 1.20–1.38 (s large, 34H, $(\text{CH}_2)_6(\text{CH}_2)_2\text{N(CH}_2)_2(\text{CH}_2)_{11}$); 1.38–1.56 (m, 4H, $\text{CH}_2\text{-CH}_2\text{N}$); 2.10–2.28 (m, 2H, $=\text{CHCH}_2$); 3.15, 3.32 (tt, 4H, $^3J = 7.3$ Hz, CH_2N); 4.00 (d, $^3J = 4.0$ Hz, CH_2NH); 5.08 (s, 2H, OCH_2Ph); 5.44–5.71 (m, 1H, $\text{CF}_2\text{CH=}$); 5.88 (m, 1H, NH); 6.27–6.48 (m, 1H, $\text{CF}_2\text{CH=CH}$); 7.20–7.35 (m, 5H, Ph). ^{13}C NMR (CDCl_3): δ 14.1 (CH_3); 22.7 (CH_3CH_2); 26.9, 27.0, 27.6, 28.0, 28.9, 29.0, 29.4, 29.6, 29.7 ($(\text{CH}_2)_7\text{-CH}_2\text{NCH}_2(\text{CH}_2)_{10}$); 31.9, 32.0 ($\text{CH}_3\text{CH}_2\text{CH}_2$, $=\text{CHCH}_2$); 42.7 (CH_2NH); 46.2, 46.9 (CH_2N); 66.8 (CH_2Ph); 116.9 (t, $^2J_{\text{CF}} = 23$ Hz, $\text{CF}_2\text{CH=}$); 128.0, 128.5, 136.8, (Ph); 143.3 (t, $^3J_{\text{CF}} = 9$ Hz, $\text{CF}_2\text{CH=CH}$); 156.3 (NHCO); 167.3 (CH_2CO). ^{19}F NMR (CDCl_3) identical to that of **2a** and **2b**, respectively.

N',N'-di-11-(F-butyl)-(resp. F-hexyl)-undec-10-enyl glycinamine, DF4E11-GlyNH₂, (resp. DF6E11-GlyNH₂). TLC ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 95/5, ninhydrine): $R_f =$

0.58 and 0.68, respectively. Synthesis of the Saturated [DFnC11]-GlyNH₂ and [F4C11][C14]-GlyNH₂ Glycinamines. The synthesis of the [DFnC11]-GlyNH₂ glycinamines has been performed in two steps using the procedures described in reference 10 from their respective perfluoroalkylated amines **3a**, **b**, and Z-Gly-ONP, giving derivatives [DFnC11]-GlyNH-Z (yields ranging from 50 to 80%), followed by Z-deprotection using $\text{H}_2/\text{Pd/C}$ (yields ranging from 90 to 95%). The [F4C11][C14]-GlyNH₂ glycinamine has been obtained by the simultaneous Z-deprotection and double bond hydrogenation of [F4E11][C14]-GlyNH-Z using $\text{H}_2/\text{Pd/C}$ (60%).

Synthesis of Tetra-*tert*-butoxycarbonylspermine-5-carboxylic Acid (Boc₄SperCOOH). This compound was synthesized in three steps as described previously with some modifications related to the first step (Remy et al., 1994). The addition of acrylonitrile (in MeOH) was performed onto the L-ornithine tetramethylammonium salt in MeOH, in place of DMF. In our hands, when we performed this synthesis in DMF, it failed in most cases. After stirring for 1 h at room temperature, the solvent was removed. The residue was dissolved in MeOH and the *N,N'*-biscyanoethylated derivative was precipitated by addition of HCl 12 N and isolated as its HCl salt by filtration (white powder; 60%). ^1H NMR (D_2O): δ 1.60–2.10 (m, 4H, CHCH_2CH_2); 2.82–3.01 (m, 4H, CH_2CN); 3.01–3.22 (m, 2H, $\text{CH}(\text{CH}_2)_2\text{CH}_2$); 3.22–3.55 (4H, $\text{CH}_2\text{CH}_2\text{CN}$); 3.58–3.80 (m, 1H, CH). ^{13}C NMR (D_2O): δ 14.8, 15.0 (CH_2CN); 21.5, 26.5 (CHCH_2CH_2); 42.2, 42.7, 47.1 (CH_2N); 62.0 (CH); 117.5 (CN); 172.4 (COO).

Synthesis of the [R¹][R²]-GS Lipospermines. The syntheses of these lipospermines were carried out in two steps from their respective [R¹][R²]-GlyNH₂ glycinamine and Boc₄SperCOOH, followed by Boc-deprotection. Boc₄SperCOOH was condensed with the glycinamines in the presence of 1.1 equiv of a coupling agent, such as DCC, DCC/HOSu, EDC, BOP, and PyBrop, in CH_2Cl_2 . When the condensation was performed with DCC/HOSu, the acid was preactivated for about 12 h before addition of the glycinamines. In all the other cases, the coupling agent was added to the solution containing the acid and the glycinamine. After 12–24 h of reaction, the organic phase was washed, dried and evaporated and the residue purified by silica gel chromatography ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 100/0 to 95/5) to afford the [R¹][R²]-GS(Boc) derivatives as colorless liquids (yields ranging from 20 to 70%). The Boc-deprotection was quantitatively achieved by dissolving and keeping the [R¹][R²]-GS(Boc) derivatives in a large excess of TFA at room temperature for 1 h. The excess TFA was removed by coevaporation in the presence of cyclohexane. Then, the product was triturated in CH_2Cl_2 to give the desired [R¹][R²]-GS lipospermines, as their tetra-TFA salts.

Tetra-*tert*-butoxycarbonylspermine-5-carboxyglycine *N,N*-di-[11-(*F*-butyl)-(resp. *F*-hexyl)-undec-10-enyl]amide, DF4E11-GS(Boc) (resp. DF6E11-GS(Boc)). Preparation of Complexes Composed of the Lipospermines and Plasmid pTG11033. The plasmid pTG11033 was produced by Transgene SA. The endotoxin content of the plasmid preparation was checked using a Limulus Amebocyte Lysat kit (Biogenic, France). This value was below 1 endotoxin unit(eu)/mg of plasmid, hence below the 5 eu/mg of DNA recommended for in vivo protocols. The quantities of compound used were calculated according to the desired DNA concentration of 0.1 mg/mL, the N/P ratio, the molar weight, and the number of positive charges in the selected lipospermine. The lipospermine/DNA complex is formulated by adding a desired volume of lipospermine preparation at a concentration of 10 mg/mL (in 20 mM HEPES buffer, pH 7.5, containing 10% DMSO and 10% EtOH) to the desired volume of DNA solution to reach desired DNA concentration (for example, 0.1 mg/mL). Thus, for the preparation of the DOGS/DNA complex at N/P ratio 5 and 0.1 mg/mL DNA, 50 μL of a DOGS solution (10 mg/mL in EtOH) was transferred to a borosilicate glass tube (16 × 100 mm). The solvent was evaporated in Rotavap evaporation system (45 °C, 30 pm, 0.2 bar, 40 min). A total of 5 μL of DMSO, 5 μL of EtOH, and 40 μL of HEPES 20 mM, pH 7.5, were added to the film obtained. The preparation was vortexed for 12 h. Then, 47.9 μL of this preparation was added to 952.1 μL of DNA solution [(100 μL of DNA (1 mg/mL) diluted with 852.1 μL of HEPES buffer)]. This preparation can be used for further experiments.

When the composition further comprises DOPE, the desired volume of 10 mg/mL chloroform solution (to get mole/mole DOGS/DOPE) was added to the volume of

DOGS solution (10 mg/mL in EtOH), and then the mixture was transferred to a borosilicate glass tube. The following steps were as described above.

Measurement of the Size of the Lipoplexes. The average sizes were measured by photon correlation spectroscopy using a Coulter N4Plus particle size analyzer. The analyses were performed at 25 °C, after equilibrating the sample at 25 °C for 20 min. One aliquot of the sample was aspirated and discharged several times prior to pipetting. The sample was diluted with 20 mM HEPES in the measurement tube and homogenized. These analyses were thus carried out on lipoplexes having a 10 μg/mL concentration of DNA. After waiting 180 s, the light diffraction at 90° was measured for 180 s. The range was 3 nm to 10 μm, using 31 bins. The size measurement is valid if the sample gives between 50 000 and 1 000 000 counts/s. The formulations and analyses were reproduced twice.

Agarose Gel Electrophoresis. Each sample (0.5 μg of plasmid) was analyzed by electrophoresis for about 90 min under 75 V/cm, through a 0.8% agarose gel in TAE 1× (Tris-acetate-EDTA) buffer. The DNA was visualized in 200 mL of TAE buffer containing 20 μL of ethidium bromide (Sigma, 10 mg/mL). The plasmid integrity in each sample (0.25 μg) was confirmed by electrophoresis after decomplexing the lipoplex (10 μL of a plasmid 0.05 mg/mL) with sodium dodecyl sulfate, SDS (10 μL, 80 g/l).

In Vitro Transfection of A549 Cells. Twenty-four hours before transfection, A549 cells (epithelial cells derived from human pulmonary carcinoma) were grown in Dulbecco-modified Eagle culture medium (DMEM) (GIBCO-BRL), containing 10% fetal calf serum, FCS (SIGMA), in 96-well plates (2 × 10⁴ cells/well), in a wet (37 °C) and 5% CO₂/95% air atmosphere. Volume of DNA/lipospermine lipoplex (20, 10, 5, and 1 μL, respectively) was diluted to 100 μL in DMEM supplemented with 10% FCS in order to obtain various amounts of DNA (2, 1, 0.5, and 0.1 μg, respectively) in the preparation. The culture medium was removed and replaced by 100 μL of DMEM supplemented with 10% FCS and containing the desired amount of DNA. After 4 and 24 h, 50 and 100 μL of DMEM supplemented with 30 and 10% FCS, respectively, were added. Forty-eight hours after transfection, the culture medium was discarded and the cells were washed twice with 100 μL of PBS and then lysed with 50 μL of lysis buffer (Promega). The lysates were frozen at -40 °C awaiting analysis of luciferase activity. This measurement was done for 10 s on 10 μL of the lysis mixture in a Berthold LB96P luminometer in dynamic mode, using the "Luciferase" determination system (Promega) in 96-well plates. The total protein concentration per well was determined using conventional techniques (BCA test, Pierce). For cells grown in the absence of lipoplexes, a well contains around 30–50 μg of proteins. Each DNA/lipospermine complex was formulated twice and each formulation was tested twice.

Statistical Analyses. Statistical analyses were performed using a Student test. The difference between two means was considered as significant when the probability *p* is ≤ 0.05.

RESULTS AND DISCUSSION

Synthesis. The syntheses of the fluorinated lipospermines have been performed using the procedures described for their hydrocarbon DOGS analogue and are shown in Schemes 1 and 2 (Remy et al., 1994). Their specificity lies in the use of perfluoroalkylated secondary amines which are not commercially available. The most

^a (i) NC-NH₂; (ii) H₂SO₄; (iii) base; (iv) C_nF_{2n+1}I/CuCl/t-BuOH/ethanolamine; (v) C_nF_{2n+1}(CH₂)₁₀COCl/NEt₃; (vi) LiAlH₄/THF; (vii) CH₂=CH(CH₂)₈COCl/NEt₃; (viii) Z-Gly-ONP; (ix) HBr/AcOH, then base; (x) H₂/Pd/C.

Scheme 2. Synthetic Route to the Fluorinated [R¹][R²]-GS Lipospermines.

straightforward synthesis of the “unsaturated” symmetrical secondary amines **2** (Scheme 1) was performed by alkylation under phase-transfer-catalysis conditions of cyanamide using 11-bromo-1-undecene followed by hydrolysis (Jonczyk et al., 1978), then grafting of the perfluoroalkyl segment onto the terminal double bonds of **1**. The addition of a linear perfluoroalkyl iodide C_nF_{2n+1}I on a terminal CH₂=CH- double bond may be performed with high yields by various processes. An attractive way is the modified method of Burton and Kehoe (1966) consisting of the one-pot two-step reaction, i.e., radical addition of C_nF_{2n+1}I initiated by CuCl/2-aminoethanol and α,β -dehydroiodination in the presence of a base, which yields the perfluoroalkenyl derivative (mainly of (*E*)-configuration). When this method was applied to **1**, the addition of the C_nF_{2n+1} group to both its C=C bonds and subsequent HI elimination, led to **2**. Under these conditions, no HF elimination was observed. However, according to ¹⁹F NMR which showed more particularly the presence of two resonances for the CF₂ in α to the C=C bonds, the isolated amines **2** consisted in a mixture of isomers differing in the configuration of their two C=C bonds. The most abundant one was the *E,E*-isomer (at least 85%). These products were contaminated by compound(s) (less than 5%) which possess(es) a CF₂-CH₂-

CH=CH- sequence in one and/or in both hydrophobic chains, as a result of a β,γ -HI elimination during the perfluoroalkylation step (Burton and Kehoe, 1966). This was evident from the ¹H-, ¹³C- and ¹⁹F NMR spectra of **2** (dt, ³J_{HH} = 7 Hz, ³J_{HF} = 18 Hz) at 2.7 ppm, t (²J_{CF} = 23 Hz) at 34.7 ppm for CH₂ and a CF₂ resonance at -115.8 ppm).

Although a mixture of alkenyl isomers are obtained, this reaction sequence remains nevertheless the best way for the synthesis of “unsaturated” fluorinated di-alkenylamines such as **2**. One of its advantages lies also in the alkylation step which is not performed with a high cost fluorinated material. Another advantage of this strategy is its versatility as the same synthon **1** can be used for the preparation of di-alkenylamines differing in the length of their perfluoroalkyl tails (such as **2a** and **2b**), and even of saturated ones such as **3** (after hydrogenolysis, vide infra).

The more demanding synthetic route to the saturated di-alkylamines **3** is depicted in Scheme 1. It requires the synthesis of the fluorinated acid chlorides (using a three-step procedure starting from 10-undecenoic acid) and of the fluorinated primary amines which are obtained in two steps from their corresponding fluorinated acid chlorides (amidation with NH₃, then reduction). We used this strategy as both the fluorinated primary amines and acid chlorides were available from this laboratory. Although a more easier way to these amines would have been to perform the hydrogenolysis of the fluorinated di-alkenylamines **2**, this strategy can be recommended for the preparation of secondary amines possessing two different fluorinated alkyl chains.

The synthesis of the mixed perfluoro-alkenyl/hydrocarbon secondary amines **4** (Scheme 1) has been performed using tetradecylamine and 10-undecenoic acid, reduction of the amide followed by the radical addition of the appropriate perfluoroalkyl group and HI elimination (vide supra).

The [R¹][R²]-GlyNH₂ glycinamines were obtained by condensing the amines **2**, **3**, or **4** with Z-Gly-ONP followed by Z-deprotection using either HBr/AcOH for the C=C derivatives or hydrogenolysis for the saturated ones. The mixed saturated perfluoroalkyl/hydrocarbon derivative [F4C11][C14]-GlyNH₂ was prepared by hydrogenolysis of the Z-protected glycinamide deriving from the perfluoro-alkenyl/hydrocarbon secondary amine **4a**. This

Figure 2. Gel electrophoresis of the DF4C11-GS/DOPE (1/1) lipoplexes (lanes 1–5: N/P = 10, 5, 2.5, 1.25, and 0.8, respectively) and of the DF4C11-GS lipoplexes (lanes 6–10: N/P = 10, 5, 2.5, 1.25, and 0.8, respectively). Lanes 11–20 are identical to lanes 1–10 but with SDS. Lane 21: naked plasmid pTG11033. For more details, see Experimental Section.

procedure resulted in the simultaneous Z-deprotection and hydrogenolysis of the C=C bond. That hydrogenolysis of the C=C bond in α to a perfluoroalkyl group occurred was quiet surprising as it has been shown elsewhere that reduction of such de-activated C=C bonds could be obtained only under high H_2 pressure (Ravily et al., 1996).

The synthesis of the fluorinated $[R^1][R^2]$ -GS lipospermines (isolated as their tetra-TFA salt, as attested by ^{19}F NMR) was achieved by coupling the $[R^1][R^2]$ -GlyNH₂ glycinamines with tetra-*tert*-butoxycarbonylspermine-5-carboxylic acid in the presence of a coupling agent, such as DCC, DCC/HOSu, EDC, BOP, and PyBrop, followed by the quantitative Boc-deprotection with TFA. The characterization and purification of these derivatives was best performed on the Boc-protected derivatives rather than on their highly hygroscopic tetra-TFA ammonium salts.

Lipoplex Formation and Characterization. The capability of the various fluorinated $[R^1][R^2]$ -GS lipospermines to condense DNA and to form lipoplexes was analyzed with or without an equimolar amount of DOPE. The size of the lipoplexes (which is an important parameter to control when in vivo uses are contemplated or when their in vitro transfection efficiency is evaluated (Thierry et al., 1997; Boussif et al., 1996)) was analyzed by light scattering spectroscopy (LSS). These studies were performed with pTG11033 plasmid, also used for the in vitro transfection assays (see below). The procedure applied for the lipoplex preparation relies on the dilution from DMSO/EtOH solution in buffer, using N/P ratios of 10, 5, 2.5, 1.25, and 0.8 (N = number of lipid cations; P = number of DNA phosphates). Table 1 collects the mean particle sizes measured for the different lipoplexes. These formulations were also analyzed by gel electrophoresis (Figure 2) which showed the absence of “free” plasmid for N/P ratios from 10 to 1.25, the plasmid being accessible to ethidium bromide in the case of N/P 0.8 formulations. When DOPE was used as co-lipid, N/P 0.8 and 1.25 formulations displayed free plasmid while from N/P 2.5 and up to 10, the DNA was totally protected from ethidium bromide interaction.

For large excesses of cationic charges, such as N/P ratios of 10, 8, and 5, all the fluorinated lipospermines were able to condense DNA into cationic lipoplexes with mean particle sizes in the 115–180 nm range. When an equimolar amount of DOPE was used for the formulation of the lipoplexes, it results in most cases in a slight lipoplex size increase (150–300 nm), although in a few cases larger sized particles (350 to 2700 nm) are formed.

For a N/P ratio of 2.5 and 1.25, and with or without the addition of DOPE, one observed often precipitates. For a N/P ratio of 0.8, the fluorinated lipospermines condensed DNA into “anionic” lipoplexes of a mean size in the 280–470 nm range. The addition of an equimolar amount of DOPE had no significant effect on lipoplex size (320–550 nm).

Table 1. Mean Size of the Lipoplexes Formed between Plasmid pTG11033 and Various Fluorinated Lipospermines, as Determined by Light Scattering Spectroscopy

lipospermine	N/P ratio ^a	mean diameter in nm (SD) ^{b,c,d}	
		lipoplexes	lipoplexes with DOPE

^a N = lipid cation equivalents; P = plasmide phosphate equivalents. ^b % of the overall population. ^c p = precipitate. ^d nt = not tested.

Altogether, these results in terms of impact of N/P ratio on lipoplex stability, i.e., formation of precipitates for N/P ratios corresponding to neutrally charged lipoplexes ($1 < N/P \leq 3$) and stable dispersions for N/P ratios outside this range (negatively and positively charged lipoplexes), are close to those reported for other lipopolyamines (Pitard et al., 1997).

As compared to DOGS, significantly smaller lipoplexes are formed with the fluorinated lipospermines for a N/P ratio of 5 or 0.8. While mixing DOGS with pTG11033

Figure 3. Luciferase expression (bars) and cell viability (points) of the fluorinated lipoplexes made of pTG11033 and **DFnC11-GS** or **DFnE11-GS** lipospermines, as compared to DOGS in A549 cells. Means $\pm$ SEM are given.

plasmid at *N/P* ratios of 2.5 and 1.25 led to aggregates, formation of small-sized DNA particles with some fluorinated lipospermines was observed. These results suggest that the fluorinated lipospermines are more effective than DOGS, in terms of compacting DNA into small-sized particles.

No impact of the nature of the lipospermine hydrophobic chains on lipoplex size could be evidenced. Indeed, the fluorinated lipospermines whether containing a saturated or an olefinic chain (e.g., **DFnC11-GS** vs **DFnE11-GS**), a fluorinated tail on each or only one hydrophobic chains (e.g., **DFnE11-GS** vs **[FnE11][C14]-GS** or **DFnC11-GS** vs **[FnC11][C14]-GS**) led to complexes of comparable sizes. Neither could we detect an effect of the length of the fluorinated tail on the lipoplex mean diameter, the F4 and their corresponding F6 lipospermines behaving very similarly.

In Vitro Transfection. The transfection potential of the fluorinated lipospermines, with an equimolar amount of DOPE and without DOPE, was assayed in vitro on lung epithelial A549 cells, from human pulmonary carcinoma. These assays were performed using plasmid pTG11033 (pCMV-intronHMG-luciferase-SV40pA) in the presence of 10% fetal calf serum for 24 h. pTG11033 is a plasmid of 9572 bps. All lipoplex formulations, even those that precipitated were tested. The transfection efficiency

of the lipoplexes (expressed in fg of luciferase/mg of protein) was evaluated for gradual *N/P* ratios (0.8, 1.25, 2.5, 5, 8 and 10) and various amounts of DNA (2, 1, 0.5, and 0.1 μ g/well) as compared to naked DNA and to the lipoplexes based on DOGS and DOGS/DOPE (1/1 mol). Cells treated with naked DNA under equivalent conditions showed expression levels of about 10² fg of luciferase/mg of protein. The cell viability of the lipoplexes was also checked by determining the total protein amount per well of the transfected cells relative to that measured for untreated cells (for which the total protein amount per well is in a 30–60 μ g/well range). The transfection and toxicity results are illustrated in Figures 3, 4, 5, and 6 for the lipoplexes formulated with the fluorocarbon/fluorocarbon lipospermines (without and with DOPE) or the mixed fluorocarbon/hydrocarbon ones (without and with DOPE), respectively, as compared to DOGS or DOGS/DOPE. These results indicate that all the fluorinated lipospermines, even without the use of the helper DOPE lipid, do enable transfection of the plasmid into the cells. All the fluorinated lipoplexes tested so far showed indeed a higher efficiency to transfect A549 cells than naked DNA and even than those based on DOGS (*vide infra*).

It is particularly noticeable that for the lowest amount of plasmid used (i.e., 0.1 μ g/well) which is a most

Figure 4. Luciferase expression (bars) and cell viability (points) of the fluorinated lipoplexes made of pTG11033 and **DFnC11-GS/DOPE** (1/1 mol) or **DFnE11-GS/DOPE** (1/1 mol) lipids, as compared to DOGS/DOPE (1/1 mol) in A549 cells. Means $\pm$ SEM are given.

important factor to consider when the *in vivo* use of lipoplexes is intended, some of the fluorinated lipospermines displayed a higher transfection potential than DOGS. Indeed, the “fluorinated” lipoplex formulations based on [DF4C11]-GS or [DF4E11]-GS and for a *N/P* ratio of 5 already peaked out at 10^5 fg of luciferase/mg of protein while for DOGS and such a low DNA amount, the luciferase expression levels stood around 10^3 fg of luciferase/mg of protein ($p < 0.001$).

A closer analysis of the results shows that the transfection efficiency of the lipospermines was statistically increasing when replacing the hydrocarbon chains of DOGS by fluorinated ones. Figure 7 displays the luciferase level ratios (LLR) measured for the double fluorocarbon/fluorocarbon lipospermine formulations vs that measured for DOGS. Considering that the effect of the number of fluorocarbon chains is significant if this ratio is out of the 0.2–5 range and if its associated p value is ≤ 0.05 , we found that, as compared to the respective DOGS formulation and irrespectively of the nature of the fluorocarbon chain, the *N/P* ratio and DNA amount, higher transfection levels were obtained with the formulations based on the double fluorocarbon/fluorocarbon derivatives (e.g., **DFnC11-GS** or **DFnE11-GS**) for 29% of the 84 formulations investigated while it was compa-

table for almost 70% of these lipoplexes. For the complexes based on the mixed fluorocarbon/hydrocarbon lipospermines and as compared to those based on DOGS (Figure 8), we measured higher and comparable luciferase expression levels for 20 and 65% of the 60 formulations, respectively, and lower ones for the remaining 15% formulations.

Where the effect on the A549 cell viability of the lipoplexes is concerned, no specific cell toxicity was evidenced for the fluorinated ones as compared to that of the DOGS lipoplexes, at least for DNA amounts ≤ 1 μ g/well.

All these results together indicate that the fluorinated lipoplexes are appealing candidates for *in vivo* purposes, highlighting the diversity of lipids leading to efficient transfection.

Where the impact on transfection of an increase of the fluorinated tail length is concerned (see Figure 9), we found that in the single fluorinated-chain lipospermine series (e.g., [F6E11][C14]-GS vs [F4E11][C14]-GS) this was accompanied by a significant increase of the transfection efficiency. Indeed and as shown in Figure 9, the fluorinated tail lengthening from F4 to F6 resulted in a luciferase expression increase in 60% of the cases while the level remained unchanged for 35% of the cases and

Figure 5. Luciferase expression (bars) and cell viability (points) of the fluorinated lipoplexes made of pTG11033 and [F4C11]-[C14]-GS or [F6E11][C14]-GS lipospermines, as compared to DOGS in A549 cells. Means $\pm$ SEM are given.

in only 5% a transfection decrease was observed. A similar tendency could be evidenced for the unsaturated fluorinated double-chain series (e.g., **DF6E11-GS** vs **DF4E11-GS**, Figure 9), although at a lower extent: for 25% of the formulations, we measured a transfection increase, while the luciferase expression remained at a comparable level for 70% and decreased for the remaining 5%.

By contrast, the opposite tendency was found for some formulations of the saturated series (Figure 9). For 20% of the cases, we observed a significant transfection decrease when going from the F4C11 to the F6C11 series and a comparable level for the remaining 80%.

The opposite tendencies resulting from lengthening the fluorinated tail in the unsaturated and saturated series could be rationalized in terms of lipid thermotropism. Previous works have shown that optimal transfection activity was achieved when using cationic lipids containing hydrophobic chains organized, at the incubation temperature, as "fluid" lamellar phases rather than "gel" lamellar ones (Balasubramaniam and Malone, 1996; Byk et al., 1998) or as inverted hexagonal phases where chains are in a fluid state as well (Koltover et al., 1998). The exact mechanism governing lipoplex endocytic uptake and cytosol DNA release from endosomes is still unclear. Although speculative, the improvement of gene expression resulting from the use of lipids which are in a "fluid" physical state, is presumably due to their larger miscibility with endogenous ones, and consequently, to their greater ability to promote membrane fusion with

and destabilization of the endosome membrane allowing optimal DNA release in the cytosol, thus preventing internalized DNA from endosome and lysosome degradation. Concerning fluorinated lipids, it has been shown that phosphatidylcholines containing two saturated F4C11 or F6C11 chains display a lamellar phase transition temperature below or above 37 °C, respectively, while those containing unsaturated F4E11 or F6E11 chains have melting temperatures far below 37 °C (Vierling et al., 1995). Therefore, the transfection decrease when going from F4C11 to F6C11 in the saturated series most likely may be attributed to a rigidifying effect which accompanies this fluorinated tail length increase (see also next section). On the other hand, in the unsaturated series when going from F4E11 to F6E11, the transfection increase which accompanies this tail length increase, may be related to an increase of the hydrophobic and lipophobic character of the lipospermine, thus better preventing the fluorinated lipoplexes from interactions with the serum components.

The effect of the C=C bond on transfection is illustrated in Figure 10 which displays the luciferase level ratios measured for the formulations with **DFnE11-GS** (each being a mixture of trans/trans (mainly), trans/cis and cis/cis isomers) or [F4E11][C14]-GS vs that measured for the corresponding **DFnC11-GS** or [F4C11]-[C14]-GS homologues, respectively. Assuming that the effect of the C=C bond is significant if this ratio is out of the 0.2–5 range and if p is ≤ 0.05 , we found that this structural element improved the transfection efficiency

Figure 6. Luciferase expression (bars) and cell viability (points) of the fluorinated lipoplexes made of pTG11033 and [F4C11]-[C14]-GS/DOPE (1/1 mol) or [F6E11][C14]-GS/DOPE (1/1 mol) lipids, as compared to DOGS/DOPE (1/1 mol) in A549 cells. Means $\pm$ SEM are given.

only for the double fluorinated-chain lipospermines which contained F6 tails. Indeed, 40% of the **DF6E11-GS** formulations display a higher transfection level than their respective **DF6C11-GS** ones and a comparable level for the remaining 60%. As discussed above, this is likely to be related to the "fluidification" effect of the C=C bonds when going from **DF6C11-GS** to **DF6E11-GS**. This is further supported by the fact that no influence of the C=C bond on transfection was found with the F4E11 vs F4C11 (single or double chain) containing lipospermines, all these lipids being expected to have chain melting temperatures below 37 °C (Vierling et al., 1995).

All these data suggest that the physical state of the fluorinated lipospermine along the cell entry pathway and the intracellular traffick up to DNA integration into the nucleus is of importance. That transfection increases with lipophobicity (fluorinated amphiphiles are usually not miscible with their hydrocarbon analogues (Rolland et al., 1997)) indicates further that the mixing of the cationic lipids with cellular lipids is not determinant for the gene transfer and expression process. It is rather attributable to some protection effects of DNA resulting from its formulation as lipophobic and hydrophobic lipoplexes with fluorinated lipospermines, thus preventing DNA from interactions with lipophilic and hydrophilic biocompounds.

The transfection efficiency and the cell tolerance of the fluorinated lipoplexes depends as well on the amount of

DNA, on the *N/P* ratio and on the lipoplex formulation (DOPE added or not) as for the conventional (poly)-cationic lipids tested so far. Some of these parameters are linked and will be discussed together.

Thus, the transfection efficiency of the fluorinated lipoplexes usually increased on raising the DNA concentration from 0.1 to 2 $\mu\text{g}/\text{well}$, and in most cases a plateau of luciferase expression was attained for a DNA concentration of 0.5 $\mu\text{g}/\text{well}$. Whatever the amount of plasmid used, luciferase expression levels usually grew when *N/P* ratio increased from 0.8 to 10. Concomitantly, cell toxicity appeared but remained however frequently at an acceptable level, comparable to the DOGS formulation. The lowest cell tolerance was observed (when observed) for the highest DNA concentration (i.e., 2 $\mu\text{g}/\text{well}$) and *N/P* ratio (i.e., 10) tested.

The transfection efficiency and toxicity increase when raising the cationic charge of the lipoplexes is most probably related to an increase of the lipoplex cellular uptake which remains at a level compatible with cell growth providing the DNA amount remained below 2 $\mu\text{g}/\text{well}$, whatever their charge ratio. The lipoplexes became more toxic for the cells, likely as a result of a high level of cellular uptake, and/or of cell membrane disruption, and/or as a result of the presence of a high amount of "free" uncomplexed lipids.

Concerning the effects on transfection resulting from the formulation of the fluorinated lipoplexes with DOPE,

Figure 7. Transfection efficiency of the fluorinated lipoplexes vs that of their corresponding DOGS lipoplexes. The luciferase level ratio LLR is the ratio of luciferase amount measured for the fluorinated lipoplexes vs that measured for the corresponding DOGS-lipoplexes. The efficiency is significantly higher if LLR is ≥ 5 , significantly lower if $0.2 < \text{LLR} \leq 0.2$, or comparable if $0.2 < \text{LLR} < 5$ ($p \leq 0.05$). The ratio and percentage value given in the insert for each LLR condition represents the number of formulations vs the total number of formulations and the corresponding percentage, respectively, which satisfy the given LLR condition. The fluorinated lipoplexes are made from the double-chain fluorinated DF6E11-GS or DF6C11-GS lipospermines.

Figure 8. Transfection efficiency of the fluorinated lipoplexes vs that of their corresponding DOGS-lipoplexes. The luciferase level ratio LLR is the ratio of luciferase amount measured for the fluorinated lipoplexes vs that measured for the corresponding DOGS-lipoplexes. The fluorinated lipoplexes are made from the mixed-chain [F6E11][C14]-GS or [F6C11][C14]-GS lipospermines. For more details concerning the significance of the results and the meaning of the ratio and percentage values given in the insert, see caption of Figure 7.

a subsequent improvement (≥ 5 -fold increase, $p \leq 0.05$) is observed for 55% of the 142 formulations investigated,

highlighting again the unique properties of DOPE as helper lipid (results not shown). A 3, 2, and 1 order of

Figure 9. Effect on transfection of the fluorinated tail lengthening. The luciferase level ratio LLR is the ratio of luciferase amount measured for the F4E11 (resp. F4C11) lipoplexes vs that measured for their corresponding F6E11 (resp. F6C11) ones. The efficiency is significantly higher if LLR is ≥ 5 , significantly lower if LLR ≤ 0.2 , or comparable if $0.2 < \text{LLR} < 5$ ($p \leq 0.05$). The ratio and percentage value given for each LLR condition and in each section of the graph represents the number of formulations vs the total number of formulations and the corresponding percentage, respectively, which satisfy the given LLR condition.

Figure 10. Effect on transfection of the double-bond. The luciferase level ratio LLR is the ratio of luciferase amount measured for the F4E11 lipoplexes vs that measured for their corresponding F4C11 ones ($n = 4$ or 6). For more details concerning the significance of the results and the meaning of the ratio and percentage values given in each section of the graph, see caption of Figure 9.

magnitude increase is indeed measured for about 8, 25, and 51% of these formulations, respectively. For 44% of the 142 formulations, a comparable luciferase expression level is attained with or without DOPE. Finally, for only about 1% of the formulations investigated, a decrease of transfection is measured by adding DOPE. A closer analysis shows that adding DOPE to the formulations increased the transfection levels for 65% formulations made of mixed-chain lipospermines and for 48% of the formulations made of lipospermines having two fluorinated chains. In these two series, respectively, 87% and 70% of the formulations made of lipospermines with F4C11 or F4E11 moieties showed a synergistic effect with DOPE while only 27 and 24% of the formulations with F6C11 or F6E11 lipospermines were improved by the addition of this helper. This behavior is likely to be attributable to the miscibility between DOPE and the fluorinated lipospermines, which is expected to be higher (i) with the mixed-chain rather than with the double-

chain fluorinated ones or (ii) with those having the shortest fluorinated tail.

One should further underline that the cell viability of the fluorinated lipoplexes remained unaffected by their co-formulation with DOPE.

CONCLUSION

The present work suggests that the new fluorinated lipospermines which were synthesized appear as promising synthetic vectors for gene delivery. The palette of structural elements explored allowed to determine those required for efficient transfection, highlighting the importance of highly fluorinated chains, and (again) the unique properties of unsaturated double-chain lipids and of the use of DOPE as helper lipid on transfection. Although encouraging, the *in vitro* results obtained here with the fluorinated lipospermines lead to a rather modest improvement over the first generation of lipo-

spermines such as DOGS, and do not compete with the efficiency of viral vectors. This conclusion does not however prejudice their *in vivo* behavior.

The *in vitro* (resistance to and gene expression in the presence of detergents, serum and nucleases to other cell types) and *in vivo* potential of these fluorinated lipospermines are currently under investigation.

ACKNOWLEDGMENT

Modification of Cyclosporin A and Conjugation of Its Derivative to HPMA Copolymers

Zheng-Rong Lu,[†] Song-Qi Gao,[†] Pavla Kopečková,^{†,‡} and Jindřich Kopeček^{*,†,‡}

Departments of Pharmaceutics and Pharmaceutical Chemistry/CCCD and of Bioengineering, University of Utah, Salt Lake City, Utah 84112. Received July 8, 2000; Revised Manuscript Received October 20, 2000

Cyclosporin A (CsA) was epoxidized with *m*-chloroperoxybenzoic acid in the presence of sodium carbonate or with *tert*-butyl hydroperoxide in the presence of dioxomolybdenum iminodiethanoxide. The CsA epoxide was not stable and rearranged into a compound with a more stable five-member ring structure. An amino group containing cyclosporin A derivative (CsA amine) was obtained by the reaction of CsA epoxide with excess ethylenediamine. The yield of the CsA amine was 30–40% based on the CsA. An HPMA copolymer–CsA conjugate was prepared by the reaction of the CsA amine with an HPMA and MA-Gly-Phe-Leu-Gly-ONp copolymer. The content of CsA amine in the conjugate was 8.7 wt %. The CsA amine was released from the copolymer by enzymatic hydrolysis with papain.

INTRODUCTION

Cyclosporin A (CsA)¹ is a neutral, hydrophobic cyclic undecapeptide (structure 1), isolated from the fungal species *Tolypocladium inflatum* Gams (1). The compound is widely used in organ transplantation and was also found to be effective in the treatment of diseases related to immunoregulatory dysfunctions, such as inflammatory bowel diseases, type I diabetes, etc. (2), as well as in depressing multidrug resistance in cancer chemotherapy (3). However, its clinical applications are associated with significant nephrotoxicity and other toxic side effects. Its poor aqueous solubility may impair its therapeutic efficacy (4). Chemical modification of cyclosporin A may increase its hydrophilicity, reduce its side effects, and improve its therapeutic efficacy. However, because of the chemical inertness of CsA, few modifications of CsA have been reported (5–9).

CsA has two functional groups that can be used for chemical modification, the hydroxyl group and the double bond on the 2-*N*-methyl-*R*-((*E*)-2-butenyl)-4-methyl-L-threonine (MeBmt) residue. Modification on the hydroxyl group requires severe reaction condition because of steric hindrance (5, 6). There are few reports on the modification of the double bond. The double bond was oxidized to form an aldehyde (7) or a lactone (8). The CsA lactone can be produced in good yield, but the yield of CsA aldehyde was very low, possibly because the aldehyde formed reacted further with the hydroxyl group in the MeBmt residue to form a more stable five-membered ring

Scheme 1. Synthesis of Cyclosporin Amine^a

^a (i) *m*-Chloroperoxybenzoic acid, anhydrous Na₂CO₃, methylene chloride, overnight, r.t.; or *tert*-butyl hydroperoxide, MoO₂(OCH₂CH₂)₂NH, benzene, refluxing, 2 h. (ii) Ethylene diamine, THF, refluxing, 24 h.

structure (structure 2). The oxidation reactions damaged the integrity of the MeBmt by cleaving the double bond. The MeBmt structure can be maintained by modifying the double bond in an addition reaction. For example, hydroformylation of the double bond introduced an aldehyde functional group (9) to CsA, and the functional group was used to conjugate CsA to HPMA copolymer–antibody conjugates (10). The biological investigation suggested that the modified CsA maintained its activity with reduced side effects after conjugation to the HPMA copolymer (10).

Here we report on the direct epoxidation of cyclosporin A and the synthesis of an amino group functionalized CsA from its epoxide, Scheme 1. The new CsA derivative was conjugated to an HPMA copolymer via tetrapeptide (Gly-Phe-Leu-Gly) side-chain termini. The release of the CsA derivative from the HPMA copolymer conjugate was investigated by enzymatic cleavage with papain.

¹ Abbreviations: CsA, cyclosporin A; DMSO, dimethyl sulfoxide; ESI MS, electrospray ionization mass spectrometry; HPMA, *N*-(2-hydroxypropyl) methacrylamide; MA, methacryloyl; MeBmt, 2-*N*-methyl-*R*-((*E*)-2-butenyl)-4-methyl-L-threonine; *M*_n, number average molecular weight; *M*_w, weight average molecular weight; ONp, *p*-nitrophenoxyl; PBS, phosphate-buffered saline; SEC, size-exclusion chromatography; TBHP, *tert*-butyl hydroperoxide; THF, tetrahydrofuran; wt %, weight percentage.

Structure 1: Cyclosporin A

RESULTS AND DISCUSSION

The epoxidation of CsA was performed by reaction with *m*-chloroperoxybenzoic acid in the presence of sodium carbonate at room temperature. The reaction with *m*-chloroperoxybenzoic acid gave very high conversion (almost 100%) of the double bond of CsA. However, the CsA epoxide (II) is not stable in acidic solution, and it may rearrange to a more stable structure (III) with a five-membered ring by an acidic ring opening reaction of the epoxide with the γ -hydroxyl group on the MeBmt residue (Scheme 1). To minimize the formation of this side product (III), sodium carbonate was added to neutralize the *m*-chlorobenzoic acid formed during the reaction. The reaction was carried out overnight at rt. Because of the low stability of the CsA epoxide, its mixture with compound III was used for the reaction with ethylenediamine immediately after their isolation from the reaction mixture.

Reaction of the CsA epoxide with ethylenediamine produced an amino group-containing CsA derivative (IV). The use of a large excess of primary amine could facilitate the complete conversion of the CsA epoxide to a CsA amine (IV). The CsA amine (IV) was formed because the nucleophilic ring opening reaction mainly occurred at the site with the least steric hindrance. The CsA amine (IV) and compound (III) were separated from the reaction mixture by silica gel chromatography. The yield of the CsA amine (IV) was 33 and 30% (based on CsA) for compound III after separation. The epoxidation products

and CsA derivatives III and IV were characterized by electrospray ionization mass spectrometry. Both the CsA epoxide and compound III had the m/z of 1219 ($+H^+$) and the CsA amine IV had a m/z of 1279 ($+H^+$). The compounds III and IV were also characterized by proton NMR. Chemical shifts of the *N*-methyl groups in the CsA amine were not as distinct as those of CsA. The peaks of the *N*-methyl groups overlapped around 2.99 ppm. This might be caused by the addition of two amino groups and one more hydroxyl group in the structure of CsA. These additional functional groups might disturb the hydrogen bonding of the cyclic peptide by forming new hydrogen bonds. The formation of new hydrogen bonds may change the conformation of the CsA and steric orientation of the *N*-methyl groups.

The yield of CsA amine or CsA epoxide was significantly affected by the presence of sodium carbonate and the reaction temperature. If CsA and *m*-chloroperoxybenzoic acid were refluxed in chloroform without the presence of sodium carbonate, the yield of CsA amine was very low, less than 10%. This was because of the acid-catalyzed transformation of the CsA epoxide to compound III by the byproduct *m*-chlorobenzoic acid. Sodium carbonate was added to neutralize the *m*-chlorobenzoic acid, and an optimum yield of CsA amine was obtained with reaction overnight at rt.

We tried to avoid acidic epoxidation conditions by using the catalytic epoxidation with *tert*-butyl hydroxyperoxide (TBHP) with a molybdenum complex, dioxomolybdenum iminodiethanoxide (11). This catalytic epoxidation is a very efficient process with a conversion of more than 90% for alkenes and TBHP and without formation of acidic byproduct. The catalytic epoxidation of CsA with TBHP was performed in benzene with refluxing for 2 h. After the benzene was removed, the residue was immediately refluxed with excess ethylenediamine in THF. The final reaction mixture was analyzed by electrospray ionization

mass spectrometry. The results indicated that the CsA was completely converted (CsA epoxide and compound III). The yield of CsA amine was 40% as estimated from the mass spectrum. There was still a considerable amount of compound III (m/z 1219, $M^+ + 1$) formed. This compound was formed by the rearrangement of the CsA epoxide at a high temperature. An unknown side product (m/z 1248) was also identified in the spectrum.

As a result of the introduction of a hydroxyl group and an ethylenediamine moiety to CsA, the CsA amine exhibits a better water solubility than CsA. The primary amino group in the CsA amine can be used for further modification, such as conjugation to an antibody or a polymeric drug carrier for targeted drug delivery.

Water soluble *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymers were developed as polymeric drug carriers for cancer chemotherapy (reviewed in ref 12). The conjugation of anticancer drugs to the HPMA copolymer reduced the side effects of drugs and improved the specific accumulation of macromolecular therapeutics in tumor tissue as a result of the enhanced permeability and retention (EPR) effect (12). The conjugation of CsA derivatives to HPMA copolymers may also improve the therapeutic efficacy of CsA with reduced side effects. It has been reported that the conjugation of a CsA derivative to a water-soluble copolymer maintained the thera-

peutic activity of CsA and increased its specificity with reduced side effects (10).

Previously, attempts to conjugate CsA to HPMA copolymers via the hydroxyl group of CsA did not succeed because of steric hindrance. With the new CsA derivative, CsA amine IV, the conjugation was achieved by reacting compound IV with a *p*-nitrophenol active ester at the tetrapeptide side chain termini in an HPMA copolymer. It is possible that the bifunctionality (primary and secondary amines) of the CsA amine IV may cause cross-linking. However, no obvious cross-linking was observed in the size-exclusion chromatographic (SEC) analysis of the HPMA copolymer-CsA conjugate. This suggested that the CsA amine was mainly conjugated via the primary amine, probably due to the steric hindrance of the secondary amine. The content of CsA in the copolymer was 8.7 wt % as determined by amino acid analysis.

The CsA amine was attached to an HPMA copolymer via a Gly-Phe-Leu-Gly tetrapeptide spacer, Scheme 2. The tetrapeptide spacer is susceptible to cathepsin B-catalyzed hydrolysis in the lysosomal compartment of a cell (13, 14). The release of the CsA amine was investigated by the incubation of an HPMA copolymer-CsA amine conjugate with papain at 37 °C (papain has a similar specificity to cathepsin B). After 24 h of incubation, the reaction mixture was extracted with methylene

dichloride. The extracts were analyzed by electrospray ionization (ESI) mass spectrometry. CsA amine (m/z 1278) and glycylated CsA amine (Gly-CsA) (m/z 1336) were identified in the mass spectrum. The release of a Gly-CsA amine indicated that the bond originating in the leucine residue was one of the cleavage sites. It is known that papain prefers a phenylalanine residue in the S_2 subsite of its active site (15). Despite the steric hindrance of the polymeric chain on the formation of the enzyme–substrate complex (16), such an arrangement of the polymeric substrate in papain's active site may be energetically favorable. With increasing the incubation time, the amount of Gly-CsA decreased eventually to a level nondetectable by ESI mass spectrometry. One can hypothesize that the bond originating in the glycine residue is also a cleavage site for papain, but slower. A detailed degradation study is needed to prove the hypothesis on the structure of the enzyme–substrate complex. However, *in vivo*, the lysosomal aminopeptidases would probably convert any Gly-CsA amine into the CsA amine, which would be the main product at longer time intervals. On another note, the identification of the glycylated CsA amine as one of the papain cleavage products confirmed the conjugation of CsA amine to the HPMA copolymer.

In summary, a new CsA derivative containing amino groups has been synthesized by the epoxidation of CsA and subsequent aminolysis with ethylenediamine. The compound was water soluble, and the primary amino group could be used for the conjugation to polymers or proteins. The CsA amine was conjugated to HPMA copolymers via a Gly-Phe-Leu-Gly spacer and was released from the copolymers by the action of papain.

EXPERIMENTAL SECTION

Chemicals. An HPMA copolymer with Gly-Phe-Leu-Gly-ONp side chains was prepared as previously described (13). CsA was provided by Galena (Czech Republic). Mo catalyst, $\text{MoO}_2(\text{OCH}_2\text{CH}_2)_2\text{NH}$, was synthesized according to method described (11). *tert*-Butyl hydroperoxide (5.5 M in decane, Fluka, Ronkonkoma, NY) and *m*-chloroperoxybenzoic acid (Aldrich, Milwaukee, WI) were used without further purification. Solvents and all other reagents were of reagent grade or better. Proton NMR spectra were recorded on a NR/200 FTNMR spectrometer (IBM Instruments). Electrospray ionization mass spectrometry was performed on a Trio 2000 single quadrupole mass spectrometer (Micromass). The amino acid analysis of the HPMA copolymer–CsA amine conjugate was performed by J. Strohalm in the Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, Prague.

Epoxidation of Cyclosporin A. Cyclosporin A (100 mg, 83 μmol), *m*-chloro-peroxybenzoic acid (16 mg, 93 μmol), and anhydrous Na_2CO_3 (20 mg, 190 μmol) in 10 mL of methylene chloride was stirred overnight at rt. The reaction mixture was washed with 20% sodium bisulfite and 10% sodium carbonate. The organic layer was dried over anhydrous sodium carbonate. The solvent was removed under vacuum producing a crystalline product. Yield: 96 mg. The product was characterized by ESI mass spectrometry, m/z 1219 ($M^+ + 1$). The product was immediately used for next reaction without further purification.

Preparation of Cyclosporin Amine IV. The product (96 mg) from the above reaction was refluxed with an excess of ethylenediamine (200 μL) in 10 mL of THF for 24 h. The solvent was removed under vacuum, and the

reaction product was isolated from the solid residue using silica gel column chromatography. Compound III was first eluted out with hexane/acetone (1:2), then the cyclosporine amine was eluted with methanol. The solvent of the first fraction was removed by a rotavapor leaving a colorless crystalline product (31 mg, 30%, based on CsA). The solvent of the second fraction was removed under vacuum leaving a yellowish solid product (38 mg, 33%, based on CsA). Both fractions were characterized by ESI mass spectrometry. The first fraction with m/z 1219 ($M^+ + 1$) was identified as compound III, and the second fraction with m/z 639 [$(M^+ + 2)/2$], 1278 ($M^+ + 1$) was characterized as the CsA amine. ^1H NMR: compound III (δ , ppm, CDCl_3), 7.96, 7.75, 7.45, 7.14 (d, 1H, CONH), 3.49 (s, 3H, NCH_3), 3.38 (s, 3H, NCH_3), 3.03 (s, 6H, NCH_3), 2.67 (s, 6H, NCH_3); CsA amine (δ , ppm, DMF-d_7), 8.25 (m, 4H, CONH), 2.99 (m, 21 H, NCH_3).

Preparation of Cyclosporin Amine (Method 2). Cyclosporin A (5 mg, 0.4 μmol) and *tert*-butyl hydroperoxide (5.5 M, 20 μL) were dissolved in 5 mL of benzene, and $\text{MoO}_2(\text{OCH}_2\text{CH}_2)_2\text{NH}$ (1 mg) was added. The reaction mixture was refluxed for 2 h. The solvent was removed under vacuum. The residue was dissolved in 10 mL THF with 100 μL of ethylenediamine (excess) and refluxed with stirring for 24 h. The reaction mixture was analyzed with ESI mass spectrometry. The yield of the cyclosporin amine (40%) was estimated from the peak intensities of the CsA derivatives in the mass spectrum.

Conjugation to HPMA Copolymers. A copolymer of HPMA and MA-Gly-Phe-Leu-Gly-ONp ($M_n = 15\,900$, $M_w = 21\,400$, ONp content = 5.1 mol %, 40 mg) was dissolved in 1 mL of DMSO and mixed with the cyclosporin amine (12 mg) in 0.5 mL of DMSO. The reaction mixture was stirred overnight at rt. The yellow solution (color of *p*-nitrophenolate) was diluted to 5 mL with methanol and was purified on a Sephadex LH-20 column and eluted with methanol. The Sephadex LH-20 purification was repeated once more. The fractions corresponding to the polymer–drug conjugate were pooled and the solvent was removed. The residue was dissolved in water and lyophilized. Yield: 35 mg, 85%. The content of cyclosporin amine in the HPMA copolymer conjugate was 8.7 wt % as determined by amino acid analysis.

Degradation of the Polymer–Drug Conjugate. The HPMA copolymer–CsA amine conjugate (10 mg) was incubated with papain (4.5 mg) in PBS buffer (5.0 mL) with 1 mM DTT at 37 °C for 24 h. The incubation mixture was extracted with methylene dichloride. The extract was characterized by ESI mass spectrometry. CsA amine (m/z 1279, $M^+ + 1$) and glycylated CsA amine (m/z 1336, $M^+ + 1$) were identified in the spectrum of the extract.

A New Strategy for Site-Specific Protein Modification: Analysis of a Tat Peptide–TAR RNA Interaction

Natarajan Tamilarasu, Jing Zhang, Seongwoo Hwang, and Tariq M. Rana*

Department of Pharmacology, Robert Wood Johnson Medical School, University of Medicine & Dentistry of New Jersey, 675 Hoes Lane, Piscataway, New Jersey 08854. Received August 25, 2000

Site-specific modification of proteins and peptides with reporter molecules provides a powerful research tool in chemistry and biology. We report the synthesis and application of a tyrosine analogue, *N*- α -*Fmoc*-3-acetyl-L-tyrosine, for selective modification of proteins. As a model system, we synthesized the human immunodeficiency virus type 1 (HIV-1) Tat peptide (amino acids 47–56) containing the arginine rich RNA-binding region and replaced the Tyr-47 with 3-acetyl-tyrosine. The acetyl-Tyr-Tat peptide was subsequently labeled with a fluorescein derivative to study RNA–protein interactions by fluorescence energy transfer experiments. Our results showed that the Tat peptide binds to the rhodamine labeled TAR RNA with a dissociation constant (K_D) of 1.0 ± 0.5 nM. This strategy of selective protein modification offers a versatile new procedure for labeling peptides of biological interest at a desired site when several nucleophilic side chains of lysine and cysteine are present. These methods would provide tools for postsynthetic peptide modification and introducing biophysical probes for structural and functional analysis of proteins.

Site-specific modification of proteins and peptides with reporter molecules provides a powerful research tool in chemistry and biology. Selective chemical modification of proteins involves covalent derivatization of the functional group (e.g., $-NH_2$ and $-SH$) of a single, unique amino acid residue in the protein without causing any effect on other functional groups (1). However, the attachment of a reporter molecule at a specific site in a protein containing multiple lysine and cysteine residues is difficult to achieve and in most cases requires some orthogonal protection of these side chains. Since the reaction of ketone and aldehyde with a hydrazide is

orthogonal to the functional groups present in proteins, this chemistry has been used to label peptides and proteins by the oxidation of N-terminal serine to the corresponding aldehyde and subsequent coupling with an appropriate hydrazide (2). Schultz and co-workers have introduced a ketone handle into a unique site in a protein by unnatural amino acid mutagenesis which was subsequently modified with a fluorescein derivative (3). Amino acid analogues preconjugated with structural probes have also been used in the solid-phase peptide synthesis, (4–7) however, this methodology has a limited application because once introduced into peptides, this specified site is no longer available for modification with other reporter molecules. Thus, the development of novel amino acid analogues with selective reactivity other than with the

Figure 1. (A) Secondary structure of TAR RNA used in this study. TAR RNA spans the minimal sequences that are required for Tat responsiveness *in vivo* (21) and for *in vitro* binding of Tat-derived peptides (34). Chemical syntheses were performed on ABI synthesizer model 392 using standard protocols. All the monomers of (2-cyanoethyl)phosphoramidites were obtained from Glen Research (Sterling, VA). TAR RNA was chemically synthesized on a rhodamine-containing CPG 500 support. Synthesis of RNA, deprotection, characterization, and purification were performed as described earlier (35, 36). (B) The Tat-derived peptide, amino acids 47 to 56, contains the RNA-binding region of Tat protein. Acetyl-Tyr was incorporated at position 47 and modified with fluorescein (12).

lysine or cysteine side chains ($-\text{NH}_2$ and $-\text{SH}$ functional groups) would be very useful for selective postsynthetic labeling of proteins. Such amino acid analogues would especially be useful for incorporation of labels into a protein without modification of cysteine and lysine residues involved in protein function (e.g., nucleic acid binding proteins requiring lysine side chains for nucleic acid recognition and cysteine side chains for metal coordination such as zinc finger structures).

Here, we report the synthesis and application of a tyrosine analogue, *N*- α -Fmoc-3-acetyl-L-tyrosine, for selective modification of proteins. We have modified the side chain of tyrosine with a keto functional group without disrupting its potential phosphorylation and metal coordination site (8) and used its Fmoc derivative in standard solid-phase peptide synthesis (Scheme 1). As a model system, we synthesized the human immunodeficiency virus type 1 (HIV-1) Tat peptide (amino acids 47–56) containing the arginine rich RNA-binding region and replaced the Tyr-47 with 3-acetyl-tyrosine (Figure 1). The acetyl-Tyr-Tat peptide was subsequently labeled with a fluorescent dye molecule (Scheme 2) to study RNA–protein interactions.

3-Acetyl-tyrosine was synthesized from tyrosine by Friedel–Crafts reaction (8–11) and converted to its Fmoc derivative by Fmoc-Osu reaction (Scheme 1) (12). Tat-derived peptide (from amino acids 47–56) was synthesized on an Applied Biosystems 431A peptide synthesizer

Scheme 2

using standard FastMoc protocols. Cleavage and deprotection of the peptide was carried out in 2 mL of Reagent K for 6 h at room temperature. Reagent K contained 1.75 mL of TFA, 100 μL of thioanisole, 100 μL of water, and 50 μL of ethanedithiol (13). After cleavage from the resin, peptide was purified by HPLC on a Zorbax 300 SB-C₈ column. The mass of fully deprotected and purified peptide was confirmed by MALDI mass spectrometry (12). The presence of this 3-acetyl-tyrosine in a peptide can easily be detected by monitoring the absorption spectrum because 3-acetyl-tyrosine gives a unique UV spectrum with absorption maxima at 254 nm ($\epsilon = 5915 \text{ cm}^{-1}\text{M}^{-1}$) and 330 nm ($\epsilon = 1643 \text{ cm}^{-1}\text{M}^{-1}$).

To site-specifically label the 3-acetyl-Tyr containing Tat peptide with a dye, we used a semicarbazide derivative of fluorescein that modified acetyl-Tyr side chain through a semicarbazone linkage (Scheme 2) (12). This reaction was carried out by the addition of 2 equiv of 30 mM solution of fluorescein-5-thiosemicarbazide in DMF to 1 mM solution of the peptide in conjugation buffer (100 mM potassium phosphate, pH 7.0, 50% DMF), and incubating the reaction mixture at 4 °C overnight. The peptide-fluorescein conjugate was purified by reversed-phase HPLC and characterized by MALDI/TOF mass spectrometry (12). The conjugation reaction of the dye to acetyl-Tyr peptide was very efficient and resulted in ~80% yields. Although this Tat peptide contains two lysine residues in its sequence, these NH_2 -groups do not react with acetyl-tyrosine to form the imine linkage because the reaction is highly reversible under the conjugation conditions.

Our main interest in developing this methodology was to achieve site-specific peptide labeling with reporter molecules to probe protein–RNA interactions. In contrast to DNA, RNA molecules can fold into extensive structures containing regions of double-stranded duplex, hairpins, internal loops, bulged bases, and pseudoknotted structures (14). Three-dimensional structures of RNA create binding sites for specific interactions with proteins. One example of such interactions is the mechanism of *trans*-activation of human immunodeficiency virus type 1 (HIV-1) gene expression that requires the interaction of Tat protein with the *trans*-activation responsive region (TAR) RNA, a 59-base stem-loop structure located at the 5'-end of all nascent HIV-1 transcripts (15–18). TAR RNA contains a six-nucleotide loop and a three-nucleotide pyrimidine bulge which separates two helical stem regions (Figure 1) (15, 19–21). The trinucleotide bulge is essential for high affinity and specific binding of the Tat protein (22, 23). Due to difficulties in Tat purification, small Tat peptides that specifically bind TAR RNA with high affinity have been used in many Tat-TAR studies (24–30). Since Tat-derived peptides which contain the basic arginine-rich region of Tat are able to form *in vitro* complexes with TAR RNA (24, 26, 27), these peptides provide a well-characterized system to test new probes to study RNA–protein interactions. Although Tat peptides-TAR-binding affinities have been well studied by

Figure 2. (A) Fluorescence spectra of Tat-Fl (solid line) and Tat-Fl with TAR RNA-Rh (dotted circles). The concentrations of TAR RNA-Rh, Tat-Rh and Tat-Fl were 3 and 5 nM, respectively. (B) Fluorescence intensity of Tat-Fl (5 nM) at 512 nm in the presence of increasing TAR-Rh concentrations. The solid line represents the best fits of the data by nonlinear regression to quadratic eq 1. The fluorescence measurements were performed on PTI fluorescence spectrophotometer controlled by Felix software. The excitation wavelength was 492 nm and slits width was set 3.5 nm for both excitation and emission. All samples were corrected for the light source excitation effect and for the background intensity of buffer fluorescence as well as for dilution factors. Buffer conditions: 50 mM Tris-HCl, pH 7.4, at 25 °C, 20 mM KCl.

electrophoretic mobility shift assays, there is no available data reporting Tat peptide-TAR affinities in solution under physiological conditions.

To determine the binding affinities of a Tat peptide under physiological conditions and test the application of 3-acetyl-Tyr, we developed a fluorescence resonance energy transfer (FRET) system containing TAR RNA and a Tat peptide uniquely labeled with donor and acceptor dye molecules (Figure 1). FRET, in which a fluorescent donor molecule transfers energy via a nonradiative dipole-dipole interaction to an acceptor molecule (which is usually also a fluorescent molecule) is a standard spectroscopic technique for measuring distances in the 10–70 Å range (31, 32). The donor's lifetime and quantum yield are reduced upon energy transfer, and the acceptor fluorescence is increased or sensitized. Quantification of the efficiency of energy transfer allows determination of the distance between the two fluorophores. We used a well-characterized donor-acceptor dye-pair, fluorescein-rhodamine, for FRET experiments.

We examined FRET between the fluorescein labeled Tat peptide (Tat-Fl) and rhodamine labeled TAR RNA (TAR-Rh) (Figure 1). Emission scans from 500 to 650 nm of Tat-Fl (solid line) and Tat-Fl with TAR-Rh (dotted circles) were recorded (Figure 2A). Tat-Fl has an emission maximum around 512 nm (solid line), whereas upon

adding TAR RNA-Rh (dotted circles), this peak is decreased and another peak at 575 nm is increased. This reduction in fluorescein emission and the corresponding increase in rhodamine emission were due to the resonance energy transfer from Tat-Fl to TAR-Rh. To determine the binding affinity between the Tat peptide and TAR RNA, we examined fluorescence quenching of Tat-Fl at several different TAR-Rh concentrations (Figure 2B). K_D values were calculated by fitting data to quadratic eq 1.

$$F = F_{\min} - \{(F_{\max} - F_{\min})[(R + P_0 + K) - ((R + P_0 + K)^2 - 4RP_0)^{1/2}]\}/2P_0 \quad (1)$$

where F is the relative fluorescent intensity, $F_{\min}$ is the fluorescent intensity at the start of the titration, $F_{\max}$ is the fluorescent intensity at saturating concentration of RNA, R , P_0 is the total concentration of Tat-Fl. K is the dissociation constant of the RNA and Tat peptide and can be obtained by fitting data to eq 1 (33). Our results showed that Tat-Fl binds to the TAR-Rh with a dissociation constant (K_D) of 1.0 ± 0.5 nM.

This strategy of selective protein modification offers a versatile new procedure for labeling peptides of biological interest at a desired site when several nucleophilic side chains of lysine and cysteine are present. These methods would provide tools for postsynthetic peptide modification and introducing biophysical probes for structural and functional analysis of proteins.

A Chemoselective Method for Site-Specific Immobilization of Peptides via Aminoxy Group

Maciej Adamczyk,* John C. Gebler, Rajarathnam E. Reddy, and Zhiguang Yu

Department of Chemistry, 9NM, Building AP20, Diagnostics Division, Abbott Laboratories, 100 Abbott Park Road, Abbott Park, Illinois 60064-6016. Received October 16, 2000

Site-specific modification of peptides and proteins is an important area of basic research for preparation of well-defined biosensors and probes. The unique properties of aminoxy group present an opportunity for chemoselective site-specific immobilization of peptides to prepare well-defined biosensors. We have prepared FLAG peptide derivatives containing L- ϵ -aminoxylysine (L- ϵ -AOLys, **1a**) and L-lysine units in their sequence at the C- and N-terminals via solid-phase synthesis. Site-specific modification of peptides through aminoxy group was demonstrated in the preparation of biosensors and selective conjugation in the preparation of biotinylated probes. Effect of the incorporation of L- ϵ -AOLys (**1a**) into the peptide sequence and its subsequent labeling on the FLAG epitopic character was measured using a surface plasmon resonance detector. It was found that incorporation of L- ϵ -AOLys (**1a**) into the FLAG peptide and site-specific immobilization through aminoxy group preserved the integrity of FLAG epitope.

INTRODUCTION

Recent advances in solid-phase chemistry and molecular biology have spurred the construction of larger peptides and small proteins through stepwise synthesis using automated instruments. A variety of biophysical probes have been produced from peptides and proteins with carefully engineered properties for applications in medicinal and biotechnology fields (1–8). In contrast to the synthesis of low molecular weight natural products, which is aided by plethora of specific reactions and protective groups, site-specific modification of unprotected peptides and proteins to prepare well-defined bioconjugates is challenging. The complexity becomes even more apparent in the preparation of solid supported probes and biosensors, for example, in applications using surface plasmon resonance technology (6, 9). The observed binding properties of a peptide or protein in solution could be compromised upon immobilization depending on its site of attachment to the solid support in a biosensor. A key requirement for site-specific conjugation is the chemoselectivity. It is desired that only the intended site in a peptide or protein be modified in the presence of other functional groups and thus leading to the formation of a well-defined bioconjugate. It is critical to use such conjugates for implementation of quality control (10, 11) and reliable interpretation of biological results. We and others have been exploring the utility of aminoxy group for a variety of applications such as detection of abasic sites in DNA (12, 13), development of reagents for immunoassays (14, 15), preparation of artificial proteins (16–20) and peptide dendrimers (21), and selective fluorescent labeling of *N*-methylaminoxy peptides (22). The unique properties of aminoxy group suggest that peptides incorporated with an unnatural amino acid bearing this functionality

could be chemoselectively conjugated to a solid support of interest (Figure 1) to provide well-defined biophysical probes. In this paper, we describe an efficient method for chemoselective site-specific immobilization of peptides **12** and **14** via primary aminoxy group ($-\text{ONH}_2$) incorporated as an L- ϵ -aminoxylysine residue (L- ϵ -AOLys, **1a**) (23) to a carboxymethyl dextran chip to form a biosensors. Binding properties of these peptides **12** and **14** and a biotinylated conjugate **16** to anti-FLAG MAb using surface plasmon resonance (BIAcore) are presented.

RESULTS AND DISCUSSION

Before attempting the site-specific immobilization of peptides through the aminoxy group, competitive reactivity of aminoxy and amino groups in model amino derivatives **6** and **7** at different pH values was studied. Thus, a mixture of **6** (1.0 M equiv) and **7** (1.0 M equiv) (Scheme 1) was treated with biotin succinimidyl ester **8** (1.0 M equiv) in DMSO and sodium phosphate buffer at pH 2.0, 3.0, 3.8, 5.0, 6.0, 7.0, 8.2, and 10.3. Any difference in the reactivity of **6** and **7** in the biotinylation to form **9** or **10** under identical conditions must arise from aminoxy or amine groups. As expected (Figure 2), **7** was found to be unreactive at a pH below 6.0, however, **6** was reactive in acidic buffers down to pH 3.0. When the pH of medium was decreased to 2.0, the rate of conjugation of **6** dropped dramatically, presumably due to the protonation of the aminoxy group or hydrolysis of **8**. Under more basic conditions (pH > 6.0), compound **7** competed with **6** for the active ester **8**. When the pH of the medium increased to 10.3, the amine **7** reacted completely and the aminoxy compound **6** remain unmodified. The competitive reactivity of aminoxy and amine groups was then studied by immobilization of compounds **6** and **7** on a carboxymethyl dextran chip and quantitated by streptavidin binding using surface plasmon resonance (SPR) (6, 9, 24). Thus, **6** and **7** were immobilized (2.0 mM, 150 μL , at pH 3.8) onto separate channels of the preactivated chip surface (35 μL of 0.25 M NHS/EDAC in water over 7 min

Scheme 1. Biotinylation of 6 and 7 at Different pH Values^a

^a Reagents and conditions: (a) biotinamidocaproate-*N*-hydroxysuccinimide ester (**8**, 1.0 M equiv), DMSO, sodium phosphate buffer (4:96 ratio, v/v), 23 °C, 16 h at 2.0, 3.0, 3.8, 5.0, 6.0, 7.0, 8.2, 10.3 pH.

at 5.0 μ L/min). Efficiency of the immobilization process was determined by passing a solution of streptavidin (10 μ g/mL in HBS buffer) over both the channels. The signal from the channel immobilized with **6** was 2500 RU, while the signal for channel with **7** was 20 RU (<0.8%), indicating that only **6** with aminoxy group was immobilized.

We then proceeded to prepare peptides, which had L-ε-AOLys (**1a**) unit incorporated on the C-terminal and N-terminal, **12** and **14**, respectively (Figure 1, Scheme 2). These model peptides are the derivatives of the "FLAG peptide" **11** for which specific antibodies are commercially available. Thus, α -Fmoc-L-Lys(ONH-*t*-Boc) (**1b**) was ac-

Figure 2. Competitive reaction of compounds **6** (dark circle) and **7** (normal circle) with succinimidyl ester **8** in DMSO, sodium phosphate buffer (4:96 ratio), 23 °C, 16 h at different pHs (2.0, 3.0, 3.8, 5.0, 6.0, 7.0, 8.2, and 10.3) as shown in Scheme 1.

Scheme 2: Solid-Phase Synthesis of Peptides with Incorporation of L-ε-AOLys (12**, **14**) and L-Lys (**13**, **15**) in Their Sequence, and the Site-Specific Conjugation of Peptide **14** and **15** with Active Ester **8**^a**

Native FLAG peptide: Asp-Tyr-Lys-Asp-Asp-Asp-Lys (**11**)

Asp-Tyr-Lys-Asp-Asp-Asp-Asp-Lys-Lys(ε-ONH₂) (**12**)

Asp-Tyr-Lys-Asp-Asp-Asp-Asp-Lys-Lys (**13**)

Lys(ε-ONH₂)-Asp-Tyr-Lys-Asp-Asp-Asp-Asp-Lys (**14**)

Lys-Asp-Tyr-Lys-Asp-Asp-Asp-Asp-Lys (**15**)

14 $\xrightarrow{a}$ Lys(ε-ONH-B)-Asp-Tyr-Lys-Asp-Asp-Asp-Asp-Lys (**16**)

15 $\xrightarrow{b}$ Lys(B₂)-Asp-Tyr-Lys(B)-Asp-Asp-Asp-Asp-Lys(B) (**17**)

^a Reagents and conditions: (a) active ester **8** (8.0 equiv), DMSO, sodium phosphate buffer (pH 3.2) 23 °C, 19 h 58%; (b) **8** (8.0 equiv), DMSO, sodium phosphate buffer (pH 8.2) 23 °C, 19 h 55%. B = -CO(CH₂)₅NH-biotinyl.

tivated (0.5 M HATU–1.0 M Et₃N) and coupled to PAL-PEG-PS resin via double coupling to ensure high loading efficiency, and the peptide **12** was then assembled on a Pioneer Peptide Synthesizer. Similarly, peptide **14** with L-ε-AOLys unit at the N-terminus was assembled starting from α -Fmoc-L-Lys(NH-*t*-Boc). Finally, peptides **12** and **14** were cleaved from the resin by treatment with TFA-water (90:10 ratio) and isolated by reversed phase preparative HPLC in 40–61% yield. In addition, the peptides **13** and **15**, which contain a L-Lys residue in the place of L-ε-AOLys, were also prepared for control experiments. The site-specific immobilization of peptides bearing an aminoxy group in the presence of primary amines (α and ϵ -amines of Lys) was then demonstrated by passing a solution of **12–15** (2.0 mM, 150 μ L) in sodium phosphate buffer (100 mM) at pH 3.8 over four dextran surfaces (channels). The chip in each channel was pre-activated using NHS-EDAC solution (35 μ L of 0.25 M NHS/EDAC in water over a period of 7 min at 5.0 μ L/min flow rate). The resulting biosensors were compared for their ability to bind to anti-FLAG MAb. The saturated response from sensors immobilized with peptides **12** and **14** were 4260 and 6950 RU, respectively. Whereas the sensors for peptides **13** and **15** generated only 75 and 60 RU respectively (<2% reactivity) indicating negligible immobilization of **13** and **15**. To confirm the selectivity in the immobilization process, a site-specific conjugation of peptide **14** with biotin active ester **8** (Scheme 2) was explored. Accordingly, a solution of **14** in sodium phosphate buffer at pH 3.8 was treated with a DMSO solution

Figure 3. Measurement of inhibition constants (IC_{50}) for native FLAG peptide **11** and conjugates **16** and **17**. Anti-FLAG MAb (5 nM) was mixed with peptide solutions of different concentrations. After equilibrium, the free MAb concentration was quantitated on a sensor immobilized with **14**. The sensor was calibrated with a range of known concentrations of anti-FLAG MAb (0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 3.0, 4.5, 5.0, and 5.5 nM). Grafit 3.0 was used to fit data to obtain IC_{50} values. (■) Native FLAG peptide (**11**); (●) conjugate **16**; (▲) conjugate **17**.

of **8** to afford the conjugate **16**. Analysis of conjugate **16** by mass spectrometry (ThermoQuest LCQ, ESI-MS) indicated that, only one biotin-label was present [1496.4 (MH) $^+$, 748.9 (MH $_2$) $^{2+}$]. The MS-MS analysis of **16** further confirmed its amino acid sequence and more importantly the location of the single biotin-label, which was found to be exclusively on the AOLys residue. As a control, the peptide **15**, which had a Lys residue in the place of AOLys, was treated with the active ester **8** (8.0 equiv) under identical conditions (pH 3.8), and no conjugation was observed even after 19 h. However, treatment of **15** with **8** at pH 8.2 resulted in all amines being conjugated with biotin (conjugate **17**). The structure of **17** was confirmed by MS analysis.

The binding properties of native FLAG peptide **11**, its derivatives **14** and **15** and biotinylated conjugates **16** and **17** with anti-FLAG MAb were investigated using SPR. The biosensor generated by site-specific immobilization of peptide **14** (antibody binding capacity: 6950 RU) was calibrated with anti-FLAG MAb (range 0.5–5.5 nM) under mass transport limiting condition. Calibration curves were then generated by plotting the slope of each sensorgram vs concentration of MAb. Then, solution competition experiments were conducted by mixing anti-FLAG MAb (5 nM) with FLAG peptide or conjugate solutions of different concentrations (Figure 3). Peptides **14** and **15** with AOLys and Lys residues had an IC_{50} value of $346 (\pm 32)$ nM and $361 (\pm 46)$ nM, respectively, a ~ 3.5 -fold affinity gain when compared to the native FLAG peptide **11** [IC_{50} 1217 (± 103) nM]. Importantly, the affinity of conjugate **16** [IC_{50} 345 (± 11) nM] was not changed, thus, demonstrating that site-specific biotinylation did not affect the epitopic character. However, conjugate **17**, which had four biotin labels, lost antibody binding affinity dramatically [IC_{50} 13 518 (± 260) nM]. Thus, incorporation of L- ϵ -AOLys (**1a**) into the FLAG peptide and site-specific conjugation through aminooxy group preserved the integrity of FLAG epitope. In summary, peptides **12** and **14** were assembled by incorporation of L- ϵ -AOLys (**1a**) unit in their sequence via solid-phase synthesis. Site-specific immobilization of unprotected peptides **12** and **14** through an aminooxy group was demonstrated in the preparation of carboxymethylated

dextran biosensors. The effect of the incorporation of L- ϵ -AOLys (**1a**) into the peptide sequence and its subsequent immobilization on the FLAG epitopic character was found to be minimal as measured by surface plasmon resonance.

Dipartimento di Chimica e Tecnologie Farmaceutiche, Via Archirafi 32, 90123 Palermo, Italia. Received November 23, 1999; Revised Manuscript Received November 2, 2000

The clinical usefulness of antitumor chemotherapy has been strongly limited by the lack of specificity of most anticancer drugs, which act also against healthy cells. The aim of this work was to design, synthesize, and evaluate a macromolecular prodrug of Cytarabine, a known antitumor drug, which is a specific substrate for plasmin enzyme whose concentration is high in various kinds of tumor mass as a result of plasminogen activator secretion. α,β -Poly(*N*-hydroxyethyl)-DL-aspartamide (PHEA), a known synthetic and biocompatible polyamino acid, was used as a drug carrier, and Cytarabine was linked to PHEA by D-Val-Leu-Lys spacer synthesized beginning from Cbz-D-Val-LeuOH dipeptide and *N*⁶-CbzLys methyl ester. The content of Cytarabine in the purified PHEA-D-Val-Leu-Lys-Cytarabine conjugate was equal to 3% w/w. In vitro experiments in the presence of plasmin evidenced the ability of this enzyme to strongly increase drug release from the macromolecular prodrug, as well as plasma incubation shows high stability of drug–polymer linkage. The direct linkage of Cytarabine to PHEA was also performed and, like PHEA-D-Val-Leu-Lys-Cytarabine conjugate, the obtained PHEA–Cytarabine conjugate showed high stability in plasma, but no release of Cytarabine was revealed in the presence of plasmin.

INTRODUCTION

The use of therapeutic systems to obtain a controlled drug release in cancer therapy is a more and more exploited approach in the modern pharmaceutical technology (1, 2). Growing interest in this field rises on one side from the often unsuccessful research of effective and nontoxic new drugs and on the other side from the new knowledge on the biochemical events around and inside tumor tissue that allow to propose novel therapeutic strategies. Many drug delivery systems have been assayed and among them drug–antibody conjugates (immunoconjugates) and conjugates obtained by linking drugs to natural or synthetic polymers (macromolecular prodrugs) (2–5). Unfortunately immunoconjugates have often disappointed starting promising expectations (6, 7) mainly because of the limited access of these relatively big macromolecules into tumor mass, the heterogeneity of tumor cells and the different humoral answer among patients.

For the past several years in anticancer therapy, strong interest has been aroused, for their potential, by macromolecular prodrugs. They are systems obtained by covalent linking of active agents to a water-soluble macromolecule (carrier) with suitable functional groups, directly or by a chemical spacer arm (8–10).

The coupling of low-molecular weight drugs to water-soluble carrier can involve: (a) the improvement of drug movement in the body prolonging its time residence in circulation (11, 12); (b) a slow release of the drug from polymeric conjugate by chemical or enzymatic hydrolysis (13, 14); (c) the promotion of drug incorporation into cells via endocytosis process (15); (d) the site-specific transport of drug by using moieties recognizing target cells (16);

(e) the exploitation of enhanced permeability and retention (EPR) effect of tumor mass (17).

In addition to these advantages the use of macromolecular prodrugs in common chemotherapeutic programs can strongly improve tumor localization of drug (17). In the recent years a lot of investigations has been performed in order to clarify the biochemical events concerning tumor growth and formation of metastasis (18–20) and to identify the sole properties of neoplastic cell that can be exploited to concentrate drug into tumor mass. These studies have demonstrated that the ability of the tumor cells to invade surrounding tissues involves an increased activity of proteolytic enzymes able to degrade the basal membrane and the extracellular matrix (18–20). These enzymes can be secreted by tumor cells or remain bound to their cellular surface (21). Although they are also produced by normal cells, their activity is normally tightly regulated by hormonal controls and by specific inhibitors (22, 23). It seems that the normal regulating mechanism is disturbed for tumor cells and they use these enzymes to activate degradation cascades close to cell surface in order to clear a path for the invading cancer cells (24). Most of these enzymes belong to the families of extracellular matrix metalloproteinases (25), cathepsins (26), and plasminogen activators (Pas), which catalyze the conversion of inactive plasminogen to plasmin, the active enzyme in extracellular matrix degradation (20, 27). The levels of Pas are high in many types of malignant cells and human tumors such as malignant lung (28) and colon (29) showing that tumor-associated plasmin activity is highly localized (20, 27, 28–31).

This phenomenon suggested to design macromolecular prodrugs by using proper peptidic spacers (usually tri- or tetra-peptides) able to release drug inside or near tumor by hydrolytic activity of this enzyme.

The chosen peptidic spacer has to be able to give rise a macromolecular prodrug resistant to the serum pepti-

dase activity but always susceptible to enzymes present around tumor mass. Since it is well-known from the literature that plasmin is a protease with specificity for arginine or lysine as amino acids participating to bond cleaved (32) and the examination of the preferred sites for plasmin cleavage of the fibrinogen molecule (physiological function of plasmin) shows that the preferred sites involves lysine linked to an hydrophobic amino acid, the choice of which peptidic sequence to use has been focused on a peptide having an hydrophobic amino acid linked to lysine; therefore, D-Val-Leu-Lys tripeptide, already proposed by literature as a possible good substrate for plasmin (33), was so chosen.

Among antitumor compounds, the cytotoxic S-phase-specific antimetabolite Cytarabine (Ara-C) (34) is the most frequently used drug for the treatment of patients with acute myelogenous leukemias though its application has a few disadvantages. First, it is not very specific, and this compound affects also healthy cells causing many toxic side effects. Second, the amino group of the heterocycle in the drug is highly sensitive to the action of deaminase enzymes; this process leads to the inactivation of the drug by formation of an ineffective uridine derivative (35). Therefore, effective blood levels of Cytarabine can be achieved by continuous infusion or saturating drug metabolizing enzyme with potentially very toxic massive doses.

Various derivatives monosubstituted at the N-4 position of the cytosine ring have been prepared, and their hydrolytic stability has been evaluated in vitro and in vivo (36). It has been demonstrated that the derivatization of this molecule by using the amino group seems to be a valid method to increase drug stability to deaminases and to obtain less toxic derivatives (33, 36, 37).

The aim of this work is to design, synthesize, and characterize a macromolecular prodrug of Cytarabine by using a peptidic spacer, which is an ad hoc substrate for plasmin enzyme, such as D-Val-Leu-Lys, and involving labile amine group of cytosine ring; this rational has the objective to improve chemical stability and then the bioavailability of Cytarabine, as well as specificity and action selectivity.

α,β -Poly(*N*-hydroxyethyl)-DL-aspartamide (PHEA), a synthetic macromolecule at protein-like structure, freely water-soluble, nontoxic, nonantigenic, and nonimmunogenic, already proposed as plasma substitute and drug carrier of antiinflammatory (38, 39) and antiviral drugs (12, 14, 40) has been used.

The obtained PHEA-D-Val-Leu-Lys-Cytarabine conjugate properly purified and characterized has been subjected to in vitro plasma and plasmin activity to verify its potential in cancer therapy.

The direct linkage of Cytarabine to PHEA has been also performed and the obtained PHEA-Cytarabine conjugate was subjected to the same in vitro hydrolysis experiments in order to evaluate its stability in these media and its possible ability to drug release in the presence of plasmin.

EXPERIMENTAL PROCEDURES

Apparatus. Infrared spectra were obtained using a Perkin-Elmer 1720 IR Fourier Transform Spectrophotometer in potassium bromide disks. Ultraviolet (UV) spectra were recorded by using a Perkin-Elmer 330 Instrument equipped with a 3600 Station.

Elemental analysis (C, H, N) was carried out on a Carlo Erba model 1106 analyzer.

The mass spectra were obtained using a Hybrid Quadrupole-TOF LC/MS/MS Mass Spectrometer (manufactured by Perkin-Elmer Sciex Instruments) equipped with an Apple Macintosh System 8.6 Hardware operating with TOFTune 1.5b37 software by using the Electron Spray Technique.

The ^1H NMR spectra were obtained with a Bruker AC-250 instrument operating at 250.13 MHz. A Brookhaven Bi-200 SM Laser Spectra Physics Spectrometer was used for determination of weight average of molecular weight.

Centrifugations were performed using a Centra MP4R IEC centrifuge. Low-temperature reactions were performed by using a Haake F3 Digital thermostat.

TLC analyses were performed on silica gel plate 60 F₂₅₄ (Merck) and on RP-18 silica gel plate F₂₅₄^S (Merck).

HPLC analyses were carried out on a system consisting of a Varian 9012 Liquid Chromatograph equipped with a Rheodyne Injector 7125 (fitted with a 10 μL loop) and a Kontron HPLC Detector 432 on line with a computerized HP workstation. In the method HPLC, a reversed-phase C₁₈ column (μ Bondapak; 10 μm of 250 mm $\times$ 4.6 mm i.d., obtained from Waters) equipped with a direct-connect guard column C₁₈ (Waters) was used.

Materials. Cytarabine (1- β -arabinofuranosylcytosine) was obtained from Upjohn as a gift; Cbz-L-lysine methyl ester hydrochloride, hydroxybenzotriazole (HOBt), and *N*-methylmorpholine (NMeMor) were purchased from Sigma (Italy); Cbz-D-Val-LeuOH was purchased from Bachem (Switzerland); DL-aspartic acid, ethanolamine, 1,1'-carbonyldiimidazole (CDI), dicyclohexylcarbodiimide (DCC), 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDCI-HCl), 10% Pd/C, Triton X-100, and acetone were purchased from Fluka (Switzerland); acetone was dried by using CaCl_2 and distilled before using; black palladium, *N*-hydroxysuccinimide (N-HSI), 4-(dimethylamino)pyridine (4-DMAP), anhydrous pyridine, *N*-methylpyrrolidone (NMP), anhydrous diethyl ether, and colloidal silica for column chromatography (60, 70–230 mesh), 60 Å were purchased from Aldrich (Italy); 4-nitrophenylchloroformate (PNFC), methanol, chloroform, and formic acid were purchased from Merck (Germany); methanol was dried by using Mg and I₂ and distilled before using *N,N*-dimethylformamide (DMF) (Hoechst), dried using P₂O₅, and distilled under reduced pressure before use. All other chemicals were reagent grade.

PHEA was prepared and purified according to a previously reported procedure (41). The weight-average molecular weight of PHEA, measured by light scattering, was 51 800 ($M_w/M_n = 1.79$).

Human plasma was obtained from voluntary healthy blood donors.

Plasmin was purchased by Boehringer Mannheim (Italy).

Synthesis of Cbz-D-Val-Leu-N⁶-Cbz-Lys-OMe (3). To a solution of 454 mg (1.372 mmol) of Cbz-L-Lysine-OMe-HCl (1) in 1.06 mL of dry pyridine and 0.17 mL of *N*-methylmorpholine at 0 °C were added 500 mg (1.372 mmol) of Cbz-D-Val-Leu-OH (2), 298 mg (2.20 mmol) of HOBt, and 454 mg (2.20 mmol) of DCC in 2.2 mL of dry pyridine.

The reaction mixture was kept under stirring at 0 °C for 4 h and at room temperature for 36 h. After this time, the reaction mixture was filtered to separate produced dicyclohexylurea and solvent was removed under pressure. The obtained residue was dissolved in CHCl_3 , and the organic solution was treated by subsequent steps with alkaline solution, water, and acid solution, and again with water, extracting aqueous phases by CHCl_3 . The

organic fractions were collected, dried over Na_2SO_4 at room temperature for some hours, and then filtered and evaporated. The obtained product was purified by column chromatography by using silica gel 60 and $\text{CHCl}_3/\text{AcOEt}$ (2:8) as mobile phase; the yield was 76% based on **2**.

The purity of product was verified by TLC on silica gel plate 60 F₂₅₄ and using $\text{CH}_3\text{COOC}_2\text{H}_5/\text{CHCl}_3$ (4/1, v/v) as mobile phase; the R_f value was 0.77.

The purified product was characterized by elemental analysis, melting point (mp), mass spectrum, IR, and ^1H NMR spectroscopies. Anal. ($\text{C}_{34}\text{H}_{48}\text{N}_4\text{O}_8$) C, 63.73; H, 7.55; N, 8.74; mp, 176–178 °C. The mass spectrum obtained by ESY Technique shows the MH^+ on at m/z 641 and mean peaks at 406 and 293 m/z . IR (KBr): 3309 cm^{-1} (ν -NH-), 3066 cm^{-1} (ν -CH- aromatic), 2958 cm^{-1} (ν -CH- aliphatic), 1735 cm^{-1} (ν C=O ester), 1691 cm^{-1} (ν C=O urethanic), 1640 cm^{-1} (ν C=O amidic), 1541 cm^{-1} (δ -NH- amide). ^1H NMR ($\text{DMSO}-d_6$): δ 0.82 (m, broad, 12H, 4CH₃ isopropyl), δ 1.2–2 (m, broad, 10H, 3CH₂ *n*-butyl of lysine, 2H isopropyl, CH₂ isobutyl), δ 2.95 (m, 2H, CH₂ *n*-butyl of lysine), δ 3.58 (s, 3H, -OCH₃), δ 3.85 (m, 1H, 1CH α of lysine), δ 4.18 (m, 1H, 1CH α), δ 4.34 (m, 1H, 1CH α), δ 4.99 (s, 4H, 2CH₂ benzyl), δ 7.34 (m, 12H, 10H aromatic, 2H -CH-NH-COOCH₂-Ph), δ 8.04 (d, 1H, -CH-NH-CO-), δ 8.14 (d, 1H, -CH-NH-CO-).

Synthesis of Cbz-D-Val-Leu-N⁶-Cbz-Lys-OH (4). To a solution of 200 mg (0.31 mmol) of Cbz-D-Val-Leu-N⁶-Cbz-Lys-OMe (**3**) in 3.0 mL of dioxane was added 1.5 mL of NaOH 1 N. Reaction mixture was kept under stirring at 0 °C for 2 h and after this time added with HCl 0.1 N until pH 3, then treated several times with CHCl_3 ; organic fractions were collected and evaporated. The purity of **4** was verified by TLC on silica gel plate 60 F₂₅₄ and using $\text{CHCl}_3/\text{CH}_3\text{OH}$ (4/1, v/v) as mobile phase; the R_f value was 0.66.

The dried product (**4**) obtained with a yield of 85% based on **3** was characterized by elemental analysis, melting point (mp), mass spectrum, IR, and ^1H NMR spectroscopies. Anal. ($\text{C}_{33}\text{H}_{46}\text{N}_4\text{O}_8$) C, 63.24; H, 7.40; N, 8.94; mp, 215–217 °C.

The mass spectrum obtained by ESY technique shows the MH^+ on at m/z at 627 and mean peaks at 536, 446, and 301 m/z . IR (KBr): 3323 cm^{-1} (ν -NH-), 3065 cm^{-1} (ν -CH- aromatic), 2958 cm^{-1} (ν -CH- aliphatic), 1738 cm^{-1} (ν C=O acid), 1688 cm^{-1} (ν C=O urethanic), 1632 cm^{-1} (ν C=O amidic), 1540 cm^{-1} (δ -NH- amide). ^1H NMR ($\text{DMSO}-d_6$): δ 0.85 (m, broad, 12H, 4CH₃ isopropyl), δ 1.2–2.1 (m, broad, 10H, 3CH₂ *n*-butyl of lysine, 2H isopropyl, CH₂ isobutyl), δ 2.96 (m, 2H, CH₂ *n*-butyl of lysine), δ 3.86 (m, 1H, 1CH α of lysine), δ 4.12 (m, 1H, 1CH α), δ 4.35 (m, 1H, 1CH α), δ 4.99 (s, 4H, 2CH₂ benzyl), δ 7.33 (m, 12H, 10H aromatic, 2H -CH-NH-COOCH₂-Ph), δ 8.04 (d, 1H, -CH-NH-CO-), δ 8.14 (d, 1H, -CH-NH-CO-).

Synthesis of Cbz-D-Val-Leu-N⁶-Cbz-Lys-Cytarabine (5). A total of 513 mg (0.81 mmol) of Cbz-D-Val-Leu-N⁶-Cbz-Lys-OH (**4**), 138 mg (1.20 mmol) of N-HSI, and 158 mg (0.82 mmol) of EDCI-HCl was dissolved in 19.7 mL of anhydrous DMF. Reaction mixture was kept under stirring at room temperature for 4 h than, at 4 °C for 12 h. After this time, 197 mg (0.85 mmol) of cytarabine were added, and the reaction mixture was kept under stirring at 45 °C for 20 h. After this time, solvent was removed under low pressure and crude residue was purified by column chromatography by using a mixture $\text{CHCl}_3/\text{CH}_3\text{OH}$ (4:1) as mobile phase.

The purity of **5** was verified by TLC on silica gel plate 60 F₂₅₄ and using $\text{CHCl}_3/\text{CH}_3\text{OH}$ (4/1, v/v) as mobile phase; the R_f value was 0.26.

The purified product obtained with a yield of 65% based on **4**, was characterized by elemental analysis, melting point (mp), mass spectrum, IR, and ^1H NMR spectroscopies. Anal. ($\text{C}_{42}\text{H}_{57}\text{N}_7\text{O}_{12}$) C, 59.21; H, 6.74; N, 11.51; mp, 139–140 °C. The mass spectrum obtained by ESY technique shows the MH^+ on at m/z 852 and mean peaks at 446 and 301 m/z . IR (KBr): 3308 cm^{-1} (ν -NH- and -OH of arabinose), 3066 cm^{-1} (ν -CH- aromatic), 2959 cm^{-1} (ν -CH- aliphatic), 1701 cm^{-1} (ν C=O urethanic), 1653 cm^{-1} (ν C=O amidic and C=O pyrimidinic ring), 1541 cm^{-1} (δ -NH- amide). ^1H NMR ($\text{DMSO}-d_6$): δ 0.85 (m, broad, 12H, 4CH₃ isopropyl), δ 1–2 (m, 10H, 3CH₂ *n*-butyl of lysine, 2H isopropyl, CH₂ isobutyl), δ 2.98 (m, 2H, CH₂ *n*-butyl of lysine), δ 3.61 (m, 2H, CH₂ C5'), δ 3.83–4.07 (m, 4H, 3H C2' C3' C4', CH α of lysine), δ 4.37 (m, 2H, 2CH α), δ 5.05 (m, 5H, 2CH₂ benzylic, OH C5'), δ 5.49 (m, 2H, (OH, C2' C3')), δ 6.05 (d, 1H C1'), δ 7.15 (d, 1H C5), δ 7.25–7.34 (m, 12H, 10H aromatic, 2NH), δ 7.90 (m, 1H, NH), δ 8.06 (d, 1H, C6), δ 8.18 (d, 1H, NH), δ 10.89 (s, 1H, NH).

Synthesis of D-Val-Leu-Lys-Cytarabine (6). To a solution of 50 mg (0.058 mmol) of Cbz-D-Val-Leu-N⁶-Cbz-Lys-Cytarabine (**5**) in 5 mL of anhydrous $\text{CH}_3\text{OH}/\text{HCOOH}$ (15/85 v/v) mixture were added 20 mg of black Pd and 30 mg of Pd/C (10%). Reaction mixture was kept under stirring and under inert atmosphere at room temperature for 20 h monitoring the progress of reaction by TLC on silica gel plate 60 F₂₅₄ and using $\text{CHCl}_3/\text{CH}_3\text{OH}$ (4/1, v/v) as mobile phase through the progressive disappearance of spot at R_f = 0.26 (related to **5**) and the appearance of a spot with R_f = 0. Reaction mixture was filtered and solvent was removed under low pressure at controlled temperature (no more than 40 °C). The obtained residue was treated several times with acetone (~50 mL), and the dried solid product obtained with a yield of 60% was characterized by elemental analysis, melting point (mp) and ^1H NMR spectroscopy. Anal. ($\text{C}_{26}\text{H}_{45}\text{N}_7\text{O}_8$) C, 53.68; H, 7.45; N, 16.85; mp, 130–132 °C. ^1H -NMR ($\text{DMSO}-d_6$): δ 0.85 (m, 12H, 4CH₃ isopropyl), δ 1–2 (m, 10H, 3CH₂ *n*-butyl of lysine, 2CH isopropyl, CH₂ isobutyl), δ 2.98 (m, 2H, CH₂ *n*-butyl of lysine), δ 3.61 (m, 2H, CH₂ C5'), δ 3.83–4.07 (m, 4H, 3H C2' C3' C4', CH α of lysine), δ 4.37 (m, 2H, 2CH α), δ 4.6–5 (m, 7H, 2-NH₂, 3H, OH C5' C2' C3'), δ 6.05 (d, 1H C1'), δ 7.15 (d, 1H C5), δ 7.70 (m, 1H, NH), δ 8.06 (d, 1H, C6), δ 8.25 (d, 1H, NH), δ 10.89 (s, 1H, NH).

Nitrophenyl Chloroformate Activation of PHEA (7). To a solution of 100 mg (0.001 93 mmol) of freshly lyophilized PHEA in 2.1 mL of NMP/pyridine (3.6:1 v/v) mixture, were added 21 mg of DMAP (0.171 mmol) and 228 mg (1.132 mmol) of PNFC at the temperature of -10 °C; the reaction mixture was kept under stirring for 1 h at the same temperature then left to go to room temperature and precipitated dropwise into an anhydrous diethyl ether/acetone (6:4 v/v) mixture (about 20 mL) kept to 0 °C. The obtained suspension was centrifuged at 4 °C for 6 min at 10 000 rpm and the residue was treated several times with the same precipitant mixture and dried.

Determination of 4-Nitrophenyl Carbonate Content of (7). The activation percentage of PHEA was evaluated by UV spectroscopy. A total of 10 mg of **7** were added to 25 mL of 0.1 N NaOH and the absorbance of solution was measured at 400 nm. The 4-nitrophenyl carbonate content of activated polymer (**7**) was equal to about 12.2% w/w, corresponding to an activation degree of polymer of 13.2 mol %.

Determination of Total Carbonate Content of 7. A total of 50 mg of activated polymer was dissolved in 7

mL of 0.1 M barium hydroxide. The mixture was kept to reflux for 1 h, preventing uptake of CO₂ from the air. After cooling the reflux condenser was washed with 5 mL of CO₂-free water and the aqueous solution was titrated with 0.1 M HCl using phenolphthalein as indicator.

Synthesis of PHEA-D-Val-Leu-Lys-Cytarabine Conjugate (8). To a solution of 114 mg of activated PHEA (7) in 2.1 mL of an anhydrous DMF/pyridine (9:1 v/v) mixture, was added 100 mg (0.171 mmol) of D-Val-Leu-Lys-Cytarabine (6); the reaction mixture was kept under stirring at 20 °C for 24 h, and after this time, it was added dropwise to an anhydrous diethyl ether/acetone (6:4 v/v) mixture (20 mL). The obtained suspension was centrifuged at 4 °C for 6 min and 10 000 rpm, then treated once with the same precipitant mixture, centrifuged, and dried under low pressure. The obtained residue was dissolved in distilled water and purified by exhaustive dialysis by using Visking Dialysis 18/32 in. (with a molecular weight cutoff of 12000–14000) then lyophilized. The purity of obtained polymeric conjugate was evaluated by HPLC analysis.

The amount of free drug in the conjugate was evaluated equal to 0.01% w/w.

PHEA-D-Val-Leu-Lys-Cytarabine conjugate (8) was characterized by elemental analysis, UV and ¹H NMR spectroscopies. Anal. calcd (C_{6.57}H_{10.87}N_{2.15}O_{3.19}) (relative to 3% w/w of substitution) C, 46.15; H, 6.41; N, 17.59. Found: C, 47.05; H, 7.15; N, 17.89. UV: the UV spectrum in the range between 230 and 350 nm shows an absorption maximum at 278 nm. ¹H NMR (DMSO-*d*₆/D₂O): δ 0.95 (m, broad, 12H, 4CH₃ isopropyl), δ 1–2 (m, 10H, 3CH₂ *n*-butyl of lysine, 2CH isopropyl, CH₂ isobutyl), δ 2.79 (m, broad, 2H -CH-CH₂-CO-NH-), δ 2.98 (m, 2H, CH₂ *n*-butyl of lysine), δ 3.36 (m, 2H -NH-CH₂-CH₂-OH), δ 3.6 (m, 4H, 2H CH₂-CH₂-OH, 1CH₂ C5'), δ 3.8–4.5 (m, 6H, 3H C2' C3' C4', 1CH_α of lysine, 2H 2CH_α), δ 4.72 (1H -NH-CH(CO)CH₂-), δ 6.1 (d, 1H, C1'), δ 6.98 (d, 1H C5), δ 8.02 (d, 1H, C6).

Synthesis of PHEA–Cytarabine Conjugate (9). To a solution of 115 mg of activated PHEA (7) in 2.1 mL of an anhydrous DMF/pyridine (9:1, v/v) mixture, was added 145 mg (0.59 mmol) of Cytarabine; the reaction mixture was kept under stirring at 40 °C for 24 h, and after this time, it was added dropwise to an anhydrous diethyl ether/acetone (6:4, v/v) mixture (15 mL). The obtained suspension was centrifuged at 10 °C for 6 min and 10 000 rpm, then washed several times with the same precipitant mixture, centrifuged, and dried under low pressure. The obtained residue was dissolved in distilled water and purified by exhaustive dialysis by using Visking Dialysis Tubing 18/32 in. The purity of obtained polymeric conjugate was calculated by HPLC analysis. The occurred linkage between Cytarabine and PHEA was verified by UV and ¹H NMR spectroscopies. The content of linked drug in the conjugate was evaluated by elemental analysis, alkaline hydrolysis followed by HPLC analysis and confirmed by ¹H NMR spectroscopy. Anal. calcd (C_{10.87}H_{16.32}N_{3.52}O_{5.75}) (relative to 4.6% w/w of substitution) C, 45.28; H, 5.71; N, 17.10. Found: C, 46.05; H, 6.05; N, 17.58. UV: the UV spectrum in the range between 230 and 350 nm shows an absorption maximum at 292 nm. ¹H NMR (D₂O): δ 2.59 (m, broad, 2H -CH-CH₂-CO-NH-), δ 3.13 (m, 2H -NH-CH₂-CH₂-OH), δ 3.37 (m, 2H, CH₂-CH₂-OH), δ 3.56 (m, 2H, CH₂ C5'), δ 3.72 (m, 1H, C4'), δ 3.98 (m, 2H, C2' and C3'), δ 4.66 (1H -NH-CH(CO)CH₂-), δ 6.20 (d, 1H, C5), δ 7.22 (d, 1H, C1'), δ 8.2 (d, 1H, C6).

Plasmatic Hydrolysis Studies of 8 and 9. PHEA-D-Val-Leu-Lys-Cytarabine and PHEA–Cytarabine conjugates were subjected to plasmatic hydrolysis by using

human plasma at 37 ± 0.1 °C. The hydrolyses were initiated by adding 50 μL of a buffered phosphate solution of 8 or 9 at pH 7.4 (at a concentration of 2 g/100 mL) to samples (1 mL) of preheated plasma. The samples were kept in a water bath at 37 ± 0.1 °C, under continuous stirring and at suitable intervals, 2 mL of 10% trifluoroacetic acid (v/v) were added in order to precipitate plasma proteins. After immediate mixing and centrifugation for 5 min at 10 000 rpm at 4 °C was analyzed 10 μL of clear supernatant by HPLC to determine released species. Every experiment was repeated in triplicate. As control, analogous experiments were performed in the absence of plasma.

After 24 h of incubation samples were added with 2 mL of carbonate buffer at pH 11.5, kept at 37 ± 0.1 °C and analyzed by HPLC at suitable time intervals.

Hydrolysis of 8 and 9 by Plasmin. The hydrolytic activity of plasmin toward PHEA-D-Val-Leu-Lys-Cytarabine and PHEA–Cytarabine conjugates was studied in 0.05 M Tris buffer solution and 0.1 M NaCl at pH 7.4 with a 1.2 × 10⁻⁴ M conjugate concentration in Cytarabine. To samples of 1 mL of 8 or 9 solutions, 85 μL of a plasmin 5.9 × 10⁻⁷ M solution in Tris buffer at pH 7.4 were added.

Solutions were incubated at 37 ± 0.1 °C and sampled at suitable interval time by HPLC analysis. After 2 h from the beginning of the experiment the same volume of fresh plasmin solution was added. As control, analogous experiments were performed by adding the proper volume of Tris buffer without enzyme to the conjugate solutions.

HPLC Analysis of Cytarabine. A single chromatographic method was used to detect Cytarabine released from 8 and 9 conjugates during in vitro hydrolysis studies in the presence of plasmin; C₁₈ column was eluted at room temperature with CH₃OH:0.1% H₃PO₄ (2:98) using a flow rate of 1 mL/min and monitoring the eluate at 280 nm. The HPLC conditions used for plasmatic hydrolysis studies were different because of the presence of an interfering endogenic peak in blank plasma chromatogram, i.e., acetonitrile: pH 7.0 phosphate buffer (1:99, v/v) at a flow of 1 mL/min; preliminary experiments showed that this method allows a recovery of Cytarabine from plasma of about 98.6% w/w. Quantification of Cytarabine was done by measuring the peak area in relation to standard solutions of drug.

RESULTS AND DISCUSSION

The ability of tumor cells to invade tissues and metastasize is thought to involve an increased expression of proteinases including cathepsins and plasminogen activators (27). The presence of these last enzymes at high concentration around and inside tumor causes an increased plasmin activity in ill tissues (42). This biochemical event can be properly exploited to achieve a targeted drug delivery. In fact the synthesis of a macromolecular prodrug of an antitumor drug by using a peptidic spacer in which the drug-spacer linkage is the ad hoc substrate for plasmin enzyme, such as D-Val-Leu-Lys, should seem to be a suitable method to achieve a high concentration of drug in target site also exploiting EPR effect that allows blood circulating macromolecules to be accumulated inside tumor mass (Figure 1).

To this aim the polymeric conjugate in which Cytarabine is linked to α,β-poly(*N*-hydroxyethyl)-DL-aspartamide (PHEA) by D-Val-Leu-Lys spacer has been synthesized.

The synthesis of PHEA-D-Val-Leu-Lys-Cytarabine conjugate involves following subsequent phases: (1) synthe-

Figure 1. Schematic representation of targeted drug release in tumor mass.

Scheme 1. Schematic Representation of Synthesis of Cbz-D-Val-Leu-N⁶-Cbz-Lys-OH Derivative (4)

sis of protect tripeptidic spacer Cbz-D-Val-Leu-N⁶-Cbz-Lys-OH; (2) linking of Cytarabine to this spacer and deprotection of amine groups of peptidic derivative; (3) coupling of D-Val-Leu-Lys-Cytarabine derivative to PHEA.

The synthesis of Cbz-D-Val-Leu-N⁶-Cbz-Lys-OH (**4**) was performed from methyl ester of Cbz-L-Lysine (**1**) and Cbz-D-Val-Leu-OH (**2**) dipeptide by using as condensing agent DCC and in the presence of HOBT (Scheme 1). In effect we are not able to reproduce literature conditions of synthesis of this compound (33) then we had to set up different experimental conditions.

The product (**3**) purified by chromatographic column and characterized (see Experimental Section) was subsequently subject to alkaline hydrolysis in order to hydrolyze methyl ester of lysine and to make available carboxylic group for coupling of Cytarabine.

The Cbz-D-Val-Leu-N⁶-Cbz-Lys-OH (**4**) so obtained was kept to react with N-HSI in the presence of EDCI-HCl (Scheme 2), to obtain the reactive *N*-hydroxysuccinimide ester. The used experimental condition for time and temperature allow to obtain high yield in the activation process, that was confirmed by the high yield in the following conjugation reaction with Cytarabine (Scheme 2). The product (**5**) isolated and purified by silica gel column chromatography was characterized by elemental analysis, FAB mass spectrum, IR and ¹H NMR analyses (see Experimental Section).

The deprotection of amine groups of Cbz-D-Val-Leu-N⁶-Cbz-Lys-Cytarabine derivative was afterward carried out (Scheme 2) since these amine groups allow tripeptide-Cytarabine derivative to be linked to polymeric backbone.

If on one side the alone hydrolysis reaction of Cbz groups is not difficult and numerous reaction conditions

are reported in the literature, on the other side, the complexity of **5**, but above all the weakness of linking between Cytarabine and tripeptidic spacer in the presence of metallic catalysts, in aqueous acid medium, makes difficult to set better reaction conditions. Many experimental conditions were tested and some of them include the use of H₂ at atmospheric pressure or greater in the presence of methanol or THF as solvent and Pd/C as catalyst or the use of HBr and CH₃COOH at room temperature or lower. The complete deprotection of **5** was obtained by using Pd/C and black Pd mixture and high concentration of anhydrous HCOOH.

The D-Val-Leu-Lys-Cytarabine derivative (**6**) so obtained was characterized by elemental analysis, FAB mass spectrum, IR and ¹H NMR analyses (see Experimental Section).

Subsequently experimental conditions to link D-Val-Leu-Lys-Cytarabine derivative to PHEA were set up.

For the coupling of drug molecules to functional groups of a macromolecular carrier a suitable preactivation reaction is generally required. This reaction can involve either chemical groups of the drug molecules or often slightly reactive groups of macromolecular chains (43). If polymer contains hydroxyl groups an attractive activation procedure commonly reported in the literature is the chloroformate activation method (43, 44). By the reaction of activated polymers with molecules bearing amine groups, conjugates with urethane linkages between these molecules and the macromolecular chain, can be obtained.

Therefore the chemical activation of hydroxyl groups of PHEA by 4-nitrophenyl chloroformate (PNFC) was

Scheme 2. Schematic Representation of Synthesis of D-Val-Leu-Lys-Cytarabine Derivative (6)

performed (see Experimental Section) and the activation percentage of **7** was evaluated by UV spectrophotometry.

Since it was demonstrated that the content of 4-nitrophenyl carbonate is equal to the present total carbonate content, the concentration of 4-nitrophenolate was used to determine the percentage of hydroxyl groups of PHEA activated by PNFC, and it was evaluated equal to 13.2 mol %.

However, it was verified that the degree of activation of PHEA is capable of being modulated, properly modifying reaction conditions such as moles of PNFC/PHEA repeating units ratio, and temperature. It was also shown that the presence of water in the reaction medium causes a strong decrease of polymer activation degree.

The synthesis of PHEA-D-Val-Leu-Lys-Cytarabine conjugate (**8**) (Scheme 3) was carried out by the reaction of activated PHEA (**7**) with D-Val-Leu-Lys-Cytarabine derivative (**6**).

Scheme 3. Schematic Representation of PHEA-D-Val-Leu-Lys-Cytarabine Conjugate (8)

The presence of unlinked drug derivative in **8**, purified by dialysis, was evaluated by HPLC analysis and estimated equal about 0.01% w/w of Cytarabine.

The occurred linkage between drug derivative and carrier was confirmed by UV and ^1H NMR spectroscopies. The UV spectrum of **8** showed an absorption band in the range 230–350 nm with a maximum of absorption at 278 nm due to Cytarabine linked to PHEA. The drug linkage to the carrier did not cause any shift in the absorption maximum. Besides, ^1H NMR spectrum of **8** (see Experimental Section) evidenced the presence of signals assignable to protons belonging to tripeptide-Cytarabine derivative (**6**) linked to PHEA.

The content of linked Cytarabine in this polymeric conjugate, determined by alkaline hydrolysis at experimental conditions that did not alter Cytarabine (carbonate buffered solution at pH 11.5, 40 °C for 24 h), followed by HPLC analysis, was evaluated equal to 3% w/w.

This result was confirmed by ^1H NMR evaluation; in fact by comparing the integral of the peaks related to protons at δ 0.95 assignable to isopropyl group of **6** with the integral of the peaks related to protons at δ 2.79 assignable to $-\text{CH}-\text{CH}_2-\text{CO}-\text{NH}-$ of polymer carrier, an average percent value of linked drug of about 2.12% mol was found, corresponding to about 3% w/w.

To evaluate the stability of this conjugate in plasma and its real ability to carry Cytarabine in plasma until action site, i.e., tumor mass, **8** was subjected to in vitro incubation with plasma.

Results are reported in Figure 2.

As it can be seen in Figure 2, the amounts of Cytarabine released from **8** both in plasma and at pH 7.4 were very similar and just about 2.5% (w/w) of linked Cytara-

Figure 2. Release of Cytarabine from PHEA-D-Val-Leu-Lys-Cytarabine conjugate in human plasma (Δ) and in phosphate-buffered solution at pH 7.4 ($\square$) at 37 ± 0.1 °C.

Figure 3. Release of Cytarabine from PHEA-D-Val-Leu-Lys-Cytarabine conjugate in the presence (Δ) and in the absence of plasmin ($\square$) at 37 ± 0.1 °C in Tris-buffered solution at pH 7.4.

bine was released from the polymeric conjugate within 24 h in both conditions. This result suggests the possibility that this drug-polymer conjugate could really carry drug to target since it is quite stable in plasma. After 24 h, to evidence the actual presence of linked Cytarabine in **8** in the intact form, samples were alkalized at pH 11.5 and then analyzed by HPLC. The complete release of Cytarabine in the intact form was then evidenced from **8**.

The possibility that the polymeric conjugate obtained can be ad hoc substrate for plasmin, proteolytic enzyme present at high concentration in the tumor mass and able to catalyze the hydrolysis of amide bonds at the level of lysine or arginine residues, has been evaluated subjecting PHEA-D-Val-Leu-Lys-Cytarabine conjugate at hydrolysis in the presence of this enzyme.

Results are reported in Figure 3.

As it can be seen from the Figure 3, about 23% (w/w) of linked drug was released from the polymeric conjugate in the presence of plasmin in the intact form after 1 h, while in the absence of enzyme just 6% (w/w) of linked drug was released at the same experimental conditions. After 2 h from the beginning of the hydrolysis experiment the drug release rate in the presence of plasmin was not different than the blank, then fresh and active enzyme solution was added. Within about 10 h from the second addition of enzyme solution the release of drug from the polymeric conjugate was complete. On the contrary in the absence of enzyme a low amount of Cytarabine was released at the same time.

The amounts of drug released from the polymeric conjugate versus time at pH 7.4 in phosphate buffer solution (Figure 2) and in Tris buffer (Figure 3, at the same pH) are different probably for the presence of different buffer species in two media. Drug release rate in Tris buffer is greater than that obtained in phosphate buffer reasonably for the occurring of a catalytic effect via Tris buffer species (45).

The stability of PHEA-D-Val-Leu-Lys-Cytarabine conjugate in plasma and its ability to release drug in the presence of plasmin suggest the actual ability of this conjugate to carry drug in the intact form to the action site and to release it inside tumor mass in the presence of plasmin.

To verify if also the direct linkage of Cytarabine to PHEA could give a macromolecular prodrug with some potential in anticancer therapy, although the presence of urethane linkage between carrier and drug, which is very stable in biological medium, we synthesized PHEA-Cytarabine conjugate (**9**) by the reaction of PHEA activated with PNFC directly with Cytarabine (Scheme 4), and this conjugate was submitted to the same in vitro hydrolysis experiments of **8**.

The absence of free drug was verified by HPLC analysis. The occurred linkage between Cytarabine and activated PHEA was evaluated by UV and ^1H NMR. UV spectrum shows an absorption band in the range 230–350 nm in which alone polymeric carrier does not absorb, with an absorption maximum at 292 nm indicating the presence of linked Cytarabine.

Figure 4. Stability of PHEA-Cytarabine conjugate in plasma.

Scheme 4. Schematic Representation of Coupling of Cytarabine to Activated PHEA (7)

The percentage of linked drug, evaluated by alkaline hydrolysis followed by HPLC, was estimated equal to about 4.6% (w/w) corresponding to 3.16 mol %. This result was confirmed by ^1H NMR spectroscopy. By comparing the integral peaks related to protons at δ 6.1 assignable to one proton of Cytarabine (d, 1H, C5) with the integral of a peak at δ 4.66 related to polymer (m, 1H, -NH-CH-CO-), the average value of linked drug was estimated equal to 4.6% w/w.

Therefore, the conjugate (**9**) was subjected to *in vitro* hydrolysis studies in plasma at 37 °C and obtained results were compared with that of plasmatic hydrolysis of free Cytarabine. The results of both experiments were reported in Figures 4 and 5 respectively; as it can be seen, while the concentration of free Cytarabine quickly decreases probably for degradation phenomena in plasma by cytosine deaminase (35) (Figure 5), PHEA-Cytarabine conjugate was quite stable and no cytarabine release was shown within 24 h from this conjugate (Figure 4). These results confirm the high hydrolytic resistance of urethane bounds in physiological environment.

After 24 h from the beginning of plasma treatment the addition of strong bases causes the complete release of Cytarabine in the intact form, evidencing a remarkable effect of protection on Cytarabine through linking to polymer.

Figure 5. Stability of Cytarabine in plasma.

This result, once again, suggests the strong protective effect of PHEA toward Cytarabine toward enzymatic inactivation but, of course, since the drug is not released from this conjugate, more studies should be necessary to evaluate the antitumor activity of Cytarabine linked to PHEA.

CONCLUSIONS

The macromolecular prodrug obtained linking Cytarabine molecules to PHEA via the D-Val-Leu-Lys spacer showed some interesting peculiarities which make it attractive in the drug delivery for anticancer therapy. It was very stable in plasma, but it was able to release drug in the presence of plasmin. The excellent result confirms the rational of our work. In fact, by the proper design of the spacer arm to be used between drug molecules and macromolecular carrier, it seems possible actually to achieve a specific and targeted drug release at the action site in the antitumor chemotherapy. Besides the Cytarabine in the linked form was protected from the deamination process by cytosine deaminase enzyme and this should allow *in vivo* a decrease of drug dose so decreasing also side effects.

The macromolecular conjugate obtained directly linking Cytarabine molecules to PHEA was very stable in plasma, but it was not able to release drug in the presence of plasmin.

Revised Manuscript Received November 6, 2000

Biotinylated indoles were prepared for application as bifunctional probes for the detection of indole-binding proteins which participate in the life processes of humans, animals, plants, and bacteria. The indole nucleus was functionalized, at ring positions 3, 5, or 6, by attachment of a 2-aminoethyl group, which was then coupled to the carboxyl moiety of biotin, via a spacer composed of 3 or 4 concatenated β -alanine residues. The constructs thus obtained were able to inhibit tryptophanase activity, similarly to indole in a concentration-dependent manner. They also bound strongly to lysozyme and weakly to bovine and human serum albumins, in accordance with the known affinities of these proteins for indole and 3-(2-aminoethyl)indole (tryptamine). The biotin end of the protein-bound bifunctional probes could then be detected by coupling to (strept)avidin conjugated to alkaline phosphatase or horseradish peroxidase, followed by incubation with substrates which are converted by these enzymes to intensely colored or chemiluminescent products.

INTRODUCTION

In bacteria, indole is an intermediate in the biogenesis and metabolism of tryptophan. Humans and vertebrates cannot synthesize tryptophan and also circumvent indole in its catabolism. Nevertheless, they have to cope with the indole produced by intestinal microorganisms and thus evolved special detoxification mechanisms resulting in products which are excreted via the urinary tract. Still, the main metabolite, indoxyl sulfate, appears to retain sufficient toxicity to contribute significantly to the progress of kidney disease (1). In plants, indole is formed by the α -subunit of tryptophan synthase to be immediately condensed with serine by the β -subunit. Under certain conditions, the indole appears to escape from being incorporated into tryptophan. Moreover, maize encodes a tryptophan synthase α that appears to synthesize indole independently of the β -subunit. The indole produced by this "indole synthase" is utilized in the production of at least one secondary metabolite: the defense compound 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (2, 3). Specific indole oxidases (EC 1.13.11.17) have been isolated from phylogenetically remote species such as *Zea mays* (4), *Jasminum grandiflorum* (5), and *Tecoma stans* (6–8), thus suggesting widespread distribution of this group of enzymes in plants. In humans and mammals, related enzymes (also classified as EC 1.13.11.17) oxidize indolealkylamines, such as serotonin and melatonin (9, 10) and may be part of a signaling cascade (11) triggered, for example, by pathogen attack (12).

Indole is now also receiving attention as one of the possible intermediates in the biosynthesis of the endogenous plant growth regulator, indole-3-acetic acid (IAA)¹

(13, 14). According to traditional concepts, IAA is made from tryptophan (15), but at least one additional, tryptophan-independent, route is suggested by tracer studies (reviewed in refs 13 and 14). Moreover, Arabidopsis *trp2* and maize *orp* mutants defective in tryptophan synthase β subunit, contain more IAA (free and conjugated) than wild-type seedlings (16, 17). Indole accumulates in these mutants and became the suspected precursor of the IAA. Indeed, stable-isotope labeled indole is incorporated into IAA by *orp* maize (18).

Here we present biotinylated indoles **3A–D** (Figure 1) as tools for the detection, isolation, and intracellular localization of the above enzymes, provided the metabolic processing of the enzyme-bound indole moiety can be prevented by withholding necessary cosubstrate(s), or by appropriate inhibitors. Compounds **3A–D** should also label proteins which, like serum albumin, bind indole without metabolizing it (19, 20), as well as enzymes which bind indole as an inhibitor (e.g., ref 21). Indeed, compounds **3A**, **3C**, and **3D** inhibited the tryptophanase-catalyzed conversion of serine to pyruvic acid in a similar fashion as previously shown for indole (22). Constructs **3A–D** also bound immobilized lysozyme, one of the readily available indole-binding proteins, and a key player in the defense of the human and animal organism against pathogenic microorganisms (23) and, at least according to some authors, against neoplasia (24). One of the probes (**3A**) was also tested with immobilized bovine and human serum albumins (BSA and HSA) and showed similar moderate to weak binding as reported for indole and tryptamine (19, 20). The oligopeptide spacer and indole moieties did not interfere with the binding of the biotin moiety to avidin. The biotin moiety of the

¹ Abbreviations: BSA, bovine serum albumin; FAB, fast-atom bombardment; HSA, human serum albumin; IAA, indole-3-acetic acid; PEG, poly(ethylene glycol); in the abbreviated names used for peptide moieties Bal stands for a β -alanine residue, Boc for *t*-butoxycarbonyl, Cbz for carbobenzoxy (= benzyloxycarbonyl), and OSu for *N*-hydroxysuccinimide ester.

Figure 1. Final steps in the preparation of biotinylated indoles **3A–D**.

bifunctional probes was thus detected using either NeutrAvidin-linked alkaline phosphatase or Streptavidin-linked horseradish peroxidase and either chemiluminescent or chromogenic substrates.

EXPERIMENTAL PROCEDURES

General. Melting points were determined in open capillaries and were not corrected. NMR spectra were recorded (at 20 °C unless stated otherwise) on a Varian Gemini 300 spectrometer operating at 300 MHz for ^1H and at 75 MHz for ^{13}C . Chemical shifts are reported in parts per million downfield from tetramethylsilane. The signals of the biotin moiety were assigned according to Ikura and Hikichi (25). For combined high-pressure liquid chromatography–mass spectrometry with ionization by fast-atom bombardment (FAB HPLC-MS) (26), samples were passed through a 250 × 0.32 mm i.d. capillary column (custom-packed by LC Packings, Am-

sterdam, The Netherlands) with reversed-phase silica gel (Waters Symmetry C₁₈), particle size 3.5 μm, eluted (5 μL/min) with 20–80% (gradient elution) aqueous methanol containing 1% each of acetic acid and glycerol (matrix for FAB). The effluent was introduced, via a frit-FAB HPLC-MS interface, into the ion source (kept at 56 °C) of a JEOL JMS SX-102 mass spectrometer (low resolution) or a JEOL SX/SX-102A tandem instrument (high resolution). Ions were generated with a beam of 5 keV xenon atoms at an emission current of 20 mA, and positive-ion mass spectra were acquired. For exact mass measurements, poly(ethylene glycol) (PEG 300 + PEG 600) was added to the HPLC solvent (0.001%) to furnish the referent ions, and the resolution was set to $R = 5000$. Notably, the ion subjected to exact mass determination was the protonated molecular ion $[MH]^+$. Analytical HPLC was on reversed-phase (octadecylsilane, particle size of 5 μm) columns using the following protocols. For

general purity check and determination of the retention times listed below: Waters Symmetry (15 cm $\times$ 3.9 mm i.d.) using solvent mixtures composed of water/trifluoroacetic acid (99.9:0.1, solvent D), acetonitrile/trifluoroacetic acid (99.9:0.1, solvent E), water/acetic acid (99:1, solvent F), and acetonitrile/acetic acid (99:1, solvent G), i.e., protocol I, 0–5 min, 90% D + 10% E; 5–30 min, exponential gradient, 90 $\rightarrow$ 0% D, 10 $\rightarrow$ 100% E; protocol II, same but substituting solvent F for solvent D, and solvent G for solvent E. *For quantification of 3A–D in stock solutions for bioassays:* Phenomenex (Torrance, CA; 50 $\times$ 4.6 mm i.d.) using a linear gradient from 18 to 50% methanol added within 15 min to 5% aqueous acetic acid. *For the final purity check for compounds 3A–D:* Nucleosil (Macherey & Nagel; 25 cm $\times$ 4.6 mm i. d.) eluted isocratically with 50% aqueous methanol. Preparative HPLC was on a C₁₈ Radial-PAK cartridge (Millipore Waters; 10 cm $\times$ 8 mm i.d., particle size 10 μ m) eluted with 50% aqueous methanol. Flow rates were 1 mL/min (analytical) and 1.5–2 mL/min (preparative). The effluent was monitored for absorbance at 215 and 278/280 nm. Column chromatography was on silica gel 60 (Merck), particle diameter: 0.063–0.2 mm. TLC was on silica gel GF₂₅₄ (Merck) developing with dichloromethane/methanol/acetic acid (90:10:1, solvent A₁; 95:5:1, solvent A₂; 80:20:1, solvent A₃), 2-propanol/ethyl acetate/25% ammonia(aq) (35:45:20, solvent B) or 2-propanol/water/25% ammonia(aq) (8:1:1, solvent C). In addition to detection by UV absorption, the following spray reagents were used: ninhydrin (0.2% in ethanol) for free amino groups, the Ehrlich reagent (1% *p*-dimethylaminobenzaldehyde in a 1/1 mixture of ethanol and 35% HCl) for indolic compounds, and *p*-dimethylaminocinnamaldehyde (0.2% in ethanol, mixed before use with an equal volume of 2% H₂SO₄ in ethanol) for the biotin moiety (27). Chromatograms of *N*-(*t*-butyloxycarbonyl)- and *N*-(benzyloxycarbonyl)-amino acids and -peptides were first sprayed with 35% HBr in acetic acid (diluted with the 4-fold volume of ethanol), and the thus deprotected amino functions were detected with ninhydrin. Preparative TLC was on silica gel PF₂₅₄ (Merck); zones were detected by UV absorption. Of the solvents used in the synthetic procedures, *N,N*-dimethylformamide, dioxane, and tetrahydrofuran (the latter two free of peroxides) must be anhydrous; for optimal results, (dry) tetrahydrofuran was distilled over sodium immediately before use. Commercial analytical grade chemicals were used, with the exception of 5- and 6-(2-aminoethyl)indole (28), *N*-(*t*-butyloxycarbonyl)- β -alanine [Boc-Bal-OH (29, 30)], β -alanyl- β -alanine (H-Bal₂-OH) as its trifluoroacetate salt (36), as well as the *N*-hydroxysuccinimide esters of *d*-biotin (31, 32) and *N*-(*t*-butyloxycarbonyl)- β -alanine (Boc-Bal-OSu) (33) which were prepared according to published procedures. To speed up the preparation of some *N*-hydroxysuccinimide esters, the parent amino acid or peptide was reacted with an excess of *N*-hydroxysuccinimide and/or 1,3-dicyclohexylcarbodiimide (38).

Syntheses. *Cbz-Bal-OSu.* Small aliquots of 1,3-dicyclohexylcarbodiimide (495 mg, 2.4 mmol) were added to a stirred solution of commercial (Sigma) Cbz-Bal-OH (446 mg, 2 mmol) and *N*-hydroxysuccinimide (253 mg, 2.2 mmol) in tetrahydrofuran (10 mL), through 45 min, at -10°C . After a further 15 min, the temperature was raised to 0°C for 2 h, and then kept at 4°C for 48 h, with a further aliquot of 1,3-dicyclohexylcarbodiimide (495 mg, 2.4 mmol) added after 24 h. The 1,3-dicyclohexylurea formed was filtered off, and the filtrate was evaporated. The residue was dissolved in 3 mL of 2-propanol at 80°C . Cooling to -5°C afforded the title

compound (558 mg, 87%), mp $58\text{--}61^{\circ}\text{C}$ [lit. (34) $83\text{--}84^{\circ}\text{C}$]. Homogeneous by TLC, $R_f = 0.8$ (solvent A₁), 0.6 (solvent A₂), except for the, well-known, minor hydrolysis during sample application. ¹H NMR (CD₃COCD₃) δ 3.00 (4H, s), 3.03 (2H, t), 3.65 (2H, quart), 5.20 (2H, s), 6.66 (1H, broad s), 7.48 (5H, m). ¹³C NMR (CD₃COCD₃) δ 25.6, 31.5, 36.7, 66.1, 128.2, 128.7, 137.8, 156.7, 167.8, 170.1.

Boc-Bal₂-OH. To an efficiently stirred solution of β -alanine (544 mg, 6.10 mmol) in 5% NaHCO₃(aq) (20 mL) was added dropwise a solution of Boc-Bal-OSu (1734 mg, 6.06 mmol) in dioxane (12 mL) through 5 min, at room temperature. When the reaction was complete (ca. 1 h), the mixture was diluted with an equal volume of water, saturated with NaCl, acidified to pH 3.0 by adding crystalline citric acid, and partitioned against ethyl acetate. The extract was washed with brine, dried (Na₂SO₄), and evaporated. The crude product (1476 mg) was dissolved in boiling ethyl acetate and crystallized by adding 30–40% (by volume) of heptane to yield pure Boc-Bal₂-OH (35) (1344 mg, 85%), mp $124\text{--}127^{\circ}\text{C}$, homogeneous by TLC, $R_f = 0.3$ (solvent A₁). Purity by HPLC (protocol I; retention time, 25.3 min) 100.0% (215 nm). FAB HPLC-MS m/z 261.1442 ([MH]⁺). C₁₁H₂₁N₂O₅ requires 261.1450. ¹H NMR [(CD₃)₂SO] δ 1.36 (9H, s), 2.20 (2H, t), 2.36 (2H, t), 3.10 (2H, quart), 3.22 (2H, quart), 6.72 (1H, t), 7.94 (1H, t). ¹³C NMR [(CD₃)₂SO] δ 28.4, 34.0, 34.9, 35.9, 36.9, 77.9, 155.9, 170.9, 173.4.

Boc-Bal₂-OSu. Boc-Bal₂-OH (1344 mg, 5.16 mmol), *N*-hydroxysuccinimide (653 mg, 5.68 mmol), and 1,3-dicyclohexylcarbodiimide (1277 mg, 6.19 mmol) in a mixture of dioxane (91 mL) and ethyl acetate (82 mL) were processed in essentially the same way as described for Cbz-Bal-OSu, except that the total amount of 1,3-dicyclohexylcarbodiimide was added within 45 min. The crude product was dissolved in a minimal volume of boiling tetrahydrofuran. An unidentified precipitate which formed on cooling was discarded. Addition of a 2-fold volume of heptane afforded the crystalline title compound (969 mg, 53%), mp $124\text{--}127^{\circ}\text{C}$, homogeneous by TLC, $R_f = 0.6$ (solvent A₁), except as detailed for Cbz-Bal-OSu. FAB HPLC-MS m/z 358.1620 ([MH]⁺). C₁₅H₂₄N₃O₇ requires 358.1614. ¹H NMR [(CD₃)₂SO] δ 1.38 (9H, s), 2.22 (2H, t), 2.82 (4H, s), 2.85 (2H, t), 3.12 (2H, quart), 3.35 (2H, quart), 6.73 (1H, t), 8.10 (1H, t). ¹³C NMR [(CD₃)₂SO] δ 25.5, 28.3, 30.6, 34.2, 35.8, 36.7, 77.7, 155.7, 167.7, 170.4, 170.9.

Boc-Bal₃-OH. A solution of Boc-Bal-OSu (1430 mg, 5 mmol) in dioxane (8 mL) was added dropwise, at room temperature, into a vigorously stirred solution of H-Bal₂-OH trifluoroacetate (1370 mg, 5 mmol) in 8% NaHCO₃(aq) (25 mL). After a reaction time of 1 h, and workup as for Boc-Bal₂-OH, recrystallization from ethyl acetate (250 mL) afforded the title compound (1200 mg, 73%), mp $135\text{--}137^{\circ}\text{C}$, homogeneous by TLC, $R_f = 0.2$ (solvent A₁), 0.3 (solvent B). Purity by HPLC (protocol I; retention time, 24.1 min) 97.4% (215 nm). FAB HPLC-MS m/z 332.1793 ([MH]⁺). C₁₄H₂₆N₃O₆ requires 332.1822. ¹H NMR [(CD₃)₂SO] δ 1.37 (s, 9H), 2.19 (t, 2H), 2.20 (t, 2H), 2.37 (t, 2H), 3.10 (q, 2H), 3.21 (q, 2H), 3.23 (q, 2H), 6.74 (t, 1H), 7.88 (t, 1H), 7.96 (t, 1H). ¹³C NMR [(CD₃)₂SO] δ 28.4, 34.0, 34.8, 35.4, 35.5, 35.9, 36.8, 77.9, 155.9, 170.8, 170.9, 173.3.

Cbz-Bal₃-OH. Crude H-Bal₂-OH trifluoroacetate, prepared by deprotection of Boc-Bal₂-OH (234 mg, 0.90 mmol) as described (36), was dissolved in 10% aqueous NaHCO₃ (2 mL) at room temperature, and a solution of Cbz-Bal-OSu (288 mg, 0.90 mmol) in dioxane (1.5 mL) was added dropwise, with efficient stirring, through 15 min. After a reaction time of 2 h, the slightly turbid

solution was filtered, acidified with crystalline citric acid to pH 3.0, and left overnight at +4 °C. The precipitate was collected by centrifugation, washed with small aliquots of cold water and recrystallized from water to yield the title compound (173 mg, 53%), mp 185–187 °C [lit. (37) 194–195 °C], R_f = 0.1 (solvent A₁), 0.3 (solvent B). ¹H NMR [(CD₃)₂SO] δ 2.21 (2H, t), 2.23 (2H, t), 2.37 (2H, t), 3.21 (6H, m), 5.01 (2H, s), 7.23 (1H, t), 7.35 (5 H, m), 7.90 (1H, t), 7.95 (1H, t). ¹³C NMR [(CD₃)₂SO] δ 34.0, 34.8, 35.39, 35.42, 35.8, 37.2, 65.4, 128.0, 128.6, 137.5, 156.3, 170.5, 170.8, 173.3.

Boc-Bal₄-OH. Boc-Bal₂-OSu (619 mg, 1.73 mmol) in methanol (4.5 mL) was added dropwise into a stirred solution of H-Bal₂-OH trifluoroacetate (517 mg, 1.89 mmol) in 5% aqueous NaHCO₃ (7 mL). Stirring was continued overnight maintaining a pH range of 7–8 by repeated addition of small aliquots of solid NaHCO₃. The mixture was centrifuged; the supernatant was acidified to pH 3.0 using crystalline citric acid, and extracted with *n*-butanol (3 × 25 mL). The combined *n*-butanol extracts were washed with small aliquots of water and evaporated. The residue was dissolved in methanol (5 mL). After filtration, precipitation with ethyl acetate gave the crude title compound. Purification by preparative TLC (solvent B) afforded Boc-Bal₄-OH (310 mg, 45%) as a white solid. The latter decomposed on heating (no sharp mp). Homogeneous by TLC, R_f = 0.1 (solvent A₁), 0.3 (solvent B). Purity by HPLC (protocol I; retention time, 24.0 min) 97.9% (215 nm). FAB HPLC-MS m/z 403.2145 ([MH]⁺). C₁₇H₃₁N₄O₇ requires 403.2193. ¹H NMR [(CD₃)₂SO] δ 1.37 (9 H, s), 2.22 (6H, t), 2.32 (2H, t), 3.10 (2H, quart), 3.21 (4H, m), 3.23 (2H, m), 6.74 (1H, t), 7.91 (2H, t), 7.93 (1H, t). ¹³C NMR [(CD₃)₂SO] δ 28.3, 34.0, 34.9, 35.4, 35.9, 36.9, 77.8, 155.8, 170.7 (2C), 170.8, 173.3.

Boc-Bal₃-OSu. To a solution of Boc-Bal₃-OH (702 mg, 2.1 mmol), *N*-hydroxysuccinimide (496 mg, 4.3 mmol), and *N*-methylmorpholine (234 μL, 2.1 mmol) (38) in *N,N*-dimethylformamide (6 mL), stirred at 4 °C, 1,3-dicyclohexylcarbodiimide (989 mg, 4.8 mmol) was added, in small aliquots, i.e., 1.6 mmol/day. When the reaction was complete (3 days), the 1,3-dicyclohexylurea formed was filtered off and the filtrate was evaporated to dryness. The residue was recrystallized from ethyl acetate to yield the title compound (646 mg, 71%), mp 169–173 °C, homogeneous by TLC, R_f = 0.5 (solvent A₁), 0.7 (solvent B), except as detailed for Cbz-Bal-OSu. FAB HPLC-MS m/z 429.1975 ([MH]⁺). C₁₈H₂₉N₄O₈ requires 429.1985. ¹H NMR [(CD₃)₂SO] δ 1.38 (9H, s), 2.20 (2H, t), 2.23 (2H, t), 2.82 (4H, s), 2.86 (2H, t), 3.11 (2H, quart), 3.23 (2H, quart), 3.35 (2H, quart), 6.73 (1H, m), 7.88 (1H, t), 8.10 (1H, t). ¹³C NMR [(CD₃)₂SO] δ 25.5, 28.3, 30.6, 34.3, 35.3, 35.4, 35.8, 36.8, 77.7, 155.8, 167.7, 170.5, 170.7, 171.0.

