Pentadeca-2'-deoxyriboadenylate-Thiazole Orange Conjugates 19a, 19b, 20a, and 20b. To determine the influence of the nature of the linker and of the stereochemistry at the phosphorus atom bearing the thiazole orange residue, modified oligo-2'-deoxyriboadenylates **19a**, **19b**, **20a**, and **20b** were hybridized with an oligo-2'-deoxyribonucleotide, ⁵d-CACT₁₅CAC^{3'}, involving the complementary sequence. The unmodified ⁵d-(A₁₅)^{3'} was used as a reference. The spectra of all four oligo-2'-deoxyriboadenylate-thiazole orange conjugates (**19a**, **19b**, **20a**, and **20b**) were almost identical. For a typical UV-visible spectrum of a pentadeca-2'-deoxyriboadenylate-thiazole orange conjugate, see the inset in Figure 3. The spectra contain one absorption band in the visible region between $\lambda = 400$ nm and $\lambda = 600$ nm (where only the thiazole orange absorbs light) with $\lambda_{\text{vis max}}^{\text{vis}} \approx 511$ nm and a shoulder at $\lambda = 485$ nm. The other absorption band in the UV range corresponds to the absorbance of the pentadeca-2'-deoxyriboadenylate and the thiazole orange with a $\lambda_{\text{uv max}}^{\text{uv}} \approx 257$ nm. A small additional band was also present at $\lambda \approx 305$ nm.

Adding increasing concentrations of ⁵d-CACT₁₅CAC^{3'} to a 0.1 μ M solution of ⁵d-(A₁₅)^{3'} in 10 mM sodium cacodylate, pH 7, buffer containing 0.1 M NaCl at 3 °C led to a sharp break when the absorbance at 260, 270,

Table 1. *T_m* Values for Oligo-2'-deoxyribonucleotides β -⁵'d-(A₁₅)^{3'}, α -⁵'d-(T₂₀)^{3'}, and β -⁵'d-(T₂₀)^{3'} and Oligo-2'-deoxyribonucleotide-Thiazole Orange Conjugates **19a**, **19b**, **20a**, **20b**, **21a**, **21b**, **22a**, and **22b** Hybridized with Their Complementary Sequences

	β - ⁵ 'd-(CACA ₁₅ CAC) ^{3'}	poly r(U)		poly r(A)
β - ⁵ 'd-(A ₁₅) ^{3'}	32.5 ^a	26.4 ^b	α - ⁵ 'd-(T ₂₀) ^{3'}	49.5 ^c
19a	41 ^a	—	21a	50 ^c
19b	40 ^a	—	21b	49 ^c
20a	40.5 ^a	35 ^b	β - ⁵ 'd-(T ₂₀) ^{3'}	34 ^d
20b	38 ^a	33 ^b	22a	36 ^d
	—	—	22b	35.5 ^d

^a Oligonucleotide concentrations are 0.1 μ M, each strand, in 10 mM sodium cacodylate, pH 7, buffer containing 0.1 M NaCl.

^b Oligonucleotide concentrations are 1 μ M (with U/A = 2) in 10 mM sodium cacodylate, pH 7, buffer containing 0.1 M NaCl.

^c Oligonucleotide concentrations are 1 μ M (with T/A = 1) in 66.5 mM, pH 7, phosphate buffer. ^d Oligonucleotide concentrations are 1 μ M (with T/A = 1) in 10 mM sodium cacodylate, pH 7, buffer containing 0.1 M NaCl.

or 280 nm was plotted versus the A/T concentration ratio (data not shown). The break occurred at a 1:1 ratio, indicating the formation of a double helix. We considered that the presence of thiazole orange in the conjugates should not have changed the stoichiometry of their binding with their complementary targets. For all the oligo-2'-deoxyriboadenylate-thiazole orange conjugates (**19a**, **19b**, **20a**, and **20b**) studied, the addition of 1 equiv of the complementary sequences at 3 °C induced a change of the absorption spectra between $\lambda = 240$ and $\lambda = 600$ nm (data not shown). Only changes observed between $\lambda = 400$ and $\lambda = 600$ nm will be discussed. Addition of 1 equiv of ⁵d-CACT₁₅CAC^{3'} to oligo-2'-deoxyriboadenylate-thiazole orange conjugates **19a**, **19b**, **20a**, and **20b** induces a blue shift of the λ_{max} of the visible spectra of thiazole orange 3, 4, 4, and 4 nm, respectively, without a significant change in intensity.

In all cases, the melting temperatures of the duplexes formed by the oligo-2'-deoxyriboadenylates and their complementary sequences increased when the thiazole orange derivative was linked to the oligonucleotides with similar $\Delta T_m = +8.5$ and $+7.5$ °C for oligonucleotide-thiazole orange conjugates **19a** and **19b** with the hydrophilic linker, respectively (Table 1). In the case of oligonucleotide-thiazole orange conjugates **20a** and **20b** involving the polymethylene linker, ΔT_m differences of +8 and +5.5 °C were observed, respectively. The greatest stabilization was observed for oligonucleotide-thiazole orange conjugate **20a** (with the *R_p* configuration) with the linker directed toward the minor groove. This result is consistent with literature data indicating that the homodimeric thiazole orange TOTO intercalates with the nitrogen atom of the quinolinium ring in the minor groove (36). The lower stabilization observed with the second isomer **20b** could be explained by the fact that the linker was directed toward the major groove and intercalation of thiazole orange is only possible if the linker fold-back is in the direction of the minor groove. Being so, the linker may be too short to permit full intercalation. In the case of conjugates **19a** and **19b**, the linker length is a little longer than it is for conjugates **20a** and **20b**. Therefore, in both cases full intercalation is possible, giving nearly the same *T_m* values.

To test the ability of the thiazole orange moiety to intercalate into DNA/RNA hybrids, we have studied the interaction of the conjugates **20a** and **20b** involving the polymethylene linker with poly r(U). Adding increasing concentrations of poly r(U) to a 0.1 μ M solution of ⁵d-

(A₁₅)^{3'} or **20b** in 10 mM sodium cacodylate, pH 7, buffer containing 0.1 M NaCl at 3 °C led to a sharp break when the absorbance at 260 nm was plotted versus the A/U concentration ratio (data not shown). The break occurred at a 1:2 ratio, indicating the formation of a triple helix. These results indicating the formation of a triplex with both the unmodified 5'-d-(A₁₅)^{3'} and the conjugate **20b** are consistent with the intercalation of the thiazole orange. Thus, when the isomer **20b** (*R_p* configuration) is hybridized with poly r(U) forming a duplex, unless being intercalated, the thiazole orange is directed toward the major groove and should prevent the binding of a second strand of poly r(U) in the major groove to form a triplex.

Addition of 2 equiv of poly r(U) to conjugates **20a** and **20b** induces a red shift of the $\lambda_{\text{vis}}^{\text{max}}$ value (≈ 5 nm) of the visible spectra of thiazole orange in both cases. No significant change in intensity of the spectra was observed, but the general shape was less broad on the left part of the visible band of the spectra. These changes are reversed when increasing the temperature. The melting of the triple helices formed between the conjugates **20a** or **20b** (or the unmodified pentadecadeoxyriboadenylate) and poly r(U) showed only one transition. Once again, the presence of the thiazole orange stabilized the duplexes (Table 1) with $\Delta T_m = +8.6$ and $+6.6$ °C for oligonucleotide-thiazole orange conjugates **20a** and **20b**, respectively. These results are in accordance with intercalation of the thiazole orange in DNA/RNA complexes.

Icosa- α -thymidylate-Thiazole Orange Conjugates 21a and 21b and Icosa- β -thymidylate-Thiazole Orange Conjugates 22a and 22b. In the same way, the stability of the complexes formed by the thiazole orange-icosa- α -thymidylate conjugate isomers **21a** and **21b** and the thiazole orange-icosa- β -thymidylate conjugate isomers **22a** and **22b** with their target poly r(A) was compared to those of the complexes formed between the corresponding icosathymidylates and poly r(A) (Table 1). In the case of the thiazole orange-icosa- α -thymidylate conjugates **21a** and **21b**, the studies were performed in the buffer used for microinjections in cells for in situ hybridization experiments, whose results will be discussed elsewhere, while in the case of thiazole orange-icosa- β -thymidylate conjugates **22a** and **22b** the buffer used was the same as for the studies carried out with oligoadenylates.

The spectra of the two icosa- α -thymidylate-thiazole orange conjugates **21a** and **21b** were almost identical. Adding increasing concentrations of α -T₂₀ to a poly r(A) solution (20 μ M) in 66.5 mM phosphate, pH 7, buffer at 3 °C led to a sharp break when the absorbance at 260, 270, or 280 nm was plotted versus the A/T concentration ratio (data not shown). The break occurred at a 1:1 ratio, indicating the formation of a double helix. As in the case of the oligo-2'-deoxyriboadenylate-thiazole orange conjugates **19a**, **19b**, **20a**, and **20b**, we considered that the presence of thiazole orange in the conjugates should not have changed the stoichiometry of their binding with their complementary targets.

In the presence of 1 equiv of the complementary sequence poly r(A), differences could be observed for the two isomers. While no change of the $\lambda_{\text{vis}}^{\text{max}}$ value (508 nm) was observed for compound **21a**, the general shape of the spectrum was less broad as compared to that for compound **21a** alone. In the case of the other isomer (compound **21b**) in the presence of 1 equiv of the target sequence, the spectrum was also less broad as compared to that for the conjugate alone and also there was a small red shift of the $\lambda_{\text{vis}}^{\text{max}}$ value (≈ 2 nm). But in the latter case the change could be observed on the left part of the

visible band of the spectrum, while for the first isomer (**21a**) changes were observed on both the left and right sides of the spectrum. No notable variations in intensity were observed in the spectra of compounds **21a** and **21b** upon hybridization with the target sequence. Spectral modifications observed between $\lambda = 400$ and 600 nm when 1 equiv of conjugates **21a** or **21b** was mixed with 1 equiv of poly r(A) at 3 °C were, however, reversed upon a temperature increase to 70 °C.

In the case of duplexes formed between icosa- α -thymidylate-thiazole orange conjugates **21a** and **21b** with poly r(A), the presence of thiazole orange did not induce any stabilizing effect (Table 1). These results indicate that intercalation of thiazole orange is unlikely to occur. This may probably be due to the difference in the structure of the duplex formed between the icosa- α -thymidylate and the poly r(A). Oligo- α -thymidylates have been reported to hybridize with poly r(A) in the antiparallel orientation, forming a type A duplex (37), but to our knowledge examples of intercalation in such duplexes have never been reported. To address this point, we have synthesized and studied the hybridization properties of the icosa- β -thymidylate-thiazole orange conjugate isomers **22a** and **22b**. The unmodified icosa- β -thymidylate was used as reference. The spectra of the icosa- β -thymidylate-thiazole orange conjugate isomers **22a** and **22b** were almost identical. The stoichiometry for the binding with poly r(A) was also equal to 1. But once again, no significant change of the visible absorption spectra of the thiazole orange was observed upon the mixing of conjugates **22a** and **22b** with 1 equiv of poly r(A), and melting studies of the duplexes indicated that hardly no stabilization ($\Delta T_m = +2$ and $+1.5$ °C for oligonucleotide-thiazole orange conjugates **22a** and **22b**, respectively) was induced by the presence of the thiazole orange (Table 1). Another explanation for this absence of stabilization could be that intercalation of TOTO was reported to occur with the quinolinium ring placed between purine bases and the thiazole ring between pyrimidine bases (36). Linkage of the thiazole orange on the pyrimidine strand (via the quinolinium ring) compared to the purine strand should change possible intercalation interactions.

We have reported the synthesis and binding properties of oligo-2'-deoxyribonucleotide-thiazole orange conjugates. The thiazole orange label was coupled to the eighth phosphate of a pentadeca-2'-deoxyriboadenylate via a phosphoramidate linkage. Two different linkers, either hydrophilic or more hydrophobic, were used to tether the oligonucleotide to the nitrogen atom of the quinolinium ring of the thiazole orange moiety. Substitution at the internucleotidic position introduces a chirality at the phosphorus atom with the formation of two stereoisomers. The latter were separated, and their absolute configurations were determined. Finally, the thiazole orange moiety was also tethered to the tenth phosphate of an icosa- α -thymidylate using the hydrophobic polymethylene linker. Once again, the thiazole orange-icosa- α -thymidylate conjugates were obtained as pure isomers. The binding properties of these oligo-2'-deoxyribonucleotide-thiazole orange conjugates with their complementary sequences were studied by absorption spectroscopy. In the case of the pentadeca-2'-deoxyriboadenylate series, the presence of the label induces a stabilization of the complexes formed both with the DNA and with the RNA targets. This is consistent with the intercalation of the thiazole orange moiety. In contrast, the stability of the duplexes formed between the icosa- α -thymidylate derivatives and poly r(A) is similar to that of the corresponding

unmodified duplex, indicating the absence of intercalation of the thiazole orange. Studies carried out with the corresponding icoso- β -thymidylate derivatives indicated also a lack of stabilization by covalent linking of the thiazole orange in the presence of poly r(A). These results could be explained by the fact that in this case the thiazole orange is linked to the pyrimidine strand via the quinolinium ring when intercalation of the TOTO was reported to take place with the benzothiazole ring between the pyrimidine bases. Work to address this question will be developed in the near future.

ACKNOWLEDGMENT

We thank the CNRS and the Region Centre for a fellowship to E.P., C. Buré for running the electrospray mass spectrometer, and H. Labbé for recording the NMR spectra. We also thank M. Chassignol for the preparation of the compound **6** sample used in this work and for providing the modified support involving α -thymidine and V. Roig for providing the phosphoramidite derivative of α -thymidine.

A Ribonuclease H–Oligo DNA Conjugate That Specifically Cleaves Hepatitis B Viral Messenger RNA

Cherie M. Walton, Catherine H. Wu, and George Y. Wu*

Department of Medicine, Division of Gastroenterology-Hepatology, University of Connecticut Health Center, Farmington, Connecticut 06032. Received February 15, 2001; Revised Manuscript Received June 15, 2001

Ribonuclease H (RNaseH) recognizes and efficiently cleaves the RNA strand of DNA–RNA hybrids, but has no inherent sequence selectivity. However, the formation of DNA–RNA hybrids does require specific sequence recognition. On the basis of this concept, we wondered whether antisense oligonucleotides complementary to target RNA covalently linked to RNase H could be used to direct specific cleavage events mediated by RNase H. The aim of this research was to couple a DNA oligonucleotide to RNase H to confer specificity of ribonuclease activity toward hepatitis B viral (HBV) mRNA. A modified 13-base oligonucleotide that is specific for the DR1 region of HBV mRNA was conjugated to modified *E. coli* RNase H using a water soluble cross-linker. A 1200 base fragment of HBV RNA including the DR1 region was synthesized as a substrate using T7 RNA polymerase. Incubation of the RNase H–oligonucleotide conjugate with the RNA transcript resulted in cleavage of the HBV mRNA transcript in a concentration dependent manner. Eighty-five percent of substrate was cleaved under optimal conditions. Controls consisting of RNase H alone, oligonucleotide alone, and incubation of the conjugate with an unrelated mRNA substrate resulted in no cleavage activity. RNase H coupled to an HBV antisense oligonucleotide can specifically cleave target HBV transcripts.

INTRODUCTION

Ribonuclease H (RNase H) is an enzyme found in a variety of organisms ranging from viruses to mammalian cells and functions as an endonuclease that can recognize and cleave the RNA strand of a DNA–RNA hybrids (1–4). *E. coli* RNase H1 is one of the best characterized (3, 5). It requires divalent cations and generates products with 5'-phosphate and 3'-hydroxyl termini (6, 7). However, RNase H activity lacks sequence specific recognition (1–3). Coaddition of antisense molecules with the enzyme has been used to direct specificity to RNase H cleavage (8–11). However, to be biologically useful, this requires that the antisense oligos and enzyme be present in the same intracellular compartment as the target and in effective concentrations. With this goal in mind, the aim of this research was to determine whether an antisense oligo DNA could be chemically coupled to RNase H to specifically target RNase H activity to the 3' direct repeat 1 (DR-1) region of the HBV¹ mRNA.

MATERIALS AND METHODS

RNase H Purification. An RNase H overproducer mutant strain (rnh gene transformed into MIC 1066, an RNase H deficient strain of *E. coli*) was a gift from Robert Crouch, NIH. RNase H was purified according to the method of Ma et al. (1). In brief, an overnight culture

was diluted in LB plus 100 μ g/mL ampicillin and grown until the OD₅₅₀ reached 1.0. Isopropylthio- β -D-galactosidase (IPTG) (Gibco, Grand Island, NY) was added to a final concentration of 1 mM, and the culture was grown for an additional 5 h. Cells were harvested by centrifugation at 1500g, 15 min at 4 °C. Cell pellets were resuspended in 0.2 M KCl, 50 mM Tris HCl, pH 7.9, 5 mM MgCl₂, 0.1 mM EDTA, and 1 mM phenylmethylsulfonyl fluoride and disrupted by sonication on ice using 5 $\times$ 15 s bursts at amplitude 40. Cell lysates were clarified by centrifugation, diluted with 50 mM Tris HCl, pH 7.9, 0.1 mM EDTA to an ionic strength equivalent to 50 mM NaCl, 50 mM Tris HCl, pH 7.9, 0.1 mM EDTA. Clarified cell lysates were loaded onto a DEAE-Sepharose column, 5 $\times$ 6 cm (Amersham Pharmacia Biotech, Uppsala, Sweden), equilibrated with 50 mM Tris HCl, pH 7.9, 0.15 M NaCl, 0.1 mM EDTA. A DEAE-sepharose column was connected in series to a P-11 phosphocellulose column, 2.5 $\times$ 20 cm (Whatman International Ltd, Maidstone, England) equilibrated with the same buffer. RNase H was eluted using 50 mM Tris HCl, pH 7.9, 0.1 mM EDTA, 0.75 M NaCl (1). Aliquots of eluted fractions were run on a 15% SDS–PAGE. Fractions found to contain RNase H were pooled and desalted using a PD-10 column (Amersham Pharmacia Biotech, Uppsala, Sweden) and concentrated through P10 centricon concentrators (Amersham Pharmacia Biotech, Uppsala, Sweden). A Bradford assay was performed to determine protein concentration (12).

Conjugation of RNase H and Oligonucleotide. A modified 13-base oligonucleotide (GCAGAGGTGAAGC) specific for the DR1 site on HBV adw strain (13) was synthesized by Keck Oligonucleotide Synthesis Facility at Yale University. The 5'-guanosine was amino-modified at the 6-carbon to provide a substrate for the *N*-(γ -maleimidobutyryloxy) sulfosuccinimide ester, sulfo-GMBS (Pierce Chemical Co, Rockford, IL), linkage, and all other

¹ Abbreviations: HBV, hepatitis B virus; NEM, *N*-ethylmaleimide; EDTA, ethylenediaminetetraacetic acid; EGTA, ethylene glycol-bis(β -aminoethyl ether)-*N,N,N',N'*-tetraacetic acid; IPTG, isopropylthio- β -D-galactosidase; SDS–PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis.

residues were phosphorothioate modified. The oligonucleotide, 360 nM, was incubated with a 50-fold molar excess of sulfo-GMBS in PBS pH 7.4 for 1 h at 25 °C. RNase H, 90 nM, was incubated with 100 mM dithiothreitol (DTT) (Sigma, St. Louis, MO) in PBS pH 7.4 at 25 °C for 1 h. Both were purified by elution through a PD-10 column (Amersham Pharmacia Biotech, Uppsala, Sweden) with PBS pH 7.4. The peaks from the DR1 oligonucleotide-GMBS and the reduced RNase H were pooled and incubated overnight at 4 °C. Conjugate was purified by passing through a HiTrap Q column (Amersham Pharmacia Biotech, Uppsala, Sweden) using a stepwise NaCl gradient, 0.3 M to 1.0 M NaCl (1). Concentrations were determined by Bradford assay and spectrophotometer readings at A_{260} . Conjugation and purity were checked by SDS-PAGE, agarose gels, and radiolabeling experiments. Activity was determined by cleavage assays as described below.

SDS-PAGE and Agarose Gels. To visualize the protein and determine the efficacy of purification, 5 μ g of RNase H and conjugate (containing the equivalent to 5 μ g RNase H) were run on a 10% SDS-PAGE. Bands were visualized by Coomassie Blue staining. To detect DNA in samples of conjugate, 5 μ g of free oligonucleotide and conjugate (containing the equivalent of 5 μ g of oligo DNA) were run on a 1% agarose gel in 0.045 M Tris-borate, 1 mM EDTA buffer, and stained with ethidium bromide to visualize DNA.

Radiolabeling. To follow conjugation products and extent of purification, the 3'-OH ends of both oligonucleotides alone and conjugates were labeled with γ - ^{32} P ATP using terminal deoxynucleotidyl transferase, Promega, Madison, WI (14). Samples with a specific activity of 2000 cpm/ng were run on a denaturing 12% polyacrylamide gel containing 8 M urea and autoradiographed (15).

Cleavage Assays. HBV and control β -globin RNA templates were synthesized from plasmid DNA using T7 polymerase (Gibco Life Technologies, Grand Island, NY). The HBV RNA template was created from an adw R9 plasmid (gift from Dr. T. J. Liang, NIH) resulting in a fragment of 1200 bases, which included the DR1 site. A control transcript consisted of a similar size fragment from nonrelated pLMR3 rabbit β -globin plasmid DNA (gift from Dr. Gordon Carmichael, University of Connecticut). One microgram (0.25 pmol) of RNA transcript was incubated with 2.5 μ mol of RNase H alone, oligonucleotide alone, or a mixture of 2.5 μ mol unconjugated RNase H plus 2.5 μ mol oligonucleotide, or 5 μ mol of conjugate in reaction buffer consisting of 40 mM Tris pH 7.5, 4 mM $MgCl_2$, 1 mM DTT, 150 mM NaCl, plus anti-RNase (Ambion, Austin, TX), which does not inhibit RNase H (Ambion Manufacturer's note).

To assess the effects of inhibitory agents on cleavage activity of the conjugate, 0.25 pmol of HBV transcript was incubated with 5 μ mol of oligo-RNase H conjugate alone or plus 25 μ M EDTA (ethylenediaminetetraacetic acid), 25 μ M EGTA [ethylene glycol-bis(β -aminoethyl ether)- N,N,N',N' -tetraacetic acid] or 25 μ M NEM (N -ethylmaleimide). To determine concentration dependence, cleavage assays were performed using increasing amounts of conjugate with constant amounts of substrate. A comparison of conjugated versus unconjugated RNase H activity was made using 5 μ mol of conjugate versus decreasing amounts of unconjugated RNase H and oligonucleotide in equimolar ratios. As a control for nonspecific cleavage, conjugate was added to a nonrelated β -globin RNA transcript. All cleavage assays were performed by incubation for 1 h at 37 °C and run on 2.2 M formaldehyde, 1% agarose gels in MOPS buffer (0.02 M MOPS

Figure 1. 10% SDS-PAGE of purified mutant RNase H and oligo-RNase H conjugate prepared as described in the Materials and Methods section. Lane 1, molecular weight marker; lane 2, 5 μ g of mutant RNase H; and lane 3, 5 μ g of oligo-RNase H conjugate.

Figure 2. Lane 1, 7.5 ng of ^{32} P-oligo alone; lane 2, 7.5 ng of ^{32} P-oligo-RNase H conjugate. Both samples had a specific activity of 2000 cpm/ng.

[3-(N -morpholino)propanesulfonic acid (Sigma, St. Louis, MO), 8 mM sodium acetate, 1 mM EDTA]. RNA bands were visualized by ethidium bromide staining and quantitated by densitometry (16).

RESULTS

From 3 L of LB culture medium, a yield of 32 mg of RNase H was obtained. SDS-PAGE analysis of purified protein revealed a band of approximately 18000 Da, which corresponds to the published size of mutant RNase H (1), Figure 1, lane 2. The oligonucleotide DNA-RNase H conjugate migrated at a position corresponding to approximately 29000 Da in the SDS-PAGE gel, lane 3.

To visualize the oligonucleotide DNA component of the RNase H conjugate, and to determine whether the sample had any contaminating free DNA, the conjugate was radiolabeled, electrophoresed, and autoradiographed. Figure 2 shows that the conjugate, lane 2, produced a labeled band migrating much slower than free oligonucleotide, lane 1, as similarly seen on the SDS-PAGE in Figure 1. Contaminating free oligonucleotide was not

seen in the conjugate sample, indicating that within the limits of detectability, the purification process successfully eliminated uncoupled oligo DNA. From the protein and DNA assays of the conjugate, it was calculated that the RNase H and oligonucleotide were linked in molar ratio of one to one.

To determine whether the conjugated oligonucleotide DNA-RNase H conjugate was functional, cleavage activity was studied using HBV mRNA substrates containing the target DRI sequence. In Figure 3, lane 2, the HBV substrate transcript is shown without exposure to any enzyme. Lane 3 shows that exposure of the HBV substrate to RNase H alone failed to result in any detectable cleavage. Similarly, lane 4 shows that incubation of HBV substrate with oligonucleotide DNA alone had no effect. However, lane 6 shows that transcripts incubated with conjugate were nearly completely digested with little intact substrate remaining. This result is similar to the positive control containing unconjugated RNase H and oligonucleotide mixed in the same proportions as provided by the conjugate and incubated under identical conditions, lane 5. A control, unrelated transcript having no HBV sequences, incubated with conjugate in the same proportions as in lane 6, showed no detectable cleavage, lane 7. Densitometry revealed that incubation of conjugated oligonucleotide DNA-RNase H or the mixture of enzyme plus free oligonucleotide DNA decreased substrate by more than 85%.

As controls for nonspecific degradation, digestions of substrate HBV mRNA with oligonucleotide DNA-RNase H conjugate were carried out in the presence of inhibitors. Figure 4 shows that addition of 25 μ M EDTA, a magnesium chelator, to the incubation mixture containing RNA

Lane 1, RNA molecular weight markers; lane 2, transcript alone; lane 3, transcript plus 5 μ mol of oligo-RNase H conjugate; lane 4, same as lane 3 plus 25 μ M EDTA; lane 5, same as lane 3 plus 25 μ M EGTA; and lane 6, same as lane 3 plus 25 μ M NEM. Panel B. A graph of densitometric analyses of residual substrate HBV RNA present in the corresponding lanes of gels which Panel A shows a representative. All assays were performed in triplicate and the results expressed as means $\pm$ S. D. in arbitrary densitometric units.

substrate prevented cleavage of HBV transcript by the conjugate, lane 4. In contrast, addition of EGTA, a calcium chelator, lane 5, or NEM, which interferes with cysteine residues, lane 6, had no significant inhibition of cleavage activity. These results are consistent with the known requirement of the RNase H enzyme for magnesium, but not calcium for cleavage activity (1,3,17). The mutant RNase H1 used in these conjugation experiments is known not to be susceptible to inhibition by sulfhydryl reagents and, therefore, is not affected by NEM (18). However, it has been shown that NEM does inhibit native RNase H1 by the steric effects of sulfhydryl modification (7). In the current studies, RNase H1 was mutated to eliminate all but one cysteine and that remaining cysteine was modified by linkage to the oligonucleotide DNA, therefore eliminating the availability of cysteine residues for interference by NEM. Furthermore, the data argue against significant contamination with RNase H2 or other RNases susceptible to inhibition by sulfhydryl reactive agents.

The dependence of cleavage activity on conjugate concentration is shown in Figure 5. The gel shows that with a constant amount of starting substrate RNA of 0.25 pmol, decreasing the amounts of oligonucleotide-RNase H conjugate from 5 to 0.625 μ mol resulted in decreasing amounts of substrate cleaved, lanes 2-6, respectively. Quantitatively, this represented a decrease from 68% at 5 μ mol to 24% at 0.625 μ mol as shown in panel B. Additional bands can be seen in this gel and correspond with the predicted sizes resulting when the HBV tran-

script is cleaved, 180, 230, and 772 nucleotides. In most studies these bands were not seen, most likely due to degradation of the smaller more unstable fragments.

To estimate the activity of the conjugated RNase H relative to the unconjugated enzyme, HBV transcript, 0.25 pmol, was incubated with conjugate, 5 μ mol, or with varying amounts of free enzyme plus free oligo in equimolar amounts relative to each other. Figure 6 shows that the cleavage activity of 5 μ mol of conjugated enzyme, lane 3, was equal to the activity seen with between 0.25 μ mol, lane 5, and 0.025 μ mol, lane 4, of mixed enzyme and free oligonucleotide. By this calculation, the conjugate was approximately 5% as active as a mixture of free enzyme and oligo on an equimolar basis.

DISCUSSION

Although a DNA virus, HBV undergoes replication through a pregenomic RNA intermediate that serves not only as a template for replication, but also as a messenger RNA species (19). Because of its importance in the viral life cycle, cleavage of this intermediate could prevent synthesis of new virus. An agent that could result in sequence specific destruction of this entity could be valuable not only in the study of the HBV replication, but also, potentially as a therapeutic agent. The data presented in this report suggest that chemical linkage of the oligonucleotide to RNase H can confer HBV sequence specificity and still maintain enzymatic activity. Because the enzyme and oligonucleotide DNA are chemically linked, the two components are brought into physical proximity, and therefore have the potential to be

delivered together into intracellular compartments. In addition, the chemical linkages created between oligonucleotide-cross-linker-RNase H are noncleavable (20) and should remain stable within intracellular compartments.

E. coli and human RNase H1 share many of the same enzymatic properties including the requirement of divalent cations. The sites of cation binding, substrate binding, and enzyme activity are highly conserved in all RNase H molecules (4). Several lysine groups in the molecule's substrate binding site are thought to interact with the phosphate groups on the substrate, and the site of this interaction is thought to be in the minor groove (1, 3). The cysteine 13 residue was chosen for disulfide linkage of antisense DNA as it is close to the active site on the enzyme, but is not essential for cleavage activity (1). The other cysteine residues, also not necessary for cleavage activity, were mutated to serine and alanine in order not to interfere with sulfo-GMBS linkage of the oligonucleotide. A restriction site was added for cloning purposes to create the mutant RNase H. This molecule was shown to have 90% activity of wild type (1). Ma et al. showed that these modifications do not interfere with binding to the target mRNA.

The antisense oligonucleotide used in current system was modified in two ways. The first was the formation of phosphorothioate linkages to inhibit degradation by cellular nucleases. Heteroduplexes consisting of RNA and

phosphorothioate-linked DNA have been shown to be suitable substrates for RNase H activity (3, 21). The second was an addition of an amino group to the 5' carbon. This provided a functional group for modification by a coupling agent for conjugation of the oligonucleotide to the mutated RNase H without interfering with the sequence specificity and binding activities. The mutations in RNase H eliminated other potentially reactive cysteines, thus permitting specific modification and coupling of the oligonucleotide to the cysteine 13 residue in the enzyme.

The length of the antisense oligonucleotide DNA is also an important consideration. The minimum RNA-DNA hybrid that has been found to result in cleavage is six nucleotides. Sequences greater than six but less than nine have been shown to be cleaved but at slower rates (3). However, the longer the length of an oligonucleotide the more likely the possibility of nonspecific binding and cleavage (2). On the basis of this information, a 13-mer sequence was selected to be used in the current studies.

The cleavage of the HBV transcript by the conjugated ribonuclease H was expected to result in fragments of 180, 230, and 772 nucleotides, based on the complementary sites predicted to be recognized by the oligonucleotide. Some of the smaller fragments were barely or not detectable in some of the cleavage assays in this current study. It is likely that the resulting cleavage fragments were unstable, and were degraded quickly as has been reported in other studies on antisense oligonucleotides against other target RNAs (22).

Successful cleavage was seen when the conjugate was incubated with the HBV RNA, but not with the rabbit β -globin transcript, indicating that the observed cleavage was not due to nonspecific degradation of the target. The fact that neither RNase H nor oligonucleotide alone resulted in cleavage activity confirmed that neither had intrinsic nonspecific nuclease activity or were contaminated with another RNase, and that the presence of both RNase H and DNA together with the RNA substrate was required for cleavage activity.

The RNase H activity in the conjugate was found to be less than that of RNase H alone, estimated to be approximately 5% of unconjugated RNase H. This is similar to but higher than activity reported by Ma et al. for a conjugated RNase H against mouse β -globin message in which activity of the conjugate was only 0.3% that of free enzyme mixed with oligonucleotide DNA (1). The difference in results may be due to the differing affinities of the oligonucleotide DNA of their respective target RNA sequences.

Experiments combining the catalytic properties of RNase H and the binding specificity of antisense DNA have been used previously to obtain sequence-specific cleavage of the target template (1, 9–11). Most of these studies involved mixing of antisense DNA with the RNase H to obtain specificity of cleavage. However, to be of practical value, both components need to be delivered to the same compartment in effective concentrations. The data in the current studies indicate that it is possible to specifically couple RNase H in an equimolar ratio of enzyme to oligonucleotide, virtually ensuring simultaneous codelivery of both components at that fixed molar ratio, and represents the first demonstration that such a chimeric molecule can specifically cleave an HBV target mRNA.

To be useful, delivery of RNase H-antisense oligonucleotide into cells must occur. This could be achieved using lipofectamine, a polycationic lipid, which has been suc-

cessful in delivering nucleic acids (23), and proteins into cultured cells without loss of biological activity (24). Alternatively, for specific delivery into liver cells, liver-specific carrier consisting of liver cell recognition component and nucleic acid binding component may be employed to bring RNase H-antisense oligonucleotide into liver cells (23).

Transformation from Block-Type to Graft-Type Oligonucleotide-Glycopolymer Conjugates by Self-Organization with Half-Sliding Complementary Oligonucleotides and Their Lectin Recognition

Tsukasa Akasaka, Kazunori Matsuura,[†] and Kazukiyo Kobayashi*

Department of Molecular Design, Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-8603, Japan. Received February 15, 2001; Revised Manuscript Received June 15, 2001

Block-type oligonucleotide-glycopolymer conjugates bearing α -mannosides and β -galactosides were prepared by coupling 5'-thiol-modified oligonucleotides with iodoacetamidated glycopolymers that were synthesized by telomerization. The conjugates minimally affected the DNA conformation and melting behavior of the duplex. Their self-organization via hybridization with the half-sliding complementary oligonucleotides produced graft-type conjugates or macromolecular gapped DNA duplexes grafted with glycopolymers at regular intervals, which was confirmed using size exclusion chromatography and electrophoresis. The binding affinity of block-type and self-organized graft-type conjugates to lectins was investigated using fluorometry. The affinity of the graft-type duplex assembly bearing mannosides to Con A was approximately 2 times stronger than that of block-type single-stranded or double-stranded conjugates with full complementary oligonucleotides. The organization strategy of DNA-glycopolymer conjugates might be useful for constructing novel glyco-clusters and also for developing a new methodology for gene therapy.

INTRODUCTION

The control of the well-defined structures of materials is a major goal of chemistry, materials science, and nanotechnology. Self-organization strategies are increasingly recognized as an efficient way to produce nanometer-scaled structural and functional materials. ODNs¹ have attracted recent attention as a "molecular glue" for supramolecular architectonics based on the self-organization strategy (1–10). ODNs are promising construction materials to arrange functional components in controlled space and direction, because DNA forms a linear, rigid double-strand helix by complementary hydrogen-bonded base-pairing. Thus, oligonucleotides offer several advantages over nonbiologic linker molecules. The size and stability of DNA-based supramolecules can be controlled through the sequence and length of the ODNs and also by changing parameters of the aqueous environments, such as concentration, solvent, temperature, pH, and electrolyte.

Oligosaccharide chains, especially as glyco-clusters, on cell surfaces participate in biologic molecular recognition and signal transduction through carbohydrate-binding proteins (11, 12). Various glycoconjugate polymers (13–26), dendrimers (27–29), calixarenes (30), nanospheres (31), and transition metal complexes (32, 33) have been developed as glyco-cluster models. Construction of glyco-clusters by the self-organization strategy is very promising for the development of a new field of glyco-clusters, but there have been only a few reports on its use (34–36).

There are several self-organized glyco-clusters in nature. In aggrecans (the major proteoglycan of cartilage), for example, many glycosaminoglycan chains (keratan and chondroitin-sulfates specifically) are attached to a protein core, and the resulting aggrecan molecules are noncovalently bound to a hyaluronan backbone through small proteins linked at regular intervals (37, 38). The noncovalent association of these proteoglycans strongly influences the properties of tissues, matrix–cell interaction, cell–cell adhesion, and diffusion of large molecules in the matrix (39, 40). Artificially self-organized glyco-clusters were prepared, for example, via incorporation of glycopolymer-carrying lipids into liposomes (34) and also as self-assembled monolayers of glycopolymers on the surface of silver colloids (35). The lectin affinities of these assemblies of glycopolymers were stronger than those of the glycopolymers themselves, and depended on the surface density of the glycopolymer chain. The distance among the glycopolymers, however, could not be controlled using these methods.

ODNs are useful as a scaffold for constructing glyco-clusters using self-organization, because ODNs produce periodic and space-controlled assemblies by hybridization due to their strict sequence-specificity and the rigid linear conformation of the duplexes. We recently synthesized

Figure 1. Schematic illustration of transformation from block-type to graft-type ODN-glycopolymer conjugates by self-organization assisted with the half-sliding complementary ODN.

site-specific galactosylated ODNs in an automated solid-phase synthesizer (41) and constructed glyco-clusters via self-organization with hybridization of the conjugate using half-sliding complementary ODN (36). In half-sliding complementary n -mer ODN, the respective right- and left-half sequences are designed to be complementary to the left- and right-half sequences of the target n -mer ODN. The hybridization produced nanometer-sized macromolecular assemblies, and the resulting periodic glyco-clustered ODNs were cooperatively recognized by the specific RCA₁₂₀ lectin.

In the present paper, we propose an easy method for constructing periodically clustered glycopolymers using self-organization of block-type ODN-glycopolymer conjugates via hybridization with half-sliding complementary (hsc) ODN (Figure 1). The block-type ODN-glycopolymer conjugates were prepared by conjugation of artificial iodoacetamidated glycopolymer with 5'-thiol-modified ODN. The self-organization of block-type conjugates in the presence of hscODN produced the graft-type conjugate assembly, which was confirmed using size exclusion chromatography (SEC) and electrophoresis, and characterized by CD spectroscopy and melting behavior. Enhanced binding affinity of the assembly to lectins was estimated using fluorometry.

EXPERIMENTAL PROCEDURES

Instruments. ¹H NMR spectra were recorded on Varian Gemini-200 and Gemini-500 NMR spectrometers. Absorption spectra were determined using a JASCO V-530 UV/VIS spectrophotometer. CD spectra were determined in a 10 mm quartz cell with a JASCO J-720 L

spectrophotometer. Fluorescence spectra were recorded on a JASCO FP-777 spectrophotometer equipped with a thermal controller. Mass spectra were obtained on a JEOL JMS-AX505HA mass spectrometer using the electron impact method operating in the positive mode. Infrared spectra were recorded with a JASCO Fourier transform IR-230 spectrophotometer. Optical rotation was determined with a JASCO DIP-1000 digital polarimeter using a water-jacketed 1 dm cell at 25 °C. SEC was recorded at 40 or 25 °C with JASCO Gulliver SB-804HQ to SB-803HQ columns and an RI detector (RI-930). Reverse-phase HPLC was recorded at 25 °C with a Shiseido Capcell Pak C18 UG120 (4.5 × 150 mm) and a JASCO Gulliver UV/VIS detector (UV-975). TLC was performed with a Merck TLC plate precoated with silica gel 60.

Materials. The following five types of ODNs were purchased from BEX Co., Ltd. (Japan): 5'-TCCTCGC-CCTTGCTCACCAT-3', 5'-TCCTCGCCCTTGCTCACCAT-3' modified with 6-mercaptohexyl phosphate at the 5'-end, 5'-ATGGTGAGCAAGGGCGAGGA-3', 5'-AGGGCG-AGGAATGGTGAGCA-3', and 5'-AGGGCGAGGATTTTTTTTTTATGGTGAGCA-3'. FITC-labeled *Ricinus communis* agglutinin (RCA₁₂₀, from *Ricinus communis*) and FITC-labeled concanavalin A (Con A, from Jack Bean, *Canavalia ensiformis*) were purchased from Sigma Co., Ltd. 2-Bromoethyl 2,3,4,6-tetra-*O*-acetyl-β-*D*-galactopyranoside (42), 2-bromoethyl 2,3,4,6-tetra-*O*-acetyl-α-*D*-mannopyranoside (42), and *N*-iodoacetoxy succinimide (43) were prepared as previously reported. 2,2'-Azo-2-

amidinopropane dihydrochloride (AAPD, Wako Pure Chemical, Osaka) was purified by recrystallization from water.

2-Azidoethyl 2,3,4,6-Tetra-O-acetyl- β -D-galactopyranoside (2-Gal) (44). 2-Bromoethyl 2,3,4,6-tetra-O-acetyl- β -D-galactopyranoside (42) (**1-Gal**, 3.25 g, 7.15 mmol) was added to a solution of sodium azide (696 mg, 10.7 mmol) in DMF (33 mL). The mixture was heated at 65 °C. TLC (ethyl acetate/hexane = 1:1 in volume): R_f of **1-Gal** = 0.57 and **2-Gal** = 0.51. After 1 h, the mixture was diluted with chloroform and washed with water, and the organic layer was treated with MgSO_4 . The filtrate was concentrated in vacuo, chromatographed on a silica gel column (eluent, ethyl acetate/hexane 1:1 in volume), and concentrated in vacuo to afford pure **2-Gal** as a crystalline solid (2.98 g, 100% yield).

2-(N-(Methacryloyl)amino)ethyl 2,3,4,6-Tetra-O-acetyl- β -D-galactopyranoside (4-Gal). Palladium carbon (1.05 g) was added to a solution of **2-Gal** (4.20 g, 10.1 mmol) in THF (420 mL). The mixture was stirred under a hydrogen atmosphere at room temperature for 40 min. TLC (ethyl acetate/hexane = 1:2 in volume): R_f of **2-Gal** = 0.74 and **3-Gal** = 0. Palladium carbon was removed by filtration on Celite. The filtrate was used for the next step without further purification.

Methacryloyl chloride (1.97 mL, 40.3 mmol) was added to the reaction mixture and triethylamine (17.2 mL, 80.6 mL) in THF at 0 °C and stirred magnetically at room temperature for 30 min. TLC (ethyl acetate/hexane = 1:2 in volume): R_f of **4-Gal** = 0.25. The solution was concentrated in vacuo, chromatographed on a silica gel column (eluent, ethyl acetate/hexane 1:2 in volume), and concentrated in vacuo to afford pure **4-Gal** as a colorless syrup (3.71 g, 80% yield). $[\alpha]_D^{25} = +0.1^\circ$ (c 0.10 in chloroform). FAB-MS: m/z 460 ($M^+ + H$). ^1H NMR (CDCl_3): δ 6.21 (1H, br-m, $-\text{C}=\text{CHH}$), 5.71 (1H, br-m, $-\text{C}=\text{CHH}$), 5.39 (1H, dd, $J_{4,5} = 1.0$ Hz, H-4), 5.37 (1H, m, amido), 5.24 (1H, dd, $J_{2,3} = 10.0$ Hz, H-2), 5.01 (1H, dd, $J_{3,4} = 3.4$ Hz, H-3), 4.55 (1H, d, $J_{1,2} = 7.8$ Hz, H-1 of β -anomer), 4.15–4.12 (2H, m, H-6), 3.92–3.40 (5H, m, H-5 and $-\text{O}-\text{CH}_2-\text{CH}_2-\text{N}$), 2.15, 2.04, 1.99, 1.96 (12H, 4s, $-\text{OCOCH}_3$), 1.56 (3H, s, $-\text{CH}_3$). IR (KBr): 2940, 1760, 1660, 1630, 1530 cm^{-1} . Anal. Calcd for $\text{C}_{20}\text{H}_{29}\text{O}_{11}\text{N}$: C, 52.29; H, 6.18; N, 3.05. Found: C, 52.26; H, 6.21; N, 3.01.

2-(N-(Methacryloyl)amino)ethyl β -D-Galactopyranoside (5-Gal). Sodium methoxide (6.6 mg) was added to a stirred solution of **4-Gal** (3.65 g, 7.95 mmol) in methanol (35 mL), and the mixture was stirred for 6 h. The mixture was neutralized with Amberlyst 15E ion-exchange resin, filtrated, and concentrated. Finally, the product was dissolved into water and freeze-dried, affording pure **5-Gal** as a white powder (2.30 g, 100% yield). mp: 61–63 °C. $[\alpha]_D^{25} = +4.0^\circ$ (c 0.10 in H_2O). FAB-MS: m/z 292 ($M^+ + H$). ^1H NMR (D_2O): δ 5.64 (1H, br-m, $-\text{C}=\text{CHH}$), 5.39 (1H, br-m, $-\text{C}=\text{CHH}$), 4.34 (1H, d, $J_{1,2} = 7.4$ Hz, H-1), 4.02–3.4 (10H, m, H-2 ~ H-6 and $-\text{O}-\text{CH}_2-\text{CH}_2-\text{N}$), 1.86 (3H, s, $-\text{CH}_3$). IR (KBr): 3360, 2950, 1660, 1610, 1540 cm^{-1} . Anal. Calcd for $\text{C}_{12}\text{H}_{21}\text{O}_7\text{N}$: C, 49.48; H, 7.27; N, 4.81. Found: C, 49.44; H, 7.32; N, 4.77.

2-Azidoethyl 2,3,4,6-Tetra-O-acetyl- α -D-mannopyranoside (2-Man) (44). Compound **2-Man** was prepared in a similar manner as **2-Gal** (97% yield).

2-(N-(Methacryloyl)amino)ethyl 2,3,4,6-Tetra-O-acetyl- α -D-mannopyranoside (4-Man). Compound **4-Man** as a colorless syrup was prepared in a similar manner as **4-Gal** (82% yield from **2-Man**). $[\alpha]_D^{25} = +39.4^\circ$ (c 0.10 in chloroform). FAB-MS: m/z 460 ($M^+ + H$). ^1H NMR (CDCl_3): δ 6.22 (1H, br-s, $-\text{C}=\text{CHH}$), 5.72 (1H, br-

m, $-\text{C}=\text{CHH}$), 5.37 (1H, m, amido), 5.34 (1H, dd, $J_{3,4} = 10.0$ Hz, H-3), 5.27 (1H, t, $J_{4,5} = 10.0$ Hz, H-4), 5.25 (1H, dd, $J_{2,3} = 3.5$ Hz, H-2), 4.83 (1H, d, $J_{1,2} = 2.0$ Hz, H-1 of α -anomer), 4.26 (1H, dd, $J_{5,6b} = 5.0$ Hz, $J_{6a,6b} = 12.0$ Hz, H-6b), 4.12 (1H, dd, $J_{5,6a} = 2.5$ Hz, H-6a), 3.96 (1H, ddd, H-5), 3.84–3.50 (4H, m, $-\text{O}-\text{CH}_2-\text{CH}_2-\text{Br}$), 2.16, 2.10, 2.05, 2.00 (12H, 4s, $-\text{OCOCH}_3$), 1.56 (3H, s, $-\text{CH}_3$). IR (KBr): 2940, 1760, 1660, 1630, 1530 cm^{-1} . Anal. Calcd for $\text{C}_{20}\text{H}_{29}\text{O}_{11}\text{N}$: C, 52.29; H, 6.18; N, 3.05. Found: C, 52.25; H, 6.23; N, 3.00.

2-(N-(Methacryloyl)amino)ethyl α -D-Mannopyranoside (5-Man). Compound **5-Man** as a hygroscopic solid was prepared in a similar manner as **5-Gal** (99% yield). $[\alpha]_D^{25} = +39.7^\circ$ (c 0.10 in H_2O). FAB-MS: m/z 292 ($M^+ + H$). ^1H NMR (D_2O): δ 5.53 (1H, br-s, $-\text{C}=\text{CHH}$), 5.30 (1H, br-m, $-\text{C}=\text{CHH}$), 4.71 (1H, d, $J_{1,2} = 1.5$ Hz, H-1 of α -anomer), 3.77 (1H, dd, $J_{2,3} = 3.5$ Hz, H-2), 3.71–3.28 (9H, m, H-3 ~ H-6 and $-\text{O}-\text{CH}_2-\text{CH}_2-\text{N}$), 1.78 (3H, s, $-\text{CH}_3$). IR (KBr): 3440, 2930, 1650, 1610, 1540 cm^{-1} . Anal. Calcd for $\text{C}_{20}\text{H}_{29}\text{O}_{11}\text{N}$: C, 52.29; H, 6.18; N, 3.05. Found: C, 52.24; H, 6.23; N, 3.02.

Telomerization (45, 46). Prescribed amounts of the monomer, AAPD, and cysteamine were charged in a glass ampule and dissolved in water. The ampule was placed in a carbon dioxide/methanol bath, and the solution was frozen and degassed. The procedure was repeated 3 times. The ampule was sealed under a reduced pressure and maintained at 60 °C. The ampule was chilled, and the product was reprecipitated from its aqueous solution into acetone. The precipitate was dissolved in water, and the solution was chromatographed through Sephadex G-25 with detection at 254 nm. Fractions containing the polymer were collected and freeze-dried to give a white powdery polymer.

The degree of polymerization was estimated from the ^1H NMR area ratios at 4.35 ppm for the anomer proton of galactoside (or at 4.75 ppm for the anomer proton of mannoside) and at 3.02 ppm for the methylene protons of the cysteamine moiety, and also estimated from SEC based on pullulan standards. ^1H NMR (D_2O): δ 4.35 (br-s, H-1 of β -anomer), 3.88–3.10 (br-m, H-2 ~ H-6 and $-\text{O}-\text{CH}_2-\text{CH}_2-\text{N}$), 3.02 (br-m, $\text{S}-\text{CH}_2-\text{CH}_2-$), 2.68 (br-m, $\text{S}-\text{CH}_2-\text{CH}_2-$), 1.92–1.50 (br-m, $-\text{CH}_2-$), 1.10–0.70 (br-m, $-\text{CH}_3$).

Iodoacetylation of Glycopolymers (47). The glycopolymer bearing the terminal amino group [poly(Gal)37- NH_2 , 4.8 μmol , 50 mg] was dissolved in 1.0 mL of 0.1 M 2-(N-morpholino)ethanesulfonic acid (MES)/NaOH buffer (pH 6.0), and then the iodoacetic acid *N*-hydroxysuccinimide ester (43) (93.4 μmol , 26.4 mg) in 200 μL of DMF was added to the solution. The progress of the reaction was monitored by the disappearance of the terminal amino groups of the glycopolymers, which was detected with ninhydrin after an aliquot of the reaction mixture was separated with TLC (ethyl acetate/acetic acid/methanol/water = 3:4:3:1 in volume): R_f of terminal amino and iodoacetamido glycopolymers = 0. After 3 h reaction at room temperature in the dark, the solution was chromatographed through a Sephadex G-25 column with detection at 254 nm. Fractions containing the product were collected and freeze-dried to obtain a white powdery polymer [poly(Gal)37- $\text{CH}_2\text{-I}$, 49.2 mg, 97%]. The iodoacetamido glycopolymer was stored in a freezer (–20 °C) and used in the following step. ^1H NMR (D_2O): δ 4.35 (br-s, H-1 of β -anomer), 3.88–3.10 (br-m, H-2 ~ H-6 and $-\text{O}-\text{CH}_2-\text{CH}_2-\text{N}$ and $\text{S}-\text{CH}_2-\text{CH}_2-\text{N}$ and $-\text{CH}_2\text{-I}$), 1.92–1.50 (br-m, $-\text{CH}_2-$), 1.10–0.70 (br-m, $-\text{CH}_3$).

Conjugation of 5'-Thiol-Modified ODN with Iodoacetamido Glycopolymers (48). Triethylamine

Scheme 1. Synthesis of Galactoside and Mannoside Glycopolymers Bearing the Amino Terminal^a

^a Reagents and conditions: (a) NaN₃, DMF, 65 °C, 1 h. (b) H₂ gas, Pd/C, THF, rt, 40 min. (c) Methacryloyl chloride, triethylamine, THF, rt, 30 min. (d) Sodium methoxide, methanol, rt, 6 h. (e) Cysteamine, AAPD, water, 60 °C.

(1.6 μL) and iodoacetamido glycopolymer [poly(Gal)37-CH₂-I or poly(Man)42-CH₂-I, 18 μL of a 31.7 mM solution in water, 571 nmol] were added to a solution of ODN with a terminal thiol group (81.5 nmol) in 63.6 μL of water. The progress of the reaction was monitored using analytical reverse-phase HPLC on a Shiseido Capcell Pak C18 UG120 with a linear gradient of acetonitrile (2–30%) in 0.1 M ammonium acetate buffer (pH 7.0) over 30 min. After 2–3 h, the solution was loaded onto an anion exchange chromatograph with Qiagen resin (Qiagen GmbH, Germany), washed with water and 0.05 M aqueous NaCl, and then eluted with 0.5 M aqueous NaCl. The appropriate fractions were collected, and the product was precipitated into ethanol and centrifuged at 14 000 rpm for 15 min, to afford pure conjugates (block-type ODN-glycopolymer conjugates). Isolated yield from starting ODN was 80% for ODN-Gal37 conjugate and 75% for ODN-Man42 conjugate, which was determined from the UV absorbance in H₂O using OD₂₆₀ = 32.7 μg/mL.

Estimation of Organization of ODN by Gel Electrophoresis. Double-stranded ODN samples were prepared by mixing ODN-glycopolymer conjugates with equimolar amounts of full complementary ODN or half-sliding complementary ODN in PBS buffer (pH 7.4) at 25 °C for 1 h. The double-strand samples (total 10 μL) were loaded onto a 3% agarose gel, and electrophoresis was performed in 0.5 × TBE buffer (90 mM Tris and 90 mM boric acid) at 25 °C at 4 V/cm. DNA bands were stained in a 6 μg/mL ethidium bromide solution and

visualized by transillumination with ultraviolet light (310 nm) using a DC40 camera equipped with 1D Image Analysis Software MAC Ver 2.0 (Kodak Digital Science). The length of DNA relative to the *Hinf*I restriction enzyme digest of φX174 was determined by agarose gel electrophoresis.

Estimation of Organization of ODN by SEC. Double-stranded ODN samples were prepared by mixing the conjugates with equimolar amounts of full complementary ODN and half-sliding complementary ODN at 3.4 × 10⁻³ M-base concentrations in PBS buffer (pH 7.4) at 25 °C. After 1 h, SEC analysis of the double- and single-strand samples (20 μL) was performed. The eluent was 0.1 M phosphate buffer (pH 7.0) for glycopolymers and ODN-glycopolymer conjugates, and PBS buffer (pH 7.4) for organized ODN-glycopolymer conjugates. The flow rate was 0.5 mL/min. Pullulan was used as the molecular weight standard.

CD Spectra. Single-strand ODN samples were prepared by dissolving the conjugates in PBS buffer (pH 7.4) at 22.5 μM-base concentrations. Double-stranded ODN samples were prepared by mixing the conjugate with an equimolar amount of full complementary or half-sliding complementary ODN at 45.0 μM-base concentrations for 1 h. CD spectra of double strands were recorded at 25 °C under equilibrium conditions.

Melting Behaviors. Double-stranded ODN samples were prepared by mixing the conjugates with an equimolar amount of full complementary or half-sliding comple-

^a Telomerization was performed with 2,2'-azo-2-amidinopropane dihydrochloride (AAPD, 2.9 mol % to the monomer) as the initiator and cysteamine as the telogen in water at 60 °C. ^b Using 0.1 M phosphate buffer (pH 7.0) eluent and pullulan standard. ^c DP was estimated from the ¹H NMR area ratios of signals for the anomer proton and the methylene protons of cysteamine moiety.

Scheme 2. Preparation of Block-Type ODN-Glycopolymer Conjugates

mentary ODN at 45.0 μ M-base concentrations in PBS buffer (pH 7.4). The absorbance was recorded at 260 nm as a function of increasing temperature at 2.0 °C/2 min on a spectrophotometer equipped with a thermal controller.

Fluorescence Assay of Lectin Binding. Aliquots (1 μ L) of a stock solution of 1.5 mM-sugar (to RCA₁₂₀) or 0.3 mM-sugar (to Con A) sample were added every 25 min to a solution of FITC-labeled RCA₁₂₀ lectin (14.7 nM, 600 μ L) in PBS buffer (pH 7.4) or to a solution of FITC-labeled Con A lectin (327 nM, 600 μ L) in PBS (pH 7.0) containing 0.1 mM Ca²⁺ and 0.1 mM Mn²⁺. Fluorescence spectra (500–600 nm) were recorded with excitation at 490 nm at 25 °C.

RESULTS AND DISCUSSION

Preparation of Block-Type ODN-Glycopolymer Conjugates. Our strategy for the molecular design of block-type ODN-glycopolymer conjugates applies a highly

efficient coupling of iodoacetamidated glycopolymer derivatives to commercially available ODN, modified with thiol at the 5'-terminal (43, 47, 48). Scheme 1 shows the synthesis of glycopolymers bearing an amino group at the terminal. Bromoethyl peracetylated β -galactosides and α -mannosides (42) were transformed to the methacrylamide monomers via a convenient synthetic route. The yields of β -galactoside monomers (**5-Gal** from **1-Gal**) and α -mannoside monomers (**5-Man** from **1-Man**) were 80% and 79%, respectively. The formation of **5-Gal** and **5-Man** was confirmed by ¹H NMR spectroscopy. Telomerization (45, 46) of **5-Gal** and **5-Man** was then performed with cysteamine as a telogen and 2,2'-azo-2-amidinopropane dihydrochloride (AAPD) as an initiator in water at 60 °C to produce glycopolymers bearing an amino group at the terminal, as summarized in Table 1. The telomerization proceeded homogeneously to give a viscous solution, and a powdery glycopolymer was obtained by reprecipitation from water into acetone, fol-

B) A mixture of reference samples

Figure 2. HPLC profiles for (A) the coupling reaction of 5'-thiol-modified ODN (20mer) with poly(Gal)37-NH₂ to give ODN-Gal37 conjugate. (B) Mixture of 5'-thiol-modified ODN (20mer), poly(Gal)37-NH₂, and isolated ODN-Gal37 conjugate. Shiseido Capcell Pak C18 UG120 column (4.5 × 150 mm); flow rate 1.5 mL/min; detected at UV 260 nm; temperature 25 °C; eluted with a linear gradient of 0.1 M ammonium acetate (pH 7.0) containing 2–30% acetonitrile over 30 min. The poly(Gal)-NH₂ sample was injected at a concentration approximately 100 times that of the ODN sample.

lowed by gel filtration chromatography. The formation of glycopolymers was confirmed using ¹H NMR spectroscopy. The average molecular weights of the glycopolymers were estimated by the ¹H NMR intensity of the cysteamine moiety and the anomer proton and by SEC. Because the ¹H NMR data were more reliable, the average degrees of polymerization were employed respectively for galactoside (*n* = 37) and mannoside (*n* = 42) glycopolymers in the following experiments.

Scheme 2 illustrates a simple synthetic route to block-type ODN-glycopolymer conjugates. The terminal amino group of the glycopolymer was iodoacetylated with *N*-iodoacetoxy succinimide in MES buffer. The introduction of the iodoacetamide group was quantitative, which was confirmed as follows: No residual amino groups were detected using the ninhydrin reagent, and ¹H NMR signals assignable to the cysteamine moiety were observed. Commercially available 5'-thiol-modified ODN (20mer) was coupled with 7 equiv of iodoacetamido glycopolymer in the presence of triethylamine for 2–3 h. The reaction profile was monitored by the absorbance of the nucleobases at 260 nm in reverse-phase HPLC (Figure 2A). There were no byproducts derived from ODN, suggesting that the coupling proceeded quantitatively in 180 min. The resulting conjugate was purified by anion exchange chromatography and by reprecipitation with ethanol. The isolated yields were 80% for the ODN-Gal37 conjugate and 75% for the ODN-Man42 conjugate. Figure 2B shows the results of the HPLC analysis of a mixture of the reactants and product, where a large amount of poly(Gal)-NH₂ sample (approximately 100 times that of ODN) was injected and was detectable at 260 nm. The peak of the conjugate was broader than that of ODN, and appeared between the retention times

Figure 3. SEC chromatogram of (A) 5'-thiol-modified ODN (20mer), (B) poly(Gal)37-NH₂, and (C) ODN-Gal37 conjugate. Shodex OH Pak SB-804 HQ to SB-803 HQ; RI detector; eluent 0.1 M phosphate buffer (pH 7.0); flow rate 0.5 mL/min; temperature 40 °C.

Figure 4. Gel electrophoresis analysis for self-organization of ODN with half-sliding cODN. Lane 1: single-strand ODN (3.3 mM-base). Lanes 2–5: ODN/full cODN duplex (0.7, 1.7, 3.3, and 6.7 mM-base, respectively). Lanes 6–9: ODN/hscODN duplex (0.7, 1.7, 3.3, and 6.7 mM-base, respectively). M: double-stranded DNA marker.

of ODN and the glycopolymer. In SEC analysis (Figure 3), the apparent molecular size of the conjugate was higher than those of glycopolymer and ODN alone.

Organization of ODN-Glycopolymer Conjugates.

Gel electrophoresis and SEC were performed to confirm whether self-organization of the block-type ODN-glycopolymer conjugates was accomplished by hybridization with hscODN to afford the graft-type conjugate assembly. Agarose gel electrophoresis (Figure 4) demonstrates that the ODN/hscODN bands (lanes 6–9) were broader and had shifted to a higher molecular weight than ODN/full cODN bands (lanes 2–5). The tendency was even more remarkable with an increase in the concentration, and the ODN/full cODN bands (lanes 2–5) were minimally shifted even at high concentrations (6.7 mM). ODN could be self-organized with the half-sliding complementary ODN to produce a high molecular weight assembly, the molecular size of which depended on the concentration. However, gel electrophoresis of the ODN-glycopolymer conjugates exhibited mobile bands that were too broad to examine the organization (data not shown).

Figure 5. SEC analysis of (A) single-strand ODN-Gal37 conjugate and hscODN, (B) duplex of ODN-Gal37 conjugate with full cODN, and (C) duplex of ODN-Gal37 conjugate with hscODN. Shodex OH Pak SB-804 HQ to SB-803 HQ; RI detector; flow rate 0.5 mL/min; temperature 25 °C; eluted with PBS buffer, pH 7.4; pullulan standard. The concentration of ODN at the injection was 1.7 mM-base for single-strand ODN and 3.4 mM-base for double-strand ODN.

Figure 5 compares SEC of the single-strand ODN-Gal37 conjugate and its duplexes with full cODN and with hscODN. The peak of the conjugate/full cODN was shifted slightly to a higher molecular size ($M_n = 23\,300$) than those of the single-strand conjugate ($M_n = 17\,500$) and full cODN ($M_n = 4700$), indicating the formation of the full-matching double-stranded complex. The peak of the conjugate/hscODN occurred at a much higher molecular size ($M_n = 71\,300$), suggesting that the block-type ODN-glycopolymer conjugates were hybridized with hscODN to form the graft-type conjugate assembly.

As shown in Figure 6, the duplexes of unmodified ODN, ODN-Gal37, and ODN-Man42 with full cODN (A) and with hscODN (B) produced almost the same CD pattern, which was shifted slightly from the B-type to the A-type ODN duplex. This finding suggests that the glycopolymer moiety of the conjugates minimally affected the conformation of the duplex with full cODN and the self-organized duplex with hscODN.

The melting curves of the duplexes of ODN-glycopolymer conjugates with their full cODN (Figure 7A) and with hscODN (Figure 7B) in PBS buffer (pH 7.4) were almost the same as the corresponding curves of the duplexes of unmodified ODN. The glycopolymer moiety in the conjugates also minimally affected the stability of the ODN duplex. The result suggests that the glycopolymer chains dangle outside from the duplexes and interact minimally with the duplexes. Melting temperatures of the organized duplex with hscODN were approximately 40 °C, which was lower and broader than those with full cODN (68 °C). The 1:1 mixture between the conjugates and hscODN sufficiently formed the organized duplex at 25 °C.

Binding Affinity to Lectins. Binding affinity of the conjugates to lectins was estimated quantitatively by fluorimetry using FITC-labeled lectins to evaluate the effects of organization of the conjugates. Because the duplex of the conjugate/hscODN was sufficiently stable at 25 °C, the binding assay was performed at 25 °C with FITC-labeled RCA₁₂₀ (*Ricinus communis*, Gal β specific) and Con A (Jack Bean, *Canavalia ensiformis*, Man α or Glc α specific). The addition of an increasing amount of ODN-Man42/full cODN and ODN-Man42/hscODN de-

Figure 6. CD spectra of the duplexes of ODN-glycopolymer conjugates with (A) full cODN and (B) hscODN at a concentration of 45 μ M-base in PBS (pH 7.4) at 25 °C.

Figure 7. Melting behaviors of ODN-glycopolymer conjugates with (A) full cODN and with (B) hscODN. The melting curves were recorded at a heating rate 2 °C/2 min at a concentration of 45.0 μ M-base in PBS buffer (pH 7.4).

creased the fluorescence intensity at 520 nm (excitation at 490 nm) without causing any turbidity. The decrement of fluorescence intensity ($\Delta F/F_0$) was plotted against the concentration per sugar unit of the conjugate (Figure 8A). Equation 1 was applied to the saturation to obtain a

Figure 8. (A) Dependence of fluorescence intensity ($\Delta F/F_0$ at 520 nm, Ex 490 nm) of FITC-Con A on the concentration of the sugar moiety of the duplexes of ODN-Man42 conjugate with full cODN and with hscODN. Initial concentration of lectin = 327 nM in PBS containing 0.1 mM Mn^{2+} and 0.1 mM Ca^{2+} (pH 7.4) at 25 °C. Table 2. Association Constants (K_a) in Binding of ODN-Glycopolymer Conjugates to Lectins

compound	Con A $K_a/(\text{M-sugar})^{-1}$	RCA ₁₂₀ $K_a/(\text{M-sugar})^{-1}$
ODN-Man42/full cODN	3.0×10^5	$<10^2$
ODN-Man42/hscODN	7.3×10^5	$<10^2$
ODN-Man42/hsc-spacer-ODN	7.2×10^5	$<10^2$
ODN-Man42	4.1×10^5	$<10^2$
poly(Man)42-NH ₂	4.1×10^5	$<10^2$
ODN-Gal37/hscODN	$<10^2$	3.1×10^5
ODN-Gal37	$<10^2$	3.7×10^5
poly(Gal)37-NH ₂	$<10^2$	2.1×10^5

linear relationship (Figure 8B). Apparent affinity constants (K_a) were calculated from the intercept and slope as summarized in Table 2.

$$\frac{F_0}{\Delta F}[\text{sugar}] = \frac{F_0}{\Delta F_{\max} K_a} + \frac{F_0}{\Delta F_{\max}}[\text{sugar}] \quad (1)$$

Both Poly(Man)42-NH₂ and ODN-Man42 conjugate were bound to Con A with a similar affinity constant, $K_a = 4.1 \times 10^5 (\text{M-sugar})^{-1}$, which was approximately 10 times higher than that of the corresponding mannoside monomer. The cluster effect (14, 49, 50) was observed in the Poly(Man)42-NH₂ and ODN-Man42 conjugates, and the affinity to the lectin was not disturbed by the block-type conjugation of ODN. In addition, the hybridization of the ODN-Man42 conjugate with full cODN did not increase the affinity [$K_a = 3.0 \times 10^5 (\text{M-sugar})^{-1}$], but the hybridization of the ODN-Man42 conjugate with hscODN increased the affinity approximately 2 times [$K_a = 7.3 \times 10^5 (\text{M-sugar})^{-1}$]. It is important to note that the affinity was enhanced by the organization between the ODN-Man42 conjugate and hscODN. The effect was not as striking as we expected, in that a large amplification of affinity should be caused by the organization. On the other hand, the organized ODN-Gal37/hscODN duplex was bound to RCA₁₂₀ lectin with a high affinity constant, $K_a = 3.1 \times 10^5 (\text{M-sugar})^{-1}$, which was similar to those of poly(Gal)37-NH₂, ODN-Gal37, and ODN-Gal37/full cODN duplex to RCA₁₂₀. The organization effect of the ODN-Gal37 to RCA₁₂₀ was not expressed under these conditions.

The small organizing effect on the lectin affinity is discussed below. Kitano et al. reported that the binding ability of glycopolymers on Ag colloids to Con A was

increased by only approximately 2.5 times that of the glycopolymers at 25 °C because of the large steric hindrance (35). Therefore, it is possible that the present small organization effect is due to steric hindrance based on the short distance between glycopolymer chains along the ODN duplex: the calculated distance between carbohydrate recognition domains of ConA was approximately 6 nm, and the calculated distance between glycopolymers along the B-type duplex of 20 nucleobases was approximately 6.8 nm. To inspect the steric effect, thymine 10mer was inserted into the middle part of the hsc-ODN sequence as a spacer (the ODN is termed hsc-spacer-ODN). However, the binding affinity of the resulting ODN-Man42/hsc-spacer-ODN assembly to ConA was not improved [$K_a = 7.2 \times 10^5 (\text{M-sugar})^{-1}$]. It is possible that the length of the spacer may not be optimized or that the organized ODN-Man42/hsc-spacer-ODN assembly may be less stable than the organized ODN-Man42/nonspacer hsc-ODN assembly since the spacer thymine 10mer cannot form duplex but remains as single chain. At present, we assume that the large cluster effect is attained by the glycopolymers alone and, hence, the organization effect is not detectable.

CONCLUSION

We propose an easy method for transformation from block-type ODN-glycopolymer conjugates to the graft-type conjugate assembly by self-organization to construct periodically clustered glycopolymers. The block-type ODN-glycopolymer conjugates bearing galactosides and mannosides were prepared effectively by coupling of terminal-iodoacetamido glycopolymer with 5'-thiol-modified ODN and then self-organized by hybridization with hscODN. The conjugation and organization of the glycopolymers with ODN did not affect the conformation and melting behavior of ODN. The graft-type conjugate assembly ODN-Man42/hscODN was bound to ConA approximately 2 times stronger than the ODN-Man42/full cODN and the ODN-Man42 alone, but the effect was not as large as expected. On the other hand, the organization effect of the ODN-Gal37 with hscODN on the binding to RCA₁₂₀ was not expressed under these conditions. We expect that the proposed self-organization strategy to assemble glycopolymer conjugates might be useful for a new method of gene therapy and for novel neoglycoconjugates.

Synthesis of Ring- and Side-Chain-Substituted *m*-Iodobenzylguanidine Analogues

Ganesan Vaidyanathan,* Sriram Shankar, and Michael R. Zalutsky

Department of Radiology, Duke University Medical Center, Durham, North Carolina 27710.
Received March 6, 2001; Revised Manuscript Received June 22, 2001

With the goal of developing MIBG analogues with improved targeting properties especially for oncologic applications, several radioiodinated ring- and side-chain-substituted MIBG analogues were synthesized. Except for 3- ^{131}I -iodo-4-nitrobenzylguanidine and *N*-hydroxy-3- ^{131}I -iodobenzylguanidine, the radioiodinated analogues were prepared at no-carrier-added levels from their respective tin precursors. The radiochemical yields generally were in the range of 70–90% except for 3-amino-5- ^{131}I -iodobenzylguanidine for which a radiochemical yield of about 40% was obtained. While the silicon precursor *N*¹,*N*²-bis(*tert*-butyloxycarbonyl)-*N*¹-(4-nitro-3-trimethylsilylbenzyl)guanidine did not yield 3- ^{131}I -iodo-4-nitrobenzylguanidine, its deprotected derivative, *N*¹-(4-nitro-3-trimethylsilylbenzyl)guanidine was radioiodinated in a modest yield of 20% providing 3- ^{131}I -iodo-4-nitrobenzylguanidine. Exchange radioiodination of 3-iodo-4-nitrobenzylguanidine gave 3- ^{131}I -iodo-4-nitrobenzylguanidine in 80% radiochemical yield. No-carrier-added ^{131}I -NHIBG was prepared from its silicon precursor *N*¹-hydroxy-*N*³-(3-trimethylsilylbenzyl)guanidine in 85% radiochemical yield.

INTRODUCTION

Despite its wide applications in oncology and cardiology, the radiopharmaceutical *m*-iodobenzylguanidine (MIBG¹) remains a less than ideal agent (Shapiro, 1991; Wafelman et al., 1994). Although MIBG is an effective diagnostic agent for neuroblastoma and pheochromocytoma (Gefland, 1993), its therapeutic efficacy is less than desired (Sisson et al., 1990). To augment the therapeutic effect of ^{131}I -MIBG, its use in a tandem with other modalities has been attempted (Gaze et al., 1995; Mas-trangelo et al., 1995). Both higher peak uptake in tumor and prolonged tumor retention of an endoradiotherapeutic agent are important for maximizing therapeutic effects. Although high uptake of radioiodinated MIBG in a number of neuroblastoma cell lines has been demonstrated, the ability of these cells to retain the radioactivity for more than a few hours was rather poor (Lashford et al., 1991; Mairs et al., 1991; Smets et al., 1989; 1990; 1991). A short biological half-life of MIBG in tumor has been observed in clinical settings as well (Sisson and Wieland, 1986), and attempts have been made to boost MIBG retention by pharmacological intervention (Blake et al., 1988).

Maximizing tumor-to-normal tissue ratios is an objective that needs to be given important consideration in order to reduce normal tissue toxicity and to improve the therapeutic outcome. Achieving higher tumor-to-normal tissue ratios rapidly is essential for diagnostic applications as well. One of the drawbacks of MIBG-aided diagnosis is that an elapsed period of 1–2 days is necessary to provide sufficient target-to-background ratios for tumor detection (Sisson and Shulkin, 1999). We have hypothesized that improvements in the selective tumor uptake and retention probably can be made by altering the structure of the MIBG molecule. For example, in SK-N-SH cells in vitro and in mouse target tissues in vivo, 4-fluoro-3- ^{125}I -iodobenzylguanidine (FIBG) was retained to a greater extent than MIBG itself (Vaidyanathan et al., 1997a). While tumor uptake depends in part on binding to norepinephrine transporter (Mairs et al., 1994; Glowinski et al., 1993; Hadrich et al., 1999), tumor retention to a certain degree is dictated by the stability of the compound. MIBG is known to be generally resistant to metabolism; however, tumor retention of radioactivity might be increased as well if MIBG was rendered less susceptible to deiodination by structural alterations. Indeed, one of the contributing factors for the enhanced retention of FIBG described above might be its higher resistance to deiodination.

In the current study, a number of ring- and side-chain-substituted MIBG derivatives have been synthesized with the goal of maximizing tumor-to-normal tissue ratios. Due to the encouraging results obtained with FIBG, we were interested in the properties of the corresponding chloro-analogue. Analogues with singly and multiply substituted polar groups such as nitro, amino, methoxy, and hydroxyl at different positions were also prepared. This paper deals with the syntheses of these novel analogues, and their biological evaluation is described in the accompanying paper.

MATERIALS AND METHODS

General. All chemicals were purchased from Aldrich Chemical Co. unless otherwise noted. Sodium [$^{131/125}$ I]iodide in 0.1 N NaOH was supplied by DuPont-New England Nuclear (North Billerica, MA).

Melting points were determined on a Haake Buchler apparatus and were uncorrected. High-pressure liquid chromatography (HPLC) was performed using one of two systems: (1) a Beckman System Gold HPLC equipped with a Model 126 programable solvent module, a Model 168 diode array detector, a Model 170 radioisotope detector, and a Model 406 analog interface module; or (2) a Perkin-Elmer Series 4 Liquid Chromatograph connected to a Perkin-Elmer LC-95 UV/visible spectrophotometer detector and a Perkin-Elmer LCI-100 Laboratory Computing Integrator. Methods were programmed using a Perkin-Elmer 6312 display terminal. For reversed-phase chromatography, a Waters μ Bondapak C18 (10 μ m, 3.9 $\times$ 300 mm) column was used. Normal-phase HPLC was performed using a 4.6 $\times$ 250 mm (10 μ m) Partisil silica column (Alltech, Deerfield, IL). Gas chromatography was performed using a SRI 8610C gas chromatograph (SRI Instruments, Torrance, CA) equipped with an FID detector. The samples were analyzed using a RESTEK 15 m MXT-1 column and using helium as the carrier gas at 5 psi; different temperature programs were used for different samples. Analytical TLC was performed on aluminum-backed sheets (Silica gel 60 F₂₅₄), and normal-phase column chromatography was performed using Silica gel 60; both obtained from EM Science (Gibbstown, NJ). Column chromatographic fractions were collected either manually, by using a Gilson model 203 micro fraction collector (Middleton, WI) or by using an ISCO Foxy 200 fraction collector (Lincoln, NE), and the products were identified by TLC. In some cases, an ISCO UA-6 UV-Vis detector was placed between the column outlet and the fraction collector to identify fractions. Preparative thick layer chromatography was performed using 20 $\times$ 20 cm, 1000 μ m plates (Whatman, Clifton, NJ). Before applying the sample, the plates were run in ethyl acetate to remove any adsorbed impurities. One plate per approximately 50 mg of sample was used. Radio-TLC was initially analyzed using a System 200 Imaging Scanner (BioScan, Washington, D.C.) and then cut into strips and counted using an automatic gamma counter (LKB 1282, Wallac, Finland). ^1H NMR (300 MHz) and ^{13}C NMR (75 MHz) were obtained on a GE Midfield GN-300 or on a Varian Mercury 300 spectrometer. Chemical shifts are reported in δ units; solvent peaks were referenced appropriately. Mass spectra were obtained on a Hewlett-Packard GC/MS/DS Model HP-5988A instrument, or on JEOL SX-102 high-resolution mass spectrometer. IR spectra were obtained on a MB-100 IR spectrometer (BOMEM, Québec, Canada). Elemental analyses were provided by Galbraith Laboratories (Knoxville, TN) or by Microanalysis Laboratory, University of Illinois (Urbana, IL).

4-Chloro-3-iodobenzyl Alcohol (2). Sodium borohydride (76 mg, 2 mmol) was added to a homogeneous mixture of **1** (Trans World Chemicals; 566 mg, 2 mmol), (benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate (BOP; Fluka; 974 mg, 2.2 mmol), and diisopropylethylamine (349 mg, 2.6 mmol) in THF (10 mL). The mixture was stirred at room temperature for 20 min. The THF was evaporated from the mixture, and 1 N HCl (5–10 mL) was added to the residue. The resultant aqueous suspension was extracted repeatedly with EtOAc. The combined organic layers were washed with 1 N NaOH and dried with Na₂SO₄. The mixture was

adsorbed onto silica gel and chromatographed using 20% EtOAc/hexane to obtain 397 mg (74%) of an oil: ^1H NMR (CDCl₃): 1.82 (br s, 1H), 4.63 (s, 2H), 7.26 (m, 1H), 7.40 (m, 1H), 7.86 (s, 1H). GCMS m/z : 286 (M + NH₄)⁺, 268 (M⁺). Anal. Calcd for C₇H₆ClIO: C, 31.32; H, 2.32. Found: C, 31.84; H, 2.32.

4-Chloro-3-(trimethylstannyl)benzyl Alcohol (3). A mixture of **2** (135 mg, 0.5 mmol), bis(triphenylphosphine)palladium dichloride (100 mg, 0.14 mmol), and hexamethylditin (900 mg, 2.75 mmol) in dioxane (10 mL) was refluxed under argon for 1 h. Dioxane was evaporated, and a suspension of the dark residue in hexane was passed through a plug of silica gel. Very nonpolar byproducts were removed by washing with hexane, and the more polar components of the reaction mixture including **3** were eluted from the silica gel with ethyl acetate. EtOAc was removed by rotary evaporation, and the residue was purified by preparative TLC using 20% EtOAc/hexane (four plates were used) to yield 38 mg (25%) of an oil: ^1H NMR (CDCl₃): 0.37 (s, 9H), 1.66 (t, 1H), 4.66 (d, 2H), 7.26–7.37 (m, 3H). GCMS m/z : cluster peaks at 307 (MH⁺). Anal. Calcd for C₁₀H₁₅ClOSn: C, 39.33; H, 4.95. Found: C, 39.41; H, 5.16.

N¹,N²-Bis(tert-butyloxycarbonyl)-N¹-[4-chloro-3-(trimethylstannyl)benzyl]guanidine (4). Diisopropyl azodicarboxylate (DIAD; 203 mg, 1 mmol) was added dropwise to a solution of **3** (153 mg, 0.5 mmol), *N,N'*-bis(tert-butyloxycarbonyl)guanidine (259 mg, 1 mmol), and TPP (275 mg, 1.1 mmol) in THF (ca. 5 mL), and the mixture was stirred overnight at room temperature. The THF was evaporated, and the residual oil was chromatographed using 10% EtOAc/hexane to obtain 184 mg (67%) of a thick oil: ^1H NMR (CDCl₃): 0.35 (s, 9H [^{119}Sn –H, d]), 1.39 (s, 9H), 1.49 (s, 9H), 5.19 (s, 2H), 7.15–7.42 (m, 3H), 9.40 (br d, 2H). MS (FAB⁺) m/z : cluster peaks at 548 (MH⁺), 492, 436. HRMS (FAB⁺) calcd for C₂₁H₃₅ClN₃O₄¹¹⁸Sn (MH⁺): 546.1334. Found: 546.1352. Anal. Calcd for C₂₁H₃₄ClN₃O₄Sn: C, 46.14; H, 6.27; N, 7.69. Found: C, 46.76; H, 6.59; N, 7.27.

N¹,N²-Bis(tert-butyloxycarbonyl)-N¹-(4-chloro-3-iodobenzyl)guanidine (5). This was prepared from **2** following a procedure similar to that used for the preparation of **4**. The crude mixture was chromatographed using a stepwise gradient of 20% CHCl₃/hexane to 100% CHCl₃ to obtain 160 mg (63%) of a solid: mp 146–147 °C. ^1H NMR (CDCl₃): 1.40 (s, 9H), 1.50 (s, 9H), 5.15 (s, 2H), 7.25 (d, 1H), 7.40 (d, 1H), 7.80 (s, 1H), 9.35 (br d, 2H). MS (FAB⁺) m/z : 510 (MH⁺), 454, 398. HRMS (FAB⁺) calcd for C₁₈H₂₆ClIN₃O₄ (MH⁺): 510.0657. Found: 510.0643. Anal. Calcd for C₁₈H₂₅ClIN₃O₄: C, 42.41; H, 4.94; N, 8.24. Found: C, 42.72; H, 4.66; N, 8.43.

N¹-(4-Chloro-3-iodobenzyl)guanidine (6). Stannic chloride (75 mg, 0.3 mmol) was added dropwise to a solution of **5** (25 mg, 0.05 mmol) in anhydrous EtOAc (0.5 mL), and the mixture was stirred at room temperature for 3 h. EtOAc and SnCl₄ were evaporated on a rotary evaporator initially using a water-aspirator and eventually with a vacuum pump. Ether (5 mL) was added to the residue with stirring, and the mixture was left stirring overnight at 4 °C. The resultant white precipitate was filtered, washed with ether, and dried to yield 14 mg (82%) of a solid: mp 262–268 °C (decomp). ^1H NMR (CD₃OD): 4.37 (s, 2H), 7.33 (d, 1H), 7.51 (d, 1H), 7.88 (s, 1H). MS (FAB⁺) m/z : 310 (MH⁺). ^{13}C NMR (CD₃OD): 44.4, 98.7, 129.6, 130.4, 138.1, 138.8, 140.0, 158.5. HRMS (FAB⁺) calcd for C₈H₁₀ClIN₃ (MH⁺): 309.9608. Found: 309.9610 $\pm$ 0.0009 ($n = 4$).

3-Chloro-4-(trimethylsilyl)toluene (8). Chlorotrimethylsilane (7.6 mL, 60 mmol) was added via a syringe

to a stirred mixture of **7** (Trans World Chemicals; 10 g, 40 mmol) and magnesium turnings (1 g, 42 mmol) in ether (40 mL), and then the mixture was slowly heated to reflux. After the initial vigorous reaction subsided, the mixture was refluxed for an additional 1 h. Saturated NH_4Cl was added to quench the reaction, and the aqueous layer was extracted twice with ether. The pooled ethereal layer was washed with brine, dried, and distilled under water-aspirator vacuum to obtain 2.7 g (34%) of an oil. Gas chromatographic analysis indicated the presence of minor impurities, but the product was used without further purification for the next step. GCMS m/z : 199 (MH^+), 183, 91.

3,4-Bis(trimethylsilyl)toluene (9). Sodium (690 mg, 30 mmol) was taken up in a mixture of anhydrous toluene (3 mL) and xylene (4.7 mL) and melted by heating the mixture to reflux. To this finely divided suspension of sodium were added dropwise **8** (2.7 g, 13.6 mmol) and chlorotrimethylsilane (1.9 mL, 15 mmol) simultaneously to maintain a steady reflux. The reaction mixture was heated for an additional 1 h at reflux. The precipitate was filtered through a Celite bed, and the filtrate was concentrated. The residual oil was chromatographed using pentane to get 1.2 g (37%) of an oil: ^1H NMR (CDCl_3): 0.35 (s, 9H), 0.36 (s, 9H), 2.34 (s, 3H), 7.18 (d, 1H), 7.46 (s, 1H), 7.59 (d, 1H). GCMS m/z : 237 (MH^+), 221, 166, 149.

4-Nitro-3-(trimethylsilyl)toluene (10). A solution of 70% nitric acid (0.56 g) in acetic anhydride (2.4 mL) was added dropwise to a solution of **9** (418 mg, 1.8 mmol) in acetic anhydride (2.9 mL), and the mixture was heated at 100 °C for 6 h, cooled, and added to 0.4 N NaOH (50 mL). The aqueous solution was extracted with ether, and the pooled ethereal extract was washed, dried, and evaporated to get an oil. The oil was chromatographed using pentane to obtain 120 mg (32%) of a pale yellow solid: mp 46–48 °C. IR (NaCl): cm^{-1} 2926, 1522, 1345, 845. ^1H NMR (CDCl_3): 0.35 (s, 9H), 2.45 (s, 3H), 7.31 (d, 1H), 7.46 (s, 1H), 8.09 (d, 1H). GCMS m/z : 227 ($\text{M} + \text{NH}_4$) $^+$, 194. Anal. Calcd for $\text{C}_{10}\text{H}_{15}\text{NO}_2\text{Si}$: C, 57.38; H, 7.22; N, 6.69. Found: C, 57.20; H, 7.36; N, 6.57. That this compound is not the isomeric 3-nitro-4-trimethylsilyl-toluene is shown by the fact that chemical shifts of aromatic protons are closer to those predicted (Chem-Draw software) for the 4-nitro derivative than for the 3-nitro isomer.

4-Nitro-3-(trimethylsilyl)benzyl Bromide (11). A mixture of **10** (157 mg, 0.75 mmol), NBS (133 mg, 0.75 mmol), and a grain of benzoyl peroxide in CCl_4 (10 mL) was refluxed for 1 h in the presence of an incandescent light. The insolubles were filtered and washed, and the CCl_4 was evaporated from the filtrate. The residue was chromatographed with pentane to obtain 97 mg (34%) of a pale yellow oil: ^1H NMR (CDCl_3): 0.37 (s, 9H), 4.52 (s, 2H), 7.56 (d, 1H), 7.66 (s, 1H), 8.16 (d, 1H). GCMS m/z : 305 and 307 ($\text{M} + \text{NH}_4$) $^+$, 272 and 274 ($\text{M} - \text{CH}_3$) $^+$. Anal. Calcd for $\text{C}_{10}\text{H}_{14}\text{BrNO}_2\text{Si}$: C, 41.67; H, 4.90; N, 4.86. Found: C, 41.53; H, 4.87; N, 4.63.

N^1, N^2 -Bis(*tert*-butyloxycarbonyl)- N^1 -(4-nitro-3-trimethylsilylbenzyl)guanidine (12). To a heterogeneous mixture of sodium hydride (60% dispersion; 9.6 mg, 0.24 mmol) in DMF (silylation grade, Pierce; 1 mL) was added N^1, N^2 -bis(*tert*-butyloxycarbonyl)guanidine (63 mg, 0.24 mmol), and the reaction mixture was stirred at room temperature for 5 min, resulting in a homogeneous solution. A solution of **11** (72 mg, 0.25 mmol) in DMF (1 mL) was added dropwise and the progress of reaction was monitored by TLC. After 30 min, the reaction mixture was partitioned between water and EtOAc, and

the organic layer was washed with brine, dried, and concentrated. Preparative TLC of the crude product using 10% EtOAc/hexane gave 51 mg (46%) of a yellow solid: mp 104–106 °C. IR (KBr): cm^{-1} 3386, 2973, 1717, 1609, 1519, 1293, 1244, 1147, 1121, 848. ^1H NMR (CDCl_3): 0.34 (s, 9H), 1.36 (s, 9H), 1.49 (s, 9H), 5.26 (s, 2H), 7.40 (d, 1H), 7.68 (s, 1H), 8.18 (d, 1H). MS (FAB^+) m/z : 467 (MH^+), 411, 355. Anal. Calcd for $\text{C}_{21}\text{H}_{34}\text{N}_4\text{O}_6\text{Si}$: C, 54.06; H, 7.34; N, 12.01. Found: C, 54.10; H, 7.60; N, 11.71.