Boc-Bal₄-OSu. To a suspension of Boc-Bal₄-OH (264 mg, 0.66 mmol), *N*-hydroxysuccinimide (153 mg, 1.33 mmol), and *N*-methylmorpholine (146 μL, 1.32 mmol) (38) in dry *N,N*-dimethylformamide (14 mL), stirred at 4 °C, 1,3-dicyclohexylcarbodiimide was added (180 mg, 0.87 mmol within the first hour and a further 122 mg, 0.59 mmol after 24 h). After 8 days of stirring, the 1,3-dicyclohexylurea formed was collected by centrifugation. The supernatant was evaporated and the residue was extracted with diethyl ether (5 × 30 mL) followed by ethyl acetate (3 × 30 mL) leaving the title compound (264 mg, 81%) as a white solid (no definite melting point). Homogeneous by TLC, R_f = 0.3 (solvent A₁), 0.6 (solvent B), except as detailed for Cbz-Bal-OSu. FAB HPLC-MS m/z 500.2368 ([MH]⁺). C₂₁H₃₄N₅O₉ requires 500.2357. ¹H NMR [(CD₃)₂SO] δ 1.37 (9H, s), 2.17–2.23 (6H, m),

2.82 (4H, s), 2.86 (2H, t), 3.10 (2H, quart), 3.21, 3.23 (4 H, 2 overlapping quart), 3.36 (2H, quart), 6.74 (1H, m), 7.90, 7.91 (2 H, 2 overlapping t), 8.13 (1H, t). ¹³C NMR [(CD₃)₂SO] δ 25.5, 28.3, 30.6, 34.3, 35.3, 35.4, 35.8, 36.8, 77.8, 155.8, 167.8, 170.5, 170.7, 171.1.

Cbz-Bal₃-OSu. To a solution of Cbz-Bal₃-OH (279 mg, 0.76 mmol), *N*-hydroxysuccinimide (193 mg, 1.68 mmol), and *N*-methylmorpholine (92 μL, 0.84 mmol) in dry *N,N*-dimethylformamide (6 mL), stirred at –10 °C, was added 1,3-dicyclohexylcarbodiimide (189 mg, 0.91 mmol) in small aliquots, through 30 min. After a further 30 min at –10 °C, stirring was continued at 0 °C, for 2 h, and at +4 °C, for 3 days. The 1,3-dicyclohexylurea formed was filtered off, and the filtrate was evaporated in vacuo. The residue was recrystallized from ethyl acetate/2-propanol (40:1) to yield the title compound as a reddish solid (312 mg, 88%), mp 141–145 °C, homogeneous by TLC, R_f = 0.5 (solvent A₁), 0.3 (solvent A₂), except as detailed for Cbz-Bal-OSu. FAB HPLC-MS m/z 463.1858 ([MH]⁺). C₂₁H₂₇N₄O₈ requires 463.1829. ¹H NMR [(CD₃)₂SO] δ 2.23 (4H, t), 2.81 (4H, s), 2.85 (2H, t), 3.19 (2H, quart), 3.23 (2H, quart), 3.35 (2H, quart), 5.01 (2H, s), 7.23 (1H, t), 7.36 (5 H, m), 7.91 (1H, t), 8.10 (1H, t). ¹³C NMR [(CD₃)₂SO] δ 25.5, 30.6, 34.3, 35.3, 35.4, 35.7, 37.2, 65.3, 128.0, 128.6, 137.5, 156.3, 167.8, 170.5, 171.0.

Boc-Bal₃-Tryptamine (1A). A solution of Boc-Bal₃-OSu (750 mg, 1.75 mmol), tryptamine [3-(2-aminoethyl)indole; 279 mg, 1.74 mmol], and *N*-methylmorpholine (193 μL, 1.75 mmol) in methanol (20 mL) was stirred at room temperature for 60 min. The mixture was evaporated to dryness, and the residue was dissolved in *n*-butanol (140 mL). The solution was partitioned against 0.1 M sodium citrate buffer, pH 3.0 (5 × 35 mL), 5% NaHCO₃(aq) (3 × 35 mL), and water (3 × 5 mL). The organic phase was evaporated to dryness. The residue was dissolved in dichloromethane/methanol (9:1) and passed through a column (72 × 2.5 cm) of silica gel (Merck), particle size 0.063–0.2 mm to yield tryptamine conjugate **1A** (624 mg, 76%), mp 176–178 °C, homogeneous by TLC, R_f = 0.5 (solvent A₁), 0.8 (solvent B). Purity by HPLC (protocol II; retention time, 25.6 min) 98.3% (280 nm). FAB HPLC-MS m/z 474.2679 ([MH]⁺). C₂₄H₃₆N₅O₅ requires 474.2716. ¹H NMR [(CD₃)₂SO] δ 1.37 (9H, s), 2.20 (2H, t), 2.21 (2H, t), 2.24 (2H, t), 2.82 (2H, t), 3.11 (2H, quart), 3.24 (2H, quart), 3.27 (2H, quart), 3.33 (2H, quart), 10.82 (1H, s), 6.75 (1H, t), 6.98 (1H, dd), 7.07 (1H, dd), 7.15 (1H, s), 7.34 (1H, d), 7.53 (1H, d), 7.90 (1H, t), 7.94 (1H, t), 8.01 (1H, t). ¹³C NMR [(CD₃)₂SO] δ 25.3, 28.3, 35.4, 35.5, 35.6, 35.9, 36.9, 39.6, 77.8, 111.6, 112.1, 118.5, 121.1, 122.9, 127.5, 136.5, 155.8, 170.6, 170.7.

Boc-Bal₄-Tryptamine (1B). To a solution of tryptamine (103 mg, 0.64 mmol) in methanol (1 mL), stirred at room temperature, a solution of Boc-Bal₄-OSu (320 mg, 0.64 mmol) in methanol (15 mL) was added dropwise, through 5 min, followed by *N*-methylmorpholine (70 μL, 0.64 mmol), and stirring was continued for 3.5 h. After solvent partition as described for compound **1A**, the crude product was dissolved in dichloromethane/methanol (1:1; 30 mL); silica gel for column chromatography (5 g) was added and the solvent was evaporated. The dried residue, suspended in dichloromethane/methanol (20:1), was placed on top of a column (64 × 2.5 cm) of silica gel (140 g) packed in the same solvent. Elution with 3 L of dichloromethane/methanol, changing the solvent ratio stepwise from 20:1 to 3:1, afforded the title compound (199 mg, 57%) as a white solid which decomposed on heating before melting. Homogeneous by TLC, R_f = 0.3 (solvent A₁), 0.5 (dichloromethane/methanol, 5:1), 0.8 (solvent B). Purity by HPLC (protocol II; retention time, 25.0 min)

99.8% (280 nm). FAB HPLC-MS m/z 545.3100 ($[MH]^+$). $C_{27}H_{41}N_6O_6$ requires 545.3088. ^1H NMR $[(CD_3)_2SO]$ δ 1.36 (9H, s), 2.17–2.23 (6H, m), 2.24 (2H, t), 2.81 (2H, t), 3.10 (2H, quart), 3.17–3.28 (6H, m), 3.32 (2H, quart), 6.75 (1H, t), 6.97 (1H, ddd), 7.06 (1H, ddd), 7.15 (1H, d), 7.34 (1H, broad d), 7.53 (1H, broad d), 7.92 (1H, t), 7.94 (1H, t), 7.97 (1H, t), 8.05 (1H, t), 10.85 (1H, broad s). ^{13}C NMR $[(CD_3)_2SO]$ δ 25.3, 28.3, 35.4, 35.5, 35.8, 36.8, 39.6, 77.8, 111.6, 112.1, 118.4, 121.1, 122.9, 127.5, 136.5, 155.8, 170.6, 170.7.

Cbz-Bal₃-5-(2-Aminoethyl)indole (1C). A solution of 5-(2-aminoethyl)indole (121 mg, 757 μ mol), Cbz-Bal₃-OSu (350 mg, 757 μ mol), and *N*-methylmorpholine (83 μ L, 757 μ mol) in dry *N,N*-dimethylformamide (7.5 mL) was stirred at room temperature for 2 h. After evaporation, the residue was extracted with ethyl acetate (8 $\times$ 10 mL) to remove *N*-hydroxysuccinimide. The remaining solid (375 mg) was dissolved in dichloromethane/methanol (2:1, 45 mL) and mixed with silica gel (5 g) which was, after evaporation of the solvent and drying, layered on top of a column (64 $\times$ 2.5 cm) of silica gel (140 g) packed in dichloromethane/methanol (20:1). Elution with 2 L of dichloromethane/methanol, changing the solvent ratio stepwise from 20:1 to 4:1, afforded the title compound as a white solid (250 mg, 65%), mp 202–205 °C, R_f = 0.4 (solvent A₁), 0.8 (solvent B). Purity by HPLC (protocol II; retention time, 25.8 min) 96.3% (280 nm). Instead of the chromatographic purification, impurities in the crude product could also be extracted with methanol (4 $\times$ 5 mL) and the small amount of coextracted **1C** recovered by preparative TLC (dichloromethane/methanol, 4:1), to yield a product with a mp of 195 $\pm$ 3 °C, pure enough for use in the subsequent syntheses. FAB HPLC-MS m/z 508.2563 ($[MH]^+$). $C_{27}H_{34}N_5O_5$ requires 508.2559. ^1H NMR $[(CD_3)_2SO]$ δ 2.22 (6H, m), 2.75 (2H, t), 3.25 (8H, m), 5.00 (2H, s), 6.35 (1H, broad s), 6.92 (1H, d), 7.24 (1H, t), 7.28–7.35 (8H, m), 7.92 (3H, m), 10.98 (1H, s). ^{13}C NMR $[(CD_3)_2SO]$ δ 35.4, 35.5, 35.6, 35.8, 37.3, 41.1, 65.3, 100.9, 111.4, 119.7, 122.3, 125.6, 128.0, 128.1, 128.6, 129.8, 134.9, 137.5, 156.3, 170.52, 170.46, 170.6.

Cbz-Bal₃-6-(2-Aminoethyl)indole (1D). Cbz-Bal₃-OSu (362 mg, 780 μ mol), 6-(2-aminoethyl)indole (126 mg, 780 μ mol), and *N*-methylmorpholine (86 μ L, 780 μ mol) in dry *N,N*-dimethylformamide (6 mL) were reacted in the same way as described for compound **1C**. The crude product was extracted with ethyl acetate and methanol to yield the title compound (289 mg) as a white solid, mp 234–236 °C, R_f = 0.4 (solvent A₁), 0.8 (solvent B). Purity by HPLC (protocol II; retention time, 25.7 min) 96.3% (280 nm). A further 15 mg was recovered from the methanol extracts using preparative TLC. Overall yield, 304 mg (77%). FAB HPLC-MS m/z 508.2592 ($[MH]^+$). $C_{27}H_{34}N_5O_5$ requires 508.2559. ^1H NMR $[(CD_3)_2SO]$ δ 2.24 (6H, m), 2.78 (2H, t), 3.23 (6H, m), 3.27 (2H, t), 5.01 (2H, s), 6.37 (1H, broadened s), 6.87 (1H, dd), 7.20 (1H, broadened s), 7.25 (1H, t), 7.27 (1H, m), 7.35 (5 H, m), 7.45 (1H, d), 7.92 (2H, t), 7.98 (1H, t), 10.97 (1H, s). ^{13}C NMR $[(CD_3)_2SO]$ δ 35.4, 35.5, 35.8, 37.3, 41.1, 65.3, 101.0, 111.3, 120.1, 120.4, 125.1, 126.3, 128.0, 128.6, 132.4, 136.5, 137.5, 156.3, 170.5, 170.6, 170.7.

H-Bal₃-Tryptamine (2A). Compound **1A** (320 mg, 0.68 mmol) was *N*-deprotected using a mixture of 90% aqueous trifluoroacetic acid (1.2 mL) and anisole (1.2 mL) (39, 40). Precipitation with diethyl ether afforded the title compound as the trifluoroacetate salt. Further purification was by preparative TLC (solvent C). The zone containing peptide conjugate **2A** (as the free base due to the ammonia content of the solvent system used) was collected and extracted with methanol/25% aq. ammonia

(10:1; the addition of ammonia is essential). The extract was evaporated to dryness. The residue was dissolved in methanol/aqueous ammonia as above and filtered to remove contaminant silica gel. Evaporation of the combined filtrates afforded 194 mg (76%) of the pure title compound, mp 178–181 °C. Homogeneous by TLC, R_f = 0.0 (solvent A₁), 0.5 (solvent B), 0.6 (solvent C). Purity by HPLC (protocol II; retention time, 24.3 min) 99.3% (280 nm)/98.5% (215 nm). FAB HPLC-MS m/z 374.2190 ($[MH]^+$). $C_{19}H_{28}N_5O_3$ requires 374.2192. ^1H NMR (D_2O) δ 2.11 (2H, t), 2.21 (2H, t), 2.25 (2H, t), 2.78 (2H, t), 2.86 (2H, t), 3.18 (2H, t), 3.19 (2H, t), 3.41 (2H, t), 7.04 (1H, dd), 7.11 (1H, s), 7.13 (1H, dd), 7.38 (1H, d), 7.55 (1H, d). ^{13}C NMR (D_2O) δ 24.9, 35.9, 36.1, 36.6, 36.7, 37.3, 40.7, 112.7, 112.8, 119.4, 120.0, 122.7, 124.2, 128.0, 137.2, 174.4, 174.6, 174.8.

H-Bal₄-Tryptamine (2B). Compound **1B** (97 mg, 0.18 mmol) was deprotected in the same way as its analogue **1A** to yield the title compound as a white solid (65 mg, 82%) homogeneous by TLC, R_f = 0.0 (solvent A₁), 0.5 (solvent B), 0.6 (solvent C), mp 215–219 °C. Purity by HPLC (protocol II; retention time, 24.4 min) 100.0% (280 nm)/100% (215 nm). FAB HPLC-MS m/z 445.2560 ($[MH]^+$). $C_{22}H_{33}N_6O_4$ requires 445.2563. ^1H NMR (D_2O , 30 °C) δ 2.09 (2H, t), 2.19 (2H, t), 2.23 (2H, t), 2.31 (2H, t), 2.83 (2H, t), 2.87 (2H, broad s), 3.15 (2H, t), 3.18 (2H, t), 3.25 (2H, t), 3.37 (2H, t), 7.01 (1H, dd), 7.08 (1H, s), 7.10 (1H, dd), 7.36 (1H, d), 7.52 (1H, d). ^{13}C NMR (D_2O , 30 °C) δ 24.9, 35.9, 36.0, 36.7, 40.7, 112.7, 112.8, 119.4, 120.0, 122.7, 124.2, 128.0, 137.2, 174.7, 174.6.

H-Bal₃-5-(2-Aminoethyl)indole (2C). Compound **1C** (123 mg, 243 μ mol) was suspended in a mixture of methanol (32 mL) and water (14 mL) and, after addition of 10% palladium-on-charcoal (139 mg) hydrogenated at room temperature and atmospheric pressure, for 1 h. The catalyst was collected by centrifugation and exhaustively rinsed with methanol/water (2:1). The combined supernatant and rinsings were evaporated and the residue was purified as described for compound **2A**, to yield **2C** (63 mg, 69%) homogeneous by TLC, R_f = 0.0 (solvent A₁), 0.5 (solvent B). Purity by HPLC (protocol II; retention time, 23.7 min) 100.0% (280 nm)/98.6% (215 nm). The compound decomposed before melting. FAB HPLC-MS m/z 374.2191 ($[MH]^+$). $C_{19}H_{28}N_5O_3$ requires 374.2192. ^1H NMR (CD_3OD) δ 2.38 (2H, t), 2.43 (2H, t), 2.44 (2H, t), 2.95 (2H, t), 3.00 (2H, t), 3.47 (4H, t), 3.53 (2H, t), 6.46 (1H, d), 7.07 (1H, dd), 7.28 (1H, d), 7.40 (1H, d), 7.47 (1H, s). ^{13}C NMR (CD_3OD) δ 37.0, 37.3, 37.5, 38.7, 39.0, 43.1, 102.4, 112.5, 121.4, 123.8, 126.3, 131.1, 131.2, 137.0, 174.2, 174.3, 174.6.

H-Bal₃-6-(2-Aminoethyl)indole (2D). A suspension of *N*-protected peptide conjugate **1D** (110 mg, 218 μ mol) in a mixture of methanol (30 mL) and water (13 mL) containing 10% palladium-on-charcoal (112 mg) was hydrogenated, and the product worked up as described for compound **2C** to yield 44 mg (54%) of the title compound homogeneous by TLC, R_f = 0.0 (solvent A₁), 0.5 (solvent B), 0.6 (solvent C). Purity by HPLC (protocol II; retention time, 26.1 min) 100.0% (280 nm)/97.8% (215 nm). The compound decomposed before melting. FAB HPLC-MS m/z 374.2177 ($[MH]^+$). $C_{19}H_{28}N_5O_3$ requires 374.2192. ^1H NMR (D_2O) δ 2.02 (2H, t), 2.18 (2H, t), 2.27 (2H, t), 2.77 (2H, t), 2.81 (2H, t), 3.13 (2H, t), 3.16 (2H, t), 3.36 (2H, t), 6.39 (1H, d), 6.87 (1H, d), 7.20 (1H, d), 7.24 (1H, s), 7.48 (1H, d). ^{13}C NMR (D_2O) δ 35.3, 35.8, 36.0, 36.6, 36.8, 37.1, 41.6, 101.9, 112.3, 121.3, 121.5, 126.5, 127.1, 133.6, 137.1, 173.9, 174.7, 174.8.

d-Biotin-Bal₃-Tryptamine (3A). A suspension of peptide conjugate **2A** (78 mg, 210 μ mol), *d*-biotin *N*-hydroxysuc-

cinimide ester (88 mg, "260 μmol ", ca. 90% pure), and *N*-methylmorpholine (23 μL , 210 μmol), in *N,N*-dimethylformamide (8 mL), was stirred at room-temperature overnight. As reactant **2A** dissolved, product **3A** separated as a flaky precipitate. The reaction mixture was evaporated to dryness, and the residue was extracted with ethyl acetate (3 $\times$ 20 mL) to remove *N*-hydroxysuccinimide and left-over reactants. Crystallization of the residue from water afforded the title compound (46 mg, 37%) as white crystals, mp 213–215 $^{\circ}\text{C}$, R_f = 0.1 (solvent A₁), 0.3 (solvent A₃), 0.6 (solvent B), with a purity (HPLC, protocol II; retention time, 26.0 min) of 97.2% (280 nm)/91.0% (215 nm). Further purification by preparative HPLC afforded a purity of 100.0% (280 nm)/98.5% (215 nm). FAB HPLC-MS m/z 600.2960 ($[\text{MH}]^+$). $\text{C}_{29}\text{H}_{42}\text{N}_7\text{O}_5\text{S}$ requires 600.2968. ^1H NMR (CD_3OD) δ 1.47 (2H, m), 1.58–1.80, (4H, m), 2.26 (2H, t), 2.41 (2H, t), 2.47 (4H, t), 2.76 (1H, d), 2.98 (1H, dd), 3.04 (2H, t), 3.23 (1H, ddd), 3.47, 3.48 (6H, 2t), 3.58 (2H, t), 4.35 (1H, dd), 4.56 (1H, dd), 7.12 (1H, dd), 7.21 (1H, dd), 7.22 (1H, s), 7.47 (1H, d), 7.67 (1H, d). ^{13}C NMR (CD_3OD) δ 25.9, 26.6, 29.2, 29.5, 36.8, 37.2, 41.0, 41.4, 56.8, 61.6, 63.4, 112.9, 113.5, 119.7, 120.2, 122.9, 124.2, 128.8, 138.1, 166.5, 174.7, 174.8, 177.3.

d-Biotin-Bal₄-Tryptamine (**3B**). Peptide conjugate **2B** (79 mg, 178 μmol), *d*-biotin *N*-hydroxysuccinimide ester (67 mg, "196 μmol ", ca. 90% pure), and *N*-methylmorpholine (19.6 μL , 178 μmol) in *N,N*-dimethylformamide (18 mL) were processed as described for the synthesis of compound **3A** to yield crude **3B** (101 mg, 84%) as a white solid. For further purification, the compound was dissolved in boiling 70% aqueous methanol and precipitated by concentrating the solution to one-third its original volume. Mp 232–234 $^{\circ}\text{C}$, R_f = 0.1 (solvent A₁), 0.6 (solvent B), with a purity (HPLC, protocol I; retention time, 25.7 min) of 94.1% (280 nm)/84.3% (215 nm). Further purification by preparative HPLC afforded a purity of 100.0% (280 nm)/100.0% (215 nm). FAB HPLC-MS m/z 671.3317 ($[\text{MH}]^+$). $\text{C}_{32}\text{H}_{47}\text{N}_8\text{O}_6\text{S}$ requires 671.3339. ^1H NMR ($\text{CD}_3\text{OD}/\text{D}_2\text{O}$ $\approx$ 4:3, 45 $^{\circ}\text{C}$) δ 1.44 (2H, m), 1.53–1.80 (4H, m), 2.26 (2H, t), 2.40 (2H, t), 2.43–2.48 (6H, m), 2.79 (1H, d), 2.99 (1H, dd), 3.04 (2H, t), 3.25 (1H, m), 3.45–3.49 (8H, m), 3.58 (2H, t), 4.37 (1H, dd), 4.59 (1H, dd), 7.16 (1H, dd), 7.25 (1H, s), 7.25 (1H, dd), 7.51 (1H, d), 7.69 (1H, d). ^{13}C NMR ($\text{CD}_3\text{OD}/\text{D}_2\text{O}$ $\approx$ 4/3, 45 $^{\circ}\text{C}$) δ 25.8, 26.6, 29.2, 29.5, 36.7, 36.8, 37.2, 41.0, 41.4, 56.8, 61.6, 63.4, 112.9, 113.5, 119.7, 120.3, 123.0, 124.3, 128.8, 138.0, 166.5, 174.7, 174.9, 177.5.

d-Biotin-Bal₃-5-(2-Aminoethyl)indole (**3C**). Compound **2C** (86 mg, 230 μmol), *d*-biotin *N*-hydroxysuccinimide ester (98 mg, "287 μmol ", ca. 80% pure), and *N*-methylmorpholine (25 μL , 230 μmol) in dry *N,N*-dimethylformamide (20 mL) were processed as described for the synthesis of compound **3A**. The crude product (133 mg) was recrystallized from water (30 mL) to yield the pure title compound (76 mg) as a white solid, mp 214–215 $^{\circ}\text{C}$, R_f = 0.2 (solvent A₃), 0.6 (solvent B) with a purity (HPLC, protocol I; retention time, 26.0 min) of 100.0% (280 nm)/93.9% (215 nm). Recrystallization of the evaporated mother liquors afforded a second crop (14 mg), mp 212–213 $^{\circ}\text{C}$. Overall yield, 90 mg (66%). Further purification of the main fraction by preparative HPLC afforded a purity of 100.0% (280 nm)/98.5% (215 nm). FAB HPLC-MS m/z 600.2797 ($[\text{MH}]^+$). $\text{C}_{29}\text{H}_{42}\text{N}_7\text{O}_5\text{S}$ requires 600.2968. ^1H NMR (CD_3OD) δ 1.50 (2H, m), $\sim$ 1.7 (4H, m), 2.26 (2H, t), 2.38 (2H, t), 2.44 (2H, t), 2.45 (2H, t), 2.77 (1H, d), 2.95 (2H, t), 2.98 (1H, dd), 3.25 (1H, m), 3.47 (2H, t), 3.51

(4H, t), 3.54 (2H, t), 4.34 (1H, dd), 4.54 (1H, dd), 6.46 (1H, d), 7.07 (1H, d), 7.29 (1H, d), 7.40 (1H, d), 7.48 (1H, s).

d-Biotin-Bal₃-6-(2-Aminoethyl)indole (**3D**). Peptide conjugate **2D** (86 mg, 230 μmol), *d*-biotin *N*-hydroxysuccinimide ester (96 mg, "280 μmol ", ca. 80% pure), and *N*-methylmorpholine (30 μL , 272 μmol) in *N,N*-dimethylformamide (12 mL) solution were processed as described for compound **3A** to yield, after recrystallization from water, 57 mg of pure **3D** as a white solid, mp 223–225 $^{\circ}\text{C}$, R_f = 0.1 (solvent A₁), 0.6 (solvent B) with a purity (HPLC, protocol II; retention time, 26.0 min) of 97.0% (280 nm)/94.1% (215 nm). A further 17 mg, mp 216–220 $^{\circ}\text{C}$, was recovered by recrystallization of the evaporated mother liquors. Overall yield, 74 mg (54%). Further purification of the main fraction by preparative HPLC afforded a purity of 99.6% (280 nm)/98.9% (215 nm). FAB HPLC-MS m/z 600.2958 ($[\text{MH}]^+$). $\text{C}_{29}\text{H}_{42}\text{N}_7\text{O}_5\text{S}$ requires 600.2968. ^1H NMR (CD_3OD) δ 1.48 (2H, m), 1.58–1.84 (4H, m), 2.26 (2H, t), 2.38 (2H, t), 2.44, (2H, t), 2.45 (2H, t), 2.77 (1H, d), 2.97 (2H, t), 2.98 (1H, dd), 3.23 (1H, ddd), 3.47 (4H, t), 3.50 (2H, t), 3.54 (2H, t), 4.34 (1H, dd), 4.54 (1H, dd), 6.47 (1H, d), 6.98 (1H, d), 7.26 (1H, d), 7.32 (1H, s), 7.55 (1H, d).

Binding Assays. Materials. Tryptamine, *d*-biotin, lysozyme (EC 3.2.1.17; lyophilized, from chicken egg white), bovine serum albumin (BSA; 1 $\times$ crystallized and fraction 5 powder), human serum albumin (HSA; 99%, essentially globulin free, approximately 0.005% fatty acids), tryptophanase (EC 4.1.99.1), pyridoxal 5-phosphate, L-serine, β -nicotinamide adenine dinucleotide, reduced form (β -NADH), and polyoxyethylenesorbitan monolaurate (Tween 20) were obtained from Sigma Chemicals (St. Louis MO). Lactate dehydrogenase (EC 1.1.1.27) was obtained from Sigma Chemicals and Worthington Biochemical Corporation (Freehold, NJ). Methanol (HPLC grade) and methyl sulfoxide were obtained from VWR Scientific Products (Bridgeport, NJ). Alkaline phosphatase-conjugated NeutrAvidin (average of 3 alkaline phosphatases/NeutrAvidin), disuccinimidyl suberate, *p*-nitrophenyl phosphate, Reacti-Bind biotin coated microtiter plates and SuperBlock blocking buffer were from Pierce Chemicals (Rockford IL). CovaLink Immuno Module plates were from Nalge Nunc International Corp. (Naperville, IL). Hybond-C nitrocellulose membrane, ECL chemiluminescent detection reagents, streptavidin-horseradish peroxidase conjugate (average of 3–4 peroxidases/streptavidin) and disodium 2-chloro-5-(4-methoxy-*spiro*-[1,2-dioxetane-3,2'-(5'-chloro)-dicyclo[3,3,1,^{3,7}]decan]-4-yl)phenyl phosphate; CDP-star were from Amersham Pharmacia Biotech (Arlington Heights, IL). Biomax X-ray film was from Eastman Kodak Corp. (Rochester, NY). Biotin-free casein was obtained from Schleicher and Schuell (Keene, NH). The binding assays were performed using buffers A (20 mM Tris/HCl, pH 7.6, 137 mM NaCl, 0.1% Tween 20), B_{7.4} (50 mM Tris/HCl, pH 7.4, 100 mM NaCl), and B_{8.0} (same components as in B_{7.4}, but pH 8.0).

The bifunctional probes **3A–D** were dissolved in methanol/water (2:1) and the respective concentrations determined by comparing the UV absorbance (278 nm) from the HPLC elution profile (see General section for

details) to the UV absorbance profile of known amounts of tryptamine.²

Tryptophanase Assays. Tryptophanase activity was assayed by measuring the velocity of pyruvate formation from serine in a coupled reaction with β -NADH and lactate dehydrogenase, essentially as described by Morino and Snell (22), but using a smaller reaction volume (300 μ L) and 5 units of lactate dehydrogenase/sample. The stock solutions (31 μ M) of compounds **3A**, **3C**, and **3D** contained 66% methanol. Thus methanol was added to the corresponding controls to compensate for its effect on enzyme activity. Tryptophanase (0.3 units, 30 μ L of stock solution) was added to start the reaction and a 100 μ L aliquot of the reaction mixture was monitored for a ten-minute period to follow the decrease of absorbance at 340 nm. The reaction proceeded linearly with time. Assays were performed in triplicate.

Avidin Binding Assays. All procedures were carried out at room temperature unless otherwise indicated. Biotin and **3A–D** were diluted to varying concentrations (10 pM to 30 μ M) in buffer A, mixed with 276 pM alkaline phosphatase-conjugated NeutrAvidin and allowed to equilibrate for 30 min. These mixtures were added to the wells of Reacti-Bind biotin-coated microwell plates and incubated with gentle shaking (75 rpm on a rotary shaker). After 30 min the wells were emptied and washed with buffer A ($3 \times 200 \mu$ L). Phosphatase substrate buffer (1.9 mM *p*-nitrophenyl phosphate, disodium salt in diethanolamine, pH 9.8) was made fresh according to the manufacturer's instructions and 100 μ L were added to the wells. After 30 min the reaction was stopped with 50 μ L of 2 M NaOH and the absorbance at 405 nm was measured. Assays were performed in triplicate.

Covalent Attachment of Lysozyme, BSA, and HSA to Microwell Plates and Assay for Biotin Conjugate Binding. CovaLink Immuno Module plates were treated with 100 μ L of disuccinimidyl suberate (339 μ M disuccinimidyl suberate in 50% methyl sulfoxide, 7.5 mM Na₂CO₃, 17.5 mM NaHCO₃, pH 9.6) for 1 h. The wells were emptied and washed with distilled water ($3 \times 100 \mu$ L). Lysozyme was made 40 μ g/mL in carbonate buffer, pH 9.6 (15 mM Na₂CO₃, 35 mM NaHCO₃), 100 μ L were added to the wells of the treated CovaLink plates and left overnight. BSA and HSA (80 μ g/mL in carbonate buffer) were covalently attached to the CovaLink plates in a similar manner. The wells were emptied and washed twice with 200 μ L of SuperBlock blocking buffer (SuperBlock reagent in buffer B_{7.4}). A fresh 200 μ L aliquot of blocking buffer was added to the wells and left for 15 min. The wells were emptied and allowed to dry for 2 h, then stored desiccated at +4 °C until further use.

The lysozyme-coated wells were washed three times with buffer A and 100 μ L of varying concentrations (1 μ M to 1 mM) of compounds **3A–D** (diluted in buffer A) were added. The plates were incubated for 1 h with gentle shaking, and then washed three times with buffer A. Next the wells were incubated with 100 μ L of alkaline phosphatase conjugated-NeutrAvidin solution (552 pM in buffer A) for 1 h with gentle shaking. The wells were emptied and washed with buffer A ($3 \times 200 \mu$ L). Substrate was added as above, the reaction stopped after 24 min and absorbance at 405 nm was measured. Assays

were performed in triplicate. The BSA- and HSA-coated wells were treated with SuperBlock as above, washed three times with buffer B_{8.0}, and 100 μ L of compound **3A** diluted to a range of concentrations (buffer B_{8.0}) were added. All subsequent steps were the same as for the lysozyme-coated wells except that buffer B_{8.0} was used in place of buffer A and all incubations were conducted at 37 °C.

Binding of Biotinylated Indoles to Proteins Immobilized on Nitrocellulose Membranes. Lysozyme (lyophilized, 95% protein), BSA (fraction 5 and 1 $\times$ crystallized), and tryptophanase were made 10 mg/mL in buffer A and 5–20 μ g were spotted on to a 0.45 μ m Hybond-C nitrocellulose membrane and allowed to air-dry. Four replicate membranes were generated in this manner. The membranes were incubated in SuperBlock blocking buffer for 20 min with gentle agitation, washed three times with buffer A and then incubated with 100 μ M of **3A**, **3C**, or **3D** (diluted in buffer A). The fourth membrane was incubated in buffer A only. After a 1-h incubation with gentle agitation, the membranes were washed three times with buffer A. Alkaline phosphatase-conjugated NeutrAvidin (552 pM in buffer A) was added to each membrane and incubated for 1 h as above. The membranes were washed as above and excess buffer allowed to drain off the surface of the membranes. CDP-star chemiluminescent substrate for alkaline phosphatase was added according to the manufacturer's instructions and the membranes were exposed to X-ray film for 1 h. In a separate experiment, 5–20 μ g of BSA (fraction 5) and tryptophanase were spotted on to a nitrocellulose membrane, incubated with a biotin-free casein blocking solution (5% casein in buffer A) for 1 h, washed with buffer A and then incubated with 100 μ M **3A** for an additional hour. The membrane was washed with buffer A and then incubated with horseradish peroxidase-conjugated streptavidin (833 pM in buffer A) for 30 min. The membrane was washed with buffer A and incubated with ECL chemiluminescent substrate according to the manufacturer's instructions and exposed to X-ray film for 1 h.

RESULTS AND DISCUSSION

Design of Biotinylated Indoles. To permit the detection of biotinylated indoles by (strept)avidin-based indicator modules, it has to be taken into account that their biotin-binding sites are located in pockets which extend deeply below the surface of the protein molecule (41–43). The spacer separating the biotin moiety from the indole ring must thus be appropriate in length. In compounds **3A–D**, we use a spacer composed of two units: an aminoethyl group attached to positions 3, 5, or 6 of the indole nucleus, and a peptide containing three to four concatenated β -alanine residues. The indole is thus separated from the biotin moiety by 16–20 aliphatic bonds. These dimensions for the spacer were suggested by published work, such as the results of Green et al. (44), who coupled biotin to both ends of α,ω -diamino-*n*-alkanes and correlated the length of the alkyl chain to the capacity of the conjugates to bind simultaneously to two avidin molecules. The oligo- β -alanine we use in our spacers is more hydrophilic than the more commonly employed ϵ -aminocaproic acid-based peptides. This appeared necessary to compensate for the low water solubility of both the biotin and the indole moieties.

The protected β -alanine oligopeptides used as starting materials were constructed in a stepwise fashion, using *N*-hydroxysuccinimide esters for the extension of the

² The respective UV spectra exhibit flat-topped absorbance maxima ($\log \epsilon = 3.7$) centered at 282 ± 2 nm with negligible drop in absorbance towards 278 nm, a wavelength passed by a standard filter available for the UV monitor used in the HPLC quantification of compounds **3A–D** in stock solutions for bioassays.

peptide chain. The sequence in which the *d*-biotin and aminoethylindole headgroups were attached to the spacer peptide was of practical significance. If the biotin was introduced first, the resulting *N*-substituted peptides were insoluble in standard solvents and thus technically inconvenient for further processing to **3A–D**. Intermediates with somewhat better (but still challenging) solubility properties were obtained when the indolic components were coupled to *N*-Boc- or *N*-Cbz- β -alanine tri- or tetrapeptides to yield compounds **1A–1D** (Figure 1). The subsequent *N*-deprotection proved to be another critical step. While the Boc-groups in compounds **1A** and **1B**, with the C-terminal end of the peptide attached to 3-(2-aminoethyl)indole (tryptamine), could be removed smoothly by the customary treatment with trifluoroacetic acid, the corresponding derivatives containing 6-(2-aminoethyl) moieties afforded mostly polymeric material (details not shown), a complication apparently due to the exceptional acid sensitivity of indole derivatives with an unsubstituted 3-position (45). *N*-Cbz- β -alanine peptides **1C–D** were thus employed in the preparation of compounds **2C–D**, the deprotection being accomplished by catalytic hydrogenation. Condensation of intermediates **2A–D** with *d*-biotin *N*-hydroxysuccinimide ester completed the synthesis of the bifunctional probes **3A–D**.

The identity of the compounds prepared was confirmed by NMR and by FAB-MS including fragmentation patterns and exact masses of the pseudomolecular ($[MH]^+$) ions. Purity was checked by TLC and, as far as possible, by HPLC. TLC was preferred for *N*-hydroxysuccinimide esters which are hydrolyzed by the aqueous solvent systems required in reversed-phase HPLC (only minor decomposition is known to occur in TLC). Intermediates **1C** and **1D** could not be recrystallized and were thus used in a purity of 96.3% (**1C**) and 93.3% (**1D**). While preparative HPLC afforded compounds **3A–D** in a purity of 98.5+%, the less rigorously purified material obtained by recrystallization proved to be sufficient for the binding assays described herein.

Binding Studies. General. A surprisingly small number of the proteins known to interact with indole and its derivatives (see Introduction) have been studied in sufficient detail to be suitable for gauging the efficacy of compounds **3A–D** as probes for indole-binding proteins. Readily available representatives of this group of proteins comprise 1. the enzyme, tryptophanase, which interacts with indole in the presence of pyridoxal phosphate and aliphatic cosubstrates and 2. the serum albumins of higher vertebrates (19, 20) and lysozyme from chicken eggwhite (46), which bind indolic compounds without mediating cofactors and cosubstrates.

Interaction of Indole and Compounds 3A, 3C, and 3D with Tryptophanase. When supplied with pyridoxal phosphate, tryptophanase converts serine to pyruvic acid. This reaction is inhibited by indole, as studied in detail by Morino and Snell (22). We attempted to replicate their assay as closely as possible in order to determine if compounds **3A**, **3C**, and **3D** mimicked indole in the inhibition of tryptophanase activity. The presence of methanol in the reaction mixtures (because stock solutions of compounds **3A**, **3C**, and **3D** were in 66% methanol) complicated enzyme kinetics and parameters such as constants of inhibition (K_i) could not be derived. However, qualitative comparison of the data presented in Table 1 clearly demonstrates inhibition of tryptophanase by biotinylated indoles. Relative to an equimolar concentration (0.031 mM) of indole, compounds **3A**, **3C**, and **3D** were more inhibitory at the lowest serine concentration (20 mM) tested, about equally inhibitory

at intermediate serine levels (60 and 100 mM), and somewhat less inhibitory at the highest serine concentration (200 mM) examined.

Binding of Biotinylated Indoles to Avidin. *d*-Biotin and the biotinylated indoles **3A–D** exhibited comparable binding in the avidin binding assay (Figure 2). A constant amount of alkaline phosphatase conjugated NeutrAvidin was mixed with varying concentrations of biotin or **3A–D** and allowed to equilibrate. The mixture was then added to microwells containing immobilized biotin. Absorbance values at 405 nm correlated inversely with the ability of the biotin or **3A–D** in solution to compete with the immobilized biotin. Compounds **3A–D** competed with the immobilized biotin similarly to *d*-biotin ($\pm 20\%$) over a range of concentrations (μM to pM). From these assays we conclude that the indole moiety and the oligopeptide spacer do not interfere, to a practically relevant extent, with the avidin binding site. The ability of **3A–D** to bind certain proteins via their indole moieties and, simultaneously, avidin via their biotin moieties, was addressed in the following experiments.

Simultaneous Binding of Biotinylated Indoles to Selected Proteins and Avidin. When compound **3A** was incubated at neutral pH with BSA that had been immobilized to a nitrocellulose membrane, we could detect the biotin moiety via chemiluminescent reaction with horseradish peroxidase-conjugated streptavidin. The signal was reproducibly faint but above background, indicating weak binding (data not shown). Tryptophanase, which was applied as a control did not afford a signal, in accord with the fact that the enzyme does not bind indole unless supplied with pyridoxal phosphate and an appropriate aliphatic cosubstrate (22). Using a slightly different protocol, we examined the ability of compounds **3A**, **3C**, and **3D** to bind lysozyme and BSA that had been immobilized on a nitrocellulose membrane. Again, tryptophanase was applied as a control. Four replicate membranes were incubated separately with 100 μM **3A**, **3C**, **3D**, or buffer A. Unbound **3A**, **3C**, or **3D** was washed off and alkaline phosphatase conjugated NeutrAvidin was added. A chemiluminescent substrate for alkaline phosphatase allowed detection of the avidin-bound biotin conjugates. Under these conditions, only lysozyme gave a positive signal above background for all three biotinyl-

lated indoles tested, indicating that they were able to bind to lysozyme (data not shown).

We also monitored binding of compound **3A** to BSA and HSA that had been covalently attached to the wells of microwell plates. Initially the incubation of **3A** with the immobilized proteins and all subsequent steps were performed over a range of pH and temperature (data not shown). We observed optimal binding at 37 °C and pH 8.0 and performed the binding assay in triplicate. Binding of **3A** (monitored by alkaline phosphatase activity) increased with increasing **3A** concentration (Table 2). The BSA and HSA concentrations in each well were kept constant, so the observed increases in absorbance at 405 nm were indicative of more biotin conjugate binding. In a similar fashion, lysozyme was covalently attached to microwell plates and binding assays were performed with compounds **3A–D**. In all four cases, binding increased as the concentrations of the biotin-indole conjugates increased (Table 3).

Concluding Remarks. The data presented support the suitability of biotinylated indoles (**3A–D**) as probes for indole-binding proteins. Compounds **3A**, **3C**, and **3D** inhibited the tryptophanase-catalyzed conversion of serine to pyruvic acid to a similar extent as indole itself. The weak affinity of **3A** for BSA and HSA that were covalently bound to microwell plates is in accord with the results of previous indole-binding studies in solution (19, 20). For lysozyme immobilized in the same fashion, statistically significant binding was observed at ligand concentrations as low as 10^{-5} to 10^{-6} M. Reliable binding constants for proteins attached to microwell plates could not be determined, because the proteins were linked at

**Figure 2.** Competition between immobilized biotin, and biotin or biotinylated indoles **3A–D** in solution, for alkaline phosphatase-conjugated NeutrAvidin binding. The phosphatase coupled to the immobilized biotin was assayed using a colorogenic substrate (see Materials and Methods) and the resulting absorbance at 405 nm was measured. The relative absorbance at this wavelength, as shown in the Figure, was determined by dividing the absorbance for the mixtures of enzyme-linked NeutrAvidin with biotin or compounds **3A–D** by the absorbance obtained for enzyme-linked NeutrAvidin alone. The data points are presented by the following symbols: filled circles, biotin; squares, compound **3A**; diamonds, compound **3B**; triangles, compound **3C**; stars, compound **3D**.

random amino groups and we could not accurately determine the fraction of protein molecules that had available indole binding sites. Even in solution, binding kinetics is highly complex and the affinity for many indole derivatives exceeds that for indole itself (19, 20, 46). It is thus barely surprising that experiments aimed at demonstrating specific binding of compounds **3A–D**, by showing competition with indole, did not afford conclusive results. Also, what is conventionally termed the "indole-binding site" of BSA and HSA is a group-specific site which will as well accommodate a number of nonindolic drugs (47, 48), while certain indole derivatives bind to a separate site (the "warfarin site") (49) and do not directly compete with ligands accommodated by the "indole-binding site proper". In lysozyme, indole derivatives bind to the center of the hydrophobic core of the protein (50), causing a conformational change and loss of hydrolytic activity toward bacterial cell wall peptidoglycan (46). This may also suggest a group-specific binding site rather than selective indole binding.

Do compounds **3A–D**, in addition to indole-binding sites, also recognize other hydrophobic sites? Only a few proteins have so far been checked for their inability to

bind indole under strictly defined conditions; tryptophanase appears to be the only commercially available representative. In the absence of pyridoxal phosphate and a suitable aliphatic cosubstrate, the protein does not bind indole (22) and, when immobilized on a nitrocellulose membrane, did not bind biotin conjugates **3A**, **3C**, and **3D** (see above). These data indicate that compounds **3A–D** exhibit at least some specificity for indole-binding sites. Even if that specificity should not be absolute (a property which will only become evident after extensive bench testing), the indole-biotin conjugates could still be useful for selective tagging of a restricted number of components in complex mixtures of proteins.

Drug Delivery Systems Employing 1,6-Elimination: Releasable Poly(ethylene glycol) Conjugates of Proteins

Stanford Lee,* Richard B. Greenwald,* Jeffrey McGuire, Karen Yang, and Celine Shi

Enzon, Inc., 20 Kingsbridge Road, Piscataway, New Jersey 08854. Received June 3, 2000;
Revised Manuscript Received October 21, 2000

Using lysozyme as a representative protein substrate that loses its activity when PEGylation takes place on the ϵ -amino group of lysine residues, various amounts of a novel releasable PEG linker (rPEG) were conjugated to the protein. rPEG–lysozyme conjugates were relatively stable in pH 7.4 buffer for over 24 h. However, regeneration of native protein from the rPEG conjugates occurred in a predictable manner during incubation in high pH buffer or rat plasma, as demonstrated by enzymatic activity and structural characterization. The rates of regeneration were also correlated with PEG number: native lysozyme was released more rapidly from the monosubstituted conjugate than from the disubstituted conjugate, suggesting possible steric hindrance to the approach of cleaving enzymes. Recovery of normal activity and structure for the regenerated native lysozyme was shown by a variety of assays.

INTRODUCTION

Conjugation of proteins with poly(ethylene glycol) (PEG),¹ a process that has been termed PEGylation (1), imparts important pharmacological properties to the modified protein. The advantages of PEGylation include increased circulatory half-life, reduced immunogenicity, reduced loss of protein to protease cleavage, and increased water solubility.

It is generally observed that protein functions, such as catalysis and receptor binding, are compromised to varying degrees following PEGylation, usually resulting in diminished activity; this may be due to the presence of the PEG substituent on or near the protein's active or regulatory sites. Early attempts to improve this situation led to the use of differently activated PEG linkers, all producing conjugates with hydrolysis-resistant permanent bonds; no one particular linker has provided consistently superior results. Therefore, it seems likely that the most effective linker for maintaining activity will vary for different proteins and will have to be determined empirically for each case (2, 3). PEG mass and the degree of protein modification have also been explored as a means of preserving activity; the use of fewer PEG strands of higher molecular weight has been reported to produce conjugates with less loss of activity (4, 5).

A novel approach for maintaining maximum activity in a conjugate would be to design a functional PEG linker that can predictably break down by enzymatic or pH directed hydrolysis. Such a releasable PEG (rPEG) would provide rPEGylated protein conjugates which are impermeant and could act as a depot or reservoir, continuously discharging native protein with full, albeit potentially short-acting, activity.

Coupling of proteins to substituted maleic anhydrides at the ϵ -amino group of lysine residues results in the

formation of maleic acid half amides which are labile at acidic pH (6, 7). By employing this property, it was demonstrated that conjugation of proteins through ϵ -amino groups with citraconic anhydride or 2,3-dimethylmaleic anhydride (8–11) led to conjugates that could be deacylated at pH <6. Modification of the amino groups of lysozyme by various acylating reagents has been reported to result in complete loss of activity. Therefore, lysozyme was effectively used as a model protein for which, after modification by maleic anhydride, 83% of enzymatic activity was recovered at pH 4.2 by a deacylation mechanism (12). The first application that combined PEG chemistry with anhydride linkers was reported by Garman in 1987 (13). The synthesis of a 5000 molecular weight (mw) PEG substituted maleic anhydride and its conjugation to tissue plasminogen activator (tPA) and urokinase (uPA) were described. Both of the resulting conjugates, unexpectedly, regenerated native protein under physiological conditions (pH 7.4, 37 °C), as shown by gel permeation chromatography (GPC). In the case of tPA, a half-life ($t_{1/2}$) of 42 min was reported, but it was stated that an accurate rate of release could not be determined due to the instability of the conjugate. For uPA a $t_{1/2}$ of 6.1 h was reported. The PEG number (molar ratio of PEG to protein) was not determined for either conjugated species, but it was stated that GPC measurements of the tPA conjugate gave a higher molecular mass than native protein. For uPA, it was reported that an implied deacylation (release) should restore full activity to the protein from the 44% observed initially for the rPEG conjugate. In another example, a novel rPEG linker, PEG (mw 5000) 4-pyridyl disulfide, was synthesized and conjugated with papain, which contains seven cysteine residues, through a disulfide linkage (14). The resulting conjugate was characterized by MALDI MS, and the major component demonstrated to be about 5000 mw larger than native papain. It was concluded that active native protein could be released from the conjugates using mild reducing conditions, but no actual parameters for this transformation were provided. A recent successful attempt (15) at rPEG design was

Scheme 1**Scheme 2**

accomplished by a modification of lysozyme (1) at the α - and ϵ -amino positions with PEG (mw 5000) CM-HBA (2), an ester of 3-hydroxybutyric acid and carboxymethyl PEG, activated on the butyric terminus as the *N*-hydroxysuccinimide (NHS) ester (3, Scheme 1). Lysozyme highly modified by 2 showed complete inactivation, but, apparently, treatment of the conjugate with pH 2.6 phosphate buffer yielded enzyme with about 60% recovered activity. It should be noted that using this type of approach, the PEG ester, when cleaved from the bifunctional spacer, leaves an amide "tag" attached to the amino moiety, thus generating a modified enzyme. Another recent communication concerned with PEG release (16) also employs lysozyme with rPEG linkers such as 4 (Scheme 2). The resulting mixture of mono, di, and tri-PEG conjugates are phenolic carbamates, a class of compounds known to be more labile than aliphatic carbamates (17). After 10 days, hydrolysis at pH 7 and 37 °C, 82% of lysozyme bioactivity was reported to be recovered from these conjugates.

We recently developed a general methodology for synthesizing PEG prodrugs of amino-containing compounds that constitutes the basis for solubilizing insoluble drugs and extending plasma circulating half-lives of the conjugates. This approach utilized a double or tripartate prodrug (18) strategy that relies on enzymatic cleavage of bound PEG, followed by a classical 1,6-benzyl elimination reaction releasing the amine (drug) bound in the form of a carbamate (Scheme 3). The prodrug trigger was composed of ester, carbonate, carbamate, or amide bonds in order to secure predictable rates of hydrolysis. Further refinement of the controlled hydrolysis was accomplished by the introduction of steric hindrance through the use of ortho substituents on the benzyl component of the prodrug. This modification led to longer circulating plasma half-lives of the final tripartate form. The "ortho" effect also had the beneficial effect of directing nucleophilic attack by ϵ -amino groups of lysine residues almost exclusively to the activated benzylic carbonate of the heterobifunctional intermediates. These releasable PEG derivatives should also be applicable to protein and peptide modification at free α - and ϵ -amino functions in the same fashion, providing predictably unstable conjugates. Application of a non-PEGylated 1,6-benzyl elimination prodrug strategy to N-Ras lipopeptides has been reported (19), but the conjugates appear to lack adequate water solubility and addition of

Scheme 3

cosolvents was found necessary in order to perform plasma experiments.

In this work, we demonstrate the application of releasable PEG technology to polypeptides using lysozyme as a model protein and rPEG linkers of mw 5000. Lysozyme, whose structure and function are well understood, also has the advantage that activity is totally lost upon permanent PEGylation. The presence of even a single PEG on its surface results in complete loss of enzymatic activity. This provides an opportunity to demonstrate unambiguously that PEG can be completely removed by regenerating the fully functional enzyme. The releasable PEG linker 6, an *N*-hydroxysuccinimidyl activated carbonate, was designed to react with amines specifically at the alkyl terminus. Reaction of the opposite acyl phenolic terminus is prevented or minimized by the strategic placement of ortho methyl groups on the aromatic ring. This modification also served to slow the rate of enzymatic cleavage of the PEG ballast and thus allows a controlled release of native protein. The rate of release was designed to be compatible with the circulating half-lives of permanently PEGylated proteins, which typically range from a few hours to several days.

EXPERIMENTAL SECTION

Materials. Chicken egg white lysozyme (EC 3.2.1.17), lysozyme substrate bacteria (*Micrococcus lysodeikticus*), and trypsin were obtained from Sigma Inc., St. Louis, MO. The SDS-PAGE precasted gel was from Novex, San Diego, CA.

Enzyme Activity Assay. In a typical lysozyme activity assay, 40–80 μg of lysozyme or rPEG-lysozyme conjugate were added to 0.015% (w/v) of the substrate *M. lysodeikticus* in 250 mL of buffer containing 66 mM

Figure 1. Structure of SC-PEG (**12**).

potassium phosphate, pH 6.2 and 0.01% (w/v) BSA. The absorbance at 450 nm was followed for 5 min. The rate of decrease in absorbance was used as a measure of enzyme activity. One unit of enzyme activity produces a change of 0.001/min at 25 °C at 450 nm. Free PEG or rat plasma had no effect on this assay.

SC-PEG-5000 (**12**) was synthesized according to published procedures (20).

Modification of Lysozyme by PEG. In a typical reaction, activated PEG (**6** or **12**) was added to lysozyme (5 mg/mL), at the indicated molar ratio, in 0.1 M phosphate buffer, pH 7.8. The reaction was quenched by lowering the pH to below 6 with acetic acid; free PEG was removed by ultrafiltration. The amount of the modification was adjusted by changing the molar ratios of PEG to protein in the reaction. Fractionation of individual species of PEG–lysozyme with varying degrees of modification was carried out by HPLC using a cation exchange column (Poros, 1-3 359-06) and a solvent system of 20 mM sodium-phosphate at pH 5.1 and a NaCl gradient.

Tryptic Peptide Mapping. Purified samples were oxidized with a performic reagent (0.912% formic acid, 0.015% hydrogen peroxide) (21), then lyophilized. The residual dry powder was resuspended at 1 mg/mL in 50 mM NaHCO₃, pH 8, 1 mM CaCl₂. The protease trypsin was added at a weight ratio of 1:100 of sample and digestion was conducted at 37 °C for 2 h. Fresh trypsin (1:50) was added and the reaction was continued for another 16 h. The digest was analyzed by reversed-phase HPLC, using a C18 column (Vydac, 218TP54) with a linear gradient of 0.1% TFA (trifluoroacetic acid) in water to 0.1% TFA in acetonitrile over 40 min at a flow rate of 1 mL/min.

Other Analytical Methods. SDS–polyacrylamide gel electrophoresis (PAGE) was used to distinguish conjugate species with different amounts of PEG. The electrophoresis was conducted using a polyacrylamide gel of 14% cross-linking and running buffer consisting of 0.29% Tris base, 1.44% glycine, 0.1% SDS at pH 8.3.

Compound 6. (A) A solution of 3,5-dimethyl-4-hydroxybenzaldehyde (5 g, 0.03 mol) in methanol (75 mL) was cooled to 0 °C and sodium borohydride (1.9 g, 0.05 mol) was added in several portions. The mixture was stirred for 30 min at 0 °C, allowed to warm to room temperature, and then stirred an additional 30 min HCl (4 mL) was added to the reaction solution and stirring continued for 10 min. The solvent was removed in vacuo and the residue dissolved in methanol (100 mL) and filtered. The filtrate was concentrated in vacuo and the residue dissolved in chloroform (1 L) and filtered. Removal of solvent gave the product, 3,5-dimethyl-4-hydroxybenzyl alcohol (3.69 g, 81%), as a pale-yellow solid.

(B) A solution of T-PEG 5000 (**25**) (18 g, 3.6 mmol), 3,5-dimethyl-4-hydroxybenzyl alcohol (2.2 g, 14.5 mmol) and 4-(dimethylamino)pyridine (1.8 g, 14.5 mmol) in anhydrous methylene chloride (90 mL) was refluxed overnight. Solvent was removed by distillation in vacuo, and the residue recrystallized from 2-propanol to yield 15 g (83%) of 3,5-dimethyl-4-hydroxybenzyl alcohol PEGylated exclusively on the phenolic OH: ¹³C NMR (67.80 MHz, CDCl₃) δ 15.75, 58.33, 63.38, 67.59, 68.73–71.31 (PEG), 126.45, 129.17, 138.77, 146.05, 167.66.

(C) The product from **(B)** (2.0 g, 0.4 mmol) and disuccinimidyl carbonate (0.2 g, 0.8 mmol) were dissolved in anhydrous methylene chloride (25 mL). The reaction flask was sealed with a rubber septum and cooled to 0 °C. Pyridine (32 μL, 0.4 mmol) was added to the mixture, which was stirred at 0–4 °C overnight. Cold ethyl ether was added to the solution at 0 °C and the solid filtered. The crude product was dissolved in anhydrous methylene chloride (10 mL) and the solution dried over anhydrous MgSO₄. The product was recrystallized from chilled methylene chloride–ether, two times, to give **6** (1.6 g, 80%): ¹³C NMR (67.80 MHz, CDCl₃) δ 15.99, 25.07, 58.63, 67.84, 67.93–71.79 (PEG), 77.19, 128.59, 130.39, 130.66, 147.92, 151.20, 167.77, 168.32.

RESULTS

Lysozyme was PEGylated to different degrees in order to characterize the release of PEG from a range of conjugates under various conditions (Table 1). First, lysozyme was conjugated with rPEG linker **6** (Scheme 3) and permanent linker (**12**, Figure 1) for comparative purposes. When rPEG was used at a 3–6-fold molar ratio with respect to lysozyme, the protein was lightly PEGylated (**7a**), with the majority of the protein having 1–3 rPEGs attached. When rPEG was used at a 10-fold molar ratio, lysozyme was moderately modified (**7b**) with 2–4 rPEGs attached. With a 20–30 molar excess of rPEG linker, the protein was highly modified (**7c**), with the majority of the protein possessing 4–6 rPEG strands. Figure 2a shows the mobility patterns in SDS–PAGE of different preparations of lysozyme, which were PEGylated lightly (**7a**), moderately (**7b**), or heavily (**7c**) using rPEG **6**. Figure 2b shows the single stranded rPEG–lysozyme (**7d**), and two-stranded rPEG–lysozyme (**7e**) used in some of the following studies. The reaction conditions, reaction rate, and SDS–PAGE patterns were similar for conjugates prepared with either rPEG or SC–PEG (Figure 2c). The reaction product typically consisted of a mixture of PEGylated species which were separated by HPLC (see Experimental Section). To more closely examine the details of release, purified subpopulations of rPEG–lysozyme with one or two PEG molecules were isolated (Figure 2b).

As conjugate **7** releases rPEG, its size is expected to diminish. Thus, the size distribution of rPEG–lysozyme conjugates can be used as evidence of the release of PEG. When all PEG molecules are cleaved from **7**, the residual protein should have the same size as native, unmodified lysozyme. This was evident from SDS–PAGE where the completely hydrolyzed rPEG–lysozyme resulted in a material that had the same molecular weight as native lysozyme. The rate of release of PEG for the particular rPEG-linker employed in this study was dependent on several factors, including pH, temperature, and the number of PEGs attached to the protein. As shown in Figure 3, release of PEG, as expected, was faster at higher pH. Lightly rPEGylated lysozyme **7a** released a small amount of PEG under physiological

conditions (PBS buffer at pH 7.4, 37 °C), while moderately rPEGylated-lysozyme **7b** was completely stable under the same conditions (not shown). When lightly rPEGylated-lysozyme **7a** was incubated in buffer at 37 °C and pH 9, all species originally present were reduced to a mixture of singly rPEGylated and native enzyme over a 24 h period. PEG was released significantly more rapidly at higher temperature (Figure 4).

The release of lysozyme from rPEG conjugates in rat plasma was also studied. SDS-PAGE patterns were difficult to interpret due to interference by rat plasma proteins, so lysozyme enzymatic activity was used to follow PEG release. Specifically, there was no activity initially observed for all samples of **7** that were free of native lysozyme (see time zero in Figure 5 for **7a**). As mentioned previously, lightly rPEGylated lysozyme (**7a**) when incubated in PBS at 37 °C produced only trace amounts of native enzyme, amounting to <3.5% recovery of the original enzyme activity after 24 h. On the other hand, 64% of the activity was recovered upon incubation in pH 9 buffer, over the same time period (Figure 5). With mono-PEGylated rPEG-lysozyme (conjugate **7d**), 50% of the enzyme activity was recovered after incubation in rat plasma at 37 °C for 20 h, and 100% of the activity was recovered after 96 h (Figure 6). When incubation of di-PEGylated rPEG-lysozyme (**7e**) was carried out under

Figure 4. Fast release of rPEG from **7a** at high pH and temperature. **7a** was treated with pH 9 borate buffer at 50 °C. Lane 1, molecular weight marker; lane 2, **7a**; lane 3, hydrolysis of **7a** after 22 h.

similar conditions, only 10% of the enzyme activity was recovered after 20 h, 50% after 57 h, and 100% of the activity was observed after 96 h (Figure 7). Note that during this same period, there was almost no recovery of activity from conjugate **7d** in PBS buffer. Since the

Figure 6. Regeneration of lysozyme from **7d** (rPEG1-lysozyme) in plasma. Compound **7d** was incubated in rat plasma and the activity regenerated was compared with the same sample incubated in phosphate buffered saline.

Figure 7. Regeneration of lysozyme from **7e** (rPEG2-lysozyme) in plasma. Compound **7e** incubated in rat plasma and the activity regenerated was compared with the same sample incubated in phosphate buffered saline.

hydrolysis rate is much slower in buffer than in plasma, the release is likely due to nonspecific enzymatic cleavage in plasma of the ester trigger of the conjugate.

In summary, after 22 h at 50 °C in pH 9 buffer, heavily PEGylated rPEG-lysozyme conjugate **7c** exhibited an SDS-PAGE pattern (not shown) that still contained more PEGylated species than was observed after similar treatment of the lightly PEGylated conjugate, **7a** (Figure 4). These results demonstrated that more heavily rPEGylated conjugate released PEG more slowly than the lower conjugate. This phenomenon was studied with the well-defined compounds **7d** and **7e**. The release kinetics of **7d** was much faster than that of **7e** (Figures 6 and 7).

In order for an rPEG protein conjugate to demonstrate effective drug delivery, activity must be regenerated before the protein is eliminated from the body by renal and hepatic clearance pathways. Published results indicate that the circulating $t_{1/2}$ of PEGylated proteins of similar molecular weight as lysozyme is about 10–30 h (3, 22). As can be seen from the data, PEG release from lysozyme **7d** in rat plasma will be in excess of 50% after 20 h which fits the appropriate time frame for delivery of native protein in a controlled fashion.

In plasma, recovery of 100% of enzyme activity was observed from **7d** after PEG was completely removed from the rPEG-lysozyme conjugate, which strongly implies that the released enzyme was identical to **1**. To prove this hypothesis, peptide mapping was used to verify the structural integrity of the regenerated enzyme.

Tryptic digestion followed by reversed-phase HPLC generates a characteristic pattern of fragments from the

Figure 8. Comparison of peptide map of released lysozyme and native lysozyme analyzed by HPLC at 214 nm. (a) Native lysozyme, (b) **7a**, (c) Regenerated lysozyme from **7a**.

native lysozyme. Fragmentation allowed the PEGylation and the recovery process after release of rPEG to be monitored (Figure 8). A similar approach has been used to characterize PEG-lysozyme (23).

In our system, the size of the group of peaks eluted at 5.23, 12.56, 13.69, 14.44, and 15.95 relative to the peak eluted at 23.13 was particularly useful in characterizing

PEGylation and release. The peak at 15.95 was drastically reduced after PEGylation. After the release of PEG, this peak returned to its original size, as shown in Figure 8, panels a–c. In fact, the peptide map of the regenerated lysozyme was the same as that of the original native enzyme, indicating the equivalence of the proteins.

Several additional analytical methods were used to compare unmodified lysozyme with lysozyme released from the rPEG–lysozyme conjugate. The isoelectric focusing pattern of the regenerated lysozyme was shown to be the same as that of native lysozyme. The amount of free amine as measured by the trinitrobenzenesulfonic acid assay was also found to increase proportionally during release of lysozyme from the rPEG conjugate. Re-PEGylation of the regenerated lysozyme with **6** resulted in newly conjugated species similar to the original rPEG-medium fraction, demonstrating restoration of PEGylation sites. Furthermore, the pH profile of the enzymatic activity of **1** was the same as that of the regenerated lysozyme, indicating that the microenvironment of the catalytic site on the enzyme was restored. In addition, the amino acid composition of the regenerated protein and that of the native protein were found to be identical. From these data, we conclude that there was a quantitative release of unstable intermediate **8**, which rapidly regenerated protein that was identical to the native species.

DISCUSSION

The degree of loss of activity when PEG is attached to a protein typically depends on the number of PEG strands attached to the protein. This loss of activity after PEGylation also depends on the site of PEGylation, the protein structure, and the protein charge (1, 2). A high PEG number may produce a longer plasma half-life, but often at the expense of protein activity. Releasable PEG, exemplified by the linker **6**, allows a high degree of PEGylation of protein with the temporary masking of activity, followed by restoration of activity by a defined mechanism.

We observed that attachment of even one PEG is sufficient to abolish the cell-wall degradation activity of lysozyme. Since the cell wall material is considerably larger than lysozyme, the contact of the enzyme with its substrate should be a relatively flat surface, rather than a deep groove. Thus, PEG covalently attached to lysozyme may prevent the proper docking of the substrate to the enzyme resulting in inhibition of activity. So et al. (23), reported 38% residual activity in lysozyme conjugated to mPEG via a different linker, while data reported by others (15) are consistent with almost total loss of activity for another PEG–lysozyme conjugate. The nature of the linking group is therefore of paramount importance in determining the enzymatic activity of PEG–lysozyme conjugates.

In addition to its cell wall degradation activity, lysozyme has weak esterase activity (24, 25). If this esterase effect was involved in cleavage of rPEG–lysozyme conjugates, then accelerating release kinetics would be expected as accumulating free lysozyme catalyzed cleavage of the remaining conjugates. However, we observed linear release kinetics for the rPEG conjugates, suggesting that the lysozyme esterase activity had little effect on the PEG release rate. Therefore, regeneration of lysozyme is most likely the result of encountering other enzyme systems in plasma.

The observed release rate of protein from conjugates **7d** and **7e** is slower than release rates of small molecules

such as daunorubicin from similar rPEG linkers (18), which generally occurs with a $t_{1/2}$ of about 2 h in rat plasma. Since **7e** had $t_{1/2}$ of hydrolysis approximately three times longer than **7d** in rat plasma, this would seem to indicate that steric factors must also be considered in the enzymatic cleavage.

The clearance $t_{1/2}$ of a protein in blood can be controlled by changing the apparent molecular size of the protein. Attachment of PEG to the protein, which increases the apparent molecular weight, results in a longer clearance $t_{1/2}$ while providing reduced immunogenicity for the conjugate. While this has generally been accomplished using activated linkers such as SC–PEG and T–PEG (25) providing permanently bonded PEG–protein conjugates, rPEG-linkers provides an alternative to these methods. While there are other means of delivering proteins in vivo, such as liposomes or hydrogels, these formulations are difficult to implement due to problems in loading of the protein and administration of the dosage form. rPEG conjugates of proteins derived from activated rPEG **6**, act as a circulating depot or carrier for the protein drug and should thus be a very useful tool for drug delivery.

Our data supports the concept of releasable PEG that predictably generates native protein from the PEG conjugate. Application of this (and similar) technology (26) to other therapeutic proteins, and their in vivo results, will be the subject of future publications. Typically, this involves rPEG-linkers that react with free amine groups present in the protein. In addition to serving as a releasable carrier, rPEG may also be used as an aqueous derived amino-protecting group on or near the active site of the protein. This can be followed by the attachment of permanently bound PEG at other sites of the protein where PEGylation is less critical to the biological activity of the protein to produce what can be termed a “PEG-hybrid”. Once permanently bonded PEG is attached, the releasable PEG can then be removed during processing, leaving a nonimmunogenic conjugate with fewer strands at less active sites and therefore, greater activity. Alternatively, the hybrid conjugate can be used directly in vivo (27), further enhancing the duration of activity of the protein pharmaceutical. Proof of this concept has been demonstrated using dimethyl maleic anhydride to block the active lysines of TNF- α , followed by PEGylation. Pretreatment in this fashion gives conjugates with 20–40% higher specific activity in vitro than directly conjugated PEG–TNF- α (28).

CONCLUSIONS

Our results show that the use of rPEG-linker **6** with the protein lysozyme produces conjugates of various degrees of PEGylation whose pH and enzymatic breakdowns are easily measurable. Lysozyme activity is completely recovered compared to the 50–60% reported by others (15), which indicates that there is no denaturation of the protein during PEGylation and the subsequent hydrolysis of rPEG conjugate **7**. In addition to the controlled release observed for rPEG conjugates, one needs to consider other properties generally required for clinically acceptable pharmaceutical preparations. For long term storage, rPEG–protein conjugates can be lyophilized and reconstituted prior to use. Since protein drugs are normally prepared in aqueous solutions, rPEG conjugates must be stable in physiological buffer solution for up to 24 h: this has been demonstrated for rPEG–protein **7**. In addition, we have shown that **7d** has a regeneration rate comparable to the blood circulation half-life of protein that was modified by a permanently

bound PEG. Thus, rPEG **6** has the potential to be used in practical ways by extension of this system to other proteins such as enzymes and cytokines, which should provide a depot of protein drug in the rPEG form. The depot effect should benefit the treatment of cancer, thrombosis, cardiovascular diseases, and autoimmune diseases with protein drugs. It should also help to reduce side effects due to the spiking caused by large amounts of native protein drug delivered in a short period of time.

ACKNOWLEDGMENT

We wish to express our deep gratitude to Dr. Yun Choe for her expert assistance in preparing this manuscript.

Received June 13, 2000; Revised Manuscript Received December 1, 2000

Two linear polyamide conjugates of $\text{Gd}(\text{DTPA})^{2-}$ were synthesized and characterized by high-resolution nuclear magnetic resonance (NMR) spectroscopy and size exclusion chromatography (SEC). DTPA was copolymerized with two different diamines, 1,6-hexanediamine and *trans*-1,4-cyclohexanediamine, yielding the polymers DTPA-HMD and DTPA-CHD, with low polydispersity. Their molecular flexibility in solution was studied using ^{13}C spin–lattice relaxation time measurements, indicating that the cyclohexanediamine linking moiety of the DTPA-HMD polymer is more rigid than that of DTPA-CHD. The influence of the flexibility of the linking functionalities on the relaxivity of the Gd^{3+} -DTPA-polymer conjugates was studied by water nuclear magnetic relaxation dispersion (NMRD). The relaxivity of the $\text{Gd}(\text{DTPA-CHD})$ polymer was only slightly higher than that of the $\text{Gd}(\text{DTPA-HMD})$ polymer, and only two times higher than the usual values for small Gd -DTPA-like chelates. The low relaxivities obtained for both polymers, much lower than expected from the polymer apparent molecular weights, result from their substantial residual flexibility, and also from a too long, nonoptimal, value of the inner-sphere water exchange rate. These polymeric compounds are also cleared very quickly from the blood of rats, indicating that they are of limited value as blood pool contrast agents for MRA.

INTRODUCTION

Contrast agents (CAs) for magnetic resonance imaging (MRI) are mainly chelates of Gd^{3+} , due to its high magnetic moment and long electronic relaxation time (1–4). A $\text{Gd}(\text{III})$ -bound water which exchanges with the bulk water of the body, determines via the enhancement of the relaxation (T_1 and T_2) of the water protons, the intensity of the water signal and thus the contrast of the images. The relaxation theory predicts that higher relaxation rates are obtained upon increase of the rotational correlation time of the Gd^{3+} complexes (1–4), which may be achieved by noncovalent or covalent binding of low-molecular weight Gd^{3+} chelates to macromolecules or polymers (3, 4). These conjugates might have prolonged residence time in the cardiovascular system, with potential applications in MRI Angiography (MRA) (5, 6).

In fact, in the past few years there has been a great interest in the development of efficient, nontoxic, blood pool CAs for MRA examinations. For this purpose, low molecular weight Gd^{3+} -chelate complexes, such as $\text{Gd}(\text{DTPA})^{2-}$ or $\text{Gd}(\text{DOTA})^-$, have been conjugated to natural or synthetic polymeric materials, like polysaccharides (7–

16), albumin (17,18), polyamino acids such as polylysine and polyornithine (19–25) or dendrimers (26). Some linear polymers of DTPA have also been prepared in which the chelate is incorporated directly in the polymeric chain (27–29). These macromolecules lead to an increase in blood pool lifetime and should be more efficient in respect to their relaxivity, as a consequence of their increased rotational correlation time resulting from their high molecular weight. However, the observed increase of their relaxivity was not as high as expected, which was attributed to a combination of two effects: the rapid internal rotational motion of the linking moieties between the Gd^{3+} -chelate in the polymeric chain and too long inner-sphere water exchange rates. The fact that dendrimer-based contrast agents show higher relaxivities compared to other systems confirms that more rigid structures lead to more efficient macromolecular contrast agents (26).

Here we report the synthesis, physicochemical characterization and in vivo pharmacokinetics in Wistar rats of two linear polyamide conjugates of $\text{Gd}(\text{III})$ -DTPA, $\text{Gd}(\text{DTPA-HMD})$, and $\text{Gd}(\text{DTPA-CHD})$ (see their structures in Figure 1), obtained by copolymerization of DTPA with two different diamines, the linear and conformationally flexible 1,6-hexanediamine and the cyclic and conformationally more rigid *trans*-1,4-cyclohexanediamine. The influence of the molecular flexibility of the respective functionalities on the relaxivity of the $\text{Gd}(\text{III})$ -DTPA-polymer conjugates is also reported and compared with other systems from the literature. As macromolecular polyamides, they should be biodegradable and biocom-

patible, and their Gd^{3+} complexes should in principle be promising as NMR angiography (MRA) contrast agents.

EXPERIMENTAL PROCEDURES

Reagents. Diethylenetriamine pentaacetic acid (DTPA) 97% purity, $GdCl_3 \cdot 6H_2O$, *trans*-1,4-cyclohexanediamine (CHD) and 1,6-hexanediamine (HMD) were purchased from Aldrich and used as supplied. Acetic anhydride, pyridine and dimethyl sulfoxide, also from Aldrich, were dried over 3 Å molecular sieves before use.

Synthesis and Characterization of DTPA Copolymers and Gd^{3+} Conjugates. *Preparation of DTPA-bis-Anhydride (DTPA-BA).* A modification of procedure described in the literature (28, 30) was applied: 0.125 mol of DTPA was mixed with 0.558 mol of dried acetic anhydride and 0.770 mol of dried pyridine. The resulting suspension was stirred for 24 h at 65 °C. Then the solid obtained was filtered, washed with dried diethylether and dried under vacuum, until constant weight at 25 °C. The DTPA-bis-anhydride was characterized by NMR. ^1H NMR ($DMSO-d_6$) δ (ppm) 3.7 (s,8H), 3.29 (s,2H), 2.43 (t,4H), 2.58 (t,4H); ^{13}C NMR ($DMSO-d_6$) δ (ppm) 171.9, 165.7, 54.5, 52.5, 51.7, 50.7. This product was considered sufficiently pure to be used in the preparation of the polymers.

Polymerization of DTPA-BA with HMD. In a round-bottom flask, 6 mmol of DTPA-BA were dissolved in 30 mL of DMSO and an equimolar amount of HMD was added. The mixture was heated at 70 °C under N_2 bubbling. Over a period of 3 h a large part of the solvent was slowly distilled under N_2 at reduced pressure (70 °C). The product was precipitated in acetone, filtered, and dissolved in 20 mL of distilled water. The solution was dialyzed for 3 days, using a MWCO 12–14000 Membrane purchased from Medical, London, U.K., and lyophilized to give 0.33 g of polymer (11.6%).

Polymerization of DTPA-BA with CHD. The same procedure as described above was followed except that 5.6 mmol of DTPA-BA and of CHD were used. After lyophilisation, 0.63 g of polymer was obtained (24%).

Preparation of the Gd^{3+} Conjugates. The polymers were dissolved in a small amount of distilled water and equimolar amounts of an aqueous solution of $GdCl_3$ were added dropwise with stirring, for the period of 1 h. The pH was maintained at 5.8 by the addition of 0.1M NaOH. The solutions were dialyzed until no free Gd^{3+} was detected, using xylenol-orange as indicator. The samples were then lyophilized.

Determination of Gd^{3+} . The metal content (%) in the polymer conjugates was determined by inductively coupled

plasma optical emission spectroscopy (ICP-OES), using a Jobin Yvon-Jy 70 Plus spectrometer.

The metal binding to the polymers was also determined by titration of aqueous solutions (D_2O) of those polymers with solid aliquots of $GdCl_3$ while maintaining neutral pH by addition of aqueous NaOH. The formation of the complex was monitored by measuring the shift of the ^{17}O NMR signal of water at 348 K (2, 16). The presence of unbound Gd^{3+} was readily detected by a dramatic increase in the chemical shift and width of the signal. Then, evaluation of the titration data allowed for determination of the percent of DTPA binding moieties of the polymer complexed to Gd^{3+} .

NMR Measurements. ^1H (499.824 MHz), ^{13}C (125.697 MHz), and ^{17}O (67.760 MHz) NMR spectra were recorded on a Varian Unity 500 spectrometer (at an external field of 11.8 T) in D_2O (99.8% D from Sigma Chem. Co.) solutions. For the ^1H NMR spectra, the water signal was used as internal reference, set at δ 4.75 ppm (at 298 K) and was suppressed by a presaturation pulse. ^{13}C NMR spectra were measured with broad-band proton decoupling, using the methyl resonance of TSP (sodium-3-trimethylsilylpropionate-2,2–3,3- d_4) as internal reference, set at δ = 0 ppm. ^{13}C NMR spin–lattice relaxation time (T_1) values were measured using the inversion–recovery technique. Assignments of the ^1H and ^{13}C NMR spectra were based on literature data for similar systems (28, 31) and on the results of two-dimensional homonuclear correlation spectra (COSY). The pH of the solutions was adjusted with DCl and CO_2 -free NaOD (from Sigma Chem. Co.) using a Crison MicropH 2002 pH-meter with an Ingold 405-M5 combined electrode. The temperature precision of the experiments was ± 0.5 °C.

SEC Measurements. The apparent molecular weights of the polymers were determined by size-exclusion chromatography (SEC) using two series of Pl-Aquagel-OH-30 columns (from Polymer Laboratories) coupled to a LC-25 RI detector. The eluent was 0.2 M NaCl. Systematic errors in the molecular weight determinations, leading to apparent values result from the charges of the polymers. The weight-average molecular weight (M_w) and number-average molecular weight (M_n) of the polymers are given by the expressions $M_w = (SN_i M_i^2)/(SN_i M_i)$ and $M_n = (SN_i M_i)/(SN_i)$, where N_i is the number of molecules of molecular weight M_i . M_w and M_n were calculated using a calibration curve of poly(ethylene glycol) standards obtained using a software program, EzChrom Chromatography V6.6, Scientific Software, Inc. The M_w/M_n ratio, named polydispersity, which is a measure of the width of the molecular weight distribution, was also calculated.

Relaxometry Studies. The chelates were dissolved in ultrapure H_2O and the water T_1 relaxation times of the solutions were measured at 9 MHz and 298 K using an MRS-4 relaxometer (Jozef Stefan Institute, Ljubljana, Slovenia), using an inversion recovery pulse sequence (180° – t – 90°) with eight delay times. The relaxivity was determined by calculating the slope of the curve of relaxation rate ($1/T_1$) versus Gd^{3+} concentration (mmol/L).

Proton nuclear magnetic relaxation dispersion (NMRD) profiles were recorded at 310 K on a field cycling relaxometer (Field Cycling Systems, Honesdale, PA) working between 0.02 and 50 MHz. Additional points at 60 and 300 MHz were obtained on a Bruker Minispec mq60 (Bruker, Karlsruhe, Germany) and on a Bruker AMX 300 spectrometer (Bruker, Karlsruhe, Germany). Fitting of the ^1H NMRD curves was performed with a previously described software using minimization routines (Minuit, CERN Library) (32, 33).

Figure 2. ^1H NMR spectra of the copolymers: (A) DTPA-HMD polymer obtained in $\text{D}_2\text{O} + \text{NaOD}$ (57.2 mg/mL) at 25 $^\circ\text{C}$, pH 10.71; (B) DTPA-CHD polymer obtained in $\text{D}_2\text{O} + \text{NaOD}$ (41.6 mg/mL) at 25 $^\circ\text{C}$, pH 11.2

Pharmacokinetics. The pharmacokinetic studies were carried out according to the following protocol: the Wistar rats were anesthetized by i.p. injection of Nembutal (100 $\mu\text{L}/100$ g b.w.), the carotid artery was catheterized for rapid blood collection, 200 μL of contrast agent were injected in the blood through the femoral vein; blood samples (± 300 $\mu\text{L}/\text{sample}$) were collected 1, 2, 5, 10, 15, 30, 45, and 60 min. afterward; the longitudinal relaxation rate R_1 was measured at 39 $^\circ\text{C}$ on a spin analyzer PC120 (Bruker, Rheinstetten, Germany) on each sample.

RESULTS AND DISCUSSION

The copolymers of DTPA obtained were synthesized by an easy method that leads to polyamides. After purification, these polymers were found to be water soluble. The structure of both polymers is represented in Figure 1. Their ^1H NMR spectra, shown in Figure 2, have narrow peaks suggesting that the polymers present are rather flexible. The assignments of the ^1H signals were based on their intensities, multiplicities and chemical shifts, and confirmed by ^1H -COSY spectra. The assignments of the methylene protons of the DTPA moiety were obtained from the previously described proton NMR titration

curves of DTPA derivatives (31). In spectrum B, we can observe the polymeric species corresponding to two conformations. The substitution groups in cyclohexane are mainly in diequatorial configuration because of the effect of 1,3-diaxial interactions. However, due to the partial double bond character of the amide $\text{N}-\text{C}$ bonds, the repeated unit in the polymer can be in three conformations, which are E,Z, E,E, and Z,Z (Figure 3). Only two sets of signals, with intensity ratios 4.9:1, were observed in the ^1H NMR spectrum. An inspection of molecular models suggests that the steric strain in the three possible configurations of the disubstituted cyclohexane moieties follows the order $\text{E,E} > \text{E,Z} > \text{Z,Z}$. Therefore, we assign the two sets of signals to the E,Z and Z,Z configurations, and we assume that the population of the E,E configuration is negligible. In the DTPA-HMD polymer only a single set of broad signals was observed, which can be explained by the fast exchange between the isomers on the NMR time scale.

Figure 4 shows the proton decoupled ^{13}C NMR spectra of the two polymers, which were assigned on the basis of the pH dependence of their chemical shifts and previous work on small DTPA-bisamides (34). For the DTPA-CHD

Figure 3. E,Z, E,E, and Z,Z conformations of the *trans*-1,4-cyclohexanediamine in the DTPA-CHD polymer.

polymer, we see two sets of resonances for carbons a–f. This is in agreement with the ^1H NMR data.

Table 1 shows the ^{13}C NMR T_1 values, obtained for the two polymers. These values are rather long for the ester and carboxylate carbons, due to the absence of efficient dipolar relaxation from neighboring protons. It is more instructive to compare the T_1 values for the CH_2 carbons, where the ^{13}C relaxation rates ($1/T_1$) are proportional to an effective local rotational correlation time, which modulates the dipolar interaction between the ^{13}C and the directly bound protons, reflecting the local mobility of the molecule (35). This relationship is valid for local rotational correlation times smaller than 10^{-9} s (36) and can be applied to polymers that have fast internal motions. Here we see that, for both polymers, the

methylene carbons of the DTPA moieties have the same mobility. This mobility is smaller than that of the linking chain for the DTPA-HMD polymer, but the same for the DTPA-CHD polymer. This surprising result may be a consequence of the slower overall tumbling rate of the second polymer, with its larger molecular weight, rather than of the local mobility of the linking moieties. However, to correlate these data with the relaxivity of the macromolecular complexes we have to take into account the mobility of the DTPA moiety and the correlation time of the water proton.

The SEC chromatograms of our samples of the two polymers and of their Gd^{3+} complexes, obtained using an eluent of high ionic strength, are shown in Figure 5. The results of their analysis (Table 2) show that the DTPA-

^a Present work.

HMD and DTPA-CHD polymers have very similar apparent molecular weights and low polydispersities, indicating that they are quite homogeneous, as we can observe in the SEC chromatograms in Figure 5. A reduction in the apparent molecular weight values of both polymers can be observed after Gd^{3+} complexation, and their low polydispersity slightly increases. The molecular weights of DTPA-HMD and DTPA-CHD must be lower than those of the corresponding Gd^{3+} complexes, due to the contribution of the cation. Thus, the observed reduction of the SEC-measured apparent values for the complexed polymers should be a result of the neutralization of charge of the DTPA polymers when bound to Gd^{3+} . In fact, even using an high ionic strength eluent (0.2 M NaCl), the repulsion forces between the negatively charged polymer carboxylate groups increase the hydrodynamic volumes of the polymeric chains, leading to lower elution volumes and over-evaluated molecular weights. This is confirmed by the observation that using a low ionic strength eluent (0.01 M NaCl), the apparent molecular weights of the of DTPA-HMD and DTPA-CHD polymers increased by a factor of 6, while those of their Gd^{3+} complexes increased only by a factor of 2 (data not shown). Thus, the determination of molecular weights for this type of compounds remains a difficult problem, casting some doubt on the reliability of some of the literature data.

The Gd^{3+} contents in the two polymers, as measured by ICP, are shown in Table 3. Similar Gd^{3+} contents were measured by Kellar et al. (29) for the Gd(DTPA-HMD) polymer. The Gd^{3+} yields obtained show that ca. 20 and 30% of the DTPA units in Gd(DTPA-CHD) and Gd(DTPA-HMD), respectively, are uncomplexed.

The Gd^{3+} yields, which give the percent of DTPA binding moieties of the polymers complexed to Gd^{3+} , were also determined by measuring the shift of the ^{17}O NMR signal of water at 348 K while titrating D_2O solutions of those polymers with solid aliquots of GdCl_3 at neutral

Gd(DTPA-HMD)	1.4×10^{-3}		9 ^c	27

^a Gd^{3+} yield defined as $[\text{Gd}^{3+}(\text{mol})/\text{repeating unit of polymer}(\text{mol})] \times 100$. ^b Present work. ^c Estimated from NMRD curve (27).

Figure 6. Plot of Gd(III) induced ^{17}O chemical shift of water (δ) versus the amount of $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ added for Gd^{3+} complexation titration of 44.8 mg of DTPA-CHD polymer in 0.6 mL of D_2O at 348 K.

pH (2). Figure 6 shows the plot resulting from a typical experiment with the DTPA-CHD polymer. The position of the break of the plot, indicating the presence of unbound Gd^{3+} gave a Gd^{3+} yield of 87% for the Gd(DTPA-CHD) polymer, a value in reasonably good agreement with that obtained for ICP data.

The relaxivities of the two Gd^{3+} polymers at 9 MHz and 298 K are also shown in Table 3. The relaxivities for the polymers were less than twice the value of $5.6 \text{ s}^{-1} \text{mM}^{-1}$, observed for the $\text{Gd}(\text{DTPA})^{2-}$ chelate itself in the same conditions. The relaxivity of Gd(DTPA-HMD) is quite similar to the value reported in the literature (29). As CHD has a more rigid structure than HMD, allowing only chain-chain conformational interconversions but no single C–C bond rotational motions, it should hinder the rotational motion of the DTPA-linking moieties in the polymeric chain. As can be seen in Table 3, the relaxivity of the Gd(DTPA-CHD) polymer was not as high as expected, being only slightly higher than that of the Gd(DTPA-HMD) polymer. This could result from the substantial residual flexibility of that polymer, and also from a nonoptimal value of the inner-sphere water exchange rate.

To be able to better understand the factors determining the relaxivity of these polymers, we undertook a full proton nuclear magnetic relaxation dispersion (NMRD) study of these systems. The proton NMRD profiles recorded at 310 K (see Figure 7) show a hump between 10 and 100 MHz characteristic of slowly tumbling paramagnetic complexes. The analysis of the proton relaxivity takes into account the outersphere (37) and the innersphere magnetic interactions (38, 39). For Gd(DTPA-HMD), the values evaluated from the NMRD profiles analysis at 310 K for the rotational correlation time τ_R , for the electronic parameters (τ_{SO} , the electronic relaxation time at low field, and τ_V , the correlation time modulating the electronic relaxation) and the residence time of the inner-sphere water molecule (τ_M) (see Table

Figure 7. Longitudinal proton relaxivity of Gd(DTPA-HMD) (0.45 mM) and Gd(DTPA-CHD) (0.424 mM) at 310 K.

Table 4. Parameters Obtained from the Fitting of the Proton NMRD Data Obtained at 310 K^a

	τ_{SO} (ps) ^b	τ_V (ps) ^c	τ_R (ps) ^d	τ_M (μ s) ^e
Gd(DTPA-HMD)	120	21	580	1.33
Gd(DTPA-CHD)	140	32	997	1.45

^a The following parameters were fixed: the distance between Gd³⁺ and the inner-sphere water proton ($r = 0.31$ nm), the distance of closest approach ($d = 0.36$ nm), the relative diffusion constant ($D = 3.5 \times 10^{-9}$ m² s⁻¹) and the number of inner-sphere water molecules ($q = 1$). ^b τ_{SO} = electronic relaxation time at low field. ^c τ_V = correlation time modulating the electronic relaxation. ^d τ_R = rotational correlation time. ^e τ_M = residence time of the inner-sphere water molecule.

4) are comparable to those reported by Toth et al. (27) (from this publication, a τ_M value of 1.03 ms can be calculated at 310 K for the compound with $n = 6$). The observed constancy of τ_M is in line with the general observation that derivatization has hardly any effect on the water exchange rate of bisamides, which limit the relaxivity values. The main difference between both compounds is the rotational correlation time, which is longer for Gd(DTPA-CHD) than for Gd(DTPA-HMD). The τ_R values obtained by the fitting of the proton NMRD curves are shorter than those expected for such polymers and are indicative of internal motion. Therefore, the unexpectedly low relaxivity of these polymers can be explained by their relatively short τ_R and the long residence time of their inner-sphere water molecules.

The present results show that introducing short, conformationally rigid DTPA-linking moieties does not prevent the fast local motions in the extended polymeric chain, which dominate τ_R and keeps the relaxivity low. Other studies with this type of DTPA copolymers, containing as linking units long hydrophilic poly(ethylene-glycol) (PEG) (40), or hydrophobic alkyl chains with a varying number (n) of methylenes (29), showed that higher relaxivities were obtained only for long hydrophobic chains with $n \geq 10$. For these polymers, hydrophobic interactions between different chains lead to intramolecular aggregates and the formation of more rigid compact, globular structures, with slower local motions and global rotation, leading to higher relaxivity (27, 29). Studies with other polymeric carriers (15, 16) have also shown that higher relaxivities are obtained for more rigid compact, globular structures, for example by increasing the degree of substitution of the carrier.

The results of pharmacokinetic studies of the two polymeric compounds Gd(DTPA-HMD) and Gd(DTPA-CHD) injected in Wistar rats are shown in Figure 8. This shows that both compounds exhibit a fast exponential clearance from the blood. With a blood half-life shorter

Figure 8. Pharmacokinetics of Gd(DTPA-HMD) and Gd(DTPA-CHD) in Wistar rats.

than 10 min, they show the same pharmacokinetic behavior as Gd(DTPA)²⁻, the extravascular/extracellular parent molecule.

CONCLUSIONS

We have obtained two main chain DTPA polymers by copolymerization of DTPA with two diamines of different structures and internal flexibilities. Despite the derivatization of two terminal carboxylate groups of each DTPA residue, with a somewhat reduced Gd³⁺ binding ability of the resulting amide moieties, the stability of the polymeric complexes should still be high enough to be used in vivo. This is supported by the observation that the reduced thermodynamic stability of small Gd³⁺ chelates of DTPA-bis amides relative to Gd(DTPA)²⁻ is compensated by their comparable or even favorable conditional stability constants and selectivity factors for Gd³⁺ relative to other biologically relevant cations such as Zn²⁺, leading to nonincreased in vivo dissociation of Gd³⁺ (31, 41, 42).

The Gd³⁺ complexes of the two polymers were obtained with Gd³⁺ yields of about 80 and 70% for Gd(DTPA-CHD) and Gd(DTPA-HMD), respectively, as measured by ICP. Solvent water ¹⁷O NMR shift monitoring of titration experiments of the polymers with solid GdCl₃ gave comparable results. The incomplete loading of the polymers with Gd³⁺, resulting in the presence of ca. 20–30% of uncomplexed, negatively charged DTPA units, while increasing their solubility and SEC-determined apparent molecular weights due to the negative charges present, will also contribute to an increased internal mobility and reduced relaxivities.

The Gd³⁺ macromolecular complexes show somewhat higher relaxivities than the small parent Gd³⁺ chelate, Gd(DTPA)²⁻. The rigidity of the cyclic diamide linking moiety did improve the relaxivity of the complexes in water, but not as much as expected. This may result from the short length of the linking groups, which prevents the hydrophobic interaction between polymeric chains and the formation of a compact polymer, as happens with similar polymers with longer chains in the linking groups (29). A substantial residual flexibility of those polymers may still be present. Alternatively, the local motions located at the linking groups in the polymer chains might be less important than those of the DTPA moieties in

determining the correlation time of the water molecule bound to the Gd^{3+} ion.

The rotational correlation time is longer for $Gd(DTPA-CHD)$ than for $Gd(DTPA-HMD)$, indicating a substantial decrease of the residual flexibility of the first polymer. However, the rotational correlation times obtained for these polymers are shorter than expected, indicating that internal motion is present. The low relaxivity of these polymers can thus be explained by their relatively short τ_R and the long residence time of the inner-sphere water molecule.

With a blood half-life shorter than 10 min., both compounds exhibit the same pharmacokinetic behavior as $Gd(DTPA)^{2-}$, the extravascular/extracellular parent molecule. Molecules with molecular weights lower than about 15 kDa pass freely through glomerular filtration in the kidneys. Large size polymers are usually cleared slowly from the blood because of a restricted glomerular filtration. However, the clearance has to be related not only to the molecular weight of the product but also to its spatial conformation. In the present case, the polymers are made of linear and flexible chains and are characterized by a molecular weight not large enough to prevent the glomerular filtration. Thus, although the polymers are stable in vivo for the short time they stay in circulation, the fast excretion properties severely restrict the applicability of this type of Gd^{3+} polymeric complexes as MRA contrast agents.

ACKNOWLEDGMENT

The authors thank Dr. Sophie Laurent and Mrs Corinne Piérart for their help in recording the relaxometric data. This work was supported by F.C.T., Portugal, through the Praxis XXI Project 2/2.2/SAU/1194/95 and the Grant BD/5056795 to M. G. Duarte, by the ARC Program 95/00-194 of the French Community of Belgium, the Fonds National de la Recherche Scientifique (FNRS) of Belgium and the E.U. Biomed II (MACE) project. This project was carried out within the framework of COST D8 and COST D18 E.U. programs.

Renal localization of radiolabeled antibody fragments constitutes a problem in targeted imaging and radiotherapy. Recently, we reported use of a novel radioiodination reagent, 3'-[¹³¹I]iodohippuryl *N* ϵ -maleoyl-L-lysine (HML), that liberates *m*-iodohippuric acid before antibody fragments are incorporated into renal cells. In mice, HML-conjugated Fab demonstrated low renal radioactivity levels from early postinjection times. In this study, renal metabolism of HML-conjugated Fab fragments prepared by different thiolation chemistries and by direct radioiodination were investigated to determine the mechanisms responsible for the low renal radioactivity levels. Fab fragments were thiolated by 2-iminothiolane modification or by reduction of disulfide bonds in the Fab fragments, followed by conjugation with radioiodinated HML to prepare [¹³¹I]HML-IT-Fab and [¹²⁵I]HML-Fab, respectively. In biodistribution studies in mice, both [¹³¹I]HML-IT-Fab and [¹²⁵I]HML-Fab demonstrated significantly lower renal radioactivity levels than those of [¹²⁵I]Fab. In subcellular distribution studies, [¹²⁵I]Fab showed migration of radioactivity from the membrane to the lysosomal fraction of the renal cells from 10 to 30 min postinjection. On the other hand, the majority of the radioactivity was detected only in the membrane fraction at the same time points after injection of both [¹³¹I]HML-IT-Fab and [¹²⁵I]HML-Fab. In metabolic studies, while [¹²⁵I]Fab remained intact at 10 min postinjection, both HML-conjugated Fab fragments generated *m*-iodohippuric acid as a radiometabolite at the same postinjection time. [¹³¹I]HML-IT-Fab registered two radiometabolites (intact [¹³¹I]HML-IT-Fab and *m*-iodohippuric acid), whereas additional radiometabolites were observed with [¹²⁵I]HML-Fab. This suggested that metabolism of both HML-conjugated Fab fragments would occur in the membrane fractions of the renal cells. The findings of this study reinforced our previous hypothesis that radiochemical design of antibody fragments that liberate radiometabolites that are excreted into the urine by the action of brush border enzymes would constitute a useful strategy to reduce renal radioactivity levels from early postinjection times.

INTRODUCTION

Antibody fragments such as Fab and single-chain Fv fragments show rapid targeting to tumor and uniform distribution in tumor tissues (1). Such properties render antibody fragments useful to deliver radioactivity for both targeted imaging and radiotherapy. However, radiolabeled antibody fragments show persistent localization of radioactivity in the kidneys, which impairs diagnostic accuracy in the kidney region and limits therapeutic potential (2–8). Thus, radiolabeled antibody fragments would become much more useful in diagnosis and targeted radiotherapy if the renal radioactivity could be reduced without impairing the radioactivity levels in the target.

Recent studies indicated that the persistent localization of the radioactivity after administration of radiolabeled antibody fragments and peptides was attributable

Figure 1. Chemical structure of [¹³¹I]HML.

to slow elimination rates of radiometabolites generated after lysosomal proteolysis of the parental Fab fragments in renal cells (7, 9–11). There have been a number of attempts to facilitate elimination of radiometabolites generated after lysosomal proteolysis of glomerularly filtered antibody fragments through the use of cleavable linkages between antibody fragments and radiolabeled compounds (12–14) (Figure 2A). Although the rationale behind the radiochemical design is well supported by recent metabolic studies as cited above, this approach may also impair target radioactivity levels when applied

Figure 2. (A) Potential mechanism of renal radioactivity localization of radiolabeled Fab fragments. Slow elimination rates of radiometabolites (■) from the lysosomal compartment would be responsible for the long residence time of the radioactivity in the kidney. (B) Proposed mechanism of renal metabolism of [¹³¹I]HML-IT-Fab. [¹³¹I]HML-IT-Fab would release *m*-[¹³¹I]iodohippuric acid (●) before the antibody fragments are incorporated into the renal cells by the action of the brush border enzymes.

to antibody fragments or peptides that are incorporated into target cells.

We recently reported that radioiodinated Fab fragments labeled with 3'-[¹³¹I]iodohippuryl *N*-maleoyl-L-lysine ([¹³¹I]HML, Figure 1) demonstrated markedly low renal radioactivity levels with kidney-to-blood ratios of 1 from 10 min to 1 h after injection into mice due to rapid release of *m*-[¹³¹I]iodohippuric acid. In addition, HML-conjugated Fab did not impair the radioactivity levels in the tumor when compared with directly radioiodinated Fab in nude mice model (15, 16). On the other hand, radioiodinated Fab via direct radioiodination reached its peak kidney-to-blood ratios of 7.3 at 1 h postinjection. Since the two simultaneously administered radioiodinated Fab fragments showed similar radioactivity levels in the blood, we hypothesized that [¹³¹I]HML-conjugated Fab fragments would release *m*-[¹³¹I]iodohippuric acid before the antibody fragments were incorporated into the renal cells (Figure 2B). That is, the glycyl-lysine sequence in HML would be cleaved by the action of the brush border enzyme carboxypeptidase M (17) present on the lumen of renal tubules (18, 19). Since high-level and persistent localization of the radioactivity is also observed with radiolabeled peptides, further investigation of the mechanism responsible for the low renal radioactivity levels of [¹³¹I]HML-conjugated Fab fragments would provide an insight for designing radiolabeled antibody fragments and peptides much more useful for both targeted imaging and radiotherapy.

In the present study, we investigated renal metabolism of [¹³¹I]HML-conjugated Fab fragments. Since esterase-mediated cleavage of the ester bonds is affected by the distance between the parental protein and the substrate

Figure 3. Preparation of radioiodinated Fab fragments. (A) [¹³¹I]HML-IT-Fab, (B) [¹²⁵I]HML-Fab, (C) [¹²⁵I]Fab. Reagents: (a) 2-IT, 0.16 M borate buffer/2 mM EDTA (pH 8.0); (b) [¹³¹I]-HML, 0.1 M phosphate buffer/2 mM EDTA (pH 6.0); (c) iodoacetamide, 0.1 M phosphate buffer/2 mM EDTA (pH 6.0); (d) 2-ME, 0.1 M phosphate buffer/2 mM EDTA (pH 7.0); (e) chloramine T, Na[¹²⁵I], 0.3 M phosphate buffer (pH 7.3).

(20, 21), radioiodinated HML was conjugated to Fab fragments via different thiolation chemistries to locate the glycyl-lysine sequence in HML at a position distal or close to the parental Fab fragments; Fab fragments were thiolated by reacting 2-iminothiolane (2-IT) with amine residues of the protein ([¹³¹I]HML-IT-Fab, Figure 3A) or by reducing the disulfide bonds with 2-mercaptoethanol (2-ME) ([¹²⁵I]HML-Fab, Figure 3B). Fab fragments were also directly radioiodinated by the chloramine T method ([¹²⁵I]Fab, Figure 3C) as a control. Subcellular localization and chemical forms of the radioactivity remaining in the kidney at early time points after injection of the three radioiodinated Fab fragments were investigated and the mechanism of renal metabolism of each radioiodinated Fab fragment will be discussed. The findings of this study provided further evidence that the low renal radioactivity levels of HML-conjugated Fab fragments are due to rapid release of *m*-iodohippuric acid before incorporation of the fragments into the renal cells.

MATERIALS AND METHODS

Reagents and Chemicals. Na[¹³¹I] and Na[¹²⁵I] were obtained from Daiichi Radioisotope Laboratories (Tokyo, Japan) and Daiichi Kagaku (Tokyo), respectively, and were diluted with 0.1 M phosphate buffer (pH 7.4) to 37 MBq (1 mCi)/2–10 μ L. Size-exclusion high-performance liquid chromatography (SE-HPLC) was performed with a Cosmosil Diol-120 column (7.5 $\times$ 600 mm, Nacalai Tesque, Kyoto, Japan) eluted with 0.1 M phosphate buffer (pH 6.8) at a flow rate of 1 mL/min. Reversed-phase HPLC (RP-HPLC) was performed with a Cosmosil 5C₁₈-AR-300 column (4.6 $\times$ 150 mm, Nacalai Tesque) eluted with a mixture of 0.1% aqueous phospho-

ric acid and acetonitrile (3:1) at a flow rate of 1 mL/min. The eluent was collected with a fraction collector (Redi-Frac; Pharmacia Biotech, Tokyo) at 30-s intervals, and the radioactivity levels in each fraction (500 μ L) were determined with an auto well counter (ARC-2000; Aloka, Tokyo). TLC analyses were performed with silica plates (Merck Art 5553). To facilitate collection of urine and feces after administration of radiolabeled Fab, mice were housed in metabolic cages (Metabolica, MM type; Sugiyama-Gen Iriki Co. Ltd., Tokyo). Other reagents were of reagent grade and were used as received.

Monoclonal Antibody (mAb). The mAb against osteogenic sarcoma (OST7, IgG₁), generated by the standard hybridoma technique, was purified by ammonium sulfate precipitation with subsequent protein A affinity chromatography (Pharmacia Biotech Co. Ltd., Tokyo), as reported previously (22). The Fab fragment was prepared by the standard procedure using papain (23).

Preparation of Radioiodinated Fab Fragments. [^{131/125}I]HML was prepared as described previously (21). Conjugation of [^{131/125}I]HML with the Fab fragment of OST7 was performed as illustrated in Figure 3.

[¹³¹I]HML-IT-Fab was prepared by treating the Fab fragment with 2-IT, followed by conjugation reaction between the thiol groups of Fab and the maleimide groups of [¹³¹I]HML (Figure 3A). Briefly, a solution of Fab (200 μ L, 2 mg/mL) in well-degassed 0.16 M borate buffer (pH 8.0) containing 2 mM EDTA was allowed to react with 7.2 μ L of 2-IT solution (1 mg/mL) prepared in the same buffer. After gentle agitation of the reaction mixture for 60 min at room temperature, excess 2-IT was removed by a centrifuged column procedure (24) using Sephadex G-50 (Pharmacia Biotech Co. Ltd.) equilibrated and eluted with 0.1 M phosphate buffer (pH 6.0) containing 2 mM EDTA. Aliquots of this mixture were sampled for estimation of the number of thiol groups with 2,2'-dipyridyl disulfide (25). The filtrate (100 μ L) was then added to a reaction vial containing crude [¹³¹I]HML. After gentle agitation of the reaction mixture for 1.5 h at room temperature, 14.8 μ L of iodoacetamide (10 mg/mL) in 0.1 M phosphate buffer (pH 6.0) containing 2 mM EDTA was added. The reaction mixture was further incubated for 30 min to alkylate the unreacted thiol groups. [¹³¹I]HML-IT-Fab was subsequently purified by the centrifuged column procedure, equilibrated and eluted with 0.1 M acetate buffer (pH 6.0).

[¹²⁵I]HML-Fab was prepared by reducing disulfide bonds in the Fab fragment with 2-ME, followed by conjugation between Fab and [¹²⁵I]HML (Figure 3B). Briefly, a solution of Fab (200 μ L, 2 mg/mL) in well-degassed 0.1 M phosphate buffer (pH 7.0) containing 2 mM EDTA was allowed to react with 5.6 μ L of 10-fold diluted 2-ME solution using the same buffer and stirred gently for 60 min at room temperature. The experimental procedures for preparation of [¹²⁵I]HML-Fab after introduction of thiol groups were similar to those used for [¹³¹I]-HML-IT-Fab except that [¹²⁵I]HML was used in place of [¹³¹I]HML.

Direct radiodination of Fab was performed by the chloramine T method (Figure 3C) (15). To 100 μ L aliquots of Fab (2.5 mg/mL) in 0.3 M phosphate buffer (pH 7.3) was added 1 μ L of Na[¹²⁵I]. Chloramine T (0.1 mg/mL, 12.5 μ L), freshly prepared in the same buffer, was then added. After incubation of the mixture for 5 min at room temperature, [¹²⁵I]Fab was purified by the centrifuged column procedure, as described above.

Radiochemical purities of the radioiodinated Fab fragments were determined by SE-HPLC and TLC developed with a mixture of methanol and water (4:1).

Biodistribution of Radioiodinated Fab Fragments. In vivo studies were performed after simultaneous administration of a mixed solution of [¹³¹I]HML-IT-Fab and [¹²⁵I]HML-Fab or after injection of a solution of [¹²⁵I]Fab. Three mL of 0.1 M phosphate buffer (pH 7.4) containing 600 μ g of unmodified Fab were mixed with 10 μ L of each radioiodinated Fab fragment (12–13 μ Ci) prior to administration. The biodistribution of radioactivity after i.v. administration of each mixture in 6-week-old male ddY mice (27–30 g) (26) was monitored at 10 and 30 min and 1, 3, 6, and 24 h postinjection. Groups of five mice, each receiving 20 μ g of Fab fragments, were used for the experiments. Organs of interest were removed and weighed, and the radioactivity was determined with a well counter (ARC 2000). A window from 29 to 97 keV was used for counting ¹²⁵I, whereas a window from 280 to 440 keV was used for ¹³¹I. Correlation factors to eliminate crossover of ¹³¹I activity into ¹²⁵I were determined by counting ¹³¹I standard in each window. The crossover of ¹²⁵I into the ¹³¹I channel was negligible. To determine the amounts and routes of excretion of radioactivity from the body, mice were housed in metabolic cages for 24 h after administration of the respective preparation. Urine and feces were collected for 6 and 24 h postinjection, and the radioactivities were determined.

Subcellular Distribution of the Radioactivity. The subcellular distribution of the radioactivity in the kidney was determined 10 and 30 min after administration of 20 μ g of [¹³¹I]HML-IT-Fab, [¹²⁵I]HML-Fab, or [¹²⁵I]Fab, according to the procedures described previously (27), with slight modifications. At the indicated times, murine kidneys were isolated, minced, and homogenized in 4 vol of ice-cold 0.25 M sucrose buffered with 10 mM phosphate buffer (pH 7.4) with a Dounce homogenizer by hand (20 strokes). This was followed by two final strokes in an ice-cold Potter–Elvehjem homogenizer with a Teflon pestle at 800 rpm. The resultant 20% homogenate was centrifuged twice for 5 min each time at 340g at 4 °C. The isolated supernatant was layered on top of iso-osmotic (0.25 M sucrose) Percoll (Pharmacia Biotech Co. Ltd.) at a density of 1.08 g/mL. After centrifugation at 20000g (RP 30 rotor, Hitachi Co. Ltd., Tokyo) for 90 min at 4 °C, the gradient (1.02–1.14 g/mL) was collected in 14 fractions before analyses of β -galactosidase (28) and alkaline phosphodiesterase I (29) activities, density, and the radioactivity of each fraction.

Radiolabeled Species in the Kidney. The radio-labeled species remaining in the kidney at 10 and 30 min postinjection of each preparation were analyzed according to the procedure described previously (27). Briefly, each [^{131/125}I]-labeled Fab (20 μ g) was administered intravenously into mice. At 10 and 30 min postinjection, both kidneys were perfused in situ with cold 0.1 M Tris-citrate buffer (pH 6.5) containing 0.15 M NaCl, 0.02% sodium azide, 1 TIU/mL aprotinin, 2 mM benzamidine-HCl, 2 mM iodoacetamide, 1 mM phenylmethanesulfonyl fluoride, and 5 mM diisopropyl fluorophosphate before being removed. Each tissue sample was placed in a test tube and subjected to three cycles of freezing (dry ice–acetone bath) and thawing. After addition of 5 vol of the same buffer containing an additional 35 mM β -octyl-glucoside, the samples were homogenized with a Polytron homogenizer (PT10-35, Kinematica GmbH Littau, Switzerland) at full speed with three consecutive 30-s bursts on ice before centrifugation at 48000g for 20 min at 4 °C (Himac CS-120 Centrifuge, Hitachi Co. Ltd.). The supernatant

was separated from the pellet, and the radioactivity was counted. The kidney supernatant was analyzed immediately by SE-HPLC after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm (Nacalai Tesque). Each sample was also analyzed immediately by RP-HPLC and TLC after ultrafiltration with a 10 kDa cutoff membrane (Microcon-10, Amicon Grace, Tokyo). TLC plates were developed with a mixture of chloroform, methanol, and water (15:8:1). Under these conditions, protein-bound radioactivity, free iodine, *m*-iodohippuric acid, and *m*-iodobenzoic acid had R_f values of 0, 0.1, 0.45, and 0.65, respectively.

Radiolabeled Species in the Urine. The radio-labeled species excreted in the urine for 6 h postinjection of each $^{131}\text{I}/^{125}\text{I}$ -labeled Fab were analyzed by SE-HPLC after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm (Nacalai Tesque). After ultrafiltration with a 10 kDa cutoff membrane (Microcon-10), the urine samples were also analyzed by RP-HPLC and TLC developed with a mixture of chloroform, methanol, and water (15:8:1) for ^{131}I HML-IT-Fab and ^{125}I HML-Fab and by TLC developed with (a) a mixture of methanol and acetic acid (100:1) or (b) a mixture of methanol and 10% ammonium acetate (10:1) for ^{125}I Fab (30). In point a, monoiodotyrosine and free iodine had R_f values of 0.5 and 0.75, whereas in point b, R_f values were 0.55 and 0.80, respectively.

Radiolabeled Species in the Plasma. Blood samples were taken at 10 and 30 min after injection of ^{131}I HML-IT-Fab, ^{125}I HML-Fab, or ^{125}I Fab. Each sample was centrifuged at 800g for 15 min at 4 °C. The supernatant of each sample was analyzed by SE-HPLC after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm (Nacalai Tesque).

RESULTS

Preparation of Radioiodinated Fab Fragments.

Treatment of Fab fragments with 2-IT or 2-ME introduced 3.65 or 3.67 thiol groups per molecule of Fab, respectively, as determined by 2,2'-dipyridyl disulfide. Conjugation of $^{131}\text{I}/^{125}\text{I}$ HML with Fab fragments was performed by reacting the thiolated Fab fragments with maleimide groups of $^{131}\text{I}/^{125}\text{I}$ HML. After purification by the centrifuged column procedure, ^{131}I HML-IT-Fab was obtained with a radiochemical purity and specific activity of 98.5% and 62.5 $\mu\text{Ci}/\text{mg}$, respectively, as determined by SE-HPLC. Radiochemical purities and specific activities were 99.3% and 192 $\mu\text{Ci}/\text{mg}$ for ^{125}I HML-Fab, and 94.9% and 640 $\mu\text{Ci}/\text{mg}$ for ^{125}I Fab, respectively.

Biodistribution of Radioiodinated Fab Fragments. Two independent biodistribution studies were performed to achieve the results shown in Figure 4. One was performed after simultaneous administration of a mixed solution of ^{131}I HML-IT-Fab and ^{125}I HML-Fab and the other was performed after injection of directly radioiodinated Fab (^{125}I Fab). ^{125}I Fab showed the lowest radioactivity levels in the blood among the three, whereas the two HML-conjugated Fab fragments registered similar radioactivity levels. In the kidney, the two HML-conjugated Fab fragments showed much lower radioactivity levels than those of ^{125}I Fab. Although ^{125}I Fab showed the highest radioactivity levels (65% injected dose per gram; ID/g) in the kidney at 30 min postinjection, ^{131}I HML-IT-Fab and ^{125}I HML-Fab had no radioactivity peaks. ^{125}I HML-Fab demonstrated significantly higher radioactivity levels than those of ^{131}I HML-IT-Fab in the kidney at 10 and 30 min postinjection. Notable differ-

Figure 4. Biodistributions of radioactivity in mice after injection of ^{131}I HML-IT-Fab (●), ^{125}I HML-Fab (○), and ^{125}I Fab (▲). Significance was determined by unpaired Student's *t*-test [(*) $p < 0.01$; (**) $p < 0.05$ compared to ^{131}I HML-IT-Fab].

ences were not observed in other tissues, except for the uptake in the stomach observed with ^{125}I Fab (data not shown).

Subcellular Distribution of the Radioactivity.

Percoll density gradient centrifugation profiles of the radioactivity at 10 and 30 min after injection of ^{131}I HML-IT-Fab, ^{125}I HML-Fab, and ^{125}I Fab are shown in Figure 5. Both ^{131}I HML-IT-Fab and ^{125}I HML-Fab indicated major radioactivity peaks only at the density of 1.04–1.05 mg/mL at both 10 and 30 min postinjection. On the other hand, ^{125}I Fab showed migration of the radioactivity peak from the fraction with the density of 1.04–1.05 mg/mL to the fraction with that of 1.10 mg/mL from 10 to 30 min postinjection, respectively. The radioactivity peak at a density of 1.04–1.05 mg/mL was copurified with alkaline phosphodiesterase I activity, whereas that at a density of 1.10 mg/mL was copurified with β -galactosidase activity.

Radiolabeled Species in the Kidney. The supernatant of each kidney homogenate was extracted with efficiencies of over 90% for all experiments. The radio-labeled species in the kidney at 10 and 30 min postinjection of radioiodinated Fab fragments were analyzed by SE-HPLC (Figure 6). Although the kidney supernatants at both 10 and 30 min after injection of ^{131}I HML-IT-Fab showed only two radioactivity peaks at retention times of 16–17 and 31 min, the kidney supernatants of ^{125}I HML-Fab showed numerous radioactivity peaks. The majority of the radioactivity in the kidney supernatant after administration of ^{125}I Fab was detected at a retention time similar to that of intact ^{125}I Fab at both postinjection time points. Figure 7 shows RP-HPLC and TLC radioactivity profiles of the kidney supernatant at 10 min after injection of ^{131}I HML-IT-Fab or ^{125}I HML-Fab. The majority of the radioactivity in the kidney had a retention time of 8 min on RP-HPLC and R_f value of 0.45 on TLC, which were identical to those of *m*-iodohippuric acid (Figure 7, panels A and B). On the other hand, the kidney supernatants of ^{125}I HML-Fab showed

Figure 5. Subcellular fractionation of the radioactivity (●) in the kidney at 10 and 30 min after injection of radioiodinated Fab fragments. Gradients were collected in 14 fractions from the top of the gradient, assayed for the lysosomal enzyme β -galactosidase (▲) and the plasma membrane enzyme alkaline phosphodiesterase I (Δ), and density was measured (○).

two radioactivity peaks at retention times of 6 and 8 min on RP-HPLC and R_f values of 0.1 and 0.45 on TLC, respectively (Figure 7, panels C and D). Similar radiochromatograms were obtained when the kidney supernatant obtained 30 min after injection of radioiodinated Fab fragments was analyzed (data not shown).

Radiolabeled Species in the Urine. Figure 8 shows radiochromatograms of urine samples obtained for 6 h postinjection of $[^{131}\text{I}]\text{HML-IT-Fab}$, $[^{125}\text{I}]\text{HML-Fab}$, or $[^{125}\text{I}]\text{-Fab}$. On SE-HPLC analyses, the majority of the radioactivity was observed in the low molecular weight fraction with a retention time of 31 min for both $[^{131}\text{I}]\text{HML-IT-Fab}$ and $[^{125}\text{I}]\text{HML-Fab}$ (Figure 8, panels A and C). On RP-HPLC, most of the radioactivity in the urine samples was observed with a retention time (8 min) identical to that of *m*-iodohippuric acid for both $[^{131}\text{I}]\text{HML-IT-Fab}$ and $[^{125}\text{I}]\text{HML-Fab}$ (Figure 8, panels B and D). This was confirmed by TLC analyses of the urine samples where most of the radioactivity was observed with an R_f value identical to that of *m*-iodohippuric acid (data not shown). On the other hand, two radioactivity peaks were observed at retention times of 16–17 and 24 min on SE-HPLC analysis for $[^{125}\text{I}]\text{Fab}$ (Figure 8E). Most of the radioactivity was detected in the fraction with an R_f value (0.75) identical to that of free iodine (Figure 8F) on TLC analysis developed with solvent system a. TLC analysis using solvent system b also indicated that most

Figure 6. SE-HPLC radioactivity profiles of kidney homogenates at 10 and 30 min postinjection of radioiodinated Fab fragments. Under these conditions, Fab (50 kDa), cytochrome C (13 kDa), aprotinin (6 kDa), and *m*-iodohippuric acid (305 Da) had retention times of 16, 21, 28.5, and 31 min, respectively.

Figure 7. Radioactivity profiles of kidney homogenates at 10 min after injection of HML-conjugated Fab fragments by RP-HPLC (A and C) and TLC (B and D). Samples were analyzed after filtration through a 10 kDa cutoff membrane. Under these conditions, *m*-iodohippuric acid had a retention time and R_f value of 8 min and 0.45, respectively.

of the radioactivity was present in the fraction with an R_f value identical to that of free iodine (data not shown). The radiochromatograms of urine samples obtained for 24 h after injection of radioiodinated Fab fragments were similar to those obtained for 6 h after injection (data not shown). For 24 h after injection of radioiodinated Fab fragments, only 2–3% of the injected radioactivity was excreted in the feces, whereas the majority of the radioactivity excreted from the body was recovered in the urine (60–70% of the injected radioactivity).

Radiolabeled Species in the Plasma. Figure 9 shows SE-HPLC radiochromatograms of plasma at 10 and 30 min after injection of radioiodinated Fab fragments. Both HML-conjugated Fab fragments showed a new radioactivity peak in the high molecular weight fraction along with intact Fab fragments. The radiochromatogram of $[^{125}\text{I}]\text{Fab}$ showed a small increase in the radioactivity at higher and lower molecular weight fractions at 30 min.

Figure 8. Radioactivity profiles of urine collected 6 h after injection of radiolabeled Fab fragments by SE-HPLC (A, C, and E), RP-HPLC (B and D), and TLC (F). Urine samples were analyzed after filtration through a polycarbonate membrane with a pore diameter of $0.45\ \mu\text{m}$ (A, C, and E) and after filtration through a 10 kDa cutoff membrane (B, D, and F). Under these conditions, $^{125}\text{I}^-$ had a retention time and R_f value of 23 min and 0.75, respectively.

Figure 9. SE-HPLC radioactivity profiles of mouse plasma at 10 and 30 min after injection of radiolabeled Fab fragments.

DISCUSSION

In this study, renal metabolism of HML-conjugated Fab fragments prepared by different thiolation chemistries was compared to understand the mechanisms responsible for the low renal radioactivity levels of HML-conjugated Fab fragments. Our previous study showed

that the spacer structure between the parental antibody molecule and the substrate (ester bonds) plays an important role in the esterase-mediated hydrolysis of ester bonds in radioimmunoconjugates (20). HML-conjugated glycoproteins prepared by different thiolation chemistries were also shown to liberate *m*-iodohippuric acid as the sole radiometabolite at similar rates after lysosomal proteolysis in hepatic parenchymal cells (21). On the basis of these findings, if both $[^{131}\text{I}]\text{HML-IT-Fab}$ and $[^{125}\text{I}]\text{HML-Fab}$ were metabolized primarily in the lysosomes of the renal cells, both radioiodinated Fab fragments would liberate *m*-iodohippuric acid as the sole radiometabolite at similar rates. If either $[^{131}\text{I}]\text{HML-IT-Fab}$ or $[^{125}\text{I}]\text{HML-Fab}$ liberates *m*-iodohippuric acid on the membrane fractions of renal cells by the action of brush border enzymes, different renal radioactivity levels and radiometabolites would be observed between the two HML-conjugated Fab fragments in the kidneys after administration. $[^{125}\text{I}]\text{Fab}$ fragments produced by direct radioiodination were used as controls to estimate lysosomal proteolysis of the antibody molecules since radiometabolites from radioiodinated proteins are rapidly eliminated from lysosomes (31–33).

In biodistribution studies, $[^{125}\text{I}]\text{Fab}$ reached its maximum renal radioactivity levels at 30 min postinjection (Figure 4). The radioactivity in the renal cells migrated from the membrane to the lysosomal fraction from 10 to 30 min after injection of $[^{125}\text{I}]\text{Fab}$ (Figure 5). In addition, SE-HPLC analyses of the kidney homogenates after injection of $[^{125}\text{I}]\text{Fab}$ showed that while most of the radioactivity was detected as intact $[^{125}\text{I}]\text{Fab}$ at 10 min postinjection, small amounts of lower molecular weight radiometabolites were observed at 30 min postinjection (Figure 6). These findings suggested that Fab fragments would be transported and metabolized in the lysosomes of murine renal cells 30 min after injection into mice.

Both $[^{125}\text{I}]\text{HML-Fab}$ and $[^{131}\text{I}]\text{HML-IT-Fab}$ showed significantly lower renal radioactivity levels than those of $[^{125}\text{I}]\text{Fab}$ as early as 10 min postinjection, as shown in Figure 4. The majority of the renal radioactivity was observed in the membrane fractions at both 10 and 30 min after injection of the two HML-conjugated Fab fragments (Figure 5). HPLC analyses of the kidney homogenates at 10 min postinjection indicated generation of *m*-iodohippuric acid as the major radiometabolite following administration of the two HML-conjugated Fab fragments (Figures 6 and 7). The absence of *m*-iodohippuric acid in the blood at 10 min after injection of both $[^{125}\text{I}]\text{HML-Fab}$ and $[^{131}\text{I}]\text{HML-IT-Fab}$ (Figure 9) indicated that the radiometabolite would be generated not in the blood but in the kidneys, as shown by our previous study (15). These findings supported our previous hypothesis that HML-conjugated Fab fragments released *m*-iodohippuric acid at the membrane before being reabsorbed and transported to the lysosomal compartment of the renal cells (Figure 2B).

However, renal analyses demonstrated generation of different radiometabolites between the two HML-conjugated Fab fragments in the kidneys. While $[^{131}\text{I}]\text{HML-IT-Fab}$ registered both intact Fab and *m*- $[^{131}\text{I}]\text{iodohippuric acid}$ at 10 min postinjection, generation of additional radiometabolites was observed with $[^{125}\text{I}]\text{HML-Fab}$ at the same postinjection time point (Figure 7, panels C and D). Since *m*-iodohippuric acid was detected as the major radiometabolite in the urine after injection of both $[^{125}\text{I}]\text{HML-Fab}$ and $[^{131}\text{I}]\text{HML-IT-Fab}$ (Figure 8), the unidentified radiometabolites derived from $[^{125}\text{I}]\text{HML-Fab}$ would include intermediate species containing the HML moiety.

The majority of the radioactivity was present in the membrane fraction of the renal cells at this postinjection time point of the two HML-conjugated Fab fragments (Figure 5). Thus, while [^{131}I]HML-IT-Fab would liberate *m*-iodohippuric acid selectively, a few sequential reactions would be required to release the final radiometabolite, *m*-iodohippuric acid, from [^{125}I]HML-Fab, which was reflected in the small but significant differences in renal radioactivity levels between [^{131}I]HML-IT-Fab and [^{125}I]HML-Fab at early postinjection time points (Figure 4). The glycyl-lysine sequence in [^{125}I]HML-Fab probably hindered enzyme access to a greater extent compared with that in [^{131}I]HML-IT-Fab due to steric interference of the parental Fab fragments as also reported previously using a radioiodination reagent with an ester bond to release *m*-iodohippuric acid from polypeptides (13, 20). Generation of the intermediate radiometabolites from [^{125}I]HML-Fab suggested that brush border enzymes may have cleaved some amino acid sequences that were exposed by reducing and alkylating the disulfide bonds in the Fab fragments. These findings also indicated that it is necessary to consider the potential differences in metabolism between the two commonly used thiolation chemistries when conjugating radiolabels or other chemicals to antibodies.

In conclusion, the findings of this study provided further evidence that the low renal radioactivity levels of HML-conjugated Fab from early postinjection times are attributable to rapid release of *m*-iodohippuric acid by the action of brush border enzymes before the fragments are incorporated into renal cells. The findings of this study also reinforced the suggestion that chemical design of radiolabeling reagents that liberate radiometabolites showing urinary excretion by the action of brush border enzymes would constitute an attractive strategy to reduce renal radioactivity levels from early postinjection times. This study suggested that chemical design of radiolabeling agents that liberate radiometabolites that are excreted into the urine from renal tubules by renal brush border enzymes but are retained in the lysosomes by lysosomal proteolysis would be useful to achieve long-term and selective target radioactivity levels using antibody fragments or peptides as vehicles regardless of whether the parental molecules are internalized into target cells.

ACKNOWLEDGMENT

We are grateful to Dr. Isamu Yomoda of Diichi Radioisotope Laboratories (Tokyo) for providing Na[^{131}I]I. This study was supported in part by Grants-in-Aid for Developing Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan.

Chemistry of Sulforhodamine–Amine Conjugates

John E. T. Corrie,* Colin T. Davis, and John F. Eccleston

National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, U.K. Received July 6, 2000; Revised Manuscript Received November 30, 2000

Commercially-available sulforhodamine sulfonyl chlorides contain two isomeric monosulfonyl chlorides. Conjugates of these isomers with amines have different properties because the sulfonamide formed from one isomer can undergo ring-closure to a colorless sultam. This chemistry has been examined for a model conjugate with methylamine and for a bioconjugate with 2'(3')-O-[N-(2-aminoethyl)-carbamoyl]ATP. The interaction of each isomer of the latter conjugates with myosin subfragment 1 has been characterized. Significant differences between the two isomers are observed in these interactions.

INTRODUCTION

Rhodamine dyes are used extensively for conjugation with biomolecules because of their excellent fluorescence properties. Among the most commonly used reactive dyes for amine labeling are the sulforhodamine chlorides, principally Sulforhodamine B¹ sulfonyl chloride **1a** and Texas Red sulfonyl chloride **2a**. We became interested

1a R¹, R² = SO₂Cl, SO₃⁻

1b R¹, R² = SO₃⁻

1c R¹ = SO₂Cl, R² = SO₃⁻

1d R¹ = SO₃⁻, R² = SO₂Cl

1e R¹, R² = SO₂Cl

2a R¹, R² = SO₂Cl, SO₃⁻

2b R¹, R² = SO₃⁻

in these dyes for preparation of ribose-modified fluorescent nucleotides (1, 2) but were intrigued to observe that treatment of commercial SRB–SC² **1a** with an excess of a primary amine reduced the intensity of the visible absorption band by ~50%. The color change was reversible upon acidification. For the product obtained from reaction with methylamine, the color was highest at pH 4 and lowest at pH 9. To explain this observation, it is necessary to consider the structure of the starting sulfonyl chloride. Compounds **1a** and **2a** are prepared from the corresponding bis-sulfonates **1b** and **2b**, typically by treatment with POCl₃ or PCl₅. The original report (3) of Texas Red sulfonyl chloride recognized the probability that two isomeric monosulfonyl chlorides were present. SRB–SC dates from a 1958 paper (4) in which isomerism

Scheme 1. Formation and Ring-Chain Tautomerism of Sulforhodamine–Amine Conjugates

was not considered, although more recent reports (5, 6) have discussed the presence of two isomers.

The presence of a sulfonyl chloride ortho to the xanthylium ring system, as in isomer **1c**, presents the opportunity for spiro-sultam formation upon reaction with a primary amine (Scheme 1) and the spiro-sultam (as shown), in which the extended rhodamine chromophore is absent, is expected to be colorless. However, these rhodamine spiro-sultams are capable of ring-opening under appropriate pH conditions. In fact, these properties of sulforhodamine spiro-sultams were first recorded in qualitative terms 100 years ago (7), and the color change in either direction has been exploited in patents related to photographic (8) and thermal (9) imaging. Despite these precedents, the origin of this pH-dependent behavior continues to be subject to misinterpretation (e.g., ref 10), evidently based on an assumption that amine conjugation takes place only on the sulfonyl group para to the xanthylium ring, i.e., reaction with isomer **1d**. We now describe a detailed study of these phenomena, with particular focus on the properties of amine conjugates derived from the different isomers and the consequences of the different structures for biological applications of these dyes. The investigation covers a conjugate of SRB–SC with methylamine as a convenient model, a full characterization of the chemistry of the recently described Rhodamine Red-X reagent **7** (11), and studies of ribose-modified ATP conjugates derived from the two different isomers of SRB–SC. The results with the ATP conjugates (and with similar GTP conjugates not reported

¹ Sulforhodamine B **1b** is also known as Lissamine Rhodamine B.

² Abbreviation: SRB–SC, sulforhodamine B sulfonyl chloride; ED–ATP, 2'(3')-O-[N-(2-aminoethyl)carbamoyl]ATP.

here) are particularly relevant to our previous work in which these analogues were used in fluorescence energy transfer measurements (1, 2). In the earlier of those studies (1), we had assumed that only the conjugate formed from isomer **1d** was present in the material used for fluorescence studies (i.e., that it was homogeneous and not subject to variations of fluorescence induced by pH changes). The present work confirms that two isomers are formed in the synthesis but are well separated by the purification protocol. The interactions reported here of the ATP conjugates with myosin subfragment 1 reveal differences in fluorescence responses for the two isomers. We note that the ring-chain tautomerization chemistry described here is relevant only to conjugates with primary amines, as similar conjugates with secondary amines cannot cyclize.

MATERIALS AND METHODS

SRB–SC **1a** (lots 1141-1 and 1161-2) and Rhodamine Red-X succinimidyl ester **7** (lot 4462) were from Molecular Probes, Eugene OR. ED-ATP² **11** was prepared as described (12). Myosin subfragment 1 was prepared by the method of Weeds and Taylor (13). Reduced Triton X-100 and DEAE-cellulose anion exchanger were from Sigma. Silica gel for flash chromatography was Merck type 9385. All other materials were from Aldrich and used without further purification. TLC was performed on Merck 60F silica gel plates.

NMR spectra were recorded on a Bruker AM400 spectrometer for solutions in CDCl₃ (unless otherwise specified) and referenced to internal tetramethylsilane. Electrospray mass spectra were determined at low resolution on a VG Platform instrument and the FAB mass spectrum at high resolution was determined on a VG ZAB–SE instrument. UV–Vis spectra were determined on a Beckman DU70 instrument. Analytical reversed-phase HPLC was carried out on a Novapak C18 column (3.9 × 150 mm) eluted isocratically with 100 mM potassium phosphate, pH 6.8, containing 25% acetonitrile (v/v) at 0.5 mL min⁻¹. Steady-state fluorescence intensity measurements were made on an SLM 8000S fluorimeter. Excitation was at 572 nm and emitted light was monitored through a monochromator at 585 nm. Fluorescence anisotropy titrations were carried out on the same instrument but with the use of Glan-Thompson polarizers. The data were fitted to eq 1:

$$A_{\text{obs}} = A_L + (A_{\text{EL}} - A_L) \frac{[\text{EL}]}{[\text{L}_T]} \quad (1)$$

where $[\text{EL}] = 0.5[(K + [\text{E}_T] + [\text{L}_T]^2) \pm \sqrt{(K + [\text{E}_T] + [\text{L}_T]^2)^2 - 4[\text{E}_T][\text{L}_T]}]$, A_{obs} = observed anisotropy, A_L = anisotropy of free ligand, A_{EL} = anisotropy of enzyme-ligand complex, $[\text{E}_T]$ = total enzyme concentration, $[\text{L}_T]$ = total ligand concentration, and K = equilibrium dissociation constant.

Stopped-flow measurements were made on a Hi-Tech Scientific MX61 instrument operating in absorbance mode for studies of pH changes with compound **3** (wavelength 567 nm) or fluorescence mode for studies with the conjugates **12–15** (excitation at 530 nm; emission monitored through a Wratten 21 cutoff filter that passed light above 540 nm). For experiments on the interaction of myosin subfragment 1 with **12–15**, all concentrations quoted are those after mixing so the syringe concentrations were twice these values. Data were analyzed using Hi-Tech software. Mean values of rate constants and amplitudes with their standard deviations

for stopped-flow data were obtained from analysis of 4–6 reactions but single data sets are shown in the Figures.

Buffer solutions for measurements in aqueous ethanol were prepared from water-ethanol (3:1 v/v) solutions of appropriate acids at the molarities specified and adjusted to the required pH values by addition of NaOH. pH values were determined with a glass electrode referenced to buffer solutions in 100% aqueous solution.

NMR Spectroscopic Characterization of SRB–SC (1a). Two batches of commercial material were examined. In the first sample (lot 1141-1), two major families of signals were distinguishable because their relative intensity ratios were ~6:4. Selected single frequency decoupling experiments confirmed the assignment to one or other set for some of the signals. The first set of signals (A) were as follows (multiplicities are consistent within each set): δ 9.05 (d, J = 2.1 Hz, 1H), 8.12 (dd, J = 8.0 and 2.1 Hz, 1H), 7.36 (d, J = 8.0 Hz, 1H), 7.22 (d, J = 9.6 Hz, 2H), 6.83 (dd = 9.6 and 2.4 Hz, 2H), 6.74 (d, J = 2.4 Hz, 2H), 3.58 (q, J = 6.5 Hz, 8H) and 1.29 (t, J = 6.5 Hz, 12H). The second set of signals (B) had δ 9.00 (d, J = 1.5 Hz, 1H), 8.55 (dd, J = 7.8 and 1.5 Hz, 1H), 7.41 (d, J = 7.8 Hz, 1H), 7.08 (d, J = 9.5 Hz, 2H), 6.90 (dd, J = 9.5 and 2.3 Hz, 2H), 6.79 (d, J = 2.3 Hz, 2H), 3.64 (q, J = 6.5 Hz, 8H) and 1.35 (t, J = 6.5 Hz, 12H). A third, minor set of signals (C) was present in this sample, but was much more prominent in a second batch of material (lot 1161-2). These signals, for which the line shapes were broader than those of the other two sets, were at δ 8.93 (d, J = 1.6 Hz, 1H), 8.77 (dd, J = 8.0 and 1.6 Hz, 1H), 8.27 (d, J = 8.0 Hz, 1H), 7.04 (d, J = 9.2 Hz, 2H), 6.97 (dd, J = 9.2 and 2.1 Hz, 2H) and 6.87 (d, J = 2.1 Hz, 2H). The signals from the ethyl side chains were not resolved from those of the other two components. In this sample the relative intensity of the signals in sets A, B, and C was approximately 18:44:38.

Reaction of SRB–SC with Methylamine: Compounds 3 and 4. A solution of SRB–SC (lot 1141-1; 100

3 $R^1 = \text{SO}_2\text{NHMe}$, $R^2 = \text{SO}_3^-$

4 $R^1 = \text{SO}_3^-$, $R^2 = \text{SO}_2\text{NHMe}$

mg, 0.17 mmol, in acetone (100 mL) was mixed with 40% aq. methylamine (20 mL) and concentrated under reduced pressure to remove most of the acetone. The remaining solution was diluted with water to ~50 mL, filtered to remove some insoluble material and lyophilized. The residue was dissolved in 50% aqueous ethanol (20 mL) and quantified by spectrophotometry of a solution at pH 4. The total rhodamine concentration was 7.08 mM (83% recovery) but fell to 4.12 mM after storage for 48 h at 4 °C because part of the solute precipitated. In this mixture the absorbance ratio at 567 nm in solutions at pH 4 and 9 was 3.6:1, which was taken to indicate that the relative proportion of compounds **3** and **4** present in solution was 2.6:1. This material was used without further processing for most of the experiments described below. For experiments in later work where pure **3** was required, a portion of the stock solution, containing 45 μmol mixed rhodamines, was lyophilized and the residue

was dissolved in MeOH and absorbed onto silica gel (1 g). This was added to a packed flash chromatography column, that was eluted with a step gradient of CHCl₃-MeOH (from 97.5:2.5 to 92:8; total volume 1200 mL). Fractions were analyzed by UV-vis spectroscopy at pH 4 and 9 and the main pH-responsive fraction (26 μ mol) was combined and evaporated. This material retained a trace contaminant ($\sim$ 3%; λ_{max} 558 nm) that was not decolorized at pH 9 and interfered with the required measurements. It was removed by repeated preparative TLC (silica gel; CHCl₃-MeOH 85:15) to give pure **3** (16.5 μ mol); ¹H NMR (MeOH-*d*₄-NaOD) δ 8.18 (d, *J* = 1.3 Hz, 1H), 7.90 (dd, *J* = 8.2 and 1.3 Hz, 1H), 6.99 (d, *J* = 8.2 Hz, 1H), 6.65 (d, *J* = 8.5 Hz, 2H), 6.32–6.35 (m, 4H), 3.29 (q, *J* = 7.0 Hz, 8H), 2.32 (s, 3H), and 1.07 (t, *J* = 7.0 Hz, 12H). The addition of NaOD was made to drive the compound into its colorless sultam form. In MeOH-*d*₄ alone the spectrum showed a mixture of the open and closed forms in $\sim$ 1:1 ratio. ES-MS, *m/e* (*M* + *H*) calcd for C₂₈H₃₃N₃O₆S₂ + *H*, 572; found, 572.

Ring Opening and Closing Kinetics of 3. For stopped-flow measurements starting from high pH, the **3**+**4** mixture was diluted to 9 μ M (i.e., 6.5 μ M **3**, 2.5 μ M **4**) in 5 mM sodium borate, pH 9.0, and for measurements in the opposite direction it was diluted in 5 mM sodium citrate, pH 4.0. In each case, these starting solutions were mixed in the stopped-flow apparatus with an equal volume of 100 mM MOPS, pH 7.0. All concentrations are premixing values. Buffer solutions were prepared in water-EtOH (3:1 v/v) as described above and experiments were conducted at 4 °C. The observation light traversed a 1-cm path length. Transmission data were converted to absorbance and analyzed as the best fit to single exponentials.

3',6'-Bis(diethylamino)-2-(2,3-dihydroxypropyl)-spiro[1*H*-isoindole-1,9'-[9*H*]xanthen]-3(2*H*)-one (6).

5 R = Me

6 R = CH₂CH(OH)CH₂OH

A mixture of Rhodamine B (330 mg) and SOCl₂ (5 mL) was kept at room temperature for 18 h and excess reagent was removed under reduced pressure. The residue was dissolved in CHCl₃ (50 mL), cooled in ice and treated with a solution of 1-aminopropane-2,3-diol (1 g) and triethylamine (1.5 g) in DMF (50 mL). The solution was stirred at room temperature for 2 h, by which time most of the color was discharged. Solvents were evaporated in vacuo and a solution of the residue in CHCl₃ was washed with water, dried and evaporated. Flash chromatography (EtOAc-hexanes 80:20) and crystallization ($\times$ 3 from benzene-hexanes) gave lactam **6** (104 mg), mp 222–224 °C; UV (EtOH) λ /nm (ϵ /M⁻¹ cm⁻¹) 240 (56 900), 273 (33 400), and 314 (13 100); ¹H NMR (CDCl₃ after D₂O exchange) δ 7.88–7.92 (m, 1H), 7.36–7.50 (m, 2H), 7.11–7.13 (m, 1H), 6.36–6.40 (m, 4H), 6.25 and 6.28 (2 $\times$ dd, *J* = 8.8 and 2.4 Hz for each, 2 $\times$ 1H), 3.40 (dd, *J* = 12.2 and 3.2 Hz, 1H), 3.29–3.37 (m, 10H), 3.15 (dd, *J* = 14.4 and 6.1 Hz, 1H), 3.04–3.09 (m, 1H) and 1.16 and 1.17 (2 $\times$ t, *J* = 9 Hz, 12H); FAB-MS, *m/z* (*M* + *H*) calcd for C₃₁H₃₈N₃O₄ + *H*, 516.2880; found, 516.2880.

Spectroscopic Titrations. For sultam **3** the mixture of **3** + **4**, prepared as described above, was diluted to a

total rhodamine concentration of 8.3 μ M in various buffers. Aqueous ethanolic buffers (each 25 mM in buffer salt) were acetate, pH 4, phosphate, pH 7, and borate, pH 10. For measurements in the presence of detergent, the buffers (each 25 mM) were citrate, pH 2.1, and borate, pH 9, each containing 0.1% reduced Triton X-100 but without ethanol. In each case, solutions were mixed in various proportions to generate $\sim$ 20 solutions at different pH values. The pH of each solution was measured and the absorbance spectrum was recorded (10 mm path length). The 567 nm absorbance values were fitted to a single p*K* equation over the pH range 4–9. For the rhodamine-ATP conjugates **12** and **13** (see below), measurements were performed similarly in either aqueous or aqueous ethanol solutions, using 0.1 M buffers prepared from MES (pH 6.5), Tris (pH 8 and 8.5), CHES (pH 9.0, 9.5 and 10.0), CAPS (pH 10.5), and sodium phosphate (pH 12.0). Absorbance data were fitted to a single p*K* equation.

For the titration of **6**, 16.7 μ M solutions of the lactam were prepared in either hydrochloric acid, pH 1 or in 25 mM sodium phosphate, pH 7, each of which contained 25% ethanol (v/v) and $\sim$ 30 solutions were prepared by mixing the two stock solutions in varying proportions. The pH values were determined as above and absorbance spectra were recorded over the range 220–400 nm. Absorbance values at 275 and 320 nm were least-squares fitted to eq 2, using the Marquardt algorithm with software written in-house by Dr. S. R. Martin.

$$\text{Absorbance} = \epsilon_{\text{H}_2\text{L}}[\text{H}_2\text{L}^{2+}] + \epsilon_{\text{HL}}[\text{HL}^+] + \epsilon_{\text{L}}[\text{L}] \quad (2)$$

where $\epsilon_{\text{H}_2\text{L}}$, ϵ_{HL} , and ϵ_{L} are absorption coefficients for the diprotonated (H₂L²⁺), monoprotanated (HL⁺), and unprotonated (L) forms, respectively. The concentrations were calculated using eq 3:

$$[\text{L}] = \frac{L_{\text{Total}}}{1 + K_{\text{L}}[\text{H}^+] + K_{\text{L}}K_{\text{HL}}[\text{H}^+]^2} \quad (3)$$

where $K_{\text{L}} = [\text{HL}^+]/([\text{L}][\text{H}^+])$ and $K_{\text{HL}} = [\text{H}_2\text{L}^{2+}]/([\text{HL}^+][\text{H}^+])$.

Reaction of SRB-SC with Methyl 6-Aminohexanoate: Compounds 8, 9, and 10. A mixture of methyl

6-aminohexanoate hydrochloride (80 mg, 0.44 mmol) and triethylamine (0.12 mL) in chloroform (8 mL) was stirred in an ice-bath and SRB-SC (lot 1161–2; 200 mg, 0.35 mmol) was added in portions over 5 min. The solution

was allowed to warm to room temperature and stirred overnight, then diluted to 50 mL with chloroform. For initial analysis, an aliquot was diluted in ethanol ($\times 50$) and further diluted into buffers at pH 4 and 9. The absorbance ratio (567 nm) at low and high pH was 1.54.

The chloroform solution was washed with water (3×30 mL) and dried, and the solvent was removed. TLC analysis (CHCl_3 -MeOH 95:5) showed three main spots, R_f 0.70, 0.25, and 0.10. Flash chromatography with a step gradient from 0 to 7.5% MeOH in CHCl_3 (total volume 850 mL) gave the first two components essentially pure (TLC), while the third was contaminated with a trace of slightly less polar material. Visible spectroscopy at pH 4 showed recoveries of 56, 33, and 24 μmol for the highest, middle and lowest mobility compounds, respectively. The total recovery based on the starting rhodamine was 32%. At pH 9, the 567 nm absorption of the highest and lowest mobility compounds was essentially zero, while that of the middle fraction was the same as at pH 4.

The highest mobility fraction was 3',6'-bis(diethylamino)-2-(5-methoxycarbonyl-1-pentyl)-6-[(5-methoxycarbonyl-1-pentyl)amino]sulfonyl]spiro[1,2-benzisothiazole-3(2H)-9'-[9H]xanthene]-1,1-dioxide **8**; ^1H NMR δ 8.34 (d, $J = 1.8$ Hz, 1H), 7.88 (dd, $J = 8.2$ and 1.8 Hz, 1H), 7.13 (d, $J = 8.2$ Hz, 1H), 6.82 (d, $J = 9.7$ Hz, 2H), 6.35–6.37 (m, 4H), 4.58 (t, $J = 6.7$ Hz, 1H), 3.66 (s, 3H), 3.60 (s, 3H), 3.35 (q, $J = 7.1$ Hz, 8H), 3.01 (q, $J = 6.7$ Hz, 2H), 2.91 (t, $J = 7.3$ Hz, 2H), 2.30 (t, $J = 7.3$ Hz, 2H), 2.11 (t, $J = 7.6$ Hz, 2H), 1.49–1.63 (m, 6H), 1.31–1.41 (m, 6H) and 1.18 (t, $J = 7.1$ Hz, 12H); ES-MS, m/z ($M + H$) calcd for $\text{C}_{41}\text{H}_{56}\text{N}_4\text{O}_9\text{S}_2 + \text{H}$, 813; found 813.

The middle fraction was 3,6-bis(diethylamino)-9-[(4-[(5-methoxycarbonyl-1-pentyl)amino]sulfonyl]-2-sulfophenyl)xanthylum, inner salt **9**; ^1H NMR (CDCl_3 -MeOH- d_4 9:1) δ 8.68 (d, $J = 1.8$ Hz, 1H), 8.04 (dd, $J = 7.9$ and 1.8 Hz, 1H), 7.29 (d, $J = 7.9$ Hz, 1H), 7.19 (d, $J = 9.4$ Hz, 2H), 6.87 (dd, $J = 9.4$ and 2.4 Hz, 2H), 6.75 (d, $J = 2.4$ Hz, 2H), 3.69 (s, 3H), 3.57–3.64 (m, 8H), 3.02 (t, $J = 7.0$ Hz, 2H), 2.35 (t, $J = 7.5$ Hz, 2H), 1.66 (quintet, $J = 7.7$ Hz, 2H), 1.60 (quintet, $J = 7.6$ Hz, 2H), 1.38–1.45 (m, 2H) and 1.33 (t, $J = 7.1$ Hz, 12H); ES-MS, m/z ($M + H$) calcd for $\text{C}_{34}\text{H}_{43}\text{N}_3\text{O}_8\text{S}_2 + \text{H}$, 686; found, 686.

The least mobile fraction was 3',6'-bis(diethylamino)-2-(5-methoxycarbonyl-1-pentyl)spiro[1,2-benzisothiazole-3(2H)-9'[9H]xanthene]-1,1-dioxide-6-sulfonic acid **10**; ^1H NMR δ 8.68 (d, $J = 1.7$ Hz, 1H) 8.35 (dd, $J = 7.8$ and 1.7 Hz, 1H), 7.24 (d, $J = 7.8$ Hz, 1H), 7.19 (d, $J = 9.4$ Hz, 2H), 6.88 (dd, $J = 9.4$ and 2.1 Hz, 2H), 6.72 (dd, $J = 2.1$ Hz, 2H), 3.60 (s, 3H) superimposed on 3.57–3.66 (m, 8H), 2.89 (t, $J = 6.5$ Hz, 2H), 2.22 (t, $J = 7.4$ Hz, 2H), 1.50 (quintet, $J = 7.4$ Hz, 2H), 1.43 (quintet, $J = 7.0$ Hz, 2H), 1.32 (t, $J = 7.0$ Hz, 12H) and 1.18–1.26 (m, 2H); ES-MS, m/z ($M + H$) calcd for $\text{C}_{34}\text{H}_{43}\text{N}_3\text{O}_8\text{S}_2 + \text{H}$, 686; found, 686.

Rhodamine-ED-ATP Conjugates 12 and 13. The procedure here amplifies that given previously (2) and describes in detail the isolation of isomers **12** and **13**. A solution of ED-ATP (0.25 mmol) in 50 mM NaHCO_3 (25 mL) was mixed with a solution of SRB-SC (lot 1141-1; 0.5 mmol) in acetone (25 mL) and kept for 2 h at 20 $^\circ\text{C}$. A control reaction without ED-ATP was set up in parallel, and, at the end of the reaction time, each solution was analyzed by TLC [2-propanol-water- $\text{NH}_3(\text{aq})$ 7:2:1]. The control reaction had a single red spot, R_f 0.9, also present in the reaction mixture, but the latter had two additional spots, one at the origin and the other with R_f 0.2. The latter spot only became colored as ammonia evaporated from the TLC plate. The reaction mixture was concentrated under reduced pressure to remove the acetone, then diluted with 1.5 vol of water and applied to a DEAE-

cellulose column (34×150 mm, bicarbonate form). The column was eluted with a linear gradient of 0–1 M triethylammonium bicarbonate (total volume 3 L) and the eluate was monitored at 254 nm. Unreacted ED-ATP eluted at 0.27 M followed by two well-resolved peaks at 0.36 and 0.60 M that both contained the rhodamine fluorophore. On reverse-phase HPLC each peak eluted as partly resolved doublets because of isomerism arising from linkage through the 2'- or 3'-hydroxyl group (12, 21). The peak that eluted at 0.60 M TEAB (later assigned as **12**) had t_R 10.2 and 12.0 min while the peak at 0.36 M TEAB (later assigned as **13**) had t_R 7.9 and 8.6 min. The 2'/3'-isomers were not separated on a preparative scale in this work. Fractions containing the resolved components **12** and **13** were separately pooled and concentrated by rotary evaporation followed by further evaporation from methanol (3×30 mL) to remove buffer salts. Each residue was redissolved in water (5 mL) and the solutions were analyzed by TLC as above. The first and second fluorescent peaks eluted from the DEAE-cellulose column had R_f 0 and 0.2, respectively, and the latter spot was reversibly bleached on the TLC plate by exposure to ammonia vapor. By comparison with the behavior of the methylamine conjugate **3**, this was assigned structure **12** while the spot that remained at the origin was assigned as structure **13**. The yields were 13.5 and 66 μmol for **12** and **13** respectively (overall yield 32% based on ED-ATP). For ^1H NMR characterization, the triethylammonium salts were converted to Na^+ salts (Dowex 50) and the spectra were interpreted with the aid of 2D TOCSY and COSY spectra to correlate overlapping spin systems that arise from the presence of unresolved 2'- and 3'-isomers, together with previous data for related ED-ATP conjugates with Cy3 (21). However, complete assignment for each isomer was not possible. Reported intensities are consistent within the data for a particular isomer. For **13** (500 MHz, D_2O , acetone ref.), the 2'-isomer had assignable signals at δ 8.56 (d, $J = 1.8$ Hz, 1 H, xanthene H-3), 8.34 (dd, $J = 7.5$ and 1.8 Hz, 1 H, xanthene H-5), 7.92 (d, $J = 7.5$ Hz, 1 H, xanthene H-6), 6.04 (d, $J = 2.0$ Hz, 1 H, H-1'), 5.24 (dd, $J = 5.6$ and 2.0 Hz, 1 H, H-2'), 4.71–4.73 (m, 1 H, H-4'), 4.21–4.28 (m, 2 H, H-5'). The signal for H-3' was obscured under the HOD peak. The 3'-isomer had δ 8.55 (d, $J = 1.8$ Hz, 1 H, xanthene H-3), 8.29 (dd, $J = 8.0$ and 1.8 Hz, 1 H, xanthene H-5), 7.59 (d, $J = 8.0$ Hz, 1 H, xanthene H-6), 5.78 (d, $J = 6.0$ Hz, 1 H, H-1'), 5.14–5.16 (m, 1 H, H-3'), 4.81–4.84 (m, 1 H, H-2'), 4.25–4.45 (m, 1 H, H-4'), 4.13–4.26 (m, 2 H, H-5'). Signals not assignable to a specific isomer were at δ 8.33 and 8.18 (purine H), 6.60–6.99 (m, xanthene H-1' to H-8'), 3.50–3.66 (m, NCH_2CH_3), 3.20–3.46 (m, NCH_2CH_2), and 1.21–1.29 (NCH_2CH_3).

The spectrum of isomer **12** in pure D_2O was complex. This was shown to be due to noncovalent rhodamine dimerization at the concentration of the NMR sample, as revealed by absorption spectroscopy (0.1 mm path length) in the range 500–600 nm, that showed a spectrum typical for rhodamine dimers (22). Dimerization was not detected by absorption spectroscopy of **13**. Addition of 50% methanol to the aqueous solution of **12** abolished the dimer absorption spectrum, and therefore, the ^1H NMR spectrum was run in D_2O -methanol- d_4 (1:1 v/v). The 2'-isomer had assignable signals at δ 6.09 (d, $J = 2$ Hz, 1 H, H-1'), 5.31 (dd, $J = 5$ and 2 Hz, 1 H, H-2'), 4.71 (t, $J = 5$ Hz, 1 H, H-3'). The 3'-isomer had δ 6.02 (d, $J = 5$ Hz, 1 H, H-1'), 5.21 (d, $J = 4$ Hz, 1 H, H-3'), 4.94 (dd, $J = 5$ and 4 Hz, 1 H, H-2'). Signals not specifically assignable to either isomer were at δ 4.05–4.18 (m, H-4',5'), 3.35–3.60 (m, NCH_2CH_3), 3.05–3.30 (m, NCH_2 -

CH_2N), and 1.10–1.13 (m, NCH_2CH_3). The xanthene protons appeared as broad envelopes in the ranges δ 7.3–8.8 (H-3,5 and 6) and 6.4–7.1 (H-1' to H-8'), evidently because of exchange broadening between the open and closed forms of the rhodamine sultam, while sharp singlets at δ 8.62, 8.47, 8.19, and 8.14 were assignable to the purine protons, that in this case were distinct in each isomer.

These ATP analogues were converted to the corresponding ADP analogues by incubating solutions of 34 μM analogue with 3.4 μM myosin subfragment 1 in 50 mM Tris·HCl, pH 7.5, 100 mM KCl, 5 mM MgCl_2 , and 1 mM DTT for 5 min at 20 °C. HPLC analysis showed quantitative conversion of both analogues to the ADP derivatives **14** (t_R 12.1 and 16.6 min; see above for the cause of double peaks) and **15** (t_R 8.8 and 10.1 min).

RESULTS

The ^1H NMR spectrum of one commercial sample of SRB–SC **1a** indicated the presence of two major components, presumed to be isomeric species **1c** and **1d**. The spectrum of a second sample used in later work revealed an additional component, inferred from the products of its reaction with an amine to be the bis-sulfonyl chloride **1e** (see below). The 567 nm absorbance of the mixture obtained by treatment of the first sample of **1a** with excess methylamine was ~ 2 -fold greater at pH 4 than at pH 9. This result is consistent with the presence of the pH-responsive compound **3** and its isomer **4** in $\sim 1:1$ ratio. The absorbance (or fluorescence) of **4** is not expected to vary with pH changes in this range, as the sulfonamide at the *para*-position cannot interact with the xanthylium system. Marchesini et al. (5) have previously reported the separation of **3** and **4** and described their ^1H NMR spectra. Our studies were mostly conducted on a mixture of **3** + **4**, in which **3** and **4** were present in $\sim 2.6:1$ ratio because a proportion of **4** selectively precipitated from the stock solution after initial preparation. Later measurements not described here required pure **3**, which was isolated from the mixture by repeated chromatography.

The colorless form of **3** was favored at alkaline pH and the apparent pK_a for ring-chain tautomerization was 7.37, determined from 567 nm absorbance measurements in 25% ethanol–75% aqueous buffer. Solutions could not be accurately manipulated without this concentration of ethanol, presumably because of losses by surface adsorption of the more hydrophobic ring-closed form. Nevertheless, an estimate of the apparent pK_a in fully aqueous solution was obtained by measuring absorbance values immediately after dilution into appropriate aqueous buffers. This gave a value of approximately 6.95, suggesting that the presence of 25% ethanol did not greatly perturb the measurement. In contrast, the presence of detergent (5) had a significant effect and with 0.1% reduced Triton X-100 in fully aqueous solution, the measured pK_a was 5.36. This difference is considered in the Discussion.

Rates of interchange between the colored and colorless forms were investigated with pH changes imposed by rapid mixing in stopped-flow experiments. At 4 °C and in the region of pH 7, observed rate constants for the color change were $\sim 200 \text{ s}^{-1}$ whether approached from the colored or colorless form (data not shown). A full data set covering the pH range 0–9.5 will be described elsewhere with an account of the detailed mechanism operating in the ring-opening and ring-closing reactions.

We considered whether an amine conjugate of a carbhorhodamine would show analogous ring-chain tautom-

Figure 1. UV absorption spectra of lactam **6** as a function of pH. The figure shows superimposed traces from 30 individual solutions at various pH values between the extremes specified.

erism. The *N*-methyl lactam **5** derived from Rhodamine B has been reported to remain colorless “to about pH 4” (14) but was insufficiently soluble in water-ethanol (3:1) for accurate investigation. However, the more hydrophilic diol **6** was sufficiently soluble for accurate titration. This compound had no visible chromophore at any pH in the range 2–7, but its UV spectrum showed significant changes (Figure 1) associated with sequential protonation of the two diethylamino groups. The mean fitted pK_a values (using separate fits to data at 240, 275, and 320 nm where the absorbance changes were greatest) were 2.97 and 4.52.

Our clarification of the chemistry of **3** and **4** enabled us to reinvestigate aspects of a recent report that describes amine conjugates of **1a** and **2a** as improved reagents for fluorescent labeling of proteins (11). For the Rhodamine Red-X conjugate derived from **1a**, the structure was shown as **7**, leaving open the possibility that the sulfonamide and sulfonate groups were present as a mixture at positions 2 and 4. However, visible spectra of aqueous solutions of a commercial sample of Rhodamine Red-X succinimidyl ester were identical at pH 4 and 9, implying that the compound was a single isomer with the sulfonamide *para* to the xanthylium system. This result was unexpected in view of other results presented here, so the first stage of preparation of the Rhodamine Red-X reagent was repeated, i.e., reaction of **1a** with methyl 6-aminohexanoate (11). This experiment used a batch of **1a** for which the NMR spectrum showed three main species. TLC analysis of the crude reaction mixture also showed three major products, that were isolated by flash chromatography and characterized by visible, mass, and NMR spectroscopy. The least polar spot (50% of total rhodamines isolated by chromatography) was sulfonamide sultam **8**, the middle spot (29% of recovered rhodamines) was monosulfonamide **9**, and the most polar spot (21%) was sultam **10**. Both **8** and **10** showed pH dependence of their visible spectra, similarly to the other sultams investigated here, while the spectrum of **9** was unaffected in the pH range 4–9. Isolation of the doubly derivatized compound **8** confirms the presence of bis-sulfonyl chloride **1e** in the starting material used for this experiment. Consequences of these results are considered in the Discussion.

Last, the influence of structural isomerism in sulforhodamine derivatives was examined for the conjugates

Figure 2. Titration of the rhodamine-ED-ATP analogues **12** (○) and **13** (■) in aqueous solution as a function of pH. The solid line is a least-squares fit to the data of **12** for a single pK_a .

12 and **13** derived by coupling SRB–SC **1a** with ED-ATP **11**. The reaction produced two species that were readily

separated analytically by reverse-phase HPLC and preparatively by anion exchange chromatography. Structures were assigned by inference from the known starting materials, the reactivity with myosin subfragment 1 (see below), the ^1H NMR spectra and the response of each compound to pH changes. The visible absorption of **12**

was pH dependent as for the methylamine conjugate **3**, with apparent pK_a 9.12 in fully aqueous solution (Figure 2), that reduced to 8.24 in solutions containing 25% ethanol (v/v). The absorption spectrum of **13** was invariant over the pH range 4–12 (Figure 2).

Figure 3. Stopped-flow fluorescence records of the interaction of the rhodamine-ATP analogues **12** (panels a and b) and **13** (panels c and d) with excess myosin subfragment 1. The reactions were monitored over two time scales.

The interactions of ATP conjugates **12** and **13** with myosin subfragment 1 were investigated under single turnover conditions (i.e., $[\text{protein}] > [\text{ATP analogue}]$) at pH 7.5, 20 °C in 50 mM Tris·HCl, 100 mM KCl, 5 mM MgCl_2 , 1 mM DTT. A 0.5 μM solution of either isomer was rapidly mixed with 2.5 μM subfragment 1 in a fluorescence stopped-flow instrument and the fluorescence was recorded with time (Figure 3). With both isomers, there was a fast initial decrease in intensity followed by a slower recovery. These phases correspond to binding of the analogue to subfragment 1 and the rate-limiting release of inorganic phosphate after hydrolysis (see Discussion). With **12** the initial fluorescence decrease was to $69.6 \pm 0.6\%$ of the starting value with subsequent recovery to $73.4 \pm 0.4\%$ of the starting value. For **13**, the initial decrease was to $57.6 \pm 0.6\%$ of the starting value followed by recovery to $81.5 \pm 1.3\%$ of the starting value. Thus, both isomers give a similar fluorescence decrease on binding to subfragment 1 but the fluorescence recovery is smaller for the pH-responsive isomer **12** than for **13**. Rate constants of the above two processes were 2.0 ± 0.1 and $0.050 \pm 0.003 \text{ s}^{-1}$ for **12** and 1.07 ± 0.08 and $0.042 \pm 0.001 \text{ s}^{-1}$ for **13**. Although a concentration dependence of the binding reactions were not made, the rate constants of the faster processes represent second-order association constants of 8.0×10^5 and $4.3 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ for **12** and **13**, respectively. These calculations depend on the subfragment 1 being 100% active and so represent lower limits of these rate constants. These single turnover experiments were repeated at pH 8.5, i.e., closer to the pK value for the color change of **12**, so perturbation of this pK on binding to subfragment 1 might have been observed. In practice, neither isomer showed differences between pH 7.5 and 8.5 in the amplitudes of either phase of the fluorescence changes (data not shown).

Dissociation rate constants of the isomeric ADP conjugates **14** and **15** from subfragment 1 were measured in displacement experiments by rapid mixing of a solution containing 2.5 μM subfragment 1 and 0.5 μM **14** or **15** with a solution containing 100 μM ATP (Figure 4). With **14** there was $41.4 \pm 0.9\%$ exponential increase in fluorescence with a rate constant of $1.15 \pm 0.07 \text{ s}^{-1}$ while **15** showed a $27.2 \pm 0.9\%$ exponential increase in fluorescence with a rate constant of $0.75 \pm 0.10 \text{ s}^{-1}$. Association rate constants, determined by mixing 0.5 μM **14** or

Figure 4. Stopped-flow fluorescence records of the displacement of rhodamine-ADP analogues **14** (panel a) and **15** (panel b) from myosin subfragment 1 by excess ATP.

Figure 5. Equilibrium binding of rhodamine-ADP analogues **14** (○) and **15** (●) to myosin subfragment 1, monitored by fluorescence anisotropy. The solid lines are best fits to eq 1, with values for K_d and limiting anisotropy as shown in the Results.

15 with $2.5 \mu\text{M}$ subfragment 1, were 1.9 s^{-1} and 1.3 s^{-1} , respectively (data not shown).

The equilibrium dissociation constants of **14** and **15** from subfragment 1 were investigated by fluorescence anisotropy titrations. Increasing concentrations of subfragment 1 were added to a solution of $1 \mu\text{M}$ **14** or **15**. The anisotropies of **14** and **15** free in solution were 0.070 and 0.060, respectively, and, as the subfragment 1 concentration increased, both isomers showed a hyperbolic increase in anisotropy (Figure 5). Fitting these data to eq 1 gave values for the limiting anisotropy of 0.168 and 0.294, and equilibrium dissociation constants of 2.62 ± 0.26 and $2.27 \pm 0.60 \mu\text{M}$ for **14** and **15**, respectively.

DISCUSSION

The pH-dependent reversible cyclization of rhodamine sultams has consequences for experiments that use sulforhodamine dyes. First, the apparent pK_a for the colored to colorless transition of **3** varies markedly with changes in solution conditions. In contrast to the value of 7.37 determined here by absorbance measurements of water-ethanol solutions, Marchesini et al. (5) reported an apparent pK_a of ~ 4.6 from fluorescence measurements in fully aqueous solutions that contained 0.1% reduced

Triton X-100. In our hands, absorbance measurements under the latter conditions gave a value of 5.36. Thus, the apparent pK_a is substantially lower in the presence of reduced Triton X-100. The critical micellar concentration of this detergent is 0.25 mM (15), substantially below the 0.1% level used by Marchesini et al. [1.6 mM based on an average molecular weight of 625 (16)]. We suggest the lipophilic sultam form of **3** would partition preferentially into micelles and the resultant stabilization of the conjugate base is responsible for enhanced acidity of the open form. The earlier proposal (5) that **3** could be used as a pH indicator for cellular compartments of acidic pH is therefore problematic. However, introduction of hydrophilic substituents on one or more of the nitrogen atoms in **3** could generate a new family of fluorescent pH indicators. Modulation of the pK_a by variable substitution of the aromatic amino groups in compounds related to **3** has been qualitatively described in the patent literature (8a). In the present work, the sensitivity of the apparent pK_a to changes in substituents is demonstrated by the values obtained for the ATP conjugate **12**, i.e., 9.12 in fully aqueous solution and 8.24 in solutions containing 25% ethanol. The overall shift to a higher value can be rationalized by the inductive effect of the β -nitrogen in the substituent on the sulfonamide, that reduces the nucleophilicity of the sulfonamide nitrogen, i.e., the driving force for ring closure is reduced. The apparent pK_a values for **3** and **12** appear to change in opposite directions when measured in water or ethanol–water. Complex solvation effects are well-known to influence acid and base strengths (17) and probably underlie these differences.

A second point is that the kinetics of the ring opening and closing reactions of the model sultam **3** at pH values near neutrality are in the millisecond time domain, i.e., comparable to rates of many biological processes. Thus small variations of pH could themselves generate rapid signals from probes that incorporate the sultam structure. Since the kinetics of the color change are slow compared to most indicators, these rhodamine sultams would not be suitable to measure very rapid pH changes.

Third, the ability to separate compounds **9** and **10** means that rhodamine probes of this type, insensitive or sensitive respectively to the effects of pH and suitable for covalent attachment to biomolecules, can be considered as accessible. In particular, the Rhodamine Red-X reagent (11) has been shown to be insensitive to pH changes and therefore must have a structure derived from isomer **9**.

The interactions of the isomeric ATP conjugates **12** and **13** with myosin subfragment 1 demonstrate the potential for the different isomers of these and other sulforhodamine conjugates to report differently on underlying biological processes. In single turnover experiments when **12** and **13** were mixed with excess subfragment 1, both isomers showed an initial exponential decrease in fluorescence followed by a slower increase in fluorescence. Such behavior has previously been observed when ATP was mixed with subfragment 1 and intrinsic tryptophan fluorescence monitored (18) or when fluorescent analogues of ATP were mixed with subfragment 1 (19–23). The results can be interpreted in light of a simplified scheme for the subfragment 1 ATPase mechanism (24).

The initial process is associated with the essentially irreversible binding of ATP (or an analogue thereof) to subfragment 1 (step 1) to form the M·ATP state, that is in rapid equilibrium with M·ADP·P_i (step 2). This is followed by the rate-limiting inorganic phosphate release step of the overall hydrolysis process (step 3), that is also essentially irreversible, and the cycle terminates with the release of ADP (step 4).

The rate constants given in the Results section for the initial fluorescence decrease when **12** or **13** were mixed with subfragment 1 show that **12** binds at over twice the rate of **13**. However, for the subsequent slow increase of fluorescence that corresponds to the rate-limiting step of the overall hydrolysis (step 3), rate constants for the two isomers were identical within experimental error and similar to that of the subfragment 1 ATPase (18).

As shown in Figure 3, the amplitudes of the slow fluorescence recovery, that corresponds to step 3 above, were markedly different for the two isomers. The much smaller amplitude of the slow phase for analogue **12** could result from its ADP form **14** binding more tightly to subfragment 1 than the isomeric ADP analogue **15** and/or that the enhancement of fluorescence on binding to subfragment 1 is greater for isomer **14**. The displacement of these ADP analogues from subfragment 1 by excess ATP gave a larger increase in fluorescence for **14** than for **15**, which again might be due to tighter binding or higher fluorescence change of **14**. The rate constant for dissociation of **14** was almost twice that for **15**. However, the equilibrium titrations based on fluorescence anisotropy measurements show that, within experimental error, the two ADP analogues bind to subfragment 1 with the same affinity, suggesting that **14** has a faster second-order association rate constant than **15**, as reported in the Results. Thus the ATP and ADP analogues are similar in that in each case the pH-responsive isomer shows more rapid binding. The differences highlight the importance of using defined isomers of these rhodamine conjugates. A particular source of potential error could have arisen in our previous FRET-based distance measurements (1, 2) using these conjugates if the pH-responsive isomer were present and underwent some degree of cyclization upon binding to a protein. The results now reported and related data not shown confirm that sulforhodamine conjugates with both GTP and ATP used in previous work were solely the nonresponsive isomers because the pH-responsive isomers were well-resolved by preparative anion exchange chromatography.

The results described in this work put the chemistry of sulforhodamine-amine conjugates on a sound foundation and clarify some previous reports. Future challenges are to define in detail the mechanism of the ring-chain tautomerization process and explore uses of these conjugates, particularly the pH-responsive forms, as probes in biophysical research.

ACKNOWLEDGMENT

We thank Drs. S. Howell and K. Welham for the low and high resolution mass spectral data, respectively, Dr. S.R. Martin for some spectroscopic pH titrations and Drs. V.R.N. Munasinghe and G. Kelly for recording NMR spectra. We are grateful to the MRC Biomedical NMR Centre for access to facilities.

Received July 15, 2000; Revised Manuscript Received October 20, 2000

A potent, long-lasting form of interferon α -2a mono-pegylated with a 40 kilodalton branched poly(ethylene glycol) was designed, synthesized, and characterized. Mono-pegylated interferon α -2a was comprised of four major positional isomers involving Lys³¹, Lys¹²¹, Lys¹³¹, and Lys¹³⁴ of interferon. The *in vitro* anti-viral activity of pegylated interferon α -2a was found to be only 7% of the original activity. In contrast, the *in vivo* antitumor activity was severalfold enhanced compared to interferon α -2a. Pegylated interferon α -2a showed no immunogenicity in mice. After subcutaneous injection of pegylated interferon α -2a, a 70-fold increase in serum half-life and a 50-fold increase in mean plasma residence time concomitant with sustained serum concentrations were observed relative to interferon α -2a. These preclinical results suggest a significantly enhanced human pharmacological profile for pegylated interferon α -2a. Results of Phase II/III hepatitis C clinical trials in humans confirmed the superior efficacy of pegylated interferon α -2a compared to unmodified interferon α -2a.

INTRODUCTION

Interferon α is comprised of a family of closely related, species-restricted proteins that exhibit anti-viral, anti-tumor, and immunomodulatory activities (1). The recombinantly produced human interferon α -2a and interferon α -2b (1) have undergone extensive clinical investigations and have become useful drugs for both viral and oncological indications (2–6).

The reported terminal half-life of interferon α ranges from 4 to 8 h, with peak serum concentrations occurring at 3–8 h following intravenous (i.v.) or subcutaneous (s.c.) administration (7). Little or no interferon α is detected 24 h following i.v. or s.c. administration (7, 8), necessitating frequent dosing of interferon α to achieve sustained efficacy. The frequency of interferon α treatment is dependent upon the disease being treated. For example, certain oncological indications require daily dosing, while viral indications may require only three times weekly dosing. Interferon α treatment for these diseases at the above-mentioned intervals may range from periods of several months to a year or longer. Furthermore, frequent treatment with interferon α produces several dose-dependent side effects (9).

In recent years, poly(ethylene glycol) (PEG) conjugated biomolecules have been shown to exhibit superior clinically useful properties than their corresponding unmodified parent molecules (10–12). These include better physical and thermal stability, greater protection against proteolytic degradation, higher solubility, longer *in vivo*

circulating half-lives, and lower clearance, thus enhancing efficacy. Additional qualities of pegylated proteins are reduced immunogenicity and antigenicity, as well as reduced toxicity.

Hepatitis C virus (HCV) infection is a blood-borne disease of the liver. In the United States alone, an estimated four million Americans are infected with HCV and up to 180 000 new infections occur each year. Currently, the only available treatment for HCV is with interferon, injected three times per week. However, the patient population experiencing sustained response of undetectable levels of HCV is only 10–15%.

In the early 1990s, an attempt was made to develop a pegylated form of interferon α -2a for hepatitis C. The desired target profile was once a week dosing with comparable efficacy to interferon α -2a given three times weekly. Interferon α -2a was pegylated with a linear 5K PEG via urea linkage (13). In 1994, development of first generation PEG-interferon α -2a with once a week dosing was discontinued during Phase II clinical trial because efficacy equivalent to interferon α -2a given three times weekly was not achieved.

Since then, many new insights have been gained on the pegylation of protein therapeutics. Among them are (1) *in vitro* activity (cell-based) of a number of cytokines, whose pharmacological effects involve receptor interactions, is shown to be inversely proportional to the attached PEG mass and is not predictive of *in vivo* biological activity (12, 14, unpublished data); (2) one large PEG at a single site is preferable to several small PEGs attached at multiple sites (12); (3) linear PEG is distributed throughout the body with larger distribution volume (15); (4) branched PEG is distributed with a smaller distribution volume and early on delivered to the liver

and spleen (15); (5) branched PEG protein conjugates exhibit increased pH and thermal stability, as well as greater stability toward proteolytic digestion (16); (6) smaller linear PEGs may deposit in the kidney vacuoles (17).

Another major development was the elucidation of a model, which predicts efficacy based upon combined pharmacokinetic and pharmacodynamic analyses (8, 18). Of great importance, the model predicts a correlation between efficacy and the trough levels of interferon-induced surrogate marker protein, 2',5'-oligoadenylate synthetase (2',5'-OAS) in peripheral blood mononuclear cells (PBMNs), but not with peak levels or area under the curve of 2',5' OAS. Pharmacokinetic data obtained from animal studies can also be used to develop simulations that will indicate what might occur in patients who receive various doses and regimens of PEG-interferon α -2a.

The ability to predict the efficacy of PEG-interferon α -2a, coupled with the latest advancements in pegylation technology convinced us to pursue the development of a second generation PEG-interferon α -2a with hepatitis C virus (HCV) as the first target indication.

A 40K branched PEG was selected because of the possibility that it would facilitate the delivery of PEG-interferon α -2a to the liver and its ability to circulate for a long period of time in the blood. Thus, interferon α -2a conjugated with a branched 40K PEG (PEG₂-IFN) would have a better chance of eradicating hepatic and extra-hepatic HCV infection.

EXPERIMENTAL PROCEDURES

Materials. Interferon α -2a (IFN) and 5K PEG-IFN were obtained from the Biopharmaceuticals Department of Hoffmann-La Roche Inc. A branched 40K succinimidyl derivative of PEG (PEG₂-NHS) was purchased from Shearwater Polymers Inc. (Huntsville, AL). Fractogel EMD CM 650(M) was supplied by EM Separations (Gibbstown, NJ). Precast SDS-PAGE gels and electrophoresis units were purchased from Novex (San Diego, CA). Titrisol, concentrated iodine solution, was from EM Science (Gibbstown, NJ). Anti-PEG AGP3 monoclonal antibody was acquired from Academia Sinica (Taipei, Taiwan). Super Signal ULTRA Western blotting kit was provided by Pierce (Rockford, IL). The LAL endotoxin kit was obtained from Associates of Cape Cod (Woods Hole, MA). All other reagents used were of highest quality available. The cannulated rats and BDF-1 mice were supplied by Charles River Laboratories (Wilmington, MA).

Preparation of PEG₂-IFN. Pegylation reaction mixture was comprised of interferon α -2a and 40K PEG₂-NHS reagent at 1:3 molar ratio in 50 mM sodium borate buffer, pH 9.0. The final protein concentration was ~5 mg/mL. Reaction mixture was stirred for 2 h at 4 °C. Reaction was stopped by adjusting the pH of the mixture to 4.5 with glacial acetic acid.

Reaction mixture was diluted 10-fold with water and applied onto a column packed with Fractogel EMD CM 650(M) resin, previously equilibrated with 20 mM sodium acetate, pH 4.5, at a linear velocity of 1.3 cm/min. Protein loading onto the column was 2 mg/mL gel. Column was washed with the equilibration buffer to remove excess

PEG reagent, reaction byproducts and PEG₂-IFN oligomers. The desired mono-pegylated PEG₂-IFN was then eluted with 200 mM sodium chloride in the equilibration buffer. Unmodified interferon α -2a still adsorbed onto the column was removed by washing with 750 mM sodium chloride in the equilibration buffer. Mono-pegylated PEG₂-IFN eluate was further concentrated to approximately 1 mg/mL and diafiltered into the final storage buffer, 20 mM sodium acetate, pH 5.0, containing 150 mM sodium chloride. Concentrated PEG₂-IFN was sterile filtered with a 0.2 μ m filter and stored at 4 °C.

Protein Determination. Protein concentrations were determined using an A_{280} value of a 1 mg/mL solution of PEG₂-IFN as 1.05.

SDS-PAGE Analysis. Reaction mixture and the purified PEG₂-IFN was subjected to sodium dodecyl (lauryl) sulfate/polyacrylamide (8–16%) gel electrophoresis according to the methods of Laemmli (19) and stained for protein using Coomassie blue dye.

PEG moieties in the PEG₂-IFN conjugates were specifically stained using Titrisol iodine solution (EM Science, Gibbstown, New Jersey) according to a modified procedure of Kurfurst (20). The SDS-PAGE gel was rinsed with distilled water and placed in 5% barium chloride solution. After 10 min, the above gel was washed with distilled water and placed in 0.1 N Titrisol iodine solution for another 10 min. Titrisol was washed off with distilled water. The PEG stained (orange brown bands) SDS-PAGE gel containing PEG₂-IFN samples was stored in distilled water in a heat-sealed Kapak/Scotchpak bag.

Western Blotting with Anti-PEG AGP3 Monoclonal Antibody. PEG₂-IFN was transferred from SDS-PAGE gel to nitrocellulose membrane using standard techniques. An anti-PEG monoclonal antibody, denoted AGP3 (21), was used as the primary antibody. Development was performed according to the manufacturer's (Pierce) instructions using SuperSignal ULTRA Western blotting kit for the detection of mouse IgG (Pierce). Secondary antibody used was goat anti-mouse IgG conjugated with horseradish peroxidase. An ultra sensitive chemiluminescent compound provided as part of the Western blotting kit (Pierce) was used as the enzyme substrate.

Amino Acid Analysis. N-Terminal sequence and amino acid composition analyses were performed with a postcolumn ninhydrin amino acid analyzer (22).

Mass Spectrometry. Matrix-assisted laser desorption time-of-flight mass spectrometry (MALDI TOF MS) was used to determine the true molecular weight of PEG₂-IFN (13).

Determination of Pegylation Sites. Positional isomers of PEG₂-IFN were separated as described (13) using cation exchange HPLC. Separated positional isomers of PEG₂-IFN were then analyzed by a combination of analytical methods including, peptide mapping, sequencing and mass spectrometry, as described (13).

Determination of Endotoxin Levels. Endotoxin level in PEG₂-IFN preparation was determined using the lumulus ameocyte lysate (LAL) method according to the manufacturer's (Associates of Cape Cod) instructions.

In vitro Anti-Viral Activity. The in vitro anti-viral activities of interferon α -2a and PEG₂-IFN were determined in a cell culture bioassay employing Mardin-Darby bovine kidney cells challenged with vesicular stomatitis virus as described (23).

In Vivo Antitumor Activity. Athymic nude mice (Harlan) received a subcutaneous implant of 2×10^6 human renal A498 cells or human renal ACHN cells or human renal G402 cells under the rear flank. Three to

¹ Abbreviations: IFN, interferon; PEG, poly(ethylene glycol); HCV, hepatitis C virus; PEG₂-NHS, branched succinimidyl ester derivative of PEG; PEG₂-IFN, 40K PEG conjugated interferon α -2a; PEGASYS, registered name of 40K branched PEG-conjugated IFN- α -2a.

six weeks were allowed for the tumors to get established. The size criteria for acceptance into the study was $0.05-0.50$ cubic centimeters ($\text{Vol.} = L \times W^2$). Mice were treated once weekly (Monday) with each of the dosages of 30, 60, 120, or $300 \mu\text{g}$ of PEG₂-IFN. In the case of interferon α -2a the mice were treated thrice weekly (Monday, Wednesday, and Friday) with 10, 20, 40, or $100 \mu\text{g}$ of interferon α -2a. The duration of treatment was 4–5 weeks depending on tumor growth. Tumor volumes were measured every Monday prior to treatments.

Pharmacokinetics. Female Sprague Dawley rats, surgically implanted with jugular cannulas with an average body mass of 240–260 g were housed individually, allowed free access to food and water and maintained in a 12 h light/dark cycle. Within 4–6 h after arrival, jugular cannulas were flushed with PBS (phosphate buffered saline). The following day, after flushing with $0.15-0.2$ mL PBS, 2×10^6 units of interferon α -2a and PEG₂-IFN were injected, followed by injection of $0.15-0.2$ mL of PBS to ensure that all drug was washed into the animal. Thus, each animal received a dosage of 8×10^6 interferon units/kg body weight.

Blood samples were drawn at 0.5, 1, 3, 5, 12, and 24 h after injection of the drugs. At all time points, after discarding the first $0.15-0.2$ mL of blood, an aliquot of 0.5 mL of blood was withdrawn using a fresh syringe via the jugular cannula. Samples were discharged into serum separator tubes at room temperature and centrifuged at $14000g$ in a refrigerated Eppendorf centrifuge for 10 min. The separated sera were then transferred into 1.5 mL microfuge tubes and kept frozen at -80°C until ready for the determination of anti-viral activity. Serum samples were diluted appropriately and the anti-viral activity was determined as described previously (23).

Neutralizing Antibodies. Normal BDF-1 mice (10/group) were injected intraperitoneally once per day five times a week with interferon α -2a, aggregates of interferon α -2a, 5K PEG-IFN and PEG₂-IFN, each having 300 000 units of anti-viral activity. Blood samples were taken 19 days following the last injection and the serum was evaluated for neutralizing antibodies as described (24).

RESULTS

Description of Branched Pegylation Reagent.

PEG₂-NHS (Figure 1) consists of two monomethoxy poly(ethylene glycol) chains each having an average molecular weight of 20K, linked to a lysine molecule via urethane bonds, one at the α -amino group and the other at the ϵ -amino group of lysine. The carboxyl group of lysine in turn is derivatized to an *N*-hydroxysuccinimide ester (16).

Synthesis of Pegylated Interferon α -2a. PEG₂-IFN was formed as a result of the reaction between an *N*-hydroxysuccinimide ester derivative of a 40K branched PEG molecule and the free amino group of interferon α -2a forming an amide bond. The reaction mechanism is illustrated in Figure 1.

Under the experimental conditions used, pegylation reaction products were a mixture containing approximately 45–50% monomer, 5–10% oligomers (predominantly dimer), and 40–50% unmodified interferon α -2a, as determined by densitometric measurements and by mass spectrometry (data not shown). Purified PEG₂-IFN was ~95–99% mono-pegylated, as determined by SDS-PAGE analysis (both protein and PEG staining, Figure 2, respectively) and mass spectrometry, as well as by Western blotting with a newly discovered high-affinity

Figure 1. Reaction mechanism of the synthesis of PEG₂-IFN. The free amino groups of interferon α -2a react with the *N*-hydroxysuccinimide ester derivative of a 40K branched poly(ethylene glycol) forming an amide bond between the two.

monoclonal antibody which recognizes PEG (21) (Figure 3). PEG₂-IFN preparation contained <2.5 endotoxin units/mg.

Characterization of PEG₂-IFN. Upon the basis of the 40K average molecular weight of the branched PEG moiety and the 19.2K molecular weight of interferon α -2a, it is estimated that the molecular weight of PEG₂-IFN is ~59.2K. However, the actual molecular weight of PEG₂-IFN is dependent upon the average molecular weight (39–43K) of PEG₂-NHS reagent used in the pegylation reaction.

Figure 2 illustrates the SDS-PAGE profiles of the pegylation reaction mixture, purified PEG₂-IFN and interferon α -2a as determined by protein specific and PEG-specific staining. In addition to the various PEG₂-IFN conjugates (mono-, di-, tri-, etc.), reaction mixture contains unmodified interferon α -2a and excess PEG reagent (Figure 2). PEG₂-IFN's electrophoretic mobility is considerably slowed because of PEG's large hydrodynamic volume (3 mol of water form an adduct with each ethylene oxide subunit of PEG) (25). In addition, branched PEG could get trapped into the polyacrylamide gel matrix, further slowing down the electrophoretic mobility. Thus, PEG₂-IFN appears to have a higher molecular weight (~96K, Figure 2A) than the calculated molecular weight when compared to molecular weight marker proteins. However, in Figure 2B, PEG₂-IFN has a molecular weight corresponding to its expected molecular weight of 59–60K when compared to standard PEG molecular weight markers. This result is consistent with that obtained by MALDI-TOF mass spectrometry (data not shown).

Western blotting with AGP3 antibody directed against PEG (21) demonstrated that the purified PEG₂-IFN is authentic, predominantly mono-pegylated and did not contain fragments of PEG or significant amounts of oligomeric forms of PEG₂-IFN (Figure 3).

Both interferon α -2a and PEG₂-IFN have identical amino acid sequence and amino acid composition (data not shown). The only difference in the composition of

Figure 2. SDS-PAGE analysis. (A) Specifically stained for protein with Coomassie blue. Lanes: 1, molecular weight marker proteins; 2, pegylation reaction mixture; 3, purified PEG₂-IFN; and 4, interferon α -2a. (B) Specifically stained for PEG with iodine. Lanes: 1, molecular weight marker PEGs; 2–4, same as in Figure 2A. Note that lane 4 containing interferon α -2a in gel B is not stained by iodine.

Figure 3. Western blotting of PEG₂-IFN with AGP3 monoclonal antibody directed against PEG. Five second exposure of the film. Lanes: 1, interferon α -2a (1 μ g), as expected, no recognition by AGP3 antibody; 2, PEG₂-IFN (0.1 μ g); 3, PEG₂-IFN (0.5 μ g); and 4, PEG₂-IFN (1 μ g).

native and modified proteins is due to the formation of an amide bond between the amino group of interferon α -2a and the PEG molecule at the point of attachment (Figure 1).

A combination of high performance cation exchange chromatography, peptide mapping, amino acid sequencing and mass spectrometric analyses were performed to identify the pegylation sites (data not shown). A single unit of branched poly(ethylene glycol) was found to be attached to either one of Lys³¹, Lys¹²¹, Lys¹³¹, or Lys¹³⁴. Collectively, ~94% of the PEG attachment takes place in these four sites. The remaining ~6% of the pegylation takes place at Lys⁷⁰ and Lys⁸³. The N-terminal cysteine, which is involved in a disulfide bond (Cys¹–Cys⁹⁸), does not appear to be a pegylation site.

In Vitro Anti-Viral Activity. The anti-viral activities of interferon α -2a and PEG₂-IFN are compared in a cell culture bioassay utilizing Mardin-Darby bovine kidney (MDBK) cells challenged with vesicular stomatitis virus. This assay measures interferon's inhibitory effect on virus induced cell lysis (cytopathic effect). Procedure

Table 1. In Vitro Antiviral Activities of Interferon α -2a and PEG₂-IFN^a

protein	anti-viral activity (IU/mg)	residual activity (%)
interferon α -2a	2×10^8	100
PEG ₂ -IFN	1.4×10^7	7

^a Antiviral activity determined in MDBK cells infected with vesicular stomatitis virus.

involves the addition of serially diluted interferon samples MDBK cells followed by a challenge with virus. The endpoint of the assay is approximately a 50% protection of MDBK cells. The quantity of interferon present is determined relative to a reference preparation of interferon. The unit of anti-viral activity is an arbitrarily established value by the World Health Organization. PEG₂-IFN had an anti-viral specific activity of approximately 7% of that of interferon α -2a. Results are listed in Table 1.

In Vivo Antitumor Activity. The in vivo antitumor activity of PEG₂-IFN and interferon α -2a were evaluated by studying their ability to reduce the size of various human tumor cells implanted subcutaneously into mice. PEG₂-IFN showed a marked reduction in human renal A498 tumor size (Figure 4, bottom panel) compared to interferon α -2a (Figure 4, top panel) for all dosage levels tested, at 7, 14, 21, and 28 days after the beginning of treatment. After 4 weeks of treatment and 7 days after treatment was discontinued, three mice in each group were sacrificed. In the three mice treated with PEG₂-IFN, no residual tumor was observed. In the mice treated with interferon α -2a, tumor weight was 1.28, 0.62, and 1.6 g, respectively. In the three control mice, the A498 tumor weights were 2.32, 2.37 and 1.94 g, respectively. Eighty days following termination of PEG₂-IFN treatment, all seven remaining mice were free of tumor as determined by palpation in the 4-week treatment group. Similarly, PEG₂-IFN effected a significant reduction in the size of ACHN and G402 human renal tumors (data not shown).

Pharmacokinetic Parameters. Pharmacokinetic parameters of PEG₂-IFN were determined after subcutaneous injection into female Sprague–Dawley rats. Figure 5 illustrates the mean serum activity versus time. Summary and individual pharmacokinetic parameters are found in Tables 2 and 3. Serum activity of interferon α -2a peaked 1 h after the subcutaneous injection, whereas the peak activity of PEG₂-IFN occurred 24 h after the injection. PEG₂-IFN's peak activity was 3-fold greater

Figure 4. In vivo antitumor activity of interferon α -2a (top panel) and PEG₂-IFN (bottom panel) in athymic nude mice subcutaneously implanted with human renal A498 cells. Insert shows the amount of interferon α -2a and PEG₂-IFN used in the treatment of the mice implanted with the tumor. x- and y-axes indicate the days and the corresponding tumor volumes, respectively.

Figure 5. Mean serum activity versus time of interferon α -2a and PEG₂-IFN after subcutaneous injection in rats. PEG₂-IFN has a 51-h half-life compared to 0.7-h for interferon α -2a concomitant with mean plasma residence time of 80 and 1.6 h, respectively. Logarithmic regression analyses were used to calculate the pharmacokinetic parameters.

than that of interferon α -2a. Area under the curve, up to the last measurable time point of PEG₂-IFN, was 6-fold greater than that of interferon α -2a. After subcutaneous injection of PEG₂-IFN, a 70-fold increase in half-life and a 50-fold increase in mean residence time (MRT) were

observed. C_{max} and AUC of the PEG₂-IFN were 3.5- and 59-fold increased, respectively compared to those of interferon α -2a. Consequently, PEG₂-IFN has a significantly increased plasma exposure.

Neutralizing Antibodies. As seen in Table 4, mice injected with PEG₂-IFN produced no detectable amount of neutralizing antibodies in 9 of the 10 animals tested. In contrast, mice injected with interferon α -2a produced neutralizing antibodies and this response was greatly pronounced in mice injected with interferon α -2a aggregates. A much-reduced response was observed with the first generation PEG-interferon α -2a in which the PEG moiety was linear and had a molecular weight of 5K.

DISCUSSION

To take full advantage of the clinically useful properties of branched poly(ethylene glycol) and to meet the minimum threshold PEG mass requirement, we chose a 40K branched poly(ethylene glycol) moiety for the pegylation of interferon α -2a. PEG₂-IFN was well-characterized using various analytical methods including immunoblotting with a newly discovered high-affinity AGP3 monoclonal antibody directed against PEG. The discovery and availability of this antibody opens whole new avenues to follow the metabolic fates of PEG₂-IFN and other pegylated protein therapeutics.

^a Interferon neutralizing units/mL. INU/mL = (units of interferon neutralized $\times$ serum dilution)/(final test volume). ^b One of 10 animals in the group produced neutralizing antibody.

PEG₂-IFN is comprised of mono-pegylated interferon α -2a (1 PEG/mol of interferon α -2a) but distributed among four major pegylation sites. In addition to the N-terminus, there are 11 lysines available for pegylation. It should be noted that when a low molecular weight poly(ethylene glycol) (e.g., 5K) was used for pegylation of interferon α -2a all 11 lysines were pegylated (13), thus more heterogeneous than the PEG₂-IFN in terms of positional isomers. Not all pegylation sites are readily accessible to the 40K branched PEG due to its larger size and shape. The end-result is fewer sites are pegylated. Thus PEG₂-IFN is less heterogeneous than the linear low molecular weight PEG-IFN.

It is postulated that the chemical attachment of PEG moieties to the polypeptide backbone of interferon α -2a produces some form of conformational perturbances, which may adversely affect receptor/ligand interactions and thus lower binding affinity (12). This is one reason in vitro anti-viral activity is considerably decreased compared to interferon α -2a. In addition, the relatively short incubation time (hours) of the in vitro assay is probably insufficient for the low affinity PEG₂-IFN to reach peak activity. On the other hand, in vivo bioassays in mice for example, are much longer (days) and are terminated after several days after the injection of the drug. The extended exposure time afforded by the longer half-life of the PEG₂-IFN (Tables 2 and 3) compensates for any slack in the binding interactions due to pegylation. The end-result is maximum biological effect. A sustained release prodrug mechanism is ruled out because the amide bond between PEG and interferon α -2a is stable.

Fish (26) and Klaus et al. (27) define amino acid domains Cys²⁹–Asp³⁵ and Phe¹²³–Trp¹⁴⁰ in interferon α -2a as responsible for receptor binding interactions, as well as constituting the receptor recognition site. These

two domains are located on the surface of interferon α -2a and are in close spatial proximity. The four major pegylation sites in PEG₂-IFN also fall within these domains. In the cell-based in vitro assay with the relatively short incubation time combined with the sites of pegylation plays a major role in how many chances PEG₂-IFN gets to interact with its receptor. However, in vivo biological effect is not expected to be affected in a similar fashion. Though there may be some interference in receptor binding due to pegylation, the very large circulating half-life combined with the flexibility of poly(ethylene glycol) provides enough opportunities for interferon α -2a to come into contact with the receptor to exert its biological effect.

Contrary to the reduced in vitro anti-viral activity of PEG₂-IFN, a significantly enhanced in vivo antitumor activity was observed in various transplanted human tumors. Reduced in vitro activity accompanied with increased in vivo biological activity has been observed with other pegylated protein therapeutics. Examples are G-CSF (28), IL-2 (29), TNF- α (30), IL-6 (31), and CD4-IgG fusion protein (32), among others. The enhanced antitumor activity suggests that PEG₂-IFN is potentially a far superior antitumor agent than interferon α -2a. Consequently, there are a number of clinical trials ongoing or planned for the treatment of several forms of cancer, such as renal carcinoma, malignant melanoma, chronic myelogenous leukemia, among others.

PEG₂-IFN provides extraordinary protection against production of antibodies against interferon α -2a in mice compared to the linear low molecular weight first generation PEG-interferon α -2a. Since interferons are species-restricted, human interferons are generally immunogenic in animals. Therefore, the lack of immunogenicity in mice is a good indication that it will be less immunogenic in humans.

A Phase II clinical trial was initiated in 1998 with PEG₂-IFN in noncirrhotic patients. The Phase II clinical trial results (33) demonstrated that hepatitis C patients treated with PEG₂-IFN once weekly showed undetectable levels of the virus in 76% of the patients, 12 weeks after treatment. Another 36% of patients had similar response, 24 weeks following completion of treatment. On the other hand, only 17% of the patients who had undergone the standard interferon α -2a treatment experienced undetectable levels of hepatitis C virus after 12 weeks of

treatment and only 3% maintained undetectable levels of virus for 24 weeks following the completion of treatment.

A Phase II/III clinical trial of PEG₂-IFN in cirrhotic hepatitis C patients had shown that 29% of the patients experienced a sustained response of nondetectable levels of hepatitis C virus, compared to only 6% of patients treated with interferon α -2a. Sustained response is measured for 24 weeks following 48 weeks of treatment (34).

Finally, in a large Phase III clinical trial (35), PEG₂-IFN exhibited superior efficacy than standard interferon. Highlights of the trial include (1) at the end of treatment virological response was 69% for PEG₂-IFN compared to only 29% for interferon treated group, (2) sustained virologic response was observed in 39% of patient population, (3) in the toughest to treat patient population; those with cirrhosis, 39% experienced sustained virological response, (4) histology was significantly improved, (5) tolerability was similar to standard interferon, and (6) dosing regimen included convenient once weekly dosing compared to thrice weekly dosing of standard interferon.

It is remarkable that although PEG₂-IFN used in the clinical trials had only 5–10% of the original in vitro antiviral activity of interferon α -2a, yet it was significantly more effective in treating HCV infection in humans than the standard interferon. Thus PEG₂-IFN, with the registered name of PEGASYN is a well-tolerated and effective treatment for hepatitis C patients, including those with difficult to treat liver cirrhosis.

ACKNOWLEDGMENT

We thank Dr. Hanspeter Michel and Ms. Barbara DeBarbieri for Mass Spectrometric Analyses. We are grateful to Dr. Wayne Levin for critical review of this manuscript and Ms. Jamie Colarusso for secretarial assistance.

4-Oxo-4*H*-quinolizine-3-carboxylic Acids as Mg^{2+} Selective, Fluorescent Indicators

Pieter A. Otten, Robert E. London, and Louis A. Levy*

National Institute of Environmental Health Sciences, Laboratory of Structural Biology, P.O. Box 12233, MR-03, RTP, North Carolina 27709. Received July 20, 2000; Revised Manuscript Received December 4, 2000

In this paper, we present the synthesis of a new series of substituted 4-oxo-4*H*-quinolizine-3-carboxylic acids and the evaluation of their fluorescent response upon complexation with Mg^{2+} and Ca^{2+} . This has led to the development of the first Mg^{2+} -selective, ratioable fluorescent indicators. We found that 4-oxo-4*H*-quinolizine-3-carboxylates are excellent fluorophores which show a strong fluorescent response to Mg^{2+} but not to Ca^{2+} ; the latter metal ion often causing interference during Mg^{2+} measurements with previously described indicators. The dissociation constants of the studied fluorophores—around 1.0 mM—are of the same order of magnitude as is usually observed for intracellular Mg^{2+} .

INTRODUCTION

Magnesium ions play a fundamental role in cellular biochemical processes (1–7), and epidemiological studies have suggested correlations between plasma or cellular Mg^{2+} levels and various chronic diseases, including ischaemic heart disease (8), hypertension (9), atherosclerosis (10), osteoporosis (11), and migraines (12). It is therefore surprising that methods for the determination of both intracellular and plasma Mg^{2+} are fairly limited. In particular, recent studies by Elin and co-workers have documented significant problems with determinations based on Mg^{2+} -selective electrodes (13–15). Fluorine or phosphorus-containing NMR indicators have proven useful, but have limited sensitivity (16–23). Fluorescent indicators for Ca^{2+} and other cations provide a high sensitivity means for the determination of intracellular ion levels (18, 24). Most currently used fluorescent indicators for cellular Mg^{2+} are based on the aminophenol triacetic acid (APTRA) structure (16, 25, 26). While this class of indicators possesses many desirable characteristics as a fluorescent indicator, most particularly a fluorescence emission or excitation shift (depending on the derivative) upon Mg^{2+} complexation, these indicators suffer from the important limitation that they have a higher affinity for Ca^{2+} than for Mg^{2+} (16). This behavior significantly limits the application of APTRA derivatives for some types of measurements; in fact, in some systems APTRA indicators have been used as low affinity Ca^{2+} indicators (27–29). We note here that a number of Mg^{2+} -selective chelators and even fluorescent indicators that have been described (e.g., refs 30 and 31) are not directly applicable to measurements in biological systems due to limited water solubility, mismatch of the K_D to physiological Mg^{2+} levels or other limiting factors.

In our search for a more Mg^{2+} selective indicator, we became aware of the fluorinated quinolones, widely used as antibiotics, which are known to chelate Mg^{2+} (32–34). The dissociation constants for Mg^{2+} , K_D^{Mg} are typically close to 1 mM, well suited for determinations of either intra- or extracellular Mg^{2+} concentrations, while the K_D^{Ca} values are typically an order of magnitude greater (32, 34). Although the K_D values for other cations are in some cases lower than the K_D^{Mg} value, these ions are

typically not present at concentrations which would be expected to compromise the measurement of Mg^{2+} . Sensitivity of the spectroscopic properties of the fluoroquinolones to ion complexation has previously been noted (32–34). Chapman et al. (35) have reported increases in the fluorescence of the benzoquinolones fleroxacin, norfloxacin, and pefloxacin in the presence of Mg^{2+} with no concomitant shift in the wavelength of the resulting complex. In contrast, the fluorescence spectra of these molecules were found to be insensitive to 1 mM Ca^{2+} .

A recent report on the synthesis and biological activity of the isomeric 4-oxo-4*H*-quinolizine-3-carboxylic acids (36) encouraged us to explore their utility as possible fluorescent chelators. In this study we describe the synthesis (Scheme 1) of a series of new 4-oxo-4*H*-quinolizine-3-carboxylic acid derivatives and the evaluation of their potential as fluorescent indicators for Mg^{2+} . Our synthetic efforts were aimed at preparing indicators with appropriate dissociation constants and, ideally, an excitation or emission shift in order to allow a determination based on a fluorescence ratio, to introduce polyvalency into the 4-oxo-4*H*-quinolizine-3-carboxylic acids, and to extend the conjugation of the parent nucleus so as to achieve 500+ nm fluorescence emission maxima. Esters of 4-oxo-4*H*-quinolizine-3-carboxylic acids were conveniently synthesized by a thermal ring closure reaction of the Michael adduct of a 2-picoline and diethyl ethoxymethylenemalonate. Further elaboration of the heterocyclic ring system was achieved by a regioselective, electrophilic aromatic substitution at the 1-position of **1**, or by a nucleophilic substitution of the Cl substituent at the 8-position of **2**. Our search has led to the finding that 4-oxo-4*H*-quinolizine-3-carboxylic acids are excellent fluorophores that respond to changing Mg^{2+} levels. The dissociation constants for Mg^{2+} were found to be in the low or submillimolar range. In addition, and most importantly, these fluorophores are hardly responsive to Ca^{2+} concentrations well above basal intracellular and even extracellular (millimolar) levels.

EXPERIMENTAL SECTION

General Remarks. Tetrahydrofuran (THF) was dried (Na/benzophenone) and distilled prior to use. Dimethyl-

Scheme 1. Synthesis of the Ethyl Esters of 4-Oxo-4H-quinolizine-3-carboxylic Acids 1, 2, and 3

formamide (DMF) was dried over molecular sieves (4 Å). Ethyl acetate, hexane, and diethyl ether and all other commercially available chemicals were used as received. After extractive workup, the combined organic phases were dried over MgSO_4 . Water used in the spectrophotometric experiments was filtered through a Hydro Picopure2 filter. Thin-layer chromatography was carried out on Sigma-Aldrich TLC Plates (silica gel on polyester). Chromatographic purifications were done by flash chromatography using Merck Silica Gel, grade 9385, 230–400 mesh, 60 Å. Melting points were measured on a Fisher-Johns melting point apparatus and are uncorrected. ^1H NMR spectra were recorded on a Nicolet NT 360 MHz NMR Spectrometer and a Varian UNITY plus 400 MHz NMR spectrometer. Chemical shifts are reported in parts per million (δ), using TMS as the internal standard, and signals are expressed as an s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), or br (broad). High resolution mass spectra were obtained from the Washington University Resource for Biomedical and Bio-organic Mass Spectrometry on samples which were chromatographically pure. Compounds **9a** and **21a** were analyzed by FABMS using NBA Li matrix. UV absorption spectra were recorded with a Beckman DU 640 spectrophotometer using Fisherbrand semimicro quartz cells (Fisher Scientific).

Fluorescence Measurements. Fluorescence measurements were recorded with an Aminco-Bowman Series 2 Spectrometer using quartz fluorimeter cuvettes from Sigma. The buffered solutions used in all experiments contained 120 mM KCl, 20 mM NaCl, and 15 mM TRIS, and were brought to pH 7.20 with concentrated HCl. A stock solution of 2 mg of the indicator in 5 mL of buffer was prepared. To record a UV spectrum, the stock solutions were diluted 40 times (25 μL in 975 μL buffer). For the fluorescence titration experiments, 25 μL of the stock solution was diluted 100 times with 2475 μL of buffer. Emission fluorescence and excitation fluorescence spectra were recorded using the appropriate excitation wavelength derived from the UV spectrum of the free indicator. To 2475 μL of a MgCl_2 solution [100 mM, 250 mM, and 500 mM (**2a**)] was added 25 μL of the stock solution of the indicator. Increasing amounts of the MgCl_2 /indicator solution were added to the solution of the free indicator; after each titration step, fluorescence emission and fluorescence excitation spectra were recorded. To determine the pK_a of **21a**, 250 μL of the stock solution of this fluorophore was added to 25 mL, 10 mM MOPS at pH 4.29. A fluorescence emission spectrum was recorded. A 0.1 M NaOH solution, containing an equal concentration of the fluorophore, was added dropwise and

after each pH increase of 0.2 an emission spectrum was recorded. At pH 6.31, no change of the fluorescence emission was observed. The fluorescence emission was plotted against the pH to determine the pK_a which was found to be 5.6.

Ethyl 8-Chloro-4-oxo-4H-quinolizine-3-carboxylate (2). A 250 mL oven-dried (140 $^\circ\text{C}$), three-necked, round-bottomed flask, equipped with an oven-dried 100 mL addition funnel and a pentane thermometer was purged with argon. The flask was charged with 50 mL of dry THF and diisopropylamine (7.2 mL, 50 mmol, dried over NaOH). The addition funnel was charged with a solution of 4-chloro-2-picoline (5.0 g, 40 mmol) in 50 mL of dry THF. The THF/amine solution was cooled to -50 $^\circ\text{C}$, and 20 mL of a 1.6 M solution of *n*-BuLi in hexanes was added rapidly via syringe. Stirring was continued for 30 min. The reaction mixture was then cooled to -78 $^\circ\text{C}$, and the picoline solution was added over a 15 min period while the temperature of the reaction mixture was maintained below -60 $^\circ\text{C}$. The reaction mixture was stirred for an additional 30 min, during which time a bright red suspension formed. The addition funnel was charged with a solution of diethyl ethoxymethylenemalonate (9.5 g, 45 mmol) in 25 mL of dry THF, and the solution was added slowly to the reaction mixture while maintaining the temperature below -60 $^\circ\text{C}$. A pale yellow, clear solution formed which was allowed to warm to -20 $^\circ\text{C}$ over a period of 2 h. The reaction mixture was poured into 500 mL of water and extracted three times with 300 mL of CH_2Cl_2 . Subsequent evaporation of the organic solvent gave a yellow oil (13.30 g, 96%) which was dissolved in 60 mL of xylene. The reaction mixture was refluxed for 16 h, allowed to cool to room temperature, and the orange crystalline residue collected by filtration. The xylene in the filtrate was evaporated in vacuo, the remaining orange solid was stirred overnight with 30 mL of Et_2O and filtered. The combined filtration residues were dried in vacuo over KOH to give pure **2** (6.28 g, 63%), mp 161–4 $^\circ\text{C}$. ^1H NMR (CDCl_3): δ 1.42 (t, $J = 7$ Hz, 3H), 4.41 (q, $J = 7$ Hz, 2H), 6.55 (d, $J = 8$ Hz, 1H), 7.09 (dd, $J = 2$ Hz, $J = 7$ Hz, 1H), 7.53 (d, $J = 2$ Hz, 1H), 8.40 (d, $J = 8$ Hz, 1H), 9.29 (d, $J = 7$ Hz, 1H). MS: m/z 251.0360; required for $\text{C}_{12}\text{H}_{10}\text{ClNO}_3$; 251.0349.

Ethyl 4-Oxo-4H-quinolizine-3-carboxylate (1). Using the procedure described for **2**, compound **1** was obtained as an orange crystalline solid (55%) by flash chromatography (EtOAc), mp 105–9 $^\circ\text{C}$. ^1H NMR (CDCl_3): δ 1.43 (t, $J = 7.0$ Hz, 3H), 4.42 (q, $J = 7.0$ Hz, 2H), 6.65 (d, $J = 8.4$ Hz, 1H), 7.16–7.24 (m, 1H), 7.52–7.66 (m, 2H), 8.41 (d, $J = 8.4$ Hz, 1H), 9.40 (d, $J = 7.3$ Hz, 1H). MS: m/z 217.0735; required for $\text{C}_{12}\text{H}_{11}\text{NO}_3$, 217.0738.

Ethyl Benzo[6,7]-4-oxo-4H-quinolizine-3-carboxylate (3). Using the procedure described for **1**, compound **3** was obtained as an orange powder (45%) by flash chromatography (EtOAc :hexanes 7:3), mp 106–8 $^\circ\text{C}$. ^1H NMR (CDCl_3): δ 1.42 (t, $J = 7.0$ Hz, 3H), 4.42 (q, $J = 7.0$ Hz, 2H), 6.49 (d, $J = 9.7$ Hz, 1H), 7.14 (d, $J = 9.2$ Hz, 1H), 7.48–7.64 (m, 4H), 8.27 (d, $J = 7.7$ Hz, 1H), 9.87 (d, $J = 8.8$ Hz, 1H). MS: m/z 267.0908; required for $\text{C}_{16}\text{H}_{13}\text{NO}_3$, 267.0895.

Ethyl 1-Nitro-4-oxo-4H-quinolizine-3-carboxylate (7). Nitric acid (1.08 g, 17 mmol) was added slowly to acetic anhydride (7 mL) at 5 $^\circ\text{C}$. Stirring was continued for 5 min and the reaction mixture was cooled to -10 $^\circ\text{C}$ (ice/salt bath). Compound **1** (920 mg, 4.2 mmol) was added in one portion. After 5 min an orange precipitate formed, and after 15 min of total reaction time the reaction was judged to be complete by TLC (EtOAc). The

reaction mixture was poured on to 250 g of crushed ice and stirred for 30 min to give an orange suspension which was extracted three times with 100 mL of CH_2Cl_2 . The combined organic layers were washed three times with 100 mL of water. Evaporation of the solvent gave a deep red solid which was further purified by flash chromatography to give 497 mg (50%) of a bright yellow solid, mp 169–70 °C. ^1H NMR (CDCl_3): δ 1.44 (t, J = 7.0 Hz, 3H), 4.45 (q, J = 7.0 Hz, 2H), 7.55, (dd, J = 7.0 Hz, J = 7.0 Hz, 1H), 8.15 (dd, J = 9.7 Hz, 7.0 Hz, 1H), 9.31 (d, J = 9.1 Hz, 1H), 9.47 (s, 1H), 9.60 (d, J = 7.0 Hz, 1H). MS: m/z 262.0601; required for $\text{C}_{12}\text{H}_{10}\text{N}_2\text{O}_5$: 262.0590.

Ethyl 1-[N,N-Di(carbomethoxymethyl)]-4-oxo-4H-quinolizine-3-carboxylate (11). A suspension of **7** (540 mg, 2.0 mmol) and 5% Pd on C in 25 mL of ethanol was stirred under an atmosphere of hydrogen until 50 mL of H_2 had been consumed. TLC (EtOAc) confirmed complete conversion of the starting material. The reaction mixture was filtered, and evaporation of the solvent in vacuo gave 400 mg (86%) of a red solid. The crude product was dissolved in 9 mL of dry acetonitrile and methyl bromoacetate (1.0 mL, 11 mmol), NaI (1.5 g, 10 mmol), and Proton Sponge (2.6 g, 12 mmol) were added. The reaction mixture was refluxed for 17 h, allowed to cool to room temperature, and poured into 200 mL of EtOAc. The resulting suspension was stirred for 1 h and filtered, and the red filtrate was washed three times with a pH 2 buffer solution. Evaporation of the solvent and purification of the crude product by flash chromatography (EtOAc) yielded 410 mg (54%) of a yellow solid, mp 145–8 °C. ^1H NMR (CDCl_3): δ 1.43 (t, J = 7 Hz, 3H), 3.88 (s, 6H), 4.08 (s, 4H), 4.42 (q, J = 7 Hz, 4H), 7.23 (dd, J = 7 Hz, J = 7 Hz, 1H), 7.72 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.50 (d, J = 8 Hz, 1H), 8.62 (s, 1H), 9.43 (d, J = 7 Hz). MS: m/z 376.1252; required for $\text{C}_{18}\text{H}_{20}\text{N}_2\text{O}_7$: 376.1270.

Ethyl 1-Formyl-4-oxo-4H-quinolizine-3-carboxylate (8). **1** (1 g, 4.0 mmol) was dissolved in 2 mL of DMF followed by the addition of POCl_3 (1.0 mL, 11 mmol). The reaction mixture was stirred for 1 h, poured into 100 mL of water and extracted three times with 100 mL of CH_2Cl_2 . Evaporation of the organic solvent gave a sticky yellow solid which was further purified by flash chromatography (EtOAc), followed by overnight stirring with Et_2O . Filtration of the suspension gave a bright yellow powder (920 mg, 93%), mp 179–81 °C. ^1H NMR (CDCl_3): δ 1.43 (t, J = 7 Hz), 4.42 (q, J = 7 Hz), 7.51 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.06 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.80 (s, 1H), 9.57 (d, J = 7 Hz), 9.90 (s, 1H). MS: m/z 245.0683; required for $\text{C}_{13}\text{H}_{11}\text{NO}_4$: 245.0688.

Ethyl 1-Bromo-4-oxo-4H-quinolizine-3-carboxylate (9). To a solution of **1** (2.33 g, 10.7 mmol) in 20 mL of HOAc was rapidly added a solution of Br_2 (1.9 g, 12 mmol) in 10 mL of HOAc. After 5 min, TLC (EtOAc) indicated complete consumption of the starting material. The solvent was evaporated in vacuo and the remaining yellow solid was dissolved in 20 mL of CH_2Cl_2 . To this solution, 3 g of silica gel was added and the solvent was evaporated in vacuo. The silica gel was poured on a prepacked column and the eluted with EtOAc to give **9** (2.1 g, 71%) as a bright yellow solid, mp 156–8 °C. ^1H NMR (CDCl_3): δ 1.43 (t, J = 7 Hz, 3H), 4.43 (q, J = 7 Hz, 2H), 7.03 (dd, J = 7 Hz, J = 7 Hz, 1H), 7.30 (dd, J = 7 Hz, J = 7 Hz, 1H), 7.80 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.63 (s, 1H), 9.49 (d, J = 7 Hz). MS: m/z 294.9839; required for $\text{C}_{12}\text{H}_{10}\text{BrNO}_3$: 294.9843.

Ethyl 1-(2,2-Dicarbethoxyvinyl)-4-oxo-4H-quinolizine-3-carboxylate (12). A 100 mL round-bottomed flask, equipped with a Dean–Stark trap was charged with 50 mL of benzene, **8** (1.22 g, 5 mmol), acetic acid

(5 g, 83 mmol), NH_4OAc (5 g, 65 mmol), and diethyl malonate (2.3 g, 9 mmol). The reaction mixture was refluxed for 48 h. The reaction mixture was allowed to cool to room temperature and washed three times with 50 mL of water. The solvent was evaporated in vacuo, and the crude product was purified by flash chromatography (EtOAc) to yield **12** as a yellow powder (1.58 g, 82%), mp 149–151 °C. ^1H NMR (CDCl_3): δ 1.31 (t, J = 7 Hz, 3H), 1.36 (t, J = 7 Hz, 3H), 1.42 (t, J = 7 Hz, 3H), 4.34 (q, J = 7 Hz, 2H), 4.36 (q, J = 7 Hz, 2H), 4.41 (q, J = 7 Hz, 2H), 7.34 (dd, J = 7 Hz, J = 7 Hz, 1H), 7.82 (dd, J = 8 Hz, 1H), 7.96 (d, J = 8 Hz, 1H), 8.05 (s, 1H), 8.60 (s, 1H), 9.50 (d, J = 7 Hz). MS: m/z 387.1331; required for $\text{C}_{20}\text{H}_{21}\text{NO}_7$: 387.1318.

Ethyl 1-(2,2-Dicarbethoxyethyl)-4-oxo-4H-quinolizine-3-carboxylate (13). To a bright yellow suspension of **12** (750 mg, 1.94 mmol) in 5 mL of ethanol was added NaBH_3CN (68 mg, 1.08 mmol). The reaction mixture turned red, and all solid material dissolved. Stirring was continued for 1 h and the reaction mixture was poured into 50 mL of water. Ethanol was added to the aqueous suspension until a clear solution was obtained which was extracted three times with 100 mL of CH_2Cl_2 . The organic solvent was evaporated, and the crude product was purified by flash chromatography (EtOAc) to give **13** as a bright yellow solid (275 mg, 36%), mp 105–8 °C. ^1H NMR (CDCl_3): δ 1.22 (t, J = 7 Hz, 6H), 1.41 (t, J = 7 Hz, 3H), 3.41 (d, J = 7 Hz, 2H), 3.65 (t, J = 7 Hz, 1H), 4.10–4.25 (m, 4H), 4.41 (q, J = 7 Hz, 2H), 7.23 (m, 1H), 7.70 (m, 1H), 7.84 (d, J = 8 Hz, 1H), 8.33 (s, 1H), 9.50 (d, J = 7 Hz, 1H). MS: m/z 389.1466; required for $\text{C}_{20}\text{H}_{23}\text{NO}_7$: 389.1475.

Ethyl 8-Azido-4-oxo-4H-quinolizine-3-carboxylate (14). An oven-dried 25 mL round-bottomed flask was purged with Ar and charged with **2** (250 mg, 1 mmol), NaN_3 (300 mg, 4.6 mmol), and 5 mL of DMF. The reaction mixture was stirred at 40 °C for 1 h, allowed to cool to room temperature, and poured into 100 mL of water. The aqueous layer was extracted three times with 100 mL of CHCl_3 , and the combined organic layers were washed three times with 100 mL of water. Evaporation of the organic solvent, followed by flash chromatography (EtOAc), gave a deep red crystalline solid (218 mg, 85%), mp 145–150 °C. ^1H NMR (CDCl_3): δ 1.42 (t, J = 7 Hz, 3H), 4.41 (q, J = 7 Hz, 2H), 6.53 (d, J = 8 Hz, 1H), 6.84 (dd, J = 2 Hz, J = 7 Hz, 1H), 7.08 (d, J = 2 Hz, 1H), 8.37 (d, J = 8 Hz, 1H), 9.36 (d, J = 7 Hz, 1H). MS: m/z 258.0751; required for $\text{C}_{12}\text{H}_{10}\text{N}_4\text{O}_3$: 258.0753.

Ethyl 8-Amino-4-oxo-4H-quinolizine-3-carboxylate (15). A suspension of **14** (253 mg, 1.0 mmol) and 20 mg of 5% Pd on C in 15 mL of ethanol was stirred under a hydrogen atmosphere. The color of the reaction mixture rapidly changed from deep red to dark yellow. After 30 mL of H_2 had been absorbed by the reaction mixture, the catalyst was filtered off and the solvent was evaporated to give pure **15**, 221 mg (94%), as a yellow/green powder, mp > 250 °C. ^1H NMR ($\text{DMSO}-d_6$): δ 1.23 (t, J = 7 Hz, 3H), 4.13 (q, J = 7 Hz, 2H), 6.23 (d, J = 7 Hz, 1H), 6.53 (d, J = 2 Hz, 1H), 6.79 (dd, J = 2 Hz, J = 7 Hz, 1H), 7.32 (s, 2H), 7.81 (d, J = 8 Hz, 1H), 8.94 (d, J = 7 Hz, 1H). MS: m/z 232.0837; required for $\text{C}_{12}\text{H}_{12}\text{NO}_3$: 232.0848.

Ethyl 8-(3-Nitrophenoxy)-4-oxo-4H-quinolizine-3-carboxylate (16). An oven-dried, 50 mL three-necked, round-bottomed flask was purged with argon and charged with NaH (200 mg, 60% suspension in oil, 5 mmol and washed with hexane,) and 10 mL of dry DMF. To this suspension, *m*-nitrophenol (626 mg, 4.5 mmol) was added in one portion. After gas evolution had ceased, **2** (1.00 g, 4 mmol) was added in one portion and stirring was

continued at room temperature for 2 h. TLC (EtOAc) indicated complete consumption of the starting material, and the reaction mixture was poured into 250 mL of water. The aqueous layer was extracted three times with 200 mL of CH_2Cl_2 , and the combined organic layers were washed three times with 200 mL of water. The organic solvent was evaporated and the crude product was stirred overnight with 30 mL of Et_2O . Filtration gave 950 mg (67%) of a bright yellow solid, mp 161–3 °C. ^1H NMR (CDCl_3): δ 1.42 (t, $J = 7$ Hz, 3H), 4.41 (q, $J = 7$ Hz, 2H), 6.39 (d, $J = 8$ Hz, 1H), 6.70 (d, $J = 2$ Hz, 1H), 6.99 (dd, $J = 0.5$ Hz, $J = 7$ Hz, 1H), 7.55 (d, $J = 7$ Hz, 1H), 7.72 (dd, $J = 8$ Hz, $J = 8$ Hz, 1H), 8.07 (s, 1H), 8.24 (d, $J = 8$ Hz, 1H), 8.32 (d, $J = 8$ Hz, 1H), 9.43 (d, $J = 7$ Hz, 1H). MS: m/z 354.0850; required for $\text{C}_{18}\text{H}_{14}\text{N}_2\text{O}_6$: 354.0852.

Ethyl 8-[3-(*N,N*-Dicarbomethoxymethyl)phenoxy]-4-oxo-4*H*-quinolizine-3-carboxylate (18). A suspension of **16** (710 mg, 2 mmol) and 200 mg of 5% Pd on C in 25 mL of ethanol was stirred under an atmosphere of hydrogen for 6 h. The resulting deep yellow solution was filtered from the catalyst, and the solvent was evaporated to give 650 mg of the crude amine as a golden brown crystalline solid. The amine was dissolved in 9 mL of acetonitrile and NaI (1.5 g, 10 mmol), methyl bromoacetate (1 mL, 10 mmol), and Proton Sponge (2.6 g, 12 mmol) were added. The reaction mixture was refluxed for 16 h, allowed to cool to room temperature and poured into 200 mL of EtOAc. The organic layer was washed with 200 mL portions of buffer (pH 2) until an acid reaction on litmus appeared. The solvent was evaporated and the crude product was purified with flash chromatography (EtOAc) to give a bright yellow powder (310 mg, 30% over two steps), mp 161–3 °C. ^1H NMR (CDCl_3): δ 1.41 (t, $J = 7$ Hz, 3H), 3.76 (s, 6H), 4.16 (s, 4H), 4.39 (q, $J = 7$ Hz, 2H), 6.29–6.45 (m, 2H), 6.51–6.64 (m, 2H), 6.71 (d, $J = 2$ Hz, 1H), 6.97 (dd, $J = 2$ Hz, $J = 7$ Hz, 1H), 7.32 (dd, $J = 8$ Hz, $J = 8$ Hz, 1H), 8.26 (d, $J = 8$ Hz, 1H), 9.38 (d, $J = 8$ Hz, 1H). MS: m/z 468.1535; required for $\text{C}_{24}\text{H}_{24}\text{N}_2\text{O}_8$: 468.1532.

Ethyl 8-[Dicarbomethoxymethyl]-4-oxo-4*H*-quinolizine-3-carboxylate (19). A solution of $\text{Na}[\text{CH}(\text{CO}_2\text{Me})]$ in DMSO was prepared by adding dimethylmalonate (5.6 g, 42 mmol) in 10 mL of DMSO to a suspension of NaH (2.0 g of a 60% suspension in oil, 50 mmol and washed with hexane) in 10 mL of DMSO. An oven-dried, 250 mL, three-necked, round-bottomed flask equipped with a 100 mL dropping funnel containing the freshly prepared malonate anion solution, was charged with **2** (3.76 g, 15.3 mmol) and 20 mL of DMSO. The malonate anion solution was added rapidly to the reaction mixture and stirring was continued overnight. The reaction mixture was poured into 500 mL of water and extracted three times with 400 mL of CH_2Cl_2 . The organic solvent was evaporated and the crude product stirred overnight with 20 mL of EtOAc. Filtration and drying in vacuo gave 3.22 g (63%) of a yellow powder, mp 195–7 °C. ^1H NMR (CDCl_3): δ 1.42 (t, $J = 7$ Hz, 3H), 3.82 (s, 6H), 4.41 (q, $J = 7$ Hz, 2H), 4.73 (s, 1H), 6.64 (d, $J = 8$ Hz, 1H), 7.22 (d, $J = 8$ Hz, 1H), 7.59 (s, 1H), 8.41 (d, $J = 8$ Hz, 1H), 9.34 (d, $J = 7$ Hz, 1H). MS: m/z 347.1021; required for $\text{C}_{17}\text{H}_{17}\text{NO}_7$: 347.1004.

Ethyl 8-[1,1-Dicarbomethoxy-2-carbethoxyethyl]-4-oxo-4*H*-quinolizine-3-carboxylate (20). An oven-dried, 50 mL, three-necked, round-bottomed flask equipped with a reflux condenser was charged with NaH (160 mg, 60% suspension in oil, 4 mmol and washed with hexane) and 10 mL of THF. Compound **19** (700 mg, 2 mmol) was added in three portions and stirring was continued for 1 h, followed by the addition of ethyl bromoacetate (0.5 mL,

5.3 mmol). The reaction mixture was refluxed overnight, allowed to cool to room temperature, and poured into 100 mL of water. The aqueous layer was extracted three times with 100 mL of CH_2Cl_2 . The organic solvent was evaporated and the crude product was purified by flash chromatography (EtOAc) to give a yellow viscous oil (630 mg, 74%). ^1H NMR (CDCl_3): δ 1.24 (t, $J = 7$ Hz, 3H), 1.42 (t, $J = 7$ Hz, 3H), 3.39 (s, 2H), 3.84 (s, 6H), 4.14 (q, $J = 7$ Hz, 2H), 4.41 (q, $J = 7$ Hz, 2H), 6.63 (d, $J = 8$ Hz, 1H), 7.14 (dd, $J = 2$ Hz, $J = 7$ Hz, 1H), 7.61 (d, $J = 2$ Hz, 1H), 8.40 (d, $J = 8$ Hz, 1H), 9.29 (d, $J = 8$ Hz, 1H). MS: m/z 433.1363; required for $\text{C}_{21}\text{H}_{21}\text{NO}_9$: 433.1372.

Ethyl 1-Bromo-8-[1,1-dicarbomethoxy-2-carbethoxyethyl]-4-oxo-4*H*-quinolizine-3-carboxylate (21). Using the bromination procedure described for the synthesis of **9**, compound **21** was isolated as an orange mass in a yield of 75% by flash chromatography (EtOAc). ^1H NMR (CDCl_3): δ 1.26 (t, $J = 7$ Hz, 3H), 1.42 (t, $J = 7$ Hz, 3H), 3.45 (s, 2H), 3.85 (s, 6H), 4.16 (q, $J = 7$ Hz, 2H), 4.41 (q, $J = 7$ Hz, 2H), 7.33 (d, $J = 8$ Hz, 1H), 8.06 (s, 1H), 8.61 (s, 1H), 9.36 (d, $J = 8$ Hz, 1H). MS: m/z 511.0473; required for $\text{C}_{21}\text{H}_{22}\text{BrNO}_9$: 511.0477.

Ethyl 8-(4-Methoxyphenyl)-4-oxo-4*H*-quinolizine-3-carboxylate (22). An oven-dried, 50 mL, round-bottomed flask, equipped with a reflux condenser, was purged with Ar and charged with **2** (500 mg, 2 mmol), 4-methoxyphenylboronic acid (372 mg, 2.4 mmol), CsF (600 mg, 3.9 mmol), $\text{PdCl}_2[\text{P}(\text{c-Hex})_3]_2$ (80 mg, 0.1 mmol), and 6 mL of DMF. The reaction mixture was stirred at 110 °C for 12 h and allowed to cool to room temperature. TLC (EtOAc) indicated that the starting material had been completely consumed. The reaction mixture was poured into 100 mL of water and extracted three times with 100 mL of CHCl_3 . The combined organic layers were washed three times with 50 mL of water. The organic solvent was evaporated and the crude product was further purified by column chromatography (5% MeOH in EtOAc) to give 340 mg (50%) of a bright yellow solid, mp 205–9 °C. ^1H NMR (CDCl_3): δ 1.43 (t, $J = 7$ Hz, 3H), 3.90 (s, 3H), 4.42 (q, $J = 7$ Hz, 2H), 6.65 (d, $J = 8$ Hz, 1H), 7.05 (d, $J = 9$ Hz, 2H), 7.43 (dd, $J = 2$ Hz, $J = 7$ Hz, 1H), 7.58–7.80 (m, 3H), 8.37 (d, $J = 8$ Hz, 1H), 9.41 (d, $J = 7$ Hz, 1H). MS: m/z 323.1159; required for $\text{C}_{19}\text{H}_{17}\text{NO}_4$: 323.1157.

Ethyl 8-(Naphth-1-yl)-4-oxo-4*H*-quinolizine-3-carboxylate (23). Using the procedure described for **22**, compound **23** was isolated (51% yield) by flash chromatography (EtOAc), mp 245–7 °C. ^1H NMR (CDCl_3): δ 1.48 (t, $J = 7$ Hz, 3H), 4.48 (q, $J = 7$ Hz, 2H), 6.73 (d, $J = 8$ Hz, 1H), 7.40 (dd, $J = 2$ Hz, $J = 8$ Hz, 1H), 7.55–7.64 (m, 4H), 7.72 (s, 1H), 7.91 (d, $J = 8$ Hz, 1H), 7.98–8.06 (m, 2H), 8.48 (d, $J = 8$ Hz, 1H), 9.52 (d, $J = 8$ Hz, 1H). MS: m/z 343.1213; required for $\text{C}_{22}\text{H}_{17}\text{NO}_3$: 343.1208.

Ethyl 8-(Benzo[6,7]fur-2-yl)-4-oxo-4*H*-quinolizine-3-carboxylate (24). Using the procedure described for **22**, compound **24** was isolated (48% yield) by flash chromatography (EtOAc), mp 195–7 °C. ^1H NMR (CDCl_3): δ 1.43 (t, $J = 7$ Hz, 3H), 4.42 (q, $J = 7$ Hz, 2H), 6.72 (d, $J = 8$ Hz, 1H), 7.22–7.54 (m, 4H), 7.57 (d, $J = 8$ Hz, 1H), 7.67 (d, $J = 8$ Hz, 1H), 7.96 (d, $J = 1$ Hz, 1H), 8.40 (d, $J = 8$ Hz, 1H), 9.37 (d, $J = 8$ Hz, 1H). MS: m/z 333.1011; required for $\text{C}_{20}\text{H}_{15}\text{NO}_4$: 333.1000.

4-Oxo-4*H*-quinolizine-3-carboxylic Acid (1a). To a suspension of **1** (100 mg, 0.46 mmol) in 4 mL of MeOH was added 300 μL of 3 M NaOH. The reaction mixture was stirred overnight followed by evaporation of the solvent in vacuo. The remaining solid was dissolved in 4 mL of water, and the clear solution was acidified with 1 M HCl to pH 1. The resulting suspension was filtered

and the residue dried in vacuo over P_2O_5 to give **1a** as yellow plates (63 mg, 72%), mp 235–40 °C. ^1H NMR (DMSO- d_6): δ 7.26 (d, J = 8 Hz, 1H), 7.64 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.03 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.14 (d, J = 9 Hz, 1H), 8.39 (d, J = 9 Hz, 1H), 9.27 (d, J = 7 Hz), 14.13 (s, 1H). MS: m/z 189.0433; required for $C_{12}H_{11}NO_3$: 189.0428.

4-Oxo-8-chloro-4H-quinolizine-3-carboxylic Acid (2a). Using the procedure described for **1a**, compound **2a** was isolated in 52% yield, mp >250 °C. ^1H NMR (DMSO- d_6): δ 7.13 (d, J = 9 Hz, 1H), 7.62 (d, J = 7 Hz, 1H), 8.34 (s, 1H), 8.40 (d, J = 8 Hz, 1H), 9.16 (d, J = 7 Hz, 1H). MS: m/z 223.0028; required for $C_{10}H_6NO_3$: 223.0036.

[6,7]Benzo-4-oxo-4H-quinolizine-3-carboxylic Acid (3a). Using the procedure described for **1a**, compound **3a** was obtained as a red powder in 50% yield, mp >250 °C. ^1H NMR ($CDCl_3$): δ 6.90 (d, J = 8 Hz, 1H), 7.33 (d, J = 9 Hz, 1H), 7.60–7.83 (m, 4H), 8.68 (d, J = 8 Hz, 1H), 9.96 (d, J = 9 Hz, 1H), 14.38 (s, 1H). MS: m/z 239.0575; required for $C_{14}H_9NO_3$: 239.0592.

1-Bromo-4-oxo-4H-quinolizine-3-carboxylic Acid (9a). Using the procedure described for **1a**, compound **9a** was obtained as a bright yellow powder in 57% yield, mp > 250 °C. ^1H NMR (DMSO- d_6): δ 7.76 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.20–8.32 (m, 2H), 8.53 (s, 1H), 9.41 (d, J = 7 Hz, 1H). 1-[N,N-Di(carboxymethyl)]-4-oxo-4H-quinolizine-3-carboxylic Acid (11a). Using the procedure described for **1a**, compound **11a** was obtained as a bright yellow powder in 50% yield, mp 231–4 °C. ^1H NMR (D_2O): δ 3.80 (s, 4H), 7.66 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.07 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.32 (s, 1H), 8.63 (d, J = 8 Hz, 1H), 9.33 (d, J = 7 Hz, 1H). MS: m/z 276.0745 (M- CO_2); required for $C_{13}H_{12}N_2O_5$: 276.0746.

1-(2,2-Dicarboxyvinyl)-4-oxo-4H-quinolizine-3-carboxylic Acid (12a). Using the procedure described for **1a**, compound **12a** was obtained as a bright yellow powder in 61% yield, mp >250 °C. ^1H NMR (DMSO- d_6): δ 7.72 (dd, J = 7 Hz, J = 7 Hz, 1H), 7.90 (s, 1H), 8.13 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.26 (d, J = 9 Hz, 1H), 8.57 (s, 1H), 9.36 (d, J = 7 Hz). MS: m/z 215.0591 (M-2 CO_2); required for $C_{12}H_9NO_3$: 215.0582.

1-(2,2-Dicarboxyethyl)-4-oxo-4H-quinolizine-3-carboxylic Acid (13a). Using the procedure described for **1a**, compound **13a** was obtained as a bright yellow powder in 49% yield, mp >250 °C. ^1H NMR (D_2O , 1% NaOD): δ 3.32 (d, J = 7 Hz, 2H), 3.42 (t, J = 7 Hz, 1H), 7.37 (dd, J = 7 Hz, J = 7 Hz, 1H), 7.74 (dd, J = 7 Hz, J = 7 Hz, 1H), 8.01 (s, 1H), 8.02 (d, J = 7 Hz, 1H), 9.22 (d, J = 7 Hz, 1H). MS: m/z 261.0627 (M- CO_2); required for $C_{13}H_{11}NO_5$: 261.0637.

8-Amino-4-oxo-4H-quinolizine-3-carboxylic Acid (15a). Using the procedure described for **1a**, compound **15a** was obtained as a bright yellow powder in 61% yield, mp >250 °C. ^1H NMR (DMSO- d_6): δ 6.61 (d, J = 9 Hz, 1H), 6.71 (d, J = 2 Hz, 1H), 6.96 (dd, J = 2 Hz, J = 8 Hz, 1H), 7.6 (br), 7.82 (d, J = 9 Hz, 1H), 8.95 (J = 7 Hz, 1H). MS: m/z 160.0634 (M - CO_2); required for $C_9H_8N_2O$: 160.0636.

8-[3-(N,N-di(carboxymethyl)phenoxy)-4-oxo-4H-quinolizine-3-carboxylic Acid (18a). Using the procedure described for **1a**, compound **18a** was obtained as a bright yellow powder in 71% yield, mp = 231–4 °C. ^1H NMR (D_2O): δ 3.98 (s, 4H), 6.38 (s, 1H), 6.52 (d, J = 7 Hz, 1H), 6.57 (d, J = 8 Hz, 1H), 6.75 (d, J = 9 Hz, 1H), 7.08 (s, 1H), 7.23–7.47 (m, 2H), 8.06 (d, J = 8 Hz, 1H), 9.12 (d, J = 8 Hz, 1H). MS: m/z 350.0160 (M - CO_2 - H_2O); required for $C_{19}H_{14}N_2O_5$: 350.2359.

8-[Carboxymethyl]-4-oxo-4H-quinolizine-3-carboxylic Acid (19a). Using the procedure described for **1a**, compound **19a** was obtained as a yellow powder in 68% yield, mp > 250 °C. ^1H NMR (D_2O): δ 3.77 (s, 2H), 7.07 (d, J = 8 Hz, 1H), 7.50 (d, J = 7 Hz, 1H), 7.78 (s, 1H), 8.26 (d, J = 8 Hz, 1H), 9.13 (d, J = 7 Hz). MS: m/z 203.0575 (M - CO_2); required for $C_{11}H_9NO_3$: 203.0582.

8-(1,2-Dicarboxyethyl)-4-oxo-4H-quinolizine-3-carboxylic Acid (20a). Saponification of **20** was done as described for **1**. After completion of the reaction, the solvent was evaporated in vacuo, and the resulting yellow solid was dissolved in water. The aqueous layer was acidified to pH 1 and extracted three times with ethyl acetate. Evaporation of the organic solvent gave **20a** as a yellow solid in 48% yield. ^1H NMR (DMSO- d_6): δ 2.72–2.76 (m, 2H), 3.02–3.06 (m, 1H), 7.14 (d, J = 9 Hz, 1H), 7.60 (dd, J = 2 Hz, J = 9 Hz, 1H), 7.99 (s, 1H), 8.34 (d, J = 9 Hz, 1H), 9.20 (d, J = 9 Hz, 1H). MS: m/z 261.0601 (M - CO_2); required for $C_{13}H_{11}NO_5$: 261.0637.

1-Bromo-8-(1,2-dicarboxyethyl)-4-oxo-4H-quinolizine-3-carboxylic Acid (21a). Using the procedure described for **1a** and heating the reaction mixture to 60 °C, compound **21a** was obtained as a yellow powder in 42% yield. ^1H NMR (D_2O , 1% NaOD): δ 2.74 (m, 1H), 2.94 (m, 1H), 4.05 (m, 1H), 7.35 (d, J = 7 Hz, 1H), 8.01 (s, 1H), 8.33 (s, 1H), 9.17 (d, J = 7 Hz, 1H). MS: m/z 389.9819; required for $C_{14}H_{10}BrNO_7Li$: 389.9801.

8-(4-Methoxyphenyl)-4-oxo-4H-quinolizine-3-carboxylic Acid (22a). Using the procedure described for **1a**, compound **22a** was obtained as a yellow powder in 49% yield, mp > 250 °C. ^1H NMR (D_2O): δ 3.62 (s, 3H), 6.40–6.62 (m, 3H), 7.11 (d, J = 8 Hz, 1H), 7.16–7.32 (m, 3H), 7.94 (d, J = 8 Hz, 1H), 8.64 (d, J = 8 Hz, 1H). MS: m/z 278.0826 (M - OH); required for $C_{17}H_{12}NO_3$: 278.0817.

8-(Naphth-1-yl)-4-oxo-4H-quinolizine-3-carboxylic Acid (23a). Using the procedure described for **1a**, compound **23a** was obtained as a yellow powder in 67% yield, mp = 245–7 °C. ^1H NMR (DMSO- d_6): δ 7.33 (d, J = 8 Hz, 1H), 7.55–7.74 (m, 4H), 7.81 (dd, J = 2 Hz, J = 7 Hz, 1H), 8.04–8.17 (m, 2H), 8.35 (s, 1H), 8.45 (d, J = 8 Hz, 1H), 9.36 (d, J = 7 Hz, 1H). MS: m/z 315.0905; required for $C_{20}H_{13}NO_3$: 315.0895.

8-(Benzo[6,7]furyl)-4-oxo-4H-quinolizine-3-carboxylic Acid (24a). Using the procedure described for **1a**, compound **24a** was obtained as a yellow powder in 47% yield, mp > 250 °C. ^1H NMR (DMSO- d_6): δ 7.26–7.40 (m, 2H), 7.48 (dd, J = 8 Hz, J = 8 Hz, 1H), 7.70 (d, J = 8 Hz, 1H), 7.79 (d, J = 8 Hz, 1H), 8.02 (s, 1H), 8.05 (dd, J = 2 Hz, J = 7 Hz, 1H), 8.38 (d, J = 8 Hz, 1H), 8.52 (s, 1H), 9.24 (d, J = 8 Hz, 1H). MS: m/z 305.0674; required for $C_{18}H_{11}NO_4$: 305.0687.

RESULTS

The ethyl esters of 4-oxo-4H-quinolizine-3-carboxylic acids **1**, **2**, and **3** were synthesized in two steps starting from the commercially available 2-picolines or 2-methylquinoline **4** (Scheme 1) (26). The first step is a Michael reaction of the lithiated 2-picoline anion **4-Li**, generated in situ with LDA, with diethyl ethoxymethylenemalonate **5**. Subsequent ring closure of the Michael adducts **6** was brought about in refluxing xylene. The desired ethyl esters of 4-oxo-4H-quinolizine-3-carboxylic acids **1**, **2**, and **3** were obtained as crystalline materials in moderate to good yields.

Electrophilic Aromatic Substitution. The introduction of functionality into compound **1** is readily achieved by regioselective electrophilic aromatic substitution at the

Scheme 2. Electrophilic Aromatic Substitution of 1**Scheme 3. Synthesis of 11**

1-position (37). Thus, treatment of **1** with HNO₃ in acetic anhydride resulted in the isolation of ethyl 1-nitro-4-oxo-4H-quinolizine-3-carboxylate (**7**) in a yield of 50%. Similarly, formylation of **1** with a Vilsmeier–Haack reaction gave ethyl 1-formyl-4-oxo-4H-quinolizine-3-carboxylate (**8**) in 93% yield. The bromination of **2** was achieved by treatment with Br₂ in acetic acid to give **9** in good yield (Scheme 2).

The nitro group and the formyl group in compounds **7** and **8**, respectively, are excellent starting points for the introduction of two extra carboxylic acid groups in the 4-oxo-4H-quinolizine-3-carboxylic acid structure to give a polyvalent fluorophore. The reduction of the nitro group of **7** was accomplished by Pd-catalyzed hydrogenation to give amine **10**. Alkylation of **10** with methyl bromoacetate in refluxing acetonitrile, in the presence of NaI and Proton Sponge, resulted in the formation of triester **11** in a 54% overall yield from **7** (Scheme 3).

An aldol condensation of aldehyde **8** with diethyl malonate led to the preparation of diethyl methylenemalonate triester **12**. The saturated derivative **13** was obtained by a selective reduction of the double bond in **12** with NaCNBH₃ in ethanol (Scheme 4).

Nucleophilic Substitution of the Cl Substituent of 1. The Cl substituent of ethyl 8-chloro-4-oxo-4H-quinolizine-3-carboxylate (**2**) is easily substituted with a variety of nucleophiles and undergoes palladium catalyzed coupling reaction with boronates (Suzuki coupling). This reactivity of **2** offers additional possibility to introduce functionality into the 4-oxo-4H-quinolizine-3-acid structure and to tune its physical and fluorescent properties. Treatment of **2** with NaN₃ in DMF at 40 °C resulted in clean replacement of the Cl substituent by an azido

Scheme 4. Synthesis of 12 and 13**Scheme 5. Synthesis of 15**

group to give **14** in 85% yield (Scheme 5). Reduction of the azido group by palladium-catalyzed hydrogenation afforded the corresponding amine **15** in almost quantitative yield. Alkylation of **15** with methyl bromoacetate, analogous to the preparation of **10** was not successful. It is believed that the strong electron deficient nature of this heterocyclic system, which facilitated the replacement of the Cl substituent in **2**, actually lowers the nucleophilic character of the amine substituent. An alternative approach, the substitution of the Cl substituent in **2** with diethyl iminoacetate [HN(CH₂COOMe)₂], also failed. Presumably, this was due to a lack of sufficient nucleophilicity of the amine.

The reaction of **2** with the anion of *m*-nitrophenol, generated in situ by deprotonation of the phenol with NaH, resulted in substitution of the Cl substituent with an oxygen nucleophile to give ether **16** in a yield of 67%. Reduction of the nitro group of **16** afforded amine **17**. A subsequent alkylation of the crude amine with methyl bromoacetate resulted in the isolation of triester **18** in 30% yield over two steps (Scheme 6).

The Cl substituent of **2** can also be replaced by a carbon nucleophile. Thus, the reaction of **2** with the anion of diethyl malonate in DMSO led to the formation of triester **19** which was isolated in 63% yield (Scheme 7). It was found that at least two equivalents of the malonate anion were required for complete consumption of **2**, most likely as a result of a deprotonation of the more acidic substitution product **19** by a malonate anion. The remaining acidic proton of **19** was readily abstracted by NaH in THF and alkylation of the resulting anion with ethyl bromoacetate afforded tetraester **20** in a yield of 74%. Bromination of **20** was achieved by the reaction with Br₂ in acetic acid to give **21** in 75% yield (Scheme 7).

The extension of the pi-system of the 4-oxo-4H-quinolizine-3-carboxylic acid structure as in **3** was found to shift the fluorescence emission maximum to longer wavelengths. It was thought that the introduction of other conjugated aromatic substituents might extend the

Scheme 6. Synthesis of 18

Scheme 7. Synthesis of 19, 20, and 21

Scheme 8. Suzuki Coupling Reaction of 2

emission maximum further, perhaps into the visible light range. A Pd-catalyzed coupling reaction of the electron poor aryl chloride **2** with an organoboron species—a Suzuki reaction—is one way of substituting the Cl atom at the 8-position of **2** with an aromatic carbon nucleophile. The two phase system, consisting of an organic solvent and an aqueous base, that is usually applied for the Suzuki coupling could not be used because of the ester group in **2**. We therefore chose to use the base free reaction conditions described by Shen (38) which has proven to be efficient for a Suzuki coupling reaction of electron poor aryl chlorides, and here gave us good yields of the coupled products. Using this procedure, a *p*-methoxyphenyl, a naphth-1-yl, and a benzo-[6,7]-furyl substituent were substituted at the 8-position of the parent 4-oxo-4H-quinolizine-3-carboxylate structure (Scheme 8).

Saponification. Compounds **1**, **2**, **3**, **9**, **11**, **12**, **13**, **15**, **18**, **19**, **20**, **21**, **22**, **23**, and **24** were saponified, followed by acidic workup to isolate the (poly)acids **1a**, **2a**, **3a**, **9a**, **11a**, **12a**, **13a**, **15a**, **18a**, **19a**, **20a**, **21a**, **22a**, **23a**, and **24a** in the protonated form. The saponification products

^a Absorption maximum of the free indicator. ^b An arrow denotes a shift of the fluorescence maximum upon saturation of the indicator.

of triester **19** and tetraesters **20** and **21** decarboxylated rapidly at low pH and at 5 °C, and the resulting diacid **19a** and triacids **20a** and **21a** were isolated (Scheme 9).

Fluorescence. The emission and excitation fluorescence spectra of **1a**, **2a**, **3a**, **9a**, **11a**, **12a**, **13a**, **15a**, **18a**, **19a**, **20a**, **21a**, **22a**, **23a**, and **24a** were recorded using 0.5–1.0 μM solutions of the chelator, buffered at pH 7.2. The solutions also contained 120 mM KCl and 20 mM NaCl to mimic the ionic composition of the intracellular milieu. These solutions were titrated with stock solutions of MgCl_2 containing an equimolar concentration of the 4-oxo-4H-quinolizine carboxylic acids to cancel out dilution effects during the titration. After each titration step, both the emission and excitation fluorescence spectra were recorded. The absorption maxima and the fluorescence emission maxima of the studied 4-oxo-4H-quinolizine carboxylic acids are presented in Table 1. The apparent dissociation constants of indicators for Mg^{2+} were determined from the fluorescence spectra as originally described by Gryniewicz et al. (39) and are also given in Table 1. Solutions of the fluorophores in the buffer proved to be stable for at least 9 months at 4 °C.

In most cases, a bathochromic shift of the fluorescence emission occurs upon binding Mg^{2+} by the indicator. The observed shifts range from 4 nm for **11a** to 37 nm for **24a**. The parent compound **1a** displays a bathochromic shift of 23 nm when saturated with Mg^{2+} and an isosbestic point was found at 437 nm (Figure 1a). This compound thus fulfills the criterion for a ratioable indicator. Figure 1b presents the fluorescent response of **1a** to increasing Ca^{2+} concentrations, and it is clear that intracellular Ca^{2+} levels in the nanomolar to submillimolar range will not effect a change in the fluorescence emission of **1a**. For most other 4-oxo-4H-quinolizine-3-carboxylic acids, the Mg^{2+} induced fluorescence shift is not sufficient for these chelators to serve as ratioable indicators as the fluorescence emission spectra of the free indicator and the Mg^{2+} -bound indicator largely overlap. The fluorescent response of the alkyl-substituted indicator **13a**, a triacid in which a 2,2-dicarboxyethyl substituent has been introduced at the 1-position to enhance

Figure 1. Fluorescence emission spectra of the indicated compounds as a function of $[\text{Mg}^{2+}]$ or $[\text{Ca}^{2+}]$ (in mM), as indicated. Excitation in each case was at the absorption maximum indicated in the Table. Spectra were recorded at 20 °C. (a) **1a** as a function of $[\text{Mg}^{2+}]$; (b) **1a** as a function of $[\text{Ca}^{2+}]$; (c) **13a** as a function of $[\text{Mg}^{2+}]$; (d) **9a** as a function of $[\text{Mg}^{2+}]$; (e) **21a** as a function of $[\text{Mg}^{2+}]$; (f) **21a** as a function of $[\text{Ca}^{2+}]$; (g) **3a** as a function of $[\text{Mg}^{2+}]$; (h) **11a** as a function of $[\text{Mg}^{2+}]$; (i) **23a** as a function of $[\text{Mg}^{2+}]$; (j) **24a** as a function of $[\text{Mg}^{2+}]$.

water solubility, is almost identical to that observed for **1a** (Figure 1c). Alkylation at the 8-position such as in **19a** and **20a**, however, results in overlap of the fluorescence spectra of both the free and complexed forms.

The presence of a Br substituent at the 1-position of fluorophores **9a** and **21a** results in a bathochromic shift of 18 and 26 nm, respectively, when binding Mg^{2+} (Figure 1, panels d and e). These fluorophores both display well-separated fluorescence maxima for the free and Mg^{2+} -bound state with isosbestic points at 446 and 451 nm, respectively. Both fluorophores show no fluorescent response to increasing Ca^{2+} concentrations up to 100 mM as shown for **21a** in Figure 1f. The pK_a of the carboxylate group at position **3** on the ring system of **21a**, which is involved in forming the metal ion complex, was determined to be 5.6 by a fluorescence/pH titration. Thus, all of the indicator is present in the deprotonated form and available for complexation at physiological pH.

Fluorophores **3a**, **11a**, **23a**, and **24a** show an increase of the fluorescence emission upon binding to Mg^{2+} (Figure 1, panels g–j) and were found to be very sensitive to changing Mg^{2+} levels. An ideal fluorescent indicator displays an emission signal above 500 nm such as triacid **11a** which has a fluorescence maximum at 552 nm. The presence of the amino group at the 1-position gave a hypsochromic shift of 117 nm with respect to the parent molecule **1a**. As expected, the introduction of an aromatic moiety at the 8-position (compounds **22a–24a**), or extension of the pi-system as in **3a** also resulted in a hypsochromic shift to longer wavelengths, albeit smaller than found for **11a**.

CONCLUSIONS

4-Oxo-4H-quinolizine-3-carboxylic acids are a new class of Mg^{2+} -selective, fluorescent indicators. The dissociation constants ranging from 0.4 to 5.0 mM correspond well with commonly observed intracellular Mg^{2+} levels, a requirement for optimum sensitivity. The fluorophores show very little if any change of the fluorescence emission in the presence of Ca^{2+} . The observed changes of the fluorescence emission with increasing Mg^{2+} levels depends on the substitution pattern of the 4-oxo-4H-quinolizine-3-carboxylic acid.

Visible light-excitable, nonratioable APTRA-type indicators which undergo a large increase of their fluorescence emission with increasing Mg^{2+} levels have found practical application (40). Similar fluorescent behavior was observed for 4-oxo-4H-quinolizine-3-carboxylic acids **3a**, **11a**, **23a**, and **24a** which proved to be very sensitive fluorophores. Fluorophore **11a**—a triacid and thus potentially loadable into the cell and with a fluorescence emission maximum at 552 nm—is a promising candidate for an ion-selective indicator for intracellular Mg^{2+} with a 500+ nm emission wavelength.

The presence of a Br substituent at the 1-position of a 4-oxo-4H-quinolizine-3-carboxylic acid proved to be a key structural element in order to obtain a ratioable fluorescent indicator. It may be expected that other electron withdrawing/halogen substituents at this position will have the same effect on the fluorescent behavior of 4-oxo-4H-quinolizine-3-carboxylic acids. Fluorophores **9a** and **21a** both display two fully separated fluorescence maxima for the free indicators and their complex with Mg^{2+} , respectively, which is ideal for a ratioable indicator. Compound **21a** is the first ratioable, loadable, Mg^{2+} -selective, fluorescent indicator and is currently being investigated in biophysical studies in our laboratories.

Revised Manuscript Received October 13, 2000

Angiogenesis is a critical step in tumor development and more than 25 angiogenesis inhibitors are currently in clinical trials. Noninvasive in vivo imaging of angiogenesis represents a unique opportunity of repeatedly quantitating microvascular parameters prior to and during anti-angiogenic treatments. While several imaging tracers have been proposed for MR and nuclear imaging, there does not exist any consensus of what constitutes an ideal size of an imaging agent. A series of synthetic pegylated DOTA derivatized graft copolymers (30, 60, 120 kDa) were synthesized and their in vivo behavior tested in two breast cancer models differing in vascular endothelial growth factor (VEGF) expression. Polymers were labeled with different lanthanides (Eu, Gd, Dy) and absolute blood and tumor concentrations were determined by ICP-AES measurements. DOTA and the 30 kDa polymers underwent renal clearance resulting in low plasma levels. Slow leakage across neovasculature into tumor interstitium was clearly dependent on the molecular mass of all tested agents in MCF-7 tumors. However, a cutoff was observed with minimal extravasation occurring at and above 120 kDa in well differentiated MCF-7 tumors. VEGF overexpression caused detectable differences in extravasation of all polymers, including the 120 kDa compound. We conclude that large molecular weight contrast agents with a molecular mass of <120 kDa extravasate from experimental tumor neovasculature and may not be an accurate marker for measuring true blood volume fractions when in vivo imaging is performed in the steady state.

INTRODUCTION

Angiogenesis, the formation of new blood vessels from an existing vascular network, is a critical step in carcinogenesis and metastagenesis (1–3). Currently, there are more than 25 inhibitors of angiogenesis in clinical trials while many other compounds await testing. New anti-angiogenic agents include compounds with different mechanism of action including (1) drugs that inhibit endothelial cell proliferation directly (e.g., TNP-470, endostatin), (2) drugs that block angiogenic activators [e.g., Anti-vascular endothelial growth factor (VEGF) monoclonal antibody, SU6668], (3) drugs that inhibit matrix breakdown (e.g., AG3340, Marimastat) and drugs with nonspecific mechanism (e.g., Interleukin-12). The main rationale for developing anti-angiogenic treatments is severalfold: (1) tumors do not grow beyond a certain size unless supplied by vasculature, (2) a single vessel supplies large tumor areas, and (3) drug resistance is unlikely to develop because endothelial cells are genetically stable. Cytostatic anti-angiogenic agents may prove particularly useful in combination with cytotoxic chemotherapeutic regimen. Irrespective of a specific regimen, antiangiogenic treatments are typically long-term and ideally require periodic assessment of treatment efficacy. For this reason and because phenotypic changes can take weeks to months to manifest (4), other surrogate endpoints of treatment efficacy are required for the clinical testing of new agents.

At present, the most widely used method of assessing angiogenesis in solid tumors is still the determination of intratumoral microvessel density (MVD) in areas of the most active neovascularization (5, 6). There are obvious limitations of using this technique repeatedly and longitudinally in the same patient. For this reason, imaging techniques have been developed to quantitate tumoral angiogenic burden using different approaches, most of them relying on the administration of a contrast agent and measuring certain microvascular parameters during first pass (small molecular weight contrast agents) or during steady-state (large molecular weight contrast agents). It is now well accepted from intravital microscopy and physiology studies that a reasonable surrogate marker of angiogenesis is the functional vascular volume fraction, i.e., the fraction of tissue that carries oxygen and nutrients to tumors (7, 8). A number of excellent in vivo angiogenesis imaging studies have been published on this subject (9–11). However, there is lack of agreement on what molecular weight (or corresponding hydrodynamic radius) an “ideal” agent should have for accurately measuring neovascular volume in tumor microcirculation. Even knowledge of approximate cutoff sizes and/or size ranges would be useful for further development of clinical contrast agents. While some quantitative data is available for certain experimental tumor models and compounds (12), this work has not been extended to clinically viable contrast agents.

The goal of the current study was to synthesize structurally identical, large molecular weight synthetic graft copolymers that could be used for imaging (either nuclear, MR, or CT imaging). The rationale for choosing polymers was the ability to control the synthesis to obtain different sized products. The developed polymers had

mean molecular masses of 30 kDa ("P30"), 60 kDa ("P60"), and 120 kDa ("P120"). Comparison compounds included a structurally related graft copolymer of 525 kDa ("PGC") (13) and 0.5 kDa DOTA. The PGC graft copolymer had previously been validated as a marker of intravascular volume in experimental tumors (14–16). To compare the compounds in different environments a slow growing well differentiated estrogen dependent human breast cancer (MCF-7) was chosen and compared to a VEGF overproducing matched MCF-7 transgenic clone (MV-165) (16). The experimental polymers were each labeled with different lanthanides (Eu, Dy, and Gd for P30, P60 and P120, respectively), mixed and then injected intravenously into orthopic tumor bearing animals. Blood and tumor concentrations were then measured at different time points by inductive coupled plasma atomic emission spectrometry (ICP-AES).

MATERIALS AND METHODS

Synthesis of Graft Copolymers. Three differently sized graft copolymers (P30, P60, and P120) were synthesized using three poly-L-lysine (PL) hydrochloride preparations (molecular mass of 3, 6, or 13 kDa respectively; Figure 1). The following is a description of P120 synthesis but was essentially similar for the smaller PL. MPEG-SPA (795 mg, MW = 5000, Shearwater Polymers, Huntsville, AL) was added slowly to an ice-cold solution of PL (100 mg, 13 kDa, Schering AG, Berlin) in bicarbonate (0.1 M, pH 8.0, 25 mL). The pH was adjusted to pH 7.7 and the mixture was stirred at room temperature for 3 h. The solution was then extensively dialyzed (cutoff 8–10 kDa) in deionized water to remove small molecular weight byproducts. The product (**I** in Figure 1) was recovered by lyophilization (774 mg). The degree of PEGylation was calculated based on the difference of free amino groups before and after the reaction using a TNBS assay.

Three hundred mg of (**I**) was dissolved in water and reacted with 1,4,7,10-tetraazacyclododecane-(1,4,7-tris-acetic acid *tert*-butyl ester)-10-(1-methyl-acetyl-glycyl)-*p*-nitrophenyl ester (Bu-DOTA-PNP, Schering Ag, Berlin; 315 mg, MW = 867.7) in DMSO at room temperature for 24 h. The reaction mixture was diluted with an additional 20 mL of PBS, dialyzed in water using 12–14 kDa cutoff membrane and lyophilized to obtain MPEG-PL-tBu-DOTA (**II**).

The protected MPEG-PL-Bu-DOTA (265 mg; **II**) was dissolved in 1.2 mL of trifluoroacetic acid/triisopropylsilane (2/1) and stirred at room temperature to remove *tert*-butyl protecting groups. The final product MPEG-PL-DOTA (**III**) was then precipitated with methyl-*tert*-butyl ether, washed with methyl-*tert*-butyl ether, redissolved in water and lyophilized overnight.

Product (**III**; P120) was labeled with gadolinium citrate at pH 4.5, 80 °C for 3 h. The Gd labeled (**III**) was then dialyzed in water using a 12–14 kDa cutoff membrane and lyophilized. The same protocol was used to label (**III**) with Eu (P30) with Dy (P60). The metal content of the labeled compounds were analyzed by ICP-AES.

To obtain a fluorescent derivative of (**III**), a 10-fold molar excess of tetramethyl rhodamine isothiocyanate (TRITC, Molecular Probes, Eugene, OR) was used (0.1 M sodium bicarbonate, pH 8.5, 1 h). The rhodamine labeled conjugate was purified by dialysis. Unreacted amino groups on (**III**) were further acetylated by treatment with acetic anhydride.

Characterization. The above synthesized compounds were subjected to size exclusion high-pressure liquid

Figure 1. Synthesis of experimental graft copolymers. The only difference among the synthesized compounds was the chain length (n) of the PL backbone. Roman numerals on the right refer to intermediary reaction products. M = Eu, Dy, Gd, In.

chromatography analysis (TSK-GEL G3000SWXL, Toso Haas, Montgomeryville, PA), measurement of molecular weight distribution (photon correlation spectrometer PCS 4700c, Malvern Instruments), elemental analysis and determination of metal content to verify that the synthesized compounds corresponded to theory.

The stability of the compounds was tested under different conditions including (1) incubating them in plasma and/or whole blood for up to 24 h, (2) lyophilization and storage for 4 months, and (3) heating at 80 °C for 3 h. Stability was tested using HPLC as described above.

Control Compounds. Two other contrast agents were also tested in the MCF-7 tumor model (Table 1). The first contrast agent was another PL-MPEG graft copolymer (PGC) of larger molecular mass (525 kDa) and containing DTPA as a chelate (rather than DOTA) and Eu as the lanthanide (13). The graft copolymer has a mean blood

half-life of 36 h in rats and of 20 h in humans (17). The second control compound was Dy labeled DOTA (MW 0.5 kDa) (18).

Tumor Model. MCF-7 breast carcinoma cells were obtained from the American Type Culture Collection (ATCC, Rockville, MD). Cells were maintained in minimal essential medium (MEM, Gibco, Gaithersburg, MD) supplemented with 10% fetal bovine serum and antibiotics. The MV165 cells (a gift from Dr. Francis Kern) are a subclone of MCF-7 cells that were stably transfected with the 165 isoform of human vascular endothelial growth factor (VEGF165) resulting in VEGF overexpression (16). MV165 cells were grown in DMEM with 10% serum and antibiotics. All cells were cultured in a humidified, 37 °C, 5% CO₂ incubator. Both cell lines were tested for VEGF expression as described in more detail elsewhere (16).

Animals. A cohort of over 50 female nu/nu athymic mice, 3–4 weeks old were obtained from Charles River Laboratories (Wilmington, MA) for tumor implantations. Three days before injection of the cells, a pellet of 17 β -estradiol (0.72 mg/pellet, 60 days release time, Innovative Research of America, Sarasota, FL) was implanted subcutaneously on the animal's back. Approximately 10⁷ cells were inoculated in each mouse. A total of 27 animals developed tumors 5–10 mm in diameter and only these animals were used for the in vivo studies (MCF-7 *n* = 18; MV165 *n* = 9). Animals received an IV injection of a mixture containing all three experimental compounds (P30-Eu, P60-Dy, and P120-Gd (group 1, *n* = 18) or PGC-Eu and Dy-DOTA (group 2, *n* = 9); 1.8 μ mol of lanthanide/mouse corresponding to approximately 0.1 mmol of lanthanide/kg). Animals were sacrificed at 3, 6, and 24 h after IV administration and tumor and other organs were removed for lyophilization and ICP-AES measurements. Blood-half-lives and biodistribution in nontumor bearing mice (*n* = 9) was determined with ¹¹¹In labeled compounds.

Determination of Metal Content in Tissue Samples. The lanthanide concentrations were analyzed by means of inductively coupled plasma atomic emission spectrometry (ICP-AES, Plasma 1000, Perkin-Elmer, Überlingen, Germany). The measurement was performed at the element-specific wavelengths for Gd (342.25 nm), Eu and Dy. Scandium was used as an internal standard and was measured at 424.6 nm by a separate optical subunit at the same time.

Histology. Tumor specimen were frozen in liquid nitrogen, stored at –86 °C and then cut into 8 μ m-thick sections (2800 Frigocut-E; Leica Instruments, Nussloch, Germany). Some sections were stained with hematoxylin/eosin. Other, sections were analyzed by fluorescence microscopy following IV administration of rhodaminated P120. Images were obtained using a cooled charge coupled device (Photometrics, Tuscon, AZ).

Figure 2. Biodistribution of the three experimental graft copolymers in normal mice (3, 6, or 24 h after IV administration). All polymers were labeled with ¹¹¹In (*n* = 3 per compound).

Analysis. Tissue concentrations of graft copolymers were expressed as % injected dose/g tissue in normal animals using gamma counting. In the remainder of the animals, total tumor, blood and muscles concentrations were expressed as nmol M/g wet weight. The amount of polymer extravasated into tumor interstitium (*C_{Ti}*) was

Figure 3. Effect of molecular mass of graft copolymers on blood/tumor ratios, a measure of extravasation into MCF-7 tumor interstitium (DOTA, 0.5 kDa; P30, 30 kDa; P60, 60 kDa; P120, 120 kDa; PGC, 525 kDa). Note the plateau with larger polymers (P120 and PGC) where incremental size increase does not result in higher ratios (arrows on right indicate arbitrary cutoff values as corroborated by histology).

calculated by subtracting vascular contributions from measured tumor samples (C_T), taking into account different blood concentrations (C_B) and vascular volume fractions (VVF) of MCF-7 (VVF = 0.017) and MV165 (VVF = 0.089) tumors (16) according to the following formula

$$C_{TI} = [C_T - (C_B \times VVF)] / 1 - VVF$$

Means and standard error of means were calculated from groups of at least three animals. Blood/tumor ratios, a measure of extravasation were calculated as

$$BT \text{ ratio} = C_B / C_{TI}$$

Differences among groups were calculated by nonparametric testing using the Wilcoxon test.

RESULTS

Characterization. Table 1 summarizes the characteristics of the different synthetic graft copolymers. The degree of MPEG modification (20–30%) and DOTA/lanthanide attachment (1:1 ratio) was within the expected range (2–3% w/w of lanthanide). There was no nonspecific lanthanide attachment to the polymer itself. Prior to testing the compounds in vivo, stability tests were performed to ensure that the attached DOTA groups would not be hydrolyzed in vivo. Results from these size

exclusion HPLC studies show that the polymers were stable without detectable degradation products after 24 h of incubation in plasma. Likewise, there was no degradation after incubation with whole blood or after heat treatment at 80 °C for 3 h.

Figure 2 summarizes the different biodistribution profiles of the three experimental compounds in nontumor bearing animals. Blood half-lives were 2 h for P30, 3 h for P60, and 5.2 h for P120. The smallest compound, PL3 had the highest urinary excretion with over 25% ID/g at the 6 h time point. Urinary excretion was lower for P60 and P120 (<5% ID/g). The organ distribution pattern was roughly similar, presumably reflecting differences in blood volume fraction in different organs.

Tumoral Behavior. For the further biological characterization of the compounds, mixtures of three compounds (Eu-P30, Dy-P60, and Gd-P120) were injected intravenously. Table 2 summarizes the absolute tissue concentrations for the different lanthanides in tumor interstitium (C_{TI}), blood (C_B) and muscle compartments. Blood tumor ratios were also calculated and are summarized in Figure 3. Extravasation from blood into tumor interstitium was dependent on (1) molecular weight, (2) time after injection, and (3) tumor environment.

Size Dependence. The blood/tumor ratio (MCF-7) increased with increasing molecular weights of the tested polymers reflecting lower extravasation and higher blood concentrations with larger polymers (Figure 3). For

Figure 4. (A) Accumulation of P120 in tumor interstitium as a function of time. Compared to MCF-7 there is higher extravasation and also larger variability in these tumors with more chaotic vasculature. (B) Comparison of blood-tumor ratios for different time points among the two tumor models: estrogen dependent moderately differentiated breast adenocarcinoma (light gray) and the same tumor cell lines but stable transfected with human VEGF (dark gray).

DOTA this ratio was <1 consistent with rapid extravasation. At 3 h after injection the blood/tumor ratios were 10:1 for P30, 14:1 for P60 and 24:1 for P120. Interestingly, further increases in molecular mass above 120 kDa did not result in higher ratios (22.5 for the 525 kDa PGC) in the MCF-7 tumor model.

Time Dependence. All of the tested polymers showed a decrease in blood/tumor ratios over 24 h, reflecting slow clearance and extravasation into tumor interstitium during the observation time. At 6 h after administration, the blood/tumor ratios were still over 13:1 for P60 and P120 and PGC. After 24 h after administration, the highest ratio (10:1) was observed for PGC.

Effect of Tumor Environment. To determine whether VEGF overexpression would alter the above distributions and ratios, we also tested the three experimental compounds in the matched MV-165 control tumors that had been transfected with VEGF (16). Figure 4A juxtaposes the tumoral interstitial concentrations for P120. In case of the MCF-7 tumors, there was slow accumulation with an initially faster component and then a slower one. The standard deviations were relatively narrow. In contra-

distinction, MV165 tumors showed higher accumulations at any time point investigated as well as larger standard deviations.

Figure 4B compares the 3 h blood/tumor ratios for the different experimental compounds in MCF-7 and MV-165 tumors. With P30, the ratios were similar, reflecting indiscriminate extravasation. For the P60 and the P120 polymer however, the differences were more marked. These data indicate that VEGF overexpression can have pronounced effects on extravasation, increasing the vascular pore cutoff to above 120 kDa.

Microscopic Evaluation. Figure 5 summarizes histologic features of the two different tumors. Hematoxylin/eosin staining of MCF-7 and MV165 tumors shows a more aggressive behavior of the latter tumor with higher vascular density.

To determine the fate of P120 in the tumor we also performed additional fluorescence microscopy experiments (Figure 5, panels C and D). At the 3 h time point, the polymer was almost exclusively found in small blood vessels consistent with a high blood/tumor ratio determined with ICP-AES (Figure 5C). At the 24-hour time point, the polymer was more homogeneously distributed throughout tumor. At higher magnifications (see Figure 5D insert), it became evident that a significant portion of the polymer was present within tumor cells as well as tumor associated macrophages. Within cells, the polymer appeared in tubular and round intracellular vesicles.

DISCUSSION

Imaging techniques such as MRI and nuclear techniques have the potential to measure a number of different microvascular parameters during angiogenesis and may thus be clinically useful in assessing the efficacy of antiangiogenic treatments. While some of these measurements can be made with first pass bolus techniques [e.g., dynamic Gd-DTPA enhanced MR imaging (10)] others require the use of contrast agents that have a more limited intravascular distribution (so-called "long-circulating", "blood-pool", or "macromolecular contrast agents"). The latter approach allows imaging of multiple tumors and multiple sections throughout a given tumor since there are fewer timing constraints than for first pass techniques. A number of different macromolecular contrast agents have been described including Gd labeled albumin (70–90 kDa) (9, 19), dendrimers (35 kDa) (20), and pegylated graft copolymers (525 kDa) (16). Despite these studies there is little consensus as to what molecular weight a given "blood pool agent" should have, to measure functional vascular volume fractions. Furthermore, little information exists on how heterogeneous such microvascular parameters are in tumors in vivo and what effect angiogenic factors such as VEGF have on the in vivo distribution of different compounds. Some prior studies have investigated capillary permeability in tumor microvessels using size markers such as fluorescent dextrans, albumins (bovine serum albumin, ovalbumin), immunoglobulins and their fragments (Fc, Fab, Fab₂) or liposomes (12, 21). Most of these experimental studies have been limited to a few human tumor lines in orthopic location (22).

In the current study, we have synthesized differently sized graft copolymers ultimately to be utilized for in vivo imaging of tumor microvasculature. The rationale for designing these types of graft copolymers has recently been laid forward, while clinical studies show acceptable tolerance (17). On the basis of results of prior studies we attempted to cover molecular masses (30–525 kDa)

Figure 5. Light (A, B) and immunofluorescence (C, D) microscopy. (A) Hematoxylin/eosin stain of MCF-7. (B) Hematoxylin/eosin stain of MV165. (C) Immunofluorescence microscopy with rhodaminated P120 at 3 h after IV administration of the compound. Note the predominant distribution within small vessels (indicated by asterisk; magnification 400 $\times$). (D) At 24 h after administration, a larger number of cells are now stained indicating slow extravasation and cellular uptake (magnification 200 $\times$). At higher magnification (insert, 600 $\times$), the rhodaminated compound is seen within small vesicular intracellular locations, presumably lysosomes and endosomes. The round signal voids represent cell nuclei at this magnification.

which are synthetically feasible. Our data show a clear size dependence on extravasation into tumors with a detectable cutoff in MCF-7 human breast adenocarcinomas. Blood/tumor ratios were highest (24:1) for the 120 kDa polymer and did not further increase with the 525 kDa polymer. As expected, the 30 and 60 kDa polymers showed much lower ratios as they extravasated into tumor interstitium. On the basis of these results a 120 kDa polymer would suffice for imaging of certain tumors such as well differentiated MCF-7, a finding which was also corroborated by fluorescence microscopy (Figure 5).