N^1 -(4-Nitro-3-trimethylsilylbenzyl)guanidine (13). Compound **12** (20.1 mg, 0.04 mmol) was dissolved in 10% (v/v) H_2SO_4 /dioxane (0.5 mL), and the mixture was stirred at room temperature for 2 h. The solvents were evaporated, and the residue in a small amount of water was loaded onto an activated C18 solid-phase cartridge (tC18 ENV; Waters). The cartridge was washed with water (4 $\times$ 5 mL), and the product was eluted with MeOH (~5 mL) in almost quantitative yield. ^1H NMR (CD_3OD): 4.19 (s, 2H), 7.55 (d, 1H), 7.70 (s, 1H), 8.20 (d, 1H). MS (FAB^+) m/z : 267 (MH^+). HRMS (FAB^+) calcd for $\text{C}_{11}\text{H}_{19}\text{N}_4\text{O}_2\text{Si}$ (MH^+): 267.1277. Found: 267.1280 $\pm$ 0.0003 ($n = 3$).

3-Iodo-4-nitrotoluene (15). A solution of sodium nitrite (110 mg, 1.6 mmol) in water (0.5 mL) was added with stirring to a cold slurry of 5-methyl-2-nitroaniline (221 mg, 1.47 mmol) in concentrated HCl (0.7 mL) and ice (1 g). The mixture was stirred for 20 min at 0 °C, the resultant cold solution was added dropwise to a stirred solution of KI (2.44 g, 14.6 mmol) in water (3 mL) at room temperature, and the resultant mixture was stirred overnight. The reaction mixture was extracted with EtOAc, and the organic layer was washed with 1 N NaOH, 1 N HCl, and brine, dried, and concentrated. Column chromatography with 1% EtOAc/hexane gave 380 mg (98%) of an oil. An analytical sample was obtained by further purification by preparative TLC using the same solvent: ^1H NMR (CDCl_3): 2.39 (s, 3H), 7.27 (d, 1H), 7.82 (d, 1H), 7.89 (s, 1H). GCMS m/z : 281 ($\text{M} + \text{NH}_4$) $^+$, 264 (MH^+), 155. Anal. Calcd for $\text{C}_7\text{H}_6\text{INO}_2$: C, 31.96; H, 2.30; N, 5.33. Found: C, 32.14; H, 2.39; N, 5.30.

3-Iodo-4-nitrobenzyl Bromide (16). The title compound was prepared from **15** (269 mg, 1.02 mmol) by a procedure similar to that used for the preparation of **11**. Chromatography using 5% EtOAc/hexane provided 45 mg (30%) of a solid: mp 61–63 °C. ^1H NMR (CDCl_3): 4.41 (s, 2H), 7.52 (d, 1H), 7.85 (d, 1H), 8.05 (s, 1H). Anal. Calcd for $\text{C}_7\text{H}_5\text{BrINO}_2$: C, 24.59; H, 1.47; N, 4.10. Found: C, 24.76; H, 1.52; N, 4.07.

N^1, N^2 -Bis(*tert*-butyloxycarbonyl)- N^1 -(3-iodo-4-nitrobenzyl)guanidine (17). The guanidination of **16** (87 mg, 0.25 mmol) was performed by a procedure similar to that used for the preparation of **12** from **11**. Chromatography using a gradient of 5–10% EtOAc/hexane yielded 74 mg (90% based on the starting material consumed) of a yellow solid: mp 142–144 °C. ^1H NMR (CDCl_3): 1.41 (s, 9H), 1.49 (s, 9H), 5.16 (s, 2H), 7.43 (d, 1H), 7.85 (d, 1H), 8.01 (s, 1H), 9.40 (br d, 2H). MS (FAB^+) m/z : 521 (MH^+). HRMS (FAB^+) calcd for $\text{C}_{18}\text{H}_{26}\text{IN}_4\text{O}_6$ (MH^+): 521.0897. Found: 521.0899. Anal. Calcd for $\text{C}_{18}\text{H}_{25}\text{IN}_4\text{O}_6$: C, 41.55; H, 4.84; N, 10.77. Found: C, 42.25; H, 5.03; N, 10.90.

N^1 -(3-Iodo-4-nitrobenzyl)guanidine (18). This was prepared quantitatively from **17** (52 mg, 0.1 mmol) in a similar fashion as **6** from **5**: mp 258–259 °C (decomp). IR (KBr): cm^{-1} 3443, 3355, 1660, 1518, 1352. ^1H NMR (CD_3OD): 4.49 (s, 2H), 7.5 (d, 1H), 7.85 (d, 1H), 8.10 (s, 1H). ^{13}C NMR (CD_3OD): 44.4, 87.3, 126.2, 128.8, 141.0,

143.8, 154.1, 158.5. MS (FAB⁺) *m/z*: 320 (M⁺). HRMS (FAB⁺) calcd for C₈H₁₀IN₄O₂ (MH⁺): 320.9848. Found: 320.9847.

3-Iodo-5-nitrobenzoic Acid (20). A heterogeneous mixture of 3-amino-5-nitrobenzoic acid (3.64 g, 20 mmol) in 10 mL of concentrated HCl was stirred at 0 °C as a solution of NaNO₂ (1.66 g, 24 mmol) in 10 mL of ice-water was added. The resultant homogeneous orange solution was stirred at ca. 0 °C for 1 h, then added slowly with stirring to a solution of KI (8.3 g, 50 mmol) in 30 mL of water at 0 °C. The reaction mixture was slowly warmed to room temperature over 2 h. The aqueous solution was extracted with EtOAc, and the organic layer was washed with water, aqueous saturated sodium metabisulfite, and brine, dried, and concentrated to give 5.3 g of a dirty brown solid. Chromatography with 20% MeOH/EtOAc afforded 5.2 g (89%) of a brown solid: IR (KBr): cm⁻¹ 3481, 3389, 1704, 1632, 1584, 1532, 1480, 1355. ¹H NMR (CD₃OD): 8.59 (t, 1H), 8.67 (dd, 1H), 8.74 (dd, 1H). ¹³C NMR (CD₃OD): 94.1, 124.4, 135.6, 136.5, 144.91, 149.7, 166.1. HRMS (FAB⁻) calcd for C₇H₃INO₄ (M - H)⁻: 291.9107. Found: 291.9115.

3-Iodo-5-nitrobenzyl Alcohol (21). A solution of **20** (1.5 g, 5.1 mmol) in 10 mL of anhydrous THF was stirred and refluxed for 3.5 h with 2 M BH₃-THF (13 mL, 25.6 mmol) and B(OMe)₃ (5.7 mL, 51.2 mmol) under a flow of argon. Excess borane was removed by addition of MeOH, and the solvents were evaporated. The resultant precipitate was reconstituted in EtOAc, washed with water and brine, dried, and concentrated by rotary evaporation to give 1.5 g of the crude product mixture. Chromatographic separation using a stepwise gradient of 50% to 75% EtOAc/hexane provided 720 mg (51%) of a pale yellow solid: IR (CCl₄): cm⁻¹ 2977, 2866, 1742, 1537, 1348, 1239, 1119. ¹H NMR (CDCl₃): 4.79 (d, 2H), 8.04 (td, 1H), 8.19 (ddd, 1H), 8.46 (dd, 1H). ¹³C NMR (CDCl₃): 63.1, 94.2, 120.7, 131.1, 141.1, 144.4. MS (FAB⁻) *m/z*: 278.93 (M⁻). HRMS (FAB⁻) calcd for C₇H₄INO₃ (M - H)⁻: 277.9314. Found: 277.9324. Anal. Calcd for C₇H₆INO₃: C, 30.13; H, 2.17; N, 5.02. Found: C, 30.03; H, 2.26; N, 4.92.

3-Nitro-5-tri-*n*-butylstannylbenzyl Alcohol (22). Compound **21** (100 mg, 0.36 mmol) in 2 mL of anhydrous toluene was refluxed with (Ph₃P)₂PdCl₂ (60 mg, 0.09 mmol) as hexabutyliditin (414 mg, 0.72 mmol) was added by syringe, and the ensuing black heterogeneous mixture was stirred and refluxed under a flow of argon for 5 h. The reaction mixture was cooled to room temperature, filtered over Celite to remove suspended particles, and washed with EtOAc. The filtrate was concentrated to provide 464 mg of a brown oil, which was purified by column chromatography using a hexanes-EtOAc gradient to give 115 mg (73%) of a brown oil: IR (NaCl): cm⁻¹ 3397, 2915, 2856, 1523, 1463, 1343. ¹H NMR (CDCl₃): 0.89 (t, 3H), 1.13 (m, 2H), 1.36 (m, 2H), 1.57 (m, 2H), 4.81 (d, 2H), 7.74 (ddd, 1H), 8.14 (td, 1H), 8.20 (dd, 1H). ¹³C NMR (CDCl₃): 10.0, 13.7, 27.4, 28.9, 29.1, 30.6, 63.6, 121.0, 129.1, 140.3, 144.9, 147.6. Anal. Calcd for C₁₉H₃₃NO₃Sn: C, 51.61; H, 7.52; N, 3.17. Found: C, 51.48; H, 7.31; N, 3.21.

N¹,N²-Bis(*tert*-butyloxycarbonyl)-N¹-(3-nitro-5-tri-*n*-butylstannylbenzyl)guanidine (23). The benzyl alcohol **22** (111 mg, 0.25 mmol) in 2 mL of anhydrous THF was stirred at room temperature under argon with *N*,*N'*-bis(*tert*-butyloxycarbonyl)guanidine (131 mg, 0.5 mmol) and TPP (331 mg, 1.25 mmol) as DIAD (247 mL, 1.25 mmol) was added, and the resulting yellow heterogeneous mixture was stirred for 3 h under a flow of argon. The solvent was evaporated, and the resulting solids were reconstituted in 15 mL of EtOAc, washed with 2 × 15 mL

of water and 20 mL of brine, dried, and concentrated. Chromatographic purification of the crude product yielded 44 mg of a mixture, composed of the protected guanidine and diisopropylhydrazine dicarboxylate, which was further purified by preparative TLC using 5% EtOAc/hexane to give 18 mg (11%) of a colorless solid: IR (NaCl): cm⁻¹ 3386, 2963, 2924, 1721, 1613, 1528, 1363, 1147. ¹H NMR (CDCl₃): 0.78 (t, 3H), 1.02 (m, 2H), 1.21 (m, 2H), 1.33 (m, 2H), 1.30 (s, 9H), 1.40 (s, 9H), 5.13 (s, 2H), 7.66 (d, 1H), 8.00 (dd, 1H dd), 8.07 (d, 1H), 9.3 (br d, 2H). ¹³C NMR (CDCl₃): 10.0, 13.7, 27.3, 28.0, 28.3, 29.0, 122.2, 129.1, 141.5. MS (FAB⁻) *m/z*: cluster peaks at 683.2 (M⁻). HRMS (FAB⁻) calcd for C₃₀H₅₁N₄O₆Sn (M - H)⁻: 681.2831. Found: 681.2806. Anal. Calcd for C₂₁H₃₆N₄O₄Sn: C, 52.72; H, 7.67; N, 8.20. Found: C, 53.61; H, 7.63; N, 7.86.

N¹,N²-Bis(*tert*-butyloxycarbonyl)-N¹-(3-iodo-5-nitrobenzyl)guanidine (24). A solution of **21** (139 mg, 0.5 mmol) in 5 mL of anhydrous THF was stirred at room temperature under argon with *N*¹,*N*²-bis-*tert*-butyloxycarbonyl-S-methylisothiurea (259 mg, 1 mmol) and TPP (656 mg, 2.5 mmol) as DIAD (492 mL, 2.5 mmol) was added, and the resulting yellow heterogeneous mixture was stirred for 5 h under a flow of argon. The solvent was evaporated, and the resulting solids were dissolved in EtOAc, washed with water and brine, dried, and concentrated to give 439 mg of crude products. Purification by column chromatography provided 156 mg (60%) of a pale yellow solid: ¹H NMR (CDCl₃): 1.45 (s, 9H), 1.53 (s, 9H), 2.38 (s, 3H), 4.78 (s, 2H), 8.0 (t, 1H), 8.20 (dd, 1H), 8.47 (dd, 1H). HRMS (FAB⁺) calcd for C₈H₉IN₄O₂ (MH⁺): 320.9848. Found: 320.9848 ± 0.0013 (*n* = 2).

The above product (130 mg, 0.24 mmol) in 1.5 mL of MeOH was refluxed in liquid NH₃ (ca. 2 mL) for 2.5 h. Rotary evaporation of the reaction mixture gave 125 mg (100%) of a pale yellow oil: ¹H NMR (CDCl₃): 1.47 (s, 9H), 1.51 (s, 9H), 5.14 (s, 2H), 8.16 (s, 1H), 8.27 (s, 1H), 8.44 (s, 1H), 9.3 (br d, 2H). MS (FAB⁻) *m/z*: 519.0 (M⁻). HRMS (FAB⁻) calcd for C₁₈H₂₄IN₄O₆ (M - H)⁻: 519.0741. Found: 519.0735.

N¹-(3-Iodo-5-nitrobenzyl)guanidine (25). A solution of **24** (125 mg, 0.24 mmol) in 4 mL of CH₂Cl₂ and 1 mL of TFA was stirred and heated at 65 °C in a sealed flask for 4 h. Evaporation of the solvents afforded 67 mg (64%) of the deprotected benzyl guanidine as an oil: IR (NaCl): cm⁻¹ 3347, 2503, 1673, 1616, 1533, 1352, 1203, 1141. ¹H NMR (CD₃OD): 4.89 (s, 2H), 8.08 (td, 1H), 8.18 (dd, 1H), 8.49 (dd, 1H). ¹³C NMR (CD₃OD): 44.3, 94.6, 122.2, 132.4, 142.0, 142.9, 149.9, 158.2.

3-Bromo-5-methoxy-4-methoxymethoxybenzaldehyde (27). To a solution of 5-bromovanillin (1.16 g, 5 mmol) in anhydrous THF (20 mL) was added dropwise a 1M solution of potassium *tert*-butoxide (5 mL) followed by MOM-chloride (0.5 mL, 6.6 mmol). The reaction mixture was stirred for about 4 h at room temperature and the solvents were evaporated. The residual material was partitioned between water and EtOAc, and the combined organic layer was washed with brine, dried, and concentrated. Chromatography using 30% EtOAc/hexane yielded 1.1 g of an oil: ¹H NMR (CDCl₃): 3.54 (s, 3H), 3.81 (s, 3H), 5.18 (s, 2H), 7.27 (d, 1H), 7.55 (d, 1H), 9.73 (s, 1H). GCMS *m/z*: 303 and 305 (M + C₂H₅)⁺, 292 and 294 (M + NH₄)⁺, 275 and 277 (M⁺). Anal. Calcd for C₁₀H₁₁BrO₄: C, 43.66; H, 4.03. Found: C, 43.95; H, 4.24.

3-Bromo-5-methoxy-4-methoxymethoxybenzyl Alcohol (28). To a stirred solution of **27** (1.05 g, 3.9 mmol) in anhydrous CH₂Cl₂ (15 mL) was added dropwise a 1 M solution of DIBAL in CH₂Cl₂ (5.4 mL), and the mixture was stirred for 1–2 h. Methanol (10 mL) and water (10

mL) were added to the cooled reaction mixture, and the resultant gelatinous material was filtered through a bed of Celite and washed alternately with a total volume of 200 mL of CH_2Cl_2 and 50 mL of water. The layers of the filtrate were separated, and the CH_2Cl_2 layer was dried and concentrated to obtain 1.06 g (100%) of an oil: ^1H NMR (CDCl_3): 2.21 (br s, 1H), 3.64 (s, 3H), 3.82 (s, 3H), 4.57 (s, 2H), 5.13 (s, 2H), 6.85 (d, 1H), 7.10 (d, 1H). GCMS m/z : 294 and 296 ($\text{M} + \text{NH}_4^+$), 278 and 280 (MH^+), 259 and 261, 215 and 217. Anal. Calcd for $\text{C}_{10}\text{H}_{13}\text{BrO}_4$: C, 43.34; H, 4.73. Found: C, 43.50; H, 5.06.

N^1, N^2 -Bis(*tert*-butyloxycarbonyl)- N^1 -(3-bromo-5-methoxy-4-methoxymethoxybenzyl)guanidine (29). The title compound was prepared from **28** (522 mg, 1.9 mmol) by a protocol similar to that used for the preparation of **4**, **5**, and **23**. Chromatography using a 10–30% EtOAc/hexane gradient afforded 506 mg (51%) of a solid: mp 131–133 °C. ^1H NMR (CDCl_3): 1.45 (s, 9H), 1.49 (s, 9H), 3.64 (s, 3H), 3.82 (s, 3H), 5.03 (s, 2H), 5.15 (s, 2H), 7.12 (m, 2H), 9.34 (br d, 2H). MS (FAB^+) m/z : 518 and 520 (MH^+), 462 and 464, 406 and 408. Anal. Calcd for $\text{C}_{21}\text{H}_{32}\text{BrN}_3\text{O}_7$: C, 48.65; H, 6.22; N, 8.11. Found: C, 48.31; H, 6.35; N, 7.94.

3-Iodo-5-methoxy-4-methoxymethoxybenzyl Alcohol (30). To a stirred solution of **28** (278 mg, 1 mmol) in THF (5 mL) under argon at -78°C was added dropwise *n*-BuLi (1.6 M in hexanes; 1.45 mL, 2.32 mmol) over a period of 5 min, and the reaction mixture was stirred at -78°C for an additional 15 min. To the resultant mixture at -78°C was then added gradually 2-iodo-1,1,1-trifluoroethane (550 μL , 5.6 mmol) over a period of 5 min. The reaction mixture was allowed to warm gradually to room temperature and left stirring overnight. Solvents were evaporated from the reaction mixture, and the residual material was partitioned between EtOAc and water. Workup and silica gel chromatography using 40% EtOAc/hexane gave 88 mg (27%) of an oil: ^1H NMR (CDCl_3): 1.79 (br s, 1H), 3.67 (s, 3H), 3.84 (s, 3H), 4.60 (s, 2H), 5.15 (s, 2H), 6.92 (d, 1H), 7.36 (d, 1H). GCMS m/z : 342 ($\text{M} + \text{NH}_4^+$), 324 (M^+), 307, 263.

The R_f values on an analytical TLC plate (50% EtOAc/hexane) were the same (~ 0.4) for both **28** and **30**. However, their retention times on a reversed-phase HPLC column were marginally different. The t_R for **28** was 22.1 min versus 23.0 min for **30** when eluted on a μ Bondapak C18 column with a 0.1% TFA in water (A) 0.1% TFA in acetonitrile (B) gradient (5% B for 10 min and then to 80% B in 20 min) at a flow rate of 1 mL/min.

N^1, N^2 -Bis(*tert*-butyloxycarbonyl)- N^1 -(3-iodo-5-methoxy-4-methoxymethoxybenzyl)guanidine (31). Compound **31** was prepared from **30** (88 mg, 0.28 mmol) by a protocol similar to that for **29**. Chromatography with 10% EtOAc/hexane gave 113 mg (74%) of a waxy solid: mp 107–109 °C. ^1H NMR (CDCl_3): 1.47 (s, 9H), 1.49 (s, 9H), 3.66 (s, 3H), 3.81 (s, 3H), 5.01 (s, 2H), 5.14 (s, 2H), 7.18 (d, 1H), 7.38 (d, 1H), 9.32 (br d, 2H). HRMS (FAB^+) calcd for $\text{C}_{21}\text{H}_{33}\text{IN}_3\text{O}_7$ (MH^+): 566.1363. Found: 566.1372 ± 0.0013 ($n = 2$). Anal. Calcd for $\text{C}_{21}\text{H}_{32}\text{IN}_3\text{O}_7$: C, 44.61; H, 5.70; N, 7.43. Found: C, 44.87; H, 5.88; N, 7.45.

N^1 -(3,4-Dihydroxy-5-iodobenzyl)guanidine (32). A solution of BBr_3 (1 M in CH_2Cl_2 ; 0.5 mL, 0.5 mmol) was added to **31** (33.8 mg, 0.06 mmol), and the mixture stirred at room temperature for 30 min. The CH_2Cl_2 was evaporated under a stream of argon, and residual BBr_3 was removed by coevaporation with 2×1 mL of EtOAc. The residual mixture was taken in 1–2 mL of water and passed through two activated C18 solid-phase cartridges (tC18 ENV; Waters) connected in series. The cartridge was washed with water, and the product was eluted with

1 mL portions of EtOH. The second EtOH fraction, containing a majority of the product (HPLC), was concentrated to yield 6 mg (33%) of an oil. An analytical sample was obtained by semipreparative reversed-phase HPLC: ^1H NMR (CD_3OD): 4.20 (s, 2H), 6.73 (s, 1H), 7.11 (s, 1H). MS (FAB^+) m/z : 330 ($\text{M} + \text{Na}^+$), 308 (MH^+). ^{13}C NMR (CD_3OD): 45.1, 84.5, 115.4, 129.3 (C1 and C6), 146.8, 147.0, 158.6. HRMS (FAB^+) calcd for $\text{C}_8\text{H}_{11}\text{IN}_3\text{O}_2$ (MH^+): 307.9896. Found: 307.9897 ± 0.0002 ($n = 3$). The structure was further confirmed by heteronuclear multi bond connectivity (HMBC, Bax and Summers, 1986) and heteronuclear multiple quantum coherence (HMQC, Summers et al., 1986) NMR correlation experiments.

N^1 -(4-Hydroxy-3-iodo-5-methoxybenzyl)guanidine (33). Stannic chloride (10 mg, 0.04 mmol) was added to a solution of **31** (24 mg, 0.04 mmol) in EtOAc (0.1 mL), and the reaction mixture was stirred at room temperature for 3 h. The EtOAc was evaporated, and ether (0.5 mL) was added with stirring resulting in a precipitate. The precipitate was washed with 2×0.5 mL of ether, the ether was decanted, and the precipitate was dried under vacuum for several hours to yield **33** as a crystalline solid in quantitative yield: mp, decomposes. ^1H NMR (CD_3OD): 3.83 (s, 3H), 4.27 (s, 2H), 6.90 (s, 1H), 7.23 (s, 1H). MS (FAB^+) m/z : 322 (MH^+). ^{13}C NMR (CD_3OD): 45.2, 56.7, 83.6, 111.9, 130.2 (C1 and C6), 130.5, 147.9, 148.6, 158.5. HRMS (FAB^+) calcd for $\text{C}_9\text{H}_{13}\text{IN}_3\text{O}_2$ (MH^+): 322.0052. Found: 322.0050 ± 0.0008 ($n = 2$). The structure was further confirmed by HMBC/HMQC NMR experiments. The title compound can be also prepared by treatment of **31** with TFA at room temperature.

3-Methoxy-4-methoxymethoxy-5-(trimethylstannyl)benzyl Alcohol (34). A solution of *n*-BuLi (1.6 M in hexanes; 750 μL , 1.2 mmol) was added to a solution of **28** (142 mg, 0.52 mmol) in THF (2.5 mL), and the mixture was stirred at -78°C for 15 min. A solution of trimethyltin chloride (1 M in hexanes; 1.2 mL, 1.2 mmol) was added, and the mixture was brought to room temperature gradually and stirred overnight. Evaporation of solvents, aqueous workup, and column chromatography with 40% EtOAc/hexane gave 51 mg (27%) of an oil: ^1H NMR (CDCl_3): 0.32 (s, 9H [$^{119}\text{Sn}-\text{H}$, d]), 3.54 (s, 3H), 3.85 (s, 3H), 4.65 (s, 2H), 5.10 (s, 2H), 6.94 (m, 2H). MS (FAB^+) m/z : cluster peaks at 362 (M^+) and 345. Anal. Calcd for $\text{C}_{13}\text{H}_{22}\text{O}_4\text{Sn}$: C, 43.25; H, 6.14. Found: C, 43.98; H, 6.56.

N^1, N^2 -Bis(*tert*-butyloxycarbonyl)- N^1 -(3-methoxy-4-methoxymethoxy-5-trimethylstannylbenzyl)guanidine (35). The title compound was prepared from **34** (51 mg, 0.14 mmol) by a procedure similar to that used for **31**. Chromatography using 10% EtOAc/hexane yielded 81 mg (95%) of an oil: ^1H NMR (CDCl_3): 0.30 (s, 9H [$^{119}\text{Sn}-\text{H}$, d]), 1.45 (s, 9H), 1.49 (s, 9H), 3.53 (s, 3H), 3.82 (s, 3H), 5.08 (s, $2 \times 2\text{H}$), 6.95 (d, 1H), 7.22 (d, 1H), 9.40 (br d, 2H). MS (FAB^+) m/z : cluster peaks at 604 (MH^+); HRMS (FAB^+) calcd for $\text{C}_{24}\text{H}_{42}\text{N}_3\text{O}_7^{120}\text{Sn}$ (MH^+): 604.2045; Found: 604.2052 ± 0.0006 ($n = 2$). Anal. Calcd for $\text{C}_{24}\text{H}_{41}\text{N}_3\text{O}_7\text{Sn}$: C, 47.86; H, 6.86; N, 6.98. Found: C, 48.25; H, 7.03; N, 7.00.

N^1 -Hydroxy- N^3 -(3-iodobenzyl)guanidine (38). A solution of CNBr (220 mg, 2.1 mmol) in methanol (0.7 mL) was added dropwise with stirring to a cooled mixture of 3-iodobenzylamine (obtained by the basification of its commercially available hydrochloride salt) (414 mg, 1.8 mmol) and NaOAc (323 mg, 3.9 mmol) in methanol (3.5 mL). The reaction mixture was stirred at 5°C for 2–3 h and at ambient temperature overnight. The mixture was filtered through a frit funnel, and the filtrate was adsorbed onto silica gel and chromatographed using 30–50% EtOAc/hexane to obtain 146 mg (32%) of a white

crystalline solid: mp 49–50 °C; ^1H NMR (CDCl_3): 3.68 (br s, 1H), 4.21 (d, 2H), 7.13 (t, 1H), 7.32 (d, 1H), 7.69 (m, 2H). GCMS m/z : 276 ($\text{M} + \text{NH}_4^+$), 259 (MH^+), 234, 217.

Since **37** was not very stable, it was carried over to the next step immediately. To a solution of $\text{NH}_2\text{OH}\cdot\text{HCl}$ (70 mg, 1 mmol) and **37** (146 mg, 0.57 mmol) in 1 mL of DMF was added Na_2CO_3 (200 mg, 1.9 mmol) in small portions. The mixture was stirred at room temperature for 2 h and partitioned between EtOAc and water. The organic phase was washed with brine, dried, and concentrated to obtain a chromatographically homogeneous oil in quantitative yield: ^1H NMR (CD_3OD): 4.15 (s, 2H), 7.07 (t, 1H), 7.29 (d, 1H), 7.58 (d, 1H), 7.70 (s, 1H). MS (FAB^+) m/z : 292 (MH^+), 276. HRMS (FAB^+) calcd for $\text{C}_8\text{H}_{11}\text{IN}_3\text{O}$ (MH^+): 291.9947; Found: 291.9940 $\pm$ 0.0000 ($n = 2$).

3-(Trimethylsilyl)benzylamine (40). To a solution of 3-bromobenzylamine (obtained from its hydrochloride salt; 393 mg, 2.1 mmol) in THF (12 mL) at -78°C was added dropwise $n\text{-BuLi}$ (1.6 M in hexanes; 3.9 mL, 6.3 mmol) over a period of 5 min. The resultant pink solution was stirred for 45 min at -78°C , and Me_3SiCl (795 μL , 6.3 mmol) was added dropwise. The mixture was gradually warmed to room temperature and stirred overnight, worked up, and chromatographed using 80/20/1 $\text{CHCl}_3/\text{MeOH}/\text{HOAc}$ yielding 144 mg (38%) of a waxy solid: mp 191–193 °C. ^1H NMR (CDCl_3): 0.28 (s, 9H), 1.47 (s, 2H), 3.88 (s, 2H), 7.29–7.46 (m, 4H). GCMS m/z : 180 (MH^+).

N^1 -Hydroxy- N^1 -(3-trimethylsilylbenzyl)guanidine (42). Compound **41** was prepared from **40** (370 mg, 2.1 mmol) by a procedure similar to that for **37**. Chromatography using a 25–100% EtOAc/hexane gradient afforded 196 mg (46%) of an oil: ^1H NMR (CDCl_3): 0.26 (s, 9H), 3.76 (br s, 1H), 4.25 (d, 2H), 7.32–7.52 (m, 4H). GCMS m/z : 222 ($\text{M} + \text{NH}_4^+$), 205 (MH^+), 163.

Compound **42** was prepared from **41** (176 mg, 0.86 mmol) in 94% yield by the same protocol used for **38**: mp 128–130 °C. ^1H NMR (CD_3OD): 0.26 (s, 9H), 4.19 (s, 2H), 7.42–7.64 (m, 4H). MS (FAB^+) m/z : 238 (MH^+). Anal. Calcd for $\text{C}_{11}\text{H}_{19}\text{N}_3\text{OSi}$: C, 55.66; H, 8.07; N, 17.70. Found: C, 55.82; H, 8.24; N, 17.66.

3-Amino-5-iodobenzyl Alcohol (43). A mixture of **21** (280 mg, 1 mmol), indium (836 mg, 7.3 mmol), saturated NH_4Cl (1.2 mL), and EtOH (4 mL) was refluxed for 1 h. The reaction mixture was worked up as per the literature protocol (Moody and Pitts, 1998), and the resultant oil was purified by silica gel chromatography using 1:1 EtOAc:hexanes to yield 83 mg (33%) of an off-white solid: mp 65–67 °C. IR (KBr): cm^{-1} 3417, 3296, 3193, 1598, 1568, 1262, 1099, 1026, 800. ^1H NMR (CDCl_3): 1.62 (br s, 1H), 3.69 (br s, 2H), 4.55 (s, 2H), 6.62 (dd, 1H), 6.96 (dd, 1H), 7.08 (d, 1H). GCMS (CI): m/z : 250 (MH^+), 232, 123. HRMS (EI^+) calcd for $\text{C}_7\text{H}_8\text{INO}$ (M^+): 248.9651; Found: 248.9653 $\pm$ 0.0011 ($n = 4$).

N^1 , N^2 -Bis(*tert*-butyloxycarbonyl)- N^1 -(3-amino-5-iodobenzyl)guanidine (44). The title compound was prepared from **43** (198 mg, 0.8 mmol) by a Mitsunobu protocol as described earlier. Chromatography using 30% EtOAc/hexane gave a solid in quantitative yield: mp 179–180 °C (dec). ^1H NMR (CDCl_3): 1.37 (s, 9H), 1.49 (s, 9H), 3.64 (br s, 2H), 5.02 (s, 2H), 6.51 (m, 1H), 6.91 (m, 1H), 6.96 (m, 1H), 9.40 (br d, 2H). MS (FAB^+) m/z : 491 (MH^+). HRMS (FAB^+) calcd for $\text{C}_{18}\text{H}_{28}\text{IN}_4\text{O}_4$ (MH^+): 491.1155; Found: 491.1149 $\pm$ 0.0014 ($n = 4$). Anal. Calcd for $\text{C}_{18}\text{H}_{27}\text{IN}_4\text{O}_4$: C, 44.09; H, 5.55; N, 11.43. Found: C, 45.55; H, 6.16; N, 12.04.

3-Amino-5-iodobenzylguanidine (45). Compound **44** (25 mg, 0.05 mmol) was treated with TFA (100 μL) at

room temperature for 15 min. TFA was evaporated and the residue was triturated thrice with EtOAc and dried under high vacuum to yield **45** as an oil in quantitative yield: ^1H NMR (CD_3OD) 4.34 (s, 2H), 6.84 (s, 1H), 7.22 (m, 2H). MS (FAB^+) m/z : 291 (MH^+). HRMS (FAB^+) calcd for $\text{C}_8\text{H}_{12}\text{IN}_4$ (MH^+): 291.0107; Found: 291.0111 $\pm$ 0.0005 ($n = 4$).

N^1 , N^2 -Bis(*tert*-butyloxycarbonyl)- N^1 -[3-amino-5-(trimethylstannyl)benzyl]guanidine (46). A mixture of **44** (20 mg, 0.04 mmol), $(\text{Ph}_3\text{P})_2\text{PdCl}_2$ (25 mg, 0.04 mmol), and $(\text{Me}_3\text{Sn})_2$ (130 mg, 0.4 mmol) in anhydrous dioxane (0.5 mL) was refluxed for 1 h. The reaction mixture was worked up as described for **3**, and the crude product was purified by preparative TLC using 20% EtOAc in hexanes (the TLC plate was dried after the first run and subjected to a second development to ensure separation between starting material and product) to obtain 19 mg (83%) of a pale amber-colored oil: ^1H NMR (CDCl_3): 0.24 (s, 9H [$^{119}\text{Sn}-\text{H}$, d]), 1.35 (s, 9H), 1.49 (s, 9H), 3.60 (br s, 2H), 5.07 (s, 2H), 6.53 (m, 1H), 6.68 (dd, 1H), 6.76 (d, 1H), 9.40 (br d, 2H). MS (FAB^+) m/z : cluster peaks around 529 (MH^+). HRMS (FAB^+) calcd for $\text{C}_{21}\text{H}_{36}\text{N}_4\text{O}_4^{120}\text{Sn}$ (M^+): 528.1763; Found: 528.1772 $\pm$ 0.0009 ($n = 4$). Anal. Calcd for $\text{C}_{21}\text{H}_{36}\text{N}_4\text{O}_4\text{Sn}$: C, 47.84; H, 6.88; N, 10.09. Found: C, 47.70; H, 6.68; N, 10.09.

N^1 -(4-Chloro-3-[^{131}I]iodobenzyl)guanidine (6a). To **4** (0.25 mg) in a $1/2$ -dram vial was added ^{131}I (~ 1 mCi in 1–2 μL of 0.1 N NaOH) followed by a solution of NCS in HOAc (0.4 mg in 20 μL). The vial was capped and heated in an oil bath at 70 °C for 30 min. Trifluoroacetic acid (20 μL) was then added to the mixture, and the vial was heated for an additional 5 min. The solvents were evaporated, and the residual activity reconstituted in methanol (25 μL) and injected onto a reversed-phase HPLC column eluted with 20/80 $\text{CH}_3\text{CN}/\text{water}$ containing 0.1% TFA at a flow rate of 1 mL/min. The product activity ($t_R = 15$ –16 min) was isolated in about 70% radiochemical yield.

N^1 -(3-[^{131}I]iodo 4-nitrobenzyl)guanidine (18a). (A) *Attempted Radioiododesilylation of 12.* To ^{131}I in 0.1 N NaOH (1 μL , 100–200 μCi) in a $1/2$ -dram vial was added a solution of NCS in TFA (0.4 mg in 10 μL) followed by **12** (0.2 mg) in TFA (10 μL). The vial was vortexed and maintained at room temperature or heated at 70 °C for 5–30 min. The contents were injected onto a reversed-phase HPLC column eluted with 15/85 THF/0.2 M $\text{NH}_4\text{H}_2\text{PO}_4$ at a flow rate of 1 mL/min. Although other unidentified radioactive peaks were observed, no activity peak corresponding to **17a** ($t_R = 26$ –27 min) was noticed.

(B) *Radioiododesilylation of 13.* To 0.2 mg of **13** in a $1/2$ -dram vial was added about 1 μL of ^{131}I in 0.1 N NaOH (50–100 μCi) followed by NCS in TFA (0.4 mg in 10 μL). The reaction mixture was left at room temperature for 30 min, and injected onto a reversed-phase HPLC column eluted with 25/75 $\text{CH}_3\text{CN}/\text{water}$ containing 0.1% TFA at a flow rate of 1 mL/min. About 18% of the injected activity eluted with a retention time (7 min) corresponding to that of **18a**. Conducting the reaction at 70 °C reduced the radiochemical yield of the product, presumably due to deiodination.

(C) *Exchange Radioiodination of 18.* In accordance with a reported procedure (Mock and Weiner, 1988), a Reacti vial fitted with a vent tube and containing 1–5 μL of ^{131}I in 0.1 N NaOH (~ 1 mCi), $(\text{NH}_4)_2\text{SO}_4$ in water (10 mg in 1 mL), and **17** (0.2 mg) was heated at 150 °C for 30 min. To ensure that radioiodination had occurred, an aliquot of the reaction mixture was injected onto a reversed-phase column eluted with 15/85 $\text{CH}_3\text{CN}/\text{water}$ containing 0.1% TFA at a flow rate of 1 mL/min. HPLC analysis

indicated that ca. 88% of the injected activity was associated with a peak coeluting with **18** ($t_R = 16$ – 17 min). The product activity from the bulk of the reaction mixture was isolated in about 75% yield using a C18 solid-phase cartridge (see below).

N^1 -(3-[^{131} I]Iodo-5-nitrobenzyl)guanidine (25a**).** A solution of **23** (0.2 mg) in 10 μ L of AcOH was added to a $1/2$ -dram vial containing ^{131} I in NaOH (~ 0.5 mCi in 1–2 μ L) and 0.4 mg NCS in 10 μ L of AcOH, capped and vortexed, and heated at 75 $^\circ$ C for 15 min. TFA (10 μ L) was added and vortexed, and the vial was heated again at 75 $^\circ$ C for 5 min. The contents of the vial were then injected onto a reversed-phase HPLC column eluted with a 85:15 water/ CH_3CN solvent system containing 0.1% TFA at a flow rate of 1 mL/min. The principal radioactive peak ($t_R = 16$ – 17 min) corresponding to **25** was isolated in 45–50% radiochemical yield. HPLC analyses indicated that extended heating of the reaction mixture resulted in deiodination of the product.

N^1, N^2 -Bis(*tert*-butoxycarbonyl)- N^1 -(3-[^{131} I]iodo-5-methoxy-4-methoxymethoxybenzyl)guanidine (31a**).** To 0.2–0.3 mg of **35** in a $1/2$ -dram vial was added 1 μ L of ^{131} I in 0.1 N NaOH (0.5–1.0 mCi) followed by a 3:1 (v/v) solution of HOAc:30% H_2O_2 . The mixture was sonicated for 30 s and injected onto a silica HPLC column eluted with 5/95 EtOAc/hexanes containing 0.2% HOAc at a flow rate of 1 mL/min. The activity corresponding to **31a** ($t_R = 15$ – 16 min) was isolated in about 80% radiochemical yield.

N^1 -(3,4-Dihydroxy-5-[^{131} I]iodobenzyl)guanidine (32a**).** About 100 μ Ci of **31a** (HPLC fractions) was taken in a $1/2$ -dram vial, and the solvents were evaporated to dryness. To the residual activity was added TFA (100 μ L), and the vial was vortexed and maintained at room temperature for 15 min. TFA was evaporated, and the residue was triturated with 2×100 μ L of EtOAc. To the residual activity was added anhydrous dichloromethane (80 μ L) followed by BBr_3 (25 mg), and the reaction was allowed to proceed at room temperature for 15 min. The solvent was evaporated and the residue triturated with 2×100 μ L of EtOAc. The activity was dissolved in water (50 μ L) and injected onto a reversed-phase HPLC column. The column was eluted with a solvent mixture consisting of 0.1% (w/v) TFA in each of water (A) and acetonitrile (B) at 1 mL/min. For the first 10 min, the solvent contained 3% of B which was then linearly increased to 90% over a period of 15 min. About 40% of the injected activity was associated with a peak corresponding to **32a** ($t_R = 12$ min); another 30–40% of the injected activity was associated with a nonpolar peak ($t_R = 19$ min) which is presumably **33a**.

N^1 -(4-Hydroxy-3-[^{131} I]iodo-5-methoxybenzyl)guanidine (33a**).** To 100 μ Ci of **31a** in 25 μ L of EtOAc in a $1/2$ -dram vial was added SnCl_4 (5 μ L), and the solution was vortexed and maintained at room temperature for 10 min. The EtOAc was evaporated, and the residue was triturated with 2×25 μ L of EtOAc. The activity was redissolved in methanol (25 μ L) and injected onto a reversed-phase column eluted with a gradient method as above starting from an initial solvent composition of 5% B. About 80–90% activity eluted at a retention time (17 min) corresponding to that for **33a**.

N^1 -Hydroxy- N^3 -(3-[^{131} I]iodobenzyl)guanidine (38a**).** To a $1/2$ -dram vial containing ^{131} I (~ 0.5 mCi) in 1–2 μ L of 0.1 N NaOH was added NCS (0.4 mg in 10 μ L of TFA) and **42** (0.2 mg in 10 μ L of TFA). The vial was vortexed and maintained at room temperature for 10 min. The contents of the vial were injected onto a reversed-phase HPLC column eluted with 85/13.5/1/0.5 water/THF/

triethylamine/ H_3PO_4 at a flow rate of 1.2 mL/min. The product activity ($t_R = 16$ – 17 min) was isolated in about 85% radiochemical yield.

3-Amino-5-[^{131} I]iodobenzylguanidine (45a**).** About 1 mCi of ^{131} I in 1 μ L of 0.1 N NaOH was added to a $1/2$ -dram vial containing **46** (0.2 mg) in CHCl_3 (20 μ L). A 1:3 mixture of 30% H_2O_2 :HOAc (10 μ L) was added to the above mixture, and the vial was sonicated for 30 s. Most of the solvents were evaporated under a flow of argon, and the residual mixture was treated with TFA (0.1 mL) at room temperature for 5–10 min. The product **45a** was isolated in 35–40% radiochemical yield by reversed-phase HPLC ($t_R = 11$ min). For this, a C18 column (μ Bondapak) was eluted initially with 99.9:0.1 water:acetonitrile each containing 0.1% (w/v) TFA at a flow rate of 1 mL/min; after 15 min, the acetonitrile content was linearly increased to 90% over 15 min. All the above radioiodinated guanidine derivatives except **32a** and **45a** were concentrated from the HPLC fractions by solid-phase extraction and reconstituted in appropriate media for biological evaluations, as has been reported earlier (Vaidyanathan et al., 1997a). Concentration by solid-phase extraction of **45a** was performed by a slightly modified protocol (Wafelman et al., 1993). While a regular C18 cartridge was used in most cases, for very polar compounds such as **32a** and **45a** a bigger cartridge (tC18 ENV; Waters) was used.

RESULTS AND DISCUSSION

From an extensive structure–activity study of MIBG analogues, it has been shown that ring substituents in general are better tolerated than are modifications to the guanidinomethyl functionality (Wieland, 1986). We anticipated that derivatives with polar substituents might yield higher tumor-to-normal tissue ratios, because these analogues may be expected to clear faster from normal tissues. Efforts to synthesize MIBG analogues with highly polar groups such as sulfonic and phosphonic acid are underway; however, in the current study, we were able to prepare other analogues of varying polarity.

FIBG, the MIBG analogue with a fluorine at the 4-position had shown increased uptake and retention in tumor cells, as well as lower levels of deiodination (Vaidyanathan et al., 1997a). Although substituting fluorine in FIBG with a chlorine is expected to decrease its polarity, we wished to investigate whether a chlorine-substituted analogue will have a higher tumor uptake without concomitant increases in normal tissue uptake. The synthetic approaches used in the preparation of the unlabeled 4-chloro-3-iodobenzyl guanidine (**6**; CIBG), and the tin precursor **4**, from which **6a** could be obtained at a no-carrier-added level, are presented in Scheme 1. Commercially available 4-chloro-3-iodobenzoic acid was converted to **2** by NaBH_4 -mediated reduction of the active ester, formed in situ by its treatment with BOP (McGeary, 1998). Compound **2** was converted to the protected guanidine **5** by using the Mitsunobu protocol (Dodd and Kozikowski, 1994), and **6** was obtained from **5** by treatment with SnCl_4 (Miel and Rault, 1997). Attempts to convert **5** to **4** either by palladium-catalyzed stannylation (Wigerinck et al., 1993), or by initial Li/I exchange and subsequent stannylation were not successful. However, it was possible to convert **2** to **3**, from which **4** was obtained. Radioiodination of **4** with NCS in acetic acid and subsequent in situ deprotection with TFA resulted in **6a** with a radiochemical yield of about 70%.

The π value, an indicator of polarity, is typically negative for a nitro group (–0.28, 0.14, and 0.71 for NO_2 ,

precursor for 3-[¹³¹I]iodo-4-nitrobenzyl guanidine (*p*[¹³¹I]-INBG) was sought (Scheme 2). Radioiodination of aryl stannanes are more facile in comparison to aryl silanes. However, due to the success we have had in the preparation of n.c.a. [¹³¹I]MIBG from a corresponding silicon precursor (Vaidyanathan and Zalutsky, 1993), **12** was initially chosen as a precursor for the preparation of radioiodinated *p*-INBG. The intermediate **10** was prepared from 3-chloro-4-iodotoluene in three steps using literature procedures (Clark et al., 1951; Eaborn et al., 1964; 1969). Benzylic bromination of **10** yielded **11** which was converted to the protected guanidine **12** by a method reported earlier (Vaidyanathan and Zalutsky, 1997b). A

different synthetic route was taken to prepare unlabeled *p*-INBG (Scheme 3). The key intermediate, the benzyl bromide **16**, was prepared from **14** in two steps and converted to the protected guanidine **17** as above. The guanidine **18** was obtained by the SnCl₄-mediated deprotection of **17**.

Radioiodination of **12** and subsequent TFA treatment did not show a peak on HPLC corresponding to that of **18a**. Our prior unpublished results have shown that TFA sometime fails to remove both Boc groups from bis-Boc guanidines. To ensure that the absence of a peak corresponding to **18a** under reversed-phase HPLC conditions did not result from this partial deprotection, **12** was deprotected to **13** before being subjected to radioiodination. Although a peak corresponding to **18a** was observed by HPLC, the radiochemical yield was poor. Before undertaking the synthesis of a tin precursor to **18a**, an exchange radioiodination method (Mock and Weiner, 1988) was used to prepare **18a** in order to check its suitability as an MIBG analogue.

One of the problems associated with *p*INBG was its *in vivo* instability (see following article). This may be due to the presence of a strong electron-withdrawing group *ortho* to the iodine which may facilitate the nucleophilic displacement of iodine. To investigate the effect of switching the NO₂ group to the *meta*-position on the stability, and to examine the overall suitability of *m*INBG as a MIBG analogue, the isomeric (3-iodo-5-nitro)benzylguanidine (*m*INBG; **25**; Scheme 4) and its tin precursor **23** were synthesized. Compound **21** was prepared in two

steps from **19**. Although **24** could have been prepared directly from **21** by its coupling with bis-Boc-guanidine under Mitsunobu conditions, the *S*-methylisothiourea derivative was first prepared serendipitously and then converted quantitatively to **24** by treatment with liquid ammonia. It is often difficult to isolate products from Mitsunobu reactions by chromatography due to the coelution of starting materials and byproducts (O'Neil et al., 1998; Falconer et al., 1999; Kiankarimi et al., 1999). While this was generally the case for the purification of our diprotected guanidines, chromatographic separation of the *S*-methylisothiourea intermediate from the byproducts was much easier, at least in this specific instance, affording the pure product in a greater isolated yield. Treatment of **24** with TFA in CH₂Cl₂ yielded **25**. No-carrier-added *m*[¹³¹I]INBG was prepared from **23** in 50% radiochemical yield. The lower radiochemical yield may be a result of the chemical instability of **25a** under these reaction conditions. Accordingly, use of protracted reaction times and higher temperatures resulted in higher amounts of radioiodide, presumably from the deiodination of **25a**.

The natural substrate of the NET is norepinephrine, which has two hydroxy substituents at the 3- and 4-positions of its benzene ring. The potential of a "norepinephrine-like" benzylguanidine analogue with two hydroxyl groups has been suggested previously (Wieland, 1986). We wanted to investigate whether an MIBG derivative with two ring hydroxyl groups would retain affinity for NET. A *nc*a synthesis of 3,4-dihydroxy-5-[¹³¹I]-

iodobenzyl guanidine ([¹³¹I]DHIBG; **32a**) was accomplished following an approach depicted in Scheme 5. The syntheses of unlabeled DHIBG and that of a suitable tin precursor were commenced from commercially available bromovanillin, **26**. To make the chemical manipulations facile, the 4-OH group of **26** was protected with a methoxymethoxy (MOM) group. The resultant **27** was reduced to the benzyl alcohol **28** which in turn was converted to **29**. Neither attempted stannylation of **29** to **35**, either by the palladium-catalyzed reaction or by the lithiation pathway, nor the conversion of **28** to **34** via the modified Stille protocol, were successful. However, **34** could be prepared by the lithium/bromine exchange of **28** and subsequent stannylation of the intermediate anion. Compounds **30** and **34** were readily converted to their respective guanidine derivatives, **31** and **35**, under Mitsunobu conditions. Both the methoxy and the MOM group as well as the Boc groups of **31** were removed simultaneously by treatment with BBr₃ to afford **32**. A radiochemical yield of about 80% was obtained for the conversion of **35** to **31a** under mild reaction conditions. Compound **31a** was smoothly converted to **33a** by its treatment with either SnCl₄ or TFA in 80–90% radiochemical yields. Treatment of **31a** with BBr₃ at room temperature gave **32a** but in meager radiochemical yields. In situ treatment of **33a**, formed by TFA treatment of **31a**, with BBr₃ increased the radiochemical yield of **32a** to some extent (ca. 40%). The potential for enhancing the radioiodination yield of **32a** by using alternative demethylating agents exists but was not investigated.

As indicated earlier, structural alterations at the side chain of MIBG have been less tolerated (Wieland, 1986). Except when the radioiodine was at the ortho position, both *N*¹-mono- and *N*¹,*N*²-dialkylated MIBG derivatives had insignificant target uptake in the dog adrenal medulla. Introduction of an amino group on the guanidine function had deleterious effects as well; however, a *N*-hydroxy-substituted MIBG derivative has not been studied. A number of *N*-hydroxyguanidines have been developed as potential replacements for the anti-hypertensive guanethidine; two of these had potencies similar to that of guanethidine (Balley and DeGrazia, 1973). MIBG itself was derived by combination of the guanidine group of guanethidine and the benzyl portion of bretylium, another neuron blocking agent. On the basis of these facts, we were interested in the development of the *N*-hydroxy-modified MIBG. The synthetic pathways for the preparation of *N*¹-hydroxy-*N*³-(3-iodobenzyl)guanidine (NHIBG; **38**) and its silicon precursor **42** are presented in Schemes 6 and 7, respectively. These were prepared from their corresponding benzylamines following a literature procedure (Balley and DeGrazia, 1973). Compound **40** (Vaidyanathan and Zalutsky, 1993) was prepared from **39** via a lithiation/silylation procedure. Radioiodination of **42** to **38a** was achieved in 80–90% radiochemical yield.

The MIBG derivative with an amino group at the 4-position (*p*AIBG) was better than the parent compound

with respect to its human myocardial uptake. However, the thyroid uptake was also higher, suggesting its higher degree of dehalogenation (Shulkin et al., 1986), probably due to the presence of an amino group *ortho* to the carbon carrying the iodine. We wanted to investigate whether the isomeric compound, wherein the amino group has been switched to the *meta* position (*m*AIBG, **45**), would exhibit less dehalogenation. The synthesis of **45** and its tin precursor were readily achieved as shown in Scheme 8. Compound **43** was prepared from the nitro derivative **21** by metallic indium-mediated reduction. Guanidinylation of **43** via the Mitsunobu protocol, followed by TFA-mediated deprotection of Boc groups from the resultant guanidine derivative **44** delivered the target benzylguanidine. The tin precursor **46** was obtained by the stannylation of **44** using the modified Stille reaction. Both **44** and **46** exhibited very similar polarity, and hence it was difficult to separate [¹³¹I]**44** from **46** by normal-phase HPLC. For this reason, **46** was directly converted to **45a** in one-pot reaction and the latter isolated by reversed-phase HPLC. Based on a few attempts, the radiochemical yield for this conversion is about 40%.

In summary, this paper describes the syntheses of various MIBG analogues and their tin or silicon precursors. Methods for the preparation of radioiodinated derivatives have been described as well. In vitro and in

vivo evaluation of these analogues is the subject of the article which follows.

ACKNOWLEDGMENT

This work was supported by Grants CA 74817 and CA 42324 from National Institutes of Health. The authors want to thank Donna Affleck and Jean Li for their excellent technical assistance.

Biological Evaluation of Ring- and Side-Chain-Substituted *m*-Iodobenzylguanidine Analogues

Ganesan Vaidyanathan,* Sriram Shankar, Donna J. Affleck, Philip C. Welsh, Susan K. Slade, and Michael R. Zalutsky

Department of Radiology, Duke University Medical Center, Durham, North Carolina 27710. Received March 8, 2001; Revised Manuscript Received June 22, 2001

A number of ring- and side-chain-substituted *m*-iodobenzylguanidine analogues were evaluated for their lipophilicity, in vitro stability, uptake by SK-N-SH human neuroblastoma cells in vitro, and biodistribution in normal mice. As expected, the lipophilicity of *m*-iodobenzylguanidine increased when a halogen was introduced onto the ring and decreased with the addition of polar hydroxyl, amino, and nitro substituents. Most of the derivatives showed reasonable stability up to 24 h in PBS at 37 °C. While *N*¹-hydroxy-*N*³-3-[¹³¹I]iodobenzylguanidine and 3,4-dihydroxy-5-[¹³¹I]iodobenzylguanidine generated a more nonpolar product in addition to the free iodide, 3-[¹³¹I]iodo-4-nitrobenzylguanidine decomposed to a product more polar than the parent compound. The specific uptake of 4-chloro-3-[¹³¹I]iodobenzylguanidine, 3-[¹³¹I]iodo-4-nitrobenzylguanidine, and *N*¹-hydroxy-*N*³-3-[¹³¹I]iodobenzylguanidine by SK-N-SH human neuroblastoma cells in vitro, relative to that of *m*-[¹²⁵I]iodobenzylguanidine, was 117 ± 10%, 50 ± 4%, and 12 ± 2%, respectively. The specific uptake of the known *m*-iodobenzylguanidine analogues 4-hydroxy-3-[¹³¹I]iodobenzylguanidine and 4-amino-3-[¹³¹I]iodobenzylguanidine was 80 ± 4% and 66 ± 4%, respectively. None of the other *m*-iodobenzylguanidine derivatives showed any significant specific uptake by SK-N-SH cells. Heart uptake of 4-chloro-3-[¹³¹I]iodobenzylguanidine in normal mice was higher than that of *m*-[¹²⁵I]iodobenzylguanidine at later time points (11 ± 1% ID/g versus 3 ± 1% ID/g at 24 h; *p* < 0.05) while uptake of 3-[¹³¹I]iodo-4-nitrobenzylguanidine and of *N*¹-hydroxy-*N*³-3-[¹³¹I]iodobenzylguanidine in the heart was lower than that of *m*-iodobenzylguanidine at all time points. In accordance with the in vitro results, none of the other novel *m*-iodobenzylguanidine derivatives showed any significant myocardial or adrenal uptake in vivo.

INTRODUCTION

Since its development about 2 decades ago, radioiodinated MIBG¹ (Table 1) has been used extensively in a number of oncologic and cardiologic applications; however, its properties are far from ideal for these applications (Wafelman et al., 1994a). As described by these authors, there are a number of compounding factors responsible for the sub-optimal performance of MIBG. Our laboratory has been investigating radiochemical variables with the goal of improving the clinical efficacy of MIBG. For example, we developed a no-carrier-added synthesis of radioiodinated MIBG (Vaidyanathan and Zalutsky, 1993, 1995), and a few centers around the world are evaluating the clinical utility of nca [¹²³I]MIBG (Farahati et al., 1997; Samnick et al., 1999; Owens et al., 2000). We also have evaluated an analogue of MIBG labeled with the alpha particle emitter ²¹¹At which might

be useful for the treatment of metastatic diseases (Vaidyanathan and Zalutsky, 1992). Currently we are looking at the possibility of developing an MIBG analogue that will yield higher tumor retention and tumor-to-normal tissue ratios.

Because polar compounds are generally eliminated rapidly via the urine, MIBG derivatives containing polar substituents may yield higher tumor-to-normal tissue ratios, provided that such analogues are taken up efficiently by the tumor. Although many compounds with diverse structural features are substrates for the norepinephrine transporter, subtle changes in the structure

of aralkylguanidines can result in significant alterations in their accumulation in adrenergic-rich tissues (Wieland, 1986; Wieland et al., 1984). Because polar substituents such as OH and NH₂ were not included in earlier structure-activity studies of aralkylguanidines (Short and Darby, 1967; Fielden et al., 1965), it was speculated that such substituents may be counterproductive (Lee et al., 1986). Indeed, our attempt to make MIBG more polar by replacing its benzene ring with a pyridine has yielded a compound that was not taken up by human neuroblastoma cells in vitro (Vaidyanathan et al., 1998). In contrast, while substituting a hydroxyl group at the 4-position of MIBG (HIBG) did not affect its adreno-medullary uptake in dogs significantly, the 4-amino derivative (*p*AIBG) had a higher uptake (Lee et al., 1986) than MIBG. Also, in patients, AIBG sequestered in pheochromocytoma tumor to a degree similar to that of MIBG (Shulkin et al., 1986).

HIBG and *p*AIBG have not been evaluated in tumor cells or xenografts containing upregulated norepinephrine transporter. It should be pointed out that there are differences in the norepinephrine uptake and storage systems not only between tumors and sympathetically innervated tissues, but also within different nontumor target tissues such as heart and salivary gland. While MIBG is stored in vesicles in tissues such as adrenals and heart, and in pheochromocytoma, SK-N-SH human neuroblastoma cells lack storage vesicles; the storage in this case seems to be cytoplasmic (Clerc et al., 1993; Sisson and Sulkin, 1999). The uptake of [¹³¹I]MIBG in heart is diminished by endogenous norepinephrine; in contrast, its uptake in parotid glands was little affected (Sisson and Wieland, 1986). Thus, the aim of the present study was to evaluate a number of newly developed MIBG analogues, as well as HIBG and *p*AIBG, in the SK-N-SH neuroblastoma cell line.

As described in the preceding paper (Vaidyanathan et al., 2001), the synthesis of several new analogues of MIBG has been developed. In the current study, these compounds have been evaluated with respect to their stability, lipophilicity, and uptake in SK-N-SH human neuroblastoma cells in vitro and in normal mouse tissues in vivo. Our results show that a number of these novel compounds completely lost their affinity for NET. Unfortunately, the others which retained the affinity do not seem to offer better in vivo properties than MIBG itself.

MATERIALS AND METHODS

General. All chemicals and reagents are obtained from Aldrich or Sigma unless otherwise noted. The details of the preparation of all new tracers used in this study are described in the preceding publication (Vaidyanathan et al., 2001). Except for *p*[¹³¹I]INBG, which was prepared by an exchange radioiodination, all radioiodinated MIBG analogues used in this study were *nca* preparations. Previously reported protocols were used for the syntheses of 4-hydroxybenzylguanidine hemisulfate and 4-hydroxy-3-iodobenzylguanidine hemisulfate (HIBG) (Lee et al., 1986). No-carrier-added (*nca*) [¹²⁵I]MIBG and radioiodinated FIBG were prepared as reported before (Vaidyanathan and Zalutsky, 1993; Vaidyanathan et al., 1997a). Details concerning the various analytical methods such as NMR, HPLC, etc., used to chemically characterize the compounds reported in this paper, are described in the preceding article (Vaidyanathan et al., 2001).

4-Aminobenzylguanidine Nitrate (ABG). A mixture of 4-aminobenzylamine (244 mg, 2 mmol) and 3,5-dimethylpyrazole-1-carboxamide nitrate (403 mg, 2

mmol) in ethanol (10 mL) was refluxed for 3 h. The solvent was evaporated, and the residual solid was washed with ethyl acetate. Recrystallization of the solid from ethanol/ether afforded 318 mg (70%) of a crystalline solid: mp 139–141 °C. ¹H NMR (CD₃OD) 4.50 (s, 2H), 7.4–7.58 (m, 3H). MS (FAB⁺) *m/z*: 165 (MH⁺).

4-Amino-3-iodobenzylguanidine (*p*AIBG). An HPLC standard of the title compound was prepared as follows: A solution of Iodogen (150 μg) in chloroform (30 μL) was taken in a half-dram vial, and the solvent was evaporated. To this vial was added a solution of ABG (0.5 mg) in acetate buffer, pH 4.5 (1 mL), followed by a solution of sodium iodide (0.45 mg) in the same buffer (420 μL). The mixture was incubated at room temperature for 30 min, and the product was isolated by semipreparative HPLC (*t*_R = 7.5 min). For HPLC, a C18 column (μ Bondapak) was eluted with 99.5:0.5 mixture of water/acetonitrile containing 0.1% (w/v) TFA. MS (ESI) *m/z*: 291 (MH⁺).

[¹³¹I]HIBG and *p*[¹³¹I]AIBG. The title compounds were prepared following protocols reported in the literature (Lee et al., 1986) and isolated by reversed-phase HPLC. For HPLC, a C18 column (μ Bondapak) was eluted with 99.7:0.3 water/acetonitrile containing 0.1% (w/v) TFA at a flow rate of 1 mL/min. The retention times of *p*[¹³¹I]AIBG and [¹³¹I]HIBG under these HPLC conditions were 9 and 15 min, respectively. Concentration of the tracers was performed by solid-phase extraction using bigger (tC18 ENV; Waters) cartridges by a method similar to that described in the preceding paper (Vaidyanathan et al., 2001). After eluting the initial solvent from the HPLC fractions, the cartridge was washed with 5 mL of water and 0.5 mL of 5 mM NaOAc, pH 4.5, in that order before eluting the tracer with methanol or ethanol.

Octanol–Saline Partition Coefficient. The lipophilicity of the MIBG analogues was compared to that of MIBG by determining their octanol–PBS (pH 7.4) partition coefficients. The assay was performed in a paired-label format, in most cases directly comparing the analogue with MIBG. Both octanol and PBS were pre-saturated with each other. About 500 000 counts of each tracer in 10 μL of PBS were added in triplicate to glass tubes containing a mixture of 2 mL each of octanol and PBS. The contents of the tubes were thoroughly mixed by vortexing, and the layers were separated by centrifugation using a microcentrifuge. Duplicate samples (50 μL) of each layer from each tube were withdrawn and counted for radioactivity. The aqueous layer was discarded, and fresh PBS (1.9 mL) was added and the process repeated. The assay was repeated a third time with 1.8 mL of fresh PBS. The partition coefficient was calculated as the ratio of counts in octanol to that in PBS. The mean and standard deviation from 18 measurements for each tracer were calculated.

In Vitro Stability. To determine the influence of various substituents on the degree of dehalogenation, the stability of some of the radioiodinated derivatives was determined. About 100–200 μCi of activity was taken in PBS (100 μL) and incubated at 37 °C. Aliquots were taken periodically over a period of about 24 h, and the percent of total activity that was associated with the intact tracer was determined by reversed-phase HPLC. The HPLC system used for each tracer was the same as reported earlier for the purification and isolation of the compound (Vaidyanathan et al., 2001).

Cells and Culture Conditions. The human neuroblastoma cell line SK-N-SH (Uptake-1 positive; Biedler et al., 1973) was purchased from the American Type

Culture Collection (Rockville, MD). The incubation medium (JRH Biosciences, Lenexa, KS) was made by mixing 440 mL of RPMI 1640, 50 mL of Serum Plus, 5 mL of penicillin-G/streptomycin (5000 units of penicillin and 5000 μ g of streptomycin in 1 mL of 0.85% saline), and 5 mL of glutamine (200 mM in saline). The cells were grown at 37 °C in a humidified incubator containing 5% CO₂. Cell viability was evaluated prior to each binding experiment by trypan blue dye (Kaltenbach et al., 1958), and was 95–98% for all studies.

Paired-Label In Vitro Uptake of MIBG Analogues by SK-N-SH Cells in Comparison to That of MIBG. SK-N-SH cells were plated in 6-well plates at an initial density of 5×10^5 cells per well in 3 mL of medium, and incubated for 24 h. The medium was removed by aspiration, and 100 nCi each of radioiodinated MIBG and one of the MIBG analogues² in 3 mL of medium was added to each well and incubated for 2 h at 37 °C. The specificity and energy dependence of tracer uptake were determined using DMI and ouabain, respectively. The initial medium was removed, and the cells were incubated with 3 mL each of 1.5 μ M DMI and 1 mM ouabain, respectively, for 30 min. The medium was removed, and tracers were added as above and incubated for 2 h at 37 °C. The energy dependence of tracer uptake was ascertained by determining the effect of temperature as well. For this, the original medium was removed, and fresh medium that was cooled to 4 °C was added followed by tracers (100 nCi each) in 10 μ L of the medium, and the cells were incubated for 2 h at 4 °C. Finally, the effect of norepinephrine and MIBG was ascertained by removing the original medium and co-incubating the cells with the tracers (100 nCi in 10 μ L each) and 3 mL each of 50 μ M norepinephrine and 10 μ M MIBG, respectively, at 37 °C for 2 h. At the end of the 2 h incubation period, the cells were solubilized by incubation with 500 μ L of 0.5 N NaOH for 30 min at room temperature and then removed with cotton swabs. The cell-bound activity was counted along with input standards using a dual-channel gamma counter. Each set of experiments was performed 3–6 times. The entire experiment was conducted twice in some cases.

Paired-Label Exocytosis of [¹³¹I]FIBG and [¹²⁵I]-CIBG from SK-N-SH Cells. In a previous study, we demonstrated that washout of FIBG from SK-N-SH cells in vitro was considerably slower than that of MIBG (Vaidyanathan et al., 1997a). To investigate whether a chlorine substituent yielded a similar effect, a paired-label study was performed comparing the washout of [¹³¹I]FIBG and [¹²⁵I]CIBG from SK-N-SH cells. Cells were added to 6-well plates at a density of $\sim 4 \times 10^5$ cells per well per 3 mL of medium and incubated at 37 °C for 24 h. After the 24 h period, the medium was replaced with fresh medium containing $\sim 1 \mu$ Ci of each tracer in a total volume of 3 mL per well. After incubating the cells with the activity for 2 h at 37 °C, the medium was removed and supplemented with 3 mL of either fresh medium or 1.5 μ M desipramine in medium. The cell-bound activity was determined at 0, 2, 4, 8, 24, 48, 72, and 96 h after the initial uptake. The medium was aspirated at the end of each period, and the cells were washed twice with 0.5 mL each of PBS. The cells were solubilized by incubating with 500 μ L of 0.5 N NaOH for 30 min and removed with cotton swabs. The cell-bound activity was counted using a dual-channel gamma counter. For each time point, the assay was performed in quadruplicate.

Table 2. Octanol–Saline Partition Coefficients of MIBG and Analogues

tracer	partition coefficient (mean $\pm$ SD)
MIBG	2.61 $\pm$ 0.07
4-chloro-3-iodobenzylguanidine	8.36 $\pm$ 1.43
4-fluoro-3-iodobenzylguanidine	3.01 $\pm$ 0.20
4-amino-3-iodobenzylguanidine	0.32 $\pm$ 0.02 ^a
4-hydroxy-3-iodobenzylguanidine	0.60 $\pm$ 0.03 ^a
3-iodo-5-nitrobenzylguanidine	2.08 $\pm$ 0.14
3-iodo-4-nitrobenzylguanidine	1.13 $\pm$ 0.03
<i>N</i> -hydroxy-3-iodobenzylguanidine	3.82 $\pm$ 0.17
4-hydroxy-3-iodo-5-methoxybenzylguanidine	0.60 $\pm$ 0.04
3,5-dihydroxy-5-iodobenzylguanidine	0.38 $\pm$ 0.02 ^a
3-amino-5-iodobenzylguanidine	0.68 $\pm$ 0.03 ^a

^a In these cases, the partition coefficient values of these compounds increased substantially with each equilibration step, while that of MIBG from the paired-label format remained fairly constant; values shown are from the first equilibration.

Biodistribution Studies in Normal Mice. These studies were performed for all tracers except [¹³¹I]HIBG and *p*[¹³¹I]AIBG in a paired-label format comparing the new tracer directly to MIBG. The study utilized male BALB/c mice weighing about 25 g with groups of five mice for each time point. Tracers (1–5 μ Ci) in 100 μ L of PBS were injected via the tail vein, and groups of animals were killed at 1, 4, and 24 h postinjection. The specificity of uptake was determined by pretreating a group of mice with DMI 30 min before injecting the tracers, and the tissue distribution was performed 1 h later. The mice were killed by an overdose of halothane, and tissues of interest were isolated, washed, blot-dried, and weighed. The tissues, along with 5% dose standards, were counted for ¹³¹I and ¹²⁵I using a dual-label program in an automated gamma counter. The uptakes were expressed as percent injected dose per gram of tissue (%ID/g) unless otherwise specified. The statistical significance in the difference between the uptake of ¹²⁵I and ¹³¹I in each tissue was calculated by the paired Student's *t*-test using the Excel computer program (Microsoft).

RESULTS

Syntheses of ABG and *p*AIBG. ABG was prepared from readily available 4-aminobenzylamine in more than 70% yield. An HPLC sample of *p*AIBG was obtained by the microscale iodination of ABG. Both were characterized by standard spectral techniques.

Octanol–Saline Partition Coefficient. The relative lipophilicities of the MIBG analogues were obtained by measuring their octanol–saline partition coefficients using their radioiodinated analogues (Table 2). As expected, halogen substitution increased lipophilicity. While the effect was only minimal with fluorine (3.01 $\pm$ 0.20 for FIBG vs 2.61 $\pm$ 0.07 for MIBG), substituting chlorine at the 4-position resulted in an almost 4-fold increase in the partition coefficient. The only other derivative with a higher partition coefficient than that of [¹²⁵I]MIBG was [¹³¹I]NHIBG. This corroborates the earlier claim that conversion of a guanidine to *N*-hydroxy-substituted guanidine results in increased lipophilicity (Balley and De-Grazia, 1973). While a nitro group at the para position decreased the lipophilicity by more than a factor of 2, meta substitution of the nitro group did not yield a similar effect. Partition coefficients for *p*[¹³¹I]AIBG, *m*[¹³¹I]-AIBG, [¹³¹I]HIBG, and [¹³¹I]DHIBG increased to a considerable extent with each equilibration step, while values for [¹²⁵I]MIBG from paired-label experiments

² If MIBG was labeled with ¹³¹I, the analogue was labeled with ¹²⁵I, and vice versa.

Figure 1. Uptake of [^{131}I]HIBG (A), $p[^{131}\text{I}]$ AIBG (B), [^{131}I]CIBG (C), and ex- $p[^{131}\text{I}]$ INBG (D) by SK-N-SH human neuroblastoma cells in vitro (open bars). Results obtained for [^{125}I]MIBG from respective paired-label assays are also shown (filled bars). The effect of various Uptake-1-blocking conditions is also presented. Cells were incubated as described in the text in the absence or presence of various Uptake-1 inhibitors or at 4 °C, and the cell-associated activity was determined as a percent of input radioactivity.

remained fairly constant. For these compounds, values from the first equilibration are shown in Table 2. $p[^{131}\text{I}]$ -AIBG was the most hydrophilic (0.32 ± 0.02) of all the compounds studied. Switching the amino group from the 4- to 5-position increased lipophilicity. While [^{131}I]HIBG had a partition coefficient of 0.60 ± 0.03 , introduction of another hydroxyl group reduced the partition coefficient to 0.38 ± 0.02 , and capping one of the hydroxyl groups in [^{131}I]DHIBG increased the lipophilicity back to 0.60 ± 0.04 .

In Vitro Stability. In vitro stabilities of radioiodinated MIBG derivatives were determined by HPLC after incubating them in PBS at 37 °C for various periods of time. [^{131}I]FIBG, [^{131}I]CIBG, $p[^{131}\text{I}]$ INBG, $m[^{131}\text{I}]$ AIBG, and [^{131}I]HIMBG were stable up to 24 h with less than 5% of free iodide formed. While there was about 5–10% of free iodide in the $p[^{131}\text{I}]$ AIBG and [^{131}I]HIBG preparations even at the beginning of incubation, no further deiodination was seen up to 4 h at 37 °C. [^{131}I]DHIBG deteriorated steadily with time with only about 30–35% of the total activity associated with the intact molecule at 4 h. While another third of the activity was free iodide, the remainder was an unidentified nonpolar compound. At 24 h, most of the activity corresponded to free iodide. Although little deiodination was seen in the case of $m[^{131}\text{I}]$ INBG, a radioactive byproduct more polar than the parent compound accrued with time. For up to 4 h, the [^{131}I]NHIBG remained intact except for the formation of a small amount of a slightly more nonpolar byproduct. Three radioactive peaks were observed at 24 h with the majority of the activity associated with the above byproduct. A commensurate amount of the activity was associated with the intact molecule, and only 5–10% of the total activity corresponded to free iodide.

Table 3. Uptake of Various MIBG Analogues by SK-N-SH Cells in Vitro

MIBG analogue	% specific uptake ^a
MIBG	100.00 $\pm$ 0.00
4-hydroxy-3-iodobenzylguanidine	66.42 $\pm$ 3.92
4-amino-3-iodobenzylguanidine	80.48 $\pm$ 4.05
4-chloro-3-iodobenzylguanidine	116.73 $\pm$ 4.80
3-iodo-4-nitrobenzylguanidine	50.40 $\pm$ 3.77
3-iodo-5-nitrobenzylguanidine	1.24 $\pm$ 0.12
3,5-dihydroxy-5-iodobenzylguanidine	0.08 $\pm$ 0.03
4-hydroxy-3-iodo-5-methoxybenzylguanidine	0.69 $\pm$ 0.24
3-amino-5-iodobenzylguanidine	0.27 $\pm$ 0.10
N-hydroxy-3-iodobenzylguanidine	12.34 $\pm$ 1.14

^a Specific uptake was obtained by subtracting uptake in the presence of DMI from that of control values. Each value is then normalized to the same value for MIBG obtained from paired-label assays; mean $\pm$ SD ($n = 3$ –6).

Uptake of MIBG Analogues by SK-N-SH Cells in Vitro. The degree of uptake, and the influence of various interventional agents and inhibitory conditions, for four analogues is shown in Figure 1. The specific uptake, defined as the difference between control values and those obtained in the presence of DMI, for each new analogue as well as for $p[^{131}\text{I}]$ AIBG and [^{131}I]HIBG is presented in Table 3. The 4-chloro derivative had a specific uptake of 117% that of [^{125}I]MIBG. The specific uptakes of $p[^{131}\text{I}]$ AIBG and [^{131}I]HIBG were 80% and 60% that of [^{125}I]MIBG, suggesting that these derivatives retain the biological characteristics of MIBG not only with respect to the canine adrenomedullary uptake in vivo reported previously (Lee et al., 1986), but also with respect to the uptake in SK-N-SH human neuroblastoma cells in vitro. The switching of the amino group to the 5-position resulted in the complete loss of specificity (specific uptake of $m[^{131}\text{I}]$ AIBG was 0.27% that of [^{125}I]-

Figure 2. Paired-label exocytosis of [^{125}I]CIBG ($\blacktriangle$, without DMI; $\triangle$, with DMI) and [^{131}I]FIBG ($\bullet$, without DMI; $\circ$, with DMI) as a function of time. Cells were allowed to take up the tracers at 37 °C for 2 h. The medium containing the tracers was replaced with fresh medium without or with DMI, and the cell-associated activity was determined periodically.

MIBG). The 4-nitro derivative had a specific uptake about half that of [^{125}I]MIBG. As with the amino derivatives, switching the nitro group to the 5-position yielded a compound with a specific uptake of about 1% that of MIBG. Both dihydroxy- and hydroxy-methoxy-substituted derivatives did not have any significant uptake. While the *N*-hydroxy derivative showed some uptake, it was not substantial. The uptake of certain derivatives such as [^{131}I]CIBG and *p*[^{131}I]INBG was not reduced to the same level as [^{125}I]MIBG by some of the Uptake-1-blocking conditions, especially incubation at 4 °C.

Washout of CIBG from SK-N-SH Cells in Comparison to That of FIBG. Figure 2 shows the results obtained from a paired-label study of retention of [^{125}I]CIBG and [^{131}I]FIBG by SK-N-SH cells. The amount of initially bound [^{125}I]CIBG activity retained was consistently higher than that of [^{131}I]FIBG at all time points with the difference increasing with time. Even at 96 h, the specifically retained [^{125}I]CIBG activity was about 2-fold higher than that for [^{131}I]FIBG.

Biodistribution. Detailed biodistribution data are presented for those novel MIBG derivatives that demonstrated a reasonable uptake in SK-N-SH human neuroblastoma cells in vitro. Figure 3 shows the %ID/g in selected normal mouse tissues obtained from a paired-label biodistribution of [^{131}I]CIBG and [^{125}I]MIBG (see Supporting Information for uptake in other tissues). The heart uptake of [^{131}I]CIBG ($12.9 \pm 2.6\%$ ID/g) was less than that for [^{125}I]MIBG ($16.6 \pm 2.1\%$ ID/g) at 1 h ($p < 0.05$); however, the $^{131}\text{I}/^{125}\text{I}$ ratio in the heart increased with time, reaching >3 at 24 h. The uptake of both [^{131}I]CIBG and [^{125}I]MIBG was similar in the adrenals, the other Uptake-1 target tissue, and the difference in uptake was statistically significant only at 4 h ($9.09 \pm 5.03\%$ ID/g vs $7.49 \pm 3.98\%$ ID/g; $p < 0.05$). The uptake of [^{131}I]CIBG in a number of other tissues was higher than that of [^{125}I]MIBG, a finding similar to that observed for [^{131}I]FIBG (Vaidyanathan et al., 1997a). Compared to FIBG, one notable difference of CIBG was in its thyroid uptake. [^{131}I]CIBG activity in thyroid was 2–3-fold higher ($p < 0.05$)

Figure 3. Paired-label uptake (%ID/g) of radioactivity in heart, spleen, liver, thyroid, blood, and adrenals at 1, 4, and 24 h after intravenous administration of [^{131}I]CIBG ($\square$) and [^{125}I]MIBG ($\blacksquare$).

than that seen for [^{125}I]MIBG, suggesting that the former was more susceptible to in vivo deiodination; in contrast, [^{131}I]FIBG was less susceptible to deiodination than [^{125}I]MIBG. Also, unlike FIBG, the blood activity from [^{131}I]CIBG was considerably higher than that of [^{125}I]MIBG. At 1 and 4 h, blood levels were $3.12 \pm 0.43\%$ ID/g and $2.35\% \pm 0.36\%$ ID/g, respectively, for [^{131}I]CIBG compared to $0.64 \pm 0.06\%$ ID/g and $0.32 \pm 0.05\%$ ID/g, respectively, for [^{125}I]MIBG.

The heart uptake of *p*[^{131}I]INBG was consistently lower than that of [^{125}I]MIBG (14.6 ± 2.6 , 11.7 ± 2.3 , and $3.4 \pm 0.6\%$ ID/g versus 20.5 ± 2.4 , 15.9 ± 2.6 , and $3.8 \pm 0.8\%$ ID/g at 1, 4, and 24 h, respectively; $p < 0.05$ for 1 and 4 h), and a similar trend was seen in adrenals as well (Figure 4). The uptake of *p*[^{131}I]INBG in a number of other normal tissues was significantly higher than that for [^{125}I]MIBG. For example, the uptake of *p*[^{131}I]INBG in spleen, lungs, and blood was 3–40-fold higher over the 24 h period. In addition, the $^{131}\text{I}/^{125}\text{I}$ ratio in the thyroid reached a value of more than 6 at 24 h, suggesting that *p*[^{131}I]INBG is very susceptible to in vivo deiodination. The biodistribution of *m*[^{131}I]INBG was quite different from that of the para-isomer. Heart uptake of *m*[^{131}I]INBG was only about one-tenth or less that of [^{125}I]MIBG at all time points. For example, at 1 h, the heart uptake of *m*[^{131}I]INBG was $1.89 \pm 0.29\%$ ID/g compared to $15.44 \pm 1.84\%$ ID/g for [^{125}I]MIBG ($p < 0.05$). Although the value of adrenal uptake for *m*[^{131}I]INBG at 1 h was roughly half that for [^{125}I]MIBG, no significant activity was left in the adrenals at 24 h ($0.24 \pm 0.02\%$ ID/g vs $6.86 \pm 0.5\%$ ID/g for [^{125}I]MIBG). The uptake in a number of other tissues such as liver, spleen, and lung was significantly less than that of [^{125}I]MIBG. The thyroid uptake of *m*[^{131}I]INBG was 2–5-fold lower than that of [^{125}I]MIBG, suggesting that, unlike the para-isomer, this derivative was less likely to undergo in vivo deiodination.

Except in the heart, adrenals, thyroid, and the brain, the uptake of [^{131}I]NHIBG was similar to [^{125}I]MIBG in most tissues at all time points (Figure 5). The heart uptake of [^{131}I]NHIBG (12.2 ± 1.0 and $8.0 \pm 1.1\%$ ID/g) was about half and two-thirds ($p < 0.05$) that of [^{125}I]MIBG (22.2 ± 2.6 and $12.0 \pm 2.1\%$ ID/g) at 1 and 4 h,

Figure 4. Paired-label uptake (%ID/g) of radioactivity in heart, spleen, liver, thyroid, blood, and adrenals at 1, 4, and 24 h after intravenous administration of $p[^{131}\text{I}]$ INIBG (□) and $[^{125}\text{I}]$ MIBG (■).

Figure 5. Paired-label uptake (%ID/g) of radioactivity in heart, spleen, liver, thyroid, blood, and adrenals at 1, 4, and 24 h after intravenous administration of $[^{131}\text{I}]$ NHIBG (□) and $[^{125}\text{I}]$ MIBG (■).

respectively, and at 24 h, the heart uptake of both tracers was similar. The adrenal uptake of $[^{131}\text{I}]$ NHIBG was lower ($p < 0.05$ except at 1 h) than that of $[^{125}\text{I}]$ MIBG, but the differences were not very substantial. Although not to a great degree, the thyroid uptake of $[^{131}\text{I}]$ NHIBG was less than that of $[^{125}\text{I}]$ MIBG at all time points ($p < 0.05$ only at 1 h). At 1 and 4 h, the brain uptake of $[^{131}\text{I}]$ -NHIBG was about 4-fold higher than that of $[^{125}\text{I}]$ MIBG, possibly due to its higher lipophilicity.

Neither heart nor adrenals had any significant uptake of $[^{131}\text{I}]$ DHIBG at any time points. The heart uptake of $[^{131}\text{I}]$ DHIBG at 1, 4, and 24 h was $1.12 \pm 0.07\%$ ID/g, $0.35 \pm 0.06\%$ ID/g, and $0.06 \pm 0.01\%$ ID/g, respectively,

compared to $25.78 \pm 5.08\%$ ID/g, $14.76 \pm 4.24\%$ ID/g, and $4.24 \pm 0.35\%$ ID/g for $[^{125}\text{I}]$ MIBG. Similarly, the adrenal uptake was also less than 10% that of $[^{125}\text{I}]$ MIBG at all time points. A number of other tissues also sequestered $[^{131}\text{I}]$ DHIBG to a considerably low degree. Thyroid uptake of $[^{131}\text{I}]$ DHIBG was almost 3-fold higher than that of $[^{125}\text{I}]$ -MIBG at 24 h, suggesting the in vivo instability of the former. While $[^{131}\text{I}]$ HIMBG did not have any significant uptake in heart and adrenals, most of the $[^{131}\text{I}]$ HIMBG-associated activity was eliminated via the urine within the first hour. The uptake of $m[^{131}\text{I}]$ AIBG in major organs including the target organs, heart and adrenals, was considerably lower than that of $[^{125}\text{I}]$ MIBG. The stomach and intestines exhibited a higher uptake of $m[^{131}\text{I}]$ AIBG at the early time points. Thyroid uptake of $m[^{131}\text{I}]$ AIBG was 2–3-fold lower than that of $[^{125}\text{I}]$ MIBG, suggesting its inertness to deiodination in vivo.

The specificity of the uptake of the various MIBG analogues in heart and adrenals was determined by measuring the effect of DMI on the uptake in these tissues at 1 h postinjection. As shown in Table 4, DMI reduced the heart uptake of $[^{131}\text{I}]$ CIBG to 58% of the control values; in comparison, $[^{125}\text{I}]$ MIBG uptake was reduced to 48% of its control values, and these reductions are statistically significant ($p < 0.05$). In adrenals, the uptake of $[^{131}\text{I}]$ CIBG and co-injected $[^{125}\text{I}]$ MIBG actually increased in animals pretreated with DMI. While the difference in $[^{131}\text{I}]$ CIBG uptake was statistically significant ($p = 0.03$), that of $[^{125}\text{I}]$ MIBG was not. The heart accumulation of $p[^{131}\text{I}]$ INIBG was reduced to 32% of the control values, and that of co-injected $[^{125}\text{I}]$ MIBG was reduced to 45%. Adrenal uptake of $p[^{131}\text{I}]$ INIBG was also reduced by DMI pretreatment, but the difference was not statistically significant. While DMI did not have any effect on the $[^{131}\text{I}]$ DHIBG uptake in heart, the uptake actually increased in the case of $m[^{131}\text{I}]$ INIBG. Considering the very low myocardial uptake of $m[^{131}\text{I}]$ INIBG, this increase may not have any significance. While the adrenal uptake of both $m[^{131}\text{I}]$ INIBG and $[^{131}\text{I}]$ DHIBG was reduced in the DMI-treated animals, the differences were not statistically significant. The heart uptake of $[^{131}\text{I}]$ -NHIBG was specific as shown by the fact that its uptake was reduced to about 48% of the control values when the mice were pretreated with DMI. As seen with $[^{131}\text{I}]$ CIBG, DMI-treatment increased the adrenal uptake of $[^{131}\text{I}]$ -NHIBG; however, the increase was not statistically significant. DMI did not have any effect on the heart uptake of $[^{131}\text{I}]$ HIMBG. Although the absolute heart uptake of $m[^{131}\text{I}]$ AIBG was considerably lower than that of $[^{125}\text{I}]$ MIBG, it seems to be mediated by the Uptake-1 pathway as it was reduced to roughly half its value by DMI, and the difference was statistically significant.

DISCUSSION

The purpose of this study was to determine the effects of ring- and side-chain substitution in MIBG on the biological properties of the compound. A number of MIBG derivatives were prepared, and most of them, with the exception of CIBG and NHIBG, had polar substituents on the ring (Vaidyanathan et al., 2001). CIBG was developed to investigate whether the encouraging results obtained with FIBG could be extended by substituting fluorine with chlorine. The canine adrenomedullary concentration of FIBG was similar to that of MIBG at 0.5 h but increased with time up to 24 h; however, by 72 h, FIBG uptake was less than that of MIBG (Wieland, 1986). On the other hand, uptake of FIBG in SK-N-SH neuroblastoma cells in vitro and mouse heart in vivo at 72 h and beyond was significantly higher than that of

^a Mean ± SD (*n* = 5); values in parentheses are those for MIBG obtained from a paired-label study.

MIBG (Vaidyanathan et al., 1997a). Another of the analogues selected for study was NHIBG, an MIBG derivative with a hydroxyl group on the guanidine side chain. Although the hydroxyl group is polar, modifying the guanidine moiety with a hydroxyl substituent in fact reduces the polarity of guanidine derivatives (Baley and DeGrazio, 1973). Nevertheless, we were interested in studying the effect of an *N*-hydroxy substituent on the biological characteristics of MIBG.

The effect of various substituents on lipophilicity was generally as expected. While introduction of fluorine at the 4-position of MIBG did not alter the lipophilicity substantially, substituting a chlorine increased the lipophilicity of MIBG 4-fold. Introduction of polar substituents such as hydroxyl, nitro, and amino onto the ring indeed reduced the lipophilicity of MIBG. In the case of INBG and AIBG, switching the position of the amino or nitro group from the para to the ortho position resulted in an increased lipophilicity.

Based on studies of the in vitro stability of MIBG and its few analogues, it has been concluded that free iodide is the major decomposition product (Lee et al., 1986; Wafelman et al., 1994b). Very small amounts of *m*-iodobenzylamine and a compound more nonpolar than MIBG, among other impurities, have been detected in the case of [¹³¹I]MIBG (Wafelman et al., 1994b). Most of the derivatives exhibited an in vitro stability comparable to that of MIBG. Although both *p*[¹³¹I]AIBG and [¹³¹I]-HIBG were purified by reversed-phase HPLC, analytical HPLC of a freshly prepared sample of these showed the presence of free iodide. As reported before for other radiotracers (Larsen et al., 1997), this may be due to radiolytic degradation during the Sep-pak concentration. The in vitro stability of the above benzylguanidine derivatives has been studied at 4 °C for extended periods of time (Lee et al., 1986). When *p*AIBG was labeled with ¹²⁵I, less than 1% of radioiodide was formed up to 5 days. On the other hand, 5% of free iodide was generated from *p*[¹³¹I]AIBG at 30 h. [¹²⁵I]HIBG was less stable than *p*[¹²⁵I]AIBG and gave rise to about 2% radioiodide at 42 h. In the current study, the stability was studied for only a short duration; however, a higher, more biologically relevant temperature was used. No extensive deiodination was seen under these conditions.

[¹³¹I]DHIBG, a [¹³¹I]HIBG analogue with an additional hydroxyl group, degraded completely during the 24 h period. A considerable amount of an unidentified, nonpolar product was the major component at 4 h. Both [¹³¹I]-DHIBG and this nonpolar product deiodinated completely

by 24 h. A peak more nonpolar than the parent compound was also seen by HPLC in the case of [¹³¹I]NHIBG. While *p*[¹³¹I]INBG remained fairly intact, a considerable amount of the meta isomer decomposed to a product more polar than the parent benzylguanidine.

The specificity of the various MIBG analogues for NET was determined by paired-label uptake assays using SK-N-SH human neuroblastoma cells (Vaidyanathan and Zalutsky, 1993; Vaidyanathan et al., 1994, 1995, 1997a). Because the uptake is dependent on the passage number of the cells (Lashford et al., 1991; Vaidyanathan et al., 1995), the uptake of the [¹²⁵I]MIBG control varied from assay to assay. Only *nca* [¹³¹I]CIBG showed specific uptake comparable to that of [¹²⁵I]MIBG; in fact, its specific uptake (116.7 ± 9.6%) was higher than that of [¹²⁵I]MIBG. This is similar to the result observed for both ¹⁸F- and ¹³¹I-labeled FIBG (Vaidyanathan et al., 1994, 1997a), and may be due in part to the increased lipophilicity as a result of the introduction of a halogen substituent.

The specific uptake of *p*[¹³¹I]INBG prepared by exchange radioiodination (specific activity = ~5 mCi/mg) was 50.4 ± 3.6% that of [¹²⁵I]MIBG. The lower uptake could not be due to the presence of the carrier, because no saturation in uptake was seen at this activity concentration when [¹³¹I]MIBG of similar specific activity was used (Vaidyanathan and Zalutsky, 1993). Switching the -NO₂ group to the 5-position resulted in complete destruction of NET specificity. This lack of specificity indicates that NET may have some steric requirements for its substrates. [¹³¹I]NHIBG had a specific uptake 12.3 ± 2.0% that of [¹²⁵I]MIBG, corroborating the earlier observation that alterations in the guanidine function are detrimental to NET-mediated uptake.

It was disappointing to note that [¹³¹I]DHIBG, the MIBG analogue structurally similar to norepinephrine, did not have any significant uptake in SK-N-SH cells. Although norepinephrine is also very polar, the lack of specificity of [¹³¹I]DHIBG for NET may be a result of its poor trans-membrane transport due to its very high polarity. The MIBG analogue with one hydroxyl group at the 4-position (HIBG) has been shown to be an excellent analogue of MIBG with respect to its adreno-medullary uptake in dogs (Lee et al., 1986). It was anticipated that capping of the 3-hydroxyl group in DHIBG with a group such as methyl (HIMBG) might enhance its specific uptake; however, this was not the case. It is unclear whether this is an intrinsic property

of HIMBG or whether it was rapidly converted to DHIBG within the cells.

Like HIBG, the 4-amino-substituted MIBG (*p*AIBG) has also been shown to be an excellent MIBG analogue (Lee et al., 1986). While it is easy to introduce iodine at the ortho and para positions of hydroxyl and amino groups of phenols and anilines, respectively, the resultant iodophenols and iodoanilines are more susceptible to deiodination. We developed a radiosynthesis of 3-amino-5-iodobenzylguanidine anticipating it to be more stable, and thus a better analogue than *p*[¹³¹I]AIBG. However, it did not show any specificity for NET in the SK-N-SH cells. Based on the lack of specificity of various MIBG derivatives in which both 3- and 5-positions were occupied, it may be fair to conclude that the presence of substituents at both meta positions in MIBG may be counterproductive. It has been reported that while 3,4-diiodobenzylguanidine exhibited high adrenomedullary uptake despite its *in vivo* instability, relocating the 4-iodo substituent to the 5-position resulted in substantial reduction in the adrenomedullary uptake (Wieland et al., 1984; Wieland, 1986).

Based on the above results, it is tempting to speculate that polar substituents in the ring of MIBG adversely affect its NET specificity. While HIBG and *p*AIBG exhibit heart and adrenomedullary uptake in dogs and monkeys, no studies have been done to demonstrate their specificity of uptake in tumor cells such as SK-N-SH. As described earlier, there are variabilities in MIBG uptake from tissue to tissue. To determine the specificity of these two compounds for potential oncologic applications, we investigated their uptake in SK-N-SH neuroblastoma cells. The results (Figure 1 and Table 3) clearly demonstrate that, although not to the same level as MIBG, these two compounds are taken up by SK-N-SH cells to a considerable degree, suggesting that polar groups such as hydroxyl and amino at the 4-position do not destroy the specificity of uptake in this cell line. The lower uptake of [¹³¹I]HIBG compared to that of *p*[¹³¹I]AIBG is somewhat similar to their behavior in dog adrenal medulla. It may be possible that, once within the cells, [¹³¹I]HIBG is deiodinated to a higher degree than *p*[¹³¹I]AIBG.

One of the motivations for investigating CIBG is the enhanced retention of FIBG seen in SK-N-SH cells *in vitro* (Vaidyanathan et al., 1997a). From a paired-label study, it was clear that SK-N-SH cells retained [¹²⁵I]CIBG specifically to an even higher degree than [¹³¹I]FIBG. Thus, potentially higher tumor doses might be delivered by [¹³¹I]CIBG compared to [¹³¹I]FIBG. At least part of the enhanced retention may be as a result of the higher lipophilicity of CIBG. It may also be possible that the halogen substituent alters the rate and the pathway of metabolism of MIBG. For example, MIBG is metabolized to HIBG, albeit to a small degree, within pheochromocytoma in humans (Mangner et al., 1986). It is not clear how the presence of a 4-substituent would alter this pathway. It is known that microsomal cytochrome P-450 hydroxylates *o*- and *m*-fluoroanilines at the para position. On the other hand, it defluorinates as well as *o*-hydroxylates *p*-fluoroaniline (Rietjens and Vervoort, 1989). Studies are in progress to determine *in vitro* metabolism of MIBG and its fluoro and chloro analogues.

A number of the novel analogues were further evaluated by determining their biodistribution in normal mice. Thyroid uptake of [¹³¹I]CIBG was 2–3-fold higher than that for [¹²⁵I]MIBG, suggesting that, contrary to the *in vitro* stability results, chlorine at the 4-position makes MIBG more prone to deiodination *in vivo*. While fluorine substitution at the 4-position increased the stability of

[¹³¹I]MIBG (Vaidyanathan et al., 1997a), it had a destabilizing effect on the astatinated derivative (Vaidyanathan et al., 1997b). These results are somewhat enigmatic and cannot be easily rationalized. Another important difference in the biodistribution of [¹³¹I]CIBG was its higher blood uptake. Because bone marrow is a critical organ with respect to the radiation dose it can receive, it is not desirable to have persistent activity in the circulation. Most of the MIBG in the circulation was found to be in the erythrocyte fraction, and its movement from erythrocyte to plasma is not clearly understood (Sisson and Wieland, 1986). Because more lipophilic compounds are sequestered into erythrocytes rapidly (Zimmerman et al., 1987; Zou et al., 1998), it is reasonable to suggest that CIBG is taken up and probably retained by erythrocytes to a greater extent than MIBG and FIBG.

The uptake of *p*[¹³¹I]INBG in tissues such as spleen, blood, thyroid, and lungs was considerably higher than that of [¹²⁵I]MIBG. The uptake in these tissues was similar to that seen for free iodide (Garg et al., 1990). This suggests that, although it was found to be stable *in vitro*, *p*[¹³¹I]INBG underwent rapid deiodination *in vivo*, and that the observed biodistribution may be that of a combination of free iodide and intact molecule. The isomeric compound *m*[¹³¹I]INBG was developed to hopefully augment the inertness to deiodination. Paradoxically, while it was more unstable than *p*[¹³¹I]INBG *in vitro*, *in vivo* results suggested it to be more stable. Nonetheless, results from both *in vitro* experiments using SK-N-SH cells and that from *in vivo* in mouse showed it to be a poor analogue of MIBG.

While the uptake of [¹³¹I]NHIBG in adrenals and a number of other tissues was comparable to that of [¹²⁵I]MIBG, it had a lower heart uptake at early time points. This corroborates the results obtained from *in vitro* experiments and suggests that introduction of a hydroxyl group on the guanidino function results in the diminution of NET specificity. Results shown for [¹³¹I]DHIBG, [¹³¹I]HIMBG, and *m*[¹³¹I]AIBG in Table 4 clearly demonstrate that, as seen in the *in vitro* system, these MIBG derivatives are not suitable substrates for NET. This suggests that this transporter possibly accepts aromatic substrates with one vacant meta position.

In conclusion, among a number of ring- and side-chain-substituted, radioiodinated MIBG analogues developed, only [¹³¹I]CIBG showed higher uptake by SK-N-SH human neuroblastoma cells *in vitro* than [¹²⁵I]MIBG. However, its biodistribution data in normal mice suggest that it may not have any advantage over MIBG. While polar substituents are tolerated at the 4-position, it appears that the 5-position needs to be left unsubstituted. We are currently taking a prodrug approach to developing MIBG analogues with masked polar substituents. Hopefully with this strategy, tumor uptake may not be hindered, and at the same time faster normal tissue clearance of the deprotected metabolites may occur.

Pretargeting with Amplification Using Polymeric Peptide Nucleic Acid

Y. Wang, F. Chang, Y. Zhang, N. Liu, G. Liu, S. Gupta, M. Rusckowski, and D. J. Hnatowich*

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, Worcester, Massachusetts 01655. Received March 8, 2001; Revised Manuscript Received June 13, 2001

One goal of this investigation was to develop a polymer conjugated with multiple copies of peptide nucleic acid (PNA) and with pharmacokinetic properties suitable for applications in vivo. The second goal was to establish whether the multiple copies of PNA on the polymer could be targeted by hybridization in vitro and in vivo with ^{99m}Tc -labeled complementary PNA (cPNA). If successful, this approach could then be considered in further investigations as an alternative to existing pretargeting approaches because of the potential for signal amplification in the target. A 80 KDa poly(methyl vinyl ether-*alt*-maleic acid) (PA) polymer was conjugated with multiple copies of PNA and with multiple copies of poly(ethylene glycol) (PEG) by reacting the NHS derivative of PA with the amine derivatives of PNA and PEG. Using ^{99m}Tc -MAG₃-cPNA, targeting of PNA-PA-PEG was studied in vitro and in vivo in inflammation and tumor mouse models, in both cases relying upon nonspecific diffusion for localization. In addition, cPNA-avidin was considered as a clearing agent with biotinylated PNA-PA-PEG. About 80 PNAs could be conjugated to PA provided that about 200 PEGs were also conjugated to raise the aqueous solubility of the PNA-PA-PEG polymer lowered by the addition of the PNAs. About 70% of the PNAs on this polymer in vitro either in solution or attached to beads could be successfully targeted with ^{99m}Tc -cPNA. In both the inflammation and tumor mouse models, between 35 and 60% of these PNAs could be targeted in the lesions. The advantage of amplification was evident when less favorable results were obtained with PNA-PA-PEG conjugated with only six PNAs. We conclude that amplification can be achieved in vivo using polymers of PNA followed by radiolabeled complementary PNA and that the application of pretargeting using polymers of PNA for amplification can improve localization.

INTRODUCTION

Since pretargeting was first introduced (1), an improvement in target/nontarget radioactivity ratios over conventional imaging has been documented in many animal and patient imaging studies. With few exceptions (2, 3), pretargeting has been achieved through the use of (strept)avidin and biotin (4–7). Mathematical modeling of pretargeting has shown clearly the importance to pretargeting of high affinities between the molecular pair employed (8). (Strept)avidin and biotin admirably satisfy this criteria as a result of an affinity of approximately 10^{-15} M (9).

Despite the obvious success of pretargeting applications with (strept)avidin and biotin, use of this molecular pair is not without its difficulties. Unless properly designed, biotin analogues carrying the radiolabel are subject to biotinadase degradation (10). Streptavidin has been found to be immunogenic when conjugated to antibodies (11). Finally, endogenous biotin (vitamin H), present in all living tissues, can saturate the biotin binding sites of (strept)avidin located in a tumor and thus prevent targeting by radiolabeled biotin (12, 13).

Complementary oligonucleotides such as deoxyribonucleic acids (DNAs) may offer an alternative to (strept)avidin and biotin for pretargeting that avoids these difficulties. Depending upon chain length and base sequence, the affinities for duplex formation of comple-

mentary DNAs in serum environments may approach or even exceed that of (strept)avidin for biotin. Furthermore, single-strand DNAs have been administered repeatedly to patients in large dosages in connection with antisense chemotherapy without evidence of immunogenicities or serious toxicities (14). Finally, there will be no interference from endogenous substances.

Native DNA with its phosphodiester backbone is generally considered unsuitable for pretargeting and other in vivo applications due to rapid degradation by nucleases (15, 16). Fortunately, numerous chemically modified oligonucleotides have been prepared and shown to be stable to nucleases (17). One such modification that, in our view, may be particularly attractive as an alternative to (strept)avidin and biotin for pretargeting, has been named "peptide nucleic acid" (PNA) (18, 19). This synthetic oligomer consists of (2-aminoethyl) glycines to which the nitrogenous based (nucleobases) are attached via methylenecarbonyl linkers. PNAs are reported to be stable to proteases as well as nucleases (20), to show hybridization affinities greater than that of DNA (21) and to be nontoxic (20).

This laboratory has previously considered PNAs for pretargeting applications (22). In that study, pretargeting was investigated in both an inflammation and tumor mouse model in which streptavidin saturated with biotinylated PNAs was administered first and allowed sufficient time to accumulate by nonspecific diffusion in the target. At that point, the radiolabeled complementary PNA was administered. For both models, pretargeting was successfully accomplished to judge by improved

lesion accumulation and improved lesion/normal tissue ratios relative to controls.

One property of (strept)avidin and biotin for pretargeting provides the potential of signal amplification by a factor of 4 when the radioactivity is attached to biotin since (strept)avidin possesses four biotin binding sites. However, among the advantages of using oligonucleotides for pretargeting is the potential of amplification far in excess of four. This could be achieved if the first administration consisted of a polymer to which multiple copies of oligonucleotides were bound. There would then be the potential that multiple copies of the radiolabeled complementary oligonucleotide within a second administration could bind with the resulting amplification of the radioactivity localized in a target containing the polymer (23).

Amplification, as defined above, obviously requires a multivalent oligonucleotide polymer. In studies preliminary to this report, we considered a number of polymers in a search for platforms upon which a suitable number of PNAs could be attached. These preliminary studies helped to define more clearly the properties needed in a polymer useful for pretargeting PNA applications: the polymer must be large enough to carry sufficient numbers of PNAs; the PNA polymer should be water soluble and stable both in saline and serum; the pharmacokinetic properties must be favorable, and the PNAs must be arranged on the polymer such that binding is not unduly hindered sterically. One of the polymers we considered was found to possess suitable properties and became the focus of this investigation.

Poly(methyl vinyl ether-*alt*-maleic acid) (PA), as used in this research is a 80 KDa (number average) linear polymer in which carboxylate groups alternate with methyl ether groups. The ethers and the negatively charged carboxylates provide aqueous solubility while the carboxylates are required for conjugation to the amine-derivatized PNAs. There are approximately 920 carboxyl groups per PA polymer molecule. In the course of preliminary studies, it was observed that conjugation of PA with PNA to the desired degree considerably reduced the aqueous solubility of the polymer unless the number of PNAs per polymer was reduced. Since reducing the number of PNAs could render the polymer less suitable for pretargeting with amplification, the PNA-PA was also conjugated with multiple copies of poly(ethylene glycol) (PEG) to improve water solubility. Ultimately, the polymer used in this investigation was conjugated with an average of 80 PNAs and 200 PEGs per PA molecule. The molecular weight was calculated to be 1400 KDa.

Pretargeting studies by their nature are complex. Among the variable are at least two dosages as well as two time periods, that between injections and that between the last injection and sacrifice or imaging. The complexity increases further if a clearing agent is used. Additional variables unique to this investigation include the nature of the polymer, its molecular weight, the number of PNAs and PEGs attached, and the length and base sequence of both the PNA and the radiolabeled complementary PNA. This report describes our first pretargeting study using PA-PEG conjugates as platforms for PNA designed to display suitable pharmacokinetics in vivo, to localize nonspecifically (i.e., by passive diffusion) in mouse models of focal infection/inflammation and tumor and to provide there a target for ^{99m}Tc labeled complementary PNA (cPNA) within a second administration. As is described, in the course of this investigation, one clearing agent was also considered to improve upon the pharmacokinetics of the radiolabel.

MATERIALS AND METHODS

The 15-base single-stranded PNAs were provided as a gift (Michael Egholm, PerSeptive Biosystems, Framingham, MA). Both PNA and cPNA were derivatized with a primary amine on the amino terminus (i.e., 5' equivalent) end via a 17-member ethylene-ether linkage. The cPNA was also prepared occasionally with a biotin group on this end via the same linker. The linker and base sequence of PNA was $\text{NH}_2(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{OCH}_2\text{CONH}(\text{CH}_2)_2\text{O}(\text{CH}_2)\text{OCH}_2\text{CO-TGT-ACG-TCA-CAA-CTA-CONH}_2$ and that for cPNA was (biotin)- or $(\text{NH}_2)-(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{OCH}_2\text{CONH}(\text{CH}_2)_2\text{O}(\text{CH}_2)\text{OCH}_2\text{CO-TAG-TTG-TGA-CGT-ACA-CO NH}_2$ as previously described (19). The expected molecular masses were 4337.23, 4634.57, and 4408.27 Da, respectively, and were observed by mass spectrometry to be 4336.90, 4633.48 and 4407.65 Da. Purity was established by reverse phase HPLC (in all cases showing a single peak) and mass spectrometry (showing one predominant peak). Avidin and methoxypolyoxyethylene amine (MW 5000) were purchased (Sigma Chemical Co., St. Louis, MO). Poly(methyl vinyl ether-*alt*-maleic acid) (PA, number average MW ca. 80 KDa), anhydrous dimethyl formamide (DMF), *N*-methyl-2-pyrrolidinone (NMP), *N*-hydroxysuccinimide (NHS), dicyclocarbodiimide (DCC), and diisopropylethylamine (DIEA) were purchased (Aldrich Chemical Co., Milwaukee, WI). All reagents were used as received without further purification. NHS-MAG₃ was synthesized according to published procedures (24). ^{99m}Tc -pertechnetate was obtained from a ^{99}Mo - ^{99m}Tc radionuclide generator (Dupont, Billerica, MA).

Preparation of MAG₃-Coupled cPNA. Because of different base sequences, PNA is more soluble in aqueous solution than is cPNA. As a consequence, in this investigation PA was always conjugated with PNA while the radiolabel was usually attached to cPNA. Amine-derivatized cPNA was conjugated with NHS-MAG₃ as previously described (24). Briefly, a solution of cPNA was prepared at a concentration of 2–5 mg/mL in 0.25 M sodium bicarbonate–1 M sodium chloride–1 mM EDTA, pH 8.5, with 10–20% (v/v) of acetonitrile occasionally added to improve the solubility of cPNA. A solution of NHS-MAG₃ in anhydrous DMF (50 mg/mL) was then added dropwise to the stirred cPNA solution until a MAG₃ : cPNA molar ratio of 20:1 was reached. This solution was then incubated at room temperature for 30 min. The conjugated oligomer was purified on a 0.7 × 20 cm P4 column (BioRad, Melville, NY) eluted with 0.25 M ammonia acetate buffer, pH 5.2. Fractions off the P4 column were collected, and the absorbency of each was measured (U-2000, Hitachi Instruments, Danbury, CT) using an extinction coefficient at 260 nm determined in this laboratory of 35 $\mu\text{L}/\mu\text{g}$. The modified cPNA was stored at –20 °C for further use.

Radiolabeling of cPNA-MAG₃. A fresh 50 mg/mL sterile solution of sodium tartrate was prepared in 0.5 M sodium bicarbonate, 0.25 M ammonium acetate, 0.18 M ammonium hydroxide, pH 9.2. The high pH of the tartrate solution was necessary to adjust the final pH to approximately 7.6. In addition, a 1 mg/mL solution of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ in 10 mM HCl was prepared just prior to use. To MAG₃-coupled cPNA (about 10–50 μg) contained in a sterile test tube was added the tartrate solution to a final concentration of about 7 $\mu\text{g}/\mu\text{L}$. To this was added sufficient ^{99m}Tc -pertechnetate solution to provide about 100 $\mu\text{Ci}/\mu\text{g}$ of PNA. The stannous ion solution was added immediately thereafter such that 3–4 μg of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ was added for each 10 μL of ^{99m}Tc -pertechnetate solution. Higher activities of ^{99m}Tc required proportionately larger

Figure 1. Schematic illustrating the preparation of NHS-PA and its conjugation with PNA and PEG.

volumes of the tin solution. After 40 min at room temperature, the labeled cPNA was purified on a 0.7×20 cm P4 gel filtration column using sterile pH 7.2 PBS eluant. Radioactivity and absorbency at 260 nm were used to identify and quantitate peak fractions. Preparations were routinely analyzed by size exclusion HPLC using a 1×30 cm Superose 12 column (Pharmacia, Piscataway, NJ).

Control labelings were performed in which the native, unconjugated cPNA was subjected to the identical labeling procedure to assess the extent of nonspecific labeling. In all cases, nonspecific radiolabeling was less than 5%.

PA Conjugation. Figure 1 illustrates the method of PNA and PEG conjugation to PA. As the first step, the NHS derivative of PA was prepared. With stirring, 20 mg of PA (0.230 mmol carboxyl groups) and 26 mg of NHS (0.226 mmol) were dissolved in 1 mL of anhydrous DMF, and the solution was cooled to 0°C . To this was added 48 mg of DCC (0.233 mmol) in 1 mL of anhydrous DMF. The molar ratio of NHS and DCC to carboxylate groups on PA was therefore about 1:1. Immediately after the addition of DCC, the solution was put on ice and kept at 0°C for 24 h. The dicyclohexylurea precipitated slowly and was filtered off at the end of the reaction. The NHS-PA solution at a concentration of 10 mg/mL was stored at -20°C and was used without further purification.

Typically, about 200 μg of the amine-derivatized PNA (0.046 μmol) was dissolved in 150 μL of anhydrous DMF and 150 μL of anhydrous NMP. To this solution were added 466 μg methoxypolyoxyethylene amine (Me-PEG-NH₂, MW 5000, Sigma, 0.093 μmole) and 3 μL anhydrous DIEA. After thorough vortexing, 100 μg of the NHS derivatized PA in dry DMF (1.15 μmol carboxyl groups) was added, and the solution thoroughly vortexed again. After 2 h at room temperature, the unreacted NHS ester was hydrolyzed by the addition of water to the reaction mixture. Early studies showed that ^{99m}Tc -labeled PA-PNA polymer localized in the liver of normal mice to an unacceptable extent ($>40\%$ id/g). This unfavorable biodistribution was considered to be due to the decreased aqueous solubility of PA when conjugated with 80 PNAs per molecule. Rather than reducing the number of PNA groups, which could adversely influence amplification, the biodistribution properties of the polymer were improved by conjugating the PA with poly(ethylene glycol) (PEG) as shown in Figure 1. The conjugation of PA with PNA and PEG was accomplished simultaneously. The molar ratio of PNA to PA was usually 100:1. In most cases, the molar ratio of PEG to PA was 200:1.

The average number of accessible PNA groups per PA was estimated using an aliquot of the conjugated polymer solution prior to purification. After adding tracer radio-labeled cPNA, the areas under the polymer peak and under the free PNA-cPNA duplex peak were compared in the radioactivity HPLC profile (Figure 2). The synthesized polymer was purified over a Sephadex G100

Figure 2. Size exclusion HPLC profiles of conjugated but unpurified PNA-PA-PEG after the addition of ^{99m}Tc -cPNA. Both UV and radioactivity traces are presented.

column (1×30 cm) using sterile water as eluant. The conjugated PA was stored in sterile water solution at -20°C .

The average number of PEGs per PA molecule was estimated using an aliquot of the conjugated polymer solution prior to purification. Using TNBS (trinitrobenzene sulfonic acid) (25), the number of free amine groups present due to unreacted PEG was quantitated and corrected for the contribution of free amine groups by PNA (the nitrogenous bases of PNA do not contribute in this assay). An aliquot of the reaction mixture containing a total of about 200 μg of PEG was removed to a glass tube and the solvent completely evaporated away with dry nitrogen. The residue was dissolved in 1 mL of 0.1 M sodium bicarbonate. To this solution was added 0.5 mL of 0.01% TNBS in 0.1 M sodium bicarbonate. After vortexing, the solution was incubated at 37°C for 2 h. After adding 0.5 mL of 10% SDS and 0.25 mL of 1 M HCl, the absorbance was measured at 335 nm. Free PEG was used to construct a standard curve. Under these conditions, the conjugation of PA with PEG was virtually quantitative.

Surface Plasmon Resonance Measurements. Recent improvements in instrumentation for biomolecular interaction analysis (BIA) has made it easier to measure rates of association and dissociation directly. Thus, BIA may be used to measure the rate of binding of an analyte on a surface to which its partner has been immobilized (26). The detection principle relies on surface plasmon resonance, an optical phenomenon that arises when light illuminates thin conducting films under specific conditions. Surface plasmon resonance forms the basis of BIA and permits the generation of sensorgrams in which the

refractive index changes due to this binding are measured in resonance units (RUs) (27).

In this investigation, surface plasmon resonance was used to estimate the association rate constants for duplex formation between immobilized cPNA and PNA both free and attached to PA polymer. In addition, the association rate constant between immobilized cPNA and PNA-PA-PEG with an average of 6 and 80 PNAs per PA was measured. The analysis was performed on a BIAcore-1000 (BIAcore, Piscataway, NJ) instrument operating at room temperature. Biotinylated-cPNA was added to a streptavidin-dextran-coated sensor chip only until a response of about 200 RUs was reached. The absence of mass transfer effects was confirmed by running separately one concentration of free PNA and one concentration of each PA polymer at three different flow rates (10, 30, and 75 $\mu\text{L}/\text{min}$) and demonstrating identical RU responses in all cases. Solutions of free PNA and both PA polymers were prepared at six concentrations (0.0 to 5.0 μM with respect to PNA) in the same running buffer (10 mM HEPES, 150 mM sodium chloride, 3.4 mM $\text{Na}_2\text{-EDTA}$, 0.005% P20, pH 7.4). Each analysis consisted of two measurements. A sample was first applied to a control surface consisting of an identical streptavidin-dextran-sensor chip but to which biotinylated PNA rather than cPNA had been added. Subtraction of the sensorgram obtained with the control surface from that obtained with the test surface at each concentration corrected for bulk refractive index changes. Following subtraction, the resulting sensorgrams were analyzed using instrument software (BIAevaluation 3.0, BIAcore) by assuming 1:1 Langmuir interaction.

Radiolabeling PNA-PA-PEG. To determine the bio-distribution of PNA-PA-PEG, the polymer was radiolabeled with $^{99\text{m}}\text{Tc}$ by adding a trace amount (about 10 μCi) of $^{99\text{m}}\text{Tc}$ -cPNA to 16 μg of the polymer in saline. The solution was repeatedly vortexed and incubated at room temperature for 20 min before administration.

In Vitro Stability of PNA-PA-PEG. Size exclusion HPLC was used to assess the stability of PNA-PA-PEG in serum. The polymer was incubated in fresh human serum at 37 $^{\circ}\text{C}$ at a concentration of 40 $\mu\text{g}/\text{mL}$, and aliquots were removed at different intervals over 24 h. To each aliquot, $^{99\text{m}}\text{Tc}$ -labeled cPNA was added in the identical fashion to radiolabel the polymer by hybridization.

Clearing Agents. Avidin conjugated with biotinylated cPNA was added as a clearing agent to reduce levels of the polymer in blood and in most normal tissues just prior to the administration of the radiolabeled cPNA. The cPNA-avidin was prepared by adding 200 μg of avidin to 40 μg of biotin-cPNA in 400 μL saline. The solution was gently vortexed, incubated at room temperature for 1 h and used without purification.

In Vitro Studies. The concept of pretageting with amplification was tested in vitro using streptavidin-coated magnetic beads 0.96 μm in diameter (Bangs Laboratories, Inc., Fishers, IN). The in vitro study consisted of three parts: involving beads without PNA (nonspecific), beads with PNA but without the addition of PNA-PA-PEG (specific without amplification), and beads with cPNA but with the addition of PNA-PA-PEG (specific with amplification).

In Vivo Biodistribution Studies. Normal CD-1 male mice (mean weight 26 g, Charles River, Wilmington, MA) were injected via a tail vein with 0.15 mL of 50 mM PBS containing 16 μg (10–12 μCi) of labeled PNA-PA-PEG. At 3 h, the animals were anesthetized with metofane (Schering-Plough, Omaha, NE) and sacrificed by cervical

dislocation. Following sacrifice, animals were dissected to provide samples of tissue for counting in a NaI (TI) well counter along with a standard of the injectate. Results were expressed as percent of injected dose per gram of tissue (% id/g).

To prepare the inflammation mouse model, a clinical isolate of *Escherichia coli* (American Type Culture Collection, Rockville, MD) was grown in LB medium (Sigma) to a density of 10^8 organisms/mL. Male CD-1 mice (Charles River) weighing approximately 30 g were anesthetized by inhalation of metofane and inoculated subcutaneously in the posterior right thigh with 0.1 mL of the bacterial suspension. Swelling was apparent after 14 h. At this time 16 μg of PNA-PA-PEG was administered through a tail vein. After 3 h, each animal received 2 μg (about 100 μCi) of radiolabeled cPNA by the same route. Two control groups of animals were used. One group (control 1) received in identical fashion the radiolabeled cPNA without having previously received the PNA-PA-PEG polymer. Another group (control 2) received in identical fashion PNA-PA-PEG but received $^{99\text{m}}\text{Tc}$ -labeled PNA instead of labeled cPNA. The anesthetized animals were imaged at 3 h post administration of the radioactivity and were then killed by cervical dislocation. Along with other tissues, the entire infected right leg and, for comparison, the whole left leg, was removed for counting.

To prepare the mouse tumor model, ACHN cells (American Type Culture Collection, Manassas, VA) were grown in minimal essential medium (Gibco, Grand Island, NY). The cells were removed from the culture flask by trypsinization and then washed in the culture media. Swiss male nu/nu mice (Taconic Labs, Germantown, NY) were each injected subcutaneously in the posterior left thigh with 3×10^6 cells each in 0.1 mL of medium. Two weeks later, when the tumors were approximately 0.6 cm in diameter, each animal received 16 μg of PNA-PA-PEG and, 3 h later, received 2 μg of $^{99\text{m}}\text{Tc}$ -cPNA. The animals were imaged 3 and 18 h later. Control animals received the radiolabeled cPNA without the prior administration of PNA-PA-PEG. After 18 h, all mice were sacrificed and tissues obtained for counting.

When under investigation, the clearance agent was administered in different dosages but always 2 h after the administration of PNA-PA-PEG polymer and 1 h before the administration of $^{99\text{m}}\text{Tc}$ -cPNA.

Imaging Studies. Scintigrams were acquired using a portable large field of view scintillation camera (Elscent APEXD 409M, Hackensack, NJ) equipped with a parallel-hole, medium-energy collimator and under computer control (Elscent APEX F1). Animals were anesthetized with nembutal (Abbott Laboratories, North Chicago, IL) and were then positioned directly on the collimator. Typically, several animals were imaged simultaneously at 3 h post administration of the radiolabel.

RESULTS

Conjugation Efficiencies. The HPLC profiles of PNA-PA-PEG, after conjugation but before purification are presented in Figure 2 for both radioactivity and UV detection at 260 nm. In both profiles, the peaks at 32–34 min are due to free PNA while that at 14 min is due to PNA-PA-PEG. A value of 80 for the average number of PNAs per PA was calculated on the basis of the ratio of UV peak areas. In this research, the PA-PEG polymer was also conjugated at a 10:1 PNA to PA molar ratio. By applying the same analysis, a value of 6 PNAs/PA was determined for this polymer. At 260 nm, the absorbance of PA and PEG are negligible.

Figure 3. Typical room-temperature sensograms after subtraction for the hybridization of PNA-PA-PEG with cPNA immobilized on the sensor chip. Traces are presented at one concentration for PA conjugated with 80 and with 6 PNAs per polymer.

The HPLC profiles presented in Figure 2 were also used to determine the number of PNAs conjugated to PA that are accessible in solution. The ^{99m}Tc -cPNA added to unpurified PNA-PA-PEG distributes between free PNAs and PNAs accessible on the polymer according to their relative concentrations. Since the free PNA is unquestionably accessible, the radioactivity under the 32–34 min peaks was used to calculate the number of counts per accessible PNA. This value was then applied to the radioactivity of the 14 min peak. In this way the number of PNAs on PNA-PA-PEG accessible in solution was estimated to be about 60. The average number of PEGs per PA molecule was determined as described above to be about 200.

Surface Plasmon Resonance. Figure 3 presents typical sensograms for the hybridization of PNA-PA-PEG to immobilized cPNA obtained at room temperature and after subtraction showing association during injection followed by dissociation. Curves are presented at one concentration for both PNA-PA-PEG conjugated with 80 and 6 PNAs/PA. The higher response observed for PA conjugated with 80 PNAs compared to 6 PNAs was expected and confirms that a higher number of PNAs are available for hybridization in the case of this polymer.

As was observed previously for DNAs (28), the slow dissociation rate of these oligomers is below the detection limits of the method. Accordingly, it was not possible to measure an equilibrium constant although, as before, it was possible to measure the association rate constants. For the 80 and 6 PNAs/PA, respectively, the association rate constant was measured as 1.5 and $1.1 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ ($N = 3$). Because each polymer presumably attaches to several immobilized cPNAs on the sensor chip, the absolute value of the association rate constant based on 1:1 Langmuir binding may be unreliable. Nevertheless, that these values are of the same order of magnitude suggests that the kinetics of binding probably is the same for both polymers. Furthermore, since the association rate constant for free PNA was measured as $1.2 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$, the hybridization of the polymer may therefore have been about 10 fold faster than that of free PNA. A faster association may be expected for polymer with multiple PNAs. Finally, these values suggest that the method used to conjugate PNA to PA probably have not chemically altered the nitrogenous bases of the oligomer.

Stability of PNA-PA-PEG in Serum. The results presented in Figure 4 demonstrate that PNA-PA-PEG is stable in 37°C serum environments. The addition of ^{99m}Tc -cPNA to aliquots of serum containing PNA-PA-PEG

Figure 4. Size exclusion HPLC radiochromatograms of ^{99m}Tc -cPNA added at different times to a 37°C serum incubate of PNA-PA-PEG.

shows essentially no change in the distribution of the radiolabel between hybridized polymer and free ^{99m}Tc -cPNA even after 24 h of incubation.

In Vitro Amplification Studies. The concept of pretargeting with amplification was tested in vitro using streptavidin-coated magnetic beads. Radiolabeled cPNA was added identically to beads prepared in three different manners: beads without PNA (nonspecific binding), beads with PNA but without the addition of PNA-PA-PEG (specific binding and including nonspecific binding), and beads with cPNA and the prior addition of PNA-PA-PEG (specific binding with amplification). Table 1 summarizes the protocol and lists the results.

About $50 \mu\text{L}$ of packed magnetic beads with a total biotin capacity of greater than 100 pmol of biotinylated PNA, according to the manufacturer, was washed and resuspended with the aid of a magnetic holder. Over a period of 20 min at room temperature with periodic vortexing, the beads were bound with $1.0 \times 10^{-3} \mu\text{g}$ (0.22 pmol) of either biotin-derivatized PNA or biotin-derivatized cPNA. Since this addition would occupy only 0.3% of the biotin binding sites, complete PNA or cPNA binding was assumed. After additional washes, the beads were resuspended. To the cPNA beads only was added $0.4 \mu\text{g}$ of PNA-PA-PEG (i.e. 0.29 pmol PA, 23 pmol of PNA) followed by another 20 min incubation at room temperature. The 0.29 pmol of polymer may be expected to saturate the 0.22 pmol of cPNA on the beads leaving about (0.22×80) or 18 pmol of PNA on the beads. These beads were then washed as before and resuspended. To each of the three samples of beads was added $0.12 \mu\text{g}$ ($24.2 \mu\text{Ci}$, 25 pmol) of ^{99m}Tc -cPNA. After incubation for 30 min at room temperature with periodic vortexing, the beads were thoroughly washed for counting in a dosage calibrator and, after sufficient decay, in a NaI(Tl) well counter.

These results show that nonspecific binding is an important contributor to what is referred to above as "specific". Thus, true "specific" binding (minus nonspecific) amounted to only a little more than $0.1 \mu\text{Ci}$ ($0.35 - 0.23$). This result is reasonable since about $0.12 \mu\text{g}$ of labeled cPNA was added to beads containing about $10^{-3} \mu\text{g}$ of PNA for a theoretic maximum binding of only $(10^{-3}/$

Table 1. Experimental Protocol and Results for in Vitro Pretargeting with Amplification Using Three Different Conditions. The Radioactivity on the Beads Follows the Identical Addition of Labeled CPNA, $N = 3$

Table 2. The Biodistribution of PNA-PA-PEG with 0, 100, and 200 PEGs per Polymer Molecule in Normal Mice at 3 h. %id/g (s.d.), $N = 5$

tissue	0 PEGs/ polymer	100 PEGs/ polymer	200 PEGs/ polymer
liver	44 (0.7)	35 (0.4)	13 (1.7)
heart	1.2 (0.2)	1.1 (0.1)	3.5 (0.5)
kidney	5.1 (0.3)	3.5 (0.3)	5.5 (0.8)
lung	1.4 (0.2)	1.0 (0.04)	4.7 (0.7)
spleen	15 (0.8)	11 (2.3)	7.5 (1.5)
stomach	0.8 (0.3)	0.7 (0.1)	1.1 (0.3)
sm. int.	0.7 (0.1)	0.8 (0.2)	1.7 (0.3)
lg. int.	0.8 (0.3)	1.1 (0.1)	1.1 (0.1)
blood	1.1 (0.2)	0.6 (0.1)	25 (1.5)
muscle	0.3 (0.02)	0.3 (0.1)	0.8 (0.2)

$0.12 \times 24 \mu\text{Ci}$) or about $0.20 \mu\text{Ci}$. In the case referred to above as “specific with amplification”, the 25 pmol of labeled cPNA was added to beads which should contain 18 pmol of PNA if amplified by the presence of 80 PNAs per PA. If 18 pmol of ^{99m}Tc -cPNA was now to bind (i.e., saturation of PNA on PA), there will be about $[(24 \mu\text{Ci}/25 \text{ pmol}) \times 18 \text{ pmol}]$ or $17 \mu\text{Ci}$ on the beads. This value is in agreement with the $15 \mu\text{Ci}$ observed and suggests that the radiolabeled cPNA has access to PNA on PA-PEG and the accessible PNAs on each immobilized PNA-PA-PEG molecule is about $[(15/17) \times 80]$ or 70. Since a value of 60 accessible PNAs per polymer molecule was determined from the UV and radioactivity HPLC profiles, the value of 70 PNAs per polymer molecule measured in the bead study suggests that the PNAs on immobilized polymer are equally accessible to the polymer in solution.

Normal Mouse Biodistributions. The biodistributions of PNA-PA-PEG with 80 PNAs but with 0, 100 and 200 PEG per polymer are shown in Table 2. The molecular weights of the polymers were calculated to be 427, 927 and 1427 KDa, respectively.

The results of Table 2 show that when PA is conjugated with 80 PNAs, the polymer must also be conjugated with more than 100 PEGs to achieve what may be a satisfactory biodistribution. Otherwise, liver levels are excessively high at about 40% id/g, blood clearance is rapid with blood levels showing only about 1% id/g at 3 h. However, when the polymer is conjugated with 200 PEGs, the liver level drops to 13% and the blood level rises to 25%.

Influences on Inflammation Imaging of PNAs per Polymer. To investigate the influence of the number of PNAs per polymer, PA-PEG was conjugated with either 80 or 6 PNAs. The molecular weights were calculated as 1427 and 1106 KDa, respectively. Figure 5 presents representative images of inflammation mice at 3 h post administration of ^{99m}Tc -cPNA in animals receiving the polymer conjugated with 6 PNAs (left) vs 80 PNAs (right). Table 3 lists the biodistribution results.

In the above table, differences in tissue values between the two polymers are significant in all cases ($P < 0.005$). These results show clearly the advantage of increasing the number of PNAs per PA. While the accumulation of radioactivity increased in all tissues sampled (for example, the target in the infected thigh increased about

7-fold), the target/nontarget ratio are more favorable in all cases. The 22% difference in molecular weight between the two polymers is unlikely in itself to alter the biodistribution to the extent shown.

Infection Studies without Clearance Agents. Table 4 presents biodistribution results in mice infected in one thigh with *E. coli* and obtained 3 h. post iv administration of labeled cPNA and 6 h post iv administration of PNA-PA-PEG. Results are presented for the study animals and for two sets of control animals. One set of animals (control 1) did not receive the first administration of PNA-PA-PEG while the second set (control 2) received the PNA-PA-PEG in the identical manner but received radiola-

Figure 6. Two pairs of images of infected mice receiving PNA-PA-PEG followed by radiolabeled cPNA 3 h later. Whole body images obtained at 3 h post administration of ^{99m}Tc -cPNA. In each pair, the control animals is on the left. The location of the inflammation in the thigh is indicated by the arrows.

beled PNA instead of radiolabeled cPNA in the second injection. The PA was conjugated with 200 PEGs and 80 PNAs.

With the exception of stomach and large intestines, tissue radioactivity levels are significantly higher in the study animals compared to the control animals. This increase is related to the presence in infected and normal tissues of PNA-PA-PEG in concentrations sufficient to bind the radiolabeled cPNA in the second injection.

These values may be used to calculate the percentage of PNAs on PA in the lesion which are targeted with radiolabeled cPNA. From the biodistribution of radiolabeled PNA-PA-PEG in infected mice (data not presented) about 4% id/g of the polymer accumulates in the target at 3 h and, as such, about 35% of the PNAs on PA were targeted in each gram of lesion. This value represents a decrease from the 60–70% of PNAs targeted on the polymer when in solution or when bound to beads *in vitro* but is still considerable for *in vivo* targeting.

The mean inflamed to normal thigh ratios from the results presented in Table 4 are 4.0, 0.89, and 1.4 for the study and two groups of control animals, respectively. The differences between study and each control animals are significant. Thus, this ratio has been more than doubled by the prior administration of the polymer. Moreover, the mean uptake in the infected thigh of animals receiving the polymer has been increased a factor of 40 over the infected thighs of control animals not receiving the polymer. Finally the inflamed thigh to tissue radioactivity ratios are higher for the study animals in all tissues compared to the control animals, except for blood.

The two pairs of whole body images in Figure 6 are representative of the infected animals. Both control animals show radioactivity in bladder with faint accumulation in the target thigh. In each pair, the image on the left is of the study animals showing similar activity in bladder, increased activity in liver and, in particular, increased uptake in the infected thigh.

Tumor Studies without Clearing Agents. Table 5 presents biodistribution results in nude mice implanted in one thigh with the ACHN tumor. The results were obtained at 18 h post administration of labeled cPNA and 21 h post iv administration of PNA-PA-PEG. Results are presented for both the study and control animals (animals not receiving PNA-PA-PEG).

Tissue radioactivity levels are again significantly higher in most tissues for the study animals compared to the control animals. This increase is again related to the presence of PNA-PA-PEG in concentrations sufficient to bind the radiolabeled cPNA in the second injection.

The mean tumored to normal thigh ratios from the results presented in Table 5 are 14.6 and 2.0 for the study and control animals, respectively. As in the study of the

Table 5. the Biodistribution Results in Tumored Nude Mice 18 h Post Administration of Radiolabeled CPNA and 21 h Post Administration of PNA-PA-PEG. ID%/gm (s.d.), $N = 5$

tissue	study mice	control mice
liver	4.0 (0.6)	0.2 (0.04)
heart	0.4 (0.1)	0.01 (0.01)
kidneys	0.6 (0.1)	0.31 (0.03)
lung	0.4 (0.1)	0.02 (0.01)
spleen	3.9 (0.5)	0.06 (0.02)
stomach	0.3 (0.1)	0.3 (0.2)
sm. int.	0.5 (0.1)	0.08 (0.03)
lg. int.	3.7 (0.8)	1.8 (0.5)
blood	1.1 (0.2)	0.03 (0.02)
muscle	0.1 (0.02)	0.01 (0.003)
tumor	1.9 (0.4)	0.02 (0.01)

Figure 7. Two pairs of images of tumored mice receiving PNA-PA-PEG and radiolabeled cPNA 3 h later. Whole body images obtained at 3 h (left images) and 18 h (right images) post administration of ^{99m}Tc cPNA. In each pair, the control animal not receiving the polymer is on the left. The location of the tumor in the thigh is indicated by the arrows.

infected mice, prior administration of the PNA-PA-PEG has significantly improved the uptake ratio. Moreover, the mean uptake in the tumored thighs has been increased a factor of 90 over that in the tumored thighs of control animals not receiving the PNA-PA-PEG polymer. Finally, the tumored thigh to tissue radioactivity ratios are higher for the study animals compared to the control animals in all tissues.

These values may be used to calculate the percentage of PNAs on PA in the tumor that are targeted with radiolabeled cPNA. From the biodistribution of radiolabeled PNA-PA-PEG in tumored mice (data not presented), at 3 h post administration, about 2.5% id/g of the polymer accumulates in the target and, as such, about 58% of the PNAs on PA were targeted by radiolabeled cPNA. This is compared to the 35% targeting in the inflammation model and is equal to the 60–70% of PNAs targeted on the polymer *in vitro*.

The whole body images of Figure 7 were obtained at 3 and 18 h post administration of radiolabeled cPNA and are representative of the tumored animals. On the left of each pair is the image of a control animal not receiving the polymer.

Inflammation Studies with Clearing Agents. Avidin-cPNA was prepared by mixing avidin with biotin-cPNA as described above. Mice were administrated IV either 0, 1, 3, 6, or 15 μg of avidin-cPNA 2 h after the iv injection of PNA-PA-PEG and 1 h before the administration of radiolabeled cPNA. The results are presented in Table 6 while Figure 8 presents representative images of animals receiving 0, 3, and 6 μg of this clearing agent. Under these circumstances, a 6 μg dosage appears to be optimum in terms of improving the target/nontarget ratios without excessively decreasing accumulation in the target.

Tumored Studies with Clearing Agent. Mice were administrated IV either 0 and 6 μg of avidin-cPNA 2 h after the first injection of PNA-PA-PEG and 1 h before the administration of radiolabeled cPNA. Table 7 presents the biodistribution results.

Biodistribution at 3 h Post Administration of Radiolabeled CPNA and 6 h Post Administration of PNA-PA-PEG to Tumor-bearing Mice Receiving Varying Amount of Avidin-cPNA as Clearance Agent. %id/g (s.d.), *N* = 5**

tissue	dosage of avidin-cPNA	
	0 μ g	6 μ g
liver	8.1 (0.6)	1.8 (0.2)
heart	1.5 (0.1)	0.2 (0.02)
kidney	3.1 (0.2)	2.0 (0.3)
lung	2.8 (0.1)	0.5 (0.1)
spleen	7.4 (2.1)	0.8 (0.2)
stomach	1.9 (0.2)	1.4 (0.2)
sm. int.	1.5 (0.2)	0.6 (0.4)
lg. int.	0.9 (0.2)	0.3 (0.03)
blood	11.8 (0.6)	1.0 (0.05)
muscle	0.4 (0.2)	0.07 (0.01)
Tumor	2.9 (0.6)	0.8 (0.3)

The use of a 6 μ g dosage of avidin-cPNA as clearing agent reduced the radioactivity levels in all tissues including the tumor, such that tumor/normal tissue ratios were improved only in liver, heart, lung, spleen, blood, and muscle. In contrast to the use of the same dosage in the infected mice where the lesion lost only about 30% of its radioactivity, in the tumor-bearing mice, the lesion lost more than 70%. Clearly, the optimal dosage of clearing agent must be determined for each model system.

DISCUSSION

Since the goal of this investigation was to determine whether polymers of PNA could be targeted with radiolabeled cPNA to improve the localization of radioactivity using a pretargeting strategy, it was often necessary in the course of this study to select among a number of possibilities. Apart from the selection of the polymer scaffold itself, the selection of PNA as oligomer was significant. By surface plasmon resonance measure-

ments, the association rate for hybridization of this 15 base PNA pair was found to be similar to that for a pair of 18 base uniformly phosphorothioate DNAs (29). Accordingly, both DNAs and PNAs were considered to display the hybridization kinetics required for in vivo targeting. However, PNA was selected because of its stability in vivo and its high binding affinity toward its complement. Furthermore, the high charge of DNA was considered a disadvantage compared to the electrically neutral PNAs if charge neutrality permits closer packing on polymers. In fact, much greater difficulties were experienced in conjugating uniform phosphorothioate DNAs to PA and other polymers, and this was attributed to charge repulsion. It may be calculated that the average spacing of PNA groups on the PNA-PA-PEG polymer used in this investigation was 3.5 nm. This is closer than that used in DNA microarrays where about 10 nm separates each DNA (30). Even at this larger spacing, charge repulsion effects and steric hindrance are occasionally encountered (FR Ortigao, Hybain, private communication, 2000). Thus the short 3.5 nm spacing might be expected to severely restrict targeting. However, PA is a linear molecular with a backbone permitting free rotation. This fact may help explain that over 70% of the PNAs on the polymer were targeted in solution and even when the polymer was immobilized on beads. That targeting was 35–58% in vivo is only slightly less impressive considering the barriers which exist in vivo compared to the in vitro situation.

The selection of PNA introduced one difficulty as the poor aqueous solubility of PNA and, in particular, of cPNA, limited the number of PNAs that could be conjugated to PA. Biodistributions of radiolabeled PA, even with limited numbers of PNA, showed rapid blood clearance and excessive accumulation in liver (data not presented), properties which were only exasperated by increasing the number of PNAs per polymer to the required levels. Fortunately, the large number of carboxylate groups on PA (about 920) over that needed for PNA conjugation permitted the addition to this polymer of sufficient numbers of PEGs to increase circulation time and decrease liver accumulation. As shown in Table 2, liver accumulation at 3 h in normal mice was 44 id%/g with no PEG on PA molecule, while this value fell to 13 id%/g at 200 PEGs/PA.

An additional consideration was the number of PNAs per polymer molecule. Fortunately, the addition of PEGs permitted up to 80 PNAs per PA to be attached without adversely influencing the biodistribution of PA. That the number of PNAs is an important determinant to the success of pretargeting with this polymer is evident from the biodistribution results of PAs conjugated with 6 vs 80 PNAs (Table 3 and Figure 5). The absolute uptake

was 7 fold higher and the target/nontarget ratios were more favorable in all tissues when the polymer conjugated with the higher number of PNAs was administered.

Most pretargeting studies employ an intermediate administration of a clearing agent to remove as much of the first injectate remaining in circulation as possible before the radioactivity is administered. This process can significantly improve the target/nontarget radioactivity ratios (7). Therefore a number of clearing agents were considered in this investigation. With biotin conjugated to PNA-PA-PEG, it was possible to use either avidin or streptavidin as a clearing agent since both proteins are tetravalent for biotin and are therefore capable of cross-linking biotinylated PA. Accumulation in the infected thigh was unchanged by either clearing agent as was expected since neither protein should interfere with the target. However, liver, kidney, and spleen levels decreased only in the case of streptavidin, but by much less than desired (data not presented).

Avidin-cPNA was also investigated since cPNA on this potential clearing agent will hybridize to PNA-PA-PEG in circulation while the avidin should encourage clearance of the complex into the liver. However, avidin-cPNA can also reduce the number of available PNAs in the target. Any clearing agent containing cPNA may hybridize to PNA-PA-PEG in the target, thereby reducing the number of PNAs available to hybridize ^{99m}Tc -cPNA. Table 6 presents biodistribution results showing the effect of dosage of avidin-cPNA. The infected thigh target shows minimal decrease with increasing dosage of this clearing agent until 15 μg are reached. However all normal tissues except kidneys show dosage-related decreases within this range. The images of Figure 8 also show this improvement.

Thus, the results of this research show that pretargeting may be accomplished with PNA polymers. Using the hyperperfusion of denatured capillaries at sites of inflammation and tumor in mice, we have observed that the PNA-PA-PEG polymer of this investigation accumulates in both lesion types. Thereafter, the polymer may be targeted with a subsequent administration of radiolabeled cPNA. This investigation is similar to those conducted in this laboratory previously using PNA but with streptavidin-PNA as the first injectate followed by ^{99m}Tc -cPNA without a clearing agent (22). Previously, in both the inflammation and tumored mouse models, it was necessary to inject a large dosage of both the streptavidin-PNA and radiolabeled cPNA (150 and 50 μg , respectively) to achieve positive pretargeting. By contrast, in this research, only 16 μg of the PNA-PA-PEG and 2 μg of the radiolabeled cPNA were required to achieve superior ratios even in the absence of a clearing agent. With the use of 6 μg of avidin-cPNA in the inflammation model, almost all target/nontarget ratios were further improved (Table 6).

In conclusion, the results of this investigation demonstrate that PA may be conjugated with a large number of PNAs and, when conjugated with sufficient PEGs as well, the polymer displays pharmacokinetic properties suitable for in vivo applications. In particular the conjugated PA was shown to accumulate by nonspecific diffusion in lesion of both inflammation and tumored mouse models. We were also able to demonstrate that the PNAs on PA may be successfully targeted in vitro and, in particular, in vivo by ^{99m}Tc -labeled cPNA. Finally, the advantage of including amplification in pretargeting applications was also shown. Although a number of polymer scaffolds were considered preliminary to this work, it is inconceivable that the ideal polymer was found

in PA. Furthermore, although PNAs have very attractive properties, other oligomers may eventually be shown to be superior for this application. Clearing agents other than those studied herein could be considered. Thus, this report may be viewed as describing only the first step to the use of oligomer polymers for pretargeting. Nevertheless, the goal of demonstrating that pretargeting using polymers of PNA for amplification can improve localization was realized.

ACKNOWLEDGMENT

We are grateful to Mike Egholm and Ivar Jensen of PerSeptive Biosystems for providing the PNA used in this investigation and for helpful discussions. We also appreciate the help of Ken Miller of BIAcore Corp with our surface plasmon resonance measurements. Financial support for this investigation was provided in part by the National Institutes of Health (CA79507).

A General Synthesis of Structurally Diverse Building Blocks for Preparing Analogues of C-Linked Antifreeze Glycoproteins

Adewale Eniade, Anastasia V. Murphy, Geraldine Landreau,[†] and Robert N. Ben*

Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13902.
Received March 26, 2001

A synthetic methodology to afford unusual glycoconjugate building blocks useful for the solid-phase synthesis of C-linked antifreeze glycoprotein (AFGP) analogues is described. Such compounds are urgently required in order to elucidate the molecular mechanism by which AFGPs function. All reactions are general in nature and accommodate structural variation in the carbohydrate moiety, polypeptide backbone, and amino acid side chain.

INTRODUCTION

Biological antifreezes are a diverse class of compounds that have the unusual ability to inhibit the growth of ice crystals in organisms inhabiting subzero environments. Consequently, these organisms are protected against cryoinjury. Antifreeze glycoproteins (AFGPs¹) are one class of biological antifreezes found in Arctic and Antarctic teleost fish. The structure of a typical AFGP is shown in Figure 1. The core unit consists of a L-threonyl-L-alanyl-L-alanyl tripeptide where the secondary hydroxyl group of the threonine is glycosylated with the β -D-galactosyl-(1,3)- α -D-N-acetylgalactosamine subunit. There are eight classes of AFGP and each differs in molecular weight (1–3). For instance, AFGP 1–4 are 20–33 kDa while AFGP 5–8 are in the 19–2.2 kDa range. Minor variations in primary structure are often found in low molecular weight AFGPs (i.e., AFGP 7–8) (4–6).

During the last 30 years, the macromolecular mechanism of action for AFGPs has been extensively investigated and is largely regarded as an adsorption-inhibition phenomenon in which the biological antifreeze binds to the surface of a growing ice crystal (7, 8). After adsorption, ice growth occurs between adjacent AFGPs, and the surface grows outward in a convex fashion. As the radius of curvature increases, it becomes energetically unfavorable to add water molecules to the ice lattice, and consequently a localized freezing point depression is observed. This is referred to as the Kelvin Effect (9). The difference between the melting and freezing points is defined as thermal hysteresis (TH).

In contrast to the macromolecular mechanism, a definitive molecular mechanism of action has not emerged and remains a source of debate among experts in the field. This has restricted the use of AFGPs in many medical, industrial, and commercial applications (10–13). Additional complications include the fact that isolation/purification of AFGPs from natural sources remains a costly and laborious process (14) while the chemical and

Figure 2. Generalized building block structure.

biological instability of natural AFGPs make them unsuitable for most applications (15).

The chemical synthesis of AFGP and AFGP analogues is an attractive alternative to the difficult isolation from natural sources. With the many recent advances in peptide and carbohydrate chemistry, the rational design of chemically and biologically stable AFGP analogues possessing enhanced activity should be feasible. However, before such compounds can be designed, a thorough understanding of how AFGPs function at the molecular level must be attained (14). In an attempt to address these issues, our laboratory has been the first to synthesize low molecular weight C-linked AFGP analogues (16). While this may seem like a dramatic structural modification, recent studies have demonstrated that C-linked glycoconjugates bind substrates with nearly identical conformations and affinities as O-linked glycoconjugates (17, 18). C-linked structures are attractive and offer significant advantages with respect to natural O-linked glycoconjugates as they are stable to a wide range of chemical and biological conditions. Our approach centers on the preparation of glycosylated tripeptide building blocks (Figure 2) that are assembled into C-linked AFGP analogues using conventional solid-phase synthesis (SPS).

We recently reported the synthesis of a C-linked AFGP analogue with a molecular weight of 1.5 kDa using this strategy (Figure 3) (19, 20). An attractive advantage of the solid-phase approach is that C-glycopeptide polymers

of a predetermined length are easily prepared. In contrast, solution-phase polymerization approaches to AFGP often produce mixtures of varying molecular weight (21). This article describes the rationale for and preparation of several structurally diverse glycoconjugate building blocks necessary to synthesize C-linked AFGP analogues using a linear solid-phase approach.

EXPERIMENTAL PROCEDURES:

General Methods. Infrared (IR) spectra were recorded using a Perkin-Elmer 1600 Series FTIR. Unless otherwise noted ^1H and ^{13}C NMR spectra were recorded using a Bruker AM 360 or a Bruker AC 300 in CDCl_3 . Chemical shift values are reported in ppm downfield from TMS as an internal standard. Multiplicities are reported as s, singlet; bs, broad singlet; d, doublet; dd, doublet of doublets; t, triplet; m, multiplet. Low-resolution mass spectra were obtained using a Hewlett-Packard series 1100 MSD instrument equipped with an API-ES ionization chamber. High-resolution mass spectra were obtained using a Micromass QToF-II high-resolution mass spectrometer and sodium iodide as an internal standard. Chromatographic separations were performed using 230–400 mesh silica gel from Natland Inc. All solvents were dried and distilled prior to utilization; THF was distilled over sodium–benzophenone, and methylene chloride was distilled over calcium hydride.

2-(2,3,4,6-Tetra-O-acetyl- α -D-galactopyranosyl)acetaldehyde (3). Ozone was bubbled into a solution of C-allylated β -D-galactose pentaacetate (866 mg, 2.33 mmol) in dry dichloromethane (12 mL) under nitrogen at -78°C until the solution turned blue in color. Nitrogen was then bubbled through the solution until it turned colorless. Triphenylphosphine (1.5 g, 5.7 mmol) was then added, and the solution was then allowed to warm to room temperature over a period of 3 h. Dichloromethane was removed under reduced pressure, and the residue was purified by column chromatography (ethyl acetate/hexanes 1:1) to afford 632 mg (73% yield) of **3** as a colorless oil. IR (CH_2Cl_2): 1738 cm^{-1} ; ^1H NMR (360 MHz, CDCl_3) δ : 9.64 (1H, s), 5.15 (1H, dd, $J = 5.8, 2.8\text{ Hz}$), 5.02 (1H, dd, $J = 8.8, 4.7\text{ Hz}$), 4.96 (1H, dd, $J = 8.8, 3.1\text{ Hz}$), 4.62 (1H, m), 4.04 (1H, dd, $J = 11.1, 7.5\text{ Hz}$), 3.9 (1H, m), 3.84 (1H, dd, $J = 11.2, 4.6\text{ Hz}$), 2.5 (2H, m), 1.87 (3H, s), 1.81 (3H, s), 1.78 (6H, s); ^{13}C NMR (90 MHz, CDCl_3) δ : 198.4, 169.6, 169.3, 169.1, 169.0, 68.8, 67.2, 66.6, 66.4, 61.0, 41.0, 19.9.

Benzyl Fluorenemethyloxycarbonyl-L-lysine[(2,3,4,6-tetra-O-acetyl- α -D-galactopyranosyl)ethyl]glycylglycinate (5). Aldehyde **3** (100 mg, 0.47 mmol) was dissolved in 10 mL of dry THF under nitrogen atmosphere at room temperature. Compound **4** (60 mg, 0.85 mmol) was dissolved in 3 mL of dry THF and added to the solution of **3**. Sodium triacetoxyborohydride (100 mg, 0.47 mmol) was then added, and the solution was stirred

at room temperature for 12 h. The solution was concentrated under reduced pressure and the residue dissolved in methanol and stirred for 20 min. This solution was concentrated under reduced pressure and the residue purified by column chromatography ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 10:1) to afford 80 mg (55% yield) of **5** as a colorless oil. IR (CH_2Cl_2): $3366, 1744, 1672\text{ cm}^{-1}$; ^1H NMR (360 MHz, CDCl_3) δ : 7.62 (2H, d, $J = 7.4\text{ Hz}$), 7.47 (2H, br s), 7.21 (9H, m), 6.50 (1H, br s), 5.30 (1H, br s), 5.10 (2H, br s), 4.91 (3H, br s), 4.37 (1H, m), 4.22 (4H, br s), 4.07 (3H, br s), 3.91 (6H, br s), 3.03 (2H, br s), 2.93 (2H, br s), 1.95 (14H, m), 1.73 (4H, br s), 1.47 (2H, br s); ^{13}C NMR (90 MHz, CDCl_3) δ : 175.5, 173.17, 170.9, 169.8, 169.7, 169.6, 169.5, 156.6, 143.7, 141.1, 135.1, 128.4, 128.3, 128.0, 127.6, 127.0, 125.1, 119.8, 69.8, 68.6, 68.3, 67.5, 67.2, 67.0, 66.9, 60.9, 54.7, 47.9, 47.0, 45.1, 42.9, 41.2, 31.3, 25.3, 23.6, 22.2, 20.9, 20.7, 20.7, 20.6. LRMS (electrospray, MeOH, positive ion mode, m/z) calcd. for $\text{C}_{48}\text{H}_{58}\text{N}_4\text{O}_{15}$ (M^+) 930.38; found 931.40 ($\text{M}^+ + \text{H}$). HRMS calcd for $\text{C}_{43}\text{H}_{38}\text{N}_4\text{O}_{15}$ ($\text{M}^+ + \text{H}$) 931.3977, found 931.3976.

Benzyl Fluorenemethyloxycarbonyl-L-lysine[bis-[(2,3,4,6-tetra-O-acetyl- α -D-galactopyranosyl)ethyl]glycylglycinate (6). Aldehyde **3** (120 mg, 0.32 mmol) was dissolved in 3 mL of dry THF and allowed to stir at room temperature under nitrogen atmosphere. Compound **4** (100 mg, 0.15 mmol) was dissolved in 6 mL of dry THF and added to the solution of **3**. Sodium triacetoxyborohydride (100 mg, 0.47 mmol) and 0.1 mL of acetic acid were added directly to this solution, and the mixture was allowed to stir at room temperature for 12 h. The solvent was removed under reduced pressure, and the resulting residue was redissolved in methanol and stirred for 20 minutes. This solution was then concentrated and the residue was redissolved in ethyl acetate. The ethyl acetate solution was washed successively with saturated sodium bicarbonate, water, and brine and the solution dried over MgSO_4 and concentrated under reduced pressure. The crude product was then purified by column chromatography ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 30:1) to afford 117 mg (63% yield) of **6** as a colorless oil.

IR (CH_2Cl_2): $1733, 1655\text{ cm}^{-1}$; ^1H NMR (360 MHz, CDCl_3) δ : 7.71 (2H, d, $J = 7.4\text{ Hz}$), 7.56 (2H, t, $J = 6.2\text{ Hz}$), 7.35 (2H, t, $J = 7.2\text{ Hz}$), 7.26 (7H, m), 7.14 (1H, br s), 5.81 (1H, br s), 5.38 (2H, br s), 5.26 (1H, s), 5.20 (3H, br s), 5.06 (2H, s), 4.36 (2H, br s), 4.26 (4H, m), 4.16 (2H, t, $J = 6.9\text{ Hz}$), 4.00 (8H, m), 2.42 (4H, br s), 2.34 (2H, br s), 2.07 (6H, s), 2.02 (6H, s), 2.00 (6H, s), 1.99 (6H, s), 1.80 (2H, br s), 1.64 (2H, br s), 1.54 (2H, br s), 1.38 (4H, br s); ^{13}C NMR (90 MHz, CDCl_3) δ : 172.4, 170.6, 169.9, 169.8, 169.4, 169.0, 156.4, 143.8, 141.1, 135.1, 128.4, 128.3, 128.1, 127.6, 126.9, 124.9, 124.9, 119.8, 70.1, 68.3, 67.9, 67.8, 67.4, 66.9, 61.4, 61.2, 54.9, 49.6, 47.0, 42.8, 41.0, 32.0, 26.6, 25.4, 23.1, 20.6, 20.5, 20.5, 20.2. HRMS calcd for $\text{C}_{64}\text{H}_{80}\text{N}_4\text{O}_{24}$ ($\text{M}^+ + \text{Na}$) 1311.5062, found 1311.5069.

Benzyl *tert*-Butoxycarbonyl-L-alaninyl-L-alaninate (10). Boc-L-Ala-OBn (842 mg, 3.0 mmol) was dissolved in 10 mL of dry dichloromethane at stirred at room temperature. Trifluoroacetic acid (5 mL) was added, and the solution was stirred for 1 h after which time the mixture was concentrated under reduced pressure. The resulting residue was then added to a flask containing a dichloromethane solution of t-Boc-Ala-OH (586 mg, 3.0 mmol) and 1,1'-carbonyldiimidazole (CDI) (535 mg, 3.1 mmol) which had been stirring for 10 min under nitrogen. The entire solution was allowed to react for 1 h at room temperature and then washed successively with 5% aqueous hydrochloric acid, saturated sodium bicarbonate, and brine. The combined organic extracts were then dried over magnesium sulfate and concentrated. The crude product was then purified by flash chromatography (ethyl acetate/hexanes 1:3) to afford 517 mg (96% yield) of **10** as a colorless oil. IR (CH₂Cl₂): 3311, 1738, 1661 cm⁻¹; ¹H NMR (360 MHz, CDCl₃) δ : 7.29 (5H, br s), 7.04 (1H, br s), 5.37 (1H, d, *J* = 7.4 Hz), 5.14 (1H, d, *J* = 12.3 Hz), 5.08 (1H, d, *J* = 12.3 Hz), 4.56 (1H, quintet, *J* = 7.1 Hz), 4.21 (1H, br s), 1.39 (9H, s), 1.35 (3H, d, *J* = 7.2 Hz), 1.28 (3H, d, *J* = 7.2 Hz); ¹³C NMR (90 MHz, CDCl₃) δ : 172.4, 172.4, 155.3, 135.2, 128.4, 128.2, 127.9, 79.7, 66.8, 49.7, 47.9, 28.1, 18.3, 17.8.

Benzyl Fluorenylmethoxycarbonyl-L-lysine(*tert*-butyloxycarbonyl)-L-alaninyl-L-alaninate (11). Compound **10** (0.624 g, 1.78 mmol) was dissolved in dry dichloromethane, and trifluoroacetic acid (8 mL) was added. The solution was stirred for 2 h at room temperature under nitrogen atmosphere after which time the reaction mixture was concentrated under reduced pressure. The resulting deprotected dipeptide was then added to a solution of Fmoc-Lys(Boc)OH (0.84 g, 1.8 mmol) and CDI (0.33 g, 2 mmol) dissolved in 10 mL of dichloromethane. The solution was stirred overnight at under nitrogen atmosphere and then washed successively with 5% HCl, water, and brine. The combined organic layers were dried using MgSO₄, filtered, and concentrated under reduced pressure. Column chromatography was performed using hexanes:EtOAc (1:2) as eluant and afforded 1.0 g (74% yield) of the desired tripeptide **11**. IR (CH₂Cl₂): 3288, 1738, 1683, 1644 cm⁻¹; ¹H NMR (360 MHz, CDCl₃) δ : 7.68 (2H, d, *J* = 7.4 Hz), 7.52 (2H, d, *J* = 7.3 Hz), 7.26 (9H, m), 7.03 (1H, dd, *J* = 11.1, 3.0 Hz), 5.85 (1H, br d, *J* = 5.8 Hz), 5.11 (1H, d, *J* = 12.2 Hz), 5.05 (1H, d, *J* = 12.3 Hz), 4.52 (2H, m), 4.31 (3H, m), 4.11 (3H, m), 3.03 (2H, br s), 1.74 (2H, br s), 1.51 (2H, br s), 1.37 (11H, br s), 1.31 (3H, d, *J* = 5.9 Hz), 1.21 (3H, d, *J* = 7.1 Hz); ¹³C NMR (360 MHz, CDCl₃) δ : 172.4, 170.4, 156.7, 156.6, 144.5, 142.3, 135.2, 128.8, 128.7, 128.4, 127.9, 127.2, 125.2, 120.1, 67.6, 54.3, 49.3, 48.6, 47.3, 32.2, 29.8, 28.6, 22.5, 18.7, 18.1. LRMS (electrospray, MeOH, positive ion mode, *m/z*) calcd. for C₃₉H₄₈N₄O₈ (M⁺) 700.34; found 723.31 (M⁺ + Na).

Benzyl Fluorenylmethoxycarbonyl-L-lysine[2-(2,3,4,6-tetra-*O*-*tert*-butyldimethylsilyl- α -D-galactopyranosyl)acetyl]-L-alaninyl-L-alaninate (12). Tripeptide **11** (370 mg, 0.528 mmol) was dissolved in CH₂Cl₂ (3 mL), and 2 mL of trifluoroacetic acid was added. The solution was stirred at room temperature, under nitrogen atmosphere for 2 h, and then concentrated under reduced pressure. A solution of **14** (110 mg, 0.161 mmol) and CDI (40 mg, 0.242 mmol) dissolved in 10 mL of dichloromethane was stirred at room temperature, under nitrogen atmosphere for 1 h. Then, the deprotected tripeptide (0.37 g, 0.528 mmol) and *N,N*-diisopropylethylamine (0.2 mL) were added to the reaction mixture, and the solution was stirred overnight at room temperature. The crude

reaction mixture was washed successively with 5% HCl, water, and brine. The organic extract was dried over MgSO₄, filtered, and concentrated under reduced pressure. Purification of the crude product was accomplished using CH₂Cl₂/MeOH (50:1) and afforded 120 mg (57% yield) of the desired glycosylated tripeptide as a colorless oil. IR (CH₂Cl₂): 3288, 1716, 1644 cm⁻¹; ¹H NMR (300 MHz, CDCl₃) δ : 7.74 (2H, d, *J* = 7.4 Hz), 7.61 (2H, m), 7.31 (9H, m), 6.85 (1H, br d, *J* = 7.7 Hz), 5.89 (1H, br d, *J* = 4.6 Hz), 5.15 (1H, d, *J* = 12.3 Hz), 5.12 (1H, d, *J* = 12.4 Hz), 4.51 (1H, m), 4.46–4.12 (6H, m), 3.73 (2H, m), 2.70 (1H, m), 2.42–2.07 (1H, m), 1.50 (1H, br s), 1.35 (3H, d, *J* = 6.0 Hz), 1.22 (3H, s), 0.88 (44H, m), 0.06 (24 H, m); ¹³C NMR (360 MHz, CDCl₃) δ : 174.5, 172.5, 167.8, 156.3, 143.9, 141.3, 138.0, 132.4, 130.9, 127.0, 125.2, 121.0, 119.9, 107.7, 79.5, 73.1, 68.1, 66.9, 58.6, 47.1, 38.7, 31.9, 28.9, 25.7, 23.7, 23.0, 18.9, 18.5, 12.0, 10.9.

2-(2,3,4,6-Tetra-*O*-*tert*-butyldimethylsilyl- α -D-galactopyranosyl)acetic Acid (14). Ozone was bubbled into a solution of **13** (4.5 g, 6.8 mmol) dissolved in dry dichloromethane and cooled to -78 °C. Once the solution turned blue in color, nitrogen was bubbled through the solution until the blue color disappeared. Triphenylphosphine (2.0 g, 7.6 mmol) was added, and the solution was then allowed to warm to room temperature over a period of 3 h. This solution was then concentrated under reduced pressure, and the residue was redissolved in 10 mL of *tert*-butyl alcohol and 10 mL of 2-methyl-2-butene. Monobasic potassium phosphate (9.3 g, 68 mmol) and sodium chlorite (6.1 g, 68 mmol) were dissolved in 20 mL of water and added to the above solution. After stirring for 4 h at 0 °C, the solution was extracted with ethyl acetate. The organic extracts were washed successively with water and brine, and the solution was then dried over magnesium sulfate and concentrated under reduced pressure. The crude product was purified by column chromatography (neat dichloromethane) to afford 3.6 g (78% yield) of **14** as a white solid. IR (CH₂Cl₂): 1722 cm⁻¹; ¹H NMR (360 MHz, CDCl₃) δ : 4.23 (3H, m), 4.02 (1H, dd, *J* = 13.4, 6.8 Hz), 3.74 (1H, t, *J* = 3.0 Hz), 3.70 (1H, dd, *J* = 12.0, 2.2 Hz), 3.51 (1H, d, *J* = 3.7 Hz), 2.70 (1H, dd, *J* = 16.6, 9.7 Hz), 2.38 (1H, dd, *J* = 16.6, 3.9 Hz), 0.89 (9H, s), 0.87 (18H, s), 0.85 (9H, s), 0.03 (24H, m); ¹³C NMR (90 MHz, CDCl₃) δ : 174.0, 79.2, 73.1, 72.8, 66.7, 63.3, 58.4, 36.0, 26.3, 25.9, 25.8, 25.6, 18.2, 18.0, 17.8, -4.5, -4.6, -4.99, -5.1, -5.3, -5.5. HRMS calcd for C₃₂H₇₀O₇-Si₄ (M⁺ + H) 679.4277, found 679.4262.

Benzyl Fluorenomethoxycarbonyl-L-lysine[2-(2,3,4,6-tetra-*O*-*tert*-butyldimethylsilyl- α -D-galactopyranosyl)acetyl]-L-prolylglycinate (15). Fmoc-Lys(Boc)-Pro-Gly-OBn (0.1582 g, 0.22 mmol) was dissolved in dry dichloromethane (5 mL), and TFA (0.15 mL) was stirred at room temperature for 1 h. The solution was concentrated under reduced pressure. Compound **14** (0.1513 g, 0.22 mmol) and CDI (0.0392 g, 0.25 mmol) were added to dry dichloromethane (5 mL). The resulting solution was stirred at room temperature, under nitrogen atmosphere. After 1 h, the deprotected tripeptide was dissolved in dry dichloromethane (3 mL) followed by the addition of diisopropyl ethylamine (0.3 mL). The solution was stirred for 12 h at room temperature and then washed successively with saturated ammonium chloride, water, and brine. The solution was dried over magnesium sulfate, filtered, and concentrated under vacuum. The crude product was purified by column chromatography (CH₂Cl₂:MeOH 30:1) and furnished 146 mg (60% yield) of **15** as a colorless oil. IR (CH₂Cl₂): 3333, 1716, 1644 cm⁻¹; ¹H NMR (300 MHz, CDCl₃) δ : 7.65 (2H, d, *J* = 7.3 Hz), 7.48 (2H, d, *J* = 6.6 Hz), 7.27 (5H, m), 5.04 (2H, s),

4.25 (4H, m), 4.18 (2H, d, $J = 7.8$ Hz), 4.09 (6H, m), 3.91 (6H, m), 3.62 (8H, br s), 3.38 (2H, d, $J = 3.7$ Hz), 1.39 (8H, m), 1.19 (1H, s), 0.80 (36H, m), -0.05 (24H, m). ^{13}C NMR (360 MHz, CDCl_3) δ : 172.5, 172.0, 171.0, 169.4, 155.9, 143.7, 143.6, 141.1, 135.0, 134.6, 130.7, 128.6, 128.4, 128.4, 128.3, 128.2, 128.1, 127.5, 126.9, 124.9, 120.3, 119.8, 78.9, 73.6, 73.4, 72.9, 66.9, 66.8, 66.5, 63.1, 58.1, 52.0, 47.0, 41.2, 36.2, 29.5, 28.2, 25.9, 25.8, 25.8, 25.7, 25.6, 25.5, 25.5, 25.5, 25.4, 18.1, 17.9, 17.8, 17.8, 17.7, -3.7 , -4.5 , -4.6 , -4.7 , -4.8 , -5.0 , -5.0 , -5.1 , -5.2 , -5.2 , -5.7 . RESULTS AND DISCUSSION

Building block **1** has been at the center of our preliminary work. The structure of **1** is different than that of the core repeating tripeptide unit in Figure 1 and serves to function as a structural analogue for the tripeptide unit in low molecular weight AFGP 7–8 which has the threonine substituted with an arginine residue (5, 6). The amide bond between the C-linked galactose and ϵ -amino group of the lysine side chain mimics the terminal guanidinium group of arginine. This may seem like a dramatic structural modification since lysine is not native to AFGPs; however, recent results have shown that polypeptides containing repeating L-lysine residues possess weak antifreeze protein-specific activity (22). In addition to the above modification, the α -D-galactosyl- β -D-N-acetylgalactosamine found in AFGP has been truncated in **1**. This is based upon early structure–function studies where the *cis*-3,4-dihydroxy group in the terminal

galactose residue was shown to be especially important for antifreeze protein-specific activity (23). This result is reminiscent of biologically significant oligosaccharides where in most cases, only the terminal residue(s) are necessary for tight interactions with a receptor (24).

Traditionally, the driving force for adsorption of AFGP onto the ice surface is thought to involve hydrophilic interactions (hydrogen bonds) between specific hydroxyl groups of the carbohydrate moiety and the ice surface. While hydrogen bond formation is a very general phenomenon, molecular modeling studies of potential interactions between the α -D-galactosyl- β -D-N-acetylgalactosamine moiety and the ice surface imply that only two hydroxyl groups are ideally positioned to hydrogen bond to the ice lattice (25). This suggests that AFGP 8 (with four glycosylated tripeptide units) will form only eight hydrogen bonds with the ice surface. Given that individual hydrogen bonds are relatively weak in nature, it is difficult to rationalize the irreversible binding of AFGP to ice, and consequently it has been proposed that the hydroxyl groups are actually incorporated *into* the ice lattice. While the above hypothesis is based upon the notion that hydrophilic interactions are a dominant force at the protein–ice interface, recent evidence has shown that hydrogen bonding might be only a secondary interaction and hydrophobic interactions might predominate (26, 27).

The assessment of AFGP analogues with structurally diverse carbohydrate moieties will lend valuable insight into hydrophilic interactions and the role they play in the molecular mechanism of action. Consequently, our laboratory has undertaken the preparation of C-linked AFGP analogues in which both the structure and orientation of a C-linked carbohydrate may be easily modified. One way to modify orientation of the saccharide residue is to alter the linkage between the saccharide and tripeptide. We are also interested in preparing AFGP analogues possessing multivalent saccharide derivatives of the native AFGP saccharide moiety. Multivalent saccharide derivatives have found numerous therapeutic applications as effective inhibitors of various carbohydrate protein interactions (28–30).

As we wish to synthesize C-linked AFGP building blocks possessing different carbon-linked carbohydrate structures, the preparative methodology must be high yielding and general in nature. To accomplish this, we employ a general and highly stereoselective allylation reaction (Scheme 1) (31). Unfortunately, the resulting olefin was produced as an 88:12 mixture of α : β anomers, and such a mixture proved very difficult to separate. However, replacement of the acetate protecting groups with the less polar *tert*-butyldimethylsilyl (TBS) ethers allowed for clean separation of the desired α -anomer (19). After exchange of the TBS protecting groups with acetates, the resulting olefin was subjected to ozonolysis and furnished aldehyde **3** in 73% yield after purification. This sequence of reactions has been successfully utilized to prepare both the α - and/or β -D-mannose and glucose derivatives of **3**.

As previously discussed, one way to alter orientation of the carbohydrate residue in our building block is to utilize different covalent linkages between the carbohydrate and amino acid side chain. Consequently, we chose to modify the amide linkage in **1**. To accomplish this we sought to employ sodium cyanoborohydride in a reductive amination protocol reported by Campbell et al. (32) where reaction of tripeptide **4** (19) with aldehyde **3** was expected to produce glycosylated tripeptide **5** (Scheme 2). However, this approach failed to produce even trace quantities of

Scheme 1. Synthesis of C-Linked Saccharide**Scheme 2. Synthesis of Mono- and Divalent Building Blocks**

5. Alternatively, sodium triacetoxy borohydride worked very well. As illustrated in Scheme 2, reaction of tripeptide **4** with 0.8 equiv of **3** in the presence of sodium triacetoxy borohydride furnished **5** in 55% yield. Two-dimensional NMR studies (NOESY and ROESY) confirmed that the C-linked galactose residue in **5** adopts a *rigid* orientation (relative to peptide backbone) that is different than in **1**.

The glycosylated tripeptide building block **5** is a precursor to structurally diverse divalent building blocks. As illustrated in Scheme 2, reaction of **4** with 2.2 equiv of **3** and sodium triacetoxy borohydride (2.2 equiv) furnished divalent tripeptide **6** in 63% yield after purification. We also sought to synthesize divalent derivatives possessing both the amide and amine linkages between the saccharide residue and polypeptide backbone as represented by compound **8** in Scheme 2. However, reaction of **5** with 1.2 equiv of carboxylic acid **7** (**19**) using 1,1'-carbonyldiimidazole (CDI) failed to produce any trace of the desired product even at elevated temperatures.

This reaction also failed in the presence of uronium coupling agents such as HBTU (*O*-benzotriazol-1-yl-*N,N,N',N'*-tetramethyluronium hexafluorophosphate) and HATU (*O*-(7-aza-benzotriazol-1-yl)-*N,N,N',N'*-tetramethyluronium hexafluorophosphate).

Studies of the solution structure of AFGP **8** have implied the existence of a polyproline type II helix (33, 34). While this structural motif is believed to be essential for antifreeze activity, definitive evidence to support this hypothesis has not been published. Thus, a preparative methodology that affords structural diversity in the polyamide backbone is highly desirable. Of potential interest are polypeptide backbones that possess the L-alanyl-L-alanyl dipeptide of native AFGP and derivatives that incorporate L-proline residues. Since the glycylglycine dipeptide residue in the tripeptide sequence of **1**, **5**, **6**, **8** is structurally dissimilar to the L-alanyl-L-alanyl dipeptide found in native AFGP, we prepared the glycosylated L-lysyl-L-alanyl-L-alanine polypeptide backbone.

Unfortunately, initial attempts to synthesize L-alanine benzyl ester **9** using standard procedures failed to produce **9** in high optical purity, and we were forced to employ an alternate approach. As illustrated in Scheme 3, reaction of commercially available *N*-tert-butoxycarbonylalanine with benzyl alcohol (2.5 equiv) in the presence of CDI furnished **9** as the trifluoroacetate salt in 82% yield after removal of the *tert*-butyl carbamate with trifluoroacetic acid. Analysis of the product by polarimetry confirmed that no racemization had taken place. Subsequent reaction of **9** with *N*-tert-butoxycar-

Scheme 3. Synthesis of Monovalent Building Block**Scheme 4. Synthesis of C-Linked Saccharide**

Figure 4. Other structurally diverse C-linked AFGP building blocks.

bonylalanine using CDI and *N,N*-diisopropylethylamine (DIPEA) in dichloromethane yielded dipeptide **10** in 96% isolated yield. Repetition of this sequence using Fmoclys(Boc)-CO₂H furnished tripeptide **11** in 74% yield and a final CDI-mediated coupling between galactose derivative **14** and the deprotected derivative of **11** furnished the glycosylated tripeptide **12** in 57% yield after purification. The C-linked galactose derivative **14** was prepared as outlined in Scheme 4 (35) from **13** (19). Building block **12** is a structural analogue of the glycosylated tripeptide in low molecular weight AFGP where the L-threonine residue is substituted with arginine (5, 6). This preparative methodology affords endless structural variations in the polypeptide backbone using other natural amino acids or even synthetic amino acid derivatives that may serve as a peptide scaffold. To further demonstrate this, building block **15** (with L-proline incorporated into the polyamide backbone, Figure 4) was easily prepared in a convergent fashion using procedures and reagents analogous to that described in Schemes 3 and 4. This is important because it has been observed that one or both L-alanine residues may be substituted with L-proline in AFGP 7–8 (4). The reason for this substitution is not understood.

It is likely that the structure and length of the amino acid side chain bearing the carbohydrate residue affects conformation and ultimately antifreeze activity. This is a complex issue since protein conformation is governed

by primary structure, glycosylation, and solvation (36–38). The relationship between changes in the solution conformation of AFGP and antifreeze protein-specific activity has not been adequately investigated. Studies probing solution conformations of AFGP 8 have postulated the existence of an intramolecular hydrogen bond between the N-Ac of *N*-acetylgalactosamine and one of the carbonyl groups of the polyamide backbone (39). While the existence of such an interaction remains uncertain (40), an optimal distance between the carbohydrate residue and polyamide backbone may exist, and close proximity of the carbohydrate residue may have a profound effect upon the solution conformation of AFGP. Consequently, structurally diverse tripeptide units possessing different amino acid side chain lengths will be useful to study possible intramolecular interactions and probe solution conformations. Our preparative methodology can easily accommodate these structural modifications as evidenced by the convergent synthesis of **16** (Figure 4) in 66% overall yield (two steps).

CONCLUSIONS

In summary, we have presented a preparative methodology for the synthesis of structurally diverse C-linked glycoconjugates useful for the solid-phase synthesis of chemically and biologically stable AFGP analogues. The approach centers on the preparation of carbon-linked glycosylated building blocks and permits structural modification of the saccharide component, polyamide backbone, and amino acid side chain. These building blocks are currently being assembled into discrete C-linked AFGP analogues. The *in vitro* assessment for antifreeze protein-specific activity will provide valuable insight into the structural features necessary to inhibit ice crystal growth.

ACKNOWLEDGMENT

The authors wish to thank Petroleum Research Fund (ACS-PRF# 35280-G1), National Institutes of Health (grant no. GM60319), and A/F Protein Inc. for funding,

the National High Magnetic Field Laboratory (NHMFL) in Tallahassee, FL, for access to high-field NMR, SUNY College of Environmental Science and Forestry (ESF) for ES-MS analysis, and Dr. Jim Kerwin (Cornell University) for MADLI-MS.

REVIEWS

Cellular Delivery of Impermeable Effector Molecules in the Form of Conjugates with Peptides Capable of Mediating Membrane Translocation

Peter M. Fischer,* Eberhard Krausz, and David P. Lane

Cyclacel Limited, Dundee Technopole, James Lindsay Place, Dundee DD1 5JJ, Scotland, UK. Received May 1, 2001

Most molecules that are not actively imported by living cells are impermeable to cell membranes, including practically all macromolecules and even many small molecules whose physicochemical properties prevent passive membrane diffusion. The use of peptide vectors capable of transporting such molecules into cells in the form of covalent conjugates has become an increasingly attractive solution to this problem. Not only has this technology permitted the study of modulating intracellular target proteins, but it has also gained importance as an alternative to conventional cellular transfection with oligonucleotides. Peptide vectors derived from viral, bacterial, insect, and mammalian proteins endowed with membrane translocation properties have now been proposed as delivery vectors. These are discussed comprehensively and critically in terms of relative utility, applications to compound classes and specific molecules, and relevant conjugation chemistry. Although in most cases the mechanisms of membrane translocation are still unclear, physicochemical studies have been carried out with a number of peptide delivery vectors. Unifying and distinguishing mechanistic features of the various vectors are discussed. Until a few years ago speculations that it might be possible to deliver peptides, proteins, oligonucleotides, and impermeable small molecules with the aid of cellular delivery peptides not only to target cells *in vitro*, but *in vivo*, was received with scepticism. However, the first studies showing pharmacological applications of conjugates between macromolecules and peptide delivery vectors are now being reported, and therapies based on such conjugates are beginning to appear feasible.