To determine the effects of VEGF on the distribution of the polymers, we performed additional experiments using a parental MCF-7 clone that had been stable transfected with human VEGF (16). The effects of VEGF as a regulator of vascular physiology are well reported while more recently some of the modes of action and consequences have been identified (4). Our results confirm prior observations on the effects of VEGF on vascular permeability of large molecular mass size markers (12, 23). MV165 tumors showed faster and higher extravasation of the 120 kDa polymer than did the MCF-7 tumors. Blood/tumor ratios were also significantly lower at 3 h after administration (19 vs 24 for P120). These results suggest that VEGF production (and likely other agonists or antagonists) can have pronounced effect on the pharmacology of a prospective imaging agents. These results suggest that a molecular cutoff size above 120 kDa is required for an intravascular agent used in the evaluation of angiogenesis.

Fluorescence microscopy confirmed the more quantitative ICP-AES measurements. While P120 was almost exclusively present in vessels in MCF-7 tumors within 3 h after IV administration, it had clearly extravasated at 24 h. Our data furthermore indicate that the polymer was partially taken up by tumor cells and also by tumor-associated macrophages. Although the percentage of uptake into either cell type was not quantitated, such studies have been performed for dextran coated particles (24) and PGC derivatives (25). The implications of such cellular uptake following extravasation is that long circulating graft copolymers could theoretically be used for tumoral drug delivery.

The current study was set out to quantitate differences among the macromolecular agents, reason for which we investigated relatively late time points following intravenous injection but not early ones where the expected changes would have been less pronounced. In a clinical scenario however, imaging would most likely be performed within the first hour after administration of a given agent, when blood-to-tumor interstitium ratios are higher. Assuming that permeability does not change significantly over time, one could roughly extrapolate ratios for earlier time points (see Figure 3). For the MCF-7 tumor, a well differentiated adenocarcinoma, the blood/tumor ratios could thus be 10–20% higher within 1 h after administration.

The current class of polymers was designed to be stable, while having DOTA chelating groups to minimize the possibility of de-chelation. This design builds on earlier version of other graft copolymers but has the

added benefits of better-controlled chemistry (e.g., non-cross-linking through DTPA and stability of PEG-PL anchorage sites). All polymers were labeled with lanthanides at high efficiency while ^{99m}Tc and ^{111}In labels could be envisioned for nuclear imaging (Figure 2). The choice of imaging modality will likely be governed by additional prerequisites such as the need to map spatial heterogeneity of microvascular parameters (high-resolution MR imaging) within a lesion or the need for quantitation (nuclear vs MR imaging).

It should be noted that the described polymers have a preferential vascular distribution and will selectively enhance macro- and microvasculature. Because leakage of larger contrast agents into tumor interstitium can be limited, these agents are unlikely to be as useful for tumor detection as low molecular weight agents. However, it is very likely that these contrast agents will be used to characterize tumors and more importantly to test the efficacy of novel antiangiogenic treatments (15).

ACKNOWLEDGMENT

The authors would like to express gratitude for the expert technical help of N. Nossiff in preparing polymer samples, Drs. M. Lewin and A. Moore for performing biodistribution experiments, T. Frenzel and colleagues for ICP-AES, and Dr. Mahmood for critical manuscript review. We are indebted to Drs. L. Josephson, B. Rüdchel, and U. Speck for many fruitful discussions.

Tumor Targeting of Radiometal Labeled Anti-CEA Recombinant T84.66 Diabody and T84.66 Minibody: Comparison to Radioiodinated Fragments

Paul J. Yazaki,^{*,†} Anna M. Wu,[†] Shih-Wa Tsai,[‡] Lawrence E. Williams,[§] David N. Ikle,^{||} Jeffrey Y. C. Wong,[⊥] John E. Shively,[‡] and Andrew A. Raubitschek[#]

Received July 31, 2000

Recombinant antibody fragments offer potential advantages over intact monoclonal antibodies in the radioimmunoscintigraphy (RIS) of solid tumors. Due to their smaller molecular size, antibody fragments have shown rapid tumor targeting and blood clearance, a more uniform tumor distribution and a lower potential to elicit a human immune response. Previously, we have expressed two genetically engineered antibody fragments, the T84.66 diabody (scFv dimer) and the T84.66 minibody (scFv-CH3 dimer), specific to carcinoembryonic antigen (CEA). When radioiodinated, both antibody fragments exhibited rapid tumor targeting and rapid blood clearance in xenografted mice. To extend and optimize their future clinical RIS utility with radiometals, these antibody fragments were conjugated with the macrocycle 1,4,7,10-tetraazacyclododecane *N,N',N'',N'''*-tetraacetic acid (DOTA) and labeled with ¹¹¹In. Tumor targeting and biodistribution studies were carried out in athymic mice xenografted with a human colorectal tumor cell line, LS174T. The [¹¹¹In]T84.66 diabody (55 kDa) exhibited very rapid tumor targeting with 12.5 ± 0.4% injected dose per gram (% ID g⁻¹ ± standard error) at 2 h and reached a maximum of 13.3 ± 0.9% ID g⁻¹ at 6 h. However, kidney uptake was observed to reach a peak of 183.5 ± 21.0% ID g⁻¹ at 6 h, a result similar to that reported by others for other low molecular weight fragments labeled with radiometals. Preadministration of an oral dose of D-lysine resulted in a 59% lowering of the renal accumulation at 6 h, but was accompanied by a 31% reduction of tumor uptake to 9.2 ± 1.2% ID g⁻¹. The second recombinant antibody fragment, the [¹¹¹In]T84.66 minibody (80 kDa), displayed rapid tumor targeting of 14.2 ± 6.1% ID g⁻¹ at 2 h, and reached a maximum activity of 24.5 ± 6.1% ID g⁻¹ by 12 h. Renal uptake achieved a plateau of 12–13% ID g⁻¹ which cleared to 7.2% ID g⁻¹ at 72 h. However, hepatic uptake was elevated and reached a maximum of 26.0 ± 1.0% ID g⁻¹ at 12 h in these xenograft-bearing mice. Experiments in nontumor bearing mice showed a reduction of hepatic activity at 12 h to 16.6 ± 1.5% ID g⁻¹, indicative of an intrinsic hepatic accumulation of the [¹¹¹In]DOTA-T84.66 minibody or metabolites. While the anti-CEA [¹¹¹In]DOTA-T84.66 diabody and T84.66 minibody retain the rapid tumor targeting properties of the radioiodinated form, the normal organ accumulation (kidneys and liver, respectively) of the [¹¹¹In]DOTA forms appeared problematic for RIS and RIT applications. Development of alternative blocking strategies or new metabolizable chelates are under investigation to enhance the utility of the radiometal form of these and other promising recombinant antibody fragments.

INTRODUCTION

Radiolabeled monoclonal antibodies (Mabs)¹ have been under continued development for the detection and imaging of primary and metastatic disease and have been extensively reviewed (1–3). However, intact Mabs have not proven to be ideal imaging agents due to their slow tumor targeting and extended blood clearance, the inability to uniformly penetrate large tumors, and the

elicitation of anti-murine or anti-chimeric human antibody responses (4). Improvements to the pharmacokinetics have come from the generation of antibody fragments by *in vitro* enzymatic digestion or the more easily produced single-chain Fv recombinant fragments (5). These antibody derived fragments have shown rapid tumor targeting and swift blood clearance. However, initial work has demonstrated that these truncated molecules may still require additional development (4, 6, 7).

¹ Abbreviations: Mab, monoclonal antibody; RIS, radioimmunoscintigraphy; scFv, single-chain Fv protein; DOTA, 1,4,7,10-tetraazacyclododecane *N,N',N'',N'''*-tetraacetic acid; CEA, carcinoembryonic antigen; DTPA, diethylenetriaminepentaacetic acid; HSA, human serum albumin; ANOVA, two way analysis of variance; CT computed tomography; pI, isoelectric point; microPET, micro positron emission tomography; RIT, radioimmunotherapy.

Figure 1. Schematic drawing shows the domain structure of the parental intact T84.66 antibody (left), T84.66 diabody (center), and the T84.66 minibody (right). In mammalian cell culture, the T84.66 diabody (scFv) is secreted as noncovalent cross-paired dimer (55 kDa), while the T84.66 minibody (scFv-CH₃) self-assembles into a covalent dimer (80 kDa).

Table 1. List of Potential Radionuclides for Radioimmunoscinigraphy^a

radionuclide	half-life	$E_{\beta \text{ max}}$ (MeV)	E_{γ} (MeV)
¹²³ I	13.2 h	0.13	0.159 (97%)
¹³¹ I	8.1 d	0.61	0.365 (81%)
^{99m} Tc	6 h	0.12	0.140 (90%)
⁶⁴ Cu	12.7 h	0.57 (β^-) 0.66 (β^+)	0.510 (38%)
⁶⁷ Cu	61 h	0.57	0.180 (40%)
¹⁰⁵ Rh	36 h	0.96	0.310 (24%)
¹¹¹ In	2.8 d	0.24	0.174 (89%) 0.250 (94%)
^{117m} Sn	13.6 d	0.13 0.16	0.158 (87%)
¹⁵³ Sm	1.9 d	0.81	0.103 (29%)
¹⁷⁷ Lu	6.8 d	0.50	0.21 (6%)
¹⁸⁶ Re	3.8 d	1.07	0.137 (9%)
¹⁸⁸ Re	17 h	2.12	0.16 (10%)

^a A table of potential radionuclides for imaging based on half-life and emission spectra. Those above the horizontal break are negative ions; those below are positive ions. All β emissions are for electrons except in the case of ⁶⁴Cu which emits both electrons and positrons. Percentages listed are the probability of a photo-emission.

The development of antibody fragments for radioimmunoscinigraphy (RIS) can be categorized in terms of selection of radionuclide, metal chelate, production of sufficient quantities of protein, and reduction of the nontargeted uptake in normal tissues. Radiolabeling with ¹³¹I is the most commonly used radionuclide for RIS but its usage in cancer imaging is restricted by a high energy photon (360 keV), a long physical half-life ($T_{1/2} = 8$ days), high energy beta emission and a significant loss of signal due to dehalogenation (3). Use of ¹²³I has been a second possible isotope, but its relatively high cost, availability and short (13.2 h) half-life may restrict its clinical usage. ^{99m}Tc has been used for RIS, but with an even shorter half-life of 6 h, there is a substantial reduction of the amount of radioactivity deposited to the tumor tissue by the time of imaging (1). To overcome some of these limitations, a number of radiometals may be considered for RIS such as ⁶⁴Cu, ⁶⁷Cu, ¹⁰⁵Rh, ¹¹¹In, ^{111m}Sn, ¹⁵³Sm, ¹⁷⁷Lu, ¹⁸⁶Re, and ¹⁸⁸Re. These radionuclides are listed in Table 1, along with their half-lives and emission details.

Developing new recombinant antibodies for RIS, two genetically engineered antibody fragments from the highly specific, anti-CEA murine antibody T84.66 have been previously expressed (Figure 1). The T84.66 diabody (55 kDa) is a single chain variable region (scFv) dimer

which when radioiodinated exhibited rapid tumor targeting and blood clearance in tumor bearing xenografted mice (8). The second construct, the T84.66 minibody, is a scFv-CH₃ fusion protein that self-assembles into a covalent 80 kDa dimer, and when radioiodinated exhibited higher tumor targeting with a longer biological half-life in xenograft-bearing mice (9).

To investigate the radiometal-labeled utility of these recombinant antibody fragments, the antibodies were conjugated with the macrocyclic chelating agent, 1,4,7,10-tetraazacyclododecane *N,N',N'',N'''*-tetraacetic acid (DOTA) (10). This allowed labeling with ¹¹¹In for biodistribution studies in tumor-bearing xenografted mice. To determine the merits and limitations of the [¹¹¹In]form, a statistical analysis was made comparing the tumor targeting and biodistributions properties between the ¹¹¹In and previous radioiodinated forms of these two promising antibody fragments.

MATERIALS AND METHODS

Antibody Development. The T84.66 diabody previously expressed in *Escherichia coli* and characterized in radioiodinated biodistribution studies (8), has now been produced in one hundred milligram quantities from mammalian cell culture (Yazaki et al., manuscript submitted). The T84.66/212 Flex minibody (scFv-CH₃) was expressed in Sp2/0 mammalian cells, radioiodinated, and characterized in animal biodistribution studies (9). A second minibody version, the T84.66/GS18 Flex minibody, was constructed from the T84.66/212 Flex minibody DNA template using the polymerase chain reaction/splice overlap extension as previously described (9). With an 18 amino acid linker (GSTSGGGSGGGSGGGSS in single letter code), the GS18 Flex minibody was expressed in NS0 murine myeloma cells (Yazaki et al., manuscript submitted) (11). The expressed proteins were purified by hydrophobic interaction chromatography (Source ISO, Amersham Pharmacia Biotech, Piscataway, NJ) followed by anion-exchange chromatography (HQ50, PE Biosystems, Foster City, CA) using a BioCAD 700E chromatography system (PE Biosystems, Foster City, CA) (Yazaki et al., manuscript submitted). Purity was determined by electrophoresis on 10% acrylamide Ready Gels (Bio-Rad Laboratories, Hercules, CA) under nonreducing conditions on SDS-PAGE (12) with Kaleidoscope protein standards (Bio-Rad Laboratories, Hercules, CA) and staining with Coomassie Blue R-250. CEA-binding activity was determined by ELISA using microtiter plates

coated with a recombinant N-A3 protein (N and A3 domains of CEA) (13) and an anti-human Fc alkaline phosphatase antibody for detection (Jackson Immuno-research, West Grove, PA). Chimeric T84.66 (cT84.66) antibody was used as the standard (14).

Conjugation and Radiolabeling. For radiometal studies, purified T84.66/GS18 Flex minibody and the T84.66 diabody were conjugated to DOTA using the water-soluble *N*-hydroxysuccinimide method (10). In a typical experiment, 400 μ g of protein was reacted with a 1000:1 molar ratio of DOTA to protein for 18–24 h at 4 °C at pH 7.0. Following conjugation, the protein was dialyzed extensively in 0.2 M NH_4OAc , pH 7.2, and concentrated to greater than 5 mg/mL. The DOTA:antibody conjugation ratio was determined by incubation of the DOTA-conjugated antibody with a labeling solution containing known quantities of ^{111}In (Mallinckrodt, Hazelwood, MO) and cold indium (Aldrich, Milwaukee, WI). ^{111}In labeling was analyzed by thin-layer chromatography using Monoclonal Antibody ITLC strips (Biodex Medical Systems, Shirley, NY). Percent bound indium was determined, and the DOTA:antibody ratio calculated. DOT-A:antibody ratios ranged from 1:1 to 6:1 chelate per minibody while for the diabody the ratio was 0.5:1. DOTA-minibody or DOTA-diabody (400 μ g of protein) were incubated with 1.3 mCi of pure ^{111}In chloride (Mallinckrodt, Hazelwood, MO) in 0.25 M NH_4OAc pH 5.0 for 1 h at 43 °C. The reaction was stopped by the addition of DTPA to a final concentration of 1 mM. Conjugated monomeric proteins were purified by HPLC size-exclusion chromatography using a TSK-G2000SW column (30 cm $\times$ 7.5 mm ID; Tosoh, Montgomeryville, PA) for the minibody and a Superdex 75 HR 10/30 column (Amersham Pharmacia Biotech, Piscataway, NJ) for the diabody.

Radioiodination of the T84.66 minibody was by the Iodogen method as previously described (15). Radio-labeling efficiency was determined by integrating areas on the size-exclusion HPLC trace and determining the percentage of radioactivity associated in the 80 kDa peak for the minibody and the 55 kDa peak for the diabody. Immunoreactivity was determined by incubation of the labeled protein with a 20-fold excess (w/w) of either purified CEA or the recombinant N-A3 fragment of CEA (13) in 0.15 mL of PBS/1% HSA. Analysis by size-exclusion HPLC was on tandem Superose 6 HR 10/30 columns (Amersham Pharmacia Biotech, Piscataway, NJ) to assess the formation of antibody:antigen complexes.

Animal Studies. Groups of 7–8-week old female athymic mice (Charles River Laboratories, Wilmington, MA) were injected subcutaneously in the flank region with 10^6 LS174T human colon carcinoma cells obtained from ATCC (Manassas, VA). After 10 days, when tumor masses were in the range of 100–300 mg, 1–3 μ Ci of ^{111}In DOTA-antibodies/animal (2–3 μ g of protein) were injected into the tail vein. Time points of analysis for the T84.66 diabody were 0, 2, 4, 6, 12, and 24 h while for the T84.66 minibody 0, 2, 6, 12, 24, 48, and 72 h were selected. For individual experiments, groups of five to six mice at the selected time points were euthanized, necropsy performed and organs weighed and counted for radioactivity. Data from several individual experiments of the same construct and radionuclide were compared and when there was not a significant statistical difference ($p > 0.01$), the data were combined. This resulted in pooled data sets of up to 16 mice/time point. All data are mean values and have been corrected for radiodecay back to the time of injection, allowing organ uptake to be reported as percent of the injected dose per gram (% ID/

Figure 2. Radiochromatograms of size-exclusion HPLC analysis of ^{111}In DOTA-T84.66 diabody (A) and ^{111}In DOTA-T84.66 minibody (B). Lower trace was the starting sample used for evaluation of immunoreactivity. Upper trace, following incubation with CEA or N-A3 (a CEA mimetic) the bulk of the ^{111}In DOTA-T84.66 diabody and ^{111}In DOTA-T84.66 minibody are found in antibody:antigen complexes.

g^{-1}) with standard errors. Blood curves were calculated using the ADAPT II software (16).

D-Lysine renal-blocking experiments were carried out according to the protocol of Behr et al. (17). Briefly, D-lysine (Sigma, St. Louis, MO) was dissolved in PBS at a concentration of 200 mg/mL and 100 mg was administered by an oral intubation catheter, 30 min prior to the injection of the ^{111}In T84.66 diabody.

Biostatistical Analysis. To compare changes in percent of the injected dose per gram over time among antibody constructs and radionuclides, two-way analysis of variance (ANOVA) was performed (16). Time (h), construct or radionuclide, and the interaction between these two factors were included in the statistical model. Dependent variables compared using this model included the percent of the injected dose per gram for organs blood, liver, spleen, kidney, lung, and intact bone as well as tumor and carcasses. Tumor-to-blood and tumor-to-liver ratios as well as tumor masses were recorded. To compare differences in mean percent of the injected dose per gram between antibody constructs at specific time points, the independent *t*-test was used. All significance testing was done at the 0.01 level, using the SAS/STAT software (SAS Inc., Cary NC).

Table 2. Biodistribution of [¹¹¹In]T84.66 Diabody in Athymic Mice Bearing LS174T Xenografts^a

	time (h)					
	0	2	4	6	12	24

^a [¹¹¹In]T84.66 diabody was injected into xenograft-bearing mice and tumor targeting and biodistribution studies were carried out. Groups of five mice were analyzed at each time point. Tumor and normal organ uptake are expressed as percent injected dose per gram (% ID/g). Standard errors of the mean (SE) are given in parentheses. The ratios presented are the averages of the tumor/blood and tumor/liver ratios for the individual mice. Tumor masses are in grams.

RESULTS

[¹¹¹In]DOTA-T84.66 Diabody. The T84.66 diabody was conjugated with the macrocycle DOTA to allow labeling of the protein with a variety of radiometals. The chelate-to-diabody ratio was 0.5:1 and when radiolabeled resulted in 67–100% incorporation of ¹¹¹In into the T84.66 diabody. Size-exclusion chromatography displayed a single radiolabeled peak with a specific activity that ranged from 1.4 to 3.2 $\mu\text{Ci}/\mu\text{g}$. The radiolabeled diabody displayed high immunoreactivity to N-A3 (CEA mimetic) with over 95% immunoreactivity (Figure 2A). For biodistribution studies, the tissues (tumor, blood, liver, spleen, kidney, lung, intact bone, and carcass) from groups of five mice per time point (0, 2, 4, 6, 12, and 24 h) were counted for radiolabel uptake and are shown in Table 2. The [¹¹¹In]T84.66 diabody exhibited very rapid tumor uptake in the CEA expressing LS 174T xenografts. There was $12.5 \pm 0.4\%$ ID g^{-1} at 2 h and the deposition of the radiolabel was persistent with $12.3 \pm 1.4\%$ ID g^{-1} at 12 h. The diabody was found to clear quickly from the blood circulation with only $2.7 \pm 0.2\%$ ID g^{-1} remaining at 2 h with a terminal phase $T_{1/2\beta}$ of 3.04 h (Table 3). Excellent tumor-to-blood ratios were observed with 39.5:1 at 6 h rising to 196:1 at 24 h. The initial hepatic accumulation at T_0 was low measuring $7.9 \pm 0.3\%$ ID g^{-1} and decreased to $3.6 \pm 0.2\%$ ID g^{-1} by 24 h. Other normal tissues showed low accumulation except for the kidney where a high level of accumulation was observed. This renal uptake reached a maximum of $183.5 \pm 21.0\%$ ID g^{-1} at 6 h with slow clearance during the 24 h time course of the experiment.

Preadministration of cationic amino acids has been shown to block the renal proximal tubular cell reabsorption of mAbs and antibody fragments without an effect on tumor uptake (18). Comparisons of the kidney and tumor uptake of the [¹¹¹In]DOTA-T84.666 diabody with and without the administration of D-lysine are shown in Figure 3. Oral administration of D-lysine resulted in a

^a The T84.66 minibody and the T84.66 diabody were labeled with radioiodine or ¹¹¹In. Current and previous (8) biodistribution studies were carried out in xenografted mice. Animal blood curves were calculated using the ADAPT II software (16) and the standard deviations are shown below the results. A₁ and A₂ are the amplitudes of the faster and slower clearance components. T_{1/2} are related to the inverse of k₁ and k₂ by the relationship: $T_{1/2} = 0.693/k$.

59.2% reduction at the 6 h time point where renal uptake reached the maximum (183.5 ± 21.0 vs $75.0 \pm 7.1\%$ ID g^{-1}). However at 6 h, there was a 31% reduction of tumor uptake, lowering the tumor activity to $9.2 \pm 1.2\%$ ID g^{-1} .

[¹¹¹In]DOTA-T84.66 Minibody. As was performed for the diabody, the T84.66 minibody was conjugated with DOTA for radiolabeling with ¹¹¹In. In three conjugations, the chelate-to-minibody ratio ranged from 1:1 to 6:1 and following radiolabeling resulted in 24–85% incorporation of ¹¹¹In. Size-exclusion chromatography displayed a single radiolabeled peak with a specific activity that ranged from 2.3 to 4.7 $\mu\text{Ci}/\mu\text{g}$. The [¹¹¹In]DOTA-T84.66 minibody retained high immunoreactivity to CEA with a range of 70 to 100% immunoreactivity (Figure 2B). Two experimental studies of the biodistributions of the [¹¹¹In]T84.66/GS18 Flex minibody in xenograft-bearing mice were carried out with groups of five mice per time point. All tissues (see above) were counted for radionuclide uptake

^a [¹¹¹In]T84.66 minibody was injected into xenograft-bearing mice and tumor targeting and biodistribution studies were carried out. Groups of 10 mice were analyzed at each time point. Tumor and normal organ uptake are expressed as percent injected dose per gram (% ID/g). Standard errors of the mean (SE) are given in parentheses. The ratios presented are the averages of the tumor/blood and tumor/liver ratios for the individual mice. Tumor masses are in grams.

Figure 3. Comparison of renal uptake of the [¹²³I]T84.66 diabody and the [¹¹¹In]T84.66 diabody, with and without preadministration of D-lysine. The [¹²³I]T84.66 diabody and [¹¹¹In]T84.66 diabody with or without preadministration of D-lysine were injected into xenograft-bearing mice. Groups of five or more mice were sacrificed at each time point, and the tissues counted for radioactivity. Activity was expressed as percent injected dose per gram (% ID/g).

at 0, 2, 6, 12, 24, and 48 h. Statistical analysis showed no significant difference between the respective tissues from both studies and the ¹¹¹In biodistributions were combined (Table 4). Tumor uptake of the [¹¹¹In]T84.66 minibody achieved $14.2 \pm 6.1\%$ ID g⁻¹ at 2 h and reached a maximum of $24.5 \pm 6.1\%$ ID g⁻¹ at 12 h. Activity remained at the tumor site with $11.3 \pm 0.9\%$ ID g⁻¹ at 48 h but decreased to $8.3 \pm 0.1\%$ ID g⁻¹ by 72 h. The [¹¹¹In]T84.66 minibody was cleared quickly from the circulation with a $T_{1/2\beta}$ of 4.51 h. It was found that the renal uptake was low, reaching a plateau of 12–13% ID g⁻¹ over the first 24 h and clearing to 7.2% by 72 h. Intact bone activity reached a level of 3.9% ID g⁻¹ during the first 24 h but was reduced to 2.3% ID g⁻¹ by 72 h. The liver showed the highest normal organ accumulation,

reaching $26.0 \pm 1.0\%$ ID g⁻¹ at 24 h with slow clearance to $17.2 \pm 1.2\%$ ID g⁻¹ at 72 h.

High hepatic uptake had been observed for the intact [¹¹¹In]chimeric T84.66 (cT84.66) antibody in xenograft bearing mice (19). This accumulation had been determined to be the result of trafficking of CEA-antibody immune complexes into the hepatocytes (20). To investigate whether similar uptake of the antibody–antigen complex was occurring for the [¹¹¹In]T84.66 minibody, biodistribution studies were also carried out in normal athymic mice. The only tissues that showed a significant difference compared to the tumor bearing animals were the liver and the spleen. The corresponding activity curves are shown in Figure 4, along with the activity curve of the radioiodinated form in tumor bearing mice. While the [¹¹¹In]T84.66 minibody showed reduced hepatic uptake in the normal mice, the hepatic activity remained elevated in particular when compared to the radioiodinated form. For the spleen, normal athymic mice had a higher accumulation of the ¹¹¹In form than the tumor bearing mice but again the radioiodinated form was much lower. No statistical significant difference was observed for blood ($p = 0.83$) or kidney distributions ($p = 0.94$).

Indium vs Iodine Analysis. To understand the biodistribution properties of radiometal labeled fragments, the ¹¹¹In data obtained was compared to the radioiodinated biodistribution data. A two way statistical comparison was made between the [¹¹¹In]T84.66 diabody data given here and previously published [¹²³I]T84.66 diabody data (8). Uptake in the tumor of the two radionuclides reached comparable levels within the first 4 h but after 6 h a higher level of activity remain for ¹¹¹-In labeled material ($p < 0.0007$). Initial blood uptake for the indium label was marginally greater ($49.5 \pm 4.4\%$ ID g⁻¹ vs $41 \pm 2.8\%$ ID g⁻¹) with the overall blood clearance slightly slower for the indium labeled material. Calculations of the effective half-lives were made and are shown in Table 3. The ¹¹¹In form showed a slower alpha

Figure 4. Hepatic and splenic uptake of the [^{111}In]T84.66 minibody in xenograft-bearing and normal mice and the radioiodinated T84.66 minibody in xenograft-bearing mice. [^{111}In]T84.66 minibody and [^{123}I] and [^{125}I]T84.66 minibody were injected into tumor-bearing mice as well as the [^{111}In]T84.66 minibody into normal athymic mice. Groups of five or more mice were sacrificed at each time point. Biodistribution of liver uptake (A) and spleen uptake (B) are shown.

phase but comparable beta phase. Hepatic uptake was significantly higher for the ^{111}In -diabody with a slower clearance pattern compared to the radioiodinated form ($p < 0.0001$). Renal uptake was substantially higher for the indium form over all but the initial time point ($p < 0.0001$). Blocking of renal absorption by D-lysine substantially lowered the [^{111}In]T84.66 diabody accumulation but the level of renal uptake was still highly elevated over the levels observed for the radioiodinated diabody (8).

Two versions of the T84.66 minibody, the GS18 Flex and the 212 Flex were expressed differing only in the length of the scFv linker. Both versions exhibited identical *in vitro* biochemical properties and antigen binding activities (Yazaki et al., manuscript submitted) and when radioiodinated displayed similar biodistributions in xenograft-bearing animals (7). The data from these two studies plus a third minibody experiment were pooled, resulting in a data set of 16 mice/time point (Table 5). Tumor uptake was $14.1 \pm 1.5\%$ ID g^{-1} at 2 h, and reached a maximum of $26.2 \pm 4.6\%$ ID g^{-1} at 12 h. Blood clearance resulted in a $T_{1/2\beta}$ of 6.99 h (Table 3). The radioiodinated T84.66 minibody exhibited some initial uptake or blood pool activity into normal tissue, but there was rapid clearance of the radiolabel. Levels immediately after injection were the following: lung ($13.6 \pm 1.1\%$ ID g^{-1}),

kidney ($9.9 \pm 0.3\%$ ID g^{-1}), liver ($7.2 \pm 0.3\%$ ID g^{-1}), and spleen ($6.2 \pm 0.3\%$ ID g^{-1}), and all were below 1% ID g^{-1} by 24 h.

In an identical manner as to the T84.66 diabody, a comparison was made between the ^{111}In and the radioiodinated forms of the T84.66 minibody. Activity in the tumor ($p = 0.18$) and blood ($p = 0.11$) showed no significant difference. There was significantly faster clearance of radioiodinated form from the liver and kidneys compared to the ^{111}In form ($p < 0.0001$).

DISCUSSION

Radiolabeled antibody fragments offer potential advantages over intact Mabs for the imaging of solid tumors. Due to their smaller molecular size, antibody fragments have exhibited rapid tumor targeting and blood clearance, increased tumor penetration and a lower potential of eliciting an immune response (4). Clinical studies with [$^{99\text{m}}\text{Tc}$]Fab' (21) and [^{123}I]scFv (22) antibody fragments have shown promise as cancer imaging agents, particularly in complement with CT scanning.

Previously, we have expressed two anti-CEA recombinant antibody fragments, the T84.66 diabody (8) and the T84.66 minibody (9), which when radioiodinated, displayed rapid tumor targeting and rapid blood clearance in xenograft-bearing mice. To extend the clinical utility of the T84.66 diabody and T84.66 minibody, labeling with one of the radiometals available (Table 1) can arguably offer many potential advantages over the radioiodinated form. These include the lack of dehalogenation, a more efficient emission spectrum for γ camera imaging, and a potentially more suitable physical half-life. In addition, radiometals compared to ^{131}I are less injurious to the patient due to a lack of 600 keV β particles produced in the decay scheme (3).

In this present work, the biodistribution properties of the [^{111}In]DOTA-T84.66 diabody displayed high level rapid tumor targeting of $12.5 \pm 0.4\%$ ID g^{-1} at 2 h and a rapid clearance from the circulation ($T_{1/2\beta} = 3.04$ h). This resulted in high tumor-to-blood ratios which reached 196:1 at 24 h compared to the 4.6:1 ratio observed for the parental cT84.66 at 24 h (23). Unfortunately, high renal uptake was observed for the [^{111}In]T84.66 diabody as has been documented for other radiometal labeled antibody fragments (4, 6, 24).

To overcome the renal accumulation problem, the T84.66 minibody was designed to have a molecular weight that exceeded the renal threshold (~ 60 kDa) (18). Two versions of the minibody were expressed, the 212 Flex and GS18 Flex, which differed in the length of the scFv peptide linker (14 vs 18 amino acids, respectively). When radioiodinated both minibody versions showed comparable animal biodistributions in xenograft-bearing mice (7) as well as identical biochemical and affinity characteristics (Yazaki et al., manuscript submitted). For all subsequent studies, the T84.66/GS18 Flex minibody was used due to the ability to produce grams of crude material from mammalian cell culture production. The [^{111}In]T84.66 minibody displayed rapid tumor targeting of $24.5 \pm 6.1\%$ ID g^{-1} at 12 h with considerable activity remaining at 72 h ($8.3 \pm 0.9\%$ ID g^{-1}) when the tumor-to-blood ratio reached 140:1. While the ^{111}In form had higher tumor uptake at 24 and 48 h compared to the radioiodinated form, overall the curves were not statistically different. Where a difference was noted between the radionuclide forms was in the normal tissue uptake. The hepatic uptake of the ^{111}In form was comparable to the level of tumor activity. This hepatic accumulation may

^a Two versions of the T84.66 minibody were labeled with ¹³¹I and ¹²⁵I, and tumor targeting and biodistribution studies were carried out in xenograft-bearing mice. Groups of 16 mice were analyzed at each time point except at 72 h where the group size was 11 mice. Tumor and normal organ uptake are expressed as percent injected dose per gram (% ID/g). Standard errors of the mean (SE) are given in parentheses. The ratios presented are the averages of the tumor/blood and tumor/liver ratios for the individual mice. Tumor masses are in grams.

be a result of circulating CEA which can complex with anti-CEA antibodies resulting in uptake by the hepatic immunoglobulin receptor system (20). Hepatic uptake with the intact [¹¹¹In]T84.66 antibody in mice had been observed to reach 9.8% ID g⁻¹ at 96 h as the result of trafficking of CEA-antibody immune complexes into the hepatocytes (19). However, with only a slight reduction of hepatic accumulation noted in normal mice as compared to tumor-bearing mice, the possibility that a circulating CEA–minibody complex was the cause of the hepatic activity was excluded. Thus, the accumulation of the majority of the hepatic activity must be presumed to be due to a protein-radiometal-chelate effect of the [¹¹¹In]T84.66 minibody and/or ¹¹¹In labeled metabolites. It should be noted that similar tumor and hepatic uptake was observed for [⁶⁴Cu]DOTA-T84.66 minibody by microPET imaging (25). However, hepatic accumulation was not observed with the radioiodinated minibody, but because of dehalogenation of the radiolabel, we do not know if the protein or metabolite was present.

Several approaches have been reported to lower the uptake of the radiolabeled antibody fragments in normal organs (4, 6, 24). To lower the renal uptake these efforts have focused on the following areas: (1) charge modification of the protein by lowering the pI, (2) blocking of the renal reabsorption by administration of cationic amino acids, and (3) use of metabolizable linkers. Since the pI of the T84.66 diabody was predicted by cDNA analysis to be acidic (pI 4.9) and verified by isoelectric focusing gels (data not shown), we attempted to lower the renal uptake by blocking the renal proximal tubular cell reabsorption process. Behr et al. (17) had reported the administration of the nonmetabolizable amino acid, D-lysine, before injection of a [⁹⁰Y]Fab in xenografted mice resulted in a 5-fold reduction in renal uptake with no effect on tumor uptake. For the [¹¹¹In]T84.66 diabody, this resulted in a 2.4-fold reduction of the kidney uptake, however this was accompanied by a 1.4-fold reduction of

the tumor uptake. This is the first report of a reduction of tumor activity with D-lysine using an immunoconjugate, although it had been noted for L-lysine in ¹¹¹In- and ¹⁶¹Tb-labeled octreotide in neuroendocrine tumors (18). This conflicting result could be due to a number of factors, the main difference being the antibody and tumor system. While this lowered tumor activity (9.2 ± 1.2% ID g⁻¹ at 6 h) still provided sufficient deposition of radionuclide for tumor imaging, a further reduction of the renal accumulation levels must be achieved. Alternative administration schedules of cationic amino acids in mice have been reported using multiple administrations (26).

This high lysine dosage when translated to human studies would appear limited due to the induction of proteinuria by blocking renal tubular reabsorption (27). One clinical study was carried out in which five patients were infused with 2 L of a commercially available nutritive solution, which contained 2.25 g/L lysine-glutamate, 2.5 g/L arginine, salts and xylitol, before injection of a [^{99m}Tc]anti-CEA Fab' (28). In this small group of patients, this much lower dose had a 38% reduction of renal activity compared to the control group who was infused with saline. Another commercially available solution is Aminosyn, which showed a 78.5% lower renal activity of a [¹⁸F] fluoromethylbenzoyl disulfide stabilized Fv in baboons (29).

In the case of the T84.66 minibody, while the renal levels appear acceptable, the elevated hepatic activity limits the use of the T84.66 minibody for RIS of CEA positive hepatic disease and subsequent radioimmunotherapy (RIT). However, this hepatic uptake should not preclude the scintigraphy of CEA-positive lesions in the colon, rectum, breast, bone, lung and other organs. Systematic mutagenesis could produce modified minibodies with further optimized pharmacokinetics.

Alternatively, the largest advances for the use of radiometal labeled antibody fragments may come from the development of metabolizable chelate chemistry.

Intervention at two points in the metabolic process have been targeted for cleavage of the radiometal/chelate complex to be excreted from the body. The first approach would rely on the cleavage of a peptide linker before cellular uptake by the catabolic enzymes that are found at the lumen of the brush border region of the renal proximal tubule cells (30) and speculatively at the surface of hepatic cells. The second approach focuses on the design of chelates that will be cleaved by lysosomal proteases to liberate radiometabolites which would be exported from the cell and rapidly excreted in the urine (24). New chelate peptide linkers and administration schemes are currently under development in our laboratory and elsewhere. Such metabolizable chelates alone, or in combination with a clinically acceptable dose of a blocking solution, may reduce the normal organ uptake of the radiometal labeled antibody fragments to acceptable levels for highly sensitive RIS and RIT in all tissues.

Phenylboronic Acid–Salicylhydroxamic Acid Bioconjugates.

1. A Novel Boronic Acid Complex for Protein Immobilization

Revised Manuscript Received January 11, 2001

A chemical affinity system exhibiting antibody-like properties is described. The system exploits bioconjugates with appended phenylboronic acid (PBA) moieties and a support-bound phenylboronic acid complexing reagent derived from salicylhydroxamic acid (SHA) for protein immobilization on a chromatographic support. The structure of the PBA·SHA complex was characterized by ¹¹B NMR and mass spectrometry and compared with complexes derived from model compounds. Protein modification reagents were synthesized from 3-aminophenylboronic acid and utilized to prepare bioconjugates from alkaline phosphatase (AP) and horseradish peroxidase (HRP). AP obtained from one source afforded PBA bioconjugates exhibiting significant loss of enzymatic activity, whereas AP obtained from a second source afforded PBA bioconjugates exhibiting only a modest loss of enzymatic activity. Conversely, HRP afforded PBA bioconjugates exhibiting no loss of enzymatic activity. SHA-modified Sepharose was prepared by reaction of methyl 4-[(6-aminohexanoylamino)methyl]salicylate with CNBr-activated Sepharose 4B, followed by treatment with aqueous alkaline hydroxylamine. PBA–AP and PBA–HRP conjugates were efficiently immobilized on SHA–Sepharose at pH 8.3. PBA–AP conjugates were retained after washing with acidic buffers at pH 6.7, 4.2, and 2.5, whereas PBA–HRP conjugates were retained after washing with buffer at pH 6.7, but were eluted to some extent at and below pH 4.2. The results are interpreted in terms of multivalent interactions involving boronic acid complex formation between the enzyme bioconjugates and immobilized complexing reagent.

INTRODUCTION

Immobilized phenylboronic acids have been utilized to prepare chromatographic supports that selectively retain polar molecules having certain requisite functionalities from diverse biological samples. Many important biological molecules including carbohydrates, catecholamines, prostaglandins, ribonucleosides, and steroids have been either analyzed or purified in this manner. The preparation and use of phenylboronic acid chromatographic supports has been the subject of several reviews (1–5). Carbohydrates having cis or coaxial 1,2-diol and 1,3-diol moieties as well as catecholamines complex with immobilized phenylboronate anions under alkaline conditions to form cyclic phenylboronic acid esters. Acidification of diol-boronate complexes to neutral pH is known to release the diol containing species, presumably due to hydrolysis of the cyclic esters.

Some years ago, in an effort to characterize the performance of a new silica phenylboronic acid (PBA) chromatographic support, an investigation was undertaken to identify compounds that would exhibit reproducible retention times when injected into PBA columns under standardized conditions. Since the columns were optimized for the analysis of catecholamines by high-

performance liquid affinity chromatography, structurally related compounds were sought as chromatographic probes of column performance. With this in mind, the retention characteristics of a series of ortho-substituted phenols with substituents thought to potentially complex with PBA were systematically determined. Phenylboronic acid and diphenylboronic acid complexes involving ortho-substituted phenols reported in the literature have included those derived from catechol and L-dopa (6–9), 4,5-dihydroxynaphthalene-2,7-disulfonic acid and 2,3-dihydroxynaphthalene-6-sulfonic acid (10–12), salicylamide, *N*-phenylsalicylamide and disalicylamide (13), salicylaldehyde (14, 15), salicylaldehyde (16, 17), and salicylic acid (10, 18).

One of the compounds investigated, salicylhydroxamic acid (SHA), exhibited retention times under mildly acidic, neutral, and alkaline conditions that were of a greater magnitude than routinely observed for structurally related ortho-substituted phenols. This was a remarkable observation, in that most PBA complexes exhibit aqueous stability only under alkaline or mildly acidic conditions. Because the PBA·SHA complex was stable under a broad range of conditions, it was proposed that the complex itself might prove useful as a chemical affinity system (12) for protein immobilization. A system was envisioned wherein PBA would function in a manner analogous to that of a hapten and SHA in a manner analogous to that of an *anti*-hapten antibody. This system would potentially exhibit many of the positive attributes associated with biological recognition systems, while circumventing many of the limitations associated with the use of macromolecules. This article, and the following paper in this issue,

describes our initial efforts toward the development of the envisioned chemical affinity system.

In a few instances, phenylboronic acids have been previously proposed as linkers for bioconjugation. 2-Acetamidophenylboronic acids have been proposed for selective conjugation via the vicinal diol moieties of the carbohydrate residues associated with glycoproteins (19). 3-Aminophenylboronic acids have been covalently appended to proteins by a variety of chemical methods and the resulting conjugates evaluated with respect to their ability to complex with mannose, sorbitol, and glycated hemoglobin (20). Unfortunately, the interactions proved to be reversible and of very low affinity, rendering the bioconjugates of limited practical use. Similarly, a PBA-alkaline phosphatase conjugate utilized in an enzyme-linked assay for glycated hemoglobin failed to detect the presence of glycoprotein. Radioactive technetium dioxime complexes have been conjugated to monoclonal antibodies with either 3-isothiocyanatophenylboronic acid (21) or 3-carboxy-5-isothiocyanatophenylboronic acid (22) and have proven useful for medical imaging.

MATERIALS AND METHODS

General. Reagents used in the syntheses were purchased from Aldrich (Milwaukee, WI) and Fluka (Ronkonkoma, NY), and utilized without further purification. CNBr-activated Sepharose 4B and Sephadex G25 were purchased from Amersham Pharmacia Biotech (Piscataway, NJ). Alkaline phosphatase (EC 3.1.3.1) was purchased from Sigma (St. Louis, MO) and Calzyme Laboratories (San Luis Obispo, CA). Horseradish Peroxidase (EC 1.11.1.7) was purchased from Calzyme Laboratories. An IgG fraction of rabbit *anti*-alkaline phosphatase and ChromPure Proteins from normal Human serum were purchased from Rockland (Gilbertsville, PA).

^1H , ^{11}B , and ^{13}C NMR spectra were recorded at 300, 121, and 75 MHz, respectively, on a Varian Gemini 2000 spectrometer with a broadband probe. Internal referencing was employed and chemical shifts are reported as δ values. Coupling constants are reported in hertz. High-resolution mass spectra of synthetic intermediates and reagents were recorded on a PE Biosystems Mariner ESI-TOF mass spectrometer in the positive ion mode. Mass spectra of phenylboronic acid complexes were recorded on a Hewlett-Packard Series 1100 LC/MSD by direct injection negative ion electrospray mass spectrometry with a fragmentation power setting of 60.

The purity of synthetic products was determined by analytical HPLC on a Hewlett-Packard 1050Ti system equipped with a diode array detector. A 2.1×220 mm C4 column (Aquapore Butyl, PE Biosystems) equilibrated with 0.1 M triethylammonium acetate, pH 6.5, was eluted at a flow rate of 0.5 mL/min after an initial period of 5 min with a linear gradient of from 0 to 100% methanol over 30 min. Product purity exceeded 95% in every instance. Protein bioconjugates were characterized with respect to incorporation ratio on a Hewlett-Packard 8453 diode array UV-vis spectrophotometer.

N-Hydroxy(2-hydroxyphenyl)-N-methylcarboxamide (4). To a stirred solution of 860 mg (10.3 mmol) of *N*-methylhydroxylamine hydrochloride in 15 mL of water cooled in an ice-water bath were added 8.00 mL of 6.25 N NaOH and 1.27 g (10.1 mmol) of Na_2SO_3 . After stirring for 5 min, 2.00 g (10.1 mmol) of 2-(chlorocarbonyl)phenyl acetate was added and the reaction was stirred for 24 h at room temperature. The solution was cooled and stirred in an ice-water bath, and concentrated

HCl added dropwise until a precipitate formed. The precipitate from the solution was filtered, and the filtrate extracted with ethyl acetate (3×15 mL). Extracts were combined, washed with brine, and dried over MgSO_4 and evaporated solvent. Crystallization from 1:1 ethyl acetate:hexane gave 420 mg (25%) of **4** as a white solid. ^1H NMR ($\text{DMSO}-d_6$): δ 3.16 (s, 3H), 6.82 (m, 2H), 7.21 (m, 1H), 7.30 (d, $J = 7.0$ Hz, 1H), 10.0 (br s, 2H). ^{13}C NMR ($\text{DMSO}-d_6$): δ 37.3, 116.2, 118.7, 122.1, 128.9, 131.0, 155.3, 167.0. HRMS (ES^+) calcd for $\text{C}_8\text{H}_{10}\text{NO}_3$: 168.0661. Obsd: 168.0661.

(2-Hydroxyphenyl)-N-methoxycarboxamide (5).

To a stirred solution of 842 mg (10.1 mmol) of methoxylamine hydrochloride in 15 mL of deionized water cooled in an ice-water bath were added 8.10 mL of 6.25 N NaOH and 1.27 g (10.1 mmol) of Na_2SO_3 . After stirring for 5 min, 2.00 g (10.1 mmol) of 2-(chlorocarbonyl)phenyl acetate was added and the reaction was stirred for 24 h at room temp. The solution was cooled and stirred in an ice-water bath, and concentrated HCl added dropwise until a precipitate formed. The precipitate from the solution was filtered, and the filtrate extracted with ethyl acetate (3×15 mL). Extracts were combined, washed with brine, and dried over MgSO_4 and evaporated solvent. The product was purified by silica gel chromatography with 1:1 ethyl acetate:hexane. The product fraction was collected, and the solvent was evaporated to give 590 mg (34%) of **5** as a white solid. ^1H NMR ($\text{DMSO}-d_6$): δ 3.71 (s, 3H), 6.88 (m, 2H), 7.38 (m, 1H), 7.62 (dd, $J = 1.6$ Hz, $J = 7.9$ Hz, 1H), 11.73 (s, 1H), 11.78 (s, 1H). ^{13}C NMR ($\text{DMSO}-d_6$): δ 63.6, 114.6, 117.4, 119.0, 127.8, 133.8, 159.1, 166.3. HRMS (ES^+) calcd for $\text{C}_8\text{H}_{10}\text{NO}_3$: 168.0661. Obsd: 168.0659.

3-[N-(3-Dihydroxyborylphenyl)carbamoyl]propanoic Acid (8). To a stirred suspension of 100 g (535 mmol) of 3-aminophenylboronic acid hemisulfate in 240 mL of pyridine cooled in an ice-water bath was added 56.5 g (565 mmol) of succinic anhydride. After 15 min, the reaction was removed from the ice-water bath and continued to be stirred for 12 h at room temperature. The solvent was evaporated to afford an amber syrup that was dissolved in 100 mL of water and concentrated by rotary evaporation to again afford an amber syrup. Syrup was dissolved in 700 mL of water, cooled by stirring in an ice-water bath, and pH adjusted to ~ 1 by adding 1 mL aliquots of concentrated HCl. The suspension was stirred in an ice-water bath for 1 h, and white precipitate was collected by filtration and washed with 50 mL of ice-cold water. Precipitate was dissolved in 700 mL of water by stirring while heating on a hot plate to a gentle boil. Solution was cooled to room temperature, and a white precipitate was allowed to form. The resulting suspension was stirred for 1 h at room temperature, placed in an ice-water bath, and stirred for an additional 1 h. The product was collected by filtration, washed with 50 mL of ice-cold water, and dried on the filter. The product was dried overnight in vacuo over NaOH pellets to give 100 g (80%) of **8** as a white solid, mp: 171–172 °C (uncorrected). ^1H NMR ($\text{DMSO}-d_6$): δ 12.07 (b s, 1H), 9.83 (s, 1H), 7.95 (s, 2H), 7.67 (s, 1H), 7.65 (d, $J = 7.9$ Hz, 1H), 7.41 (d, $J = 7.0$ Hz, 1H), 7.20 (t, $J = 7.8$ Hz, 1H), 2.60–2.40 (m, 4H). ^{13}C NMR ($\text{DMSO}-d_6$): δ 174.2, 170.2, 138.7, 129.0, 127.8, 125.2, 121.2, 31.0, 28.9. HRMS (ES^+) calcd for $\text{C}_{10}\text{H}_{12}\text{BNO}_5\text{Na}$: 260.0706. Obsd: 260.0707.

2,5-Dioxopyrrolidinyl 3-[N-(3-(1,3,2-Dioxaboran-2-yl)phenyl)carbamoyl]propanoate (9). To a stirred suspension of 28.4 g (120 mmol) of **8** in 120 mL of 1,4-dioxane in a 1 L round-bottom flask was added 8.7 mL (120 mmol) of 1,3-propanediol. The flask was fitted with

a West condenser, placed in boiling-water bath, and stirred for 10 min until all solids dissolved. The solution was concentrated by rotary evaporation to give either a light yellow syrup or an off-white solid. The product was dissolved in 50 mL of 1,4-dioxane, concentrated by rotary evaporation, and the product was again dissolved in 50 mL of 1,4-dioxane and again concentrated by rotary evaporation. The product was dissolved in 450 mL of stirred 1,4-dioxane, and 14.9 g (129 mmol) of *N*-hydroxysuccinimide added followed by 26.3 g (127 mmol) of DCC. The reaction was stirred under nitrogen for 4 h, white precipitate from solution was filtered and washed with 50 mL of 1,4-dioxane. The filtrate was combined, washed, and concentrated by rotary evaporation to ~100 mL. To the vigorously stirred concentrate was slowly added 400 mL of diethyl ether to produce a white precipitate. The suspension was stirred in an ice–water bath for 30 min, and the product was collected by filtration. The product on the filter was washed with 30 mL of diethyl ether, and the filter cake was dried by maintaining a vacuum for at least 5 min. The product was dried overnight in vacuo over NaOH pellets to give 42.5 g (95%) of **9** as a white solid. ^1H NMR (DMSO- d_6): δ 9.99 (s, 1H), 7.87 (s, 1H), 7.65 (d, J = 8.0 Hz, 1H), 7.32 (d, J = 7.3 Hz, 1H), 7.22 (t, J = 7.6 Hz, 1H), 4.09 (t, J = 5.4 Hz, 4H), 2.95 (t, J = 6.7 Hz, 2H), 2.79 (s, 4H), 2.69 (t, J = 6.7 Hz, 2H), 1.98 (q, J = 5.4 Hz, 2H). ^{13}C NMR (DMSO- d_6): δ 174.4, 169.0, 168.9, 138.7, 128.4, 128.1, 124.3, 121.4, 61.6, 30.3, 26.9, 25.7, 25.4. HRMS (ES^+) calcd for $\text{C}_{14}\text{H}_{15}\text{BN}_2\text{O}_7\text{Na}$ (**9** minus 1,3-propanediol): 357.0870. Obsd: 357.0876.

***N*'-Amino-*N*-(3-dihydroxyborylphenyl)butane-1,4-diamide (**10**, PBA-X-hydrazide).** To a stirred suspension of 9.0 g (24 mmol) of **9** in 125 mL of 1,4-dioxane in an ice–water bath was added 6 mL (124 mmol) of hydrazine monohydrate, and the reaction was stirred at room temperature for 1 h, during which time all solids dissolved. Solution was concentrated by rotary evaporation to afford a white solid that was taken up in 100 mL of water and filtered through a coarse porosity glass sinter. The insoluble residue on the filter was washed with 10 mL of water. The filtrate was combined, washed, and stirred in an ice–water bath for 10 min, and then the pH was adjusted to ~3 by adding 1 mL aliquots of concentrated HCl. A white precipitate formed upon addition of each aliquot of acid. The resulting suspension was stirred in an ice–water bath for 1 h, and the precipitate was collected by filtration and washed on the filter with 15 mL of ice-cold water. The product was dried overnight in vacuo over NaOH pellets to give 4.9 g (80%) of **10** as a white solid. ^1H NMR (DMSO- d_6): δ 9.86 (s, 1H), 9.02 (s, 1H), 7.98 (s, 2H), 7.81 (s, 1H), 7.68 (d, J = 8.2 Hz, 1H), 7.44 (d, J = 7.0 Hz, 1H), 7.23 (dd, J = 8.2 and 7.3 Hz, 1H), 4.27 (br s, 2H), 2.54 (t, J = 7.3 Hz, 2H), 2.33 (t, J = 7.3 Hz, 2H). ^{13}C NMR (DMSO- d_6): δ 171.1, 170.4, 138.6, 128.9, 127.8, 125.2, 121.2, 31.6, 28.6. HRMS (ES^+) calcd for $\text{C}_{10}\text{H}_{14}\text{BN}_3\text{O}_4\text{Na}$: 274.0975. Obsd: 274.0978.

6-{3-[*N*-(3-Dihydroxyborylphenyl)carbamoyl]propanoylamino}hexanoic acid (11**).** To a stirred suspension of 5.75 g (44 mmol) of 6-aminocaproic acid and 15 mL of diisopropylethylamine in 300 mL of 1,4-dioxane in an ice–water bath was added 15.0 g (40 mmol) of **9**. After stirring for 5 min, 300 mL of methanol was added, and the reaction was removed from the ice–water bath and stirred for 1 h at room temp. solvents were removed by rotary evaporation to afford a pale yellow syrup. The product was dissolved in 40 mL of water, and water was removed by rotary evaporation. Again, the product was dissolved in 40 mL of water, and again, water was

removed by rotary evaporation. The product was dissolved in 120 mL of water, stirred in an ice–water bath and adjusted pH to ~1 by dropwise addition of concentrated HCl. A white precipitate formed upon addition of each aliquot of acid. The resulting suspension was stirred in an ice–water bath for 1 h, and the precipitate was collected by filtration and washed on the filter with 15 mL of ice-cold water. The product was dried overnight in vacuo over NaOH pellets to give 10.0 g (70%) of **11** as a white powder, mp: 174–177 °C (uncorrected). ^1H NMR (DMSO- d_6): δ 11.98 (s, 1H), 9.84 (s, 1H), 7.97 (s, 2H), 7.83 (t, J = 5.4 Hz, 1H), 7.81 (s, 1H), 7.68 (d, J = 8.2 Hz, 1H), 7.44 (d, J = 7.3 Hz, 1H), 7.22 (t, J = 7.8 Hz, 1H), 3.00 (q, J = 6.3 Hz, 2H), 2.52 (t, J = 7.1 Hz, 2H), 2.36 (t, J = 7.1 Hz, 2H), 2.17 (t, J = 7.3 Hz, 2H), 1.50–1.41 (m, 2H), 1.39–1.32 (m, 2H), 1.28–1.23 (m, 2H). ^{13}C NMR (DMSO- d_6): δ 174.7, 171.3, 170.6, 138.7, 128.9, 127.8, 125.2, 121.2, 8.4, 33.6, 31.7, 30.4, 28.9, 26.0, 24.2. HRMS (ES^+) calcd for $\text{C}_{16}\text{H}_{23}\text{BN}_2\text{O}_6\text{Na}$: 373.1547. Obsd: 373.1542.

2,5-Dioxopyrrolidinyl 6-{3-[*N*-(3,3,2-Dioxaboran-2-yl)phenyl]carbamoyl}propanoyl-amino}hexanoate (12**, PBA-XX-NHS).** To a suspension of 6.3 g (18 mmol) of **11** in 60 mL of 1,4-dioxane was added 1.37 g (18 mmol) of 1,3-propanediol. The suspension was stirred in a boiling-water bath until a solution was obtained. The solvent was evaporated to afford either a colorless syrup or an off-white solid. The product was dissolved in 30 mL of 1,4-dioxane, and the solvent was removed by rotary evaporation. Again, product was dissolved in 30 mL of 1,4-dioxane, and solvent was removed by rotary evaporation. The product was dissolved in 225 mL of 1,4-dioxane, and 2.3 g (20 mmol) of *N*-hydroxysuccinimide (2.3 g, 20 mmol) was added followed by 4.1 g (20 mmol) of DCC. The reaction was stirred gently for 6 h, during which time a white precipitate formed. The precipitate was removed by filtration and washed with 50 mL of 1,4-dioxane. The precipitate was discarded, and the filtrate was combined and washed, and the solvent was removed by rotary evaporation until a colorless syrup was obtained (do not evaporate to dryness). Triturated product under 200 mL of diethyl ether to produce a white precipitate. Collected precipitate by vacuum filtration and washed with 30 mL of diethyl ether. The product was dried overnight in vacuo over NaOH pellets to give 8.0 g (91%) of **12** as a white powder, mp: 111–117 °C (uncorrected). ^1H NMR (DMSO- d_6): δ 9.85 (s, 1H), 7.85 (s, 1H), 7.82 (t, J = 5.7 Hz, 1H), 7.64 (d, J = 7.9 Hz, 1H), 7.29 (d, J = 7.3 Hz, 1H), 7.22 (dd, J = 7.6 Hz and J = 7.6 Hz, 1H), 4.07 (t, J = 5.4 Hz, 4H), 3.05–2.95 (m, 2H), 2.79 (s, 4H), 2.62 (t, J = 7.3 Hz, 2H), 2.50 (t, J = 6.7 Hz, 2H), 2.36 (t, J = 6.7 Hz, 2H), 1.50–1.41 (m, 2H), 1.41–1.30 (m, 4H). ^{13}C NMR (DMSO- d_6): δ 171.3, 170.6, 170.5, 169.2, 138.9, 128.1, 128.0, 124.3, 121.4, 61.5, 38.2, 31.7, 30.4, 30.1, 28.6, 26.8, 25.4, 23.9, 15.1. HRMS (ES^+) calcd for $\text{C}_{20}\text{H}_{27}\text{BN}_3\text{O}_8\text{Na}$ (**13** minus 1,3-propanediol): 448.1891. Obsd: 448.1887.

Methyl 4-Methylsalicylate (13**).** To 100 g (658 mmol) of 4-methylsalicylic acid dissolved in 500 mL of anhydrous methanol was added 25 mL of concentrated H_2SO_4 . The solution was heated under reflux for 18 h and concentrated to 150 mL, and the product was extracted into 250 mL of ethyl acetate. Ethyl acetate was washed with saturated aqueous NaHCO_3 (2 $\times$ 250 mL) and brine (100 mL). Ethyl acetate solution was dried over Na_2SO_4 and concentrated by rotary evaporation to afford a clear, reddish-brown liquid. The crude ester was vacuum distilled (oil pump) to give 98.1 g (90%) of **13** as a clear viscous liquid. ^1H NMR (CDCl_3): δ 2.32 (s, 3H), 3.91 (s, 3H), 6.67 (d, J = 8 Hz, 1H), 6.78 (s, 1H), 7.69 (d, J = 8

Hz, 1H), 10.71 (s, 1H). ^{13}C NMR (CDCl_3): δ 21.8, 52.1, 110.0, 117.9, 120.6, 129.9, 147.3, 161.9, 170.9. HRMS (ES^+) calcd for $\text{C}_9\text{H}_{10}\text{O}_3\text{Na}$: 189.0528. Obsd: 189.0528.

Methyl 4-(Bromomethyl)salicylate (14). To 98.1 g (590 mmol) of **13** dissolved in 600 mL of carbon tetrachloride was added 105.0 g (590 mmol) of *N*-bromosuccinimide followed by 0.7 g (3 mmol) of benzoyl peroxide. The solution was heated for 2 h under reflux, and an additional 0.7 g (3 mmol) of benzoyl peroxide was added and heated an additional 6 h under reflux. The reaction mixture was cooled to room temperature, during which time some solid formed. The solid was removed by filtration, and the filtrate evaporated to afford a viscous yellow syrup that solidified on standing. A total of 500 mL of hexanes was added to solid and heated at near boiling until almost all solids dissolved. The hot solution was filtered and concentrated until the solid just began to precipitate. The solution was heated again until the solids dissolved, and the resulting solution was allowed to cool slowly to room temperature, during which time pale yellow crystals formed. The mixture was cooled in an ice-water bath for 2 h to complete crystallization. The product was filtered, washed with 100 mL of cold hexanes, and dried in vacuo to give 83.5 g (58%) of **14** as off-white needles, mp: 73–75 °C (uncorrected). ^1H NMR (CDCl_3): δ 3.95 (s, 3H), 4.40 (s, 2H), 6.90 (d, J = 8 Hz, 1H), 7.00 (s, 1H), 7.80 (d, J = 8 Hz, 1H), 10.78 (s, 1H). ^{13}C NMR (CDCl_3): δ 32.1, 52.5, 112.4, 118.2, 120.1, 130.7, 145.8, 162.0, 170.5. HRMS (ES^+) calcd for $\text{C}_9\text{H}_9\text{O}_3\text{NaBr}$ 266.9633. Obsd: 266.9635.

Methyl 4-(Azidomethyl)salicylate (15). To a stirred solution of 83.5 g (341 mmol) of **14** dissolved in 150 mL of dry DMF was added 25.0 g (380 mmol) of sodium azide. The resulting solution turned brown, and a precipitate of NaBr formed. The suspension was stirred for 16 h, and the precipitate was filtered from solution and concentrated by rotary evaporation to afford a brown oil. The oil was dissolved in 100 mL of a mixture of 1:1 ethyl acetate:hexanes and adsorbed onto 25 g of silica gel (flash chromatography grade). Silica gel was washed on a glass sinter funnel with 1:1 ethyl acetate–hexanes (3×50 mL). The washes were combined, and the solvents evaporated to afford a colorless oil (**15**). Crude **15** was utilized for subsequent reaction without further purification. ^1H NMR (CDCl_3): δ 3.94 (s, 3H), 4.32 (s, 2H), 6.82 (d, J = 8 Hz, 1H), 6.93 (s, 1H), 7.83 (d, J = 8 Hz, 1H), 10.80 (s, 1H). ^{13}C NMR (CDCl_3): δ 52.5, 54.3, 112.3, 117.0, 118.7, 130.8, 143.9, 162.1, 170.5.

Methyl 4-(Aminomethyl)salicylate Hydrochloride (16). Crude **15** was dissolved in 750 mL of methanol and transferred to a Parr hydrogenation flask, and 3.8 g of palladium on carbon catalyst (10% w/w) was added in 25 mL of water followed by 35 mL of concentrated HCl. The mixture was shaken on a Parr apparatus for 16 h at room temperature under 40 psi of hydrogen gas. The reaction mixture was filtered through a 0.45 mm nylon filter, and the retained solid washed with 150 mL of methanol, 100 mL of water, and 150 mL of methanol. The filtrates were combined and concentrated by rotary evaporation to afford a tan solid. The solid was dissolved in 150 mL of hot denatured ethanol, and the solution was allowed to cool to room temperature, during which time white crystals quickly formed. The suspension was cooled for 18 h at 4 °C to complete crystallization. The solid was filtered, washed with 50 mL of cold ethanol, and 150 mL of diethyl ether. The product was dried in vacuo over KOH pellets to give 51.5 g (65% yield for two steps) of **16** as an off-white powder, mp: 225–227 °C (uncorrected). ^1H NMR ($\text{DMSO}-d_6$): δ 3.87 (s, 3H), 4.00 (s, 2H),

7.06 (d, J = 8 Hz, 1H), 7.13 (s, 1H), 7.77 (d, J = 8 Hz, 1H), 8.59 (br s, 3H), 10.55 (s, 1H). ^{13}C NMR ($\text{DMSO}-d_6$): δ 41.6, 52.6, 113.0, 117.7, 119.8, 130.4, 142.1, 160.0, 169.1. HRMS (ES^+) calcd for $\text{C}_9\text{H}_{12}\text{NO}_3$: 182.0817. Obsd: 182.0820.

Methyl 4-([6-[(*tert*-Butoxy)carbonylamino]hexanoylamino)methyl)salicylate (17). A total of 2.25 g (10.3 mmol) of **16** was suspended in 30 mL of anhydrous DMF, and 3.6 mL of diisopropylethylamine (20.7 mmol) was added followed by 3.38 g (10.3 mmol) of 2,5-dioxopyrrolidinyl 6-[(*tert*-butoxy)carbonylamino]hexanoate. The mixture was stirred gently under dry nitrogen for 18 h, during which time all solids dissolved. The solvent was removed by rotary evaporation to afford a light brown syrup that was partitioned between 100 mL of ethyl acetate and 100 mL of 1 N HCl. The layers were separated, and ethyl acetate was washed with 100 mL of saturated aqueous NaHCO_3 and 100 mL of brine. Ethyl acetate was dried over Na_2SO_4 , filtered, and concentrated by rotary evaporation to afford an amorphous off-white solid. The product was crystallized from 1:1 ethyl acetate:hexanes, filtered, and dried in vacuo to give 3.25 g (80%) of **17** as an off-white powder, mp: 120–121 °C (uncorrected). ^1H NMR ($\text{DMSO}-d_6$): δ 1.22 (m, 2H), 1.36 (m, 2H), 1.36 (s, 9H), 1.51 (m, 2H), 2.13 (t, J = 7 Hz, 2H), 2.87 (q, J = 6 Hz, 2H), 3.87 (s, 3H), 4.24 (d, J = 6 Hz, 2H), 6.75 (t, J = 6 Hz, 1H), 6.80 (d, J = 8 Hz, 1H), 6.82 (s, 1H), 7.72 (d, J = 8 Hz, 1H), 8.35 (t, J = 6 Hz, 1H), 10.53 (s, 1H). ^{13}C NMR (CDCl_3): δ 25.0, 26.0, 28.2, 29.3, 35.3, 41.7, 52.4, 77.4, 111.2, 115.5, 118.3, 130.1, 148.7, 155.8, 160.5, 169.5, 172.6. HRMS (ES^+) calcd for $\text{C}_{20}\text{H}_{31}\text{N}_2\text{O}_6$: 395.2182. Obsd: 395.2178.

Methyl 4-[(6-Aminohexanoylamino)methyl]salicylate Hydrochloride (18). A total of 3.00 g (7.6 mmol) of **17** was dissolved in 100 mL of ethyl acetate, and dry HCl gas was slowly bubbled through the solution. After 5 min, the gas stirred reaction was discontinued for 30 min at room temperature, during which time a white precipitate formed. The reaction mixture was cooled for 2 h in an ice-water bath. The precipitate was filtered, washed with 50 mL of diethyl ether, and dried in vacuo over KOH pellets to give 2.50 g (99%) of **18** as an off-white powder, mp: 158–160 °C (uncorrected, decomposes with effervescence). ^1H NMR ($\text{DMSO}-d_6$): δ 1.28 (m, 2H), 1.54 (m, 4H), 2.16 (t, J = 8 Hz, 2H), 2.71 (m, 2H), 3.85 (s, 3H), 4.22 (d, J = 6 Hz, 2H), 6.80 (d, J = 8 Hz, 1H), 6.83 (s, 1H), 7.70 (d, J = 8 Hz, 1H), 8.10 (br s, 3H), 8.54 (t, J = 6 Hz, 1H), 10.35 (br s, 1H). ^{13}C NMR (CDCl_3): δ 24.8, 25.6, 26.7, 35.1, 41.7, 111.5, 115.6, 118.4, 130.2, 148.6, 160.4, 169.4. HRMS (ES^+) calcd for $\text{C}_{15}\text{H}_{23}\text{N}_2\text{O}_4$: 295.1658. Obsd: 295.1656.

Preparation of SHA-Sepharose. A total of 15.0 g of CNBr-activated Sepharose 4B was suspended in 150 mL of ice-cold 1 mM HCl, collected in a medium porosity glass sinter funnel, and washed with 850 mL of ice-cold 1 mM HCl. The liquid was removed by vacuum filtration to afford a moist cake that was quickly transferred into a 100 mL wide-mouth screw cap plastic bottle containing a solution of 0.3 g of **18** dissolved in 50 mL 0.2 M NaHCO_3 . A total of 5 mL of 1 M NaHCO_3 was added, and the bottle was attached to a rotator, and the reaction was allowed to proceed overnight. Methyl salicylate-modified Sepharose intermediate (**19**) was collected in a medium porosity glass sinter funnel, washed with 1 L of deionized water, and dried on the funnel to a moist cake. A solution containing 0.5 M NH_2OH and 50 mM Na_2SO_3 was prepared by dissolving 3.4 g of hydroxylamine hydrochloride and 0.62 g of sodium sulfite in 80 mL of deionized water. 10 N NaOH was added dropwise to the

hydroxylamine solution until pH $\sim$ 8.5, after which added 10 mL of 1 M NaHCO₃, pH 10.0. The final volume of hydroxylamine solution was adjusted to 100 mL, and the pH was checked to ensure that it was in the range 9.8–10.0. Modified Sepharose was transferred into a 100 mL wide-mouth screw cap bottle, 50 mL of the hydroxylamine solution was added, the bottle was attached to a rotator, and the reaction was allowed to proceed for 2 h. SHA-Sepharose (**20**) was collected in a medium porosity glass sinter funnel, washed with 1 L of deionized water, and stored as a slurry in 20% (v/v) ethanol.

Capacity of SHA-Sepharose. The capacity of the SHA-Sepharose was estimated by first suspending 1 mL of gel in 2 mL of 50% (v/v) glycerol, removing a 0.5 mL aliquot of the suspension, and further diluting with 2.5 mL of 50% (v/v) glycerol. Finally, the SHA content of the gel was determined by comparing the absorbance at 320 nm ($\epsilon_{320} = 3200$) of SHA-Sepharose to that of unmodified Sepharose 4B.

Preparation of PBA–Alkaline Phosphatase (PBA–AP) Conjugates. Alkaline phosphatase (Type VII-T, 50,000 DEA units, Sigma, St. Louis, MO) was dialyzed against 1 L of 0.1 M NaHCO₃ buffer, pH 8.3, for 72 h at 4 °C (Slide-A-Lyzer; 3500 MWCO; Pierce). Determined concentration of dialyzed enzyme from the absorbance at 280 nm ($\epsilon_{280} = 107\,500$). A stock solution of PBA-XX-NHS (**12**) was prepared by dissolving 47.5 mg in 1 mL of DMF. The reactivity of the stock solution was checked by adding 1 μ L of stock solution to 700 μ L of TBS buffer [10 mM tris(hydroxymethyl)aminomethane, 140 mM NaCl, pH 8.0] and monitoring the increase in absorbance at 260 nm over time corresponding to the hydrolysis of the 2,5-dioxopyrrolidiny ester. A total of 2.5 mg (450 μ L of 5.6 mg/mL) of alkaline phosphatase was conjugated by adding an appropriate volume of PBA-XX-NHS stock solution to afford a 5-, 10-, and 50-fold molar excess of reagent. Reactions were incubated on ice for 1 h. Conjugates were dialyzed against 1 L of 0.1 M NaHCO₃ buffer, pH 8.3, for 48 h at 4 °C. Incorporation ratios were determined by comparing the ratio of the absorbance at 260 nm ($\epsilon_{260} = 4500$) for PBA to the absorbance at 280 nm ($\epsilon_{280} = 107\,500$) for AP. Enzymatic activity was determined of each of the PBA–AP conjugates employing *p*-nitrophenyl phosphate as substrate (pNPP, Sigma). A pNPP stock solution was prepared by dissolving a 15 mg pNPP tablet in 15 mL of DEA buffer (1 M diethanolamine, 1 mM MgCl₂, 0.1 mM ZnSO₄, pH 10.2). In a multiwell plate, 100 μ L of each of the conjugate solutions diluted to 1.0 μ g/mL with TBS buffer was added to each of six wells and assayed for AP activity by adding 100 μ L of pNPP stock solution to each well and incubating at 37 °C for 10 min. Enzymatic activity of the PBA–AP conjugates was determined relative to unmodified AP from the average absorbance at 405 nm obtained from each of six determinations. Multiwell plates were analyzed on a Bio-Tek Instruments ELx808 plate reader.

Preparation of PBA–Horseradish Peroxidase (PBA–HRP) Conjugates. A total of 25 mg of Horseradish Peroxidase (HRP) was weighed into each of three 15 mL conical tubes and dissolved in 2.5 mL of 0.1 M sodium acetate, 0.1 M sodium chloride buffer, pH 5.5. A total of 70 μ L of 350 mM sodium periodate was added to each of the tubes, and solutions were incubated in the dark for 30 min at 4 °C. A total of 130 μ L of 0.4 M Na₂SO₃ was added to each tube to quench the oxidation reaction. A stock solution of PBA-X-hydrazide was prepared by first dissolving 24.1 mg of **10** in 800 μ L of DMSO and then adding 800 μ L of 0.1 M sodium acetate, 0.1 M sodium chloride buffer, pH 5.5. Horseradish peroxidase was

conjugated by adding an appropriate volume of PBA-X-hydrazide stock solution to afford a 5-, 10-, and 50-fold molar excess of reagent and incubating the solution in the dark for 4 h at 4 °C. Enzyme conjugates were dialyzed against 2 L of 0.1 M NaHCO₃, pH 8.3, for 72 h at 4 °C (Slide-A-Lyzer; 3500 MWCO; Pierce). Incorporation ratios were determined by comparing the absorbance at 260 nm ($\epsilon_{260} = 4500$) to the absorbance at 404 nm ($\epsilon_{404} = 97\,700$). Enzymatic activity was determined of each of the PBA–HRP conjugates employing 2,2'-azine-di(3-ethylbenzthiazoline sulfonate) as HRP substrate (1-Step ABTS, Pierce). In a multiwell plate, 100 μ L of each of the conjugate solutions (0.05 μ g/mL) was added to each of six wells and assayed for HRP activity by adding 100 μ L of ABTS stock solution to each well and incubating at 37 °C for 10 min. The multiwell plate was read on a Bio-Tek Instruments ELx808 plate reader at 405 nm. Enzymatic activity of the PBA–HRP conjugates was determined relative to unmodified HRP from the average A_{405} value obtained from each of six determinations.

Chromatography of PBA–HRP and PBA–AP Conjugates on SHA-Sepharose. Equilibrated a 0.5 $\times$ 15 cm column containing 1 mL of SHA-Sepharose with 50 mL of 0.1 M NaHCO₃, pH 8.3. Protein concentrations of the PBA–HRP and PBA–AP conjugates prepared above were determined from the absorbance at 404 and 280 nm, respectively, and adjusted to 0.2 mg/mL by addition of 0.1 M NaHCO₃, pH 8.3. Conjugates (5 mL, 0.2 mg/mL) were applied to SHA-Sepharose column and eluted by addition of 5 mL of 0.1 M NaHCO₃, pH 8.3. A fraction of 10 mL was subsequently collected and stored at 4 °C. The column effluent was continuously monitored by measuring the absorbance at 280 nm with an EM-1 Econo UV Monitor equipped with a 280 nm filter (Bio-Rad). During collection of each 10 mL fraction, the absorbance at 280 nm first increased, indicating the elution of unretained conjugate, and then returned to baseline. Aliquots (10 mL) of each of three buffers of progressively lower pH were subsequently applied to the column, collected, immediately adjusted to pH 8.3 by addition of 1 N NaOH, and stored at 4 °C. The buffers included 0.1 M phosphate buffer, pH 6.7; 0.1 M phosphate buffer, pH 4.2; and 0.1 M glycine hydrochloride buffer, pH 2.5. This wash protocol was undertaken to explore the potential impact of an acidic elution gradient on retention of PBA conjugates. Unconjugated HRP and AP controls were applied to the SHA-Sepharose column to determine the extent of nonspecific binding. The relative quantity of protein in each of the fractions collected was determined by assaying the enzymatic activity of the controls and conjugates as described above, taking into account the reduced enzymatic activity associated with some of the conjugates.

RESULTS AND DISCUSSION

Structural Elucidation of PBA Complexes. Figure 1 illustrates the ¹¹B NMR spectra obtained for the complexes prepared from phenylboronic acid (PBA, **1**) and each of salicylhydroxamic acid (SHA, **2**), (2-hydroxyphenyl)-*N*-methoxycarboxamide (**5**), and *N*-hydroxy-(2-hydroxyphenyl)-*N*-methylcarboxamide (**4**) at pH 5.0, 7.0, 9.0, and 11.0 and ambient temperature. Samples were dissolved in 85:15 (v/v) deuterium oxide/methanol at a concentration of 5 mg/mL, and the pH adjusted as appropriate with concentrated hydrochloric acid or aqueous sodium hydroxide. The chemical shift(s) of the ¹¹B nucleus of **1** alone and of **1** complexed with **2**, **4**, and **5** as a function of pH are given in Table 1.

Figure 1. ^{11}B NMR spectra of phenylboronic acid complexes recorded at pH 5.0, 7.0, 9.0, and 11.0. Complexes were prepared from (left), phenylboronic acid and (2-hydroxyphenyl)-*N*-methoxycarboxamide (**1**·**5**); (center), phenylboronic acid and salicylhydroxamic acid (**1**·**2**); and (right), phenylboronic acid and *N*-hydroxy-(2-hydroxyphenyl)-*N*-methylcarboxamide (**1**·**4**).

Table 1. ^{11}B NMR Chemical Shifts^a of Phenylboronic Acid (**1**) and Complexes Prepared from PBA with Salicylhydroxamic Acid (**1**·**2**), *N*-Hydroxy-(2-hydroxyphenyl)-*N*-methylcarboxamide (**1**·**4**), and (2-Hydroxyphenyl)-*N*-methoxycarboxamide (**1**·**5**)

pH	1	1·2 complex	1·4 complex	1·5 complex
11.0	5.1	ND, ^b 4.9	9.0, 5.1	5.3
9.0	22.3	ND, ^b 5.3	9.1	5.5
7.0	30.7	ND, ^b 5.4	9.1	5.6
5.0	30.7	30.6, ND, ^b 5.1	31.2, 9.1	31.3, 5.4

^a Chemical shifts reported above, measured relative to NaBF_4 at 0.0 ppm, represent estimates due to difficulties encountered when phasing spectra containing broad signals. ^b The chemical shift of the signal recorded as a shoulder downfield of the signal associated with the predominant PBA·SHA complex cannot be precisely determined due to its low intensity, but is estimated to be in the range 9–10 ppm.

It is known that the chemical shift of the ^{11}B NMR signal from boronic acids is dependent on the hybridization state of the boron nucleus (trigonal or tetrahedral). As can be seen in the data for PBA, at pH 5.0 (approximately four pH units below the pK_a of 8.9), the chemical shift is 30.7 ± 0.1 ppm (characteristic of trigonal boronic acid); while at pH 11.0 (approximately two units above the pK_a), the chemical shift is 5.1 ± 0.1 ppm (characteristic of tetrahedral boronate anion). Only one signal is observed in the ^{11}B NMR spectrum of PBA at all three pH values, indicating that the exchange reaction involving the interconversion of boronic acid and boronate anion is rapid on the NMR time scale. These data are consistent with previous reports regarding the ^{11}B NMR spectrum of PBA (8, 23–25).

The center panel of Figure 1 shows the ^{11}B NMR spectrum of PBA in the presence of 1 equiv of SHA (**2**) as a function of pH. At pH 5.0, three signals are

observed: a large signal at about 31 ppm, a large signal at about 5 ppm, and a small signal at 9–10 ppm (observed as a shoulder on the 5 ppm signal). The signal at 31 ppm can be assigned to uncomplexed PBA by comparison with the spectrum of PBA alone at this pH. We assign the other two signals to different structural forms of the PBA·SHA complex, as these signals are absent in the spectrum of PBA alone at pH 5.0. Both of these signals appear at chemical shift values characteristic of tetrahedral phenylboronate. We thus conclude that the interaction of PBA and SHA results in the conversion of trigonal boronic acid to tetrahedral boronate anion in both of the observed structural forms. It appears that the two PBA·SHA complexes are in slow exchange with uncomplexed PBA as well as with each other, based on the observation of three distinct signals.

When the pH of the PBA and SHA mixture is raised to 7.0 (approximately two units below the pK_a of PBA), the amount of free PBA diminishes to near zero as the complex becomes dominant. At pH 9.0, no signal arising from free PBA is observed (it would appear at about 22 ppm; see Table 1), indicating that complex formation is complete at this pH. It is not possible to determine the extent of complex formation at pH 11.0 from the NMR data, since both the complex and any free phenylboronate anion would give rise to signals around 5 ppm. It is interesting to note that amount of the minor structural form of the complex decreases relative to the major structural form as the pH increases.

Figure 2 presents two possible structures of the PBA·SHA complex (**6** and **7**). Structures **6** and **7** are proposed based on the known propensity of phenylboronic acid to form five-membered and six-membered ring complexes with 1,2- and 1,3-diols, catechols, 2-aminoethanol, and

Figure 2. Proposed structures consistent with phenylboronic acid complexes prepared from salicylhydroxamic acid (**1**·**2**), benzenecarbohydroxamic acid (**1**·**3**), *N*-hydroxy-(2-hydroxyphenyl)-*N*-methoxycarboxamide (**1**·**4**), and (2-hydroxyphenyl)-*N*-methoxycarboxamide (**1**·**5**).

similar compounds. They are compatible with the ^{11}B NMR results discussed previously in that each structure contains a tetrahedral boronate anion.

Compounds **4** and **5** were chosen to facilitate the assigning of structures to the two forms of the PBA·SHA complex observed in the ^{11}B NMR spectra. As indicated in Figure 2, **4** can form a five-membered ring complex with PBA similar to PBA·SHA complex **7**, but cannot form a six-membered ring complex similar to **6** by virtue of the replacement of the hydrogen on the nitrogen of the hydroxamic acid with a methyl group. Conversely, **5** can form a six-membered ring complex with PBA but not a five-membered ring complex, again due to the substitution of a methyl group for hydrogen.

The ^{11}B NMR spectra of PBA in the presence of 1 equiv of **4** or **5** as a function of pH are shown in the first and third panels of Figure 1. In both cases, two peaks are observed at pH 5.0, assignable to free PBA and complexed PBA. Both systems mimic the PBA·SHA system, in that at pH 7.0 the respective complex dominates the spectrum

and complex formation is complete at pH 9.0. However, the signal assigned to the PBA·**5** complex (a six-membered ring) is observed at 5 ppm, while that assigned to the PBA·**4** complex (a five-membered ring) appears at 9 ppm.

It is again not possible to determine the extent of complex formation between PBA and **5** at pH 11.0 from the NMR data, since both the complex and any free phenylboronate anion would give rise to signals around 5 ppm. However, in the case of PBA and **4**, the appearance of two signals in the pH 11.0 spectrum, one at 9 ppm and one at 5 ppm, indicates that at least this complex is somewhat unstable at this pH, producing some free phenylboronate anion (hence the signal at 5 ppm).

Complexes prepared from PBA and **2**, **4**, **5**, or benzenecarbohydroxamic acid (**3**) proved to be sufficiently stable for analysis by electrospray mass spectrometry when ionized at low fragmentation power. The data from the mass spectral analysis of these complexes is given in Figure

Scheme 1. Synthesis of Phenylboronic Acid Reagents^a

^a (i) Succinic anhydride in pyridine; (ii) 1,3-propanediol; (iii) *N*-hydroxysuccinimide and DCC; (iv) hydrazine monohydrate in 1,4-dioxane; (v) 6-aminocaproic acid and diisopropylethylamine in 1,4-dioxane; (vi) 1,3-propanediol; and (vii) *N*-hydroxysuccinimide and DCC.

2. In all cases, only the mass values predicted by the structures in Figure 2 were observed in the mass spectra. Since structures **6** and **7** are isomeric, it is not possible to determine the relative amounts of each from the mass data.

On the basis of these observations, we can thus assign the structural form **6** of the PBA-SHA complex to the major peak at 5 ppm and the structural form **7** to the minor peak at 9–10 ppm observed in the ¹¹B NMR spectra of this complex. These assignments are further supported by previously reported observations that six-membered tetrahedral phenylboronate complexes exhibit greater stability than five-membered tetrahedral phenylboronate complexes (presumably due to reduced ring strain) and that ¹¹B NMR signals for six-membered tetrahedral phenylboronate complexes generally appear upfield of signals for five-membered membered tetrahedral phenylboronate complexes (**7**, **8**). Additionally, complexes analogous to **6**, prepared from PBA and salicylamide or *N*-phenylsalicylamide, have been reported (**13**), as have complexes analogous to **7**, prepared from PBA and *N*-substituted hydroxamic acids (**26**).

Reagent Syntheses. Phenylboronic acid reagents **10** and **12** were prepared by 3- and 4-step optimized syntheses, respectively, as outlined Scheme 1. The starting material, 3-aminophenylboronic acid, was first reacted with succinic anhydride in pyridine to afford the succinamic acid **8** in 80% yield. Protection of the boronic acid moiety of **8** with 1,3-propanediol and subsequent reaction with *N*-hydroxysuccinimide in the presence of 1,3-dicyclohexylcarbodiimide next produced the *N*-hydroxysuccinimidyl ester **9** in 95% yield. Reaction of **9** with hydrazine monohydrate in 1,4-dioxane produced the hydrazide reagent **10** (PBA-X-hydrazide) in 80% yield. Attempts to employ **9** as a protein conjugation reagent failed owing to rapid intramolecular cyclization to the corresponding succinimide upon introduction into alkaline aqueous buffer. To circumvent this limitation, reac-

tion of **9** with 6-aminocaproic acid in 1,4-dioxane in the presence of diisopropylethylamine produced **11** in 70% yield. Finally, protection of the boronic acid moiety of **11** with 1,3-propanediol and subsequent reaction with *N*-hydroxysuccinimide in the presence of 1,3-dicyclohexylcarbodiimide afforded the *N*-hydroxysuccinimidyl ester **12** (PBA-XX-NHS) in 90% yield. Compounds **4** and **5** were prepared in small quantities without optimization of yields for use as model compounds for ¹¹B NMR and mass spectrometric studies involving their phenylboronic acid complexes.

Reagent **18** was prepared by a 6-step synthesis as outlined in Scheme 2. The starting material, 4-methylsalicylic acid, was esterified by refluxing with methanol and sulfuric acid to afford **13** in 90% yield. Reaction of **13** with *N*-bromosuccinimide in carbon tetrachloride in the presence of benzoyl peroxide and UV light next produced **14** in 58% yield. A small amount (≤10%) of α,α-dibrominated material as well as minor amounts of ring bromination products are also produced, leading to the modest yield of desired product. Alkylation of **14** with sodium azide in DMF produced crude **15**, which was hydrogenated in acidified aqueous methanol with palladium on carbon to produce **16** as the hydrochloride salt (65% yield for two steps). Reaction of **16** with 2,5-dioxopyrrolidinyl 6-[(*tert*-butoxy)carbonylamino]hexanoic acid in DMF in the presence of diisopropylethylamine produced **17** in 80% yield. Finally, deprotection of **17** by hydrogen chloride gas in ethyl acetate afforded **18** in 99% yield as the hydrochloride salt.

SHA-Sepharose was prepared by a two-step synthesis as outlined in Figure 3. Methyl 4-[(6-aminohexanoylamino)methylsalicylate] hydrochloride (**18**) was neutralized with sodium bicarbonate and reacted with cyanogen bromide activated Sepharose 4B in the pH range 9.8–10.0 to produce an immobilized intermediate (**19**), which was subsequently reacted with excess aqueous hydroxylamine at pH 10 in the presence of an antioxidant (Na₂-

^a (i) Sulfuric acid and methanol; (ii) *N*-bromosuccinimide and benzoyl peroxide in carbon tetrachloride; (iii) sodium azide in DMF; (iv) hydrogen gas and palladium on carbon in acidified aqueous methanol; (v) 2,5-dioxopyrrolidinyl 6-[(*tert*-butoxy)carbonylamino]hexanoic acid in DMF; and (vi) hydrogen chloride gas in ethyl acetate.

Figure 3. Preparation of SHA-Sephacrose. CNBr-activated Sepharose 4B is reacted with **18** under alkaline aqueous conditions to afford synthetic intermediate **19**. Reaction of **19** with excess alkaline aqueous hydroxylamine affords SHA-Sephacrose (**20**). PBA-AP, prepared by conjugation of AP with PBA-XX-NHS, is immobilized on SHA-Sephacrose by formation of the PBA-SHA complex. The illustration represents an oversimplification in that immobilization results from a multivalent interaction involving several boronic acid complexes.

SO₃) to produce SHA-Sephacrose (**20**). Capacity was determined to be 1.21 μmol SHA/mL settled bed volume by comparing the absorbance at 320 nm to that of unmodified Sepharose 4B. The methodology employed for determining the capacity does not differentiate between the immobilized intermediate (**19**) and immobilized SHA (**20**). Consequently, some percentage of the reported capacity may not be available for complex formation with PBA.

Characterization of PBA-HRP and PBA-AP Conjugates. Phenylboronic acid enzyme bioconjugates were prepared from alkaline phosphatase and horseradish peroxidase and characterized with respect to retention of enzymatic activity. Enzymes were conjugated with PBA at molar input ratios of 5-, 10-, or 50-fold. Alkaline phosphatase was conjugated through the lysine amino acid side-chains by reaction with a PBA-XX-NHS at pH 8.3, whereas the glycoprotein horseradish peroxidase was

conjugated through carbohydrate residues by periodate oxidation and subsequent reaction with a PBA-X-hydrazide. Table 2 summarizes the incorporation ratios obtained corresponding to each molar input ratio as well as the enzymatic activities associated with each of the bioconjugates. Horseradish peroxidase proved particularly tolerant with respect to PBA conjugation in that the activity of the enzyme was unaffected even after appending an average of 9.6 PBA moieties. This tolerance presumably results from the site-specific nature of the conjugation reaction, wherein the modified carbohydrate residues are remote from the active site of the enzyme. Alkaline phosphatase (Sigma, catalog no. P6774 from bovine intestine) proved less tolerant with respect to PBA conjugation; however, in that appending an average of 6.2 PBA moieties to the enzyme was accompanied by the loss of nearly 50% of the enzymatic activity. Similar results have been reported for biotinylation of alkaline phosphatase when employing an *N*-hydroxysuccinimidyl ester (27). A sample of alkaline phosphatase obtained from a different source (Calzyme Laboratories, catalog no. 235B45400 from calf intestine) was conjugated in an identical manner. In this instance, appending an average of 5.9 PBA moieties to the enzyme was accompanied by the loss of less than 20% of the enzymatic activity.

Retention of PBA–AP and PBA–HRP Conjugates on SHA–Sephacrose. Table 2 also summarizes the retention of PBA–AP and PBA–HRP bioconjugates on SHA–Sephacrose at pH 8.3. The alkaline phosphatase conjugate was immobilized at an efficiency of $\geq 80\%$ when the incorporation ratio exceeded six PBA moieties. However, the horseradish peroxidase conjugate was efficiently immobilized only at the highest incorporation ratio obtained (9.6:1). When the horseradish peroxidase conjugate was first prepared and the excess reagent removed by dialysis, the formation of an insoluble aggregate was observed. In retrospect, we now speculate that aggregation resulted from intermolecular complex formation involving conjugated PBA moieties and carbohydrate residues. In this instance, aggregation results from the well-known interaction involving the phenylboronate anion and vicinal diol containing compounds. Accordingly, we conclude that the reduced immobilization efficiency of PBA–HRP on SHA–Sephacrose observed at low incorporation ratios results from competitive interactions involving carbohydrate residues. This complication can be potentially mitigated by adjusting the pH to neutral or slightly acidic conditions prior to immobilization so as to minimize the availability of the phenylbo-

ronate anion ($pK_a = 8.9$), thereby minimizing the potential for diol interaction. It is interesting to note that the principal site of phenylboronate interaction with carbohydrate residues, the vicinal diol groups, is also the site of the periodate oxidation reaction that was exploited for the purpose of conjugating PBA moieties to the enzyme. Consequently, one might assume that periodate oxidation would represent a preferred mechanism of glycoprotein conjugation with PBA, in that it eliminates a potential site of secondary interaction while simultaneously affording a site of conjugation. However, such an approach would be subject to considerable optimization and may only prove viable for glycoproteins with modest carbohydrate content. In the case of Horseradish Peroxidase, the persistent potential for phenylboronate–carbohydrate interaction under alkaline conditions may be attributable to the high carbohydrate content of the enzyme, which is 20 wt %.

Careful examination of Table 2 reveals that the efficiency with which both PBA–AP and PBA–HRP are immobilized is directly related to the incorporation ratio, in that only conjugates having on average six or more PBA moieties are immobilized with efficiencies of $\geq 80\%$. In light of the limited capacity of the SHA–Sephacrose ($\leq 1.2 \mu\text{mol}$ of SHA/mL of gel), we conclude that immobilization of PBA conjugates on SHA–Sephacrose results from multivalent complex formation involving several PBA moieties. From the available data it is impossible to estimate the minimum number of interactions required for efficient immobilization, but we can conclude that for the system described herein, that number appears to be greater than one and less than six. Further details regarding these phenomena and their implications will be described in a future manuscript.

Table 3 summarizes the release of immobilized PBA conjugates from SHA–Sephacrose attributable to washing with solutions of progressively lower pH. When the incorporation ratio exceeded six PBA moieties, the PBA–AP conjugates were insensitive to acidic washes of pH 6.7, 4.2, and 2.5. Only in the instance of the lowest incorporation ratio (4.7:1) was a modest amount of enzyme eluted, and then only in the most acidic wash. The PBA–HRP conjugate was more sensitive to acidic washes, in that modest amounts of enzyme were eluted in the pH 6.7 and pH 4.2 washes. At pH 2.5, significant elution of enzyme conjugate was observed (18% for the 3.9:1 conjugate and 32% for the 9.6:1 conjugate). This trend is opposite that observed for PBA–AP, and may represent a further artifact of competitive carbohydrate interaction. Specifically, at low pH, phenylboronate–carbohydrate complexes are completely dissociated, resulting in elution of that percentage of the enzyme that

was initially retained on SHA-Sepharose by intermolecular phenylboronate-carbohydrate complex formation, rather than through specific formation of the PBA-SHA complex.

CONCLUSION

The complexes derived from phenylboronic acid and salicylhydroxamic acid were characterized by ^{11}B NMR and mass spectrometry and structures were assigned based on model complex studies. Subsequently, conjugation reagents incorporating the PBA moiety (PBA-XX-NHS and PBA-X-hydrazide) were synthesized and shown to be useful for the preparation of protein conjugates from alkaline phosphatase and horseradish peroxidase. PBA-enzyme conjugates retained enzymatic activity after conjugation, and were efficiently immobilized on pre-packed columns of SHA-Sepharose at pH 8.3 by simple gravity-flow application. The protocol employed was analogous to one involving immobilization of a biotinylated or hapten-conjugated protein on either an Avidin or anti-hapten antibody column, respectively. Immobilized PBA-AP was retained on SHA-Sepharose even after washing with buffers of increasing acidity at pH 6.7, 4.2, and 2.5. Immobilized PBA-HRP was retained on SHA-Sepharose at pH 6.7, but significant elution of the conjugate was observed at lower pH. Retention of the HRP conjugate at low pH apparently suffers from the presence of acid labile intermolecular complexes involving phenylboronate moieties and the carbohydrate residues associated with the glycosylated enzyme.

Owing to the encouraging results we have thus far obtained and the relative simplicity of the chemical affinity system described herein, we have begun the process of further optimizing the requisite reagents to better characterize the utility of this approach.

Phenylboronic Acid–Salicylhydroxamic Acid Bioconjugates.

2. Polyvalent Immobilization of Protein Ligands for Affinity Chromatography

Jean P. Wiley, Karin A. Hughes, Robert J. Kaiser, Edward A. Kesicki,[†] Kevin P. Lund, and Mark L. Stoltz*

Prolinx, Inc., 22322 20th Avenue SE, Bothell, Washington 98021. Received August 8, 2000;
Revised Manuscript Received January 11, 2001

Phenylboronic acid bioconjugates prepared from alkaline phosphatase by reaction with either 2,5-dioxopyrrolidinyl 3-{*N*-[3-(1,3,2-dioxaboran-2-yl)phenyl]carbamoyl}propanoate (PBA-XX-NHS) or 2,5-dioxopyrrolidinyl 6-{[3,5-di-(1,3,2-dioxaboran-2-yl)phenyl]carbonylamino}hexanoate (PDBA-X-NHS) were compared with respect to the efficiency with which they were immobilized on salicylhydroxamic acid-modified Sepharose (SHA-X-Sepharose) by boronic acid complex formation. When immobilized on moderate capacity SHA-X-Sepharose (5.4 μ mol of SHA/mL of gel), PDBA–alkaline phosphatase conjugates were shown to be stable with respect to both the alkaline (pH 11.0) and acidic (pH 2.5) buffers utilized to recover *anti*-alkaline phosphatase during affinity chromatography. Boronic acid complex formation was compared to covalent immobilization of alkaline phosphatase on Affi-Gel 10 and Affi-Gel 15. PDBA–AP–SHA-X-Sepharose was shown to afford superior performance to both Affi-Gel 10 and Affi-Gel 15 with respect to immobilization of alkaline phosphatase, retention of *anti*-alkaline phosphatase and recovery of *anti*-alkaline phosphatase under alkaline conditions. High capacity SHA-X-Sepharose (≥ 7 μ mol of SHA/mL of gel) was shown to afford superior performance to moderate capacity SHA-X-Sepharose (4.5 μ mol of SHA/mL of gel) with respect to stability at pH 11.0 and pH 2.5 when a PDBA– α Human IgG conjugate with a low incorporation ratio of only 1.5:1 was immobilized on SHA-X-Sepharose and subsequently utilized for affinity chromatography of Human IgG. The results are interpreted in terms of either a bivalent or trivalent interaction involving boronic acid complex formation.

INTRODUCTION

In the previous paper (1) we introduced a small molecule polyvalent system that exploits the interaction between phenylboronic acid (PBA) and salicylhydroxamic acid (SHA) for protein immobilization. The utility of this system was demonstrated by preparing a PBA-modified alkaline phosphatase conjugate (PBA–AP), immobilizing the conjugate on a SHA-modified chromatographic support (SHA-Sepharose), and utilizing the resulting chromatographic support for affinity chromatography of *anti*-alkaline phosphatase. Initial results were promising, although a potential limitation was identified relating to the need to append several PBA moieties when preparing conjugates. The present paper describes the further optimization of the PBA–SHA system with respect to the immobilization of protein ligands for affinity chromatography. Our efforts were directed toward optimizing the reagent components of the system so as to minimize the requisite number of phenylboronic acid moieties while concomitantly increasing both the efficiency and stability with which PBA conjugates are immobilized on SHA chromatographic supports. We report here the development of a new boronic acid reagent that incorporates two equivalents of boronic acid per site of conjugation, PDBA-X-NHS, as well as the development of a new high capacity chromatographic

support, SHA-X-Sepharose. The performance of PDBA-X-NHS and SHA-X-Sepharose is compared to that of PBA-XX-NHS and SHA-Sepharose, respectively.

In nature, polyvalent interactions involving the simultaneous binding of multiple ligands on one biological entity (a macromolecule or cell surface) to multiple receptors on another are often collectively much stronger than the corresponding monovalent interactions. A recent review of polyvalent systems states, “The possibility that multiple simultaneous interactions have unique collective properties that are qualitatively different from properties displayed by their constituents, which interact monovalently, suggests new strategies for the design of drugs and research reagents for biochemistry and biology” (2). Although polyvalent systems usually involve protein receptors, dimeric derivatives prepared from vancomycin and peptides containing D-Ala-D-Ala have recently provided small molecule model systems for investigating polyvalency (3–5). Trimeric derivatives prepared from vancomycin and L-Lys-D-Ala-D-Ala were reported to bind to one another 25 times tighter than avidin-biotin, one of the strongest biological interactions known (6).

MATERIALS AND METHODS

Materials. Reagents used in the syntheses were purchased from Aldrich (Milwaukee, WI) and Fluka (Ronkonkoma, NY) and utilized without further purification. 2,5-Dioxopyrrolidinyl 6-(3-{*N*-[3-(1,3,2-dioxaboran-2-yl)phenyl]carbamoyl}propanoylamino)hexanoate (PBA-XX-NHS), methyl 4-aminomethylsalicylate hydrochloride, and SHA-Sepharose were prepared as previously re-

ported (1). 2,5-Dioxopyrrolidinyl 6-[[3,5-di(1,3,2-dioxaboran-2-yl)phenyl]carbonylamino}hexanoate (PDBA-X-NHS) and SHA-X-Sepharose were prepared as described below and are now available from Prolinx (Bothell, WA). EAH Sepharose 4B and Sephadex G25 were obtained from Amersham Pharmacia Biotech (Piscataway, NJ). Affi-Gel 10 and Affi-Gel 15 were obtained from Bio-Rad (Hercules, CA). Alkaline phosphatase (EC 3.1.3.1) was obtained from Calzyme Laboratories (San Luis Obispo, CA) and rabbit *anti*-alkaline phosphatase (IgG fraction) was obtained from Rockland (Gilbertsville, PA). Goat *anti*-human IgG and ChromPure proteins (purified whole molecule immunoglobulins from normal Human serum) were obtained from Jackson (West Grove, PA).

^1H , ^{11}B , and ^{13}C NMR spectra were recorded at 300, 121, and 75 MHz, respectively, on a Varian Gemini 2000 spectrometer with a broadband probe. Internal referencing was employed and chemical shifts are reported as δ values. Coupling constants are reported in hertz. High-resolution mass spectra of synthetic intermediates and reagents were recorded on a PE Biosystems Mariner ESI-TOF mass spectrometer in the positive ion mode.

The purity of synthetic products was determined by analytical HPLC on a Hewlett-Packard 1050Ti system equipped with a diode array detector. A 2.1 cm $\times$ 0.22 cm C4 column (Aquapore Butyl, PE Biosystems) equilibrated with 0.1 M triethylammonium acetate, pH 6.5, was eluted at a flow rate of 0.5 mL/min after an initial period of 5 min with a linear gradient of from 0 to 100% methanol over 30 min. Product purity exceeded 95% in every instance. Protein bioconjugates were characterized with respect-to-incorporation ratio on a Hewlett-Packard 8453 diode array UV-vis spectrophotometer.

3,5-Di(dihydroxyboryl)benzoic Acid (1). A total of 5.0 g (17.9 mmol) of 3,5-dibromobenzoic acid was dissolved in 300 mL of THF and cooled to -78°C . A total of 12.7 mL (17.8 mmol) of methyllithium was added over 2 min and stirred for 5 min, and 58.0 mL (98.6 mmol) *tert*-butyllithium was added over 5 min. The solution was stirred at -78°C for 15 min, and the solution was allowed to warm to -45°C , stirred for 45 min, and then again cooled to -78°C . A total of 27.0 mL (117 mmol) of triisopropylborate was added, stirred for 15 min at -78°C , and then allowed to warm to room temperature. The solution was stirred at room temperature for 2 h, and the bulk of solvent was removed by rotary evaporation and residual solvent under high vacuum while warming for 1 h to 60°C . The solids were dissolved in 60 mL of water, cooled to 0°C for 1 h and then filtered off solids (borate salts). The filtrate was cooled to 0°C and adjusted pH to ~ 4 by dropwise addition of concentrated HCl. The solution was allowed to stand overnight at 4°C , and solids were collected by filtration, washed with cold water, and dried under high vacuum. The volume of filtrate was reduced to ~ 70 mL, and again the solution was allowed to stand at 4°C overnight. Finally, solids were collected by filtration, washed with cold water, and dried under high vacuum to give 2.23 g (60%) of **1** as a white powder. ^1H NMR (DMSO- d_6): δ 8.18 (s, 4H), 8.41 (s, 3H), 12.65 (br s, 1H). ^{13}C NMR (DMSO- d_6): δ 129.1, 133.5, 137.0, 144.9, 168.4. ^{11}B NMR (DMSO- d_6): δ 27.7. HRMS (ES^+) calcd for $\text{C}_7\text{H}_8\text{B}_2\text{O}_6\text{Na}$: 233.0405. Obsd: 233.0410.

6-[[3,5-Di(dihydroxyboryl)phenyl]carbonylamino}-hexanoic Acid (3). A total of 3.2 g (15.2 mmol) of **1** was suspended in 300 mL of 1,4-dioxane, 2.2 mL (30.4 mmol) of 1,3-propanediol and heated to near reflux while stirring until the solution became homogeneous. The solvent was removed by rotary evaporation, the solid was

dissolved by heating in 150 mL of 1,4-dioxane. Again, the solvent was removed by rotary evaporation, the solid was dissolved by heating in 150 mL of 1,4-dioxane, and then the solvent was removed by rotary evaporation. The solid was dissolved with heating in 400 mL of 1,4-dioxane, the solution was allowed cool to room temperature, and then 1.84 g (16.0 mmol) of *N*-hydroxysuccinimide was added followed by 3.30 g (16.0 mmol) of DCC. The solution was stirred gently overnight at room temperature, during which time a white precipitate formed, the precipitate was filtered from solution, and the filtrate was concentrated by rotary evaporation. The intermediate was dissolved (**2**, colorless solid) in 100 mL of methanol, 3.99 g (30.4 mmol) of 6-aminohexanoic acid (3.99 g, 30.4 mmol) and 10.6 mL (60.9 mmol) of diisopropylethylamine were added. The solution was stirred for 24 h at room temperature, the solvent was concentrated by rotary evaporation, and then the product was dissolved in 75 mL of 0.25 N NaOH. The solid was filtered off, and the filtrate cooled to 0°C and then acidified to pH ~ 4 with 1 N HCl. The product was allowed to stand for 1 day at 4°C . Finally, the precipitate was collected by filtration, washed with cold water, and dried under high vacuum to give 3.59 g (73%) of **3** as a white solid. ^1H NMR (DMSO- d_6): δ 1.29 (m, 2H), 1.51 (m, 4H), 2.19 (t, $J = 7.3$ Hz, 2H), 3.22 (q, $J = 6.3$ Hz, 2H), 8.05 (br s, 4H), 8.19 (s, 2H), 8.28 (s, 1H), 8.47 (t, $J = 11.1$ Hz, 1H), 11.92 (br s, 1H). ^{13}C NMR (CD_3OD): δ 24.0, 25.7, 28.3, 33.1, 39.0, 132.7, 133.3, 141.5, 169.5, 176.1. HRMS (ES^+) calcd for $\text{C}_{13}\text{H}_{19}\text{B}_2\text{NO}_7\text{Na}$: 346.1245. Obsd: 346.1254.

2,5-Dioxopyrrolidinyl 6-[[3,5-Di(1,3,2-dioxaboran-2-yl)phenyl]carbonylamino}hexanoate (4, PDBA-X-NHS). A total of 5.67 g (17.6 mmol) of **3** was suspended in 200 mL of 1,4-dioxane, 2.55 mL (35.3 mmol) of 1,3-propanediol and heated stirred suspension for 15 min under reflux. Decanted solution into another flask leaving behind an oily material. The solvent was removed by rotary evaporation, the solid was dissolved in 150 mL of 1,4-dioxane. Again, the solvent was removed by rotary evaporation, the solid was dissolved in 150 mL of 1,4-dioxane and the solvent was removed by rotary evaporation. The solid was dissolved in 200 mL of 1,4-dioxane, 2.18 g (18.9 mmol) of *N*-hydroxysuccinimide and 3.80 g (18.4 mmol) of DCC and stirred at room temperature overnight, during which time a white precipitate formed. The precipitate was filtered from solution, and the filtrate was concentrated by rotary evaporation. The product was dissolved in a minimum volume of 1,4-dioxane and added to 250 mL of rapidly stirred methyl *tert*-butyl ether. The product initially precipitates as an oil but affords a white solid after 24 h of rapid stirring. The product was collected by filtration and washed with methyl *tert*-butyl ether to give 6.52 g (74%) of **4** as a white powder. ^1H NMR (DMSO- d_6): δ 1.38 (m, 2H), 1.53 (m, 2H), 1.64 (m, 2H), 1.99 (p, $J = 5.1$ Hz, 4H), 2.66 (t, $J = 7.3$ Hz, 2H), 2.79 (s, 4H), 3.22 (q, $J = 6.4$ Hz, 2H), 4.10 (t, $J = 5.4$ Hz, 8H), 8.13 (s, 1H), 8.16 (s, 2H), 8.49 (t, $J = 5.5$ Hz, 1H). ^{13}C NMR (DMSO- d_6): δ 24.0, 25.4, 25.5, 26.9, 28.6, 30.1, 38.9, 61.6, 131.8, 133.4, 134.5, 141.6, 166.7, 169.2, 170.5. HRMS (ES^+) calcd for $\text{C}_{17}\text{H}_{22}\text{B}_2\text{N}_2\text{O}_9\text{Na}$ (**4** minus two 1,3-propanediols): 443.1409. Obsd: 443.1429.

Methyl 4-[[*tert*-Butoxy]carbonylamino]methyl}-salicylate (5). A total of 10.9 g (50 mmol) of methyl 4-aminomethylsalicylate hydrochloride was suspended in 200 mL of anhydrous methanol, and 8.7 g (50 mmol) of di-*tert*-butyl dicarbonate and 7.0 mL (50 mmol) of Et_3N

were added. The solid rapidly dissolved with the slow evolution of gas. The reaction mixture was stirred under dry N₂ for 18 h at room temperature and then evaporated to dryness to afford an amorphous white solid. The solid was partitioned between 200 mL of ethyl acetate and 100 mL of water, the layers were separated, ethyl acetate was dried over Na₂SO₄, the solution was filtered, and the filtrate was evaporated to a white solid. The solid was crystallized from 1:1 ethyl acetate:hexanes, and the product was filtered and dried in vacuo to give 13.7 g (97%) of **5** as a white solid, mp: 95–96 °C (uncorrected). ¹H NMR (CDCl₃): δ 1.42 (s, 9H), 3.90 (s, 3H), 4.26 (d, *J* = 6 Hz, 2H), 4.99 (t, *J* = 6 Hz, 1H), 6.75 (d, *J* = 8 Hz, 1H), 6.84 (s, 1H), 7.73 (d, *J* = 8 Hz, 1H), 10.72 (s, 1H). ¹³C NMR (CDCl₃): δ 28.5, 44.4, 52.4, 80.0, 111.5, 115.9, 118.2, 130.5, 150.0, 156.3, 162.1, 170.8. HRMS (ES⁺) calcd for C₁₄H₁₉NO₅Na: 304.1161. Obsd: 304.1152.

4-[(*tert*-Butoxy)carbonylamino]methyl]salicylic Acid (6**).** A total of 8.7 g (30.9 mmol) of **5** was dissolved in 100 mL of dry THF, and 4.4 g (30.9 mmol) of potassium trimethylsilanolate (90% pure) was added and heated for 24 h under reflux, during which time a tan precipitate formed. The mixture was evaporated to dryness, and the solid was dissolved in 100 mL of water. The stirred solution was cooled in an ice–water bath, and the pH was adjusted to ~2 by dropwise addition of saturated aqueous KHSO₄, thereby producing an off-white precipitate. The precipitate was filtered, washed with ice-cold water, and dried in vacuo over KOH pellets to give 6.7 g (81%) of **6** as a white solid, mp: 141–144 °C (uncorrected, decomposes with effervescence). ¹H NMR (CDCl₃): δ 1.47 (s, 9H), 4.33 (d, *J* = 6 Hz, 2H), 5.07 (t, *J* = 6 Hz, 1H), 6.80 (d, *J* = 8 Hz, 1H), 6.88 (s, 1H), 7.81 (d, *J* = 8 Hz, 1H), 10.72 (br s, 2H). ¹³C NMR (CDCl₃): δ 28.5, 44.4, 80.5, 111.1, 115.9, 118.3, 131.5, 148.5, 156.6, 162.6, 174.1. HRMS (ES⁺) calcd for C₁₃H₁₇NO₅Na: 290.1004. Obsd: 290.1005.

Cyanomethyl 4-[(*tert*-Butoxy)carbonylamino]methyl]salicylate (7**).** A total of 8.2 g (30.6 mmol) of **6** was suspended in 25 mL of chloroacetonitrile, 4.3 mL (30.6 mmol) of Et₃N was added, and the mixture was stirred under dry N₂ for 8 h at 50 °C. The mixture was cooled to room temperature, the solvent was evaporated, and the residue was partitioned between 250 mL of ethyl acetate and 250 mL of water. The layers were separated, and ethyl acetate was washed with 100 mL of saturated aqueous NaHCO₃ and 100 mL of saturated aqueous NaCl. The solution was dried over Na₂SO₄ and filtered, and the filtrate was evaporated to dryness. The pale tan solid was dissolved in 100 mL of ethyl acetate, and the produce was adsorbed onto 10 g of silica gel. Silica gel on a glass frit was collected by vacuum filtration and washed with 100 mL of ethyl acetate, and the filtrate was evaporated to dryness. The residue was crystallized from 1:1 ethyl acetate:hexanes to give 7.9 g (88%) of **7** as an off-white solid, mp: 144–146 °C (uncorrected). ¹H NMR (CDCl₃): δ 1.45 (s, 9H), 4.30 (d, *J* = 6 Hz, 2H), 5.00 (s, 2H), 5.05 (t, *J* = 6 Hz, 1H), 6.83 (d, *J* = 8 Hz, 1H), 6.91 (s, 1H), 7.77 (d, *J* = 8 Hz, 1H), 10.12 (s, 1H). ¹³C NMR (CDCl₃): δ 28.4, 44.3, 49.0, 80.1, 109.6, 114.2, 116.1, 118.7, 130.5, 149.7, 156.2, 162.5, 168.5. HRMS (ES⁺) calcd for C₁₅H₁₈N₂O₅Na 329.1113. Obsd: 329.1111.

Cyanomethyl 4-(Aminomethyl)salicylate Hydrochloride (8**).** A total of 7.7 g (26.2 mmol) of **7** was dissolved in 150 mL of THF, and dry HCl gas was slowly bubbled through the solution. After 5 min, the gas was discontinued, and the reaction was stirred for 30 min at room temperature, during which time a creamy white precipitate formed. The reaction mixture was cooled for

2 h in an ice–water bath. The precipitate was filtered, washed with 100 mL of diethyl ether, and dried in vacuo over KOH pellets to give 5.8 g (91%) of **8** as a white powder. ¹H NMR (DMSO-*d*₆): δ 4.00 (s, 2H), 5.20 (s, 2H), 7.05 (d, *J* = 8 Hz, 1H), 7.15 (s, 1H), 7.75 (d, *J* = 8 Hz, 1H), 8.62 (br s, 3H), 10.38 (s, 1H). ¹³C NMR (DMSO-*d*₆): δ 41.6, 49.7, 113.0, 116.1, 118.0, 119.7, 131.1, 142.3, 159.5, 166.1. HRMS (ES⁺) calcd for C₁₀H₁₁N₂O₃: 207.0770. Obsd: 207.0768.

4-[N-({4-[(Cyanomethyl)oxycarbonyl]-3-hydroxyphenyl)methyl}carbamoyle]butanoic Acid (9**).** A total of 1.22 g (5.0 mmol) of **8** was suspended in 100 mL dry DCM and stirred in an ice–water bath, and a solution of 0.57 g (5.0 mmol) of glutaric anhydride and 0.7 mL (5.0 mmol) of Et₃N was added in 25 mL of dry DCM over 15 min. The reaction was stirred for 18 h at room temperature. The mixture was evaporated to dryness, and the solid was triturated under 50 mL of ice-cold 0.1 N HCl. The solid was collected by filtration, washed with cold water, and dried in vacuo over KOH pellets to give 1.43 g (89%) of **9** as a white solid, mp: 125–126 °C (uncorrected). ¹H NMR (DMSO-*d*₆): δ 1.75 (q, *J* = 7 Hz, 2H), 2.19 (t, *J* = 7 Hz, 2H), 2.22 (t, *J* = 7 Hz, 2H), 4.24 (d, *J* = 6 Hz, 2H), 5.17 (s, 2H), 6.81 (d, *J* = 8 Hz, 1H), 6.85 (s, 1H), 7.70 (d, *J* = 8 Hz, 1H), 8.39 (t, *J* = 6 Hz, 1H), 10.5 (br s, 1H), 11.7 (br s, 1H). ¹³C NMR (DMSO-*d*₆): δ 20.7, 33.1, 34.5, 41.8, 49.7, 111.2, 115.9, 116.2, 118.5, 130.9, 149.1, 160.2, 166.6, 172.3, 174.5. HRMS (ES⁺) calcd for C₁₅H₁₆N₂O₆Na: 343.0906. Obsd: 343.0909.

2,5-Dioxopyrrolidinyl 4-[N-({4-[(Cyanomethyl)oxycarbonyl]-3-hydroxyphenyl)methyl}carbamoyle]butanoate (10**).** A total of 1.00 g (3.1 mmol) of **9** was dissolved in 50 mL of dry THF, 0.36 g (3.1 mmol) of *N*-hydroxysuccinimide and 0.64 g (3.1 mmol) of DCC were added, and the mixture was gently stirred under dry N₂ for 1 h at room temperature, during which time a white precipitate formed. The reaction was stirred for 24 h at room temperature and then cooled for 4 h at –20 °C. The precipitate was filtered from cold solution and washed with 10 mL of THF. The filtrate and wash were combined and evaporated to dryness. The residue was crystallized from 1:1 2-propanol:hexanes and filtered and dried in vacuo to give 1.04 g (80%) of **10** as white needles, mp 116–119 °C (uncorrected). ¹H NMR (DMSO-*d*₆): δ 1.88 (q, *J* = 7 Hz, 2H), 2.30 (t, *J* = 7 Hz, 2H), 2.71 (t, *J* = 7 Hz, 2H), 2.80 (s, 4H), 4.26 (d, *J* = 6 Hz, 2H), 5.18 (s, 2H), 6.82 (d, *J* = 8 Hz, 1H), 6.86 (s, 1H), 7.71 (d, *J* = 8 Hz, 1H), 8.44 (t, *J* = 6 Hz, 1H), 10.18 (br s, 1H). ¹³C NMR (DMSO-*d*₆): δ 20.4, 25.5, 29.7, 33.6, 41.8, 49.6, 111.2, 115.9, 116.2, 118.4, 130.9, 148.9, 160.1, 166.5, 169.0, 170.5, 171.7. HRMS (ES⁺) calcd for C₁₉H₁₉N₃O₈Na: 440.1070. Obsd: 440.1068.

Preparation of SHA-X-Sepharose. Collected EAH Sepharose 4B (50 mL slurry) by vacuum filtration in a Buchner funnel fitted with filter paper (Whatman #1) and washed with 100 mL of deionized water followed by 100 mL of 0.1 M NaHCO₃ buffer, pH 9.8. The moist cake was suspended in 12.5 mL of 0.1 M NaHCO₃ buffer, pH 9.8, and transferred into a 50 mL wide-mouth screw cap plastic bottle. A total of 1.252 g (3.0 mmol) of **10** was dissolved in 3 mL of dry DMF and added to the reaction bottle. The bottle was rotated for 1 h at room temperature. Sepharose was collected on a Buchner funnel and washed with 200 mL of deionized water. The moist cake was transferred to a 200 mL wide-mouth screw cap plastic bottle. A total of 8.686 g (0.125 mmol) of hydroxylamine hydrochloride in 12.5 mL of 1 M NaHCO₃, pH 10.0, was added to 100 mL of deionized water. The pH of hydroxylamine solution was adjusted to 10.0 by

dropwise addition of 10 N NaOH, and then the final volume of the solution was adjusted to 125 mL by adding deionized water. A total of 125 mL of freshly prepared hydroxylamine solution was added to the reaction bottle and the bottle rotated for 16 h at room temperature. Finally, SHA-X-Sepharose was collected on a Buchner funnel, washed with 250 mL of deionized water, and stored as a slurry in 20% (v/v) ethanol/water.

Determined SHA concentration of modified Sepharose by first suspending 1 mL of gel in 2 mL of 50% (v/v) glycerol/water, removing a 0.5 mL aliquot of the suspension, and further diluting with 2.5 mL of 50% (v/v) glycerol/water. Finally, the SHA concentration was estimated by comparing the absorbance of the suspension of SHA-modified gel at 320 nm ($\epsilon_{320} = 4900$) to that of unmodified EAH Sepharose 4B.

Enzymatic Activity of PBA- and PDBA-AP Conjugates. Alkaline phosphatase (AP, 50 000 units; Sigma) was dialyzed in a Slide-A-Lyzer (3500 MWCO, Pierce) against 2 L of 0.1 M NaHCO₃, pH 8.3, for 48 h at 4 °C. Determined concentration of AP dialysate by measuring the absorbance at 280 nm ($\epsilon_{280} = 107\,500$). Conjugated six aliquots of AP dialysate (~4.3 mg/mL) by adding a 5-, 10-, or 50-fold molar excess of either PBA-XX-NHS (100 mM stock solution in DMF) or PDBA-X-NHS (100 mM stock solution in DMF). Reactions were incubated on ice for 1.5 h, and conjugates were transferred to Slide-A-Lyzers (3500 MWCO, Pierce) and dialyzed against 2 L of 0.1 M NaHCO₃, pH 8.3, at 4 °C over 48 h. Incorporation ratios (to within 0.5:1) were estimated by comparing the ratio of the absorbance at 260 nm ($\epsilon_{260} = 4500$ for PBA and $\epsilon_{260} = 4000$ for PDBA) to the absorbance at 280 nm. Enzymatic activity was assayed with 4-nitrophenyl phosphate (pNPP) as substrate. A stock solution of pNPP was prepared by dissolving 15 mg of pNPP in 15 mL of DEA buffer (1 M diethanolamine, 1 mM MgCl₂, 0.1 mM ZnSO₄, pH 10.2). Diluted 5 aliquots (100 μ L) of each of the six conjugates to 0.05 μ g/mL with TBS buffer (10 mM tris(hydroxymethyl)aminomethane hydrochloride, 140 mM NaCl, pH 8.0), in a 96-well plate, and assayed for AP activity by adding 100 μ L of pNPP stock solution to each well and incubating for 10 min at 37 °C. Enzymatic activity was determined of conjugates relative to unmodified AP from the average absorbance at 405 nm obtained from each of five aliquots. A_{405} values were determined on a Bio-Tek Instruments EL_X808 plate reader.

Immobilization of PBA- and PDBA-AP Conjugates on SHA-X-Sepharose. Each of six SHA-X-Sepharose columns (0.5 mL in 0.5 $\times$ 15 cm column; 5.4 μ mol of SHA/mL of gel) were equilibrated with 50 mL of 0.1 M NaHCO₃, pH 8.3. Aliquots of 0.5 mL of each of the conjugates prepared above were diluted to 5 mL total volume with 0.1 M NaHCO₃, pH 8.3. Loaded conjugates on SHA-X-Sepharose columns by simple gravity-flow, and washed columns with 10 mL of 0.1 M NaHCO₃, pH 8.3 (a sufficient quantity of buffer for the A_{280} to return to baseline). Determined the quantity of conjugate immobilized on each column by subtracting the quantity of conjugate in each of the eluents (as determined by the absorbance at 280 nm) from the quantity of conjugate loaded onto each column.

Affinity Chromatography of α AP on PBA-AP-SHA-X-Sepharose and PDBA-AP-SHA-X-Sepharose. Reconstituted 25 mg of rabbit *anti*-alkaline phosphatase Ab (α AP, Rockland) in 5 mL of water and dialyzed in a Slide-A-Lyzer (3500 MWCO; Pierce) against 2 L of 0.1 M NaHCO₃, pH 8.3, for 48 h at 4 °C. Aliquots of 4 mg of α AP were diluted with 0.1 M NaHCO₃, pH 8.3, to a final volume of 5 mL and loaded by simple

gravity-flow onto each of the six columns prepared as described above containing 0.5 mL of either PBA-AP-SHA-X-Sepharose or PDBA-AP-SHA-X-Sepharose. Columns were washed with 15 mL of 0.1 M NaHCO₃, pH 8.3, collecting the first 10 mL fraction of each eluent. Determined protein concentration in each of the fractions from the absorbance at 280 nm ($\epsilon_{280} = 210\,000$) and calculated the quantity of α AP retained on each column by subtracting the quantity of α AP in each of the fractions from the quantity loaded onto each column. Initially, α AP was eluted from each column with 15 mL of 50 mM phosphate buffer, pH 11.0 (high pH eluent), collecting a 10 mL fraction into a tube containing 1 mL of 1 M phosphate buffer, pH 5.75. Subsequently, additional α AP was eluted from each column with 15 mL of 100 mM glycine hydrochloride buffer, pH 2.5 (low pH eluent), collecting a 10 mL fraction. Low pH of the eluent fraction was adjusted to pH 8–9 by addition of 1 drop of 10 N NaOH. Determined protein concentration in each of the fractions from the absorbance at 280 nm and calculated recovery of α AP.

High pH eluent fractions and low pH eluent fractions for affinity purified α AP were analyzed by SDS-PAGE on 7.5% gels according to Laemmli (7). Aliquots of 25 μ L of each fraction were diluted with 25 μ L of reducing application buffer [63 mM tris(hydroxymethyl)aminomethane hydrochloride, pH 6.8, 10% (v/v) glycerol, 2% (w/v) SDS; 0.05% (v/v) 2-mercaptoethanol, and 0.001% (w/v) bromophenol blue] and heated for 3 min at 95 °C prior to loading 10 μ L/lane. PAGE was run at 200 V until bromophenol blue reached the bottom of the plate. Visualized proteins by staining gel with Silver stain (Bio-Rad).

Immobilization of AP on SHA-X-Sepharose, Affi-Gel 10, and Affi-Gel 15. Six alkaline phosphatase samples (300 000 units each, Sigma) were dialyzed in six Slide-A-Lyzers (3500 MWCO; Pierce) against 2 L of 0.1 M NaHCO₃, pH 8.3, over 48 h at 4 °C. The concentration of each AP dialysate was determined from the absorbance at 280 nm ($\epsilon_{280} = 107\,500$). A total of 2.0 mg of AP dialysate was conjugated by adding a 15-fold molar excess of PDBA-X-NHS (100 mM stock solution in DMF). The reaction was incubated on ice for 1.5 h, and then the conjugate was dialyzed in a Slide-A-Lyzer (3500 MWCO; Pierce) against 2 L of 0.1 M NaHCO₃, pH 8.3, over 24 h at 4 °C. The extent of PDBA incorporation was determined from the ratio of the absorbance at 260 nm ($\epsilon_{260} = 4000$) to the absorbance at 280 nm. A SHA-X-Sepharose column (0.25 mL in 0.5 $\times$ 15 cm column; 5.3 μ mol of SHA/mL of gel) was equilibrated with 50 mL of 0.1 M NaHCO₃, pH 8.3. PDBA-AP conjugate was loaded on the column by simple gravity-flow, the column was washed with 50 mL of 0.1 M NaHCO₃, pH 8.3, and the first 10 mL fraction of eluent was collected. Protein concentration in the eluent was determined from the absorbance at 280 nm ($\epsilon_{280} = 107\,500$), and the quantity of PDBA-AP immobilized on the column was calculated by subtracting the quantity of PDBA-AP in the eluent from the quantity loaded onto the column.

A total of 0.25 mL of Affi-Gel 10 (Bio-Rad) and 0.25 mL of Affi-Gel 15 (Bio-Rad) were transferred to each of two 1.5 mL micro test tubes. Gels were washed three times each by vortexing with 1 mL of cold deionized water, centrifuging at low speed to pellet the gel, and then removing the supernatant. A total of 2.0 mg of AP dialysate was added to each of the gel suspensions. Rotated Affi-Gel 10 suspension for 2 h at room temperature and Affi-Gel 15 suspension for 4 h at 4 °C. A total of 0.25 mL of a 1 M solution of glycine ethyl ester was

added, pH 8.0, to each of the gel suspensions to consume excess reactive sites and rotated for 1 h at room temperature. Gel suspensions were transferred to 0.5×15 cm columns and washed with 50 mL of 0.1 M NaHCO_3 , pH 8.3, collecting the first 10 mL fraction from each column. Determined the protein concentrations of the two fractions from the absorbance at 280 nm ($\epsilon_{280} = 107\,500$), and calculated the quantity of AP immobilized on each of the columns by subtracting the quantity of AP in each of the fractions from the quantity loaded onto each of the columns.

Affinity Chromatography of α AP on PDBA-AP-SHA-X-Sepharose, AP-Affi-Gel 10, and AP-Affi-Gel 15. A total of 50 mg of rabbit *anti*-alkaline phosphatase Ab (α AP, Rockland) was reconstituted in 5 mL of deionized water and dialyzed in a Slide-A-Lyzer against 2 L of 0.1 M NaHCO_3 , pH 8.3, for 48 h at 4 °C. Aliquots of 2.0 mg of α AP dialysate were diluted with 0.1 M NaHCO_3 , pH 8.3, to a final volume of 5 mL and loaded by simple gravity-flow onto each of the three 0.5×15 cm columns prepared as described above, containing 0.25 mL of either PDBA-AP-SHA-X-Sepharose (5.3 μ mol of SHA/mL of gel), AP-Affi-Gel 10, or AP-Affi-Gel 15. The columns were eluted by gravity-flow sequentially applying 15 mL of 0.1 M NaHCO_3 , pH 8.3, 15 mL of 50 mM sodium phosphate buffer, pH 11.0 (high pH eluent) and 15 mL of 100 mM glycine hydrochloride buffer, pH 2.5 (low pH eluent). The first 10 mL fraction of the high pH eluent and low pH eluent was collected from each of the columns. The protein concentration of each of the fractions was determined from the absorbance at 280 nm ($\epsilon_{280} = 210\,000$) and calculated the recovery of α AP associated with each fraction by subtracting the quantity of protein in each fraction from the quantity loaded onto the corresponding column. Analyzed high pH fractions and low pH fractions for affinity purified α AP by SDS-PAGE as described above.

Purification of Human IgG on PDBA- α Human IgG-SHA-X-Sepharose. A total of 10.0 mg of goat *anti*-human IgG (α Human IgG, Jackson) was dialyzed in a Slide-A-Lyzer (3500 MWCO; Pierce) overnight against 2 L of 0.1 M NaHCO_3 , pH 8.3, at 4 °C. The protein concentration of dialysate was determined from the absorbance at 280 nm ($\epsilon_{280} = 210\,000$). A total of 8.0 mg of α Human IgG dialysate was conjugated by adding a 10-fold molar excess of PDBA-X-NHS (100 mM stock solution in DMF). The reaction was incubated on ice for 1 h, and then the conjugate was desalted on a Sephadex G25 column (13 cm $\times$ 1.5 cm) eluted with 0.1 M NaHCO_3 , pH 8.3. The column effluent was monitored at 280 nm, and the PDBA- α Human IgG fraction was collected. The extent of PDBA incorporation was determined from the ratio of the absorbance at 260 nm ($\epsilon_{260} = 4000$) to the absorbance at 280 nm. Approximately 1.5 mg of PDBA- α Human IgG was diluted to a total volume of 5.0 mL with 0.1 M NaHCO_3 , pH 8.3, and loaded onto a SHA-X-Sepharose column (0.25 mL in 0.5×15 cm column; 7.1 μ mol of SHA/mL of gel). The column was washed with 10 mL of 100 mM glycine hydrochloride buffer, pH 2.5, to remove PDBA- α Human IgG which was unstable with respect to the low pH eluent and then equilibrated column with 50 mL of 0.1 M NaHCO_3 , pH 8.3. A total of 25.0 mg of ChromPure proteins (Jackson) was reconstituted in 10 mL of 0.1 M NaHCO_3 , pH 8.3, and then loaded by simple gravity-flow onto a PDBA- α Human IgG-SHA-X-Sepharose column. Human IgG was eluted with 15 mL of 50 mM phosphate buffer, pH 11.0, collecting a 10 mL fraction into a tube containing 1 mL of 1 M phosphate buffer, pH 5.75. Additional Human IgG was eluted with

15 mL of 100 mM glycine hydrochloride buffer, pH 2.5, collecting a 10 mL fraction. The pH of the low pH eluent fraction was adjusted to pH 8–9 by addition of 1 drop of 10 N NaOH. The protein concentration of each fraction was determined from the absorbance at 280 nm ($\epsilon_{280} = 210\,000$), and the recovery of Human IgG was calculated by subtracting the quantity of protein in each fraction from the quantity loaded onto the column.

Fractions for Human IgG were analyzed by SDS-PAGE on 12.5% gels according to Laemmli (7). Aliquots of 25 μ L of each fraction were diluted with 25 μ L of reducing application buffer and heated for 3 min at 95 °C prior to loading 10 μ L/lane. PAGE was run at 200 V until bromophenol blue reached the bottom of the plate. Proteins were transferred onto ProBlott membranes (Applied Biosystems) with a Mini Trans-Blot Cell (Bio-Rad) by electroblotting at 50 V for 2 h at room temperature in 10 mM CAPS buffer, pH 11, containing 10% methanol. Nonspecific binding to ProBlott membranes was blocked by incubating overnight at room temperature in freshly prepared TBS buffer [10 mM tris(hydroxymethyl)aminomethane hydrochloride, 140 mM NaCl, pH 7.4], containing 5% (w/v) nonfat dried milk followed by washing three times for 5 min with TBST (TBS containing 0.5% (v/v) Tween 20). Membranes were incubated with either monoclonal *anti*-human IgG-alkaline phosphatase conjugate (1:50000 dilution, Sigma) in TBST or rabbit *anti*-goat IgG-alkaline phosphatase conjugate (1:50000 dilution, Sigma) in TBST for 2 h at room temperature with constant agitation. Membranes were washed three times for 5 min with TBST and developed by incubating with 5-bromo-4-chloro-3-indolyl phosphate and nitroblue tetrazolium (BCIP/NBT FAST Tablets, Sigma). Finally, after sufficient color developed, membranes were rinsed briefly in methanol and dried.

RESULTS AND DISCUSSION

The structures of the target reagents 2,5-dioxypyrrolidinyl 6-[[3,5-di(1,3,2-dioxaboran-2-yl)phenyl]carbonylamino]hexanoate (**4**, PDBA-X-NHS) and 2,5-dioxypyrrolidinyl 4-[*N*-({4-[(cyanomethyl)oxycarbonyl]-3-hydroxyphenyl}methyl)carbamoyl]butanoate (**10**, cyanomethyl SA-X-NHS) are illustrated in Figure 1. Also illustrated, for comparison, are the related reagents 2,5-dioxypyrrolidinyl 6-{3-[*N*-(3-(1,3,2-dioxaboran-2-yl)phenyl)carbamoyl]propanoylamino}hexanoate (PBA-XX-NHS) and methyl 4-[(6-aminohexanoylamino)methyl]salicylate hydrochloride (methyl SA-X-Amine) which were previously prepared (1). The structures of the chromatographic supports SHA-X-Sepharose (**12**) and SHA-Sepharose are illustrated in Figure 2. The results that follow compare the performance of the reagents and chromatographic supports described herein to those previously prepared with respect to the immobilization of protein ligands for affinity chromatography.

Syntheses of Reagents. Reagent **4** was prepared by the synthesis outlined Scheme 1. The starting material, 3,5-dibromobenzoic acid, was sequentially reacted with methyllithium, *tert*-butyllithium, and triisopropylborate in THF to afford 3,5-di(dihydroxyboryl)benzoic acid (**1**) in 60% yield. Protection of the boronic acid moieties of **1** with 1,3-propanediol in 1,4-dioxane and subsequent reaction with *N*-hydroxysuccinimide and DCC next produced the intermediate NHS ester **2**. Reaction of **2** with 6-aminohexanoic acid and diisopropylethylamine in methanol produced the long-chain carboxylic acid **3** in 73% yield. Finally, protection of the boronic acid moieties of **3** with 1,3-propanediol in 1,4-dioxane and subsequent

^a (i) Methyllithium, *tert*-butyllithium, and triisopropylborate in THF; (ii) aqueous HCl (pH <4); (iii) 1,3-propanediol in 1,4-dioxane; (iv) *N*-hydroxysuccinimide and DCC in 1,4-dioxane; and (v) 6-aminohexanoic acid and diisopropylamine in methanol.