INTRODUCTION

Biological membranes are natural barriers central to compartmentalization in living systems. They prevent unchecked influx and efflux of solutes from cells and

cellular organelles. All biological membranes contain a phospholipid bilayer as the basic structural unit. Phospholipids consist of hydrophobic tails and hydrophilic heads. Under physiological conditions they aggregate spontaneously into a bilayer, where the fatty acyl chains are sequestered within the hydrophobic interior and the polar heads face the aqueous surfaces. Disposed within the fluid but discrete bilayer structure are proteins and

protein complexes that act as specific pumps and channels to permit active transport of solutes. More primitive channels are found in bacterial membranes, nuclei, and mitochondria. These function essentially as molecular sieves with defined size exclusion limits.

The ability to introduce membrane-impermeable molecules into mammalian cells has been an invaluable tool for the study of intracellular processes. Both physical and chemical methods have been developed to this end. Microinjection, electroporation, freeze-thaw techniques, etc., belong to the former, whereas the latter involve transient cell membrane permeabilization with the aid of solvents such as toluene or dimethyl sulfoxide, hypotonic buffers, and various detergents. The main problem with these methods is the fact that they are not readily reproducible, they are not quantitative, and they generally compromise cellular integrity. Furthermore, such methods are obviously only relevant for *in vitro* cell biology applications but not suitable for *in vivo* use. One of the main constraints in the design of drugs whose interaction targets are located within host cells is thus membrane permeability. Only compounds within a narrow range of molecular size, net charge, and polarity are able to diffuse effectively through the lipid bilayers of biological membranes and can thus reach their pharmacological target (1). The vast majority of molecules, including many natural products and biomolecules, i.e., compounds often possessing inherent biochemical selectivity and potency, are thus apparently precluded from therapeutic application.

The conventional mode of cellular entry for hydrophilic macromolecules is endocytosis. This process involves absorption of the macromolecules to the plasma membrane or to membrane-associated receptors, followed by energy-dependent formation of vesicles. The endocytic machinery of the cell then tags and directs the internalized molecules to appropriate compartments for either destruction or recycling. In general, molecules that enter cells via the endocytic route are not released to the cytoplasm in unaltered form, if at all. Liposomes have been used widely in order to enhance the cellular delivery of biomolecules via the endocytic route. Liposomal delivery, as well as liposomes in general, have been reviewed very comprehensively elsewhere (2, 3). Efficient cellular uptake via endocytosis is generally observed but the efficiency is then limited downstream by insufficient endosomal escape, restricted diffusion, especially of high-molecular weight substances, in the gellike cytosol, dissociation of the complexes, or nuclear entry. Enhanced endosomal escape has been achieved through modification of liposomes, i.e., pH-sensitive liposomes (4, 5), or association with helper lipids such as DOPE, or complexation with endosome-disrupting or destabilizing additives, i.e., PEG (5, 6), cholesterol (7), or lytic peptides (8–10). The nuclear barrier may be crossed efficiently by attachment of nuclear localization signals (11). Although numerous encouraging strategies to overcome various limitations of liposomal delivery are being developed, there is still a need for further improvement and consideration of alternative delivery strategies. For this reason, delivery systems addressing their molecular cargo to cells through endocytosis are only partly or not at all suitable if the molecular targets are cytosolic or nuclear, as is usually the case. Many of the peptide vectors described below, however, can effect cell entry of their molecular conjugates through mechanisms best described as penetration (12). Although poorly understood, these mechanisms appear to be energy-independent and address conjugates to the cytosol and/or the nucleus. No

distinct membrane receptors seem to be involved and membrane translocation is nonselective in terms of cell type. A recent study compared the cellular uptake of a number of different delivery peptides by a combination of high-performance liquid chromatography and confocal laser-scanning microscopy (13). The presence of both endocytic and nonendocytic modes of uptake were observed. Contrary to current opinion, the authors propose a general ability of peptides to cross plasma membranes and suggest that effective delivery with certain peptides may be due to prevention of wash-out in certain cases, e.g., enhancement of binding to intracellular components. While there is probably insufficient evidence at present to support this hypothesis, it highlights the fact that the mechanisms of cell membrane translocation by delivery vector peptides are far from clear. An additional complication stems from the fact that each vector-effector conjugate will probably behave differently, depending on the nature of different effector molecules.

Infective organisms such as viruses and bacteria possess proteins endowed with properties to penetrate living cells indiscriminately (14). For example, the HIV TAT protein, the HBV VP22 protein, pore-forming toxins such as tetanus toxin (15), anthrax toxin (16), cytolysins (17), diphtheria toxin (18), etc., can gain entry into cells in essentially receptor-independent fashion. Peptides derived from some of these proteins, particularly those of viral origin, have been developed as delivery vectors and these are discussed below.

Secreted proteins, some membrane proteins, and proteins of membrane-enveloped organelles of eukaryotic cells are partially or fully transported across membranes and contain signal sequences which direct them to the correct subcellular compartment. Most signal sequences are *N*-terminal extensions of the functional proteins and as a rule are removed proteolytically after translocation. Surprisingly, no sequence homology has been found for sequences directing proteins to the same subcellular compartment, and only general features such as charge distribution and hydrophobicity seem to be common. The secreted proteins of prokaryotes and proteins destined for the endoplasmic reticulum of eukaryotes generally contain a signal sequence consisting of a few charged residues, followed by an uninterrupted stretch of 7–16 apolar residues. Mitochondrial signal sequences, and those of many bacterial proteins consist of 12–30 apolar, polar, and charged residues, arranged in a pattern potentially allowing formation of secondary structures with polar/charged and apolar faces (helical amphiphilicity) or ends (segmental amphiphilicity). Mammalian and insect host defense peptides, including e.g., melittin, protegrins, defensins, tachyplesins, cecropins, etc., as well as pore-forming proteins and peptides in general (19), also fall within this class of substances. Numerous studies on such peptides have shown that they are capable of forming amphiphilic structures and that this propensity correlates with membrane activity (20). Both classes of signal peptides have led to the development of vector systems, and these are discussed more fully below. Amphiphilic peptides have gained some importance in cellular delivery of oligonucleotides, particularly as an endosomal entrapment escape device.

Yet other endogenous mammalian proteins possess the innate ability to cross cell membranes due to their function in intercellular signaling. At least in some cases such proteins do not appear to rely on membrane receptors or transporter systems. The best-documented case falling within this category concerns homeoproteins. Because much pioneering work on peptide-based cellular

delivery vectors was originated with this system, a separate section is devoted to this topic.

APPLICATIONS OF VECTOR CONJUGATES

Polypeptides. Only the very shortest of peptides, such as di- and tripeptides, can enter cells nonspecifically, either using general peptide transporter systems (21), or by diffusion (22). Although very short peptides may be rendered permeable by derivatization with membrane-active lipids such as myristic acid (23, 24), native polypeptides cannot traverse membrane barriers, unless they participate in specific cellular or subcellular processes, in which case appropriate and highly specific receptor and transporter systems exist. While some of the methods developed in the context of gene transfer are also applicable to cellular delivery of polypeptides, e.g., transient chemical cell permeabilisation (25) or liposomal delivery (4, 26, 27), it is the recent development of peptidic cell delivery vectors that has made possible the routine intracellular administration of polypeptides.

Traditionally, delivery vector-derivatized polypeptides have been used as tools in order to elucidate signaling pathways and generally to probe protein–protein interactions in cellular systems. Perhaps the most surprising finding with vectorized polypeptides has been their ability to internalize into cells and there to exert their biological function almost irrespective of molecular mass. Thus, short effector peptides containing only a few amino acid residues can be transported across membranes, as well as entire proteins. For example, the 20-kDa p16^{INK4a} tumor suppressor and the 120-kD β -galactosidase proteins have been shown to penetrate into cells using the pAntp and TAT peptide vectors (refer to Table 1), respectively (28, 29).

Oligonucleotides. Apart from receptor-mediated approaches (30, 31) and viral transfection methods, which have gained therapeutic importance for gene therapy but are not discussed here, carrier-mediated oligonucleotide and gene delivery falls into two categories. The first depends on the reversible association of condensing molecules with oligonucleotides. The carriers that have been used most frequently are composed of polymers, particularly polylysines (32) and polyethyleneimine (33), lipids (34–36), or cationic peptides that bind to anionic sites on the oligonucleotides (34). In all these cases, noncovalent association between the carriers and the oligonucleotides leads to compaction and condensation of the oligonucleotides into small particles that gain entry

into cells by nonspecific fluid-phase pinocytosis (37). Some synthetic peptide-based carriers falling within this category have been used successfully, e.g., AlkCWK₁₈ (38), and others (39, 40). Because pinocytotic uptake usually leads to endosomal trapping of the oligonucleotide complexes, helper molecules such as chloroquine (facilitator of endocytic exit through limitation of DNA degradation by lysosomal enzymes (41, 42)) and glycerol (enhanced uptake of particles and labilization of vesicular membranes (43)) are being used, and peptides capable of rupturing endosomal membranes at the low pH of this compartment have been developed. These are discussed under the amphiphilic peptide vectors below. The second category of carrier-mediated oligonucleotide delivery concerns vectors capable of mediating direct cytosolic delivery of oligonucleotides across the plasma membrane. Several peptide vectors in this category have been described and are referred to specifically below. Early examples using antisense oligonucleotides and pAntp vector conjugates showed not only successful cellular delivery of such constructs, but also clear antisense effects: inhibition of neurite outgrowth due to suppression of amyloid precursor protein neosynthesis (44) and cell death due to down-regulation of Cu/Zn superoxide (45), respectively.

Nanoparticles. Intracellular magnetic labeling of cells with ferro/superparamagnetic substances can be achieved, e.g., by fluid phase endocytosis, receptor-mediated endocytosis, or phagocytosis. The cellular uptake of dextran-coated superparamagnetic iron oxide particles was shown to be over 100-fold more efficient when the particles were derivatized with an HIV TAT-delivery vector peptide (46). In this approach, a monodispersed superparamagnetic iron oxide colloid was cross-linked and aminated. The pendant amino groups were first derivatized with the heterobifunctional cross-linker *N*-succinimidyl 3-(2-pyridyldithio)propionate, followed by disulfide exchange using a cysteinylated TAT(48–57) vector peptide. The resulting peptidyl conjugate particles had an average size of 41 nm and contained ca. 6.7 TAT peptides. Internalization of these particles into lymphocytes was very efficient, resulting in up to 10⁷ particles/cell, permitting NMR imaging techniques. This technology has recently been applied to the in vivo tracking and recovery of progenitor cells (47).

Organic Molecules. Not only biomolecules, but also many small-molecule natural products, as well as numerous synthetic drug candidates, are membrane-

impermeable due to unfavorable physicochemical properties. Here too, administration in vectorized form may be useful. Furthermore, effective therapeutic application of many organic molecules is prevented because of their poor solubility, absorption, or distribution. It is conceivable that some of these difficulties could be overcome with drug–vector peptide conjugates. One such problem is the delivery of neuropharmaceuticals across the blood–brain barrier. Various strategies, including peptide–vector approaches, have been proposed for the brain delivery of drugs (48). Thus it was shown that the anticancer agent doxorubicin was able to cross the blood–brain barrier in a brain perfusion model (49), as well as after parenteral administration to mice, when covalently linked to Pegelin (50, 51) or pAntp vector peptides (52).

VECTORS

Some of the more prominent vector peptides are summarized in Table 1. Although various different membrane translocation mechanisms are implicated, depending on the vectors, certain low-order structural similarities between the peptides can be discerned. Apart from the highly lipophilic signal peptide-derived vectors, amphiphilicity and the preponderance of positively charged amino acid residues (Arg and Lys) are noted. Recent systematic approaches to investigate the latter observation demonstrated that natural Arg-rich peptides, including RNA-binding and DNA-binding peptides derived from all types of organisms (viruses and yeasts to human), as well as synthetic polyarginines, can translocate across membranes and are able to deliver proteins (53). Furthermore, selected Lys- and Arg-rich peptides derived from a phage-displayed library were capable of delivering β -galactosidase *in vitro* and *in vivo* (54). Many of the vectors also possess oligonucleotide-binding properties, as indeed do most proteins with nuclear localization signals (55, 56) and in many cases DNA-binding and translocation capacities appear to be interdependent. Few studies have been reported where different vectors have been applied to the same delivery problem, and it is thus difficult to assess accurately the relative advantages and disadvantages of the various vector systems. In one study, three vector systems (Penetratin, MPS, and model amphiphilic peptide; refer to Table 1) were compared for the delivery of SH3 domain blocker peptides (57). Here Penetratin was found to be the superior vector, with the other two peptides either reducing biochemical affinity of the blocker peptide in vectorized form and the vector displaying cellular toxicity, respectively.

Homeoprotein Vectors. The homeobox encodes the 60-amino acid sequence of the homeodomain in the products of many developmental genes. These products are often regulatory proteins, which affect the expression of other developmental genes through binding to cognate DNA sequences. The fact that a synthetic peptide (pAntp) encompassing the entire homeodomain of the *Drosophila* homeoprotein antennapedia was sufficient to bind to specific DNA had already been demonstrated (58), when it was discovered that this peptide was also capable of penetrating nerve cells in culture and to accumulate in their nuclei through an energy-independent mechanism (59). Initially, α -2,8-polysialic acid (PSA) chains specific to the neural cell adhesion molecule were proposed as the neuronal cell surface receptors (60). However, the ability of pAntp to penetrate efficiently into a large number of cells devoid of PSA suggested the existence of a more general cell internalization mechanism (61). Even lymphocytes, which are notoriously difficult to transfect, take up the pAntp peptide efficiently (62). After delivery

into cells, pAntp conjugates are generally localized to the cytosol and the nucleus. However, mitochondrial delivery is also possible with the aid of chimaeric pAntp – mitochondrial signal sequence vectors (63).

Homeodomains are composed of three α -helices, with a β -turn between helices 2 and 3 (64) and are highly conserved among homeoproteins and across species (65). The region of the Antp homeodomain responsible for internalization of the protein by cells was mapped to the third helix (66), and this finding led to the demonstration that a 16-residue peptide corresponding to that helix is necessary and sufficient for the translocation of biological membranes (67). Subsequent structure–activity studies based on that peptide showed that cell internalization was receptor-independent and correlated in some way with a proposed bioactive amphipathic structure (68). Thus membrane translocation was equally efficient at 4 °C and 37 °C for the native sequence, as well as *retro*- and *inverso*-peptide isomers. The same was independently shown to be true for *retro-inverso* analogues of the same sequence (69). An analogue derived from pAntp(43–58), and consisting entirely of Arg and Trp residues (70–72), has also been studied, and the exclusive presence of cationic and hydrophobic groups in this peptide support the notion that amphipathicity is involved in the mechanism of action. The minimal sequence necessary and sufficient for functional membrane translocation of pAntp peptides, previously thought to correspond to pAntp(43–58), has recently been mapped to the C-terminal heptamer encompassing residues 52–58 (73). A pAntp-derived vector, designed from known structure–activity relationships and incorporating peptidomimetic elements was also reported recently (74). The fact that several homeoproteins and homeodomains investigated to date appear to internalize into cells suggests that additional peptides, mechanistically related to pAntp(43–58), may yet be discovered (12, 65, 75, 76).

Although pAntp(43–58) adopts amphipathic helical structure in various solvents and in the presence of SDS micelles (77), helicity does not appear to be a prerequisite for activity, since Pro-containing substitution analogues presumably incapable of helical structures nevertheless traversed membranes (78). In fact it has been shown recently that the pAntp(43–58)'s secondary structure in membrane-mimicking environments is dominated by β -structures (79, 80). The peptide exhibits high surface activity in the presence of phospholipids, and translocation properties appear to be linked with the disorder induced by the peptide in charged lipid layers. The cellular uptake mechanism appears to involve only peptide–membrane lipid interactions (81), and the translocation does not apparently involve pore formation (82, 83). However, although models have been proposed (72, 84), the exact mechanism responsible for membrane translocation by pAntp peptides remains largely elusive.

The question of how certain proteins without a signal sequence can be secreted has been raised in connection with homeoproteins (84). A detailed study (85, 86) with the homeoprotein Engrailed, which, when expressed in cells, is secreted into the culture medium, revealed a short sequence (termed Δ 1) that appears to be necessary for nuclear export and secretion. The sequence in question is positioned N-terminally of the cellular import sequence (helix 3) and partly overlaps with it. This situation is suggestive of an import–export model that may apply to other homeoproteins, and messenger proteins in general. Furthermore, these findings may lead to the discovery of vector peptides capable not only of cellular import, but also cellular trafficking.

The use of pAntp vectors in order to probe protein–protein interactions with short peptide sequences in the context of whole-cell function has been very extensive, while protein transduction has been analyzed to a much lower extent (28, 76). Thus peptides involved in regulation of cell proliferation (28, 57, 87–102), cell migration (103, 104), cellular immune processes (105), and peptidic active-site antagonists and other modulators of cellular processes (106–110), have all been delivered to cells in vitro, and, in some cases, in vivo, and effector mechanism-based functional read-outs have generally been obtained. Applications involving successful cellular delivery of antisense oligonucleotides (44, 111, 112) and antisense peptide nucleic acids (PNAs) (113, 114), leading to antisense target-related effects, have also been reported, again including in vivo applications.

HIV TAT Vectors. The human immunodeficiency virus (HIV) encodes several regulatory proteins not present in other retroviruses. One of these is the 86-residue TAT protein, which *trans*-activates certain viral genes and is essential to viral replication. Independent studies using bacterially expressed (115) and chemically synthesized (116) TAT protein, respectively, showed that this protein could enter cells when added to the medium of cells in culture. Furthermore, the protein located to the nucleus and was capable of *trans*-activating viral promoters. The domain responsible for translocation was shown to encompass the basic domain of the TAT protein. A peptide extending from residues 37–72 enabled cellular delivery of protein cargoes such as β -galactosidase, horseradish peroxidase, RNase A, a *Pseudomonas* exotoxin A fragment not only in vitro, but also in vivo (117, 118). Similarly, a vector based on the sequence 37–62 was successfully used to deliver an antibody Fab fragment to cells (119, 120).

A peptide containing the TAT sequence including residues 38–60 was shown to adopt an α -helical conformation under certain conditions; in particular, the sequence 38–45 appeared capable of forming an helix with amphipathic characteristics, whereas the basic sequence 49–57 was unstructured (121). The latter sequence was demonstrated to contain a nuclear localization sequence (NLS) (122). Furthermore, using a β -galactosidase-TAT cellular expression vector, it was demonstrated that the TAT-NLS was able to confer nuclear entry and binding to nuclear components through a novel import pathway (123). A detailed study (124) involving peptides derived from the TAT(37–60) sequence showed that the amphipathic helix was in fact not required for cellular peptide uptake. In contrast, the whole basic domain from the TAT sequence, which appears unstructured in solution (125), was necessary for cell internalization. The minimal sequence necessary and sufficient for membrane translocation was TAT(48–57). Although intact HIV-1 TAT protein contains an RGD cell adhesion site (126) and enters cells by energy-dependent absorptive endocytosis (127), uptake of TAT peptide constructs does not apparently involve classical receptor-, transporter-, endosome- or adreptive-endocytosis-mediated processes. However, unlike the inverted micelle model of membrane transduction favored for pAntp, a mechanism involving direct penetration of the lipid bilayer caused by the localized positive charge of the vector, in which the momentum of the molecule drives the covalently attached cargo into the cytoplasm, has been proposed (128). On the other hand, a similar mechanism is indicated by studies with equine TAT protein which suggest that the structural elements responsible for the cell membrane transduction

properties of TAT and homeoproteins could be related by evolution (129).

Short TAT peptide vectors have been used widely in order to introduce various functional peptides and oligonucleotides into cells (112, 130–132). Furthermore, TAT peptide vectors have been used particularly successfully for cellular transduction with functional proteins. An interesting example is the design of a transducing, modified, apoptosis-promoting caspase-3 protein, in which endogenous proteolytic cleavage sites were substituted with HIV protease-specific ones (133). The application of this TAT peptide-caspase construct to HIV-infected cells led to apoptosis, while remaining without effect on uninfected cells. Although entire proteins can be delivered into living cells using TAT peptide vectors (118, 128, 134–136), membrane transduction appears to be a stringent process that involves partial or complete unfolding of the protein cargo (137). For example, although delivery of correctly folded TAT-GFP fusion protein into cells was efficient, it was accompanied by significant loss of GFP fluorescence emission (128).

Very recently, a detailed structure–activity relationship study (138) based on the HIV TAT(49–57) sequence RKKRRQRRR (139) revealed that while further truncation of the 9mer sequence led to abolition of membrane-translocation properties, the sequence could be *retro*-, *enantio*-, and *retroenantio*-modified with beneficial effects. Furthermore, of the nine residues only Gln⁵⁴ was particularly sensitive to Ala substitution. Replacement of the two Lys and the Gln residues with Arg, i.e., formation of an Arg₉ homopolymer, afforded a peptide with improved cell internalization properties. This could be further enhanced by using D-Arg residues exclusively (r9). Of the D-Arg homopolymers the 9mer had optimal properties but here truncation down to the 7mer (r7) was tolerated in terms of internalization properties. Corresponding Lys, Orn, and His oligomers were less effective at entering cells (140). Comparison of r9 with HIV TAT(47–59) and pAntp(43–58) showed that the former entered cells significantly faster than the native TAT sequence and the pAntp sequence. Peptoid analogues of the HIV TAT sequence (141, 142), i.e., peptidomimetics containing *N*- rather than *C* α -substituted α -amino acid monomers, were also studied. Here similar findings as with the Arg homopolymers were made. Additionally, cellular uptake was proportional to the length of the alkyl chain in the *N*-alkylguanidine monomer side chains. In this study the energetics of cellular uptake of the peptides and peptoids were assessed not only in terms of temperature-dependence, but also by performing penetration assays in the presence or absence of sodium azide. While temperature did not apparently influence membrane translocation (consistent with results obtained elsewhere with many different vectors), azide, an inhibitor of oxidative phosphorylation (143), was found to inhibit cell internalization.

An application of the r7 vector, conjugated through a pH-sensitive linker to cyclosporin A, has been reported (144). Cyclosporin A is ineffective for topical applications due to its poor skin-penetration properties. In contrast, it was found that the r7 conjugate was transported efficiently into mouse and human skin, reached dermal T lymphocytes, and inhibited cutaneous inflammation.

HBV PreS2 Vector. A permeable peptide, referred to as PreS2-TLM (translocation motif), was recently reported (145). The presence of a masked fusion peptide in the PreS2 surface antigen of hepatitis-B virus had previously been postulated (146), when it was observed that proteolytic digestion of viral particles enabled

infection of otherwise nonpermissive cells (147). The PreS2-TLM corresponds to an amphipathic α -helix between residues 41 and 52 of the PreS2 protein. The peptide appears to be able to penetrate a variety of cells, including plant cells, by an energy-independent mechanism. Once inside a cell, it distributes evenly over the cytosol. Recombinant PreS2 protein, when infused into the portal vein of anesthetized rats, was detected in various liver cells, including cell layers distant from capillaries (145). Interestingly, in comparison to the TAT-peptide, Penetratin, and other peptides rich in positively charged residues, PreS2-TLM contains only one negatively and one positively charged amino acid. Therefore, this peptide may follow a different translocation mechanism.

HSV VP22 Vector. A 38-kDa structural protein, VP22, from herpes simplex virus-1 has the remarkable property of intercellular transport (148). When expressed in a subpopulation of cells, the protein spreads to every cell in a monolayer, where it concentrates in the nucleus and binds chromatin. VP22 is also a target for phosphorylation in the nucleus after viral infection, presumably as a result of casein kinase II activity (149). Apparently, intercellular trafficking occurs via a nonclassical Golgi-independent mechanism that may involve the actin cytoskeleton. The utility of VP22 as a transport vector was demonstrated using fusion proteins with a 12-residue epitope tag or the 27-kDa jellyfish green fluorescent protein (GFP). In the former case, transport properties were found using either endogenous synthesis, or by application to the medium and uptake. The GFP fusion protein was expressed in COS-1 cells and was observed to move to surrounding untransfected cells in the same way as wt-VP22. Although intercellular transport of GFP-VP22 constructs was discussed controversially (150), recent reports have confirmed intercellular transport, not only to proliferating cells, but also to terminally differentiated cells (151–154). Furthermore, transport was quantitated (155) and *in vivo* delivery demonstrated (156). VP22-mediated protein transport has also been used in order to deliver thymidine kinase (TK) to neuroblastomas in live mice, rendering the tumors sensitive to the TK-activated prodrug ganciclovir and causing tumor regression (157). Functional application relevant to gene therapy was shown with a chimaeric protein consisting of VP22 linked to the tumor suppressor protein p53 (158). Not only was spreading between cells seen using this protein, but induction of apoptosis in p53-negative human osteosarcoma cells, resulting in a widespread cytotoxic effect. A mutant VP22 protein lacking the C-terminal 34 residues was found to be synthesized in transfected cells at similar levels as wt-VP22; however, it was not detected in the nuclei of surrounding cells. This indicates that the sequence responsible for imparting membrane permeability to the protein is located in the C-terminus and that, as has been found in many similar cases, a short permeable peptide may be derived from the sequence of this protein. As far as can be ascertained, this has not as yet been achieved. Identification of such peptides would be desirable as immunogenicity is likely to be a problem with full-length VP22 chimaeras (134). Viral VP22 is known to be a T-cell antigen (159) and VP22-reactive T-cells may play a role in the control of recurrent HSV infection. Nevertheless, VP22-mediated delivery of transgene products is now considered a promising strategy for successful gene therapy, overcoming current problems associated with limited delivery (160).

Apolar Signal Peptide Vectors. Although hydrophobic signal sequences lack primary sequence identity,

the critical characteristic which correlates with membrane activity appears to be residue-average hydrophobicity in the h region (161), and neither the positively charged N-terminal segment nor the C-terminal signal peptidase cleavage site are necessary for membrane translocation (162). The h region, comprising 7–16 nonconserved residues, is thus the dominant structure determining membrane-translocating signal sequence function (163, 164) and has been identified in numerous signal peptides (165). Synthetic peptides corresponding to the h region of signal sequences from Kaposi FGF (166), integrin β_3 (167), and *Caiman crocodylus* Ig(v) light chain (168) have been developed as delivery vectors. Kaposi FGF and β_3 -integrin derived delivery peptides are also known as MPS (membrane permeable sequences) in the literature.

As with other peptide vectors, cell permeability is not limited to particular cell types, and membrane translocation appears to be independent of ATP, since cells depleted of their metabolic ATP pool were nevertheless able to internalize vector peptide (166). However, the mechanism of membrane translocation here is clearly different to the cases discussed above, since transport of apolar signal peptide vectors is temperature-dependent (166). Presumably membrane translocation in this case is dependent in some way on membrane fluidity. Again the precise mechanism remains unclear, although it is clear that import is not dependent on caveolae (164). Conformational analysis of a delivery vector constructed by fusing the signal sequence of *caiman crocodylus* Ig(v) light chain (169) and the NLS of the SV40 large T antigen (170) showed that the peptide adopted a disordered structure in water, α -helical structure in the presence of trifluoroethanol or detergent micelles, but mainly antiparallel β -sheet form in the presence of lipids, regardless of the nature of the phosphate headgroup, and embedded in the lipid cores (171). Unlike other apolar signal peptide vectors, this particular peptide was observed to internalize efficiently into cells at low temperature.

The apolar signal peptide vectors have been applied extensively and successfully in dissecting intracellular signaling pathways (172, 173), particularly those concerning intracellular integrin signaling (166, 174) and blocking of signaling to the nucleus through specific NLSs (167). Recent studies with the latter approach also suggest potential *in vivo* utility of apolar signal peptide vectors (175–177). As with the HIV TAT peptide, large macromolecular cargo can be imported into cells. Thus a 12mer apolar signal peptide vector was fused to the 41-kDa protein glutathione S-transferase, and the resulting construct was imported into cells efficiently (178).

Although several examples of functional molecular cargoes being imported into living cells using these vectors are documented (164, 179), a question remains concerning their universal applicability. This question concerns intracellular targeting and localization, since hydrophobic signal peptides generally direct the polypeptides they form part of to the endoplasmic reticulum (180). At least in one case (181), where antisense oligonucleotides were fused with these vectors, efficient membrane translocation was observed, but no appreciable antisense effect was obtained. Examination of the cellular distribution revealed endosomal trapping of the conjugates. Interestingly, this was the case regardless of whether a NLS was appended to the vector sequence. In a different approach (182), the K-FGF vector was conjugated with a polycationic linker, which was then complexed electrostatically with an oligonucleotide. In this case cytosolic and nuclear accumulation of the

construct after application to cell cultures was shown, although no functional read-out was reported.

Fusion Peptide from HIV gp41. Because of their role in cell fusion, the hydrophobic amino-terminal regions of transmembrane proteins of various enveloped viruses, including the orthomyxoviruses, paramyxoviruses, and retroviruses, are known as fusion peptides (183). Viral fusion reactions fall into two classes, low pH-dependent (see below) and pH-independent. Viruses with low pH-dependent activity fuse with membranes of acidic endosomes, whereas those with pH-independent activity fuse with both plasma membranes and endosomes. Thus, cells expressing the fusion proteins of simian virus 5, respiratory syncytial virus or HIV fuse at neutral pH. A fusion peptide consisting of 28 contiguous hydrophobic amino acid residues was shown to be present in the HIV gp41 glycoprotein (184), and its function in syncytium formation was demonstrated (185). Certain mutations in the conserved *N*-terminal fusion domain of gp41 (186, 187), as well as antibodies specific for this domain, inhibited HIV infection, syncytium formation, and HIV cytopathy (188, 189). Furthermore, the ability of synthetic gp41 fusion peptides to perturb and lyse artificial lipid bilayers has been demonstrated and the membranotropic ability shown to be dependent on peptide length, sequence, and temperature (190–192). Using human erythrocyte membranes it was shown that at subhaemolytic doses *N*-terminal gp41 fusion peptides bind to erythrocytic lipids, whereas at doses of $\geq 5 \mu\text{M}$ haemolysis takes place (193).

The potential utility as a cellular delivery vector of a gp41-derived peptide (residues 1–17), also containing the NLS of SV40 large T-antigen (170, 194), was suggested (195). Until recently it has been assumed that peptide vectors had to be tethered covalently to their cargo in order to effect cellular delivery. This concept has now been challenged. The fact that cellular transfection with oligonucleotides can be mediated by cationic liposomes and other cationic amphiphilic species is well established (37). Here, packaging and compaction resulting from electrostatic and hydrophobic interactions with anionic oligonucleotides is important. Similar effects have recently been shown with the above gp41/SV40T vector peptide, when noncovalently complexed with oligonucleotides (196). Some of the claimed advantages over traditional transfection methods of this system are as follows: delivery does not follow the endosomal pathway, it is not cytotoxic, and it is not affected by serum proteins. More surprisingly, noncovalent association of the vector with a hydrophobic peptide has recently been shown to permit cellular delivery (197). High-affinity interaction between the peptide and the vector, presumably involving the hydrophobic *N*-terminus of the latter, resulting in vector–peptide complexes (ca. 20:1 ratio), were demonstrated. It remains to be seen how general this promising approach is in terms of polypeptide delivery.

Amphiphilic Peptide Vectors. Lipid-enveloped viruses infect their host cells by fusing with either the plasma membrane or the endosome membrane after endocytosis of the virion. The former process is mediated by hydrophobic fusion sequences (see above), which are normally expressed on the surface of the fusion proteins, whereas the fusion sequence of, e.g., influenza virus haemagglutinin (HA), is exposed only at the low pH of endosomes, at pH 5–6 (198, 199). The low pH results in a change of conformation of HA leading to the exposure of the amino terminus, which consists of an amphiphilic helix ending in a short hydrophobic sequence of about 10 residues. Short synthetic peptides containing the first

17–23 residues of the HA2 subunit of HA also display pH-dependent lytic properties, with little activity at neutral pH but with >100 -fold increase in transfection efficiency at pH 5. The lytic properties of these anionic peptides are only revealed as the Asp and Glu side-chain carboxyl groups are protonated, allowing the peptides to adopt amphiphilic helical structures (200, 201). Oligonucleotide–peptide conjugates containing such HA peptides have been used successfully in order to overcome the frequent phenomenon of endosomal trapping after transfection (39, 202, 203). While certain anionic peptides cause membrane fusion at acidic pH, corresponding cationic peptides may have the same effect at alkaline pH. Thus amphiphilic anionic and cationic peptides formally derived from the influenza virus HA fusion segment, have been proposed as vehicles for oligonucleotide transfection (8, 204, 205). A study examining a large number of influenza fusion sequences, as well as many other different lytic peptides (19), led to the design of the amphipathic endosomolytic vector peptide JTS-1 (GLFE-ALLELLESLWELLEA), whose application for gene delivery, in conjunction with the synthetic poly-Lys (40, 206, 207) substitute YKAK₈WK, has been advocated (208). Many other naturally occurring and designed amphiphilic lytic peptides, including, e.g., ones derived from the wasp venom component mastoparan (209), from the *C*-terminus of the HIV-1 gp41 protein (210), and from synthetic ion channel peptides (119), are known and have been studied as delivery vectors (134). In many of these constructs containing endosomolytic peptides, DNA-binding and compacting sequences, and NLSs have also been incorporated (11, 211, 212).

A particularly interesting system is represented by the so-called GALA (213) and KALA peptides. The latter peptide (WEAKLAKALAKALAKHLAKALAKALKACEA (214)) undergoes a pH-dependent random coil to amphiphilic α -helical conformational change as the pH increases from 5.0 to 7.5. KALA is efficient at causing membrane leakage from neutral and negatively charged liposomes and causes complete leakage of entrapped contents over the pH range of 4.0–8.5. Furthermore, KALA binds to oligonucleotides and plasmid DNA and assists their nuclear delivery when complexes are prepared at a 10/1 $\pm$ charge ratio. In fact such complexes mediated transfection of a variety of cell lines. It seems likely that here direct plasma membrane translocation to the cytosol, as well as endocytic uptake and release, may be involved. For a similar model α -helical amphiphilic peptide (KLALKLALKALKALKLA, (215, 216)), nonendocytic uptake mechanisms were in fact demonstrated. Further examples of designed cationic amphiphilic α -helical delivery peptides are known (217).

Not only do peptide-based oligonucleotide delivery systems now offer a viable alternative to traditional *in vitro* lipofection methods (33, 34, 36, 218), but synthetic peptide-based gene delivery systems consisting of Lys-rich oligonucleotide binding regions and pH-sensitive endosomolytic motifs have been developed for *in vivo* gene delivery and expression (38). In general it should be remembered, however, that amphiphilic peptides are generally cytolytic and cannot therefore be expected to provide delivery vectors permitting delivery of effector molecules at high therapeutic indices.

Anti-DNA Antibody-Derived Peptide Vectors. The fact that certain anti-DNA Abs are capable of entering living cells has been known for some time (219–221). Studying naturally occurring polyreactive anti-DNA mAbs derived from the spleen cells of a nonimmunized lupus mouse, Avrameas et al. (222) found that many

hybridomas cloned secreted cell-penetrating IgG mAbs. These Abs, or their Fab' and (Fab')₂ fragments, were capable of penetrating various different cell types through an energy-dependent mechanism, entering the nucleus, and accumulating there. This process did not apparently alter either cell viability or metabolism and internalization was mediated in some way by mAb binding to cell surface structures. Interestingly, only polyreactive anti-DNA mAbs could penetrate cells. They appear to represent clones of natural polyreactive autoantibodies that escape normal control and which are expanded in lupus disease. Penetrating mAbs or their fragments were effective vectors for the delivery of haptens, oligonucleotides, and polypeptides ($389 > M_r > 40000$).

Sequencing of three mAbs revealed high homology in the V_H CDR2. A synthetic peptide corresponding to one of these CDR2 sequences did not bind antigen or translocate membranes. A peptide corresponding to the V_H CDR3, however, had some penetration properties. When both sequences were linked in the form of a peptide, full DNA-binding, polyreactivity, and efficient cell penetration properties were observed. This peptide vector (P3) was capable of carrying molecular cargo into cells in the same way as the parent mAb. It has been speculated that by combining the CDR2 and CDR3 of different penetrating anti-DNA mAbs or their mimotopes (223), peptide vectors with various properties may be designed (222).

Incubation of cells with complexes between penetrating mAb and plasmid DNA encoding a tumor antigen resulted in expression of the antigen in no more than 0.1% of cells. It is unclear whether this is due to misrouting of the internalized plasmids or hindrance to internalization arising from structural alterations imposed on the mAbs through plasmid binding. The latter is more probable, as site-directed mutagenesis studies of penetrating anti-DNA mAbs have shown that the same residues are involved in DNA binding and mediation of cell entry (221). Vector P3 was also ineffective in oligonucleotide delivery. Extension of the peptide with 19 Lys residues to achieve DNA condensation (38), however, afforded an efficient gene delivery vehicle. For example, efficient transfection of cells with plasmids carrying the genes of the green fluorescent protein or luciferase was reported (224).

Transportans. Transportan is a 27-residue peptide vector (225). Its sequence is composed of 12 residues derived from the neuropeptide galanin, connected, via a Lys residue, with 14 residues corresponding to the wasp venom peptide mastoparan. The former represents the smallest active galanin-receptor ligand with agonist properties. Mastoparan has the ability to penetrate membranes, where it creates short-lived pores by translocating into the inner leaflet; it inhibits Golgi transport and facilitates the opening of mitochondrial permeability pores. Transportan appears to enter cells in an energy-independent manner unrelated to endocytosis. Like other peptide vectors, it does not seem to be selective for particular cell types. It first localizes to the outer membrane, followed by redistribution into the nuclear membrane and uptake into the nuclei and concentration in the nucleoli. Because of its derivation from bioactive peptides, it can be expected that this vector may have undesirable biological effects. Thus it lowers GTPase activity in Bowes cell membranes with an apparent IC₅₀ of 50 μ M, although apparently not exhibiting cytotoxic effects at concentrations below 20 μ M. An improved version, termed transportan 2, containing an inactive mastoparan analogue, has been proposed to overcome these problems (226). The utility of transportans as

delivery vectors has not as yet been examined extensively. Nevertheless, comparative studies with the Antp vector (227) and using cellular and in vivo delivery of PNAs suggest promise (114). A truncation analysis of transportan has also been reported recently (228).

PHARMACOLOGY IN LIVING ANIMALS

The utility of peptidic delivery vectors in the context of cell biology has been demonstrated extensively. However, the ultimate aim of the technology is to provide novel therapeutic modalities for macromolecules. Although the first report on peptide vector-mediated systemic delivery of polypeptides into whole animals dates back to 1994 (118), comparatively few in vivo studies with vector conjugates have been reported since then and more detailed pharmacological studies are required. In the case of the 11mer TAT vector it was demonstrated that a fusion protein with the 120-kD β -galactosidase protein could be delivered in vivo (29). After intraperitoneal injection of this construct into mice, specific galactosidase activity could be developed in all tissues, including the brain. In fact several in vivo protein transduction applications have been reported using this vector; the subject was reviewed recently (135). The pAntp delivery peptide system, as well as several other vectors discussed above, have also been used for in vivo applications (105, 106, 114, 229).

The main concern regarding therapeutic utility concerns the rapid and highly efficient uptake of vector conjugates by tissues. For example, it was shown that intraperitoneal administration of 0.6 nmol of a HIV TAT peptide-derived vector to mice resulted in complete transduction into all cells present in whole blood after only 30 min exposure, with no additional increases at 60 min postadministration (230). Pharmacokinetically this situation suggests that targeting to tissues in vivo will be difficult and that high doses may be required. Little appears to be known about the inherent toxicity of peptidic delivery vectors; however, cationic peptides such as polylysines are known to be toxic. Thus the potential for rate-limiting toxicity, if high conjugate doses are required, clearly exists. A further area requiring examination concerns the peptidic nature of the delivery vectors in relation to immunogenicity. Since the majority of applications will presumably require repeated administration of conjugates, avoiding the induction of an immune response to peptidic conjugates will be important. One of the advantages with the peptide vectors is the fact that they appear to be able to cross the blood-brain barrier (49, 114). Furthermore, topical applications have recently been shown to hold promise (106, 144).

VECTOR CONJUGATION METHODS

Polypeptide-Vector Conjugates. In the majority of vector peptide applications, the effector parts of the conjugates are peptides themselves. In these cases the two sequences are usually synthesized contiguously. This approach is practically feasible for conjugates up to about 50 amino acid residues in length. For longer constructs, genetic engineering methods or chemoselective conjugation can be used. The latter approach is also sometimes preferred for shorter constructs when a modular approach is desired. Apart from ligation techniques, protein conjugation methods are not discussed here as there are excellent treatises on this subject (231). Methods that have found application in the preparation of permeable polypeptide conjugates are summarized in Scheme 1, and some are discussed in more detail below in the context

Scheme 1. Chemoselective Conjugation Methods

of oligonucleotide-peptide conjugation. Of particular importance are peptide heterodimers formed through disulfide bond formation (Scheme 1a). Specific and efficient methods for the synthesis of such heterodimers by titration of thiol-activated peptides with thiol-containing peptides have been developed (232). In principle the same considerations as for polypeptide constructs apply for peptide nucleic acid (PNA)-peptide hybrids. These can be obtained by synthesis in tandem (233) or through conjugation (114).

Ligation of an aldehyde group in one reactant with a 1,2-aminothiol function in the second reactant is site-specific and rapid, resulting in a conjugate containing a stable thiazolidine ring (Scheme 1d). This method has been used to prepare functionally active permeable peptides, and it was found that the thiazolidine-linked conjugates were equipotent with those containing a conventional amide linkage (234). The required C-terminal peptide aldehydes were elaborated by periodate oxidation of a 1,2-diaminopropanediol or 1,2-amino alcohol group.

Oligonucleotide-Peptide Conjugates. The fact that thiol groups can readily be introduced during solid-phase oligonucleotide synthesis at either the 3'-end by using appropriate thiol linkers (235, 236), or 5'-terminally (237-240), has often been exploited in order to obtain conjugates. Thus thiolated oligonucleotides have been conjugated with cysteinyl vector peptides through disulfide bond formation (44, 112, 114, 168, 181, 241). To favor formation of the heterodimeric conjugate in such reactions, disulfide-exchange between the free thiol in one reaction partner with a pyridylsulfenyl-activated form in the other is usually employed (242, 243) (Scheme 1a). Maleimide-thiol chemistry (244) provides the required selectivity in order to obtain unambiguous oligonucleotide-peptide hybrids from unprotected precursors in most cases (Scheme 1c). Coupling of thiolated oligonucleotides with maleimido-peptides has thus been used successfully for the synthesis of thioether-conjugated hybrids (245, 246). Specifically, thiolated oligodeoxy-

nucleotides were shown to react selectively and efficiently with maleimide-derivatized 18mer TAT and 22mer C-terminal gp41 vector peptides (247). Alternatively, 5'-amino-modified oligonucleotides can be maleimide-functionalized and then conjugated with Cys-containing peptides (248, 249) or with thiol-peptides obtained from SPPS using a disulfide bond-based linker (250). The latter method was applied to prepare oligonucleotide conjugates with a fusogenic peptide (203). Similar thioether conjugation can be achieved using bromoacetyl-instead of maleimide-functionalized peptides (251) (Scheme 1b).

Nonselective covalent attachment of peptides to DNA can also be achieved, e.g., by using a method based on the DNA alkylating moiety cyclopropylpyrroloindole (CPI). A bromoacetyl-CPI derivative is first alkylated with a cysteinyl peptide, and the resulting complex is then conjugated to DNA through *N*-alkylation of purine bases.

Unsatisfactory reactivity during macromolecular condensations in solution frequently derives from limited and incompatible solubility of macromolecular substrates. This situation has been shown to be ameliorated to a large extent by employing solid-phase segment condensation methods (252). This approach is applicable to the synthesis of peptide-oligonucleotide hybrids: for example, protected solid phase-bound oligonucleotides can be derivatized 5'-terminally with an aminoalkyl group, followed by amidation with suitably side-chain protected *N*^α-Fmoc-blocked peptide acids. The protected immobilized hybrids are then liberated from the support through appropriate deprotection and cleavage (253). A linker-free version using a 3'-terminal aminothymidine building block, followed by stepwise Fmoc-based SPPS, has also been reported (254). Although various approaches toward total stepwise solid-phase synthesis of oligonucleotide-peptide hybrids have been taken (255-258), this attractive method of synthesis cannot as yet be regarded as mature enough for general application.

Native ligation techniques (259), originally devised for the splicing of unprotected peptide segments in the

chemical synthesis of proteins, have also been adapted to the conjugation of peptides with oligonucleotides (Scheme 1e). In one such approach (260), oligodeoxynucleotides are equipped with a *S*-*tert*-butylsulfenylcysteine phosphoester at the 3' end during solid-phase synthesis. After cleavage and deprotection, the product is condensed with a peptidyl benzyl thioester. The latter is also obtained through solid-phase assembly using an activated thiosuccinate to introduce the thioester moiety. The ligation reaction is catalyzed by the water-soluble reducing agent tris(2-carboxyethyl)phosphine, and an auxiliary thiol nucleophile is employed in order to facilitate thiol exchange. The reaction proceeds through nucleophilic attack of the oligonucleotide Cys thiol group on the peptide thioester. The resulting thioester ligation product undergoes rapid intramolecular rearrangement to the amide, due to the favorable geometry of the Cys amino and thioester carbonyl groups. A similar approach was also reported (261), in which the oligonucleotide is equipped 5'-terminally with a guanosine-5'-phosphorothioate. A phenyl thioester group was then introduced via *S*-alkylation of the terminal phosphorothioate moiety with phenyl α -bromothioacetate. The 5'-thioester oligonucleotide product was then transthioesterified with a stoichiometric amount of a peptide containing *N*-terminal Cys. As in the preceding example, facile intramolecular attack of the free peptidyl α -amino group on the newly formed thioester bond led to rearrangement to the stable amide-bonded conjugate. In effect, the ligation mechanism provides entropy activation for the eventual amide bond formation (262) and is therefore particularly attractive for condensation of macromolecular species. Ligations can be carried out in aqueous or mixed aqueous/organic media, even in the presence of powerful solubilizing agents such as urea or guanidinium hydrochloride. Furthermore, due to the near-complete chemoselectivity of native ligation, fully deprotected peptide and oligonucleotide components can be employed.

Template-directed ligation of peptides to oligonucleotides has also been reported (263): An activated peptide thioester was reacted with a 5'-thiolated oligodeoxynucleotide¹, resulting in a thioester linked peptide-oligodeoxynucleotide¹. This was then brought into close proximity with a 3'-amino-modified oligodeoxynucleotide² by hybridization to adjacent sites on a complementary oligodeoxynucleotide template. The nucleophilic amine then attacked the thioester carbonyl group of the peptide-oligodeoxynucleotide¹, forming an amide bond between the oligodeoxynucleotide² and the peptide, and releasing the 5'-thiol-oligodeoxynucleotide¹. This method relies on a template to promote the ligation reaction and to confer specificity for a particular combination of oligonucleotides and peptide. Because here ligation is carried out in an addressable format, different combinations of oligonucleotides and peptides should be able to be joined simultaneously. The full scope of this approach does not appear to have been explored to date.

Selective conjugation of biosynthetic oligonucleotides with peptides is more difficult. In the case of RNA, periodate oxidation of the 2',3'-cis diol group of the 5'-terminal ribose and coupling of, for example, peptide hydrazides or thiosemicarbazides to the dialdehyde product would appear to offer a possibility (264, 265). It has been shown that modified nucleotides can be incorporated enzymatically into both RNA and DNA (266, 267). It should therefore be possible similarly to introduce peptides, suitably modified with TTP or UTP moieties. A synthetic route for the preparation of peptides carrying

such a group, linked through an acylphosphoramidate linkage, appears to be available (268).

CONCLUSIONS

While the *in vitro* and *in vivo* cellular delivery of membrane-impermeable therapeutic agents, including inherently selective macromolecules such as proteins and oligonucleotides, now seems feasible, the next question to address will be how such agents might be delivered in a tissue- and cell type-selective manner. Here too, significant advances have been made (134, 269, 270), again using peptide-based approaches. In particular, targeted nonviral systems for gene transfer have shown promise (271–273). In fact it may soon prove possible to combine cellular delivery and targeting functions using truly modular and discriminating delivery vector systems.

Despite these prospects, more detailed answers to many mechanistic questions are still required. Thus it remains unclear in most cases if and to what extent target cells are damaged by the delivery vectors. Very little is as yet known about the ability of delivery vector conjugates to penetrate into tissues, e.g., tumors. Also, intrinsic cell selectivity has not been addressed in sufficient detail. Generally absorption, distribution, metabolism, immunogenicity, and cellular fate of delivery peptide vector conjugates will need to be studied in depth before the current promise of these agents can be realized for therapeutic applications.

Kinetics of Coupling Reactions That Generate Monothiophosphate Disulfides: Implications for Modification of RNAs

Chung-Wen Wu,^{†,‡} Paul S. Eder,[‡] Venkat Gopalan,^{*,†} and Edward J. Behrman^{*,†}

Department of Biochemistry, The Ohio State University, Columbus, Ohio 43210-1292, and
Message Pharmaceuticals, Inc., Malvern, Pennsylvania 19355. Received June 27, 2001

The inclusion of guanosine-5'-monothiophosphate (GMPS) in an in vitro transcription reaction facilitates enzymatic synthesis of an RNA transcript with a monothiophosphate group at the 5' end. A kinetic study of the modification reactions that generate monothiophosphate disulfide linkages with either 5'-GMPS alone or 5'-GMPS-primed RNA as the substrate revealed that the second-order rate constants increased as the pH was decreased. For example, when the reaction pH was lowered from 8 to 4, the k_2 value for the coupling reaction between N-(6-[biotinamido]hexyl)-3'-(2'-pyridyldithio)-propionamide (biotin-HPDP) and GMPS increased 67-fold from 1.84 to 123 M⁻¹ s⁻¹. In addition to discussing a possible mechanism for coupling reactions that involve GMPS and disulfides, we also indicate conditions that are likely to be optimal for modification of the nucleophilic sulfur in 5'-GMPS-primed RNAs.

INTRODUCTION

Impetus for the design of simple strategies for site-specific incorporation of biochemical and biophysical probes in RNAs is fueled by the increasing realization that the role of RNA and RNA–protein interactions is pervasive in various cellular and developmental processes. Advances in solid-phase oligonucleotide synthesis of small RNAs have facilitated the site-specific introduction of functional groups that lend themselves to subsequent chemical modification. For instance, a 2' amino group in an RNA oligonucleotide can be converted to a thiol (by treatment with an activated ester and a reducing agent), which in turn can be modified to incorporate a probe of choice (4). However, for large RNAs that cannot be synthesized chemically, a commonly employed approach has been to include guanosine-5'-monothiophosphate (GMPS) in an in vitro transcription reaction to enable enzymatic synthesis of an RNA transcript whose 5' end contains the monothiophosphate group (10). The nucleophilic sulfur at the 5' end can be subsequently modified to introduce a photoaffinity cross-linking agent or a spin label or an affinity tag (3, 7, 9). Despite recent reports of successful modifications of 5'-GMPS-primed RNAs, the kinetics and mechanism of the coupling reactions remain uncharacterized. In this report, we have examined the kinetics and pH-dependence of the modification reactions that generate monothiophosphate disulfide linkages using either 5'-GMPS or 5'-GMPS-primed RNA as the substrate.

RESULTS AND DISCUSSION

Spectrophotometric measurement of the kinetic rates for the coupling reactions with GMPS was made possible by choosing 2-thiopyridyl derivatives (such as 2-PDS and biotin-HPDP, Figure 1) as modifiers. The modification reactions were carried out at 24 (±2) °C under pseudo-first-order conditions with the pyridine disulfide in at least 30-fold excess. Plots of log[GMPS] versus time were linear over two half-lives and the calculated second-order rate constants (k_2) did not exhibit any significant variation when the concentrations were varied over a 3-fold range. When k_2 values were examined as a function of pH, an increase in the rate was observed as the pH of the reaction was decreased (Figure 2). For instance, the second-order rate constant for the reaction between GMPS and 2-PDS in 20% DMF (v/v) showed an 18-fold increase as the pH was decreased from 8 to 5.8 (Figure 2). Similarly, the coupling reaction between biotin-HPDP and GMPS was accelerated 67-fold (from 1.84 to 123 M⁻¹ s⁻¹) as the reaction pH was lowered from 8 to 4 (Figure 2).

These findings with GMPS as a substrate prompted us to pursue the biotin-HPDP modification reaction with a 5'-GMPS-primed precursor tRNA (ptRNA). The rate of biotinylation of 5'-GMPS-primed ptRNA was enhanced 2 orders of magnitude upon lowering the pH from 8 to 4 (Figure 2). However, since this conclusion is based on 2-thiopyridone release and not based on direct quantitation of biotin content in the RNA, we decided to employ an independent measure of biotinylation. The modification reaction was performed at different pH values, and the putative biotinylated ptRNAs were transferred to a nylon membrane where-in they were probed with a streptavidin–horseradish

Figure 1. Generation of disulfide linkages using GMPS as the substrate. The coupling reactions between GMPS (synthesized as described elsewhere (1)) and either 2,2'-pyridine disulfide (2-PDS, Sigma) or N-(6-[biotinamido]hexyl)-3'-(2'-pyridyldithio)-propionamide (biotin-HPDP, Pierce) are illustrated. A variation on the latter reaction involves the modification of a 5'-GMPS-primed RNA with biotin-HPDP. The ptRNA^{Gln} substrate was synthesized in vitro by incubating 38 $\mu\text{g/mL}$ BstN I-linearized pUC-pGln (8) with 4.8 mM GMPS, 1.2 mM GTP, 6 mM ATP, 6 mM CTP, 6 mM UTP, and 400 U T7 RNA polymerase (Ambion) for 5 h at 37 $^{\circ}\text{C}$ in 200 μL of 200 mM HEPES, 40 mM DTT, 2 mM spermidine, and 28 mM MgCl_2 . After DNase I treatment and phenol/chloroform extractions, the RNA in the aqueous phase was washed over a Microcon YM-10 membrane to remove unutilized rNTPs and GMPS.

Figure 2. The pH dependence of second-order rate constants for the various GMPS-coupling reactions (see text for details). Inset provides a key to the symbols used in the figure. The averages were calculated using second-order rate constants obtained from at least two independent experiments. 2-PDS and biotin-HPDP were dissolved in either 50% (v/v) ethanol or DMF and diluted appropriately for the modification reactions. The reactions of GMPS with either 2-PDS or biotin-HPDP were performed in 0.1 M phosphate or citrate or acetate buffer. Reactions were initiated by rapid mixing (Sigma cuvette mixer) of stock GMPS. Kinetics of the coupling reactions were measured using a BioSpec-1601 spectrophotometer (Shimadzu) by following the appearance of 2-thiopyridone at 343 nm (using $\epsilon = 7060 \text{ M}^{-1} \text{ cm}^{-1}$) for reactions in either 20% (v/v) ethanol or 20% (v/v) DMF.

peroxidase (HRP) conjugate. Increased biotinylation of ptRNA with decreasing pH would result in greater binding of the HRP-linked streptavidin. In the presence of a chemiluminescent substrate for HRP, the signal produced would be proportional to the amount of RNA that was biotinylated. The chemiluminescence signal is at least 5-fold more intense when the GMPS-primed ptRNA was modified with biotin-HPDP at pH 4 than at pH 8 (Figure 3). Since a 70-min incubation period was used for these ptRNA modification reactions, the 100-fold difference in second-order rate constants between pH 4 and 8 manifests itself as a much smaller (5-fold) apparent difference between the two pH values (Figures 2 and 3). Although this explanation could be validated by performing the tRNA modification reaction for a much shorter time (e.g., only 5 min), this was not technically feasible due to the inability to terminate the reaction prior to loading the products on the polyacrylamide gel.

The pH-rate profiles for the reactions that we have studied provide some clues with regard to the mechanism of the GMPS-modification reactions. The reactions are first-order in hydrogen ion concentration over the pH range that we studied. The first pK_a of GMPS is not known with accuracy, but it is probably around zero; the second pK_a is about 5.2 (6). The first pK_a for 2-PDS is 0.35 and the second pK_a is 2.37 (5). Since the rates of the coupling reactions are very slow at pH 7 and above (Figure 2), a significant reaction between the dianionic form of GMPS and the neutral form of 2-PDS (or similar 2-thiopyridyl derivatives) is excluded. The rates do increase remarkably with a decrease in pH and suggest that the most significant contribution to the reaction rate is probably due to the GMPS monoanion attacking either (or both) the monocation or the dication of 2-PDS. Moreover, the increased rates at acidic pH values could be attributed to the fact that protonation of both the ring nitrogens in 2-PDS not only enhances the electrophilic nature of both the sulfurs but creates a better leaving group in the protonated thiopyridone (2, 5).

It is instructive to compare the predominant pathways for the reaction of 2-PDS with either a thiol (e.g., 2-mercaptoethanol) or GMPS. The former reaction involves the nucleophilic attack of the thiolate anion on the unprotonated disulfide at pH values near and above neutrality. As expected, the pH-rate profile reveals that when the pH is decreased from pH 10 to pH 5, the rate decreases sharply probably due to a reduction in the thiolate anion concentration (2, 5). However, between pH 5 and 1, a plateau is observed in the pH-rate profile. In this pH range, protonation of the pyridine rings results in enhanced reactivity of 2-PDS and offsets the drop in rate due to decreased thiolate concentration. Although the increased electrophilicity of the protonated 2-PDS prevents the rate from falling further, it is unable to cause an overall increase in the rate; hence, the plateau. In contrast, we find that the reaction of 2-PDS with GMPS displays an increase as the pH is decreased from 8 to 4 (Figure 2). This is due principally to the increased electrophilicity of 2-PDS at acidic pH values.

A practical outcome of this study is the optimization of reaction conditions for modifications involving 5'-GMPS-primed RNAs and 2-thiopyridyl derivatives coupled to different probes. While others have performed GMPS-coupling reactions at near-neutral pH values and succeeded in $\sim 70\%$ modification (9), we believe that by

Figure 3. RNA modification and Northern blot analysis. Panel A, the pH dependence of biotinylation of GMPS-primed tRNA as detected by chemiluminescence (see below). Panel B, quantitation of the data shown in panel A. Multiple reactions (20 μ L each) were set up with 10 μ M GMPS-primed tRNA and 300 μ M biotin-HPDP in 0.1 M buffer of varying pH in the range 4 to 8. The RNA samples were then electrophoresed in a 7 M urea/ 10% polyacrylamide gel and electroblotted to a Zeta-probe membrane (Bio-Rad). After blocking the membrane for 1 h in 50 mL of nonfat dry milk [5% (w/v)]-supplemented TBST buffer (10 mM Tris, 150 mM NaCl, 0.1% Tween 20), the membrane was washed thrice with TBST and incubated for 1 h in 30 mL of TBST containing 30 μ L of 0.1 mg/mL peroxidase-conjugated streptavidin. After washing the membrane thrice in 50 mL of TBST, 3 mL of luminol/enhancer solution (SuperSignal West Dura Extended Duration Substrate) was added directly to the membrane for 1 min. The membrane was exposed to an X-ray film to obtain the photographic record displayed in Panel A. The chemiluminescence generated by the peroxidase was quantitated by using a FluorChem 8000 (Alpha Innotech) to obtain the data shown in Panel B.

lowering the pH of the reaction, the efficiency can be easily made to approach 100% and the reaction time can be shortened considerably (e.g., 5 min at pH 5 instead of 70 min at pH 8). Moreover, longer incubations at high pH are undesirable since both the 2-thiopyridyl substrates and the monothiophosphate disulfide product are unstable at alkaline pH values (9).

ACKNOWLEDGMENT

We are grateful to Prof. Gary Means for helpful discussions on the mechanistic aspects of the GMPS modification reactions. We thank Dr. Tony Giordano, Message Pharmaceuticals, Inc., for support and encouragement. Research in V.G.'s laboratory is supported by the National Science Foundation, American Heart Association (Southern and Ohio Valley Consortium), and Message Pharmaceuticals, Inc.

ARTICLES

A Derivative of Diethylenetriaminepentaacetic Acid for Europium Labeling of Proteins

Reiko T. Lee and Yuan C. Lee*

Department of Biology, Johns Hopkins University, Baltimore, Maryland 21218. Received September 19, 2000; Revised Manuscript Received April 27, 2001

Preparation of a reagent that will incorporate diethylenetriaminepentaacetic acid (DTPA) into proteins under mild conditions and make a strong europium chelate is described. Aminoacetaldehyde diethyl acetal was reacted with DTPA dianhydride, and mono- and disubstituted products as well as unsubstituted DTPA were separated by gel filtration. The monosubstituted product, after conversion into the corresponding aldehyde by mild acid hydrolysis, is conjugated to protein or other amino-containing compounds via reductive amination at neutral pH. Although the DTPA–Eu-labeled proteins are themselves not fluorescent, a strong fluorescence of europium can be generated easily by the dissociation–enhancement mechanism. A direct measurement of lectin–ligand interaction using Eu-labeled ligand and lectin immobilized on 96-well plate illustrates that the assay utilizing Eu fluorescence is as sensitive as the radioactive assays.

INTRODUCTION

Radioactive labeling has been an indispensable tool in the investigation of biological activities that requires high sensitivity and specificity. In recent years, however, the use of fluorescence of lanthanide chelates (e.g., europium and terbium) has been gaining favor as a viable alternative to the radioactivity, since lanthanide fluorescence has high sensitivity (detection level in the sub-pmol range) and its fluorescence is more specific than that of conventional fluorescent probes (1, 2). The higher specificity and sensitivity result from the fact that the fluorescence emission of these lanthanide ions is narrow-banded with a long Stokes shift and a very long fluorescence decay time (3). The latter two characteristics allow detection of lanthanide fluorescence in the presence of background fluorescence derived from biological samples and common plastic ware, especially if the time-resolved fluorescence measurement is made.

The obvious advantage of lanthanide is that there is no need for special handling, including the waste disposal, such as that required for radioactive materials. However, the major disadvantage of lanthanide labeling is the requirement for incorporating a chelating agent, a structure much larger than radioisotopes, which may affect the property of the compound labeled. For this reason it is prudent to aim for minimum level of

incorporation of a chelater (ideally <1 mol/mol on the average) into biological macromolecules, such as proteins.

Diethylenetriaminepentaacetic acid (DTPA) and related polyaminocarboxylic acids and derivatives thereof are proven chelaters of lanthanide ions. Simple polyaminocarboxylate–lanthanide chelates are not fluorescent. To potentiate the fluorescence of lanthanide for measurement, two strategies are generally used. One way is to incorporate a suitable aromatic group close to the chelater which will deliver the captured light to lanthanide so as to make it fluorescent. The second way is to use DELFIA (dissociation-enhanced lanthanide fluorescence immunoassay) technique, in which at the final stage of fluorescence measurement the lanthanide is displaced from the polyaminocarboxylate chelate and transferred into a micellar chelating environment, which will make it highly fluorescent. The former method is required when a lanthanide is used for certain experiments, e.g., fluorescence resonance energy transfer (FRET), and for which a number of synthetic compounds based on DTPA and related polyaminocarboxylates have been reported (4–7). The second method requires an extra enhancement step, but the incorporation of DTPA group into proteins is as simple as reacting them directly with commercially available DTPA dianhydride (8). The shortcomings of reacting directly with the dianhydride are (1) difficulty in controlling the extent of DTPA incorporation; (2) possibility of conjugation via both anhydride groups, which will cause undesirable cross-linking and incorporation of a lanthanide chelate that is unstable in the acidic pHs; and (3) possible change in protein stability due to neutralization of the amino group utilized in conjugation. A monofunctional reagent, *p*-isothiocyanatobenzyl DTPA, is available commercially (Wallac, Gaithersburg, MD). However, this reagent introduces an aromatic group as well as neutralizes the positive charge of the amino group

¹ Abbreviations used: BCA, bicinchoninic acid; BSA, bovine serum albumin; DMF, dimethylformamide; DMSO, dimethyl sulfoxide; DTPA, diethylenetriaminepentaacetic acid; HEPES, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; TPTZ, 2,4,6-tripyridyl-*s*-triazine; TFA, trifluoroacetic acid; RCA-I, *Ricinus communis* agglutinin I.

when it reacts with proteins. Both of these facts may introduce undesirable characteristics to the protein modified (9). For these reasons, we developed a nonaromatic reagent that has a single functional group through which proteins can be derivatized under mild conditions.

MATERIALS AND METHODS

Materials. DTPA dianhydride and aminoacetaldehyde diethyl (and dimethyl) acetal are from Aldrich (Milwaukee, WI). Europium nitrate and 2,4,6-tripyridyl-s-triazine (TPTZ) are from GFS chemicals (Columbus, OH). Bicinchoninic acid (BCA) protein assay reagent and *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) are from Pierce (Rockford, IL) and from Research Organic (Cleveland, OH), respectively. Human immunoglobulin G (IgG) is from Sigma Chemical Co. (St. Louis, MO), and bovine serum albumin (BSA) is from Pentex Division of Bayer (Kankakee, IL). *Ricinus communis* agglutinin (RCA-I) is from E-Y Labs, Inc. (San Mateo, CA). The lanthanide fluorescence enhancing solution (10) is from Wallac (Gaithersburg, MD). The neoglycoproteins were prepared as described (11). Lac₄₀-BSA is a BSA derivative containing, on the average, 40 mol of lactosyl residues per mol of BSA, and likewise Man₃₅-BSA contains ca. 35 mol/mol of mannosyl groups on the average.

General Methods. ¹H NMR spectra were recorded using a Bruker AMX 300 spectrometer, and FAB-MS spectra were taken with 70-S gas chromatograph/mass spectrometer (VG Instruments) using nitrobenzoic acid as matrix. Acetal group was determined by neocuproine method (12) after mild acid hydrolysis. For hydrolysis, a sample solution (<5 μL) was mixed with 0.2 mL of 50 mM HCl and heated in a boiling water bath for 20 min. After cooling, the hydrolysate was neutralized with 0.2 mL of 50 mM NaOH, and the neocuproine assay was carried out. The protein content was determined using micro-BCA assay as described (13).

Determination of DTPA Derivatives. The TPTZ method was originally designed for determination of an oxidant such as periodate ion (14). We adapted the method for determination of DTPA derivatives, utilizing their ability to compete ferrous ion off from the TPTZ-Fe²⁺ complex (deep blue color) (15). The decrease in the blue color (*A*_{593 nm}) is proportional to the amount of the DTPA derivative present. For monitoring of column effluent, an appropriate volume of column fraction was added to 3 mL of 2-fold-diluted TPTZ stock solution (which will give *A*_{593 nm} of 0.95–1). The tubes were incubated at 37 °C for 0.5 h and *A*_{593 nm} was determined.

Determination of Europium Content. Fluorescence determination of europium chelate was carried out in a 96-well microtiter plate. To each well containing sample (0.2–1 pmol of europium in <20 μL) was added 0.2 mL of enhancing solution, and the plate was tapped for a few seconds to mix the content of the well. After 20 min at room temperature, the fluorescence was read in a fluorometer (1420 Victor multilabel counter, Wallac) using the time-resolved fluorescence mode set for europium.

RESULTS

Preparation of Mono[2-(diethoxy)ethylamido]-DTPA (1) (Scheme 1). DTPA dianhydride (0.89 g, 2.5 mmol) was suspended in 18 mL of dry DMSO. To this suspension was added, while being stirred, a solution of aminoacetaldehyde diethyl acetal (363 mL, 2.5 mmol) in 2 mL of DMF a few drops at a time. The cloudiness completely dissipated by the end of addition. The mixture

Scheme 1

was kept for several hours at room temperature and then was evaporated under vacuum to reduce the volume by ~1/3. To this was added 5- to 6-fold volume of toluene, and the resulting cloudy solution was left standing at room-temperature overnight. A clear solution was then decanted off, and the precipitate was washed with toluene and ether and dried. The residue was dissolved in 5 mL of water and left standing for a few hours at room temperature and then in the cold overnight. The crystalline DTPA formed was filtered and washed with cold water. The filtrate was evaporated to ~5 mL and fractionated on a column (2.5 × 140 cm) of Sephadex G-15 equilibrated in 0.1 M acetic acid, collecting 6-mL fractions. The effluent was assayed by TLC on silica gel using 2-propanol–acetic acid–water (2:1:1) as eluant and by the TPTZ method. Both the desired product (**1**) and the disubstituted product (**2**) can be detected on the TLC plates by charring after spraying with 15% sulfuric acid in 50% ethanol. *R_f* of the di- and monosubstituted products are 0.26 and 0.19, respectively. The column fractions were also examined by TPTZ method, especially to detect the presence of DTPA. On a molar basis, the capacity of **1** to compete for TPTZ is similar to DTPA, while that of **2** was about one-half of DTPA. This means that the presence of five or four carboxylate groups makes little difference in the Fe²⁺-complexing capacity, while the presence of only three carboxylate group (disubstituted) greatly diminishes the capacity to complex. As expected, the compounds were eluted in the order of di-, mono-, and unsubstituted DTPA with some overlap between compounds. The column fractions having more than one component were refractionated on the same G-15 column. After two rounds of fractionation, the yield of the desired product, **1**, was ~30% and that of **2**, ~10%.

This preparation scheme was also carried out using dimethyl acetal of aminoacetaldehyde instead of diethyl acetal with similar yield, but the separation on TLC plates is clearer when the diethyl acetal is used.

Characterization of Products. The content of acetal in the two products was determined using neocuproine method after a mild acid hydrolysis. (β -D-Galactopyranosylthioglycolyl)aminoacetaldehyde dimethyl acetal (Gal-AAA) (16), a synthetic product that had been characterized sufficiently, was used as standard. Calculated on the weight basis, both products **1** and **2** had the acetal content that is 84% of the expected amount based on 1 and 2 mol of acetal per mol of the compound, respectively. We suspected that this low color yield (A_{460}) might be due to the presence of polycarboxylate interfering in the color development. Indeed when Gal-AAA was assayed in the presence of DTPA (in the amount comparable to that present in **1** and **2**), its molar absorbance was suppressed by 13%. With this correction factor, the acetal content of **1** and **2** would be 97% of the expected.

NMR spectra in D_2O were taken of the dimethoxyethyl derivatives. As expected from the molecular symmetry, the spectrum of the disubstituted product was much simpler than that of the monosubstituted product. Both products registered correct ratios of methine signal (triplet at 4.6 ppm) to methylene signals, which was about 1:18 for the mono- and about 1:10 for the disubstituted product. ^1H NMR of monosubstituted product: δ 3.269–3.303 (m, 2 H, CH_2); 3.325–3.385 (m, 2 H, CH_2); 3.456 (s, 6 H, CH_3); 3.534–3.578 (m, 2 H, CH_2); 3.727 (s, 2 H, CH_2); 3.873 (s, 2 H, CH_2); 3.978 (s, 4 H, CH_2); 4.016 (s, 2 H, CH_2); 4.604 (t, 1 H, OCHO). There are probably 4 unresolved Hs in 3.423–3.468. Disubstituted product: δ 3.352–3.368 (d, 2 H, CH_2); 3.393–3.410 (d, 2 H, CH_2); 3.457 (s, 12 H, CH_3); 3.47 (s, 4 H, CH_2); 3.771 (s, 2 H, CH_2); 3.78 (s, 4 H, CH_2); 3.91 (s, 4 H, CH_2); 4.586–4.620 (t, 2 H, OCHO). There are probably four unresolved Hs in 3.45–3.465. FAB-MS spectra of the same two products taken with nitrobenzoic acid as matrix gave peaks for the mass of 481.2 (M + H) and 503.2 (M + H) for mono- and disubstituted product, respectively.

Eu-DTPA Labeling of Proteins and Poly-L-lysine Using Compound 1. An appropriate amount of **1** (1–10-fold molar excess over the protein to be labeled) was dissolved in 0.5 mL of water, and an equal volume of TFA was added. The tube was heated at 55 °C for 2 h. The hydrolysate was evaporated after adding ~5 volumes of absolute ethanol, and this process was repeated three times. The residue was kept in a vacuum desiccator over fresh NaOH pellets overnight. The exposed aldehyde group was used to link to the protein amino group via reductive amination. The reaction was carried out for 24 to 48 h at room temperature using 5 mg of protein in 1 mL of 0.1 M HEPES buffer, pH 7.4, with up to 10-fold molar excess of hydrolyzed **1** (see below for detail) and with enough pyridine borane added to make it ~25 mM in concentration. After the reaction, the mixture was passed through a small Sephadex G-50 column (1 $\times$ 47 cm) equilibrated in 5 mM HEPES buffer at pH 7.4 to separate the excess reagent from the protein. The protein peak was located by micro-BCA method. Fractions containing protein were combined and lyophilized to a small volume (<1 mL). A 10-fold molar excess of $Eu(NO_3)_3$ was added, and the protein solution was refractionated on a smaller Sephadex G-50 column (1 $\times$ 19 cm) in 10 mM HEPES buffer, pH 7.4. The protein peak was located by analyzing the fractions for Eu fluorescence. The peak fractions were combined and lyophilized to dryness and then dissolved in a desired volume of water.

When IgG and BSA were modified using 5–10-fold molar excess of reagent over protein, the incorporation of Eu-DTPA was around 1–3 mol/mol. In the case of

Figure 1. Binding of Eu-Lac₄₀-BSA to RCA-I immobilized on microtiter wells. The bound ligand in terms of Eu fluorescence (y axis) was plotted against the amount of RCA-I used per well. ■, bound amount in the absence of inhibitor; ▼, bound amount in the presence of 6.2 μ M Lac₄₀-BSA; ▲, bound amount in the presence of 5.1 μ M Man₃₅-BSA.

Lac₄₀-BSA, which has most of its readily accessible amino groups already being used up in the lactoside incorporation, the incorporation of Eu-DTPA was only 0.4 mol/mol with the reagent-to-protein ratio of 10. In contrast, when the amino group is in a large excess as in poly-L-lysine of DP 240, the incorporation of Eu-DTPA was quantitative, meaning that the DTPA reagent was totally incorporated into polylysine.

Binding of Eu-Lac₄₀-BSA to a Galactose-Recognizing Lectin (RCA-I) Immobilized on Microtiter Plates. RCA-I solutions (100 μ L) in 25 mM HEPES buffer, pH 8.2, containing 0.15 M NaCl were placed in wells of Immulon 2 removawell strips (Dynatech Labs, Inc., Chantilly, VA) and left in the cold for 24 h. The liquid is removed by suction and replaced with 5% BSA in the same buffer. After 2 h at room temperature, the BSA solution was removed, and the wells were washed once with incubation buffer (25 mM HEPES buffer, pH 7.2, containing 0.15 M NaCl and 1% BSA). Incubation mixtures (100 μ L) containing Eu-Lac₄₀-BSA at 400 nM with or without potential inhibitor (Lac₄₀-BSA or Man₃₅-BSA) at ~5 μ M were added to the wells (in triplicate) and incubated for 24 h in the cold with rocking motion. After removal of the mixture, wells were washed once with incubation buffer that contained 0.05% Tween 20 instead of 1% BSA. To each well was added 0.2 mL of the enhancing solution, and fluorescence was determined as described in Methods. Fluorescence in million counts per second (Mcps) was plotted against amount of RCA-I added to the well, as shown Figure 1. The figure shows that there was an RCA-I dependent binding of Eu-Lac₄₀-BSA, which leveled off at about 200 ng of RCA-I per well. The binding was inhibited by unlabeled Lac₄₀-BSA, but not by Man₃₅-BSA.

DISCUSSION

Tracer labeling technique is a powerful method for measurement of biological activities. In the labeling process, it is important to strive for as low an incorporation of tracer as practical, in order not to cause change in the characteristics of the biomolecule to be labeled. This is particularly important when the incorporated label is a lanthanide (i.e., lanthanide ion + chelator) instead of a radioactive element, since the incorporated group is very much larger.

DTPA is a frequently used chelator for europium that contains five carboxylic acid groups clustered in close proximity, through which efficient chelation of europium ion is achieved. One of its carboxylic acids can be used for modification of proteins and other amino-containing compounds without affecting the chelating efficiency much. However, the loss of the second carboxylate group will compromise the stability of Eu-DTPA complex considerably (6). DTPA dianhydride is a convenient, commercially available reagent for labeling of amino-containing compounds, such as proteins. However, it has two major drawbacks. The more serious drawback is its potential for reacting with two amino groups of the macromolecule to be labeled, so as to cause intra- and intermolecular cross-linking, and to produce in the process an inferior chelator of europium having only three carboxylic acid groups. Although one may rarely encounter this complication for labeling of proteins, it posed a grave problem for us when we attempted to introduce DTPA into polylysines, because the amino group is present in a large excess of DTPA dianhydride needed for labeling. In one of the labeling experiments, polylysine actually became insoluble, presumably due to intermolecular cross-linking. In another case, although the labeled polylysine stayed soluble, the incorporated Eu was easily lost during protein-ligand binding assays if the pH was below 6. At pH 4, less than 10% of Eu remained associated with polylysine at the end of the assay, whereas europium on a similarly labeled neoglycoprotein remained totally associated. The second drawback is difficulty in controlling the amount of DTPA incorporated. Typically DTPA dianhydride is added to a protein solution in mildly alkaline medium (e.g., 10% NaHCO₃) in 10 to 50-fold molar excess (8). The large excess is necessary because anhydride is hydrolyzed rapidly in a mildly alkaline medium. To attain a low but sufficient level of DTPA incorporation under such conditions is not easy.

To overcome these problems, we prepared a monovalent labeling reagent, **1**, that will provide a single potentially reactive group and will ensure the presence of four free carboxylate groups in the labeled protein. Compound **1** was prepared by *N*-acylating an acetal-containing compound with DTPA dianhydride. This reaction as well as the formation of benzylhydrazide by reacting benzyl hydrazine with the dianhydride proceeded well, producing both mono- and disubstituted products. However, the conversion of the acetal in **1** to aldehyde did not proceed as easily as of expected, presumably due to the presence of carboxylate groups in proximity. For deacetalization of **1**, a more forcing condition, i.e., 50% TFA at 55 °C for 2 h, than that employed for a similar acetal (50% TFA at room temperature, 5–10 min) (11) had to be used. Similarly, the hydrazide group of DTPA monohydrazide (obtained from the mono-benzylhydrazide by hydrogenation) was quite unreactive when used in a reductive amination reaction (not shown). In contrast, the reductive amination proceeded well when the hydrolyzed **1** was used to

label proteins. Presumably the added distance away from the cluster of carboxylate allowed the reductive amination to proceed. The efficiency of incorporation of DTPA by this reagent depended on availability of the amino group, from being quantitative for a polylysine which possesses a large excess of amino group to somewhat sluggish for Lac₄₀-BSA which has only a few reactive amino groups remaining, since most of the reactive amino groups had been consumed in the lactose incorporation. Still, a suitable level of incorporation required no more than 10-fold excess of reagent even for unreactive proteins.

We have used Eu-labeled proteins and small ligands in the investigation of a number of lectin-ligand interactions. To illustrate the sensitivity of assays based on Eu fluorescence measured in the time-resolved mode, we present an example of a lectin (RCA-I)-ligand (Eu-Lac₄₀-BSA) interaction carried out in microtiter wells. As shown in Figure 1, the binding can be measured directly by Eu fluorescence without relying on any enhancement mechanism such as enzyme-linked color production. Although the Eu-labeled ligand used here contained on the average 0.4 mol of Eu per mol of protein, the fluorescence signal generated was more than sufficient for the measurement, indicating that the Eu fluorescence method rivals radioactive method in sensitivity. In fact, in our experience a protein with low incorporation of DTPA-Eu (<1 mol/mol) generally gave lower nonspecific binding when used as ligand in the lectin-ligand binding assays and longer shelf life when stored as solution.

Received November 2, 2000; Revised Manuscript Received April 30, 2001

In vitro selection or the systematic evolution of ligands by an exponential enrichment (SELEX) technique using a biotin-carrying nucleotide monomer was used for the development of a new type of molecular recognition sensor. Cytidine triphosphate (CTP) carrying the biotinyl group at the *N*⁴-position was applied for the technique. A pool of random sequence RNAs containing biotinyl groups in the side chains was prepared, and the RNAs binding to adenosine 5'-triphosphate (ATP) were selected. The selected nonnatural RNAs were used for an assay of ATP. Since they carried multiple biotin groups in the side chains, the sensitivity was high.

INTRODUCTION

Two methods, namely antibody production (1) and molecular imprinting (2), have been used to synthesize molecules sensing a target molecule. On the other hand, in vitro selection, also known as the systematic evolution of ligands by exponential enrichment (SELEX), was devised in 1990 for the identification of oligonucleotides, which are highly specific to target molecules. (3, 4) The selected oligonucleotides were named as aptamers and have been used as a new type of molecular sensor (5). These aptamers offer several potential advantages over traditional antibody-based reagents because they are not derived from living organisms and can be reproducibly, precisely, and quickly synthesized by automated processes. Recently, chemically modified nucleic acids were used in SELEX to expand the scope of the potential molecules (6–24). In the present study, cytidine 5'-triphosphate carrying a biotinyl group at the *N*⁴-position {*N*⁴-[*N*-(*N*-biotinyl- ϵ -aminocaproyl)-6-aminoethyl]cytidine 5'-triphosphate, Biotin-CTP} was subjected to the SELEX protocol, and a biotin-carrying RNA aptamer was synthesized and used as a new molecular recognition element. The molecular recognition element was expected to have a high sensitivity because it carried many biotin groups as probes.

EXPERIMENTAL PROCEDURES

Chemicals. Biotin-CTP was purchased from the Life Technologies Co. (Rockville, MD). Custom synthesis of DNA oligomers was performed by the Sawady Technology Co. (Tokyo, Japan). AmpliTaq DNA polymerase was obtained from the Perkin-Elmer Co. (Foster City, CA). T7 RNA polymerase and RNasin were purchased from Promega Co. (Madison, WI). Dithiothreitol (DTT) was purchased from the New England Biochemicals Co. (Beverly, MA). [α -³²P]GTP was purchased from the Am-

ersham Pharmacia Biotech. Co. (Buckinghamshire, UK). Reverse transcriptase Superscript II and a Photogene streptavidin/alkaline phosphatase conjugate were purchased from the Life Technologies Co. (Rockville, MD). ATP-immobilized gel and nucleoside 5'-triphosphates (NTPs) were purchased from the Sigma Co. (St. Louis, MO). Biotinylated nylon membrane was purchased from the Pall BioSupport Co. (East Hills, NY).

Transcription Reaction. A synthetic DNA pool containing a random region of 59 bases (5'-TAG-GGA-ATT-CGT-CGA-CGG-ATC-C-N₅₉-CTG-CAG-GTC-GAC-GCA-TGC-GCC-G-3') (80 ng) was amplified by 10 PCR cycles (94 °C, 15 s; 55 °C, 15 s; 72 °C, 15 s) in 800 μ L of reaction solution containing AmpliTaq DNA polymerase [Perkin-Elmer Co. (Foster City, CA)], 10 mM Tris-HCl (pH 8.3), 50 mM KCl, 1.5 mM MgCl₂, 0.001% gelatin, 200 μ M dNTPs, 0.5 μ M 5'-primer (P1) containing the T7 promoter sequence (5'-TAA-TAC-GAC-TCA-CTA-TAG-GGA-ATT-CGT-CGA-CGG-AT-3'), and 0.5 μ M 3'-primer (5'-CGG-CGC-ATG-CGT-CGA-CCT-G-3'). The amplified template was precipitated with ethanol, and the resulting pellet was dissolved in 30 μ L of RNase-free water. The DNA was transcribed with T7 RNA polymerase (4 μ L, 1200 U) in a reaction mixture (100 μ L) consisting of 80 mM Tris-HCl (pH 7.9), 12 mM MgCl₂, 4 mM spermidine, 20 mM DTT, 20 μ M [α -³²P] GTP, 0.4 U/ μ L RNasin, 1 mM of Biotin-CTP, and 1 mM other unmodified NTPs. This gave an approximate yield of 1 μ g of random RNA. After incubation at 37 °C for 4 h, RQ1 RNase-free DNase (Promega, 2U) was added to the reaction solution to digest the DNA template. After incubation at 37 °C for 45 min, a small aliquot (10 μ L) of the solution was analyzed by 7 M urea/8% denaturing polyacrylamide gel electrophoresis (PAGE). Dot blotting was carried out as described below. The transcripts were transferred to a Biotinylated nylon membrane using the electroblotting method. The transcripts were then detected with a Photogene streptavidin-alkaline phosphatase conjugate according to the protocol provided by the manufacturer.

Reverse Transcription. The transcription product (5 μ L) was mixed with 5 μ L RNase-free water and 2 μ L

[§] NAIST.

of 10 μ M 3'-primer P2. The mixture was incubated at 70 °C for 10 min and then chilled on ice. To this mixture were added 4 μ L of a concentrated reverse transcription buffer (250 mM Tris-HCl, pH 8.3; 375 mM KCl; 15 mM MgCl₂), 2 μ L of 0.1 M DTT, and 1 μ L of 20 mM dNTPs. Reverse transcriptase Superscript II (Life Technologies Co.) (200 U) was added to the mixture solution. After incubation at 42 °C for 50 min, the reaction was stopped by incubation at 70 °C for 15 min. Subsequently, the cDNA was amplified by PCR. Five microliters of the reverse-transcription reaction solution was added to a PCR solution (100 μ L). After 10 PCR cycles on the same thermal condition as described, small aliquots (10 μ L) were analyzed by 3% NuSieve GTG agarose gel electrophoresis.

In Vitro Selection. The randomly sequenced RNA pool was prepared as described in the transcription experiment section and purified by denaturing PAGE on an 8% gel (100 mm $\times$ 100 mm in size, 2 mm thick). After excision of the band and elution into 0.6 mL of an elution buffer (0.5 M ammonium acetate; 10 mM magnesium acetate; 1 mM EDTA, pH 8.0; 0.1% SDS), the recovered RNA was precipitated with ethanol. The ³²P-labeled RNA pool (1 μ g) was dissolved in a binding buffer (0.3 M NaCl; 5 mM MgCl₂; 20 mM Tris-HCl, pH 7.6; 5% DMSO; 0.5% Triton X-100), and the solution was incubated at 85 °C for 5 min. The solution was applied onto a column (0.5 mL) packed with an ATP-immobilized gel, and the solution and the gel were equilibrated for 30 min at 15 °C. Unbound RNAs were washed away with 40 column volumes of the binding buffer. The bound RNAs were eluted with six column volumes of a binding buffer containing 3 mM ATP and precipitated with ethanol in the presence of glycogen (200 μ g). The resulting RNA pellet was dissolved in 30 μ L of RNase-free water.

The collected RNAs were amplified by RT-PCR, as described in the RT-PCR, and transcribed with [α -³²P]-GTP and Biotin-CTP, as described in the transcription experiments. The labeled RNA pool was again applied onto a column packed with ATP-immobilized gel, and bound RNAs were eluted. The amount of ³²P-labeled RNAs was measured by Cerenkov counting. These processes were repeated.

Binding Assay. The RNAs (1 μ g) were added to the ATP-immobilized gel (0.1 mL). After washing with the binding buffer, 0.1 mL of GTP (3 mM), CTP (3 mM), UTP (3 mM), or ATP (0, 1, 2, 3 mM) was added to the gel to investigate the ligand specificity and the sensitivity for ATP. After incubation with the gel for 20 min, each of the eluted RNAs (5 μ L) was spotted onto a Biotinylated nylon membrane (1 cm $\times$ 1 cm). After each membrane dried for 15 min, it was irradiated with UV (365 nm) for 30 s and was incubated in 800 μ L of blocking solution [3 wt % bovine serum albumin in TBS-Tween 20 buffer (100 mM Tris-HCl, pH 7.5, 150 mM NaCl, 0.05 v/v Tween 20)] at 65 °C for 1 h. Subsequently the membrane was incubated in TBS-Tween 20 buffer (800 μ L) containing streptavidin-alkali phosphatase (0.083 μ g/mL, GIBCO) for 10 min at room temperature. The membrane was washed with the TBS-Tween 20 buffer twice (800 μ L $\times$ 2), was placed in a microplate well, and was incubated with a final buffer (800 μ L, 100 mM Tris-HCl, pH 9.5, 100 mM NaCl, 50 mM MgCl₂) containing 10 mM *p*-nitrophenyl phosphate for 1.5 h at 37 °C. The absorbance (405 nm) of supernatant of each well was measured, and the amount of eluted RNAs was determined.

RESULTS AND DISCUSSION

For each round, the SELEX process requires the transcription of RNA, the isolation and reverse transcription of the target-bound RNA, and PCR amplification of the cDNA. To introduce modifications to RNA, a modified nucleotide triphosphate must be a substrate for T7 RNA polymerase. The modified RNA, on the other hand, must be a substrate for reverse transcriptase for cDNA synthesis. The use of Biotin-CTP in place of CTP in the transcription reaction gave biotin-incorporated transcripts (Figure 1). The biotin-incorporated transcripts migrated more slowly in gel electrophoresis than normal transcripts. The yield of biotin-modified transcripts was lower than that of normal transcripts. The presence of the biotinyl group in the biotin-incorporated transcripts was confirmed by dot blotting (Figure 2).

Another requirement for the SELEX protocol is that the modified RNA must serve as a template for reverse transcriptase to produce cDNA. When the biotin-incorporated transcripts were reverse-transcribed to cDNA, they gave the full-length of cDNA (Figure 3). The band density increased with the increase of the PCR cycle. Comparing the efficiency of the reverse transcription reaction in the presence of Biotin-CTP with that of CTP, both were almost the same. The sequential analysis of the product cDNA demonstrated that the cDNA was the same as that of the original synthetic DNA.

Figure 4. Secondary structure of cloned RNAs. The symbols — and • represent Watson-Crick base-pairing and Wobble base-pairing, respectively. Biotin-CTP was used instead of CTP.

These results demonstrated that Biotin-CTP is applicable to the SELEX experiment, although the bulky biotin group existed.

In Vitro Selection. The selection of aptamers for ATP was started from a biotin-modified random sequence pool of RNA molecules, which were prepared by transcription reaction using synthetic DNA with random sequences as templates. The diversity was theoretically considered to be 10^{12} – 10^{13} according to the estimation by Ellington and Szostak (3). The transcripts were added to the ATP-immobilized agarose gel. After being washed with the binding buffer, the bound RNA molecules were eluted using soluble ATP. The collected RNA molecules were reverse-transcribed and amplified by PCR. The amplified cDNAs were again transcribed to RNA molecules using Biotin-CTP again, and the transcripts were added to ATP-immobilized gel. These processes were repeated. At the final round, counter-SELEX was carried out using soluble GTP. When measuring the binding ratio of RNA to ATP-immobilized gel by dividing the amount of RNA molecules eluted by soluble ATP with that of all RNA molecules added, it was found that the ratio increased with the increase of the selection round (1st, 0%; 2nd, 3%; 3rd, 7%; 4th, 7%; 5th, 8%; 6th, 12%; and 7th, 31%). After eight rounds of selection process, 42% of RNA molecules were found to bind to the ATP-immobilized gel.

At this point, PCR-amplified DNA was cloned, and 32 clones were sequenced, resulting in only two different sequences (Figure 4). The sequential variety of the selected biotin-modified RNA, which was lower than that of normal RNA, might be explained in terms of the lower yield of transcription products of biotin-modified RNA as compared with that of normal RNA. Both of the biotin-modified RNAs had approximately 10% of the Biotin-CTP component. This result indicated that the biotin residue suppressed the incorporation of Biotin-CTP in the transcripts.

The requirement of the biotin residues for affinity binding was tested by synthesizing normal transcripts with unmodified CTP. The transcripts did not bind to the ATP-immobilized gel (Figure 5). This result suggested that the presence of the biotin groups was critical for the high affinity of the biotin-modified RNA. The biotin groups should contribute to adopt conformations suitable for recognizing ATP or to interact directly with ATP.

After selected RNAs were bound on the ATP-immobilized gel, known concentrations of nucleotide triphos-

	ATP	CTP	UTP	GTP
noncloned	100	10	7	20
clone 1	100	7	5	7
clone 2	100	2	4	3

^a The percentage of RNAs eluted by ATP was taken as 100%.

phate were added to elute the RNAs, and the eluted RNAs were measured by conventional biotin-avidin interaction (Table 1). The selected RNAs were eluted only by ATP. It was indicated that the triphosphate region is not important for the recognition of RNAs. When adenosine monophosphate (AMP), adenosine diphosphate (ADP), or 3'-deoxyadenosine triphosphate (dATP) was added to the clone 2 bound to ATP-immobilized gel, the clone was eluted (ADP, 85%; AMP, 90%; and dATP, 80%). These results indicated that the RNAs recognized the ATP at the base moiety.

When streptavidin was added to the clone 2 bound to the ATP-immobilized gel, no significant amount of clone was eluted from the gel. However, the biotin of the clone could be detected with a conventional biotin-streptavidin detection kit. It was considered that the bound clone had a folded structure to inhibit streptavidin from invading the biotin residue in the binding state but that the biotin of the eluted clone binds the streptavidin after the denaturation (unfolding) for detection (Figure 6).

The dissociation constants of both clones 1 and 2 were 10 and 15 μM , respectively. The dissociation constants of normal RNA or DNA selected for ATP ranged from 14 to 6 μM according to the reports of Sassanfar and Szostak (25) and Huizenga and Szostak (26), respectively. The dissociation constants of biotin-carrying RNA aptamers in the present study were almost the same order of those of normal oligonucleotide aptamers. Dieckmann et al. (27) reported that several highly conserved nucleotides in the binding pockets could be substituted while retaining binding under NMR conditions. Figure 7 shows the result of sensing the concentration of ATP by clone 2. The clone 2 RNA bound to the ATP-immobilized gel was released from the gel with the increase of ATP. This result demonstrates that the selected RNAs quantitatively recognize ATP and can therefore be used as a molecular sensor for ATP. All of the six biotin residues on the aptamer were not recognized by the streptavidin. The sensitivity of the assay using the aptamer carrying multiple biotin residues had about three times as much as that labeled with single biotin. Considering the development of a new biotin detection system (28), the

Figure 6. Schematic drawing of interaction of biotin-carrying RNA aptamer with target molecule, ATP. Streptavidin did not bind the biotin of aptamer bound to the ATP-immobilized gel but bound to the eluted aptamer.

Figure 7. Binding assay of ATP concentration by using aptamers carrying multiple biotin groups in the side chains. $n = 4$. Bars represent standard deviations.

aptamers carrying multiple biotin groups will offer a new detection system with higher sensitivity.

Recently, aptamers have been used for various analytical purposes (7). The present study develops a new methodology to synthesize a chemosensor instead of using antibodies. For biotin-carrying RNAs, it is a great advantage not to have to worry about denaturation by the labeling or modification process in comparison with antibodies. In addition, these RNAs carry a number of probes in a chain to increase sensitivity in comparison with other aptamers consisting of natural nucleotides. Taking into consideration the convenience of RNA preparation in vitro, this type of RNA sensor will replace the traditional antibody sensors, which are produced from animals.

Kinetic Evaluation of a Metalated Diglycine Conjugate as a Functional Mimetic of Phosphate Ester Hydrolase

C. Madhavaiah and Sandeep Verma*

Department of Chemistry, Indian Institute of Technology-Kanpur, Kanpur-208016 (UP), India.

Received November 13, 2000; Revised Manuscript Received May 25, 2001

The crucial role of phosphate ester hydrolysis in various biological processes has spurred vigorous research activities to understand mechanisms of phosphate ester hydrolysis and to develop model systems that assist the above-mentioned reaction in a catalytic fashion. In the present study, we describe a novel, metalated peptide conjugate **4** possessing phosphate ester hydrolyzing activity against a phosphate monoester, diester, and a RNA chemical model. The design of conjugate **4** is inspired by the ATCUN binding tripeptide motif of serum albumin and involves tethering of two diglycine units by a flexible 1,3-diaminopropane linker. Detailed kinetic investigations of phosphate ester hydrolysis using model substrates and efforts to decipher underlying mechanisms are presented.

INTRODUCTION

The amino terminal Cu (II) and Ni (II) (ATCUN) binding motif has been known for the last 40 years (1), and its presence in serum albumin has been implicated for the transport of small molecules and metal ions (2). This motif occurs naturally in human, bovine and rat serum albumin, neuromedins C and K, human sperm protamine P2a, and histatins (2). Gly–Gly–His (GGH) tripeptide sequence represents Cu (II) coordinating motif in albumin, and structural features of this motif include a free amino terminus, a histidine residue at the C-terminus, and two intervening peptide nitrogens. The metalated tripeptide motif (Cu (II)-GGH-*N*-methyl amide) has been characterized through X-ray crystallography (3), and the metal ion was tetracoordinated with the participation of NH₂-terminal nitrogen, two peptide nitrogens, and a histidyl nitrogen, in a slightly distorted square planar arrangement. The arrangement of coordinating atoms is depicted in Figure 1.

Pauling and co-workers were the first ones to report the antitumor activity of copper (II)-GGH tripeptide/ascorbate system in Ehrlich ascites tumor cells (4). This activity was presumably manifested through the generation of reactive hydroxyl radicals (5), which could lead to DNA strand cleavage as demonstrated for other Fenton-type of reagents used for DNA footprinting (6). GGH and related tripeptide motifs capable of coordinating to Cu (II) have been engineered into larger peptide segments for the design of artificial nucleases. Examples include attaching of GGH motif to the NH₂-terminus of DNA binding segment of Hin recombinase (7), to a zinc finger protein Sp1 (8), and to the basic domain of Fos (9), to study their DNA cleavage activity. Considerable efforts have been invested in the design of GGH tripeptide variants through combinatorial approaches to develop a formal structure–nuclease activity relationship database (10). It has been proven that the prerequisite of having a GGH motif at the N-terminus is not valid. It could reside within a much longer peptide, undergo metalation, and exhibit nucleic acid cleavage activities.

Figure 1. Binding of copper to the Gly–Gly–His tripeptide unit of the ATCUN motif.

This motif has also been conjugated to a wide array of small molecules to generate new DNA binding and cleaving analogues (11). Metalated GGH motif not only causes nucleic acid damage but is also capable of cross-linking proteins through oxidative pathways. Several proteins have been cross-linked in the presence of oxidants such as oxone and magnesium monoperoxyphthalate, using copper or nickel as the cofactor (12).

We have tried to further prune the GGH motif to the diglycine level to investigate whether a dipeptide conjugate alone, lacking the C-terminus histidine residue, will support phosphate ester hydrolysis and DNA cleavage. Our strategy of using metalated *bis*-diglycine conjugate has drawn inspiration from several literature reports regarding crystal structures of metal ions complexed to this dipeptide, and moreover, a bis derivative of GGH tripeptide, appended to an anthraquinone moiety, has previously shown activity in DNA cleavage assays (11b). Interestingly, diglycine has been found to be a versatile ligand for a variety of metal ion complexation, as exemplified by numerous crystal structures containing Cu, Sr, Se, Te, Nd, Eu, V, Sn, and Na (13).

In the present study, we have synthesized a *bis*-diglycine derivative, where the two dipeptide units are tethered by a flexible diaminopropyl linker, through amide bonds (Scheme 1). The resulting bis compound **3** was spectroscopically characterized, metalated with copper (II), and subjected to exhaustive kinetic analysis using three commonly used activated phosphate ester substrates: *p*-nitrophenyl phosphate (pNPP), *bis*-(*p*-nitrophenyl phosphate) (bNPP), and 2-hydroxypropyl

p-nitrophenyl phosphate (hNPP). Pseudo-first-order rate constants and Michaelis–Menten kinetic parameters were determined for the three phosphate ester substrates. As metalated peptide **4** was completely insoluble in aqueous buffer solutions, this study could be considered as an example of heterogeneous catalysis of phosphate ester hydrolysis (14).

EXPERIMENTAL SECTION

Glycylglycine (Aldrich), dicyclohexyl carbodiimide and $\text{Cu}(\text{OAc})_2 \cdot \text{H}_2\text{O}$ (Lancaster), benzoyl chloride and methanol (S. D. Fine Chemicals, India), and *p*-nitrophenyl phosphate (pNPP) and *p*-nitrophenol (SRL, India) were used as supplied. Phosphodiester substrate, *bis*-(*p*-nitrophenyl phosphate) (bNPP, Fluka) was converted to its sodium salt prior to use. RNA model substrate, 2-hydroxypropyl *p*-nitrophenyl phosphate (hNPP) was synthesized as described in the literature (15), and the final compound was characterized by ^1H , ^{13}C , and ^{31}P NMR and by FAB mass spectral analysis. 1,3-Diaminopropane (Fluka) and triethylamine (S. D. Fine Chemicals, India) were distilled prior to use. NMR spectra were recorded using a JEOL 400 MHz spectrometer in $\text{DMSO}-d_6$ (Aldrich) and tetramethylsilane (TMS, Aldrich) was used as an internal standard. Elemental analysis and FAB mass spectra was recorded at RSIC, Lucknow, while EI mass spectra (EIMS) and AAS values were recorded at FEAT Laboratory, IIT-Kanpur.

N-Benzoylglycylglycine (1). Glycylglycine (10 g, 75 mmol, 1 equiv) was dissolved in 10% NaOH solution (50 mL) and cooled to 0 °C. Benzoyl chloride (11.64 g, 83 mmol, 1.1 equiv) was then added to this solution with vigorous stirring. The stirring was continued for an hour at room temperature. The reaction mixture was then cooled in an ice-bath and acidified with concentrated HCl. The precipitated product was filtered and washed with acetone (3 × 10 mL) and CCl_4 (3 × 10 mL). The product was recrystallized from hot water (8.5 g, 47% yield). mp: 205–206 °C (lit. 206.5 °C) (16); ^1H NMR: δ (ppm) 3.76 (2H, d), 3.91 (2H, d), 7.5 (3H, m), 7.9 (2H, m), 8.2 (1H, t), 8.7 (1H, t).

N-Benzoylglycylglycine *p*-Nitrophenyl Ester (2). **1** (4.74 g, 20 mmol, 1 equiv) and *p*-nitrophenol (3.05 g, 22 mmol, 1.1 equiv) were dissolved in dry DMF (50 mL) and cooled in an ice-bath. DCC (4.14 g, 20 mmol, 1 equiv) was added in portions, and the solution was stirred for

30 min in an ice-bath, followed by 4 h at room temperature. The reaction mixture was filtered, and solvent was evaporated under reduced pressure. The residue was washed with cold methanol (5 × 10 mL) and was recrystallized from hot methanol (5.1 g, 71% yield). mp: 181–183 °C; ^1H NMR: δ (ppm) 3.96 (2H, d), 4.18 (2H, d), 7.48 (5H, m), 7.9 (2H, m), 8.3 (2H, m), 8.5 (1H, t, D_2O exchangeable), 8.84 (1H, t, D_2O exchangeable); EIMS: m/z 358 ($\text{M}+1$)⁺, 219, 162, 105.

***N',N''*-bis-(*N*-Benzoylglycylglycine)-1,3-propane Diamine (3).** Product **2** (2.35 g, 6.5 mmol, 2 equiv) from the previous reaction was dissolved in dry DMF (35 mL). A mixture of 1,3-diaminopropane (0.242 g, 6.5 mmol, 1 equiv) and triethylamine (0.66 g, 6.5 mmol, 2 equiv) in dry DMF (5 mL) was then added to the above solution with vigorous stirring at room temperature for 2 h. The reaction mixture was filtered, and the residue was washed with methanol (5 × 10 mL) and acetone (5 × 10 mL). Product was recrystallized thrice from hot DMF (1.41 g, 84% yield). mp: 255–257 °C; ^1H NMR: δ (ppm) 1.56 (2H, m), 3.07 (4H, m), 3.68 (4H, d), 3.89 (4H, d), 7.5 (6H, m), 7.76 (2H, t, D_2O exchangeable), 7.88 (4H, m), 8.22 (2H, t, D_2O exchangeable), 8.82 (2H, t, D_2O exchangeable); ^{13}C NMR: δ (ppm) 29.03, 36.26, 42.1, 42.9, 127.3, 128.2, 131.3, 133.8, 166.7, 168.7, 169.34; EIMS: m/z 510 (M^+), 291, 162, 77; anal. calcd: C, 58.82; H, 5.88; N, 16.47; anal. found: C, 59.16; H, 6.08; N, 16.55.

Cu (II)-metalated *bis*-Dipeptide 4. A mixture of **3** (0.34 g, 0.67 mmol, 1 equiv) and $\text{Cu}(\text{OAc})_2 \cdot \text{H}_2\text{O}$ (1.08 g, 5.4 mmol, 8 equiv) were stirred in methanol–water (43:13) for 48 h, at room temperature. After this time, the precipitate so formed was filtered and washed with warm DMSO (4 × 10 mL), methanol (4 × 10 mL), followed by acetone (4 × 10 mL). The pale blue solid so obtained was air-dried and subjected to atomic absorption spectroscopic analysis to determine its copper content.

KINETICS

All hydrolytic reactions were performed in duplicate in centrifuge tubes thermostated at 40 °C, unless otherwise specified. The assay mixture contained 3 or 5 mL of substrate solution of appropriate concentration prepared in 0.01 M *N*-ethylmorpholine (NEM) buffer (pH 8.0) in 50% aqueous methanol. The reference cell contained substrate without **4** to correct for background hydrolysis. The amount of metalated dipeptide used

for kinetic analysis were either 0.1 mg/mL or 1 mg/3 mL of buffered substrate solution, and the concentration of the catalyst corresponded to the amount of copper present in dipeptide conjugate **4**. Control experiments proved that incubation of unmetalated peptide conjugate **3** and copper acetate alone, with phosphate ester substrates, did not accelerate hydrolysis. Initial velocities were determined as a function of time-dependent release of *p*-nitrophenolate anion ($\epsilon_{400} = 1.65 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$), with a Shimadzu UV-160 spectrophotometer. Michaelis–Menten parameters were determined using corresponding Lineweaver–Burk plots, while the pseudo-first-order rate constants were derived from $\ln A_{\infty}/A_{\infty} - A_t$ vs time plots. All hydrolytic reactions were performed at least over five half-lives of each substrate.

RESULTS AND DISCUSSION

The goal of the present study was to design a metallopeptide conjugate, based on the ATCUN motif found in serum albumins, to study its ability to facilitate hydrolytic cleavage of phosphate ester substrates, over corresponding uncatalyzed reactions. It is hoped that these studies will serve as model observations for the development of metalated dipeptide conjugates as a new class of nucleolytic reagents. Consequently, we have synthesized a *bis*-derivative of glycylglycine containing a 1,3-diaminopropane tether, using the active ester method (Scheme 1). Benzoyl protecting group was purposefully introduced and retained in the final product to make the derivative insoluble in common solvents as our long-term aim is to generate novel reagents that effect heterogeneous catalysis of chemical and biochemical reactions (17). Conjugate **3** was characterized by spectroscopic methods and was subjected to metalation using copper acetate monohydrate.

Successful incorporation of copper in conjugate **4** and its actual content was determined by atomic absorption spectroscopy and was found to be 268 mg/g of *bis*-dipeptide. Alternatively, amount of copper incorporated in conjugate **4** was ascertained by digesting a known amount of sample in 8 M HNO_3 , followed by spectrophotometric analysis. A standard curve was prepared by using known concentrations of copper acetate in 8 M HNO_3 , and the amount of copper present in conjugate **4** was determined to be 241 mg/g of *bis*-dipeptide. These data together indicate a stoichiometry of >2 copper atoms per dipeptide conjugate.

Conjugate **4** was insoluble in common organic solvents and water, including 50% aqueous methanol in which all the kinetic measurements were performed. The latter solvent system was chosen because of its known ability to support phosphate ester hydrolytic reactions and, moreover, for studying activation of water *vis-à-vis* alcohol hydroxyl group (17).

The catalytic potential of derivative **4** was evaluated using three different phosphate monoester, phosphodiester, and RNA model substrates. These nonnatural, model substrates included *p*-nitrophenyl phosphate (pNPP), bis-(*p*-nitrophenyl phosphate) (bNPP), and 2-hydroxypropyl *p*-nitrophenyl phosphate (hNPP). Remarkable rate enhancements were observed for conjugate **4** assisted cleavage of all phosphate ester substrates, when compared to the respective uncatalyzed reactions. Out of the three substrates studied by us, the results were most striking for the phosphodiester substrate, bNPP, where a 10^6 -fold acceleration was obtained over the uncatalyzed reaction. This rate enhancement is similar to previously reported synthetic catalysts used for the

hNPP	1.37	1.52×10^{-3}	1.08×10^{-3}

^a All reactions were performed in duplicate with dipeptide conjugate **4** in 0.01 M NEM buffer prepared in 50% aqueous methanol [pH 8.02, 30 °C (hNPP) or 40 °C (pNPP and bNPP)]. The amount of **4** was 1 mg/5 mL for pNPP, while it was 1 mg/3 mL for bNPP and hNPP. ^b pNPP and bNPP concentrations, [S] = 1–5 mM; hNPP concentration, [S] = 0.2–0.5 mM.

hydrolysis of this substrate (17c and references therein). Dipeptide conjugate **4** also assisted cleavage of a monoester and an RNA model substrate, thus demonstrating its versatility as a synthetic phosphate ester hydrolase. For phosphate monoester substrate (pNPP), about 1500-fold rate enhancement was observed as compared to the uncatalyzed reaction, while the cleavage rate enhanced nearly 3000-fold for the RNA model compound (hNPP), over corresponding uncatalyzed reactions (18). Pseudo-first-order rate constants (k_{obs}) for individual substrates are mentioned in Table 1. Saturation curve for this catalytic system was determined using substrate concentration vs initial velocity profile by employing pNPP as the substrate. As indicated by Figure 2, good Michaelis–Menten behavior was observed for conjugate **4** catalyzed cleavage of pNPP. We have also performed detailed kinetic characterization of conjugate **4** by determining Michaelis–Menten constants (K_m), maximal velocities (V_{max}), and the turnover number (k_{cat}), from respective Lineweaver–Burk plots $1/[S]$ vs $1/V_i$ (Figures 3–5). The values of these kinetic parameters for individual substrates are listed in Table 2.

All the phosphate ester cleavage experiments were performed at pH 8. Several literature reports have demonstrated that the effect of pH on phosphoester

cleavage rate may provide clues regarding catalytic mechanism (19). In the present study, we have sought to understand the mechanism of phosphate monoester cleavage by studying effect of pH on the rate of pNPP cleavage. Pseudo-first-order rate constants were recorded at seven different pH values ranging from 7.3 to 9.2, and, as evident from Figure 6, k_{obs} values virtually remained constant thus indicating the lack of influence of pH on pNPP cleavage assisted by conjugate 4. This result

The substrate concentration was fixed at 2 mM. ^b Relative rates are reported with respect to k_{obs} obtained for pure ethylene glycol.

indirectly suggests a free radical-induced mechanism rather than a hydrolytic phosphoester bond cleavage. Interestingly, a free radical based mechanism of DNA cleavage by metalated ATCUN peptide motif is already documented (10c).

Such indirect evidence of free radical-assisted phosphate monoester cleavage prompted us to perform this reaction in the presence of a hydroxyl radical scavenger, such as D-mannitol (20). We surmised that a decrease in the catalytic rate, in the presence of radical scavengers, would provide more evidence for free radical-assisted phosphate ester cleavage. Accordingly, pNPP cleavage experiments were performed in the presence of 0.1 and 0.2 M D-mannitol. A 10-fold decrease in k_{obs} was observed in the presence of 0.2 M mannitol, and correspondingly, the decrease was about 4 times in the presence of 0.1 M mannitol, when compared to the control reaction. These observations further indicate a crucial role for reactive species in cleaving pNPP and other phosphate esters. However, a possible role of D-mannitol in copper ion coordination, thereby leading to a reduction in the observed rate, cannot be ruled out at this stage.

As all of our cleavage kinetic experiments were performed in 50% aqueous methanol, we also became interested in delineating the effect of aqueous medium versus alcoholic medium, on phosphate ester bond cleavage. Preferential activation by conjugate 4 was determined by performing cleavage reactions in water, ethylene glycol, and 50% aqueous ethylene glycol, using pNPP as a substrate. Ethylene glycol was used instead of methanol to ensure optimum solubility of pNPP. Pseudo-first-order rate constants were determined for the three systems (Table 4). As compared to the rate of solvolysis in pure ethylene glycol, about a 2-fold increase in k_{obs} was found for 50% aqueous ethylene glycol system, while the rate enhancement was over 5-fold if the reaction was performed in water alone. These observations indicate enhanced cleavage efficiency of conjugate 4 in water when compared to ethylene glycol. It can be surmised that in mixed aqueous solvent systems, ethylene glycol (or methanol) quenches reactive species that are generated due to conjugate 4, leading to a decrease in k_{obs} for pNPP hydrolysis. This is in accordance with the potential of ethanol and other alcohols to act as hydroxyl radical scavengers. Keeping the possible role of reactive free

radical species and preferential catalytic activation in aqueous medium by conjugate **4** in mind, it will be of interest to apply this system to compare cleavage of DNA versus intramolecular cleavage of RNA substrates.

One of our long-term goals is to devise recyclable catalysts possessing nucleolytic activity. We have achieved some success in this direction with nucleobase containing resins (17), and therefore, it was of considerable interest for us to extend this design paradigm for peptide conjugates as well. As mentioned before, we purposefully introduced benzoyl groups to render the peptide conjugate insoluble in aqueous medium for subsequent recycling experiments. In a typical recycle experiment, conjugate **4** was filtered, washed copiously with 50% aqueous methanol, methanol, and acetone, and air-dried. Recycled conjugate assisted the cleavage of pNPP, albeit with a reduced initial rate, demonstrating its reusability toward catalysis of phosphate ester hydrolysis (data not shown).

Hydrolytic reactions were also performed in the presence of two different concentrations of EDTA to determine if leached out copper ions were responsible for the catalytic activity and for the generation of reactive species. The initial rate of hydrolysis, using pNPP as the substrate, did not appreciably change in the presence of 0.1 and 1 mM EDTA, when compared to the initial hydrolytic rate obtained in the absence of EDTA (data not shown). This observation suggests that the acceleration of phosphate ester hydrolysis is probably due to copper species coordinated to **4**, rather than free copper ions in solution. The precise mode of copper ion coordination remains unclear at the present time and would require crystal structure data to unequivocally establish the coordination geometry. For this reason, we are now trying to generate soluble peptide conjugates to determine their crystal structure and to predict the geometry of copper ion binding within the *bis*-dipeptide motif, through detailed EPR and magnetic moment measurements.

In summary, we have crafted a novel and catalytically competent metalated dipeptide conjugate possessing the ability to cleave phosphate esters in a highly efficient fashion. Michaelis–Menten kinetic parameters have been determined for this conjugate and initial efforts have also been made to probe for the mechanism of cleavage. Differential solvent effects and the reusable nature of such *bis*-dipeptides merit further attention and are worthy of being developed as potential nucleolytic reagents. Future efforts in this direction will also aim for engineering specificity in such constructs for site-specific cleavage of nucleic acids.

ACKNOWLEDGMENT

C.M. thanks Council of Scientific and Industrial Research (CSIR, India) for financial support. This work was made possible through funding by CSIR to one of us (S.V.). An anonymous referee is thanked for suggestions regarding possible quenching of phosphate ester hydrolytic reactions, catalyzed by conjugate **4**, in aqueous methanol medium due to scavenger action.

Physicochemical Characterization of Poly(ethylene glycol)-Modified Anti-GAD Antibodies

Robert S. Larson, Virginie Menard, Harvey Jacobs, and Sung Wan Kim*

Center for Controlled Chemical Delivery, Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, 30 South 2000 East Room 201, Salt Lake City, Utah 84112. Received December 2, 2000; Revised Manuscript Received June 16, 2001

Monoclonal antibodies against glutamic acid decarboxylase (anti-GAD) were modified with poly(ethylene glycol) (PEG), and the resulting conjugates were characterized. Monoclonal anti-GAD antibodies were purified from ATCC HB184 hybridoma cells by either cell culture supernatant or ascites fluid from BALB/c mice. Polyclonal rabbit IgG antibodies were also used as a model protein. Polyclonal rabbit IgG or purified anti-GAD was modified by PEG (MW = 5000 or 20000 Da) through either the lysine residues or through the carbohydrate moiety. Lysine modification was performed in PBS (pH 7.4) or 0.1 M borate (pH 9.2) by adding a molar excess (5–80) of a succinimidyl activated propionic acid terminated mPEG (SPA-PEG) while stirring at room temperature. Carbohydrate modifications were performed in PBS (pH 6.2) by first oxidizing the antibody with sodium periodate followed by incubation with hydrazide-terminated PEG followed by reduction with sodium cyanoborohydride. The degree of modification was assessed by ^1H NMR or TNBS (trinitrobenzenesulfonic acid). Circular dichroism (CD) spectra were obtained for lysine-modified rabbit IgG at various degrees of modification ranging from 5 to 60 PEG per antibody. Binding was assessed using an ELISA method with GAD or rabbit anti-mouse-IgG (H+L) coated plates. The TNBS and ^1H NMR analysis of the modified antibody showed reasonably similar results from 5 to 60 PEG per antibody. The ^1H NMR method showed greater sensitivity at low modifications (below 20:1) and was fairly linear up to about 60 PEG per antibody. The CD spectra of the polyclonal rabbit IgG showed only small differences at variously modified antibody. The binding affinity of anti-GAD is lower for all PEG modifications with respect to unmodified anti-GAD. Modifications at pH 7.4 show lower binding to GAD than modifications at pH 9.2. Binding to GAD or anti-mouse-IgG is decreased as the degree of modification is increased. Lysine modifications showed lower binding to GAD or anti-mouse-IgG than carbohydrate modifications. Binding to GAD or anti-mouse-IgG is lower for PEG20000-modified anti-GAD with respect to PEG5000-modified anti-GAD.

INTRODUCTION

Type I diabetes, or insulin-dependent diabetes mellitus (IDDM), is an autoimmune disorder in which the patient's immune system selectively attacks and destroys the insulin-producing β -cells of the pancreas (1). Type I diabetes is an irreversible condition that usually occurs before adulthood in a patient's life. The autoimmune process in Type I diabetes is characterized by macrophage infiltration into the pancreas followed by T-cell and macrophage activation which then leads to β -cell destruction and loss of insulin production (1–4). Once the β -cells are completely destroyed, no further insulin production is observed, and exogenous insulin must be administered to maintain normal glucose levels.

There is a strong genetic component to Type I diabetes which seems to be linked to certain major histocompatibility complex (MHC or HLA) genes, and individuals with this tissue type show an increased susceptibility toward developing Type I diabetes (5–8). The MHC molecules present on antigen-presenting cells (APCs), such as macrophages, phagocytes, and B-lymphocytes, serve as sites of antigen presentation to T-cells of the immune system. When APCs phagocytize cellular debris,

they breakdown the ingested proteins into small peptides which are then presented on the cell surface in association with these MHC molecules. Here, they can interact with the T-cells which will either recognize the complex as being native or foreign. In the case of Type I diabetes, T-cells recognize some of the peptide sequences from β -cell proteins as being foreign which cause the T-cells to become activated. This eventually leads to β -cell destruction and the onset of clinical diabetes.

There have been many proteins studied which are suspected to be important in the initiation and progression of the disease (9–12). Among the most intensely studied autoantigens is the protein glutamic acid decarboxylase (GAD) which can be found at appreciable levels in the β -cells of the pancreas. It is thought that GAD is one of the most important autoantigens responsible for Type I diabetes (13–15). In fact, studies using the NOD (nonobese diabetic) mouse model show that diabetes can be eliminated if GAD production in the β -cells is eliminated (16).

It has been shown that antibodies bound to proteins can affect the resulting peptides produced by enzymatic cleavage (17–19). In this manner, it would seem possible to alter the specific GAD peptides presented to T-cells by using antibodies against GAD (anti-GAD). By binding to the GAD, the anti-GAD antibodies will alter how the APCs process GAD which may lead to a difference in the

specific peptides presented by these cells and thereby alter the immune response to GAD.

In our laboratory, we have studied the effect of the administration of monoclonal anti-GAD antibodies in the progression of Type I diabetes in the NOD mouse model (20). We have found that weekly injections of anti-GAD antibodies can reduce the incidence of diabetes from greater than 80% in untreated NOD mice to less than 20% in treated mice.

PEG modification of proteins has been shown to improve a number of properties of proteins. Typically, PEG-modified proteins will show an increased resistance to enzymatic attack (21–23), a reduced immunogenic response (24–26), an increase in plasma half-life (25–28), and an increase in solution stability (29–31).

Of particular interest is the alteration of the enzymatic degradation of PEG-modified proteins. Thus, it is thought that PEG modification of an antibody against a protein may have a greater effect at altering the resulting enzymatic peptide sequences than the antibody alone which may further decrease the incidence of diabetes.

In this report, we describe the synthesis and characterization of PEG-modified, monoclonal anti-GAD. We studied the effect of the degree of modification (number of PEG chains per antibody), the site of modification (lysine residues versus carbohydrate moiety), reaction conditions (low pH versus high pH for lysine modification), and PEG molecular weight on the antibody structure, the binding affinity toward GAD, and the ability of other antibodies to recognize the anti-GAD-PEG conjugates.

EXPERIMENTAL PROCEDURES

Antibody Production. Ascites fluid was produced by injecting hybridoma cells (HB184, ATCC) intraperitoneally into pristane-treated BALB/c mice. The monoclonal antibody, anti-GAD, was purified from ascites fluid by ammonium sulfate precipitation followed by diethylaminoethyl (DEAE) cellulose chromatography. Purity was gauged by native PAGE. Polyclonal rabbit IgG was obtained from Sigma and used without further purification.

Antibody Modification. The reaction scheme for the antibody modifications is shown in Figure 1. The purified antibody was exchanged into the appropriate buffer for

each modification by ultrafiltration (50 kDa MWCO). Lysine modifications were done in either a phosphate buffer at pH 7.4 or in a borate buffer at pH 9.2. Antibody concentrations were 3 mg/mL. Succinimidyl propionate activated PEG (SPA-PEG) (MW = 5 or 20 kDa) (Shearwater Polymers), see Figure 1, was dissolved in DMSO and added to the anti-GAD buffered solutions in a dropwise manner while stirring. The solutions were stirred at room temperature for 1 h and incubated at 4 °C overnight. As a model, polyclonal rabbit IgG was modified with molar excesses SPA-PEG (MW = 5000 Da) of 5, 10, 20, 30, 40, 60, or 80. Carbohydrate modifications (32–33) were done in a phosphate buffer at pH 6.2. The carbohydrate was first oxidized by addition of sodium periodate (NaIO_4) in a 1000 molar excess with respect to anti-GAD concentration. After stirring 1 h at 4 °C, the oxidation was quenched with ethylene glycol, and the reaction byproducts were removed by ultrafiltration (50 or 100 kDa MWCO). A 50 molar excess of hydrazide-PEG (Shearwater Polymers) was added to the oxidized antibody at pH 6.2. After stirring at room temperature for 1 h, an excess of sodium cyanoborohydride (NaBH_3CN) was added and stirred at room temperature for another hour. The modified antibodies were then purified by ultrafiltration (50 or 100 kDa MWCO) against PBS, pH 7.4.

^1H NMR Analysis. The modified antibody was exchanged into phosphate buffered D₂O by ultrafiltration (50 kDa MWCO). The molar amount of antibody in 400 μL was calculated by UV absorbance at 280 nm based on an extinction coefficient of 1.38 mL/mg/cm and an antibody molecular weight of 150000 Da. Antibody concentrations were between 3 and 5 mg/mL. Stock solutions of acetone, DMSO, and sodium benzoate were made in D₂O at known concentrations. Known amounts of the standards were added to the solutions, and the total volume is brought up to 700 μL with D₂O. The amount of each standard added to each sample is based on the estimated number of PEG chains attached to the antibody such that the integrations of the PEG peak and the reference peaks will be close. For example, if the final molar concentrations of acetone and DMSO were 76 times larger than the estimated molar concentration of PEG5000 in the sample, the integrated peaks should be close to the same. Spectra were gathered on a Bruker 200 MHz NMR. The acetone (2.06 ppm), DMSO (2.56

ppm), PEG (3.54 ppm) and aromatic benzoate (7.31–7.72 ppm) peaks were integrated. The ^1H NMR spectrum was taken, and the integration of the methylene ($-\text{CH}_2-$) hydrogen peak of the PEG was compared to the acetone and DMSO peaks to calculate the PEG concentration. The number of PEGs per anti-GAD is determined by dividing the concentration of PEG by the concentration of anti-GAD.

TNBS Assay. For TNBS analysis (34–35), the modified antibody solutions were diluted to about 3 mg/mL in 600 μL in 0.1 M borate buffer pH 9.2. To keep the antibody soluble throughout the reaction, DMSO was added to 33%. Absorbance blanks consisting of buffer and DMSO were also made. To each solution was added 8 μL of a 1 M TNBS solution. The solutions were mixed well and incubated at room temperature for 6 h. To stop the reaction, 4 μL of 12 N HCl was added to each solution. Dilutions of the samples were made by measuring between 30 and 120 μL of the sample and the bringing this volume to 120 μL by the addition of the blank solution. This was done to keep the background constant in all the dilutions. Then 1080 μL of 0.1 N HCl was added to each solution. The absorbance blank was made by adding 120 μL of the blank solution to 1080 μL of 0.1 N HCl. The absorbance at 345 nm was then taken for each sample.

CD Spectroscopy. Lysine-conjugated (PEG5000) rabbit IgG was used at conjugation ratios ranging from 0 to 56 PEG per IgG. The antibody concentration of each was brought to 0.5 mg/mL in PBS (pH 7.4), as determined spectrophotometrically, ϵ_{280} (mL/mg/cm) = 1.38. The samples were degassed under vacuum pressure for 20 min prior to the CD measurements. The molar ellipticity was read between 200 and 250 nm using a 0.1 cm path length cell.

Binding Affinity. The binding of the modified anti-GAD to GAD as well as an anti-mouse-IgG antibody was assessed by ELISA. Glutamic acid decarboxylase (GAD) from E-coli (Sigma, EC 4.1.1.15) or rabbit-anti-mouse-IgG (H+L) (Zymed) was used to coat 96-well ELISA plates by incubating each well with a 2 $\mu\text{g}/\text{mL}$ GAD or 5 $\mu\text{g}/\text{mL}$ anti-mouse-IgG solution at pH 9.5. After 2 h, the solution was removed, and the plates were incubated with a 1% BSA in PBS, pH 7.4 solution for 1 h. Dilutions of the anti-GAD (modified or unmodified) were made with PBS, 1% BSA, pH 7.4, and incubated in the plates for 2 h. The plates were then incubated with a 1:100 dilution of alkaline phosphatase-coupled anti-mouse-IgG antibody (Zymed) for 2 h. The plates were then washed four times with 125 $\mu\text{L}/\text{well}$ of PBS, 0.05% Tween20. A solution of *p*-nitrophenyl phosphate (Pierce) in a diethanolamine buffer, pH 9.8, was added. After sufficient color developed, the absorbance at 405 nm of each well was measured by an automated ELISA plate reader.

RESULTS

The degree of modification was assessed by a TNBS method. The number of lysines was previously determined by amino acid analysis to be approximately 86, data not shown, which yields a total number of free amines about 90 due to the four N-terminal amines per antibody. The absorbances at 345 nm of the TNBS samples were normalized to the unmodified sample. Thus, the approximate number of free amines per antibody in each sample is 90 multiplied by the normalized absorbance at 345 nm. Thus, the number of PEG chains conjugated per antibody is the difference between 90 and the number of free amines.

Figure 2. ^1H NMR spectrum of a PEG5000-modified antibody with acetone, DMSO, and sodium benzoate standards.

For ^1H NMR analysis, it is important that all unreacted PEG be removed before analysis. Ultrafiltration was used in this study to remove the unreacted PEG. The molecular weight cutoff of the ultrafiltration membrane used was 50 kDa. Permeability of the PEG (MW = 5000) through the membrane was confirmed by analyzing the ultrafiltrate for PEG, data not shown.

To quantitate the PEG peak of an ^1H NMR spectrum, it is necessary to reference peaks of known concentration. Integration standards (acetone, DMSO, and sodium benzoate) were added to the PEG-antibody conjugate solution at known concentrations. In this manner, the integration of the PEG peak can be used to calculate its concentration based on the integrations of the reference peaks. Figure 2 shows a typical ^1H NMR spectrum of a solution of a PEG-modified antibody with the three reference standards. This clearly shows that PEG (3.54 ppm) and the three reference standards of acetone (2.06 ppm), DMSO (2.56 ppm), and sodium benzoate (7.27–7.73 ppm) are easily resolved from each other.

The integration of an ^1H NMR peak is proportional to the number of resonant hydrogens at the particular chemical shift. Each peak can be defined as the product of the concentration and the number of resonant hydrogens. Thus, the concentration of PEG can be easily solved since the concentrations of the standards and the antibody are known.

When the calculated PEG ratios are plotted versus the PEG reaction ratio, as shown in Figure 3, the plot reveals a linear relationship between the measured PEG conjugation ratio with respect to the activated PEG reaction ratio for the NMR calculations. When a linear regression is performed, it shows a slope of 0.73 with an R^2 of 0.996 when the fit is forced through zero. This indicates that approximately 73% of the activated PEG added to the reaction conjugated to the antibody under the reaction conditions used.

For comparison, the TNBS analysis results are plotted with the NMR analysis in Figure 3. In contrast to the NMR analysis, the TNBS analysis shows a nonlinear trend of PEG conjugation. The results of the two techniques match only at two points, 40 and 60 PEG reaction ratio. Since the TNBS method relies on an indirect method of subtraction, it seems to have difficulty detecting conjugation at lower reactions ratios (<20) since it involves the difference of two large numbers to obtain a small number. However, the direct detection by NMR easily measures the PEG at all conjugations.

The direct detection of PEG by NMR also allows the quantification of PEG conjugated by any method. Except

Figure 3. Plot of the calculated number of PEG per antibody versus the molar excess of activated PEG in the reaction mixture.

Figure 4. CD spectra of PEG-modified polyclonal rabbit IgG.

for the absolute values of the various peak integrations, the NMR spectrum of a carbohydrate-modified antibody was indistinguishable from the lysine-modified antibody depicted in Figure 2. The number of PEG chains attached per antibody were typically between two and six for the carbohydrate modifications. This is consistent with the number of aldehydes generated by periodate oxidation, as determined by a Lucifer Yellow assay (36), data not shown.

The CD spectra were obtained for a range of modified polyclonal rabbit IgG antibody. Figure 4 shows the obtained spectra. The spectra shows the very characteristic trough (37) of the β -sheet secondary structure element, which is the most predominant structural element of antibodies (38, 39). The spectra suggest a high degree of structural homology among the modified antibodies with very little change in the structure even at a high modification of 57 PEG5000 chains per antibody.

Monoclonal anti-GAD antibody was modified by PEG5000 and PEG20000 by either the lysine residues or by the carbohydrate moiety. The importance of the modification pH during lysine modification was studied by performing the modification at pH 7.4 or 9.2. Table 1 shows the number of coupled PEG chains to each anti-GAD molecule for the various modifications studied.

By varying the reaction pH of lysine-modified anti-GAD-PEG, the importance of the particular amines undergoing reaction can be examined. At low pH, the

Figure 5. Effect of modification pH on the binding of modified anti-GAD antibodies to GAD; solid line, k varied; dashed line $A_{\max}$ varied.

Figure 6. Effect of degree of modification on the binding of anti-GAD to GAD; solid line, k varied; dashed line $A_{\max}$ varied.

Table 1. The Modification Conditions and PEG to Anti-GAD Ratios for the Modified Anti-GAD Samples

sample id	modification conditions	PEG MW, Da	no. of PEG
Lys5-7-10	Lys, pH 7.4	5000	10
Lys5-9-05	Lys, pH 9.2	5000	5
Lys5-9-10	Lys, pH 9.2	5000	10
Lys5-9-20	Lys, pH 9.2	5000	20
Lys20-9-05	Lys, pH 9.2	20000	5
Carb5	carbohydrate	5000	3
Carb20	carbohydrate	20000	5

reaction will favor amines of lower pK_a ; at high pH, the reaction will be more random. Figure 5 shows that the binding of lysine-modified anti-GAD is affected by the modification pH. A low modification pH of 7.4 shows a much greater loss of binding than high modification pH of 9.2 when the degree of modification is constant at about 10 PEG per anti-GAD. This indicates that there may be some primary amines with a lower pK_a which have a great effect on binding when modified by PEG.

It is assumed that as the number of PEG chains attached to the anti-GAD antibody was increased, there would be a greater coverage of the antibody by the PEG, and that this would reduce the binding of anti-GAD to GAD. Figure 6 confirms that the binding of lysine-modified anti-GAD to GAD decreases with increasing degree of modification (from 5 to 20 PEG per anti-GAD).

Modification of anti-GAD antibodies through its carbohydrate moiety is in stark contrast to modification

Figure 7. Comparison of lysine and carbohydrate modification methods and PEG molecular weight on the binding of anti-GAD to GAD; solid line, k varied; dashed line $A_{\max}$ varied.

Figure 8. Comparison of the effect of degree of modification on the binding of the modified anti-GAD to anti-mouse IgG (H+L) antibodies.

through its lysine residues. The carbohydrate is localized to a single region well away from the antigen binding region, and the lysine residues are distributed, more or less, randomly throughout the antibody. Figure 7 shows that the binding of the carbohydrate-modified anti-GAD to be quite close to the unmodified anti-GAD and higher than a lysine-modified anti-GAD of similar degree of modification.

It was suspected that the molecular weight of PEG would be an important factor in the binding of modified anti-GAD. The longer chains of PEG20000 should have a greater influence than PEG5000. The effect of PEG molecular weight can be seen in Figure 7. The PEG20000-modified anti-GAD samples show lower binding affinities than their PEG5000 counterparts. It appears that the site of modification influences the binding to a greater extent than molecular weight. PEG attached only to the carbohydrate will affect binding much less than PEG attached randomly over the antibody.

The ability of anti-mouse-IgG antibodies to recognize and bind to anti-GAD-PEG antibodies is a good measure of how well the PEG chains can shield or hide the surface of antibody. Figure 8 shows the effect of degree of modification on the binding of anti-mouse antibodies to PEG-modified anti-GAD. As expected, the binding of anti-mouse-IgG antibodies is reduced as the number of PEG chains attached is increased.

The site of modification is also an important parameter in PEG shielding. The random attachment of PEG

Figure 9. Comparison of the effect of modification site and PEG molecular weight on the binding of the modified anti-GAD to anti-mouse IgG (H+L) antibodies.

through the lysines is expected to provide a more effective coverage than the localized attachment through the carbohydrate. Thus, the effect of PEG molecular weight should have a greater effect with the lysine modification than the carbohydrate modification. Figure 9 shows the effect of molecular weight and site of modification on the binding of anti-mouse antibodies to PEG-modified anti-GAD. The carbohydrate-modified anti-GAD-PEG samples appear to be recognized more by the anti-mouse-IgG antibodies than the lysine-modified samples. The molecular weight of the PEG also has a greater influence on the lysine-modified than the carbohydrate-modified anti-GAD.

To quantitate the effect of the PEG on binding, the ELISA data were fitted to the following equation (40):

$$A = A_{\max} \frac{(k \times \text{concn})^a}{1 + (k \times \text{concn})^a} + b$$

This is a generalized form of the Langmuir equation which was adapted by Nisonoff and Pressman from an equation by Sips (40) and includes an ' a ' parameter to account for multiple binding sites. In general, for cooperative binding, such as hemoglobin/oxygen, ' a ' will be greater than one, and for nonspecific, multiple binding site binding, such as polyclonal antibodies, ' a ' will be less than 1. Thus, for the binding data from the anti-mouse-IgG-coated plates, ' a ' was fitted to account for the range of affinities of the polyclonal anti-mouse-IgG antibodies. For the binding data from the GAD-coated plates, ' a ' was fixed at 1 due to the singular specificity of the monoclonal anti-GAD antibody to the GAD protein. In this equation, A represents the absorbance of the sample at 405 nm, and $A_{\max}$ is the calculated absorbance plateau and is related to the maximum number of antibodies that can bind in each well and will be referred to as binding activity; k is the affinity constant for the antibody; concn is the concentration of the antibody; b accounts for background absorbance. Within each data group, b and either $A_{\max}$ or k was assumed to be the same for all series, and k or $A_{\max}$, respectively, was fitted for each series.

For each plot and curve-fit, the affinity constant or the absorbance maximum for unmodified anti-GAD was designated as k° or $A_{\max}^\circ$, respectively. Thus, to easily compare across data sets, k or $A_{\max}$ for each sample was divided by the k° or $A_{\max}^\circ$ fitted to the unmodified anti-GAD. In this manner, the binding activity of each

modified anti-GAD can be seen as a fraction of the unmodified anti-GAD. As seen in Table 2, there were noticeable differences in the relative binding calculated by these two methods. However, with each method, it can be seen that the binding affinity of all carbohydrate-modified anti-GAD is higher than any lysine-modified anti-GAD, regardless of PEG molecular weight. The effect of PEG molecular weight appears also to have a greater effect on lysine-modified anti-GAD with respect to the carbohydrate-modified anti-GAD. The lysine-modified anti-GAD shows an additional loss of approximately 73% of its binding affinity or 40% of its binding activity when PEG20000 is used over PEG5000. However, the carbohydrate-modified anti-GAD shows an additional loss of about 39% of its affinity or 20% of its binding activity when PEG20000 is used over PEG5000. When the lysines are used for modification, it appears to be critical that a high pH be used. Otherwise, the binding may be further reduced by 81% (affinity) or 73% (activity), with respect to modification at pH 9.2.

Interactions with anti-mouse-IgG antibodies, which bind to various sites throughout the anti-GAD antibody, are also more affected by molecular weight for lysine-modified versus carbohydrate-modified anti-GAD. There was no difference in the calculated loss in binding with either curve-fitting method used, as seen in Table 2. The binding affinity of anti-GAD to anti-mouse IgG (H+L) antibodies are very close, regardless of molecular weight, when the carbohydrate is used for conjugation. However, when the lysines are used for conjugation, the binding affinity of PEG20000-modified anti-GAD is reduced about 21% with respect to PEG5000-modified anti-GAD.

DISCUSSION

To accurately characterize PEG-modified antibodies, it is important to confirm the PEG modification and to accurately quantify its conjugation. In most studies using the lysine groups for conjugation, the degree of PEG modification is typically measured by a TNBS assay. However, in the case of low modification ratios where the overall number of lysines per molecule are high, this method can be unreliable. For example, at reaction feed ratios (PEG:antibody) below 20:1, the TNBS method shows a conjugation efficiency of 0–40%. Above 20:1, the conjugation efficiency ranges between 62 and 105%, with an average of 84%. Thus, in this case, where the desired modification ratios are below 20:1, a better method for determining this ratio is needed.

Using a polyclonal rabbit IgG as a model antibody system, an ¹H NMR method for quantitating the conjugated PEG was developed. The principle of the method relies on the strong singlet peak of PEG at 3.54 ppm. As seen in Figure 2, the peaks from the antibody protein

**Figure 10.** A schematic structural representation of a typical IgG antibody.

itself could not be used to quantify the PEG peak, since the protein did not exhibit a strong enough peak above the baseline to integrate when compared to the PEG peak. Thus, standards were added to the PEG–antibody solution at known concentrations. In this manner, the peaks of the standards could be used to calculate the concentration of the PEG. The standards acetone (2.06 ppm), DMSO (2.56 ppm), and sodium benzoate (7.27–7.73 ppm) were chosen such that their peaks would not interfere with the PEG peak. As seen in Figure 2, the reference peaks are easily resolved from the PEG peak.

The amount of each reference sample added was calculated based on the expected amount of PEG in the solution. In this manner, the actual amount of PEG is simply the integration of the PEG peak divided by the average of the integration of the reference peaks multiplied by the expected amount of PEG.

As seen in Figure 3, the results of the ¹H NMR analysis of the PEG5000-modified polyclonal rabbit IgG show ratios very close to those calculated using the TNBS method. When a linear curve fit was applied, a slope of 0.73 was obtained with an R^2 of 0.996, indicating a very good fit. Thus, the average conjugation efficiency as calculated from the NMR measurements is 73% which was equally valid at low modifications up to relatively high modifications.

The other great advantage of this technique is that it is a direct measure of the PEG in solution and thus can be applied to PEG-modified proteins regardless of the conjugation method employed. In this case, we successfully used this method to calculate the PEG:antibody ratios for lysine-modified and carbohydrate-modified antibodies.

As seen in Figure 10, IgG antibodies are comprised of four chains: two identical chains of about 50000 Da and two identical chains of about 25000 Da, known as the heavy and light chains, respectively. The four chains associate to form a rough T or Y configuration. The antibody structure is further labeled as having an Fc and Fab segments. The Fc represents the stem of the T or Y, and the Fab represents the two arms of the T or Y and contains the antigen region at the ends of the arm. Each arm of the antibody contains two domains of antiparallel β -sheets. Since, the antibody is comprised almost entirely of the β -sheet secondary structure element, CD spectroscopy can be easily used to measure perturbations in the antibody structure.

As can be seen in Figure 4, the shape of the CD spectra curves closely follow that expected for a β -sheet (37), as seen by the symmetric trough between 210 and 230 nm. At all modification ratios, there is a clear predominance of the β -sheet conformation. There does not appear to be any trend toward a lessening of the β -sheet structure as the modification ratio is increased. Even at its highest modification, at 57 PEG5000 chains per antibody, there is no noticeable change in the trough depth or shape. This indicates that the antibody structure is quite stable and resistant to change upon PEG modification.

The function of antibodies is to bind to antigens. Thus, it is critical that the binding of a modified antibody to retain as much binding activity as possible. In this report, we investigated the effect of PEG on the binding of anti-GAD, a monoclonal antibody against GAD. We investigated the influence of the reaction conditions, the degree of modification, the molecular weight of PEG, and the site of conjugation on the binding activity.

When the lysines are used for PEG conjugation, the modification pH affects the reactivity of the primary amine on the lysine side chain. The pK_a of the ϵ -amine of a lysine in a protein can be expected to be between 9 and 10, whereas, the N-terminal amine of a protein chain can be expected to have a pK_a of around 8 (41). When the solution/reaction pH is equal to the pK_a of an amine, there is an equal number of protonated and unprotonated amines. Thus, since the pK_a of the side-chain amine of the lysines is expected to be between 9 and 10, there should be between 40 and 45 unprotonated amines per antibody, based on 86 lysines and four N-terminal amines, when the solution pH is between 9 and 10. In order for a primary amine to undergo a reaction, it must be unprotonated. Therefore, the pH should be elevated to promote the reaction at the lysines.

At a pH between 9 and 10, there should be approximately 10 reactive lysines for every reactive N-terminal-amine, since there are four N-terminal amines per antibody. Thus, reactions at lysine residues are more likely than at the N-terminal amines at an elevated pH. At a neutral reaction pH, the reaction of the lysines will be much slower. At pH 7.4, the number of unprotonated lysine amines will be approximately 100 times lower than at pH 9.4. However, since the pK_a of the N-terminal amines is about 8, there should still be an unprotonated N-terminal amine at pH 7.4. Thus, we can expect the reactive-lysine:N-terminal-amine ratio to be closer to 1:1. Thus, at pH 7.4, reactions at the N-terminal amines will be equally likely as the lysine ϵ -amines. Thus, it can be expected that N-terminal amines will be modified in addition to lysine amines at a low pH, but at higher pH's, there will many fewer N-terminal amines modified at a pH greater than 9.

The antigen combining region of antibodies is located proximal to the N-terminal amines, and thus a reaction of an N-terminal amine would introduce a massive steric impedance to antigen binding. This is demonstrated in Figure 5. Based on the curve fits, the calculated binding constants show a loss of about 73% of its activity or 81% of its affinity of the pH 7.4-modified with respect to the pH 9.2-modified anti-GAD. Thus, as expected, it appears likely that modification at a low pH will modify an N-terminal amine. Assuming that the loss is due to modified N-terminal amines, this would indicate a loss of activity. According to the binding activity calculations, this would indicate that at least 3 in 8 overall (1 to 2 per antibody) N-terminal amines are modified when a reaction pH 7.4 is used.

When the lysines are used to conjugate the PEG, the PEG chains appear to be randomly attached throughout the antibody. As the modification ratio is increased, the coverage of the antibody by PEG chains will increase. This applies to the area near the antigen combining region as well. Attachment of PEG chains near the antigen combining region will increase the steric hindrance to antigen binding. This can be seen in Figure 6. When the number of PEG chains attached is increased from 5 to 20 per antibody, the binding activity decreases. The specific loss in binding can be approximated by applying a curve fit to the data. When this is done, the loss is approximately 55, 68, and 79% in affinity or 48, 60, and 72% in activity for 5:1, 10:1, and 20:1 modified anti-GAD, respectively.

The carbohydrate moiety of IgG antibodies is located in the Fc region near the hinge of the antibody which is distal to the antigen combining site. Thus, when PEG was conjugated through the carbohydrate, there is a localized attachment of the PEG with minimal interference to the antigen binding. As seen in Figure 7, carbohydrate-modified anti-GAD showed a much higher binding affinity to GAD than lysine-modified anti-GAD. Based on the curve fit, the lysine-modified shows an approximate 30–60% loss of binding affinity with respect to carbohydrate-modified anti-GAD.

The molecular weight of the PEG also has an effect on antigen binding. The effect of PEG with molecular weights of 5000 and 20000 Da was studied. Anti-GAD was modified through the lysine as well as through the carbohydrate with the two molecular weights. The degree of modification was kept between three and five PEG chains per anti-GAD. As seen in Figure 7, the PEG20000 has a greater effect on binding than PEG5000. On the basis of the calculated constants, there is a loss of 40% (carbohydrate-modified) to 73% (lysine-modified) in binding affinity or 20% (carbohydrate-modified) to 40% (lysine-modified) in binding activity of PEG20000-modified anti-GAD with respect to PEG5000-modified anti-GAD.

Binding of modified anti-GAD to antibodies against mouse antibody was studied. These anti-mouse antibodies are polyclonal and are directed against epitopes on both the heavy and light mouse IgG chains. Thus, these antibodies will bind to many sites throughout the anti-GAD protein. This can be a measure of the ability of the PEG at preventing nonspecific-type binding to the anti-GAD. As seen in Figure 8, the degree of modification affects the binding to anti-mouse antibodies when the PEG is conjugated to lysines. A loss of about 16% can be seen in the 5:1 modified sample, and a loss of about 25% can be seen in the 10:1 modified sample. This clearly demonstrates the effect of the greater coverage by the PEG at higher modification ratios. The effect of PEG molecular weight and site of modification can be seen in Figure 9. As expected, the carbohydrate conjugated anti-GAD-PEG show higher binding than the lysine-conjugated anti-GAD-PEG samples. Both the PEG5000 and PEG20000 carbohydrate-modified samples are very close to the PEG5000-modified lysine sample. The molecular weight does not seem to have as much of an effect on the binding to anti-mouse antibodies as it does with the lysine-modified samples. The PEG20000 lysine-modified anti-GAD shows a loss of about 21% of the binding activity toward anti-mouse antibodies with respect to PEG5000-modified anti-GAD. This is in contrast to the carbohydrate-modified anti-GAD, which shows only a small decrease of about 5%, at most, of the PEG20000 versus PEG5000-modified anti-GAD.

These effects can be easily explained by the localization of the PEG at the carbohydrate for the carbohydrate-modified samples. This gives a lower overall coverage of the anti-GAD by the PEG than can be achieved with the lysine-conjugated samples. However, the 95% confidence error bars are relatively wide in these figures, and thus, while differences and trends can be seen, the precision of the calculated numbers may not be reflective of actual values, especially in the carbohydrate- and lysine-PEG5000 curves in Figure 9.

Binding is a function of the degree of modification. The fewer the number of PEG polymer chains attached to the antibody, the more its binding is preserved. Binding is a function of modification pH when the lysine residues are used to couple the PEG. Modification at higher pH values leads to a greater preservation of binding. This is most likely due to the lower pK_a value of the N-termini amino groups. Their lower pK_a values suggest that they will more likely be modified at a lower pH than the lysine ϵ -amine. Since the N-termini are proximal to the binding site on the antibody, their modification would be detrimental to binding to the antigen. Binding is a function of modification site. The carbohydrate-modified anti-GAD shows a much greater binding than the lysine-modified anti-GAD due to the localized manner in which the PEG is attached to the carbohydrate of the antibody.

Sequence-Specific DNA Cleavage by Dipeptides Disubstituted with Chlorambucil and 2,6-Dimethoxyhydroquinone-3-mercaptoacetic Acid

Andrew Minnock,[‡] Li-Seng Lin,[†] Julie Morgan,[‡] Stephen D. G. Crow,[‡] Michael J. Waring,^{*,‡} and Leung Sheh^{*,†}

Department of Chemistry, Tunghai Christian University, Taichung, Taiwan 407, Republic of China, and Department of Pharmacology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QJ, England, U.K. Received December 4, 2000; Revised Manuscript Received May 10, 2001

Two dipeptides, each containing a lysyl residue, were disubstituted with chlorambucil (CLB) and 2,6-dimethoxyhydroquinone-3-mercaptoacetic acid (DMQ-MA): DMQ-MA-Lys(CLB)-Gly-NH₂ (DM-KCG) and DMQ-MA-β-Ala-Lys(CLB)-NH₂ (DM-BKC). These peptide–drug conjugates were designed to investigate sequence-specificity of DNA cleavage directed by the proximity effect of the DNA cleavage chromophore (DMQ-MA) situated close to the alkylating agent (CLB) inside a dipeptide moiety. Agarose electrophoresis studies showed that DM-KCG and DM-BKC possess significant DNA nicking activity toward supercoiled DNA whereas CLB and its dipeptide conjugate Boc-Lys(CLB)-Gly-NH₂ display little DNA nicking activity. ESR studies of DMQ-MA and DM-KCG both showed five hyperfine signals centered at $g = 2.0052$ and are assigned to four radical forms at equilibrium, which may give rise to a semiquinone radical responsible for DNA cleavage. Thermal cleavage studies at 90 °C on a 265-mer test DNA fragment showed that besides alkylation and cleavage at G residues, reactions with DM-KCG and DM-BKC show a preference for A residues with the sequence pattern: 5'-G-(A)_n-Pur-3' > 5'-Pyr-(A)_n-Pyr-3' (where $n = 2-4$). By contrast, DNA alkylation and cleavage by CLB occurs at most G and A residues with less sequence selectivity than seen with DM-KCG and DM-BKC. Thermal cleavage studies using N7-deazaG and N7-deazaA-substituted DNA showed that strong alkylation and cleavage at A residues by DM-KCG and DM-BKC is usually flanked on the 3' side by a G residue whereas strong cleavage at G residues is flanked by at least one purine residue on either the 5' or 3' side. At 65 °C, it is notable that the preferred DNA cleavage by DM-KCG and DM-BKC at A residues is significantly more marked than for G residues in the 265-mer DNA; the strongest sites of A-specific reaction occur within the sequences 5'-Pyr-(A)_n-Pyr-3'; 5'-Pur-(A)_n-G-3' and 5'-Pyr-(A)_n-G-3'. In pG4 DNA, cleavage by DM-KCG and DM-BKC is much greater than that by CLB at room temperature and at 65 °C. It was also observed that DM-KCG and DM-BKC cleaved at certain pyrimidine residues: C40, T66, C32, T34, and C36. These cleavages were also sequence selective since the susceptible pyrimidine residues were flanked by two purine residues on both the 5' and 3' sides or by a guanine residue on the 5' side. These findings strongly support the proposal that once the drug molecule is positioned so as to permit alkylation by the CLB moiety, the DMQ-MA moiety is held close to the alkylation site, resulting in markedly enhanced sequence-specific cleavage.

INTRODUCTION

Alkylating agents such as chlorambucil (CLB) have been widely used in clinical practice against chronic lymphocytic leukemia for more than 30 years (2). Chlorambucil is also widely used clinically against lymphoma, Hodgkin's disease, and testicular cancer and is effective against other types of cancer in combination therapy (3–9). Chlorambucil, melphalan, and other alkylating agents are known to alkylate DNA preferentially at the N7 position of guanine nucleotides, resulting in intra- or interstrand cross-linking of the double helix and thus interfering with DNA replication (10). In a recent paper we reported the DNA binding and sequence specificity of some cyclic peptide–chlorambucil conjugates (11). Apart from DNA alkylation at the guanine-N7 position, no propensity to cause DNA cleavage was observed with these cyclic peptide conjugates. They displayed similar sequence specificity as regards DNA alkylation to that

seen with CLB alone. The specificity of alkylation for both CLB and its peptide conjugates appears to be 5'-Pyr-G-Pur-3' > 5'-Pyr-G-Pyr-3' > 5'-Pur-G-Pyr-3' = 5'-Pur-G-Pur-3'. However, there are some apparent differences in the selectivity of alkylation between the peptide derivatives and CLB at certain guanine-containing sequences. We concluded that the spacing of the two CLB moieties in these cyclic peptides can impose certain sequence selectivity over and above that of CLB (11).

The design and synthesis of sequence-specific DNA cleaving agents has been and remains an important research topic in chemistry and molecular biology. Various agents have been reported to have sequence-specific DNA cleaving ability, including antibiotics, triple-helix forming oligonucleotides, and peptides (12–19). In this work we report the synthesis and DNA cleavage properties of two dipeptides containing a lysyl residue disubstituted at the ε-amino and α-amino positions, respectively, with chlorambucil (CLB), and 2,6-dimethoxyhydroquinone-3-mercaptoacetic acid (DMQ-MA, **1**), which possesses significant DNA cleaving activity (23). Two disubstituted dipeptides were synthesized: DMQ-MA-Lys-

^a Structures of DM-KCG, DM-BKC, and CLB.

(CLB)-Gly-NH₂ (DM-KCG) and DMQ-MA-β-Ala-Lys(CL B)-NH₂ (DM-BKC) (Chart 1). The peptide conjugates were designed such that the average intramolecular separation between the CLB and DMQ-MA groups in DM-BKC is greater than that of DM-KCG. We anticipated that the spacing between the two cytotoxic groups might impose certain differences in binding affinity and alkylation sequence specificity on DNA. Previous reports have shown that DMQ-MA and its derivatives can nick supercoiled DNA efficiently in the absence of L-ascorbic acid, suggesting that radicals such as the semiquinone might be involved (23). Radicals such as the semiquinone and hydroxyl radicals are potent biological oxidants and can readily attack DNA. We envisaged that once the CLB moiety of the dipeptide derivative is positioned suitably to alkylate the N7 position of a guanine nucleotide, the DMQ-MA group would lie in close proximity to the DNA backbone, thus facilitating the cleavage of the strand/strands by various forms of radicals. These considerations led us to investigate the efficiency of DNA cleavage and DNA sequence specificity directed by the proximity effect of the CLB and DMQ-MA moieties in this series of peptide–drug conjugates.

EXPERIMENTAL SECTION

Drugs. Chlorambucil, DM-KCG, DM-BKC, and DMQ-MA were dissolved in methanol to yield a 1 mM stock solution. Appropriate concentrations of drugs were made by dilution with phosphate-buffered saline (PBS, pH 7.4).

Chemicals. All of the protected amino acid derivatives were purchased from Bachem California (Torrance, CA) and Sigma Chemical Co. (St. Louis, MO) or synthesized in our laboratory according to published procedures. Ammonium persulfate, tris base, acrylamide, bis-acrylamide, ultrapure urea, boric acid, sodium citrate, tetramethylethylenediamine, and dimethyl sulfate were from BDH. X-ray film was from Fuji Photo Film Co. Ltd. Formic acid, piperidine, and formamide were from Aldrich. Bromophenol blue and xylene cyanol were from Sigma. Melting points were determined on a Mel-Temp apparatus (Cambridge, MA) and were uncorrected. Medium-pressure column chromatography was performed using Merck 230–400 mesh silica gel. TLC was per-

formed on Merck silica gel 60-coated aluminum sheets. Optical rotations were determined on a Rudolph Autopol II instrument. Low-resolution and high-resolution mass spectra were taken from a JEOL JMX-HX 110 instrument operating in the FAB mode. Elemental analyses were performed at the Chemistry Department, Cheng-Kung University.

Biochemicals. Radiolabeled nucleoside triphosphates, [γ -³²P]ATP and [α -³²P]dATP, were obtained from NEN Life Science Products at a specific activity of 6000 Ci/mmol. Taq polymerase (Promega), T4 polynucleotide kinase (Promega), AMV reverse transcriptase (Promega), and the restriction endonucleases EcoRI (Roche) and PvuII (New England Biolabs) were used according to the supplier's recommended protocol in the activity buffer provided. The primers, 5' AACAGCTATGACCATG (M13/pUC reverse sequencing primer) or 5' GTTTTCCCACTCAGGAC (M13/pUC forward sequencing primer) bearing a 5'-OH were obtained from the Department of Biochemistry, University of Cambridge, England. The pG4 template was a kind gift of Dr. N. E. Møllegaard (Center for Biomolecular Recognition, Department of Medical Biochemistry and Genetics, The Panum Institute, University of Copenhagen, Denmark). All other chemicals were analytical grade reagents, and all solutions were prepared using doubly deionized, Millipore-filtered water.

Boc-Lys(Z)-Gly-NH₂ 2. This compound was prepared by coupling Boc-Lys(Z) (1.0 g, 2.63 mmol) with glycylamide (0.43 g, 2.63 mmol) by the DCC/HOBt method in DMF at pH 7.5. After sonicating at room temperature for 2 h, the reaction mixture was filtered and the filtrate evaporated in vacuo. The residue was redissolved in EtOAc and washed successively with citric acid (10%, 3 × 10 mL), saturated NaHCO₃ (3 × 10 mL), and water (3 × 10 mL), dried (MgSO₄), and evaporated in vacuo to give a white solid. Medium-pressure chromatography using stepwise elution (CHCl₃/MeOH, 100:0, 99:1, 98:2, 97:3, 96:4, 95:5, 94:6) afforded a white solid (1.0 g 88%). TLC [(CHCl₃/MeOH, 90:10), *R_f* 0.45; mp 102–103 °C; [α]_D³⁰ –7.5 (MeOH/CHCl₃, 1:1, *c* 0.03). Anal. (C₂₁H₃₂N₄O₆·0.5 H₂O) C, H, N.

Boc-Lys(CL B)-Gly-NH₂ 3. This compound was prepared by coupling CLB-Pfp with the TFA salt of dipeptide 2 in DMF at pH 7.5. Medium-pressure chromatography using stepwise elution (CHCl₃/MeOH, 100:0, 99:1, 98:2, 97:3, 96:4, 95:5, 94:6) afforded a white solid (0.77 g 82%). TLC [(CHCl₃/MeOH, 90:10), *R_f* 0.52; mp 82–83 °C; [α]_D³⁰ –10.8 (MeOH/CHCl₃, 1:1, *c* 0.03). Anal. (C₂₇H₄₃N₅O₅Cl₂·H₂O) C, H, N.

DMQ-MA-Lys(CL B)-Gly-NH₂ 4. The dipeptide 3 was deblocked with TFA/CH₂Cl₂ and reacted with DMQ-MA-Pfp in DMF at pH 7.0 by sonication for 2 h. The reaction mixture was evaporated in vacuo to give a crude brown solid. Medium-pressure chromatography using stepwise elution (CHCl₃/MeOH, 100:0, 99:1, 98:2, 97:3, 96:4, 95:5, 94:6, 93:7) afforded an orange solid (0.33 g 65%). TLC [(CHCl₃/MeOH, 90:10), *R_f* 0.51; mp 81–82 °C; [α]_D³⁰ –17.3 (MeOH/CHCl₃, 1:1, *c* 0.03). HRFABMS 730.2437 [MH]⁺.

Boc-β-Ala-Lys(Z)-NH₂ 5. This compound was prepared by coupling Boc-β-Ala (0.49 g, 2.6 mmol) with the TFA salt of Boc-Lys(Z)-NH₂ (1.0 g, 2.6 mmol) by the DCC/HOBt method in DMF at pH 7.5. After sonicating at room temperature for 2 h, the reaction mixture was filtered and the filtrate evaporated in vacuo. The residue was redissolved in EtOAc and washed successively with citric acid (10%, 3 × 10 mL), saturated NaHCO₃ (3 × 10 mL), and water (3 × 10 mL), dried (MgSO₄), and evaporated in vacuo to give a white solid. Medium-pressure chro-

matography using stepwise elution (CHCl₃/MeOH, 100:0, 99:1, 98:2, 97:3, 96:4, 95:5, 94:6, 93:7) afforded a white solid (1.0 g 86%). TLC [(CHCl₃/MeOH, 90:10), *R_f* 0.46; mp 120–122 °C; [α]_D³⁰ –11.02 (MeOH/CHCl₃, 1:1, *c* 0.03). Anal. (C₂₂H₃₄N₄O₆) C, H, N.

Boc- β -Ala-Lys(CLB)-NH₂ **6**. This compound was prepared by coupling CLB-Pfp with the TFA salt of dipeptide **5** in DMF at pH 7.5. Medium-pressure chromatography using stepwise elution (CHCl₃/MeOH, 100:0, 99:1, 98:2, 97:3, 96:4, 95:5) afforded a white solid (0.59 g 78%). TLC [(CHCl₃/MeOH, 90:10), *R_f* 0.56; mp 136–137 °C; [α]_D³⁰ –37.73 (MeOH/CHCl₃, 1:1, *c* 0.03). Anal. (C₂₈H₄₅N₅O₅-Cl₂) C, H, N.

DMQ-MA- β -Ala-Lys(CLB)-NH₂ **7**. The dipeptide **6** was deblocked with TFA/CH₂Cl₂ and reacted with DMQ-MA-Pfp in DMF at pH 7.0 by sonication for 2 h. The reaction mixture was evaporated in vacuo to give a crude brown solid. Medium-pressure chromatography using stepwise elution (CHCl₃/MeOH, 100:0, 99:1, 98:2, 97:3, 96:4, 95:5, 94:6, 93:7) afforded an orange solid (0.195 g 63%). TLC [(CHCl₃/MeOH, 90:10), *R_f* 0.62; mp 102–104 °C; [α]_D³⁰ –10.03 (MeOH/CHCl₃, 1:1, *c* 0.03). HRFABMS 744.2533 [MH]⁺.

Electron Spin Resonance Spectroscopy Studies. The ESR spectra were obtained on a Bruker EMX-10 EPR spectrometer; microwave power 20 mW; modulation frequency 100 kHz; sweep time 4.0 G/min; receiver gain 8.93×10^5 ; time constant 2.62 s. Drugs were dissolved in 0.5X PBS (containing 2.5 μ M ferrous sulfate) at a final concentration of 40 μ M in a volume of 0.4 mL. The spectrum of DMQ-MA was taken without UV irradiation whereas that of DMQ-KCG was taken by irradiating with a 500 W mercury lamp.

Preparation, Purification, and Labeling of DNA Fragments. Plasmid pBluescript was isolated from *E. coli* by a standard sodium dodecyl sulfate–sodium hydroxide lysis procedure and purified by banding in CsCl–ethidium bromide gradients. Ethidium bromide was removed by several 2-propanol extractions followed by exhaustive dialysis against Tris–EDTA buffer. The purified plasmid was then precipitated and resuspended in appropriate buffer prior to digestion with *Eco*RI and *Pvu*II. After precipitation, the DNA was resuspended in AMV reverse transcriptase buffer. The DNA was then 3'-end labeled with [α -³²P]dATP in the presence of AMV reverse transcriptase. This yielded two appropriately sized fragments, a 117-mer and a 265-mer which were then separated on a 6% polyacrylamide gel. After electrophoresis for about 90 min, the gel was exposed to X-ray film for about 5 min. After developing the film, the bands were located, excised, crushed, and soaked overnight in TN buffer (pH 7.0) at 37 °C. This suspension was filtered through a Millipore 0.22 μ m filter, and the DNA was precipitated with ethanol. Following washing with 70% ethanol and vacuum-drying of the precipitate, the purified DNA was resuspended in TN buffer (pH 7.0) to 4800 Cerenkov cpm/ μ L.

Primer Labeling. The 5'-OH M13/pUC reverse sequencing primer was 5'-end labeled with [γ -³²P]ATP in the presence of T4 polynucleotide kinase.

Polymerase Chain Reaction (PCR). The protocol used to incorporate N7 deazaadenosine and/or N7 deazaguanosine residues into DNA was comparable to that previously described (25). PCR reaction mixtures contained 10 ng of pG4 template, 0.1 μ M of the M13/pUC forward sequencing 5'-OH primer and M13/pUC reverse sequencing 5'-³²P primer, 250 μ M of each appropriate dNTP (dATP or N⁷dATP, dGTP or N⁷dGTP, dCTP, dTTP according to the desired DNA), and 1 unit of *Taq*

polymerase in a volume of 50 μ L containing 50 mM KCl, 10 mM Tris-HCl, pH 8.3, 0.1% Triton X-100, and 1.5 mM MgCl₂. To prevent unwanted primer–template annealing before the cycles began, the reactions were heated to 60 °C before adding the *Taq* polymerase. After an initial denaturing step of 3 min at 94 °C, 30 amplification cycles were performed. Parallel reactions were pooled and several extractions with water-saturated *n*-butanol were performed to reduce the volume prior to loading the samples on to a 6% nondenaturing polyacrylamide gel. After electrophoresis for about 90 min, the DNA was isolated as described for the 3'-end labeled DNA.

Alkylation Studies. 1 μ L of the labeled DNA fragment (117-mer, 265-mer or pG4) was added to 20 μ L of the appropriate concentration of drug dissolved in 10 μ L of PBS (pH 7.4). The samples were then incubated for 2 h at 37 °C, ethanol-precipitated, washed, and resuspended in the appropriate solvent for the assay.

Thermal Cleavage Assay. To determine whether the N3 or N7 of adenines or guanines were alkylated, the samples were resuspended in 100 μ L of 1.5 mM sodium citrate buffer containing 15 mM NaCl (pH 7.2), heated to 90 °C for 30 min, and then cooled on ice. The samples were then ethanol-precipitated. After a further ethanol precipitation, the samples were lyophilized and resuspended in 80% formamide containing tracking dyes, heated at 90 °C for 4 min, and then cooled on ice.

DNA Cleavage at Lower Temperatures in the Presence and Absence of Ferrous Ions. To determine the influence that the presence of iron(II) had on the level of cleavage by the compounds, the samples were resuspended in PBS containing 10 μ M ferrous sulfate solution. They were heated at 65 °C or room temperature for 30 min or for specified periods of time and then ethanol-precipitated. After cleavage treatments, the samples were lyophilized, washed twice with 50 μ L of water, lyophilized again, and finally resuspended in 4 μ L of an 80% formamide solution containing tracking dyes. Samples were heated at 90 °C for 4 min and chilled in ice for 4 min prior to electrophoresis.

Electrophoresis and Autoradiography. The products of DNA cleavage were resolved by polyacrylamide gel electrophoresis under denaturing conditions (0.3 mm thick, 8% acrylamide containing 8 M urea). After electrophoresis (about 2.5 h at 60 W, 1600 V in TBE buffer, BRL sequencer model S2), gels were soaked in 10% acetic acid for 15 min, transferred to Whatman 3MM paper, dried under vacuum at 80 °C, and placed against a Molecular Dynamics 425E PhosphorImager storage screen overnight (24). Baseline-corrected scans were analyzed by integrating all the densities between two selected boundaries using ImageQuant for the Macintosh version 1.2 software. Each resolved band was assigned to a particular bond within the DNA fragment by comparison of its position relative to sequencing standards. For the 5'-end labeled pG4 fragments, G and G+A tracks were generated by treatment of the radiolabeled DNA with dimethyl sulfate and formic acid, respectively, followed by piperidine-induced cleavage at the sites of reaction (11). For the 3'-end labeled 117-mer and 265-mer DNA fragments, G+A tracks were made. Briefly, to 2 μ L of the treated DNA were added 20 μ L of water and 5 μ L of an 80% formamide solution containing tracking dyes. The sample was then heated at 90 °C for 45 min with the Eppendorf tube cap opened, cooled on ice for 4 min, and then loaded on the gel.

Scheme 1

RESULTS AND DISCUSSION

A. Synthesis of DMQ-MA-Lys(CLB)-Gly-NH₂ (DM-KCG) and DMQ-MA-β-Ala-Lys(CLB)-NH₂ (DM-BKC).

The strategy for the synthesis of CLB and DMQ-MA disubstituted dipeptides is shown in Scheme 1. The dipeptides **2** and **5** were synthesized by coupling the corresponding protected amino acids using the DCC/HOBt procedure. For the synthesis of the dipeptide derivatives **3** and **6**, we avoided conjugating the DMQ-MA moiety to the dipeptide in the first step since the DMQ-MA moiety is prone to decomposition during the removal of the lysyl ϵ -amino Z protecting group of the dipeptides by catalytic hydrogenation or by treatment with HBr/HOAc in the following step. Thus, the lysyl Z protecting group of the dipeptides **2** and **5** were deblocked by catalytic hydrogenation, and the CLB moiety was then conjugated using DCC/HOBt. Subsequent removal of the α -Boc protecting groups of **3** and **6** by TFA followed by acylation with DMQ-MA pentafluorophenyl ester at neutral pH afforded the target peptides **4** and **7**.

B. Agarose Gel Electrophoresis and ESR Studies.

In common with other DMQ-MA conjugates, the dipeptide conjugates DM-BKC and DM-KCG brought about efficient nicking of supercoiled DNA whereas chlorambucil produced little DNA cleavage even at 100 μ M. The DNA nicking effects of DM-KCG and CLB on pBluescript SKII plasmid are illustrated in Figure 1. Similar results were obtained with DM-BKC (not shown). It is interesting to note that DM-KCG and DM-BKC can quite efficiently nick supercoiled DNA in the absence of ferrous ions and L-ascorbic acid. However, ferrous ions exert little dose-dependent enhancement of DNA nicking induced by either of the drugs, although addition of Fe²⁺ ions alone often produced a significant (though rather variable) amount of background nicking.

Since the generation of hydroxyl radicals by DMQ-MA and its conjugates in the absence of L-ascorbic acid is very slight (21, 22), we reasoned that other radicals such as the semiquinone could be responsible for the DNA nicking process. ESR studies of DMQ-MA in PBS showed five hyperfine signals centered at $g = 2.0052$ (lower trace, Figure 2). Similarly, DM-KCG also showed identical ESR signals at $g = 2.0052$, but notably weaker (upper trace, Figure 2), due to its much lower aqueous solubility. It was also reported that 2,6-dimethoxybenzoquinone which

is much less soluble than its derivative DMQ-MA, has very weak ESR spectrum assigned to semiquinone signals (27). We propose that these five hyperfine signals of DMQ-MA and DM-KCG correspond to radical structures III and IV of the equilibrium and resonance forms shown in Figure 3. The semiquinone (radical structure II), being stabilized by four resonance forms, may be responsible for the DNA nicking process.

C. DNA Cleavage Studies. Thermal Cleavage Studies. This methodology detects alkylation sites and cleavage sites by incubating DNA with different concentrations of drug at 37 °C for 2 h and then incubating at 90 °C in 1.5 mM sodium citrate buffer containing 15 mM NaCl (pH 7.2) for 30 min (26). In the 117-mer DNA fragment, the DNA cleavage pattern of DM-KCG (Figure 4b) and DM-BKC (results not shown) was similar to that of CLB (Figure 4a). However, the intensity of the cleaved bands produced by both conjugate drugs was considerably greater than that of CLB. Besides cleavage at guanine residues, all three drugs also show a propensity to attack a consecutive sequence of four adenines: A42–A45 (Figure 4).

In the 265-mer DNA fragment once again all/most G residues show alkylation and cleavage. However, there are some indications that the substitutions cause the compounds to interact differently with DNA. For example, DM-KCG produces strong alkylation and cleavage at a consecutive sequence of three adenines: A53–A54–A55 whereas A56 was only relatively weakly cleaved. By contrast, CLB exhibits strong alkylation and cleavage at all four adenines: A53–A54–A55–A56 (Figure 4). Other notable sites of alkylation and cleavage by DM-KCG occur at positions A74, A86, A107–G108, A110–A111, whereas DNA alkylation and cleavage by DM-BKC was seen at positions A74–A75, A79, A81, A86, A92, A110–A111 (results not shown). Hence DM-BKC and DM-KCG seem to show a preference for A residues within the sequence pattern: 5'-Pur-(A)_n-G-3' > 5'-Pyr-(A)_n-Pyr-3' (where $n = 1-3$). This is in marked contrast to CLB which alkylates DNA at most G and A residues with little sequence specificity.

Thermal Cleavage Using N7-Deaza-guanosine DNA and N7-Deaza-adenosine DNA. Having established that the substitutions alter the sequence specificity of DM-KCG and DM-BKC, we decided to further probe

Figure 1. DNA cleavage of plasmid pBluescript DNA induced by DM-KCG and chlorambucil (CLB) in the presence or absence of ferrous ions. Samples were incubated at 37 °C for 10 min and then at 65 °C for 30 min. The upper band represents the open-circular form, and the lower band the supercoiled form.

Figure 2. ESR spectra obtained by adding DMQ-MA to PBS (lower spectrum) or DM-KCG to PBS containing 2.5 μM ferrous sulfate (upper trace). The spectrum of DMQ-MA was taken without UV irradiation whereas that of DMQ-KCG was taken by irradiating with a 500 W mercury lamp. Microwave power 20 mW; modulation frequency 100 kHz; sweep time 3.6 G/min; receiver gain 8.93×10^5 ; time constant 2.62 s. $g = 2.0052$.

the molecular interactions involved by incorporating modified nucleotides into another DNA fragment, pG4. The pG4 DNA fragment was substituted with either N7-deaza-guanosine residues in place of guanositines or N7-deaza-adenosine residues in place of adenosine. When N7-deaza-guanosine residues were substituted in the DNA, all alkylation reactions at guanosine residues by DM-BKC (Figure 5) and DM-KCG (results not shown) were abolished. This indicates that the N7 position is crucial for alkylation at guanosine residues. Conversely, when N7-deaza-adenosine residues were substituted in the DNA, all of the bands corresponding to alkylation at

Figure 3. Proposed equilibrium and resonance forms of DMQ-MA or its conjugates in aqueous solution. R represents the side-chain of DMQ-MA or its conjugates.

adenosine residues disappeared, showing that the N7 position is required for alkylation at adenosine residues.

The alkylation and cleavage by DM-BKC (Figure 5) in N7-deazaG DNA shows a preference for A residues with the following sequence specificity: 5'-AAG-3' > 5'-CAG-

Figure 4. (a) Autoradiograph showing thermal cleavage of 117-mer or 265-mer DNA incubated with chlorambucil (CLB) at different drug concentrations for 2 h at 37 °C and then at 90 °C for 30 min in 1.5 mM sodium citrate buffer containing 15 mM NaCl (pH 7.2). GA represents the Maxam–Gilbert purine specific sequencing track. The autoradiograph on the right-hand panel and left-hand panel corresponds to the 265-mer and 117-mer DNA, respectively. (b) Autoradiograph showing thermal cleavage of 117-mer or 265-mer DNA incubated with DM-KCG under the same conditions.

3' > 5'-TAG-3' = 5'-GAG-3' = 5'-TAC-3' > 5'-CAA-3' > 5'-CAT-3' > 5'-GAC-3'. This result shows that strong alkylation and cleavage of A residues requires flanking at the 3' side by a G residue. However, since the 3' flanking G will be deazaG, alkylation at the N7 of G is not possible. Thus cleavage seen at an A residue is caused by alkylation of the drug at the same A residue or by, for example, the O6 of the 3' flanking G residue. By contrast, alkylation and cleavage by DM-BKC in N7-deazaA DNA shows a preference for G residues with the

following sequence specificity: 5'-AGG-3' = 5'-GGT-3' = 5'-AGG-3' > 5'-AGC-3' > 5'-AGA-3' = 5'-TGC-3' > 5'-CGC-3'. This indicates that strong alkylation and cleavage at G residues requires flanking by at least one purine residue at either the 5' or 3' side. Alkylation and cleavage by DM-KCG in N7-deazaG DNA was found to be similar to that seen for DM-BKC, showing a preference for A residues with the following sequence specificity: 5'-AAG-3' > 5'-TAG-3' = 5'-GAG-3' = 5'-CAG-3' > 5'-CAA-3' = 5'-TAC-3' >> 5'-GAC-3' > 5'-CAT-3'. Once more, strong

Figure 5. Autoradiograph showing thermal cleavage of pG4 DNA containing normal nucleotides, N7-deazaG for G (N7-deazaA DNA) or N7-deazaA for A (N7-deazaG DNA) in the presence of increasing concentrations of DM-BKC. The substituted DNA was incubated with different concentrations of DM-BKC for 2 h at 37 °C and then at 90 °C for 30 min in 1.5 mM sodium citrate buffer containing 15 mM NaCl (pH 7.2).

alkylation and cleavage at A residues requires flanking by a G residue at the 3' side. The rationale for this sequence specificity is similar to that described for DM-BKC. Moreover, alkylation and cleavage by DM-KCG in N7-deazaA DNA was also similar to that seen for DM-BKC (results not shown).