**Figure 1.** Reagents utilized to prepare PDBA conjugates (PDBA-X-NHS), PBA conjugates (PBA-XX-NHS), SHA-X-Sepharose (cyanomethyl SA-X-NHS), and SHA-Sepharose (methyl SA-X-amine).

reaction with *N*-hydroxysuccinimide in the presence of DCC afforded the target *N*-hydroxysuccinimidyl ester **4** in 74% yield. Reagent **10** was prepared by the synthesis outlined in Scheme 2. The starting material, methyl 4-aminomethylsalicylate hydrochloride was prepared as described in the previous paper in this issue (*1*) and protected by reaction with di-*tert*-butyl dicarbonate and Et₃N in anhydrous methanol to produce the *tert*-butyl-carbamate (**5**) in 97% yield. Reaction of **5** with potassium

**Figure 2.** Salicylhydroxamic acid-modified Sepharose for immobilization of protein ligands for affinity chromatography.

trimethylsilanolate in THF next produced the salicylic acid (**6**) in 81% yield. Reaction of **6** with chloroacetonitrile in the presence of Et₃N produced the cyanomethyl salicylate (**7**) in 88% yield. Deprotection of **7** with hydrogen chloride gas in THF next produced the amine (**8**) as the hydrochloride salt in 91% yield. Reaction of **8** with glutaric anhydride in the presence of Et₃N in DCM produced the long-chain acid **9** in 89% yield. Finally, reaction of **9** with *N*-hydroxysuccinimide and DCC in THF afforded the target *N*-hydroxysuccinimidyl ester (**10**) in 80% yield.

SHA-X-Sepharose. The preparation of SHA-X-Sepharose is outlined in Figure 3. A suspension of EAH Sepharose 4B in bicarbonate buffer, pH 9.8, was reacted with **10** to produce the immobilized synthetic intermediate **11**, which was subsequently reacted with excess aqueous hydroxylamine, pH 10.0, to produce SHA-X-Sepharose (**12**). The SHA concentration of the modified Sepharose was estimated from the absorbance at 260 nm. Unfortunately, the analytical method does not differentiate among immobilized cyanomethyl salicylate intermediate (**11**), immobilized salicylic acid (potentially resulting from alkaline hydrolysis of cyanomethyl salicylate), and immobilized SHA (**12**). Consequently, some percentage of the estimated SHA concentration may not be available for PBA-SHA complex formation.

The preparation of SHA-X-Sepharose from EAH Sepharose 4B by reaction with **10** affords an affinity chromatographic support with an average of from 3.5 to 7.0 μ mol of SHA/mL of gel, whereas, the preparation of SHA-Sepharose from CNBr-activated Sepharose 4B by

Table 1. Incorporation Ratios and Enzymatic Activity of Alkaline Phosphatase Conjugates Prepared from Either PBA-XX-NHS or PDBA-X-NHS

reagent	input ratio ^a	incorporation ratio ^b	enzymatic activity (%) ^c
PBA-XX-NHS	5:1	4:1	61
PBA-XX-NHS	10:1	6:1	47
PBA-XX-NHS	50:1	18.5:1	18
PDBA-X-NHS	5:1	3:1	54
PDBA-X-NHS	10:1	4.5:1	44
PDBA-X-NHS	50:1	11.5:1	29

^a Input ratio is defined as the ratio of moles of reagent introduced per mole of protein modified. ^b Incorporation ratio is defined as the ratio of moles of reagent incorporated per mole of protein modified. ^c Alkaline phosphatase activity of conjugates determined with *p*-nitrophenyl phosphate substrate relative to unconjugated alkaline phosphatase and reported as the average value obtained for five determinations.

reaction 12 affords an affinity chromatographic support with an average of from 1.5 to 3.0 μmol of SHA/mL of gel. In neither instance does the analytical method differentiate between the immobilized synthetic intermediates and salicylhydroxamic acid itself. Consequently, in neither instance is it possible to exactly determine the extent to which the intermediates are amidated. The cyanomethyl ester was selected to supersede the methyl ester as an immobilized intermediate due to the greater reactivity exhibited by cyanomethyl esters with respect to amidation by α -nucleophiles such as hydroxylamine as well as their resistance toward alkaline hydrolysis (8–12).

Enzymatic Activity of PBA- and PDBA-AP Conjugates. An alkaline phosphatase known to be particularly sensitive with respect to conjugation was intentionally selected to investigate the impact of either PBA or PDBA conjugation on biological activity in a model system. Table 1 summarizes the incorporation ratios obtained (moles of reagent incorporated per mole of protein modified) corresponding to each molar excess of reagent introduced as well as the enzymatic activity associated with each of the conjugates. At identical input ratios PBA-XX-NHS affords somewhat higher incorpora-

tion ratios than PDBA-X-NHS. At similar incorporation ratios the PBA moiety appears somewhat less detrimental than the PDBA moiety with respect to retention of enzymatic activity. In neither instance is the difference particularly pronounced. These observations may be attributable to the longer spacer associated with the PBA reagent, which is 12 atoms in length, as compared to the PDBA reagent, which is only 8 atoms in length (see Figure 1).

Immobilization of PBA-AP and PDBA-AP Conjugates on SHA-X-Sepharose. Table 2 summarizes the immobilization efficiency of alkaline phosphatase conjugates on SHA-X-Sepharose. Immobilization of PDBA-AP on SHA-X-Sepharose by boronic acid complex formation is illustrated in Figure 3. In the previous paper in this issue, we concluded that incorporation of a minimum of six PBA moieties was necessary to ensure efficient immobilization and subsequent stability of the immobilized species with respect to both alkaline and acidic washes (1). For PBA, the results reported here support that conclusion. However, incorporation of only three PDBA moieties affords performance comparable to that of six PBA moieties. Since each PDBA moiety is comprised of two boronic acids, this observation suggests that six boronic acids, either in the form of three PDBA moieties or six PBA moieties remains the requisite number of boronic acids to ensure ideal conjugate performance. In all probability, this conclusion is somewhat dependent upon the SHA concentration of the chromatographic support (see below). The question arises as to how many of the boronic acids incorporated into a conjugate are complexed, on average, with immobilized SHA. Since it is unlikely that both of the boronic acids associated with a single PDBA moiety are simultaneously complexed with SHA as model complexes of the type $\text{PDBA} \cdot (\text{SHA})_2$ have not been detected by either ^{11}B NMR or mass spectrometry, and since a PDBA conjugate with an incorporation ratio of only 3:1 affords efficient immobilization and subsequent stability, we conclude that on average either two or three of the boronic acid moieties associated with the conjugate must be simultaneously

Figure 3. Preparation of SHA-X-Sepharose and AP-PDBA·SHA-X-Sepharose. EAH Sepharose 4B is reacted with cyanomethyl SA-X-NHS (**10**) under alkaline aqueous conditions to afford a synthetic intermediate (**11**). Reaction of **11** with excess alkaline aqueous hydroxylamine affords SHA-X-Sepharose (**12**). PDBA-AP, prepared by conjugation of the lysine amino acid side-chains of alkaline phosphatase, is immobilized on SHA-X-Sepharose by formation of the PBA·SHA complex. The illustration may represent an oversimplification in that indirect evidence suggests that immobilization results from a polyvalent interaction involving at a minimum formation of either two or three PBA·SHA complexes.

Table 2. Immobilization of PBA-AP and PDBA-AP on SHA-X-Sepharose and Affinity Chromatography of anti-Alkaline Phosphatase on PBA-AP·SHA-X-Sepharose and PDBA-AP·SHA-X-Sepharose

AP conjugate (incorporation ratio ^a)	AP immobilized (mg) ^b	αAP retained (mg) ^c	pH 11 αAP recovered (mg) ^d	pH 2.5 αAP recovered (mg) ^e	total αAP recovered (mg)
PBA (4:1)	1.76 (88%)	1.42	0.93 (66%) ^f	0.43 (30%) ^f	1.36 (96%) ^f
PBA (6:1)	1.81 (90%)	1.42	0.68 (48%) ^f	0.27 (19%) ^f	0.95 (67%) ^f
PBA (18.5:1)	1.94 (97%)	1.22	0.38 (31%)	0.11 (9%)	0.49 (40%)
PDBA (3:1)	(>95%)	1.40	0.42 (30%)	0.43 (31%)	0.85 (61%)
PDBA (4.5:1)	(>95%)	1.37	0.38 (28%)	0.15 (11%)	0.53 (39%)
PDBA (11.5:1)	(>95%)	1.03	0.31 (30%)	0.08 (8%)	0.39 (38%)

^a Incorporation ratio is defined as the ratio of moles of reagent incorporated per mole of protein modified. ^b AP conjugates (2.0 mg) in 5 mL of 100 mM sodium bicarbonate buffer, pH 8.3, were immobilized on 0.5 mL of SHA-X-Sepharose (5.5 μmol of SHA/mL of gel). ^c Crude αAP (5 mg) in 5 mL of 100 mM sodium bicarbonate buffer, pH 8.3, was applied to either PBA-AP·SHA-X-Sepharose or PDBA-AP·SHA-X-Sepharose. ^d Recovered in 10 mL of 50 mM sodium phosphate buffer, pH 11.0. ^e Recovered in 10 mL of 100 mM glycine hydrochloride buffer, pH 2.5. ^f SDS-PAGE revealed the presence of contaminating PBA-AP in recovered αAP.

complexed with immobilized SHA. Alternatively, these results could be interpreted to imply at any time only a single boronic acid complex need be present to retain the immobilized species but that as many as six boronic acid moieties may be required to ensure that on average at least one boronic acid complex is always present.

Affinity Chromatography of anti-Alkaline Phosphatase on PBA-AP·SHA-X-Sepharose and PDBA-AP·SHA-X-Sepharose. Results obtained for purification

of αAP on PBA-AP·SHA-X-Sepharose and PDBA-AP·SHA-X-Sepharose are also summarized in Table 2. In every instance, AP columns efficiently retained αAP at pH 8.3, which was subsequently recovered in either an alkaline (pH 11.0) or acidic (pH 2.5) eluent. However, the results involving PBA-AP·SHA-X-Sepharose are misleading in that they represent an overestimate of from about 1 to 10% with respect to protein recovery owing to the presence of trace amounts of contaminating PBA-

^a PDBA- α Human IgG (1.5 mg) was immobilized on SHA-X-Sepharose (0.25 mL). ^b Large excess of ChromPure proteins (purified whole molecule immunoglobulins from normal Human serum) applied so that the amount retained was proportional to the amount of immobilized PDBA- α Human IgG. ^c Recovered in 10 mL of 50 mM sodium phosphate buffer, pH 11.0. ^d Recovered in 10 mL of 100 mM glycine hydrochloride buffer, pH 2.5. ^e PDBA- α Human IgG detected in Western blot with enzyme-linked detection employing α Goat IgG-AP for detection of (Goat) PDBA- α Human IgG. ^f Trace amounts of PDBA- α Human IgG detected in Western blot with enzyme-linked detection employing α Goat IgG-AP for detection of (goat) PDBA- α Human IgG.

Figure 4. (A) SDS-PAGE of fractions containing α AP recovered from SHA-X-Sepharose in pH 11.0 eluent; (B) SDS-PAGE of fractions containing α AP recovered from SHA-X-Sepharose in pH 2.5 eluent; (1) α AP recovered from PBA-AP (4:1 incorporation ratio) column; (2) α AP recovered from PBA-AP (6:1 incorporation ratio) column; (3) α AP recovered from PBA-AP (18.5:1 incorporation ratio) column; (4) α AP recovered from PDBA-AP (3:1 incorporation ratio) column; (5) α AP recovered from PDBA-AP (4.5:1 incorporation ratio) column; (6) α AP recovered from PDBA-AP (11.5:1 incorporation ratio) column. Note that the arrows indicate the presence of contaminating PBA-AP in fractions recovered from PBA-AP-SHA-X-Sepharose columns. The mobility of PBA and PDBA conjugates is related to the incorporation ratio with low incorporation ratios affording the least reduction in electrophoretic mobility and high incorporation ratios affording the greatest reduction in electrophoretic mobility.

AP that was revealed by SDS-Page. Figure 4 illustrates SDS-PAGE analyses of α AP fractions recovered from both PBA-AP-SHA-X-Sepharose and PDBA-AP-SHA-

X-Sepharose columns at pH 11.0 and 2.5. PBA-AP conjugates with average incorporation ratios of 4:1 and 6:1 were found to be present as contaminants in both high pH and low pH eluent fractions, indicating that some portion of the immobilized conjugate was unstable with respect to the elution conditions. On the other hand, SDS-PAGE revealed that both the high pH and low pH eluent fractions recovered from PDBA-AP-SHA-X-Sepharose columns were essentially free of contaminating conjugate.

Affinity Chromatography of *anti*-Alkaline Phosphatase on PDBA-AP-SHA-X-Sepharose, AP-Affi-Gel 10, and AP-Affi-Gel 15. The performance of PDBA-AP-SHA-X-Sepharose was compared to that of AP-Affi-Gel 10 and AP-Affi-Gel 15 with respect to affinity chromatography of *anti*-alkaline phosphatase so as to compare the approach described herein with covalent immobilization of a protein ligand. Affi-Gel 10 and Affi-Gel 15 are activated immunoaffinity supports for coupling ligands with primary amino groups by reaction with support-bound *N*-hydroxysuccinimidyl esters (7). Similar to Sepharose in many respects, Affi-Gels are prepared from beaded cross-linked agarose and are reported by the manufacturer (Bio-Rad) to have 15 μ mol of *N*-hydroxysuccinimidyl ester/mL of gel. Affi-Gel 10 contains a hydrophilic 10-atom spacer, whereas Affi-Gel 15 contains a hydrophilic 15-atom spacer with a central quaternary amine. Results for affinity chromatography of α AP on immobilized AP are summarized in Table 3. PDBA-AP-SHA-X-Sepharose proved significantly more efficient than both AP-Affi-Gel 10 and AP-Affi-Gel 15 with respect to immobilization of alkaline phosphatase, retention of *anti*-alkaline phosphatase, and recovery of *anti*-alkaline phosphatase at high pH. PDBA-AP-SHA-X-Sepharose proved comparable to both AP-Affi-Gel 10 and AP-Affi-Gel 15 with respect to recovery of *anti*-alkaline phosphatase at low pH. From a practical standpoint, immobilization of PDBA-AP on SHA-X-Sepharose proved far less laborious and time consuming (70 min, including preparation and desalting of PDBA-conjugate) than immobilization of AP on either Affi-Gel 10 (210 min) or Affi-Gel 15 (330 min).

Purification of Human IgG on PDBA- α Human IgG·SHA-X-Sepharose. The purification of Human IgG on PDBA- α Human IgG·SHA-X-Sepharose was employed to investigate the impact of immobilized SHA concentration on the performance of the PDBA·SHA system. Goat *anti*-human IgG was conjugated with PDBA-X-NHS at an input ratio of 10:1 to afford a conjugate (PDBA- α Human IgG) with an average incorporation ratio of only 1.5:1. PDBA- α Human IgG was then immobilized on each of three SHA-X-Sepharose columns with SHA concentrations of 7.1, 4.5, and 4.1 μ mol of SHA/mL of gel. The columns were washed with low pH eluent to remove any loosely complexed conjugate prior to equilibration. A protein fraction from normal human serum comprised primarily of whole molecule immunoglobulins was applied to each of the columns and Human IgG was recovered by eluting the columns with high pH eluent followed by low pH eluent. The results are summarized in Table 4. The fractions were reduced, separated by SDS-PAGE, blotted onto membranes, and analyzed by enzyme-linked immunological detection employing either monoclonal *anti*-human IgG-alkaline phosphatase conjugate (α Human IgG-AP) for detection of human IgG or rabbit *anti*-goat IgG-alkaline phosphatase conjugate (α Goat IgG-AP) for detection of PDBA- α Human IgG (Figure 5). The Western blot detected with *anti*-goat IgG-AP confirmed the immunoreactivity of the conjugate with respect to PDBA- α Human IgG and revealed the presence of trace amounts of PDBA- α Human IgG in the low pH fractions obtained from each of the columns (although PDBA- α Human IgG is barely visible in the low pH fraction recovered from the SHA-X-Sepharose column having 7.1 μ mol of SHA/mL of gel). Qualitatively, the amount of contaminating conjugate detected appears to be inversely proportional to the SHA concentration of the column. Owing to the low incorporation ratio of the PDBA- α Human IgG conjugate (only 1.5:1) it is somewhat remarkable that more contaminating conjugate was not detected.

We concluded above that for efficient immobilization and subsequent stability with respect to both high pH and low pH eluents, either two or three of the boronic acid moieties associated with PDBA conjugates must be available for simultaneous complex formation with immobilized SHA. The results described immediately above imply that, in this instance, only two boronic acid moieties need be available for complex formation with immobilized SHA to confer stability when the effective SHA concentration is relatively high. Since the reported incorporation ratio (1.5:1) represents an average value (implying on average three boronic acid moieties per α Human IgG), the contaminating conjugate found in the low pH fractions may have resulted from that fraction of the conjugates having only a single PDBA moiety.

It is interesting to note that empirical studies involving the purification of recombinant C-terminal polyhistidine fusion proteins on immobilized metal ion affinity chromatography columns indicate that six is the requisite number of C-terminal histidine residues needed to routinely enable efficient retention of fusion proteins on columns charged with nickel ions. This observation is particularly remarkable in light of the fact that nickel ion complexation is known to involve the participation of only two adjacent histidine residues (12–16).

CONCLUSIONS

Alkaline phosphatase conjugates prepared from either PDBA-X-NHS or PBA-XX-NHS were directly compared

Figure 5. (A) Western blot of Human IgG fractions obtained at high pH (11.0) and low pH (2.5) from PDBA- α Human IgG·SHA-X-Sepharose columns (7.1, 4.1, and 4.5 μ mol of SHA/mL of gel). Blot prepared to detect the presence of residual PDBA- α Human IgG. Stained with *anti*-human IgG-alkaline phosphatase and BCIP/NBT substrate; (B) Western blot of Human IgG fractions obtained at high pH (11.0) and low pH (2.5) from PDBA- α Human IgG·SHA-X-Sepharose columns (7.1, 4.1, and 4.5 μ mol of SHA/mL of gel). Blot prepared to detect the presence of residual PDBA- α Human IgG. Stained with rabbit *anti*-goat IgG-alkaline phosphatase and BCIP/NBT substrate.

with respect to the efficiency with which they were immobilized on SHA-X-Sepharose by PBA·SHA complex formation. For efficient immobilization, it was necessary to prepare conjugates having a minimum of either three appended PDBA moieties or six appended PBA moieties. When immobilized on high capacity SHA-X-Sepharose, alkaline phosphatase conjugates were shown to be stable with respect to both the alkaline (50 mM phosphate buffer, pH 11.0) and acidic (100 mM glycine HCl buffer, pH 2.5) buffers that were utilized to recover *anti*-alkaline phosphatase during affinity chromatography. From indirect evidence we conclude that for efficient immobilization and subsequent stability, on average either two or three boronic acid moieties associated with a protein conjugate must be available for complex formation with immobilized SHA.

Boronic acid complex formation was compared to direct covalent immobilization of alkaline phosphatase on Affi-Gel 10 and Affi-Gel 15 for affinity chromatography of

anti-alkaline phosphatase. PDBA-AP-SHA-X-Sepharose was shown to afford superior performance to both AP-Affi-Gel 10 and AP-Affi-Gel 15 with respect to immobilization of alkaline phosphatase, retention of *anti*-alkaline phosphatase at pH 11.0. Furthermore, immobilization of PDBA-AP on SHA-X-Sepharose proved both less laborious and less time-consuming than immobilization of alkaline phosphatase on either Affi-Gel 10 or Affi-Gel 15.

High capacity SHA-X-Sepharose ($\geq 7 \mu\text{mol}$ of SHA/mL of gel) was shown to afford superior performance to moderate capacity SHA-X-Sepharose (4.1–4.5 μmol of SHA/mL of gel) with respect to immobilized ligand stability at pH 11.0 and pH 2.5 when a PDBA- α Human IgG conjugate with an incorporation ratio of only 1.5:1 was immobilized.

In vivo gene delivery mediated by cationic lipids is often compromised by aggregation due to complexation with proteins in the blood. To improve the stability of cationic lipid–DNA complexes, the present study aimed to develop a novel approach in which a poly(cationic lipid) (PCL) is utilized to form stable cationic polyplexes for gene transfection. Hydrogenation of the acrylamide analogue of β AE-DMRI, the polymerizable precursor of PCL, provided a monomeric lipid derivative (MHL) which was used for direct comparison of corresponding lipoplex stability, toxicity, and transfection activity. Various formulations of cationic liposomes, such as MHL, MHL-cholesterol (Chol), PCL, PCL-Chol, DOTAP-Chol, and commercially available lipofectamine were generated and examined in this study. The new poly(cationic lipid) did not display any significant toxicity to rat hepatocytes or Hep G₂ cells as indicated by an LDH leakage assay. Furthermore, PCL was significantly less toxic than MHL, DOTAP-Chol or lipofectamine. Suspensions of PCL were resistant to aggregation even after 24 h of exposure to solutions containing 50 and 100% fetal bovine serum (FBS). In contrast, suspensions of lipofectamine extensively aggregated after 24 h of exposure to 50% FBS. To examine the influence of lipid polymerization on gene transfer activity, liposome-mediated transfections of a luciferase vector (pGL₃) were performed in Hep G₂ and Alexander cell lines. The luciferase activity of the PCL formulations in Hep G₂ cells were similar to those of the MHL, DOTAP-Chol and lipofectamine formulations, demonstrating that lipid polymerization does not compromise transfection activity. In comparison to the monomeric precursor MHL and to the industry transfection standards DOTAP and lipofectamine, the novel poly(cationic lipid) exhibited the lowest cytotoxicity, was the most resistant to serum-induced aggregation and had comparable transfection activity when coformulated with cholesterol. This novel polymerization approach for the development of stable and active polyplexes may prove a valuable alternative for in vivo gene delivery.

INTRODUCTION

The prospect for improving nonviral methods of DNA complexation and transfer to mammalian cells continues to motivate researchers in a variety of disciplines. Among the many constructs that have been used to facilitate the intracellular delivery of DNA, cationic lipids and cationic polymers have received the greatest attention (1, 2), and consequently, the technology has since advanced to clinical trials (3, 4). Over the course of the past several years it has become clear that the use of cationic lipid systems for in vivo DNA transfection is compromised by substantial problems that are uniquely dependent on the route of lipid–DNA complex (lipoplex) administration. For example, the systemic administration of lipoplex preparations results in their rapid clearance due to destabilization arising from interactions with serum proteins (5). This obstacle prompted the development of stabilized plasmid lipid particles wherein poly(ethylene glycol) (PEG) chains are conjugated to the surface of lipoplex preparations to provide a measure of steric protection (6). Issues of practicality also point toward the development of more stable lipoplex preparations. For

instance, the majority of transfection protocols require that lipoplexes are freshly prepared prior to use to avoid problems associated with lipoplex aggregation (7). Given these and other challenges, we have focused much of our attention on developing new lipid-based constructs to improve lipoplex transfection activity (8, 9).

One approach that has been used to enhance stability and prevent aggregation of lipid-based assemblies is liposome polymerization (10, 11). We have recently developed methods for the polymerization of a novel cationic acrylamide lipid and reconstitution of the resultant poly(lipid) to yield stable cationic vesicles (12). We now report our observations on the ability of this cationic polymer to mediate gene delivery. Although cationic polymers such as poly(L-lysine) (13, 14), poly(ethyleneimine) (15, 16), poly(methacrylate) (17), and polyamidoamine dendrimers (18, 19) have been well studied, to our knowledge the use of a poly(cationic lipid) as a transfection agent remains unexplored. We report herein the first examples of poly(lipid)-mediated DNA transfection and the results of stability and toxicity studies using the new cationic polymer. The attributes of lipid polymerization are defined by comparison of the poly(cationic lipid) (PCL)¹ with lipoplex preparations derived from structurally analogous monomeric cationic lipids.

^a H₂, 10% Pd/C, EtOAc, room temperature, 6 h. ^b Polymerization: (1) H₂O, dodecylmercaptan (10% w/w), sonication, 50 °C, 20 min; (2) AAPH (0.1 eq), 80 °C, 15 h.

MATERIALS AND METHODS

General Experimental Procedures. CH₂Cl₂ was distilled from CaH₂ prior to use. After reaction workup, solutions were dried using Na₂SO₄ and solvents were subsequently removed by rotary evaporation. NMR spectra were recorded with a General Electric QE-300 spectrometer (¹H at 300 MHz, ¹³C at 75 MHz). Infrared spectra were recorded with a Mattson Genesis II FTIR spectrometer. Melting points are uncorrected. Mass analysis was performed by UCR Mass Spectrometry (Riverside, CA). All sonications were performed in a bath sonicator (Laboratory Supplies Inc., Hicksville, NY).

Lipids. The cationic liposomal formulation lipofectamine (DOSPA-DOPE, 3:1 w/w) was obtained from Gibco Life Technologies (Gaithersburg, MD). *N*-(2,3-(dioleoyloxy)propyl)-*N,N,N*-trimethylammonium chloride (DOTAP) was purchased as a chloroform solution from Avanti Polar Lipids (Alabaster, AL). Cholesterol (Chol) was purchased from Sigma Chemical Company (St. Louis, MO).

Synthesis of the polymerizable acrylamide lipid (AL) (Scheme 1) proceeded from commercially available 3-bromo-1,2-diol by bis(esterification) with myristoyl chloride (12). Bromide displacement using *N,N'*-dimethylethylenediamine (15 equiv, DMF, 70 °C, 45 min) installed the amine-linker required for subsequent attachment of the polymerizable acrylamide group. Direct treatment of the crude displacement product with acryloyl chloride (1.5 equiv, CH₂Cl₂, room temperature, 2 h) followed by chromatographic purification afforded the corresponding acrylamide lipid. Methyl iodide quaternization and subsequent chloride counterion exchange using an established protocol (20) gave cationic acrylamide lipid AL.

Synthesis of PCL (Scheme 1) was accomplished by first preparing a 5 mL aqueous liposome suspension containing AL (50 mg, 73.0 μmol) and *n*-dodecylmercaptan (5 mg, 25.0 μmol). The lipid mixture was vigorously mixed for 30 s and then sonicated for 20 min at 50 °C to afford

a clear suspension. To the liposome suspension was added 2,2'-azobis(2-methylpropionamidine) dihydrochloride (AAPH) (2.0 mg, 7.3 μmol) as a solution in 0.5 mL of H₂O. The resultant mixture was degassed using nitrogen and then placed in a constant-temperature bath heated to 80 °C. After 15 h, the solvent was removed and the polymerized product was analyzed by IR, ¹H, and ¹³C NMR spectroscopy; IR (neat) 2917, 2856, 1747, 1638, 1169 cm⁻¹; ¹H NMR (CDCl₃) δ 0.83 (t, *J* = 6.5 Hz, 6H), 1.25 (m, 40H), 1.57 (m, 4H), 2.32 (m, 4H), 3.39 (m, 3H), 3.53 (m, 6H), 3.87 (m, 4H), 4.10 (m, 2H), 4.31 (m, 1H), 4.53 (m, 1H), 5.66 (m, 1H); ¹³C NMR (CDCl₃) δ 14.0, 22.6, 24.7, 29.0–29.6 (four signals) 31.9, 33.8, 34.1, 36.6, 42.3, 51.7, 62.1, 63.1, 64.0, 65.5, 172.7, 173.1. In all cases examined, the vinyl proton signals of monomer AL (δ 6.57, 6.29, and 5.73 ppm) were absent in the product spectra, suggesting at least a 95% conversion of monomer to polymer. The poly(cationic lipid) was stored at 4 °C without detectable decomposition for periods up to six months.

AL was hydrogenated to obtain a more representative monomer for direct comparison with PCL. A solution of AL (50 mg, 79 μmol) in ethyl acetate (2 mL) at room temperature was treated with 10% palladium on carbon (20 mg). The suspension was placed under an atmosphere of hydrogen and stirred 6 h at which time the suspension was diluted with ethyl acetate and filtered through a short pad of Celite. Removal of the solvent afforded the monomeric hydrogenated lipid (MHL) (46 mg, 92%) as an amorphous white solid, mp = 109–110 °C; TLC, *R*_f = 0.32 (9:1, CH₂Cl₂:MeOH); IR (neat) 2921, 2853, 1747, 1635, 1172 cm⁻¹; ¹H NMR (CDCl₃) δ 0.83 (t, *J* = 6.2 Hz, 6H), 1.06 (t, *J* = 6.7 Hz, 3H), 1.22 (m, 40H), 1.54 (m, 4H), 2.29 (m, 6H), 3.16 (s, 3H), 3.38 (s, 3H), 3.41 (s, 3H), 3.86 (m, 2H), 4.02 (m, 4H), 4.34 (d, *J* = 13.5 Hz, 1H), 4.46 (dd, *J* = 1.5, 13.2 Hz, 1H), 5.57 (m, 1H); ¹³C NMR (CDCl₃) δ 5.0, 13.9, 22.5, 24.7, 25.7, 29.5–29.0 (four signals), 31.8, 33.8, 34.1, 35.5, 42.3, 51.0, 61.5, 63.3, 63.9, 65.8, 171.5, 172.7, 175.0; HRMS (C₃₉H₇₇O₅N₂, M⁺) calcd, 653.5832; found, 653.5865.

Liposome Formulations. Monomer MHL and polymer PCL were hydrated separately using 10 mM Tris-HCl buffer containing NaCl (150 mM) at a concentration of 1 mg/mL (1.5 mM cationic construct). The hydrated lipid suspensions were vigorously mixed and then sonicated for 5 min at 50 °C to afford turbid liposome suspensions. To generate the cholesterol-containing liposome formulations of MHL, PCL, or DOTAP, the lipids were dissolved separately in chloroform and mixed with cholesterol at a 1:1 molar ratio, except for DOTAP, which was mixed with cholesterol in a 3:1 molar ratio. The chloroform was evaporated and the thin lipid films were dried using a stream of nitrogen followed by drying under vacuum for 30 min. The MHL-Chol and DOTAP-Chol mixtures were subsequently hydrated using 10 mM Tris-HCl buffer containing NaCl (150 mM) at a concentration of 1 mg/mL (1.5 mM cationic lipid) and then briefly sonicated at 50 °C. The PCL-Chol mixture was hydrated in identical fashion and at the same concentration, but was sonicated 20 min at 50 °C. Lipofectamine was purchased from Gibco Life Technologies and used as received.

Cytotoxicity Study. Sprague–Dawley rats were purchased from Harlan Laboratory, Inc. (Indianapolis, IN), kept at 12-h light/dark cycles and fed a commercial chow diet. The protocol for rat hepatocyte isolation was approved by the UCD Institutional Animal Use and Care Administrative Advisory Committee. Rat hepatocytes were isolated by two-step collagenase digestion according

¹ Abbreviations: AL, acrylamide lipid; Chol, cholesterol; DOPE, 1- α dioleoyl phosphatidylethanolamine; DOTAP, *N*-(2,3-(dioleoyloxy)propyl)-*N,N,N*-trimethylammonium chloride; FBS, fetal bovine serum; LDH, lactate dehydrogenase; MHL, monomeric hydrogenated lipid; PCL, poly(cationic lipid).

Figure 1. Cytotoxicity of liposomal formulations to isolated rat hepatocytes. Rat hepatocytes were exposed to cationic liposomes (final concentration of lipofectamine = 14 $\mu\text{g}/\text{mL}$, final concentration of all other lipid agents = 20 $\mu\text{g}/\text{mL}$) for 24 h. LDH release from the cells, an indication of cytotoxicity, expressed as percentage of cell death based on the control levels. Each data point represents the mean value of $n = 4$ and the standard deviation from the mean. (**) $p < 0.01$ compared to MHL; (#) $p < 0.05$ compared to PCL. Chol = cholesterol, DOTAP = *N*-(2,3-(dioleoyloxy)propyl)-*N,N,N*-trimethylammonium chloride, LDH = lactate dehydrogenase, Lipofect. = lipofectamine, PCL = poly(cationic-lipid), MHL = monomeric hydrogenated lipid.

to a method reported previously (21) and cultured at 37 °C in 5% CO₂ and air with Williams' medium E with 10% fetal bovine serum (FBS). The cells were cultured overnight and washed with 10 mM PBS, pH 7.4, before being subjected to the cytotoxicity experiments. Hep G₂ cells were cultured in MEM medium with 10% FBS, and the cell passage was performed one or 2 days before analysis in Costar 12-well plates (250 000 cells/well) until the cell culture was 80–90% confluent.

All liposome formulations except lipofectamine were added directly to the cultured rat hepatocytes to reach a final cationic lipid concentration of 20 $\mu\text{g}/\text{mL}$. In the case of lipofectamine, the liposome formulation was added directly to the cultured rat hepatocytes to achieve a final concentration of 14 $\mu\text{g}/\text{mL}$. Experiments in Hep G₂ cells were performed using several concentrations of cationic lipids (10, 20, and 40 $\mu\text{g}/\text{mL}$). The culture medium was sampled 24 h after the cells were exposed to the lipid agents. Lactate dehydrogenase (LDH) leakage from the cells was determined by a commercially available kit from Roche Molecular Biochemicals (Indianapolis, IN), and the cytotoxicity was calculated based on a formula provided by the manufacturer and expressed as percentage of cell death based on the control levels.

Particle Size Determination: Stability Study. The particle sizes of liposome formulations were measured using a laser-based, submicron particle size analyzer from Beckman Coulter, Inc as previously described (22). To test the stability of these liposome suspensions against culture medium containing serum, 200 μL of each liposome suspension was added to 0.5 mL of Williams' medium E containing 10% FBS and then diluted with Tris-HCl buffer to a total volume of 3.5 mL. After equilibration for 2 min, the particle size was measured. To test the stability of MHL, PCL and lipofectamine at higher serum concentrations and longer time intervals, a series of three FBS solutions were prepared containing 10, 50, and 100% FBS by diluting FBS with MEM medium to the appropriate concentration. To these solutions was added a 50–100 μL aliquot of the cationic lipid suspensions. Particle size measurements and size distributions were recorded at 5, 30, 50, 75, and 120 min. A measurement was also taken at 24 h to examine the long-term effect of serum exposure.

Transfection Protocols. Plasmid vector pGL₃-Control which encodes firefly luciferase was purchased from

Promega, Inc. (Madison, WI) and transformed (amplified) into competent *Escherichia coli* cells from Gibco Life Science Technologies (Grand Island, NY). The plasmid DNA was extracted from overnight cultures of the competent cells and purified by affinity chromatography with an Endofree plasmid extraction kit from Qiagen, Inc. (Valencia, CA). The quality of the DNA was determined by UV spectroscopy and agarose gel electrophoresis (1.0% agarose gel) with 0.5 mg/mL ethidium bromide after cleavage by specific restriction endonucleases (23). The DNA concentration was quantitated spectrophotometrically. The plasmid DNA was frozen at –20 °C until immediately prior to use.

The protocol for transfection followed that recommended by the manufacturer for the use of lipofectamine. Hep G₂ cells and Alexander cells were plated at 250 000 cells/well on a standard Costar 12-well plate 48 h prior to transfection. Cells were approximately 60–70% confluent at the time of transfection. Solutions of plasmid DNA in 100 μL of Opti-MEM were mixed gently with 100 μL Opti-MEM solutions containing cationic agents, and then the lipid–DNA suspensions were diluted to a final volume of 0.5 mL. Typically (e.g., using PCL and MHL), 20 μg of the cationic lipid was used to complex 2.0 μg of the plasmid DNA, representing a cationic:DNA phosphate charge ratio of 5:1. Lipofectamine was used at the lipid:DNA weight ratio of 14 μg of lipofectamine to 2 μg of DNA, the ratio determined for maximum expression in Hep G₂ cells. Cationic lipid–DNA complexes were incubated for 15–25 min. The cells were washed twice with 2 mL of 10 mM PBS, pH 7.4, and then the 0.5 mL lipid–DNA solutions were added to the cells. Six hours after adding the lipid–DNA complexes to the cell culture, the Opti-MEM medium was replaced with MEM containing 10% FBS. The transfected cells were lysed following two washes with PBS 48 h after transfection. The luciferase activity in the lysates was measured with a luciferase kit from Promega Inc. and a luminometer from EG&G Wallac (Gaithersburg, MD).

Statistical Analysis. Particle size data were taken directly from the laser light scattering instrument. LDH leakage data and luciferase activity were evaluated by means of the one-way variance test and Newman-Keuls test for multiple comparisons between groups. A p -value of less than 0.05 was considered as statistically significant.

Figure 2. Cytotoxicity of liposomal formulations to Hep G₂ cells. Hep G₂ cells were exposed to cationic liposomes of final cationic lipid/polymer concentrations ranging from 0–40 μg/mL. LDH release from the cells, an indication of cytotoxicity, was measured after 24 h and is expressed as a percentage of cell death based on the control levels. (○) PCL; (●) PCL-Chol; (□) MHL; (■) MHL-Chol. Each data point represents the mean value of *n* = 4, and the standard deviation from the mean.

RESULTS AND DISCUSSION

To examine the influence of cationic lipid polymerization on cytotoxicity, we compared the liposome formulations of monomer MHL, MHL-cholesterol, polymer PCL, PCL-cholesterol, DOTAP-cholesterol, and lipofectamine in a cytotoxicity assay using rat hepatocytes (Figure 1). We examined the influence of cholesterol in these formulations since the addition of cholesterol to cationic liposome preparations such as DOTAP has been reported to improve both transfection activity (24) and resistance to serum (25). Isolated rat hepatocytes in primary cultures were treated with the cationic agents at the concentrations indicated in Figure 1, which are the concentrations that were found to be optimal for DNA transfection (vide infra). The culture medium was sampled after 24 h and LDH activity in the medium was assayed using a commercially available kit. Relative cytotoxicity was calculated based on the control experiment and expressed as the percentage of cell death.

It is clear from Figure 1 that MHL alone caused significantly greater cell death compared to the control, and that the polymer PCL did not display obvious cytotoxicity to isolated hepatocytes at 20 μg/mL. Comparison of PCL with its monomeric analogue MHL reveals that lipid polymerization significantly reduced cytotoxicity to rat hepatocytes. This result is notable since cationic polymers are generally believed to elicit greater cytotoxic responses (26, 27). The cytotoxicity of the popular transfection formulations DOTAP-Chol (20 μg/mL) and lipofectamine (14 μg/mL) also led to significant LDH leakage from the isolated hepatocytes, and their toxicity was more profound than PCL or PCL-Chol.

To further examine the influence of cationic lipid polymerization on cytotoxicity, we exposed Hep G₂ cells to liposome formulations of MHL, MHL-Chol, PCL, and PCL-Chol at varying concentrations (Figure 2). In each case, the culture medium was sampled at 24 h and LDH activity in the medium was assayed as previously described. All formulations were relatively nontoxic (<2% cell death) at 20 μg/mL, which is the concentration that was used for the transfection of Hep G₂ cells. However, at the 40 μg/mL dose, MHL caused significantly greater cell death than its polymerized analogue PCL. The addition of cholesterol to MHL and PCL formulations significantly reduced their respective cytotoxicity in Hep

Table 1. Particle Size Distribution of PCL Liposomes

time (min)	no serum	10% serum	50% serum	100% serum

G₂ cells. The cytotoxicity results show that polymerization of a cationic acrylamide lipid does not impart cytotoxicity, as has been observed with other polymeric constructs, but rather significantly reduces cytotoxicity in hepatocytes and Hep G₂ cells.

We next investigated the susceptibility of PCL formulations to serum-induced aggregation. The change in particle size of a liposome formulation is an important index of stability. Lipoplex aggregation with serum components has been shown to be detrimental to *in vivo* transfection activity (5). We examined the size distribution of PCL and the representative cationic lipid standards by dispersion in Tris-HCl buffer (Figure 3). PCL and its cholesterol formulation PCL-Chol exhibit a narrow range of particle size distribution (275 ± 50 nm) similar to lipofectamine (340 ± 110 nm) and slightly larger than monomeric MHL and its cholesterol formulation MHL-Chol (180 ± 61 nm). On exposure to medium containing 10% fetal bovine serum (FBS), the sizes of the MHL and MHL-Chol liposomes were increased 213 and 167%, respectively, relative to those in Tris-HCl buffer. When the DOTAP-Chol formulation was dispersed in serum-containing medium, the average particle size was more than 10-fold larger than its original size suggesting extensive aggregation. However, exposure of the PCL and PCL-Chol formulations to the medium containing serum minimally increased the average particle size by 25 and 18%, respectively. Resistance to aggregation under this short period of exposure also was observed when lipofectamine was subjected to the serum conditions, which is not unexpected since resistance to 10% serum was noted previously (28).

To test the stability of PCL and MHL liposomes at higher serum concentrations with longer time intervals, a series of three FBS solutions were prepared containing 10, 50, and 100% FBS. Particle size measurements and size distributions were recorded at 5, 30, 50, 75, and 120 min. A measurement was also taken at 24 h to examine the long-term effect of serum exposure. The liposomal formulations of PCL were remarkably stable to all serum concentrations and resisted aggregation even when exposed to serum for up to 24 h (Table 1). In contrast, the liposome formulations of MHL were dramatically affected, even with exposure to only 10% serum, producing an erratic distribution of lipid aggregates (Table 2).

For additional comparison, exposure of lipofectamine to an elevated serum level also revealed that the PCL

Figure 3. Particle size distribution of cationic lipid formulations and the results of exposure to serum. Solid bars represent particle size of lipid formulations in Tris-HCl buffer. Hashed bars represent particle size of lipid formulations in Williams' medium E containing 10% FBS and Tris-HCl buffer wherein 200 μ L of each lipid suspension was added to 0.5 mL Williams' medium E containing 10% FBS and then diluted with Tris-HCl buffer to a total volume of 3.5 mL. The error bars represent the polydispersity.

Figure 4. Influence of prolonged exposure to 50% FBS on particle size. PCL and lipofectamine suspensions were exposed 50% FBS. A 100 μ L aliquot of the cationic lipid suspension was added to 3.5 mL of 50% FBS in a cuvette. Particle size measurements were recorded at the times indicated. The error bars represent the polydispersity.

formulation is superior in its ability to resist serum-induced aggregation. When lipofectamine was exposed to 50% FBS, the mean particle size increased from 358 ± 7 nm at 120 min to 2206 ± 311 nm by 24 h (Figure 4). In contrast, the PCL formulation showed no significant increase in particle size, maintaining a size range from 309 ± 45 to 277 ± 25 nm.

Having established that PCL has low cytotoxicity and is resistant to serum-induced aggregation, we examined PCL formulations as transfection agents in two hepatoma cell lines (Figure 5). Transfection experiments were performed on Hep G₂ and Alexander cells using the pGL₃-Control vector encoding firefly luciferase. For purposes of direct comparison, lipid- and polymer-DNA complexes were prepared at a 5:1 cationic:DNA phosphate charge ratio. Preliminary transfection experiments (data not shown) had established that the 5:1 charge ratio was effective for MHL- and PCL-mediated transfections, and the 5:1 charge ratio also had been recommended for DOTAP-mediated transfection (29). Our preliminary transfection experiments determined that lipofectamine was most effective in Hep G₂ cells at a lipid/DNA ratio of 14/2 μ g. The data shows that cationic lipid polymerization does not compromise transfection activity (Figure 5). Comparison of monomer MHL and polymer PCL

revealed that these agents possess similar transfection efficacies in both cell lines. The 1000-fold increase in luciferase expression for MHL relative to naked DNA (control) in Hep G₂ cells was not unexpected since MHL is structurally analogous to the highly efficacious transfection agent γ AP-DLRIE (30). The corresponding cholesterol formulations of MHL and PCL also displayed similar luciferase activity in Alexander cells, each apparently unchanged by co-formulation with cholesterol. However, the influence of cholesterol was more pronounced in Hep G₂ cells where the activity of the PCL-Chol formulation was >10-fold higher than the MHL-Chol formulation. Moreover, the transfection activity of the PCL-Chol was similar to those of the well-established transfection lipids DOTAP-Chol and lipofectamine in Hep G₂ cells.

To probe the influence of charge ratio on the transfection activity of PCL formulations, we transfected Hep G₂ cells using PCL polyplexes having PCL:DNA and PCL-Chol:DNA charge ratios of 1.5:1, 2.5:1, 5:1, and 10:1. The data shows that PCL formulations efficiently deliver DNA to Hep G₂ cells at most charge ratios examined (Figure 6). No significant differences in transfection activity were noted for the activity of PCL from the 1.5:1 to 5:1 range. At the highest charge ratio of 10:1, a slight

Figure 5. Transfection of Hep G₂ cells (solid bars) and Alexander cells (hashed bars). Cationic vesicles were prepared from the cationic lipid panel and poly(cationic lipid) with and without equimolar cholesterol and were used to deliver 2 μ g DNA/well. All lipoplex and polyplex preparations were formulated at a 5:1 cationic lipid:DNA phosphate charge ratio except lipofectamine, which was used at a lipid:DNA ratio of 14:2 μ g. Luciferase activity in the cell lysates was determined 48 h after transfection and expressed as relative light units (RLU). Each data point reflects the mean value from $n = 6$, and the standard deviation from the mean.

Figure 6. Influence of cationic lipid:DNA phosphate charge ratio on transfection of Hep G₂ cells using PCL (solid bars) and PCL-Chol (hashed bars). Cationic vesicles were prepared from the lipid polymer with and without equimolar cholesterol, and were used to deliver 2 μ g of DNA/well. All polyplex preparations were formulated at charge ratios ranging from 1.5:1 to 10:1. Luciferase activity in the cell lysates was determined 48 h after the transfection and expressed as relative light units (RLU). Each data point represents the mean value from $n = 4$, and the standard deviation from the mean.

drop in PCL-mediated transfection was noted. Coformulation of PCL with cholesterol at a 1:1 molar ratio appears to slightly improve the transfection activity at all ratios examined. We were gratified to note efficient delivery of DNA at the low charge ratio of 1.5:1 using both the PCL and PCL-Chol formulations since most cationic polymers for gene transfer typically require higher charge ratios (2).

In summary, we have presented the first examples of poly(lipid)-mediated DNA transfection. The absolute transfection activity of the novel poly(lipid) PCL, and certainly the improvement in the transfection activity over its monomeric form MHL, documents that the lipid polymerization process may be a useful method for converting transfection-active agents into polymers which have lower cytotoxicity and improved serum resistant properties with comparable transfection activity. In comparison to the monomeric precursor MHL and to the industry transfection standards DOTAP and lipofectamine, the novel cationic polymer PCL exhibited the lowest cytotoxicity, was the most resistant to serum-induced aggregation and had comparable transfection activity when co-formulated with cholesterol. More importantly, this work points toward the potential of lipid polymeri-

zation as a promising new approach for developing biocompatible materials for gene transfer.

ACKNOWLEDGMENT

This work was supported by grants from the Cystic Fibrosis Foundation (NANTZ96PO), NSRA from NIDDK (DK-09762), NIH (AA-06386), and by a Liver Scholar Award from the American Liver Foundation and a UC Davis Health System Award to J.W. M.E.L. is grateful for the receipt of an R. Bryan Miller Memorial Fellowship.

Diquaternary Ammonium Compounds as Transfection Agents

Howard S. Rosenzweig, Vera A. Rakhmanova, and Robert C. MacDonald*

From the Department of Biochemistry, Molecular Biology and Cell Biology, Northwestern University, Evanston, Illinois 60208. Received August 10, 2000; Revised Manuscript Received January 17, 2001

Diquaternary ammonium salts constitute a new class of reagent for mediating transfection of DNA in mammalian cell lines. *N,N'*-dioleoyl-*N,N,N',N'*-tetramethyl-1,2-ethanediamine (TmedEce), *N,N'*-dioleoyl-*N,N,N',N'*-tetramethyl-1,3-propanediamine (PropEce), *N,N'*-dioleoyl-*N,N,N',N'*-tetramethyl-1,6-hexanediamine (HexEce), and their corresponding *N,N'*-dicetyl saturated analogues (TmedAce, PropAce and HexAce) have all been synthesized and characterized. They were prepared via a bis-Menschutkin reaction of the corresponding tetramethyldiamine with 2.2 M equiv of a long-chain alkyl halide (saturated or unsaturated). The reaction was run in anhydrous acetonitrile for ca. 3 days at 60 °C, which produced the diquaternary ammonium halides in good to nearly quantitative yields for most derivatives. DNA transfection comparable to commercially available reagents such as Lipofectin, Lipofectace, Lipofectamine, and *O*-ethyl dioleoylphosphatidylcholine triflate has been achieved in vitro with these new reagents. There was no need to use a colipid for effective transfection, but serum did significantly inhibit transfection. The saturated and the unsaturated derivatives differed with respect to hydration behavior. The saturated derivatives appeared to retain a lamellar-type crystalline array structure upon hydration, whereas the unsaturated versions formed micelles and/or liposomes, depending on the ionic strength: HexEce was micellar in both water and saline; PropEce was micellar in water but lamellar in saline; and TmedEce was lamellar in both. Despite these different hydration patterns, all of these unsaturated derivatives formed productive transfection complexes with DNA. Varying the distance between the quaternary sites affected transfection efficacy in the order HexAce > TmedAce = PropAce for the saturated derivatives and in the order PropEce = HexEce > TmedEce, with a smaller spread, for the unsaturated derivatives.

INTRODUCTION

The in vitro introduction of plasmid DNA into mammalian cells (transfection) for transient expression of a variety of desired proteins has become a standard technique in molecular biology. Earlier methods involved the use of DNA coprecipitation with calcium phosphate, soluble DEAE or Polybrene resins (1), as well as electroporation (2). More recently, the use of cationic amphiphiles or more simply "cationic lipids" for mediating DNA transfection has become widespread. This trend was initiated by the demonstration of Felgner et al. that the cationic lipid, DOTMA (dioleolxypropyl-trimethylammonium bromide), was much faster, simpler, cheaper, and generally more effective than alternative methods in transfecting DNA into cultured cells (3). Since that time, there have been additional reports of different cationic lipids with transfection activity (e.g., refs 4–11).

One of the potentially most important applications of cationic lipids is as DNA delivery agents for gene therapy (12). Another potential clinical application is delivery of antisense oligonucleotides (13). Other molecules can be delivered to cells as cationic complexes, such as a transcription regulator protein (14), a viral trans-activator protein (15), and a mushroom toxin (16) and it is likely that additional applications will be developed.

Our investigation was prompted by the fact that dimethyldioctadecylammonium bromide, when formulated with an equimolar amount of dioleoylphosphatidylethanolamine (DOPE), was shown to be quite an

effective DNA transfection agent (6). (This mixture is marketed by Life Technologies under the trade name Lipofectace.) It appeared possible that introduction of a second quaternary ammonium group could increase the strength of interaction with DNA and perhaps generate an improved transfection agent. We thus sought a synthetic route to generate a molecule with two dimethylammonium groups, and two long-chain alkyl groups. The route we chose involved alkylating tetramethyldiamines with long-chain alkyl halides; it was found to provide convenient and efficient access to dialkyltetramethyldiquaternary ammonium transfection agents.

EXPERIMENTAL PROCEDURES

Materials. Chemical reagents and solvents were normally purchased either from Aldrich Chemical Co. (Milwaukee, WI) or Sigma Chemical Co. (St. Louis, MO) and were used without further purification. BHK-21 cells (Syrian or Golden Hamster) were obtained from American Type Culture Collection (Rockville, MD). Tissue culture reagents were purchased from Life Technologies (Grand Island, NY). The DNA plasmid with the β -galactosidase gene driven by the cytomegalovirus promoter (pCMV- β -gal) was also purchased from Life Technologies. It was propagated in DH5 cells and purified with a Plasmid Mega Kit from Qiagen (Valencia, CA).

Synthetic Methods for Diquaternary Ammonium Salts. To an oven-dried and desiccated 1.2 $\times$ 2.5 cm screw cap vial was added anhydrous acetonitrile (1 mL), followed by either tetramethylethylenediamine, tetramethyl-1,3-propanediamine, or tetramethyl-1,6-hexanediamine (300 μ mol), and finally by the long-chain alkyl halide (cetyl iodide or oleyl bromide, 665 μ mol), and the

vial was sealed tightly. The reaction vial was then placed in a dry heating block at 60 °C, covered with aluminum foil, and allowed to react for ca. 3 days. In the case of the saturated analogues TmedAce and HexAce, significant precipitation of product was observed when the reaction mixture was heated, while PropAce only precipitated after it cooled. After cooling, the solid was triturated with absolute ethanol and then suction filtered. The solid was dried under high vacuum and weighed. Yields were 60–84% for TmedAce and HexAce and 17% for PropAce. The unsaturated analogues did not precipitate in the reaction mixture until they cooled to RT. Their workup was modified due to their different solubility characteristics (soluble in absolute ethanol and chloroform). The acetonitrile above the solid was first decanted away, and then the residue dissolved in 1–2 mL of chloroform. The latter solution was transferred to a culture tube, and the bulk of the volatiles were removed with a stream of argon under warming. The solid residue was redissolved in 3–6 mL of chloroform and subjected to silica gel chromatography. Typically, the CHCl_3 solution containing the crude product was applied to a dry silica gel column of ≥ 2.5 mL. The column was washed with ca. 5 vol of CHCl_3 , followed by 9:1 CHCl_3 : CH_3OH , at which point the bulk of the product eluted from the column. After collection of six 6-mL fractions, the remaining product was eluted with 5:1 and then 4:1 CHCl_3 : CH_3OH (three fractions each). The desired product has an R_f value of ca. 0.57 when run on an analytical silica gel TLC plate (in CHCl_3 : CH_3OH :acetic acid, 65:25:4). The yield for TmedEce was 19%, while the yields for PropEce and HexEce were essentially quantitative.

Synthesis of Dimethyl-2-dimethylaminoethylcetyl-ammonium Iodide (Quatamine-1). To an oven-dried and desiccated 1.2×2.5 cm screw cap vial was added anhydrous acetonitrile (1 mL) followed by tetramethylethylenediamine (35 mg, 302 μmol) and finally cetyl iodide (106 mg, 301 μmol), and the vial was sealed tightly. The vial was then placed in a dry heating block at 60 °C, covered with aluminum foil, and then allowed to react overnight. After this time, the sample was cooled to room temperature, and a small precipitate was removed by gravity-filtration through Celite (ca. 2 cm). The bulk of the volatiles were evaporated away with a gentle stream of argon (while warming in a water bath), yielding a light orange-yellow residue. Unreacted tetramethylethylenediamine was removed by extraction as follows. The mixture was dissolved in chloroform (5 mL), which solution was then transferred to a 50 mL graduated cylinder. Methanol (2.5 mL) was added, followed by 10% HCl (3 mL). After mixing, the lower organic layer was removed and gravity-filtered through granular sodium sulfate. It was then transferred to a tared vial, and the bulk of the volatiles removed as described above. The sample was then placed under high vacuum for 35 min and weighed. Fifty milligrams (35% Yield) of very pure monoquaternized salt (as determined by ^1H NMR) was obtained.

Product Characterization. Liquid secondary ion mass spectra were obtained on a VG70 mass spectrometer (VG Analytical) with Cs ion as a primary source. Proton NMR spectra were obtained on a Varian Gemini 300 MHz spectrometer, using tetramethylsilane as an internal reference, and chemical shifts are given in δ (ppm).

By TLC and proton NMR, all of the diquaternary ammonium compounds were found to be pure. No evidence of starting materials or monoquaternary interme-

diate was observed in the proton NMR spectra or analytical TLC of the purified products.

Spectral Data (all ^1H NMR spectra were obtained at 300 MHz). *TmedAce*, in deuteriochloroform:methanol- d_4 [1:1]: δ 4.21 (singlet, 4H, internal methylenes adjacent to quaternary nitrogens), 3.57 (broad triplet, $J = 8$ Hz, 4H, external methylenes adjacent to quaternary nitrogens), 3.32 (singlet, 12H, quaternary methyl groups), 1.84 (broad singlet, 4H), 1.5–1.2 (multiplet, 52H), 0.89 (triplet, $J = 7$ Hz, 6H, terminal methyl groups). MS: 552 ($\text{M}^+ - \text{methyl}$).

PropAce, in deuteriochloroform:methanol- d_4 : δ 3.57 (broad triplet, $J = 8$ Hz, 4H, internal methylenes adjacent to quaternary nitrogens), 3.46 (broad triplet, $J = 8$ Hz, 4H, external methylenes adjacent to quaternary nitrogens), 3.23 (singlet, 12H, quaternary methyl groups), 2.41 (broad singlet, 2H, central internal methylene), 1.83 (broad singlet, 4H), 1.5–1.2 (multiplet, 52H), 0.89 (triplet, $J = 7$ Hz, 6H, terminal methyl groups). MS: 708 ($\text{M}^+ + \text{I}^-$), 566 ($\text{M}^+ - \text{methyl}$).

HexAce, in deuteriochloroform:methanol- d_4 : δ 3.44 (broad triplet, $J = 8$ Hz, 4H, internal methylenes adjacent to quaternary nitrogens), 3.36 (broad triplet, $J = 8$ Hz, 4H, external methylenes adjacent to quaternary nitrogens), 3.14 (singlet, 12H, quaternary methyl groups), 1.95–1.7 (multiplet, 8H), 1.55 (broad singlet, 4H), 1.48–1.2 (multiplet, 52H), 0.89 (triplet, $J = 7$ Hz, 6H, terminal methyl groups). MS: 750 (M^+), 608 ($\text{M}^+ - \text{methyl}$).

TmedEce, in deuteriochloroform: δ 5.38–5.3 (overlapping triplets, $J = 6$ Hz, 4H, vinyl), 4.77 (singlet, 4H, internal methylenes adjacent to quaternary nitrogens), 3.71 (broad triplet, $J = 8$ Hz, 4H, external methylenes adjacent to quaternary nitrogens), 3.50 (singlet, 12H, quaternary methyl groups), 2.06–1.92 (multiplet, 8H, allylic), 1.92–1.70 (multiplet, 12H), 1.5–1.2 (multiplet, 36H), 0.88 (triplet, $J = 7$ Hz, 6H, terminal methyl groups). MS: 697/699 ($\text{M}^+ + \text{Br}^-$), 604 ($\text{M}^+ - \text{methyl}$).

PropEce, deuteriochloroform: δ 5.38–5.3 (overlapping triplets, $J = 6$ Hz, 4H, vinyl), 3.92 (broad triplet, $J = 8$ Hz, 4H, internal methylenes adjacent to quaternary nitrogens), 3.48 (broad triplet, $J = 8$ Hz, 4H, external methylenes adjacent to quaternary nitrogens), 3.36 (singlet, 12H, quaternary methyl groups), 2.83–2.7 (multiplet, 2H, central internal methylene), 2.06–1.92 (multiplet, 8H, allylic), 1.92–1.70 (multiplet, 12H), 1.46–1.2 (multiplet, 36H), 0.88 (triplet, $J = 7$ Hz, 6H, terminal methyl groups). MS: 711/713 ($\text{M}^+ + \text{Br}^-$), 618 ($\text{M}^+ - \text{methyl}$).

HexEce, deuteriochloroform: δ 5.38–5.3 (overlapping triplets, $J = 6$ Hz, 4H, vinyl), 3.80–3.65 (multiplet, 4H, internal methylenes adjacent to quaternary nitrogens), 3.50–3.29 (overlapping broad triplet and singlet, 16H, external methylenes adjacent to quaternary nitrogens and quaternary methyl groups), 2.06–1.92 (multiplet, 8H, allylic), 1.81–1.55 (multiplet, 12H), 1.42–1.20 (multiplet, 44H), 0.88 (triplet, $J = 7$ Hz, 6H, terminal methyl groups). MS: 753/755 ($\text{M}^+ + \text{Br}^-$), 660 ($\text{M}^+ - \text{methyl}$).

Quatamine-1, deuteriochloroform: δ 4.40–4.30 (broad singlet, 2H, internal methylene adjacent to quaternary nitrogen), 4.20–4.10 (broad singlet, 2H, external methylene adjacent to quaternary nitrogen), 3.60–3.50 (multiplet, 2H, methylene adjacent to dimethylamino-group), 3.45 (broad singlet, 6H, quaternary methyl groups), 3.13 (broad singlet, 6H, dimethylamino-group), 1.88–1.74 (broad singlet, 2H), 1.40–1.16 (multiplet, 26H), 0.88 (triplet, $J = 7$ Hz, 3H, terminal methyl group). MS: 341 (M^+).

Storage of Diquaternary Ammonium Salts and their Dispersal. Diquaternary ammonium salts were

Figure 1. Reactions used for the synthesis of the diquaternary ammonium compounds. The upper scheme describes the synthesis of the saturated series and the lower scheme describes that of the unsaturated derivatives. In each series, compounds with 2, 3, and 6 carbons separating the nitrogen atoms were prepared.

normally stored at -20°C as 10–40 mg/mL $\text{CHCl}_3\text{:CH}_3\text{OH}$ [1:1] or CHCl_3 solutions for the dicetyl and dioleyl derivatives, respectively. An age-dependent reduction of transfection activity was observed with the unsaturated derivatives, and therefore, we recommend that they be used within 1–2 months after final purification and solution preparation.

Formation of Aqueous Dispersions of Diquaternary Ammonium Salts. Aliquots of stock were transferred to vials where the bulk of the solvent was removed under a stream of argon. The vial was then placed under an oil pump vacuum for at least 30 min/mg to remove residual solvent. Next, the appropriate amount of phosphate-buffered saline (PBS) was added in order to obtain a 1 mg/mL solution, and the tube was vortexed or bath-sonicated briefly.

Transfection Protocol. BHK cells were transfected with pCMV- β gal plasmid in 96 well microplates. Complete medium was GMEM containing 5 or 10% fetal bovine serum, 2 mM glutamine, 2% tryptose phosphate, and 1/100 PenStrep. The cells were incubated at 37°C in 5% CO_2 . Cells were seeded on the day before transfection at densities such that they would be approximately 70% confluent when transfected. Cells were prepared for transfection by removal of complete medium and replacing it with medium lacking serum, tryptose, and antibiotics. Amphiphiles, suspended in PBS at 1 mg/mL, were added to the plasmid DNA in PBS at 0.1 mg/mL with gentle mixing and allowed to incubate for 20–30 min. The DNA–amphiphile complex was then added to the cells and incubated 4–6 h at 37°C . After this time, the cells were returned to complete medium, either following washing with PBS or simply upon addition of 1/10 or 1/20 volume of fetal bovine serum. Twenty hours after treatment with the DNA–amphiphile complex, the cells were assayed for β -galactosidase activity using a microplate fluorometric assay (17). Briefly, the cells were washed with PBS and permeabilized by adding 100 μL of PBS containing 0.03% Triton X-100. Ten microliters of 0.1 mM fluorescein digalactoside was added to the wells (final volume was 100 μL); 30 and 60 min after addition of substrate, the plate was read in a microplate fluorometer (Packard Instruments). The rate of reaction was linear in this time range and the fluorescence intensity difference between the two times was propor-

tional to β -galactosidase activity. Standards of purified β -galactosidase (Sigma) were run on each plate to validate the assay reaction. We did not routinely quantify the number of cells or protein in transfected cultures, so we normally express the galactosidase activity in terms of light units. To date, optimum conditions yield approximately 10 milliunits of enzyme activity/well of a 96 well plate.

RESULTS

All of the diquaternary ammonium salts were prepared via a bis-Menshutkin reaction of their corresponding tetramethyldiamines with 2.2 M equiv of a long-chain alkyl halide (saturated or unsaturated). The reaction was run in anhydrous acetonitrile for 3 days at 60°C in the dark, which provides the diquaternary ammonium halides in good to nearly quantitative yields for most derivatives (see Figure 1). An example of a monoquaternarized version of TmedAce, Quatamine-1, was produced through an analogous procedure, with the exception that only 1 M equiv of the cetyl iodide was used, and the reaction was only run overnight. For more details, see Materials and Methods.

The diquaternary ammonium halides were characterized by both ^1H NMR and mass spectral analysis. As can be seen in the Spectral Data section of Materials and Methods, the NMR resonances are consistent with the diquaternary structure assigned for each derivative. The mass spectral data consistently show both a parent ion minus one halide, as well as a parent ion minus one methyl group, for each derivative.

Most cationic amphiphiles described in the literature as transfection reagents are more effective in the presence of DOPE (4, 11, 15), although there are exceptions (7, 18). In the case of the diquaternary ammonium salts, transfection efficiency was actually reduced by DOPE (see Figure 2 for a representative example), therefore, most of our studies were done without colipid.

The monoquaternary Quatamine-1 was found to be highly toxic, even at low doses (data not shown) and underscores the need to isolate pure diquaternary ammonium salt for transfection purposes. Generally, investigators have not examined the effects of small amounts

Figure 2. Transfection activity of TmedAce/DOPE at different ratios of TmedAce to DOPE. Transfection complexes were prepared in DPBS according to the standard protocol. Then lipid/DNA complexes were applied to BHK cells in the amounts: 0.2/0.2, 0.5/0.5, and 1.0/1.0 μg (first, second, and third bars, of each set, respectively). Error bars indicate high and low values of replicates.

of side products that may be carried over in the final product as impurities. Given the high toxicity of some monoalkylamines, small variations in the purity of even highly pure materials could generate errors in evaluation of transfection agents and perhaps also account for some of the unexplained variations in the response of different cells to different compounds.

The diquaternary compounds exhibited a variety of hydration behavior. The saturated derivatives, according to freeze–fracture electron microscopy, formed stacked, planar lamellae. The unsaturated compounds were observed by light microscopy to form liposomes at high ionic strength. At low ionic strength, two of the unsaturated compounds generated clear solutions, implying the formation of a micellar phase. Specifically, HexEce was micellar in both water and saline, PropEce was micellar in water but lamellar in saline, and TmedEce was lamellar in both aqueous phases.

All of the diquaternary ammonium salts exhibited good to excellent transfection activity in BHK cells. Many transfection lipids are more active when formulated with equimolar DOPE, although this is not the case with the diquaternary compounds. Transfection activity of TmedAce formulated with DOPE at several ratios is shown in Figure 2. The TmedAce without colipid was most active and a similar pattern was found with the other diquaternary compounds (data not shown).

The most efficient reagent of the saturated derivatives was HexAce (Figure 3). TmedAce and PropAce were 3–4 times less effective. This was observed under a variety of doses and lipid to DNA ratios (Figure 4). In the case of the unsaturated derivatives, PropEce and HexEce were both found to be highly efficient and essentially equivalent (Figures 5 and 6, respectively), with TmedEce only slightly less effective (Figure 7). In all cases, the presence of 10% serum was found to significantly reduce if not completely inhibit the transfection efficacy of these reagents.

The diquaternary ammonium salts were, at optimal lipid:DNA ratio and dose, at least as effective transfection agents as *O*-ethyl-dioleoylphosphatidylcholine (EDOPC), the cationic lipid with which we have had the most experience. EDOPC, a phospholipid derivative, was previously shown to be as effective as one of the current

Figure 3. Comparison of TmedAce, PropAce and HexAce in transfection of BHK cells. Transfection complexes were formed in DPBS and applied to cells in the amounts: 0.5/0.5, 1.0/0.5, and 1.0/1.0 μg (first, second, and third bars, of each set, respectively). Error bars indicate high and low values of replicates.

Figure 4. Comparison of TmedAce and HexAce transfection activities for different lipid/DNA ratios and doses. BHK cells were treated with plasmid DNA complexed with either TmedAce (first bar of each pair) or HexAce (second bar of each pair) in the amounts ($\mu\text{g}/\text{well}$) shown. Bars indicate high and low values of replicates.

Figure 5. Transfection activity of PropEce as a function of the lipid/DNA ratio and dose. BHK cells were treated with plasmid DNA complexed in DPBS with PropEce in the amounts ($\mu\text{g}/\text{well}$) shown. The data of transfection with EDOPC are presented for comparison. Bars indicate high and low values of replicates.

benchmarks of transfection reagents, Lipofectamine, in mediating transfection of BHK cells (19, 20). Its activity was also similar to that of Lipofectace and considerably superior to that of Lipofectin (unpublished).

Figure 6. Transfection efficiency of HexEce with and without serum. BHK cells were transfected with HexEce/DNA complexes prepared in DPBS at different lipid/DNA ratios. Transfection was performed in medium without supplements (first and open bar of each group) and in medium containing 10% FBS (second and filled bar of each group) in the amounts ($\mu\text{g}/\text{well}$) shown. Bars indicate high and low values of replicates.

Figure 7. Transfection efficiency of TmedEce with and without serum. BHK cells were transfected with TmedEce/DNA complexes prepared in DPBS at different lipid/DNA ratios. Transfection was performed in medium without supplements (first bar of each group) and in medium containing 10% FBS (second bar of each group) in the amounts ($\mu\text{g}/\text{well}$) shown. Bars indicate high and low values of replicates.

DISCUSSION

The diquatary ammonium salts are conveniently synthesized in a single step, via a bis-Menschutkin reaction of their corresponding tetramethyldiamines with long-chain alkyl halides (either saturated or unsaturated). Yields ranged from good to nearly quantitative. Such straightforward chemistry as well as the commercial availability of a range of various tetramethyldiamines as well as long-chain alkyl halides, provides the opportunity to explore many permutations through solution phase combinatorial chemistry.

The observation that DOPE is not necessary for highly efficient transfection contrasts with the requirement of LipofectAce for DOPE. A number of other transfection lipid mixtures also contain DOPE as an integral component. Therefore, it appears that the addition of a second permanent positive charge in the diquatary compounds somehow obviates the requirement for DOPE that is exhibited by the monoquatary dimethyldioctadecylammonium bromide component of LipofectAce.

The low transfection efficacy observed in the presence of 10% serum may preclude the *in vivo* usage of the

diquatary ammonium salts as vectors for systemic gene therapy, although procedures to reduce or eliminate the serum sensitivity of other cationic lipid formulations (18, 21) may well be applicable to the diquatary compounds.

The hydration behavior of the unsaturated derivatives follows a logical pattern, given the length of the alkyl chain that separates the two quatary sites and the known effects of molecular shape on polymorphic phase preferences (22). TmedEce remains lamellar in both water and saline since the ethyl bridge between the two quatary sites geometrically precludes anything but a parallel orientation of the two oleyl chains, which thus leads to a lamellar phase in both media. PropEce, possessing an extra carbon in its tether group, has enough space to allow ionic strength to affect its phase stability; it assumes a lamellar configuration in saline, wherein chloride anions screen the repulsion between the two positive sites and allow them to come close enough that the oleyl chains may be parallel, whereas in water, the two quatary sites must move further away due to electrostatic repulsion, which consequently causes the oleyl chains to assume a wedge shape, favoring a micellar phase. Finally, HexEce was micellar in both water and saline since the two quatary sites are held apart by the hexyl chain tether, the steric effect of the oleyl chain is independent of ionic strength, so the molecule is wedge-shaped and hence micellar in both media.

The fact that efficient transfection was obtained with both HexEce and TmedEce shows that their different initial hydration behavior does not preclude either from forming a productive complex with DNA [in analogy to what has been observed with *O*-alkyl-dioleoylphosphatidylcholine compounds (23)].

In conclusion, diquatary ammonium salts constitute a new class of reagent for mediating transfection of DNA. Some of the derivatives we studied do so with high efficiency without a requirement for colipid. At least in the absence of serum, diquatary compounds exhibit transfection activity that is at least as effective, if not superior to that of a number of popular, commercially available agents. Their low cost, extreme ease of synthesis and suitability to varying their chemical (and hence also physical) properties in a very straightforward manner allows for optimizing activity for particular cell and transfection conditions.

ACKNOWLEDGMENT

This work was presented in part at the 214th American Chemical Society National Meeting, Las Vegas, NV, in September 1997. H.S.R. wishes to thank Dr. Maria Papadopoulou for carefully reviewing the manuscript, as well as for her constant encouragement and inspiration. We thank Yury Tarahovsky for electron microscopy. This research was supported by the NIH (Grant GM52329).

Received August 10, 2000; Revised Manuscript Received December 21, 2000

Radiometal-labeled antibody fragments are promising reagents for radioimmunotherapy due to their high tumor uptake and rapid pharmacokinetics, but their therapeutic potentials are limited by high uptake and retention in the kidney. Identification of metabolic products is a first step in designing rationale approaches to lower kidney uptake. Previous studies in rats have shown that ^{111}In -labeled DTPA-conjugated antibody fragments (via lysine residues) were degraded to an DTPA- ϵ -amino-lysine derivative and retained in the lysosomal compartments of the liver and kidney [Rogers et al. (1995) *Cancer Res.* 55, 5714s–5720s]. To determine the metabolic profile of another widely used metal-chelate, [^{111}In]DOTA conjugated to lysines in antibody fragments via active ester chemistry, we analyzed kidney homogenates from nude mice injected with an [^{111}In]DOTA-Fab generated enzymatically from the anti-lymphoma intact antibody Rituxan. The major kidney metabolite was identified as [^{111}In]DOTA- ϵ -amino-lysine by comparison to an authentic synthetic standard. This end product was also identified in the urine, along with relatively small amounts of [^{111}In]DOTA-Fab. Since injection of [^{111}In]DOTA- ϵ -amino-lysine into nude mice resulted in rapid clearance into the urine without kidney retention, it is likely that the renal retention observed was due to kidney uptake of [^{111}In]DOTA-Fab, followed by lysosomal degradation to [^{111}In]DOTA- ϵ -amino-lysine, which is only slowly cleared from this compartment. This observation is supported by autoradiographs of the kidney showing rapid localization of radioactivity into the distal regions of the kidney cortex. To extend this analysis to clinical trials, we have also analyzed urine taken from a patient injected with the intact antibody [^{111}In]DOTA-cT84.66. In that example, we found that the major radioactive species was also [^{111}In]DOTA- ϵ -amino-lysine.

INTRODUCTION

Antibodies can be used to deliver radionuclides (Klein et al., 1989), toxins (Spitler, 1987), or cytotoxic drugs (Starling et al., 1988) to tumors due to their high specificity for tumor surface antigens. Radiometals that are conjugated to antibody via chelates are a good choice for radioimmunotherapy (RIT),¹ as exemplified by clinical studies with radiometal labeled anti-lymphoma (Press, 1999), anti-colon cancer (Wong et al., 1995), and anti-breast cancer antibodies (DeNardo et al., 1997). In RIT, the use of intact immunoglobulin conjugates lead to a long circulation time in blood, thus exposing normal tissues to unwanted radiation (LoBuglio et al., 1989). Due to its large size (150 kDa), the IgG molecule also shows a relatively slow diffusion from the vasculature into tumors (Yokota et al., 1992; Blumenthal et al., 1995). While IgG fragments exhibit a faster biodistribution and better tumor penetration than intact IgG (Yokota et al.,

1992), this advantage is offset by nonspecific organ uptake, especially in the kidney (Andrew et al., 1988). Although this problem may be partially corrected by using metabolically labile isotopes such as radioiodine (Andrew et al., 1988), this is attained at the price of reduced tumor retention, thus requiring higher amounts of radioactivity to achieve the same radiation absorbed dose achieved with lower amounts of radiometal. Thus, although radiometal labeled antibody fragments have faster blood clearance and better tumor penetration than their intact IgG counterparts, their uptake and retention in the radiation sensitive kidney has limited their therapeutic application.

The first step to lowering kidney uptake is to identify the radiolabeled metabolic products. A series of studies with [^{111}In]DTPA-conjugated (via lysine residues) glycoproteins (Duncan and Welch, 1993; Arano et al., 1994) or antibody fragments (Anderson et al., 1995; Rogers et al., 1995) in animal models revealed that these conjugates were metabolized in the lysosomal compartment at both tumor and nontumor sites. For example, Duncan and Welch (Duncan and Welch, 1993) found that [^{111}In]DTPA-labeled glycoproteins targeted to cell surface receptors were degraded to [^{111}In]DTPA- ϵ -amino-lysine, which was then slowly released from cells and recovered intact in both urine and feces. Rogers et al. (1995) identified [^{111}In]DTPA- ϵ -amino-lysine as the major metabolites of DTPA-conjugated (via lysines) antibodies and antibody fragments. These findings suggest that lysosomal enzymes are unable to cleave the amide bond of [^{111}In]DTPA- ϵ -

¹ Abbreviations: DOTA, 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid; DTPA, diethylenetriaminepentaacetic acid; RIT, radioimmunotherapy; IgG, immunoglobulin; EDC, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide; sulfo-NHS, *N*-hydroxysulfosuccinimide; CEA, carcinoembryonic antigen; BFC, bifunctional chelate; TFA, trifluoroacetic acid; BFC, bifunctional chelate.

amino-lysine and the end product is only slowly cleared from this compartment.

Although DTPA is an excellent chelate for radiometal-based immunoconjugates, its radiometal stability constants, especially for the imaging and therapeutic radiometals $^{111}\text{In}^{3+}$ and $^{90}\text{Y}^{3+}$, respectively, are such that significant amounts of radionuclide escape into nontarget organs such as the bone (Williams et al., 1996; Govindan et al., 1998). For this reason we have begun to utilize the more stable macrocycle chelate DOTA (Li et al., 1994) which can be conveniently linked to lysines in proteins via simple active ester chemistry (Lewis et al., 1994). Using the metabolic studies on [^{111}In]DTPA-lysine based conjugates as a guide, we speculated that DOTA-lysine-based conjugates would be degraded to [^{111}In]DOTA- ϵ -amino-lysine and retained in the lysosomal compartment. Therefore, we synthesized this derivative, studied its biodistribution in nude mice, the usual preclinical model for RIT, and showed that it is rapidly cleared into the urine with no net organ retention. However, when [^{111}In]DOTA-Fab fragments are injected into nude mice, high kidney retention of [^{111}In]DOTA- ϵ -amino-lysine is observed, suggesting that kidney filtration of the fragment results in cellular uptake, followed by metabolism and retention in the lysosomal compartment.

EXPERIMENTAL PROCEDURES

Preparation and Radiolabeling of Antibody Fab Fragment Conjugate. Rituxan (75 mg, IDEC) was digested with immobilized papain (Pierce) and purified on a protein A column (Bio-Rad) according to manufacturer's protocols. Purified Rituxan-Fab (70% yield) gave a single band at 50 kDa on a 10–15% nonreducing SDS–polyacrylamide gel. The Fab was conjugated to DOTA using the water-soluble EDC/sulfo-NHS method according to Lewis et al. (1994) with a DOTA-ester-to-antibody ratio of 100:1. Following conjugation, the protein was dialyzed against 0.2 M NH_4OAc , pH 7.2, and concentrated to 3 mg/mL. The antibody was radiolabeled with In-111 at a ratio of 2.5–3 mCi/mg. Indium-111 chloride in 0.05 N HCl was buffered with an equal volume of 0.2 M NH_4OAc at pH 7 prior to addition of antibody. The reaction mixture was incubated at 43 °C for 1 h, then 10 mM DTPA solution was added to give a final concentration of 1 mM DTPA. This was followed by a 15 min incubation at room temperature, after which purification was performed by HPLC using a Superdex 75 HR 10/30 gel filtration column (Pharmacia) eluted with normal saline at a flow rate of 0.5 mL/min. Fractions of 0.5 mL each were collected into tubes containing 1 drop 25% human serum albumin. Labeling efficiency, as determined during HPLC purification, ranged from 84 to 96%.

Synthesis of DOTA- ϵ -amino-lysine and Radiolabeling. DOTA active ester was prepared as follows: DOTA (trisodium salt, 100 mg, 213 μmol), EDC (81 mg, 425 μmol), and sulfo-NHS (92 mg, 425 μmol) in were reacted in 150 μL of water at RT at pH 7.0 for 1 h. α -Boc-Lys (104 mg, 425 μmol) dissolved in 1 mL of water was reacted with 0.5 equiv of the DOTA active ester for 22 h at RT. The solution was cooled to 4 °C and acidified with 1 mL of HCl and passed over a Bio-Rad Ag50W-X8 column (6 mL in the ammonium form). After extensive washing with water, the product was eluted with stepwise 10 mL aliquots of 0.5, 1.0, 2.0, and 4.0 M NH_4OH . The fractions (1 mL) were dried and the product was identified by ESI/MS (Finnigan LCQ ion trap). The product was loaded onto a Dowex AG1-X4 (6 mL in the formate form), washed with water, and eluted stepwise with 10 mL each of 0.1, 0.2, 0.5, 1.0, and 2.0 M formic acid. The fractions (1 mL) were dried, and the product

identified as before. The product (29 mg of white powder) had the correct mass by ESI/MS (MH^+ of 532.6 expected, 532.9 observed) and the following proton NMR: (D_2O , 500 MHz) δ 1.32–1.46 (m, 2H, γ - CH_2 of lysine), 1.52–1.57 (m, 2H, β - CH_2 of lysine), 1.80–1.94 (m, 2H, δ - CH_2 of lysine), 2.92–3.04 (m, 4H, ring protons of DOTA), 3.06–3.20 (m, 6H, ϵ - CH_2 of lysine plus ring protons of DOTA), 3.18–3.45 (m, 8H, ring protons of DOTA), 3.46 (s, 2H, acetate protons of DOTA), 3.52 (s, 2H, acetate protons of DOTA), 3.74–3.78 (m, 2H, α - CH_2 of lysine), 3.80 (s, 2H ring protons of DOTA), 3.83 (s, 2H, ring protons of DOTA). Unreacted DOTA (60 mg) was recovered and recycled for further reactions. The product (15 μL of a 37.5 mM solution in water) was radiolabeled at 43 °C with 531 μCi of $^{111}\text{InCl}_3$ (an equal volume of 0.2 M 7.0 NH_4OAc buffer of pH 7.0 was added to 35 μL of $^{111}\text{InCl}_3$ in 0.04 M HCl).

Biodistributions of [^{111}In]DOTA-Rituxan-Fab and [^{111}In]DOTA- ϵ -amino-lysine. Groups of five nontumor-bearing nude mice (Charles River) per time point were injected with 5.0 μCi (2.0 μg) of ^{111}In -labeled DOTA-Rituxan Fab via tail vein. Animals were sacrificed at 0, 1, 2, 4, 6, and 12 h after injection. Major organs and blood were weighed and radioactivity measured and expressed as percentage injected dose per gram of tissue. In a separate experiment, groups of two nontumor-bearing nude mice per time point were injected with 10 μCi (4.0 μg) of [^{111}In]DOTA-Rituxan-Fab or 50 μCi (30 μg) of [^{111}In]DOTA- ϵ -amino-lysine. Kidneys, blood, and urine samples were collected at 1, 5, and 9 h after injection and the radioactivity measured.

Kidney Cryostat-Sections. Kidney tissues were dissected from the mice injected with 5.0 μCi (2.0 μg) Rituxan Fab at 0, 4, and 12 h after injection. Renal tissues were embedded in O. C. T. (Miles Inc.), quick frozen on dry ice, cut into 4 μm thick slices, and were then mounted on slides. Frozen section slides were fixed in cold acetone for 10 min, and then exposed to a phosphor imager (Molecular Dynamics) for 2 weeks.

Kidney Metabolites of [^{111}In]DOTA-Rituxan Fab. Kidneys were removed from mice injected with 5 μCi (2.0 μg) or 10 μCi (4.0 μg) of [^{111}In]DOTA-Rituxan Fab. The organs were rinsed with PBS, frozen and thawed, and homogenized in an equal volume of PBS using a Bounce homogenizer. The PBS insoluble fractions were boiled and solubilized in 1% SDS. Samples were then centrifuged in an Eppendorf centrifuge at 12 000 rpm for 60 min, passed through a 0.22 μm filter, and were analyzed by SDS–PAGE 10 to 15% gradient gels (Pharmacia, Phast gel), gel filtration chromatography (Pharmacia, tandem Superose 12 columns, each 1 $\times$ 30 cm, flow rate 0.5 mL/min in PBS) and anion-exchange chromatography (Perceptive Biosystems, Poros HQ, 4.6 $\times$ 100 mm, flow rate 1 mL/min in 20 mM Tris, pH 8.5. Gradient started 5 min after injection and increased to 0.02 M Tris, pH 7.0, 0.5 M NaCl over 35 min).

Analysis of Patient Urine Sample. Urine was collected from a patient enrolled in a phase I therapy trial involving pretherapy imaging with the anti-CEA intact antibody (Williams et al., 1996) [^{111}In]DOTA- chT84.66 . The urine sample was collected between 24 and 48 h after administration of the pretherapy [^{111}In]DOTA- chT84.66 antibody (5 mCi, 5 mg of antibody). Aliquots (200 μL) were applied to the anion-exchange column as described above.

RESULTS

[^{111}In]DOTA-Rituxan Fab Biodistribution. DOTA was conjugated to the lysine residues of purified Fab fragments of Rituxan using active ester chemistry and

^a Groups of five nontumor-bearing mice were injected with 5.0 μCi (2.0 μg) of ^{111}In -labeled DOTA-Rituxan Fab. Mean values ($\pm\text{SD}$) are in units of percent injected dose per gram (% ID/g) for each organ at each time point. ^b Approximately 20 min after injection.

Figure 1. Kidney cryostat-sections. Kidneys excised from four mice injected with 5.0 μCi (2.0 μg) [^{111}In]DOTA-Rituxan Fab at $t = 0, 4$, and 12 h were cut into 4 μm thickness and then exposed onto a phosphor imager for 2 weeks. Little movement of the activity was observed in these specimens over the 12 h interval.

radioabeled with ^{111}In (5.0 μCi , 2.0 μg). Biodistribution studies in tumor-free nude mice showed rapid blood clearance ($<2\%$ ID/g at 1 h) and high kidney accumulation (up to 95% ID/g at 12 h), as shown in Table 1. Accumulation in all other organs, including spleen and liver were at the order of 2% ID/g after 1 h.

Localization of [^{111}In]DOTA Rituxan Fab in the kidney. To determine the anatomical location of the radioactivity in the kidneys, kidneys were harvested from the nude mice injected with [^{111}In]DOTA-Rituxan-Fab at 0, 4, and 12 h. Frozen sections were exposed on a phosphor imager. The results show that the radioactivity accumulated in the cortical region of the kidney, corresponding to the tubules (Figure 1).

Comparative Biodistributions of [^{111}In]DOTA- ϵ -amino-lysine and [^{111}In]DOTA-Rituxan Fab. Since it was suspected that the metabolic end product containing the radioactivity was [^{111}In]DOTA- ϵ -amino-lysine, the parent compound was synthesized and radiolabeled with ^{111}In . To determine if this compound is directly retained by the kidneys, 50 μCi of [^{111}In]DOTA- ϵ -amino-lysine was injected into one group of nontumor-bearing nude mice and compared to a second group injected with 10 μCi (4.0 μg) of [^{111}In]DOTA-Rituxan-Fab, and analyzed at 1, 5, and 9 h. Kidney, blood, and urine samples were collected and the percentage injected dose per gram of tissue (% ID/g) calculated (Table 2). In the group injected with [^{111}In]DOTA- ϵ -amino-lysine, accumulation of radioactivity in blood and kidney was negligible ($<2\%$) compared to the group injected with [^{111}In]DOTA-Rituxan-Fab ($>200\%$ ID/g in the kidney at 9 h). The higher renal uptake in this group (Table 1 vs Table 2) is attributed to the higher dose injected and the fact that we have not reached saturation. While we did not collect total urine excreted by mice during the course of the experiment, substantial counts were recovered at 1 h for the [^{111}In]DOTA- ϵ -amino-lysine group compared to the [^{111}In]DOTA-Rituxan-Fab group. These data demonstrated that free [^{111}In]DOTA- ϵ -amino-lysine passed quickly from blood, did not accumulate in kidney and was rapidly excreted into the urine. The radiolabeled Fab fragment, on the other hand, was taken up, metabolized and retained in renal cells.

Table 2. Biodistribution of ^{111}In -Labeled DOTA-Rituxan Fab and [^{111}In]DOTA- ϵ -amino-lysine in Non-Tumor-Bearing Nude Mice^a

organs	1 (h)	5 (h)	9 (h)
kidney (DOTA Rituxan Fab)	262.0 (4.2)	191.5 (96.9)	258.5 (2.1)
kidney (DOTA-Lys)	1.7 (0.4)	1.5 (0.2)	1.5 (0.0)
blood (DOTA Rituxan Fab)	1.1 (0.2)	0.6 (0.4)	0.3 (0.0)
blood (DOTA-Lys)	0.2 (0.1)	0.2 (0.0)	0.1 (0.0)

^a Groups of two nontumor-bearing mice were injected with either 10 μCi (4.0 μg) of [^{111}In]DOTA-Rituxan Fab or 50 μCi (30 μg) of [^{111}In]DOTA- ϵ -amino-lysine. Kidneys were excised and blood samples drawn at 1, 5, or 9 h after injection. Mean values ($\pm\text{SD}$) are in units of percent injected dose per gram (% ID/g) for each tissue at each time point.

Gel Filtration Chromatography of Kidney Homogenates and Urine Samples. Kidneys from mice injected with 7.5 μCi [^{111}In]DOTA-Rituxan-Fab were collected at 12 h and the homogenates analyzed on tandem Superose 12 columns. More than 90% of the counts found in the kidney could be extracted into a fraction soluble in PBS. [^{111}In]DOTA and DOTA-Rituxan Fab were run as markers. In this analysis, the kidney metabolites coelute with [^{111}In]DOTA as a low molecular weight species (Figure 2A). The elution profile of kidney homogenate at 12 h showed mostly low molecular weight peaks, although there is a trace of a higher molecular weight species, corresponding to undegraded [^{111}In]DOTA-Rituxan-Fab.

Urine was collected at 1 h and analyzed by gel filtration. At this time point, the urine sample contained about 50% of the counts as intact [^{111}In]DOTA-Rituxan-Fab and 50% as two low molecular weight species, one of which corresponds to the [^{111}In]DOTA standard (Figure 2B). These results demonstrate that appreciable amounts of intact [^{111}In]DOTA-Rituxan-Fab can be filtered into the urine without degradation and that low molecular weight metabolic end products are also excreted into the urine. However, these amounts are insufficient to account for the total accumulation of the low molecular species retained in the kidney ($<10\%$). Thus, the low molecular species are only excreted at a low rate. Interestingly, the

Figure 2. Gel filtration chromatography of kidney metabolites and urine samples. (A) Kidney homogenates made from mice injected with 5.0 μCi (2.0 μg) of [^{111}In]DOTA-Rituxan Fab at 12 h were analyzed on tandem Superose 12 columns, equilibrated in PBS and eluted at 0.5 mL/min. The elution positions of DOTA-Rituxan Fab, [^{111}In]DOTA- ϵ -amino-lysine, and [^{111}In]DOTA are indicated by arrows. (B) Urine samples collected from mice injected with 5.0 μCi (2.0 μg) of [^{111}In]DOTA-Rituxan Fab at 1 h were analyzed on tandem Superose 12 columns.

low molecular species in the urine separates into two peaks by this analysis. Possibilities include separation of [^{111}In]DOTA from [^{111}In]DOTA- ϵ -amino-lysine. Since we cannot distinguish [^{111}In]DOTA from [^{111}In]DOTA- ϵ -amino-lysine (or other low molecular species) by this analysis, further studies were required.

SDS-PAGE Analysis of Kidney Metabolites. Kidney homogenates generated from nude mice injected with [^{111}In]DOTA-Rituxan-Fab were also analyzed on SDS gradient gels (10–15%) and exposed to X-ray film for 1 week (Figure 3). Although both the PBS-soluble and SDS-solubilized fractions were analyzed, the PBS-soluble fractions contained >90% of the counts. [^{111}In]DOTA and $^{111}\text{InCl}_3$ standards ran anomalously at an apparent mass of 20 kDa while [^{111}In]DOTA- ϵ -amino-lysine failed to enter the gel. While we cannot explain the anomalous behavior of these compounds on SDS gel electrophoresis, the migrations were reproducible and served to uniquely identify them. [^{111}In]DOTA-Rituxan-Fab ran as expected at 48 kDa. By this analysis, the kidney homogenates at 0 h contain a small amount of intact [^{111}In]DOTA-Rituxan-Fab. By 6 h, the kidney homogenates containing the radioactive metabolites have the same pattern as that of [^{111}In]DOTA- ϵ -amino-lysine, suggesting that they are completely degraded to this end product.

Anion-Exchange Chromatography of Kidney Metabolites. Kidneys harvested from mice injected with 10 μCi of [^{111}In]DOTA-Rituxan-Fab were analyzed on a strong anion-exchange column (Figure 4). [^{111}In]DOTA-

ϵ -amino-lysine eluted as a sharp peak at 2 min (Figure 4A) and [^{111}In]DOTA eluted as a broad peak at about 4.5 min (Figure 4B). The major kidney metabolites showed a single sharp peak that coeluted with [^{111}In]DOTA- ϵ -amino-lysine at all time points analyzed (Figure 4C showing $t = 5$). The urine sample taken at 5 h eluted as a sharp peak at 2 min (Figure 4D) corresponding to the [^{111}In]DOTA- ϵ -amino-lysine standard. We conclude that [^{111}In]DOTA- ϵ -amino-lysine is the ultimate end product of kidney metabolism of [^{111}In]DOTA-Rituxan-Fab, and that this product is then excreted into urine. Unlike the gel filtration analysis, there was no evidence of a second metabolite. We conclude that the peak splitting of the low molecular weight metabolite on the gel filtration analysis was probably an artifact.

Anion-Exchange Chromatography of Patient Urine Sample. Since we had access to urine samples from patients being imaged with an [^{111}In]DOTA conjugated intact antibody, we hypothesized that their urine would contain the same radioactive end product. The rationale is that DOTA was conjugated to lysines of intact antibody by the same active ester chemistry. Indeed, the urine of these patients contained substantial amounts of a peak corresponding to [^{111}In]DOTA- ϵ -amino-lysine when analyzed by anion-exchange chromatography (Figure 5). In this study, urine from a patient receiving [^{111}In]DOTA-chT84.66 (an anti-CEA antibody) in a phase I trial involving a preimaging dose of [^{111}In]DOTA-chT84.66 to be followed by a therapy dose of [^{90}Y]DOTA-chT84.66 was analyzed by anion-exchange chromatography (Figure 5). As shown in the figure, approximately 80% of the detected urine activity corresponded to [^{111}In]DOTA- ϵ -amino-lysine. We have not identified the minor peak eluting at 11 min. Nonetheless, using both murine and human data, we conclude that [^{111}In]DOTA- ϵ -amino-lysine is the common and ultimate end product for kidney metabolism of active ester DOTA-conjugated antibody and antibody fragments, and that there is no obvious difference in this metabolism between mice and men. This preliminary analysis only describes the final metabolic product and does not address the difference in kinetics between the two protein species.

DISCUSSION

The routine use of radiolabeled antibody fragments for tumor therapy is limited by their rapid kidney uptake and metabolism within the lysosomal compartment of kidney tubule cells. Thus, it appears that antibody fragments are not simply filtered by the kidney into the urine, but are actively degraded to recycle their constitutive amino acids. If the attendant radiolabel is scavenged and/or cleared, as in the case of radioiodine on tyrosine residues, there is no net radiolabel accumulation. However, in the case of chelate-conjugated antibodies labeled with radiometals, there is a net accumulation in the lysosomal compartment, suggesting a slow clearance mechanism for the ultimate radiolabeled end product. The relative abundance of lysine residues in proteins and the nucleophilic reactivity of the ϵ -amino group of lysine has led to a variety of approaches for attaching bifunctional chelates (BFC) to these residues (Meares et al., 1984; Deshpande et al., 1990). The advantage of this approach is to produce conjugates that can be radiolabeled just prior to use. For example, first generation chelates based on EDTA contained a benzyl-isothiocyanate group for coupling to lysine residues (Meares et al., 1984; Deshpande et al., 1990). Arano and co-workers (1994) showed that neoglycoproteins (a deliberate model system for inducing high liver uptake) labeled with this [^{111}In]EDTA BFC had high liver uptake (65–95% ID/g at 1 h), and identified an [^{111}In]EDTA- ϵ -amino-lysine

Figure 3. SDS-PAGE analysis of kidney homogenates. Kidney homogenates from mice injected with 5.0 μCi (A) or 10 μCi (B) [^{111}In]DOTA-Rituxan Fab and markers were analyzed on 10–15% gradient SDS gels under nonreducing conditions. (A) Lane 1, [^{111}In]DOTA. Lane 2, [^{111}In]DOTA Rituxan Fab. Lane 3, prestained MW markers. Lanes 4–5, $t = 0$ h, PBS soluble and SDS solubilized fractions. Lanes 6–7, $t = 12$ h, PBS soluble and SDS solubilized fractions. Lane 8, $t = 6$ h, PBS soluble fraction. The elution positions of $^{111}\text{InCl}_3$ and [^{111}In]DOTA- ϵ -amino-lysine were indicated by arrows. (B) Lane 1, [^{111}In]DOTA-Rituxan Fab. Lanes 2–4, $t = 9, 5$, and 1 h SDS solubilized fractions. Lanes 5–7, $t = 9, 5$, and 1 h PBS soluble fractions. Lane 8, [^{111}In]DOTA- ϵ -amino-lysine.

derivative as the main metabolic end product in the lysosomal compartment. In the case of the second generation chelates based on DTPA (the bicyclic anhydride of DPA conjugated to lysines in neoglycoproteins), Duncan and Welch (Duncan and Welch, 1993) also found a low molecular weight ^{111}In -labeled metabolite in the lysosomal compartment of the liver. Subsequently, this group identified the metabolite as [^{111}In]DTPA- ϵ -amino-lysine (Franano et al., 1994). Significantly, radioactivity cleared more slowly from the DTPA-based BFC than from the EDTA-based BFC. In the case of antibody fragments labeled with [^{111}In]DTPA BFC, high kidney uptake and retention were observed in the lysosomal compartment, and the major metabolic end product was again identified as [^{111}In]DTPA- ϵ -amino-lysine (Rogers et al., 1995).

More recently, many groups have turned their attention to third generation chelate, DOTA, which has stability constants $>10^{30} \text{ M}^{-1}$ and negligible off rates for trivalent metals such as In^{3+} and Y^{3+} (Craig et al., 1989; Deshpande et al., 1990; Moi et al., 1990; Peterson et al., 1999). As with previous generation BFCs, lysines have been the major target residue for coupling to proteins (Moi et al., 1990). In our own work, we have shown that DOTA can be coupled to lysines in proteins using a simple activated ester chemistry (Lewis et al., 1994). In the case of intact antibodies labeled with [^{111}In]DOTA, liver retention in the nude mouse model is moderate ($\approx 10\%$ ID/g at 1–48 h) and kidney retention low ($\approx 12\%$

ID/g at 1–48 h) (Williams et al., 1998). However, the same BFC coupled to a Fab antibody fragment and labeled with ^{111}In resulted in 45–95% ID/g in the kidneys (Table 1). This exceptionally high uptake was similar to that observed for [^{111}In]DTPA labeled F(ab')_2 fragments (Kuhlmann and Steinstrasser, 1988; Massuger et al., 1991; Yemul et al., 1993). On the basis of the results for EDTA and DTPA based BFCs, we examined that possibility that the major metabolic end product would be [^{111}In]DOTA- ϵ -amino-lysine.

Our analysis of the kidney homogenates by three methods (gel filtration, SDS-PAGE, and ion-exchange chromatography) revealed [^{111}In]DOTA- ϵ -amino-lysine as the ultimate metabolic end product with only trace amounts of intact [^{111}In]DOTA-Fab found at the earliest time points. Analysis of the urine shows appreciable amounts of [^{111}In]DOTA-Fab is filtered without degradation at early time points, but later on only [^{111}In]DOTA- ϵ -amino-lysine is found. Additionally, analysis of urine samples from a patient injected with [^{111}In]DOTA-chT84.66 showed the identical end product, thus confirming that this conclusion can be extended to other species and intact antibodies.

In earlier studies, Schott et al. (1992) conjugated a benzyliothiocyanato derivative of DOTA to a recombinant scFv version of the antitumor antibody CC49, radio-labeled it with ^{177}Lu and compared its biodistribution to an ^{125}I -labeled version. At 1 h the kidney uptake was

Figure 4. Anion-exchange chromatography analysis of kidney homogenates and urine samples. Kidney homogenates and urine samples taken at 5 h from mice injected with 10 μCi of [^{111}In]DOTA-Rituxan Fab were analyzed on a Poros-HQ column and compared with markers. (A) [^{111}In]DOTA- ϵ -amino-lysine. (B) [^{111}In]DOTA. (C) Kidney homogenate, 5 h. (D) Urine, 5 h.

>200% ID/g for the [^{177}Lu]DOTA-scFv and slowly dropped to >150% ID/g by 48 h. As expected, the ^{125}I -labeled version had low kidney uptake (10% ID/g at 1 h and <2% ID/g at 48 h). More recently, Govindan et al. (1998) studied the biodistribution of ^{88}Y -labeled DOTA-F(ab')₂ fragments of two antibodies (anti-CEA and anti-lymphoma). High retention was observed in the kidneys at 4, 24, and 48 h (70–104% ID/g). Although the Fab fragment used in our study has a smaller molecular size and we utilized ^{111}In rather than ^{88}Y as the radiometal, the biodistributions were quantitatively similar. In addition, the presence of tumor in their study did not affect the high kidney uptake. This study suggests the possibility of in vivo breakdown of their F(ab')₂ to Fab' fragments which are small enough to be cleared by the kidney. In agreement with this possibility Lamki et al.

Figure 5. Anion-exchange chromatography analysis of patient urine sample. Urine sample from a patient being imaged with [^{111}In]DOTA-chT84.66 was analyzed on a Poros-HQ column. The urine sample corresponded to 24–48 h after administration of the pre-therapy [^{111}In]DOTA-chT84.66 antibody. An aliquot (200 μL) was applied to the column. The elution positions of [^{111}In]DOTA and [^{111}In]DOTA- ϵ -amino-lysine are indicated by arrows.

(Lamki et al., 1990) showed that chemically stabilized ^{111}In -labeled F(ab')₂ fragments have low kidney uptake.

An alternative approach to lower renal uptake has been to attach chelates to antibody fragments via a metabolically labile linker such as cleavable ester linkers (Meares et al., 1988; Paik et al., 1989; Weber et al., 1990; Arano et al., 1996). However, the results have been uniformly disappointing, giving only a modest reduction in kidney retention, and sometimes leading to cleavage within the blood.

While our study showed that [^{111}In]DOTA-Fab has high kidney uptake, injection of the metabolite [^{111}In]DOTA- ϵ -amino-lysine, results in excretion directly into the urine. These data suggest that [^{111}In]DOTA- ϵ -amino-lysine produced by metabolism of radiolabeled DOTA-antibody in other tissues would clear rapidly from the blood and not be retained in the kidney. Thus, the accumulation in kidney occurs at the level of the antibody fragment and failure to excrete the majority of the metabolic product produced there (e.g., see Figure 1).

On the basis of these results, we are now designing DOTA-based chelates that are expected to have enhanced kidney clearance. Our strategy is based on the peptide approach of Arano and co-workers (Wakisaka et al. 1997; Arano 1998; Arano, Fujioka et al. 1999) and Meares and co-workers (Li and Meares 1993; Peterson et al. 1999) who have appended their radiolabeled moiety to peptides. This approach promises to decrease renal uptake and/or increase the rate of metabolism in the kidney.

ACKNOWLEDGMENT

We gratefully acknowledge Stephanie Wright and Jianyi Yuan for assistance in animal work and Randall Woo in radiolabeling. This work was supported by NCI Grant CA43904.

Carbohydrate-Directed Conjugation of Cobra Venom Factor to Antibody by Selective Derivatization of the Terminal Galactose Residues

Qinglan Fu and D. Channe Gowda*

Department of Biochemistry and Molecular Biology, 3900 Reservoir Road, Georgetown University Medical Center, Washington, DC 20007. Received August 14, 2000; Revised Manuscript Received January 12, 2001

Cobra venom factor (CVF) can cause cell death by complement-mediated bystander cell lysis. Several studies have investigated CVF for application in cancer therapy by conjugating CVF to antibodies against tumor cell surface-specific antigens via the side-chain amino acid residues. In most cases, the activity of CVF was markedly impaired, presumably by modification of the factor B binding domain due to random derivatization. Since CVF is a glycoprotein and its oligosaccharide chains are distal to the factor B binding domain, coupling of CVF to antibodies through its oligosaccharide chains is expected to yield immunoconjugates with retention of CVF activity and elimination of the immunoreactivity of the terminal α -galactosyl residues. In this study, we investigated the carbohydrate site-directed conjugation of CVF to a monoclonal IgG specific to a cell-surface antigen of human ovarian cancer cells. The terminal galactosyl residues of CVF were selectively modified at C-6 by treatment with galactose oxidase, and the generated aldehyde groups were derivatized in situ with hydrazides containing either protected thiol or maleimide functional groups. The CVF derivatives were allowed to react with thiol groups introduced to the antibody by derivatization with 2-iminothiolane to yield carbohydrate site-directed CVF–antibody conjugates. In both cases, 30–40% of the antibody cross-linked to CVF to yield predominantly monovalent CVF–antibody conjugates. The purified immunoconjugates retained 70–75% of CVF activity and significant level of antigen-binding capacity. This is the first study to exploit the oligosaccharide chains of CVF for the preparation of active immunoconjugates.

INTRODUCTION

Cobra venom factor (CVF),¹ a nontoxic complement-activating glycoprotein in cobra venom, is a functional analogue of mammalian complement component C3b. When added to mammalian serum, CVF forms CVF,Bb, a C3/C5 convertase of the alternative pathway of the complement (1, 2). CVF,Bb can activate the complement in a manner similar to C3b,Bb, the physiologic C3/C5 convertase. However, CVF,Bb is completely resistant to the action of complement regulatory factors H and I. Therefore, when administered to animals, CVF can deplete the complement and build up membrane-attaching complexes; the latter can cause bystander lysis of cells (1). This property of CVF has been used for selective killing of tumor cells by conjugating to antibodies against cancer-specific cell surface antigens (1, 3–10).

CVF consists of three polypeptide chains, designated α , β , and γ , and three N-linked oligosaccharides; two in

the α -chain, one in the β -chain, and no carbohydrates in the γ -chain (11, 12). More than 80% of the oligosaccharide chains of CVF terminate with the unusual α -galactosylated Lewis X structures (12–14). CVF is immunoreactive to natural human anti- α -Gal antibody because of the presence of terminal Gal α 1–3Gal residues in its oligosaccharide chains (12, 15). Therefore, therapeutic application of CVF requires the abolition of this immunoreactivity. Although the anti- α -Gal antibody immunoreactivity of CVF can be abolished by the removal of terminal galactosyl residues, the exposed Lewis X structures are recognized by liver cell lectins, leading to rapid clearance of CVF from the circulation (16).

The complement-activating activity of CVF is not affected by either the removal of its oligosaccharide chains or the binding of the terminal α -galactosyl residues with lectin or antibodies (12). This implies that the oligosaccharide chains of CVF are distal to the factor B binding domain. Therefore, coupling of CVF through the terminal galactosyl residues to antibodies should yield immunoconjugates with the retention of the CVF activity and simultaneously eliminating the anti- α -Gal immunoreactivity due to masking of the terminal α -galactosyl residues. In addition, this mode of cross-linking of CVF to antibodies should avoid the rapid, asialoglycoprotein receptor-dependent, hepatic clearance of CVF immunoconjugates from the circulation. We have recently shown that the terminal galactosyl residues of CVF can be modified conveniently at C-6 by galactose oxidase treatment and in situ derivatization with hydrazides (17) and that this modification completely abolishes the anti- α -Gal immunoreactivity without affecting CVF activity (17).

¹ Abbreviations: CVF, cobra venom factor; PDPH, 3-(2-pyridyldithio)propionic acid hydrazide; MPBH, 4-(4-N-maleimidophenyl)butyric acid hydrazide; M₂C₂H, 4-(maleimidomethyl)-cyclohexane-1-carboxylic acid hydrazide; PDPH-CVF, PDPH derivative of CVF; M₂C₂H-CVF, M₂C₂H derivative of CVF; MPBH-CVF, MPBH derivative of CVF; DTNB, 5,5'-dithiobis(2-nitrobenzoic acid); SDS–PAGE, sodium dodecyl sulfate-polyacrylamide electrophoresis; HRP, horseradish peroxidase; FITC, fluorescein isothiocyanate; DTT, dithiothreitol; OVB-3, mouse monoclonal IgG_{2b} directed against a cell surface antigen of human ovarian cancer cells.

In this study, we used this site-specific derivatization procedure to conjugate CVF to a monoclonal antibody (OVB-3) directed against a cell surface antigen of human ovarian cancer cells and assessed the purified immunokonjugates for CVF and antibody activities.

EXPERIMENTAL PROCEDURES

Materials. CVF was isolated from *Naja naja kaouthia* venom as described previously (18). 3-(2-Pyridyldithio)propionic acid hydrazide (PDPH) and 4-(4-*N*-maleimidophenyl)butyric acid hydrazide (MPBH) were synthesized as reported previously by Zara et al. and Chamow et al., respectively (19, 20). 4-(Maleimidomethyl)-cyclohexane-1-carboxylic acid hydrazide (M_2C_2H), 5,5'-dithio-bis(2-nitrobenzoic acid) (DTNB) and 2-iminothiolane hydrochloride were purchased from Pierce Chemical Co. (Rockford, IL). Galactose oxidase (25 units/mg of protein) and coffee bean α -galactosidase (10 units/mg of protein) were from Boehringer Mannheim (Indianapolis, IN). HRP (type VIA, 1000 units/mg) was from Sigma Chemical Co. (St. Louis, MO). Centricon 30 tubes were from Amicon (Danvers, MA). FITC-conjugated goat anti-mouse IgG was from Southern Biotechnology Associates, Inc. (Birmingham, AL). RPMI 1640 medium, insulin, penicillin/streptomycin were from Life Technologies (Gaithersburg, MD). Guinea pig erythrocytes were obtained by femoral vein puncture. OVB-3, a mouse monoclonal antibody (IgG_{2b}, ref 21) was a generous gift from Dr. Ira Pastan, National Cancer Institute, NIH.

Carbohydrate Analysis. OVB-3 antibody (50 μ g) was hydrolyzed with 400 μ L of 2.5 M trifluoroacetic acid at 100 °C for 5 h. The hydrolysates were evaporated to dryness in a Speed Vac, dissolved in water and then analyzed for neutral sugars and hexosamines using a Dionex HPLC (Dionex Corp., Sunnyvale, CA) with pulsed amperometric detection on a CarboPac PA1 column (4 $\times$ 250 mm) (22). Elution was with 20 mM NaOH at a flow rate of 0.9 mL/min.

Sialic acids from OVB-3 antibody (20 μ g) were quantitatively released either by hydrolysis with 0.1 M sulfuric acid (40 μ L) at 80 °C for 50 min or by treatment with *Clostridium perfringens* sialidase (20 milliunits) in 50 μ L of 50 mM sodium acetate, pH 5.5, at 37 °C for 24 h. The released sialic acids were analyzed on a CarboPac PA1 high-pH anion-exchange column (4 $\times$ 250 mm) with 100 mM NaOH/150 mM NaOAc at a flow rate of 0.8 mL/min (22).

Derivatization of the Terminal Galactosyl Residues of CVF by Acid Hydrazides. Derivatization of the primary hydroxyl groups of the terminal galactosyl residues of CVF was carried out by a modification of the published procedures (23, 24). CVF (2–2.5 mg) in 1 mL of 100 mM sodium phosphate, pH 6.5, was incubated with galactose oxidase (10 units, added in two equal aliquots at 0 and 8 h), HRP (30 units/mL) and PDPH (50–100 mol/mol CVF) at 37 °C for 30 h (17). To minimize the hydrolysis of reactive maleimide groups to maleic acid, derivatization of the enzyme-oxidized CVF with MPBH or M_2C_2H was performed at the end of enzyme incubation for 2 h at room temperature. Uncoupled hydrazides were removed by filtration using Centricon 30 tubes or by gel filtration on Sephadex G-25 columns (0.9 $\times$ 15 cm) in 50 mM sodium phosphate, 150 mM NaCl, 2 mM EDTA, pH 6.5, 7.2 or 8.0.

To determine the extent of derivatization, an aliquot of PDPH-CVF (150 μ g in PBS, pH 7.2) was reduced with 50 mM DTT at room temperature for 20 min (25). The released pyridine-2-thione was determined by measuring

the absorbance of the solution at 343 nm and by using the molar extinction coefficient of $8.08 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ (25).

To determine the amount of M_2C_2H or MPBH coupling to CVF, M_2C_2H -CVF, and MPBH-CVF were reduced with sodium borohydride and treated with coffee bean α -galactosidase. The released galactose was measured by HPLC using high-pH anion-exchange column (see below).

Stability of M_2C_2H and MPBH in Buffer Solutions. Stock solutions of M_2C_2H or MPBH (28 mM in *N,N*-dimethylformamide) were diluted to 350 nM with 100 mM NaOAc (pH 5.5) or 100 mM sodium phosphate (pH 6.5, 7.0, 7.5, or 8.0). The hydrolysis of the maleimide moiety of M_2C_2H and MPBH was monitored at intervals by measuring the increase in absorbance at 320 nm for M_2C_2H or the decrease in absorbance at 300 nm for MPBH (20).

Derivatization of OVB-3 with 2-Iminothiolane. OVB-3 (1.2 mg) in 800 μ L of 50 mM sodium phosphate, 150 mM NaCl, 2 mM EDTA, pH 8.0, was incubated in a nitrogen atmosphere with 2-iminothiolane (104 μ g) at room temperature for 1 h (26). The unreacted 2-iminothiolane was removed by gel filtration on Sephadex G-25 columns (0.9 $\times$ 15 cm) in 150 mM NaCl, 2 mM EDTA, pH 8.0. The amount of 2-iminothiolane that coupled to OVB-3 was determined by treating the derivatized antibody with DTNB and measuring spectrophotometrically the released 2-nitro-5-thiol-benzoic acid (26).

Coupling of Hydrazide-Derivatized CVF to 2-Iminothiolane Derivative of OVB-3. PDPH-CVF, M_2C_2H -CVF and MPBH-CVF (0.5 mg each) were separately mixed with 2-iminothiolane-derivatized OVB-3 (0.5 mg) in 400 μ L of 150 mM NaCl, 2 mM EDTA, pH 6.5, 7.2, or 8.0, and incubated overnight at 25 °C with gentle rocking in a nitrogen atmosphere. Unreacted thiol groups in the derivatized OVB-3 and maleimide groups in M_2C_2H -CVF and MPBH-CVF were blocked with cysteine at 25 °C for 1 h. Aliquots of the solutions were analyzed by SDS-PAGE under nonreducing conditions (27).

The reaction mixtures (200–250 μ g protein) were chromatographed on Bio-Silect SEC 400-5 gel filtration HPLC columns (300 $\times$ 7.8 mm) (Bio-Rad, Hercules, CA) using a Dionex Bio-LC HPLC in PBS, pH 7.2. The elution was with 50 mM sodium phosphate, 150 mM NaCl, pH 7.2, at a flow rate of 0.9 mL/min. Proteins were monitored by on-line UV detection at 280 nm using a Dionex variable wavelength detector. Fractions corresponding to CVF-IgG conjugates were pooled and analyzed for CVF activity.

Derivatization of the Oligosaccharide Chains of OVB-3 with PDPH. OVB-3 (2 mg/mL) in 50 mM sodium phosphate, 150 mM NaCl, pH 6.5, was treated with 5 mM sodium periodate (1 mL) in the above buffer at 4 °C for 10 min. Excess periodate was allowed to react with glycerol (25 μ L) at 4 °C for 30 min. The solution was dialyzed against 50 mM sodium phosphate, 150 mM NaCl, pH 6.5, and then incubated with 50-fold molar excess PDPH at 25 °C for 5 h. The amount of PDPH coupled to the antibody was determined as described above (25).

Coupling of CVF to OVB-3 via the Carbohydrate Moieties of Both Proteins. The PDPH-derivatized OVB-3 (0.5 mg) was treated with 20 mM DTT in 200 μ L of 100 mM NaOAc, pH 4.5, at 25 °C for 20 min. The solution was chromatographed on Sephadex G-25 (0.9 $\times$ 15 cm) in 50 mM sodium phosphate, 150 mM NaCl, 2 mM EDTA, pH 8.0. The void volume fractions were concentrated in Centricon 30 tubes and allowed to react with PDPH-CVF (0.5 mg) in 250 μ L of 50 mM sodium

Figure 1. Scheme for the derivatization of the terminal galactosyl residues of the oligosaccharide chains (partial structure is shown) of CVF with heterobifunctional hydrazides. Oxidation of CVF with galactose oxidase in the presence of HRP generates aldehyde groups at the C-6 positions of the terminal galactose residues. The derivatization of the aldehyde groups with protected thiol group- or maleimide group-containing hydrazides yielding stable hydrazones offers a convenient approach to couple CVF to antibodies.

phosphate, 150 mM NaCl, 2 mM EDTA, pH 8.0, overnight at 25 °C in a nitrogen atmosphere. Unreacted thiol groups were blocked with cysteine at 25 °C for 1 h. Aliquots of the solutions were analyzed on 5% SDS-polyacrylamide gel under nonreducing conditions.

Hemolytic Assay for CVF Activity. CVF, hydrazide-derivatized CVF, or CVF-OVB-3 conjugates (8–2000 ng CVF protein in each case) in PBS, 1 mM CaCl_2 , 0.5 mM MgCl_2 , and 0.1% (w/v) gelatin, pH 7.2 (20 μL) were mixed with guinea pig serum (20 μL) and guinea pig erythrocytes (10×10^6 in 20 μL of the above buffer) and incubated at 37 °C for 40 min (12). Cold PBS, pH 7.2 (1 mL), was added, the unlysed erythrocytes were removed by centrifugation and the released hemoglobin was measured at 412 nm.

OVB-3 Binding to Ovarian Cancer Cell Surface Antigen. Human ovarian cancer cells (NIH:OVCAR-3 cells obtained from ATCC, Rockville, MD) were cultured as monolayers in RPMI 1640 medium with 10% fetal calf serum, insulin (10 $\mu\text{g}/\text{mL}$), penicillin (100 units/mL), and streptomycin (100 $\mu\text{g}/\text{mL}$), according to Pirker et al. (28). Cells were detached by gentle scraping, washed with serum-free medium and suspended in PBS, pH 7.2, containing 2% bovine serum albumin. The cells were treated with OVB-3, 2-iminothiolane-derivatized OVB-3 or CVF-OVB-3 conjugates (5 μg antibody/mL in PBS, pH

7.2) at 4 °C for 2 h. After washing with PBS, pH 7.2, the cells were treated with FITC-labeled goat anti-mouse IgG at 4 °C for 1 h, washed, fixed with 2% paraformaldehyde, and surface fluorescence was measured using a Becton Dickinson FACS II analyzer at the Georgetown University Lombardi Cancer Center core facility.

RESULTS

Derivatization of Terminal Galactosyl Residues of CVF with Hydrazides. CVF contains approximately 5.6 terminal galactosyl residues (~ 4.1 α -linked and ~ 1.5 β -linked) (17). The C-6 hydroxyl groups of the terminal galactosyl residues were oxidized with galactose oxidase in the presence of HRP and the generated aldehyde groups were derivatized with three different hydrazides, which contain electrophilic centers for cross-linking of CVF to antibodies as depicted in Figure 1 (17). Treatment of PDPH-CVF with DTT released about 5.5 mol of pyridyl-2-thione, indicating that $>95\%$ of the terminal galactosyl residues of CVF were derivatized. In agreement with this result, treatment of sodium borohydride-reduced PDPH-CVF, $\text{M}_2\text{C}_2\text{H}$ -CVF, or MPBH-CVF with coffee bean α -galactosidase did not release detectable amounts of galactose. The hemolytic activity of CVF derivatized with all three hydrazides, as measured by the

Figure 2. Scheme for the conjugation of OVB-3 to the oligosaccharide chains of CVF. The derivatization of the OVB-3 with 2-iminothiolane introduces thiol groups to the antibody. When the derivatized antibody allowed to react with PDPH-CVF (A) or M₂C₂H-CVF (B) under nitrogen atmosphere yields disulfide- or thioether-linked CVF-OVB-3 conjugates.

Figure 3. SDS-polyacrylamide gel electrophoresis of CVF-OVB-3 conjugates. The hydrazide-derivatized CVF (5–10 μ g), 2-iminothiolane derivatized OVB-3 (5–10 μ g) and CVF-OVB-3 conjugates (20–30 μ g), prepared as outlined in Figure 2, were electrophoresed on 5% (panel A) and 6% (panel B) SDS-polyacrylamide gel under nonreducing conditions. The gels were stained with Coomassie blue. (A) Lane 1, PDPH-CVF; lane 2, 2-iminothiolane derivative of OVB-3; lane 3, CVF-OVB-3 conjugates prepared from PDPH-CVF. Panel B: Lane 1, CVF-OVB-3 prepared from MPBH-CVF; lane 2, CVF-OVB-3 prepared from M₂C₂H-CVF; lane 3, MPBH-CVF; lane 4, 2-iminothiolane derivatized OVB-3.

bystander lysis of guinea pig erythrocytes in guinea pig serum, was similar to that of untreated CVF (see Figure 5).

Carbohydrate Moieties of OVB-3. In view of coupling hydrazide-derivatized CVF to carbohydrate moieties of the monoclonal antibody OVB-3, the nature of the carbohydrate moieties of the antibody was examined. More than 90% of the carbohydrate moiety of OVB-3 was released by *N*-glycanase, an enzyme that removes asparagine-linked oligosaccharides in glycoproteins (29). Carbohydrate compositional analysis of the enzyme-released carbohydrates revealed sialic acid, galactose,

Figure 4. HPLC fractionation of CVF-OVB-3 conjugates. The CVF-OVB-3 conjugates prepared as shown in Figure 2 were fractionated by HPLC gel filtration. Shown is the separation of CVF-OVB-3 prepared from the conjugation of 2-iminothiolane-derivatized OVB-3 to PDPH-CVF. PDPH-CVF monovalent conjugates (fraction III, $M_r \approx 300$ kDa) and multivalent conjugates (fractions II and I, $M_r \approx 450$ and 600 kDa, respectively) were pooled as indicated. The immunoconjugates prepared by cross-linking 2-iminothiolane derivatized OVB-3 to MPBH-CVF and M₂C₂H-CVF were also fractionated by HPLC (not shown).

N-acetylglucosamine, mannose, fucose, *N*-acetylgalactosamine in the approximate molar ratios of 2.1:2.8:4.4:3.0:0.9:0.3. Sialic acid was found to be a mixture of 60% *N*-acetylneuraminic acid and 40% *N*-glycolylneuraminic acid. The results suggest that the carbohydrate moieties of OVB-3 are predominantly complex type *N*-linked oligosaccharides, present most likely in the Fc region of

Figure 5. Effect of hydrazone derivatization and conjugation of the antibody on CVF activity. CVF activity was measured by complement-mediated lysis of unsensitized guinea pig erythrocytes. The indicated amounts of the hydrazone derivatives of CVF and CVF-antibody conjugates were incubated with unsensitized guinea pig erythrocytes in guinea pig serum. The absorbance of the released hemoglobin was measured at 412 nm. the antibody. IgGs contain two *N*-linked oligosaccharides in their Fc regions; one oligosaccharide per polypeptide chain.

Derivatization of OVB-3 with 2-Iminoethanol and Conjugation to Hydrazone Derivatives of CVF.

The OVB-3 antibody was derivatized with 2-iminoethanol, a widely used reagent for the introduction of thiol groups to proteins for cross-linking (26, 30–33). Treatment of OVB-3 with ~90-fold molar excess of 2-iminoethanol introduced 4–5 thiol groups/molecule of the antibody. The derivatization procedure did not significantly affect the antigen-binding activity of the antibody (see legend to Figure 6).

OVB-3 derivatized with 2-iminoethanol was allowed to react separately with the PDPH-, M_2C_2H -, and MPBH-derivatives of CVF at various pH according to the scheme outlined in Figure 2. SDS-PAGE analysis of the reaction mixtures showed that the derivatized OVB-3 efficiently conjugated to PDPH-CVF at pH 8.0, yielding a major product at ~300 kDa and minor products at >450 kDa; approximately 40% of OVB-3 was coupled to CVF (Figure 3). The cross-linking of OVB-3 to PDPH-CVF was 5–10% at pH 6.5 or 7.2 (not shown). In the case of M_2C_2H -CVF and MPBH-CVF, the coupling efficiency at pH 8.0 was <10% (not shown), which is likely due to the rapid hydrolysis of maleimide groups compared with the rate of conjugation under the basic reaction conditions employed (see below).

To determine appropriate conditions for cross-linking OVB-3 to MPBH-CVF and M_2C_2H -CVF, we studied the rate of hydrolysis of maleimide groups in MPBH and M_2C_2H by incubating these compounds in aqueous buffers at pH 5.5, 6.5, 7.0, 7.5, and 8.0, as described previously (20). The maleimide groups in these compounds were relatively stable at pH ≤ 7, but hydrolyzed significantly at pH 8.0 (not shown). These results agree with the previously reported property of maleimide functional group-containing compounds (20, 32, 33). Therefore, we carried out the conjugation of 2-iminoethanol-derivatized OVB-3 to M_2C_2H -CVF and MPBH-CVF at pH 7.2. Under this condition, approximately 30–35% of OVB-3 was coupled to CVF, yielding immunoconjugates at levels similar to those formed in the case of PDPH-CVF (Figure 3).

HPLC separated the immunoconjugates from the unreacted compounds as multiple peaks; in each case, a major conjugate corresponding to peak at ~300 kDa, a minor partially resolved peak at ~450 kDa, and a minor unresolved shoulder at ~600 kDa (Figure 4). The CVF-antibody conjugate fractions (fractions I, II, and III) were pooled as shown in Figure 4. The conjugates obtained from the cross-linking OVB-3 to PDPH-CVF were treated with DTT and analyzed by SDS-PAGE under reducing conditions. Fractions I and III contained approximately equal amounts of CVF and OVB-3, whereas fractions II had about 30–40% CVF and 60–70% OVB-3. These results together with the observed molecular weights of the conjugate fractions suggest that fraction III is a monovalent conjugate (one molecule each of CVF and OVB-3), fraction II is CVF₂-IgG and CVF-IgG₂, and fraction I is CVF₂-IgG₂.

The HPLC-fractionated CVF-OVB-3 conjugates (see Figure 4) were analyzed for CVF activity and OVB-3 antigen-binding capacity. CVF in the CVF-OVB-3 monovalent conjugate (fraction III) exhibited 70–75% hemolytic activity compared with that of the unmodified or the PDPH-, MPBH-, or M_2C_2H -derivatized CVF (Figure 5), whereas CVF in conjugate fractions I and II showed ~20–30% and 40–50% activity, respectively (Figure 5). The antigen-binding activity of OVB-3 in CVF-OVB-3 conjugate fractions was assessed by measuring cell surface immunofluorescence using NIH:OVCAR-3 cells cultured as monolayers. OVB-3 in the immunoconjugate fraction III showed a significant level of antigen-binding capacity, whereas the antibody in conjugate fractions I and II exhibited only marginal activity (Figure 6).

Cross-Linking of OVB-3 to CVF via the Carbohydrate Moieties of Both Glycoproteins. Since 40% of the sialic acid residues in OVB-3 are *N*-glycolylneuraminic acid, which is not expressed in man, therapeutic use of OVB-3 requires the removal or masking of these residues. Cross-linking of CVF to the sialic acid residues of OVB-3 is expected to mask the possible adverse effects of *N*-glycolylneuraminic acid. Besides, this approach should yield immunoconjugates with retention of the CVF and antibody activities because the factor B-binding site in CVF and antigen-binding site in OVB-3 are not modified. Therefore, we studied the coupling of PDPH-CVF to the carbohydrate moieties of OVB-3. Aldehyde groups were generated on the sialic acid residues of the oligosaccharides of OVB-3 by mild oxidation with sodium periodate and they were then derivatized with PDPH. This procedure introduced 3–3.5 residues of PDPH to OVB-3. The PDPH derivative of OVB-3 was treated with DTT, and the generated thiol groups were allowed to react with PDPH-CVF as outlined in Figure 7. SDS-PAGE analysis showed that the coupling efficiency of the reaction was very low; <5% CVF and the antibody were coupled to form CVF-OVB-3 conjugates (Figure 8). This low coupling efficiency was surprising considering that OVB-3 and CVF contained 3.5 and 5.5 reactive groups per mol of protein, respectively. The reason for this low coupling efficiency could be due to the limited accessibility of the carbohydrate moieties of OVB-3 because of their localization in the sterically hindered hinge region of the antibody. This is consistent with the results of a previous study in which the reactive groups on the side-chain amino groups of an antibody were better accessible than those on the carbohydrate chains in the Fc regions of the antibody for coupling with CVF containing protected thiol groups (34). Another reason for the low coupling efficiency could be that the presence of reactive functional groups on the flexible oligosaccharide chains of both proteins

Figure 6. Effect of coupling of OVB-3 to CVF on the antigen-binding activity of the antibody. NIH:OVCAR-3 cells were incubated with nonspecific mouse IgG (A), OVB-3 (B), or CVF-OVB-3 conjugate (fraction III in Figure 4) (C). After washing, the cells were treated with FITC-conjugated goat anti-mouse IgG, washed, fixed with paraformaldehyde, and the intensity of cell surface immunofluorescence was measured by flow cytometry. 2-Iminothiolane-treated OVB-3 showed a similar immunofluorescence profile (not shown) compared with that of the untreated OVB-3. The binding of CVF-OVB-3 conjugate fractions I and II to NIH:OVCAR-3 cells was also examined; both fractions exhibited only marginal activity (not shown).

Figure 7. Scheme for the conjugation of the antibody OVB-3 to CVF through the carbohydrate moieties of CVF and OVB-3. Treatment of OVB-3 with sodium periodate under mild conditions forms aldehyde groups at C-7 or C-8 of the terminal sialic acid residues of OVB-3. Derivatization of the aldehyde groups with PDPH and treatment with DTT generates free thiol groups in OVB-3. Incubation of the derivatized OVB-3 overnight at room temperature with PDPH-CVF under nitrogen atmosphere yields CVF-OVB-3 conjugates.

markedly limits the probability of the functional groups to come in close proximity of one another for efficient coupling.

DISCUSSION

CVF immunoconjugates offer several advantages over conjugates of toxins (35, 36) or drugs (38) for the targeted killing of tumor cells. First, CVF is nontoxic, and cell

Figure 8. SDS-polyacrylamide gel electrophoresis of CVF-OVB-3 conjugates. The CVF-OVB-3 conjugates (20–30 μg) prepared as shown in Figure 7 were electrophoresed on 6% SDS-polyacrylamide gel under nonreducing conditions. The gels were stained with Coomassie blue. Lane 1, PDPH-CVF; lane 2, PDPH-OVB-3; lane 3, CVF-OVB-3 conjugates.

killing is mediated by the host effector mechanism, namely the complement activation (1). Second, unlike toxins or drugs, CVF does not require internalization by the target cells. Third, since CVF is not a drug or a mutagen, it does not cause complications such as induction of secondary malignancies or resistance to cytotoxicity (36). However, the immunoreactivity of the carbohydrate moieties of CVF to natural anti- α -Gal antibodies in humans limits the therapeutic application of CVF. Carbohydrate site-directed conjugation of CVF can mask this immunoreactivity.

Previously, CVF-antibody conjugates have been prepared by coupling CVF to various tumor-cell surface specific antigens and studied the ability of conjugates to kill tumor cells by complement-mediated cell lysis (1, 3–10). In those studies, CVF was coupled to the antibodies through the ϵ -amino groups of lysine residues using heterobifunctional reagents containing amino group-reactive succinimidyl esters (33, 37–39). The activity of CVF was markedly impaired because the random derivatization of the amino acid side chains of CVF resulted in the conjugation of antibodies at or in the proximity of the factor B binding domain, presumably blocking factor B binding. However, the oligosaccharide chain-directed coupling of CVF to antibodies should yield immunoconjugates with retention of CVF activity while simultaneously masking the anti- α -Gal immunoreactivity (12). In this study, we pursued the carbohydrate site-directed cross-linking of CVF to OVB-3, a monoclonal antibody specific to a cell surface antigen of human ovarian cancer cells, and assessed the complement-activating activity of CVF and the cell surface antigen-binding capacity of the antibody (21).

Carbohydrate-directed cross-linking of glycoproteins to proteins is commonly accomplished by derivatization of terminal sugar residues with heterobifunctional hydrazides. Oxidation with sodium periodate under mild conditions to generate aldehyde groups has been used extensively for the hydrazide-derivatization of the terminal sugar residues of glycoproteins (40–42). When this approach was used for the derivatization of terminal galactosyl residues of CVF, the complement-activating activity of CVF was markedly decreased due to the oxidation of critical methionine residue(s) (43). To overcome this problem, we sought a derivatization method

for the facile introduction of functional groups into the carbohydrate moiety of CVF that are amenable to conjugation. Recently, we reported that oxidation of CVF with galactose oxidase in the presence of acid hydrazides introduces functional groups on the C-6 position of the terminal galactosyl residues of CVF that can be used for conjugation to antibodies (17). This procedure selectively and quantitatively derivatizes the terminal galactosyl residues of CVF with complete retention of functional activity and simultaneous elimination of the anti- α -Gal immunoreactivity (17). In the present study, we used this strategy for the conjugation of CVF to the OVB-3 antibody. Three different heterobifunctional hydrazides, PDPH, M_2C_2H , and MPBH, which are amenable to cross-linking to antibodies, were coupled to the aldehyde groups formed at the C-6 positions of the terminal galactosyl residues of CVF (17). The derivatization was quantitative irrespective of the hydrazide used. As reported previously, this procedure eliminated the anti- α -Gal immunoreactivity without affecting CVF activity (17).

When PDPH-CVF, M_2C_2H -CVF, and MPBH-CVF were allowed to react at pH 8.0 with OVB-3 derivatized with 2-iminothiolane, a significant difference in coupling efficiency was apparent. Whereas about 40% of OVB-3 coupled to PDPH-CVF at pH 8.0, only about 10% of the antibody coupled to M_2C_2H -CVF or MPBH-CVF under this condition. The low antibody coupling efficiency to M_2C_2H -CVF and MPBH-CVF was likely due to the rapid inactivation of maleimide groups by base-catalyzed hydrolysis at pH 8.0. The maleimide functional group-containing heterobifunctional reagents have been widely and successfully used for protein-protein or protein-hapten conjugation (20, 33). Although the maleimide group is relatively stable under acidic pH, it undergoes rapid hydrolysis at pH >8.0. Therefore, protein-protein cross-linking involving nucleophilic addition of thiol group to maleimide moiety have been performed in most cases at pH between 6.5 and 7.0 (20, 33). When the thiol group-containing OVB-3 was allowed to couple to M_2C_2H -CVF or MPBH-CVF at pH 6.5, the efficiency was poor; only 5–10% of the antibody conjugated to CVF. However, when the reaction was carried at pH 7.2, the yield of the CVF-OVB-3 conjugates was 30–35%. Thus, the results of this study demonstrate that the hydrazides containing either protected thiol group or reactive maleimide group are amenable, under appropriate conditions, for the carbohydrate site-directed conjugation of CVF to antibodies. The results also demonstrate that the hydrazides containing protected thiol groups are superior reagents compared with those containing maleimide function for the preparation of CVF immunoconjugates. One major advantage of using protected thiol group-containing hydrazides is their stability during enzymatic oxidation of galactose residues of CVF. Thus, efficient hydrazide derivatization of the aldehyde formed on the oligosaccharide chains by the action of galactose oxidase can be achieved in situ during enzyme incubation. However, use of such a procedure for the maleimide group-containing hydrazides is likely inactivate significant amount of the maleimide moiety, despite slow hydrolysis at pH 6.5, because of long incubation period with the enzyme. Although this disadvantage can be surmounted by the addition of the hydrazides at the end of the enzyme reaction, the possibility of further oxidation of some aldehyde groups to carboxylic groups could adversely affect the derivatization of hydrazides (44). Over oxidation would be particularly significant when HRP was not added to the reaction mixture.

2-Iminothiolane is a widely used reagent to introduce reactive thiol groups into proteins for protein-protein conjugation (26, 30–33). The relatively reduced reactivity of 2-iminothiolane compared with open chain methyl 3-mercaptopropionimides allows for the better control of the degree of protein modification (31). This is important when biological activity of proteins has to be retained. Therefore, in this study, we chose to use 2-iminothiolane. While derivatization of OVB-3 with 2-iminothiolane had little or no effect on the antigen-binding capacity of OVB-3, coupling of the derivatized antibody to CVF appreciably reduced the antibody activity. Since the antigen-binding activity of 2-iminothiolane derivatized OVB-3 was similar to that of the untreated OVB-3, the results suggest that the side-chain amino acid residues in the antigen-binding sites of the antibody were not modified to a significant level. However, it appears that some of the amino acid residues proximal to the antigen-binding sites were derivatized, since coupling of OVB-3 to bulky CVF molecules caused an appreciable level of steric blockage to antigen binding.

To overcome this problem, we explored the carbohydrate site-directed coupling of OVB-3 to PDPH-CVF. OVB-3 was treated with sodium periodate under mild conditions to selectively oxidize the side-chain carbons of the terminal sialic acid residues to form aldehyde groups, which were then derivatized with PDPH. Reactive thiol groups were generated on the terminal sugar residues of oligosaccharide chains by treating PDPH-OVB-3 with DTT under conditions that specifically reduced the disulfide bonds of PDPH moiety, but not those of OVB-3. The thiol groups on the oligosaccharide chains of OVB-3 were then allowed to react with PDPH-derivative of CVF. Although this carbohydrate-to-carbohydrate coupling approach was expected to yield antibody-CVF conjugates with maximal retention of both antibody and CVF activity while simultaneously abolishing the immunoreactivities due to the α -galactosyl residues, the low coupling efficiency (<5%) limits the use of this approach for the preparation of CVF immunoconjugates.