DNA Cleavage at Lower Temperatures in the Presence and Absence of Ferrous Ions. Since it is known that DMQ-MA and its peptide conjugates can nick DNA in the presence or absence of ferrous ions and that this can be influenced by the temperature (23), we monitored the time course of DNA cleavage by DM-KCG (Figure 6), DM-BKC, and CLB (results not shown) at 65 °C in the presence and absence of ferrous ions. The cleavage bands produced from the 265-mer DNA fragment by CLB were much weaker than those produced

by DM-KCG and DM-BKC both at room temperature and at 65 °C (results not shown).

Initial inspection of the autoradiograph (Figure 6) reveals that the presence of iron has little influence on either the specificity of the cleavage by DM-KCG (Figure 6) and DM-BKC (results not shown) or the magnitude of that cleavage. However, increasing the incubation time at 65 °C does appear to exert some effect on the level of cleavage by these compounds. The strongest bands cleaved in the 117-mer DNA by DM-KCG and DM-BKC were seen at positions A42-A43-A44-A45. Therefore DM-KCG and DM-BKC show a preference for A residues with the following sequence pattern: 5'-Pyr-(A)_n-Pyr-3' (Figures 6a and 6b). The cleavage pattern for the remainder of the sequence is similar to that seen following thermal cleavage at 90 °C (Figure 4). A similar result is seen with

Figure 6. Autoradiograph showing cleavage of 117-mer and 265-mer DNA incubated with DM-KCG in the presence or absence of ferrous ions (10 μ M) at 37 $^{\circ}$ C for 2 h and then incubated at 65 $^{\circ}$ C up to 60 min.

the 265-mer fragment. The strongest bands cleaved are seen at positions A53-A54-A55, indicating a preference for A residues with the sequence pattern: 5'-Pur-(A) $_n$ -G-3'. There was also strong cleavage at positions A63-A64-A65, indicating a preference for A residues with the sequence pattern: 5'-Pyr-(A) $_n$ -G-3'. The other bands that were cleaved significantly correspond to positions A58-A59 (sequence pattern: 5'-Pur-(A) $_n$ -Pyr-3'); A74-A75 (sequence pattern: 5'-Pyr-(A) $_n$ -Pyr-3'); A78-A79-A80 (sequence pattern: 5'-Pur-(A) $_n$ -Pyr-3'); A86-A87 (sequence pattern: 5'-Pyr-(A) $_n$ -G-3'); and A110-A111-A112 (sequence pattern: 5'-Pur-(A) $_n$ -Pyr-3').

At 65 $^{\circ}$ C, it is noticeable that guanine residues G81, G85, G90, and G96 in the 265-mer DNA were barely cleaved. In addition guanine residues G52, G60-G61-G62 were only slightly cleaved (Figures 6). By contrast, all of these guanine residues were strongly cleaved by CLB at

90 $^{\circ}$ C. Taken together these data indicate that DNA cleavage by DM-KCG and DM-BKC at A residues is significantly enhanced compared to that seen at G residues.

Using pG4 DNA we further examined the influence of temperature on the cleavage by both DM-BKC and DM-KCG. From this it is clear that the levels of DNA cleavage by DM-KCG and DM-BKC at room temperature and 65 $^{\circ}$ C greatly exceed those by CLB (Figures 7 and 8). For CLB, almost no DNA cleavage was observed up to base number 100 at room temperature, and little was seen up to base number 70 at 65 $^{\circ}$ C. When the reaction was performed at 65 $^{\circ}$ C in the presence of 10 μ M Fe $^{2+}$, some DNA cleavage was seen with CLB. However, the levels of cleavage were always much lower than those seen with DM-KCG and DM-BKC under all experimental conditions (Figure 8).

Figure 7. Autoradiograph showing cleavage of pG4 DNA incubated with CLB, DM-KCG, DM-BKC, or in the absence of drug at 37 °C for 2 h and then incubated at various temperatures as shown for 30 min. The conditions for thermal cleavage are identical to that shown in Figure 5.

At 65 °C, the strongest bands cleaved by DM-BKC and DM-KCG correspond to consecutive guanine residues. In addition, it is noteworthy that DM-KCG and DM-BKC at 100 μ M also produced cleavage at some pyrimidine residues in the pG4 DNA under each experimental condition. However, the levels of cleavage were much less than for purine residues. For example, cleavage at pyrimidine residues C40, T66, C32, T34, C36 is evident under the four different experimental conditions (Figure 7). These are considered to be sequence-specific cleavage effects since only a few pyrimidine residues flanked by two purine residues on both the 5' and 3' sides or by one purine residue on the 5' side are affected. This ability to cleave pyrimidine residues is attributable to the DMQ-

MA moiety of the peptide conjugates. It demonstrates sequence specificity of DNA cleavage directed by a proximity effect of the DNA scissoring chromophore (DMQ-MA) situated close to the alkylation chromophore (CLB) inside a dipeptide moiety. The conjugation of DMQ-MA to CLB is mandatory for this sequence selectivity since in the presence of DMQ-MA and iron, only random nonselective cleavage effects are seen (Figure 7).

SUMMARY AND CONCLUSIONS

This paper reports efforts to investigate the sequence-specificity of DNA cleavage directed by a DNA cleavage chromophore (DMQ-MA) in close proximity to an alkylation agent (CLB) in dipeptide conjugates. In summary,

Figure 8. Comparison of band intensities produced by CLB, DM-KCG, and DM-BKC on the cleavage of pG4 DNA at room temperature (a), at 65 °C (b), and at 65 °C in the presence of 10 μM Fe²⁺ (c). The thick solid line represents CLB, the light solid line DM-BKC, and the dashed line DM-KCG.

Figure 9. Nucleotide sequence of 117-mer DNA fragment, 265-mer DNA fragment and PG4 DNA fragment.

thermal cleavage studies have shown that although the gross sequence preferences of DM-KCG and DM-BKC in the 117-mer DNA are similar to those of CLB, the intensity of cleavage produced by both drugs is much greater than for CLB. In the 265-mer DNA, besides alkylation and cleavage at G residues, DNA alkylation and cleavage by DM-KCG and DM-BKC is also seen at A residues within the sequence pattern: 5'-Pur-(A)_n-G-3' > 5'-Pyr-(A)_n-Pyr-3' (where *n* = 1–3). By contrast, DNA alkylation and cleavage by CLB occurs at most G and A residues with much less sequence specificity than seen with DM-KCG and DM-BKC.

Thermal cleavage studies using N7-deazaG and N7-deazaA DNA exposed to DM-BKC and DM-KCG showed that strong alkylation and cleavage at A residues requires G residues flanking the 3' side whereas strong alkylation

and cleavage at G residues requires flanking by at least one purine residue on either the 5' or 3' side.

From agarose gel electrophoretic studies it is clear that DM-KCG and DM-BKC exhibit efficient nicking of supercoiled DNA at concentrations as low as 10 μM whereas CLB causes little DNA nicking even at 100 μM. The addition of ferrous ion has little effect on the enhancement of DNA nicking by these drugs, showing that the presence of iron is not mandatory for DNA cleavage. In addition, cyclic peptide-CLB conjugates (11) and Boc-Lys(CLB)-Gly-NH₂ (data not shown) are incapable of nicking supercoiled DNA. These studies indicate that the conjugation of DMQ-MA (a DNA cleavage agent) (23) to the dipeptide is required for DNA nicking activity. ESR studies of DMQ-MA and DM-KCG both showed five hyperfine signals centered at *g* = 2.0052, corresponding

to two equilibrium radical forms. We propose that the semiquinone structure II is responsible for cleaving the DNA strand (Figure 3).

DNA cleavage studies at lower temperatures in the presence or absence of ferrous ions provide us with more valuable information. At 65 °C and at room temperature, DNA cleavage by CLB was much weaker than that seen with DM-KCG and DM-BKC. With the 265-mer DNA, very few G residues are cleaved by DM-KCG and DM-BKC at 65 °C. By contrast, all of these G residues were strongly cleaved by CLB at 90 °C during thermal cleavage. It is notable that DM-KCG and DM-BKC cleave more readily at A residues than G residues. At 65 °C, the strongest levels of cleavage by DM-KCG and DM-BKC are seen at A residues within the sequences 5'-Pyr-(A)_n-Pyr-3'; 5'-Pur-(A)_n-G-3' and 5'-Pyr-(A)_n-G-3'. The structural differences between DM-KCG and DM-BKC did not alter the sequence specificity of DNA cleavage since the cleavage pattern appears to be quite similar under all experimental conditions studied.

In the pG4 DNA, DNA cleavage by DM-KCG and DM-BKC is much greater than that by CLB at room temperature and at 65 °C. Almost no DNA cleavage is seen with CLB. At 65 °C, the strongest cleavage by DM-KCG and DM-BKC occurs at consecutive G residues. It is noteworthy that DM-KCG and DM-BKC at 100 μM also cleaved some pyrimidine residues: C40, T66, C32, T34, and C36. This must be due to sequence proximity effects since these pyrimidine residues are flanked by two purine residues on both the 5' and 3' sides or by a guanine residue on the 5' side. These findings strongly support the proposal that once the drug molecule is positioned so as to permit alkylation by the CLB moiety, the DMQ-MA moiety is placed close to the alkylation site resulting in the sequence-specific cleavage observed. Whether productive alkylation by the CLB moiety is a necessary prerequisite for nearby radical cleavage by the DMQ-MA moiety we cannot tell, but mutual positioning-enhancement by the functional substituents seems not to be in doubt.

Inert Phosphorescent Nanospheres as Markers for Optical Assays

Jens M. Kürner,[†] Ingo Klimant,^{*,†} Christian Krause,[†] Harald Preu,[‡] Werner Kunz,[‡] and Otto S. Wolfbeis[†]

Institute of Analytical Chemistry, Chemo- and Biosensors, and Institute of Physical and Theoretical Chemistry, University of Regensburg, D-93040 Regensburg, Germany. Received December 14, 2000; Revised Manuscript Received June 12, 2001

A simple encapsulation technique is presented to produce highly phosphorescent, inert nanospheres that are suitable luminescent markers. It is based on the coprecipitation of phosphorescent ruthenium(II)-tris(polypyridyl) complexes and polyacrylonitrile (PAN) derivatives from a solution in *N,N*-dimethylformamide. The beads precipitate in the form of very small aggregates of spherical shape and a typical particle diameter of less than 50 nm. This process allows the encapsulation of phosphorescent and fluorescent dyes in an individual nanosphere provided that they are sufficiently lipophilic. Quenching by oxygen is negligible due to the use of PAN. The nanospheres were characterized with respect to their spectral properties (quantum yields of the luminophores, brightness, luminescence decay time), stability in aqueous buffered suspensions, and in terms of size, shape, and surface charge of the particles, as well as storage stability, quenching by oxygen, and dye leaching.

INTRODUCTION

Micro- and nanospheres are popular tools for the use as markers in optical luminescence and bioanalysis to increase the sensitivity of assays (1, 2). Intrinsic background fluorescence of samples is a problem often faced in optical analysis. When trying to eliminate background luminescence, two approaches are feasible. On one hand, NIR dyes can be used since most samples show no fluorescence in this region. On the other hand, phosphorescent dyes with long decay times can be employed. Here, the background fluorescence decays comparatively fast and can be eliminated by the measuring arrangement. The latter pathway shall be discussed here.

Basically, three groups of phosphorescent dyes are known that are potentially useful for labeling biomolecules. The first and most important group includes the rare earth metal chelates such as Eu(III)- or Tb(III)-complexes (3–7). They are excitable in the UV-region only, for instance, with a xenon flash lamp, and their lifetimes can be as long as 1 ms. Despite the advantage that the phosphorescence of those chelates is hardly quenched by oxygen, they suffer from the fact that they must be excited by UV-light sources. Nevertheless, they are very useful in single-shot assays. The second group comprises the Pt- and Pd-complexes of the porphyrins with lifetimes between 40 μ s and 1 ms. Unfortunately, these are strongly quenched by oxygen and other notorious quenchers. The third type of long-lived luminescent dyes includes the ruthenium, osmium, and rhenium complexes with polypyridyl ligands. Their lifetimes are between 100 ns and 10 μ s (8–11). The latter two groups of luminophores can be excited by semiconductor light

sources in the visible region. The third group is cationic, but their counteranions can easily be exchanged. Yet, those compounds are prone to luminescence quenching by both oxygen and oxidative or reductive quenchers, but the quenching is less crucial than for the Pt- or Pd-porphyrins.

One efficient way to prevent quenching consists of shielding the dyes from quenching gases or ions. This is accomplished by encapsulation of the dyes in micro- or nanospheres of a material that is impermeable to oxygen. Polystyrene and poly(methyl methacrylate) are common materials to produce micro- and nanospheres. However, they are permeable to oxygen so that some quenching still occurs.

It was shown recently that ruthenium(II) complexes dissolve in films of polyacrylonitrile (PAN), and these are not at all quenched by oxygen. Such materials were applied to design luminescent temperature sensors (12). Thin films of polyacrylonitrile are also used as gas-impermeable barriers in food technology.

By taking advantage of those findings, we have encapsulated luminescent transition metal complexes in beads made of polyacrylonitrile and various copolymers. We present a simple technique for manufacturing phosphorescent nanospheres in high quantities and in a reproducible manner. The resulting nanospheres are practically not quenched by oxygen. The spheres were characterized in terms of spectra, photophysical properties, storage stability in aqueous suspensions, and in terms of particle size, shape and surface charge, quenching by oxygen, and dye leaching.

MATERIAL AND METHODS

Chemicals and Reagents. All chemicals and solvents used were of analytical grade and used without further purification. Doubly distilled water was used throughout. Polyacrylonitrile (MW 150 000) was purchased from Polyscience (Warrington, PA). Poly-(acrylonitrile-co-acrylic acid) containing 5% (w/w) of acrylic acid and the copolymers of Table 1 were obtained from Optosense GmbH (Wörth a. d. Isar, Germany). TransFluoSpheres

T-8865 were purchased from Molecular Probes (Eugene, OR). The preparation of ruthenium(II)-tris-4,7-diphenyl-1,10-phenanthroline dichloride [Ru(dpp)₃Cl₂] was described elsewhere (13–15).

Preparation of Polyacrylonitrile Nanospheres. A total of 118.5 mg of polymer **1** and 1.19 mg of Ru(dpp)₃Cl₂ were dissolved in 25 mL of DMF. While the sample was stirred vigorously, 125 mL of water was added dropwise with a dropping funnel upon which the solution turned slightly opalescent due to the spontaneous formation of the nanospheres after addition of the initial roughly 20 mL of water. Then, 1 mL of a saturated aqueous solution of sodium chloride (360 g/L at 20 °C) was pipetted to the flask at once to precipitate the finely dispersed nanospheres. The DMF/water mixture was centrifuged at 3000 rpm for 15 min, and the colored residue was washed twice with 50 mL of a 5% (w/w) sodium chloride solution and then three times with 50 mL of water, the wash solutions always being colorless. The residue was taken up in 50 mL of water and heated to 70 °C for 15 min. They were centrifuged and then taken up in 50 mL of phosphate buffer (pH 7.00, ionic strength = 20 mM). After sonification for 1 h, the suspensions were stored in the dark at 10 °C.

Preparation of Poly(acrylonitrile-co-polymer) Nanospheres. A total of 118.5 mg of polymers **2–9** (for samples **2** and **5–11**), 59.3 mg of polymer **2** (for sample **3**), or 23.7 mg of polymer **2** (for sample **4**), and 1.19 mg (for samples **2** and **5–11**), 0.59 mg (for sample **3**), or 0.24 mg (for sample **4**) of Ru(dpp)₃Cl₂ were dissolved in 25 mL of DMF. While the sample was stirred vigorously, 125 mL of a 1 mM solution of sodium hydroxide (for samples **2–7** and **9–10**), 125 mL of water (for sample **8**), or 125 mL of 1 mM hydrochloric acid (for sample **11**) were added dropwise with a dropping funnel. After addition of roughly 20 mL of either sodium hydroxide (samples **2–7** and **9–10**), water (sample **8**), or hydrochloric acid (sample **11**), spontaneous formation of nanospheres occurred. Except for samples **8** and **11**, where the suspensions turned turbid, all other solutions remained clear. Then, hydrochloric acid was added to samples **2–10** and sodium hydroxide solution to sample **11** until the pH was 4.0 for samples **2–10** and 9.0 for sample **11**. This caused the precipitation of finely dispersed nanospheres. The DMF/water mixtures were centrifuged at 3000 rpm for 15 min, and the colored residues were washed twice with 50 mL of 10⁻⁵ M hydrochloric acid (for samples **2–10**) or 50 mL of 10⁻⁵ M sodium hydroxide (for sample **11**), and finally three times with 50 mL of water. All washing solutions remained colorless. The residues were taken up in 50 mL of water and heated to 70 °C for 15 min. They were

centrifuged and then taken up in 50 mL of phosphate buffer (pH 7.00, ionic strength = 20 mM). After sonification for 1 h, the suspensions were stored in the dark at 10 °C.

Instrumentation and Measurements. Absorption spectra were acquired on a Perkin-Elmer Lambda 14 P spectrophotometer, and fluorescence excitation and emission spectra on a Perkin-Elmer LS 50 B spectrofluorometer. Corrected fluorescence emission spectra were obtained with an Aminco Bowman series 2 luminescence spectrometer and used for calculating quantum yields with the following expression:

$$\Phi_x = \Phi_R \left(\frac{A_R(\lambda_R)}{A_x(\lambda_x)} \right) \left(\frac{I(\lambda_R)}{I(\lambda_x)} \right) \left(\frac{n_x^2}{n_R^2} \right) \left(\frac{D_x}{D_R} \right)$$

where Φ are the quantum yields, $A(\lambda)$ is the absorbance/cm of the solution at the wavelength of excitation λ , $I(\lambda)$ is the relative intensity of the exciting light at wavelength λ , n is the average refractive index of the solution, and D is the integrated area of the corrected emission spectrum. Subscripts x and R refer to the unknown and reference (ruthenium(II)tris(2,2-bipyridyl) chloride hexahydrate) solutions, respectively. Because of the similarity of both unknown and reference emission spectra, no conversion of wavelength to frequency is needed for the calculation of quantum yields. Since the voltage of the detector was kept constant during those quantum yield measurements and since all solutions were aqueous, the following simplifications can be made:

$$I(\lambda_R) \approx I(\lambda_x) \text{ and } n_x \approx n_R$$

Luminescence frequency spectra (1–500 kHz) were acquired on an ISS K2 multifrequency phase fluorometer. All other decay time measurements were performed at a modulation frequency of 45 kHz with a fiber-optic setup as described previously (16). Apparent decay times τ were calculated by a simple mathematical formalism from phase angles θ obtained by a single frequency measurement:

$$\tau = \frac{\tan \theta}{2\pi\nu}$$

A bifurcated fiber bundle with glass fibers (NA 0.46, $d = 2$ mm) was connected to a thermostated ($T = 25$ °C) cell with the fiber bundle tip being dipped into the stirred sample solution.

RESULTS AND DISCUSSION

Choice of Matrix. Polyacrylonitrile and its derivatives are attractive polymeric matrixes for the encapsulation of phosphorescent dyes in micro- and nanospheres (17, 18). They display an extraordinarily poor permeability for gases and ionic as well as neutral chemical species. Hence, they can protect luminescent dyes against potential luminescence quenchers such as oxygen. Polyacrylonitrile polymers are soluble in DMF, swell in DMF/water mixtures, and act themselves as solvents for lipophilic dyes. In addition to plain polyacrylonitrile, we have employed functional copolymers such as the ones listed in Table 1. Both anionic and cationic charges were introduced into the polymer and no significant change was observed in the permeability of the copolymers for oxygen.

Polyacrylonitrile is amphiphilic in a sense that it is both hydrophilic and lipophilic. This makes polyacrylo-

nitrile and its functional copolymers soluble in DMF and, in turn, opens the way to produce nanospheres by the precipitation process. On dropwise addition of water to a diluted solution of polyacrylonitrile in DMF, a stable dispersion of nanoscale polyacrylonitrile aggregates is formed. Surprisingly, the nanospheres do not tend to aggregate and sediment.

If the spheres are precipitated from DMF solutions containing Ru(dpp), the dye is coprecipitated with the spheres. This is an elegant way to stain nanospheres in a defined manner. Solvents other than water may also be used to precipitate the polyacrylonitrile nanospheres provided (a) that the solvent is miscible with DMF and (b) that the polymer is not soluble in the binary mixture. Since polyacrylonitrile and its copolymers are soluble in DMF only (they swell in dimethyl sulfoxide), the nanospheres may be suspended in almost any other solvent.

Choice of PAN-Copolymer. Among the various polyacrylonitrile-based copolymers investigated as encapsulation matrixes (polymers 2–9), polyacrylonitrile with an acrylic acid content of 5% (w/w) proved to be the best choice as far as a preferable combination of low oxygen quenching, high quantum yields, long decay times, and a small nanosphere diameter is concerned. With increasing amount of acrylic acid comonomer, the apparent decay time gets shorter and the quantum yield gets smaller as a result of a more polyelectrolyte character of the nanospheres. When still decreasing the content of acrylic acid, the nanosphere suspensions become more instable due to too little electrostatic repulsion of the surface of the nanospheres. Using other copolymers than acrylic acid-containing ones to introduce active groups such as hydroxyl, sulfonic acid, or primary amine groups (polymers 6–9) goes along with a higher oxygen quenching and less stable nanosphere suspensions. The active groups on the surface of the nanospheres ($-\text{COOH}$, $-\text{OH}$, $-\text{SO}_3\text{H}$, $-\text{NH}_2$) depending on the different comonomers used enable the covalent coupling of biomolecules by conventional methods. This will be demonstrated in subsequent work.

Choice of Dye. The requirements to meet for ideal dyes are an extremely good solubility in both PAN (copolymer matrix) and DMF (solvent), insolubility in water for precipitation of the nanospheres, and a positive charge to cross-link them with the negatively charged matrix. The long-lived phosphorescent ruthenium(II)-tris-pyridyl complexes were selected as dyes since they exhibit those positive features. They yield bright luminescent nanospheres with a large Stokes' shift of about 150 nm ($\lambda_{\text{ex}} = 465 \text{ nm}$, $\lambda_{\text{em}} = 613 \text{ nm}$). Because of their positive charge, it is possible to cross-link them with copolymers containing negatively charged groups. Furthermore, the dyes can be made lipophilic by using proper ligands. The lipophilic dyes are then extracted quantitatively into the nanospheres during the preparation process because they are very well soluble in the polymer. Even in a lipophilic environment, e.g., if proteins are present in the sample, no dye leaching in aqueous solutions is occurring. The high quantum yields ($\Phi > 40\%$) and the large extinction coefficients ($\epsilon \approx 30\,000 \text{ L mol}^{-1} \text{ cm}^{-1}$) of the ruthenium dyes are further advantages. They are excitable with a blue argon ion laser at 488 nm or cheap bright blue light emitting diodes (LEDs) at 450 or 470 nm. The use of phosphorescent nanospheres eliminates background fluorescence, leading to a higher sensitivity. Last but not least, the complexes are stable against the loss of ligands, and its emission spectrum is broad enough to overlap with the absorbance spectra of various luminescence acceptor dyes.

Figure 1. Schematic of the process for making poly-(acrylonitrile-co-polymer) nanospheres.

Among the several ruthenium(II)-tris-polypyridyl complexes, the ruthenium(II)-tris-4,7-diphenyl-1,10-phenanthroline complex with chloride as counterion $[\text{Ru}(\text{dpp})_3\text{Cl}_2]$ is most suitable as indicator dye since it is very easily prepared, and when incorporated into a PAN-matrix, its quantum yield is the highest and its decay time is the longest, even though the free dye has the highest oxygen quenching of all ruthenium complexes. This shows the superb shielding effect of the matrix.

Choice of Ligand. When using transition metal complexes other than $\text{Ru}(\text{dpp})_3^{2+}$, the apparent decay time does not cover the desired long microsecond range anymore. Exchanging the diphenyl-phenanthroline (dpp) ligand against phenanthroline (phen) or bipyridyl (bipy) makes the resulting complexes $\text{Ru}(\text{phen})_3^{2+}$ and $\text{Ru}(\text{bipy})_3^{2+}$ water-soluble. Consequently, they cannot be extracted into the polymer matrix. Actually, ruthenium complexes with ligands such as diphenyl-bipyridyl show an even lower oxygen cross-sensitivity than diphenyl-phenanthroline but unfortunately a shorter apparent decay time, as well.

Choice of Counterion. Chloride is preferred as a counterion for $\text{Ru}(\text{dpp})_3^{2+}$ since the resulting nanosphere suspensions are much more stable due to a cross-linking of the matrix. The chloride ions easily exchange with the carboxylic groups on the copolymer surface and thus build a three-dimensional network with the double positive charged ruthenium dye by electrostatic interaction (compare Ca^{2+} as cross-linking agent in alginate fibers). Otherwise, individual polymer chains might be washed out.

There are a number of important details in the preparation process (compare Figure 1 for the copolymer approach) of the phosphorescent nanospheres that need to be mentioned. The size, surface charge, and reactive groups of the nanospheres can be varied distinctively by the preparation process.

In contrast to the widely used emulsion polymerization, the particles (polymers 1–9) were prepared by the precipitation polymerization technique. By using those prepolymerized particle systems, it is provided that all nanospheres can be made of the same stock polymer which leads to reproducible properties of the nanospheres.

Matrix Concentration. The maximum amount of matrix with respect to its organic solvent that still yields clear solutions is 1.0% (w/w) matrix/DMF, but a concentration of 0.5% (w/w) proved to be the optimal choice (compare samples 2–4 with 0.50, 0.25, and 0.10% (w/w) matrix/DMF, respectively). A higher percentage leads to larger nanosphere diameters and finally makes the precipitation polymerization impossible since larger, jelly-like aggregates are formed at the dropping location that cannot be redissolved anymore.

Dye Loading. The concentration of incorporated phosphorescent dye is aimed to be as high as feasible to yield higher luminescence intensities. The amount of ruthenium complex (for chemical structure compare

Figure 2. Dependence of the apparent decay time on the addition of sodium hydroxide solution to a DMF solution of the matrix during the precipitation polymerization process (sample 2).

insert in Figure 3) within the nanospheres can be up to 10% (w/w) dye/matrix for polymer 2. If this is exceeded, the apparent decay time becomes shorter and the nanosphere suspensions become instable. This is probably due to a compensation of the repulsing negative carboxylic groups on the surface by the double positively charged ruthenium dye. Then aggregates are formed immediately, and no dispersions are obtained anymore.

Precipitation Details. The amount of doubly distilled water (when starting with polymers 1 and 6), 10^{-3} M sodium hydroxide (for polymers 2–5 and 7–8), or 10^{-3} M hydrochloric acid (for polymer 9) added to the DMF solution of the matrix and the dye has to be present in at least the 5-fold amount as compared with the volume of organic solvent to extract all of the DMF out of the nanospheres. Adding a 1 mM solution of sodium hydroxide to polymers with acidic comonomer components or 1 mM hydrochloric acid to polymers with basic comonomer components leads to a higher concentration of those reactive comonomer groups on the surface of the nanospheres. This way the hydrophilic parts (e.g., carboxyl or amine groups) are primarily on the outside and the PAN main monomer mostly on the inside of the nanospheres. The resulting suspensions are more stable due to electrostatic repulsion of the deprotonated carboxyl groups and the protonated amine groups.

The reason for using doubly distilled water is to avoid flocculated systems that would form immediately in the presence of electrolytes. In contrast to other solvents such as ethanol, for example, water has the advantage that the ruthenium dyes are insoluble here and a complete extraction of the lipophilic dyes into the nanospheres is guaranteed.

The system PAN/DMF/water allows the precipitation of the nanospheres at a defined point of time, controlled by the amount of water in the DMF solution. Moreover, stable dispersions are obtained without any content of emulsifiers such as sodium lauryl sulfate (SDS) that would otherwise have to be removed in a complicated process (e.g., by dialysis). During the precipitation polymerization process, at a characteristic concentration of between 10 and 20% (w/w) 10^{-3} M sodium hydroxide solution in the DMF solution of the copolymer matrix, the apparent decay time increases sharply (Figure 2 for polymer 2). This is due to the completion of the formation of the nanospheres and a subsequent extraction of DMF out of the nanospheres. Since the decay time measurement was performed in an air-saturated solution what is actually seen is the oxygen quenching which decreases drastically after that point. Now the polymer gets more and more rigid with more water added. Only up to this concentration of roughly 10–20% (w/w) water/DMF,

depending on the copolymers used, are the polymers soluble in the water/DMF mixture. Afterward, when adding more water, the nanospheres precipitate, which can be observed by the slightly opalescent appearance of the solution. Continuously measuring the apparent decay time of the solution allows one to monitor the preparation process and to quantify the amount of water needed to precipitate a specific polymer.

When precipitating the nanospheres with hydrochloric acid (polymers 1–8) or sodium hydroxide solution (polymer 9), the pH should be lowered to approximately 4.0 for the flocculation of the nanospheres with acidic surface groups (polymers 1–8) and to a pH of roughly 9.0 for nanospheres with basic surface groups (polymer 9). Only then it is provided that the carboxylic groups (polymers 1–5 and 7–8) on the surface of the nanospheres are all protonated and the amine groups (polymer 9) are deprotonated. Associates are then formed due to the neutral surface. Since this process is fully reversible, when adjusting the pH back to 7.0, the nanospheres can be suspended once again due to electrostatic repulsion. This shows the importance of the pH value at all preparation stages and the possibility to precipitate or resuspend the nanospheres as needed. It should be mentioned that the nanospheres can be only resuspended from freshly prepared associates. After several days, there is a tendency to irreversibly form large and stable aggregates. During the washing steps, no leaching of the dye out of the polymer matrix was observed.

To resuspend the nanospheres, it is sufficient to treat them in an ultrasonic bath for 1 h. The heating of the aqueous suspensions to about 70 °C is meant to remove traces of DMF that might still be present in the suspensions even after the washing steps. Residues of DMF in the nanospheres result in a higher gas permeability and therefore a higher level of oxygen quenching.

Buffer Composition and Storage Conditions. The tendency of the nanospheres to aggregate and their stability in general was also examined. This is of importance for the use of the nanospheres as labels. Nanospheres from pure PAN show a strong tendency to form aggregates. It was found that when kept in phosphate buffer solution at pH 7.00 with an ionic strength (adjusted with NaCl) of at least 20 mM, the nanospheres made of PAN copolymers were stable over a period of several months. No sedimentation in buffered systems was observed. The higher the ionic strength gets, the more repulsion among the nanospheres is created in addition to the one originating from the deprotonated acidic groups (polymers 1–8) or the protonated amine groups (polymer 9) on the surface, leading to even more stable solutions. An ionic strength of up to 100 mM was successfully applied, as well. The resulting suspensions are clear and stable over months if stored in the dark at 10 °C and thus prove the superb dispersibility of the nanospheres in an aqueous buffered environment.

Photophysical Characterization. Figure 3 shows the excitation and emission (aerated/deaerated) spectra of the incorporated ruthenium dye $\text{Ru}(\text{dpp})_3\text{Cl}_2$ in a buffered aqueous suspension. Since the excitation spectrum is very broad, various excitation light sources can be applied. $\text{Ru}(\text{dpp})$ can be excited with a bright blue (470, 450 nm) and blue-green (505 nm) LED or with the argon ion laser at 488 nm. Even the violet diode lasers (404 nm) are a potential light source. The excitation and emission spectra show almost no overlapping and a very large Stokes' shift of about 150 nm ($\lambda_{\text{ex}} = 465$ nm, $\lambda_{\text{em}} =$

Figure 3. Spectral characteristics (absorbance and emission spectra, $\lambda_{\text{ex}} = 488$ nm) of encapsulated Ru(dpp)_3^{2+} dye (sample 2).

613 nm). In the emission spectra in Figure 3, one can also notice the negligible amount of quenching caused by oxygen.

The brightness of the nanospheres was compared to the luminescence intensity of the carboxylate modified microspheres (TransFluoSpheres T-8865, $\lambda_{\text{em}} = 605$ nm) from Molecular Probes (Table 2). Those TransFluoSpheres have comparable spectral properties to the $\text{Ru(dpp)}_3\text{Cl}_2$ dye and are known to be extremely strong fluorescent. To examine the luminescence intensity, an aqueous solution of both micro- and nanospheres of identical polymer concentration (w/w) was measured. It can be seen that when excited with the blue diode laser (at 404 nm) or blue LEDs (at 450 or 470 nm), the nanospheres have an up to 4-fold intensity as compared to the TransFluoSpheres microspheres due to their broad excitation spectrum. Only at the longer wavelengths of the blue argon ion laser (488 nm), for which the TransFluoSpheres were specifically designed, or the blue-green LED (505 nm), the TransFluoSpheres show a higher brightness. Nevertheless, if the blue LEDs are the preferred light source, the presented nanospheres are much brighter.

As expected, with increasing dilution of the nanosphere suspensions, no change in the decay behavior of the dyes was observed. This also indicates that the dye is not washed out of the matrix. A concentration of 0.5% (w/w) matrix/DMF of the original polymer solution during the preparation process proved to be the best choice because a lower ratio means shorter apparent decay times, higher oxygen cross-sensitivity, lower quantum yields, and a higher consumption of DMF.

In the luminescence frequency spectra (Figure 4) for sample 2, one can see the dependence of the phase angle and the modulation on the applied modulation frequency. An evaluation of the data points to a biexponential fit as the best choice (and not a monoexponential one), which is typical for incorporated dyes. The apparent decay time varies between 6 and 7 μs for the main component (~95%) and 1–2 μs for a second component (~5%). The minor component results from surface-bound dye which

Figure 4. Luminescence frequency spectra (top) and error distribution (bottom, $\xi^2 = 7.1$) displaying the modulation (●) and phase angle (◆) for sample 2.

can be quenched by oxygen. Even though ξ^2 (7.1) is relatively high, a systematic error can be ruled out because the errors are evenly distributed over the whole frequency range.

Physical Characterization. Table 3 summarizes the type of suspension, the average diameter d (by dynamic-light scattering at 90°), the apparent decay time τ (air/ N_2), the oxygen cross-sensitivity $\Delta\tau$ (change of τ air/ N_2), and the quantum yield ϕ for all of the nanospheres investigated.

The most important characteristic of the new nanospheres is their very low oxygen cross-sensitivity as can be seen in Table 3. Whereas free $\text{Ru(dpp)}_3\text{Cl}_2$ dye in water (sample 0) has a tremendously high oxygen quenching $\Delta\tau$ of about 75% and a quantum yield ϕ of below 0.30 in nitrogen, the incorporated dye in the proper polymers (e.g., polymer 2) has a quenching rate of only 3–5% and a quantum yield of up to 0.40. The apparent decay time of the free ruthenium complex in water varies between 1.20 μs in air and 4.70 μs in nitrogen, but can be as high as 6.00 μs in apolar organic solvents. The extremely low oxygen quenching of the incorporated dye proves the excellent shielding effect of the PAN copolymers and thus shows that the matrix itself does not act as a quencher. With decreasing nanosphere diameter, the oxygen quenching increases due to a higher surface-to-bulk ratio. Increasing the amount of carboxylic groups in the polymer by using more acrylic acid comonomer unfortunately leads to a higher quenching, as well, since the nanospheres become more hydrophilic and can take up more water. But since carboxylic functional groups are essential for stabilizing the suspensions, for cross-linking the nanospheres with the positive ruthenium dye and for the covalent coupling of biomolecules to the nanosphere surface, a compromise is necessary.

For all of the polyacrylonitrile polymers 1–9, membranes (200 μm films on Mylar polyester foils) were also measured. The oxygen cross-sensitivity was always less than 2%.

Transmission electron microscopic pictures of the nanospheres showed a nearly circular shape and a

diameter of roughly 10 nm (Figure 5 for sample 2). Static and dynamic light-scattering (Figure 6 for samples 1 and 2) along with laser Doppler anemometry experiments revealed a polydisperse coil with a diameter of the nanospheres of down to about 5 nm (for sample 7) and a zeta potential (ζ = -54.0 mV for sample 2) confirming the negative surface charge resulting from the carboxylic groups.

Even though the light-scattering distributions point to a not extremely monodisperse shape of the nanospheres, the very simple preparation technique fully compensates this handicap. The nanosphere diameter can be influenced by the preparation process. Both increasing the amount of carboxylic groups in the copolymer and increasing the concentration of the matrix in DMF leads to larger nanospheres. Some matrixes (e.g., polymers 6 and 9) show a higher tendency to aggregate and a rather polydisperse size distribution.

CONCLUSION

Polyacrylonitrile derivatives are attractive matrixes for the encapsulation of organic phosphorescent dyes since they have a poor permeability for gases and dissolved ionic and neutral chemical compounds. Thus, they are shielded efficiently against luminescence quenching, e.g., caused by molecular oxygen, and therefore, they show constant decay times and quantum yields in samples of variable and unknown composition. In addition, many lipophilic dyes are well soluble in these materials and will be not washed out into the sample.

The nanospheres have a very high surface-to-bulk ratio, which is evidence for a highly branched structure. Polyacrylonitrile with a acrylic acid content of 5% proved to be the best choice as encapsulation matrix. Suspensions of such phosphorescent nanospheres are only poorly quenchable by oxygen, show no tendency to sedimentation, and have an activated surface for the coupling of biomolecules or chemically responsive indicators. In case of using the ruthenium(II)-tris(4,7-diphenyl-1,10-phenanthroline) complex as phosphorescent dye, bright luminescent nanospheres with a large Stokes shift were obtained. No dye leaching was observed in aqueous solutions. They can be excited with either the blue argon ion laser or bright blue LEDs.

The new nanospheres can be used as bright phosphorescent markers in immuno- or DNA-sensing or as nanoprobe to measure intracellular chemical parameters. Furthermore, they are excellent phosphorescence standards and are useful to design phosphorescent chemical sensors.

ACKNOWLEDGMENT

This work was supported by CRAFT project SMT4-CT98-5510. We are grateful to Dr. Christian Krause (Optosense GmbH) for a gift of the copolymers. We would like to thank Dr. Jürgen Spinke and Dr. Ludger Jürgens (Roche, Mannheim, Germany) for providing the transmission electron microscopic pictures of the nanospheres.

Enhanced Biorecognition and Internalization of HPMA Copolymers Containing Multiple or Multivalent Carbohydrate Side-Chains by Human Hepatocarcinoma Cells

Ayelet David,[†] Pavla Kopečková,[‡] Abraham Rubinstein,^{*,†} and Jindřich Kopeček^{*,‡}

The Hebrew University of Jerusalem, Faculty of Medicine, School of Pharmacy, P.O. Box 12065, Jerusalem, 91120, Israel, and Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112. Received February 9, 2001; Revised Manuscript Received June 14, 2001

N-(2-Hydroxypropyl)methacrylamide (HPMA) copolymers containing pendant saccharide moieties (galactosamine, lactose, and triantennary galactose) were synthesized. The relationship between the content of saccharide moieties and three-dimensional arrangement of galactose residues and their biorecognition and internalization by human hepatocarcinoma HepG₂ cells was investigated. The results obtained clearly indicated preferential binding of the trivalent galactose and the lactose-containing copolymers to these cells. The higher the saccharide moieties content in HPMA copolymers, the higher the levels of binding. The biorecognition of the glycosylated HPMA copolymers by HepG₂ cells was inhibited by free lactose. The data on the internalization and subcellular trafficking of HPMA copolymer conjugates obtained by confocal fluorescence microscopy correlated well with the flow cytometric analysis of their biorecognition by target cells. Structural features of the glycosides responsible for the specific recognition of the HPMA copolymers have been identified. The results underline the potential of glycosylated HPMA copolymers for delivery of pharmaceutical agents to hepatocarcinoma cells.

INTRODUCTION

The extensive participation of saccharides in recognition processes has led to the concept of targetable glycosylated drug delivery systems (1–3). Carbohydrate specific cell surface receptors play essential roles in various biological recognition processes, including intercellular recognition, adhesion, cell growth regulation, and cell differentiation (4, 5). Receptors expressed at the surface of cells, which mediate endocytosis of their ligands, are attractive targets for delivering bioactive macromolecules to specific cells (6, 7). Several cell surface lectins have been discovered that sort their ligands into the cell. For example, it was recognized that liver parenchymal cells have cell surface receptors specific for galactose (7), phagocytic cells have receptors specific to mannose (8), and L1210 leukemia cells have receptors specific to fucose (9). The galactose binding receptor of hepatocytes has been widely investigated, and its specific interactions with asialoglycoproteins (ASGP¹) (10) and neoglycoproteins (11) have been documented. The asialoglycoprotein receptor (ASGP-R), also known as the hepatic lectin, is a recycling endocytotic receptor that recognizes terminal galactose (Gal) and *N*-acetylgalactosamine (GalNAc) (10). The ASGP-R is composed of three or more subunits that project their CRD (carbohydrate recognition domain) extracellularly (1). The affinity of a ligand for this receptor is highly dependent on the valency of sugar residues, as well as on their three-dimensional arrangement (12). Schwartz et al. have previously described the presence of the galactose-recep-

tor on human hepatoma cell line HepG₂, suggesting approximately 150000 binding sites per cell (13, 14).

Glycosylated polymers, in which saccharide residues are displayed from side-chains as pendant groups, appear to increase binding affinity (15). Saccharide-substituted polymer derivatives have diverse potential uses, such as multivalent inhibitors of cell or virus binding, specific binding to cell surface, artificial antigens, and drug delivery agents (16, 17). The chemically well-defined, water-soluble carbohydrate containing synthetic copolymers, the “glycopolymers”, can be readily synthesized for various biological assays (18). Most studies of carbohydrate-substituted polymers have focused on the polyacrylamide backbone (19–21), polylysine (22), or HPMA copolymers (23, 24). These glycopolymers may have lower molecular weight and higher sugar densities compared with synthetic glycoproteins. Water-soluble polylactoside copolymers have increased binding properties and have demonstrated enhanced binding affinity to plant lectins

¹ Abbreviations: AIBN, 2,2'-azobis(isobutyronitrile); AH, amino-hexyl; AHT, (6-amino-hexanamido)tris(hydroxymethyl)methane; ASGP, asialoglycoprotein; ASGP-R, asialoglycoprotein receptor; Cbz, benzyloxycarbonyl; DMF, dimethylformamide; DMSO, dimethyl sulfoxide; DPBS, Dulbecco's phosphate-buffered saline; EEDQ, *N*-(ethoxycarbonyl)-2-ethoxy-1,2-dihydroquinoline; FBS, fetal bovine serum; FITC, fluorescein-5-isothiocyanate; Gal, galactose; GalN, galactosamine; GalNAc, *N*-acetylgalactosamine; Hex, hexanoyl; HPMA, *N*-(2-hydroxypropyl)methacrylamide; Lac, lactose; MA, methacryloyl; MALDI-TOF MS, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry; MEM- α , minimum essential medium; Mw, weight average molecular weight; ONp, *p*-nitrophenoxy; P, HPMA copolymer backbone; PNp, *p*-nitrophenol; SEC, size-exclusion chromatography; TLC, thin-layer chromatography; TNBS, 2,4,6-trinitrobenzenesulfonic acid; TriGal, tris-based galactoside; Tris, 2-amino-2-(hydroxymethyl)-1,3-propanediol.

(25). Poly-L-lysine substituted with mannose and glucosyl residues displays a high specificity toward membrane lectins (26). It is expected that sugar residues exposed on macromolecular delivery systems will mediate targeting to corresponding receptors expressed on certain organs or cells.

During the past decade, targetable *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer conjugates have been designed, developed, and evaluated for their potential use in cancer therapy (reviewed in ref 27). Phase 1 clinical trial data indicate their great potential for applications in oncology (28, 29). Various targeting moieties, including carbohydrates (30, 31) have been used to promote HPMA copolymer conjugate recognition at the plasma membrane. It has been found that HPMA copolymers containing side chains terminating in *N*-acylated galactosamine behaved similarly to the ASGP and were biorecognizable *in vivo*. Their biorecognition by the ASGP-R of hepatocytes was dependent on the number of saccharides displayed on the polymer (23). The polymeric backbone of HPMA copolymers could be designed for a desired property such as biodegradation and stability (27). The design, activity, and mechanism of action of HPMA copolymer drug conjugates have been reviewed in detail (32). Incorporation of certain glycoside moieties (targeting residues) into HPMA copolymer conjugates has been used to facilitate targeting of anthracyclines to the vicinity of tumor cells. One of the most successful polymer-drug-saccharide conjugate systems reported are the HPMA copolymer–adriamycin (ADR)–sugar conjugates, in which both ADR and sugar were attached to the polymer backbone via lysosomally cleavable oligopeptide spacers (33). The conjugates containing galactosamine moieties were reported to accumulate in the liver selectively (34).

Our knowledge of the ligand binding preferences of the ASGP-R may be exploited for targeting molecules to hepatocytes (1). However, one of the main difficulties associated with using carbohydrates to target lectins is their low binding affinity. The interactions of individual saccharide groups are generally of low affinity (35), and dissociation constants (K_d) are generally in the mM to μ M range. To obtain adequate binding affinities for some proteins, multiple carbohydrate moieties are often needed. Many naturally occurring glycoproteins contain multi-antennary structures (36). When the density and relative spatial arrangements of the carbohydrate residues incorporated are appropriate, glycoconjugates can induce a marked enhancement of binding affinity toward proteins due to the multivalent recognition of ligand (37). The incorporation of numerous biorecognizable moieties into one macromolecule can enormously enhance its rate of uptake by cells, by enhancing adherence to the plasma membrane being internalized. Such polyvalent interactions can collectively be much stronger than the corresponding monovalent interactions (38). The most comprehensive description of an enhancement in binding affinity for a series of polymeric sialosides was reported by Sigal et al. (17). The inhibitory properties of polyacrylamides containing pendant sialoside groups illustrate the value of cooperative polyvalent interaction in the design of potent inhibitors of virus-mediated agglutination of erythrocytes. Similar polyvalency effect (cooperative binding) was observed for synthetic glycosylated systems as well (23, 24). Thus, it may be possible to generate synthetic glyconjugates, organized as multivalent (cluster) structures that compensate for weak-binding interactions (39, 40). Classical studies by Lee et al., (41) have established the “glycoside cluster effect”, which is defined

as an “affinity enhancement over and beyond what would be expected from the concentration increase for the determinant sugar in a multivalent ligand” (42). Triantennary glycopeptide with three terminal galactose residues showed approximately a 10^5 -affinity enhancement over a monovalent ligand for the human hepatic lectin expressed on the human hepatoma cell line HepG₂. In the same study, data from partial structures of the triantennary glycopeptide suggested that the affinity increased about 1000-fold per galactoside residue.

This paper describes the synthesis of novel HPMA copolymers bearing pendant saccharide moieties of different structure and content, which facilitates targeting. The saccharides were chosen based on their specific interactions with the asialoglycoprotein receptor of hepatocytes. The ultimate aim of our research is to investigate the influence of the structure and content of the targeting saccharide group on the specific recognition of saccharide-containing HPMA copolymers by hepatocarcinoma cells. The purpose of this characterization is to identify saccharide moieties with improved attachment properties. The influence of multiple sugar residues attached to individual monomers composing HPMA copolymers (clustering) and the degree of polymer substitution (monitored as sugar concentration: 10–30 mol %) were assessed with regard to delivery efficacy to hepatocarcinoma cells.

EXPERIMENTAL SECTION

Materials. All sugars were of D configuration and in the pyranose form. 2,2'-Azobis(isobutyronitrile) (Polysciences, Warrington, PA) was recrystallized from methanol. Solvents were freshly distilled. D-(+)-Galactosamine hydrochloride, D-(+)-galactose, and β -D-lactose, and Dulbecco's phosphate-buffered saline (DPDS) were obtained from Sigma, St. Louis, MO. Palladium-on-charcoal (Aldrich, Milwaukee, WI) and 6-(benzyloxycarbonamido)-hexanoic acid (Bachem, King of Prussia, PA) were used without further purification. 2,3,4,6-Tetra-O-acetyl- β -D-galactopyranosyl bromide (43) and 4-bromo-2,3,6,2',3',4',6'-hepta-O-acetyl- β -lactoside (44) were prepared by the published methods indicated. MEM- α medium and FBS (fetal bovine serum) were obtained from HyClone (Logan, UT). Monensin (sodium salt) was purchased from Calbiochem, La Jolla, CA.

Cell Line. The human hepatocarcinoma cell line HepG₂ was purchased from the American Type Culture Collection (ATCC, Rockville, MD). HepG₂ cells were cultured in MEM- α medium supplemented with 10% FBS. Cells were grown at 37 °C in a humidified atmosphere of 5% (v/v) CO₂ in air.

Methods. The intermediary and final products were characterized by classical methods (SEC, UV spectrophotometry, ¹H NMR, elemental analysis) and by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). Colorimetric quantification of natural sugars by the phenol–sulfuric-acid assay and of *N*-acetylated sugars by the Morgan-Elson assay were conducted by the published procedures (45). Amino groups were quantified by modified TNBS assay (46) using glycine as the standard. The TLC examination of reaction mixtures and products was performed on silica gel layers (F₂₅₄) precoated on aluminum sheets. Carbohydrate-containing compounds were visualized by spraying the sheets with 15% sulfuric acid in 50% ethanol and heating on a hot plate at ~150 °C. Amino-containing components were detected by spraying the sheets with 0.5% ninhydrin in ethanol and heating the plates briefly. Aromatic groups were detected by exposing the plate to iodine vapor in an enclosed chamber for a few minutes.

N-Methacryloyl glycyglycylgalactosamine (MA-GG-GalN) [3].

4-Methacryloylamidophenyl- β -lactoside (MA-Ph-Lac) [6].

N-methacryloyl-6-(aminohexanamido)-tris-(β -D-galactopyranosyloxymethyl) methane (MA-AHT-(Gal)₃) [9].

Figure 1. Scheme of the synthesized monomers.

Monomer Synthesis. *N*-(2-Hydroxypropyl)methacrylamide [HPMA] [1] and 5-[3-(methacryloylaminopropyl)-thioureidyl] fluorescein [MA-AP-FITC] [2] were prepared according to previously described procedures (47 and 48, respectively).

N-Methacryloyl glycyglycylgalactosamine (MA-GG-GalN) [3]. *N*-Methacryloyl glycyglycine *p*-nitrophenyl ester (MA-Gly-Gly-ONp) and *N*-methacryloyl glycyglycylgalactosamine [MA-Gly-Gly-GalN] were prepared as previously described (49). Briefly, MA-Gly-Gly-ONp was synthesized by reacting methacryloyl chloride (MA-Cl) with glycyglycine (Gly-Gly-OH) in a basic solution to yield methacryloyl glycyglycine (MA-Gly-Gly-OH) (yield 82%), which was then coupled with *p*-nitrophenol (PNp) in DMF in the presence of DCC to give MA-Gly-Gly-ONp in 79% yield. MA-Gly-Gly-GalN was prepared by reacting MA-Gly-Gly-ONp (3.21 g, 0.01 mol) with galactosamine (2.80 g, 0.013 mol) at 0 °C, in dry DMSO (20 mL), in the presence of triethylamine (1.5 mL, 0.015 mol). The reaction mixture was continuously stirred at 20 °C for 6 h. The obtained methacryloyl glycyglycylgalactosamine was purified and crystallized to give 2.31 g (65%) of MA-GG-GalN; mp 179–181 °C (dec). Its ¹H NMR (200 MHz, D₂O) spectrum and elemental analysis were in agreement with the structure given (32): δ 1.8 (s, 3H), 3.5–3.7 (m, 4H), 3.9 (m, 6H), 5.1 (d, 1H), 5.3 (s, 1H), 5.7 (s, 1H). Anal. Calcd for C₁₄H₂₃N₃O₈ (361): C, 46.53; H, 6.41; N, 11.64. Found: C, 46.37; H, 6.51; N, 11.69. The structure of MA-GG-GalN is shown in Figure 1.

4-Aminophenyl 2,3,6,2',3',4',6'-hepta-O-acetyl- β -lactoside [4] was prepared as previously described by Roy et al. (25). Briefly, transformation of lactose into acetobromolactose through the intermediary of octa-O-acetyl-lactose was carried out using 45% w/v HBr in glacial acetic acid (44) to give acetobromo-lactose in 55% overall yield. The 2,3,6,2',3',4',6'-hepta-O-acetyl- β -lactopyranosyl bromide was then glycosylated with PNP using

phase transfer-catalyzed (PTC) condition, in the presence of tetrabutylammonium hydrogen sulfate (TBAHS), to result in 4-nitrophenyl 2,3,6,2',3',4',6'-hepta-O-acetyl- β -lactoside in 53% yield. Transformation of the nitro group into the amino one was performed by using 10% Pd/C in the presence of ammonium formate. A solution of 4-nitrophenyl β -lactoside (241.5 mg, 0.319 mmol) and ammonium formate (400 mg) in 40 mL of MeOH containing 10% Pd/C (50 mg) was gently warmed for 5–10 min in a stoppered round-bottom flask. After cooling, the reaction mixture was filtered and rinsed with methylene chloride. TLC in hexane/EtOAc (1:1) indicated a complete conversion of the nitro into amino. The reaction product gave a positive response in a ninhydrin test. The solvents were evaporated, and the residue was dissolved in methylene chloride. The organic phase was washed with water and dried with sodium sulfate. The residue obtained from the solvent gave pure 4-aminophenyl-2,3,6,2',3',4',6'-hepta-O-acetyl- β -lactoside (240 mg, 96%), which failed to crystallize from ethanol/methanol. ¹H NMR spectrum and elemental analysis of intermediary and compounds are identical to the given structures (13,24). mp 104–124 °C. Anal. Calcd for C₃₂H₄₁NO₁₈: C, 52.82; H, 5.68; N, 1.92. Found: C, 52.19; H, 5.74; N, 1.89. ¹H NMR (200 MHz, CDCl₃): δ 6.74 (d, 2 H), 6.55 (d, 2 H), 5.29–4.76 (6dd, 6H), 4.43 (d, 2 H), 4.07–4.02 (m, 3 H), 3.85 (m, 2 H), 3.63 (m, 1 H), 2.10–1.89 (7s, OAc).

4-Methacrylamidophenyl 2,3,6,2',3',4',6'-hepta-O-acetyl- β -lactoside [5] was synthesized according to the procedure described by Roy et al. (25). Compound [4] (460 mg, 0.632 mmol) and triethylamine (385 μ L, 3.82 mmol) in CH₂Cl₂ (44 mL) were cooled to 0 °C. Methacryloyl chloride (89 μ L, 1.25 equiv) in CH₂Cl₂ (16.5 mL) was added dropwise, while the temperature was kept at 0 °C for a further 30 min, after which it was allowed to reach room temperature. MeOH (2 mL) was then added, and the reaction mixture was stirred for a further hour. Water (60 mL) was then added, and the organic phase was washed successively with 0.5 M HCl, saturated NaHCO₃, and water. The dried (Na₂SO₄) organic phase was filtered and evaporated to dryness. The residue was purified by silica gel column chromatography with CHCl₃/EtOAc to give pure 4-methacrylamidophenyl 2,3,6,2',3',4',6'-hepta-O-acetyl- β -lactoside, (480 mg, 95%), which failed to crystallize. Anal. Calcd For C₃₆H₄₅NO₁₉ (795): C, 54.34; H, 5.66; N, 1.76. Found: C, 54.85; H, 6.32; N, 1.50. ¹H NMR (200 MHz, CDCl₃): δ 7.41 (d, 2 H), 6.89 (d, 2 H), 5.71 (s, 1 H), 5.40 (s, 1 H), 5.28–4.91 (m, 4 H), 4.43 (d, 2 H), 4.05–3.81 (m, 5 H), 2.09–1.90 (7s, OAc), 1.53 (t, 3 H), 1.19 (t, 3 H), 0.82 (t, 2 H).

4-Methacryloylamidophenyl- β -lactoside (MA-Ph-Lac) [6] was prepared by de-O-acetylation of 5 in methanol containing a catalytic amount of sodium methoxide. Compound 5 (480 mg, 0.603 mmol) was dissolved in warm MeOH (15 mL) containing 0.5 M sodium methoxide (40 μ L). After a few hours at room temperature, an additional 15 mL of MeOH containing sodium methoxide was added, and the solution was warmed again. The solution was stirred overnight at room temperature. Ether (25 mL) was added to the cold solution. Filtration yielded with pure 6 (336 mg, 67%). mp 208–212 °C. Anal. Calcd for C₂₂H₃₁NO₁₂ (501): C, 52.69; H, 6.19; N, 2.73. Found: C, 51.73; H, 6.32; N, 2.65. ¹H NMR (200 MHz, CDCl₃): δ 7.25 (d, 2 H), 7.01 (d, 2 H), 5.67 (s, 1 H), 5.42 (s, 1 H), 5.01 (d, 1 H), 4.34 (d, 1 H), 3.80–3.20 (m, 11 H), 1.67 (s, 3 H), 1.03 (t, 1 H). The structure of MA-Ph-Lac is shown in Figure 1.

6-(Aminohexanamido)tris(2,3,4,6-tetra-O-acetyl- β -D-galactopyranosyloxymethyl)methane, (AHT-

[Gal(OAc)₄]₃ [7]. According to the method reported by Lee et al. (49), Tris was coupled with Cbz-aminoheptanoic acid in absolute ethanol in the presence of 2-ethoxy-*N*-(ethoxycarbonyl)-1,2-dihydroquinoline (EEDQ) to afford a 65% yield of [6-(benzyloxycarbonamido)hexanamido]-tris(hydroxymethyl)methane (Cbz-AHT). Transformation of galactose into 2,3,4,6-tetra-*O*-acetyl- β -D-galactopyranosyl bromide was carried out using 45% w/v HBr in glacial acetic acid (43) to effect a 97% yield of 1-Br-Gal-(OAc)₄. The acetylated sugar was glycosylated by coupling with Cbz-AHT, as described by Polidori et al. (51), in acetonitrile in the presence of mercuric cyanide (catalyst) followed by sonication under nitrogen atmosphere to give a 66.5% yield of the [6-(benzyloxycarbonamido)hexanamido]tris(2,3,4,6-tetra-*O*-acetyl- β -D-galactopyranosyloxymethyl)methane (Cbz-AHT-[Gal(OAc)₄]₃) conjugate. Hydrogenolysis in 60% acetic acid in the presence of 10% palladium on carbon was performed, to give 74% yield of AHT-[Gal(OAc)₄]₃. ¹H NMR analysis (CDCl₃) data indicated the removal of the benzyl group, showing the presence of aminoheptanoyl group at 5.6 ppm and the presence of acetylated galactose in correct ratios. Mass spectrum analysis (+FAB): 1225.7 (M + H⁺). Furthermore, colorimetric analysis for the amino group (TNBS method) and galactose (phenol-sulfuric acid method) indicated the ratio of these groups to be 1:3. The ¹H NMR spectrum and MS analysis of intermediary and final product are in agreement with the given structures (45, 52, 53).

***N*-Methacryloyl-6-(aminohexanamido)-tris(2,3,4,6-tetra-*O*-acetyl- β -D-galactopyranosyloxymethyl)methane (MA-AHT-[Gal(OAc)₄]₃) [8].** The monomer in the acetylated form was synthesized by coupling AHT-[Gal(OAc)₄]₃ with methacryloyl chloride (MA-Cl) in CH₂-Cl₂ in the presence of triethylamine at 0 °C. A solution of AHT-[Gal(OAc)₄]₃ (20 mg, 0.0163 mmol) and triethylamine (20 μ L, 11 equiv) in CH₂Cl₂ (1.0 mL) was cooled to 0 °C. Methacryloyl chloride (2 μ L, 1.1 equiv) in CH₂-Cl₂ (0.5 mL) was added dropwise while the temperature was allowed to reach room temperature. The reaction mixture was stirred for 2 h. Water (2 mL) was then added, and the organic phase was successively washed with 0.5 M HCl, saturated NaHCO₃, and water. The dried (Na₂SO₄) organic phase was filtered and evaporated to dryness. MA-AHT-[Gal(OAc)₄]₃ was obtained in 65% yield. TLC in EtOAc:acetic acid:H₂O (3:2:1) indicated complete consumption of the amino-compound. ¹H NMR spectra (200 MHz, CDCl₃) confirmed the appropriate functional groups (acetylated galactose, aminohexanoyl, oxymethylene, and double bond at 5.4 and 5.5 ppm). Mass spectrum analysis (+FAB): 1316 (M + Na⁺).

***N*-Methacryloyl-6-(aminohexanamido)tris(β -D-galactopyranosyloxymethyl)methane (MA-AHT-(Gal)₃) [9].** De-*O*-acetylation of MA-AHT-[Gal(OAc)₄]₃ was performed in methanol containing a catalytic amount of sodium methoxide. MA-AHT-[Gal(OAc)₄]₃ (20 mg, 0.0154 mmol) was dissolved in dry methanol (800 μ L) containing 0.5 M sodium methoxide (20 μ L). After 24 h stirring at room temperature, an additional amount of dry methanol (800 μ L) containing 0.5 M sodium methoxide (20 μ L) was added, and the reaction mixture was stirred at room temperature for a further 24 h. Sixty-percent acetic acid (200 μ L) was then added (deionization), evaporated, and coevaporated with EtOH/water. The TLC in mixed solvents of EtOAc:acetic acid:H₂O (3:2:1) and EtOAc:2-propanol:H₂O (5:3:2) indicated a conversion of the per-*O*-acetylated derivative into a more polar product, MA-AHT-(Gal)₃ in a yield of 74%. ¹H NMR spectra (200 MHz, D₂O): δ 5.44 (s, 1H, =CH₂), 5.68 (s, 1H, =CH₂), 4.7–5.0

Table 1. Characteristics of HPMA Copolymer Conjugates Containing Pendant Saccharide Moieties

polymer	polymer no.	targeting moiety	mol % sugar ^a	mol % FITC ^b	approx Mw of conjugate (Da) ^c
P-Gal	10a	GalN	14.8	2.04	15000
	10b	GalN	20.4	2.42	16000
	10c	GalN	29.1	2.64	16000
P-Lac	11a	lactose	11.1	1.58	18000
	11b	lactose	19.9	1.76	20000
	11c	lactose	27.6	1.90	19500

	12c	tri-galactose	24.4	2.52	14000
P-F	13	—	—	2.51	20000

^a The contents of galactose and lactose residues were determined spectrophotometrically using the phenol-sulfuric acid assay; the content of galactosamine was determined by the Morgan–Elson assay. ^b The content of FITC was determined spectrophotometrically using $\epsilon = 82000 \text{ M}^{-1} \text{ cm}^{-1}$ (FITC; 495 nm, pH 9.1 (0.1 M sodium borate)). ^c Weight average molecular weights (Mw) of copolymers were estimated by SEC using a Superose 12 column, FPLC system, PBS buffer pH 7.3, calibrated with poly(HPMA) fractions.

(m, 3H, α -H), 3.5–4.5 (m, 24H, sugar), 3.28 (m, 2H, CH₂N), 2.30 (t, 2H, CH₂O), 1.95 (s, 3H CH₃), 1.5–1.7 (m, 2H, CH₂), 1.2–1.4 (m, 2H, CH₂), 0.8–1.1 (m, 2H, CH₂). Mass spectrum analysis (+FAB): 788.3 (M + H⁺), 809.8 (M + Na⁺). The structure of MA-AHT-(Gal)₃ is shown in Figure 1.

Polymer Synthesis. Polymer glycoconjugates containing fluorescein were synthesized by radical precipitation copolymerization as described below. The polymers are of the general structure shown in Figure 2. The characterization of polymers and the method of preparation are shown in Table 1. All the polymerizations were conducted using free radical copolymerization of three monomers: HPMA, MA-AP-FITC, and the saccharide-containing monomer (either MA-GG-GalN, or MA-Ph-Lac, or MA-AHT-(Gal)₃). Three copolymers of each saccharide moiety (i.e., galactosamine, lactose, or trivalent-galactose) were synthesized. The monomer feed concentrations were 3 mol % of MA-AP-FITC; 10 mol %, 20 mol %, and 30 mol % of the saccharide-containing monomer, and 87 mol %, 77 mol % and 67 mol % of HPMA, respectively. The concentration of monomers, with respect to initiator and solvent, was in the weight ratio of 12.5:1.0:86.5, respectively. The monomer mixture of the control copolymer, which did not contain carbohydrate moiety, was composed of 98 mol % of HPMA to make up the lack of carbohydrate-containing monomer. The polymerization was initiated using AIBN.

Synthesis of P-(AP-FITC)-GalN [10a–c]. Galactose-containing HPMA copolymers were synthesized by copolymerization of HPMA, MA-GG-GalN, and MA-AP-FITC in acetone/DMSO (7:3). All monomer mixtures contained 3 mol % (17.7 mg) of MA-AP-FITC; the contents of MA-GG-GalN were 10 mol % (40 mg), 20 mol % (80 mg), and 30 mol % (120 mg), and of HPMA were 87 mol % (138 mg), 77 mol % (122.2 mg), and 67 mol % (106.4 mg), respectively. MA-GG-GalN and MA-AP-FITC were dissolved in DMSO, HPMA, and AIBN were dissolved in acetone. The solutions were mixed, transferred to an ampule, bubbled for 10 min with nitrogen and sealed, and the mixture was polymerized in a water bath at 50 °C for 40 h while stirring. After polymerization, the ampules were cooled to room temperature and opened, and the volume was reduced under vacuum. The viscous liquid thus obtained was precipitated into a large excess of acetone. The precipitated polymer was dissolved in distilled water, dialyzed against water for 24 h, and

etone. Yields: 97% (271 mg). The characterization of copolymer is shown in Table 1.

Flow Cytometric Analysis. Cell suspensions were prepared by trypsinization of cell monolayers. Cells (1×10^6) were seeded in 24-well plates in 2 mL of MEM- α medium supplemented with 10% FBS. The cells were incubated separately with 500 ng/mL of the saccharide-containing HPMA copolymers (P-Gal, P-Lac, and P-TriGal) for 24 h at 37 °C under 5% CO₂ atmosphere. Control cells were incubated with the same concentration of the FITC-labeled HPMA copolymer without sugar moiety (P-F). Inhibition experiments were performed with the same concentrations of the saccharide-containing copolymers, but in the presence of 150 mM lactose in the incubation medium. After incubation, the polymeric solutions were removed from the well, and the cells were washed twice with 1 mL of cold PBS containing 1mM CaCl₂, 1mM MgCl₂ and 0.5% BSA. Cells were harvested by trypsinization with 0.25% (w/v) trypsin and further incubated for 30 min at 4 °C in PBS containing 50mM monensin. Cell suspensions were immediately analyzed by flow cytometry using fluorescence activated cell sorter (FACS, Becton Dickinson). Cells were gated according to light-scattering parameters.

Confocal Microscopy. The intrinsic fluorescence of FITC was also used to monitor the subcellular fate of the saccharide-containing HPMA copolymer conjugates (P-Gal, P-Lac and P-TriGal) with different contents of pendant saccharide moieties. After trypsinization, 2×10^4 cells were seeded on a N1 coverslip (Corning) and cultured for 24 h. The culture medium was replaced with medium containing polymer conjugates (20 μ g/mL) and cultured for 24 h at 37 °C. Unbound conjugates were removed by washing the cell layer three times with cold PBS. Cells were fixed with 3% paraformaldehyde for 10 min at room temperature and washed again. The fate of glycoconjugates in cells was analyzed on a BioRad (Hercules, CA) MRC-600 laser scanning confocal imaging system with a Zeiss (Oberkochen, Germany) Axioplan microscope with a plan-apo objective (60x, NA=1.4, oil) and a krypton/argon laser. Images were acquired with a Fluor filter block (excitation at 488 nm, emission collected with a 515 nm barrier filter). Settings were adjusted so that control (untreated) cells always yielded dark images. Fluorescent images were scaled to 256 Gy levels. Quantitative analysis was performed using Image-Pro Plus 4.0 (Media Cybernetics). Fluorescence intensities were expressed in arbitrary units per square micron.

RESULTS

The saccharide-containing monomers (MA-GG-GalN, MA-Ph-Lac, and MA-AHT-(Gal)₃) copolymerized with HPMA and small amounts of MA-AP-FITC gave high molecular weight compounds soluble in water. Analysis of the sugar content in the copolymers (Table 1) confirmed that the saccharide-containing monomer units present in the polymerization mixture were polymerized to give a final product in which the ratio of monomer units was close to their initial ratio in the reaction mixture. SEC analysis of the final preparations confirmed that the weight average molecular weight (Mw) of all copolymers was similar and did not alter under the influence of saccharide (substitution) attachment. These data indicate that the monomers synthesized did not contain minute amounts of dimethacryloylated impurities. The latter would act as cross-linking (branching) agents increasing the molecular weight with increasing content of saccharide-containing monomers in the polymerization mixture.

Figure 3. Flow cytometry analysis of the binding of 10% P-Gal (10 μ g/mL) to HepG₂ cells, in the presence of 150-mM lactose (solid bars) and the absence of lactose (open bars), after 2 and 24 h incubation at 37 °C. HPMA copolymer (P-F), which did not contain sugar moiety served as control (gray bars).

Figure 4. Flow cytometry analysis of the binding of the saccharide-containing HPMA copolymers (500 ng/mL) to HepG₂ cells after 24 h incubation at 37 °C. Upper panel (4A): Binding in the presence (solid bars) and absence of free lactose (150-mM). In all studies P-F (gray bars, left) served as control. (P-Gal, open bars; P-Lac, hatched bars; P-TriGal, dotted bars). Lower panel (4B): Binding dependency on the type and the content of the sugar moiety in the copolymer.

The results of binding of the fluorescein-labeled glycoconjugates to HepG₂ cells are shown in Figures 3 and 4. The total amount of cell-associated conjugate increased

Figure 5. Confocal fluorescence images of HepG₂ cells incubated with the saccharide-containing HPMA copolymer conjugates, after 24 h incubation at 37 °C. Internalized glycoconjugates were transported into the lysosomal compartment of the cells. Upper three images (left to right): 10% P-Gal, 20% P-Gal, and 30% P-Gal; Centered three images (left to right): 10% P-Lac, 20% P-Lac, and 30% P-Lac. Lower three images (left to right): 10% P-TriGal, 20% P-TriGal, and 30% P-TriGal.

when the incubation period was raised (Figure 3). At 37 °C the fluorescence intensity of all cells incubated with the glycoconjugates was greater than that of the cells incubated at 4 °C, suggestive of an endocytic process (data not shown). The cell-associated fluorescence of HepG₂ cells after incubation with the HPMA copolymer conjugates for 24 h at 37 °C is summarized in Figure 4. The flow cytometry analysis revealed strong binding of the copolymers to HepG₂ cells. The fluorescence intensity indicated that their biorecognition by hepatocarcinoma cells was dependent on the type and the content of the pendent saccharide moieties in the copolymer. The increased glycosylation level of copolymers with galactose and lactose, caused an increase in cell binding. In general, the binding of the trivalent galactoside and the lactoside-containing copolymers was found to be greater than that of the galactoside-containing copolymers (Figure 4). In the lowest sugar concentration (10 mol %), a 5.6-fold difference in binding intensity was observed between the trivalent-galactoside- and the monovalent-galactoside-containing copolymer. Twenty mol % concentration resulted in a difference of 4.5-fold, whereas in the highest concentration (30 mol %) the difference was only 2 times greater between the trivalent and monovalent galactoside-containing copolymers. The specificity of lectin–glycopolymers interactions was verified by an inhibition assay. The incubation of cells with 150 mM lactose (competitive inhibitor) completely abolished cell binding of copolymers and indicated sugar specificity of the process involved (Figures 3 and 4). In addition, copoly-

mers with no sugar bound very weakly to the cells, ruling out nonspecific reactivity (Figure 3).

The uptake and subcellular trafficking of FITC-labeled HPMA copolymer conjugates by HepG₂ cells were followed by confocal fluorescence microscopy. Cells were incubated with the HPMA copolymer conjugates for 24 h at 37 °C, before optical sections were taken. Confocal images indicated the lysosomotropism of the conjugates, i.e., internalized glycoconjugates were transported into the lysosomal compartment of the cells (Figure 5). The internalization rate of conjugates was dependent on the type and the content of the pendant carbohydrate moiety in the copolymers. The higher the contents of each sugar moiety in the HPMA copolymer, the brighter the image. Furthermore, the internalization rates correlated well with the biorecognition of the saccharide moieties by the cells, as detected by flow cytometry, i.e., the trivalent galactoside- and the lactoside-containing copolymers were internalized more efficiently than the galactoside-containing copolymers (Figure 6). The fluorescence images of cells stained with the untargeted copolymer P-F (which did not contain sugar) were dimmer than the targeted polymer at the same polymer concentration, indicating no presence of the nontargeted copolymer inside the cells.

DISCUSSION

HPMA copolymers designed in this study can be used as drug carriers to achieve optimal targeting to hepatocarcinoma cells. The incorporation of sugar residues into HPMA copolymers results in effective biorecognition by

Figure 6. Fluorescence intensity of HepG₂ cells incubated with the saccharide containing HPMA copolymer-FITC conjugates, after 24 h at 37 °C. The fluorescence intensity is expressed in arbitrary units per square micron.

liver cells (52). The copolymers were evaluated for their potential to induce a marked enhancement of binding affinity toward hepatocytes.

The copolymers used in this study were synthesized by radical copolymerization of HPMA, MA-AP-FITC, and the saccharide-containing monomers. From the similarity in the structure of the polymerizable parts of the comonomers, it was expected that the copolymerization parameters would be close (49) and consequently the monomer units randomly distributed along the polymer backbone. In addition, the distribution of chemical composition of the resulting copolymers was expected to be narrow, despite the high polymerization yields.

Of the mammalian lectins discovered to date, the ASGP-R has been studied in greatest detail (10, 13, 14, 53, 54). Although the ASGP-R binds and internalizes most galactose-terminated ligands, binding affinity is strongly influenced by the ligand structure. Lee et al. demonstrated that monovalent ligands such as galactose, lactose, and monoantennary galactosides bind the ASGP-R with a millimolar dissociation constant (12, 41). Ligands containing a cluster of three galactose residues bind to the receptor with a nanomolar dissociation constant which appear to be the affinity threshold needed to achieve appreciable targeting of glycoconjugates under physiological conditions (37). This relationship between sugar-clustering and enhanced binding affinity is related to the structure of the ASGP-R, which is composed of three subunits, that each of them contains a galactose binding site (1, 37). Although small polyvalent ligands often display enhanced binding affinity for target proteins, glycosylated polymers could achieve better biorecognition just by increasing the concentration of the biorecognizable sugar moiety along the polymeric chain (15).

To learn more about the relationship between the structural features of glycosylated polymers containing multiple glycoside residues and their biorecognition, we synthesized HPMA copolymers containing side-chains terminated with galactosamine, lactose, or trivalent-galactose. The relationship between the content of saccharide moieties, the three-dimensional arrangement of galactose residues, and their biorecognition and internalization by human hepatocarcinoma cells was investigated.

The observed strong binding of saccharide-containing HPMA copolymers to hepatocarcinoma cells in these

studies supports the hypothesis that the saccharide groups serve as ligands for hepatic lectins. Furthermore, it was demonstrated that efficient internalization of the saccharide-containing polymers by hepatocarcinoma cells occurred. This internalization increased with increasing the content of the sugar residues bound to the polymer. The endocytosis of the glycoconjugates was not clearly defined in the flow cytometry experiments. However, when considered together with the confocal data, there is a strong evidence to suggest that receptor-mediated endocytosis was responsible for the increased internalization of the glycopolymers. The internalization rates were dependent on the type of sugar bound to the polymer. Inhibition studies in the presence of a competitive inhibitor (free lactose) revealed a complete blockage of copolymer binding, indicating the sugar specificity of the process involved. Moreover, the binding intensity of the monovalent galactoside containing copolymer to HepG₂ cells is rather weak. However, the trivalent-galactoside-bearing copolymer displayed stronger binding intensities, which were attributed to the clustering of galactose residues. To achieve biorecognition of monosaccharides at levels comparable to multiantennary structures, HPMA copolymers must contain a high content (above 20 mol %) of randomly distributed carbohydrate moieties at side chain termini. About 30 mol % of galactose in the copolymer was needed to achieve binding similar to the 10% trivalent-galactose. Nevertheless, the enhancement in binding affinity observed in these studies was somehow less dramatic than expected (as described by Lee (37) and Whitesides (38)). The increase in valency was only weakly reflected in the reactive potency of the glycoconjugates to enhance binding affinity. This factor did not exceed 5.6-fold binding enhancement of the triantennary over the monoantennary galactoside-containing copolymer. A possible explanation could be that in these binding studies the polymer concentration was relatively high. At high polymer concentrations, receptor saturation may occur and consequently decrease the efficiency of targeting to the cells (55). If that was the case, it could explain why high concentrations of the lactoside- and trivalent-galactoside-containing copolymers maintained, more or less, similar binding intensities.

Our findings are consistent with the data reported by Vansteenkiste et al., indicating that dextran substituted with trigalactose units was captured by the liver only 1.6-times faster than the mono-galactose-substituted dextran (56). Interestingly we found that the HPMA copolymer substituted with triantennary galactose exhibits a larger binding intensity difference between the triantennary- and monoantennary-substituted copolymers than the substituted-dextran, at the same concentrations (5.6-fold difference for HPMA compared with 1.6-fold difference for dextran). This difference may be attributed to the influence of the polymer backbone on the recognition, i.e., HPMA copolymer backbone is more flexible than dextran, thus the chain may have a conformation in which several sugar moieties from the same chain interact with one receptor. The fact that the ratio of tri- to mono-binding decreases with increasing contents of sugar in the copolymer also supports this point.

Affinity studies of ligands containing glycoside residues were traditionally been undertaken using glycoconjugates labeled with radioactive probes. This approach allows binding affinities to be tested even at the nanomolar concentration range. Perhaps incubation studies at these low concentrations may be more indicative of the extent of copolymer uptake by receptor mediated endocytosis, and will exhibit more pronounced clustering effect.

In conclusion, the binding of the saccharide-containing HPMA copolymers to HepG₂ cells was demonstrated by flow cytometry. While the results of the binding experiments could not distinguish endocytosis from surface adherence, the use of confocal microscopy did show the presence of the glycoconjugates inside the cells. The receptor-mediated endocytosis is suggested since the nontargeted copolymer could hardly be detected inside the cells under similar conditions. The data are in agreement with the results of Omelyanenko et al. (50) who observed in human ovarian carcinoma cells that subcellular organelles containing HPMA copolymer conjugates were morphologically similar to organelles containing a lysosomal marker, Neutral Red. The relative rate or extent of endocytosis of the glycoconjugates was dependent on the type and the content of the sugar moiety. Our results suggest that the copolymers containing multivalent carbohydrate clusters may be considered as a targetable delivery system with enhanced binding affinity toward hepatocytes. It appears that high sugar concentrations facilitate multiple binding domains and therefore enhance the binding of the polymer to recognition sites on hepatocytes. Since the ASGP-R is expressed on HepG₂ cells, it is reasonable to speculate that the increased binding of the saccharide-containing HPMA copolymers reported here is due to endocytosis mediated by the asialoglycoprotein receptor.

Enhancing Sequence-Specific Cleavage of RNA within a Duplex Region: Incorporation of 1,3-Propanediol Linkers into Oligonucleotide Conjugates of Serinol–Terpyridine

Bobby N. Trawick,[†] Todd A. Osiek,[†] and James K. Bashkin^{*,‡}

Received February 15, 2001; Revised Manuscript Received May 25, 2001

The syntheses and RNA cleavage efficiencies of a new series of oligonucleotide conjugates of Cu(II)–serinol–terpyridine and 1,3-propanediol are reported. These reagents, termed ribozyme mimics, were designed such that they would yield *multiple* unpaired RNA residues directly opposite the site of the RNA cleavage catalyst upon ribozyme mimic–RNA duplex formation. This design effect was implemented using the 1,3-propanediol linker **3**, which mimics the three-carbon spacing between the 5′- and 3′-hydroxyls of a natural nucleotide. Incorporation of one or more of these 1,3-propanediol linkers at positions directly adjacent to the serinol–terpyridine modification in the ribozyme mimic DNA strand resulted in cleavage at multiple phosphates in a complementary 31-mer RNA target sequence. The linkers effectively created artificial mismatches in the RNA–DNA duplexes, rendering the opposing RNA residues much more susceptible to cleavage via the transesterification/hydrolysis pathway. The RNA cleavage products produced by the various mimics correlated directly with the number and locations of the linkers in their DNA strands, and the most active ribozyme mimic in the series exhibited multiple turnover in the presence of excess 31-mer RNA target.

INTRODUCTION

As the impact of scientific research at the interface of chemistry and biology continues to expand, so does our recognition of the potential that exists in the area of biological mimicry by synthetic reagents. One such area of interest today is the development of synthetic mimics of ribozymes (or ribozyme mimics). Since the earliest reports of sequence-specific RNA cleavage by this unique class of bioconjugates (1–5), much effort has been devoted to the establishment of structure–activity relationships for these reagents (2, 6–15). One of the principal goals is to achieve catalytic cleavage of specific RNA substrates with efficiencies approaching and/or exceeding those of natural ribozymes and ribonucleases (16). A ribozyme mimic is typically synthesized by the covalent attachment of an RNA cleavage catalyst to a synthetic DNA strand (or DNA analog) via a linker arm. The catalyst is usually a metal complex or nitrogen-containing organic molecule that catalyzes the scission of RNA phosphodiester bonds via transesterification and/or hydrolysis reactions. The DNA probe serves as the recognition domain of the ribozyme mimic, and the catalyst serves as the active site. Through the convenience of automated DNA synthesis and the specificity of complementary Watson–Crick base pairing, the DNA strand can be custom-tailored to direct the RNA cleaving capability of the catalyst toward any RNA target of known base sequence.

The central concept behind ribozyme mimic development is that upon selectively binding to its complementary RNA sequence, the mimic will deliver the attached RNA cleavage catalyst across the major or minor groove

of the DNA–RNA duplex and within sufficient proximity of the RNA phosphodiester backbone to effect the RNA transesterification reaction. Theoretically, the ribozyme mimic should disengage from the resultant RNA product fragments and subsequently bind to and cleave another complementary RNA target sequence. This would in effect create a catalytic cycle of specific RNA destruction.

Our approach over the last decade (1, 13, 16, 17), coupled with Magda's recently proven strategy (6) for achieving catalytic activity with ribozyme mimics, encourages placement of the catalyst at an internal position within the ribozyme mimic DNA strand rather than simply tethering the catalyst to the end of the sequence. This is because cleavage of the RNA target within the duplex region is more favorable for product release, given that cleavage outside of the duplex region will be plagued by product inhibition. One of the major concerns with this particular strategy, however, is the ability of ribozyme mimics to cleave the RNA residues within the double-stranded regions of DNA–RNA hybrids (18). RNA in a DNA–RNA duplex is relatively inert to cleavage by metal ions and complexes in comparison to its single-stranded form (19). This is likely a consequence of the conformational rigidity that is characteristic of duplexed RNA. In fact, this pronounced difference in cleavage susceptibility between single- and double-stranded RNA has been exemplified by pioneering efforts from several research groups. For example, Kolasa et al. demonstrated that when a short DNA oligonucleotide was annealed to a segment of t-RNA^{Phe}, the complementary RNA sequence was protected from cleavage by Eu³⁺- and La³⁺-based RNA cleavage catalysts (18). The results of this study led the authors to conclude that in the design of ribozyme mimics, it may be more advantageous to place the catalyst at the end of the DNA strand (proximate to single-stranded RNA) rather than at an internal position where the RNA is duplexed by DNA and inert to cleavage. In a related study, Hegg et al. investigated the

cleavage of RNA hairpin structures by a macrocyclic Cu^{2+} complex (20). Cleavage occurred in both the single- and double-stranded regions of the RNA hairpins; however, the amount of cleavage in double-stranded regions was not as pronounced as that observed in single-stranded regions. In another relevant study, Huesken et al. showed that RNA bulges in DNA–RNA duplexes are highly susceptible to cleavage by Mg^{2+} ion and La^{3+} hexadentate-Schiff base macrocycles (21). The authors concluded that the single-stranded RNA in the bulged region has a high degree of conformational freedom, which allows the RNA to adopt the in-line conformation required for the transesterification reaction. On the basis of these findings, the same research group designed ribozyme mimics that would place lanthanide-based RNA cleavage catalysts directly opposite induced bulges in the RNA target strand (11). These mimics were found to be 13 times more reactive than those that formed perfect duplexes with the RNA target. Most recently, this group reported ribozyme mimics that function with multiple turnover (12). In that study, lanthanide metal complexes were covalently linked to the 5'-ends of 2'-methoxyethyl (MOE) oligonucleotides. The key to this approach was that the oligonucleotide portions of the ribozyme mimics were designed such that upon binding to the RNA target, a bulge would be formed in the RNA strand near the center of the DNA–RNA duplex region. The attached catalyst could subsequently be folded back to preferentially cleave the single-stranded RNA in the bulged region. This creative design yielded catalytic turnover with the 2'-MOE conjugates, but no evidence of catalytic activity was observed with conjugates comprised of unmodified DNA probes.

In an analogous context, we demonstrated that the extent of sequence-specific RNA cleavage by $\text{Cu}(\text{II})$ terpyridine-based ribozyme mimics could be substantially increased using the concept of minimal nucleotide replacement (13). In that study, serinol–terpyridine modification **2** was incorporated in place of a single nucleotide residue in the ribozyme mimic DNA strand. The serinol–terpy effectively served as an artificial abasic site, which (upon DNA–RNA duplex formation) left an unpaired RNA residue directly opposite the site of the modification. The increased level of conformational freedom provided by the serinol–terpyridine modification rendered its opposing RNA residue much more susceptible to cleavage than when in the fully base-paired state and resulted in a greater than 3-fold increase in overall RNA cleavage efficiency in comparison to our first-generation, fully duplexed ribozyme mimics based on modification **1**.

The work described in this report represents the next logical step in our group's efforts to design ribozyme mimics that exploit the enhanced cleavage susceptibility of single-stranded RNA over double-stranded RNA. We have designed a new series of ribozyme mimics that yield *multiple* unpaired RNA residues directly opposite the site of the RNA cleavage catalyst ($\text{Cu}(\text{II})$ -terpy) upon duplex formation. This design effect was achieved using the 1,3-propanediol linker **3**, which, like serinol, mimics the three-carbon spacing between the 5'- and 3'-hydroxyls of a natural nucleotide. Incorporation of single and multiple linkers at positions adjacent to a serinol–terpyridine modification in the DNA strand resulted in perturbations to the opposing RNA backbone that allowed for the cleavage of multiple phosphodiester linkages by metal-catalyzed transesterification and/or hydrolysis reactions. The most active ribozyme mimic in the series exhibited cleavage of multiple equivalents of its complementary

RNA substrate, revealing a catalytic rather than stoichiometric mode of action for this reagent.

EXPERIMENTAL PROCEDURES

Synthesis of Ribozyme Mimics. The parent DNA sequence and the conjugates containing the serinol–terpyridine or 1,3-propanediol linker modifications (Figure 2) were prepared by automated DNA synthesis on an ABI Model 380B DNA synthesizer. The modified phosphoramidite building blocks **2** and **3** were placed on two of the free auxiliary ports of the synthesizer and incorporated at appropriate positions in the synthesis protocols. The detailed synthesis of phosphoramidite **2** has been previously reported by our group (13). Linker phosphoramidite **3** was purchased from Glen Research and used as received. All oligonucleotides were purified by UV-shadow excision from preparative 20% denaturing polyacrylamide gels, followed by elution from the gel fragment and ethanol precipitation. The structures of probes 1–7 were confirmed by negative-ion MALDI-TOF mass spectrometry (Table 1). The concentrations of the oligonucleotide conjugates were determined by UV absorbance at 260 nm utilizing molar extinction coefficients (ϵ) calculated with the Oligo Analyzer program (version 2.0) from Integrated DNA Technologies (IDT). [ϵ (L/mol·cm): probe 1, 283,700; probe 2, 276,500; probe 3, 269,000; probe 4, 276,500; probe 5, 266,600; probe 6, 269,300; probe 7, 252,500].

Preparation of 3'-End-Labeled 31-mer RNA Target Sequence. The synthetic 31-mer RNA sequence (5'-AAACCAACCCUUCAGAGACUCUGUCGACGGG-3') was purchased from IDT. The RNA was 3'-end labeled using α - ^{32}P -dATP (Amersham) and poly(A) polymerase (USB) according to standard procedures (22). Note that this procedure adds a single dA residue to the 3' end of the RNA, increasing the total length to 32 nucleotides. The labeled RNA was phenol extracted, ethanol precipitated, and purified by excision from a 20% denaturing polyacrylamide gel. The RNA was then eluted from the gel fragment, ethanol precipitated, and diluted to the appropriate concentrations with RNase-free water. RNA concentrations were determined by UV absorbance at 260 nm using the molar extinction coefficient calculated using the Oligo Analyzer program (version 2.0) from IDT [ϵ (L/mol·cm): 302 500].

Sequence-Specific RNA Cleavage Reactions. RNA cleavage reactions were carried out in a total volume of 10 μ L containing 10 mM (*N*-[2-hydroxyethyl]piperazine-*N'*-[2-ethanesulfonic acid]) (HEPES) buffer (pH 7.4), 0.1 M NaClO₄ (to control ionic strength), 250 nM 31-mer RNA, 5 μ M ribozyme mimic, and 5 μ M CuSO₄. The ribozyme mimic and CuSO₄ were premixed and added to a solution of the RNA, buffer, and NaClO₄. The reactions tubes were tightly sealed and completely submerged in a 45 °C water bath for 40 h. Quenching of the reactions was achieved through the addition of 10 μ L gel-loading buffer. Aliquots of 10 μ L were run on 20% denaturing polyacrylamide sequencing gels, alongside partial RNase T1 digests and base hydrolysis lanes for mapping of the RNA cleavage sites. The electrophoresis images were quantified using a Molecular Dynamics PhosphorImager and the ImageQuant software package (Version 5.0).

Catalytic Cleavage of RNA with Probe 6. The sequence-specific RNA cleavage reactions with probe 6 in the presence of excess RNA target were carried out in a total volume of 10 μ L containing 10 mM (*N*-[2-hydroxyethyl]piperazine-*N'*-[2-ethanesulfonic acid]) (HEPES) buffer (pH 7.4), 0.1 M NaClO₄, 125 nM probe 6, 125 nM CuSO₄, and either 250 nM, 500 nM, 1.0 μ M, or 1.25 μ M of 31-mer RNA. The ribozyme mimic and CuSO₄ were premixed and added to a solution containing the RNA, buffer, and NaClO₄. The reactions tubes were tightly sealed and completely submerged in a water bath at 45 °C for 40 h, after which the reactions were quenched by the addition of 10 μ L gel-loading buffer. Aliquots of 10 μ L were run on 20% denaturing polyacrylamide sequencing gels, and the electrophoresis images were quantified using a Molecular Dynamics PhosphorImager and the ImageQuant software package (Version 5.0).

RESULTS AND DISCUSSION

The structures of the ribozyme mimics employed in this study are detailed in Figure 1. Figure 2 is a representative autoradiograph of a 20% denaturing polyacrylamide gel obtained after treatment of the 3'-³²P-end labeled 31-mer RNA target with probes 1–7.

In these experiments, ribozyme mimics containing from zero to four linkers surrounding the serinol-terpyridine modification were tested for sequence-specific RNA cleavage activity in the presence of Cu²⁺ ion. For each probe, the serinol-terpy modification was located at position 16 (from the 5'-end) of the 31-mer DNA sequence. The 1,3-propanediol linkers were placed to the 3'-side, to the 5'-side, and to both sides of the modification simultaneously. The ribozyme mimic and RNA target were incubated in the presence of Cu²⁺ for 40 h at 45 °C and pH 7.4. For electrophoretic analyses, RNA cleavage lanes were run alongside partial RNase T1 digests and base hydrolysis lanes to allow mapping of the exact sites of cleavage produced by the different mimics. The relative RNA cleavage percentages of the probes are denoted in Figure 2.

The ribozyme mimics employed in this study have structural differences in their respective DNA strands that yield unique RNA cleavage patterns for each reagent (Figure 1). The patterns are clearly governed by the locations of the 1,3-propanediol linkers in the DNA sequences. Probe 1, which contains a single serinol terpyridine modification in the middle of the DNA strand (16th position), cleaves the RNA phosphodiester linkages directly opposite the expected location of the catalyst upon RNA–DNA duplex formation. The serinol-terpy modification of the DNA strand is located directly opposite nucleotide rA¹⁶ in the complementary RNA strand, and the major site of cleavage is observed at this position as expected. There is also a minor cleavage band at residue rG¹⁵ to the 5' side of the cleavage site. These results were consistent with our previous observations using these types of reagents (13).

Cleavage of the RNA target with probe 2, which contains a single three-carbon linker to the 3'-side of the serinol-terpy in the DNA strand (directly across from rG¹⁵), yielded slightly different results. The major site of cleavage remained at nucleotide rA¹⁶; however, the number of minor cleavage bands increased toward the 5'-side of the RNA. A minor cleavage band was observed at nucleotide rA¹⁴ in addition to the minor band at rG¹⁵. There was also a slight increase in the amount of cleavage at position rG¹⁵ in comparison to probe 1.

Incorporation of two linkers to the 3'-side of the serinol-terpy residue in the DNA strand (probe 3) results in an even further extension of the number of minor cleavage bands to the 5'-side of the major cleavage site (rA¹⁶) in the RNA strand. In this case, the amount of cleavage at rA¹⁴ increased, but the amount of cleavage at rG¹⁵ did not (in comparison to probe 2).

For comparison, we investigated the effects of placing the linker to the 5'-side of the serinol-terpy modification in the DNA strand. Cleavage of the RNA target with probes 4 and 5, which contain one and two linker(s) to the 5'-side of the serinol-terpy respectively, yielded results similar to those obtained with the analogous probes 2 and 3. Nucleotide rA¹⁶ was the major site of cleavage, and rG¹⁵ was a minor site of cleavage in each case. Probe 4, which was designed to place a linker across from nucleotide rG¹⁷ in the RNA strand, led to an additional minor cleavage band at position rG¹⁷. Probe 5, which was designed to place linkers directly opposite positions rG¹⁷ and rA¹⁸ yielded two additional minor cleavage bands at these locations as expected.

To provide further corroboration of the utility of this approach, we prepared ribozyme mimics having linkers on both the 3'- and 5'- sides of the serinol-terpy modification in the DNA strand. Probe 6 consisted of one linker to the 3'-side of the modification, in addition to one linker to the 5'-side of the modification. Interestingly, cleavage of the RNA target with this reagent revealed a shift in the major site of cleavage from nucleotide rA¹⁶ (as observed with probes 1–5) to nucleotide rG¹⁵—a one-nucleotide shift toward the 5'-end of the RNA sequence. Minor cleavage bands were also observed at nucleotides rA¹⁴, rA¹⁶, rG¹⁷, and rA¹⁸. These cleavage products essentially represented a combination of the cleavage products obtained separately with probes 2 and 4, except that the major site of RNA cleavage was shifted by one nucleotide. A similar phenomenon was observed with probe 7, which contains two linkers to the 3'-side of the serinol-terpy as well as two linkers to the 5'-side of the serinol-terpy. In this case, the major site of cleavage was shifted even further to the 5'-side of the RNA to position rA¹⁴. Minor cleavage bands were also observed at nucle-

Figure 1. Structures of the ribozyme mimics and 31-mer RNA target sequence employed in this study. The “X” indicates the location of the serinol–terpyridine modification in the DNA strand, while the “S” represents the 1,3-propanediol linker modification. The 31-mer RNA target sequence is shown in **bold** text.

otides rC¹³, rG¹⁵, rA¹⁶, rG¹⁷, and rA¹⁸, which represents a combination of the cleavage products obtained with probes 3 and 5 separately. In this instance, however, the major site of cleavage was shifted by *two* nucleotides toward the 5′-end of the RNA target. The observed shifts in the major site of cleavage with probes 6 and 7 may offer some structural insights into the orientation of the serinol–terpyridine modification in the DNA–RNA duplex. When the degree of flexibility is equal on both sides of the serinol–terpy modification, cleavage occurs preferentially toward the 5′-side of the RNA strand, suggesting a preference for delivery of the catalyst across the larger major groove of the DNA–RNA duplex.

In addition to the sequence-specific RNA cleavage reactions using modified probes as described above, control experiments were conducted with the parent and control probes (Figure 1). Both of these probes lack the serinol–terpyridine modification in their DNA strands and hence possess no RNA cleavage capabilities. The parent probe is simply the full complement of the 31-mer RNA target sequence employed in this study. As

expected, no cleavage of the RNA target was effected by this probe in the presence of Cu(II) under our standard assay conditions (Figure 2, lane 4). The control probe, which contains four consecutive 1,3-propanediol linkers in the center of the DNA strand, also effected no significant cleavage of the RNA target (<3%) in the presence of excess Cu(II) (data not shown). These control experiments explicitly prove that the RNA cleavage products obtained with ribozyme mimics 1–7 are the direct result of the serinol–terpyridine modification in the DNA strand and not merely the effect of free Cu(II) ions on the induced single-stranded regions of the RNA target.

To further define the RNA cleavage efficiencies of this new series of ribozyme mimics, the most active probe in the series, probe 6, was examined for its ability to cleave multiple equivalents of complementary 31-mer RNA target. The experiments were designed such that the probe concentration was held constant at 125 nM, while the concentration of RNA target was increased from 250 nM (a 2-fold excess) to 1.25 μ M (a 10-fold excess).

Figure 2. Autoradiograph of the sequence-specific cleavage of 31-mer RNA with probes 1–7. Lane 1: 31-mer RNA starting material; lane 2: RNase T1 digest of 31-mer RNA (rG-specific); lane 3: NaOH hydrolysis of 31-mer RNA; lanes 4–11: Incubation of 31-mer RNA in the presence of the parent strand (PS) and probes 1–7. The reactions in lanes 4–11 were carried out at 45 °C in a total volume of 10 μ L containing the following: 0.1 M NaClO₄, 10 mM HEPES (pH 7.4), 250 nM RNA, 5 μ M probe, and 5 μ M CuSO₄. The probes and CuSO₄ were premixed, and the reactions were stopped after 40 h with gel loading buffer. The cleavage percentage for each probe is shown at the top of the gel and is reported as the average of three experimental runs.

Figure 3. Autoradiograph of a 20% denaturing polyacrylamide gel showing the results of cleavage reactions involving probe 6 in the presence of excess 31-mer RNA target. The reactions were carried out in a total volume of 10 μ L containing 10 mM HEPES buffer (pH 7.4), 0.1 M NaClO₄, 125 nM probe 6, 125 nM CuSO₄, and the concentrations of 31-mer RNA target specified below. The reaction tubes were submerged in a water bath at 45 °C for 40 h and quenched by the introduction of gel loading buffer. Lane 1: 125 nM probe 6 with 250 nM RNA; lane 2: 125 nM probe 6 with 500 nM RNA; lane 3: 125 nM probe 6 with 1.0 μ M RNA; lane 4: 125 nM probe 6 with 1.25 μ M RNA.

Quantification of the cleavage results from these experiments (Figure 3) revealed that up to 6.7 equiv of RNA were cleaved by probe 6 in the presence of 10 equiv of RNA substrate (Figure 3, lane 4). In addition, as the concentration of excess RNA decreased, so did the number of turnovers (Figure 3, lanes 1–3). The findings of this study reveal that probe 6 functions in a catalytic rather than stoichiometric mode of action under these

conditions. This represents a major discovery, considering that there have been only two additional reports of catalytic activity with ribozyme mimics to date (6, 12). Interestingly, each of the prior studies also encompassed the idea of increasing the degree of flexibility in the target RNA strand, thereby highlighting the importance of this strategy in the design of ribozyme mimics that function with multiple turnover.

CONCLUSIONS

A new series of ribozyme mimics has been designed to cleave multiple phosphates in the RNA backbone. This was achieved by increasing the total number of unpaired RNA residues directly opposite the site of the RNA cleavage catalyst in the ribozyme mimic–RNA duplex. The RNA residues were forced into the unpaired state by replacing their complementary nucleotides with the 1,3-propanediol linker **3**, which lacks the sugar ring and the nucleobase of a normal deoxynucleoside. Incorporation of one or more of these linkers at positions directly adjacent to the serinol–terpyridine modification in the ribozyme mimic DNA strand resulted in cleavage at multiple phosphates in the RNA target sequence. The linkers effectively created artificial mismatches, which distorted the phosphodiester backbone of the RNA target and increased its susceptibility to cleavage by Cu(II)–serinol–terpyridine. The RNA cleavage products produced by these ribozyme mimics correlated directly with the number and locations of the linkers in the DNA strands. A major finding of this study was that the most active ribozyme mimic in the series, probe 6, cleaved multiple equivalents of complementary RNA target in the presence of an excess of the target. The results of this study will serve as important additions to the growing set of selection rules for the design of highly efficient mimics of ribozymes. We are currently combining this strategy with other approaches to make fully optimized ribozyme mimics that may ultimately have utility as catalytic antisense therapeutics and as tools for molecular biology.

A pH-Sensitive Polymer That Enhances Cationic Lipid-Mediated Gene Transfer

Charles Y. Cheung, Niren Murthy, Patrick S. Stayton,* and Allan S. Hoffman*

Department of Bioengineering, University of Washington, Seattle, Washington 98195. Received March 7, 2001; Revised Manuscript Received June 5, 2006

The efficient release of nonviral gene carriers from endosomes is an important step for the successful delivery of DNA into the cell nucleus. A synthetic pH-sensitive anionic polymer, poly(propylacrylic acid) (PPAA), was designed to aid in endosomal escape of nonviral vectors and improve the transfection efficiencies with these vectors. Transfection of NIH3T3 fibroblasts with ternary physical mixtures of the cationic lipid DOTAP, pCMV β plasmid DNA, and PPAA showed marked enhancement of both gene expression levels and fraction of cells transfected compared to binary control mixtures of DOTAP and DNA. PPAA also significantly improved the serum-stability of DOTAP/DNA vectors. The DOTAP/DNA/PPAA vectors maintained high levels of transfection in media containing up to 50% serum. The striking enhancement of transfection efficiency with cationic lipid/DNA/PPAA mixtures, along with the enhanced serum-stability, suggests that PPAA may provide significant improvements for the *in vivo* intracellular delivery of drugs such as DNA, oligonucleotides, proteins, and peptides.

INTRODUCTION

Gene therapy represents a promising approach for the treatment of a wide variety of diseases. DNA delivery systems based on attenuated viruses have shown the greatest successes to date (1), but numerous concerns over the safety of these vectors (2–6) have led to the development of nonviral vectors for use in gene therapy. The efficacy achieved with these nonviral vectors, however, is significantly lower than that achieved with viral vectors. The low transfection efficiencies are due to the multiple biological barriers encountered during their delivery from extracellular locations into the cell nucleus (7). One of the major problems with systemic nonviral gene delivery is that these particles are typically unstable in the circulation. Furthermore, if the particles are able to reach the target cell and are endocytosed, the endosomes are generally trafficked to lysosomes, where degradation of the DNA occurs.

A number of biological organisms have evolved surface proteins to solve similar trafficking problems, and a variety of viral-based, fusogenic peptides have been studied as pH-dependent membrane-disruptive components in gene delivery systems to enhance transport from the endosome to the cytoplasm. For example, fusogenic peptides derived from the N-terminal domain of hemagglutinin (INF peptides, from the influenza virus) (8, 9) and the rationally designed GALA-based peptides developed by Szoka (10–12) undergo a conformational change at acidic pHs from a negatively charged, random coil to a hydrophobic, amphipathic α -helical structure. This structural transition leads to the insertion of the peptides into phospholipid bilayers and subsequent pore formation and disruption of these bilayers (13, 14). Significantly

Figure 1. Chemical structure of poly(propylacrylic acid).

higher levels of gene expression have been reported when INF peptides or GALA were added to polyplex carriers (8, 9, 12), while only moderate enhancements were observed upon addition of the peptides to lipoplexes (15–18).

While these results show the potential of incorporating additives that enhance endosomal release into gene carrier systems, the peptides may exhibit intrinsic limitations of immunogenicity (19–21), stability, and/or cost. The development of synthetic, pH-sensitive polymers that can mimic the function of fusogenic peptides may provide an alternative to peptide-based pH-dependent membrane destabilization in drug delivery. Tirrell and co-workers previously detailed the pH-dependent mechanism of vesicle disruption of poly(ethylacrylic acid) (PEAA) (22, 23). We have synthesized other polymers belonging to the alkyl acrylic acid family of polymers that exhibit greater pH-sensitive membrane disruption than PEAA (24, 25). In this study, we show that the incorporation of a particularly active polymer, poly(propylacrylic acid) (PPAA) (Figure 1), into lipoplex carriers can significantly enhance gene expression levels and provide serum stability in an *in vitro* cell culture model.

EXPERIMENTAL SECTION

Synthesis of Poly(propylacrylic acid). Poly(propylacrylic acid) (PPAA) was synthesized according to the protocols published previously (24). Briefly, polymeriza-

E-mail: hoffman@u.washington.edu. Patrick S. Stayton, Department of Bioengineering, Box 352125 University of Washington, Seattle, WA 98195. Telephone: 206-685-8148. Fax: 206-685-8256. E-mail: stayton@u.washington.edu.

tion of propylacrylic acid was performed using 2,2'-azobisisobutyronitrile (AIBN) as the initiator and cystamine as a chain transfer agent. Polymerization reactions were performed at 60 °C for 24 h. The resulting polymer was dissolved in methanol and precipitated using diethyl ether. The average molecular weight of PPAA was 61 kD as determined by GPC using PEG standards on Ultra-hydrogel 250 and 1000 columns (Waters Corporation, Milford, MA). The pH-sensitive membrane-disrupting activity of the PPAA produced was confirmed by red blood cell hemolysis assays as described previously (24, 25).

In Vitro Transfection. NIH3T3 mouse fibroblast cells were cultured in DMEM supplemented with 10% fetal bovine serum (FBS) at 37 °C and 5% CO₂. The cells were seeded into 12-well cell culture plates the day prior to the transfection experiments at a density of 7.5×10^4 cells/well. These cells were transfected with ternary physical mixtures of particles consisting of PPAA, the cationic lipid dioleyltrimethylammonium propane (DOTAP) (Roche Molecular Biochemicals, Indianapolis, IN), and the pCMV β plasmid DNA (CLONtech, Palo Alto, CA) which encodes for β -galactosidase. Control mixtures consisted of the DOTAP and plasmid DNA without PPAA. The DOTAP was first mixed with pCMV β in HEPES-buffered saline (HBS, pH 7.4), incubated for 30 min, with subsequent addition of PPAA. Mixtures were prepared with theoretical charge ratios ranging from 1.0 to 1.9 ($\pm$). The charge ratio was determined as the total positive to negative charge, calculated using the assumption of 33% PPAA ionization at pH 7.4 as determined from titration experiments (data not shown). For cell transfections, 0.7 mL of DMEM with variable amounts of FBS and 0.3 mL of solutions containing ternary mixtures of DOTAP/DNA/PPAA or binary control mixtures of DOTAP/DNA were added to each well. All formulations were tested in triplicate. The cells were incubated with these transfection mixtures for 4 h at 37 °C. The media was removed after this incubation period and replaced with 2 mL DMEM/10%FBS. The cells were then incubated for an additional 48 h prior to assaying for reporter gene activity.

Quantitation of Transfection Efficiency. The amount of β -galactosidase activity present within the transfected cells was quantified by utilizing the β -Galactosidase Enzyme Assay System (Promega, Madison, WI). Cell extracts were collected after lysis of the cells with the addition of Reporter Lysis Buffer. *o*-Nitrophenyl- β -D-galactopyranoside (ONPG) was added to the extracts, and the amount of β -galactosidase activity was measured spectrophotometrically with a plate reader at 415 nm. Concurrently, the total protein produced by the cells was determined by measuring the protein content in the cell extracts by the BCA method (Pierce, Rockford, IL). The transfection efficiency was also monitored by histological staining of the NIH3T3 cells. NIH3T3 cells were cultured in two-well glass chamber slides (Nalge Nunc, Rochester, NY) and transfected using the procedure described above. The cells were then fixed with 2% formaldehyde/0.2% glutaraldehyde in PBS for 30 min following the 48 h incubation after transfection. After fixation, the cells were stained with X-gal (1 mg/mL X-gal, 2 mM MgCl₂, 5mM K₄Fe(CN)₆, and 5mM K₃Fe(CN)₆) and 20 μ g/mL 4',6-Diamidino-2-phenylindole (DAPI) for 2 h at 37 °C. The chambers were then removed and the slides mounted. A Nikon Eclipse E800 upright fluorescence microscope was used to examine the slides for β -galactosidase activity.

Cellular Uptake of Particles Using [³⁵S]-Labeled Plasmid DNA. The uptake of DOTAP vectors containing radiolabeled plasmid DNA with and without PPAA was

Figure 2. β -Galactosidase gene expression levels following transfection of NIH3T3 cells with either DOTAP/DNA or DOTAP/DNA/PPAA formulations in serum-free conditions. Both formulations were prepared at theoretical charge ratios ranging from 1.0 to 1.9. Each well of cells was transfected with particles containing 1.6 mg/mL of plasmid DNA. All formulations were tested in triplicate.

examined. The pCMV β plasmid DNA was labeled with [³⁵S]-dCTP (NEN, Boston, MA) by nick translation (26) using the Nick Translation System (Promega, Madison, WI). Purification of labeled plasmid DNA from unincorporated nucleotides and enzymes was performed by centrifugation with Microspin S-400 HR columns (Amersham Pharmacia, Piscataway, NJ). Uptake studies were performed by incubating NIH3T3 cells with either DOTAP/DNA or DOTAP/DNA/PPAA particles incorporating [³⁵S]-labeled plasmid DNA for 4 h at 37 °C. The cells were washed twice with PBS and then trypsinized from the substrate surface. The trypsinized cells were centrifuged to recover the cells and then lysed with a solution containing 0.3N NaOH/0.1% Triton X-100. The level of radioactivity within the cells was determined by liquid scintillation counting.

RESULTS

Transfection Enhancement in Serum-Free Conditions. Addition of PPAA to DOTAP/DNA lipoplexes significantly enhanced transfection efficiencies in NIH3T3 mouse fibroblast cells at all charge ratios tested (Figure 2). The level of β -galactosidase gene expression with ternary DOTAP/DNA/PPAA carriers was increased ca. 20-fold over control DOTAP/DNA vectors prepared with a particle charge ratio of 1.3 ($\pm$). A control experiment was performed incorporating another synthetic polymer, poly(acrylic acid) (PAA), which is also a carboxylic polyanion similar to PPAA but does not contain the repeating propyl groups along the backbone. Results from these transfections showed that an enhancement in gene expression was observed only with formulations containing PPAA (data not shown). This finding indicates that the enhancement of transfection by PPAA is due specifically to the unique properties of the PPAA polymer, which contains the repeating propyl group that confers the unique pH-dependency and hydrophobic membrane destabilizing properties. Histological staining of NIH3T3 cells with X-gal showed that the increase in gene expression levels correlated with an increase in the number of cells transfected with DOTAP lipoplexes containing PPAA (Figure 3).

Serum Stabilization of Lipoplexes with PPAA. Cationic lipoplexes are often inactivated by interactions with serum proteins (27, 28), so the ability of PPAA to influence the serum stability of DOTAP/DNA lipoplexes

Figure 3. Histological staining of NIH3T3 cells with X-gal. Cells were transfected with (A) DOTAP/DNA 1.9 ($\pm$ charge ratio) particles in serum-free DMEM. (B) DOTAP/DNA/PPAA 1.3 ($\pm$) particles in serum-free DMEM. (C) DOTAP/DNA 1.9 ($\pm$) particles in DMEM/10% FBS. (D) DOTAP/DNA/PPAA 1.3 ($\pm$) particles in DMEM/10% FBS.

was tested. Cells were transfected with the DOTAP/DNA lipoplex with and without added PPAA, using formulations that provided the highest gene expression in serum-free conditions (at $\pm$ charge ratios for DOTAP/DNA = 1.9 and for DOTAP/DNA/PPAA = 1.3) and using media containing increasing levels of serum up to a maximum of 50% FBS. The DOTAP/DNA control formulation was inactivated in media containing as little as 10% FBS, while the DOTAP/DNA/PPAA particles exhibited high levels of transfection throughout the entire range of serum levels tested (Figure 4). Close to 70% of the gene expression level found in serum-free conditions was retained with DOTAP/DNA/PPAA particles at 50% FBS, and thus expression at serum levels simulating whole blood remained over 2-fold higher than the peak expression level of DOTAP/DNA particles observed in serum-free conditions (0% FBS). Histological staining for β -galactosidase in the presence of 10% FBS confirmed the absence of transfected cells, reiterating the inability of DOTAP alone to mediate transfection in the presence of serum. In contrast, a significant number of stained cells were evident after transfection with DOTAP/DNA/PPAA (Figure 3), confirming that high levels of transfection are retained in serum conditions upon addition of PPAA to the particles.

Quantitation of Particle Uptake with [^{35}]S-Labeled pCMV β . To measure the levels of plasmid uptake into cells, transfection studies were performed utilizing

Figure 4. Effects of variable serum concentration on gene transfer efficiency. The ability of DOTAP/DNA and DOTAP/DNA/PPAA formulations, prepared at the optimal charge ratios as determined from serum-free conditions, were assessed in media containing FBS levels up to 50% of the media. Each formulation was tested in triplicate at each serum level.

a [^{35}]S-labeled plasmid DNA that was incorporated into the DOTAP lipoplex particles. The quantitative uptake of these particles was investigated in the presence of both serum-free DMEM and DMEM containing 10% FBS. The presence of serum proteins within the media reduced overall particle uptake with all formulations. The uptake of DOTAP/DNA formulations was reduced 10-fold, whereas uptake was reduced only 2-fold with DOTAP/DNA/PPAA particles (Table 1). Therefore, the differences in trans-

Table 1. Radioactive Uptake of [³⁵S]-labeled Plasmid DNA Incorporated into Transfection Formulations into NIH3T3 Cells^a

particles	media	particle uptake
DOTAP/DNA 1.9	serum-free DMEM	6.4 ± 0.23%
	DMEM/10% FBS	0.70 ± 0.077%

	DMEM/10% FBS	4.9 ± 0.41%

^a Percentages represent the fraction of radioactivity found within cells compared to the total radioactivity exposed to the cells. Each percentage represents the uptake from triplicate wells.

fection efficiencies with DOTAP/DNA/PPAA and DOTAP/DNA particles in the presence of serum, as measured both by level of expression and number of transfected cells, correlates with greater intracellular uptake of DNA from particles containing PPAA. The addition of PPAA also enhances intracellular uptake in the absence of added serum, although to a lesser extent than that observed in the presence of serum.

DISCUSSION

Our group has been designing and characterizing synthetic polymers that enhance the endosomal release of biotherapeutics based on strategies utilized by biological organisms such as viruses and toxins. These organisms utilize fusogenic proteins or peptides that contain amino acids with pendant hydrophobic alkyl groups as well as others containing ionizable carboxyl moieties that become protonated within endosomes, leading to secondary structural changes within the peptides that promote membrane disruption at low pH. The alkylacrylic acid family of polymers also contains pendant alkyl groups along with carboxyl moieties. PEAA has previously been shown to destabilize model lipid bilayers at pHs within the range for endosomal acidification (pH 5.5–6.5). PPAA differs from PEAA by the addition of one methylene group to the pendant hydrophobic side chain in each monomer subunit. The increased hydrophobicity gained by the additional methylene group in PPAA, relative to PEAA, results in the enhanced association of PPAA with red blood cell membranes at low pH, which leads to enhanced hemolysis as well as a higher pH sensitivity of this disruption (24, 25). PPAA also exhibits no cytotoxic effects when added to NIH3T3 mouse fibroblasts at concentrations up to at least 100 µg/mL (highest concentration tested, unpublished data). This information suggests the potential for using PPAA for the intracellular delivery of therapeutic molecules.

In the study reported here, we have tested the ability of PPAA to enhance cell transfections by incorporating PPAA into nonviral lipoplex gene delivery vectors. Ternary physical mixtures of particles consisting of DOTAP, pCMVβ plasmid DNA, and PPAA were prepared for transfection. These particles were formed by the electrostatic interactions between the positively charged DOTAP liposomes and the negatively charged DNA and PPAA. The carrier nanoparticles containing PPAA showed greatly enhanced gene expression levels and a higher percentage of transfected cells compared to control carriers lacking PPAA. Incorporation of PPAA into these lipoplex particles also provided an unexpected protection of these particles against serum inactivation upon exposure of up to 50% serum levels. Radioactive uptake experiments indicated that vectors containing PPAA maintained high levels of particle uptake even in the presence of serum. This high level of particle uptake may be due to an ability of the added PPAA to provide steric

stabilization of the lipoplex particles, as is well established with other hydrophilic polymers such as poly(ethylene glycol) (PEG) (29–31) and poly[N-(2-hydroxypropyl)methacrylamide] (pHPMA) (32). Therefore, PPAA in its hydrophilic state (i.e., pH 7.4) is likely inhibiting serum protein adsorption and/or nanoparticle disruption.

While the exact molecular mechanism of PPAA enhancement is currently unknown, the results presented here suggest that the polymer is increasing the cytoplasmic delivery of the plasmid DNA. Studies examining the interaction of PEAA with model liposomal bilayers have shown that the polymer undergoes a conformational transition from a hydrophilic extended coil to a more hydrophobic globule state at low pH, which leads to membrane association and destabilization (22). More recently, PEAA has been shown to form ion-selective membrane channels in lipid vesicle membranes, which has been shown to mediate the release of model, vesicle-entrapped drugs from liposomes (33, 34). Our studies showing that DOTAP/DNA nanoparticles incorporating PAA did not exhibit higher transfection efficiency demonstrates that the enhancement is not due to a nonspecific effect of adding a polyanionic polymer to the DOTAP/DNA carriers. Therefore, the pendant propyl groups in PPAA are required to confer the proper hydrophobic/hydrophilic balance essential for pH-dependent membrane disruption and the endosomal release of nanoparticle gene delivery systems. The overall ability of the PPAA-containing particles to transfect cells in media containing 50% serum suggests that PPAA may provide both serum stabilizing and endosomal escaping properties to lipoplex carriers in systemic or local in vivo delivery applications for gene therapy.

Cellular Internalization of a Cargo Complex with a Novel Peptide Derived from the Third Helix of the Islet-1 Homeodomain. Comparison with the Penetratin Peptide

Kalle Kilk,^{†,§} Mazin Magzoub,[‡] Margus Pooga,^{†,‡} L. E. Göran Eriksson,[‡] Ülo Langel,[†] and Astrid Gräslund^{*,‡}

Received March 8, 2001

Cellular translocation into a human Bowes melanoma cell line was investigated and compared for penetratin and pIsl, two peptides that correspond to the third helices of the related homeodomains, from the Antennapedia transcription factor of *Drosophila* and the rat insulin-1 gene enhancer protein, respectively. Both biotinylated peptides internalized into the cells with similar efficacy, yielding an analogous intracellular distribution. When a large cargo protein, 63 kDa avidin, was coupled to either peptide, efficient cellular uptake for both the peptide–protein complexes was observed. The interactions between each peptide and SDS micelles were studied by fluorescence spectroscopy and acrylamide quenching of the intrinsic tryptophan (Trp) fluorescence. Both peptides interacted strongly and almost identically with the membrane mimicking environment. Compared to penetratin, the new transport peptide pIsl has only one Trp residue, which simplifies the interpretation of the fluorescence spectra and in addition has a native Cys residue, which may be used for alternative coupling reactions of cargoes of different character.

INTRODUCTION

Homeodomains are approximately 60 amino acids long DNA binding regions of transcription factors (Müller et al., 1988). It has been shown that several homeodomain-containing transcription factors exhibit cell-penetrating properties (Chatelin et al., 1996; Prochiantz, A., 1999; Han et al., 2000). For the Antennapedia homeodomain protein of *Drosophila*, it was found that the fragment corresponding to the third helix (residues 43–58) of the homeodomain penetrates cell membranes (Derossi et al., 1994, 1996, 1998). The peptide with the corresponding sequence was named “penetratin”, and this was the first homeoprotein-derived cell-penetrating peptide (CPP) (Table 1). The cellular internalization of penetratin occurs at 4 °C and is unsaturable, suggesting that it does not require a chiral receptor protein (Derossi et al., 1994). To reveal the mechanism by which penetratin is internalized, modified (with deletions, additions, replacements or inversions) penetratin analogues have been synthesized and studied (Brugidou et al., 1995; Derossi et al., 1996; Fischer et al., 2000; Thorén et al., 2000; Drin et al., 2001), but a detailed knowledge of the mechanisms of membrane penetration is still lacking.

As previous studies demonstrate, the homeodomains have similar and well-organized secondary and tertiary

structures (Ippel et al., 1999). The homeodomain proteins consist of three α -helices. The third helix contains highly conserved amino acid motifs and is also amphipathic. It has been discussed whether the amphipathic α -helical conformation is essential for the membrane-translocating properties (Dathe et al., 1996; Magzoub et al., 2001).

The present study concerns a novel peptide sequence, pIsl, derived from the homeodomain of the rat transcription factor Islet-1 (Isl-1) (Karlsson et al., 1990) and homologous to penetratin. The Islet-1 protein was initially shown to function as an insulin-1 gene enhancer. Later, Isl-1 protein has been shown to possess other important regulatory functions, e.g., in motor neuron differentiation (Pfaff et al., 1996), regulation of amylin (Wang and Drucker, 1996), proglucagon expression (Wang and Drucker, 1995), and estrogen receptor modulation (Gay et al., 2000). The sequence corresponding to the third helix (residues 45–60) of the homeodomain of Isl-1 (pIsl) is similar, although not identical to penetratin (Table 1). The pIsl sequence has only one Trp residue, which is a simplification for studies with optical spectroscopy, and it has a native Cys residue, which may be useful in coupling reactions of cargoes.

We demonstrate that pIsl and penetratin peptides internalize efficiently into human Bowes melanoma cells. As shown before, penetratin can translocate relatively large molecules, coupled to it, across the cell membrane (Allinquant et al., 1995; Pooga et al., 1998; Derossi et al., 1998). Here, the biotin-labeled pIsl peptide and penetratin are complexed to fluorescently labeled avidin, a biotin binding protein with a molecular weight of about 63 kDa (Pugliese et al., 1993). The cell translocation of the two complexes is studied and compared. The intrinsic Trp fluorescence in either peptide is used to characterize the interaction of the peptide with negatively charged SDS

Table 1. Comparison of the Penetratin and pIsl Internalization into Bowes Cells as well as Acrylamide Quenching Constants Calculated from the Tryptophan Fluorescence Spectra in Water and SDS Micelles

name	peptide sequence	localization		quenching constant (M^{-1})	
		cytoplasm	nucleus	water	SDS micelles
penetratin	RQIKIWFQNRRMKWKK	+	+	35	25
pIsl	RVIRVWFQNKRCDDKK	+	+	39	22

**Figure 1.** Localization of biotinyl-pIsl (A), biotinyl-penetratin (B), and natural background (C) in Bowes melanoma cells. Concentration of peptides was 10 μM , incubation time 1 h at 4 $^{\circ}C$. Staining was done using 150 nM streptavidin-FITC.

micelles, which may be considered as a simple solvent model for a biomembrane.

MATERIALS AND METHODS

Peptide Synthesis. The peptides (Table 1) were synthesized using the *t*-Boc/DCC/HOBt strategy of solid-phase peptide synthesis on a PE Applied BioSystems stepwise peptide synthesizer model 431A. The N-terminal biotin was coupled manually using TBTU/HOBt activation, to increase the coupling yield. Cleavage from resin was performed with liquid HF. Highly pure peptides were obtained by purification on a reversed-phase HPLC C_{18} column. Molecular weights were determined using a plasma desorption time-of-flight mass spectrometer (Bio-Ion) and always corresponded to calculated values. Both peptides were C-terminally amidated.

Cells. The human Bowes melanoma cell line was cultivated in a minimal essential medium with Earl-salts (MEM), supplemented with 10% foetal calf serum, 2 mM L-glutamine, 5 IU/mL penicillin, and 5 $\mu g/mL$ streptomycin, in air enriched with CO_2 to 5% at 37 $^{\circ}C$. For the penetration assay the cells were grown on round glass coverslips in a 24 well plate to approximately 50% confluence.

Cellular Penetration of Biotin-Labeled Peptides.

The serum-containing medium was replaced by a serum-free medium, and an aqueous stock solution of the peptide was added directly into the medium surrounding the cells, to reach the concentration of 10 μM . For detection of a natural level of intracellular biotin and estimation of nonspecific staining, water instead of the peptide solution was added, and in all other respects these negative controls were handled identically to other coverslips. The cells were incubated with peptides for 1 h at 37 $^{\circ}C$ in 5% CO_2 enriched air or 4 $^{\circ}C$ in air. Thereafter, the cells were washed three times in PBS, fixed, and permeabilized with methanol for 10 min at $-20^{\circ}C$, washed with PBS, and incubated for 1 h in a 5% (w/v) solution of fatfree milk in PBS in order to block nonspecific binding sites. The peptides were visualized by staining with 150 nM streptavidin-FITC (Amersham-Pharmacia Biotech) for 1 h at room temperature. The cell nuclei were visualized by staining the DNA with Hoechst 33258 (0.5 $\mu g/mL$) for 5 min. Thereafter, the coverslips were washed three times in PBS and mounted in 20% glycerol in PBS. The images were obtained by a Zeiss Axioplan 2 fluorescence microscope (Carl Zeiss Inc., Germany).

Figure 2. Cellular penetration of biotinyl-peptide-avidin-TRITC complexes. Bowes melanoma cells were incubated for 2 h with 5 μ M biotinyl-pIsl-avidin-TRITC or biotinyl-penetratin-avidin-TRITC in serum free medium at 37 °C. Nuclei of pIsl treated cells: (A) Hoechst 33258 staining showing DNA, (B) TRITC fluorescence showing avidin transported by pIsl. Nuclei of penetratin treated cells: (C) Hoechst 33258 staining showing DNA, (D) TRITC fluorescence showing avidin transported by penetratin.

Cellular Penetration of Peptide-Cargo Complexes. The cells for protein transport experiments were grown on round glass coverslips in 24-well plates to about 50% confluence. A solution of biotinylated pIsl or penetratin complexed with avidin-TRITC in serum-containing medium was added to the cells. The Bowes cells were incubated for 2 h at 37 °C with 5 μ M of peptide-protein complex. The coverslips with cells were washed two times with PBS, fixed with the mixture of 4% paraformaldehyde and 1% glutaric aldehyde in PBS and permeabilized with methanol for 15 min at -20 °C. Nonspecific binding was blocked with 5% BSA in PBS. After final rinsing with PBS, the prepares were mounted in Slow Fade mounting medium (Molecular Probes, Inc.). The localization of the peptide-avidin complexes was examined and photographed by a Vanox AH2-NAS microphotograph system (Olympus) or by a laser confocal scanning microscope MRC-1024 (Bio-Rad).

Fluorescence Spectroscopy. Fluorescence spectra were recorded on a Perkin-Elmer LS 50B Luminescence Spectrometer equipped with FL WinLab software. All measurements were made in 4 $\times$ 10 mm cuvettes at an ambient temperature of 20 °C. Spectra were recorded in water or a 100 mM solution of sodium dodecyl sulfate (SDS, Kebo), at pH of about 3, well above the critical micellar concentration. The fluorescence was excited at 280 nm, and the emission was recorded from 300 to 500 nm. Emission spectra were recorded with 10 nm excitation and emission bandwidths.

For the fluorescence quenching experiments, acrylamide (Sigma) from a 1 M stock solution was added to

the peptide solution, resulting in concentrations between 4 and 100 mM. Quenching constants K_{SV} were determined by a linear regression with the Stern-Volmer equation for a dynamic process (Lakowicz, 1999):

$$\frac{F_0}{F} = 1 + K_{SV}[Q] \quad (1)$$

where F and F_0 are the fluorescence intensities in the presence and the absence of acrylamide, respectively, and $[Q]$ is the molar concentration of acrylamide in the solution.

RESULTS

Cellular Penetration. The membrane penetration efficacy of pIsl and penetratin peptides was estimated and compared. Bowes melanoma cells were incubated with 10 μ M solution of each biotinylated peptide and stained with streptavidin-FITC after fixing the cells. Both peptides yielded identical high intensities of intracellular fluorescence that strongly exceeded the registered natural background (Figure 1). No obvious differences in cellular distribution were observed between pIsl and penetratin, as demonstrated in Figures 1A and 1B. Both peptides were able to penetrate into the cells also at 4 °C (data not shown). The observations show that pIsl, with a sequence analogous to that of penetratin, translocates into the cells in a nonendocytotic manner, because at temperatures below 18 °C endocytosis is abolished. The results also suggest that both peptides penetrate through

Figure 3. Stern–Volmer plots for the acrylamide quenching of the tryptophan fluorescence from the two homeopeptides in water (open symbols), or 100 mM SDS micelles (filled symbols). The concentration of pIsl (Δ $\blacktriangle$) and penetratin ($\circ$ $\bullet$) was 10 μ M. Insert: The fluorescence emission spectra (excitation at 280 nm) of pIsl and penetratin in buffer and in 100 mM SDS micelles.

the cell membranes by the same mechanism, and their intracellular localization is similar.

Delivery of Cargo Protein over the Plasma Membrane. The property of avidin (MW about 63 kD) to form a very strong and specific complex with biotin was used to demonstrate the ability of pIsl, as well as penetratin, to carry large molecules into the cells. The cell nuclei are shown in Figure 2A and C by staining with the DNA-binding substance Hoechst 33258. The strong complexes between the biotinylated pIsl or penetratin and TRITC-labeled avidin were preformed by incubating the components together in a minimal volume for 5 min at room temperature. This solution was added directly into the culture medium over the cells. Incubation of Bowes cells for 30 min or longer with these complexes resulted in accumulation of fluorescent particles in the cells (Figures 2B and 2D), confirming that avidin–TRITC was conveyed into cells also by the pIsl peptide as a noncovalent complex. With both transport peptides, the cargoes are clearly present both in the cytoplasm and in the nucleus of the cells (Table 1).

Spectroscopic Studies. Transport peptides have the common feature to interact strongly with biomembrane model systems. The intrinsic Trp fluorescence of the

nonbiotinylated peptides was used to study this interaction. Penetratin contains two Trp residues and pIsl only one (Table 1). Figure 3 (insert) shows the fluorescence emission spectra of penetratin and pIsl in buffer (pH 7) and in 100 mM solution of SDS, a negatively charged detergent that forms micelles in an aqueous solution. In this membrane mimetic solvent both peptides show a 15–20 nm (“blue”) shift of the Trp fluorescence emission peak to shorter wavelengths as compared to the aqueous solutions, indicating that the Trp residues interact with a less polar environment than water, i.e., SDS micelles. In a highly hydrophobic environment the wavelength shift of Trp fluorescence could reach 30–35 nm (Lakowicz, 1999). Therefore, the present data suggest a partial shielding from the aqueous solvent.

To evaluate the accessibility of Trp residues to the solvent, acrylamide was used as a neutral hydrophilic fluorescence quenching agent. Figure 3 shows the quenching graphs for the two peptides in water and in SDS micelles. In all cases the graphs obey the linear Stern–Volmer equation. The calculated quenching constants are 35 and 39 M^{-1} in aqueous solution and of 25 and 22 M^{-1} in micellar solution, for penetratin and pIsl, respectively (Table 1). The values observed for the two peptides are

not significantly different within the accuracy of the measurements. It should be noted that the quenching behavior in the current case is also not significantly dependent on the number of Trp residues.

DISCUSSION

The present study is the first to demonstrate that a sequence homologous to penetratin taken from a different homeodomain of a transcription factor is also able to carry a large cargo protein through cell membranes. The pIsl peptide efficiently penetrates into the cells in culture and can be therefore considered as a new member of the homeoprotein-derived class of CPPs. We have compared the transport and membrane interaction properties of two homeodomain-derived peptides, penetratin and pIsl, which have somewhat different sequences and net charges (Table 1), but with identical positions of the positive charges. Recently, it was demonstrated that only the C-terminus of penetratin, RRMKWKK, is obligatory for cellular penetration (Fischer et al., 2000). Corresponding sequences are present in many of the known homeoproteins. In the transcription factor PDX-1 the same motif is present, and it was demonstrated to be a nuclear localization signal (NLS) for proteins (Moede et al., 1999). However, in that study the tagged cargo was introduced into the cells by a transfection technique.

The results suggest that the translocation property of the CPPs is mainly dependent on the presence of the positive charges in the C terminus. Moreover, L-Ala-scanning showed that all basic amino acid residues in the RRMKWKK fragment are necessary for efficient translocation (Fischer et al., 2000). Substitution of any charged residue in this motif by L-Ala decreases the penetration yield by 60% or more, whereas replacing Trp does not cause any such drastic drop in the penetration yield. Our results support the previous observations on penetratin analogues that the Trp⁵⁶ of penetratin is not a major determinant for cellular penetration (Fischer et al., 2000). In a solution with SDS micelles the single Trp of pIsl shows similar fluorescence properties as the two Trp residues in penetratin do. These results suggest that both Trp residues in penetratin are in an environment of similar polarity and accessibility from the solvent as the one Trp residue in pIsl. In both peptides, the Trp residues are partially shielded from the interaction with the aqueous solvent.

The detailed secondary structures induced in a cell-penetrating and transporting peptide by the interaction with a membrane do not seem to be directly related to the penetration properties (Derossi et al., 1996; Scheller et al., 2000; Drin et al. 2001; Magzoub et al., 2001). Instead, the strength of the interaction with the charged membrane and possibly the overall topology of the peptide relative to the membrane surface may be decisive factors for the translocation process. How the cargo will then then become accommodated in a nonlytic manner in the translocation process remains a challenging phenomenon.

The presentation of the pIsl peptide as a novel CPP and comparing its properties with penetratin gives further understanding of the cell-penetrating mechanisms of CPPs. Additionally, the native Cys residue in the pIsl sequence may be used for various coupling reactions, which should make pIsl useful as an alternative for cellular delivery of different hydrophilic cargo molecules.

Novel Polymer–DNA Hybrid Polymeric Micelles Composed of Hydrophobic Poly(D,L-lactic-co-glycolic Acid) and Hydrophilic Oligonucleotides

Ji Hoon Jeong and Tae Gwan Park*

Department of Biological Sciences, Korea Advanced Institute of Science and Technology,
Taejeon 305-701, South Korea. Received April 17, 2001; Revised Manuscript Received June 27, 2001

Biodegradable poly(D,L-lactic-co-glycolic acid) (PLGA) was chemically conjugated to oligonucleotide (ODN) to form an amphiphatic structure which is similar to an A–B type block copolymer. A terminal end of PLGA was activated and reacted with primary amine-terminated ODN. The ODN/PLGA conjugates self-assembled in aqueous solution to form a micellar structure by serving PLGA segments as a hydrophobic core and ODN segments as a surrounding hydrophilic corona. Critical micelle concentration was determined by a spectrofluorometric method. Atomic force microscopic observation revealed that the micelle size was around 80 nm. These micelles could release ODN in a sustained manner by controlled degradation of hydrophobic PLGA chains. Compared to unconjugated ODN, the ODN/PLGA micelles could be more efficiently transported within cells, presumably by endocytosis. This study proposes a potential delivery method of ODN into cells by forming hybrid ODN/PLGA micelles.

INTRODUCTION

Recently, much attention has been drawn to various amphiphatic block polymers, which can self-associate to form micelles in aqueous milieu. They can be utilized as potential drug carriers (1–6). Most polymeric micelles have a core–shell structure composed of hydrophobic segments as an internal core and hydrophilic segments as a surrounding corona (7). The size of polymeric micelles, approximately less than 100 nm in diameter, not only makes them ideal drug delivery carriers for escaping from renal exclusion and the reticuloendothelial system, but also provides them with enhanced endothelial cell permeability in the vicinity of solid tumors (8, 9). In particular, amphiphatic A–B type diblock copolymers demonstrated a fairly good thermodynamic stability in physiological solution by virtue of their relatively low critical micelle concentration (cmc) (10). Various polymeric micelles have been used to deliver anticancer drugs for passive targeting to solid tumors in vivo. For example, diblock copolymers composed of poly(aspartic acid) and poly(ethylene glycol) (PEG) have been used for delivering doxorubicin to solid tumors in a target specific manner by the “enhanced permeation and retention (EPR)” mechanism (11). More recently, a variety of biodegradable polymeric micelles, based on diblock copolymers composed of aliphatic polyesters and PEG, were synthesized. Poly(D,L-lactic-co-glycolic acid) (PLGA) has been most popularly used as a constituent of the diblock copolymers because it can be hydrolyzed in vivo into lactic and glycolic acid forms, which can be metabolized further into carbon dioxide and water (12).

Oligonucleotides (ODNs) represent short DNA molecules, which have been tested for treating various genetic diseases. Oligomeric antisense DNA and RNA have been used to block the expression of specific proteins

by hybridization with specific (target) mRNA sequences. The antisense effect of ODNs has been demonstrated in both in vitro cell culture (13, 14) and in vivo studies (14–16), and their therapeutic potentials have been proposed (17). However, one of the most serious problems is to efficiently deliver them into cells (18, 19). To obtain the most potent antisense effect, the formulation of ODN with suitable carriers must be developed to facilitate cellular uptake. A variety of nonviral vectors such as cationic liposomes (20) and synthetic polymers (19) have been used for delivering antisense ODNs into mammalian cells.

In this study, we conjugated *c-myc* antisense ODN as a model ODN to biodegradable PLGA to make an amphiphilic structure, which could form micelles in an aqueous phase, like A–B type diblock copolymers. The ODN/PLGA micelles were used as vectors for the delivery of antisense ODNs, which can facilitate the cellular uptake of ODN via endocytosis. Characteristics and cellular uptake behaviors of the ODN/PLGA polymeric micelles were investigated.

MATERIALS AND METHODS

Materials. Poly(D,L-lactic-co-glycolic acid) (PLGA5010) having a lactic/glycolic molar ratio of 50/50 was obtained from Wako Chemicals (Japan). This polymer (nominal MW 10000) has a free hydroxyl and a carboxyl group at its terminal ends. Oligodeoxynucleotide (antisense *c-myc* ODN, CACGTTGAGGGGCAT), which has a primary amine group at the end of its 5′ phosphate, was synthesized, modified, and purified by Bioneer (Korea). Dicyclohexyl carbodiimide (DCC), *N*-hydroxysuccinimide (NHS), and dimethyl sulfoxide (DMSO) were purchased from Sigma (St. Louis, MO). All other chemicals were of analytical grade.

Conjugation of Oligonucleotide to PLGA. PLGA (1.0 g, 0.1 mmol) dissolved in 5 mL of DMSO was activated by DCC (61.9 mg, 0.3 mmol) and NHS (34.5

* Corresponding author. Tel: +82-42-869-2621, fax: +82-42-869-2610, e-mail: tgpark@mail.kaist.ac.kr.

mg, 0.3 mmol) (PLGA/DCC/NHS stoichiometric molar ratio: 1:3:3). The activated polymer was precipitated in cold ethanol followed by drying under reduced pressure. ODN (1.0 mg, 0.2 μ mol) dissolved in 100 μ L of 5 mM sodium borate buffer (pH 8.0) was added to DMSO (0.9 mL). Insoluble salt particulates were removed from the buffer solution by centrifugation at 14000 rpm for 10 min. The supernatant solution was then dropped into the DMSO solution (1 mL) containing the activated PLGA (2 mg, 0.2 μ mol) (stoichiometric ratio: 1:1). The reaction mixture was incubated at room temperature for 12 h and then dialyzed against deionized water for the removal of unreacted ODN and the generation of ODN/PLGA micelles. The concentration of ODN in the micelles was determined by measuring absorbance at 260 nm using a Shimadzu UV-Vis spectrophotometer (UV-1601, Japan). The formation of self-assembled micellar structure was characterized by gel permeation chromatography using Bio-Rad Bio-columns SEC 250 (300 $\times$ 7.8 mm) in an aqueous mobile phase with a flow rate of 1 mL/min. Elution profiles of micelles and ODN were detected by absorbance at 260 nm.

Characterization of ODN/PLGA Micelles. Effective hydrodynamic diameter of the micelle was measured by dynamic light scattering at 25 $^{\circ}$ C using a dynamic light scattering photometer (Zeta Plus, Brookhaven Instrument Co., New York) equipped with He-Ne laser at a wavelength of 632 nm. The measurement was carried out in triplicate.

Measurement of Critical Micelle Concentration (cmc). The critical micelle concentration was determined by a fluorescence probe technique using pyrene as a fluorescence probe, as described previously (21, 22). Pyrene dissolved in acetone was added to deionized water to make a concentration of 12×10^{-7} M, and acetone was subsequently removed by stirring for 5 h at room temperature. The final concentration of pyrene was adjusted at 6×10^{-7} M. The concentration of ODN/PLGA conjugate was varied from 0.05 to 500 mg/mL. Combined solution of pyrene solution and ODN/PLGA conjugate was equilibrated at room temperature in a dark room for 1 day before measurement. Fluorescence spectra were monitored at room temperature using a Shimadzu spectrofluorometer (RF-5301PC, Japan) at an excitation and emission wavelength of 339 and 390 nm, respectively. The spectra were accumulated with an integration of 2 s/nm.

Atomic Force Microscopy (AFM). Five microliters of ODN/PLGA micellar solution (100 μ g/mL) was dropped on a clean glass surface and air-dried at room temperature. The AFM analysis was carried out in a constant tapping mode by using Nanoscope III (Digital Instruments). A standard Nanoprobe silicon single-crystal lever was used as a cantilever and a constant force mode was used with a scan speed at 0.5 Hz. The scanned image was collected from a $2.5 \times 2.5 \mu$ m area.

In Vitro ODN Release. Five milliliters of the micelle solution containing 300 μ g of ODN/PLGA conjugate in dry weight basis was put into a dialysis membrane (molecular cutoff: 50000). The dialysis bag was placed in a 50 mL conical tube filled with 4 mL of Tris-EDTA buffer (10 mM Tris-Cl, 1 mM EDTA, pH 8.0), which was maintained at 37 $^{\circ}$ C with gentle shaking (100 rpm). The buffer was collected and replaced at desired interval times. The collected sample was filtered and stored at 4 $^{\circ}$ C until analyzed at 260 nm.

Fluorescence Labeling of Micelles. A fluorescence-labeled oligonucleotide having a complementary sequence to antisense *c-myc* ODN (sense *c-myc* ODN) was used to

label the ODN incorporated in micelles by hybridization between sense and antisense ODNs. The sense ODN (ATGCCCCCTCAACGTG) having a primary amine group at its 5' end, was labeled by using rhodamine-NHS in PBS (pH 7.6) at room temperature for 12 h. Dialysis was carried out to remove unlabeled fluorescent dye. The labeled ODN was concentrated by using Centricon (Amicon). The labeled sense oligonucleotide was added to the micelle solution for labeling the ODN/PLGA micelles. The mixture was heated at 65 $^{\circ}$ C for 5 min and cooled in ice.

Endocytosis of Micelles. NIH 3T3 murine fibroblast was purchased from Korea Cell Line Bank (Seoul, Korea) and were cultured in DMEM supplemented with 10% FBS, streptomycin at 100 μ g/mL, penicillin at 100 IU/mL, and 2 mM L-glutamine. Cells were maintained at 37 $^{\circ}$ C in a humidified 5% CO₂ atmosphere. Ten thousand cells per well were plated in a six-well plate (35 mm diameter, Nunc) containing collagen-coated coverglass in 1.5 mL DMEM with 10% FBS and incubated for 24 h before further experiments. After the replacement of the medium with fresh serum-free medium, the ODN/PLGA micelles hybridized with rhodamine-labeled sense ODN were added to attain a concentration of 80 μ g/mL. After 3 h incubation, medium was discarded and the cells were washed four times with PBS. The cells were fixed by adding a fixing solution (0.2% glutaraldehyde, 0.5% formaldehyde in PBS) followed by incubation at 4 $^{\circ}$ C for 15 min. The cells were then washed once with PBS and visualized by a Zeiss LSM 510 confocal microscopy (Carl Zeiss, Germany). An argon/krypton mixed gas laser with excitation line at 568 nm was used to induce rhodamine fluorescence, which was observed by using 575–640 nm band-pass filter.

Flow Cytometry. The efficiency of endocytosis was determined by using a flow cytometry. Ten thousand cells per well were plated and cultured in a six-well plate as described above. The medium was replaced with fresh serum-free medium prior to the addition of the micelles. The fluorescence-labeled ODN/PLGA micelles were then added to the cells to obtain a final concentration of 80 μ g/mL. After 3 h incubation, the cells were washed four times with PBS, trypsinized, and fixed. The number of cells, which had endocytosed the micelles, was measured in a flow cytometry (FACSCalibur, Becton-Dickinson, Mountain View, CA). The cellular uptake efficiency of ODN/PLGA micelles was quantified by counting the number of cells within an arbitrarily selected gate region (50 < FL2-H < 350).

RESULTS AND DISCUSSION

In our previous reports, various bioactive molecules and drugs, such as peptides, enzymes, and anticancer drugs, were directly conjugated to the terminal group of PLGA for achieving a sustained release from nanoparticles and microspheres (23, 24). Slow degradation of PLGA chain provided the controlled release of conjugated bioactive moieties over the desired period. More recently, doxorubicin was conjugated to the terminal end of PLGA in a block copolymer of PEG-*b*-PLGA to form polymeric micelles, where doxorubicin was chemically entrapped within a hydrophobic micelle core (6). It was found that chemically entrapped doxorubicin within PEG-*b*-PLGA could be transported within cells to a greater extent than doxorubicin alone, possibly due to an endocytosis process. In general, when hydrophilic synthetic polymers were linked to water insoluble PLGA in a diblock polymer structure, the A-B type diblock polymers self-assembled in aqueous solution to form micelles. We selected ODN

Figure 1. The schematic diagram of micelle formation of amphiphilic conjugate of oligonucleotide and poly(D,L-lactic-co-glycolic acid) in aqueous medium.

as a hydrophilic segment to conjugate to the terminal end of PLGA to form a novel hybrid polymeric micelle structure in aqueous solution (Figure 1). It is postulated that ODN, as the hydrophilic constituent part of ODN/PLGA conjugate, can be more efficiently delivered within cells by an endocytosis mechanism, in contrast to ODN itself which is transported across the cell membrane by passive diffusion. An antisense ODN, *c-myc*, was used as a model ODN in this study. It is a single strand DNA with a molecular weight of 4633 and a nucleotide sequence of CACGTTGAGGGGCAT. The potential application of the antisense *c-myc* ODN for the suppression of smooth muscle cell proliferation was suggested in a previous study (25). Smooth muscle cell proliferation is believed to play a critical role in reoccurring the blockade of coronary artery after a balloon angioplasty treatment (restenosis).

A reaction scheme for the conjugation of oligonucleotide and PLGA is shown in Figure 2. *c-myc* oligonucleotide terminally derivatized with a primary amine group was first dissolved in buffer solution. The solution was then added into DMSO containing preactivated PLGA with DCC and NHS. The volume ratio of aqueous to organic phase was adjusted to 1:10. The ODN/PLGA micelle was obtained and unreacted ODN was removed by dialysis against deionized water. The conjugation efficiency was determined by measuring the amount of ODN in ODN/PLGA micelles via an UV spectrophotometric method and was about 75%. In addition, aqueous gel permeation chromatography was used to confirm the formation of ODN/PLGA micelles (Figure 3). The micelles were eluted in a void volume fraction at ca. 4.3 min, while ODN was eluted at ca. 9.3 min. This GPC result indirectly proves the formation of hybrid DNA/polymer micelles in aqueous solution.

To determine the hydrodynamic volume of ODN/PLGA micelles, DLS was carried out as shown in Figure 4. It showed an effective diameter of 65.2 nm with a narrow size distribution. Atomic force microscopy was also used for the direct visualization of size and morphology of the ODN/PLGA micelles. In Figure 5, it can be seen that the micelles have a spherical shape with an average diameter of 80 nm. The morphological characters of ODN/PLGA micelles are quite similar to those of other reported synthetic polymeric micelles (26, 27). The diameter of micelles in the AFM image is slightly greater relative to that obtained from the DLS measurement. This was possibly caused by the change of micelle size during

drying the spherically shaped hydrated micelles onto the flat surface for the AFM sample preparation.

ODN/PLGA conjugate, consisting of a hydrophilic and negatively charged ODN segment and a hydrophobic PLGA segment, provided an opportunity to form self-assembled micellar structure in an aqueous phase. The conjugate has an amphiphatic structure like other synthetic diblock copolymers. The critical micelle concentration (cmc) of ODN/PLGA micelles was determined by using pyrene as a fluorescence probe, which partitioned into the hydrophobic PLGA core of micelles above the cmc value (21, 22). The cmc is an important physical property of the micelles and also indicates the stability of the micellar structure. Excitation and emission spectra of pyrene are shown at varying concentrations of ODN/PLGA conjugate (Figure 6). In the excitation spectra, with increasing concentration of ODN/PLGA conjugate, greater fluorescence intensity was observed at around 339 nm (Figure 6A). It was reported that the excitation intensity of pyrene in an aqueous phase is very small at 339 nm, but it increases dramatically when pyrene is partitioned into a hydrophobic environment (10, 21). This suggests that the ODN/PLGA conjugate spontaneously formed micelles in aqueous solution that enabled pyrene to partition into the hydrophobic core of micelles. With increasing the concentration of the ODN/PLGA conjugate, a red shift, a characteristic feature of pyrene excitation spectra, was also noticed. The (0,0) band of pyrene shifted from 334 to 339 nm upon the partition of pyrene into the hydrophobic core of the micelles. Fluorescence intensity ratio at the two excitation wavelengths (I_{339}/I_{334}) as a function of ODN/PLGA conjugate concentration was used to determine the cmc value of ODN/PLGA micelles according to the previous reports (10, 28). The cmc value determined by this method was about 5 mg/L as shown in Figure 7A. Figure 7B presents another method of determining the cmc value of micelles based on plotting the intensity ratio of I/III pyrene emission bands as a function of ODN/PLGA conjugate concentration. The cmc value of ODN/PLGA micelles was around 10 mg/L. Thus, an average cmc value of ODN/PLGA micelles calculated from the above two methods was determined as 7.5 mg/L. Although the cmc of ODN/PLGA micelles is higher than that of PEG-PLA diblock copolymer (cmc < 2 mg/L) (28), it is much lower than that of oligo(methyl methacrylate)–poly(acrylic acid) micelles (cmc = 100 mg/L) (10). It is conceivable that negatively charged ODN chains in the shell layer surrounding the PLGA core repel each other by charge-to-charge repulsions, thus increasing the cmc value compared to those of synthetic polymeric micelles containing PEG as a shell layer. This result indicates that the ODN/PLGA micelles are relatively stable compared to conventional diblock polymeric micelles.

ODN/PLGA micelles were subjected to incubation in aqueous solution to examine the release profile of ODN. Since the major constituent of the core region in ODN/PLGA micelles is a biodegradable polymer, it was expected that ODN could be solubilized in an aqueous phase by slow degradation of PLGA chain. Random hydrolytic scission of the PLGA backbone would produce water-soluble oligo(lactic-co-glycolic acid) having a molecular weight of less than 1000. In our previous reports, it was shown that constant release of drugs could be attained from nanoparticles or microspheres prepared by PLGA–drug conjugates (23, 24). It can be seen in Figure 8 that ODN/PLGA micelles exhibited a near zero-order release over 50 days without any burst. The release profile suggests that ODN was released from the polymeric

micelles by a degradation-controlled process of PLGA. Slow degradation of PLGA chains in the micelle core was likely to disintegrate the core structure of micelles, resulting in the release of ODN into the incubation medium. It should be noted that the released ODN fraction was not an intact ODN, but a mixture of ODN-oligo(lactic-co-glycolic acid) conjugates which were soluble in water. The sustained release profile of ODN from ODN/PLGA micelles was not similar to that from PLGA microspheres physically encapsulating ODN molecules (19). The ODN/PLGA micelles exhibited a burst-free zero order release, whereas ODN containing PLGA microspheres showed a nonzero order release pattern with an initial burst release upon incubation. In the case of PLGA

microspheres, a depot formulation for subcutaneous and intramuscular tissues, it is difficult to precisely control the release rate of hydrophilic drugs such as ODN over a desired period, because diffusion and erosion processes are combined in a complicated manner to affect the release profile (24). In contrast, ODN/PLGA micelles that can be injected intravenously control the ODN release rate depending on the molecular weight and composition of PLGA to be conjugated.

To visualize the endocytosis process of ODN/PLGA micelles into cells, a rhodamine-labeled sense ODN was hybridized with complementary antisense ODN present in the shell of micelles. This resulted in the micelle structure composed of double stranded ODN in the shell and PLGA in the core. These micelles were readily taken up by NIH3T3 mouse fibroblast cells as shown in Figure 9. It was found that the rhodamine labeled micelles were distributed over the entire intracellular space of the cytoplasm. In contrast, hybridized double stranded ODN labeled with rhodamine exhibited negligible fluorescence intensity within cells due to the limited passive diffusion of the ODN across the cell membrane. The confocal microscopic observation reveals that ODN can be

Figure 6. Excitation spectra of pyrene in the presence of ODN/PLGA conjugate at a fixed emission wavelength of 390 nm (A), and fluorescence emission spectra of pyrene in the presence of ODN/PLGA conjugate at a fixed excitation wavelength of 339 nm (B). The concentration of pyrene was 6×10^{-7} M. The concentration of ODN/PLGA conjugate was varied from 0.05 to 500 mg/mL.

effectively transported within cells because cells recognize the self-assembled ODN/PLGA micelles as particulates. Thus, the increased cellular uptake of ODN/PLGA micelles was likely due to an endocytosis process. Presumably, a fluid phase pinocytosis played a pivotal role in the intracellular transport process of ODN/PLGA micelles, because the ODN surface of micelles was highly negatively charged. Due to charge-to-charge repulsion between micelles and cells, adsorptive endocytosis might have a minor role in the transport process. The fact that some micelles were located in the nucleus (dark and round area inside cells) suggested that the micelles can also be delivered into the nucleus. It was reported that PEO–PBLA[poly(β -benzyl L-aspartate)]–FITC micelles could be delivered into the nucleus using endothelial monolayer cells (27). Our results suggest the possibility of ODN fragments intracellularly released from the micelles to enter the nucleus and act as an antisense agent, interacting with specific sequence in mRNA of

Figure 7. (A) The intensity ratio (339 nm/334 nm) of pyrene in the excitation spectra, (B) I/III band intensity ratio of pyrene as a function of logarithm of the ODN/PLGA conjugate concentration.

interest to block the expression of a target protein. The cellular uptake efficiency of the rhodamine-labeled ODN/PLGA micelles was measured by a flow cytometry analysis. In an arbitrarily selected gate ($50 < \text{FL2-H} < 350$), the cellular uptake efficiency of ODN/PLGA micelles against fibroblast cells was 68.3% compared to ODN itself that showed a negligible cellular uptake of $< 0.1\%$.

In conclusion, it was shown that a new class of hybrid micelles composed of DNA and biodegradable polymer was synthesized and characterized. The ODN/PLGA micelles were around 65.2 nm in diameter with a very narrow size distribution. ODN and PLGA constituted a

hydrophilic shell layer and a hydrophobic core in the micelle structure, respectively. The cmc value, very close to that of other synthetic diblock polymers, indicated that their self-assembling tendency in an aqueous phase was good enough to use as a stable delivery vehicle of ODN. The ODN/PLGA micelles released ODN in a sustained manner by controlled degradation of PLGA. They also exhibited enhanced cellular uptake within cells presumably by an endocytosis mechanism. The ODN/PLGA micelles can be potentially applied in therapeutic uses of inhibiting specific gene expression within cells. Therapeutic effects of ODN delivered in the form of ODN/PLGA micelles are to be evaluated in further studies using *in vitro* and *in vivo* models.

A bifunctional fusion enzyme system constructed by gene splicing is proposed as a new model to develop sequence biosensors, taking maltose biosensor as an example. The cDNA fragment of *Aspergillus niger* glucoamylase (E.C 3.2.1.3, GA) was fused to the 3' end of *Aspergillus niger* glucose oxidase (E.C 1.1.3.4, GOD) gene with the insertion of a flexible linker peptide [-(Ser-Gly)₅-] coding sequence. The fusion gene was cloned into the vector pPIC9 and expressed in *Pichia pastoris* GS115 under the control of the AOX1 promoter. It was found that a bifunctional hybrid protein with a molecular weight of 430 kDa was secreted after induction with methanol. The fusion enzyme GOD-(Ser-Gly)₅-GA (GLG) was purified using Q Sepharose Fast Flow ion-exchange chromatography. Kinetic analysis demonstrated that GLG retained the typical kinetic properties of both GA and GOD. After being immobilized on an aminosilanized glass slide through covalent bonding by glutaraldehyde, GLG showed much higher sequential catalytic efficiency than the mixture of separately expressed GA and GOD (GA/GOD). Maltose biosensors were fabricated with GLG and GA/GOD, respectively. The performance characteristics of the maltose biosensor with respect to reproducibility, signal level, and linearity were effectively improved by using the fusion enzyme. Our findings offer a basis for the development of other sequence biosensors.

INTRODUCTION

Sequence biosensors, which involve two or more enzymes for sequential catalysis, are widely used in the determination of biochemical substances, such as disaccharides (1–4), starch (5), inosine (6), total cholesterol (7), etc. Upon review of the abstract books of the World Congress on Biosensors of the past decade, it is found that about 30% of the reported biosensors are sequence biosensors. For a two-enzyme sequence biosensor, for example, the reaction in the enzyme membrane could be described as follows:

The substrate S is catalyzed by the first enzyme E1 to produce the intermediate product D in step I. D then serves as the substrate of the second enzyme E2 in step II, giving the final product P and byproduct B, which could be a chemical substance or a physical signal. S is then determined by measuring P or B through an appropriate transducer. However, the performance of the sequence biosensors is normally not as good as the sole enzyme biosensors. The main reason is that the existing

immobilization methods, cross-linking or covalent bonding in most cases, provide no warranty to prepare the high quality multiple enzyme membrane that is the key element of a biosensor. The quality of an enzyme membrane greatly depends on the amount, ratio, and distribution control of E1 and E2 in it. Failure of the control results in poor linearity, sensitivity, and reproducibility (also known as interchangeability); the last one is extremely important in the manufacture of disposable biosensors. Many investigators tried to optimize the enzyme ratio in the membrane simply by adjusting the enzyme loadings (1–7), but the results were not always satisfying because the immobilization efficiency of the enzymes may differ from each other under the same immobilization conditions. On the basis of the studies of protein molecular structure, here we proposed a fusion enzyme method by gene manipulation to solve the problems.

Fusion protein technique has been widely used in the field of molecular biology and biotechnology for a variety of applications. Proteins or peptides which bind to specific molecular structures, such as glutathione S-transferase (8), maltose-binding protein (9), polyhistidine (10), streptag (11), are often employed as fusion partners to facilitate expression, purification, or immobilization of recombinant proteins. Green fluorescent protein (GFP) has been fused to some proteins as a reporter for protein

Figure 1. Schematic process of the fusion enzyme formation.

expression and localization (12, 13). Recently, there is a growing interest in a fusion enzyme possessing more than one catalytic function. Though the fragility and complexity of protein structures largely limit the success for accomplishing functionally active fusion enzymes, a few artificial fusion enzymes have been reported to exhibit noticeable performance in a concerned fashion (14–19). To our knowledge, there is no report concerning fusion enzyme application in biosensors yet.

The maltose biosensor, which employs GA and GOD as recognition elements, is one of the typical sequence biosensors (20). GA catalyzes hydrolysis of maltose to produce glucose that serves as specific substrate of GOD. Maltose is thus quantified by electrochemical measurement of oxygen consumption or release of hydrogen peroxide. GA is a monomer with a molecular weight of 99–112 kDa (21), and GOD is a dimeric flavoprotein with a molecular weight ranging from 150 to 186 kDa (22). The fusion enzyme constructed through gene fusion consists of two molecules of GA and one molecule of GOD. Since little information is available for predicting the structure and function change of a fusion enzyme, there is high risk in construction of such a complex hybrid protein. To avoid failure, a flexible linker peptide [-(Ser-Gly)₅-] was inserted between GA and GOD. This was thought to aid the independent folding of the two components (23). Figure 1 shows the schematic formation of GLG. Theoretically, GA and GOD would be adjacently immobilized with constant ratio by the proposed method if the fusion enzyme were successfully expressed. Reaction kinetics and reproducibility of the sequence biosensor should be accordingly improved. Details are reported herein.

MATERIALS AND METHODS

Materials. Restriction enzymes, DNA polymerase, and T4 DNA ligase were obtained from Takara and Promega. Lyticase, bovine serum albumin (BSA), O-dianisidine, soluble starch, PEG3350, glucose oxidase, and glucoamylase were purchased from Sigma. Yeast nitrogen base (YNB) was from Difco. All single strand oligonucleotides used in this study were obtained from Sangon (Shanghai, China). DNA purification columns and Q Sepharose Fast Flow ion exchange chromatography were from Qiagen and Pharmacia, respectively. A stirred cell system used for protein concentration was purchased from Filtron. *Aspergillus niger* 9029 containing GOD encoding region and plasmid pRD112 containing *Aspergillus niger* GA cDNA fragment were from American Type Culture Collection (ATCC). The methylotrophic yeast *Pichia pastoris* GS115 and its expression vector pPIC9 were kindly donated by professor Sheng-Li Yang. *Escherichia coli* DH5 α was used for all bacterial transformations and plasmid propagations. All other reagents used were of analytical-reagent grade available.

Construction of Expression Vectors. All oligonucleotides were designed to incorporate proper restriction sites for cloning. Primers GODN-1 (5'-TACGTAAGCAATGGCATTGAAGCCAGC-3') and GODC-1 (5'-AAGCTTCATGGAAGCATAATCTTCCAAG-3'), spanning the *Aspergillus niger* GOD encoding gene, were synthesized to amplify GOD gene with *Aspergillus niger* genome as template. Restriction sites SnaB I and Hind III were introduced to the N- and C-terminal primers, respectively. The fragment was first cloned into pGEM-T vector, and correct orientation was identified by restriction analysis. The resulting plasmid pGEM-TGOD was digested by SnaB I and Not I, and GOD encoding fragment was recovered and inserted into the SnaB I/Not I site of pPIC9, yielding GOD expression vector pPICGOD. The GA expression vector pPICGA1 was similarly constructed by using primers GAN-1 (5'TACGTAGCGACCTTGGATTCTATGGTTGAG-3') and GAC-1 (5'GCGGCCGCGAAATGGATTGATTGTCACC-3') to amplify GA encoding sequence with plasmid pRD112 as template.

For the construction of GLG fusion gene, GOD gene was first amplified and cloned into pGEM-T vector as described above. The synthesized oligonucleotides containing [-(Ser-Gly)₅-] coding sequence (in bold) and an additional Hind III site (underlined) were annealed at 65 °C for 5 min to form a dsDNA fragment:

5'-AGCTC***AGCGGCTCTGGTTCCGGTAGCGGTTCCGGCAAGCTTAGCGGTGC**-3'
3'-**GTCGCCGAGACCAAGGCCATCGCCAAGGCCGTTCAATCGCCACGCCCGG**-5'

This resulting short fragment was inserted to replace the sequence between Hind III and Not I site in pGEM-TGOD, yielding plasmid pGEM-TGL. Using primers GAN-2 (5'-AAGCTTGCGACCTTGGATTTCATGGTTGAG-3') and GAC-1 (5'-GCGGCCGCGAAATGGATTGATTGTCACC-3'), the GA encoding sequence containing Hind III and Not I site at its N- and C-termini was amplified and cloned into pGEM-T vector. The GA fragment was obtained by digesting the resulting plasmid pGEM-TGA2 with Hind III and Not I and then ligated to pGEM-TGL linearized with the same restriction enzymes, yielding plasmid pGEM-TGLG. Because the Hind III restriction site immediately behind GOD gene had been silenced by a base mutation, which is indicated by an asterisk, in linker peptide coding sequence, the resulting plasmid pGEM-TGLG contains intact GLG encoding sequence. Plasmid pGEM-TGLG was digested with SnaB I and Not I, and the fragment encoding the fusion enzyme was cloned into the SnaB I/Not I site of pPIC9, yielding GLG fusion enzyme expression vector pPICGLG. The vectors, shown in Figure 2, contain expression cassettes of the 5'AOX1 promoter and 3' AOX1 transcription termination fragment for regulated transcription and a-factor signal peptide for secretion.

Preparation of *Aspergillus niger* Genomic DNA.

Aspergillus niger genomic DNA was prepared by a modified method of Zhu et al. (24). *Aspergillus niger* cells were grown in YEP medium (peptone 20 g, yeast extract 10 g, glucose 20 g per liter) for 2 days. The mycelia harvested by centrifugation were washed with 10 mL of extracting solution (100 mM Tris-HCL, 40 mM EDTA, pH 8.5) twice and then mixed with 10 mL of extracting solution, 2 mL of 10% SDS, and 6 mL of benzyl chloride. The mixture was incubated at 50 °C for 1 h to digest the cell walls. The reaction mixture was supplemented with 6 mL of 3 M sodium acetate (pH 5.2) and kept in ice-bath for about 15 min. The mixture was then centrifuged at 10000 rpm for 15 min. After the mixture was deproteinized with PCA (phenol-chloroform-isoamyl alcohol,

Figure 2. Constructed vectors for expression of (a) GOD, (b) GA, and (c) GLG fusion enzyme in *Pichia pastoris*.

25:24:1, vol/vol/vol), the DNA in the supernatant was precipitated with equal volume of 2-propanol.

Transformation of *Pichia pastoris*. pPICGOD, pPICGA1, and pPICGLG were digested with *Stu* I, and the linearized plasmid fragments containing GOD, GA, and GLG fusion gene, respectively, were introduced into GS115 as described previously (25). Integration of linearized pPICGOD, pPICGA1, and pPICGLG into the genome of GS115 was confirmed by PCR using yeast genomic DNA as templates.

Expression and Purification of the Yeast-Derived Enzymes. GOD, GA, and GLG were expressed respectively in *Pichia pastoris* under the control of AOX1 promoter. Yeast cells were cultured at 30 °C in 400 mL of MD medium (YNB 1.7 g, glucose 20 g, ammonium sulfate 5 g, and biotin 400 µg per liter) until the culture reached an optical density ($\lambda = 600$ nm) of 1.2–1.5. The cells were harvested by centrifugation and resuspended in 200 mL of MM medium (YNB 1.7 g, methanol 12 mL, ammonium sulfate 5 g, biotin 400 µg, and casamino acids 10 g per liter, pH 6.0) to induce the production of recombinant enzymes. After 5-day induction, the culture supernatant was concentrated to 30–40 mL using the FILTRON stirred cell system and dialyzed against 1000 mL of citrate buffer (pH 6.0, 0.02 M) overnight.

The yeast-derived enzymes were purified using Q Sepharose Fast Flow ion exchanger chromatography. Initially, the column was washed with 20% (v/v) ethanol and then equilibrated with citrate buffer (pH 6.0, 0.02 M). The sample solution was applied to the column, and unbound protein was washed out with equilibration buffer. The protein bound to the column was eluted using a salt gradient in the equilibration buffer. Fractions containing enzyme activity were pooled and concentrated using a FILTRON stirred cell system. Homogeneity of the purified enzymes was checked by SDS–PAGE (10%), and a Bio-Rad protein assay kit was used to determine the protein concentration of each sample.

Enzyme Assays. For all enzyme assays one unit of activity was defined as the amount of enzyme that generated 1 µM of product per minute. GOD activity was determined using fresh *Aspergillus niger* GOD (Sigma) as standard. Assays were performed according to the method described by Frederick et al. (26). The steady-state kinetic parameters of purified GOD and GLG to glucose at pH 5.6, 30 °C were calculated by assaying initial velocities over a range of glucose concentrations from 10 mM to 100 mM under oxygen saturation condi-

tion. Lineweaver–Burk plots were used to determine the parameters on the assumption that simple Michaelis–Menten kinetics was followed.

GA was assayed by measuring the amount of glucose released from starch hydrolysis using 3,5-dinitrosalicylic acid (DNS) method (27). When assaying GA activity of the fusion enzyme, nitrogen bubbling was employed to remove oxygen from the reaction system, thereby blocking GOD activity. For determination of kinetic parameters, initial rates of starch hydrolysis catalyzed by yeast-derived GA and GLG were determined using up to 15 substrate concentrations from 0.2 mg/mL to 20 mg/mL.

Enzyme Immobilization. Immobilization of yeast-derived enzymes was carried out by a modified method of Fonseca (28). A glass slide with desired well assay was cleaned thoroughly and then coupled to γ -(aminopropyl)-triethoxysilane in a toluene solution. The glass slide was soaked in 100 mL of 2.5% (v/v) glutaraldehyde solution in phosphate buffer (pH 7.0, 0.05 M) for about 1 h at room temperature. The glutaraldehyde-activated slide was washed five times with phosphate buffer to remove unreacted glutaraldehyde. 5 µL of 50 µg/mL GLG fusion enzyme and a mixture of yeast-derived GOD and GA equivalent to corresponding enzyme activities of GLG (GA/GOD) were applied to the wells of the glass slide and incubated at room temperature for 4 h. Unbound enzymes were removed by washing thoroughly with phosphate buffer containing 0.05% Tween-20 and 0.5 M NaCl. Finally, 5 µL of substrate solution containing 4 mg/mL soluble starch, 0.01 mg/mL horseradish peroxidase, and 0.1 mg/mL *o*-dianisidine were added. Color change of the wells was observed and compared.

Preparation of the Enzyme Electrodes. The enzyme membranes were prepared by cross-linking method using glutaraldehyde as described in our previous report (29). Typically, 3 µL of 20% (w/v) BSA, 4 µL of 2.5% (v/v) glutaraldehyde solution, and 20 µL of enzyme solution were dropped onto a porous Teflon membrane, followed immediately by mixing and spreading on 7 mm diameter circular area with a tiny glass rod. Cross-linking reaction was allowed to perform for 1 h at room temperature. The enzyme membrane was then formed on the Teflon membrane. The enzyme constitutions in the electrodes were 18U of GOD for GOD electrode, 18U of GOD and 10U of GA for both GA/GOD electrode and GLG electrode.

The enzyme membrane was covered with a piece of nylon gauze and fixed on the tip of an oxygen electrode with an 'O' ring. The enzyme electrodes were soaked in

Figure 3. SDS-PAGE analysis of the total secreted proteins of *Pichia pastoris* cells. citrate buffer (pH 4.8, 0.02 M), which was also used to prepare maltose solution, overnight to wash out unimmobilized enzymes and activated in 40 mM maltose solution at least 1 h before use.

Maltose Measurement. Maltose was measured using enzyme electrodes in combination with a flow injection analysis system (30). The working system was mainly composed of the enzyme electrode, amplified and digital display, peristaltic pump, injection unit, tubing system with citrate buffer (pH 4.8, 0.02 M) as carrying stream, and a printer. The carrier stream was pumped through the flow line at a flow rate of 2.0 mL/min, and 25 μ L of sample solution was injected into the flow stream when the background current was stabilized. When the sample flowed through the surfaces of the electrodes, consumption of oxygen was measured through current drop.

RESULTS

Expression of GOD, GA, and GLG in *Pichia pastoris*. As a preliminary experiment, the expression vectors were transformed into host yeast separately. Positive transformants were confirmed by PCR analysis of the yeast genome. Expression of the recombinant proteins was induced by methanol. Enzyme assays indicated that pPICGOD, pPICGA1, and pPICGLG directed separately the synthesis and secretion of active GOD, GA, and GLG displaying both GOD and GA activity. The total proteins in the culture supernatant were analyzed by SDS-PAGE (Figure 3). It was found that GOD and GA secreted from *Pichia pastoris* migrated more slowly than the enzymes from *Aspergillus niger*. Yeast-derived GA and GOD monomer were visualized to have molecular weights of about 135 and 85 kDa, respectively. The difference of the molecular weight between proteins expressed in *Aspergillus niger* and *Pichia pastoris* was also observed by other investigators (26, 31). They concluded that this was due to yeast-derived proteins tending to show substantially more N-linked carbohydrate than *Aspergillus niger* proteins. The protein band corresponding to GLG monomer on SDS-PAGE was observed at approximately 215 kDa. The molecular weight of GLG monomer agreed well with the sum of those of GA and GOD monomer. The native GLG which consists of two GA monomer and one GOD dimer has a molecular weight up to 430 kDa.

To optimize the production conditions, effects of pH and methanol concentration on the yield of GLG were studied. Although *Pichia pastoris* cells grew normally in all induction conditions tested, the optimal conditions for

production of GLG were around 1.2% methanol added once a day and initial pH 5–6 (Figure 4). In addition, the activity of GLG did not increase appreciably upon induction for periods longer than 5 days in all shake flask studies. Hence induction in pH 6, MM medium for 5 days with daily addition of 1.2% methanol was chosen to produce GOD, GA, and GLG for further studies.

Purification of the Yeast-Derived Enzymes. After removal of the *Pichia pastoris* cells from the fermentation culture, the supernatant was concentrated by ultrafiltration and dialyzed to remove salt. GOD, GA, and GLG were purified using anion-exchange chromatography on a Q Sepharose Fast Flow column. Elution profile of all yeast-derived enzymes is shown in Figure 5a. It is clear that GOD, GA, and GLG require different elution time and ionic strength of the elution buffer. GOD was eluted from the column by using 0–0.1 M NaCl gradient solution, while GA and GLG were eluted by a NaCl gradient of 0–0.4 M. Among these enzymes, the fusion enzyme required the highest ionic strength. The purity of the proteins was checked by SDS-PAGE (Figure 5b).

Kinetic Properties of the GLG Fusion Enzyme.

To examine the effect of protein fusion on the kinetic properties of both GOD and GA moieties of the fusion enzyme, the kinetic parameters of GLG were compared with those of individual enzymes from either *Pichia pastoris* or *Aspergillus niger*. Table 1 summarizes the kinetic constants of all enzymes studied here. GOD and GA secreted from *Pichia pastoris* had very high catalytic activity and showed about 1.6-fold and 2.0-fold increase of specific activity over that of the *Aspergillus niger* GOD and GA, respectively. Compared with the values of 426.62 U/mg protein and 238.34 U/mg protein measured for yeast-derived GOD and GA, the specific activities of the fusion enzyme toward glucose and soluble starch were determined to be 195.21 U and 116.56 U, respectively, per mg protein, showing that the catalytic activities of the fusion enzyme were successfully maintained. The k_{cat} and K_m of GLG to glucose were similar to the values determined for the yeast-derived GOD. The k_{cat} of GLG to soluble starch was 2.3 times as high as that of the yeast-derived GA due to the fact that 1 mol of GLG consists of 2 mol of GA. The higher turnover number of the fusion enzyme to soluble starch is thought to be advantageous for the sequential catalysis occurred in maltose biosensor. Compared with GOD and GA from *Aspergillus niger*, the yeast-derived GOD, GA, and GLG showed slightly lower affinity for substrates. However, the k_{cat} and k_{cat}/K_m determined for the yeast-derived enzymes were obviously higher than those of *Aspergillus niger* enzymes.

Enzyme Immobilization. Cross-linking and covalent bonding using glutaraldehyde are the most widely used enzyme immobilization methods. Immobilization of the yeast-derived enzymes was performed by depositing GLG and GA/GOD onto the glutaraldehyde-activated glass slide, respectively, with four duplicates. The immobilization profile would be a direct indication of whether the fusion enzyme had benefited the enzyme immobilization or not if so to what extent. After adding substrate solution containing soluble starch, horseradish peroxidase and o-dianisidine, the slide was incubated at 30 $^{\circ}$ C for more than 1 h to develop brown color, which in fact is a measure of the overall reaction efficiency catalyzed sequentially by GA and GOD. Relative recovery activities of GLG and GA/GOD were evaluated according to the darkness of the color spots. It was found that wells with immobilized GLG developed color much faster than those with immobilized GA/GOD. Visible color change appeared

Table 1. Kinetic Parameters of Native and Yeast-derived Enzymes

enzymes	specific activity (U/mg protein)	K_m (mM for GOD, mg/mL for GA)	k_{cat} (s^{-1})	k_{cat}/K_m ($s^{-1} mM^{-1}$ for GOD, $s^{-1} mL \cdot mg^{-1}$ for GA)
<i>A. niger</i> GOD	266.31	33.44	2303.56	68.89
<i>P. pastoris</i> GOD	426.62	38.25	3492.66	91.31
<i>A. niger</i> GA	118.75	1.347	557.33	413.76
<i>P. pastoris</i> GA	238.34	1.703	1123.71	659.84
GOD of GLG	195.21	37.16	3314.13	89.19
GA of GLG	116.56	1.774	2601.33 ^a	1466.36

^a The k_{cat} value was calculated per GLG, which contains two GA active sites.

within 1 h for the fusion enzyme, but only a faint color developed in the spots with immobilized GA/GOD even after 5 h incubation (Figure 6). The result demonstrates that GLG fusion enzyme is obviously superior to GA/GOD in terms of immobilization efficiency. No detectable signal was observed in the spots of negative controls where the yeast-derived GA and GOD were immobilized individually on the glass chip with the same procedure.