The low coupling efficiency of carbohydrate-to-carbohydrate site-directed cross-linking of CVF to OVB-3 may be due in part to the limited accessibility of the OVB-3 carbohydrate chains, which are localized most likely in the sterically hindered hinge regions (34). This conclusion agrees with the reported very low coupling efficiency of SPDP-derivatized CVF to the hydrazide-derivatized carbohydrate moieties of an IgM (34). Additionally, the placement of reactive functional groups on highly extended, flexible oligosaccharide chains of CVF and antibody appears to drastically limit the probability of the functional groups to come in close enough proximity for conjugation.

In summary, the results presented in this paper demonstrate for the first time that the carbohydrate site-directed conjugation of CVF to the side-chain amino acid residues of antibodies is a viable approach for the preparation of CVF immunoconjugates. The conjugates obtained by this approach retained high levels of CVF and antibody activities while eliminating the anti- α -Gal immunoreactivity of CVF. The results presented here also show that derivatization of terminal sugar residues of CVF with the protected thiol-containing hydrazides offers significant advantage over the maleimide-containing hydrazides for efficient in situ derivatization of the enzyme-generated aldehyde groups. Conjugation via the carbohydrate moieties of both CVF and antibody is not practical because of very low coupling efficiency.

Effects of Structure of β -Cyclodextrin-Containing Polymers on Gene Delivery

Suzie J. Hwang,[†] Nathalie C. Bellocq,[†] and Mark E. Davis*

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received September 8, 2000; Revised Manuscript Received December 21, 2000

Linear cationic β -cyclodextrin-based polymers (β CDPs) are capable of forming polyplexes with nucleic acids and transfecting cultured cells. The β CDPs are synthesized by the condensation of a diamino-cyclodextrin monomer A with a diimide comonomer B. In this paper, the effects of polymer structure on polyplex formation, in vitro transfection efficiency and toxicity are elucidated. By comparison of the β CDPs to polyamides lacking cyclodextrins, the inclusion of a cyclodextrin moiety in the comonomer A units reduces the IC₅₀s of the polymer by up to 3 orders of magnitude. The spacing between the cationic amidine groups is also important. Different polymers with 4, 5, 6, 7, 8, and 10 methylene units (β CDP4, 5, 6, 7, 8, and 10) in the comonomer B molecule are synthesized. Transfection efficiency is dependent on comonomer B length with up to 20-fold difference between polymers. Optimum transfection is achieved with the β CDP6 polymer. In vitro toxicity varied by 1 order of magnitude and the lowest toxicity is observed with β CDP8. The LD₄₀ of the β CDP6 to mice is 200 mg/kg, making this polymer a promising agent for in vivo gene delivery applications.

INTRODUCTION

The development of polyplexes [cationic polymer + nucleic acid (1)] for gene delivery has grown rapidly to include cationic polymers such as poly-L-lysine (PLL) (2), chitosan (3), pAMAM dendrimers (4), polyethylenimine (PEI) (5), and many other polycations. A recent review of cationic polymer based delivery systems is presented by De Smedt et al. (6). Cationic polymers are able to deliver plasmid DNA into cells by self-assembling with the anionic DNA via electrostatic interactions with subsequent condensation into small particles that are readily endocytosed.

While cationic polymers share a similar mechanism of delivery, their transfection efficiencies differ greatly from polymer to polymer. Indeed, significant transfection and toxicity variations have been noted with the use of various molecular weight fractions of the same polymer. Ziady et al. observed both in vitro and in vivo behavioral differences with the use of short (36-mer) and long (256-mer)-chain PLL (7). Additionally, polyplexes formed with these polymers had different physicochemical characteristics. The transfection efficiency of PEI is also highly dependent on molecular weight and structure (8, 9). Remy et al. compared in vitro gene delivery for various branched and linear PEIs and found significant variations with PEI structure (10). Malik et al. also found that the dendrimer generation influences the efficacy of pAMAM dendrimers (11).

Plank et al. studied peptide derivatives within a low molecular weight range by synthesizing branched cationic peptides with variations in number and type of amino acids within the peptides (12). They found DNA binding affinity to be mainly a function of the number of cationic residues, and the transfection efficiency to be

influenced by the type of cationic residues used. It is evident from these reports that polycation structure impacts delivery efficiency. Additionally, it is clear that further investigation into the features of polycations that influence their behavior in gene delivery is merited. Here, we perform a structure–property study of this type.

We have reported the synthesis of a new family of β -cyclodextrin-based polymers (β CDPs) that are prepared by the condensation of difunctionalized CD monomers (comonomer A) with other difunctionalized comonomers (comonomer B) (13). The modular synthesis of the β CDPs allows for the systematic study of the effects of polymer structure on polyplex formation and polyfection. Previously, the importance of a spacer between the cyclodextrin and amine functional groups in the comonomer A units has been discussed (13). The spacer was shown to be required for DNA binding of comonomer A, most likely by relieving the steric hindrance of the bulky cyclodextrin cups. Here, we study the effect of comonomer B structure on DNA delivery and toxicity, since variations in comonomer B result in changes in polymer charge density and hydrophobicity. To better understand the origin of the functional differences, the polyplexes are characterized by comparing particle size, DNase protection ability, and relative DNA binding constants.

MATERIALS AND METHODS

β -Cyclodextrin-Polymers. β -Cyclodextrin polymers (β CDPs) were prepared by the polymerization of a difunctionalized β -CD monomer (A) with a difunctionalized comonomer (B) to give an ABAB product as described previously (13). The synthesis procedure involves the preparation of the difunctionalized β -CD (6A,6D-dideoxy-6A,6D-di(2-aminoethanethio)- β -cyclodextrin; denoted dicysteamine- β -cyclodextrin) and the synthesis of the difunctionalized comonomer B.

Synthesis of the Comonomer A (**3**, Figure 1). β -CD (Wacker Biochem Corp, Adrian, MI) was dried in vacuo (<0.1 mTorr) at 120 °C for 14 h before use. Biphenyl-

Figure 1. Synthesis of comonomer A (dicysteamine- β -cyclodextrin).

4,4'-disulfonyl chloride (Aldrich, Milwaukee, WI) was recrystallized from chloroform/hexane. Potassium iodide was powdered with a mortar and pestle and dried in an oven at 200 °C. Cysteamine (Fluka, Milwaukee, WI) was sublimed at 40 °C under reduced pressure before use. All other reagents were obtained from commercial suppliers and were used as received without further purification.

First step: synthesis of biphenyl-4,4'-disulfonate-capped β -CD **1**. The capped β -CD was synthesized according to a modified procedure of Tabushi et al. (14). To a solution of dried β -CD (10 g, 8.81 mmol) in 250 mL of freshly distilled anhydrous pyridine (Aldrich) was added 2.78 g (7.93 mmol) of biphenyl-4,4'-disulfonyl chloride in four equal portions at 15 min intervals. The resulting solution was stirred at 60 °C under nitrogen for an additional 3 h and the solvent was removed to dryness in vacuo at room temperature. The residue was subjected to C8 reversed-phase column chromatography using a gradient elution of 0–40% acetonitrile in water. Fractions were analyzed by HPLC and the appropriate fractions were combined. After removing the acetonitrile on a rotary evaporator, the resulting aqueous suspension was lyophilized to dryness. This procedure gave 5.42 g (40% yield) of **1**. ¹³C NMR (Bruker 500 MHz, Me₂SO-d₆) δ ppm 60.3 (C6), 70.9, 71.6, 72.7 (C2, C3, C5), 82.4 (C4), 102.0 (C1), 128.4–143.2 (phenyl).

Second step: synthesis of diiodo β -CD **2** (15). To a solution of 5.42 g (3.52 mmol) of **1** in 100 mL of anhydrous DMF (Aldrich) was added 17.53 g (0.106 mol) of dry powdered potassium iodide. The solution was kept at

80 °C for 2 h with stirring. After the mixture cooled to room temperature, insoluble materials were removed by filtration and the solution was evaporated to dryness in vacuo. The residue was then dissolved in 60 mL of water and 6 mL of tetrachloroethylene was added at 0 °C with vigorous stirring. The precipitate formed was collected and dried in vacuo to give 4.69 g (90% yield) of a slightly yellow colored solid. ¹³C NMR (Bruker 500 MHz, Me₂SO-d₆) δ ppm 10.4 (C6 adjacent to I), 60.3 (C6 adjacent to OH), 70.9, 71.6, 72.7 (C2, C3, C5), 82.4 (C4), 102.0 (C1).

Third step: synthesis of dicysteamine β -CD **3**. To a solution of 4.69 g (3.17 mmol) of **2** in 100 mL of degassed water was added 0.489 g (6.34 mmol) of freshly sublimed cysteamine. The solution was stirred under reflux for 2 h. After cooling to room temperature and acidifying with 1 N HCl, the solution was applied to a Toyopearl SP-650M ion-exchange column (NH₄⁺ form) and the product was eluted with a 0 to 0.2 M ammonium bicarbonate gradient. Appropriate fractions were combined and lyophilized to dryness. This procedure gave 1.87 g (39% yield) of a white solid. The solid was characterized by TLC [silica gel, *n*-PrOH-AcOEt-H₂O-NH₃(aq) 5/3/3/1, detection by ninhydrin] and exhibited a major spot corresponding to **3** and a minor spot corresponding to free cysteamine. This unreacted cysteamine was eliminated on a rotary evaporator after dissolution of the solid in water with monitoring by Ellman's reagent (16). Matrix-assisted laser desorption/ionization (MALDI) time-of flight (TOF) mass spectrum was recorded on 2 m ELITE instrument supplied by PerSeptive Biosystems,

Figure 2. Polymerization scheme for β -cyclodextrin polymers.

Inc. MALDI-TOF m/z calcd for **3**, 1252; found, 1253.5 [$M + H$]⁺, 1275.5 [$M + Na$]⁺, 1291.4 [$M + K$]⁺. ¹³C NMR (Bruker 500 MHz, D₂O) δ ppm 32.1 (S-CH₂) and 38.8 (CH₂-NH₂), 32.9 (C6 adjacent to S), 60.2 (C6 adjacent to OH), 70.8, 71.4, 72.5 (C2, C3, C5), 81.8 (C4), 101.7 (C1).

Synthesis of Comonomer B [4a–f (17)].

Dimethyladipimide·2HCl, **4a**; dimethylpimelimate·2HCl, **4b**; and dimethylsuberimide·2HCl, **4c** (DMS) were purchased from Pierce Chemical Co. and were used as received.

Synthesis of Dimethylazelimate·2HCl, 4d. Azelani-trile (1.08 g, 7.2 mmol) (Aldrich) was dissolved in an ice-cold mixture of anhydrous methanol (4 mL) and anhydrous diethyl ether (30 mL). Anhydrous hydrogen chloride was passed through the solution for 60 min and the reaction mixture was left at 0 °C for 24 h. Dry diethyl ether (50 mL) was added to precipitate the product that was washed twice with 100 mL of dry methanol/diethyl ether [mixture (volume ratio 1:3)] under anhydrous conditions. The solid was dried under vacuum for 2 h. This procedure gave 1.64 g (79% yield) of **4d**. Calcd for C₁₁H₂₄O₂N₂Cl₂: C, 45.96; H, 8.36; N, 9.75. Found: C, 45.48; H, 8.30; N, 9.71. ¹³C NMR (Bruker 500 MHz, CD₃-

OD) δ ppm 26.1, 29.4, 29.5, 33.9 (4 CH₂), 59.9 (OCH₃), 183.2 (C=NH).

Synthesis of Dimethylsebacimide·2HCl, 4e. This compound was obtained from 1.16 g (7.1 mmol) of sebaconitrile (Aldrich) by the same procedure used to prepare **4d** and gave 2.04 g (96% yield). Calcd for C₁₂H₂₆O₂N₂Cl₂: C, 47.81; H, 8.63; N, 9.30. Found: C, 47.68; H, 8.51; N, 9.23. ¹³C NMR (Bruker 500 MHz, CD₃OD) δ ppm 26.2, 29.6, 29.7, 33.9 (4 CH₂), 59.9 (OCH₃), 183.2 (C=NH).

Synthesis of Dodecanediimide·2HCl, 4f. This compound was obtained from 1.35 g (7.0 mmol) of dodecanedinitrile (TCI America Organic Chemicals, Portland, OR) by the same procedure used to prepare **4d** and gave 1.85 g (80% yield). Calcd for C₁₄H₃₀O₂N₂Cl₂: C, 51.03; H, 9.11; N, 8.51. Found: C, 50.96; H, 9.08; N, 8.44. ¹³C NMR (Bruker 500 MHz, CD₃OD) δ ppm 26.3, 29.8, 30.0, 30.3, 33.9 (5 CH₂), 60.0 (OCH₃), 183.4 (C=NH).

Polymerization (Figure 2). β CDPs were synthesized as described previously (13). In a typical experiment, a 25 mL vial was charged with a solution of the bis-(hydrogen carbonate) salt of dicysteamine β -CD **3** (399.6 mg, 0.269 mmol) dissolved in 500 μ L of 0.5 M Na₂CO₃. The comonomer B, e.g., **4c** (73.5 mg, 0.269 mmol) was added and the solution was centrifuged briefly to dissolve the components. The resulting mixture was stirred at 25 °C for 15 h. The mixture was then diluted with 10 mL of water and the pH brought below 4 with the addition of 1 N HCl. This solution was then dialyzed against a Spectra/Por 7 MWCO 3500 dialysis membrane (Spectrum) in dH₂O for 24 h. The dialyzed solution was lyophilized to dryness. ¹³C NMR (Bruker 500 MHz, D₂O) δ ppm 25.8, 26.0, 27.0, 28.7, 29.9, 32.2, 37.5, 38.1, 41.1, 60.0, 71.6, 72.3, 72.6, 80.8, 101.4, 167.9.

Polyamidine Polymers. Polyamidine polymers were synthesized as described for β CDPs except methylenediamines were used as the comonomer A instead of dicysteamine- β -CD. These non- β -CD-containing polymers were prepared for comparison to the β CDPs in order to ascertain the influence of the β -CD in the polymer backbone upon gene delivery.

C6-C6 Polyamidine. An 8 mL glass vial was charged with 80 mg of hexamethylenediamine (comonomer A, 0.690 mmol, Aldrich) and 195 mg of dimethylsuberimidate-2HCl (comonomer B, 0.714 mmol, Pierce). The solids were dissolved by the addition of 0.25 mL of 0.5 M Na_2CO_3 . The mixture was stirred at 25 °C for 15 h, yielding a viscous, clear solution. The mixture was diluted with water and pH brought below 4 with the addition of 1N HCl. The solution was transferred to a Spectra/Por 7 MWCO 1000 dialysis membrane and dialyzed for 24 h in dH_2O . The dialyzed material was lyophilized to dryness, yielding 30 mg of a white, fluffy solid (13% yield).

C6-C6 Polyamidine:

C9-C6 Polyamidine. The C9-C6 polyamidine polymer was synthesized as described above for the C6-C6 polyamidine polymer except 1,9-diaminononane (comonomer A, Aldrich) was reacted with dimethylsuberimidate-2HCl (comonomer B) to result in a 21% yield of a white, fluffy solid. The C9 distance is a reasonable approximation to that of the β -CD.

C9-C6 Polyamidine:

Light Scattering and Molecular Weight Determination. β CDPs were analyzed on a Hitachi D6000 HPLC system equipped with a ERC-7512 RI detector, a Precision Detectors PD2020/DLS light scattering detector and a Progel-TSK G2000 SW_{XL} column using 0.3M NaCl as eluant at a 0.7 mL/min flow rate as described previously (13).

End Group Analysis by Amine Quantification. β CDPs were dissolved in 0.1 M NaHCO_3 at a concentration of 0.25 mg/mL, and the amine concentration of these solutions was determined by reaction with TNBS (16). In brief, 250 μL of 0.01% TNBS in 0.1 M NaHCO_3 were added to 500 μL of polymer solutions and resulting mixture placed in a 37 °C water bath. After 2 h, 250 μL of 10% sodium dodecyl sulfate and 125 μL of 1N HCl was added to each sample. The absorbance at 335 nm was determined and compared to a dicysteamine- β -CD standard curve.

Plasmids. Plasmid pGL3-CV (Promega, Madison, WI), that contains the luciferase gene under the control of the SV40 promoter, and plasmid pCA-EGFP (generously donated by Dr. Rusty Lansford and Prof. Scott Fraser at the California Institute of Technology), that contains the EGFP gene under a chick actin promoter, were amplified by *Escherichia Coli* strain DH5 α and were purified using Qiagen's Endotoxin-free Megaprep kit (Valencia, CA).

Complex Formation and Characterization. An equal volume of cationic polymer dissolved in dH_2O was added to plasmid DNA (0.1 mg/mL in dH_2O) at the appropriate charge ratios (cationic to anionic, denoted as "+/-").

Dynamic Light Scattering. For particle sizing by dynamic light scattering (DLS), 2 μg of pCA-EGFP was complexed with polymers at 50+/- and allowed to stand for 10 min before diluting with 1.2 mL of dH_2O . Particle size was measured using a ZetaPals dynamic light scattering instrument (Brookhaven Instruments Corporation, Holtsville, NY).

Transmission Electron Microscopy. One microgram of DNA was complexed with cationic polymer at 50+/- charge ratio and applied to Formvar carbon-coated grids for 45 s before removing excess liquid. Samples were then stained with 2% uranyl acetate for 45 s before blotting. Images were recorded using a Philips 201 Electron Microscope operated at 80V.

DNase Protection Assay. The DNase protection assay was modified from a procedure by Gao et al. (18). One microgram of DNA (pCA-EGFP) was complexed with cationic polymer at 5+/- . The complexes were then incubated with 20 μL of fetal bovine serum (FBS, Gibco BRL, Gaithersburg, MD) for 30 min. Five microliters of 10% SDS was added to the complexes to displace the polymers from the DNA. Twenty microliters of FBS were added to "control" complexes followed by immediate addition of SDS for the "0 min" timepoint. The samples were then applied to a 0.8% agarose gel containing 6 μg of ethidium bromide/100 mL of TAE buffer (40 mM Tris-acetate, 1 mM EDTA) after the addition of 1 μL of loading buffer and electrophoresed.

Competitive Displacement by Heparan Sulfate. Cationic polymer was complexed with 0.5 μg of pGL3-CV at a 20+/- charge ratio. Heparan sulfate (5 mg/mL in water, from porcine intestinal mucosa, Sigma, St. Louis, MO) was then added to the complexes. After a 5 min incubation, 1 μL of loading buffer was added and samples were electrophoresed in an agarose gel as described for the DNase protection assay.

Cell Culture and Polyfections. BHK-21 cells were purchased from ATCC (Rockville, MD) and maintained in Dulbecco's Modified Eagle Medium supplemented with 10% FBS, 100 units/mL penicillin, 100 $\mu\text{g}/\text{mL}$ streptomycin, and 0.25 $\mu\text{g}/\text{mL}$ amphotericin at 37 °C and 5% CO_2 . Media and supplements were purchased from Gibco BRL (Gaithersburg, MD). For transfections, BHK-21 cells were plated at 50 000 cells/well in 24-well plates. Cells were transfected with 1 μg of pGL3-CV complexed with β CDPs at various charge ratios in serum-free media. Lysates were analyzed for luciferase activity as described previously (13). The toxicities associated with the transfections were assessed by the Lowry protein assay, also described previously (13).

IC₅₀ Determination. BHK-21 cells were plated at 5000 cells/0.1 mL/well in 96 well plates and incubated at 37 °C for 24 h. β CDPs (16 mg/mL in complete media) were then added to the third column of cells and diluted serially across the rows. The cells were incubated with the polymers for 24 h at 37 °C. The media was then

Table 1. Effect of the Length of Comonomer B on the Polymerization

polymer	yield (%)	M_w (kDa) ^a	M_w/M_n ^a	average degree of polymerization	M_n (kDa) ^b

β CDP7	29	6.9	1.14	4	4.6
β CDP8	37	7.6	1.16	5	6.2

^a Determined by static light scattering. ^b Estimated by end group analysis.

removed from the cells and cells were washed once with PBS. Fifty microliters of MTT (2 mg/mL in PBS) was added to each well followed by 150 μ L of complete media. The cells were incubated for an additional 24 h before the media was removed and blue formazan crystals formed were dissolved in 150 μ L of DMSO. The absorbances were read at 562 nm in a microplate reader (EL-312e Biokinetics Reader, Biotek Instruments, Winooski, VT).

Intravenous Toxicity of β CDP6 in Mice. Groupings of five outbred male mice were injected intravenously with a single dose of β CDP6 (8.33 μ L/g mouse). Stock dosing solutions of β CDP6 were prepared in 0.9% NaCl, sterilized by passing through a 0.2 μ m filter, and diluted with 0.9% NaCl as needed. Mice were observed for 3 days postinjection.

RESULTS

β CDPs Synthesis and Characterization. β CDPs were synthesized using comonomer Bs with 4, 5, 6, 7, 8, and 10 methylene units. The length of the comonomer B was found to influence the polymerization as shown by the data given in Table 1. The molecular weight M_w and the polydispersity index M_w/M_n as determined by light scattering are provided in Table 1 for each polymer. Molecular weight M_n was also estimated by end group analysis. The two possible terminal functional groups for the β CDPs are carboxylic acids or amines. Attempts to conjugate a fluorescent tag (Alexa Hydrazide from Molecular Probes) to the polymer by DCC coupling assuming carboxylic end groups resulted in no observed reaction. However, the conjugation of TNBS (reacts with primary amines) resulted in the detection of molecular weights M_n similar to those detected by SLS (Table 1). These molecular weights give an average degree of polymerization of 4–5 for all β CDPs studied. The yield of polymer increased with the number of methylene groups within comonomer B. The yield of β CDP10 was 56%; however, this polymer was synthesized from a different batch of comonomer A than all the other polymers. Therefore, direct comparison to the other β CDPs may not be appropriate.

Polyplex Characterization. β CDPs were complexed with plasmids at various charge ratios and polyplex size was measured by dynamic light scattering (DLS) and TEM. Particle size depended on polymer and DNA concentrations during polyplex formulations. However, above 3 $\pm$, polyplex size remained largely independent of charge ratio. When measured by DLS, particle sizes of polyplexes formulated at DNA concentrations of 50 μ g/mL ranged from 124 to 152 nm (Figure 3). β CDP4, β CDP5, and β CDP10-based polyplexes gave the largest particles, with diameters of 148, 141, and 144 nm, respectively. β CDP6, β CDP7, and β CDP8-based particles had smaller diameters of 127, 128, and 124 nm, respectively. Electron micrographs of all β CDP-polyplexes

prepared in water showed uniform particles that appeared spherical in shape. β CDP6-based polyplexes are shown in Figure 4 as an example.

DNase Protection. The ability of the β CDPs to protect plasmid DNA from DNase degradation was assessed. Plasmid DNA was complexed with β CDPs and incubated with an equal volume of fetal bovine serum for 30 min at 37 $^{\circ}$ C. The DNA was released from the complexes by the addition of sodium dodecyl sulfate and run on an agarose gel (Figure 5). β CDPs with 4, 6, 8, and 10 methylene units completely protected DNA, while β CDP5 and β CDP7 offered only partial protection.

In Vitro Transfection and Toxicity of β CDP Polyplexes. BHK-21 cells were plated in 24-well plates and transfected under serum-free conditions with 1 μ g of pGL3-CV complexed with the β CDPs at various charge ratios. Transfection efficiencies were determined by assaying for luciferase protein activity, with results reported in relative light units (RLUs). Several polymer to DNA charge ratios were tested (Figure 6) and a comparison of relative transfection efficiencies and cell survival are reported here for 50+/- (Figure 7). At this charge ratio, the transfection efficiencies have reached their maximum and the toxicity differences between the polymers become evident. The β CDP with six methylene units, β CDP6, gives the highest transfection efficiency: 2.5×10^{10} RLU/mg protein. The transfection efficiencies of all the polymers are normalized to the β CDP6 transfection achieved at 50+/- and reported as a fraction of β CDP6 transfection (Figure 7). β CDP7 and β CDP8 transfected at 50 and 64%, respectively, of the β CDP6 levels while β CDP4, β CDP5, and β CDP10 compared even less favorably at 22, 6, and 10%, respectively.

The toxicity of the β CDPs associated with the transfections at 50+/- was measured by determining the total protein concentration in cell lysates 48 h after transfection and comparing with protein levels of untransfected cells. The fraction cell survival in the presence of the polyfection mixture was also dependent on comonomer B length (Figure 7). No toxicity was observed for β CDP8. However, toxicity in general increased for all comonomer B lengths differing from that used in β CDP8.

The IC_{50} s of the β CDPs to BHK-21 cells were determined by plating the cells in 96-well plates, exposing the polymers to the cells in serial dilutions for 24 h and monitoring cell viability by the MTT assay. The polymer IC_{50} s show the same trend as the toxicities associated with polyplex transfection (Figure 8). β CDP8 had the highest IC_{50} (2200 μ M, reported as cyclodextrin concentration), followed in order of decreasing IC_{50} s by β CDP7 (1800 μ M), β CDP6 (1100 μ M), β CDP4 (380 μ M), β CDP5 (350 μ M), and β CDP10 (330 μ M).

Polyamide polymers were synthesized by the condensation of methylenediamines (hexylmethyldiamine and 1,9-diaminononane) as comonomer A with dimethylsuberimidate (DMS, comonomer B with 6 methylene units) to give C6–C6 polyamide and C9–C6 polyamide, respectively. The IC_{50} s of the polyamide polymers to BHK-21 cells were determined to be 4.6 μ M (reported per repeat unit) for C6–C6 polyamide and 34.0 μ M for C9–C6 polyamide.

Polymer Displacement by Heparan Sulfate. Polyplexes can be unpackaged by the addition of an anionic competitor such as heparan sulfate to bind to the cationic polymer and release the DNA (19). The relative binding constants of the β CDPs were determined by complexing the polymers with plasmid DNA at a 20+/- charge ratio and then adding increasing amounts of heparan sulfate. The solutions were loaded onto an ethidium bromide-

Figure 3. Hydrodynamic diameter of β CDP-based polyplexes as measured by dynamic light scattering. Polyplexes were prepared with 2 μ g of plasmid DNA at a DNA concentration of 0.05 mg/mL and then diluted with dH₂O to 1.2 mL final volume for measurements. The results shown are mean $\pm$ SD for three experiments, each measured in triplicate.

Figure 4. Electron micrograph depicting polyplexes of β CDP6 and pGL3-CL at a 50+/- charge ratio.

containing agarose gel and electrophoresed. Complexed DNA remained in the loading well. Successful polymer displacement by heparan sulfate released the DNA, that migrated in the electric field and was visualized by ethidium bromide intercalation. A comparison of the amount of heparan sulfate required to release the DNA from the β CDPs reflected the relative binding constants. β CDP6 demonstrated the highest DNA binding constant, requiring the addition of 22 μ g of heparan sulfate (heparan sulfate to β CDP6 charge ratio of 3+/-) before any DNA release could be observed (Figure 9). A total of 14 μ g (1.8+/-) of heparan sulfate were necessary to

Figure 5. DNase protection of plasmid DNA by β CDP complexation. Polyplexes of DNA complexed with the various β CDPs were incubated with an equal volume of fetal bovine serum for 0 or 30 min. β CDPs were then displaced by SDS and DNA visualized by electrophoresis in an agarose gel.

displace β CDP4 while 16 μ g (2.1+/-) were required to displace β CDP5. The polymers with comonomer B longer than 6 methylene units showed a different behavior. For β CDP7, β CDP8, and β CDP10, the addition of heparan sulfate, even as low as 6 μ g (0.8+/-), resulted in the visualization of some uncomplexed DNA. For β CDP8 and β CDP10, the DNA release remains only partial, even with the addition of 32 μ g of heparan sulfate.

Figure 6. Transfection efficiencies (■) and cell survival (●) for BHK-21 cells transfected with 1 μ g of pGL3-CV complexed with β CDP5 (dashed lines) and β CDP6 (solid lines) at charge ratios ranging from 10 to 50+/- . Luciferase protein activity is reported as relative light units (RLU) per milligram of total cellular protein, as determined by Lowry protein assay. Cell survival was calculated by dividing cellular protein levels of transfected cells by untransfected cells. Data are reported as the mean $\pm$ SD of three samples.

Figure 7. Comparison of luciferase transfection and cell survival for β CDP-based polyplexes at 50+/- charge ratios. The data reported are the mean $\pm$ SD of three experiments, each performed in triplicate. Transfection results for the different polymers are normalized with the average transfection achieved by β CDP6-based polyplexes for each experiment. Cell survival (X) was determined by assaying for total protein concentrations and normalizing each sample with protein levels for untransfected cells.

DISCUSSION

The objective of this study is to investigate the structure-property relationships between a family of β -cyclodextrin containing, cationic polymers and their interaction with and ability to deliver to cells plasmid DNA. To accomplish these goals a series of β CDPs were prepared using comonomer Bs with 4, 5, 6, 7, 8, and 10 methylene

units. The polymer yields were proportional to the comonomer B length with β CDP10 $\approx$ β CDP8 $>$ β CDP7 $>$ β CDP6 $>$ β CDP5 $>$ β CDP4. Higher reaction yield with longer diimide **4a-f** linkers was also noted by Denking et al. (17) who cross-linked poly(allylamine) with esters of diimide acids such as those used here (**4a-f**) to form hydrogels. The β CDP molecular weights, detected

Figure 8. IC₅₀s of β CDPs to BHK-21 cells. β CDPs were added in serial dilutions to BHK-21 cells plated in 96-well plates. Cell viability was determined 24 h after polymer exposure by MTT assay. The IC₅₀s, reported as cyclodextrin concentration, were determined by interpolation on a best-fit line and are reported as the mean $\pm$ SD for three replicates.

by both static light scattering and end group analysis, ranged from 5800 to 7600, corresponding to a average degree of polymerization of 4–5 and giving 8–10 cationic charges/chain. Therefore, differences in polymer performance should be a result of polymer structure and not molecular weight since they all have similar molecular weights and polydispersities.

The β CDPs form polyplexes with DNA by rapid self-assembly in aqueous solutions. Polyplexes formed in water are relatively monodisperse and uniform in size, as evidenced by DLS and TEM. The size of the polyplexes depends on the formulation conditions, as has been described previously by Duguid et al. (20). Particles formed with β CDP6 have an average diameter of 60 nm at 2 μ g/mL final DNA concentration but an average diameter of 130 nm at 50 μ g/mL as measured by DLS. The latter particles were used for the DLS, TEM and transfection studies presented here. Electron micrographs of β CDP6-based polyplexes show particles smaller than 100 nm in diameter. DLS measurements, due to calculations that are based on weighting by particle light scattering intensity, are biased toward larger particles. DLS also determines the hydrodynamic diameter and hence DLS size measurements of particles are larger than the sizes of the polyplexes pictured by electron micrographs.

Polyplexes formed from β CDP4, β CDP5, and β CDP10 are larger in diameter than polyplexes formed from the other β CDPs (Figure 3). These larger particles transfected cultured cells less efficiently (Figures 6 and 7). A correlation between particle size and transfection efficiency has been described for other systems (6), although it is normally observed that the larger the particle size the greater the transfection. Here, the differences in the particle size are not large and likely not the reason for the large differences in transfection. In addition, the cationic polyplexes are prone to rapid aggregation under physiological salt conditions. Thus, the variations in particle size are more likely to be indicative of differences in the polymer–DNA binding interactions rather than directly affecting particle uptake.

For effective gene delivery, the polycation must protect the DNA from nuclease activity. While β CDP4, β CDP6,

β CDP8, and β CDP10 completely protected plasmid DNA from DNase degradation, β CDP5 and β CDP7 offered only partial protection (Figure 5). Yoshikawa et al. observed a difference in binding of various methylenediamines to DNA; however, they noticed greater DNA condensation with odd numbers of methylene units and larger particles with even numbers of methylene units (21). Thus, small differences in charge separation can produce dramatic effects. It is interesting to note that the two β CDPs with odd numbers of methylenes are the only ones to not completely protect the DNA.

All of the synthesized β CDPs are able to transfect BHK-21 cells, although with varying efficiencies. Transfection increases with charge ratios up to 50+/- (Figure 6). This high optimal charge ratio is probably due to the short nature of the polymers, a phenomenon also noticed by Plank et al. (12) for short peptides. The transfection profiles as a function of polymer to DNA charge ratio are similar for all of the polymers; however, the magnitude of the profiles differs greatly between polymers. To illustrate differences in transfection and toxicity, we chose to compare delivery performance between the polymers at 50+/-, as displayed in Figure 7. The highest transfection efficiency, as determined by luciferase protein activity, is consistently achieved by the β CDP6-based polyplexes. The transfection efficiency is found to be dependent on the comonomer B length. For example, when compared to β CDP6, luciferase transfections with β CDP5 result in a 20-fold reduction of luciferase protein activity, while the difference between the two comonomer B lengths is only 1.8 Å. Therefore, a few Å change in comonomer B length reduces the transfection by up to 1 order of magnitude (Figure 7).

A possible rationalization for the large decrease in transfection is that the spacing between the cationic amidine groups in β CDP6 is optimal for DNA binding. In an attempt to study β CDP–DNA interactions, polymer binding kinetics were monitored via a quartz crystal microbalance and DNA condensation kinetics by DLS. It was found that binding and condensation were complete within one second for all the polymers. Because of the speed of these processes, the procedures used here were unable to provide useful information. Thus, only

Figure 9. Determination of relative binding constants by heparan sulfate displacement. The amount of heparan sulfate (in μg) required to free DNA from βCDP -based polyplexes (prepared with 1 μg of DNA at 20 $\pm$ –). The first lane of each gel is uncomplexed DNA. The uncomplexed and freed DNA was visualized by ethidium bromide in an agarose gel.

relative binding constants were determined by heparan sulfate displacement. The amount of heparan sulfate required to release DNA from the polyplexes should be related to the DNA binding constant of the displaced polymer. The heparan sulfate displacement studies (Figure 9) reveal that βCDP6 has a significantly higher binding constant than the other βCDPs . The polymers synthesized from shorter comonomer Bs (βCDP4 , βCDP5 , and βCDP6) also seem to bind differently from βCDP7 , βCDP8 , and βCDP10 . The former set of polymers bound tightly to the DNA at low heparan sulfate concentrations but are mostly displaced from the DNA at a critical heparan sulfate concentration that increases with increasing distance between the charges. The latter polymers are slightly displaced from the DNA even at low heparan sulfate concentrations, with a higher intensity of free DNA visualized with increased heparan sulfate

concentration. Therefore, the DNA binding characteristic of βCDP6 likely contributes to its gene delivery properties.

The toxicity of the βCDPs also depends on comonomer B length. βCDP8 reveals no cell death under the tested transfection conditions while βCDP7 is only slightly toxic. Because the comonomer Bs for these polymers were synthesized in our lab while comonomer Bs for βCDP4 , βCDP5 , and βCDP6 were purchased from commercial sources, it is possible that an impurity in the commercial samples could be the origin of toxicity. The βCDP6 was therefore synthesized from three different comonomer Bs: (i) purchased DMS, (ii) purchased and recrystallized DMS, and (iii) freshly synthesized in our labs DMS. The transfection and toxicity of the three βCDP6s were very similar, thus confirming cell toxicity to be caused by the βCDPs and not reaction impurities.

Although no toxicity was detected for β CDP8 at a charge ratio of 50+/-, cell death was observed for the other β CDPs at charge ratios above 20+/- with the toxicity differences between the polymers becoming evident by 50+/- (Figure 7). At this high charge ratio, most of the polymer is free in solution and not bound to DNA. The noted toxicity is therefore probably due mostly to the free polymer in solution. The IC_{50} s of β CDPs alone to BHK-21 cells were determined by the MTT assay. The trends in the IC_{50} s for the β CDPs correlated nicely with the toxicities detected at the 50+/- transfection conditions (Figure 8). Again, the IC_{50} s cover nearly an order of magnitude range. The IC_{50} s increase as the charge density decreases in going from β CDP4 to β CDP8. Additionally, as the comonomer B lengthens, the corresponding polymer becomes less soluble. Therefore, it is possible that the lower solubilities may contribute to the toxicity observed for β CDP10. If such is the case, then there is a tradeoff between charge density and solubility and for the polymers investigated here, the β CDP8 appears to be the optimal material with regard to toxicity.

Wadhwa et al. (22) and Fisher et al. (8) reported reduced cytotoxicity for low molecular weight fractions of PLL and PEI, respectively. Although the β CDPs presented here are low molecular weight polymers, we tested the cytotoxicity of a β CDP capable of being further degraded in the cell. To this end, we synthesized a disulfide-containing β CDP (β CDP-disulfide), as reported

β CDP-Disulfide

previously (13).

The disulfide was incorporated in a comonomer of length 11.9 Å between the charges; that is, 0.9 Å longer than β CDP6 but shorter than β CDP7. β CDP-disulfide should be reduced to monomeric units in the cellular environment. The β CDP-disulfide polymer was able to bind to DNA at the same charge ratio as the β CDP6 and transfect cells with efficiencies between those observed for β CDP6 and β CDP7. However, the toxicity of β CDP-disulfide associated with these transfections was higher than β CDP6 toxicity (62% cell survival versus 70%). These results indicate that the β CDP toxicity will not be decreased further with a polymer that can be reduced to molecules within the cell.

The idea behind the synthesis of the β CDPs was to ascertain whether polymers incorporating relatively non-toxic building units, i.e., cyclodextrins, could maintain the low toxicity of the cyclodextrin while simultaneously providing the properties necessary for gene delivery (13). The influence of cyclodextrin incorporation in the polymer backbone was tested by comparing β CDP polymer behavior to those having methylenediamines as comonomer As rather than CD-dicysteamine. Because the noncyclodextrin polymers were also synthesized by an A-B condensation, the average degree of polymerization was comparable to those achieved for β CDPs (average degree of polymerization of 5 for C6-C6 polyamidine and 8 for C9-C6 polyamidine). These polyamidine polymers are

able to bind to plasmid DNA by charge ratios of 1.5+/-, form polyplexes with hydrodynamic diameters of ~140 nm, and transfect cultured cells as well as the β CDPs. However, their IC_{50} s are 2-3 orders of magnitude lower than the IC_{50} s for β CDP8. These results indicate that cyclodextrin incorporation into the backbone of the cationic polymers greatly reduces the polymer toxicity.

On the basis of the in vitro results, the β CDP6 polymer was chosen for in vivo toxicity testing. This polymer gives the highest transfection efficiency with a reasonably high IC_{50} . Groupings of five mice were injected intravenously with a single dose of β CDP6 ranging from 2 to 200 mg/kg. No toxicity was observed at 100 mg/kg and the LD_{40} was found to be 200 mg/kg. Previously, we have tested a disulfide-containing β CDP for in vivo toxicity and determined it to be well tolerated at 200 mg/kg (13). However, the previous disulfide-containing β CDP displayed lower DNA binding affinity and transfection efficiency than the β CDP6. The in vivo toxicity parallels the in vitro studies in that increased charge density appears to yield higher toxicities. Thus, the in vivo toxicity limit should increase when the β CDP are complexed with DNA.

Here, it is demonstrated that the structure of the β CDPs critically determines performance in DNA delivery and cell toxicity. The difference of a few Å in comonomer B length can affect transfection and polymer IC_{50} values by orders of magnitude. In addition, the incorporation of β -cyclodextrin in the polymer backbone is shown to significantly decrease polymer toxicity. The low in vitro and in vivo toxicity of these β CDPs make them promising and attractive agents for in vivo gene delivery applications.

Revised Manuscript Received December 10, 2000

We describe the synthesis and characterization of a pH-sensitive poly(ethylene glycol)-diortho ester-distearoyl glycerol conjugate (POD). POD was prepared by a one-step synthesis, and its acid sensitivity characterized by TLC. The conjugate was found to be stable at neutral pH for greater than 3 h but degraded completely within 1 h at pH 5. Liposomes composed of 10% of POD and 90% of a fusogenic lipid, dioleoyl phosphatidylethanolamine (DOPE) were readily prepared and remained stable for up to 12 h in neutral buffer as shown by photon correlation spectrometry and a liposome contents leakage assay. However, when POD/DOPE liposomes were incubated in acidic pH as mild as 5.5, they aggregated and released most of their contents within 30 min. The kinetics of content release from POD/DOPE liposomes consisted of two phases, a lag phase, and a burst phase. The lag phase is inversely correlated with pH and the logarithm of the length of lag phase showed a linear relationship with the buffer pH. When the POD/DOPE liposomes were incubated in 75% of fetal bovine serum at 37 °C, they remained as stable as traditional PEG-grafted liposomes for 12 h but released 84% of the encapsulated ANTS in the following 4 h. Upon intravenous administration into mice, liposomes composed of 10% POD and 90% DOPE were cleared from circulation by a one-compartment kinetics with a half-life of about 200 min. POD is an example for the design of a novel category of pH sensitive lipids composed of a headgroup, an acid-labile diortho ester linker and a hydrophobic tail. The uniquely fast degradation kinetics of POD at pH 5–6 and its ability to stabilize liposomes in serum make the conjugate suitable for applications for triggered drug release systems targeted to mildly acidic bioenvironments such as endosomes, solid tumors, and inflammatory tissues.

INTRODUCTION

Diacyl chain lipids represent an important class of amphipathic molecules that contain both a polar headgroup and a large hydrophobic moiety. In aqueous phase, such lipids self-assemble into colloidal particles such as liposomes, micelles and hexagonal phase. Liposomes are widely used as models of membrane bilayers and carriers of a variety of diagnostics and medicines (1). Examples of their use in drug delivery include PEG stabilized liposomes that carry cytotoxic drugs to leaky tumor tissues (2) and cationic liposomes that improve gene transfection (3).

Ideally, a targeted drug delivery system, including liposomes, should remain stable until it reaches the target site to minimize the premature loss of its payload (2, 4). Upon accumulation at the target site, drug release needs to be at a high enough level for an effective therapeutic response. Since the decrease of pH is implicated in many physiological and pathological progressions such as endosome processing (5), tumor growth (6), inflammation (7), and myocardial ischemia (8), it has been extensively exploited to trigger the release of drugs from liposomal delivery systems in the past 20 years (9–11). Most of the reported pH-sensitive liposomes are based on the neutralization of excess negative charges on their surface upon protonation, which reduces the hydrodynamic diameter of lipid headgroups and triggers the change of lipid bilayers to hexagonal phases (10).

Figure 1. General structure of the diortho ester conjugates.

However, at neutral pH, these excess negative charges induce undesired interactions with serum proteins and fixed macrophages, leading to rapid elimination of the liposomes from circulation (12, 13). Efforts to circumvent this difficulty and provide a nonionic pH-sensitive lipid have employed a neutral monosaccharide as the headgroup, which is attached to long hydrophobic chains via an acetal moiety (14). However, these acetal analogues hydrolyzed relatively slowly at pHs 5 to 7 as found in physiological environment and need a pH less than 4 for rapid degradation. Recently, Thompson and co-workers have reported a number of acid- and light-sensitive lipids containing vinyl ether moieties (15–17). Although vinyl ethers represent a promising approach, their rate of hydrolysis at pH 5 is not optimal for rapid drug release. To develop a versatile strategy to prepare biocompatible liposomes, which are sensitive to small pH decrease, we propose a novel class of lipids (Figure 1) that possess an acid-labile diortho ester linker between the hydrophilic headgroup and the hydrophobic tail. In this case, a variety of headgroups and tails could be conjugated together to render pH-sensitive lipids of different properties.

Ortho esters are relatively stable under basic and neutral conditions but hydrolyze quickly at acidic pH due to a stabilized dialkoxy carbocation intermediate (Scheme

Scheme 1. Mechanism of Ortho Ester Hydrolysis

1) (18–20). Heller and co-workers (21) have prepared a series of polymers based on the diortho ester moiety and exploited their pH-sensitive properties to develop sustained drug release systems. As an example of the proposed diortho ester lipidic conjugates, we report in this paper the design, preparation, and characterization of a novel lipid (**1**, POD, Scheme 2)¹ that consists of a PEG headgroup, a diortho ester linker, and a distearoyl glycerol hydrophobic tail. We show that POD can be used to prepare long circulating and acid-triggerable liposomes in combination with DOPE, a lipid that by itself does not form stable liposomes, but hexagonal phases at neutral pH.

EXPERIMENTAL PROCEDURES

General Techniques. The diketene acetal, 3,9-diethylidene-2,4,8,10-tetraoxaspiro[5,5]undecane was received as a generous gift from Dr. Jorge Heller at Advanced Polymer Systems (Redwood City, CA). Monomethyl ether of PEG (MW 2000) was purchased from Shearwater Polymers, Inc (Huntsville, AL). Distearoyl glycerol was purchased from Genzyme (Cambridge, MA). Triethylamine was purchased from Aldrich and redistilled under Ar before use. 1-Palmitoyl-2-oleoylphosphatidylcholine (POPC), 1-palmitoyl-2-oleoylphosphatidylglycerol sodium salt (POPG), dioleoylphosphatidylethanolamine (DOPE), and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[poly(ethylene glycol)-2000] (DSPE-PEG) were purchased from Avanti Polar Lipids (Birmingham, AL). Cholesteryl hemisuccinate (CHEMS) was purchased from Sigma. 8-Aminonaphthalene-1,2,3-trisulfonic acid (ANTS) and *p*-Xylenebis(pyridinium) bromide (DPX) were from Molecular Probes, Inc. (Junction City, OR). MilliQ water, which had a pH of approximately 8 when freshly prepared, was used to prepare all the aqueous buffers. All other chemical reagents and solvents were purchased from Aldrich or Fisher. Ratios of components in chromatography solvent systems are in volume unless stated otherwise. Ratios of lipid components in liposomes are in mole units.

¹H NMR spectra were recorded on an Oxford AS 400. Electrospray mass spectra (ESIMS) were recorded on a Sciex (PE, Foster City, CA) at the Mass Spectrometry Facilities, University of California at San Francisco. Fourier-transformed infrared spectra were measured

with a Nicolet Impact 400. The FT-IR samples were applied as a CHCl₃ solution onto the surface of a NaCl crystal, dried under Ar, and subsequently analyzed. Elemental analysis was carried out by Microanalytical Lab at College of Chemistry, University of California at Berkeley.

3,9-Diethyl-3-(2,3-distearoyloxypropyloxy)-9-(methoxypoly(ethylene glycol)2000-1-yl)-2,4,8,10-tetraoxaspiro[5,5]undecane (POD, **1).** One gram of PEG (2000) monomethyl ether (0.5 mmol) and 312.5 mg of distearoyl glycerol (0.5 mmol) were dissolved in 5 mL of anhydrous THF under Ar. A heat gun was used to melt 3,9-diethylidene-2,4,8,10-tetraoxaspiro[5,5]undecane and 100 μ L (110 mg, 0.5 mmol, $d = 1.1$) of the melted compound was taken by a dry syringe and injected into the THF solution. One drop (~ 40 μ L) of 0.6 mg/mL *p*-toluenesulfonic acid in anhydrous THF was added and the reaction mixture was stirred at 40 $^\circ$ C under Ar for 2 h. The reaction was stopped by adding 200 μ L of triethylamine followed by quenching the reaction into 30-fold volume excess of 1% volume of triethylamine in methanol. Four grams of silica gel were added to the solution and the mixture was evaporated under reduced pressure. The residue was poured onto a silica gel column (45 g) equilibrated with the eluting solvent system (triethylamine/chloroform = 1/50). The column was eluted and fractions corresponding to the product were pooled, evaporated, and dried in high vacuum to give 275 mg (20%) purified product. TLC = R_f 0.4 in CHCl₃/MeOH/30% w/w NH₄OH (100:15:1); FTIR 2910 cm⁻¹ (CH₂ and CH₃), 2850 cm⁻¹ (CH₂ and CH₃), 1743 cm⁻¹ (ester C=O), 1109 cm⁻¹ (PEG and ortho ester C–O); ¹H NMR (400 MHz, CDCl₃, chemical shifts relative to TMS signal) δ 5.22 (1H, m, glycerol methine), 3.7–4.2 (4H, m, glycerol methylene), 3.0–3.7 (~ 170 H, m, OCH₂ and OCH₃), 2.2–2.4 (4H, m, CH₂COO), 1.65–1.76 (4H, m, CH₂CH₂COO), 1.54–1.65 (4H, m, CH₂CH₃ on spiro rings), 1.04–1.36 (56H, m, CH₃(CH₂)₁₄CH₂CH₂COO), 0.82–0.97 (12H, m, CH₂CH₃); ESIMS, calcd for [M + Na]⁺ with 36–48 CH₂-CH₂O units from PEG: C₁₂₃H₂₄₀O₄₆Na 2476.6, C₁₂₅H₂₄₄O₄₇-Na 2520.7, C₁₂₇H₂₄₈O₄₈Na 2564.7, C₁₂₉H₂₅₂O₄₉Na 2608.7, C₁₃₁H₂₅₆O₅₀Na 2652.7, C₁₃₃H₂₆₀O₅₁Na 2696.8, C₁₃₅H₂₆₄O₅₂-Na 2740.8, C₁₃₇H₂₆₈O₅₃Na 2784.8, C₁₃₉H₂₇₂O₅₄Na 2828.8, C₁₄₁H₂₇₆O₅₅Na 2872.9, C₁₄₃H₂₈₀O₅₆Na 2916.9, C₁₄₅H₂₈₄O₅₇-Na 2960.9, C₁₄₇H₂₈₈O₅₈Na 3004.9, found 2478.3 (33%), 2521.1 (47%), 2565.3 (62%), 2609.3 (77%), 2654.2 (94%), 2697.3 (100%), 2741.4 (98%), 2785.3 (93%), 2830.4 (85%), 2874.4 (60%), 2917.5 (46%), 2962.4 (37%), 3006.4 (26%). Thin Layer Chromatography (TLC) Analysis of POD Degradation in Buffers of Different pH at 37 $^\circ$ C. Conical polystyrene microcentrifuge tubes (0.5 mL) containing 20 μ L of 100 mM sodium phosphate buffer of different pH were prewarmed at 37 $^\circ$ C for 30 min and silica gel TLC plates (Whatman from Whatman Ltd, Maidstone, Kent, England) were pre-equilibrated with the solvent system (CHCl₃/MeOH/ NH₄OH = 100:15:1) by running the plates without samples followed by brief air-drying. Eight milligrams of POD was dissolved into 100 μ L of water by vortexing and 20 μ L of the solution was added into each of the prewarmed tubes and mixed thoroughly. The tubes were incubated at 37 $^\circ$ C and 10 μ L of the solutions were aliquoted at different time points and mixed with 10 μ L of 10% concentrated NH₄OH (30% w/w) in acetone to stop the hydrolysis. Five microliters

of the mixture was spotted onto preequilibrated TLC plates. Three microliters of distearoyl glycerol, monomethyl ether of PEG2000 and POD in 10 mg/mL CHCl_3 solution were also spotted as standards. TLC plates were developed, heated at 150 °C for 5 min and stained in I_2 chamber for 1 h to observe the locations of POD and its degradation products.

Liposome Preparation for Aggregation and Leakage Assays. Reversed-phase vesicles (REV) were prepared as described previously (22) in 50 mM ANTS, 50 mM DPX, and 5 mM HEPES at pH 8.5. The vesicles were extruded five times through a 0.2- μm polycarbonate membrane (Nucleopore Corp., Pleasanton, CA) through a hand held extrusion device (Avestin, Ottawa, Ontario, Canada). A Sephadex G-75 column was used to separate vesicles from unencapsulated material with an elution buffer composed of 5 mM HEPES and 145 mM NaCl, pH 8.5. All freshly prepared liposomes had mean diameters ranging from 180 to 200 nm (cumulant results) and a polydispersity index of less than 0.2 as measured by a Malvern Zeta1000 Dynamic Light Scattering Instrument using the PCS 1.32a software. The encapsulated volume was 0.25–0.3 $\mu\text{L}/\mu\text{mol}$ total lipid. Lipid concentrations were determined based on lipid phosphorus by a modification of the Bartlett method (23).

Liposome Aggregation Assay. Conical polystyrene microcentrifuge tubes (0.5 mL) containing 300 μL of buffers of various pH (50 mM NaOAc/HOAc and 100 mM NaCl for pH <6; 50 mM $\text{NaH}_2\text{PO}_4/\text{Na}_2\text{HPO}_4$ and 100 mM NaCl for pH 6 and above) were incubated at 37 °C for 30 min. The liposome preparation was warmed to room temperature and an aliquot (100 μL) was added to each tube and mixed thoroughly. The tubes were incubated at 37 °C for different time periods and 30–40 μL of the mixtures were aliquoted and transferred into disposable polystyrene fluorimeter cuvettes containing 1.5 mL of 100 mM NaHCO_3 /50 mM NaCl buffer at pH 9. The samples were mixed by gently inverting the cuvettes 2–3 times.

Photon correlation spectrometry of the samples was then measured with a Malvern apparatus (Zeta 1000) to determine the size distribution of the liposomes. Typically, three measurements of 2–5 min were made for each sample, using the automatic algorithm mode for data analysis. The average of the three cumulant results of each sample that agreed to within 10% is reported in the paper.

ANTS/DPX Leakage Studies. The ANTS/DPX assay (24) was used to monitor leakage of ANTS from liposomes. Fluorescence measurements were made on a Spex Fluorolog photon counting instrument (Edison, NJ) using a 150-W xenon light source. Excitation was at 370 nm (1.25 mm slit). The 90° emission signal at 550 nm (5 mm, 5 mm slits) resulting from the dequenching of ANTS released out of liposomes was observed through a Corning 3-68 nm cutoff filter (>530 nm). The raw fluorescent data were converted into ASC data files and processed mathematically by Microsoft Excel. The residual fluorescence of the liposomes at the starting time (t_0) of leakage experiments, F_0 , was set as 0% release. At the end of each leakage experiment the liposomes were lysed with the detergent dodecyloctaethylene glycol monoether (C_{12}E_8) and the maximal fluorescence thus obtained, F_{100} , was taken as 100% release. The leakage of ANTS at a particular time point was then determined by the formula: percentage of leakage = $(F_t - F_0)/(F_{100} - F_0) \times 100$, where F_t corresponds to the fluorescence intensity observed at the time point.

In leakage experiments of POD/DOPE liposomes in aqueous buffers of different pHs, the assays were started

by injecting small volumes (5–10 μL , using a Hamilton syringe) of concentrated liposome suspensions into a magnetically stirred quartz cuvette containing 2 mL of the buffer (50 mM NaOAc/HOAc and 100 mM NaCl, pH <6; 50 mM $\text{NaH}_2\text{PO}_4/\text{Na}_2\text{HPO}_4$ and 100 mM NaCl, pH 6 and above) at 37 °C. The starting time, t_0 was set 5–10 s after the injection when the fluorescence signal first became stable.

In serum stability assays, aliquots of fetal bovine serum (180 μL in each tube) in 0.6 mL tubes were prewarmed at 37 °C for 30 min. An aliquot of stock liposome solution was diluted to 2 mM of total lipid by phosphate buffered saline (50 mM $\text{NaH}_2\text{PO}_4/\text{Na}_2\text{HPO}_4$ and 100 mM NaCl, pH 7.4), which had been prewarmed at 37 °C for 30 min. An aliquot of the diluted liposome solution (60 μL) was then mixed with 180 μL of prewarmed fetal bovine serum to give a 75% final serum concentration. At different time points, a 20 μL aliquot was added into a polystyrene fluorimeter cuvette, containing 2 mL of HEPES-buffered saline (5 mM HEPES and 145 mM NaCl, pH 8.5) at room temperature. The cuvette was covered with Parafilm and inverted gently for 3–4 times. The fluorescence thus measured subtracted by the fluorescence of the buffer before the addition of the sample was taken as F_t . The F_t of an aliquot extracted and measured immediately after mixing a liposome sample with fetal bovine serum was taken as F_0 . At the end of each assay an aliquot of the liposome-serum mixture was pipetted into 2 mL of HEPES buffered saline (5 mM HEPES and 145 mM NaCl buffer, pH 8.5), followed by adding the detergent dodecyloctaethylene glycol monoether (C_{12}E_8). The fluorescence measured after adding the detergent minus the fluorescence of the buffer was taken as F_{100} . Each data point of the leakage assay in fetal bovine serum represents the average and standard deviation of three independent samples.

Animals. Blood clearance, distribution and excretion studies were conducted on 4-week-old female ICR mice (about 25 g in weight) purchased from Simonsen (Gilroy, CA). All animals were handled in accordance with protocols established by the National Institute for Health Guidelines for the Care and Use of Laboratory Animals and with the approval of the Committee for Animal Research at the University of California, San Francisco. Animals were sacrificed at stated times with a sodium pentobarbital overdose.

Preparation of ^{125}I -Labeled Liposomes for Animal Studies. *p*-Hydroxybenzamidinium phosphatidylethanolamine (BPE) was synthesized and radiolabeled with Na^{125}I as previously described (25) and the purity assessed by thin-layer chromatography. The labeled lipid contained less than 0.5% of free ^{125}I . The labeled lipid, in chloroform solution, was added to POD/DOPE (1/9) or DSPE-PEG/DOPE (1/9) mixture in chloroform to yield 8.3×10^{11} dpm/mol of total lipid. Chloroform was evaporated under reduced pressure and the resultant lipid film was placed under high vacuum for 2 h to remove the remaining solvent. The dried lipid film was hydrated with HEPES buffered saline (10 mM HEPES and 145 mM NaCl, pH 7.4) over 20 min by intermittent agitation on a vortex mixer and the suspension extruded three times through a 0.1 μm polycarbonate membrane. The diameter of the extruded liposomes, as measured by photon correlation spectrometry, was 140–160 nm. Each mouse received a tail-vein injection of 150 μL of the extruded liposomes containing 0.9 μmol total lipid.

Blood Clearance Assay. At various time points following administration of ^{125}I -labeled liposomes, ani-

Scheme 2. Synthesis of PEG–Diortho Ester–Distearoyl Glycerol Conjugate (POD, 1)

imals were anesthetized with inhalation of isoflurane. Approximately 50 μ L of blood was collected with a glass pasteur pipet from the orbital sinus vein, weighed and its γ -activity measured in Beckman Gamma 8000 (Fullerton, CA). The γ -activity in whole blood and hence, the percentage of dose remaining in the blood was calculated assuming 0.07 g of blood/gram of animal weight. The average and standard deviation of samples collected from three animals were presented.

Tissue Distribution Assay. At various time points following administration of ^{125} I labeled liposomes, animals were anesthetized with an intraperitoneal (i.p.) injection of 100 μ L of anesthetics cocktail (44 mg/kg ketamine, 2.5 mg/kg xylazine, and 0.75 mg/kg acepromazine). Approximately 1 mL of blood was removed *via* intracardiac puncture. One milliliter of phosphate-buffered saline (containing 0.2 g/L KH_2PO_4 , 2.16 g/L $\text{Na}_2\text{HPO}_4 \cdot 7\text{H}_2\text{O}$, 0.2 g/L KCl, and 8.0 g/L NaCl) was perfused through the right cardiac ventricle. The heart, lungs, liver, spleen, kidneys, stomach, intestines, head, mid section, and tail were collected and weighed, and the radioactivity counted in the Beckman Gamma 8000. The γ -activity in whole blood and hence the percentage of dose remaining in the blood was calculated assuming 0.07 g of blood/gram of animal weight. The average and standard deviation of samples from three animals were reported.

RESULTS

Design and Synthesis of PEG–Diortho Ester–Distearoyl Glycerol Conjugate (POD, 1). To devise a lipid that degrades specifically in a low-pH environment but is inert under neutral physiological conditions, we chose PEG as the headgroup since it is one of the most stable synthetic polymers *in vivo* and liposomes coated by PEG have a prolonged circulation period (26). The monomethyl ether of PEG-2000 was used for synthesis to preclude cross-linking or polymerization. The 3,9-diethyl-2,4,8,10-tetraoxaspiro[5,5]undecane moiety was chosen as the diortho ester linker, based on previous research by Heller and co-workers (27), who showed its pH sensitivity and biocompatibility in polymeric drug delivery systems. Distearoyl glycerol, with two saturated hydrocarbon side chains, is attached to the diortho ester linker as the hydrophobic tail to anchor the conjugate into lipid bilayers (28, 29). If the conjugate is incorporated into liposomes of unsaturated phosphatidylethanolamine, distearoyl glycerol would be regenerated in the bilayers upon hydrolysis, and would favor the formation of hexagonal phases due to its conical structure (30).

POD was prepared by a one-step synthesis as illustrated in Scheme 2. The monomethyl ether of PEG2000 and distearoyl glycerol were dissolved in dry THF under

atmospheric Ar. The solid diketene acetal, 3,9-diethylidene-2,4,8,10-tetraoxaspiro[5,5]undecane was melted with a heat gun under atmospheric Ar and added with a syringe to the THF solution to avoid contact with air. The reaction was then initiated by adding a trace amount of *p*-toluenesulfonic acid dissolved in dry THF. The mixture was stirred at 40 $^{\circ}\text{C}$ under Ar for 2 h and the reaction was stopped by addition of triethylamine. Silica gel chromatography with a solvent system containing 2% triethylamine as a stabilizer afforded the purified conjugate (20% synthetic yield) that appears homogeneous on TLC. Although the yield of the reaction was modest, we chose this synthetic route since the method is quick and the reagents are relatively inexpensive.

It should be noted that POD is actually a mixture of conjugates with the mPEG headgroup comprising of a narrow distribution of molecular weights around 2000, due to the polydisperse nature of the commercially available PEG2000 monomethyl ether. The electrospray mass spectrometry showed a distribution of peaks centered on 2697 Da, corresponding to monosodiumated molecular cations with different numbers of ethylene glycol units. The heterogeneity of mPEG as well as the stereochemistry of the conjugate also resulted in NMR peaks of POD appearing as multiplets, a feature which has been previously reported in the literature (31).

Acid Sensitivity of POD. To quickly estimate the sensitivity of the conjugate toward mildly acidic conditions relevant to biological scenarios, we employed a simple TLC assay to monitor the degradation of POD after it was incubated for different time periods at 37 $^{\circ}\text{C}$ in buffers of pH ranging from 4 to 7.4. As shown in Figure 2, within 1 h of incubation at 37 $^{\circ}\text{C}$, POD was completely degraded in buffers of pH 4 and 5 as indicated by the disappearance of the compound spot at $R_f \approx 0.4$. However, in the buffer of neutral pH 7.4, most of the conjugate remained intact over 3 h. In the buffer of pH 6, POD degraded with an approximate half-life of 2.5 h. As expected from the acid-catalyzed hydrolysis illustrated in the Introduction, the degradation of POD yielded both more hydrophilic ($R_f \approx 0.3$) and more hydrophobic ($R_f \approx 0.8$) materials, presumably derivatives of mPEG and distearoyl glycerol, respectively. The hydrophilic degradation products gave more intensely stained spots than the hydrophobic derivatives, because mPEG derivatives are much more sensitive to iodine staining than are the saturated acyl chains. Similar results were obtained when the TLC plates were stained with Molybdate reagent, which clearly showed the hydrophobic degradation products (Data not shown).

Liposome Formation. Encouraged by the TLC results on POD degradation, we proceeded to study whether POD incorporated into a high percentage of DOPE, a fusogenic lipid, can stabilize a lamellar structure in neutral and alkaline solutions, and yet induces destabilizing phase changes upon cleavage of its mPEG headgroup by hydrolysis at low pH. ANTS and DPX (24) were encapsulated into liposomes by reverse phase evaporation (22) and their leakage from the vesicles were used to monitor pH triggered release of liposomal contents. Liposomes of defined size were prepared by extruding five times through polycarbonate membranes of 200 nm pore diameter. Unencapsulated ANTS/DPX was then removed by size-exclusion chromatography. Liposomes composed of 10% POD and 90% DOPE were readily prepared and remained stable for up to 2 weeks in an alkaline HBS buffer (5 mM HEPES, 145 mM NaCl, pH 8.5) at 4 $^{\circ}\text{C}$ with no significant increase in particle size or in residual ANTS fluorescence.

Figure 2. TLC monitored degradation of POD. Lipids were incubated for the period of 1 h (A), 2 h (B), and 3 h (C) in Na_2HPO_4 buffers of the pH indicated under the application origin. POD, mPEG, and DSG in CHCl_3 solution were spotted alongside as standards.

Acid-Triggered Liposome Aggregation. When pH sensitive liposomes composed of phosphatidylethanolamine (PE) are subjected to low pH, the PE lipids undergo a contact-induced aggregation and a phase transition from the lamellar to the hexagonal phase (24). PEG lipids at a high enough concentration on the liposome surface can shield the PE lipids of one liposome from contacting those of another liposome, thus preventing aggregation and membrane-destabilizing phase changes. Thus one can follow the loss of the PEG coating from the liposome surface as a result of POD hydrolysis by monitoring the aggregation of POD/DOPE liposomes at different pHs with photon correlation spectroscopy (PCS). However, as indicated by the TLC assays, the kinetics of the aggregation, particularly at pH below 5.5, may be too fast to be monitored by PCS, which takes about 10–20 min for a triplicate measurement. To circumvent this problem, we elected to “freeze” the aggregation process by quenching aliquots of samples in excess buffer of pH 9. The quenching stopped the acid-catalyzed POD hydrolysis and prevented the liposomes/lipid particles from contacting each other by inducing negative charges to their surfaces via deprotonation of the amine in DOPE. We found “base-freezing” to be a valid method to prevent size increases in the aggregation products. To determine if quenching of the reaction to pH 9 resulted in dispersion of aggregates into smaller particles, we took aliquots of liposomes incubated at pH 6 and diluted them in the same pH 6 buffer. The particle size of the liposomes was then immediately determined by a single PCS measurement of 2 min. The size data thus obtained were not significantly different from the diameters measured after “base-freezing”. Furthermore, the samples quenched at pH 9 gave the same PCS readings after being left overnight at room temperature. Thus, the base quenching yielded a reproducible value that reflected the particle size distribution at the quench time. Therefore, the light scattering of the aliquots quenched at pH 9 was recorded and the particle diameter from the cumulant results was plotted against incubation time in Figure 3.

Figure 3. Aggregation of POD/DOPE (1/9) liposomes in buffers of different pH. (■) pH 4; (●) pH 4.5; (▲) pH 5; (▼) pH 5.5; (◆) pH 6.2; (+) pH 7.5.

The aggregation process showed a pH-dependent lag phase followed by a rapid increase in diameter (Figure 3). At pH 7.5, the POD/DOPE liposomes were relatively stable and the aggregation did not occur after more than 10 h of incubation at 37 °C. In buffers of lower pH, the lag phase was much shorter. At pH 6.2, the liposome size started to increase after 1 h and when the pH was decreased to 5, extensive aggregation was observed within 10 min. Thus, the kinetics of the liposome aggregation correlated with that of pH-dependent POD degradation shown by the TLC studies. These results demonstrate the ability of POD to protect the DOPE-containing liposomes from aggregating and converting into hexagonal phases until the mPEG headgroups are removed from the surface of the liposomes at low pH.

Acid-Triggered Content Leakage. Since POD was designed for potential applications in liposomal drug delivery, we used POD/DOPE liposomes containing ANTS/DPX as a model system to examine if the hydrolysis of POD can trigger the release of the contents from DOPE liposomes in response to a low pH environment. The ANTS/DPX method is often used to study pH sensitive liposomal leakage since the fluorescence of ANTS is

Figure 4. Acid-triggered content release from POD/DOPE (1/9) liposomes. (A) ANTIS leakage in buffers of different pH. The pH is indicated adjacent to the corresponding trace. DSPE-PEG/DOPE (1/9) liposomes were incubated at pH 5 as a control. (B) Length of lag phase in buffers of different pH. The logarithm of the length of lag phase in seconds is regressed versus the buffer pH to give $\log_{10}(\text{seconds of lag phase}) = -1.92 + 0.883 \times \text{pH}$, $r = 0.984$.

virtually unchanged from pH 4 to 8 (24). When both compounds remain encapsulated, the fluorescence of ANTIS is quenched by DPX (24). Upon leakage from the liposomes, ANTIS is no longer quenched by DPX and gives an increase of fluorescent signal at 550 nm (excitation wavelength = 370 nm). As shown in Figure 4A, the release of ANTIS at different pH also occurs in two distinct phases, a lag phase, where a small portion of ANTIS slowly leaks out of the liposomes, followed by a burst phase, when most of the ANTIS is quickly released. The burst phase correlates well with the aggregation of the POD/DOPE liposomes in Figure 3 and the collapse of the lamellar phase. As the liposomes are subjected to more acidic environments, the lag phase shortens. At pH 7.4, the lag phase lasts approximately 12 h; at pH 6, the lag phase is reduced to 60 min; at pH 5, the lag phase is less than 5 min. As a control, ANTIS/DPX was encapsulated into liposomes composed of 90% DOPE and 10% of a pH insensitive PEG lipid, DSPE-PEG. Less than 5% of the encapsulated ANTIS was released over 12 h when the vesicles were treated in the same way as the POD/DOPE liposomes even at the lowest pH. This confirms the role of acid-catalyzed hydrolysis of the PEG-diortho ester-DSG conjugate in the leakage of the POD/DOPE liposomes.

In Figure 4B, we plot the logarithm of the length of lag phase in Figure 4A against buffer pH from 4 to 6 and observe a clear linear relationship ($r = 0.984$). The lag time at pH 7.4 was not plotted in the graph since the

Figure 5. Contents leakage from liposomes of various compositions in 75% fetal bovine serum. ANTIS leakage was monitored after the liposomes were incubated in 75% fetal bovine serum at 37 °C for different time periods. (■) POD/DOPE (1/9); (○) DSPE-PEG/DOPE (1/9); (▲) CHEMS/DOPE (3/7); (×) POPG/POPC/Chol (1/9/8).

transition is too slow to allow a precise determination. The slope of the regressed line is 0.883. This linear relationship demonstrates that the buffer pH plays a pivotal role on the kinetics of liposomal leakage. This phenomenon is discussed in detail in the discussion section, where we propose a mathematical model to account for the data.

Stability of POD Containing Liposomes in Serum. To test the idea that POD should help stabilize liposomes in circulation, we carried out an in vitro stability test in fetal bovine serum. POD/DOPE (1/9) liposomes containing ANTIS/DPX were incubated with 75% fetal bovine serum at 37 °C and the release of ANTIS was measured every 4 h for 16 h (Figure 5). For comparison, ANTIS/DPX was also encapsulated into liposomes composed of DSPE-PEG/DOPE (1/9), CHEMS/DOPE (3/7), POPG/POPC/Chol (1/9/8), and the ANTIS leakage was monitored in the same manner.

POD/DOPE liposomes were found to be relatively stable over 12 h, when less than 25% of the ANTIS leaked out. However, after 16 h of incubation, 84% of the ANTIS was released, indicating a transition from the lag phase to the burst phase. The POD/DOPE liposomes were as stable as the pH-insensitive, PEG-stabilized DSPE-PEG/DOPE liposomes for the first 12 h, but released ANTIS much faster for the next 4 h, indicating a liposome destabilization process specifically mediated by POD hydrolysis. In the first 12 h of incubation, the POD/DOPE liposomes released 2–3-fold less ANTIS than CHEMS/DOPE liposomes, whose excess negative charges from CHEMS tend to induce more interactions with serum components (12). The stable liposome formulation composed of POPG/POPC/Chol released less than 10% of the contents after 12 h of incubation with serum (32). Thus, POD is able to stabilize liposomes in fetal bovine serum as effectively as traditional PEG-derived lipids for up to 12 h, which is consistent with our findings on ANTIS leakage of these liposomes in HEPES buffered saline. (Figure 4).

Stability of Liposomes in Blood Circulation. The steric-stabilizing effect of POD on liposomes in vivo was evaluated by tail-vein injection of radiolabeled liposomes composed of 10% POD and 90% of DOPE into female ICR mice and measuring their rate of elimination from the blood (Figure 6). For comparison, we also administered radiolabeled liposomes composed of 10% DSPE-PEG, a pH-insensitive lipid-PEG conjugate, and 90% DOPE. Liposomes composed of pure DOPE are not stable enough at pH 7.4 to allow their injection into animals. For both

Figure 6. Clearance of [^{125} I]BPE POD/DOPE (1/9) liposomes (■) and [^{125} I]BPE DSPE-PEG/DOPE (1/9) liposomes (○) from circulation. (A) The percentage of the injected dose remaining in blood ($n = 3$, mean $\pm$ SD) is plotted against the elapsed time postinjection. (B) The natural logarithm of the percentage of dose remaining in blood is plotted against elapsed time postinjection and regressed to obtain the liposomal half-life. For POD/DOPE (1/9) liposomes, $\ln(\text{percentage of dose in blood}) = 4.41 - 0.00358 \times (\text{min})$, $r = 0.997$, $T_{1/2} = \ln 2 / 0.00358 = 193.6$ min. For DSPE-PEG/DOPE (1/9) liposomes, $\ln(\text{percentage of dose in blood}) = 4.62 - 0.00235 \times (\text{min})$, $r = 0.997$, $T_{1/2} = \ln 2 / 0.00235 = 295.0$ min.

POD/DOPE and DSPE-PEG/DOPE liposome formulations, the percentage of injected dose remaining in circulation showed a single log-linear decay with a correlation coefficient constant greater than 0.995, indicating a one-compartment clearance kinetics. The blood clearance profile of the POD/DOPE liposomes is similar to the pH-insensitive, sterically stabilized DSPE-PEG/DOPE liposomes than to conventional liposomes, which usually exhibit a two-compartment elimination kinetics (33). The half-life of the POD/DOPE liposome and the DSPE-PEG/DOPE liposome is about 194 and 295 min, respectively. This reasonably close correspondence of the elimination rate between the two formulations is strong evidence that the mPEG headgroup in the pH-sensitive ortho ester conjugate provides a steric-stabilizing effect on the fusogenic DOPE liposomes in circulation.

Distribution and Excretion of Liposomes. To investigate the distribution of radiolabeled POD/DOPE liposomes in more detail, we measured the radioactivity associated with different organs of mice at 270 min, 810 min and 28 h following liposome injection. In previous studies with the ^{125} I-labeled BPE (25), it is known that this radioactive lipid label is metabolized only after being endocytosed together with the liposomes. The urine and the feces were also collected at the 28-h time point and their radioactivity measured to determine the routes of ^{125} I excretion. At 270 min postinjection (Figure 7A), about 20% of POD/DOPE liposomes and 45% of DSPE-PEG/DOPE liposomes remained in circulation. For both formulations, the liver and intestine were the two major organs of radioactivity disposition.

At later time points (810 min and 28 h postinjection), most of the radioactivity of both formulations was excreted from the animals (Figure 8); the liver and intestine were the major organs for the disposition of the remaining radioactivity in the body (Figure 7B, 7C). Twenty-eight h after injection, the residual radioactivity from POD/DOPE liposomes was distributed preferentially to the head (Figure 7C), probably due to an accumulation of the iodine in the thyroid followed by a slow clearance of ^{125} I from this organ. For both formulations at 28 h postinjection, about 70% of radioactivity was excreted into urine and about 20% was found in feces (Figure 9). Overall, POD/DOPE liposomes were eliminated from circulation about 50% faster than DSPE-PEG/DOPE

liposomes but the patterns of distribution and excretion of the two formulations were very similar.

DISCUSSION

The novel pH-sensitive ortho ester lipid derivative introduced here is a useful addition to the other reported pH-sensitive linkages for modifying liposome surfaces. The synthesis is simple and versatile. Although we illustrate the process with monomethyl ether of PEG, the chemistry could be used to attach various other headgroups to diacyl/steryl hydrophobic groups. For instance, anionic groups, cationic groups and even targeting ligands can be attached to a lipid anchor to create a triggerable headgroup for liposome formulations, micelles and other particulates. Modified glycerols, dendrons (34), or poly(vinylpyrrolidone) (35) could also be conjugated to lipids using this chemistry.

Regarding to the synthesis of POD, it should be noted that the acid-catalyzed conjugation does not produce POD as the unique product. Our preliminary TLC observations suggested that the side-products of the reaction include the conjugate of two mPEG or two distearoyl glycerol molecules on both ends of the diortho ester linker. The presence of side reactions, along with the loss of POD during its chromatography purification, may account for the moderate yield of the synthesis.

POD showed a remarkably quick degradation even at a mildly acidic pH of 5–6. Such sensitivity to acidic pH is significantly higher than that of acetals, vinyl ethers, and polyortho esters. We attribute the higher sensitivity of POD to the following two factors. First, the dialkoxy carbocation intermediate of ortho ester hydrolysis has four lone pairs of electrons over which to distribute the positive charge from the carbon, and hence is much more stable (Scheme 1) than the monoalkoxy carbocation intermediate, stabilized by two lone pairs of electrons, in the case of acetals and vinyl ethers. Second, the PEG headgroup of POD is more hydrophilic than the functional groups of the reported polyortho esters, allowing better hydration and faster proton transfer to the diortho ester linkage (36). When POD was incorporated into liposomes composed of a high percentage of DOPE, POD hydrolysis at pH 5–6 triggered the extensive aggregation and leakage of the liposomes in 10–100 minutes.

Figure 7. Distribution of [^{125}I]radioactivity of POD/DOPE (1/9) (solid bars) and DSPE-PEG/DOPE (1/9) (open bars) liposomes in female ICR mice at 270 min (A), 810 min (B), and 28 h (C) postinjection. ($n = 3$, mean $\pm$ SD).

We believe that the rapid hydrolysis of POD at mildly acidic pH is a very useful property for drug/gene delivery systems because the decrease of pH at potential therapeutic sites may be only one pH unit or less. For example, the transit through the endosomes in cells occurs in about 10 to 30 min with pH in the range of 5–6 before the endosomal contents are delivered into the lysosome (37, 38). Therefore, it is important for pH sensitive liposomes

Figure 8. Excretion kinetics of [^{125}I]radioactivity of POD/DOPE (1/9) (■) and DSPE-PEG/DOPE (1/9) (○) liposomes.

to respond quickly to the initial drop in pH and release their contents prior to trafficking into the lysosomal compartment. The pH-dependent release profile of POD/DOPE liposomes may also be important for triggered release at inflammatory tissues (7, 40) and solid tumors (6, 39), where the pH is only 0.5–1 unit more acidic than that of the circulation.

The lag phase of ANTS leakage (Figure 4) corresponds quite closely to the lag time needed for liposome aggregation as measured by the increase of particle diameter (Figure 3). On the basis of these observations, we propose the following model of acid-catalyzed destabilization of POD/DOPE liposomes. Once the liposomes are subjected to an aqueous phase of mildly acidic or neutral pH, the mPEG headgroups are continuously cleaved off the liposome surface as shown in Scheme 1. However, the lipids remain in the lamellar phase until the amount of mPEG on the liposome surface decreases to a critical level, at which point the bilayers of two vesicles can come in contact. The bilayer contact is what triggers the aggregation of liposomes, the transition to the hexagonal phase and the release of liposome contents (24). The model is consistent with the known properties of PEG coated liposomes (41) and the requirement of bilayer contact to trigger the lamellar-hexagonal transition in PE liposomes (24). Assuming complete hydration and unaltered local pH at the liposome surface, the following equation holds:

$$dA/dt = -kA[\text{H}^+] \quad (1)$$

where A is the number of mPEG groups on the surface of a liposome of certain size, $[\text{H}^+]$ is the proton concentration of the aqueous medium, and k is the rate constant for ortho ester hydrolysis. In a buffer of constant pH, the equation can be integrated to give

$$A = A_0 \exp(-k[\text{H}^+]t) \quad (2)$$

where A_0 is A at an arbitrary starting point of POD hydrolysis and t is the incubation time from the starting point. At the transition point between the lag phase and the burst phase of liposomal leakage, we have

$$A_c = A_0 \exp(-k[\text{H}^+]t_c) \quad (3)$$

where A_c is the critical amount of mPEG on the surface of the liposomes necessary to stabilize the lamellar structure and t_c is the length of the lag phase. If the same liposome preparation is incubated in buffers of different pH, both A_c and A_0 should be constant and we can write

Figure 9. Mass balance of injected radiolabeled liposomes. [^{125}I]Radioactivity of POD/DOPE (1/9) (A) and DSPE-PEG/DOPE (1/9) (B) liposomes from all parts of body (white), urine (black), and feces (gray) were measured 28 h postinjection and plotted in percentage of the total radioactivity recovered. The percentage of injected dose recovered is 110% for POD/DOPE liposomes and 93% for DSPE-PEG liposomes.

the following equation:

$$[\text{H}^+]t_c = C \quad (4)$$

where C is a composite constant composed of A_c , A_o , and k . After taking the logarithm of eq 4 followed by rearrangement, the length of the lag time and the pH of the buffer would have the following relationship:

$$\log t_c = \text{pH} + C' \quad (5)$$

where C' is a constant.

Equation 5 fits closely to the observed leakage data in Figure 4B. The linear relationship between the logarithm of observed lag time and buffer pH, as well as the slope of the regressed line in Figure 4B (0.883 versus 1 in eq 5), support this mechanistic model of acid triggered phase changes of POD/DOPE liposomes. Further biophysical studies are required to confirm this model but the simple model is consistent with previous studies on lamellar-hexagonal transition as well as the data presented in Figure 2, 3, 4, and 5.

When incubated in 75% fetal bovine serum, POD was able to stabilize POD/DOPE (1/9) liposomes for up to 12 h, a finding consistent with the lag time for ANTS leakage of POD/DOPE liposomes in HEPES buffered saline at the same pH. Thus the stability characteristics vis-à-vis drug retention of this two component formulation are compatible for targeted delivery of encapsulated molecules given the observed intravenous elimination rate ($T_{1/2} = 194$ min) of the formulation. Based on the distribution and the excretion data, we propose that both formulations were cleared mainly by liver from circulation, after which the [^{125}I]BPE labels were degraded and excreted into urine and bile.

The half-life of the POD/DOPE formulation in circulation is similar to other formulations that consist primarily of DOPE and that are stabilized by PEG (42, 43). It is not surprising that such formulations have a shorter serum half-life than the traditional sterically stabilized formulations that consist of saturated phosphatidylcholine/Chol/PEG-DSPE (44). Such composition yields an inherently more rigid bilayer that is capable of resisting the penetration of serum components that might contribute to a more rapid elimination of a liposome even when it has a steric coat. Thus, we suspect that further improvements of the serum half-life and drug release characteristics can be achieved by modification of the

lipid composition such as by the inclusion of cholesterol in the formulation (32).

CONCLUSION

In conclusion, a PEG-diortho ester-distearoyl glycerol conjugate (POD) was designed and prepared by a one-step synthesis. POD was characterized for its pH sensitivity and ability to stabilize liposomes in serum and in blood circulation. POD was found to be highly sensitive to acidic conditions but relatively stable at neutral pH. Liposomes composed of 10% POD and 90% DOPE aggregated and released their contents at a mildly acidic pH similar to that found in an endosome. The destabilization of POD/DOPE liposomes consists of two phases, a lag phase where encapsulated contents slowly leaked from the vesicles, and a burst phase that was associated with liposome aggregation and rapid release of contents. Liposomes composed of 10% POD and 90% DOPE remained stable in 75% fetal bovine serum at 37 °C for 12 h and had a half-life of about 200 min in blood circulation of female ICR mice. The fast kinetics of acid-catalyzed POD hydrolysis and its ability to stabilize liposomes in serum and in blood circulation may provide important advantages for the lipid to be used for drug and gene delivery.

ACKNOWLEDGMENT

This work was partially supported by NIH Grant DK 46052. We thank Dr. J. Heller at Advanced Polymer Systems, Redwood City, CA, for the generous gift of 3,9-diethylidene-2,4,8,10-tetraoxaspiro[5,5]undecane, L. Gagné for technical help with animal studies, Dr. R. Eliaz for the gift of [^{125}I]BPE. Thanks is also extended to the UCSF Mass Spectrometry Facilities supported by the NIH Division of Research Resources, Grant RRO1614.

Received September 15, 2000; Revised Manuscript Received December 27, 2000

Laccase from *Coriopsis gallica* was conjugated to the renewable biopolymer chitosan using carbodiimide chemistry. The laccase–chitosan conjugate was observed to offer three unique properties. First, the laccase–chitosan conjugate displayed pH-responsive behavior such that the conjugate was soluble and active under acidic conditions, but precipitated when the pH was raised toward neutrality. Second, the laccase–chitosan conjugate was more stable than free laccase at extreme pHs. At pH 1, the inactivation rate constant (k_{in}) for the soluble laccase–chitosan conjugate was 20-fold less than that for free laccase. At pH 13, k_{in} for the insoluble laccase–chitosan conjugate was nearly 3-fold less than that for free laccase. Finally, the laccase–chitosan conjugate could be cross-linked under mild conditions to create biocatalytic hydrogels. Potential benefits for enzyme–chitosan conjugates are discussed.

INTRODUCTION

There are a variety of reasons for coupling polymers with enzymes. Polymer conjugation has been reported to reduce the autolysis of proteolytic enzymes (1) and to allow enzymes to dissolve in nonaqueous solvents (2–4). “Smart” biocatalysts have been prepared by conjugating enzymes to stimuli-responsive polymers that respond to changes in pH (5, 6), ionic strength (7), temperature (8–10), redox potential (6), and light (11). Biocatalytic composites have been created by grafting olefinic functionality to enzymes and then incorporating these enzyme-monomers into synthetic polymer matrices through standard free radical polymerization reactions (12, 13). Similarly, biocatalytic composites have been created with polyurethane-based (14–16) and silicon-based materials (17). Advantages of these biocatalytic composites are that the matrix can be selected to enhance performance (18) and the composites can be cast or formed into various shapes and sizes including foams (14–16) and monoliths (17). Finally, there are numerous examples in which enzymes bound to sugars, or sugar-based polymers are stabilized. Although the stabilization mechanism is not understood it may be due to; a reduction of autolysis (for proteases) (19, 20), multipoint attachment that may limit enzyme distortions (21, 22), or microenvironmental effects (23).

Here we describe the use of chitosan as our polymer for enzyme conjugation. Chitosan is a biopolymer derived from chitin and, as shown in Figure 1, chitosan is made primarily of glucosamine repeating units. Because of its

high amino content, chitosan is soluble in mildly acidic aqueous solutions but is insoluble near and above its pK_a of 6.3 (24, 25). As indicated in the upper path of Figure 1, we examined whether conjugation to chitosan could confer pH-responsive behavior to an enzyme. Additionally, chitosan's amino groups are nucleophilic and reactive at higher pHs. The reactivity of these amino groups allows chitosan to be cross-linked under mild conditions to create gel matrixes (26) of various shapes and sizes including beads (27), membranes (28–30), and fibers (31–33). The lower path in Figure 1 shows that we examined whether cross-linking could be used to incorporate a conjugate into a chitosan hydrogel. It should be noted that cross-linked chitin and chitosan have been extensively studied as insoluble supports for enzyme immobilization (34, 35).

As a model enzyme, we selected the fungal laccase from *Coriopsis gallica*. Laccases are oxidative enzymes that function under acidic conditions (36, 37) and are actively being studied for applications in the pulp and paper industry (38) and for environmental remediation (39). The laccase from *C. gallica* has also been tested for the decolorization of textile effluents (40, 41), and has been observed to be capable of oxidizing polycyclic aromatic hydrocarbons (42). Because of the interest in laccase, several groups have examined its immobilization (43 and references therein) and one group recently reported the immobilization and cross-linking of laccase and chitosan (44).

MATERIALS AND METHODS

Chitosan, 2,2'-azino-bis-(3-ethylbenzthiazoline-6-sulfonic acid)(ABTS), and buffer salts were obtained from Sigma Chemicals Co. (St. Louis, MO). *N*-(3-dimethylaminopropyl)-*N'*-ethylcarbodiimide hydrochloride (ECD) was purchased from Fluka Chemie AG (Buchs, Switzerland). Laccase was obtained from the white-rot fungus *C. gallica* and purified as described previously (40).

Figure 1. Enzyme-chitosan conjugate for pH-responsive solubility (upper path) and biocatalytic hydrogels (lower path).

The laccase–chitosan conjugate was prepared by mixing laccase (33 units) and chitosan (final concentration 1.0 w/w %) at pH 4.0 to obtain a solution with a molar ratio of glucosamine monomer/protein of 8000. To this solution, 1.6 mM of ECD was added (200 molar excess of relative to laccase). The reaction mixture was kept at room temperature for 2 h, and then the pH was increased to 8.0 by adding 10 volumes of 100 mM Tris buffer pH 8.0 and the suspension was cooled on ice. The precipitated laccase–chitosan conjugate was separated by centrifugation at 5000 rpm for 5 min. The pellet was then dissolved into 3 mL of 60 mM phosphate buffer and the pH was adjusted to 4.0 by adding 0.2 M HCl. When the laccase–chitosan conjugate was prepared for determining the pH-activity profile, for measuring stability at extreme pHs, and for preparing biocatalytic hydrogels, the preparation was precipitated and solubilized three additional times to remove nonconjugated laccase. The laccase–chitosan conjugate was stored in solution (pH 4) at 4 °C.

Enzymatic activities for free and conjugated laccase were determined colorimetrically using ABTS as the substrate. Assays were conducted in 1 mL reaction mixture containing 1 mM ABTS in a 60 mM acetate buffer (pH 4.5). Reactions were initiated by adding free or conjugated enzyme and laccase activity was estimated from the absorbance increase at 436 nm using an extinction coefficient of $23\,900\text{ M}^{-1}\text{ cm}^{-1}$ (45). Laccase units are defined as 1 μmol of substrate oxidized/min at 25 °C.

The stability of free and conjugated laccase at extreme pHs was compared by incubating 100 μL of each preparation in buffered solutions of different pH. An acetate-HCl buffer (60 mM) was used to achieve a pH of 1, while a sodium carbonate-NaOH buffer (60 mM) was used for pHs of 12 and 13. After incubation, the mixture was diluted to 1 mL with acetate buffer, pH 4.5, and enzyme activity was assayed at pH 4.5 as described above. The inactivation rate constants (k_{in}) were determined from a first-order fit of the loss of enzyme activity over time.

Biocatalytic gels were prepared by glutaraldehyde cross-linking. A solution containing laccase–chitosan conjugate (5.19 units/mL) was mixed with solution containing nonconjugated chitosan to obtain a solution with a laccase activity of 0.5 units/mL and a chitosan

concentration of 1 w/w %. To initiate cross-linking, differing amounts of a concentrated glutaraldehyde solution were added to these solutions to obtain glutaraldehyde concentrations between 3.1 and 31 mM (glutaraldehyde/glucosamine monomer molar ratios ranging from 0.05 to 0.5). Cross-linking was allowed to occur overnight at room temperature. The enzyme activity for the cross-linked chitosan gels could not be determined by the colorimetric procedure because the gels absorbed the colored product of the ABTS reaction. To determine the laccase activity of the biocatalytic gels, the consumption of dissolved oxygen (Microelectronics Inc., Bedford, NH) was measured for the reaction of catechol (20 mM) in 60 mM acetate buffer, pH 4.5. The reactions were carried out in a sealed container and initiated by adding catechol.

The relative stiffness (i.e., “strength”) of the cross-linked hydrogels was determined by a penetration method described by Gregson et al. (46). For this measurement, gels were formed in a cylindrical container (42.3 mm diameter $\times$ 9.0 mm high) by mixing varying amounts of concentrated glutaraldehyde to a chitosan solution (1 w/w %). The relative stiffness was determined by forcing a cylindrical probe (15.64 mm diameter) into the gels at a constant velocity of 0.1 mm/s. After correcting for the buoyancy, the measured force could be used to calculate an “apparent Young’s modulus” which is a relative measure of gel stiffness (46).

RESULTS AND DISCUSSION

Purified laccase (33 units) from *C. gallica* was conjugated to chitosan using carbodiimide chemistry. Conjugation was performed at a pH of 4.0 and after conjugation, the solution pH was raised to 8 resulting in the formation of a white precipitate. The precipitate and supernatant were separated, and after adding phosphate buffer (pH 4) to the precipitate it was observed to redissolve in about 10 min. A sample of the redissolved precipitate was tested and observed to have 9.3 units of laccase activity. The unprecipitated, supernatant fraction was observed to have 16.3 units of laccase activity. This sample (designated cycle 1 in Figure 2) shows that 28% of the initial laccase activity was conjugated and the laccase–chitosan conjugate possess pH-responsive behavior.

Figure 2. pH-responsive solubility of the laccase–chitosan conjugate. Laccase–chitosan conjugate was subjected to sequential cycles of precipitation at pH 8 and solubilization at pH 4. The activity of the precipitated (conjugate) and soluble (free laccase) fractions were measured under standard conditions (pH 4.5) after allowing about 10 min for the conjugate to redissolve. Cycle 1 represents the conjugation step and the soluble laccase from cycle 1 includes the activity of nonconjugated laccase. Precipitation can completely recover laccase activity of the conjugate.

Figure 3. pH-activity profile for free laccase and the laccase–chitosan conjugate. Activity was measured colorimetrically using ABTS as substrate. Conjugation does not affect laccase's pH-activity profile.

To test the reversibility and completeness of precipitation, we subjected the laccase–chitosan conjugate to several cycles of precipitation (pH 8) and redissolution (pH 4). In each cycle, the precipitate was separated from the supernatant and redissolved in fresh buffer. Figure 2 shows that over the course of 10 cycles only small amounts of laccase activity were lost in the supernatants. More importantly, Figure 2 shows that the activity of the laccase–chitosan conjugate was almost quantitatively recovered by precipitation. Further, these results indicate that precipitation does not inactivate laccase.

We measured the activity of free and conjugated laccases at various pHs to determine if conjugation affects the pH-activity profile. Figure 3 shows that laccase is active at pH 2 and the activity decreases monotonically to zero at neutral pHs. This pH-activity profile is similar to that reported by Xu (36) for the ABTS substrate. Figure 3 shows that conjugation to chitosan does not alter the pH-activity profile of laccase. Similar results were reported by D'Annibale et al. (44) for laccases that had been immobilized onto insoluble chitosan supports.

The effect of conjugation on enzyme stability was compared by exposing free and conjugated enzyme to pH extremes. At various times, samples from extreme pH solutions were assayed for laccase activity under stan-

Figure 4. Stabilization of laccase to extreme acid conditions. Enzyme was incubated for varying times at pH 1 and activities were measured under standard conditions (pH 4.5). Conjugation resulted in a 20-fold reduction in the inactivation rate constant (k_{in} was 85 h^{-1} for free laccase and 3.6 h^{-1} for the laccase–chitosan conjugate).

Figure 5. Stabilization of laccase to extreme base conditions. Enzyme was incubated for varying times at pH 12 or 13, and activities were measured under standard conditions (pH 4.5). The laccase–chitosan conjugate was fully stable at pH 12. Conjugation resulted in nearly a 3-fold reduction in the inactivation rate constant at pH 13 (k_{in} was 4.5 h^{-1} for free laccase and 1.6 h^{-1} for the laccase–chitosan conjugate).

dard conditions (pH 4.5). Figure 4 shows that exposure to pH 1 leads to a rapid loss of activity for free laccase, while the soluble laccase–chitosan conjugate loses activity more slowly. The first-order inactivation rate constants (k_{in}) for this extreme acid condition were estimated to be 85 and 3.6 h^{-1} for free and conjugated laccases, respectively. Figure 5 shows results for the alkaline extremes. At pH 12, the free enzyme was gradually inactivated ($k_{in} = 0.89 \text{ h}^{-1}$), while no inactivation could be detected for the insoluble laccase–chitosan conjugate. The protective effect of chitosan persisted even when the laccase–chitosan conjugate was incubated at pH 12 and 3 M NaCl (data not shown). At the extreme pH of 13, Figure 5 shows that the free laccase was inactivated more rapidly ($k_{in} = 4.5 \text{ h}^{-1}$) than the laccase–chitosan conjugate ($k_{in} = 1.6 \text{ h}^{-1}$).

Fungal laccases have relatively good pH stabilities (47) and the results in Figures 4 and 5 show that conjugation to chitosan improves stabilities under acidic and basic pH extremes. This stabilization was observed with both soluble (low pH) and insoluble (high pH) conjugate. D'Annibale et al. (44) also observed that laccases that had been immobilized onto insoluble chitosan supports were more stable to acidic conditions. The nature of this stabilization is not known although various investigators

Figure 6. Biocatalytic hydrogels created by glutaraldehyde cross-linking. Laccase-chitosan conjugate was mixed with non-conjugated chitosan (final laccase activity 0.5 units/mL and final chitosan concentration 1 w/w %) and cross-linked with varying levels of glutaraldehyde (a molar ratio of glutaraldehyde to glucosamine monomer of 0.5 corresponds to the use of 32 mM glutaraldehyde). The apparent Young's modulus was measured by a penetration method (46) while laccase activity was measured from dissolved oxygen consumption with catechol as the substrate.

have observed that sugars and sugar-based polymers can stabilize enzymes during lyophilization (23) and in non-aqueous environments (19, 20). Also, stabilization has been reported when enzymes are bound through multiple points (21, 22). Conceivably, the laccase may be covalently conjugated to chitosan at more than one "point". Also, since laccases have a large number of surface carboxylates (48), it is possible that electrostatic interactions with chitosan's amino groups could lead to multi-point, stabilizing interactions. Interestingly, when we "conjugated" laccase to glucosamine (the monomeric unit of chitosan), we observed no stabilization of laccase (data not shown).

Laccase-containing chitosan hydrogels were prepared by glutaraldehyde cross-linking. To prepare these hydrogels, laccase-chitosan conjugate was diluted with nonconjugated chitosan (final polymer concentration 1 w/w % and final laccase activity 0.5 units/mL), and varying levels of glutaraldehyde were added to these solutions (pH 4). Over the course of several hours, these solutions were observed to form gels. As expected, Figure 6 shows that the stiffness, or apparent Young's modulus, of the cross-linked chitosan gels increased with increasing glutaraldehyde levels. The enzymatic activities of glutaraldehyde-cross-linked chitosan hydrogels were measured by adding 100 μ L of gel to substrate solution (1 mL total volume) and measuring consumption of dissolved oxygen. Figure 6 shows that laccase activity was unaffected by cross-linking when less than 9 mM glutaraldehyde was used (<0.15 glutaraldehyde/glucosamine monomer molar ratio). At intermediate glutaraldehyde levels of 12–25 mM (0.2–0.4 molar ratio), Figure 6 shows that laccase activity decreased with increasing glutaraldehyde. At glutaraldehyde levels above 28 mM (>0.45 molar ratios) laccase activity was completely lost. The results in Figure 6 indicate that glutaraldehyde can be used to create laccase-containing chitosan hydrogels and the cross-linker level must be selected to balance the need to retain enzymatic activity with the desire to achieve a given gel strength. It should be noted that this compromise is not limited to conditions examined in Figure 6, as alternative chitosan concentrations and different cross-linkers could also be considered.

One additional characteristic of chitosan that must be considered, is that the amino groups may react with

electrophilic substrates or products. Chitosan's reactivity may limit its use in some applications, but it also provides additional opportunities. For instance, tyrosinase-containing chitosan gels can convert phenols into electrophilic quinones that react with the chitosan matrix (49). Because the substrate specificity of tyrosinase confers selectivity to the conversion and the quinone-chitosan reaction results in strong binding, tyrosinase and chitosan can be used to selectively remove phenolic contaminants from intermediate chemical process streams for industrial waste minimization (50–53).

In conclusion, chitosan is a versatile biopolymer that is obtained from renewable resources and is readily biodegraded in the environment. We report three useful features that result from conjugating enzymes to chitosan. First, the laccase-chitosan conjugate has pH responsive behavior such that the conjugate is soluble at pHs of maximal laccase activity, yet insoluble at neutral pHs. This pH-responsive behavior endows the conjugate with the mass transfer advantages of soluble enzymes, while allowing the enzyme to be readily recoverable, the characteristic benefit of immobilized enzymes. Second, conjugation to chitosan stabilized laccase to extreme pHs. This stabilization occurred with soluble (low pH) and precipitated (high pH) conjugate. Third, the enzyme-chitosan conjugate can be cross-linked under mild conditions to yield biocatalytic hydrogels. This result suggests the potential for cross-linking biocatalytic hydrogels in various shapes and sizes including beads, membranes, fibers, and monolith coatings.

ACKNOWLEDGMENT

Financial support for this research was provided by grants from Venture Innovations (as a subcontract to NSF Grant DMI-9901868), the Arthritis Foundation, and CONACYT for support of R.V.-D.'s sabbatical visit. The authors also appreciate technical assistance from Dr. Oleg Vesnovsky in the UMBC Laboratory for Implantable Materials.

Synthesis of Fluorogenic Substrates for Continuous Assay of Phosphatidylinositol-Specific Phospholipase C

Tatiana O. Zaikova,[†] Aleksey V. Rukavishnikov,[†] G. Bruce Birrell,[‡] O. Hayes Griffith,^{*,†,‡} and John F. W. Keana^{*,†}

Department of Chemistry and Institute of Molecular Biology, University of Oregon, Eugene, Oregon 97403. Received September 19, 2000; Revised Manuscript Received December 21, 2000

An improved synthesis of fluorogenic substrate analogues for phosphatidylinositol-specific phospholipase C (PI-PLC) is described. The water-soluble substrates, which are derived from fluorescein, are not fluorescent until cleaved by the enzyme, and provide a convenient means to continuously monitor PI-PLC activity. The improvement in the synthesis lies in the method used to protect the hydroxyl groups of the inositol portion of the substrate molecule and allows a milder deprotection procedure to be used. The result is a much more reproducible synthesis of the substrate. The improved procedure has been employed to synthesize a series of fluorogenic substrates, which differ in the length of the aliphatic tail attached to the fluorescein portion of the molecule. The length of the tail was found to have a significant effect on the rate of cleavage of these substrates.

INTRODUCTION

The phosphatidylinositol specific phospholipase C (PI-PLC) family of enzymes plays an important role in cellular signaling (1–4). These enzymes cleave phosphatidylinositol and its phosphorylated analogues, forming inositol phosphates and diacylglycerol, which can act as intracellular second messengers in eukaryotes, ultimately leading to a variety of cellular responses. Bacterial PI-PLCs are of interest as model systems for the mammalian signal transduction isozymes, as possible virulence factors, and for their ability to cleave glycosylphosphatidylinositol (GPI)-anchored proteins (5). PI-PLC activity is most often measured in a discontinuous assay using radiolabeled phospholipids as substrates, with the assays requiring the separation of product from uncleaved substrate before enzyme activities can be determined (6). The discontinuous nature of these assays has led to a search for water-soluble substrates for PI-PLC which would also allow continuous monitoring of PI-PLC activity (7). Being able to monitor assays continuously is especially advantageous when carrying out studies of enzyme kinetics (8).

We previously reported the synthesis of the first fluorescein-containing substrate for the continuous fluorescence assay of PI-PLC (9). This compound **1** (Scheme 1) is the only reported fluorogenic substrate that is cleaved by both the bacterial and mammalian forms of PI-PLC (10). Three specific properties make this compound especially attractive as a fluorogenic probe: (a) the high fluorescence quantum yield of fluorescein compounds, (b) the nonfluorescence of the substrate **1** itself, and (c) the relatively low pK_a (~4.8) of the fluorescent product **3**, ensuring that a high percentage of the product is deprotonated, and therefore fluorescent, at physiological pH.

The useful properties of probe **1** prompted us to investigate its closest analogues by varying the aliphatic tail attached to the fluorescein part of the molecule. The different substituents on the aromatic ring can have a significant impact on certain physicochemical characteristics of the substrate, e.g., lipophilicity and water solubility. The availability of a set of such probes would provide a better optimization of the particular substrate to a specific assay experiment. However, as indicated below, problems with reproducibility were encountered with the synthetic scheme previously described for compound **1**. In this paper, we describe a general procedure that overcomes these difficulties and permits the reproducible preparation of high quality fluorogenic substrates for assay of PI-PLC activity.

EXPERIMENTAL PROCEDURES

Reagents and General Procedures. Reagent-grade solvents were used without further purification unless otherwise noted. All reagents were purchased from Aldrich Chemical Co. and were used as received. ¹H NMR spectra were recorded on a Varian INOVA spectrometer at 300 MHz. Chemical shifts are in δ units (ppm) referenced to residual proton signals of the deuterated solvents. Coupling constants (J) are reported in hertz (Hz). NMR splitting patterns are designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; and br, broad. Column chromatography was carried out on Davisil silica gel (60–200 mesh). Analytical TLC was performed on Kieselgel 60 F₂₅₄, and spots were rendered visible by exposing the plate to UV light. Radial chromatography (RC) was performed on a Chromatotron 7924T using 1, 2, and 4 mm disks covered with silica gel 60PF₂₅₄ containing gypsum. High-resolution FAB mass spectrometry was performed by Dr. Brian Arbogast (mass spectroscopy facility, Oregon State University) on a Kratos MS-50TC mass spectrometer (Manchester, England). Elemental analyses were obtained from Robertson Microlit Laboratories, Madison, NJ.

Scheme 1

methanol (200 mL) was added fluorescein **11** (8.30 g, 25.0 mmol). The mixture was stirred for 30 min or until all of the fluorescein dissolved. The resulting solution was evaporated and the residue was dried in a vacuum to give the disodium salt of fluorescein (9.40 g, quantitative). It was powdered and used for the alkylation step. In a typical experiment, the disodium salt **12** (9.40 g, 25.0 mmol) was suspended in DMF (200 mL) containing the alkyl bromide or iodide (200 mmol). The reaction mixture was stirred at RT (for methyl iodide) or at a higher temperature that did not exceed the boiling temperature of the alkyl bromide used. After stirring for 48–60 h the mixture was diluted with 5% NaHCO_3 (200 mL) and extracted with ether (2×100 mL). The combined extracts were washed with brine (50 mL), dried over Na_2SO_4 , and evaporated to give the corresponding ester-ether **13** as a brown oil. This substance was dissolved in methanol (150 mL) and mixed with a 2 M aqueous solution of NaOH (50 mL). The resulting mixture was stirred for 2 h at RT, concentrated under vacuum and diluted with water (80 mL). Impurities were extracted with ether (2×50 mL), and then the aqueous phase was acidified with concentrated HCl to pH about 2. The mixture was extracted with ether (3×80 mL), and the combined extracts were washed with brine (50 mL), dried over Na_2SO_4 , and evaporated to give the crude alkylation product **14** which was finally purified by chromatography on silica gel using a gradient of ether in hexanes (from 1:1 to 3:1). Evaporation of appropriate fractions gave the alkylation product **14** (50–60% yield) which was pure by TLC and NMR.

14a, ^1H NMR (CDCl_3) δ 3.83 (s, 3H), 6.54–6.79 (m, 6H), 7.16 (d, $J = 7.2$, 1H), 7.59–7.69 (m, 2H), 8.01 (d, $J = 7.5$, 1H). **14b**, ^1H NMR (CDCl_3) δ 1.05 (t, $J = 7.5$, 3H), 1.84 (sextet, $J = 6.9$, 2H), 3.98 (t, $J = 6.6$, 2H), 6.60–6.95 (m, 6H), 7.17 (d, $J = 6.6$, 1H), 7.60–7.70 (m, 2H), 8.07 (d, $J = 7.2$, 1H). **14c**, ^1H NMR (CDCl_3) δ 0.98 (t, $J = 7.2$, 3H), 1.46 (sextet, $J = 7.2$, 2H), 1.78 (m, 2H), 3.99 (t, $J = 6.3$, 2H), 6.50–6.70 (m, 5H), 6.79 (dd, $J = 2.4$, 11.7, 1H), 7.16 (d, $J = 6.9$, 1H), 7.25–7.70 (m, 2H), 8.03 (d, $J = 6.6$, 1H). **14d**, ^1H NMR (CDCl_3) δ 0.91 (t, $J = 6.6$, 3H), 1.32 (m, 6H), 1.77 (m, 2H), 3.96 (t, $J = 6.7$, 2H), 6.68–6.72 (m, 2H), 6.76–6.72 (m, 2H), 7.16 (d, $J = 7.2$, 1H), 7.66 (m, 2H), 8.02 (d, $J = 6.9$, 1H).

2. Phosphate Triesters, 17a–d. General Procedure. To a suspension of alkylated fluorescein **14** (1.75 mol) in methylene chloride (10 mL) was added diisopropylethylamine (2.60 mmol) followed by addition of *N,N*-diisopropylmethylphosphonamidic chloride (2.60 mmol). The reaction mixture was stirred for 20 min at RT, diluted with ether (50 mL), washed with 5% NaHCO_3 (10 mL), brine (10 mL), dried over Na_2SO_4 , and evaporated to dryness. The residue was chromatographed on a short silica gel column with 50:50:1 ether-hexanes- Et_3N mixture. The appropriate fractions were combined and evaporated, and the residue was reevaporated twice from toluene to give the corresponding phosphorimidite **15** as a clear oil. This was dissolved in methylene chloride (20

mL) and racemic pentaprotected inositol **16** [0.300 g, 0.930 mmol, prepared as described (11)] was added to the above solution followed by the addition of tetrazole (0.190 g, 2.70 mmol) dissolved in acetonitrile (5 mL, needs warming to dissolve). The reaction mixture was stirred for 3 h at RT, then a 3 M solution of *tert*-butyl hydroperoxide in isooctane (0.7 mL, 2.1 mmol) was added to the solution, and the mixture was stirred for 1 h. Then it was diluted with methylene chloride (25 mL) and washed with 5% NaHCO_3 (15 mL). The solution was dried over anhydrous MgSO_4 and evaporated to give the crude phosphate **17** which was purified on silica gel twice; first with hexanes–ether mixture (from 4:1 to pure ether) then with a methylene chloride–ethyl acetate mixture (from 50:1 to 50:4). The corresponding phosphate **17** was a yellow foam, which was pure by TLC and NMR.

17a, 60%, ^1H NMR (CDCl_3 –py- d_5 50:1) δ 1.10–1.60 (m, 18H), 3.22–3.40 (m, 1H), 3.42–3.60 (m, 1H), 3.60–3.78 (m, 1H), 3.75–3.90 (m, 6H), 4.00–4.18 (m, 1H), 4.40–5.05 (m, 5H), 6.45–6.80 (m, 4H), 6.83–7.00 (m, 1H), 7.10–7.20 (m, 1H), 7.58–7.70 (m, 2H), 7.99 (m, 1H). **17b**, 56%, ^1H NMR (CDCl_3 –py- d_5 50:1) δ 0.80–1.45 (m, 21H), 1.70 (sextet, $J = 7.5$, 2H), 3.20–4.00 (m, 11H), 4.37 (brs, 1H), 4.72 (brs, 1H), 4.87 (m, 1H), 6.30–6.60 (m, 5H), 6.79 (brs, 1H), 6.98 (brs, 1H), 7.45–7.60 (m, 2H), 7.90 (d, $J = 6.9$, 1H). **17c**, 45%, ^1H NMR (CDCl_3 –py- d_5 50:1) δ 0.96 (t, $J = 7.5$, 3H), 1.15–1.60 (m, 20H), 1.70–1.82 (m, 2H), 3.29–3.40 (m, 1H), 3.50–3.60 (m, 1H), 3.65–3.75 (m, 1H), 3.80–4.15 (m, 8H), 4.45–4.65 (m, 1H), 4.75–4.85 (m, 1H), 4.95–5.05 (m, 1H), 6.50–6.75 (m, 4H), 6.85–6.98 (m, 1H), 7.10–7.15 (m, 1H), 7.25–7.36 (m, 1H), 7.55–7.70 (m, 2H), 8.01 (d, $J = 6.6$, 1H). **17d**, 69%, ^1H NMR (CDCl_3 –py- d_5 50:1) δ 0.88 (t, $J = 6.9$, 3H), 1.10–1.60 (m, 24H), 1.76 (quintet, $J = 8.4$, 2H), 3.29–3.40 (m, 1H), 3.45–3.60 (m, 1H), 3.65–3.75 (m, 1H), 3.85–3.98 (m, 5H), 4.00–4.13 (m, 3H), 4.44–4.62 (m, 1H), 4.50–4.82 (m, 1H), 4.94–5.04 (m, 1H), 6.56–6.74 (m, 4H), 6.85–6.96 (m, 1H), 7.08–7.14 (m, 1H), 7.30–7.35 (m, 1H), 7.56–7.68 (m, 2H), 8.00 (d, $J = 6.6$, 1H).

3. Phosphate Diesters, 18a–d. General Procedure. To a solution of phosphate **17** (0.260 mmol) in acetone (5 mL) was added LiI (0.035 g, 0.26 mmol). The resulting mixture was stirred at reflux for 1 h. After that, the acetone was evaporated and the residue was chromatographed using a Chromatotron (2 mm silica gel disk). The product was eluted with a methylene chloride–methanol mixture (from 50:1 to 50:10). The eluate was evaporated to give the appropriate phosphate diester **18** as a viscous oil, which was pure by TLC and NMR.

18a, 89%, ^1H NMR (CDCl_3 –py- d_5 50:1) δ 0.80–1.60 (m, 18H), 3.20–4.30 (m, 9H), 4.49 (brs, 1H), 4.81 (brs, 1H), 4.92 (brs, 1H), 6.30–6.65 (m, 3H), 6.87 (brs, 1H), 7.03 (brs, 1H), 7.26 (brs, 2H), 7.50–7.70 (m, 2H), 7.96 (d, $J = 6.0$, 1H). **18b**, 85%, ^1H NMR (CDCl_3 –py- d_5 50:1) δ 0.93 (t, $J = 7.5$, 3H), 1.00–1.50 (m, 18H), 1.71 (m, 2H), 3.30 (brs, 1H), 3.50 (m, 1H), 3.62 (t, $J = 7.8$, 1H), 3.77 (m, 1H), 3.91 (m, 4H), 4.40 (brs, 1H), 4.75 (brs, 1H), 4.91 (m,

1H), 6.40–6.65 (m, 5H), 6.87 (brs, 1H), 7.02 (brs, 1H), 7.56 (m, 2H), 7.94 (d, $J = 6.3$, 1H). **18c**, 96%, ^1H NMR (CDCl_3 -py- d_5 50:1) δ 0.94 (t, $J = 7.3$, 3H), 1.00–1.60 (m, 20H), 1.75 (m, 2H), 3.20–4.00 (m, 8H), 4.30 (brs, 1H), 4.75 (brs, 1H), 4.95 (brs, 1H), 6.40–6.60 (m, 4H), 6.88 (brs, 1H), 7.02 (brs, 1H), 7.22 (m, 1H), 7.56 (m, 2H), 7.94 (d, $J = 6.3$, 1H). **18d**, 98%, ^1H NMR (CDCl_3 -py- d_5 50:1) δ 0.88 (t, $J = 6.3$, 3H), 0.90–1.50 (m, 24 H), 1.74 (quintet, $J = 7.5$, 2H), 3.30–4.00 (m, 8H), 4.45 (brs, 1H), 4.80 (brs, 1H), 4.93 (brs, 1H), 6.30–6.70 (m, 4H), 6.85 (brs, 1H), 7.02 (brs, 1H), 7.20 (brs, 1H), 7.57 (brs, 1H), 7.95 (brs, 1H).

4. *Deprotected Phosphate Diesters, 19a–c and 1. General Procedure.* Phosphate **18** (268 mmol) was suspended in the mixture of 8 mL of water and 2 mL of acetic acid. The reaction mixture was stirred for 16 h at RT and then extracted with ether (3×20 mL). The aqueous solution was diluted with ethanol and evaporated to dryness (bath temperature did not exceed 40 °C). The residue was re-evaporated from ethanol to remove acetic acid and dissolved in water (about 1 mL). Then ethanol (30 mL) was added to the solution and the resulting solid was filtered. The solid was washed subsequently with ethanol and ether and then it was dried in a vacuum to give the desired phosphate as a white powder, pure by NMR.

19a, 60%, ^1H NMR ($\text{CD}_3\text{OD}-\text{D}_2\text{O}$ 10:1) δ 3.28 (t, $J = 9.3$, 1H), 3.46 (dd, $J = 2.7$, 9.0, 1H), 3.65 (t, $J = 9.3$, 1H), 3.80 (t, $J = 9.9$, 1H), 4.08 (dt, $J = 3.0$, 8.4, 1H), 4.23 (t, $J = 2.7$, 1H), 6.60–6.75 (m, 3H), 6.92 (d, $J = 2.1$, 1H), 7.01 (d, $J = 8.7$, 1H), 7.19 (d, $J = 7.6$, 1H), 7.30 (s, 1H), 7.70–7.90 (m, 2H), 8.05 (d, $J = 7.2$, 1H). 5. *Acid, 9.* Phosphate diester **5** [10 mg, prepared by the earlier method (9)] was dissolved in 1 mL of water and the resulting solution was mixed with 875 mL of 0.0286 M aqueous NaOH. The solution was kept for 2 h

at RT and then acidified with 2 M HCl to pH about 2. The mixture was extracted with ether (2×50 mL), the combined extracts were washed with brine (20 mL), dried over Na_2SO_4 and evaporated. The residue was purified using a Chromatotron (1 mm silica gel disk). The product was eluted with 1:1 hexanes–ether mixture. Evaporation of the eluate gave 2 mg of acid **9** as clear viscous oil, pure by TLC and NMR. ^1H NMR (CDCl_3) δ 0.90 (s, 3H), 1.20–1.50 (m, 6H), 1.76 (quintet, $J = 7.2$, 2H), 3.92 (t, $J = 7.2$, 2H), 6.36 (s, 1H), 6.44 (dd, $J = 2.7$, 8.7, 1H), 6.51 (dd, $J = 2.4$, 8.4, 1H), 6.60–6.63 (m, 2H), 6.89 (d, $J = 8.4$, 1H), 6.94 (d, $J = 9.0$, 1H), 7.11 (d, $J = 7.5$, 1H), 7.18 (t, $J = 6.9$, 1H), 7.32 (t, $J = 8.1$, 1H), 7.92 (dd, $J = 1.2$, 7.8, 1H). HRMS (EI) calcd for $\text{C}_{26}\text{H}_{26}\text{O}_5$: 418.17802. Found: 418.17795 (M^+). Enzymatic hydrolysis of **5** was accomplished as described below for PI-PLC assay. The aqueous phase after hydrolysis was extracted with ether (2×10 mL) and the combined extract was washed with brine (10 mL), dried over Na_2SO_4 and concentrated in a vacuum. The extracted product was identical by TLC with the product obtained after hydrolysis of **5** with sodium hydroxide.

PI-PLC Assays. Stock solutions of substrate (~ 2 mg/mL) were prepared in deionized water, and accurate concentrations were determined by phosphate assay (12). A stock solution containing 0.5 nM PI-PLC (13) from *Bacillus cereus* was prepared in 6 mM HEPES, 0.06 mM EDTA, pH 7.0 [containing 0.1% poly(ethylene glycol) (PEG, average molecular weight 8000)]. Enzyme assays were carried out in 100 mM HEPES, 1 mM EDTA, pH 7.0 (containing 0.008% PEG) in a total volume of 0.8 mL in polymethacrylate cuvettes at 26 °C. Fluorescence measurements were made using a Hitachi F-4500 fluorescence spectrometer equipped with a yellow filter to reduce scatter from the excitation peak. Excitation was at 465 nm, emission was measured at 520 nm, and excitation and emission slits were set at 10 nm. After addition of enzyme, the fluorescence emission was recorded for 3 min in time scan mode. The change in fluorescence over the 3 min period was then converted to activity units ($\mu\text{mol product/min/mg enzyme}$) using a calibration curve of fluorescence vs concentration of product (produced by NaOH-induced cleavage of the substrate) and the concentration of enzyme used in the assay.

RESULTS

The search for an alternative synthetic route for compound **1** was stimulated by the fact that some of the subsequent batches prepared by the published procedure exhibited 2–5-fold lower rates of production of fluorescence by PI-PLC. To investigate this phenomenon, a larger (100 mg) batch of substrate was prepared using the published protocol. Surprisingly, this larger batch did not show any rise of fluorescence characteristic of substrate **1** after exposure to PI-PLC under standard conditions. The NMR spectrum of the desired compound **1** differs from the NMR spectra of this freshly made batch of product in the aromatic region, and indicates that concomitant hydrogenolysis of the lactone ring took place during the hydrogenolysis reaction used to remove the benzyl groups in **4** (Scheme 2). The HRMS (FAB) spectra of the resulting reduced compound shows a peak at m/e 659.18979 ($[\text{M} - \text{H}]^-$, calcd for $\text{C}_{32}\text{H}_{36}\text{O}_{13}\text{P}$, 659.18936) which corresponds to the opened ring form **5**. By comparison, the presumptive oxidized compound gives a peak 657.17368 ($[\text{M} - \text{H}]^-$, calcd for $\text{C}_{32}\text{H}_{34}\text{O}_{13}\text{P}$, 657.17370) corresponding to the lactone form **1**.

Scheme 2

Scheme 3

Scheme 4

A search of the literature revealed that hydrogenolysis of fluorescein 3,6-bis(dibenzyl phosphate) **6** can produce either ring-opened product **7** or fluorescein biphosphate **8** by using different hydrogenation conditions (Scheme 3). Hydrogenolysis at -5°C at atmosphere pressure in the presence of palladium on carbon gives mostly fluorescein biphosphate **8**. At temperatures higher than 5°C the spiro lactone ring underwent hydrogenolysis to give the reduced acid **7** (14).

Further experiments showed that keeping the diluted solution of compound **5** at room temperature in the presence of room light resulted in spontaneous conversion to substrate **1** (Scheme 2), which did produce a fluorescent product **3** when exposed to *B. cereus* PI-PLC (Scheme 1). Cleavage of **5** with either PI-PLC or sodium hydroxide produced the nonfluorescent reduced fluorescein derivative **9** (Scheme 4).

We did not explore the mechanism of oxidation of nonfluorogenic compound **5** to fluorogenic substrate **1**. It is possible that a photooxidation reaction is responsible for the conversion of **5** to **1**. An example of a similar transformation is the known process of photooxidation

Scheme 5

of leuco-fluorescein **10** which gives fluorescein **11**, as shown in the Scheme 5 (15).

To avoid the problematic hydrogenolysis step, we developed an improved synthesis of fluorogenic substrates **1** and **19a–c** (Scheme 6).

This scheme makes use of pentaprotected inositol derivative **16** which was previously utilized for the improved synthesis of the chromogenic substrate 4-nitrophenyl *myo*-inositol-1-phosphate (NPIP) (**11**). Easily hydrolyzable protective groups in **16** facilitate the final acid-mediated deprotection. The fluorescein-derived phosphorimidites **15a–d** were prepared from fluorescein **11**

Scheme 6

as described earlier (9). Different substituents on the aromatic ring were introduced by varying the alkylating agent reacting with fluorescein disodium salt **12**. The resulting ester-ether intermediates **13a-d** were hydrolyzed to provide alkyl substituted fluoresceins **14a-d**. Reaction of the alkylated fluorescein intermediates with MeOPCINⁱPr₂ gave **15a-d**. Protected inositol intermediate **16** was coupled with fluorescein-derived phosphorimidites **15a-d** to form, after oxidation, protected phosphates **17a-d**. Demethylation of the phosphate triester was accomplished using lithium iodide in acetone in place of trimethylsilyl bromide, which was used in our earlier synthesis (9). This change resulted in an increase in the yield of demethylated compound **18** from ~65 to ~95%. Finally, all inositol-protecting groups were removed at once using aqueous acetic acid. The resulting fluorogenic substrates were purified by precipitation with ethanol from aqueous solution followed by washing of the precipitates with ether and drying under vacuum.

The final products **1** and **19a-c** are likely mixtures of two racemic diastereomers because of the racemic nature

of the inositol moiety and the chirality center in the fluorescein moiety. The latter is not expected to have a significant effect on the enzyme-catalyzed hydrolysis reaction given that a wide variety of hydrophobic residues have been attached to D-*myo*-inositol and shown to be enzyme substrates (7). In the present case, the fluorescein moiety and the attached alkyl groups serve as the hydrophobic segment of the substrate. In previous studies of chromogenic substrates (i.e., NPIP) for PI-PLC, we found that racemic phosphoinositols posed no difficulties. One enantiomer (D-NPIP) was a substrate while the other enantiomer (L-NPIP) was neither a substrate nor an inhibitor (16). Other studies demonstrate that PI-PLC cleaves only the D-enantiomer of *myo*-inositol phosphate esters (17, 18). Thus, **1** and **19a-c** should be adequate for most enzymatic and cell biological studies.

Fluorogenic substrates **19a-c** readily dissolved in water. Substrate **1** dissolves in water with some difficulty, due to the longer hydrophobic tail. All of these solutions exhibited only very low levels of fluorescence, which was due to the small quantity of fluorescent

Figure 1. (A) Change in fluorescence emission intensity for the cleavage of 50 μM substrate **1** as a function of time. The numbers on the right indicate the amount of PI-PLC added. (B) Correlation between the initial rates and enzyme concentration. The initial rates were obtained from the slopes of the curves in Figure 1A and a calibration plot of fluorescence vs concentration of product. Assays were carried out at 26 $^{\circ}\text{C}$ in 100 mM HEPES, 1 mM EDTA, pH 7.0 [containing 0.008% poly(ethylene glycol) 8000]. Excitation was at 465 nm and emission (in arbitrary units) was measured at 520 nm.

product (e.g., **3**; <0.1% of the total substrate) present in each preparation of substrate. At ambient temperature and pH 7, this background fluorescence exhibited essentially no change over the course of the 3-min period in which activity data were recorded. On addition of *B. cereus* PI-PLC to solutions of each of the fluorogenic substrates, a rapid increase in fluorescence was observed, as shown in Figure 1 for substrate **1**. The slopes of the fluorescence vs time curves (Figure 1A) were dependent upon both the concentration of the enzyme and that of the substrate. The activity was linear with enzyme concentration (Figure 1B). The increase in fluorescence was also dependent upon the length of the aliphatic tail attached to the fluorescein part of the molecule with the substrate molecules having the shortest tails being cleaved less readily than those with longer tails. The specific activities for the cleavage of the fluorogenic substrates **1** and **19a–c** determined at an enzyme concentration of 6 pM and substrate concentrations of 500 μM are shown in Table 1. The data in Table 1 were obtained using duplicate samples, i.e., one set of data was taken with the four substrates on each of two different days. Both runs used the same batches of the various substrates and a fresh stock of diluted enzyme. Larger differences (10–20%) were observed when different batches of the same substrate were compared. Part of the variation is due to the difficulty in reproducibly pipetting the very small amounts (2 μL) of enzyme from the 50% glycerol solution in which it was stored (at -20

Table 1. Cleavage of Fluorogenic Substrates by *B. cereus* PI-PLC^a

fluorogenic substrate	acronym	no. of carbon atoms in side chain	specific activity ($\mu\text{mol min}^{-1} \text{mg}^{-1}$)
19a	methyl FLIP	1	27 $\pm$ 3
19b	propyl FLIP	3	86 $\pm$ 2
19c	butyl FLIP	4	122 $\pm$ 4
1	hexyl FLIP	6	110 $\pm$ 4

^a Determined using 500 μM substrate at 26 $^{\circ}\text{C}$ in 100 mM HEPES, 1 mM EDTA, pH 7.0 (containing 0.008% PEG 8000).

$^{\circ}\text{C}$ to preserve activity). In the biochemical literature, it is common practice to use acronyms for chromogenic and fluorogenic substrates. For this purpose, we suggest the name FLIP (fluorescein *myo*-inositol phosphate) for this series of substrates by analogy with NPIP for the chromogenic 4-nitrophenyl *myo*-inositol-1-phosphate. For example, compound **1** is hexyl FLIP.

DISCUSSION

Because of the high sensitivity potentially obtainable using fluorescence (approaching that of radiometry), a number of earlier attempts have been made to prepare fluorogenic substrates for assaying PI-PLC activity. A pyrene derivative, 4-(1-pyrenyl)butylphosphoryl-1-*myo*-inositol, which is cleaved by bacterial PI-PLC, was reported in 1991 (19). However, since the fluorescent properties of both this substrate and its product are similar, it was necessary to separate them by either HPLC or TLC before any analysis could be carried out, resulting in a discontinuous assay (20). In contrast, a continuous assay can be carried out much more rapidly and has the added advantage that the time course of the reaction can be observed directly. Any deviation from linearity can therefore be detected immediately. The first reported fluorogenic substrate for continuous assay of bacterial PI-PLC activity was 2-naphthyl *myo*-inositol-1-phosphate, which is cleaved by the enzyme to form 2-naphthol, which is fluorescent, and inositol phosphates (21). In this case, the fluorescent properties of the substrate and product were sufficiently different that no separation step was required. However, the pH at which maximal fluorescence of 2-naphthol occurs is 10.5, making it necessary to carry out the assay at a pH which is not optimal for the activity of the enzyme (maximal activity occurs around pH 6.5). The result was a very low turnover of substrate by the enzyme in the pH range suitable for fluorescence measurement of product (21). A coumarin-derived fluorogenic substrate for bacterial PI-PLC, 4-methylumbelliferyl-*myo*-inositol-1-phosphate, was recently reported to be useful for detection of bacterial PI-PLC activity (22). This substrate has been only partially characterized, although it should not be fluorescent until hydrolysis occurs. However, like 2-naphthol, phenolic dyes such as β -methylumbelliferone (the product formed by the cleavage of the fluorogenic substrate) have high pK_a values (~ 7.8) and are not fully deprotonated and thus not fully fluorescent if the pH is below 10 (23). Because of this, methylumbelliferyl-based substrates have not been widely used for enzyme assays which are carried out under physiological conditions (23). In contrast, due to the lower pK_a (~ 4.8), the new series of FLIP substrates **1** and **19a–c** provide significantly greater sensitivity in PI-PLC assays carried out under physiological conditions than those derived from β -naphthol and coumarin, and at the present time offer the best prospects for continuous fluorescence assays of PI-PLC activity. The present investigation identified the source

of the high variability in apparent activity as being due to the presence of the nonfluorescent reduced derivative **5** with the desired substrate **1**. The improved synthetic procedure described here solves this problem, yielding pure fluorogenic substrates. A series of substrates prepared with the new procedure show that the specific activity is strongly affected by the length of the hydrocarbon tail, with butyl FLIP and hexyl FLIP exhibiting substantially greater activities than the shorter methyl and propyl derivatives.

ACKNOWLEDGMENT

We thank our colleague Margret Ryan for helpful advice and for preparation of the high purity PI-PLC used in this study. We are also indebted to Dr. Iain D. Johnson at Molecular Probes for useful discussions. We gratefully acknowledge NIH Grants GM 27137 and GM 25698 from the National Institute of General Medical Sciences for financial support.

Mechanistic Investigation of Smart Polymer–Protein Conjugates

Tsuyoshi Shimoboji, Zhongli Ding, Patrick S. Stayton,* and Allan S. Hoffman*

Department of Bioengineering, University of Washington, Seattle, Washington 98195.

Received September 25, 2000; Revised Manuscript Received November 8, 2000

Many affinity separation and diagnostic applications rely upon both capture and release steps. There is thus a need for methods to enhance the reversibility of biomolecular interactions. We have previously demonstrated that stimuli-responsive polymers can be used to gate biomolecular reactions when conjugated near the active site of proteins. Here we have used a new smart polymer, *N,N*-dimethyl acrylamide-*co*-4-phenylazophenylacrylate that has allowed a mechanistic investigation of the smart polymer switches. This polymer was conjugated via a vinyl sulfone terminus to cysteine residues of genetically engineered streptavidin mutant E116C, where the polymer is conjugated close to the biotin-binding site, and streptavidin mutant S139C, where the conjugation site is distant. The biotin binding switching activity was strongly dependent on conjugation position, as the E116C conjugate displayed a large thermal response while the S139C conjugate displayed only small effects. Kinetic measurements of biotin release demonstrated that the off-rate of biotin was unperturbed and that the thermally triggered release of biotin with the E116C conjugate was due to the blocking the reassociation of biotin. The addition of free polymer to purified E116C conjugates was also shown to increase the blocking and release properties of the switch. This effect was site dependent, suggesting that the conjugated polymers were directing a physical aggregation near the binding site that effectively enhanced the switching activity. These investigations provide mechanistic insight that can be utilized to design better molecular switches for a variety of stimuli-responsive polymer–protein conjugates.

INTRODUCTION

Capture and release steps are involved in many affinity separation and diagnostic applications, and the reversibility of affinity interactions is thus an important underlying aspect of these technologies. Reversibility is intrinsically problematic, however, because the capture step typically requires high binding energy and specificity. This often makes it necessary to use relatively harsh conditions for release that can damage delicate biological components or targets. A striking example of these conflicting needs is found with streptavidin, one of the most utilized affinity reagents. Streptavidin (SA)¹ displays a remarkably high affinity for the ligand biotin, and this interaction is utilized in a wide variety of biological, clinical, and diagnostic applications (1, 2). The high affinity is also a major limitation, however, for applications where the recovery of the biotinylated molecules are desirable.

Many strategies for reversibly manipulating biomolecular recognition have been devised, but there is still a clear need for improvement. We have been developing a new approach that utilizes site-specific conjugation of

stimuli-responsive polymers near the protein-binding site. These stimuli-responsive polymers undergo a large change in size and physical properties in response to external stimuli such as temperature, pH, or specific wavelengths of light. We have previously demonstrated that the change in physical properties can be used as a temperature- or pH-dependent activity switch to control ligand capture and release (3–5). We report here an investigation into the mechanism of these smart polymer–protein conjugates that utilizes the new end-reactive polymer *N,N*-dimethyl acrylamide-*co*-4-phenylazophenylacrylate (DMAA). The use of this polymer and a control streptavidin mutant has allowed a determination of the role of conjugation site and free polymer, along with the mechanism of biotin release.

EXPERIMENTAL PROCEDURES

Materials. 4-Hydroxyazobenzene (Aldrich, Milwaukee, WI) was recrystallized from ethanol and water, and dried in vacuo. *N,N*-Dimethyl acrylamide (DMA) (Fluka, Milwaukee, WI), diethyl ether, acryloyl chloride, triethylamine, and 2-mercaptoethanol (MEO) (Aldrich, Milwaukee, WI) were purified by distillation under reduced pressure. 2,2'-azoisobutyronitrile (AIBN) (J. T. Baker, Phillipsburg, NJ) was recrystallized from methanol. Ethanol, dimethylformamide (DMF), tetrahydrofuran (THF), methylene chloride, potassium *tert*-butoxide, divinyl sulfone (DVS), 5,5'-thiobis (2-nitrobenzoic acid) (DTNB), ethylenediamine tetraacetic acid (EDTA) (Aldrich, Milwaukee, WI), tris(2-carboxy ethyl)-phosphine hydrochloride (TCEP-HCl) (Pierce, Rockford, IL), iminobiotin beads, cysteine hydrochloride (Pierce, Rockford, IL), Microcon-30, Centrprep-10 (Millipore, Bedford, MA), and [³H]biotin (d-[8,9-³H(N)]biotin, Dupont, Wilmington, DE) were used as received. All other reagents were of

analytical grade. Restriction enzymes (*MscI*, *MluI*, and *HindIII*) and T4 DNA Ligase were purchased from New England Biolabs (Beverly, MA). Qiaex II kit for extracting DNA was purchased from Qiagen (Santa Clarita, CA). pET21a vector was obtained from Novagen (Madison, WI).

Azobenzene Monomer Synthesis. We synthesized an azobenzene-containing monomer, 4-phenylazobenzyl acrylate (AZAA). 4-Hydroxyazobenzene (0.2 mol) and triethylamine (0.26 mol) were dissolved in diethyl ether (200 mL). Acryloyl chloride (0.24 mol) dissolved in 80 mL of diethyl ether was added dropwise at 0 °C under nitrogen atmosphere with stirring. The reaction mixture was allowed to come to room temperature and stirred for 4 h. The reaction solution was filtered to remove triethylammonium chloride, washed with water and evaporated. The product was recrystallized from ethanol–water mixture and dried in vacuo. The structures were confirmed by ^1H NMR (d-DMSO). AZAAm: δ 5.7–6.7 (m, 3H), 7.4–7.8 (m, 5H), 7.8–8.2 (m, 4H). AZAA: δ 6.1–6.7 (m, 3H), 7.3–7.7 (m, 5H), 7.8–8.2 (m, 4H).

Temperature Responsive Polymer Preparation. We synthesized a temperature responsive polymer with hydroxyl termini, DMAA (DMA-*co*-AZAA copolymer), by free-radical polymerization in DMF at 60 °C for 20 h, using MEO as a chain transfer reagent and AIBN as an initiator (monomer concentration = 2 mol/L, monomer/MEO/AIBN = 100/1/0.2 molar ratio) (Figure 1). The feed ratios of AZAA was 4.0 mol %. The product was purified by precipitation into diethyl ether three times and dried in vacuo.

The content of AZAA incorporated in the copolymers was determined by ^1H NMR (Spectrospin and Bruker, dpx200), comparing the ratio of aromatic and aliphatic hydrogens. The molecular weight (MW) of the polymer was determined by gel permeation chromatography

(GPC, Water, Styragel HR3 and 4) in THF, using polystyrene as standards.

The hydroxyl terminus of DMAA was converted to a vinyl sulfone (VS) group for conjugation to the protein SH sites (Figure 1). DMAA was dissolved in 20 mL of methylenechloride with 0.03 g of potassium *tert*-butoxide, and 100 μL of divinyl sulfone (DVS) (DVS/OH = 10/1 molar ratio). The solution was stirred for 12 h at room temperature under nitrogen atmosphere. The polymer was precipitated and then washed in diethyl ether and dried in vacuo.

The amount of active VS in VS-terminated DMAA (DMAA-VS) was determined by the reaction with cysteine. Since cysteine was detected colorimetrically by the reaction with 5,5'-thiobis (2-nitrobenzoic acid) (DTNB), the amount of VS was calculated by the consumed cysteine in the solution. Briefly, 0.2 mL of polymer solution (10 mg/mL in 0.1 M PB, pH 8.0) was mixed with 2 mL of cysteine solution (1.5 mM cysteine hydrochloride in 0.1 M PB, pH 8.0, with 10 mM EDTA), and reacted for 4 h. A total of 0.2 mL of the solution was mixed with DTNB solution (0.2 mg of DTNB in 2 mL of 0.1 M PB, pH 8.0) and incubated for 15 min. Then, the absorbance at 412 nm was measured to calculate the amount of cysteine reacted with DTNB.

The LCST of the polymer was determined as the temperature at 10% of the maximum absorbance at 600 nm. The polymer concentration was 2 mg/mL in double-distilled water or 100 mM phosphate buffer (PB) pH 7.4.

Genetic Engineering of Streptavidin. The streptavidin mutant E116C and S139C were constructed by site-directed, cassette mutagenesis, using a synthetic "core" streptavidin gene previously designed and constructed for protein expression in *Escherichia coli* (5). The construction and characterization of the E116C (5) and S139A (6) have been previously described. Analysis of the

streptavidin mutants to confirm the correct production included SDS-PAGE, mass spectrometry, and biotin binding studies.

Conjugation of Polymer to Protein. Conjugation between streptavidin (E116C, S139C) and the polymer (DMAA-VS) was carried out in 100 mM sodium tetraborate buffer, pH 8.0, containing 50 mM sodium chloride and 5 mM EDTA. Cysteine residues in E116C or S139C form disulfide bonds during storage. To reduce disulfide bonds to sulfhydryl groups, TCEP at 50-fold molar excess to the mutants was added into the solution, which was then rotated at room temperature for 20 min. Then, DMAA-VS was added in 50-fold molar excess to the mutants to obtain high conjugation efficiency, and reacted for 1 h at room temperature, followed by the reaction for 24 h at 4 °C. The conjugates were separated from the unconjugated mutants by thermally induced precipitation, i.e., centrifuging the mixture at 15 000 rpm (31000*g*) for 15 min at 50 °C with 4 wt % ammonium sulfate to enhance the precipitation. The unconjugated mutants were retained in the supernatant. The thermal-induced precipitation was repeated three times.

Further purification was carried out by using an iminobiotin column to investigate the biotin-binding properties of the isolated conjugates from free polymers. Iminobiotin has been used for purifying streptavidin and avidin widely owing to its reversible binding to these proteins at different pHs. The conjugates were bound to iminobiotin on the beads in the binding buffer (50 mM sodium carbonate, 500 mM sodium chloride, pH 11) at room temperature, and the free polymers were washed off by the same buffer. Then, the bound conjugates were eluted in the elution buffer (100 mM acetic acid, pH 2.6) at room temperature. The purified conjugates were condensed by a Centriprep-10 (MW cut off: 10 000) to 30–300 µg/mL.

Biotin-Binding Assay. [³H]Biotin was employed to quantitate biotin binding. A total of 10 µg of the conjugate was suspended in 0.9 mL of 100 mM of sodium phosphate buffer, pH 7.4, containing 50 mM of sodium chloride and 5 mM of EDTA. A mixture of [³H]biotin and unlabeled biotin (1% of [³H]biotin) was added to the conjugate solution (total volume was 1 mL) after incubation at 52 °C for 1 h. The ratio of total biotin/biotin binding sites was 1.5 (molar ratio). The solution was incubated at a certain temperature, and a 100 µL aliquot was taken at the end of each incubation. The unbound biotin was separated from the bound biotin by ultrafiltration of the aliquot using a Microcon-30 (MW cutoff: 30 000) at the incubation temperature of the solution. A 30 µL aliquot of the filtrate that contained unbound biotin was counted in a β-counter (LS7000 Liquid scintillation system, Beckman Instruments, Inc. Fullerton, CA), to determine the unbound biotin. The biotin binding could be quantitated by the decrease of free biotin in the solution.

RESULTS AND DISCUSSION

Polymer Characterization and Protein Conjugation. The DMAA copolymer terminated with a hydroxyl group was synthesized by free radical copolymerization of DMA and AZAA in DMF using MEO as a chain transfer reagent (Figure 1). GPC and ¹H NMR analyses showed that the DMAA had a weight average molecular weight (MW) of 18 kDa and an AZAA content of 5.9 mol %. The LCST of DMAA was measured by the absorbance change at 600 nm and determined to be 37 °C. The hydroxyl terminus of DMAA was reacted with DVS to

Figure 2. Three-dimensional model of the streptavidin displaying the relative locations of position 116 and the C-terminus. The X-ray crystal structure is defined to the highlighted position 134, with the 139 position three residues away. The biotin-binding site and Trp 120 are also shown for orientation.

make DMAA-VS (Figure 1). DMAA-VS contained 97.5 molar percentage of reactive VS as determined with the colorimetric DTNB assay.

The polymer was conjugated to SA site specifically by the reaction of the vinyl sulfone group of the polymer with the sulfhydryl groups of the protein. The conjugate was separated from the unreacted SA by thermally induced precipitation of the polymer. The polymer–protein conjugates could be subsequently purified from free polymer by affinity chromatography. The number of polymer molecules conjugated to a SA was calculated from spectral analysis of the protein and polymer absorption spectra as 2.03 for the E116C–DMAA conjugate and 2.11 for the S139C–DMAA conjugate. This suggests that one polymer chain is conjugated to each of the two streptavidin binding faces, with steric repulsion likely preventing the conjugation of a second polymer at each face.

Conjugation Site Dependence of Activity Switch. Each subunit of E116C has a unique cysteine residue, which replaces the glutamic acid at position 116 (Figure 2). This conjugation site was previously chosen to be as close as possible to Trp120, one of the energetically most important biotin binding contacts (7). To test the site-dependence of conjugation for the activity switch, we have characterized the S139C mutant, which has a unique cysteine, engineered at the C-terminus of streptavidin (Figure 2). The streptavidin structure is crystallographically determined to residue 134, where the distance to the biotin binding site is approximately 2.4 nm.

The relative change in biotin binding capacity for the E116C conjugate is shown in Figure 3. The thermal response for the purified S139C conjugate was also determined, and compared both to protein alone and physical mixtures of SA and hydroxyl terminated polymers as controls. The E116C conjugate displayed a striking thermally dependent biotin binding capacity that translated into biotin blocking and releasing activities. Moving the conjugation site away from the biotin binding site had a large effect on the switching ability, as the S139C conjugate did not display a thermal dependence above the controls of protein alone and protein/polymer physical mixtures. These results demonstrate that the switching activity is strongly dependent on the location

Figure 3. The effect of thermal cycling on the biotin-binding capacity for the E116C–DMAA conjugate, the S139C–DMAA conjugate, physical mixtures of E116C or S139C and DMAA, and E116C and S139C alone in 100 mM sodium phosphate buffer at pH 7.4. The biotin-binding capacity was determined assuming 100% binding at 4 °C after 1 h incubation. For the conjugates, the biotin-binding capacity was plotted as the percentage of conjugated sites.

of the conjugation site, consistent with the need for the polymer to be near the binding site.

Mechanism of Biotin Releasing Activity. To investigate whether the off-rate of biotin was increased when the polymer was collapsed, the time dependence of biotin release was characterized (Figure 4). The unconjugated E116C exhibits the same biotin off-rate as wild-type streptavidin, and the increase in off-rate at 52 °C for unconjugated E116C is not large enough to significantly reduce the amount of bound biotin at equilibrium. This can be observed in Figure 4B, where there is no significant change in the percentage of bound biotin for the control E116C as the temperature is shifted from 4 to 52 °C. When biotin was first added to the DMAA–E116C conjugate at 52 °C, binding was largely blocked by the collapsed polymer. The temperature was then cycled to 4 °C where the polymer was hydrated, and this opened the blocked binding sites.

After recycling back to 52 °C, the time course of biotin release was quantitated. From these data, the first-order dissociation rate constant for biotin was determined to be $1.6 \times 10^{-4} \text{ s}^{-1}$ for the E116C–DMAA conjugate. The off-rate is thus very close to the $3.0 \times 10^{-4} \text{ s}^{-1}$ constant of wild-type SA at 52 °C. This finding suggests that the collapse of DMAA is not inducing an intrinsic increase in the biotin off-rate, but is blocking the reassociation of biotin. It is interesting that the biotin can exit through the collapsed polymer from the binding pocket, but not re-enter from bulk solution.

Role of Free Polymer in Switching Activity. Iminobiotin affinity chromatography was used to purify the E116C–DMAA and S139C–DMAA streptavidin conjugates. This purification allowed the study of the role of free polymer in the blocking and release switching activity. The thermal cycling response for binding and release of purified conjugates is compared in Figure 5 to conjugates where free polymer was also present. Although the purified conjugates showed reversible thermal switching for biotin binding, they exhibited smaller responses than when free polymer was added. The responses increased in magnitude as more of the free polymer was added.

Figure 4. Kinetics of biotin release after cycling to 52 °C from 4 °C. (A) E116C–DMAA conjugate and (B) E116C control. Assays were performed in 100 mM sodium phosphate buffer, pH 7.4. The biotin-binding capacity is determined assuming 100% binding at 4 °C after 1 h incubation.

Figure 5. Effect of adding free polymer on the biotin-binding capacity at 52 °C for E116C-DMAA and S139C-DMAA in 100 mM sodium phosphate buffer, pH 7.4. The unpurified samples were those isolated by thermal precipitation from the conjugation reaction. The biotin-binding capacity was determined assuming 100% binding at 4 °C after 1 h incubation. For the conjugates, the biotin-binding capacity was plotted as the percentage of conjugated sites. The molar ratios of free polymer/conjugate in the unpurified states were calculated as 1430 for E116C-DMAA and 1150 for S139C-DMAA conjugates by use of the conjugation conversions.

This effect was clarified by characterizing the S139C-DMAA streptavidin conjugate. The purified S139C-DMAA conjugate did not display any switching capability, and addition of free polymer led to only a small increase in activity. Taken together with the E116C-DMAA results, this suggests that the free polymer is likely aggregating with the conjugated polymer in the collapsed state. When directed to a site near the binding pocket, as with the E116C mutant, this DMAA aggregate more effectively blocks biotin association. But the aggregation effect is insignificant if the free polymer is directed toward a conjugation site that is too distant from the binding site. These findings confirm that the MW and type of smart polymer will likely provide important avenues to engineer the molecular switch activity. For example, larger and/or grafted polymers could provide better barriers near the binding site.

CONCLUSIONS

We have utilized a new thermally responsive polymer to investigate the mechanism of the smart polymer activity switches. The use of the DMAA polymer allowed an accurate determination of the conjugation ratio. The site-selectivity of the switch was first investigated with the S139C streptavidin mutant that contains a unique cysteine at the C-terminus. The purified S139C conjugate, where the DMAA is distant from the binding site, did not display switching activity. The previously characterized E116C streptavidin mutant did display switching activity when the DMAA was conjugated at this cysteine near the biotin-binding site. Because the release of biotin was shown to proceed with the same kinetics as the biotin off-rate for wild-type streptavidin, the mechanism for release was shown to be the blocking of biotin reassociation by the collapsed DMAA. The magnitude of the switching activity could be significantly increased by the addition of free polymer, but only if the conjugated polymer was near the binding site. This suggests that the conjugated polymer is directing a

physical aggregation of the free polymer at the defined position near the biotin-binding site. Taken together, these studies elucidate the importance of conjugation site and suggest that the molecular weight and type of stimuli-responsive polymer will be essential to optimize the switching activity.

ACKNOWLEDGMENT

We would like to thank Dr. J. Milton Harris of Shearwater Polymers for his advice on the addition of the polymer end hydroxyl groups to vinyl sulfone groups of DVS. We also wish to thank C. Lackey, C. J. Long, and Dr. R. To for the construction and expression of the SA mutants. The NIH (Grant 53771), UW Office of Technology Transfer, the Washington Research Foundation, and the Washington Technology Center are gratefully acknowledged for their support of this project.

An Improved Method for Conjugating Monoclonal Antibodies with *N*-Hydroxysulfosuccinimidyl DOTA

Michael R. Lewis,[†] Jim Y. Kao,[‡] Anne-Line J. Anderson,[‡] John E. Shively,^{*,§} and Andrew Raubitschek[‡]

City of Hope Graduate Program in Biological Sciences, Department of Radioimmunotherapy, City of Hope National Medical Center, and Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, California 91010. Received July 26, 2000; Revised Manuscript Received December 5, 2000

A simple, water-soluble procedure for conjugation of monoclonal antibodies to 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (DOTA) has been improved by optimizing pH, buffer, and temperature conditions for the preparation of *N*-hydroxysulfosuccinimidyl DOTA and its conjugation to the human/murine chimeric anti-carcinoembryonic antigen antibody cT84.66. This improved method results in a 6-fold increase in conjugation efficiency, a 3–7-fold decrease in antibody cross-linking, a more homogeneous population of conjugate species, and a 5-fold decrease in the quantities of reagents needed for conjugation. The cT84.66–DOTA conjugate was labeled to high specific activity with ¹¹¹In, ⁹⁰Y, ⁸⁸Y, ⁶⁴Cu, and ⁶⁷Cu, affording near-quantitative incorporation of the majority of these radiometals. This improved conjugation procedure facilitates large-scale production and radiometal labeling of cT84.66–DOTA for clinical radioimmunotherapy trials.

INTRODUCTION

Cancerous tumors can be targeted specifically by radiolabeled monoclonal antibodies (mAbs)¹ used in clinical imaging and therapy (1, 2), and a wide variety of medically useful radiometals are available for these applications. Considerable effort has been devoted to the development of bifunctional chelating agents (BCAs) for covalent attachment of radiometal ion complexes to mAbs (3–5). An important property of the BCA is that it chelates radiometals with high in vivo stability, resulting in minimal deposition of free radiometal in normal tissues (6). The macrocyclic chelating agent 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (DOTA) is an attractive candidate for conjugation of radiometals to antibodies. DOTA binds a large number of metal ions with extremely high thermodynamic (7, 8) and kinetic (9, 10) stability, and mAb–DOTA conjugates have shown minimal loss of chelated radiometal in vivo (11–14).

Recently, we developed a simple, water-soluble chemical method for conjugation of DOTA to proteins using commercially available reagents (15). This method involved the preferential activation of one carboxyl group of DOTA with *N*-hydroxysulfosuccinimide (sulfo-NHS)

and 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide (EDC) and reacting the resulting DOTA active ester with proteins at pH 8.5–9.0. The systematic development of elevated temperature, optimum pH, and appropriate buffer conditions allowed rapid, efficient, and kinetically stable labeling of immunoconjugates with ¹¹¹In(III) and ⁹⁰Y(III) at high specific activities. In this report, we describe improvements to this method, which make practical large-scale antibody conjugation for clinical radioimmunotherapy trials and result in near-quantitative labeling yields with radioisotopes of In, Y, and Cu.

EXPERIMENTAL PROCEDURES

Reagents. The antibody cT84.66, a human/murine chimeric anti-carcinoembryonic antigen (anti-CEA) mAb, isotype IgG₁, κ , was prepared as described previously (16). DOTA internal salt was purchased from Parish Chemical Co. (Orem, UT). Sulfo-NHS and EDC were obtained from Pierce (Rockford, IL). Cobalt powder (99.995%) was obtained from Aldrich (Milwaukee, WI). Chelex 100 (Biotechnology Grade, 100–200 mesh, sodium form) was purchased from Bio-Rad (Hercules, CA), and buffers used for radiolabeling reactions were passed over a Chelex 100 column (1 × 15 cm). ⁵⁷CoCl₂, ¹¹¹InCl₃, ⁹⁰YCl₃, ⁸⁸YCl₃, ⁶⁴CuCl₂, and ⁶⁷CuCl₂ were obtained from ICN (Costa Mesa, CA), Amersham (Arlington Heights, IL), NEN (Boston, MA), Los Alamos National Laboratory (Los Alamos, NM), Washington University (St. Louis, MO), and Brookhaven National Laboratory (Upton, NY), respectively. Ultrapure water (18 M Ω cm) was used for all procedures, and all other reagents were of the highest purity obtainable.

Thin-Layer Chromatography. Thin-layer chromatography was performed on ITLC plates (silica gel 60F-254, 0.5 × 10 cm, EM Science, Gibbstown, NJ), using 10% (w/v) ammonium acetate:methanol (1:1) as the mobile phase. In this system, radiometal-labeled antibody remains at the origin, while radiometal-DTPA complexes migrate to *R_f* = 0.7–0.9. Radiation counting of TLC plates

¹ Abbreviations: mAb, monoclonal antibody; BCA, bifunctional chelating agent; DOTA, 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid; DOTA–OSSu, *N*-hydroxysulfosuccinimidyl DOTA; sulfo-NHS, *N*-hydroxysulfosuccinimide; EDC, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide; EDTA, ethylenediaminetetraacetic acid; DTPA, diethylenetriaminepentaacetic acid; HSA, human serum albumin; IEF, isoelectric focusing; CEA, carcinoembryonic antigen; cT84.66, human/murine chimeric anti-CEA mAb; cT84.66–DOTA, cT84.66 conjugated to DOTA using DOTA–OSSu; HACA, human anti-chimeric antibody.

was performed with a Packard Cobra Auto-Gamma model 5003 counter with the appropriate energy window set for ^{57}Co or ^{111}In .

High-Performance Liquid Chromatography. HPLC was performed at room temperature on a Gilson chromatograph (models 307 pump, 506C System Interface Module, 715 System Controller Software, and FC 203 Fraction Collector). The column, solvent system, and flow rate used are described below. UV detection was accomplished at 280 nm using a Gilson 112 detector (10-mm, 11- μL analytical flow cell). Radioactivity detection was accomplished using a NaI detector and a Technical Associates PRS-5 analyzing miniscaler/ratemeter.

Ultraviolet Spectrophotometry. Concentrations of antibody were determined by UV spectrophotometry, measuring the absorbance at 280 nm (A_{280} at 1 mg/mL = 1.42, within 5% of the concentration determined by amino acid analysis). UV measurements were obtained on a Pharmacia LKB Ultrospec III spectrophotometer, using a 1-cm sample cell.

Preparation of N-Hydroxysulfosuccinimidyl DOTA (1). A solution of 16.2 mg of DOTA in 810 μL of H_2O was adjusted to pH 5.45 with 80 μL of 1 M NaOH and cooled to 4 $^\circ\text{C}$. To 239 μL (4.35 mg, 10.7 μmol) of the DOTA solution was added 2.33 mg (10.7 μmol) of sulfo-NHS in 117 μL of H_2O , freshly prepared at 4 $^\circ\text{C}$. Then 8.25 μL (0.207 mg, 1.08 μmol) of EDC, freshly prepared in H_2O (25 mg/mL), was added, and the reaction mixture was stirred at 4 $^\circ\text{C}$ for 30 min. The theoretical concentration of **1** in the reaction mixture was 2.97 mM. Prior to being added to the mAb, the pH of the reaction mixture was adjusted to 7.3 with 40 μL of 0.2 M Na_2HPO_4 , pH 9.2.

Preparation of cT84.66-DOTA Conjugate. An aliquot of 8.64 mg of cT84.66 in 1 mL of PBS, pH 7.4, was dialyzed against 1 L of 0.1 M Na_2HPO_4 , pH 7.5, containing approximately 1.2 g of Chelex 100, for 42 h at 4 $^\circ\text{C}$, with one buffer change. Then, the solution of **1** (1.08 μmol of DOTA-OSSu theoretical) was added to 8.06 mg (53.7 nmol) of cT84.66 in 1 mL of 0.1 M Na_2HPO_4 , pH 7.5. The reaction mixture was incubated at 4 $^\circ\text{C}$ for 24 h with continuous end-over-end mixing, after which it was dialyzed against 1 L of 10 mM Na_2HPO_4 /150 mM NaCl, pH 7.5, containing approximately 1.2 g of Chelex 100, for 24 h at 4 $^\circ\text{C}$. The conjugate was then dialyzed against 1 L of 0.25 M ammonium acetate, pH 7.0, containing approximately 1.2 g of Chelex 100, for 139 h at 4 $^\circ\text{C}$, with five buffer changes.

Determination of the Average Number of Chelates per Antibody Molecule. An aliquot of 10 μL of cT84.66-DOTA, containing approximately 400 pmol of conjugate, was added to 10 μL of 0.25 M ammonium acetate, pH 7.0, followed by 10 μL of a standardized CoCl_2 solution (402 μM , 4.02 nmol, containing >350000 cpm/ μL of $^{57}\text{CoCl}_2$) or InCl_3 solution (428 μM , 4.28 nmol, containing $>4.40 \times 10^6$ cpm/ μL of $^{111}\text{InCl}_3$). The reaction mixture was incubated at 43 $^\circ\text{C}$ for 3 h, after which 3.3 μL (33 nmol) of 10 mM DTPA, pH 6.0, was added. The reaction mixture was incubated at room temperature for 15 min. An aliquot of 1 μL of the reaction mixture was spotted onto an ITLC plate, which was developed until the solvent front had migrated 7 cm from the origin. The plate was cut in 1-cm increments from 1 cm above the origin to 6 cm above the origin, and the resulting seven sections were counted in the gamma counter. The number of chelates per antibody molecule was calculated from the ratio of counts remaining at the origin (0–1 cm, R_f = 0–0.14) to the total number of counts, using the method of Meares et al. (17).

Radiolabeling of cT84.66-DOTA. Representative conditions are given for labeling cT84.66-DOTA with the radiometals ^{111}In (III), $^{88,90}\text{Y}$ (III), and $^{64,67}\text{Cu}$ (II). In the ^{111}In and ^{90}Y labeling reactions, 88.8 μL of 0.25 M ammonium acetate, pH 7.0, was added to 2.0 mCi of $^{111}\text{InCl}_3$ in 111 μL of 0.04 N HCl or 6.0 mCi of $^{90}\text{YCl}_3$ in 4.6 μL of 0.05 N HCl, followed by 0.250 mg of cT84.66-DOTA in 50.4 μL of 0.25 M ammonium acetate, pH 7.0. The reaction mixture was incubated at 43 $^\circ\text{C}$ for 1 h, and then the reaction mixture was made 1 mM in DTPA with the addition of one-ninth of a reaction volume of 10 mM DTPA, pH 6.0. The reaction mixture was allowed to stand at room temperature for 15 min, after which the ^{111}In - or ^{90}Y -labeled antibody was purified by size-exclusion HPLC using a TosoHaas TSKgel G2000 SW column (7.5 $\times$ 300 mm, 10 μm), an isocratic mobile phase of normal saline, and a flow rate of 1.0 mL/min. The mAb peak, eluting at 10.3 min retention time, was collected in 0.5-mL fractions containing 1 drop of 25% (w/v) human serum albumin (HSA) each.

For ^{88}Y labeling, a longer reaction time was needed to achieve optimal labeling efficiency, presumably because of higher concentrations of trace metal contaminants in preparations of this isotope. In a typical ^{88}Y labeling reaction, 190 μL of 0.25 M ammonium acetate, pH 7.0, was added to 0.287 mCi of $^{88}\text{YCl}_3$ in 102 μL of 0.1 N HCl, and then 0.300 mg of cT84.66-DOTA in 69 μL of 0.25 M ammonium acetate, pH 7.0, was added. The reaction mixture was incubated at 43 $^\circ\text{C}$ for 3.5 h, after which 40.1 μL of 10 mM DTPA, pH 6.0, was added. The reaction mixture was incubated at 37 $^\circ\text{C}$ for 15 min, and the ^{88}Y -labeled conjugate was purified by size-exclusion HPLC in the same manner as the ^{111}In -labeled antibody.

In the ^{64}Cu labeling reaction, 120 μL of 0.1 M ammonium citrate, pH 5.5, was added to 1.4 mCi of $^{64}\text{CuCl}_2$ in 3.5 μL of 0.1 N HCl, followed by 0.205 mg of cT84.66-DOTA in 45 μL of 0.25 M ammonium acetate, pH 7.0. For ^{67}Cu labeling, 200 μL of 0.1 M ammonium citrate, pH 5.5, was added to 1.17 mCi of $^{67}\text{CuCl}_2$ in 100 μL of 0.1 N HCl, and then 0.228 mg of cT84.66-DOTA in 50 μL of 0.25 M ammonium acetate, pH 7.0, was added. The reaction mixtures were incubated at 43 $^\circ\text{C}$ for 1 h, after which they were made 1 mM in EDTA with the addition of one-ninth of a reaction volume of 10 mM EDTA, pH 5.5. The reaction mixtures were allowed to stand at room temperature for 15 min, and the ^{64}Cu - or ^{67}Cu -labeled mAb was purified by size exclusion HPLC in the same manner as the ^{111}In -labeled conjugate.

Immunoreactivity Determination. A dilution of the purified radiolabeled cT84.66-DOTA conjugate, containing approximately 200 000 cpm of radioactivity, was mixed with a 20-fold molar excess of purified CEA (18, 19) in 150 μL of 1% HSA/PBS, pH 7.4. A control sample was prepared in an identical manner, except that CEA was not added. The reaction mixtures were incubated at 37 $^\circ\text{C}$ for 15 min with continuous end-over-end mixing, after which aliquots of 100 μL were analyzed by gel filtration HPLC, using two Pharmacia Superose 6 HR 10/30 columns (1 $\times$ 30 cm) in series and an isocratic mobile phase of 0.05 M Na_2SO_4 /0.02 M NaH_2PO_4 /0.05% NaN_3 , pH 6.8, at a flow rate of 0.5 mL/min. Immunoreactivity was calculated as the percentage of the total radioactivity shifted to complexes with apparent molecular weights higher than that of the mAb.

Isoelectric Focusing. Aliquots of 5 μg of cT84.66 and each of three lots of cT84.66-DOTA were analyzed by isoelectric focusing (IEF) on pH 3–10 precast gels (NOVEX, Invitrogen Corp., Carlsbad, CA). IEF gels were run at constant voltage for 1 h at 100 V, 1 h at 200 V,

Scheme 1

Figure 1. Average number of chelates per molecule of human IgG conjugated with 100 theoretical equiv of DOTA–OSSu, determined by a $^{57}\text{Co}(\text{II})$ binding assay, as a function of the pH at which DOTA–OSSu was prepared.

and then 30 min at 500 V. The gels were fixed in 0.14 M 5-sulfosalicylic acid/0.7 M trichloroacetic acid for 30 min at room temperature, stained with Coomassie Brilliant Blue R-250 for 30 min at room temperature, and destained in H_2O overnight.

RESULTS AND DISCUSSION

The previously reported method for conjugation of monoclonal antibodies with *N*-hydroxysulfosuccinimidyl DOTA (15) was a simple, aqueous phase procedure using only commercially available reagents (Scheme 1). However, large-scale preparation of clinical lots of mAb–DOTA conjugates, using 250 mg of antibody, would consume approximately 675 mg of DOTA. Therefore, it was desirable to improve the efficiency of the conjugation reaction, to reduce the amount of chelating agent required.

Several modifications to the original procedure were made. First, the pH of the active ester synthesis was optimized. In the original method, activation of trisodium DOTA with EDC and sulfo-NHS was performed at ambient pH, approximately 2.5–2.6. However, water-soluble carbodiimides are more stable at higher pH, in the range of 4 to 10 (20, 21). Above pH 7, the hydrolytic stability of sulfo-NHS esters decreases markedly (22), and many active ester-mediated protein coupling reactions have been performed in the range of pH 5–6 (23, 24). Therefore, in the present work, human IgG was used as a model system and conjugated with 100 theoretical equiv of DOTA–OSSu prepared at pH 2.5, 3.75, 4.5, and 5.5. As shown in Figure 1, a linear relationship was found between the pH of activation and the degree of antibody modification. Determination of the average number of chelates per antibody molecule indicated that the efficiency of conjugation increased approximately 6-fold when DOTA–OSSu was synthesized at pH 5.5, compared to ambient pH.

Second, pH and buffer conditions of the antibody conjugation reaction were improved. Several groups have

reported optimum coupling yields at pH values of 5–8 (21–24), where rates of amidation of succinimidyl esters increase more rapidly than rates of hydrolysis. In the previously described method (15), the anti-CEA mAb cT84.66 was dialyzed against 0.25 M ammonium acetate prior to dialysis against the conjugation buffer, 0.1 M NaHCO_3 /0.1 M K_2HPO_4 , pH 8.5. Under these conditions, the concentration of ammonium acetate in the conjugation reaction was 0.41 mM, resulting in a theoretical DOTA–OSSu:ammonia molar ratio of 7.4:1. Even though ammonia is a relatively poor nucleophile in aqueous media, competing aminolysis of the DOTA active ester may have decreased the efficiency of antibody conjugation. In the present work, no ammonia-containing buffers were used for dialysis prior to conjugation, and cT84.66 was reacted with DOTA–OSSu in sodium phosphate buffer at pH 7.5. On the basis of previously published studies, it was anticipated that the lower pH conditions would decrease the rate of hydrolysis of *N*-hydroxysulfosuccinimidyl DOTA by a factor of 2–2.5 (22) while maintaining the reactivity of the active ester with primary amines at neutral to slightly alkaline pH (24, 25).

EDC has been shown to react readily with inorganic phosphate to form an *O*-phosphoisourea, which hydrolyzes rapidly to give a substituted urea and phosphate (20). Thus, the pH of the DOTA–OSSu solution was adjusted to 7.0–7.5 with sodium phosphate before being added to the mAb. This procedure not only minimized the potential for mAb cross-linking by unreacted EDC, but also reduced the acidity of the active ester preparation and the possibility of protein denaturation. When analyzed by gel filtration HPLC, antibody–DOTA conjugates prepared by the previously published procedure were found to contain between 2.35 and 6.00% antibody dimers. Conjugates prepared under the improved pH and buffer conditions contained 0 to 0.862% dimers, as determined by gel filtration HPLC.

Model conjugation studies with cytochrome *c* (15) suggested that the reaction was equally efficient at 4 °C and room temperature. However, cytochrome *c* is a small, hydrophilic, and very lysine-rich protein and, compared to antibodies, may react with active esters at a rate more comparable to that of competing hydrolysis. Hydrolysis of *N*-hydroxysulfosuccinimide esters is an order of magnitude slower at 0 °C than at 31 °C, increasing the half-life of active esters from 0.87 h at 31 °C to 11 h at 0 °C (22). Thus, mAb conjugations with *N*-hydroxysulfosuccinimidyl DOTA were performed at 4 °C to minimize the rate of hydrolysis of the active ester. It was expected that a long incubation time (24 h) at low temperature (4 °C) would maximize both the lifetime of DOTA–OSSu in solution and the efficiency of antibody conjugation.

Using the optimized activation and conjugation conditions, the reaction of *N*-hydroxysulfosuccinimidyl DOTA with antibodies was approximately 6-fold more efficient than when the previously published procedure was used (Figure 1). Therefore, for subsequent conjugations the molar ratio of DOTA–OSSu:cT84.66 was reduced from

100:1 to 20:1. Table 1 gives the activation and conjugation conditions, as well as the number of chelates per mAb determined by ⁵⁷Co and ¹¹¹In binding assays, for one lot of cT84.66–DOTA prepared by the original method and three lots of cT84.66–DOTA prepared using the procedure described here. The results of the radiometal binding assays show that conjugates prepared by the two procedures contain similar numbers of functional chelates, yet the quantities of reagents used to conjugate the antibody were reduced by a factor of 5 when the new method was used.

DOTA conjugates of cT84.66, prepared by the original procedure and the improved method, were analyzed by isoelectric focusing (Figure 2). The pI of unmodified cT84.66 (lane 1) was determined to be 6.5–7.3 by IEF. Modification with DOTA resulted in expected decreases in the isoelectric points of the mAb conjugates. The pI of cT84.66–DOTA, conjugated by the previously published method (lot RJ121296, lane 5), was found to be 5.0–6.7. However, a pair of predominant bands at a pI value of 5.3 suggested the presence of a relatively large population of highly modified mAb species. In contrast, cT84.66–DOTA conjugates prepared by the new method (lots MA071098, 010297NC, and 021997; lanes 2, 3, and 4) showed a more uniform distribution of antibody modification over a pI range of 5.2–7.0. Thus, the improved conjugation procedure described here gives a more homogeneous product, with fewer highly modified conjugates. Overmodification of mAbs with BCAs can lead to decreases in immunoreactivity and tumor uptake (26), so it was desirable to reduce the fraction of heavily conjugated species.

The results of ¹¹¹In, ⁹⁰Y, ⁸⁸Y, ⁶⁴Cu, and ⁶⁷Cu labeling reactions of cT84.66–DOTA under no-carrier-added conditions are listed in Table 2. The ¹¹¹In and ⁹⁰Y labeling reactions were performed over a wide range of specific activities, for the purposes of animal biodistribution, patient imaging, patient therapy, and human anti-chimeric antibody (HACA) studies. When unconjugated, demetalated cT84.66 was incubated with ¹¹¹In or ⁹⁰Y, no nonspecific binding of either radiometal to the mAb was observed after DTPA challenge and HPLC purification. Labeling of cT84.66–DOTA proceeded with >85% efficiency with all radiometals except ⁶⁷Cu. The relatively low specific activity of ⁶⁷Cu (185 Ci/mmol, compared to 20 000 Ci/mmol for ⁶⁴Cu) likely contributed to its lower labeling efficiency, because of competition by cold copper for chelation sites on the conjugate. Compared to the previously published work (15), ¹¹¹In labeling was increased by 15%, and ⁹⁰Y labeling was improved by 27%.

Figure 2. IEF analysis of unconjugated cT84.66 (lane 1) and cT84.66–DOTA conjugates prepared by the method reported herein, Lot MA071098 (lane 2), lot 010297NC (lane 3), lot 021997 (lane 4), and cT84.66–DOTA prepared by the previously published method (15), lot RJ121296 (lane 5). Isoelectric point markers are shown to the right.

However, the standard deviation of ⁹⁰Y labeling efficiency was larger than those of the other radiometals. The variation in ⁹⁰Y labeling did not correlate with specific activity, mAb conjugate lot, or storage of the conjugate over a period of 14 months. Rather, the efficiency of labeling seemed to vary with the lot of ⁹⁰Y used. Table 2 also lists the immunoreactivities of the radiometal-labeled conjugates, as determined by a solution-phase CEA binding assay. For all conjugates analyzed, immunoreactivity was essentially quantitative.

By optimizing pH, buffer, and temperature conditions for both the preparation of *N*-hydroxysulfosuccinimidyl DOTA and its conjugation to the anti-CEA monoclonal antibody cT84.66, several improvements to the previously published procedure were made. These improvements

included a 6-fold increase in conjugation efficiency, a 3–7-fold decrease in antibody dimerization, a more homogeneous population of conjugate species, and a 5-fold reduction in the quantities of DOTA and coupling reagents required for the conjugation. Furthermore, ^{111}In and ^{90}Y labeling of cT84.66–DOTA was increased significantly, and high specific activity labeling with Cu radioisotopes was achieved, while maintaining quantitative immunoreactivity. This procedure has been scaled up to produce two lots of 233 and 215 mg, respectively, of clinical-grade cT84.66–DOTA. We are currently evaluating ^{90}Y -labeled cT84.66–DOTA in a Phase I/II clinical trial for radioimmunotherapy of CEA-positive malignancies.

ACKNOWLEDGMENT

The authors wish to thank Randall Woo and Militza Botic for excellent technical assistance, as well as Michael J. Welch, Deborah W. McCarthy, and Todd A. Perkins of Washington University in St. Louis for providing ^{64}Cu . This work was supported by Research Grant CA43904 from the National Cancer Institute, NIH.

Synthesis and Biological Evaluation of an Anticancer Vaccine Containing the C-Glycoside Analogue of the Tn Epitope

Francesco Peri, Laura Cipolla, Maria Rescigno, Barbara La Ferla, and Francesco Nicotra*

Department of Biotechnology and Biosciences, University of Milano-Bicocca, Piazza della Scienza 2, I-20126 Milano, Italy. Received November 28, 2000

The C-saccharide analogue of the GalNAc (Tn epitope) has been covalently linked to the T cell epitope peptide ³²⁸⁻³⁴⁰OVA using a chemoselective convergent synthetic approach. In this way, a non-hydrolyzable synthetic vaccine was obtained composed by a B epitope conjugated to a T cell epitope. This compound was tested in a proliferation assay with spleen cells from DO11.10 mice. The molecule was recognized by transgenic T cells although at a slightly lower efficiency if compared with the reference peptide OVA. An additional experiment with dendritic cells fixed with glutaraldehyde shows that the glycopeptide can bind to extracellular MHC molecules without need of internalization and processing and that the C-glycoside part does not interfere with TCR recognition. These observations constitute an important starting point for the use of this molecule as vaccine against the Tn-expressing TA3-Ha mouse mammary carcinoma.

Tumor immunotherapy is based on the theory that tumor-associated antigens (TAA) become immunogenic if presented to a properly trained immunosystem (1). Many of the tumor antigens are constituted by sugars, because the malignant cells are commonly characterized by incomplete glycosylation or neoglycosylation, and a large number of tumor-associated carbohydrate antigens (TACA) expressed on glycolipids and glycoproteins have been identified (2, 3). In particular, the monosaccharide α -GalNAc, called Tn antigen, has been extensively studied, since it is expressed on mucin-type glycoproteins by the majority of human adenocarcinomas as a consequence of aberrant glycosylation, whereas it is hidden in normal cells (4).

Figure 1. Chemical structure of the synthetic vaccine 1.

An immune response directed against carbohydrate antigens results in the induction of antibodies that could eradicate the micrometastases and the circulating tumor cells in the blood stream, thus providing protection against tumor. However, carbohydrate-based vaccines have so far been unsuccessful in inducing detectable T cell immunity (5). To overcome this limitation, and in

Figure 2. Overlay of RP-HPLC chromatograms of the conjugation reaction. Conditions: A: 0.1% TFA in water, B: 0.1% TFA in CH₃CN; gradient: from 0% to 100% B in 30 min; detection at 214 nm. After 90 min at rt, the HPLC profile of reaction crude shows the complete disappearance of aminoxy-peptide **3** and the appearance of the conjugation product **1** constituted by two peaks (*syn* and *anti* oxime isomers).

order to induce an immunological memory toward a carbohydrate epitope, a suitable vaccine has to provide an helper T cell response for B cell induction and IgG production. According to this concept, semisynthetic vaccines have been prepared by conjugation of a carbohydrate B-epitope with a protein and it has been shown that these molecules are capable to induce IgM and IgG anti-Tn antibody responses (6). Totally synthetic vaccines composed by a carbohydrate B-epitope covalently linked to the lipopeptide tripalmitoyl-*S*-glycerylcysteinylserine as a combined carrier and adjuvant system have been prepared (7, 8, 9). Vaccines with a more complex molecular structure have been developed by assembling covalently a carbohydrate (B-epitope), a peptide T-epitope and the lipopeptide dipalmitoyloxypropyl-*N*-palmitoyl-cysteine (Pam₃-Cys) (10). However, the outcome of the immune response for this molecule has not been reported.

Following the same concept we designed a totally synthetic vaccine (Figure 1) by linking covalently a sugar B and a peptide T cell epitope through a spacer. In our design, the spacer containing an oxime bond has the function to keep the saccharide and the peptide apart, thus minimizing a possible negative interference of the sugar in the formation of the complex between peptide and MHCII¹ and its recognition by the TCR. We verified our hypothesis *in vitro* by testing the capacity of the glycopeptide to form a complex with MHCII on dendritic cells (DC). However, the main innovation in the design of our vaccine consists of the use of the α -C-glycosidic analogue of the GalNAc instead of the glyco-amino acid GalNAc-Ser/Thr as Tn epitope. The C-glycosidic bond is stable toward acids, bases, and enzymatic hydrolysis; this makes **1** a promising candidate for drug development.

Finally, we tested the ability of dendritic cells to present glycopeptide **1** to TCR.

DC are the only antigen presenting cells capable of priming a T cell response; thus, vaccines targeted to DC are potentially more powerful (11).

^a Reagents and conditions: i, TFA, TIS, H₂O (95: 2.5: 2.5); ii, **2** (1.2 equiv), **3** (1 equiv), acetate buffer 0.1 M, pH 4.5.

The ^{328–340}OVA peptide in **1** corresponds to a part of the epitope for the TCR–OVA transgenic T cells derived from DO11.10 mice (12). The ^{327–339}OVA peptide was chosen as a model antigen to provide T cell help either in DO11.10 mice or in mice that have been previously immunized with soluble OVA in an immunogenic fashion. The latter will mimic a situation of immunized animals and it will be a “proof of principle” for the use of a recall T-helper antigen, such as the tetanus toxoid in humans. In particular, it will be possible to test the effectiveness of the synthetic vaccine **1** in providing protection against challenge with a highly invasive mouse mammary carcinoma, TA3-Ha, which expresses the Tn antigen (13).

The synthesis of the vaccine was accomplished according to a convergent strategy based on the chemoselective coupling (14) of the α -C-glycosyl ketone **2** with peptide **3** bearing an aminoxy group at the N-terminal end (Scheme 1). The preparation of the C-glycosyl analogue

Figure 3. OVA peptide in compound **1** is recognized by TCR–OVA transgenic T cells. Spleen cells from DO11.10 mice were incubated with the indicated concentrations of **1** and of reference $^{327-339}$ OVA peptide. The proliferative response was measured after 2 days as ^3H -thymidine incorporation by TCR–OVA T cells. As shown, compound **1** was recognized although with slightly lower efficiency as compared to the reference peptide.

of GalNAc has been reported by our group (15); the peptide sequence was assembled on Wang resin using the Fmoc/*tert*-butyl solid-phase strategy (16) (SPPS, Scheme

1). The aminoxy functionality was introduced by solid-phase condensation of *N*-hydroxysuccinimide activated Boc-aminoxyacetic acid in the presence of the base DIPEA. Aminoxy antigen **3** was obtained with 40% overall yield after cleavage from resin, complete side chain deprotection, and RP-HPLC purification. The chemoselective oxime bond formation between the Tn-ketone and the aminoxy antigen was carried out in aqueous solution (acetate buffer, pH 4.5) by monitoring the reaction by RP-HPLC (Figure 2); the coupling turned out to be complete after 90 min at rt (35% yield after HPLC product purification). Compound **1** presents two isomeric forms in equilibrium at rt, deriving from the *cis*/*trans* isomerism of the oxime bond, detectable by HPLC analysis and characteristic of oxime-linked glycoconjugates (14). The glycopeptide was tested in a proliferation assay with spleen cells from DO11.10 mice in order to assess if the carbohydrate group interferes with the capacity of TCR–OVA transgenic T cells to recognize the peptide in association with MHC II. As shown in Figure 3, compound **1** was recognized by transgenic T cells although at a slightly lower efficiency if compared with the reference peptide OVA. Next, we analyzed whether the glycopeptide **1** has to be internalized and processed by DC in order to be presented to T cells. We used a well-characterized nonimmortalized DC cell line (D1 cells)–(17) which is the prototype of immature DC able to

Figure 4. Internalization and processing of compound **1** is not necessary for OVA peptide presentation. D1 cells were either fixed (A) or nonfixed (B) with 0.001% glutaraldehyde for 1 min on ice, loaded with the different peptides and incubated with the costimulation-insensitive hybridoma (BO97.10) which is specific for the $^{327-339}$ OVA peptide. Activation of the hybridoma was tested by measuring the IL-2 produced in culture supernatants as a function of ^3H -thymidine incorporation by a CTL line which is dependent on IL-2 for its growth (CTLL-2). Peptides **1** and **3** were similarly presented to T cells by fixed and nonfixed cells, indicating that processing is not required for efficient antigen presentation. (C) As a control, fixed DC were unable to present whole ovalbumin which requires processing for the generation of the OVA peptide.

present antigens to T cells in vitro. DC were thus fixed with 0.001% glutaraldehyde in phosphate-buffered saline (PBS) before exposure to the peptides to avoid the internalization and processing of the compounds. To overcome the need of costimulation which is essential for T cell priming and cannot be provided by fixed DC, a costimulation-insensitive hybridoma (BO97.10) recognizing the same OVA peptide in association with MHC II molecules was used. As a control we analyzed the capacity of fixed D1 cells to present ovalbumin which has to be internalized and degraded to produce the OVA^{327–339} peptide recognized by the hybridoma. Both the glycopeptide **1** and the aminooxy peptide **3** could be presented by fixed D1 cells (Figure 4A) with similar efficiencies as non fixed cells (Figure 4B) indicating that the peptide can bind to extracellular MHC molecules and that the carbohydrate does not interfere with TCR recognition. The antigen presentation is very similar in both **1** and **3** but less efficient than in the OVA epitope, suggesting that the aminooxy linker interferes with MHC binding or with TCR recognition. As expected, the whole ovalbumin could not be presented by fixed cells (Figure 4C).

Thus, we have validated our vaccine **1** in vitro by showing that it can be presented by DC and that the C-glycosidic analogue of GalNAc, stable toward enzymatic and chemical hydrolysis, does not influence the antigen specificity of the compound. Future perspectives of this work will aim to study the capacity of compound **1** to induce an antibody response to GalNAc in immunized animals in vivo. The requirement of T cell help delivered by the OVA peptide for antibody production will also be evaluated and this will be correlated with the capacity of vaccine **1** to protect mice from lethal challenge with the TA3-Ha mouse mammary carcinoma.

ACKNOWLEDGMENT

We gratefully acknowledge Antonella Leone and Felice Daverio for their contribution to the experimental work.

Design of Acridinium-9-carboxamides and Anti-acridinium Antibodies for Chemiluminescent Signal Enhancement

Maciej Adamczyk,* Phillip G. Mattingly, Jeffrey A. Moore, You Pan, Kevin Shreder, and Zhiguang Yu

Department of Chemistry (9NM), Abbott Diagnostics Division, Abbott Laboratories, Abbott Park, Illinois 60064-6016. Received December 22, 2000

A novel system of signal enhancement is presented in which every labeled antibody is capable of generating a signal. Three chemiluminescent acridinium-9-carboxamide haptens (**1**, **2**, and **3**) which incorporated differences in charge and location of the linker were designed and synthesized. Anti-acridinium polyclonal antibodies for each hapten were screened using surface plasmon resonance instrumentation to determine specificity for each hapten. Anti-acridinium **2** antibodies were found to be non-cross-reactive to acridinium **1**. This property was exploited to design secondary antibody conjugates which would bind to primary antibodies labeled with **2** yet could still be labeled with the structurally similar acridinium **1**. Consequently, both layers contributed to the overall chemiluminescent signal. This format is an advance over other signal amplification formats which employ non-signal-generating, labeled antibodies to construct multilayered systems.

A variety of assays used for biological research, clinical diagnostics, and high throughput screening employ a detection reagent labeled with species capable of generating a colorimetric, fluorescent, or chemiluminescent signal (*1*). In turn, the signal generated is used to detect an analyte of interest. Frequently, multiple layers of signal generating conjugates must be applied to a captured analyte to achieve signal enhancement.

In the area of immunoassays, immunoconjugates can be prepared with increasing label-to-antibody ratios until an optimal signal is achieved (*2*). While this approach is straightforward, it does have its practical limitations. Conjugates with high label-to-antibody ratios can result in detection reagents with lowered solubility and compromised binding affinity relative to their unconjugated state (*3, 4*). To overcome such limitations, systems that build multiple layers of detection reagents can be used. In this way, the number of labeled antibodies increases, *not* the number of labels per antibody (*5*). A common method makes use of a biotin label (B) in conjunction with an anti-biotin antibody labeled with a signal generating species (S). In this scheme, the system achieves an enhanced signal relative to a single labeled anti-analyte antibody (Figure 1b). Many analogous systems exist; schemes incorporating labeled avidin are perhaps the best known (*6–8*).

While such systems are effective, they are simultaneously wasteful. In the example detailed in Figure 1a, the biotin "extender" is merely a means to noncovalently bind the signal bearing antibody and itself does not generate a signal. We reasoned that a signal generating extender would increase the overall effectiveness of the system by ensuring the contribution of *every* labeled antibody. In such a proposition, B, the extender, becomes a signal-generating species, S₁, and the signal-generating species on the secondary antibody is designated S₂ (Figure 1c).

The design of a signal generating extender and its corresponding receptor poses certain challenges. First,

Figure 1. Schematic representation of immunoassay formats.

Figure 2. Acridinium-9-carboxamides used in this study.

S₁ and S₂ should be capable of generating a signal using an identical method of induction. Otherwise, multiple triggering events may be needed, thereby increasing the complexity of the system. Finally, because an anti-S₁ antibody would need to be labeled with S₂, cross-reactivity between the secondary label and the secondary antibody must be eliminated. If not, the secondary antibody conjugate would have limited capacity to bind S₁ and would be prone to insolubility caused by immunoprecipitation.

To overcome these challenges, three chemiluminescent acridinium-9-carboxamide haptens (**1a**, **2a**, and **3a**) were designed and synthesized (Figure 2). Acridinium deriva-

Figure 3. Determination of antibody cross-reactivity using SPR.

tives have proved themselves to be efficient chemiluminescent labels used in a variety of applications (9). In the case of antibodies specific for acridinium-9-carboxamides, the antibodies would need to discriminate between acridinium labels that, by necessity, must be structurally conserved to retain their chemiluminescent properties. Differences between the structures, such as their overall charge and the location of the linker, were incorporated to generate hapten specific antibodies. Conjugation of **1b**, **2b**, and **3b** to keyhole limpet hemocyanin (KLH) yielded the hapten-carrier conjugates **1c**, **2c**, and **3c**, respectively, which were used to immunize New Zealand White rabbits. Three anti-sera for each immunogen were generated. IgG polyclonal antibodies (pAbs) were isolated from rabbit serum using ammonium sulfate precipitation followed by protein A chromatography.

To ascertain specificity, surface plasmon resonance (SPR) was employed to gauge the relative affinities of the polyclonal antibodies for the three different haptens. SPR has previously been shown to be an effective method for characterization of antibody binding phenomena (10). Amine-bearing congeners of the haptens (**1d**, **2d**, and **3d**) were covalently attached to a carboxymethylated dextran sensor chip using NHS and EDAC. The resulting sensor chips were then capped using ethanolamine. Solutions of each of the anti-hapten pAbs were injected over the surface of the sensor chips. The resulting saturated responses were then compared (Figure 3).

Significantly, of the nine possible combinations of pAbs versus hapten screened, one combination exhibited no observable cross-reactivity: Anti-2 pAbs showed no response for an acridinium **1** derivatized chip. This particular combination showed the greatest divergence with respect to charge and position of the linker. Post-conjugation to KLH, **2b**, yielded a hapten with a positive charge in contrast to the negative charge of the conjugated form of **1**. Furthermore, the linker of **2** emanates from the nitrogen of the sulfonamide. By contrast, the linker of **1** is attached to the tosyl ring. In general, antibody specificity was similar among the set of three rabbits immunized with the same immunogen. This trending would support that the observed specificity was the result of a general immunological response to hapten structure as opposed to the isolated response of a single rabbit. Interestingly, the opposite configuration, anti-1

pAbs in combination with a **2d** derivatized sensor chip showed cross-reactivity.

Once a requisite pair of hapten and anti-hapten pAbs was found, immunoconjugates were designed to demonstrate the utility of the combination for construction of a signal generating layer in a model system. An anti-L-T₄ monoclonal antibody (mAb) was used to detect a bovine serum albumin (BSA)-L-T₄ conjugate passively absorbed to a polystyrene microtiter plate (11). The anti-L-T₄ mAb was labeled with the active ester **2b** in sodium borate buffer, pH 8.5. The anti-2 pAbs were oxidized using sodium periodate and purified from excess periodate into sodium acetate buffer, pH 5.1. Coupling of the oxidized pAbs with **1e** resulted in the formation of a stable, oxime-linked immunoconjugate. Both conjugates were purified using a desalting column equilibrated with PBS in order to remove unconjugated label. The resulting conjugates were characterized using UV-visible spectroscopy and were shown to have label-to-antibody ratios of 3.4 and 4.0, respectively. Prior to or after the purification of the labeled anti-2 pAbs, no precipitation of the antibodies was observed, as might be expected if cross-linking and subsequent immunoprecipitation was to be a problem.

To demonstrate the use of **2** as a signal generating extender, the chemiluminescent signals of the labeled anti-L-T₄ mAb complexed to labeled or unlabeled anti-2 pAbs were compared. Specifically, the anti-L-T₄ mAb conjugate was incubated with a BSA-L-T₄ conjugate passively absorbed to a polystyrene plate and unbound antibody then was washed away. This incubation was followed by a second incubation using either labeled or unlabeled anti-2 pAbs (Figure 4a and 4b, respectively). After a second wash, the addition of basic peroxide resulted in a chemiluminescent signal. The observed increase in signal when labeled secondary antibody was used was taken as evidence for the ability of the label **2** to act as a chemiluminescent extender between the primary and secondary antibodies used for detection. To rule out apparent signal enhancement caused by non-specific binding of the labeled antibodies, two controls were performed. Neither replacement of the BSA-L-T₄ conjugate with BSA (Figure 4c) nor the replacement of the anti-L-T₄ mAb conjugate with unlabeled mAb (Figure 4d) in the system yielded any significant signal. Both of these latter experiments indicated that the observed

Figure 4. Normalized chemiluminescence microtiter plate results.

signal enhancement in Figure 4b is due to specific binding as opposed to nonspecific absorption of the immunoconjugates.

In conclusion, a novel system of chemiluminescent signal enhancement has been presented in which every antibody layer is capable of generating a signal. A combination of synthetic design and ligand screening was utilized to find the appropriate hapten–antibody pair to enhance signal. Alternative synthetic or enzymatic labels also can be envisioned. Furthermore, the application of this concept to build multilayered systems should provide even higher degrees of signal enhancement.

Received July 20, 2000; Revised Manuscript Received December 20, 2000

In view of future generations of biosensors and advanced biomaterials, photochemistry in the near field using scanning near-field optical microscopy is investigated. The potential of direct near-field-induced photoactivation is demonstrated on standard photoresist. Photoimmobilization of maleimidoaryldiazirine on silicon substrates and bovine serum albumin on glass substrates is achieved, opening the way to a controlled biopatterning of surfaces with submicrometer feature size. The obtained patterns are characterized using atomic force microscopy, time-of-flight secondary ion mass spectrometry (ToF-SIMS), and near-field fluorescence microscopy.

INTRODUCTION

In view of future generations of biosensors and advanced biomaterials, the construction and integration of complex biological systems onto selected materials or transducers is of primary importance. Chemical treatment of a material surface through functionalization is the first step in engineering of biosensors and biomaterials. Immobilization of biomolecules on transducer surfaces can be achieved by different means: physical adsorption (physisorption), receptor-mediated adsorption (bioaffinity), or covalent binding. The first two processes are reversible, while the latter leads to the formation of irreversible chemical bonds (1). An elegant way toward covalent immobilization is the use of photoactivable reagents. Indeed, the interaction of light with the reagents induces reaction intermediates that can lead to covalent chemical bonds to the substrate surface. Among the photoactivable reagents available, aryldiazirine has been successfully used on a wide range of materials (from polymer to metal oxides) (2). Its activation wavelength is in the range of 350 nm, which does not impair biological activity. Meanwhile, topical addressability, which allows multicomponent domain-limited devices, has been achieved with a standard masking technique as it is commonly used in microtechnology. However, this technique is limited in spatial resolution by the diffraction of light. The use of deep-UV wavelengths to improve the resolution is not possible without destroying the biological properties of the attached molecules. Future

needs for photopatterning of biomolecules include high spatial localization of the biomolecules, and thus it involves the development of new techniques going beyond the diffraction limit. Near-field illumination potentially allows to overcome this limit.

Scanning near-field optical microscopy (SNOM) is, in first use, a technique to optically investigate surfaces beyond the diffraction limit. An optical probe is scanned a few nanometers above the object to be investigated where it interacts with the sample via the near electromagnetic field either emitted or scattered by the probe or by the object.

The resolution of SNOM is not limited by diffraction, but rather by the size of the optical probe and the distance between the probe and the sample.

Although already proposed decades ago (3), the principle has been rediscovered and experimentally realized only in 1984 with the demonstration of optical resolution below diffraction limit (4), when technology allowed fabrication of sub-wavelength size probes and control of its distance to the sample with nanometer precision. This technique offers a wide area of applications for the study of biomaterials, allowing exploitation of most of the optical contrast mechanisms (fluorescence, phase, polarization, etc). SNOM has been successfully used in investigation of single molecules (5), cells (6), and in combination with fluorescence energy transfer (7).

This work demonstrates that SNOM can be used not only as an observation tool, but also as a structuring tool, that exploits the high localization of the light in the probe's near field, to very locally induce photochemical effects. Combining SNOM lateral resolution with photochemical immobilization of aryldiazirine on material surfaces, we perform near-field photochemistry to immobilize nanostructures on surfaces obtaining submicrometric domains of recognition. In this paper, we first illustrate the potential of direct near-field induced photoactivation on standard photoresist and show that sub-wavelength patterning is achievable. In a second step, immobilization of maleimidoaryldiazirine (MAD) on a

silicon substrate is obtained by near-field photoactivation, opening the way to a controlled biopatterning of surfaces. This configuration offers the advantage of a small molecule that forms a thin and homogeneous layer on the sample surface. Finally, the technique is applied to photoimmobilize a larger biomolecule (bovine serum albumin, BSA), obtaining patterns of proteins with submicrometer feature size on a glass substrate.

EXPERIMENTAL SECTION

Near-Field Instrumentation. Near-field photoimmobilization and near-field sample observation are performed with a homemade scanning near-field optical microscope, mounted on a standard inverted optical microscope (Zeiss Axiovert 100). The SNOM head is composed of a near-field probe holder and a compact distance control module. The probe-to-sample distance control is based on interferometric detection of the lateral force induced when the tip is laterally vibrating over the sample. This technique, described in detail in ref 8, allows interaction forces between the probe and the sample to be kept constant. Assuming that the distance-to-sample is directly correlated to the interaction forces, topographical information of the sample is obtained.

The near-field probes are obtained by chemical etching of monomode optical fibers and subsequent metallization with aluminum (9). Before using them for photoimmobilization, the optical probe quality is tested by a set of optical measurements with a characterization of transmission and light distribution at the apex. Scanning of a calibrated test object allows evaluation of the diameter of the optical probe. Tips used in this study show a diameter between 60 and 110 nm with transmission between 6×10^{-4} and 5×10^{-3} .

The samples are scanned under the tip with an x - y - z linear piezo scanner (Physik Instrument). The linearity and the absence of creep are ensured by a closed loop control of the scanner.

Near-field photochemistry is induced by UV light emitted from an argon laser (Spectra Physics 2020) coupled into the optical fiber-based probe. Detection of fluorescein-labeled BSA is performed by near-field fluorescence, excited by 488 nm Argon laser light. Emitted fluorescence light is collected by a microscope objective (Zeiss 40x, N.A.: 0.6) and, after filtration of the excitation light with a notch filter (OD6), it is finally analyzed with an avalanche photodiode (APD, EG&G, SPCMAQ131FC).

Photoresist. Photoresists are radiation-sensitive materials commonly used in semiconductor technology for patterning. The resist is exposed to ultraviolet radiation through a mask containing the desired patterns. In positive photoresists, the exposed regions are made soluble, whereas in negative photoresists they remain insoluble and the nonilluminated resist is dissolved away. A diazoquinone-inhibited novolak positive photoresist S1813 available from Shipley is used for all experiments. The hydrophobic diazoquinone inhibitor strongly absorbs UV light (350–400 nm). The addition of the hydrophobic inhibitor to the hydrophilic novolak resin retards the dissolution of the mixture in alkaline developer. Upon photoexposure, the inhibitor is destroyed and rearranged into hydrophilic acid, which dissolves in the alkaline developer. The coating and the developing processes are made using Rite Track 88 series equipment. Four-inch diameter plain silicon wafers are coated with 1.5 μ m photoresist. MF-319 is used for development of the exposed wafer. The obtained patterns are preliminary

observed with a far-field optical microscope. Precise characterization of patterns is carried out with an atomic force microscope (Autoprobe CP, Thermomicroscopes).

Photoreagents. *N*-(*m*-(3-(Trifluoromethyl)diazirine-3-yl)phenyl)-4-maleimidobutyramide (MAD) is synthesized according to Collioud et al. (10). Silicon wafers with a naturally grown oxide layer are used as substrate. The 5×5 mm² samples are cut from the wafer, washed with an ultrasonic treatment (2×5 min in ethanol Uvasol and then 2×5 min in hexane Uvasol), and dried for 2 h at 10^{-2} mbar. The MAD solution (0.5 mM in ethanol, 10 μ L) is deposited as a droplet released by a micropipette. The samples are dried for 2 h at room temperature under vacuum of 50 mbar before irradiation. Irradiation is performed at 350 nm, keeping a constant irradiance of 3.8 mW/cm² during 5 min. The samples are then washed according to the following process: 2×5 min ethanol Uvasol, 2×5 min hexane Uvasol. Samples are characterized and analyzed with time-of-flight secondary ion mass spectroscopy (ToF-SIMS). The ToF-SIMS system used is a mass spectrometer from PHI-EVANS & Associates (described in detail in (11)) equipped with a pulsed FEI Ga⁺ ion gun operated at 25 kV for high lateral resolution (unbunched beam). Sample surface is biased ± 3 kV with respect to the grounded extraction electrode for positive and negative mode SIMS, respectively. The 400 pA DC ion beam current is pulsed at 5 kHz repetition rate (8 ns pulse width, measured with the unbunched beam). The analyzed area is estimated to 126×126 μ m². The analysis is performed under so-called "static" conditions with an ion dose in the order of 9×10^{11} ions/cm². F[−] is the most characteristic ion of the MAD molecule (12), and images of this ion are displayed to demonstrate the topical addressability with ToF-SIMS imaging.

Bovine serum albumin (BSA) is functionalized with 3-(trifluoromethyl)-3-(*m*-isocyanophenyl)diazirine (TRIMID), a light activable agent that absorbs UV light at 350 nm to obtain T-BSA. The detailed protocol for the preparation of T-BSA is described in (13). After modification, T-BSA carries 7 to 9 mol aryldiazirines per mole of BSA. For subsequent fluorescence detection, BSA labeled with fluorescein (F-BSA) is mixed with T-BSA. Glass substrates are prepared according to the following protocol: overnight treatment in HCl 37%, 3×5 min sonification in Millipore quality water, and drying 2 h under vacuum/3 mbar at ambient temperature. A solution of proteins (4 μ g of F-BSA, 4 μ g of T-BSA, 10 μ L of PBS 1:100 = 0.5 mM sodium phosphate buffer pH 7.4 containing 1.5 mM NaCl) is deposited on the glass substrate as a droplet released from a micropipette and then dried under vacuum at 30 to 40 mbar. After photoimmobilization by UV argon laser light, the sample is washed to eliminate the physically adsorbed molecules according to the following process: 3×10 min in 3 M KSCN, overnight in PBS/0.05% Tween solution, 3×10 min in PBS/0.02% Tween, 2×5 min in PBS 1:100, 10 min in 10 mM HCl, 3×5 min in Millipore quality water. The obtained patterns are observed and characterized using near-field fluorescence optical microscopy and atomic force microscopy in contact and noncontact mode (Autoprobe CP, Thermomicroscopes).

RESULTS

Cruciform patterns have been polymerized into photoresist, scanning the near-field probe above the deposited resist in two successive perpendicular lines. Figure 1 shows an AFM observation (contact mode) of the resulting pattern obtained after resist development. The

Figure 1. AFM recording of a near-field-induced cruciform pattern in S1813 positive photoresist (AFM image by E. Dupas, IGA-EPFL).

Figure 2. Imaging of ToF-SIMS (registration of F^-) of a MAD-coated surface after mask-assisted photopatterning.

estimated size of the near-field probe used in this experiment is 120 nm (optical aperture), for a transmission of 9.2×10^{-4} . This leads to an estimated illumination dose of 29.8 mJ/cm^2 . The line width measured at a typical line section is 223 nm FWHM, with a depth of 43 nm. This shows that sub-wavelength patterning is possible with the SNOM technique, even with a standard photoresist deposited as a 1.5 μm thick layer.

The same technique applied to polymerize the photoresist is used to photobond a cruciform pattern of biomolecules. Two approaches are considered: In the first one, demonstration of near-field photoimmobilization is performed with a low molecular weight diazirine-based molecule (MAD), that can be used as a “building block” in the functionalization of surfaces. In the second approach, a biologically relevant molecule is directly photoimmobilized onto the surface. This is demonstrated using BSA functionalized with the photoactive diazirine and illuminated in the near-field of the probe.

Figure 2 is a ToF-SIMS image of MAD photobonded onto a Si surface. The photobonding is obtained by illuminating a monolayer of MAD deposited onto a Si wafer, using a mask patterning technique with parallel beam far field illumination with a light irradiance of 8.5 mW/cm^2 . The light dose for optimal photobonding of MAD is measured in the range between 1.1 J/cm^2 to 1.6 J/cm^2 . At lower doses, no immobilization occurs. The square

patterns of $40 \times 40 \text{ μm}^2$ show a transition width of 2 μm from immobilized to nonimmobilized zones. Using near-field immobilization with a comparable light dose, it is possible to immobilize MAD with a finer spatial resolution. However, we have not succeeded in clearly demonstrating sub-wavelength patterns of photoimmobilized MAD. This is related to the difficulty to observe a deposited monolayer with submicrometer lateral feature size. Several analysis techniques have been applied to observe the near-field immobilized MAD pattern, such as ToF-SIMS and scanning microscopies (AFM, SEM, fluorescence SNOM). ToF-SIMS submicrometer imaging is in principle possible. However, it requires a small probed area that implies the use of an increased ion dose. This leads, in the case discussed here, to surface damage, which prohibits the acquisition of images on ultrathin submicrometer MAD structures. Further imaging techniques such as AFM, or SEM of OsO_4 -treated surfaces (OsO_4 reacts with the maleimido group, thus enhancing contrast), do not lead to a sufficient contrast to allow quantitative characterization of the patterns. Even near-field fluorescence microscopy with fluorescence-labeled MAD leads to inconclusive results when performed on immobilized monolayer. This is attributed to quenching of the fluorescence when the fluorescent marker is directly bound to the surface.

In a second approach, biomolecules have been photoimmobilized using the same technique. This is performed onto a glass substrate using BSA, previously functionalized with the photoactivable diazirine and labeled with fluorescein isothiocyanate for subsequent detection. Immobilization in the near-field is obtained with a light dose of 2.1 J/cm^2 . The threshold for immobilization is sharp at the lower end. When the dose is increased up to 5 times above that threshold, no significant difference in the attachment is observed. The thickness of the adsorbed proteins is measured by AFM before immobilization, the average result being $165 \text{ nm} (\pm 30 \text{ nm})$. Far-field fluorescence microscopy is used to localize where immobilization has taken place and to optimize the illumination dose. Working with small structures and low concentration requires an optimal washing process. This process, described in the previous paragraph, is 2.5 times more efficient to eliminate the adsorbed proteins compared to standard procedures without chaotropic agents.

Figure 3 shows the topography (a) and the near-field fluorescence image (b) of the immobilized BSA pattern. Observation and immobilization are performed with the same tip. The cruciform pattern is clearly visible, both in topography and as near-field fluorescence contrast. Figure 4 shows the topographical and light profile of the smallest structure obtained. The width (FWHM) of the topographical profile is 470 nm. The immobilized proteins thickness is $40 \text{ nm} \pm 15 \text{ nm}$ as confirmed by independent AFM observations.

For comparison, the best resolution obtained on BSA by mask-assisted photoimmobilization is 3.8 μm applying mask-contact modes and 1.9 μm with the mask-projection procedure.

DISCUSSION

The potentiality of SNOM for nanostructuring is clearly demonstrated using standard photoresist chemistry. Sub-wavelength feature size has been obtained with standard coating and development processes. Improvement in feature size can be obtained by using an ultrathin photoresist layer ($<100 \text{ nm}$), as recently demonstrated by Alkaisi et al. (14) with evanescent near-field optical lithography.

Figure 3. SNOM observation of photobonded BSA. The cruxiform structure is induced by near-field patterning. (a) Topographical image. (b) Fluorescence near-field image.

The aryldiazirine chemistry is appropriate for surface engineering, as shown using mask-assisted illumination. The size of the molecules and their capacity to form ultrathin films is advantageous for near-field structuration at submicrometer size, due to the strong exponential decay of the near-field intensity with the sample to surface distance. Thus, immobilization of the photocrosslinker MAD should be considered as a first step in building more complex structures (15). However, the contrast between derivatized and nonderivatized zones is difficult to monitor except as a chemical contrast (ToF-SIMS), which is limited in lateral resolution in this case due to surface damaging. Topographical and optical contrasts, including derivatization of MAD with a fluorophore (thiolated FITC), did not reveal the surface patterns. Attaching molecules offering functionality to the MAD is, however, a promising route to develop submicrometer scale patterns.

The photoimmobilization of T-BSA shows that near-field photochemistry of more complex structures such as proteins is also achievable using SNOM. The feature sizes obtained in near field are four times smaller than the

Figure 4. SNOM topographical image of photoimmobilized BSA (a). The curves display the topographical and optical profiles across the BSA structure, along the AB line (b).

structures obtained with mask techniques, showing the advantage of a near-field approach. The present study shows, however, that on the processing side, the key factors for submicrometer scale immobilization are the thickness of the protein layer before photoimmobilization and the efficiency of the washing process. The first factor is important to ensure that photoactivation is performed in the near field, thus exploiting the high spatial localization of the light. The second factor is necessary to maintain a sufficient contrast between photobonded and adsorbed molecules when working at low molecular density. The adsorbed proteins that are not washed away from the surface are of critical importance when the thickness of the proteins layer is reduced. To take full advantage of the near field, it is mandatory to use thin layers, optimally monomolecular layers. For BSA, the decrease of the layer thickness reduces the signal ratio between the immobilized zones and the nonimmobilized zones, as the residual nonspecific adsorption (after washing) does not depend on the thickness of the initially deposited molecule layer.

On the instrumental aspect, the critical point in the achievement of fine immobilized patterns is the quality of the optical probes. This criterion is even more important when SNOM is used as structuring tool, as it is when used as an observation tool. Indeed, tips giving similar results in the test process on calibrated objects can lead to very different pattern size in the immobilization process. The only way so far to determine if a tip is suitable for near-field immobilization is by experimental surface structuration. Reproducibility of the pattern size depends highly on the tips characteristics, and future improvements in tip fabrication will contribute to the development of reliable near-field photochemistry.

CONCLUSION

Investigations presented in this work show that near-field photoimmobilization using the SNOM technique is a yet unexploited way to induce submicrometer biopatterning of surfaces. The potential of using the SNOM as a structuring tool is demonstrated with standard photoresist, showing structures down to 223 nm. This method is also suitable to achieve immobilization of diazirine-based compounds, as it is shown with feature sizes as small as 470 nm.

The two key factors of near-field photoimmobilization are the chemistry process and the optical probes. On one hand, further development and fine-tuning of chemistry aspects are needed to fully exploit the potential of near-field photoimmobilization and reach even smaller structure size. On the other hand, the reproducibility of the method is highly dependent on the quality of the optical probe, and special attention should be paid to the fabrication or the choice of the optical probe. Near field photoimmobilization may thus become a very promising approach for the immobilization of nanometer size domains in future generations of biosensors.

Water-Soluble Lipopolymer for Gene Delivery

Sang-oh Han, Ram I. Mahato, and Sung Wan Kim*

Center for Controlled Chemical Delivery (CCCD), Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112. Received October 6, 2000; Revised Manuscript Received December 27, 2000

The use of biocompatible polymeric gene carriers may overcome the current problems associated with viral vectors in safety, immunogenicity, and mutagenesis. Nontoxic water-soluble lipopolymer (WSLP), poly{(ethylenimine)-co-[N-(2-aminoethyl) ethyleneimin]-co-N-(N-cholesteryl oxycarbonyl-(2-aminoethyl)-ethylenimine)} was synthesized using branched poly(ethylenimine) (PEI, mw 1800) and cholesteryl chloroformate. Following synthesis and purification, the structure and molecular weight of WSLP were confirmed by ^1H NMR and MADI-TOF mass spectrometry, respectively. The percentage of cholesterol conjugated to PEI was about 47%, and the average molecular weight of WSLP was approximately 2000 Da. WSLP/pDNA complexes were prepared at different N/P (nitrogen atoms of WSLP/phosphate of plasmid DNA) ratios and characterized in terms of particle size, ζ potential, osmolarity, surface morphology, and cytotoxicity. WSLP condensed plasmid DNA when N/P ratio reached 2.5/1 and no free DNA was detected at N/P ratio of 5/1 and above, as determined by agarose gel electrophoresis. The mean particle size was in the range of 25.9 to 148.5 nm and was dependent on N/P ratios. Atomic force microscopy (AFM) showed complete condensation of plasmid DNA with spherical particles of ~ 50 nm in diameter. WSLP/pDNA complexes or WSLP itself were nontoxic to CT-26 colon adenocarcinoma and 293 T human embryonic kidney transformed cells when formulated at the N/P ratio of 10/1 and below as determined by MTT assay. In contrast, PEI25000/pDNA complexes were toxic to these cells. Erythrocytes aggregated when incubated with PEI25000/pCMV–Luc complexes at high DNA concentrations, but there was little aggregation with WSLP/pCMV–Luc complexes. WSLP/pCMV–Luc complexes demonstrated higher transfection efficiency in both CT-26 and 293 T cells compared to PEI25000- or PEI1800-based formulations. WSLP/pCMV–Luc complexes are nontoxic and showed enhanced in vitro transfection. Thus, WSLP will be a suitable carrier for in vivo gene delivery.

INTRODUCTION

Development of improved gene transfer methods is prerequisite for gene therapy to realize its clinical potential. Although currently less effective than viral vectors, cationic lipids and polymers are increasingly being considered for in vivo gene delivery into the animal models and patients due to their relative stability, greater carrier capacity, and ease of large scale production (1). Current cationic liposomes and polymers from complexes with plasmid DNA via electrostatic interaction and tend to form large aggregates on storage. These complexes are efficient at transfecting cells in culture, yet are poor at diffusing within a tissue or escaping from blood vessels (2–5). Polyethylenimine (PEI) has been reported to be effective for gene delivery, because plasmid DNA can be delivered to the cytoplasm via endosomes due to the proton-sponge effect of PEI (6, 7). However, high molecular weight PEI is toxic to the cells, and PEI/DNA complexes are prone to aggregation (8).

The general structure of a cationic lipid has three parts: (i) a hydrophobic lipid anchor group, which helps in forming micellar structure and can interact with cell membranes; (ii) linker group, such as an ester, amide or

carbamate; and (iii) a positively charged headgroup, which interacts with plasmid DNA, leading to its condensation. The hydrophobic group lipid anchors can be either a cholesterol group or fatty acid chains (9). The linker group is an important component and determines the chemical stability and biodegradability of cationic lipids. These linker groups should be biodegradable yet strong enough to survive in a biological environment. Ester linkage between hydrophobic lipid anchors and cationic headgroups are likely to provide biodegradability to cationic lipids. Cationic lipids with T-shaped headgroups tend to be more effective than linear counterparts (10). However, current cationic lipids are water insoluble, and most of them require the formation of liposomes. Complex formation between plasmid DNA and cationic liposomes usually produces large size complexes, which are poorly extravasated through the capillary endothelia.

In this study, we designed an effective water-soluble lipopolymer (WSLP) by combining the advantages both of cationic liposomes and PEI, which condenses DNA and enhances endosomal release due to its tertiary amines, while the lipid coating on the DNA increases its permeability through cell membranes (11). Monomolecular pDNA collapse has been suggested to occur only for cationic lipid or lipopolymer concentrations below the critical micellar concentrations (CMC) and are used for complex formation with DNA (12). We synthesized WSLP using PEI and cholesteryl chloroformate, and characterized it for its physicochemical properties, cytotoxicity, and in vitro transfection efficiency.

MATERIALS AND METHODS

Materials. Poly(ethylenimine) (PEI, mw 1800) was purchased from Polysciences, Inc. (Warrington, PA). Cholesteryl chloroformate, PEI (mw 25000), triethylamine, glucose, deuterium oxide (D_2O), and 1,6-diphenyl-1,3,5-hexatriene (DPH) were purchased from Aldrich Chemical Co. (Milwaukee, WI). 3-[4,5-Dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), terrific broth, ampicillin, Rosewell Park Memorial Institute (RPMI-1640) medium, Dulbecco's modified essential medium (DMEM), and 1,4-dioxane- d_8 were purchased from Sigma Chemical Co. (St. Louis, MO). LipofectAMINE, phenol:chloroform:isoamyl alcohol (25:24:1, v/v) and proteinase K were purchased from Gibco-BRL (Gaithersburg, MD). QIAGEN maxi plasmid purification kit were purchased from QIAGEN (Valencia, CA). Methylene chloride and dimethyl sulfoxide (DMSO) were purchased from Fisher Scientific (Fair Lawn, NJ). RQ1 RNase-free DNase, λ HindIII, ScaI, buffer B, 100bp DNA stepladder, 1kb DNA stepladder, reporter lysis buffer, and bacterial strain DH5 α were purchased from Promega (Madison, WI). Albumin standard and bicinchoninic acid (BCA) protein assay kit were purchased from Pierce Chemical Co. (Rocford, IL). PCMV-Luc was obtained as a kind gift from Dr. Mitsuru Hashida of Kyoto University, Japan.

Synthesis of Water Soluble Lipopolymer. Three grams of PEI (mw 1800) was stirred on ice in a mixture of 10 mL of anhydrous methylene chloride and 100 μ L of triethylamine for 30 min. One gram of cholesteryl chloroformate was dissolved in 5 mL of anhydrous ice-cold methylene chloride and then slowly added to the PEI solution for 30 min. The mixture was stirred for 12 h on ice, and the resulting product was dried on a rotary evaporator. The powder was dissolved in 50 mL of 0.1 N HCl and then filtered through the glass microfiber filter. Cholesteryl chloroformate is well soluble in methylene chloride, diethyl ether, and acetone. Therefore, nonreacted cholesteryl chloroformate was removed from the product by washing three times in these different organic solvents as follows: the aqueous solution was extracted three times with 100 mL of methylene chloride to remove nonreacted cholesterol chloroformate, and then extracted aqueous solution was filtered through a glass microfiber filter. The product was concentrated by solvent evaporation, precipitated with large excess acetone, and dried under vacuum. The powder was dissolved in water and precipitated three times with acetone. After washing with methanol, the product was washed three times with diethyl ether. The white powder product was analyzed using matrix-assisted laser desorption-time-of-flight (MALDI-TOF) mass spectrophotometry (Perspective Voyager-DE STR, PE Applied Biosystem Co., Framingham, MA) with *trans*-4-hydroxy-3-methoxycinnamic acid as matrix and 400-MHz ^1H nuclear magnetic resonance (^1H NMR, Varian, Inc., Palo Alto, CA) and then stored at $-20^\circ C$ until used.

Critical Micellar Concentration. The critical micellar concentration (CMC) of WSLP was determined using the dye solubilization methods as described previously by Jeong et al. (13). Various amounts of WSLP was dissolved in 1 mL of deionized water to adjust the concentrations of WSLP ranging from 9.28 to 76021.76 μ g/mL. To prepare 0.4 mM stock solution of 1,6-diphenyl-1,3,5-hexatriene (DPH), 2.2 mg of DPH was dissolved in 23.54 mL of methanol followed by sonication for 15 min. Ten microliters of 0.4 mM DPH was added to 1 mL of WSLP and stored in dark for 6 h. The reference solution was also prepared by adding 10 μ L of 0.4 mM DPH to 1

mL of water. The absorption spectra of these samples were measured at 200–600 nm using a UV/vis/NIR spectrometer (Perkin-Elmer Lambda 19). The absorbance at 356 nm was plotted against the concentration of WSLP, and the crossing point of the extrapolated two straight lines was defined as the CMC of WSLP.

Amplification and Purification of Plasmid. Plasmid DNA encoding Luciferase driven by CMV promoter (pCMV-Luc) was constructed by inserting the HindIII/XbaI firefly Luciferase cDNA fragment from pGL3-control vector into the HindIII/XbaI site of pcDNA3 (14). This plasmid DNA was transformed in *Escherichia coli* DH5 α and amplified in terrific broth media at $37^\circ C$ overnight with 225 rpm. The amplified plasmid DNA was purified by QIAGEN Maxi plasmid purification kit. Purified plasmid DNA was dissolved in Tris-EDTA (TE) buffer, and its purity and concentration were determined by ultraviolet (UV) absorbance at 260 nm. The optical density ratios at 260–280 nm of these plasmid preparations were in the range of 1.7–1.8. To confirm that there is no rearrangement of the gene during cloning and propagation of the plasmid DNA, restriction enzyme assay was done using ScaI and HindIII followed by 1% agarose gel electrophoresis.

Gel Retardation and DNase Protection Assays. WSLP/pDNA complexes were prepared at various N/P (nitrogen atoms of WSLP/phosphate of plasmid DNA) ratios ranging from 1.25 to 20.0. In phosphate buffered saline, the positively charged polymer/plasmid complexes tend to aggregate on storage. Therefore, WSLP/pLuc complexes were prepared in the presence of 5% glucose to adjust the osmolality at 290–310 mOsm and incubated for 15–20 min at room temperature to allow complex formation between lipopolymer and pDNA. The samples were electrophoresed on agarose gel in $1\times$ Tris-boric acid-EDTA (TBE) buffer at 80 V until the $1\times$ orange blue loading dye ran through 80% of the gel. A 1kb marker was used as a DNA size marker. The gel was stained with 0.5 μ g/mL ethidium bromide for 45 min and analyzed on UV illuminator to show the location of DNA.

For DNase protection assay, WSLP/pDNA (5/1, N/P) complexes were incubated at $37^\circ C$ in the presence of DNase I (45 μ L). At 0, 5, 10, 15, 30, 60, and 120 min postincubation, 50 μ L of the samples was taken into Eppendorf tubes and was mixed with 100 μ L of stop solution (400 mM NaCl, 100 mM EDTA) under mild vortexing. The samples were then mixed with 12 μ L of 10% sodium dodecyl sulfate (SDS) and incubated at $65^\circ C$ overnight. The DNA was then extracted with the mixture of Tris-EDTA saturated phenol: chloroform: isoamyl alcohol (25:24:1, v/v). The extracted DNA was precipitated with 700 μ L of absolute ethanol at 12000 rpm for 30 min and washed with 70% ethanol. The DNA precipitate was dried by air followed by dissolving in 10 μ L Tris-EDTA buffer, and the plasmid DNA integrity was assessed using 1% agarose gel electrophoresis.

Atomic Force Microscopy. Morphology of WSLP/pDNA complexes was analyzed using atomic force microscopy (AFM) as described by Maheshwari et al. (15). Briefly, red mica was freshly cleaved as a thin wafer and then soaked in 33 mM MgAc $_2$ overnight to favor the replacement of potassium ions by divalent magnesium ions for stronger DNA binding. Mica was then sonicated for 30 min in distilled water, and its surface was subjected to glow discharge for 15 s in a vacuum between 100 and 200 mTorr. As soon as the mica surface was exposed to air, 20 μ L of 0.1 mg/mL of WSLP/pDNA complexes was placed on mica surface and allowed to

stick for 2 min. The mica surface was then rinsed gently with deionized water and blow-dried with nitrogen gas. Nanoscope II SFM (Digital Instruments, Santa Barbara, CA) was used for imaging at room temperature in the attractive force regime and under 30–60% relative humidity. The microscope was operated using cantilever oscillation frequencies between 12 and 24 kHz. Force minimization was maintained by reducing the set point voltage to minimize sample damage. To remove the high frequency noise in the slow scan direction, only minimal filtering was applied to the image.

Particle Size and ζ Potential Measurement. ζ potential and particle size of WSLP/pDNA complexes were measured as described by Mahato et al. (16). Briefly, polymer/pDNA complexes were prepared as discussed above and were diluted four times in the cuvette, and the electrophoretic mobility was determined with Zeta-PALS (Brookhaven Instruments Corp, Holtsville, NY). All experiments were performed at 25 °C, pH 7.0 and 677 nm wavelength at a constant angle of 15°. The ζ potential was automatically calculated from the electrophoretic mobility based on Smoluchowski's formula. Following the determination of electrophoretic mobility, the samples were subjected to mean particle size measurement by the same equipment using the same light source and wavelength. The particle size was reported as effective mean diameter.

Cell Lines. 293T human embryonic kidney transformed cells were obtained from ATCC (Rockville, MD) and were grown and maintained in DMEM medium containing 10% FBS, 100 units/mL penicillin and 2.2 mg/mL sodium bicarbonate at 37 °C humidified 5% CO₂.

CT-26 colon adenocarcinoma cell lines was a kind gift from Dr. Charles Tannenbaum of Cleveland Clinic Foundation, Cleveland, OH (17). Tumor cells were grown and maintained in RPMI 1640 medium which was supplemented with 10% fetal bovine serum (FBS), 100 units/mL penicillin and 2.2 mg/mL sodium bicarbonate at 37 °C and humidified 5% CO₂.

Cytotoxicity Assay. Cytotoxicity of WSLP/pDNA complexes prepared at various charge ratios were assessed as described by Fisher et al. (18). The fraction of nitrogen atoms that are protonated at neutral pH is unknown. Therefore, the PEI/DNA ratios are usually calculated on the basis of PEI nitrogen per DNA phosphate (i.e., N/P ratio) (19). The optimal N/P ratio of PEI/pLuc complexes was determined, according to several publications, to be around 5/1 (6, 20–23). However, Boussif et al. mentioned that the transfection efficiency of PEI (800 and 50 kDa) was highest at 13/1 N/P ratio (19). In their studies, the transfection efficiency was reported in terms of relative light units (RLU). Transfection efficiency/cytotoxicity balance is known to increase with increase in the polymer molecular weight and charge ($\pm$) or N/P ratios. Although PEI (mw 800 or 50 kDa)/pDNA complexes showed high transfection at 13/1 N/P ratio, many cells might have died due to high toxicity. To normalize the cytotoxic effect of the polymer, we reported our transfection results in terms of RLU/mg of total proteins. CT-26 cells and 293T cells were seeded in 96 well plates at 4000 cells/well and incubated at 37 °C for 24 h. After checking the cell confluency, which was over 70%, gene carriers were added to the cells. Following 48 h of incubation at 37 °C, 25 μ L of 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) stock solution in phosphate-buffered saline (5 mg/mL) was poured into each well until it reached a final concentration of 0.5 mg/mL MTT. The plate was then incubated at 37 °C in 5% CO₂ for 5 h. The medium

Figure 1. Synthesis scheme of poly{(ethylenimine)-co-[N-2-(aminoethyl)ethylenimine]-co-[N-(N-cholesteryloxycarbonyl-(2-aminoethyl))ethylenimine]}.

was removed, and 150 μ L of DMSO was added to dissolve the formazan crystals. The plate was read spectrophotometrically at 570 nm using an ELISA plate reader. The relative cell viability was calculated as $[\text{Abs}]_{\text{sample}}/[\text{Abs}]_{\text{control}} \times 100$.

Erythrocyte Aggregation Assay. Erythrocyte aggregation assay was done as described by Ogris et al. (24). Briefly, fresh blood was collected from a BALB/c female mouse and immediately mixed with sodium citrate to a final concentration of 25 mM. Erythrocytes were washed on ice three times in Ringer's solution. Five and ten microliters of erythrocytes/well of six well plate were mixed with WSLP/pCMV–Luc (10/1, N/P) complexes at a dose of 20 μ g DNA/well. PEI 25000/pCMV–Luc (5/1, N/P) complexes were used as a control. The cells containing erythrocytes were incubated for 1 h at 37 °C.

In Vitro Transfection. CT-26 cells and 293 T cells were seeded separately in six well tissue culture plates at 3×10^5 cells per well in 10% FBS containing RPMI 1640 or DMEM media. Cells achieved 70% confluency within 24 h after which they were transfected with WSLP/pDNA complexes prepared at different charge (N/P) ratios ranging from 5/1 to 20/1. The total amount of plasmid DNA loaded was maintained constant at 2.5 μ g/well and transfection was carried out in absence of serum. The cells were allowed to incubate at 37 °C in the presence of complexes for 6 h in CO₂ incubator followed by replacement of 2 mL of RPMI 1640 or DMEM containing 10% FBS. Thereafter the cells were incubated 37 °C for additional 36 h. Cells were lysed using 1X lysis buffer after washing with cold PBS. Total protein assays were carried out using BCA protein assay kit. Luciferase activity was measured in terms of relative light units (RLU) using 96 well plate Luminometer (Dynex Technologies Inc, Chantilly, VA). The Luciferase activity was monitored and integrated over a period of 30 s. The final values of Luciferase were reported in terms of RLU/mg total protein. In all the above experiments, both naked DNA as well as untreated cultures were used as positive and negative controls, respectively.

RESULTS

Synthesis of Water-Soluble Lipopolymer. Water-soluble lipopolymer (WSLP) was synthesized using branched PEI of 1800 Da and cholesteryl chloroformate

Figure 2. Determination of chemical structure and molecular weight of water-soluble lipopolymer (WSLP) by ¹H NMR spectra (A) and MALDI-TOF mass spectra (B).

(Figure 1). Following synthesis and purification, the structure and molecular weight of WSLP were determined using 400-MHz ¹H NMR and MALDI-TOF mass spectrometry. The NMR results are as follows (Figure 2 A): ¹H NMR (400 MHz, D₂O + 1,4-dioxane-*d*₆) δ 0.93 (s, 4.28 H of CH₃ from cholesterol (a)); δ 1.08 (d, 17.89 H of (CH₃)₂ from cholesterol (b)); δ 1.14 (d, 8.9 H of CH₃ from cholesterol (c)); δ 1.24 (d, 9.0 H of CH₃ from cholesterol (d)); δ 1.35 and δ 1.48 (t, 16.68 and 17.53 H from CH₂-CH₂ and CHCH₂ from cholesterol (e)); δ 3.1 (59.6 H of NHCH₂CH₂ from the side chain of PEI (f)); δ 3.4 (80.8 H of =NCH₂CH₂NH₂ from backbone of PEI (g)); δ 5.65 (1 H of =C=CHC from cholesterol (h)). The peak appearing at δ 0.8–1.9 was from cholesterol. The amount of

cholesterol conjugated to PEI was determined to be about 47%. MALDI-TOF mass spectrophotometric analysis of WSLP showed its molecular weight to be approximately 2000 (Figure 2B). Many intensity peaks appeared from 1000 to 3500 (*m/z*); however, the majority peaks were at around 2000 (*m/z*). Expected position is 2414: 1800 (mw of PEI) + 449–35 (mw of cholesteryl chloroformate after removal of one chloride). The data suggest that the majority of WSLP synthesized were of 1/1 molar ratio of cholesterol and PEI of 1800 Da, although some were either not conjugated or conjugated at the molar ratio of 2/1 (cholesterol/PEI). The molecular weight of WSLP could not be measured using MALDI-TOF mass spectrophotometry at various concentrations and matrices.

Figure 3. Determination of critical micellar concentration of water-soluble lipopolymer (WSLP) by dye solubilization methods.

Critical Micellar Concentration. WSLP is amphiphilic in nature because water is a poor solvent for hydrophobic cholesterol while it is a good solvent for hydrophilic PEI. With increasing its concentration, WSLP may form multimolecular micelles or micellar aggregates. The solubility of WSLP in water greatly depends on the molar ratio of PEI and cholesterol, and thus it is important to maintain the hydrophobic–hydrophilic balance. DPH is a hydrophobic dye, which has a significantly lower absorptivity at 356 nm in an aqueous environment compared with that in the hydrophobic environment. With the formation of micelles, DPH is preferentially partitioned into the hydrophobic core of micelles, resulting in the increase in the absorbance of DPH (13). The abrupt increase in absorbance reflects the micelle formation. As shown in Figure 3, CMC of WSLP was determined to be 1.43 mg/mL which was the cross-point of extrapolating the absorbance at low and high concentration regions.

Band Retardation and DNase Protection Assays. DNA condensing ability of WSLP was determined by gel retardation assay. The positively charged headgroup of WSLP makes strong complexes with the negatively charged phosphate ions on the base backbone on plasmid DNA. When the value of N/P reached 5/1, free DNA could not be detected on agarose gel electrophoresis (data not shown). WSLP could protect pDNA from digestion by DNase at least for 2 h at 37 °C, whereas naked DNA was completely digested by DNase within 5–10 min of incubation at 37 °C (data not shown).

Surface Morphology. DNA condensation, its reduction in overall size and the resulting surface morphology were captured by AFM (Figure 4). Plasmid DNA when complexed with WSLP at the N/P ratio of 10 was completely condensed and formed spherical particles of ~50 nm. The AFM image revealed that the naked pDNA was condensed from its natural extended state in water to about one-tenth of its size in the complex. The small-sized complexes might be of special significance, as it could facilitate enhanced mobility of the complex through the plasma membrane as well as trafficking across the cytoplasm.

Particle Size and ζ Potential. The compaction of plasmids into particulates of defined colloidal and surface

Figure 4. Atomic force microscopy (AFM) image of WSLP/pCMV–Luc complexes (10/1, N/P). Condensed plasmid DNA forms an ellipsoidal structure as seen in z-direction.

properties plays a major role in controlling stability, biodistribution, and intracellular fate of formulated plasmids. Interaction with the tissue components and transport in the interstitial space and uptake characteristics by the cells. Low aggregate formulation and a small-sized complex would enhance the diffusivity and cellular uptake of plasmid DNA in the tissues. The particle size distribution of WSLP/pDNA complexes was determined by dynamic light scattering. In contrast to the large size of naked DNA (25), complex formation between WSLP and plasmid DNA produced small size particles. The mean particle size of the complexes was in the range of 25.9 to 148.5 nm and was dependent on N/P ratios (Table 1). At the N/P ratio of 1.25, plasmid DNA was not completely neutralized, resulting in the formation of heterogeneous particles with the mean diameter of 148.5 nm. In contrast, the mean particle size of WSLP/pDNA complexes 40 nm or below, when the complexes were formed at the N/P ratios of 2.5 and 10. However, at 20/1 (N/P) ratio these complexes had narrow particle size distribution with a mean diameter of 61.8 nm.

ζ potential of WSLP/pDNA complexes prepared at different charge ratios was greatly dependent on the charge ratio and linearly increased with the increase in the charge ratios. At the N/P ratio of 2.5/1, it was -41.35 mV, but increased to 8.23 mV when formulated at N/P ratio of 5/1. The gel retardation data confirm the above finding, as there was no DNA movement seen at the N/P ratio of 2.5/1 or above.

Cytotoxicity Assay. The cytotoxicity of WSLP and WSLP/pCMV–Luc complexes after 24 h of incubation at 37 °C was determined using MTT assay on CT-26 colon adenocarcinoma (Figure 5 A) and 293 T human embryonic kidney transformed cells (Figure 5 B). The cytotoxicity of WSLP and WSLP/pCMV–Luc complexes was compared with commercially available cationic liposomes (LipofectAMINE/pCMV–Luc, 5/1 w/w) and branched PEI of 25000 Da (PEI25000/pCMV–Luc, 5/1 N/P) complexes. LipofectAMINE reagent is 3:1 (w/w) liposome formulation of the polycationic lipid 2,3-dioleoyloxy-*N*-[2(sperminecarboxyamido)ethyl]-*N,N*-dimethyl-1-propanaminium trifluoroacetate (DOSPA, mw 867) and the neutral lipid dioleoyl phosphatidylethanolamine (DOPE, mw 744) in membrane-filtered water. Based on its chemical structure, LipofectAMINE has two primary amines, two

Table 1. Mean Particle Size and ζ Potential of WSLP/pDNA Complexes

N/P ratios of WSLP/pDNA	1.25/1	2.5/1	5.0/1	10.0/1	20.0/1
mean particle size (nm)	148.5 $\pm$ 0.18	25.9 $\pm$ 0.02	41.6 $\pm$ 0.05	42.1 $\pm$ 0.53	61.8 $\pm$ 0.07
mean ζ potential (mV)	-59.12 ± 2.79	-41.35 ± 2.18	8.23 $\pm$ 0.25	37.40 $\pm$ 0.46	61.67 $\pm$ 0.06

Figure 5. Cell viability assay of CT-26 colon adenocarcinoma (A) and 293 T human embryonic kidney transformed (B) cell lines after transfection with WSLP/pCMV-Luc complexes prepared at different N/P ratios in 5% (w/v) glucose. Naked pCMV-Luc, PEI 25000 (25 Kda) and LipofectAMINE were used for comparison. Relative cell viability was at least 85% for all WSLP/pCMV-Luc complexes. In contrast, PEI 25000/pCMV-Luc (5/1, N/P) complexe-based transfection resulted in less than 60% cell viability.

secondary amines, and one quaternary amine, total five positive charges per molecule (26). Subsequent calculations show that 5/1 (w/w) corresponds to 6.82/1 ($\pm$) for LipofectAMINE/pDNA complexes. Following normalization by ($\pm$) charge ratios, we thus confirmed that WSLP/pDNA complexes or WSLP itself were indeed nontoxic to the cell when formulated at N/P ratio of 10 and below (Figure 5). In contrast, LipofectAMINE/pDNA and PEI 25000/pDNA complexes were toxic to the cells. Compared to 293T cells, these complexes were more toxic to CT-26 cells, which granulated and the cell population decreased under the same or lower concentration as WSLP. Similar to WSLP, PEI of 1800 Da was less toxic to both CT-26 and 293T cells compared to PEI 25000 or LipofectAMINE (Figure 5).

Interaction with Erythrocytes. To investigate the interaction of WSLP/pDNA complexes with erythrocytes,

an erythrocyte aggregation assay was performed (Figure 6). Mouse erythrocytes were incubated with either WSLP/pCMV-Luc (10/1, N/P) or PEI25000/pCMV-Luc (5/1, N/P) complexes at a dose of 20 μ g DNA/well. After 2 h of incubation at 37 °C, several erythrocytes were aggregated, when the cells were incubated with PEI25000/pCMV-Luc complexes. In case of WSLP/pCMV-Luc complexes, the extent of erythrocyte aggregation was minimal (Figure 6). Although we did not check the effect of N/P ratios on erythrocyte aggregation, we expect significant increase in erythrocyte aggregation with the increase in N/P ratios of WSLP/pCMV-Luc complexes.

In Vitro Transfection. WSLP/pCMV-Luc complexes formulated at different N/P ratios in 5% (w/v) glucose were evaluated for their transfection efficiency in CT-26 colon carcinoma and 293 T human embryonic kidney transformed cells. Following transfection, cells were

Figure 6. Interaction of WSLP/pCMV-Luc complexes with erythrocytes. Freshly collected erythrocytes were washed thrice with Ringer's solution and incubated with WSLP/pCMV-Luc (10/1, N/P) containing 20 μ g DNA/well of six well plates. Untreated erythrocytes were used as control. PEI25000/pCMV-Luc (5/1, N/P) complexes treated erythrocytes were used for comparison. (A) Nontreated erythrocytes, (B) erythrocytes treated with 5 μ L of WSLP/pCMV-Luc (10/1, N/P), (C) erythrocytes treated with 10 μ L of WSLP/pCMV-Luc (10/1, N/P), and (D) erythrocytes treated with 10 μ L of PEI25000/pCMV-Luc (5/1, N/P) complexes.

lysed, and RLU and total protein concentration were measured. Transfection efficiency increased with the increase in N/P ratios. Among the N/P ratios tested, highest Luciferase activity (RLU/ μ g total protein) was observed at N/P ratio of 20/1 for both CT-26 and 293T cells (Figure 7). The RLU values for WSLP/pCMV-Luc complexes gave several orders of magnitude higher Luciferase levels compared to naked pCMV-Luc. The Luciferase activity of WSLP/pCMV-Luc complexes was also higher than PEI25000/pCMV-Luc (5/1, N/P) complexes when formulated at the N/P ratio of 20/1, but similar when formulated the N/P ratio of 10/1.

DISCUSSION

Current cationic lipid and polymer-based gene carriers are not satisfactory due to the low transfection efficiency, high toxicity, and poor storage stability. In an attempt to combining these two modalities, namely cationic liposomes and polycations, Huang and associates (27) synthesized lipopolylysine for gene transfer. However, treatment for endosomal disruption, such as chloroquine treatment or liposome preparation with colipid DOPE was essential for enhanced gene transfer by lipopolylysine (28). Behr (29) synthesized lipopolyamine, which mediates transfection by itself and does not require any phospholipid to form liposomes. In other words, a micellar complex of lipopolyamine and DNA was sufficient for transfection. Pitard et al. (30) attempted to determine the conditions under which DNA molecules can collapse

into oligomolecular complexes rather than forming large multimolecular aggregates when mixed with lipopolyamine micelles. As lipopoly(L-lysine) requires the addition of chloroquine or the formation of liposomes with colipid DOPE for efficient transfection, Yamazaki et al. (11) grafted cetyl groups as hydrophobic lipid anchors on to PEI with molecular weights of 1800 and 25000 Da and prepared polycation liposomes for gene transfer. However, there is the growing need to avoid the preparation of cationic liposomes and the variability associated with it, especially because the large DNA particles are not good for many in vivo applications, due to their poor extravasation through the capillary endothelia and dispersibility inside the tumor tissues.

Several cholesterol-based cationic lipids have been proven been used for gene transfer. Gao and Huang (2) were the first to synthesize a cholesterol-based cationic lipid 3 β [N, (N',N'-dimethylaminoethane)carbamoyl]cholesterol (DC-Chol) using cholesteryl chloroformate and N,N-dimethylethylenediamine and mixed with colipid DOPE to form cationic liposomes that efficiently transfect mammalian cells. DC-Chol liposomes have already been used in gene therapy applications in the clinical settings (31, 32). These early successes spurred recent interest in the development of novel cholesterol-based cationic lipids. Spermine cholesteryl carbamate and spermidine cholesteryl carbamate have been shown to be more active than DC-Chol, which has only a single protonatable amine. Furthermore, spermine cholesteryl carbamate,

Figure 7. Luciferase activity in cultured CT-26 colon carcinoma (A) and 293 T human embryonic kidney transformed (B) cells after transfection with WSLP/pCMV–Luc complexes prepared at different (N/P) charge ratios in 5% (w/v) glucose. Naked pCMV–Luc, PEI 1800/pCMV–Luc and PEI 25000/pCMV–Luc complexes were used for comparison. Nontransfected cells (in vitro) were used as negative controls. Luciferase activity is expressed as RLU/mg of total protein.

which contains three protonatable amines, was more effective compared to two protonatable spermidine cholesteryl carbamate (10).

In this study, we conjugated cholesterol as a hydrophobic lipid anchor to PEI, a cationic polymer known to have high transfection activity. PEI is a cationic polymer composed 25% primary amines, 50% secondary amines, and 25% tertiary amines. Massive vesicular ATPase-driven proton accumulation followed by passive chloride influx into endosomes buffered with PEI should cause osmotic swelling and subsequent endosome disruption (19). For gene transfer, PEI of high molecular weight, namely 25000 Da or above, is commonly used, which is highly toxic to the cells even at low N/P ratios, and PEI25000/pDNA complexes are prone to aggregation (33). Since micellization may concentrate positive charge on the lipid surface, polycations with high molecular weight might not be required. Furthermore, anchoring of polymers with lipids may strongly be observed with polymers of low molecular weight (11). Thus, in the present study, we used PEI of 1800 Da, which has about 41 monomer units of aziridine and around 13 units of primary amines in one molecule. WSLP can destabilize the endosomal membrane by protonation of PEI itself without the requirement of nonbilayer lipids. PEI has many protonation sites, which may cause influx of chloride ions into the endosomes, and as a result of this proton-sponge effect, endosomes are broken to release their internal contents (1). Thus, this water-soluble lipopolymer (WSLP) should deliver plasmid DNA without the requirement of

any colipid as a liposomal compartment. The percentage of cholesterol conjugated to PEI was about 47%, and the average molecular weight of WSLP was about 2000 Da (Figure 2). WSLP forms micelles in water with a critical micellar concentration value of 1.43 mg/mL (Figure 3). Since WSLP was found to form micellar solutions, we investigated its potential usefulness as transfection reagent by direct mixing its solution with plasmid containing solution. The particle size of WSLP/pDNA complexes was in the range of 25.9 to 148.5 nm and was dependent on N/P ratios. Atomic force micrographs suggest that these complexes are spherical particles of ~50 nm (Figure 4).

WSLP and WSLP/pDNA complexes were not toxic to CT-26 colon carcinoma and 293T human embryonic kidney transformed cells even at N/P charge ratios, whereas both PEI25000 and LipofectAMINE-based formulations were fairly toxic to these cells (Figure 5). WSLP/pDNA complexes did not cause any aggregation of freshly prepared murine erythrocytes, whereas PEI25000/pDNA complexes aggregated the erythrocytes (Figure 6). This result suggests that cholesterol of WSLP may provide some shielding effect to WSLP/pDNA complexes and thus preventing erythrocytes aggregation.

WSLP/pDNA complexes efficiently transfected CT-26 colon carcinoma and 293T human embryonic kidney transformed cells (Figure 7). The transfection efficiency of WSLP was dependent on the N/P ratios, and the highest Luciferase activity was observed at the N/P ratio of 20/1 (Figure 7). Our findings on the usefulness of water soluble lipopolymers are in good agreement with Vigneron et al. (34), who reported the synthesis of guanidinium cholesterol lipids and their use for the efficient transfection of various mammalian cell lines as water-soluble lipopolymer as well as in the form of cationic liposomes.

In summary, we designed a water soluble nontoxic lipopolymer, which efficiently condenses and protects plasmid DNA from degradation by nucleases, and promotes enhanced transfection into mammalian cells.

ACKNOWLEDGMENT

We would like to thank Expression Genetics, Inc. for final support, Mr. Jay Olsen of Medicinal Chemistry for his assistance with NMR measurement, and Dr. Vajira Nanayakkara of Mass Spectrophotometry Facility for his help with MALDI-TOF measurement. We would also like to acknowledge Dr. Andras Pungor and Mr. Gangadhar Jogikalmath of Materials Science for their help with AFM, and Professor Jan Miller of the Department of Metallurgy for his assistance with particle size and ζ potential measurement.

Peptide and Small Molecule Microarray for High Throughput Cell Adhesion and Functional Assays

James R. Falsey,[†] M. Renil,[†] Steven Park, Shijun Li, and Kit S. Lam*

UC Davis Cancer Center, Division of Hematology/Oncology, and Department of Internal Medicine, University of California Davis, 4501 X Street, Sacramento, California 95817. Received November 21, 2000

A novel class of chemical microchips consisting of glass microscope slides was prepared for the covalent attachment of small molecule ligands and peptides through site-specific oxime bond or thiazolidine ring ligation reaction. Commercially available microscope slides were thoroughly cleaned and derivatized with (3-aminopropyl)triethoxysilane (APTES). The amino slides were then converted to glyoxylyl derivatives via two different routes: (1) coupling of Fmoc-Ser followed by deprotection and oxidation, or (2) coupling with protected glyoxylic acid and final deprotection with HCl. Biotin or peptide ligands derivatized at the carboxyl terminus with a 4,7,10-trioxa-1,13-tridecanediamine succinimic acid linker and an amino-oxy group or a 1,2-amino-thiol group (e.g., cysteine with a free N^α-amino group) were printed onto these slides using a DNA microarray spotter. After chemical ligation, the microarray of immobilized ligands was analyzed with three different biological assays: (1) protein-binding assay with fluorescence detection, (2) functional phosphorylation assay using [γ -³²P]-ATP and specific protein kinase to label peptide substrate spots, and (3) adhesion assay with intact cells. In the cell adhesion assay, not only can we determine the binding specificity of the peptide against different cell lines, we can also determine functional cell signaling of attached cells using immunofluorescence techniques in situ on the microchip. This chemical microchip system enables us to rapidly analyze the functional properties of numerous ligands that we have identified from the “one-bead one-compound” combinatorial library method.

INTRODUCTION

Ever since the introduction of solid-phase peptide synthesis by Professor Bruce Merrifield in 1963, there has been a revolutionary advancement in peptide and organic synthesis (1). This technique was rapidly improved and modified for the synthesis of long peptides or proteins, peptide libraries and even small organic molecule libraries (2–5). A decade ago, by adopting the solid-phase peptide synthesis method, we reported the synthesis and screening of a “one-bead one-compound” combinatorial peptide library (6, 7). In this method, using a split synthesis approach (6, 8, 9), millions of peptide-beads were generated such that each bead displays only one chemical entity (6, 7). Because each compound-bead is spatially separable, the “one-bead one-compound” combinatorial library can be viewed as a huge microarray platform that is not addressable. Using various screening techniques (7), we can identify the compound-beads with a specific biological, chemical, or physical property and isolate them for structural determination. Over the last 10 years, we have successfully used this technology to identify ligands for various protein targets (6, 10–13) or small molecule dyes (14), and peptide substrates for various protein kinases (15–17). In addition, using intact cell lines as a probe, we were able to identify ligands that bind to cell surface receptors (18). Many ligands for various molecular targets can be identified with this combinatorial approach. There is an urgent need for the development of a highly minaturized and high-throughput technique to characterize the binding specificity of

these ligands. The DNA microarray technique has been developed in recent years as a powerful tool for genomic analysis. In this method, thousands of genes (cDNA) are immobilized as individual tiny spots on microscope slides, and fluorescent-labeled cDNA derived from mRNA of whole cell lysate is then used to probe the gene microarray (19, 20). This elegant technique enables one to determine expression levels of multiple genes in one single experiment. This method has inspired us to develop a peptide and small molecule microarray based technique to achieve our goal of rapidly analyzing the binding and functional properties of the leads identified from our combinatorial libraries. We reported the chemical microarray work at the American Peptide Symposium in June of 1999 (21). Independently, a similar microarray method has also been reported by Schreiber's group (22). More recently, MacBeath and Schreiber modified their method to protein microarrays (23).

Spot synthesis on cellulose sheets and light-directed parallel synthesis on special glass slides have already been reported for the generation of peptides in a microarray format (24, 25). Photogenerated acids have been introduced to make the light-directed synthesis simpler on a glass slide for microarray preparation (26). Proteins and enzymes have been immobilized on either acrylamide-gel pads or glass slides with special Teflon cover in a microarray format for high throughput screening (27, 28). In these cases, proteins or enzymes are bound to the slides through covalent nonspecific site of attachment, or noncovalently by hydrophobic or electrostatic interaction. Several types of chemistries have been applied in a DNA microarray system using glass surface modified with amino, epoxide, carboxylic acid, aldehyde, or sulfhydryl groups (29, 30). Schreiber's group has reported

[†] J. Falsey and M. Renil contributed equally to the project.

the Michael addition of thiol-containing compounds onto maleimide-derivatized glass slides for the microarray printing of small molecules (22). In the last five years, chemoselective ligation methods have been developed to chemically link unprotected peptide fragments together to form larger peptides or proteins (31–34). These coupling reactions are efficient and highly specific. We have reported the use of these ligation methods to iodinate peptide (35) and to derivatize the N-terminal cysteine of a single chain monoclonal antibody molecule via thiazolidine ring formation (36). In this report we applied this chemoselective ligation reaction to covalently attach peptides or small molecules onto the glyoxylyl-derivatized glass slide via oxime bond or thiazolidine ring formation. These chemical microarrays were then subjected to a number of biological assays, including protein binding, substrate phosphorylation, and cell adhesion.

EXPERIMENTAL PROCEDURES

Materials. Avidin-Cy5 and Streptavidin-Cy3 were obtained from Pharmacia, Amersham; anti-phosphotyrosine antibody-FITC and anti-Mouse IgG-Cy5 conjugates from Sigma, St. Louis, MO; Calcein AM or Cell-Tracker Orange from Molecular Probes, Eugene, OR; anti- β -endorphin monoclonal antibody (clone 3-E7) was obtained from Boehringer Mannheim, Indianapolis, IN; *O*-(hydrazinocarbonyl methyl) *O*-methyl-poly(ethylene glycol)-5000 (PEG₅₀₀₀-NHNH₂) from Fluka, Milwaukee, WI; stearic acid, glyoxylic acid, all other fatty acids and other chemicals used in this study were obtained from Aldrich Chem Co., Milwaukee, WI. All Fmoc-protected amino acids and resins were purchased from Nova-Bachem, Switzerland or Advanced ChemTech, Louisville, KY; human p60^{csrc} protein tyrosine kinase was purchased from Upstate Biotechnology Inc., Lake Placid, NY. Thin-wall polycarbonate 96 well plates were obtained from Corning Inc. New York, NY. Ordinary microscope slides were obtained from Corning or Fisher, and amino-functionalized slides from CEL Associates, Houston TX. The anti-human insulin antibody was purified from ascites derived from HB125 murine hybridoma cell line (ATCC) using a protein G column (Pharmacia).

Preparation of Glyoxylyl Modified Glass Slides. Ordinary glass microscope slides (75 mm $\times$ 25 mm; 1.06 mm thickness) were cleaned extensively by dipping in 1% NaOH followed by 3% HCl both at 90 °C for 10 min. The slides were then placed in boiling 35% HNO₃ in a reaction vessel fitted with a water condenser and the outlet passed through cold 1% NaOH solution for 1 h. The slides were thoroughly washed six times with distilled water, followed by methanol, and dried under vacuum overnight. The dry slides were dipped in 2% (3-aminopropyl)triethoxysilane (APTES) in dry toluene containing anhydrous Na₂SO₄ or 4 Å molecular sieves and stirred at room temperature for 3 h. The amino slides were thoroughly washed with toluene followed by dichloromethane (DCM) and N₂ dried. The slides were then cured overnight at 190 °C. The amino slides were placed in a Fmoc-Ser-OH solution (50 mM) in DMF along with DIC and HOBt (50 mM each) for 1.5 h and washed five times with DMF. The Fmoc group was removed by 20% (v/v) piperidine in DMF, and the deprotected Ser was oxidized by a NaIO₄ solution (100 mM) for 2 h. This procedure results in surface derivatization of both sides of the slides by a glyoxylyl group.

Alternatively, we have also used protected glyoxylic acid to derivatize the amino slide. To a solution of glyoxylic acid (1 M) in DMF was added HCl to give a

concentration of 0.1 mM, followed by addition of ethylene glycol to give a final concentration of 5 M. The solution was allowed to react in a boiling water bath for 30 min to obtain protected glyoxylic acid. The product was directly used for DIC–HOBt coupling reaction. The amino slides were placed in a solution of freshly prepared protected glyoxylic acid (10 mM), stearic acid (40 mM), DIC (50 mM), and HOBt (50 mM) dissolved in DMF and stirred at room temp for 2 h. The slides were washed with DMF (four times) and DCM (three times) and air-dried. The acetal protecting group was removed by placing the slides in 0.01 M HCl solution with stirring at room temp for 2 h. Finally the glyoxylyl slides were washed four times with distilled water and three times with methanol and dried under vacuum overnight. In a similar manner, different fatty acids (in place of stearic acid) along with different proportions of glyoxylic acid were used for the slide preparation.

Peptide Synthesis. Peptides were synthesized according to standard Fmoc-chemistry on Rink resin. After TFA cleavage, the peptides were purified on a C-18 reverse phase column (Vydac, Hesperia, CA) using a Beckman HPLC system and characterized by ESMS. The hydrophilic linker, Fmoc-4,7,10-trioxa-1,13-tridecanediamine succinimic acid (Fmoc-Ttds-OH), was synthesized according to our previous report (36), and its purity was confirmed by HPLC and ES MS.

Microarray Spotting. Peptides or biotin containing a Ttds-linker and an amino-oxycetyl group or Lys (Cys) at their carboxyl termini were used for microarray spotting. The compounds were dissolved in 300 mM NaCl and 250 mM NaOAc (pH 5.2) at a concentration of 1–3 mM and distributed into a thin-wall polycarbonate 96 well plate (15 μ L per well). Both linear and array mode of spotting were carried out using the Affymatrix 417 arrayer (Santa Clara, CA). A spacing of 500 μ m or 300 μ m was employed between the spots with one to three repetitions for each spot. Soon after spotting, the slides were transferred to a plastic rack inside a plastic box containing saturated NaCl and incubated at room temperature overnight. The slides were thoroughly washed with distilled water, air-dried, and stored under N₂.

Fluorescent Binding Assay. The microarray slides were blocked for 3 h with 1% (w/v) BSA solution in PBS (1 mL per slide), rinsed with water (six times), and air-dried. Protein labeled with fluorescent dye Cy3 or Cy5 (1–2 μ g/mL) was added to the slides and kept in dark for 45 min. In the case of secondary antibody detection technique, the slides were first incubated with the primary antibody (anti-insulin antibody or anti- β -endorphin antibody) for 1.5 h and washed with distilled water, followed by incubation with fluorescent dye conjugated secondary antibody for 45 min. The slides were washed with deionized water, air-dried, and scanned on both channels of the General Scanning (ScanArray 3000) confocal microscope fluorescence scanner.

Protein Kinase Functional Assay. The microarray slides were blocked with 1% BSA solution in PBS as mentioned above. Human p60^{csrc} protein tyrosine kinase (30 units) and [γ -³³P]-ATP (3000 Ci/mmol) were mixed in 1 mL of MES buffer (50 mM, pH 6.8) and placed over the slides and allowed to react for 5 h. The slides were washed thoroughly with deionized water and placed in boiling HCl (1 M) for 5 min. The slide was rinsed with water, air-dried, and exposed to low energy X-ray film (Kodak Biomax MR film) for 5 h, after which the film was developed.

Cell Adhesion Assay. To block nonspecific binding of the cells, each slide was covered with 1 mL of

Scheme 1. Preparation of Amino Slides**Scheme 2. Preparation of Glass Slides for Microarray Spotting by the Fmoc-Ser Method**

O-(hydrazinocarbonyl methyl)-O-methyl-poly(ethylene glycol)-5000 (PEG₅₀₀₀-NHNH₂, 2 mM) in 0.2 mM NaOAc buffer at pH 5.2. After 4 h, the slides were rinsed with deionized H₂O and dried in a desiccator. The slides were then covered with a suspension of intact cancer cell line (2×10^6 cells in 1 mL of medium) and incubated at room temperature for 30 min. After gentle washing with PBS, if the slides were to be studied under fluorescent microscope or array scanner, the cells were then stained with Calcein AM or Cell-Tracker Orange, respectively. After 30 min of incubation, the slides were washed gently with PBS before analysis. In some experiments, the bound cells were fixed with acetone and stained with Giemsa stain.

Immunofluorescence Microscopy. Immunofluorescence microscopy was performed in continuation of cell adhesion assay. After cell binding, the slides were covered with 1 mL of 3.7% paraformaldehyde to fix the cells. After 15 min, paraformaldehyde solution was aspirated, and the slides were washed with 0.5% Triton X-100 in TBS buffer for 5 min and TBS for another 5 min. To detect the effect of cell adhesion on intracellular tyrosine phosphorylation of proteins, 45 μ L of FITC conjugated anti-phosphotyrosine antibody (1/40 dilution) was added. The slides were incubated for 1 h at room temperature and washed in TBS for 5 min. The slides were then mounted for observation under fluorescent microscope. For the negative control slide (without peptide), cell attachment to the glass slide was accomplished with cytospin. The cells were then fixed, processed, and examined under the fluorescent microscope as above.

RESULTS AND DISCUSSION

Slide Preparation. We have tried various commercially available microscope slides for this microarray technique. Corning and Fisher slides were found to be the best for our purpose. First the slides were treated with NaOH and HCl, followed by boiling with HNO₃ to remove all organic matter and free up more surface Si-OH groups for the derivatization with APTES. Optimal conditions for the amino modification was to incubate 2% APTES solution in dry toluene for 3 h (Scheme 1). Strict

anhydrous conditions were maintained during this step to avoid white precipitate formation on the surface of the slides (probably a polymer of the silane). We have also tried prederivatized amino slides from CEL Associates with satisfactory results. The amino slides reacted with Fmoc-Ser in the presence of DIC, HOBt, followed by removal of the Fmoc group. Final oxidation with NaIO₄ will generate slides with a uniform coating of glyoxylyl groups (Scheme 2). Alternatively acetal protected glyoxylic acid was directly coupled to the amino slides followed by deprotection with dilute HCl (Scheme 3). We have found that this alternative method is more convenient, efficient, and consistent. To maximize the signal-to-noise ratio, we need to create a glass surface that has minimal nonspecific binding during biological assays. In addition, the printed chemical spots need to be uniform, precise, and cannot spread to the adjacent areas of the microarray. We believe that these requirements can be achieved through (1) the creation of an optimal hydrophobic-hydrophilic balance on the glass surface, and (2) the use of appropriate blocking agents prior to the biological assays. To achieve these goals, we added various fatty acids such as butyric, valeric, hexanoic, heptanoic, octanoic, decanoic, lauric, myristic, palmetic, and stearic acids separately along with protected glyoxylic acid during the coupling step. Stearic acid was found to be best in this regard. We also tried various ratios of glyoxylic acid to stearic acid and found that a 1:4 ratio was optimal for the least nonspecific binding and reproducible well-defined spots. These slides are designated as (10:40) slides. Slides without the addition of fatty acids tend to generate larger spots that often spread to the adjacent areas. This is probably due to the hydrophilic character of the modified glass surface that leads to greatly reduced surface tension between the aqueous spot and the surface of the slide. Spots generated from the (10:40) slides are smaller and usually do not have the problem with spreading.

Peptides were synthesized by Fmoc-chemistry using DIC/HOBt as coupling reagents. The Ttds-linker was used to connect the carboxyl terminus of the peptide to the glass slide as shown in Scheme 4. The linker is

Scheme 3. Preparation of Glass Slides for Microarray Spotting by the Glyoxylic Acid Method**Scheme 4. Covalent Attachment of Peptides or Small Molecules to a Glass Slide via a Thiazolidine Ring**

critical in some biological assays (see below). The glyoxylyl group exhibits desirable reactivity in that it will react specifically with oxy-amine to form oximes, with 1,2-amino-thiols (e.g., N-terminal cysteine) to form thiazolidine rings, or with hydrazines to form hydrazones at acidic pH. We have tried various additives for this ligation reaction. These include glycerol, ethylene glycol, PEG-1000, PEG-4000, and PEG-6000. High molecular weight PEG caused more spreading of the spots, and hence they were avoided. We have tried various blocking agents such as *O*-allyl-hydroxylamine, *O*-ethyl-hydroxylamine, trimethylsilyl hydroxylamine, *tert*-butyldimethylsilyl-hydroxylamine, *O*-*tert*-butyl-hydroxylamine, and PEG₅₀₀₀NHNH₂ to improve the background of slides. PEG₅₀₀₀NHNH₂ was found to be the best in the case of cell adhesion assay. For protein binding assay, we found

that chemical blocking of the glyoxylyl group is not needed. Blocking with 1% BSA prior to biological assay is sufficient.

Fluorescent Binding Assay. Previously we have identified peptide sequences that bind specifically to avidin (e.g., HPYPP) and streptavidin (e.g., HPQ) using the "one-bead one-compound" combinatorial library approach (6, 12). Biotin and peptides (WSHPQFEK and HPYPP) containing Ttds-linker with Dpr (Aoa) at the carboxyl end were printed onto the glass slide and then probed with a mixture of streptavidin-Cy3 and avidin-Cy5 conjugates. As expected, biotin bound to both streptavidin and avidin. Peptide WSHPQFEK only bound to streptavidin, whereas peptide HPYPP bound to avidin only (Figure 1). This result validates that the microarray methodology could be applied to both peptides and small

Figure 1. Binding of streptavidin-Cy3 (red) and avidin-Cy5 (green) conjugates to a microarray of biotin, and peptides HPYPP and WSHQPFEK. As expected, avidin bound to HPYPP, streptavidin bound to WSHQPFEK, and both avidin and streptavidin bound to biotin.

Figure 2. Binding of anti-human insulin monoclonal antibody to the immobilized mimotope peptide pqrGstG in a microarray format. The microarray was first treated with the primary anti-human insulin antibody, followed by secondary anti-mouse IgG-Cy5 conjugate. The peptides were spotted in triplets. Column 1: YGGFL, 2: wGeyidvk, 3: pqrGstG, 4: WSHQPFEK, and 5: biotin. As expected, anti-human insulin antibody bound to pqrGstG peptide only.

molecules, such as biotin. In another experiment, several peptides (YGGFL, wGeyidvk, pqrGstG, WSHQPFEK) and biotin were spotted in a microarray format, and their binding specificity to an anti-insulin MoAb (HB125) was evaluated. From our previous epitope mapping effort, pqrGstG was a mimotope peptide that we had discovered for the anti-insulin MoAb (37). As expected, after incubating with the primary HB125 MoAb followed by anti-mouse IgG-Cy3, only peptide pqrGstG was positive (Figure 2, column 3). To confirm the applicability of this technique in a microarray format, we spotted the pqrGstG peptide on five identical (10:40) slides along with biotin in an alternate pattern. Four of the five slides were incubated with the primary anti-insulin MoAb (HB125) for 1.5 h, followed by one of the following secondary reagents: streptavidin-Cy3, avidin-Cy5, anti-mouse IgG-Cy3, or a mixture of avidin-Cy5 and anti-mouse IgG-Cy3. The remaining slide was treated with a mixture of avidin-Cy5 and anti-mouse IgG-Cy3. As expected, no staining was observed in the microarray that had been incubated with the secondary antibody anti-mouse IgG-Cy3 alone. For the slide that had been incubated with HB125 MoAb followed by a mixture of avidin-Cy5 and anti-mouse IgG-Cy3, the biotin spot was labeled with Cy5 and the pqrGstG spot labeled with Cy3 (Figure 3). On the same slide, the reference spot that had both biotin and pqrGstG was labeled with both Cy3 and Cy5 (see arrow in Figure

Figure 3. Biotin-linker-Dpr (Aoa) and pqrGstG-linker-Dpr(Aoa) peptide were spotted alternatively on this slide. The amino slide was functionalized with 10:40 glyoxylic acid:stearic acid. The green spots are due to the avidin-Cy5 binding to biotin and red spots due to the anti-insulin monoclonal antibody binding to pqrGstG peptide. The slides were first treated with anti-insulin antibody (1 $\mu\text{g}/\text{mL}$) followed by a mixture of avidin-Cy5 and anti-mouse IgG-Cy3 (1:1000 each). The slide was scanned under red and green channels. The color shown is not original. The final image was obtained by overlaying the two pictures that were scanned separately. The distance between the spots is 500 μm . The arrow marks the spot that both pqrGstG peptide and biotin were printed onto the glass. As expected, this spot bound to both avidin and anti-insulin antibody.

3). For the slides that had been incubated with HB125 MoAb followed by streptavidin-Cy3 or avidin-Cy5, only the biotin spots were labeled (data not shown). For the slide that had been incubated with HB125 MoAb followed by anti-mouse IgG-Cy3, only the pqrGstG spots were labeled (data not shown).

Protein Kinase Functional Assay. To demonstrate the versatility of the chemical microarray approach for functional assays, we carried out a solid-phase phosphorylation assay that is very similar to the condition we used to screen a combinatorial bead library for peptide substrates with specific protein kinases (15–17). A known peptide substrate for p60^{c-src} protein tyrosine kinase EEIYGEFF (38, 39) was used in this study. Figure 4 shows the autoradiogram of the peptide microarray that has been phosphorylated by p60^{c-src} using [$\gamma^{32}\text{P}$]ATP, instead of [$\gamma^{32}\text{P}$]ATP as the phosphoryl donor. ^{32}P was used because it gives a much better resolution of the radiolabeled microarray. In another experiment, we

Figure 4. Autoradiogram of [^{32} P]-labeled EEIYGEFF peptide microarray (spotted at various concentrations) that had been phosphorylated by p60^{c-src} protein tyrosine kinase.

evaluated the importance of the Ttds linker in the phosphorylation assay. The peptide substrate EEIYGEFF was ligated directly to the glass slide without the use of the Ttds linker. No phosphorylation was observed on this peptide microarray (data not shown), indicating the importance of a long flexible hydrophilic linker in this assay.

Cell Adhesion Assay. We have reported the use of a whole cell binding assay to screen a “one-bead one-compound” combinatorial library peptide library for the identification of cell surface binding ligands (18). In addition, we have previously reported the use of an enzyme-linked colorimetric screening method, with purified idiotype derived from WEHI-231 murine lymphoma cell line, to screen an all-D-amino acid 8-mer peptide library. We identified wGeyidvk as a peptide that bound specifically to the surface idiotype of the WEHI-231 cells (40). Furthermore, this peptide (in a tetrameric form) was able to induce tyrosine phosphorylation of intact WEHI231 but not WEHI279 cells. We have decided to use this peptide as a model system for the development of a cell adhesion assay for the microarray. Peptide wGeyidvk was synthesized with a Ttds linker and Lys(Cys) at the carboxyl terminus (Scheme 4) and spotted onto the glyoxylyl-functionalized (10:40) slides. After reaction overnight in a moisture chamber, the slide was treated with PEG₅₀₀₀NH₂. Each of the areas of the microarray were then covered separately with various cell lines which includes WEHI-231, Jurkat, OC1LY8, K562, MOLT-4, and HL-60. The slides were then washed and stained with Giemsa stain and observed under a light microscope. Only the WEHI 231 cell was found to bind to the spotted area of the slide with minimal background (Figure 5). The slides that were incubated with other cell lines had no binding (data not shown). To determine whether the cell binding could be quantified, different concentrations of wGeyidvk peptide were spotted on the slide. The slide was then treated with Cell-Tracker Orange stained WEHI 231 cells and scanned by the microarray scanner. The scanned picture was analyzed and quantitated by the ImageQuant 5.0 program. With this quantitative analysis, we were able to determine that maximal cell binding to the microarray spots could be reached with 30 min of incubation (data not shown). As indicated above, wGeyidvk peptide was known to induce tyrosine phosphorylation in WEHI 231 cell line (40). To confirm this finding by the microarray method, cells were fixed after the cell adhesion assay. After permeation with nonionic detergent, FITC-conjugated anti-phosphotyrosine antibody was added. After incubation and washing, the cells were examined under a fluorescent microscope. Cells bound to wGeyidvk peptide fluoresced brightly

(Figure 6a), whereas the negative control where WEHI 231 cells were bound to the slide by cytospin was completely dark (data not shown). To make sure we still had bound cells in the negative control slide, we turned the background light on and showed that the cells were present but did not fluoresce (Figure 6b). To avoid nonspecific binding of cell onto the slide, PEG₅₀₀₀NH₂ blocking was essential.

Comparison with Other Microarray Techniques.

One of the earlier reports on peptide or chemical microarray was the light-directed photolithographic synthetic microchip system first reported by Fodor et al. (25). They synthesized 1042 peptides on microscope slides and used a fluorescent-labeled antibody to probe the peptide microarray. The method, while elegant, is inefficient as the synthetic method requires new synthesis on each slide and requires expensive instrumentation that is not readily available. The spotting of peptides or small molecules onto the slide (the method described in this report and that of Schreiber's (22), on the other hand, is much more efficient. Similar to the DNA microarray method, once the peptides or chemical compounds are synthesized, they can be spotted repeatedly onto hundreds of slides. The main difference between the Schreiber's approach and our approach is that Schreiber used the Michael addition chemistry to couple free thiol group of the ligand to the maleimide-functionalized slide. This free radical addition reaction, while efficient, is not site-specific as the ligation chemistries described in this report and cannot be used for ligands with a sulfhydryl group that may be essential for binding. Furthermore, the chemoselective ligation method employed in this study can also be used to generate a protein microarray by ligating specifically to proteins with a free N-terminal cysteine (36).

Potential Applications. In this report, we describe three distinct biological assays to analyze the chemical microarrays: the fluorescent-protein binding assay, the functional phosphorylation assay, and the whole cell adhesion assay. All these assays have been used in the screening of the “one-bead one-compound” combinatorial libraries (7). As indicated earlier, each compound-bead is spatially separable and the bead-library can be viewed as a huge microarray platform (10^7 compounds) that is nonaddressable. The identity of the compound-bead is known only after one picks up the positive bead and determines the chemical structure. On the other hand, the chemical microarray described in this report can be viewed as a mini-microarray (up to 10 000 compounds per slide) that is addressable. That is, the chemical identity of each spot is known prior to the biological assays. The two methods, although quite different, are highly complementary. Many ligands can be identified from bead-library screening. Once the chemical structure of these positive ligands are identified, they can be resynthesized, spotted as multiple sets of ligands onto the microscope slide, and characterized under several conditions. For instance, one may use the bead-library method to identify hundreds to thousands of specific peptide substrates for a large number of different protein kinases. These peptide substrate sets can then be used to profile protein kinase activities of cell extracts derived from patient specimens. This profile may be able to direct us to use the appropriate kinase inhibitor for cancer therapy. Similarly, the whole cell binding assay in conjunction with the peptide microarray method may enable us to select the most appropriate peptide or peptide cocktails for targeted-therapy of cancer (41). The in situ functional assay after cell adhesion on the

Figure 5. Cell adhesion assay of intact WEHI 231 murine lymphoma cells to wGeyidvk peptide microarray. (A) Fluorescent micrograph of calcein AM-labeled cells bound to peptide microarray that was spotted at different peptide concentrations. (B) Giemsa staining of cells bound to the peptide microarray (low power). (C) Giemsa staining of cells bound to the peptide microarray (higher power).

Figure 6. (A) Fluorescent micrograph of WEHI 231 lymphoma cells bound to immobilized wGeyidvk peptide. The bound cells were first fixed with paraformaldehyde and then treated with FITC-labeled anti-phosphotyrosine antibody. Strong fluorescence indicates that cell binding to the immobilized peptide triggers cell signaling. (B) Control slide with WEHI 231 cells bound to the glass by cytospin, fixed with paraformaldehyde, and treated with FITC-labeled anti-phosphotyrosine antibody as above. No fluorescence was observed (data not shown), but the cells could still be seen with dim background light.

microarray is particularly powerful because one can easily envision that hundreds to thousands of interactions between different cell lines and many ligands can

be examined concurrently with respect to binding as well as the different functional responses after binding. Using the appropriate fluorescent-labeled antibodies against a large number of signaling proteins, one can perform numerous experiments and answer many questions on one single microarray slide, using only a minute amount of cell suspension. The method is highly miniaturized and could potentially be fully automatic, from peptide synthesis, to peptide spotting, to cell adhesion, to immunofluorescence staining, to final image analysis with confocal microscopy.

CONCLUSION

We have demonstrated the preparation and optimization of a novel class of microchip, which consists of glyoxylyl-modified microscope glass slides and their application for high-throughput analysis of biomolecules and even whole cells. Peptides or small molecules were spotted and covalently attached to slides by site-specific chemical ligation procedure via thiazolidine ring or oxime bond formation. Slides with optimal hydrophobic–hydrophilic balance were obtained by coupling-protected glyoxylic acid and stearic acid in a ratio of 1:4. The peptide and biotin spots on this microchip bound specifically with their receptor protein conjugates (with dye Cy3 or Cy5) and could be easily visualized under a confocal array scanner. We were able to carry out functional phosphorylation assay as well as whole cell binding assay on this microchip. In the cell adhesion assay, nonspecific binding could be eliminated by modifying the glass surface with PEG₅₀₀₀NH₂. One major advantage of this type of slide comes from the site-specific attachment of C-terminal modified peptides or small molecules with a Ttds linker molecule to the solid-support, thereby facilitating the binding or functional assays on these chemical microarrays.

ACKNOWLEDGMENT

We would like to thank Professor Jeff Gregg and Ms. Stephenie Liu of the Pathology Department of UC Davis for their assistance with the operation of the DNA Arrayer and Scanner. This work was supported by grants NIH CA78868, NIH CA78909, NIH CA86364, and NSF MCB950621. The Undergraduate Biology Research Program (UBRP) of the University of Arizona, that partly funded Mr. Falsey, was supported by the Howard Hughes Foundation.

Radiolabeling of small receptor-avid peptides at specific predetermined chelation sites with radioactive metals has been an effective approach for production of target-specific radiopharmaceuticals for diagnosis and therapy of diseases. Among various electron-donating groups found on chelator frameworks, phosphines are unique because they display versatile coordination chemistry with a wide range of transition metals. We have recently reported the utility of a dithia-bis(hydroxymethyl)-phosphine-based (P_2S_2) bifunctional chelating agent (BFCA) containing air-stable primary phosphine groups to form ^{99m}Tc -labeled receptor-avid peptides by the preconjugation approach. Here we report a novel strategy for labeling small peptides with both ^{99m}Tc and ^{188}Re using the P_2S_2 -COOH (6,8-bis-[3-(bis(hydroxymethyl)phosphanyl)propylsulfanyl]octanoic acid) BFCA by a postconjugation radio-labeling approach. The first step in this approach involves the coupling of the corresponding $(\text{PH}_2)_2\text{S}_2$ -COOH intermediate to the N-terminus of the peptide(s). Formylation of P–H bonds with aqueous formaldehyde in the presence of HCl in ethanol affords the corresponding (hydroxymethyl)phosphine- P_2S_2 -peptide conjugates in the form of an oxidatively stable phosphonium salt. The P_2S_2 -peptide conjugates are generated (where the PH_2 groups are converted to $\text{P}(\text{CH}_2\text{OH})_2$ groups) by treatment of the P_2S_2 -peptide phosphonium salt(s) with 1 M sodium bicarbonate solution at pH 8.5. Complexation of BFCA conjugates with ^{99m}Tc is achieved by direct reduction with Sn(II) tartarate to yield the ^{99m}Tc - P_2S_2 -peptide conjugate in near quantitative yields. Complexation of the BFCA conjugates with ^{188}Re is achieved by transchelation with ^{188}Re citrate in yields of $\geq 90\%$. In this study, $(\text{PH}_2)_2\text{S}_2$ -COOH BFCA was conjugated to model peptides. The glycylglycine ethyl ester (GlyGlyOEt)- $(\text{PH}_2)_2\text{S}_2$ -COOH BFCA conjugate was converted to the hydroxymethylene phosphine form and complexed with ^{99m}Tc to produce the $^{99m}\text{TcO}_2$ - P_2S_2 - GlyGlyOEt conjugate **8** in RCPs of $\geq 95\%$. This singular ^{99m}Tc product is stable over 24 h in aqueous solution as confirmed by HPLC. Identical retention times of the $^{99m}\text{TcO}_2$ - P_2S_2 - GlyGlyOEt complex and its cold rhenium analogue (ReO_2 - P_2S_2 - GlyGlyOEt) on HPLC indicates similarity in structures at the macroscopic and the tracer levels. The utility of this postconjugation strategy was further demonstrated by synthesizing a P_2S_2 -D-Lys⁶-LHRH conjugate and producing its corresponding ^{99m}Tc complex in RCPs of $\geq 88\%$. Finally, the P_2S_2 -5-Ava-BBN[7–14] NH_2 bombesin (BBN) analogue was synthesized, the PH_2 groups converted to $\text{P}(\text{CH}_2\text{OH})_2$ groups and subsequently labeled with ^{188}Re to yield a ^{188}Re -labeled bombesin analogue with a RCP of $\geq 90\%$. The biological integrity of this conjugate was demonstrated in both in vitro and in vivo. The results of this investigation demonstrate that the $(\text{PH}_2)_2\text{S}_2$ -COOH BFCA can be conveniently used as a precursor for labeling small receptor-avid peptides with diagnostic (^{99m}Tc) and therapeutic (^{188}Re) radionuclides via the postconjugation approach in high yields.

INTRODUCTION

The labeling of small peptides with diagnostic and/or therapeutically useful radiometals has attracted a great degree of attention in recent years due to wide applicabil-

ity into the development of target-specific radiopharmaceuticals.^{1–10} ^{99m}Tc continues to be the most commonly used radiometal for SPECT imaging due to its favorable physical properties and availability (i.e., $t_{1/2} = 6$ h).^{11,12} The suitable nuclear emission properties, the physical half-life ($t_{1/2} = 17$ h), the decay characteristics ($E_\beta = 1.7$ MeV), and its availability as a no-carrier-added (NCA) reagent makes ^{188}Re one of the most attractive radionuclides for potential use in therapeutic applications.^{12,13} However, the number of research and development studies with ^{188}Re -labeled biomolecules has been limited.² The reason is due, in part, to the more complex labeling chemistry required for ^{188}Re .^{7,14–20} For example, a large excess of reducing agent [e.g., Sn(II)] is required to convert the rhenium from an oxidation state of VII in the $^{188}\text{ReO}_4^-$, to a lower oxidation state(s) (e.g., +5, +3,

or +1) to facilitate ^{188}Re complexation to coordinating ligand frameworks.^{14–20} In context of $^{99\text{m}}\text{Tc}$, Re(VII) is more difficult to reduce than Tc(VII) , and the presence of strong reducing agents can alter the metalation reactions and/or the integrity of the biomolecular conjugate.^{2,12} Overcoming these and other related issues (e.g., Re is often more readily oxidized and less stable at low oxidation states than Tc) to produce well-defined ^{188}Re -labeled compounds in high yields while also maintaining their ability for high specific in vivo targeting of cancers is not trivial.^{2,12}

The use of phosphines in nuclear medicine has been well established. $^{99\text{m}}\text{Tc}$ –Tetrafosmin and $^{99\text{m}}\text{Tc}$ –Technecard, which utilize the phosphine ligands 1,2-bis(bis(ethoxyethyl)phosphino)ethane and tris(3-methoxy-1-propyl)phosphine are currently being clinically used as myocardial perfusion agents for imaging the heart.^{21,22} Furthermore, Deutsch et al. have demonstrated the stabilization of technetium in the oxidation states (V), (III), and (I) using the bidentate dimethylphosphinoethane (DMPE).^{22–28} Katti et al. have reported the utility of hydroxymethylphosphines (HMPs) as chelating ligands for $^{99\text{m}}\text{Tc}$ in (V) and (I) oxidation states.^{29–35} Alkyl phosphines are excellent ligands for binding the transition metals, as they form stable and well-defined complexes with a variety of transition-metals.³⁶ However, the high affinity of alkyl phosphines toward oxidation limits their use for the radiometal labeling of biomolecules.

Development of hydrophilic chelating moieties to facilitate efficient clearance of the $^{99\text{m}}\text{Tc}/^{188}\text{Re}$ activity from the blood pool through the kidneys and into the urine, with low retention of the radioactivity in the liver and the kidney is an important endeavor in development of effective radiopharmaceuticals.^{1,37–40} With this aim, we previously reported development of a $\text{P}_2\text{S}_2\text{-COOH BFCA}$ based on the dithia-bis(hydroxymethyl)phosphine framework (Figure 1) that can be linked to peptides or other biomolecules to produce $^{99\text{m}}\text{Tc}$ -labeled conjugates.^{33,34} The complexes of $\text{Tc-}^{99\text{m}}$ with the new chelating framework demonstrate excellent in vitro and in vivo stability and desirable clearance and excretion properties (from the blood stream).^{29,32,34,35} This study describes an effective approach for synthesizing P_2S_2 conjugated peptides to produce products in which the two hydroxymethylene phosphine (HMP) groups are not oxidized by convenient routes (e.g., automated SPPS is exceptionally challenging). For example, the HMP groups are oxidized when P_2S_2 conjugated peptides synthesized by SPPS are cleaved from the resin by TFA. This study demonstrates the utility of an effective approach for synthesis of P_2S_2 bioconjugates, using $(\text{PH}_2)_2\text{S}_2$ -precursors or intermediates, that are exceptionally stable to most harsh synthetic conditions. The phosphorus hydride groups (PH_2) present in the $(\text{PH}_2)_2\text{S}_2$ -ligand framework will not be oxidized or chemically altered by a variety of reaction conditions (including exposure to high TFA concentrations at elevated temperatures), yet they can be readily converted to HMP groups for chelating with $^{99\text{m}}\text{Tc}$ and ^{188}Re via the postconjugation approach.

EXPERIMENTAL SECTION

All solvents were either ACS certified or HPLC grade solvents were obtained from Fischer Scientific and used as received. Fmoc-amino acids, coupling agents, and resins were purchased from Calbiochem-Novabiochem Corp., CA. All other reagents were purchased either from Aldrich Chemical Co., Fischer Scientific, or Acros Chemicals. $^{99\text{m}}\text{TcO}_4^-$ and $^{188}\text{ReO}_4^-$ were eluted from either a $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator (Mallinckrodt Medical, Inc.) or a $^{188}\text{W}/^{188}\text{Re}$ generator (Oakridge National Laboratories), respectively, using sterile 0.9% saline. $(\text{PH}_2)_2\text{S}_2\text{-COOH}$, $\text{ReO}_2\text{-P}_2\text{S}_2\text{-COOH}$, and $\text{ReO}_2(\text{py})_4\text{Cl}$ were prepared according to previously reported procedures.^{33,34,41} Nuclear magnetic resonance spectra were recorded on a Bruker ARX-300 spectrometer using D_2O , CDCl_3 , or CD_3OD as solvents. The ^1H and ^{13}C chemical shifts are reported in ppm, downfield from external standard tetramethylsilane. The ^{31}P NMR (121.5 MHz) spectra were recorded with 85% phosphoric acid as an external standard, and positive chemical shifts lie downfield of the standard. Infrared spectra were recorded on a Mattson FT-IR Galaxy 3000 spectrometer using KBr pellet for solid samples and NaCl crystals for liquid samples. FAB mass spectral analyses were performed by the Washington University Resource for Biomedical and Bio Organic Mass Spectrometry, St. Louis, MO. Electrospray mass spectral analyses were performed by Synpep Corporation, Dublin, CA.

Solid-Phase Peptide Synthesis (SPPS). Peptide synthesis was carried out on a Perkin-Elmer – Applied Biosystems Model 432 automated peptide synthesizer employing traditional fmoc chemistry with HBTU activation of carboxyl groups on the reactant with the N-terminal amino group on the growing peptide anchored via the C-terminus to the resin. Rink Amide MBHA resin (25 μmol) and fmoc-protected amino acid with appropriate side-chain protections (75 μmol) were used for the synthesis. The final products were cleaved by a standard procedure using a cocktail containing thioanisole, water, ethanedithiol, and trifluoroacetic acid in a ratio of 2:1:1:36 and precipitated into methyl *tert*-butyl ether. Crude peptides were purified by HPLC, and the solvents were removed on a SpeedVac concentrator.

High Performance Liquid Chromatography (HPLC). HPLC analyses of all peptide conjugates and their metal complexes were performed on a Waters 600E system equipped with a Waters 486 tunable absorption detector, a sodium iodide crystal containing a radiometric detector, and a Waters 746 Data Module integrating recorder. HPLC solvents consisted of H_2O containing 0.1% trifluoroacetic acid (Solvent A) and acetonitrile containing 0.1% trifluoroacetic acid (Solvent B). Conditions: Either a C-18 Hamilton PRP-1 column (10 μm , 4.1 $\times$ 150 mm) or a Phenomenex Jupiter C-18 (5 μm , 4.1 $\times$ 250 mm) column was used with a flow rate of 1.5 mL/min. This HPLC gradient system begins with a solvent composition of 95% A and 5% B from 0 to 2 min, followed by a linear gradient 95% A:5% B to 50% A:50% B from 2 to 17 min. The gradient remains at 50% A:50% B for 8 min, after which the column is reequilibrated.

Synthesis of $(\text{PH}_2)_2\text{S}_2\text{-GlyGlyOEt}$ (1a). To a solution of $(\text{PH}_2)_2\text{S}_2\text{-COOH}$ (712 mg, 2.0 mmol) in acetonitrile (25 mL) were added GlyGly ethyl ester hydrochloride (395 mg, 2.0 mmol), triethylamine (606 mg, 6.0 mmol), and HBTU (770 mg, 2.05 mmol). The reaction mixture was stirred for 30 min at room temperature (25 $^\circ\text{C}$) under nitrogen. The solvent was removed under reduced pressure, and the crude product was chromatographed on a silica gel column using a hexane/ethyl acetate solvent

system. The pure conjugate **1a** was obtained (857 mg, 86%) as a colorless viscous oil. ^1H NMR (300 MHz, CDCl_3): δ = 6.71 (bs, 1H), 6.39 (bs, 1H), 4.17 (q, J = 7.8 Hz, 2H), 4.05–3.91 (m, 4H), 3.041–2.94 (m, 2H) 2.71–2.44 (m, 8H), 2.37–2.29 (m, 2H), 2.21 (t, J = 7.5 Hz, 2H), 1.85–1.68 (m, 6H), 1.67–1.36 (m, 8H), 1.23 (t, J = 8.1 Hz, 3H); ^{13}C NMR (75 MHz, CDCl_3): δ = 173.58 (s), 169.54 (s), 169.22 (s), 61.65 (s), 44.69 (s), 43.01 (s), 41.31 (s), 36.15 (s), 34.74 (s), 32.96 (s), 32.73 (s), 30.89 (s), 29.35 (s), 26.43 (s), 25.38 (s), 14.12 (s), 13.05 (bs); ^{31}P NMR (121 MHz, CDCl_3): δ = –136.5 (s), –136.56 (s). HRMS (FAB) calcd m/z for $[\text{M} + \text{H}]^+$: 499.1998; found: 499.1970.

Synthesis of $(\text{PH}_2)_2\text{S}_2$ –5-Ava-BBN[7–14] NH_2 (1b**).** A solution of 5-Ava-BBN[7–14] NH_2 (10 mg, 9.63 μmol) in DMF (0.5 mL) was added to a reaction mixture containing $(\text{PH}_2)_2\text{S}_2$ –COOH (6.0 mg, 16.85 μmol), HBTU (7.0 mg, 18.47 μmol), and triethylamine (10 μL) in DMF (0.5 mL). The reaction mixture was stirred for 30 min at room temperature. The resultant $(\text{PH}_2)_2\text{S}_2$ –5-Ava-BBN[7–14] NH_2 peptide conjugate was purified by reversed-phase HPLC and analyzed by ^{31}P NMR spectroscopy and electrospray mass spectrometry. The pure product (9.3 mg, 70%) was obtained as a white powder. ^{31}P NMR (121 MHz, D_2O): δ = –137.91 (s). ^{31}P NMR (121 MHz, proton coupled, D_2O): δ = –137.90 (t, $J_{\text{P-H}}$ = 190.2 Hz). Electrospray MS calcd m/z for $(\text{M} + 1)^+$: 1377; found: 1377.

Synthesis of $(\text{PH}_2)_2\text{S}_2$ –D-Lys⁶–LHRH (1c**).** The same synthetic procedure described to produce **1b** was used. The pure product was obtained in a yield of 68% as a white powder. ^{31}P NMR (121 MHz, D_2O): δ = –137.91 (s). ^{31}P NMR (121 MHz, proton coupled, D_2O): δ = –137.90 (t, $J_{\text{P-H}}$ = 190.2 Hz). Electrospray MS calcd m/z for $(\text{M} + \text{H})^+$: 1591.9; found: 1592.0.

Synthesis of P_2S_2 –GlyGlyOEt (2a**).** To a solution of conjugate **1a** (500 mg, 1.0 mmol) in degassed ethanol (5 mL) was added 37% aqueous formaldehyde solution (650 μL , 8.0 mmol) in the presence of 5 N hydrochloric acid (0.5 mL) to produce the phosphonium salt. The reaction mixture was stirred at room temperature (25 °C) for 15 min under nitrogen. Removal of the solvent under reduced pressure afforded conjugate **2a** (1.2 g, 97%) as a colorless viscous oil. ^1H NMR (300 MHz, D_2O): δ = 4.67 (bs, 12H), 4.06 (q, J = 5.5 Hz, 2H), 3.88 (s, 2H), 3.82 (s, 2H), 2.76–2.67 (m, 1H), 2.64–2.48 (m, 6H), 2.42–2.27 (m, 4H), 2.26–2.15 (m, 2H), 1.96–1.78 (m, 4H), 1.75–1.55 (m, 2H), 1.54–1.39 (m, 4H), 1.36–1.22 (m, 2H), 1.12 (t, J = 7.1 Hz, 3H); ^{13}C NMR (75 MHz, D_2O): δ = 177.59 (s), 172.35 (s), 171.81 (s), 62.88 (s), 50.44 (d, J = 53.9 Hz), 44.43 (s), 42.71 (s), 41.73 (s), 35.77 (s), 34.13 (s), 32.08 (d, J = 15.6 Hz), 30.53 (d, J = 15.5 Hz), 28.66 (s), 25.99 (s), 25.42 (s), 21.77 (s), 21.29 (s), 13.82 (s), 13.32 (d, J = 10.8 Hz), 12.78 (d, J = 10.8 Hz); ^{31}P NMR (75 MHz, D_2O): δ = 30.14 (s); HRMS (FAB) calcd m/z for $[\text{M} - \text{Cl}]^+$: 715.2383; found: 715.2376.

Synthesis of P_2S_2 –5-Ava-BBN[7–14] NH_2 (2b**).** To a solution of **1b** (5.0 mg, 3.63 μmol) in ethanol (200 μL) and DMF (100 μL) were added 5 N hydrochloric acid (25 μL) and 37% aqueous formaldehyde (50 μL). The reaction mixture was stirred at room temperature (25 °C) for 5 min. The formation of the P_2S_2 –5-Ava-BBN[7–14] NH_2 conjugate phosphonium salt was confirmed by ^{31}P NMR spectroscopy. The reversed-phase HPLC purification yielded the pure P_2S_2 –5-Ava-BBN[7–14] NH_2 conjugate phosphonium salt (4.6 mg, 81%) as a white powder. ^{31}P NMR (121 MHz, D_2O): δ = 30.1 (s). Electrospray MS calcd m/z for $(\text{M} + \text{H})^+$: 1376; found: 1376.

Formylation on solid phase was accomplished by first synthesizing $(\text{PH}_2)_2\text{S}_2$ –5-Ava-BBN[7–14] NH_2 on the resin by SPPS using standard fmoc chemistry. The presence

of PH_2 groups on $(\text{PH}_2)_2\text{S}_2$ –5-Ava-BBN[7–14] NH_2 -resin was confirmed by FTIR spectroscopy indicated by characteristic singlet band at 2284 cm^{-1} due to P–H stretching. To 90 mg of $(\text{PH}_2)_2\text{S}_2$ –5-Ava-BBN[7–14] NH_2 -resin in ethanol (300 μL) was added a solution of 5 N HCl (50 μL) and 37% aqueous formaldehyde (100 μL). The reaction mixture was stirred for 1 h at room temperature. The resultant P_2S_2 –5-Ava-BBN[7–14] NH_2 -resin was washed with water (10 mL) and dried. P_2S_2 –5-Ava-BBN[7–14] NH_2 conjugate phosphonium salt was cleaved from the resin by a standard procedure using a cocktail consisting of thioanisole, water, ethanedithiol, and trifluoroacetic acid in a ratio of 2:1:1:36. The new peptide conjugate was precipitated into methyl *tert*-butyl ether. The crude peptide conjugate was purified by reversed-phase HPLC, and the solvents were removed on a SpeedVac concentrator. ^{31}P NMR spectroscopy and electrospray mass spectrometry confirmed product formation. The analytical data was consistent with the product prepared by the solution phase formylation method. The P_2S_2 –5-Ava-BBN[7–14] NH_2 conjugate phosphonium salt was obtained as a white powder in 31% yield.

Synthesis of P_2S_2 –D-Lys⁶–LHRH (2c**).** To a solution of **1c** (0.5 mg) in ethanol (400 μL) and DMF (100 μL) were added 0.1 N HCl (25 μL) and 37% aqueous formaldehyde (25 μL). The solution was stirred at room temperature (25 °C) for 5 min. The formation of the P_2S_2 –D-Lys⁶–LHRH hydroxymethyl phosphonium chloride was confirmed by ^{31}P NMR spectroscopy (δ = 31.4 ppm). The P_2S_2 –D-Lys⁶–LHRH hydroxymethyl phosphonium chloride was converted to corresponding hydroxymethyl phosphine by the addition of 1 M aqueous sodium bicarbonate (30 μL) to increase pH to 8.5. The conjugate was formed in near quantitative yield as monitored by ^{31}P NMR spectroscopy (δ = –24.2 ppm).

Synthesis of ReO_2 – P_2S_2 –GlyGlyOEt (3a**).** To a solution of compound **2a** (500 mg, 0.81 mmol) in water (25 mL) was added a solution of $[\text{ReO}_2(\text{py})_4]\text{Cl}$ (432 mg, 0.8 mmol) also in water (75 mL). The reaction mixture (pH = 5) was refluxed for 1 h. The reaction mixture was concentrated under reduced pressure and purified on a C-18 Sep-Pak reverse phase column with a water/methanol solvent system. The pure rhenium complex **3a** was obtained (610 mg, 70%) as a purple viscous oil. ^1H NMR (300 MHz, D_2O): δ = 4.47–4.11 (m, 8H), 4.00 (q, J = 7.2 Hz, 2H), 3.81 (s, 2H), 3.76 (s, 2H), 3.41 (bs, 4H), 3.24 (bs, 1H), 3.04–2.86 (m, 2H), 2.55–2.45 (m, 6H), 3.33–3.08 (m, 6H), 1.92–1.18 (bm, 6H), 1.06 (t, J = 5.5 Hz, 3H); ^{13}C NMR (75 MHz, D_2O): δ = 176.86 (s), 171.93 (s), 171.49 (s), 62.51 (s), 59.24–57.82 (m), 42.45 (s), 41.43 (s), 38.37 (s), 38.19 (s), 37.05 (s), 35.41 (s), 33.14 (s), 30.10 (s), 25.22 (s), 25.22 (s), 20.87 (s), 17.83 (s), 17.53 (s), 13.56 (s); ^{31}P NMR (121 MHz, D_2O): δ = –6.26 (d, J = 10.1 Hz), –7.14 (d, J = 9.9 Hz); IR (NaCl): ν = 3385 (bs, $\nu_{\text{O-H}}$), 1730 (s, $\nu_{\text{C=O}}$), 1647 (s, $\nu_{\text{C=O}}$), 793, 912 (s, $\nu_{\text{O=Re=O}}$), (s, $\nu_{\text{as O=Re=O}}$) cm^{-1} ; HRMS (FAB) calcd m/z for $[\text{M} - \text{HCl}]$: 836.1705; found: 836.1699.

Synthesis of ReO_2 – P_2S_2 –5-Ava-BBN[7–14] NH_2 (4a**).** The ReO_2 – P_2S_2 –5-Ava-BBN[7–14] NH_2 **4a** was synthesized by solid-phase peptide synthesis using traditional fmoc chemistry. The precomplexed ReO_2 – P_2S_2 –COOH was introduced onto the bioconjugate as the last residue in the synthetic sequence.³⁴ Synthesizing the “cold” Re product in this manner allows incorporation of the metal as the ReO_2 – P_2S_2 -moiety at the N-terminal of the peptide. The ReO_2 – P_2S_2 –5-Ava-BBN[7–14] NH_2 **4a** was cleaved from the resin by a standard procedure using cocktail consisting of thioanisole, water, ethanedithiol, and trifluoroacetic acid in a ratio of 2:1:1:36. The new bio-

Scheme 1. Synthesis of $(\text{PH}_2)_2\text{S}_2$ -Peptide and P_2S_2 -Peptide Conjugates

conjugate was precipitated into methyl *tert*-butyl ether. The crude peptide conjugate was purified by reversed-phase HPLC, and the solvents were removed on a SpeedVac concentrator. The $\text{ReO}_2\text{-P}_2\text{S}_2\text{-5-Ava-BBN}[7\text{-}14]\text{NH}_2$ **4a** was obtained as a pale-colored powder in 41% yield. ^{31}P NMR (121 MHz, D_2O): $\delta = -6.44$ (s), -7.41 (s); electrospray MS calcd m/z for $[\text{M} + \text{OH}]$: 1732.9; found: 1732.9.

$^{99\text{m}}\text{Tc}$ Labeling of $\text{P}_2\text{S}_2\text{-GlyGlyOEt}$ (3b**).** *Postconjugation Labeling.* A ligand stock solution of $\text{P}_2\text{S}_2\text{-GlyGlyOEt}$ **2a** was prepared by dissolving 5 mg of the conjugate in 1 mL of water, and the pH was raised to 8.5 with 1 M sodium bicarbonate buffer. A 30 μL (0.37 μmol , concentration in final 550 μL solution = 6.6×10^{-4} M) amount of the stock solution was added to a solution of $\text{Na}^{99\text{m}}\text{TcO}_4$ (500 μL , 8 mCi). An aliquot of saturated aqueous stannous tartarate (10 μL) was added to the solution. The solution (pH = 6) was allowed to incubate at room temperature for 30 min. $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-GlyGlyOEt}$ complex **3b** was formed in a yields of $\geq 98\%$, as a single species. The retention time of the new complex was 10.6 min using those conditions previously described. The tracer level complex is identical to that of the Re complex **3a**, monitored at $\lambda = 300$ nm. HPLC conditions were the same for each of the $^{99\text{m}}\text{Tc}$ and Re complexes.

Preconjugation Labeling. The $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-COOH}$ complex was produced by the method described above. Upon confirmation of the formation of the $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-COOH}$ complex by HPLC, the PFP activated ester was prepared by reacting the $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-COOH}$ complex (400 μL , 185–740 MBq) with an excess of 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC) (10 mg) and pentafluorophenol (PFP) (7 mg) in acetonitrile (100 μL).

Scheme 2. Complexation of $\text{P}_2\text{S}_2\text{-GlyGlyOEt}$ **2a with Re(V) and $^{99\text{m}}\text{Tc}$** 

The resultant solution was incubated at room temperature for 1 h. HPLC confirmed the formation of a single species at 17.1 min. An aliquot of the HPLC purified $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-PFP}$ (500 μL) solution was added to GlyGlyOEt (0.5 mg), and the pH was adjusted to 8.5 using 1 M sodium bicarbonate. The reaction mixture was incubated at room temperature for 30 min. HPLC confirmed the formation of the $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-GlyGlyOEt}$ complex **3b** as a single species at 10.6 min, with a yield of $\sim 95\%$.

$^{99\text{m}}\text{Tc}$ Labeling of $\text{P}_2\text{S}_2\text{-D-Lys}^6\text{-LHRH}$ (5**).** To a solution of $(\text{PH}_2)_2\text{S}_2\text{-D-Lys}^6\text{-LHRH}$ **2c** (575 μg , 0.36 μmol) in ethanol (400 μL) and DMF (100 μL) were added 0.1 N HCl (25 μL) and 37% aqueous formaldehyde (25 μL). The (hydroxymethyl)phosphine derivative of $\text{P}_2\text{S}_2\text{-D-Lys}^6\text{-LHRH}$ conjugate was obtained by adjusting the pH of the ligand solution to 8.5 using 1 M NaHCO_3 (25 μL). The concentration of the ligand solution was 1 $\mu\text{g}/\mu\text{L}$. Finally, 50 μL (50 μg , concentration in final 560 μL solution = 5.2×10^{-5} M) of ligand stock solution was added to a solution of $\text{Na}^{99\text{m}}\text{TcO}_4$ (500 μL , 185–370 MBq) in 0.9% saline. A 10 μL aliquot of saturated aqueous stannous tartarate was added to the solution. The solution (pH = 6) was incubated at room temperature for 30 min. The product $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-D-Lys}^6\text{-LHRH}$ **5**, was formed in yields of $\sim 88\%$. A retention time of 12.7 min indicated the formation of a singular species using HPLC conditions previously described.

^{188}Re Labeling of $\text{P}_2\text{S}_2\text{-5-Ava-BBN}[7\text{-}14]\text{NH}_2$ (4b**).** The free (hydroxymethyl)phosphine derivative ligand stock solution of the $\text{P}_2\text{S}_2\text{-5-Ava-BBN}[7\text{-}14]\text{NH}_2$ conjugate **2b** was prepared by treating **2b** (1.0 mg, 0.6 μmol) in water (200 μL) with 1 M aqueous sodium bicarbonate

Scheme 3. Solid-Phase Synthesis of P_2S_2 -5-Ava-BBN[7-14]NH₂ 2b

(20 μ L) (pH = 7.5). ^{188}Re labeling was achieved via transmetalation from ^{188}Re citrate. An aliquot of the P_2S_2 -5-Ava-BBN[7-14]NH₂ ligand stock solution (30 μ L, 150 μ g) was added to ^{188}Re citrate (700 μ L, 37–74 MBq) and heated at 90 $^\circ\text{C}$ for 30 min. Gentisic acid was added to the ^{188}Re citrate solution for quenching of the free radicals produced by high energy β^- radiation. ^{188}Re citrate was prepared by adding $^{188}\text{ReO}_4^-$ (500 μ L, 37–74 MBq) in 0.9% saline to a solution of stannous chloride (15 mg) in 1 M sodium citrate (200 μ L). The reaction mixture (pH = 5.5) was heated at 90 $^\circ\text{C}$ for 30 min. The product, $^{188}\text{Re}-P_2S_2$ -5-Ava-BBN[7-14]NH₂ conjugate **4b**, was formed in yields of $\geq 95\%$, as a single species as confirmed by reversed-phase HPLC.

In Vitro Binding Assay of $\text{Re}-P_2S_2$ -5-Ava-BBN[7-14]NH₂ Conjugate (4a). In vitro gastrin releasing peptide (GRP) receptor binding capabilities of the labeled peptide was assessed utilizing displacement binding assays conducted at 37 $^\circ\text{C}$ in Swiss 3T3 fibroblast cells, which exhibit high GRP receptor expression, by a method

similar to that designed by Mahmoud et al.⁴² The IC₅₀ value was determined for the nonradiolabeled $\text{Re}-P_2S_2$ -5-Ava-BBN[7-14]NH₂ analogue by analyzing displacement of bound ^{125}I -Tyr⁴-bombesin.

In Vivo Biodistribution of $^{188}\text{Re}-P_2S_2$ -5-Ava-BBN[7-14]NH₂ Conjugate (4b) in PC-3 Tumor-Bearing SCID Mice. The biodistribution and uptake of $^{188}\text{Re}-P_2S_2$ -5-Ava-BBN[7-14]NH₂ conjugate (**4b**) with PC-3 cell derived xenografts in SCID mice was studied. The SCID mice (average weight, 25 g) were injected in each flank of the limb leg with 5×10^6 human prostate cancer PC-3 cells (obtained from ATCC). These cells exhibit an overexpression of GRP receptors on their cell surface. When the tumor reached a weight of between 0.5 and 0.7 g (0.64 ± 0.03 g for these studies) at approximately six weeks after inoculation, aliquots (50–100 μ L) of the labeled peptide solution (55–75 kBq) were injected in each animal via the tail vein. Tissues, organs, and tumors were excised from the animals sacrificed at 1 h postinjection. The activity was counted in a NaI counter and

Figure 2. (a) ^{31}P and (b) Proton-coupled ^{31}P NMR spectra of $(\text{PH}_2)_2\text{S}_2$ -5-Ava-BBN[7-14] NH_2 **1b** and (c) ^{31}P NMR spectrum of P_2S_2 -5-Ava-BBN[7-14] NH_2 **2b**.

the mean percent injected dose per gram calculated. The percent injected dose (% ID) in the blood was estimated assuming a blood volume equal to 6.5% of the total body weight.

RESULTS AND DISCUSSION

To initial evaluate the feasibility of using the $(\text{PH}_2)_2\text{S}_2$ -COOH BFCA as an intermediate for labeling biologically active peptides via the postconjugation method with both Tc-99m or Re-188, a model peptide, glycylglycine ethyl ester (GlyGlyOEt) was selected. The $(\text{PH}_2)_2\text{S}_2$ -GlyGlyOEt conjugate **1a** was synthesized according to Scheme 1. The PH_2 groups in the peptide conjugate conjugate **1a** were formylated using aqueous formaldehyde in the presence of acid to yield $^+\text{P}(\text{CH}_2\text{OH})_3$ groups

Figure 3. IR spectra of (a) 5-Ava-BBN[7-14]-resin and (b) $(\text{PH}_2)_2\text{S}_2$ -5-Ava-BBN[7-14]-resin.

(phosphonium salt) (Scheme 1). The formation of the phosphonium salt protects the P^{III} centers in the form of $\text{P}(\text{CH}_2\text{OH})_2$ ((hydroxymethyl)phosphine) groups against oxidation.^{43,44} Since the peptide conjugate in the form of the phosphonium salt can be stored for long periods of time under aerobic conditions, this provides an important advantage for formulating stable kit formation of radiopharmaceuticals.⁴⁵ We have previously shown that $\text{RP}(\text{CH}_2\text{OH})_2$ groups are stable, even under high levels of

Scheme 4. Synthesis of $^{99\text{m}}\text{Tc-P}_2\text{S}_2$ -GlyGlyOEt **3b** Using Postconjugation Labeling Strategy

Scheme 5. Complexation of P_2S_2 -D-Lys⁶-LHRH **2c with ^{99m}Tc** 

dilution, in aqueous media for several days.^{29–35} The $^+P(CH_2OH)_3$ groups in the peptide conjugates, **2**, can be readily converted to $P(CH_2OH)_2$ groups by treatment with a base (bicarbonate buffer) prior to complexation with a metal center.^{33–35} The high σ -donating nature of the $R_xP(CH_2OH)_{3-x}$ groups allows these peptide conjugates the high affinity for coordination with transition metals.^{46–50} The P_2S_2 -GlyGlyOEt conjugate containing $P(CH_2OH)_2$ groups was reacted with a Re(V) precursor in water to yield the corresponding rhenium complex, ReO_2 - P_2S_2 -GlyGlyOEt **3a** (Scheme 2). The peptide conjugates **1a**, **2a**, and **3a** were characterized by using ^1H , ^{13}C , and ^{31}P NMR and IR spectroscopy and high-resolution FAB mass spectrometry. The spectral data is consistent with our previously reported ReO_2 - P_2S_2 -COOH complex, suggesting that the geometry around the Re(V) center in ReO_2 - P_2S_2 -GlyGlyOEt complex **3a** is identical to that in the ReO_2 - P_2S_2 -COOH complex.^{34,35} The conjugation chemistry of the $(PH_2)_2S_2$ -COOH precursor was extended to produce receptor-avid peptide conjugates P_2S_2 -5-Ava-BBN[7–14]NH₂ **2b** and P_2S_2 -D-Lys⁶-LHRH **2c** (Scheme 1).^{5–8,51–54} The peptide conjugate

2b was also synthesized in an alternative method using a solid-phase peptide synthesizer employing traditional fmoc chemistry (Scheme 3). The $(PH_2)_2S_2$ -COOH BFCA was introduced as the last residue in the sequence. Figure 3 shows the FTIR spectra of the resin containing 5-Ava-BBN[7–14]NH₂ before and after the coupling of the $(PH_2)_2S_2$ -COOH BFCA. The characteristic singlet band at 2294 cm^{-1} , attributed to P–H stretching in the IR spectrum of the $(PH_2)_2S_2$ -5-Ava-BBN[7–14]NH₂-resin, confirms the presence of the PH_2 functionality.³⁶ Treatment of the $(PH_2)_2S_2$ -5-Ava-BBN[7–14]NH₂-resin with aqueous formaldehyde in the presence of dilute hydrochloric acid, followed by cleavage from the resin, yielded the P_2S_2 -5-Ava-BBN[7–14]NH₂ **2b**. The ReO_2 - P_2S_2 -5-Ava-BBN[7–14]NH₂ conjugate **4a** was also synthesized using solid-phase peptide synthetic methods. All new peptide conjugates were characterized by ^{31}P NMR spectroscopy and electrospray mass spectrometry, and the purity was confirmed by HPLC. The presence of phosphorus atoms in these P_2S_2 -peptide conjugates provides an excellent opportunity for using ^{31}P NMR spectroscopy for monitoring the reactions and product for-

Scheme 6. Complexation of P_2S_2 -5-Ava-BBN[7-14]NH₂ **2b with ^{188}Re** 

mation as well as purity of the products in addition to HPLC. The metalated peptide $\text{ReO}_2\text{-P}_2\text{S}_2\text{-5-Ava-BBN-[7-14]NH}_2$ conjugate **4a** exhibited an IC_{50} value of 0.8 ± 0.4 nM for the GRP receptors expressed on Swiss 3T3 fibroblast cells, relative to ^{125}I -Tyr⁴-bombesin, which is similar to that observed with native bombesin.⁴²

Radiolabeling of the P_2S_2 -GlyGlyOEt **2a** with $^{99\text{m}}\text{Tc}$ was carried out using pre- and postconjugation labeling strategies as described in Schemes 2 and 4. In the preconjugation labeling approach (Scheme 4), the $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-COOH}$ complex was first prepared according to our previously reported procedure.^{34,35} The formation of the $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-COOH}$ complex was confirmed by HPLC. The carboxylic functionality was activated by formation of its pentafluorophenol (PFP) ester. The $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-PFP}$ activated ester was produced by a similar procedure reported in the literature.^{18,34,45} The HPLC chromatographic profile indicated the formation of the $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-PFP}$ complex as a single species at 17.1 min. The $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-PFP}$ complex was purified by HPLC and incubated with GlyGlyOEt at room temperature for 30 min at a pH of 8.5. The HPLC profile showed the formation of the $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-GlyGlyOEt}$ complex **3b** as a single species at 10.6 min with a yield of $\geq 95\%$. The retention time of the $^{99\text{m}}\text{Tc}$ -labeled species matched the corresponding $\text{ReO}_2\text{-P}_2\text{S}_2\text{-GlyGlyOEt}$ complex **3a**.

In the postconjugation labeling strategy (Scheme 2), the P_2S_2 -GlyGlyOEt conjugate phosphonium salt **2a** was treated with 1 M aqueous sodium bicarbonate (pH = 8.5) solution prior to complexation. A direct labeling procedure with $^{99\text{m}}\text{TcO}_4^-$ in the presence of stannous tartarate

was used. High labeling yields were obtained at a 0.1 mM P_2S_2 -GlyGlyOEt concentration at room temperature. The product, $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-GlyGlyOEt}$ complex **3b** was formed in a yield $\geq 98\%$, as a single species with a retention time of 10.6 min as determined by reversed-phase HPLC. Radiolabeling using both pre- and postconjugation labeling strategies produced same HPLC chromatograms demonstrating the formation of identical species. The utility of using this postconjugation labeling strategy with larger peptides was further tested by using the $(\text{PH}_2)_2\text{S}_2\text{-D-Lys}^6\text{-LHRH}$ conjugate **1c**. In this case, the $P_2S_2\text{-D-Lys}^6\text{-LHRH}$ conjugate phosphonium salt was produced in situ by formylation of **1c**, which was then treated with 1 M bicarbonate buffer to generate the required (hydroxymethyl)phosphine containing $P_2S_2\text{-D-Lys}^6\text{-LHRH}$ conjugate. The formation of the $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-D-Lys}^6\text{-LHRH}$ conjugate **5** was achieved by the postconjugation labeling reaction conditions described earlier. The product, $^{99\text{m}}\text{Tc-P}_2\text{S}_2\text{-D-Lys}^6\text{-LHRH}$ conjugate **5**, was formed in $\sim 88\%$ yield as a single species as confirmed by reversed-phase HPLC.

This postconjugation labeling strategy was also used for labeling of the P_2S_2 -peptide conjugate **2b** with ^{188}Re (Scheme 6). The $P_2S_2\text{-5-Ava-BBN[7-14]NH}_2$ conjugate **2b** was treated with 1 M aqueous sodium bicarbonate and adjusted to a pH of 7.5. ^{188}Re labeling was achieved via transmetalation from ^{188}Re citrate by heating at 90 °C for 30 min. Gentisic acid was added to the ^{188}Re citrate solution for quenching of the free radicals produced by high-energy β^- particle emissions. ^{188}Re citrate was prepared by addition of $^{188}\text{ReO}_4^-$ to a solution of stannous

chloride in 1 M sodium citrate. The reaction mixture (pH = 5.5) was heated at 90 °C for 30 min. The product, $^{188}\text{Re}-\text{P}_2\text{S}_2-5\text{-Ava-BBN}[7-14]\text{NH}_2$ conjugate **4b**, was formed in yields of $\geq 95\%$ yield, as a single species as confirmed by reversed-phase HPLC. The retention time of the ^{188}Re -labeled matched the corresponding $\text{ReO}_2-\text{P}_2\text{S}_2-5\text{-Ava-BBN}[7-14]\text{NH}_2$ conjugate **4a**, monitored at $\lambda = 280$ nm, and was found to be identical to the corresponding $^{99\text{m}}\text{Tc}-\text{P}_2\text{S}_2-5\text{-Ava-BBN}[7-14]\text{NH}_2$ conjugate previously reported.³⁴ The HPLC purified $^{188}\text{Re}-\text{P}_2\text{S}_2-5\text{-Ava-BBN}[7-14]\text{NH}_2$ conjugate was found to be stable over a period of 18 h with $\leq 5\%$ decomposition. This indicates that the $^{188}\text{Re}-\text{P}_2\text{S}_2-5\text{-Ava-BBN}[7-14]\text{NH}_2$ conjugate **4b** has an identical structure to that of the corresponding $^{99\text{m}}\text{Tc}$ -analogue. Furthermore, the new Re-188 conjugate is stable, even in the absence of excess tin and citrate. For example, the Re-188 conjugate was HPLC purified and found to be stable in vitro for time points in excess of 24 h. Preliminary in vivo studies in SCID mice bearing human prostate cancer xenografts derived from PC-3 cells show that $4.7 \pm 0.8\%$ ID/g of the $^{188}\text{Re}-\text{P}_2\text{S}_2-5\text{-Ava-BBN}[7-14]\text{NH}_2$ conjugate **4b** uptake in these tumors at 1 h postinjection. These data, compiled with the results that an average of 2.3% ID (1.8% ID/g) and average of 0.9% ID (1.0% ID/g) were found in the blood and stomach, respectively, show that this ^{188}Re conjugate retains high in vivo targeting specificity for GRP-receptor-expressing cells and undergoes minimal in vivo decomposition to $^{188}\text{ReO}_4^-$. The postconjugate labeling approach using the $(\text{PH}_2)_2\text{S}_2$ precursor as described herein provides a viable strategy to formulate freeze-dried kit preparations of P_2S_2 -peptide conjugates or other bioactive compounds that can be subsequently labeled in high yields with $^{99\text{m}}\text{Tc}$ or ^{188}Re .

CONCLUSION

The synthetic procedures described here successfully demonstrated the conjugation of the $(\text{PH}_2)_2\text{S}_2\text{-COOH}$ BFCA on peptide backbones that contain a free primary amine group. The peptide conjugates are used as precursors containing phosphine hydrides can be readily formylated to produce the corresponding hydrophilic, (hydroxymethyl)phosphine functionalized, peptide conjugates for potential applications in radiopharmaceutical formulations. The synthesis of the well-defined $^{99\text{m}}\text{Tc}-\text{P}_2\text{S}_2\text{-GlyGlyOEt}$ and radiolabeled receptor-avid peptides, $^{99\text{m}}\text{Tc}-\text{P}_2\text{S}_2\text{-D-Lys}^6\text{-LHRH}$ and $^{188}\text{Re}-\text{P}_2\text{S}_2-5\text{-Ava-BBN}[7-14]\text{NH}_2$, in high yields via postconjugation labeling techniques was demonstrated.

Nanostructured DNA–Protein Aggregates Consisting of Covalent Oligonucleotide–Streptavidin Conjugates

Christof M. Niemeyer,^{*,†} Michael Adler,[†] Song Gao,[‡] and Lifeng Chi[‡]

Universität Bremen, FB2 - UFT, Biotechnologie und Molekulare Genetik, Leobener Strasse, D-28359 Bremen, Germany, and Physikalisches Institut der Universität Münster, Wilhelm-Klemm Strasse 10, D-48149 Münster, Germany. Received July 26, 2000; Revised Manuscript Received November 30, 2000

Covalent conjugates consisting of streptavidin and a 24-mer single-stranded DNA oligonucleotide have been oligomerized by cross-linking with a 5',5'-bis-biotinylated 169-base-pair double-stranded DNA (dsDNA) fragment. The oligomeric conjugates formed have been analyzed by nondenaturing gel electrophoresis and scanning-force microscopy (SFM). The comparison of analogous oligomers, prepared from native STV and the bis-biotinylated dsDNA fragment, revealed that the covalent STV–oligonucleotide hybrid conjugates self-assemble to generate oligomeric aggregates of significant smaller size, containing on average only about 2.5 times less dsDNA fragments per aggregate. Likely, this is a consequence of electrostatic or steric repulsion between the dsDNA and the single-stranded oligomer covalently attached to the hybrid, as indicated from control experiments. Nevertheless, the single-stranded oligonucleotide moiety within the oligomeric conjugates can be used as a selective molecular handle for further functionalization and manipulation. For instance, it was used for specific DNA-directed immobilization at a surface, previously functionalized with complementary capture oligonucleotides. Moreover, we demonstrate that macromolecules, such as STV and antibody molecules, which are tagged with the complementary oligonucleotide, specifically bind to the supramolecular DNA–STV oligomeric conjugates. This leads to a novel class of functional DNA–protein conjugates, suitable, for instance, as reagents in immuno-PCR or as building blocks in molecular nanotechnology.

INTRODUCTION

Molecular nanotechnology concerns the fabrication of well-defined nanoscaled structural and functional devices, using the “bottom-up” approach, in which small molecular building blocks self-assemble to form larger elements (1). Current advances in this area suggest that biological macromolecules are suitable components in the biomimetic synthesis of nanostructured elements and materials. For this purpose, DNA is a particularly powerful construction material (2–4). Due to its unique recognition capabilities, physicochemical stability, mechanical rigidity, and high precision processibility, DNA has extensively been used to fabricate nanostructured scaffolds (3) as well as for the selective positioning of proteins (5, 6), and metal and semiconductor nanoclusters (7–9). In addition, other biomimetic approaches to assemble inorganic nanoparticles have been reported which are based on the use of protein recognition systems, such as the bacterial surface layer proteins (10, 11) and the streptavidin–biotin system (6, 12).

We have recently reported on the self-assembly of bis-biotinylated DNA **1** and the biotin-binding protein streptavidin (STV) **2** which leads to the formation of oligomeric DNA–protein networks **3** (Figure 1) (13). The nanostructured networks had been characterized using scanning-force microscopy (SFM). These studies revealed that the STV molecules predominantly function as a bivalent or trivalent linker between adjacent double-stranded DNA (dsDNA) molecules, despite the tetravalent binding capacity of STV for biotinylated ligands. As a conse-

quence, the supramolecular DNA–STV networks **3** have a high residual biotin-binding capacity, and thus they can be employed as powerful reagents in Immuno-PCR (IPCR) (14), a method for the ultrasensitive detection of proteins and other antigens. In addition, the oligomeric networks **3** have also great potential for applications in biomolecular nanotechnology. For instance, the networks **3** can be used as a starting material for the synthesis of well-defined nanostructures, supramolecular DNA cycles consisting of a single STV and one dsDNA molecule (15). Moreover, the dsDNA–STV oligomers **3** are suitable model systems for basic studies on self-assembled nanoparticle networks and might even be used for the fabrication of ion-switchable nanoarchitecture (16).

We here report on the incorporation of covalent oligonucleotide–STV conjugates **4** as distinct building blocks within oligomeric dsDNA–STV networks **5** (Figure 1). Since the coupling of biotinylated macromolecules occurs preferentially at terminal STV molecules of the oligomeric chains **3**, and also, since some biotinylated compounds degrade the networks (13), we anticipated that the covalently attached oligonucleotide moiety in **4** might be a suitable molecular handle for the selective modification of oligomeric nanostructures **5**. For instance, the coupling of other macromolecules tagged with a complementary oligonucleotide should be attainable. Thus, oligomeric aggregates **5** containing the covalent hybrids were assembled and characterized using native gel electrophoresis and SFM. It was observed that the oligonucleotide-containing oligomeric aggregates **5** are significantly smaller in size than comparable aggregates **3** assembled from native STV. Nevertheless, the oligomers were found to be functional with respect to the hybridization of complementary nucleic acids. This allowed, for instance, the selective immobilization of **5** to capture oligonucleotide-modified surfaces, and the use of

Figure 1. Synthesis of oligomeric streptavidin networks using 5',5'-bis-biotinylated DNA spacers. (A) Formation of supramolecular networks consisting of a 169 bp dsDNA fragment **1** and native streptavidin (STV) **2**. Note that the schematic drawing of the oligomers **3** is simplified, since branch-points occur due to the presence of tri- and tetra- valently conjugated STV (see Figure 3). (B) Assembly of networks from the dsDNA **1** and covalent oligonucleotide-STV conjugates **4**. The latter hybrid molecules were synthesized by covalent coupling of 5'-thiol-modified oligonucleotides and STV using a heterobispecific cross-linker (**5**). The assembly of **2** and **4** leads to the formation of oligomers **5** containing oligonucleotide moieties which can be used for functionalization of **5** by hybridization with complementary oligonucleotide-tagged macromolecules (see Figure 5). For simplification, complementary DNA strands are drawn as parallel lines. The 3'-ends are indicated by the arrowheads.

5 as a novel class of supramolecular reagents in IPCR applications.

MATERIALS AND METHODS

Synthesis and purification of covalent DNA-STV hybrids, **4a** and **4b**, were carried out from the corresponding thiolated oligonucleotides, 5'-thiol-AGC GGA TAA CAA TTT CAC ACA GGA-3' (**4a**), 5'-thiol-TCC GTG GTG AAA TTG TTA TCC GCT-3' (**4b**), respectively, and recombinant streptavidin **2** (IBA, Göttingen), similar as previously described (**5**). In brief, STV (10 nmol) was derivatized with maleimido groups using a heterobispecific cross-linker (sulfo-SMCC, Pierce), reacted with a 5'-thiolated oligonucleotide (10 nmol) and subsequently the unreacted maleimido groups were quenched with an excess of mercaptoethanol. The crude product was purified by anion-exchange chromatography, and the one-to-one molar ratio of the oligonucleotide and STV moiety within the hybrids was verified by gel-electrophoretic and photometric analysis (**5**). For control purposes, STV **2a** was activated with the cross-linker but quenched with an excess of mercaptoethanol instead of the reaction with the thiolated oligonucleotide.

The 169 base pair bis-biotinylated dsDNA fragment **1** was prepared from M13mp18 template (Promega) by preparative polymerase chain reaction (PCR), using two biotinylated primers: 5'-biotin-AGC GGA TAA CAA TTT CAC ACA GGA-3' (bcA) and 5'-biotin-AAG GCG ATT AAG TTG GG-3' (bG) as previously described (**13**). A monobiotinylated 169 bp dsDNA fragment **1a** was synthesized for the preparation of model conjugates. An additional bisbiotinylated 256 bp dsDNA fragment was prepared from pUC19 template, similar as described in

reference (**13**). The dsDNA products were purified by gel-filtration chromatography, quantified by photometry and characterized by nondenaturing agarose gel electrophoresis in the presence of a DNA molecular weight standard. Oligomeric conjugates **3** and **5** were prepared from recombinant STV **2** or the DNA-STV hybrids **4**, respectively. As an example, 1 μ L of the dsDNA, 3 μ M in 10 mM Tris buffer, pH 7.3 containing 5 mM EDTA (buffer A), was mixed with 14 μ L of STV or hybrids **4** (0.2 μ M in Buffer A), and the mixture was incubated typically for out about 24 h at 4 $^{\circ}$ C. The low ionic strength buffer A was chosen to avoid the condensation of the DNA fragments during immobilization on mica for SFM inspection (**16**). For gel electrophoretic analysis, the molar ratio of dsDNA to STV ranged from 4:1, 2:1, 1:1, 1:2, 1:4, to 1:10, respectively, as indicated in Figure 2.

Samples for SFM imaging were prepared by placing a 6 μ L drop of a solution containing 4 μ M MgCl_2 and about 500 nM DNA-STV conjugates on a Parafilm sheet. The droplet was adsorbed onto freshly cleaved mica and left to fix for 1 min. The drop was then quickly washed three times with 50 mL of deionized water and immediately blown dry for 5 min with nitrogen gas. The SFM inspection was carried out with commercial instruments (Digital Instrument, Dimension 3000 TM and Multimode III TM) using Si cantilevers purchased from Nanosensor TM. The SFM images were taken with instruments operating in high-amplitude dynamic mode with a home-made active feedback circuit (**17**), preventing the onset of intermitted contact (tapping). With this circuit, SFM can be run stable in the attractive interaction regime in air so that the interaction between the scanning tip and the sample is minimized.

Figure 2. Gel electrophoretic analysis of the self-assembly of biotinylated dsDNA and streptavidin. (A) Formation of adducts from native streptavidin (STV) **2** and DNA–STV hybrid **4** with biotinylated dsDNA fragments. This is a nondenaturing 2% agarose gel stained with ethidium bromide. Adducts were formed by mixing bisbiotinylated dsDNA **1** with 1 or 4 mol equiv of native STV (lanes 9 and 10, respectively). The coupling of equimolar amounts of **1** and **2** leads to the formation of an immobile band (position k in lane 9), while in the case of the coupling of **1** and STV-hybrid **4a** (lanes 4, 5), individual bands of lower molar weight are observed. As model compounds, adducts obtained from STV and varying amounts of monobiotinylated dsDNA **1a** are analyzed in lanes 6–8. The analogous adducts obtained from hybrid **4a** are shown in lanes 1–3. The small letters at the right side indicate the mobilities observed for free dsDNA **1** (a) and the adducts STV–DNA₁ (b, f), STV₂–DNA₁ (c), STV–DNA₂ (d, g), STV–DNA₃ (e, h), and STV–DNA₄ (i). Lane M contains a DNA molecular weight marker, the lengths are indicated as base pairs. The free conjugate **4a** comigrates with the 396bp fragment of the molecular weight marker (not shown). (B) Comparison of native STV **2**, chemically activated STV **2a**, and DNA–STV hybrid **4a** in the aggregation with bisbiotinylated dsDNA **1**. This is a nondenaturing 1.5% agarose gel stained with ethidium bromide. A fingerprint-like band pattern of adducts is formed by mixture either **2**, **2a**, or **4a** with different ratios of **1**, ranging from 0.1 to 2 mol equiv of the DNA. Note the similarity of the patterns observed for **2** (lanes 9–12) and **2a** (lanes 5–8), compared to the smaller products obtained from **4a** (lanes 1–4). Some differences between **2a** and **2** are visible in lanes 7 and 11. While native STV and an equimolar amount of **1** form an immobile product band (lane 11, see also position k in Figure 2a), this band is missing for the STV **2a** (lane 7), and also smaller aggregates are obtained in the case of an excess of the STV components **2** and **2a** in lanes 9 and 5, respectively. In contrast, a completely different band pattern is obtained from **4a**, indicating the formation of a dumbbell-shaped conjugate STV₂–DNA₁ as the major product (position c in Figure 2a).

Solid-phase hybridization of the conjugates **5** were carried out on STV-coated microplates, functionalized with a biotinylated capture oligonucleotide, complementary to **4a**, similar as described earlier (18). A 30 μ L volume of a 3.3 fM solution of **5** in buffer A was incubated in the wells of this microplate for 30 min at room temperature, and after washing, the immobilized DNA was amplified by PCR. The low ionic strength buffer A was chosen to allow for comparison with previous experiments. Quantification of the PCR products was carried out by microtiter-plate based enzyme-linked immunosorbent assay (19).

For Immuno-PCR analysis, serial dilutions of rabbit IgG model antigen (Sigma, St. Louis, MO) immobilized in TopYield modules (Nunc) were used as a model antigen as previously reported (13, 19). For preparation of conjugates **6** and **7**, 5 μ L of a 500 nM solution of biotinylated goat anti-rabbit antibody (Coulter Immuno-tech, Hamburg, Germany) was either coupled with 15 μ L of a 166 nM solution of **3**, or else, similar amounts of the antibody were coupled with 10 μ L of a 250 nM of **4b**. In the latter case, the antibody-conjugated DNA-STV hybrid **4b** was quenched with excess D-biotin and subsequently mixed with equimolar amounts of the D-biotin saturated oligomer **5**. The mixture was incubated for 3 h at room temperature and then used in IPCR assay, as described (13).

RESULTS AND DISCUSSION

Self-Assembly of the DNA-Streptavidin Complexes 3 and 5. A 169 bp bis-biotinylated dsDNA **1** was synthesized by preparative PCR using two 5'-biotin derivatized primer oligonucleotides, and, for control purposes, the analogous mono-biotinylated dsDNA fragment **1a** was similarly prepared from one 5'-biotin derivatized and one unlabeled primer. Covalent hybrids of DNA and streptavidin, **4a** and **4b**, were synthesized from 5'-thiolated oligonucleotides and recombinant streptavidin by chemical cross-linking as previously described (5). The chief products, hybrids containing a single oligonucleotide moiety per STV, were purified by chromatography.

Figure 2a shows the electrophoretic comparison of the adducts of monobiotinylated **1a** and the STV hybrid **4a** (lanes 1–3), or else, with native STV (lanes 6–8), respectively. Lanes 2 and 7 compare the conjugates obtained from the coupling of monobiotinylated dsDNA **1a** with equimolar amounts of **4a** or STV **2**, respectively. The covalently linked oligonucleotide domain in **4a** influences the electrophoretic mobility of the monoadducts, STV–DNA₁ and **4a**–DNA₁, respectively (position b, f in Figure 2a). Moreover, it can be seen that the relative ratio of the mono- and bis-adducts is about 1:4 in the case of native STV, while in the case of the STV hybrid **4a**, this ratio is only about 5:1. This suggests that the affinity of **4a** for the biotinylated dsDNA **1a** is decreased compared to the native STV. The comparison of lanes 2 and 7 in Figure 2a supports this assumption. Native STV forms adducts of a relative stoichiometry of STV–DNA_{3,4} to a small but significant extent. The preferential formation of bis-adducts has previously been observed (13). However, in the case of the hybrid **4a** (lane 2), the analogous complex, **4a**–DNA₄ is entirely missing. The reduced affinity of **4a** for the biotinylated dsDNA can also be deduced from the comparison of lanes 4 and 9 (Figure 2a), in which the bis-biotinylated dsDNA **1** was mixed with equimolar amounts of STV **2** or **4a**, respectively. In the case of native STV, this coupling leads to

the formation of a single immobile band (position k), indicating the formation of large oligomeric networks **3** in lane 9. In contrast, the coupling of **4a** leads to the formation of individual bands, representing the presence of small supramolecular aggregates **5** (lane 4).

The reduced affinity of **4a** for the biotinylated dsDNA might be due to an increased steric or electrostatic repulsion of the dsDNA and the covalently bound oligonucleotide, or else, due to a decreased biotin-binding affinity itself, possibly caused by a conformational change induced by the chemical treatment of the STV's surface. The latter might be possible despite the fact that we had previously established the complete tetravalent binding capacity of the covalent hybrids **4** for the binding of low molecular weight D-biotin (**5**). To further elucidate why only small aggregates are formed from the hybrids **4**, controls were carried out with STV **2a**, activated with the cross-linker but not exposed to the thiolated oligonucleotide (Figure 2b). The coupling of various molar equivalents of the bis-biotinylated dsDNA **1** revealed an almost unchanged capability of the control STV **2a** for binding the biotinylated dsDNA, as compared to either the native STV **2** or the DNA-STV hybrid **4a**. These results suggest that the decrease in oligomer formation of **4a** is mainly due to steric and/or electrostatic repulsion of the dsDNA and the single-stranded oligomer. It seems likely that an increase in the ionic strength of the buffer would compensate for electrostatic repulsion. However, we have used a low salt 10 mM Tris buffer throughout this initial study for two reasons. First, these conditions are equal to that of a previous study, thereby allowing for a direct comparison of the results (13). Second, the use of higher salt concentration, in particular the presence of magnesium, leads to the formation of anomalous aggregate structures (16). In particular, a condensation of the DNA fragments occurs which makes the aggregates difficult to analyze by SFM. Nevertheless, we anticipate that the detailed optimization of coupling conditions, such as a systematic variation of polyvalent cations and ionic strengths, will lead to novel means of affecting the aggregate's supramolecular structure.

To study the structures of the oligomeric DNA-STV complexes, samples of **3** and **5** were imaged using dynamic SFM working in attractive regime mode. Representative images are shown in Figure 3, and statistical analysis of the complexes observed are given in Table 1. As expected from the gel electrophoretic characterization (Figure 2), the average size of **3** is more than 2-fold greater than that of **5**. On average, the oligomers **5** contain only about 2.0 dsDNA fragments per supramolecular conjugate. Even more significant, however, is the complete lack of highly oligomerized networks, containing more than 10 DNA molecules per conjugate (Table 1). Moreover, the comparison of the streptavidin's valency reveals that in the case of the oligomers **5**, on average, only 1.46 dsDNA fragments are coupled per protein particle. In contrast, an average STV valency of 2.4 is observed in the oligomers **3**. Experiments carried out with DNA-STV hybrids containing other sequences of the single-stranded oligomer, such as **4b**, led to similar aggregation patterns, as judged from gel-electrophoretic analysis (data not shown). These observations again indicate the decreased affinity of **4** for the binding of biotinylated dsDNA, as compared to native STV **2**.

Functionality of the Oligonucleotide Domain of Oligomers 5. As an initial test of the functionality of the oligonucleotide domain of **5**, the supramolecular aggregates **5** were hybridized to complementary capture oligonucleotides, previously immobilized in STV-coated

Figure 3. Scanning force microscopy images of oligomeric dsDNA-STV conjugates. (A) DNA-STV networks **3** obtained from native STV. (B) Oligomers **5** obtained from dsDNA **1** and covalent oligonucleotide-STV conjugates **4**. (C) A preformed oligomer **5** was coupled with the complementary DNA-STV hybrid **4b**. The arrows indicate the occurrence of **4a-4b** dimers, formed by hybridization of the two complementary oligonucleotide moieties. (D) Interconnected networks obtained from the self-assembly of two complementary STV hybrids **4a** and **4b**, subsequently oligomerized using a bis-biotinylated 256 bp dsDNA. Note that these nanoparticle networks contain two different dsDNA spacers, the ca. 87 nm dsDNA and the about 7 nm dsDNA formed by the hybridization of **4a** and **4b** (arrows). The latter dsDNA spacer fragment, however, cannot directly be observed by SFM imaging.

^a The values are not affected by treatment of the oligomers **3** and **5** with an excess of D-biotin. The total number of molecules counted was greater than 2000. ^b The numbers are average values obtained from **4a** and **4b**, with a relative deviation between the two hybrids of less than 5%. ^c Percentage fraction of oligomeric conjugates, containing the number of dsDNA fragments specified below. ^d Maximum size of the supramolecular complexes. ^e Average size of the supramolecular complexes. ^f The valency depicts the number of biotinylated dsDNA fragments that are bound to individual STV molecules within the oligomers **3** and **5**.

microtiter plates (Figure 4). Successful binding of **5** was measured using PCR-amplification of the immobilized material and subsequent quantification by PCR-ELISA analysis (19). For comparison, similar amounts of **5** were

also incubated in wells, previously modified with a noncomplementary capture oligonucleotide. In addition, similar amounts of **5** were directly amplified by PCR to allow for estimation of the immobilization efficiency. As indicated in Figure 4, the immobilization efficiency of **5** was about 40%, and thus the assay provided evidence for the functionality of the oligonucleotide domain within the oligomers **5**. Since a single solid-phase binding contact leads to the adsorption of multiple DNA fragments; however, this efficiency is not necessarily identical with the hybridization efficiency of the oligonucleotide moiety in **5**. To estimate the latter, oligomers **5** were mixed with equimolar amounts of DNA-STV hybrid **4b**, containing a complementary oligonucleotide sequence, and the resulting conjugates were analyzed by SFM after hybridization (Figure 3C). In the resulting bioconjugates, STV-STV dimers were clearly distinguishable by SFM inspection. Statistical analysis revealed that about 20% of the STV hybrids **4a** have hybridized with the complementary hybrid **4b**.

As a further test of the hybridization capabilities, the two complementary STV hybrids **4a** and **4b** were mixed, and after hybridization, the dimers were subjected to oligomerization using bis-biotinylated dsDNA. A sample of the products was characterized by SFM (Figure 3D). The image obtained showed interconnected networks **5** in which the dimer of the two complementary conjugates **4** were clearly distinguishable. The use of the two complementary hybrids leads to the formation of “true” tetravalent connectors, the **4a-4b** dimers, and thus the size of the oligomers **5** is significantly increased. A maximum of up to 40 and, on average, about 4.4 dsDNA

Figure 4. Site-specific immobilization of oligonucleotide-containing networks **5** by hybridization to complementary surface-bound capture oligonucleotides. The schematic drawing of the immobilized oligomers **5** is shown in the boxed inlay. The histograms represent the signal intensities obtained from PCR amplification of surface-bound oligomers **5**. As a positive control (PC), similar amounts of **5** were directly amplified by PCR. Note that the comparison of signals obtained from surface hybridization of **5** and PC indicates an immobilization efficiency of about 40%. As negative controls, similar amounts of **5** were incubated in wells, modified with noncomplementary capture oligonucleotides (NC1), or else no conjugate **5** was applied to the wells (NC2).

fragments were present in the individual oligomers. This is more than twice as much as observed in the regular oligomers **5**, and the size of the networks even exceeds those obtained from native STV **2** (Table 1).

The Use of Oligomers **5 As Reagents in Immuno-PCR.** We had previously demonstrated that immunoglobulin (IgG)-functionalized oligomers **3** are powerful reagents in immuno-PCR (IPCR) (13), in particular, when preformed and purified IgG-containing aggregates are used (see **6** in Figure 5). The employment of purified **6** leads to an about 100-fold enhancement of IPCR sensitivity, compared to the standard IPCR protocol using successive coupling strategies. Likely, this is not only a consequence of the oligomeric nature of **6**, leading the binding of multiple DNA marker fragments per antigen contact. In addition, the oligovalency of **6** should allow for cooperative avidity effects due to a polyvalent interaction with the surface-immobilized target structures to be detected (13). To accomplish an efficient IgG-coupling with the oligomeric dsDNA-STV conjugates, we reasoned that the linkage with biotinylated IgG might be attained by hybridization of the oligomers **5** with a preconjugate, obtained from complementary STV hybrid **4b** and a biotinylated antibody (Figure 5). To investigate this hypothesis, an oligomeric conjugate **7** was prepared from equimolar amounts of **5** and a conjugate of **4b** and

biotinylated anti-mouse IgG. As a control, a similar mixture was prepared from **5** and an antibody-STV hybrid conjugate that is noncomplementary to the oligonucleotide moieties within **5**. The resulting bioconjugates were analyzed by nondenaturing gel electrophoresis (data not shown). While the control sample only showed the typical band pattern of oligomer **5**, the presence of an immobile band in the case of **7** suggested the formation of high molecular weight species, likely the supramolecular oligomer proposed in Figure 5.

To further evaluate the formation of **7** the functionality of the putative bioconjugate was tested in the IPCR detection of a rabbit IgG model antigen. For comparison, the negative control, consisting of the noncomplementary STV hybrid **4b**-IgG conjugate described above, and also the conventional supramolecular oligomer **5** were used as reagents. The IPCR signals obtained in this assay are shown in Figure 6. While in the case of the negative control no significant signal intensity was observed, both supramolecular reagents, **6** and **7**, revealed distinct IPCR performance. Both preparations were used as crude assembly products without any purification, and thus the reagent **6** was of lower performance than the conventional IPCR, using successive incubation of the biotinylated antibody, STV, and the biotinylated dsDNA marker (19). Strikingly, the supramolecular oligomer **7** showed

Figure 5. Functionalization of oligomeric DNA–STV networks with biotinylated antibodies. (A) Direct coupling of oligomers **3** with a biotinylated antibody. The conjugation predominantly occurs at the terminal STV molecules of the oligomers (**13**). (B) Functionalization of the oligonucleotide-containing oligomers **5**, using a conjugate previously assembled from a complementary STV hybrid **4b** and a biotinylated antibody.

greater signals, suggesting the efficient incorporation of the biotinylated antibody. We anticipate that the performance of this novel class of reagents might further be optimized, for instance, by variations in the coupling stoichiometry, ionic strength of reaction buffers, and also the purification of the supramolecular oligomers after their assembly.

CONCLUSIONS

In this report, oligomeric aggregates consisting of bis-biotinylated dsDNA fragments and the biotin-binding protein STV have been functionalized by incorporating semisynthetic building blocks, covalent conjugates of STV, and a single-stranded oligonucleotide moiety. The incorporation of the latter hybrid molecules led to significant decrease of the size of the dsDNA–linked oligomeric aggregates, compared to those obtained from native STV which form large oligomeric networks. This indicates a decreased affinity of the covalent STV hybrids for binding biotinylated DNA fragments, likely due to steric or electrostatic repulsion of the DNA moieties. Nevertheless, the covalently attached oligonucleotide of the STV hybrids can be used as a selective molecular handle for convenient modification of the oligomeric DNA–STV aggregates. For instance, the oligonucleotide moiety was used to specifically immobilize the oligomeric bioconjugates to capture oligomer-modified surfaces or else for generating interconnected networks consisting of two different lengths of dsDNA linkers. Moreover, the coupling of immunoglobulins, tagged with complementary oligonucleotides, was attained by nucleic acid hybridization. This leads to a novel class of functional supramolecular bioconjugates, suitable, for instance, as reagents

Figure 6. Use of the supramolecular bioconjugates **6** and **7** shown in Figure 5 as reagents in Immuno-PCR. The signals were obtained in the Immuno-PCR detection of rabbit immunoglobulin as a model antigen, using either the antibody-functionalized oligomer **6**, or else the antibody-functionalized supramolecular bioconjugate **7** as a reagent. Signal intensities are given as normalized values, obtained from fluorescence intensities of the samples divided by the intensity of the negative controls in which no antigen was present. Both supramolecular bioconjugates were used as crude assembly products without further purification. The signal intensities were obtained by PCR-ELISA quantification of the IPCR products.

in immuno-PCR. Further studies of this approach will focus on the development of optimized coupling conditions, in particular the systematic variation of cations and ionic strengths, to attain an efficient hybridization of oligonucleotide-containing supramolecular networks and complementary oligonucleotide-tagged macromolecules.

This manuscript describes initial steps of the systematic development of self-assembled DNA–protein conjugates. The novel aggregates described here almost exclusively form chainlike structures and thus are much more regular than aggregates obtained from native STV displaying randomly branched networks. We anticipate that the extensive study of such systems will eventually lead to novel approaches toward the use of such components as building blocks in biomolecular nanotechnology. DNA–STV aggregates might serve as molecular framework for the bottom-up construction of devices, decorated by attachment and selective positioning of biotinylated functional molecular components, such as proteins (20), inorganic metal nanoclusters (6), or low molecular weight peptides and fluorophores (21). Further exploration of nucleic acid- and streptavidin-based recognition systems will open the door to the fabrication of novel biomaterials and thus will contribute to the current development of the novel discipline, descriptively termed as “nanobiotechnology”. Applications might include the fabrication of supramolecular hybrid materials, useful as nanosensors, catalytic and light-harvesting devices, ultrafast

molecular switches and transistors, supramolecular mediators between electrical and living systems, and other bio- and optoelectronic elements.

Quantitative Assays of the Amount of Diethylenetriaminepentaacetic Acid Conjugated to Water-Soluble Polymers Using Isothermal Titration Calorimetry and Colorimetry

Sébastien Gouin and Françoise M. Winnik*

Faculté de Pharmacie, Université de Montréal, C.P. 6128, succursale Centre-ville, Montréal, Québec, Canada H3C 3J7. Received September 10, 2000; Revised Manuscript Received January 10, 2001

The level of conjugation of diethylenetriaminepentaacetic acid (DTPA) to the polysaccharide sodium hyaluronan (HA) has been measured by a colorimetric assay, isothermal titration calorimetry (ITC), and ^1H NMR spectroscopy. The colorimetric assay is based on the red shift, upon complexation with gadolinium ion (Gd^{3+}), of the wavelength of maximum absorption of the dye arsenazo III. It can be performed in a few minutes using as little as $10\ \mu\text{g}$ of polymer with a detection limit of $\sim 0.03\ \text{mmol}$ of DTPA ($\text{gram of polymer}^{-1}$). The ITC measurements yield values of the amount of DTPA linked to HA identical to those obtained by colorimetry. The levels of DTPA conjugation calculated by integration of signals at 3.1–3.2 ppm (DTPA protons) and at 2.0 ppm (HA acetamide protons) in the ^1H NMR spectrum of HA–DTPA are consistently overestimated by a factor of ~ 2 , compared to the data obtained by ITC and colorimetry. The longer relaxation times of protons of the polymer backbone, compared to those of protons attached to the freely moving DTPA side-chains may account for the discrepancy.

INTRODUCTION

Magnetic resonance imaging (MRI) contrast agents are intended to improve diagnosis of disease by changing tissue signal intensity and, consequently, to enhance detection and characterization of lesions. The more specific the accumulation of contrast agent within a target tissue, the better the resulting lesion–tissue contrast. An effective approach toward precise targeting of the imaging agent consists of its conjugation to a biopolymer, the “carrier” (1), with inherent affinity for a particular lesion. Typical carrier systems include antibodies, proteins, peptides, polysaccharides, such as dextrans (2, 3), sodium hyaluronate (4), and other natural polymers (5–9).

The contrast agents most widely used in MRI are complexes of the gadolinium ion (Gd^{3+}) and polyaminocarboxylate ligands, such as diethyltri-aminepentaacetic acid (DTPA) (2, 5, 10–13). Indeed, Magnevist, the contrast agent currently used clinically is an aqueous solution of DTPA–Gd. To date, no polymer derivative of DTPA–Gd is available for routine clinical applications. We developed recently several syntheses of DTPA–Gd conjugates of hyaluronan (HA), an alternating copolymer of D-glucuronic acid and 2-acetamido-2-deoxy- β -D-glucopyranose (Figure 1) (4). As the project progressed, it became imperative to be able to determine precisely the amount of DTPA–Gd linked to the polymer. At first, we relied on high-field ^1H NMR spectroscopy, since in spectra of the DTPA–HA conjugates, signals attributed to protons linked to the polymer backbone and signals due to the resonance of the chelate protons were distinct enough to allow precise integration. However, the ratios chelate: polymer chain determined by ^1H NMR turned out to be

Figure 1. Chemical structure of HA–DTPA.

artificially high, since this analysis does not take into account the fact that relaxation times of protons linked to the freely rotating chelate moieties are usually much shorter than the relaxation times of protons on the polymer backbone (14). Several quantitative analytical methods have been reported for the determination of DTPA/polymer coupling efficiency. They include elemental analysis (5), EDTA titration (2), and acid–base titration (15). We evaluated all the published methods to determine the efficiency of DTPA/HA conjugation and observed that none of the standard protocols yielded sufficiently accurate results to allow reliable comparisons of polymer characteristics and performance as contrast agents *in vivo*. This situation led us to design two new analytical methods: a colorimetric assay with the dye arsenazo III and a Gd binding assay by isothermal titration calorimetry (ITC).

We report here the detailed protocols of the colorimetric and ITC assays using two samples of HA–DTPA. We compare the results of the newly developed assays with data obtained from elemental analysis and ^1H NMR spectroscopy performed on the same polymers. The methods are assessed in terms of ease of performance,

accuracy, repeatability, and sensitivity. Although the assays have been tested only on hyaluronan–DTPA conjugates, they should be applicable also to the analysis of other DTPA-conjugates of water-soluble polymers and can be modified easily to the quantification of chelators other than DTPA.

EXPERIMENTAL SECTION

Materials. Sodium hyaluronate (HA, ~500 kDa) was a gift of Hyal Pharmaceutical Corporation (Mississauga, ON, Canada). Gadolinium chloride hexahydrate ($\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$), europium chloride (EuCl_3), and arsenazo III (2,2'-[1,8-dihydroxy-3,6-disulfonaphthylene-2,7-bisazo]-bisbenzene arsonic acid) were purchased from Aldrich Chemical Corporation and used as received. The following buffers were prepared using water ($R = 18 \text{ M}\Omega \text{ cm}$) deionized by a Millipore water purification system: pH 5.25: acetic acid–sodium acetate (0.1 M); pH 2.0: hydrochloric acid–sodium chloride (0.1 M); pH 6.5: PBS (4.400 g of NaCl, 7.576 g of Na_2HPO_4 , 1.600 g of NaH_2PO_4 in 1 L, adjusted with HCl 1 N) or MES (2.13 g of morpholineethanesulfonic acid in 1 L, adjusted with HCl 1 N). HA–DTPA (see Figure 1) was prepared following methods described elsewhere (4, 16). Briefly, HA was reacted first with ethylenediamine in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide as the coupling agent in a 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer solution (pH 4.5). The ethylenediamine-modified HA was purified by dialysis. It was reacted with DTPA activated separately with a dicyclohexylcarbodiimide/*N*-hydroxysulfosuccinimide mixture in dimethyl sulfoxide (DMSO) prior to the addition. The resulting HA–DTPA was purified by three consecutive ultrafiltrations using membranes with a molecular cutoff of 3500 Da.

The following test was performed in order to confirm the absence of free DTPA in purified HA–DTPA. A solution of HA and DTPA (0.15 mol DTPA/1 mol Glucuronic acid) in water (pH 9.0) was subjected to three consecutive ultrafiltrations with water. The combined filtrates were lyophilized yielding a solid residue identified as DTPA. The amount of DTPA recovered was determined by the arsenazo test (see below) and by gravimetry. Both techniques agreed, indicating a recovery of $97\% \pm 1\%$.

^1H NMR Experiments. ^1H NMR spectra were run with a 400 MHz NMR spectrometer (Bruker). Samples (polymer concentration: 1% w/w) were prepared in deuterated water (Cambridge Isotope Inc). Typically, 96 scans were recorded with interscan delays of 1 or 5 s and water was used as an internal standard. The intensity of the signal at 3.1 ppm (2 protons of the DTPA amide methylene) was determined and compared with the intensity of the methyl amide group of the glucuronic residue (3 protons). The level of DTPA incorporation was calculated from the ratio of the signals at 3.1 and 2.0 ppm assuming a level of incorporation of 100% for a ratio of 0.66.

Isothermal Titration Calorimetry. Binding isotherms were obtained using a Microcal VP–ITC ultrasensitive titration calorimeter (MicroCal Inc., Northampton, MA). The sample cell had a volume of 1.43 mL. It was filled with an aqueous buffered solution of either DTPA (0.25 mM) or HA–DTPA (0.60 mM Glu). An aqueous buffered solution of Gd^{3+} (6.5 mM) was placed in a 300- μL continuously stirred (300 rpm) syringe and injected into the cell in 15 to 25 5- μL aliquots, delivered over 10 s in intervals of 6–8 min. Data points were

collected every 2 s. The measurements were performed at 25 °C. All titrations were carried out three times to ensure consistency of the data and stability of the solutions. This was particularly important in the case of measurements conducted at pH 2. Even under such acidic conditions, data was reproducible, confirming the stability of HA–DTPA during analysis. Data analysis was carried out using the Microcal ORIGIN software. The principles and basic thermodynamic conventions of ITC are discussed in a recent publication (17).

Colorimetric Assays. Absorbance spectra were measured with a Hewlett-Packard 8542A photodiode array spectrometer. A calibration curve was obtained by measuring the absorbance at 660 nm of a series of standard solutions of the arsenazo III/ Gd^{3+} complex prepared by mixing stock solutions of GdCl_3 (0.2 mM) and arsenazo III (0.2 mM) in pure water.

Method I. Solutions for analysis were prepared by adding to a solution of HA–DTPA (10 mg L^{-1} , 1.0 mL) an excess of Gd^{3+} in aqueous solution (~0.6 to 1.0 mL), followed by an arsenazo III stock solution (1.0 mL), the final solution being made up exactly to 10 mL. The absorbance of the solution at 660 nm was measured. The concentration of Gd^{3+} that is not bound to HA–DTPA was determined using the calibration curve fitted with a 3rd order polynomial function. The concentration of polymer-bound DTPA was obtained by subtracting the excess Gd^{3+} determined colorimetrically from the total amount of Gd^{3+} added to the sample.

Method II. Excess $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ (usually about 4–7 mg depending on the expected level of DTPA conjugation) was added to a solution of HA–DTPA (20 mg in 13 mL water). The solution was subjected to ultrafiltration using a Diaflo system fitted with YM-10 membranes (Amicon, Beverly, MA, molecular weight cutoff: 10 kDa). The polymer solution was washed with 10-mL portions of water, and four samples of filtrate (10.0 mL each) were collected during ultrafiltration. The concentration of Gd^{3+} in the filtrate was analyzed as follows: An aliquot of the filtrate (500 μL) was added to the arsenazo III stock solution (1.0 mL). The solution was made up to exactly 10 mL. The absorbance of the solution was measured at 660 nm. The arsenazo III/ Gd^{3+} concentration of the sample was determined using the calibration curve. This value corresponds to the excess Gd^{3+} added to the HA–DTPA solution analyzed. The concentration of polymer-bound DTPA was obtained by subtracting the excess Gd^{3+} determined by colorimetry from the total amount of Gd^{3+} added to the sample.

RESULTS AND DISCUSSION

Isothermal Titration Calorimetry. ITC is commonly used to determine the thermodynamics of substrate/ligand interactions, since it provides in a single measurement the enthalpy of binding ($\Delta H_{\text{binding}}$), the equilibrium constant K , and the stoichiometry of binding (17). The quantitative determination of the number of DTPA groups linked to a polymer backbone relies on the precise measurement of the number of binding sites offered to Gd^{3+} by the conjugated polymer. Such measurement has to be performed at concentrations above K_D of the complex. The binding constant of the DTPA–Gd complex was measured previously by potentiometry [18], but there are no reports of its determination by ITC. To validate our protocol, we set about to carry out a titration of the

Figure 2. Titration of Gd^{3+} (0.2 mM) into water (a) and aqueous DTPA (0.25 mM) (b) at 25 °C and pH = 5.25. Above: calorimetric traces (heat flow against time). Below: reaction enthalpy (obtained by integrating the peaks in curves above) vs the $\text{Gd}^{3+}/\text{DTPA}$ ratio (mol/mol).

DTPA–Gd system, before undertaking the analysis of polymer-bound DTPA. Experimental titration curves of a concentrated Gd^{3+} solution in buffered water (curve a) and in a buffered aqueous solution of DTPA (curve b) are represented in Figure 2 (top). In the simple dilution experiment (curve a), each injection produces a small endothermic signal corresponding to the heat of dilution of Gd^{3+} in the buffer. In the binding experiment (curve b), the first injections produce strong exothermic signals associated with the formation of the DTPA–Gd complex. Then, as the Gd^{3+} concentration reaches the value corresponding to a DTPA/ Gd^{3+} molar ratio of 1, the signal decreases rapidly and at even higher $[\text{Gd}^{3+}]$ the signal takes a constant endothermic value, corresponding to ΔH_{dil} . The dilution enthalpy and the binding enthalpy were determined by integration of each peak in the respective experimental curves (Figure 2, bottom). We note that ΔH_{dil} decreases slightly with increasing Gd^{3+} concentration. This effect is taken into account in the data treatment by subtracting the heat of dilution from the raw binding data. The curve corresponding to the titration shows a sharp transition for DTPA/Gd = 1. From the enthalpy of the transition one can calculate the binding constant. It turns out that the DTPA–Gd binding constant at pH = 5.25 is too high to be determined accurately by ITC (17). The suggested upper limit of detection is $\sim 10^8 \text{ L mol}^{-1}$. The reported value at this pH is more than 5 orders of magnitude higher. To circumvent this difficulty, we determined a conditional binding constant K_{cond} at a lower pH (2.0). The thermodynamic stability constant, K_{therm} , was calculated using the eq 1 (acidity constants are reported elsewhere (18)) where K_1 is the acidity constant of H_5DTPA , K_2 is the acidity

constant of H_4DTPA^- , K_3 is the acidity constant of $\text{H}_3\text{DTPA}^{2-}$ and so on. The value of pK (23.02) thus determined compares satisfactorily with the reported value 22.46 (18). The binding constant of HA-conjugated DTPA was determined at pH 2.0, following the same protocol. A thermodynamic pK value of 23.3 was calculated from eq 1, using the acidity constant of free DTPA as an approximation. This value turns out to be identical, within experimental error, to the pK of free DTPA, in contrast to previous reports indicating that the DTPA–Gd binding constant for protein conjugated DTPA is lower than that of free DTPA (19). For example, pK values of 18.80 and 18.87 were determined for BSA–DTPA–Gd and IgG–DTPA–Gd, respectively. Further experiments are in progress to assess the generality of this observation.

It is worth noting that choosing the adequate buffer for the ITC experiments is a critical task. The buffer has to satisfy three criteria: (a) it must dissolve a Gd^{3+} salt in sufficiently high concentration; (b) it must maintain a pH close to neutral (~ 5 to 7) to prevent undesirable degradation of the polymer; (c) the enthalpy of dilution (ΔH_{dil}) of the Gd^{3+} solution in the buffer should be small, compared to the enthalpy of binding. In practice ΔH_{dil} varies greatly with the chemical composition of the buffer. For example, in PBS and MES buffers, the ΔH_{dil} is very large, compared to the enthalpy of binding ($\Delta H_{\text{binding}}$). Since the ΔH_{dil} needs to be subtracted from the data collected in a binding study, using these buffers led to large uncertainties in the titration data. In an acetate buffer (pH 5.25), the ΔH_{dil} , although still endothermic, is small relative to $\Delta H_{\text{binding}}$. Since this buffer is also a good solvent for the gadolinium salt, we selected it for all the titrations.

Next, we carried out titrations of Gd^{3+} in solutions of various HA–DTPA samples, as well as in a solution of unmodified HA. Two sets of data are presented in Figure 3: the experimental titration curves for Gd^{3+} in buffer (a), in a buffered solution of HA (b), and in a buffered solution of HA–DTPA (c); and the corresponding binding curves obtained by integration of each peak of the HA–DTPA curve in the top part of Figure 3. We observe that the dilution of Gd^{3+} into the buffer is not affected by the presence of HA (compare traces a and b), confirming that Gd^{3+} does not bind to HA under the conditions of the titration. On the other hand, trace c in Figure 3 undergoes a sharp transition for a $\text{Gd}^{3+}/\text{polymer}$ ratio of 0.321 mmol g^{-1} or 0.150 mol DTPA/mol Glu. If we assume that exactly 1 gadolinium ion binds to 1 DTPA unit, the titration indicates that 15.0 mol % of the carboxylic acid groups of HA bear a DTPA unit in the sample analyzed. Since DTPA forms stable complexes with several transition metals (18), it is not necessary to carry out the titration of HA–DTPA with Gd^{3+} . For instance, the europium ion Eu^{3+} forms a complex with DTPA with a pK value of 22.39 at 25 °C (18). A titration of the same HA–DTPA sample using Eu^{3+} , instead of Gd^{3+} , yielded the same degree of conjugation: 0.149 ± 0.001 mol DTPA/mol Glu, or 0.320 ± 0.003 mol DTPA (g polymer) $^{-1}$.

Colorimetric Studies. The colorimetric assay of the level of DTPA incorporation in HA–DTPA is based on the large bathochromic shift of the absorbance of arsenazo III in the presence of transition metals, such as

$$K_{\text{therm}} = K_{\text{cond}} \frac{K_1 K_2 K_3 K_4 K_5}{[\text{H}]^5 + [\text{H}]^4 K_1 + [\text{H}]^3 K_1 K_2 + [\text{H}]^2 K_1 K_2 K_3 + [\text{H}] K_1 K_2 K_3 K_4 + K_1 K_2 K_3 K_4 K_5} \quad (1)$$

Figure 3. Titration curves of Gd^{3+} into aqueous polymer solutions at 25 °C and pH = 5.25. Above: calorimetric traces (heat flow against time) for (a) the blank, (b) HA, and (c) HA-DTPA1. The curves were shifted vertically for clarity. Below: reaction enthalpy (obtained by integrating the peaks in curves above) vs the Gd^{3+} /polymer ratio (mol/g).

Gd^{3+} , due to the formation of a stable complex (20). The pK of the Gd^{3+} –arsenazo III complex is 15.85 (18), a value approximately 7 orders of magnitude lower than the binding constant of gadolinium to HA-DTPA (vide supra). The free dye has a strong visible absorption at 548 nm. It absorbs at 660 nm when complexed with heavy metals (Figure 4). The colorimetric assay provides the degree of conjugation of DTPA on HA-DTPA via a protocol based on (1) the addition of an excess Gd^{3+} to a solution of HA-DTPA, and (2) the quantitative analysis of the excess of gadolinium detected as its complex with arsenazo III ($\lambda_{\text{max}} = 660$ nm) (see method I, Experimental Section). The changes in the absorption spectrum of arsenazo III as a function of added Gd^{3+} are illustrated in Figure 4, where we display spectra of arsenazo III in the absence of Gd^{3+} ($\lambda_{\text{max}} = 548$ nm), and in the presence of increasing amounts of Gd^{3+} . The intensity of the band with a maximum absorbance at 548 nm decreases, while the band characteristic of the complexed dye ($\lambda_{\text{max}} = 660$ nm) increases in intensity with increasing amounts of Gd^{3+} . We note the occurrence of two isosbestic points at $\lambda = 460$ and 582 nm.

In the titration described, we assume that the DTPA–Gd complex does not dissociate in the presence of arsenazo III, as expected from the large difference in the

Figure 4. Absorption spectra of arsenazo III as a function of the concentration of Gd^{3+} ; [arsenazo III] = 20 mmol L^{-1} ; $[\text{Gd}^{3+}] = 0$ –18 mmol L^{-1} . The thick curve represents the spectrum of arsenazo III in the absence of Gd^{3+} .

binding constants of the two Gd^{3+} complex. To confirm the validity of this working hypothesis, we performed an analysis of the excess gadolinium added to a HA-DTPA solution, not in the presence of HA-DTPA–Gd as described previously, but after its separation from the polymer via ultrafiltration (Method II, Experimental Section). The two colorimetric methods gave identical results, within experimental error (see Table 1). Therefore, the time-consuming separation of unreacted Gd^{3+} from the polymer solution is not necessary for accurate colorimetric quantitation of the degree of DTPA conjugation. Method I is fast, accurate, and extremely economical in terms of polymer required (minimum amount: ~ 10 μg). The detection limit of this method is about 150 μg $\text{Gd}^{3+} \text{L}^{-1}$. Levels of DTPA incorporation as low as 0.03 mmol (gram of polymer) $^{-1}$ can be quantified accurately.

NMR Studies. All HA-DTPA samples were characterized by NMR spectroscopy. The ^1H NMR spectra, while useful to ascertain linking of DTPA to the polymer backbone, cannot be relied upon for a quantitative determination of the level of DTPA incorporation on the polymer, at least in the case of high molecular HA. Signals due exclusively to either the resonance of DTPA protons or HA protons were identified, as illustrated in Figure 5, which presents the relevant section of the ^1H NMR spectrum of HA-DTPA. The singlet at 2.0 ppm was attributed to the resonance of the acetamide protons linked to HA. The broad signal centered at 3.1 ppm was assigned to the resonance of the two methylene protons of the DTPA moiety, indicating conjugation of DTPA to the polymer backbone. The ratio of the integrated areas of these two signals, weighed for the respective numbers of protons, should yield the degree of DTPA substitution.

Table 1. Level of DTPA Incorporation As Determined by NMR, ITC, and Colorimetry for Two Different HA-DTPA Polymers

method	HA-DTPA1		HA-DTPA2	
	mol DTPA/mol Glu	mmol DTPA/g polymer	mol DTPA/ mol Glu	mmol DTPA/g polymer
NMR	0.27 ± 0.02	0.68 ± 0.05	0.73 ± 0.01	1.03 ± 0.03
ITC	0.155 ± 0.001	0.321 ± 0.003	0.415 ± 0.001	0.720 ± 0.003
UV(I)	0.16 ± 0.01	0.32 ± 0.02	0.44 ± 0.01	0.74 ± 0.02
UV(II)	0.17	0.384	0.40	0.71

Figure 5. ^1H NMR spectrum of HA-DTPA (solvent: D_2O).

The value extracted from the spectra (Table 1) is significantly higher than the amount determined by either colorimetry or ITC. The enhancement of the NMR-derived value may be attributed to the fact that the relaxation times of the DTPA methylene protons are shorter than those of the methyl protons of the 2-acetamido-2-deoxy- β -D-glycopyranose moieties (16). A ^1H NMR spectrum was obtained using a longer interscan delay (5 s vs 1 s) for the same HA-DTPA sample, to determine if an increased delay would allow enough time for all the spins to get back to equilibrium. A slightly lower ratio HA/DTPA (22%) was calculated from this spectrum. The value remains significantly higher than the true value.

It should be pointed out that the methods described are intended to detect DTPA in a polymer solution, but they do not distinguish between bound DTPA and free DTPA. Therefore, it is important to ascertain the absence of free DTPA. To rule out the possibility of strong ionic interactions between free DTPA and HA, we conducted tests to ensure the effectiveness of the HA-DTPA purification protocol (see Experimental Section). Qualitative indication of covalent binding between DTPA and HA is given by obtained the ^1H NMR spectra (Figure 5).

CONCLUSION

We have compared three analytical techniques for the quantitative determination of the level of DTPA conjugation onto water-soluble polymers. Our study indicates that high-field ^1H NMR spectroscopy grossly overestimates the amount of DTPA incorporation. In contrast, titrations carried out by colorimetry and ITC are more accurate. They yield identical results. The colorimetric test is fast, requires only standard laboratory instrumentation, and can be performed using as little as 200 μg of polymer. The minimal level of DTPA detectable by colorimetry is about 25 nmol and the best detection window is between 50 and 500 nmol. Isothermal titration calorimetry is more demanding in terms of analysis time (a few hours) and of polymer sample (~ 2 mg). The advantage of ITC, however, is that a single experiment yields the level of DTPA conjugation and the thermodynamic parameters of the complexation. It is not limited to the DTPA-Gd complex. Other chelating agents/transition metal complexes can be analyzed by the identical protocol. While the present study was limited to two samples of HA-DTPA, either the colorimetry assay or the ITC measurement can easily be applied to other modified water-soluble polymers.

C-Terminal and N-Terminal Fusions of Aequorin with Small Peptides in Immunoassay Development

Sapna K. Deo, Jennifer C. Lewis, and Sylvia Daunert*

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506-0055. Received September 18, 2000; Revised Manuscript Received January 30, 2001

Aequorin fusion proteins have been used extensively in intracellular Ca^{2+} measurements and in the development of binding assays. Gene fusions to aequorin for production of fusion proteins have been so far limited to its N-terminus, as previous studies have indicated that aequorin loses its activity upon modification of its C-terminus. To further investigate this, two model peptides, an octapeptide (DTLDDDDL), and leu-enkephalin (TGGFL), an opioid peptide, were fused to the C-terminus of a cysteine-free mutant of aequorin through genetic engineering. The octapeptide was also fused to the N-terminus of the aequorin–leu-enkephalin fusion protein, which enables its affinity purification. Contrary to reports of earlier studies, we found that aequorin retains its bioluminescence activity after modification of the C-terminus. The half-life of light emission and the calibration curves obtained with the fusion proteins were comparable to those of the cysteine-free mutant of aequorin. Dose–response curves for the octapeptide were generated using two aequorin–octapeptide fusion proteins with the octapeptide fused to the N-terminus in one case, and to the C-terminus in the other. Similar detection limits for the octapeptide were obtained using both fusion proteins. The C-terminal fusion system has advantages in cases where antibodies recognize only the C-terminus of the peptide, as well as in cases where the functionality of the peptide lies in its C-terminus. The purification is also simplified as the affinity tag can be engineered at one terminus and the peptide of interest at the other.

INTRODUCTION

Aequorin, a bioluminescent photoprotein was originally isolated from *Aequorea victoria*, a hydromedusan jellyfish (1). Aequorin is composed of an apoprotein (apoequorin, 189 amino acid residues), a chromophore (coelenterazine, an imidazopyrazine compound), and molecular oxygen. Aequorin has three calcium binding sites, namely EF-hand structures, that are characteristic of the family of Ca^{2+} binding proteins. Upon binding to Ca^{2+} , aequorin undergoes a conformational change that results in the oxidation of coelenterazine to coelenteramide. This reaction produces CO_2 and emission of a flash of light at 469 nm (2, 3).

The sequencing and subsequent cloning of the cDNA of apoequorin has enabled researchers to expand the potential applications of aequorin (4, 5). This photoprotein has been widely employed in the measurement of Ca^{2+} in various cellular compartments and to monitor gene expression (6, 7). It has also been used as a highly sensitive label in binding assays (8–12) and in the detection of proteolytic bond cleavage (13). Aequorin can be detected in the femtomole to attomole range, which has allowed its employment as an alternative label to fluorescent probes in the calibration of micropipets (14). This photoprotein offers several advantages such as no photobleaching and the production of signal with virtually no background.

Aequorin fusion proteins have been widely employed in the development of immunoassays and in targeting aequorin to specific cellular locations for Ca^{2+} measure-

ments (6–8). Since the modification of the N-terminus of aequorin does not have any adverse effect on its luminescence activity, the gene fusions prepared thus far had been made only through its N-terminus (7, 8, 15). Literature reports had shown that modifications on the C-terminus of aequorin caused a significant decrease in the bioluminescence. Moreover when the C-terminal proline 189 was deleted or its position was changed, the result was complete loss of aequorin bioluminescence (16). In another study, a glycine was added to proline 189, resulting also in loss of the luminescent activity of aequorin (15). Thus, these studies indicated that the C-terminal proline was essential for the activity of aequorin and that its C-terminus was not amenable to modifications, which restricted its use in C-terminal gene fusions. In that respect, the goal of this study was to explore the possibility of preparing gene fusions of aequorin through its C-terminus without deleting or changing the position of proline 189 and to determine whether this modification has any effect on the luminescence activity of the protein. The crystal structure of aequorin which has recently been published shows that its C-terminal region forms a flexible loop structure and extends itself into the solvent, implying the feasibility of gene fusion through its C-terminus (17). These observations led us to believe that gene fusions can be done through the C-terminus of aequorin.

To prepare these fusions, a cysteine-free mutant of aequorin constructed in our laboratory was selected because we had found that this mutant is more stable than native aequorin. We genetically conjugated the N-terminus of a model octapeptide to the C-terminus of a cysteine-free mutant of aequorin to extend the C-terminal region of aequorin. The octapeptide employed

has an amino acid sequence of Asp-Tyr-Lys-Asp-Asp-Asp-Asp-Lys and is often used as an affinity tag for protein purification. Since the octapeptide is a highly polar peptide, another study was performed by fusing the N-terminus of a relatively weakly polar peptide to the C-terminus of mutant aequorin to determine whether the polarity of the peptide has any effect on the activity of aequorin. For that purpose, the N-terminus of leu-enkephalin, a mammalian opioid peptide, which has the amino acid sequence of Tyr-Gly-Gly-Phe-Leu was fused genetically to the C-terminus of aequorin. Leu-enkephalin has morphine-like pharmacological properties, and it acts as an agonist on opiate receptor sites (18, 19). The C-terminus of the same octapeptide used in the earlier study described above was also fused genetically to the N-terminus of the aequorin-leu-enkephalin fusion protein, allowing for the affinity purification of the fusion protein. Immunoassays were then developed for the octapeptide using both of these fusion proteins; in one, an octapeptide was fused to the N-terminus, and in another, it was fused to the C-terminus. The results were compared to see whether the sensitivity and the detection limit for the peptide would differ based on the different site of attachment to aequorin.

EXPERIMENTAL SECTION

Materials. Tris(hydroxymethyl)aminomethane (Tris) free base, ethylenediaminetetraacetic acid (EDTA) sodium salt, agar, glucose, sodium dodecyl sulfate (SDS), isopropyl β -thiogalactopyranoside (IPTG), sodium phosphate, glycine, 3-chloro-4-naphthol, hydrogen peroxide, nitrocellulose membrane, and all other reagents were purchased from Sigma (St. Louis, MO). Microlite 2 polystyrene microtiter plates were from Dynex (Chantilly, VA). Reactibind 96-well neutravidin-coated white polystyrene microtiter plates and biotin-free bovine serum albumin (BSA) were obtained from Pierce (Rockford, IL). A Bradford protein assay kit was purchased from Bio-Rad Laboratories (Hercules, CA). Coelenterazine was from Biosynth International (Naperville, IL). Biotinylated Anti-FLAG M2 antibody, unlabeled octapeptide and Anti-octapeptide M2 agarose affinity column were from Sigma (St. Louis, MO). Rabbit anti-leu-enkephalin antibody and horseradish peroxidase conjugated affinity purified anti-rabbit secondary antibody was purchased from Chemicon (Temecula, CA). Luria Bertani (LB) broth, *Eco*R I, *Hind* III and *Sal* I restriction enzymes, *Taq* and *Pfu* polymerases, and all other molecular biology reagents were obtained from Gibco-BRL (Gaithersburg, MD). All the primers used for the polymerase chain reaction (PCR) were purchased from Operon Technologies (Alameda, CA). All chemicals were reagent grade or better, and solutions were prepared using deionized (Milli-Q Water Purification System, Millipore, Bedford, MA) distilled water.

Apparatus. PCR was performed on a Perkin-Elmer Gene Amp PCR System 2400 (Norwalk, CT). Cells were sonicated using 550 Sonic Dismembrator from Fisher Scientific (Pittsburgh, PA). Fractions containing the aequorin fusion protein were lyophilized using a VirTis Bench Top 3 freeze-dryer (Gardiner, NY). The purity of the fusion protein was verified by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) on a Phast System (Pharmacia Biotech, Uppsala, Sweden). The protein was transferred to the nitrocellulose membrane using the Phast transfer system from Pharmacia Biotech (Uppsala, Sweden). Bioluminescence measurements were made on a MLX microtiter plate luminometer from Dynex (Chantilly, VA) using a 100 μ L-fixed volume

Figure 1. Schematic representation of plasmid pSD1002 containing the oligonucleotide sequences of the apoaequorin-octapeptide fusion protein and plasmid pSD1003 containing the gene sequence encoding for the octapeptide-apoaequorin-leu-enkephalin fusion protein.

injector. All luminescence intensities reported are the average of a minimum of three replicates and have been corrected for the contribution of the blank. All molecular biology procedures were performed using standard protocols (20).

METHODS

Construction of Plasmid pSD1002. The gene of a mutant apoaequorin in which all three cysteines of the native aequorin were replaced by serines was used as a template for the PCR (21). The following two primers were used to introduce the restriction endonuclease site for *Hind* III and *Sal* I restriction enzymes on mutant apoaequorin gene:

(1) TCTTCTTCTTCTTCTAAGCTTGTCAAGCTTACATCAGACTTCGACCCAAGA; (2) AGAAGAAGAAGAGTCGACCAGATCTGGTACCCGGAATT.

The DNA obtained by PCR and the vector pFLAG-CTC which consists of the gene sequence for the octapeptide downstream of the multiple cloning site (MCS) were digested with the restriction enzymes *Hind* III and *Sal* I. Next, the digested DNA fragment was ligated into the plasmid pFLAG-CTC, to yield the pSD1002 vector (see Figure 1). DNA sequencing was performed at the Macromolecular Center (University of Kentucky) to confirm the presence of the gene encoding for the apoaequorin-octapeptide fusion protein.

Construction of Plasmid pSD1003. The gene of a mutant apoaequorin was used as a template for the PCR (18). The following three primers were designed to obtain the gene construct, which codes for the apoaequorin-leu-enkephalin fusion protein:

(1) TCTTCTTCTTCTTCTAAGCTTGTCAAGCTTACATCAGACTTCGACCCAAGA; (2) GTACAGATCTGGTACCCGGAATTGGGGACAGCTCCACCGGAGCTT; (3) AGAAGAATTCTATTACAGGAAACCACCGTACAGATCTGGTACCCGGGAA.

Primer 1 was used to introduce the restriction site for the endonuclease *Hind* III. Primers 2 and 3 were used to introduce the seven amino acid spacer, sequence for leu-enkephalin, and restriction site for the enzyme *Eco*R I. The DNA obtained by PCR was digested with the restriction enzymes *Hind* III and *Eco*R I. The vector pFLAG-MAC, which consists of the sequence for the octapeptide upstream of the MCS, was also digested with the restriction enzymes *Hind* III and *Eco*R I. Next, the digested DNA fragment was ligated into the plasmid pFLAG-MAC, to yield the pSD1003 vector (see Figure 1). DNA sequencing was performed at the Macromolecular Center (University of Kentucky) to confirm the presence of the gene encoding for the octapeptide-apoaequorin-leu-enkephalin fusion protein.

Expression and Isolation of Apoaequorin-Peptide Fusion Proteins. Bacteria (*E. coli*, strain JM109) were transformed with the pSD1002 or pSD1003 vector and then cultured to express the fusion protein. Specifically, bacteria were grown in 2 mL of LB broth containing ampicillin (100 μ g/mL) for 16–18 h. The culture was then transferred to 250 mL of LB broth containing ampicillin (100 μ g/mL) and grown to an absorbance value of 0.6 measured at 600 nm. Next, IPTG was added to the culture, adjusting its final concentration to 1 mM, and the culture was grown for an additional of 3 h. The culture was then centrifuged at 5930g at 4 °C for 30 min to collect the cells. The bacterial pellet obtained was resuspended in 30 mM Tris-HCl, pH 7.0 containing 2 mM EDTA, followed by sonication for 3 min. The mixture was then centrifuged at 5930g at 4 °C for 30 min, and the supernatant containing the fusion protein was obtained.

Purification of the Apoaequorin-Peptide Fusion Proteins. The protein was purified by using an anti-octapeptide M2 agarose affinity column. The column was equilibrated with 50mM Tris-HCl, pH 7.4 containing 150 mM NaCl and 2 mM EDTA (TBS buffer). The solution containing protein was loaded on the column, and the column was washed three times with 15 mL of TBS buffer. The protein was eluted using 1 mL aliquots of 0.1 M glycine, pH 3.0, into tubes containing TBS buffer. The purity of the fractions containing the protein was determined by SDS-PAGE using 12.5% polyacrylamide gels, which were developed by silver staining (Pharmacia Biotech, Uppsala, Sweden). Fractions containing the fusion protein were pooled together, and glucose was added to a final concentration of 30 mM followed by lyophilization. The lyophilized protein was resuspended in deionized distilled water. Excess salt was removed through dialysis using TBS buffer. The protein concentration was determined by using the Bradford protein assay, with BSA as the standard. A 3-fold molar excess of coelenterazine was added to the apoaequorin fusion protein, and this mixture was stirred for 15 h at 4 °C. Excess of the coelenterazine was removed from the protein by dialyzing twice against 1.0 L of TBS buffer.

Bioluminescence Emission Study. A volume of 50 μ L of the two fusion proteins at a concentration of 1.0×10^{-10} M was added to a Microlite 2 polystyrene microtiter plate, and the bioluminescence was measured by injecting 100 μ L of luminescence triggering buffer (100 mM Tris-HCl, 100 mM CaCl₂, pH 7.5). The bioluminescence signal was collected at 0.1-s intervals over a 3-s time period.

Calibration Curves for Aequorin-Peptide Fusion Proteins. Stock solutions of the fusion proteins were serially diluted in assay buffer (30 mM Tris-HCl, pH 7.5 containing 2 mM EDTA, 150 mM NaCl, and 0.1% BSA), and the bioluminescence intensity of 50 μ L of each dilution was measured after injecting 100 μ L of luminescence triggering buffer.

Binder-Dilution Studies. Biotinylated anti-FLAG M2 antibody was serially diluted in the dilution buffer (50 mM sodium phosphate, pH 7.4 containing 100 mM NaCl and 0.1% biotin-free BSA). A volume of 50 μ L of differing concentration of antibody was added to the wells of neutravidin-coated plate and incubated with shaking for 2 h at room temperature. After that, the plate was washed three times with the wash buffer (30 mM Tris-HCl, pH 7.5 containing 2 mM EDTA and 150 mM NaCl). Next, 50 μ L of 1×10^{-10} M of the aequorin-peptide fusion proteins in assay buffer were added to the wells containing immobilized antibody. The plate was incubated for an additional 2 h with shaking at 4 °C. Then, it was washed with the washing buffer three times, and the bioluminescence intensity was measured by injecting 100 μ L of the luminescence triggering buffer.

Association Plots of Aequorin-Peptide Fusion Proteins. Biotinylated anti-FLAG M2 antibody (50 μ L, 8 μ g/mL) was immobilized on the neutravidin-coated wells of the microtiter plate as described previously. A volume of 50 μ L of a 1×10^{-10} M solution of the fusion proteins was added to the plate, and the plate was incubated with shaking for various time periods. At the end of each time period, the plate was washed three times with washing buffer, and the luminescence intensity was measured as described previously.

Dose-Response Curves for the Octapeptide. Dose-response curves were generated in either a competitive or a sequential binding mode. For the competitive binding mode, 50 μ L of unlabeled octapeptide of differing concentrations and 50 μ L of the fusion proteins of a 1×10^{-10} M concentration were added simultaneously to the wells of the plate containing immobilized biotinylated anti-FLAG M2 antibody (50 μ L, 8 μ g/mL). The plate was incubated for 1 h with shaking. After that, the plate was washed with washing buffer three times, and the luminescence intensity was measured by injecting 100 μ L of the luminescence triggering buffer. A dose-response curve was also generated in a sequential binding mode. In this case, the unlabeled peptide of differing concentrations was incubated with the immobilized antibody for 1 h. The plate was then washed three times, and the fusion proteins (50 μ L, 1×10^{-10} M) were added to the plate. The plate was incubated for an additional 1 h with shaking followed by a washing step. The luminescence intensity was measured by injecting 100 μ L of the luminescence triggering buffer.

Western Blotting for Octapeptide-Aequorin-Leu-Enkephalin Fusion Protein. A Western blott was performed using rabbit anti-leu-enkephalin antibody and horseradish peroxidase-conjugated affinity purified anti-rabbit secondary antibody by following a standard protocol (24).

RESULTS AND DISCUSSION

Fusion proteins have been produced for a variety of applications such as affinity purification, receptor-protein interaction studies, and development of binding assays. Gene fusion to a protein is produced through either the N-terminus or the C-terminus of the protein. These fusions can, sometimes, result in the improper

folding of the protein causing loss of its activity (22, 23). Various proteins and peptides have their active site at their N- or C-terminal region (24, 25). Therefore, in such cases, the flexibility of the label with regard to conjugation to either of its termini is of paramount importance. For example, the sequence of the different enkephalin peptides only differs at their C-terminus whereas the sequence of angiotensin II and III differs at their N-terminus. Thus, to develop immunoassays for these peptides, the label should be conjugated either at the C- or N-terminus such that the peptide can be selectively recognized by the antibody. Aequorin is a photoprotein that has been used as a sensitive label in a variety of immunoassays. It has been reported in the literature that the C-terminal proline of aequorin is essential for its bioluminescence activity, and that any modifications at this terminus result in the loss of its activity. Hence, to date, gene fusions of aequorin have been limited to those involving its N-terminus (16). In this study, we decided to investigate the feasibility of generating gene fusions through the C-terminus of aequorin, keeping the C-terminus proline intact. For that, two fusion proteins were constructed with different peptides fused to the C-terminus of aequorin. The N-terminus of an octapeptide and an opioid peptide, leu-enkephalin, were fused genetically to the C-terminus of aequorin.

To produce the fusion protein between aequorin and the octapeptide, the gene encoding for apoequorin was ligated into the multiple cloning site (MCS) of the expression vector pFLAG-CTC, yielding plasmid pSD1002 (see Figure 1). The vector pFLAG-CTC consists of the gene sequence for the octapeptide downstream from the MCS. The fusion protein thus produced has the sequence, apoequorin-Asn-Ser-Arg-Val-Pro-Asp-Leu-octapeptide. The seven amino acids between apoequorin and the octapeptide are encoded in the MCS of the pFLAG-CTC vector between the recognition sequence of the restriction enzyme *EcoR* I and the gene sequence for the octapeptide. These amino acids can act as a spacer between aequorin and the octapeptide, thus allowing for the proper folding of the protein. To produce the fusion protein between aequorin and leu-enkephalin, the DNA encoding for apoequorin-leu-enkephalin was constructed using PCR. This gene was then ligated into the MCS of the expression vector pFLAG-MAC, which also has a sequence for the octapeptide upstream of the MCS, to yield plasmid pSD1003 (see Figure 1). The resulting fusion protein has the sequence octapeptide-apoequorin-Asn-Ser-Arg-Val-Pro-Asp-Leu-leu-enkephalin. This fusion protein has the same spacer as used in the case of the apoequorin-octapeptide fusion protein. *E. coli* cells were then transformed either with pSD1002 or with pSD1003 plasmid. The expressed proteins were purified by affinity chromatography using anti-octapeptide M2 antibody covalently linked to agarose beads. Crude extracts were loaded onto preequilibrated columns followed by a washing step to remove nonspecifically bound proteins. The proteins of interest were eluted using glycine buffer, pH 3.0. The purity and concentration of the protein was determined using SDS-PAGE and the Bradford assay, respectively. The yields of the purified proteins were 2 mg/L and 1.8 mg/L for the apoequorin-octapeptide and the octapeptide-apoequorin-leu-enkephalin fusion protein, respectively. The apoequorin-peptide fusion proteins obtained were stirred with a 3 molar excess of the coelenterazine chromophore to regenerate the aequorin-peptide fusion proteins. Unbound coelenterazine was subsequently removed by dialysis.

As mentioned earlier, previous studies reported that aequorin became inactive upon modification of its C-terminus. Thus, the first step in our study was to determine whether the protein prepared through a C-terminal fusion had any effect on the luminescence activity of aequorin. Bioluminescence emission studies were then performed to characterize the fusion proteins in terms of their luminescence properties. The fusion proteins demonstrated the same flash-type emission characteristics as that of the native protein with 95% of the total light being emitted during a 3-s time period. Thus, a 3-s light integration time was chosen for all remaining experiments. The half-life of the bioluminescence decay of the fusion proteins was determined to be 0.97 s for both, the aequorin-octapeptide and the octapeptide-aequorin-leu-enkephalin fusion protein. These half-life values are comparable to that of the unconjugated cysteine-free mutant aequorin (1.0 s) (18). The luminescence activities of the aequorin-octapeptide and octapeptide-aequorin-leu-enkephalin fusion proteins were found to be 100% and 97%, respectively, when compared to the activity of the aequorin cysteine-free mutant (100%). This virtual no loss of bioluminescence activity after the C-terminal modification of aequorin is contrary to previous observations reported in the literature. It should be pointed out, however, that there are some differences between the literature work (15, 16) and our study. Previously, C-terminal modification studies were carried out using native aequorin, whereas we have employed a cysteine-free mutant of aequorin. This mutant has higher bioluminescence activity than native aequorin (21). Also, in the previous studies either the C-terminal proline, believed to be necessary for aequorin activity, was deleted or its position was changed, but in our study we have maintained this proline in the 189 position (15). The spacer between apoequorin and the peptides may play an important role in the proper folding of aequorin, thus maintaining the luminescence activity of aequorin. Further studies to elucidate the effect of different spacers located at the C-terminus on the aequorin activity are underway in our laboratory. Next, a study was conducted to determine whether the fusion of the octapeptide to either the C- or N-terminus of aequorin would alter the bioluminescence assay performance when aequorin is used as the label. For that, immunoassays were developed for this peptide using the two different fusion proteins.

To select the optimum amount of fusion proteins to develop the assays for the peptides, a calibration study was performed for both fusion proteins. A working range extending over 4 orders of magnitude was obtained for both proteins as shown in Figure 2. A concentration of 1×10^{-10} M of both fusion proteins was selected for the remaining studies, as it generates a signal well above the background one.

The next step in our study was to determine the optimum amounts of antibodies to be used in the assay development. To determine this, binder-dilution curves were generated using biotinylated anti-FLAG M2 antibody. The biotinylated antibody was immobilized on neutravidin coated plates by taking advantage of strong binding between biotin and neutravidin. The antibody was immobilized by shaking the plate at room temperature for 2 h followed by a washing step. Next, the fusion proteins were added to the plate and incubated for an additional 2 h. The luminescence intensity was measured after washing the plate. The binder-dilution curves for both fusion proteins are shown in Figure 3. As it can be seen from the figure, the binder-dilution curves for both

Figure 2. Calibration curves for the aequorin-octapeptide (□) and octapeptide-aequorin-leu-enkephalin (◆) fusion proteins. Data are the average $\pm$ one standard deviation ($n = 3$). All error bars are less than 10% and are represented as obtained.

Figure 3. Binder-dilution curves for the aequorin-octapeptide (□) and the octapeptide-aequorin-leu-enkephalin (●) fusion proteins. Data are the average $\pm$ one standard deviation ($n = 3$). All error bars are less than 10% and are represented as obtained.

proteins follow a similar path. This indicates that neither the C- nor the N-terminal fusion of the peptide to aequorin affects the binding of the fusion protein to the antibody. The optimum concentration of antibody to be used for the subsequent steps was determined using these binder-dilution curves. A concentration of antibody of 8 $\mu\text{g/mL}$ was selected for both fusion proteins to be used in the development of the assays for the peptide. This concentration was selected since it was the highest concentration of antibody that was within the linear portion of the curve; at higher antibody concentrations the binding sites on the plate are saturated and no further increase in the signal was observed.

Another important parameter to be determined in assay development is the optimum time required for binding of the fusion protein to the antibody, which allows reduction of the total assay time. An association study was performed in the same manner as the binder-dilution study, except that the incubation time for binding the fusion protein to the antibody was varied. The association curves are shown in Figure 4. Maximum signal was observed at an association time of 1 h, and it was selected for the rest of the experiments.

Figure 4. Association curves for the aequorin-octapeptide (□) and the octapeptide-aequorin-leu-enkephalin (◆) fusion proteins. Data are the average $\pm$ one standard deviation ($n = 3$). All error bars are less than 10% and are represented as obtained.

Figure 5. Dose-response curves for the octapeptide generated in a competitive binding mode by employing the aequorin-octapeptide (□) and the octapeptide-aequorin-leu-enkephalin (◆) fusion proteins. Data are the average $\pm$ one standard deviation ($n = 3$). All error bars are less than 10% and are represented as obtained.

Once the optimum amounts of fusion proteins, antibody, and the association time were determined, the final step in the assay development was to generate dose-response curves for the peptides. These curves were generated in two binding modes, namely, a competitive mode and a sequential binding mode. In the competitive binding mode the unlabeled peptide and the fusion proteins were incubated along with the immobilized antibody. This type of assay mode offers the advantage of having fewer steps, thus decreasing the overall assay time. The dose-response curves generated using competitive binding are shown in Figure 5. To generate a dose-response curve in a sequential binding mode, the unlabeled peptide was first incubated with the immobilized antibody followed by a washing step. Next, the fusion proteins were added, and an incubation step was performed. The luminescence intensity was measured after a washing step. In this case, the addition of labeled peptide is delayed; thus, this binding mode offers the advantage of producing lower detection limits (26). The dose-response curves generated in the sequential binding mode are shown in Figure 6. The dose-response

Figure 6. Dose-response curves for the octapeptide generated in a sequential binding mode by employing the aequorin-octapeptide (□) and the octapeptide-aequorin-leu-enkephalin (◆) fusion proteins. Data are the average $\pm$ one standard deviation ($n = 3$). All error bars are less than 10% and are represented as obtained.

curves for both fusion proteins showed a decrease in luminescence intensity with increasing amounts of unlabeled peptide, as expected. The working range of the curve spans over 3 orders of magnitude. The detection limits obtained in the case of the competitive binding mode are higher in comparison to the sequential binding mode. However, the detection limits obtained with the N-terminal and C-terminal aequorin-octapeptide fusion proteins are the same for the same binding mode. This demonstrates that hydrophilic peptides can be fused to either of the aequorin termini without affecting the performance of the assay. In the competitive binding assay mode a detection limit of 4×10^{-9} M for the octapeptide was obtained, whereas in the case of the sequential binding assay mode the detection limit was 1

$\times 10^{-9}$ M. The detection limits obtained compared well with the detection limit obtained when the same octapeptide was fused to the N-terminus of aequorin as reported in the literature (7).

In this study, we have also demonstrated that no loss in activity of aequorin was observed when the N-terminus of another peptide, leu-enkephalin, was genetically fused to the C-terminus of aequorin. A Western blot was performed using anti-leu-enkephalin antibody to determine whether the antibody can bind to the octapeptide-aequorin-leu-enkephalin fusion protein. The Western blot is shown in Figure 7. As it can be seen from the figure, the antibody binds selectively to the fusion protein. Therefore, an immunoassay can be developed for the leu-enkephalin peptide using this system. Currently, work is underway in our laboratory toward achieving this goal. This study also indicates that we can detect two peptides using the same fusion protein reagent by immobilizing the respective antibodies in separate wells. This potentially offers an advantage of reduced reagent preparation cost.

In conclusion, we have demonstrated that the C-terminus of a cysteine-free mutant of aequorin can be modified without any loss of its activity. To our knowledge, this is the first time that the C-terminus of aequorin is being modified without any loss of its luminescence activity. Immunoassays for the octapeptide were developed using aequorin-octapeptide fusion proteins. In one case, the peptide was fused to the N-terminus, whereas in the other case it was fused to the C-terminus of aequorin. No significant difference in performance was observed between the two systems as evident by the similar detection limits for the peptide obtained. This demonstrated that peptides or proteins can be fused through either of the terminus of aequorin, thus increasing the flexibility of aequorin in terms of peptide/protein conjugation. An additional advantage of this system is that dual functionalities can be attached to the aequorin molecule. For example, at one terminus of aequorin an

Lane 1: crude protein, lane 2: purified fusion protein.

epitope tag for antibody recognition can be attached, while at the other terminus an affinity tag can be attached simplifying the purification of the fusion protein as demonstrated in this study. In summary, given the flexibility that C- and N-terminal fusions afford to aequorin in terms of analyte conjugation, it is envisioned that the range of potential applications of aequorin in assay development will be increased.

Enzymes by Design: Chemogenetic Assembly of Transamination Active Sites Containing Lysine Residues for Covalent Catalysis

Dietmar Häring and Mark D. Distefano*

Department of Chemistry, University of Minnesota,
Minneapolis, Minnesota 55455. Received September 25, 2000; Revised Manuscript Received February 23, 2001

Artificial enzymes can be created by covalent conjugation of a catalytic active group to a protein scaffold. Here, two transamination catalysts were designed via computer modeling and assembled by chemically conjugating a pyridoxamine moiety within the large cavity of intestinal fatty acid binding protein. Each catalyst included a lysine residue, introduced via site-directed mutagenesis, that promotes catalysis by covalent interactions with the pyridoxamine group. Evidence for such interactions include the formation of a Schiff base with the pyridoxal form of the catalyst and a rate versus pH dependence that is bell shaped; both of these features are manifested in natural transaminases. The resulting constructs operate with high enantioselectivity (83–94% ee) and increase the rate of reaction as much as 4200-fold over the rate in the absence of the protein; this is a modest (12-fold) increase in catalytic efficiency (k_{cat}/K_M) compared to the conjugate lacking the lysine residue. Most importantly, these artificial aminotransferases are the first examples of designed bioconjugates capable of covalent catalysis, highlighting the potential of this chemogenetic approach.

INTRODUCTION

Artificial enzymes can be designed by covalent conjugation of a catalytic active group to a protein scaffold (Kaiser and Lawrence, 1984; Distefano et al., 1998). This concept has been successfully applied to the construction of a variety of so-called semisynthetic enzymes, such as thiazol-papain (Suckling and Zhu, 1993), flavo-papain (Kaiser and Lawrence, 1984), flavo-hemoglobin (Kokubo et al., 1987), oligonucleotide-nuclease (Corey and Schultz, 1987), or seleno-subtilisin (Wu and Hilvert, 1989; Häring and Schreier, 1999). The protein scaffold enhances the binding of substrates and provides a chiral environment, thus mimicking an enzymatic active site. However, another important feature of native enzymes has not yet been incorporated in such conjugates: the interaction of functional groups from the protein framework with the cofactor or substrates for covalent catalysis.

Pyridoxamine is a versatile catalytic engine for a diverse array of reactions including transamination, decarboxylation, racemization, and aldol condensation. To achieve highly efficient catalysis, interactions with neighboring functional groups are critical. For example, in all known pyridoxamine phosphate utilizing enzymes, the aldehyde form of the cofactor is bound covalently to the ϵ -amino group of a lysine residue via a Schiff base linkage. Upon nucleophilic attack of this internal imine by the amino group of an incoming substrate, the lysine residue is released and an internal ketimine complex between the substrate and the aldehyde is formed (Scheme 1). Moreover, this same lysine residue also serves as a general base in the subsequent conversion of the ketimine intermediate to the internal aldimine. Deletion of this residue via mutagenesis results in an enzyme exhibiting a 10^6 fold decrease in transamination activity (Malashkevich et al., 1995a).

Scheme 1. Simplified Transamination Half Reaction^a

^a For detailed information about the reaction mechanism and the role of lysine cf. literature (Hayashi et al., 1998; Goldberg and Kirsch, 1996).

To correctly position functional groups in a three-dimensional fashion that can modulate catalyst reactivity and selectivity, a sphere-shaped scaffold is useful for the design of an artificial enzyme. Fatty acid binding proteins are a well-characterized family of intracellular transport proteins involved in lipid metabolism (Banaszak et al., 1994; Veerkamp and Maatman, 1995). These proteins bind their cognate ligands in a cavity consisting of a β -barrel and a α -helical lid. Intestinal fatty acid binding protein from rats (IFABP¹) is a cysteine-free 15 kDa protein with an internal cavity volume of 600 Å³. Its established structure (Scapin et al., 1992; Hodson et al., 1996) as well as the convenient overexpression of mutants in *Escherichia coli* make IFABP a conceptually simple framework for the design and assembly of an active site.

Recently, we developed an approach for catalyst design that combines elements of chemical modification with genetic engineering. For example, a pyridoxamine derivative was covalently linked inside the cavity of IFABP via a disulfide bond to a cysteine residue, which has been introduced by site-directed mutagenesis (Kuang and Distefano, 1998). These experiments demonstrated that the catalytic efficiency of pyridoxamine could be increased by up to 360-fold by introducing the cofactor in the cavity at a specific site.

Here we have used this chemogenetic approach to position functional groups for participation in catalysis in this artificial enzyme. Our goal was to construct a transaminase active site that would contain a lysine residue capable of Schiff base formation and general acid/base catalysis. An approach based on geometric constraints for residue introduction into an existing catalytic system was developed. Two lysine mutants were prepared and conjugated with pyridoxamine. Spectroscopic evidence for covalent bond formation between the new lysine residues and the cofactor was obtained. The rate versus pH profile for both mutants was measured and shown to be bell shaped, similar to natural transaminases. Finally, kinetic investigation showed that the new lysine mutants exhibited an increased catalytic efficiency relative to the free cofactor and the protein without the lysine residues.

MATERIALS AND METHODS

Materials. Pyridoxamine dihydrochloride was converted into 5-(2-pyridyldithio)pyridoxamine **1** as described previously (Kuang et al., 1996). The mutagenic primers were obtained from the Microchemical Facility of the Institute of Human Genetics (University of Minnesota). The site-directed mutagenesis kit ("Quick-Change") was obtained from Stratagene. The expression vector pMON-IFABP was used previously for the preparation of IFABP-V60C (Kuang and Distefano, 1998). The protein purification was carried out at 4 °C unless otherwise noted.

Modeling. Molecular modeling experiments were performed using Insight II 97.0/Discover 3.00 (Molecular Simulations). The potential energy was calculated on basis of a consistent valence force field and minimized sequentially by steepest descents and conjugate gradients. The distances and angles of various native amino-transferases used in this study, listed in Table 1, were averaged from literature data (Peisach et al., 1998; Suigo et al., 1995; Miyahara et al., 1994; Malashkevich et al., 1995b; Okamoto et al., 1998).

Site-Directed Mutagenesis. Site-directed mutations were introduced in the expression vector of pMON-IFABP recombinant plasmid with the QuickChange mutagenesis kit. The sequence for the mutagenic oligomers was 5'-CATGACAACCTGAAAAAGACGATCACACAGGAAG-3' for L38K and 5'-AAATAAATTCACAGTCAAAAAATCAAGCAACTTC-3' for E51K. The proteins were overexpressed in *E. coli* strains JM105, which were grown under shaking at 37 °C in LB media (6 × 1 L) and induced with nalidixic acid.

Protein Purification. IFABP-V60C/E51K was purified according to a published procedures (Jiang and

Frieden, 1993). IFABP-V60C/L38K was expressed as inclusion bodies. They were repeatedly pelleted (3000 g) and resuspended in 0.5 M urea, 50 mM TRIS pH 7.5, 10 mM EDTA, 5 mM dithiothreitol (DTT), and 1% Triton X-100. After a final resuspension in the above buffer without urea, the protein was denatured in 3 M guanidine in buffer A (20 mM HEPES pH 7.5, 10 mM EDTA and 10 mM DTT). Refolding was achieved by slowly dropping the protein solution in a 25-fold volume of 250 mM sodium chloride in buffer A. The IFABP mutant was finally isolated after gel filtration chromatography (Sephacryl S-100).

Conjugation to Pyridoxamine Cofactor. Prior to conjugation, the IFABP-mutants were desalted by gel filtration, and the concentration of free thiol was determined by titration with DTNB. The conjugation reagent 5-(2-pyridyldithio)pyridoxamine **1** was added in 10-fold excess, and the reaction was allowed to proceed for 18 h at 20 °C in 20 mM HEPES (pH 7.5). The conjugated protein was purified by gel filtration and the concentration of pyridoxamine determined by its UV absorbance ($\epsilon_{326} = 6140 \text{ M}^{-1}\text{cm}^{-1}$ in 6 M guanidine, 20 mM HEPES, pH 7.5). To convert the pyridoxamine to the pyridoxal form, the conjugates were incubated with 50 mM α -ketoglutarate for 24 h at 37 °C. The excess of keto acid was removed with a desalting column (Sephadex G25).

Kinetic Analysis. Reactions were performed with 50 μM catalyst, 5 mM phenylalanine (in the case of PMP 5 mM tyrosine was used) and varying concentrations of α -ketoglutarate in 0.2 M HEPES (pH 7.5) at 37 °C. The formation of glutamate was monitored by reversed-phase HPLC (Kuang et al., 1996; Buck and Krummen, 1987).

Electrospray Mass Spectrometry. For mass spectral experiments, protein samples were desalted (NAP-5 column, elution with 0.5% formic acid), lyophilized, and analyzed by direct infusion (5 $\mu\text{L}/\text{min}$) electrospray ionization mass spectroscopy in water/acetonitrile (1:1) containing 0.5% formic acid at a protein concentration of 50 μM .

pH-Dependence. The reactions were performed with 50 μM IFABP-PxK38, 5 mM phenylalanine, and 50 mM α -ketoglutarate acid in "MHP-buffer" (Gloss and Kirsch, 1995) with constant ionic strength $I = 0.2$ (25 mM HEPES, 25 mM MES, 50 mM 4-hydroxy-*N*-methylpiperidine, 0.1 M KCl). The formation of the glutamate-enantiomers was monitored by HPLC (Buck and Krummen, 1987), and the data points of the initial rate were fitted to a standard bell curve.

RESULTS AND DISCUSSION

Our goal in this work was to design and construct a transaminase active site containing a lysine residue capable of Schiff base formation and general acid/base catalysis. Such a site would be prepared by covalently tethering a pyridoxamine moiety to a cysteine residue (introduced via mutagenesis) within the cavity. On the basis of examination of the crystal structure of IFABP, a V60C mutant form of IFABP was chosen, since it is in a region proximal to the proposed site of entry for fatty acids (and hence putative substrates). Furthermore, attachment of the pyridoxamine to Cys60 positions the cofactor close to the cationic residue Arg126 which could facilitate the binding of carboxylate-bearing substrates via electrostatic interactions (Figure 1). The conformation of the pyridoxamine derivative tethered by a disulfide bond to Cys60 was optimized by energy minimization to provide a starting point for exploring possible sites for Lys introduction.

Figure 1. Stereoview of a computational model of IFABP-PxK51 developed from the crystal structure of IFABP (Scapin et al., 1992). The pyridoxal is bound via a disulfide bond to Cys60, and a Schiff base linkage to Lys51; a cationic residue (Arg126) is close to the catalytic center. The figure was generated using MOLSCRIPT (Kraulis, 1991).

Table 1. Critical Geometric Parameters for the Placement of a Lysine Residue near Pyridoxamine in a Transamination Catalyst

	$C_{\alpha}-C_{4'}$ (Å)	$C_{\alpha}-X$ (Å)	$C_{\alpha}-C_{5'}$ (Å)	α (deg)	β (deg)
native AT ^a	6.5–8.7	7.3–8.9	8.1–9.5	70–145	80–135
IFABP-PxK38 ^b	7.1–8.8	8.0–8.8	7.4–9.6	134–153	33–37
IFABP-PxK51 ^b	6.9–7.6	5.6–6.4	6.8–8.1	130–140	22–35

^a The data for native aminotransferases (AT) were averaged from crystal structures of D- and L-aspartate AT as well as aromatic amino acid AT in their pyridoxal, Schiff base, and glutamate ketimine form. ^b The data for the IFABP conjugates were determined by computational modeling (C_{α} of lysine; X: $O-PO_3^{2-}$ for native AT or S-Cys60 for IFABP-PX conjugates; α : angle $N_{Ar}-C_{4'}-C_{\alpha}$; β : dihedral angle $C_{5'}-N_{Ar}-C_{4'}-C_{\alpha}$).

As guidance for the positioning of a Lys residue capable of Schiff base formation with pyridoxal, we used geometric parameters from the active site of native aminotransferase (AT). Table 1 summarizes critical distances and angles between the cofactor and the C_{α} -atom of lysine in various AT structures. The neighborhood of the IFABP-bound pyridoxal was searched with these parameters. This resulted in the identification of 10 possible C_{α} -positions where lysine mutations could be introduced. Four of these mutations were ruled out for reasons of obvious steric hindrance or because they are highly conserved throughout this protein family. Optimized models of the pyridoxal form, the Schiff base to the lysine and the substrate (α -ketoglutarate) ketimine complex were calculated for the other six lysine mutations (L38K, F47K, E51K, Q115K, Y117K, R126K). The geometric parameters of the two most promising mutations, L38K and E51K are summarized in Table 1; a model for one of these constructs is presented in Figure 1.

The structural parameters for the L38K and E51K mutants are closely related to those of the native amino transferases that are also included in Table 1 for comparison. It should be noted that although wild-type IFABP has 15 lysine residues, modeling experiments suggest that none of these are oriented appropriately for Schiff base formation with the pyridoxal linked to Cys 60.

Based on the modeling results described above, two possible catalysts were assembled by a chemogenetic approach. The desired mutations V60C/L38K and V60C/E51K of IFABP were introduced by site-directed mutagenesis and the proteins purified to homogeneity. Using the activated pyridoxamine (Px) derivative 5-(2-pyridylthio)pyridoxamine, the cofactor was chemically linked to Cys60 of both mutants on a 50–100 mg scale with over 90% conjugation efficiency based on DTNB titration and UV/vis spectroscopy of the denatured protein constructs. The resulting assemblies IFABP-PxK38 and IFABP-PxK51 (the number indicates the position of the lysine

Table 2. Masses of Various IFABP-Px Conjugates in Their Pyridoxamine Form (amine) and after Reduction with $NaBH_4$ (red. imine)

conjugate	calcd mass (Da)	found (Da)
IFABP-Px (amine)	15179.3	15178.0
IFABP-Px (red. imine)	15180.3	15179.0
IFABP-PxK38 (amine)	15194.3	15193.0
IFABP-PxK38 (red. imine)	15177.3	15188.0
IFABP-PxK51 (amine)	15178.3	15177.0
IFABP-PxK51 (red. imine)	15161.3	15160.0

mutation) show the UV absorption of both the protein (280 nm) and the pyridoxamine (326 nm). Analysis of the proteins via electrospray mass spectrometry clearly indicates the attachment of the cofactor; all of the conjugates are within 2 Da of their expected calculated masses (the pyridoxamine forms) as noted in Table 2.

The conjugates IFABP-PxK38 and IFABP-PxK51 were next examined for their ability to catalyze the transamination of α -ketoglutarate and phenylalanine to glutamate and 3-phenylpyruvate.

Kinetic parameters, determined by measuring the initial rate at varying concentrations of α -ketoglutarate, were obtained for IFABP-PxK38 and IFABP-PxK51. The rate data, summarized in Table 3, were compared to the unliganded cofactor as well as to IFABP-Px; this latter construct lacks either of the new lysine residues. Both IFABP-PxK38 and IFABP-PxK51 show improved values for k_{cat}' and K_m' . The overall catalytic efficiency (k_{cat}'/K_m') of IFABP-PxK51 is 4200-fold increased compared to the unliganded pyridoxamine phosphate and 12-fold greater compared to IFABP-Px. The predominant kinetic effect of the lysine residues is on K_m' . IFABP-PxK38 has a K_m' value 2.2-fold lower than IFABP-Px

Table 3. Kinetic Parameters for Transaminations Reactions Catalyzed Unbound Pyridoxamine Phosphosphate (PMP) and IFABP-Px Conjugates

	PMP	IFABP-Px	IFABP-PxK38	IFABP-PxK51
K_m' (mM)	73 ± 7	1.8 ± 0.5	0.81 ± 0.08	0.24 ± 0.02
k_{cat} (h^{-1})	$3.2 \times 10^{-2} \pm 0.2 \times 10^{-2}$	0.29 ± 0.02	0.44 ± 0.01	0.44 ± 0.004
k_{cat}/K_m' ($\text{h}^{-1} \text{mM}^{-1}$)	$4.4 \times 10^{-4} \pm 0.7 \times 10^{-4}$	0.16 ± 0.06	0.54 ± 0.07	1.83 ± 0.17
$(k_{cat}/K_m')_{rel}$	1	360	1200	4200

**Figure 2.** UV absorption spectra of IFABP conjugates (IFABP-PxK38 dotted line; IFABP-PxK51 dashed; IFABP-Px solid; all $100 \mu\text{M}$ in 20 mM HEPES, pH 7.5). The insert shows the second derivatives of the spectra.