Evaluation of the Enzyme Electrodes by Measuring Maltose. The responses of the three kinds of enzyme electrodes to maltose solution were investigated. As shown in Figure 7, the GOD electrode did not response to maltose, while the response values of GLG electrode and GA/GOD electrode were proportional to maltose concentration. To the same maltose solution, the response signal of GLG electrode is higher than that of GA/GOD electrode. A linear response range up to 40 mM was

Figure 6. Immobilization of the enzymes on a glass chip. The spots that developed brown show positive reactions, others show negative reactions, and each loaded four duplicates. Experimental detail is in the text. (A) denotes the detection of GLG; (B) denotes the detection of GOD; (C) denotes the detection of GA; (D) denotes the detection of the mixture of GA and GOD (GA/GOD).

obtained for GLG electrode and 30 mM for GA/GOD electrode. The increased signal level and extended measuring linearity of the GLG system should be attributed to the higher immobilization efficiency of GA and GOD as well as their proximity effect in the enzyme membrane.

To investigate the precision and reproducibility of the electrodes, both GLG electrode and GA/GOD electrode were fabricated with six repeats, and each electrode was used to measure 10 mM maltose solution five times in succession. Good precision was obtained for both GLG electrode and GA/GOD electrode. The variation coefficients of the response values varied from 0.6% to 4.2%

Figure 7. Responses of the enzyme electrodes to maltose.

Table 2. Analysis of Reproducibility of Enzyme Membranes

electrode	the responses of six enzyme membrane ^a (nA)	variation coeff of the enzyme membranes (%)
GA/GOD	0.346, 0.489, 0.401, 0.395, 0.547, 0.528	18.1
GLG	0.527, 0.613, 0.583, 0.645, 0.505, 0.577	9.1

for six GLG electrodes and from 1.3% to 5.4% for six GA/GOD electrodes. However, the reproducibility, which represents the interchangeability between enzyme membranes, of GLG membranes was much better than that of GA/GOD membranes. Compared with the values of 18.1% calculated for GA/GOD membranes, the variation coefficient of GLG membranes was determined to be 9.1% (Table 2).

DISCUSSION

The large hybrid fusion enzyme GLG was successfully constructed in this study. The linker peptide composed of serine and glycine was designed to minimize the steric hindrance between GA and GOD so as to provide enough space for both proteins to remain in native conformation. This was indirectly proved by comparison of its catalytic activities with the native GA and GOD expressed in the same host. The same linker had been successfully used in our previous work where the alkaline phosphate was actively fused to strep-tag through it (32). Our observations suggest that the linker peptide play an important role in the successful expression of the fusion enzyme. The resulting fusion enzyme GLG maintained typical characteristics of both GA and GOD. No any detectable activity of the fusion enzyme was obtained at cellular

level without the linker insertion (data not shown). On the other hand, it is interesting that this heterogeneous hybrid protein up to 430 kDa can still correctly fold in yeast cell and secrete. The mechanism is worth studying.

For process development, GOD and GA have also been separately expressed in the same host. It is presumed that all yeast-derived enzymes here were hyperglycosylated according to their lower electrophoretic mobility (Figures 3, 5b). Yeast is known to hyperglycosylate some secreted foreign protein, especially those using α -Factor signal leader for secretion (26, 31). However, at present the reason for the differential glycosylation of protein between yeast and *Aspergillus niger* is still not clear. A detailed kinetic comparison of the various enzymes demonstrated that the yeast-derived GOD and GA showed increased specific activity and catalytic efficiency than the *Aspergillus niger* enzymes.

In the fabrication of enzyme sensors, the immobilization of enzymes on the electrode surface is a crucially important step, which determines the performance characteristics of the biosensors. Sequence biosensors require coimmobilization of more than one enzyme in the same membrane. The discrepancy of immobilization efficiency between enzymes, without doubt, will affect the performance of the biosensor, especially in case one enzyme having relatively poor immobilization efficiency. The fusion enzyme offers several advantages over individually coimmobilized enzymes. First, it provides fixed molecular ratio of immobilized enzymes, ensuring the desired activity of the enzyme membrane. The compositions and structures of both *Aspergillus niger* GA and GOD were resolved and released (26, 33–36). There are 13 and 30 lysine residues in the structures of GA and GOD, respectively. Most of them are located on the surface of the structures (Figure 8). Lysine provides an amino group for coupling to glutaraldehyde, a bifunctional reagent for cross-linking reaction or covalent bonding. It clearly demonstrates why GA is more difficult to be immobilized than GOD using glutaraldehyde. In case of GLG, neither GA nor GOD could escape whichever reacted with the bifunctional reagent during immobilization process. This assumption has been proved by the evidence shown in Figure 6, where the recovery activity of the sequence reaction catalyzed by GLG was much higher than that of GA/GOD, despite of the same enzyme activity loading in both cases. Second, the ratio control of GA and GOD activity greatly improved the homogeneity of the enzyme membranes from batch to batch of manufacture (Table 2), which is one of the main factors affecting the quality of enzyme sensor. Poor homogeneity results in difficulty of interchangeability between the enzyme membranes. It is, as mentioned above, the major premise to develop

Figure 8. The crystal structures of (a) granular starch binding domain of *Aspergillus niger* GA bound to β -cyclodextrin (Sorimachi et al.) and (b) *Aspergillus niger* GOD subunit (Hecht et al.). Lysines are shown in space-filling models.

the disposable biosensors where no calibration step can be carried out when in use. Similar requirement can be met in construction of other biomolecular devices, such as protein chips. Third, the distance between the active centers of the fused enzymes is shortened and controlled, which makes the intermediate produced by the first enzyme readily available to the second enzyme, leading to a faster reaction rate and thus higher response signal or sensitivity of the biosensor (Figure 7). It is argued that fusion enzymes may not function at their highest active level because the optimal working conditions for the enzymes to be fused may differ from each other. The working condition, however, could be compromised if there is no better choice.

Our findings suggest that GA and GOD can be effectively used as fusion partners to construct a genetically artificial fusion enzyme despite their complex tertiary structure. And, in conclusion, the method proposed in this study offers a basis to develop high quality sequence biosensors as well as other sequential enzyme reaction applications.

Precise control of the size and structure is one critical design parameter of micellar systems for drug delivery applications. To control the size of self-aggregates, chitosan was depolymerized with various amounts of sodium nitrite, and hydrophobically modified with deoxycholic acid to form self-aggregates in aqueous media. Formation and physicochemical characteristics of size-controlled self-aggregates were investigated using dynamic light scattering, fluorescence spectroscopy, and computer simulation method. The size of self-aggregates varied in the range of 130–300 nm in diameter, and their structures were found to depend strongly on the molecular weight of chitosan ranging from 5 to 200 kDa. Due to the chain rigidity of chitosan molecule, the structure of self-aggregates was suggested to be a cylindrical bamboolike structure when the molecular weight of chitosan was larger than 40 kDa, which might form a very poor spherical form of a birdnestlike structure. To explore the potential applications of self-aggregates as a gene delivery carrier, complexes between chitosan self-aggregates and plasmid DNA were prepared and confirmed by measuring the fluorescence intensity of ethidium bromide and electrophoresis on agarose gels. The complex formation had strong dependency on the size and structure of chitosan self-aggregates and significantly influenced the transfection efficiency of COS-1 cells (up to a factor of 10). This approach to control the size and structure of chitosan-derived self-aggregates may find a wide range of applications in gene delivery as well as general drug delivery applications.

INTRODUCTION

Colloidal systems have found numerous applications as promising delivery vehicles of drugs, proteins, antigens, and genes due to their reduced toxic side effect and improvement of therapeutic effect (1, 2). Polymeric self-assembly systems, as one of colloidal systems, have been widely investigated in terms of their micellar behavior as well as their application to the fields of biotechnology and pharmaceuticals (3–5). Polymeric self-assemblies are usually formed from block copolymers (6–8) or hydrophobically modified water-soluble polymers (9–11). It may be fascinating to develop polymeric self-aggregates from hydrophobically modified water-soluble polymers rather than block copolymers, as it is generally difficult to synthesize new types of block copolymers.

One attractive utilization of polymeric self-aggregates to date is as a gene delivery vehicle in order to cure many hereditary diseases and treat acquired disease resulting from either multigenetic disorders or foreign viral genes

(12, 13). Viral delivery systems have many advantages for gene delivery due to their high efficiency and wide range of cell targets. However, they have some drawbacks of immune responses and oncogenic effect in vivo. Non-viral delivery systems including cationic liposomes and polymeric systems have therefore been extensively investigated (14–18). Cationic liposomes are widely applicable to many animal cells due to their nonspecific ionic interaction and low toxicity. However, due to the poor stability in vivo of cationic liposomes, many polymeric systems have been studied as alternatives for in vivo and in vitro applications (16–18).

Chitosan is generally considered biocompatible, biodegradable, and of low toxicity (19). In addition, chitosan has cationic characters even in neutral condition to form complexes with negatively charged plasmid DNA, and promotes cell transfection (20–23). We have previously demonstrated that self-aggregated nanoparticles, prepared from hydrophobically modified chitosan, could find a potential application as a gene delivery vehicle, due to the controlled complex formation with plasmid DNA (24). However, the size of the chitosan self-aggregates was not precisely controlled by varying the degree of substitution, pH, and/or ionic strength of the medium, probably due to the rigidity of chitosan backbone chain, and their diameter was in the range of 160–180 nm (10, 24). To be used as a delivery vehicle, the size of self-aggregates should be more precisely controlled, and their structure should be further investigated.

¹ Abbreviations used: DAMC, deoxycholic acid-modified chitosan; DPH, 1,6-diphenyl-1,3,5-hexatriene; DS, degree of substitution; EDC, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide; EtBr, ethidium bromide; PEO, poly(ethylene glycol).

It is thus the aim of this paper to control the size and its distribution of self-aggregates of deoxycholic acid-modified chitosan (DAMC) and to verify their structure in order to utilize as a gene delivery carrier. In brief, chitosan was depolymerized using sodium nitrite and modified with deoxycholic acid in the presence of carbodiimide. We hypothesized that the chitosan derivatives could form self-aggregates with different sizes and structures, depending on the molecular weight of chitosan. Micellar characteristics were investigated by fluorescence spectroscopy, dynamic light scattering method, and computer simulation. In addition, the chitosan self-aggregates were considered to form complexes with plasmid DNA by ionic interactions. Complexation behavior between plasmid DNA and chitosan self-aggregates, as well as their transfection activity, were investigated and interpreted in relation to their micellar structures.

MATERIALS AND METHODS

Materials. Chitosan ($M_w = 1.0 \times 10^6$, degree of deacetylation = 80%) was purchased from Fluka (Milwaukee, WI). Sodium nitrite, deoxycholic acid, ethidium bromide, and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) were purchased from Sigma (St. Louis, MO) and used without further purification. Pyrene and 1,6-diphenyl-1,3,5-hexatriene (DPH) were purchased from Aldrich (St. Louis, MO) and used as a fluorescence probe. DNA molecular weight marker II (λ DNA/Hind III digested) was purchased from Boehringer Mannheim GmbH (Germany). The water was purified by distillation, deionization, and reverse osmosis (MilliQ Plus).

Depolymerization of Chitosan. Chitosan was dissolved in a 2% acetic acid solution and treated for 3 h at room temperature with different amounts of sodium nitrite in a range from 0.01 to 0.25 mol/mol glucosamine residues. The resulting solution was neutralized with a 1.0 N sodium hydroxide solution, precipitated with acetone, and dried in a vacuum at room temperature. The molecular weight of the depolymerized chitosan was determined by gel permeation chromatography (GPC) through Ultrahydrogel linear columns (Waters, USA) at a flow rate of 1.0 mL/min. A buffer solution of 0.15 M acetic acid and 0.5 M sodium acetate was used as a mobile phase. Pullulan (Showa, Japan) was used as a molecular weight standard. Degree of deacetylation of chitosan was determined by the titration method as previously reported (25).

Synthesis of Deoxycholic Acid-Modified Chitosan (DAMC). The depolymerized chitosan was hydrophobically modified with deoxycholic acid (0.05–0.34 mol/mol glucosamine residues of chitosan) in the presence of EDC for 24 h at room temperature (24). The reaction mixture was poured into a methanol/ammonia solution (7/3, v/v). The precipitates were filtered off, washed thoroughly with methanol and ether, and then followed by vacuum-drying at room temperature. The degree of substitution, defined as the number of deoxycholic acid groups per 100 anhydroglucose units of chitosan, was determined by calculation of the C/N ratio from an elemental analyzer (LECO). Infrared spectra of chitosan derivatives were monitored on an FT-IR spectrophotometer (resolution, 4 cm^{-1} ; 32 scans; MIDAC) to confirm the conjugation reaction between chitosan and deoxycholic acid (KBr pellet: 1655 (NHC=O) cm^{-1}).

Preparation of DAMC Self-Aggregates. DAMC was suspended in a phosphate-buffered saline (PBS) solution (pH 7.2) under gentle shaking at 37 °C for 48 h, followed by sonication using a probe type sonifier (Sigma Ultra-

sonic Processor, GEX-600) at 30 W for 2 min. The sonication was repeated three times to get an optically clear solution. To inhibit the heat build-up during sonication, the pulse function was used (pulse on, 5.0 s; pulse off, 1.0 s) (10).

Fluorescence Measurements. Fluorescence spectra of DAMC self-aggregate solutions, which contained 6.0×10^{-7} M of pyrene as a probe, were obtained with an ISS K2 fluorometer (ISS, Champaign, IL). For the measurement of the intensity ratio of the first and the third highest energy bands in the pyrene emission spectra, the slit openings were set at 1 mm (excitation) and 0.5 mm (emission). The excitation wavelength (λ_{ex}) was 336 nm, and the spectra were accumulated with an integration time of 5 s/nm.

Assuming simple partition equilibrium, the equilibrium constant (K_v) for partitioning of pyrene between water and micellar phases was calculated according to the method of Wilhelm et al. (26)

$$\frac{F - F_{\min}}{F_{\max} - F} = \frac{K_v x c}{1000 \rho} \quad (1)$$

where F is the intensity ratio ($= I_{336}/I_{333}$) from the fluorescence excitation spectrum at the intermediate concentration range of DAMC ($\lambda_{\text{em}} = 390$ nm), $F_{\min}$ and $F_{\max}$ are the intensity ratios at low concentration and at high concentration, respectively, x is the weight fraction of deoxycholic acid in DAMC, and ρ is the density of the inner core of self-aggregates that is assumed to be the same value of deoxycholic acid in water ($= 1.31$ g/mL) (27).

Fluorescence anisotropy of the DAMC self-aggregate solution containing DPH (2.1×10^{-6} M) was measured using L-format geometry of detection ($\lambda_{\text{ex}} = 360$ nm, $\lambda_{\text{em}} = 430$ nm). Fluorescence anisotropy (r) was calculated from the following relationship.

$$r = \frac{(I_{\text{VV}} - I_{\text{VV}}^s) - G(I_{\text{VH}} - I_{\text{VH}}^s)}{(I_{\text{VV}} - I_{\text{VV}}^s) + 2G(I_{\text{VH}} - I_{\text{VH}}^s)} \quad (2)$$

where I^s is the contribution of scattered light from a sample solution in the absence of DPH, $G (= I_{\text{VH}}/I_{\text{HH}})$ is an instrumental correction factor, and I_{VV} , I_{VH} , I_{HV} , and I_{HH} correspond to the resultant emission intensity polarized in the vertical or the horizontal detection planes (the second subscript) when excited with vertically or horizontally polarized light (the first subscript) (28).

Dynamic Light-Scattering Measurement. An argon ion laser (Lexel Laser Model 95) was operated at a wavelength of 488 nm. The intensity autocorrelation was measured with a Brookhaven BI-9000AT digital autocorrelator ($\theta = 90^\circ$, $T = 25 \pm 0.1$ °C). A nonlinear regularized inverse Laplace transformation technique (CONTIN) was used to obtain the distribution of decay function. Mean diameter (d) was calculated from the Stokes–Einstein equation.

Computer Simulation. Based on the experimentally observed data, the structures of native chitosan, DAMC, and DAMC self-aggregate were simulated using Cerius2 programs that contain the modules such as polymer builder, open force field, energy minimizer, and molecular dynamics (MSI, San Diego, CA). Chitosan and DAMC were initially created on a computer and energy-minimized using the modules of polymer builder and energy minimizer. The micellar structure of DAMC was obtained from the molecular dynamics simulation method

for 20 ps (20000 steps $\times$ 0.001 ps/step) using Dreiding 2.21 force field and Universal 1.02 force field.

Plasmid DNA. The pCMV-Luc+, obtained from the plasmid pGL3 (Promega, Madison, WI) using Xba I and Hind III, consists of a cytosolic form of *Photinus pyralis* luciferase cDNA (29). The plasmid was amplified in the *Escherichia coli* DH5- α strain and purified by a Qiagen kit (Chatsworth, CA) according to the manufacturer's instruction. DNA purity was determined by measuring the optical density (OD), and DNA with $OD_{260}/OD_{280} \geq 1.8$ was used.

Characterization of DAMC Self-Aggregate/DNA Complexes. Complexes were prepared by the addition of DNA solution (0.1 μ g/mL) to DAMC self-aggregate solution (1 mg/mL) at different charge ratios, following incubation for 20 min at room temperature. The charge ratio ($\pm$) was defined as the ratio of the number of amino groups in DAMC self-aggregates to the number of phosphate groups in DNA. Both DNA and DAMC self-aggregate solutions were prepared in PBS solution, and the final volume of the complexes was 25 μ m. Complex formation between plasmid DNA and DAMC self-aggregates was confirmed by electrophoresis using agarose gels as previously reported (24). The DAMC self-aggregate/DNA complexes were further characterized by fluorescence spectroscopy. Briefly, the complex solution containing EtBr (2 nmol) was incubated for 10 min, and the fluorescence intensity was measured using the ISS K2 fluorometer at $\lambda_{ex} = 488$ nm (slit width 2.0 mm) and $\lambda_{em} = 594$ nm (slit width 1.0 mm) ($n = 3$).

Cell Culture and In Vitro Transfection. A simian kidney cell line (COS-1) was cultured in the Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS) at 37 $^{\circ}$ C in a humidified 5% carbon dioxide incubator. Cells were seeded at 2×10^4 cells per well of a 96-well plate 12 h before transfection. Cells were 70–80% confluent at the time of transfection. The plasmid of pCMV-Luc+ (0.5 μ g) was mixed with the DAMC self-aggregate solution at a charge ratio of 4 in the absence of serum and added to the single well. Naked DNA was also used as a control. After 1 h incubation, the cells were washed with serum-free DMEM to remove the remaining complexes, fed again with fresh media containing FBS, and cultured for 24 h after transfection. The transfected cells were assayed for luciferase activity using a Promega kit (Madison, WI) with a luminometer (Turner Designs Luminometer Model TD-20/20, Promega). The luciferase content was calculated from the relative light units using a standard curve obtained from the purified firefly luciferase (Sigma). The background level of luciferase activity in untreated cell lysates was measured from the organs of mice without any treatment and found to be negligible.

RESULTS AND DISCUSSION

Depolymerization and Hydrophobic Modification of Chitosan. Chitosan was depolymerized using sodium nitrite to obtain samples with various molecular weights. The depolymerization reaction was selective and could be easily controlled by adjusting the amount of sodium nitrite used in the reaction. The weight average molecular weights of the depolymerized chitosans, determined by GPC, were in the range of 5–200 kDa and the polydispersity of about 2. However, their degree of deacetylation was not significantly affected by the depolymerization reaction in this range of molecular weights (Figure 1).

The depolymerized chitosan was hydrophobically modified with deoxycholic acid in the presence of EDC, which

is known to promote amide linkage formation between amine and carboxylic acid (30). EDC initially reacts with the carboxyl group of deoxycholic acid to form an active ester intermediate, and the intermediate readily reacts with a primary amine of chitosan as a result of amide linkage formation (Figure 2). The characteristic peak at 1655 cm^{-1} from FT-IR spectra confirmed the amide bond formation between chitosan and deoxycholic acid (data not shown). The degree of substitution (DS) increased with increasing mole ratio of deoxycholic acid and was in the range from 2 to 10. The chitosan derivatives with DS = 6 of various molecular weights were used in this study in order to investigate the effect of the molecular size on self-aggregate formation in aqueous media. The number following the sample code DAMC in Table 1 indicates the molecular weight of chitosan.

Characteristics of DAMC Self-Aggregates. The self-aggregation behavior of DAMC in aqueous media was initially investigated by a fluorometry in the presence of

Figure 3. Changes of the anisotropy value (r) for DPH in the presence of DAMC self-aggregates in PBS solution (■, DAMC5k; ●, DAMC25k; ▲, DAMC40k; ▼, DAMC200k).

pyrene as a fluorescent probe. Pyrene is poorly soluble in water, but strongly emits when the self-aggregates or other hydrophobic microdomains are formed in an aqueous solution, as it preferably lies close to (or inside) the microdomains (28). The intensity of the third highest vibrational band as well as the total emission intensity of pyrene started to drastically increase over a certain concentration of DAMC, which was defined as a critical aggregation concentration (cac). The cac was determined from the intensity ratio (I_1/I_3) of the first (372 nm) and the third (383 nm) highest energy band in the emission spectra of pyrene. The cac values of DAMC self-aggregates were in the range of $1.2\text{--}6.7 \times 10^{-2}$ mg/mL, depending on the molecular weight of chitosan (Table 1). Since the unmodified chitosan did not form self-aggregates, it was used as a control.

Polarity of the inner core of self-organized structure is one important factor in its application as a drug delivery vehicle. Polarity of DAMC self-aggregates can be expressed with an equilibrium constant (K_v) of pyrene. In principle, the higher K_v value implies the lower polarity. So, the K_v value increasing with the molecular weight of chitosan indicates the existence of less polar microdomains inside the self-aggregates (Table 1).

Microviscosity, defined as viscosity of the inner core of self-aggregates, can be determined by measuring the molecular anisotropy (r) resulting from the restricted rotational motion of DPH. The higher r value with increasing molecular weight of chitosan indicates the enhanced rigidity of hydrophobic domain of DAMC self-aggregates (Table 1). The mean diameter of DAMC self-aggregate was mainly dependent on the molecular weight of chitosan and was in the range of 130–300 nm with unimodal size distribution (Table 1).

Structure of DAMC Self-Aggregates. Figure 3 represents the anisotropy value (r) of DPH measured at different concentrations of DAMC self-aggregates with different molecular weights. The r values abruptly increased near cac , probably due to the dye-induced self-aggregate formation, and the values remained almost constant above cac independent of the self-aggregate concentration, except for DAMC200k. One interesting finding in this experiment is the increased r value of DAMC200k with increasing micelle concentrations. This might indicate a transition of self-aggregate shape from bamboo-like cylindrical structure to a poorly organized birdnest-like structure. This could possibly be the case

because the DAMC molecules have chain rigidity to a great extent, arising from the rigidity of parent chitosan and bulky deoxycholic acid groups. On the basis of the assumption that a single chain forms a conventional structure of a self-aggregate (i.e., spherical unimer), the diameter of an expected self-aggregate (d_{cal}) can be calculated by considering the length of monomer unit of chitosan (ca. 4 Å) and the molecular weight of chitosan. Therefore, the ratio between the measured and calculated diameter of self-aggregates (d_{real}/d_{cal}) could suggest the minimum aggregation number necessary to assemble a self-aggregate of spherical shape. Table 1 shows the existence of the calculated aggregation number (d_{real}/d_{cal}), which implies the formation of nonspherical self-aggregates above molecular weight of 40 kDa. Computer-simulated structure of chitosan and DAMC also supports the previous results. Indeed, Figure 4 shows that it is very difficult for the chitosan molecule itself to coil due to its chain rigidity (Figure 4a). When chitosan is modified with deoxycholic acid, DAMC chains tend to kink due to some intramolecular interaction at low concentration (Figure 4b). However, when DAMC concentrations increase, DAMC chains tend to be straightened due to the intermolecular interactions with concurrent self-association of deoxycholic acid units of neighboring DAMC chains (Figures 4c and 4d). By this way, the DAMC self-aggregates may form a cylindrical bamboo-like structure, particularly when the molecular weight of chitosan backbone in DAMC is higher than 40 kDa. Even when the molecular weight is lower than 40 kDa, the micellar structure of DAMC may not be in the form of perfect sphere that has been commonly reported for the self-aggregates of poly(ethylene oxide) (PEO) based diblock copolymer that has high chain flexibility. This might be attributed to the rigidity of chitosan chains, likely due to the 1,4- β -glycosidic linkages and/or possible existence of multicore structure (rather than one) as previously reported (10), resulting in the formation of pseudosphere that might be formed very similar to the way of construction of a birdnest with debris of a tree.

Complex Formation between DAMC Self-Aggregates and DNA. One interesting feature of chitosan is its cationic character due to the amino group in each repeating unit. Therefore, DAMC self-aggregates were expected to form complexes with DNA, a representative anionic macromolecule existing in nature. The electrophoretic mobility of DNA, complexed with DAMC self-aggregates, decreased gradually on the agarose gel with increasing the molecular weight of DAMC at the same charge ratio (Figure 5). The addition of low molecular weight of DAMC5k self-aggregates, however, could not result in complete retardation of DNA even at higher charge ratios (data not shown). This could be attributed to the lower stability of DAMC5k self-aggregates (Figure 3). A similar behavior of complex formation was also confirmed by a fluorometer using ethidium bromide (EtBr) as a probe (Figure 6). The fluorescence intensity of EtBr was normalized by the intensity in the presence of DNA only. This loss in the fluorescence intensity indicates the condensation of DNA and the compaction of the complex particle, which could result in the exclusion of EtBr from DNA. The decrease in the fluorescence intensity was dependent on the molecular weight of DAMC. DAMC5k self-aggregates did not show the dramatic reduction in the fluorescence intensity after complexation with DNA, irrespective of charge ratios. However, the complexes from higher molecular weight DAMC were stable, and no significant change in the fluorescence intensity was observed over the charge ratio of 4.

In Vitro Transfection Efficiency. The transfection of COS-1 cells with DAMC self-aggregate/DNA complexes were studied next. The complexes at a charge ratio of 4 were chosen, as it was considered stable (Figures 5 and 6). In the absence of serum, it is evident that DAMC40k was the most efficient to deliver DNA to COS-1 cells, whereas DAMC5k self-aggregates showed the lowest

Figure 7. In vitro transfection activity of DAMC self-aggregate/pCMV-Luc+ complexes in COS-1 cells. Gene expression was determined by luciferase activity using a Promega kit.

transfection efficiency, likely due to the low stability of the complexes (Figure 7). Although DAMC5k self-aggregate slightly condenses the plasmid DNA from the measurement of the fluorescence intensity of EtBr (Figure 6), the DAMC5k self-aggregate/DNA complex does not seem to be strong enough at physiological ionic strength. DAMC200k self-aggregates could form highly condensed complexes with DNA. However, the complexes might have been too tight to release DNA. In the presence of serum, the transfection efficiency increased with increasing the molecular weight of DAMC due to the abundant proteins, which may act as an inhibitor of complex formation, resulting in weakening the ionic interaction between DAMC self-aggregates and DNA. Therefore, the optimum condition for cell transfection could be controlled using DAMC self-aggregates with different physicochemical properties including the size and structures.

CONCLUSIONS

Consideration of information generated in this analysis lead us to believe that structure of deoxycholic acid-

modified chitosan self-aggregate is dependent on the molecular weight of chitosan, and the condition of gene transfection is correlated to the structure of self-aggregates. This approach to control the size and structure of self-aggregates may find wide utility in the development of gene carriers, as well as many drug delivery applications.

Received March 14, 2001; Revised Manuscript Received August 15, 2001

The detailed syntheses of the sulfhydryl-modified guanosine monophosphates 5'-deoxy-5'-thioguanosine-5'-monophosphorothioate (GSMP), *O*-[ω -sulfhydryl-tetra(ethylene glycol)]-*O*-(5'-guanosine) monophosphate (5'-HS-PEG₄-GMP), and *O*-[ω -sulfhydryl-di(ethylene glycol)]-*O*-(5'-guanosine) monophosphate (5'-HS-PEG₂-GMP) are reported. Transcription reactions employing GSMP, 5'-HS-PEG₄-GMP, or 5'-HS-PEG₂-GMP as the initiator nucleotide for T7 RNA polymerase introduce a thiol group at the 5'-end of RNA. The efficiency of thiol incorporation at the 5'-terminus of modified RNA compounds was assayed with three different thiol-reactive biotinylated reagents followed by streptavidin gel-shift methods. The transcription efficiency with various ratios of GTP to 5'-HS-PEG₂-GMP was explored by reaction with a sulfhydryl-reactive maleimide-conjugated protein. This is an efficient method to incorporate enzymatically a thiol group into the 5'-end of RNA.

INTRODUCTION

RNA molecules play important roles in cellular processes including regulation, protein biosynthesis, RNA splicing, and retroviral replication. Site-specific substitution and derivatization provide powerful tools for studying RNA structure and function (Favre, 1990; Uhlmann and Peyman, 1990; Somtheimer and Steitz, 1993; Griffin et al., 1995; Cech and Herschlag, 1996; Dewey et al., 1996; Thomson et al., 1996; Allerson et al., 1997; Sontheimer et al., 1997; Strobel and Shetty, 1997). Although solid phase chemical synthesis can be used to introduce functional groups at any specific position of oligonucleotides shorter than approximately 40 nt (Gait et al., 1998), investigations of larger RNA molecules face a limited number of methodologies for site-specific modification and substitution. Several 5'-modifications of RNA molecules have been shown to have broad applications in studying RNA structures, in mapping RNA–protein interactions, and in the in vitro selection of catalytic RNAs.

In vitro transcription reactions are widely used to synthesize RNA from recombinant DNA templates. RNA generated in vitro has been used for many applications, for example, RNA processing, translation, RNA–protein interactions, and the generation of ribozymes. In vitro selection and in vitro evolution methods (Ellington and Szostak, 1990; Robertson and Joyce, 1990; Tuerk and Gold, 1990) have provided powerful tools for isolating ribozymes that can catalyze a wide range of chemical and biochemical reactions. Molecules have been isolated from pools of random RNA sequences that catalyze polynucleotide kinase activity (Lorsch et al., 1994), alkylation (Wilson et al., 1995), carbon–sulfur bond formation (Wecker et al., 1996), and the Diels–Alder reaction

(Tarasow et al., 1997; Seelig et al., 1999). Aminoacyl transfer reactions can be catalyzed by ribozymes to form 3'-terminal (Illangasekare et al., 1995, 1999; Lee et al., 2000) or 2'-internal aminoacyl esters (Jenne et al., 1998), 5'-terminal esters or amide bonds (Lohse et al., 1996; Wiegand et al., 1997), and peptide bond formation (Zhang and Cech, 1997, 1998). RNA can also catalyze nucleotide synthesis (Unrau et al., 1998). These findings have greatly expanded the catalytic versatility of RNA and provided support for the hypothesis that the first biological catalyst may have been an RNA molecule. Most of these selection methodologies employed the use of 5'-end-modified RNA transcripts. The inclusion of a disulfide bond is a desirable feature of many of these 5'-end modifications. A key functional group required for the selection scheme may be tethered distal to the disulfide bond. Following the isolations of the desired RNA, reduction of the disulfide bond may be used to affect the liberation of the selected RNA in a soluble form suitable for reverse-transcription.

Phosphorothioate modification is one of the most popular methods for functionalizing the 5'-terminus of RNA by a transcription or kinase reaction (Burgin and Pace, 1990; Joseph and Noller, 1996; Zhang and Cech, 1997). Fluorophores are the most attractive probes for RNA structure (Qin and Pyle, 1999), but only a low efficiency of conjugating terminal phosphorothioates with fluorophores has been achieved (Czworkowski et al., 1991). The sulfhydryl group is another special reactive group that can be incorporated into nucleic acids (Fidanaza et al., 1994; Musier-Forsyth and Schimmel, 1994; Sun et al., 1996; Sigurdsson et al., 1996; Cohen and Cech, 1997) as an alternative to the use of phosphorothioates. The thiol-reactive functional groups are primarily alkylating reagents, including haloacetamides, maleimides, benzylic halides, and bromomethyl ketones (Haugland, 1996). The thiol group demonstrates a unique property, that is, the thiol–disulfide exchange reaction. A pyridyl disulfide group is the most popular type of thiol–disulfide exchange functional group used in the construction of cross-linkers or modification reagents. A pyridyl disulfide

will readily undergo an interchange reaction with a free sulfhydryl to yield a single mixed-disulfide product. Once a disulfide linkage is formed, it may be cleaved subsequently using disulfide reducing agents (DTT etc.). Although 5'-phosphorothioate-RNA (5'-GMPS-RNA) can react with pyridyl disulfide to form a phosphorothioate sulfide compound (R-S-SPO₃-RNA) (Lorsch and Szostak, 1994; Macosko et al., 1999), a limitation of the thiophosphate disulfide product is the relative lability (Goody and Eckstein, 1971; Sengle et al., 2000). A free thiol group can be introduced into the 5'-termini of RNA chemically using carbodiimide and cysteamine, but the phosphoramidate linkage is not very stable (Chu et al., 1986; Chu and Orgel, 1988).

To overcome these limitations, we have developed a method to introduce a 5'-terminal sulfhydryl group into the 5'-termini of RNA molecules by in vitro transcription. We (Zhang et al., 2001) reported that a thiol group can be indirectly introduced into 5'-termini of RNA with an initiator, 5'-deoxy-5'-thioguanosine-5'-monophosphorothioate (GSMP), by T7 RNA polymerase. The method requires an additional step of dephosphorylation of 5'-GSMP-RNA to produce 5'-HS-G-RNA. Herein, we report two new 5'-modified guanoses as initiator for T7 RNA polymerase to directly incorporate a free thiol to 5'-termini of RNA by in vitro transcription. The new initiators are *O*-[ω -sulfhydryl-bis(ethylene glycol)]-*O*-(5'-guanosine) monophosphate (5'-HS-PEG₂-GMP) and *O*-[ω -sulfhydryl-tetra(ethylene glycol)]-*O*-(5'-guanosine) monophosphate (5'-HS-PEG₄-GMP). These initiators are not only to introduce directly a free thiol into 5'-end of RNA, but also to provide a flexible PEG linker between the HS group and RNA, which is important for some bioconjugation applications. We describe the detailed synthesis of 5'-deoxy-5'-thioguanosine-5'-monophosphorothioate, *O*-[ω -sulfhydryl-di(ethylene glycol)]-*O*-(5'-guanosine) monophosphate, and *O*-[ω -sulfhydryl-tetra(ethylene glycol)]-*O*-(5'-guanosine) monophosphate. Three thiol-reactive biotin agents have been tested to couple with the 5'-thiol of RNA molecules. The bioconjugation of maleimide-activated horseradish peroxidase with the 5'-sulfhydryl of RNA is also studied.

EXPERIMENTAL PROCEDURES

General Procedure. (2-Cyanoethyl-*N,N*-diisopropyl)-chlorophosphoramidite was purchased from Peninsula Laboratories. Biotin-PEG₃-iodoacetamide, biotin-HPDP, and biotin-PEG₃-maleimide were purchased from Pierce and Molecular Biosciences. Maleimide-activated horseradish peroxidase was purchased from Pierce, [α -³²P]ATP from NEN Labs, and NTPs and Taq DNA polymerase from New England Biolabs. All other materials were obtained from Aldrich, Sigma, and Acros, and used without additional purification unless otherwise noted. All solvents were distilled before use. Dichloromethane, acetonitrile, and pyridine were dried by refluxing with calcium hydride. ¹H, ¹³C, and ³¹P NMR spectra were obtained on Varian 300 and 400 spectrometers. Corresponding operating frequencies were as follows: 299.95/400.14 MHz (¹H), 75.43/100.61 MHz (¹³C), 121.42/161.98 MHz (³¹P). Internal references used are TMS for ¹H and ¹³C, and 85% H₃PO₄ for ³¹P. Mass spectra were obtained on a Finnigan LCQ^{DUO} spectrometer and high-resolution MS (FAB) spectra on a JMS-700 MStation mass spectrometer.

Di(ethylene glycol) Monotosylate 2b. To a solution of di(ethylene glycol) (**1b**, 95 mL, 1.0 mol) and anhydrous pyridine (40.5 mL, 0.5 mol) in 250 mL of anhydrous

dichloromethane was added dropwise a solution of *p*-toluenesulfonyl chloride (38.1 g, 0.2 mol) in 150 mL of dichloromethane. The mixture was stirred at room temperature overnight. The reaction solution was washed with cold water (2 × 100 mL) and brine (2 × 100 mL). The aqueous solution was extracted with dichloromethane (2 × 100 mL), and the combined organic layers were dried over magnesium sulfate. The solvent was evaporated under reduced pressure to give a slightly yellow oil. The crude product was purified by flash silica gel column chromatography using a gradient of dichloromethane/methanol (0–5%) to yield a colorless oil: 42.3 g; yield = 81.2%; TLC (silica gel, chloroform/methanol = 95:5); *R*_f = 0.42. ¹H NMR (CDCl₃): δ 1.99 (s, 1H), 2.46 (s, 3H), 3.54 (t, *J* = 4.5 Hz, 2H), 3.68 (m, 4H), 4.20 (t, *J* = 4.6 Hz, 2H), 7.35 (d, *J* = 8.4 Hz, 2H), 7.81 (d, *J* = 8.4 Hz, 2H). ¹³C NMR (CDCl₃): δ 21.9, 61.8, 68.8, 69.5, 72.5, 128.2, 130.1, 133.1, 145.2. ESI mass (*m/z*): calcd for C₁₁H₁₆O₅S 260.1, found 283.3 [M+Na]⁺.

Tetra(ethylene glycol) Monotosylate 2c. To a solution of tetra(ethylene glycol) (**1c**, 100 mL, 0.58 mol) and anhydrous pyridine (40 mL, 0.50 mol) in 200 mL of anhydrous dichloromethane was added dropwise a solution of *p*-toluenesulfonyl chloride (19.1 g, 0.10 mol) in 100 mL of dichloromethane. The mixture was stirred at room temperature for 20 h. The reaction solution was washed with cold water (2 × 100 mL) and brine (2 × 100 mL). The aqueous solution was extracted with dichloromethane (2 × 100 mL), and the combined organic layers were dried over magnesium sulfate. Evaporation of solvent under reduced pressure gave a slightly yellow oil. The crude product was purified by flash silica gel column chromatography using a gradient of dichloromethane/methanol (0–5%) to give a colorless oil: 31.3 g; yield = 90%; TLC (silica gel, dichloromethane/methanol = 95:5); *R*_f = 0.43. ¹H NMR (CDCl₃): δ 2.43 (s, 3H), 2.48 (s, 1H), 3.56–3.70 (m, 14H), 4.14 (t, *J* = 4.8 Hz, 2H), 7.32 (d, *J* = 8.4 Hz, 2H), 7.78 (d, *J* = 8.4 Hz, 2H). ¹³C NMR (CDCl₃): δ 21.5, 61.6, 68.6, 69.2, 70.6–70.2 (m), 72.3, 127.9, 129.7, 132.8, 144.7. ESI mass (*m/z*): calcd for C₁₅H₂₄O₇S 348.1, found 371.5 [M+Na]⁺.

2-(Thioacetyl)ethanol 3a. To a suspension of potassium thioacetate (11.4 g, 0.1 mol) in 500 mL of acetone was added dropwise 3.55 mL of bromoethanol (**1a**, 0.05 mol). The mixture was stirred at room temperature for 1 h, producing a white precipitate. The solid was filtered, and the solvent was evaporated under reduced pressure. The residue was stirred in 100 mL of dichloromethane, and refiltered and diluted to 500 mL with dichloromethane. The organic solution was washed with water (2 × 50 mL) and brine (2 × 50 mL). The aqueous wash solutions were reextracted with dichloromethane (2 × 50 mL), and the combined organic layers were dried over magnesium sulfate and evaporated under reduced pressure to give an orange oil in almost quantitative yield and high purity. The crude product was purified through a silica gel column eluted with hexane/ethyl acetate (6:1) to afford 8.4 g of the desired product (70% yield); TLC (silica gel, hexane/ethyl acetate = 1:2); *R*_f = 0.56. ¹H NMR (CDCl₃): δ 2.34 (s, 3H), 2.43 (br, 1H), 3.05 (t, *J* = 6.1 Hz, 2H), 3.72 (t, *J* = 6.1 Hz, 2H). ¹³C NMR (CDCl₃): δ 30.8, 32.2, 61.8, 196.7.

Di(ethylene glycol) Monothioacetate 3b. To a suspension of potassium thioacetate (17.2 g, 0.15 mol) in 650 mL of acetone was added a solution of **2b** (15.6 g, 60.3 mmol) in 100 mL of acetone at room temperature. The mixture was stirred at room temperature for 1 h and then refluxed for 4 h. After cooling to room temperature, the solid was filtered off and the solution was evaporated

under reduced pressure. The residue was dissolved in ethyl acetate (150 mL) and washed with water (2 × 40 mL) and brine (2 × 50 mL). The aqueous wash solutions were reextracted with ethyl acetate (2 × 50 mL), and the combined organic layers were dried over magnesium sulfate and evaporated under reduced pressure to give a yellow oil. The crude product was purified through a flash silica gel column eluted with hexane/ethyl acetate (6:1) to give 8.75 g of desired product, yield = 88.8%. TLC (silica gel, hexane/ethyl acetate = 1:2); R_f = 0.38. ^1H NMR (CDCl_3 , 400 MHz): δ 2.30 (s, 3H), 2.51 (br, 1H), 3.06 (t, J = 6.1 Hz, 2H), 3.59–3.52 (m, 4H), 3.68 (t, J = 4.6 Hz, 2H). ^{13}C NMR (CDCl_3 , 400 MHz): δ 29.0, 30.7, 61.8, 69.7, 72.2, 195.8. ESI MS calcd for $\text{C}_6\text{H}_{12}\text{O}_3\text{S}$ 164.1, found 187.0 $[\text{M}+\text{Na}]^+$.

Tetra(ethylene glycol) Monothioacetate 3c. To a suspension of potassium thioacetate (10.1 g, 88 mmol) in 650 mL of acetone was added a solution of **2c** (15.4 g, 44 mmol) in 100 mL of acetone. The mixture was stirred at room temperature for 1 h and then refluxed for 4 h. After filtration, the solvent was evaporated under reduced pressure. The residue was dissolved in ethyl acetate (150 mL) and washed with water (2 × 50 mL) and brine (2 × 50 mL). The aqueous wash solutions were reextracted with ethyl acetate (2 × 50 mL), and the combined organic layers were dried over magnesium sulfate and evaporated under reduced pressure to give a yellow oil. The crude product was purified through a flash silica gel column eluted with hexane/ethyl acetate (6:1) to afford 10.5 g of the desired product, yield = 95%. TLC (silica gel, hexane/ethyl acetate = 1:4); R_f = 0.24. ^1H NMR (CDCl_3): δ 2.26 (s, 3H), 2.95 (br, 1H), 3.01 (t, J = 6.1 Hz, 2H), 3.56–3.64 (m, 14H). ^{13}C NMR (CDCl_3): δ 28.8, 30.6, 61.7, 69.8, 70.3, 70.4, 70.5, 70.7, 72.6, 195.6. ESI mass (m/z): calcd for $\text{C}_{10}\text{H}_{20}\text{O}_5\text{S}$ 252.1, found 275.3 $[\text{M}+\text{Na}]^+$.

2',3'-O,O-Isopropylidene Guanosine 5. To a suspension of guanosine (8.7 g, 30.7 mmol) in 600 mL of acetone was added 3 mL of 70% perchloric acid. A clear colorless solution was formed after ca. 0.5 h. The mixture was stirred at room temperature for 1 h, and 3 mL of concentrated $\text{NH}_3\cdot\text{H}_2\text{O}$ was added, leading to a white precipitate. The solvent was evaporated under reduced pressure to afford a white solid that was stirred with 40 mL of H_2O for several hours, filtered, and washed with cold water. Drying over phosphorus pentoxide in vacuo gave a white solid (8.3 g, 83.6%). ^1H NMR ($\text{DMSO}-d_6$): δ 1.30 (s, 3H), 1.50 (s, 3H), 3.52 (m, 2H), 4.10 (dt, J = 3.0, 5.4 Hz, 1H), 4.95 (dd, J = 3.0, 6.3 Hz, 1H), 5.05 (t, J = 5.4 Hz, 1H), 5.17 (dd, J = 2.7, 6.3 Hz, 1H), 5.90 (d, J = 2.7 Hz, 1H), 6.50 (br, 2H), 7.90 (s, 1H), 10.66 (s, 1H).

2-N,N-Dimethylaminomethylene-2',3'-O,O-isopropylidene Guanosine 6. A solution of **5** (9.78 g, 30.2 mmol) and dimethylformamide dimethyl acetal (15 mL, 0.11 mol) in anhydrous DMF (100 mL) was stirred under argon at 55 °C for 1 day. The clear light yellow solution was evaporated under reduced pressure. The residue was stirred in 40 mL of methanol, leading to precipitation of a white solid. More product was precipitated by addition of ethyl acetate (100 mL). The mixture was cooled to –20 °C and filtered. The solid was dried over phosphorus pentoxide in vacuo to give 6.6 g of **6**. The mother liquor was concentrated to about 20 mL; white solid was formed again which was filtered and washed with ethyl acetate and dried over phosphorus pentoxide in vacuo to give 2.2 g more product (total 8.8 g, yield = 90%). TLC (silica gel, ethyl acetate/methanol = 3:1); R_f = 0.42. ^1H NMR ($\text{DMSO}-d_6$): δ 1.32 (s, 3H), 1.53 (s, 3H), 3.03 (s, 3H), 3.15 (s, 3H), 3.52 (m, 2H), 4.13 (m, 1H), 4.95 (dd, J = 2.8, 6.4

Hz, 1H), 5.07 (t, J = 5.4 Hz, 1H), 5.26 (dd, J = 3.0, 5.8 Hz, 1H), 6.03 (d, J = 2.8 Hz), 8.02 (s, 1H), 8.57 (s, 1H), 11.37 (s, 1H). ^{13}C NMR ($\text{DMSO}-d_6$): δ 25.2, 27.1, 34.6, 40.8, 61.4, 81.1, 83.5, 86.3, 88.5, 113.1, 119.8, 137.2, 149.5, 157.4, 157.6, 158.2. ESI mass (m/z): calcd for $\text{C}_{16}\text{H}_{22}\text{N}_6\text{O}_5$ 378.2, found 379.2 $[\text{M}+\text{H}]^+$.

2-Cyanoethyl-N,N-diisopropylamino-5'-(2-N-dimethylaminomethylene-2',3'-O,O-isopropylidene guanosine) Phosphoramidite 7. To a suspension of **6** (5.0 g, 13.2 mmol) in anhydrous dichloromethane (50 mL) was added 10 mL of *N,N*-diisopropylethylamine in argon atmosphere. The mixture was cooled to 0 °C, and 2-cyanoethyl-*N,N*-diisopropylaminophosphorus chloride (5 mL, 21.4 mmol) was added dropwise. The reaction was completed after 30 min and diluted with ethyl acetate (500 mL). The solution was washed with cold water (2 × 100 mL) and brine (2 × 100 mL). The combined aqueous layers were reextracted with ethyl acetate (2 × 150 mL), and the combined organic layers were dried over magnesium sulfate and filtered. Evaporation of solvent gave a slightly yellow residue that was applied to flash column chromatography (silica gel) and eluted with ethyl acetate/triethylamine (95:5) to yield a white foam solid (6.37 g, 83.5% yield). TLC (silica gel, ethyl acetate/methanol/triethylamine = 85:10:5); R_f = 0.73. ^1H NMR (CDCl_3): δ 1.14 (m, 12H), 1.38 (s, 3H), 1.61 (s, 3H), 2.68 (m, 2H), 3.10 (s, 2H), 3.18 (s, 3H), 3.55 (m, 2H), 3.78 (m, 4H), 4.41 (m, 1H), 4.97 (m, 1H), 4.97 (m, 1H), 5.12 (m, 1H), 6.11 (dd, J = 2.7, 4.7 Hz, 1H), 7.85, 7.88 (2s, 1H), 8.61 (s, 1H), 9.63 (br, 1H). ^{13}C NMR (CDCl_3): δ 20.6 (dd, J = 2.7, 7.3 Hz), 24.8 (m), 27.5, 35.4, 41.7, 43.3 (dd, J = 6.8, 12.3), 58.8 (dd, J = 18.4, 22.6), 63.4 (dd, J = 16.1, 21.4), 81.7 (d, J = 2.3), 85.2 (d, J = 7.7), 85.9 (t, J = 9.2), 89.8 (d, J = 8.4), 114.4 (d, J = 1.5), 118.0 (d, J = 12.3), 120.8, 136.8, 150.1 (d, J = 1.5), 157.1, 158.3, 158.4. ^{31}P NMR (CDCl_3): δ 150.0, 151.1. ESI mass (m/z): calcd for $\text{C}_{25}\text{H}_{39}\text{N}_8\text{O}_6\text{P}$ 578.3, found 579.1 $[\text{M}+\text{H}]^+$.

2-Cyanoethyl 5'-(2-N-Dimethylformamidino-2',3'-O,O-isopropylidene-guanosine) (ω -Thioacetyethyl) Phosphate 8a. To a solution of 1*H*-tetrazole (1.4 g, 20 mmol) in 40 mL of anhydrous acetonitrile was added a solution of 2-thioacetyethanol **3a** (0.6 g, 5 mmol) in 10 mL of anhydrous acetonitrile under argon atmosphere. A solution of **7** (1.92 g, 3.32 mmol) in 7 mL of acetonitrile was then added dropwise and stirred at room temperature. More 2-thioacetyethanol **3a** (0.6 g, 5 mmol) was added after 0.5 h, leading to complete disappearance of **7** in ca. 0.5 h. An 8.0 mL aliquot of *tert*-butyl hydroperoxide was added, and the mixture was stirred at room temperature for 0.5 h. After evaporation of solvent under reduced pressure, the residue was dissolved in 250 mL of ethyl acetate and washed with cold water (2 × 30 mL) and brine (2 × 50 mL). The combined aqueous layers were back-extracted with ethyl acetate (2 × 50 mL), and the combined organic layers were dried over magnesium sulfate. After removal of solvent under reduced pressure, the residue was applied to a silica gel flash column and eluted with ethyl acetate/methanol (0–20%). Evaporation of solvent gave the desired compounds as a white foam solid (1.51 g, 74.0%). TLC (silica gel, ethyl acetate/methanol = 4:1); R_f = 0.55. ^1H NMR (CDCl_3): δ 1.40 (s, 3H), 1.63 (s, 3H), 2.32, 2.33 (2s, 3H), 2.76 (m, 2H), 3.05 (m, 2H), 3.10 (s, 3H), 3.22 (s, 3H), 4.05–4.35 (m, 6H), 4.42 (m, 1H), 5.05 (dd, J = 3.6, 6.6 Hz, 1H), 5.29 (m, 1H), 6.10 (s, 1H), 7.82, 7.84 (2s, 1H), 8.60 (s, 1H), 9.05 (s, 1H). ^{31}P NMR (CDCl_3): δ –2.3, –2.2. ESI mass (m/z): calcd for $\text{C}_{23}\text{H}_{32}\text{N}_8\text{O}_9\text{P}$ 613.2, found 614.3 $[\text{M}+\text{H}]^+$.

2-Cyanoethyl 5'-(2-N-Dimethylaminomethylene-2'-O,3'-O-isopropylidene-guanosine) [ω -Thioacetyl

Di(ethylene glycol) Phosphate 8b. To a solution of 1*H*-tetrazole (1.4 g, 20 mmol) in 40 mL of anhydrous acetonitrile was added a solution of **3b** (0.82 g, 5 mmol) in 10 mL of anhydrous acetonitrile under argon atmosphere. A solution of phosphoramidite **7** (2.0 g, 3.46 mmol) in 20 mL of acetonitrile was then added dropwise. After the mixture was stirred for 0.5 h at room temperature, more **3b** (0.5 g, 3 mmol) was added, and the mixture was stirred for an additional 0.5 h. An 8.0 mL aliquot of *tert*-butyl hydroperoxide was added, and the mixture was stirred at room temperature for 0.5 h. After evaporation of solvent under reduced pressure, the residue was dissolved in 250 mL of ethyl acetate, and washed with cold water (2 × 30 mL) and brine (2 × 50 mL). The combined aqueous layers were back-extracted with ethyl acetate (2 × 50 mL), and the combined organic layers were dried over magnesium sulfate. After removal of solvent, the residue was applied to a silica gel flash column and eluted with ethyl acetate/methanol (5–15%). The pure product was obtained as a white foam solid (1.86 g, 81.9%). TLC (silica gel, ethyl acetate/methanol = 4:1); R_f = 0.25. ^1H NMR (CDCl_3): δ 1.38 (s, 3H), 1.60 (s, 3H), 2.30, 2.31 (2s, 3H), 2.74 (m, 2H), 3.02 (m, 2H), 3.10 (s, 3H), 3.20 (s, 3H), 3.52–3.64 (m, 4H), 4.11–4.33 (m, 6H), 4.40 (m, 1H), 5.04 (dd, J = 3.5, 6.4 Hz, 1H), 5.27 (dt, J = 2.6, 6.6 Hz, 1H), 6.06 (dd, J = 2.6, 4.0 Hz, 1H), 7.71, 7.72 (2s, 1H), 8.58 (s, 1H), 9.71 (br, 1H). ^{13}C NMR (CDCl_3): δ 19.8, 25.6, 27.4, 28.8, 30.8, 35.5, 41.8, 62.4, 67.1, 67.6, 69.6, 69.9, 81.0, 84.5, 89.8, 114.9, 116.8, 121.0, 136.9, 150.0, 157.2, 158.1, 158.4, 195.6. ^{31}P NMR (CDCl_3): δ -0.7, -0.6. ESI mass (m/z): calcd for $\text{C}_{25}\text{H}_{36}\text{N}_7\text{O}_{10}\text{PS}$ 657.2, found 658.1 $[\text{M}+\text{H}]^+$.

2-Cyanoethyl 5'-(2-*N*-Dimethylaminomethylene-2'-*O*,3'-*O*-isopropylidene-guanosine) [ω -Thioacetyl Di(ethylene glycol)] Phosphate 8c. To a solution of 1*H*-tetrazole (2.9 g, 41.4 mmol) in 80 mL of anhydrous acetonitrile was added a solution of **3c** (2.27 g, 9 mmol) in 20 mL of anhydrous acetonitrile under argon atmosphere. A solution of **7** (4.0 g, 7.0 mmol) in 20 mL of acetonitrile was then added dropwise, and the mixture was stirred at room temperature. More **3c** (0.76 g, 3 mmol) was added after 0.5 h, and the reaction was stirred for an additional 0.5 h. A 10 mL aliquot of *tert*-butyl hydroperoxide was added, and the mixture was stirred at room temperature for 0.5 h. After removing solvent, the residue was dissolved in 400 mL of ethyl acetate and washed with cold water (2 × 50 mL) and brine (2 × 50 mL). The combined aqueous layers were reextracted with ethyl acetate (2 × 50 mL), and the combined organic layers were dried over magnesium sulfate. After evaporation of solvent under reduced pressure, the residue was applied to a silica gel flash column and eluted with ethyl acetate/methanol (5–20%) to yield the desired product as a white foam solid (4.96 g, 95.0%). TLC (silica gel, ethyl acetate/methanol = 4:1); R_f = 0.22. ^1H NMR (CDCl_3): δ 1.37 (s, 3H), 1.59 (s, 3H), 2.30 (s, 3H), 2.72 (m, 2H), 3.05 (m, 2H), 3.09 (s, 3H), 3.19 (s, 3H), 3.52–3.66 (m, 12H), 4.10–4.30 (m, 6H), 4.38 (m, 1H), 5.03 (m, 1H), 5.26 (m, 1H), 6.04 (t, J = 3.0 Hz, 1H), 7.71, 7.72 (2s, 1H), 8.57 (s, 1H), 9.57 (br, 1H). ^{31}P NMR (CDCl_3): δ -1.7. ESI mass (m/z): calcd for $\text{C}_{29}\text{H}_{44}\text{N}_7\text{O}_{12}\text{PS}$ 745.3, found 746.1 $[\text{M}+\text{H}]^+$.

The compound **8c** was also prepared from the reaction of **6** and **11**. To a suspension of **6** (189.2 mg, 0.5 mmol) in anhydrous dichloromethane (15 mL) was added a solution of 1*H*-tetrazole (210.1 mg, 3.0 mmol) in anhydrous acetonitrile (6 mL) and a solution of **11** (226 mg, 0.5 mmol) in anhydrous acetonitrile (5 mL) under argon atmosphere. After stirring the mixture at room temperature for 0.5 h, more 1*H*-tetrazole (210 mg, 3.0 mmol)

and **11** (290 mg, 0.64 mmol) were added. After the disappearance of compound **6**, *tert*-butyl hydroperoxide (2 mL) was added, and the mixture was stirred at room temperature for an additional 0.5 h. After evaporation of solvents under reduced pressure, the oil residue was dissolved in dichloromethane (150 mL) and washed with water (2 × 20 mL) and brine (2 × 20 mL). The combined aqueous solutions were back-extracted with dichloromethane (2 × 20 mL), and the combined organic layers were dried over magnesium sulfate. After removal of solvent, the residue was applied to a flash column (silica gel) eluted with ethyl acetate/methanol (0–20%) to give the desired product as a white foam solid (344 mg, 92.8%).

2-Cyanoethyl 5'-Guanosine (3-Thioacetyl) Phosphate 9a. The fully protected compound **8a** (1.53 g, 2.5 mmol) was dissolved in 40% formic acid (50 mL), and the solution was stirred at room temperature for 3 days to affect a complete deprotection of the 2',3'-acetonide group. After removal of solvent under reduced pressure, the residue was coevaporated with methanol twice to afford a crude product that was used for the next step of the reaction without further purification. An analytical amount of product was obtained by silica gel flash column eluted with ethyl acetate/methanol (3:1). ^1H NMR (D_2O): δ 2.07, 2.09 (2s, 3H), 2.74 (m, 2H), 2.88 (m, 2H), 3.85–4.45 (m, 8H), 4.70 (m, 1H, partially overlapped by H_2O signal), 5.74 (d, J = 5.4 Hz), 7.75 (s, 1H). ^{31}P NMR (D_2O): δ -2.2, -2.1. ESI mass (m/z): calcd for $\text{C}_{17}\text{H}_{23}\text{N}_6\text{O}_9\text{PS}$ 518.1, found 519.5 $[\text{M}+\text{H}]^+$.

2-Cyanoethyl 5'-Guanosine [ω -Thioacetyl Di(ethylene glycol)] Phosphate 9b. The fully protected compound **9b** (1.53 g, 2.5 mmol) was dissolved in 60% formic acid (50 mL), and the solution was stirred at room temperature for 3 days to deprotect the 2',3'-acetonide group. After evaporation of solvent under reduced pressure, the residue was coevaporated with methanol twice to afford a crude product that was used for the next step of the reaction without further purification. ^1H NMR (D_2O): δ 2.12, 2.14 (2s, 3H), 2.72 (m, 2H), 2.80 (dd, J = 6.4 Hz, 12 Hz, 2H), 3.40 (dd, J = 5.6, 12 Hz, 2H), 3.46 (m, 2H), 3.85–4.40 (m, 8H), 4.7 (m, 1H), 5.74 (d, J = 5.4 Hz, 1H), 7.78 (s, 1H). ^{31}P NMR (D_2O): δ -1.9, -1.8. ESI mass (m/z): calcd for $\text{C}_{19}\text{H}_{27}\text{N}_6\text{O}_{10}\text{PS}$ 562.1, found 563.2 $[\text{M}+\text{H}]^+$.

2-Cyanoethyl 5'-Guanosine [ω -Thioacetyl Tetra(ethylene glycol)] Phosphate 9c. The fully protected compound **9c** (1.64 g, 2.5 mmol) was dissolved in 60% formic acid (50 mL), and the solution was stirred at room temperature for 3 days to affect complete deprotection of the 2',3'-acetonide group. After evaporation of solvent under reduced pressure, the residue was coevaporated with methanol twice to yield a crude product that was used for the next step of the reaction without further purification. An analytical amount of product was obtained by silica gel flash column eluted with ethyl acetate/methanol (3:1). ^1H NMR ($\text{DMSO}-d_6$): δ 2.30 (s, 3H), 2.90 (m, 2H), 3.02 (m, 4H), 3.40–4.20 (m, 18 H, overlapped with water signal), 4.44 (m, 1H), 5.72 (d, J = 6.4 Hz, 1H), 6.75 (br, 2H), 7.84 (s, 1H), 8.46 (s, 1H). ^{31}P NMR (D_2O): δ -1.6. ESI mass (m/z): calcd for $\text{C}_{23}\text{H}_{35}\text{N}_6\text{O}_{12}\text{PS}$ 650.2, found 651.1 $[\text{M}+\text{H}]^+$.

O- ω -Mercapto-di(ethylene glycol)-O-(5'-guanosine) Monophosphate 10b. The crude product **9b** (1.4 g, 2.5 mmol) was dissolved in methanol (40 mL) under argon atmosphere, and an excess of 2-mercaptoethanol (2 mL, 28.5 mmol) was added. To the above solution was added ammonia in methanol (7.0 N solution, 20 mL). The mixture was stirred at 55 °C for 1 day. After

removal of solvent, the solid residue was washed with ethyl acetate to remove excess mercaptoethanol. The crude product was applied to a reverse phase column and eluted with water and water/methanol (10–50%). The collected fractions were evaporated under reduced pressure, and the aqueous solution was lyophilized to yield a pure product (1.06 g, 88%). TLC (silica gel, 2-propanol/ammonia/water = 7:1:2); R_f = 0.45. ^1H NMR (D_2O): δ 2.40 (t, J = 6.3 Hz, 2H), 2.51 (s, 1H), 3.33 (t, J = 6.3 Hz, 2H), 3.37 (m, 2H), 3.69 (m, 2H), 3.90 (m, 2H), 4.12 (m, 1H), 4.30 (t, J = 4.7 Hz, 2H), 4.59 (t, J = 5.3 Hz, 1H), 5.71 (d, J = 5.5 Hz, 1H), 7.95 (s, 1H). ^{31}P NMR (D_2O): δ 1.3. HRMS calcd for $\text{C}_{14}\text{H}_{23}\text{O}_9\text{N}_5\text{PS}$ 468.0954, found 468.0927.

O-[ω -Mercapto-tetra(ethylene glycol)]-O-(5'-guanosine) Monophosphate 10c. The compound **9c** (1.5 g, 2.3 mmol) was dissolved in methanol (40 mL) in argon atmosphere, and an excess of 2-mercaptoethanol (2 mL, 28.5 mmol) was added. To the above solution was added ammonia in methanol (7.0 N solution, 20 mL). The mixture was stirred at 55 °C for 1 day. After evaporation of solvent under reduced pressure, the residue was coevaporated with methanol (3×25 mL), and washed with ethyl acetate to remove excess mercaptoethanol. The solid product was dried in vacuo and then was applied to a reverse phase column and eluted with water and water/methanol (10–50%). The desired fractions were collected and evaporated under reduced pressure to remove organic solvent, and the aqueous solution was dried by lyophilization to yield a cotton-like solid (1.22 g, 93%). TLC (silica gel, 2-propanol/ammonia/water = 7:1:2); R_f = 0.45. ^1H NMR (D_2O): δ 2.48 (t, J = 6.3 Hz, 2H), 2.52 (s, 1H), 3.41–3.45 (m, 12H), 3.74 (m, 2H), 3.93 (m, 2H), 4.14 (m, 1H), 4.30 (t, J = 4.5 Hz, 2H), 4.58 (t, J = 5.1 Hz, 1H), 5.75 (d, J = 5.5 Hz, 1H), 8.11 (s, 1H). ^{31}P NMR (D_2O): δ 1.3. HRMS calcd for $\text{C}_{18}\text{H}_{31}\text{N}_5\text{O}_{11}\text{PS}$ 556.1478, found 556.1479.

2-Cyanoethyl *N,N*-Diisopropylamino [ω -Thioacetyl Tetra(ethylene glycol)] Phosphoramidite 11. To a solution of **3c** (1.0 g, 3.96 mmol) in anhydrous dichloromethane (7 mL) was added *N,N*-diisopropylethylamine (2.0 mL, 11.5 mmol). The solution was cooled to 0 °C, and then 2-cyanoethyl diisopropylamino phosphorus chloride was added dropwise. After stirring at 0 °C for 0.5 h, ethyl acetate (100 mL) was added, and the solution was washed with water (2×20 mL) and brine (2×20 mL). The combined aqueous layers were back-extracted with ethyl acetate (2×20 mL), and the combined organic layers were dried over magnesium sulfate. After removal of solvent, the residue was applied to a flash silica gel column eluted with heptane/ethyl acetate/triethylamine (80:15:5) to give a colorless oil (1.2 g, 67.0%). TLC (silica gel, ethyl acetate/heptane/triethylamine = 10:9:1); R_f = 0.57. ^1H NMR (CDCl_3): δ 1.20 (d, J = 6.6 Hz, 6H), 1.21 (d, J = 6.6 Hz, 6H), 2.36 (s, 3H), 2.68 (t, J = 6.5 Hz, 2H), 3.12 (t, J = 6.5 Hz, 2H), 3.60–3.95 (m, 18H). ESI mass (m/z): calcd for $\text{C}_{19}\text{H}_{37}\text{N}_2\text{O}_6\text{PS}$ 452.2, found 475.3 [$\text{M}+\text{Na}$] $^+$.

Synthesis of 5'-Deoxy-5'-iodo-2',3'-isopropylidene Guanosine 12. Methyltriphenoxyposphonium iodide (0.86 g, 1.91 mmol) was added to a cooled (−78 °C) suspension of 2',3'-*O*-isopropylidene guanosine (0.41 g, 1.27 mmol) in tetrahydrofuran (20 mL). The mixture was allowed to warm to room temperature after 10 min. After 4 h the excess methyltriphenoxyposphonium iodide was destroyed by addition of 1 mL of methanol, and the solvent was removed under reduced pressure. The residue was suspended in a mixture of ethyl ether and hexane (1:1), and the solid was filtered and washed thoroughly by the addition of ethyl ether and hexane. The

crude product was purified by flash chromatography (gradient of methanol/chloroform) (0.34 g, 61.8%). R_f = 0.53 (chloroform/methanol = 4:1); ^1H NMR ($\text{DMSO}-d_6$): δ 1.31 (s, 3H), 1.50 (s, 3H), 3.35 (m, 2H), 4.25 (m, 1H), 5.04 (dd, J = 4.0 Hz, 8.4 Hz, 1H), 5.30 (dd, J = 2.8 Hz, 8.4 Hz, 1H), 6.01 (d, J = 2.8 Hz, 1H), 6.55 (b, 2H), δ 7.88 (s, 1H).

Synthesis of 5'-Deoxy-5'-thioguanosine-5'-monophosphorothioate 14. A suspension of 5'-deoxy-5'-iodo-2',3'-isopropylidene guanosine **12** (2.88 g, 6.65 mmol) in 50% aqueous formic acid (100 mL) was stirred for 2.5 days, and then the solvent was removed by evaporation. The crude deprotected product **13** (2.83 g) was used without further purification in the next reaction. R_f = 0.78 (*i*-propyl alcohol/ $\text{NH}_3/\text{H}_2\text{O}$ = 6:3:1). To a suspension of 5'-deoxy-5'-iodoguanosine **13** (2.83 g, 7.2 mmol) in 140 mL of water was added trisodium thiophosphate (4.8 g, 26 mmol). The reaction mixture was stirred for 3 days at room temperature under argon atmosphere. After filtration to remove any precipitate, the solvent was evaporated under reduced pressure. The residue was dissolved in 100 mL of water and precipitated by the addition of 200 mL of methanol. After removing the precipitate by filtration, the solvent was evaporated and the residue was dissolved in a small amount of water and subjected to reverse phase chromatography and eluted with water. The desired product was collected and dried by lyophilization (1.9 g, 68% for two steps). R_f = 0.36 (isopropyl alcohol/ $\text{NH}_3/\text{H}_2\text{O}$ = 6:3:1). ^1H NMR ($\text{DMSO}-d_6 + \text{D}_2\text{O}$): δ 2.83 (m, 2H), 4.08 (m, 2H), 4.28 (dd, J = 3.9 Hz, 5.3 Hz, 1H), 5.63 (d, J = 5.9 Hz, 1H), 7.82 (s, 1H). ^{31}P NMR ($\text{DMSO}-d_6 + \text{D}_2\text{O}$): δ 16.4. HRMS: $\text{C}_{10}\text{H}_{15}\text{N}_5\text{O}_7\text{PS}$ calcd 380.0430, found 380.0482.

Preparation of 5'-HS-PEG₂-GMP-RNA, 5'-HS-PEG₄-GMP-RNA, and 5'-HS-G-RNA. The 5'-GTP-RNA, 5'-GSMP-RNA, and 5'-HS-PEG-GMP-RNA were prepared by runoff transcription in the presence of the four ribonucleotides or the four ribonucleotides supplemented with GSMP or **10b** or **10c** (Scheme 4). In general, the 222 bp DNA template for *in vitro* transcription was generated by PCR from pC25 plasmid DNA (Zhang and Cech, 1997). Transcription reactions were carried out with 4 μL of T7 RNA polymerase in the presence of 2 mM each NTP, 7.2 μg of DNA template, 10 μCi of [α - ^{32}P]-ATP, 4 mM spermidine, 0.05% Triton X-100, 12 mM MgCl_2 , 20 mM DTT, and 40 mM Tris buffer (pH 7.5) in a total 200 μL reaction at 37 °C for 3 h. A 4 μL aliquot of 0.5 M EDTA (pH 7.4) was added to dissolve the white Mg^{2+} -pyrophosphate precipitate, and 80 μL of formamide dye was added, and then loaded on an 8% polyacrylamide gel. RNA was purified through an 8% polyacrylamide [29:1 acrylamide:bis(acrylamide)]/8 M urea gel. RNA was visualized by UV-shadowing and excised from the gel. The gel slice was crushed and soaked overnight in TE buffer (10 mM Tris-HCl, pH 7.5, 1 mM EDTA, and 250 mM NaCl) at 4 °C to elute the RNA. After filtering the soaking solution, RNA was recovered by ethanol precipitation, and the pellet was dissolved in 10–50 μL of ddH₂O. The sequence of the full-length RNA is the following: 5'-GGG AGA GAC CUG CCA UUC ACG CUG GAU AAA ACU UCA CAG CCA UAC GUU GUG UUU GAC UAA GCC AGA AUA UCC AGA UAA GGU AGC UGG AGA GAG CAG CGA CUU ACA UCC CCG GUA GAU ACG AAC AGG ACC CCU GCC AUG CAG UGA CCU UUC GUA GCC GCC AGU UCU UGA CCU CUA AGC AGC GUC AGG AUC CGU G-3'.

To prepare 5'-HS-PEG_{*n*}-GMP-RNA (where *n* = 2 or 4), 5'-HS-PEG_{*n*}-GMP (**10b** or **10c**) was added into the transcription reaction with a ratio of 5'-HS-PEG_{*n*}-GMP

Scheme 1. Synthesis of 5'-HS-PEG_n-GMP 10a, 10b, and 10c^a

^a (a) Acetone, 70% HClO_4 ; (b) $\text{Me}_2\text{NCH(OMe)}_2$, DMF, 55 °C; (c) $\text{CIP(NPr}_2\text{)(OCH}_2\text{CH}_2\text{CN)}$, NPr_2Et , CH_2Cl_2 , 0 °C; (d) (1) $\text{H(OCH}_2\text{CH}_2)_n\text{SCOCH}_3$, 1*H*-tetrazole, MeCN, (2) *t*-BuOOH; (e) 60% $\text{HCOOH/H}_2\text{O}$; (f) NH_3/MeOH , $\text{HS-CH}_2\text{CH}_2\text{OH}$.

to GTP of 1:1, 4:1, 8:1, or 16:1. A 20 μL aliquot of 0.5 M EDTA (pH 7.4) was added to dissolve the white precipitate before adding formamide-loading dye. The RNA transcript was purified as described above.

To prepare 5'-HS-G-RNA, 5'-GSMP-RNA was synthesized by runoff transcription in the presence of GSMP with a ratio of GSMP:GTP:ATP:CTP:UTP = 8:1:1:1:1 mM. The 5'-GSMP-RNA was dephosphorylated by calf intestinal alkaline phosphatase (New England Biolabs) in NEBuffer 3 (50 mM Tris-HCl, 10 mM MgCl_2 , 100 mM NaCl, 1 mM dithiothreitol, pH 7.9) at 37 °C for 3 h to generate 5'-HS-G-RNA. The reaction was stopped by the addition of 10 μL of 200 mM EGTA and incubation at 65 °C for 10 min. The 5'-HS-G-RNA was recovered and resuspended as described above.

Conjugation of Thiol-Reactive Agents with 5'-HS-G-RNA and 5'-HS-PEG_n-RNA. The 5'-GTP-RNA, 5'-HS-G-RNA, and 5'-HS-PEG_n-RNAs were incubated with biotin-PEG₃-iodoacetamide (**15**), biotin-HPDP (**16**), and biotin-PEG₃-maleimide (**17**), in 10 mM HEPES (pH 7.8), 300 mM NaCl, and 1 mM EDTA at room temperature for 2 h. The reaction mixtures were extracted with phenol/chloroform/isoamyl alcohol (25:24:1) (pH 6.7) once and chloroform once, and precipitated with ethanol. The RNA pellets were resuspended in 20 μL of pure water and stored at -20 °C. A 2 μL aliquot of each of the biotinylated RNAs was incubated with 15 μg of streptavidin in the binding buffer (20 mM HEPES, pH 7.4, 5.0 mM EDTA, and 1.0 M NaCl) at room temperature for 20 min prior to mixing with 0.25 volume of formamide loading buffer (90% formamide, 0.01% bromophenol blue, and 0.025% xylene cyanol). The biotinylated RNA products were resolved by electrophoresis through 7.5 M urea/polyacrylamide gels. The biotinylated RNA can complex with streptavidin, and the mobility of the 5'-biotin-RNA/streptavidin complex through the gel will be retarded relative to unbiotinylated RNA. The fraction of product

formation relative to total RNA at each lane was quantitated with a Molecular Dynamics PhosphorImager.

For conjugation with maleimide-activated horseradish peroxidase (HRP), a 1.0 μL aliquot of 5'-GTP-RNA or 5'-HS-PEG_n-GMP-RNA was incubated with 10 μg of HRP in maleimide conjugation buffer (100 mM sodium phosphate, 5 mM EDTA, pH 7.6) at room temperature for 1 h. The HRP-conjugated RNA was then resolved by electrophoresis through an 8% urea/8% polyacrylamide gel. Detection of the HRP-maleimide-RNA conjugate was based on the electrophoretic mobility change of the conjugated RNA which obviated the need to assay for HRP's enzymatic activity. The mobility of HRP-labeled RNA will be slower than unmodified RNA on the 8% urea/8% polyacrylamide gel.

RESULTS AND DISCUSSION

Synthesis and Characterization of 5'-HS-PEG_n-GMP. The *O*-[ω -sulfhydryl-di(ethylene glycol)]-*O*-(5'-guanosine) monophosphate **10b** and *O*-[ω -sulfhydryl-tetra(ethylene glycol)]-*O*-(5'-guanosine) monophosphate **10c** were synthesized by phosphoramidite chemistry. The synthetic strategy was to synthesize 5'-phosphoramidite-2',3'-*O*,*O*-isopropylidene-2-*N*-(*N*',*N*'-dimethylaminomethylene)-guanosine **7** first, and then the free hydroxyl groups of ω -thioacetate-poly(ethylene glycol) compounds (**3a**, **3b**, and **3c**) were coupled with **7** in the presence of 1*H*-tetrazole (Scheme 1). Different lengths of PEG linkers were incorporated at the 5'-phosphate of guanosine depending upon the specific version of **3a-c** chosen.

A large excess of di- or tetra(ethylene glycol) was reacted with *p*-toluenesulfonyl chloride in pyridine and then reacted with potassium thioacetate to afford monothioacetate **3b** or **3c**. Guanosine **4** was treated with acetone and 70% perchloric acid at room temperature to give 2',3'-*O*,*O*-isopropylideneguanosine **5** in 83% yield. Compound **5** was reacted with *N*,*N*-dimethylformamide

Figure 2. (A) Autoradiogram of RNAs transcribed using various GTP:5'-HS-PEG₂-GMP ratios and incubated with maleimide-activated horseradish peroxidase prior to electrophoresis. (B) Quantitative analysis of transcription yield and incorporation efficiency of **10b** using maleimide-activated horseradish peroxidase to detect 5'-HS-PEG₂-GMP-initiated RNA. The total RNA was quantitated using a Varian UV spectrometer (260 nm); the height of the bars represents the total RNA yield after the gel purification of each RNA transcript. The shaded portions are the fraction of the **10b**-initiated RNA. Percentage values are normalized to an in vitro transcription reaction with each NTP at 1.0 mM without the **10b** initiator nucleotide.

We explored the efficiency of incorporation of 5'-HS-PEG₂-GMP (**10b**) during in vitro transcription reactions performed with varying molar ratios of GTP to 5'-HS-PEG₂-GMP (Figure 2). The molar ratio of GTP to **10b** was adjusted by maintaining a consistent concentration of 1 mM GTP while varying the concentration of **10b** between transcription reactions. The thiol-containing RNAs generated by the transcription reactions were conjugated to maleimide-activated HRP during a subsequent incubation step. Assuming that the thiol-maleimide reaction was quantitative, resolution of the 5'-HRP-S-PEG₂-GMP-RNA from the unconjugated RNA allowed us to determine the percent of RNA transcripts that successfully employed **10b** as the initiator nucleotide in lieu of GTP. No 5'-HRP-RNA was formed when **10b** was absent from the transcription reaction (Figure 2A, lane 1), confirming that the conjugation of the maleimide-activated HRP with the RNA was dependent upon the use of the thiol-containing initiator nucleotide.

The efficiency of incorporation of **10b** may be dissected in terms of both relative and absolute yields (i.e., what fraction of the total transcripts were initiated with **10b**, and how many moles of transcripts were produced). This is an important distinction since the absolute yield from the transcription reactions decreased at the highest concentrations of **10b** tested (Figure 2B). When the ratio of GTP to **10b** was 1:1, approximately 28% of the nascent transcripts were initiated with **10b**. The percent of transcripts initiated with **10b** increased to 51%, 60%, and 72% as the GTP:**10b** ratio was varied from 1 mM:4 mM, 1 mM:8 mM, and 1 mM:16 mM, respectively. Interestingly, the fraction of 5'-HRP-S-PEG₂-GMP-RNA increased significantly over this interval, but the absolute yield of 5'-HRP-S-PEG₂-GMP-RNA remained relatively constant as the absolute total transcription yield (including GTP-initiated transcripts) decreased (Figure 2B). When the concentration of **10b** reached 8 mM, it appeared to slightly inhibit transcription by T7 RNA polymerase. Normalizing the absolute yield of total RNA to 100% when the ratio of GTP to 5'-HS-PEG₂-GMP was 1 mM:0 mM, the yield decreased to 98% for 1 mM:4 mM, 65% for 1 mM:8 mM, and 68% for 1 mM:16 mM transcription reactions.

Scheme 4. General Overview of Enzymatic Incorporation To Yield 5'-Sulfhydryl-Modified RNA and Their Subsequent Detection by Conjugation with Thiol-Reactive Reagents

A comparison of these incorporation efficiencies with published reports using similar initiator nucleotides is complicated by the facts that each laboratory prefers slightly different transcription conditions and that the nucleotide concentrations frequently vary between studies. Certainly, however, our yields compare favorably with the yields reported by Sengle et al. (2000) in which transcription reactions employing a 1 mM:4 mM ratio of GTP to their biotinylated-GMP analogue resulted in one-fourth of their transcripts initiating with their analogue. Under similar GTP:GMP analogue conditions, we observed that 51% of the transcripts initiated with our thiol-containing GMP analogue **10b**. Interestingly, they reported that GMPS at low concentrations appeared to enhance the absolute total transcription yield and then began to decrease the total yield as the GMPS concentration was raised further. In contrast, the addition of AMP and GMP decreased the transcription yields in a concentration-dependent manner. We find that our **10b** nucleotide behaves more similar to the effect reported for AMP and GMP addition, specifically a concentration-dependent decrease in yields from transcription reactions utilizing T7 RNA polymerase.

We chose to use poly(ethylene glycol) (PEG) linkers because the flexibility that they provide enables their future use in applications in which steric hindrance may be an issue. In light of the finding that PEG-containing GMP nucleotides are incorporated less efficiently as initiator nucleotides as the length of the PEG linker increases (Seelig and Jäschke, 1999a,b), we sought to balance the competing demands of linker flexibility with incorporation efficiency. The results from Figure 2 suggest that we have found an acceptable balance; the initiator nucleotide **10b**, containing two PEG subunits, decreased the absolute total transcription yield when present at a GTP:**10b** ratio at 1 mM:8–16 mM but without significantly lowering the absolute yield of the desired **10b**-capped-RNA.

Thiol-Reactive Biotin Conjugation with 5'-HS-PEG₂-GMP-RNA. The streptavidin gel-shift results of 5'-HS-PEG₂-GMP-RNA with the biotinylated thiol-reactive **15**, **16**, and **17** (from Molecular Biosciences, Boulder, CO) (Scheme 5) are shown in Figure 3. When 5'-HS-PEG₂-GMP-RNA was reacted with **15**, **16**, and **17**, the thiol-modified RNA molecules were biotinylated and detected as band-shifts in the presence of streptavidin upon gel electrophoresis that represented streptavidin/

Figure 3. Autoradiogram of the streptavidin gel-shift analysis of transcription products (5'-GTP-RNA and 5'-HS-PEG₂-RNA) following an incubation with **15**, **16**, or **17**. Lanes 1–3, 5'-GTP-RNA; lanes 4–8, 5'-HS-PEG₂-RNA.

Figure 4. Autoradiogram of the streptavidin gel-shift analysis of transcription products (5'-GTP-RNA and 5'-GSMP-RNA) following an incubation with **15**, **16**, or **17**. Lanes 1–3, 5'-GTP-RNA; lanes 4–10, 5'-HS-G-RNA.

Scheme 5. Chemical Structures of Thiol-Reactive Agents

RNA complexes (lanes 4, 6, and 7); no retarded band was detected without streptavidin (lane 8). When 5'-GTP-capped-RNA was treated with **15**, **16**, and **17**, no biotinylated RNA was detected in the presence of streptavidin (lanes 1, 2, and 3, respectively). The retarded band disappeared after treatment with DTT (lane 5), which reduced the product of the thiol–disulfide exchange reaction between 5'-HS-RNA and biotin-HPDP **16**. The overall fraction of biotinylated RNA was 39% after reaction with **16**, 45% with **17**, and 23% with **15** for 5'-HS-PEG₂-GMP (lanes 4, 6, and 7, respectively).

Thiol-Reactive Biotin Conjugation with 5'-HS-G-RNA. The bridging phosphorothioate 5'-GSMP-RNA was dephosphorylated by alkaline phosphatase to generate 5'-HS-G-RNA (i.e., RNA containing a 5'-thiol instead of a 5'-hydroxyl group). The streptavidin gel-shift results of 5'-HS-G-RNA following reaction with **15**, **16**, and **17** are shown in Figure 4. When 5'-HS-RNA was reacted with **15**, **16**, and **17**, the thiol-modified RNA molecules were biotinylated and detected as band-shifts in the presence of streptavidin (lanes 4, 6, and 9, respectively); no retarded band was detected without streptavidin (lanes 5, 7, and 10) nor when 5'-GTP-capped-RNA was treated with **15**, **16**, and **17** (lanes 1, 2, and 3, respectively). The retarded band disappeared after treatment

with DTT (lane 8), which reduced the product of the thiol–disulfide exchange reaction between 5'-HS-RNA and biotin-HPDP **16**. These results suggest that the biotin group was transferred to the terminal thiol of the 5'-HS-RNA, not to other nucleophilic groups of RNA. The overall yield (three steps) of biotinylated RNA is 57% with **15** and 60% with **16** for GSMP (lanes 6 and 9, respectively). The experiments demonstrated that GSMP **14** can serve as a better initiator nucleotide for transcription by T7 RNA polymerase than **10b** and **10c** for the purpose of introducing a sulfhydryl group at the 5'-end of RNA.

CONCLUSION

We have developed a general method to introduce a single thiol group tethered to the 5'-end of RNA via spacers of various lengths. Our results demonstrate that GSMP and 5'-HS-PEG_n-GMP can serve as initiator nucleotides for T7 RNA polymerase, thus introducing a sulfhydryl group into the 5'-end of RNA. Fluorophores, biotinylated compounds, peptides, proteins, DNAs, RNAs, enzymes, and other chemical entities containing thiol-reactive functional groups can be attached to the thiol-modified RNA molecules using the techniques described here. These methods may have potential applications in analysis and detection of RNA, mapping RNA–protein interactions, in vitro selection of novel catalytic RNAs, and even gene array technologies.

In Vitro Cationic Lipid-Mediated Gene Delivery with Fluorinated Glycerophosphoethanolamine Helper Lipids

Jérôme Gaucheron,[†] Caroline Boulanger,[†] Catherine Santaella,^{†,||} Nicolas Sbirrazzuoli,[‡] Otmane Boussif,^{§,⊥} and Pierre Vierling^{*,†}

Laboratoire de Chimie Bioorganique, UMR 6001 CNRS, Laboratoire de Thermodynamique Expérimentale, Université de Nice-Sophia Antipolis, 06108 Nice Cédex 2, France, and Transgène, SA, 11, rue de Molsheim 67082 Strasbourg Cédex, France. Received March 19, 2001; Revised Manuscript Received July 3, 2001

There is a need for the development of nonviral gene transfer systems with improved and original properties. "Fluorinated" lipoplexes are such candidates, as supported by the remarkably higher in vitro and in vivo transfection potency found for such fluorinated lipoplexes as compared with conventional ones or even with PEI-based polyplexes (Boussif, O., Gaucheron, J., Boulanger, C., Santaella, C., Kolbe, H. V. J., Vierling, P. (2001) Enhanced in vitro and in vivo cationic lipid-mediated gene delivery with a fluorinated glycerophosphoethanolamine helper lipid. *J. Gene Med.* 3, 109–114). Here, we describe the synthesis of fluorinated glycerophosphoethanolamines (*F*-PEs), close analogues of dioleoylphosphatidylethanolamine (DOPE), and report on their lipid helper properties vs that of DOPE, as in vitro gene transfer components of fluorinated lipoplexes based on pcTG90, DOGS (Transfectam), or DOTAP. To evaluate the contribution of the *F*-PEs to in vitro lipoplex-mediated gene transfer, we examined the effect of including the *F*-PEs in lipoplexes formulated with these cationic lipids (CL) for various CL:DOPE:*F*-PE molar ratios [1:(1 - *x*):*x* with *x* = 0, 0.5 and 1; 1:(2 - *y*):*y* with *y* = 0, 1, 1.5, and 2], and various *N/P* ratios (from 10 to 0.8, *N* = number of CL amines, *P* = number of DNA phosphates). Irrespective of the *F*-PE chemical structure, of the colipid *F*-PE:DOPE composition, and of the *N/P* ratio, comparable transfection levels to those of their respective control DOPE lipoplexes were most frequently obtained when using one of the *F*-PEs as colipid of DOGS, pcTG90, or DOTAP in place of part or of all DOPE. However, a large proportion of DOGS-based lipoplexes were found to display a higher transfection efficiency when formulated with the *F*-PEs rather than with DOPE alone while the opposite tendency was evidenced for the DOTAP-based lipoplexes. The present work indicates that "fluorinated" lipoplexes formulated with fluorinated helper lipids and conventional cationic lipids are very attractive candidates for gene delivery. It confirms further that lipophobicity and restricted miscibility of the lipoplex lipids with the endogenous lipids does not preclude efficient gene transfer and expression. Their transfection potency is rather attributable to their unique lipophobic and hydrophobic character (resulting from the formulation of DNA with fluorinated lipids), thus preventing to some extent DNA from interactions with lipophilic and hydrophilic biocompounds, and from degradation.

INTRODUCTION

Gene (or DNA) transfer systems into cells have become powerful tools for gene and cellular therapy that are very promising novel forms of molecular medicine. Successful gene therapy depends on the efficient delivery of genetic material to cells and its effective expression within these cells. Although at present, the in vivo expression levels of synthetic nonviral gene transfer vectors based on (poly)cationic lipids, liposomes, and polymers (e.g., lipoplexes and polyplexes, respectively (1)) are lower than for viral vectors and gene expression is transient, these

systems are likely to present several advantages including low-cost and large-scale production, safety, lower immunogenicity, and capacity to deliver large gene fragments. Such systems have therefore gained wide acceptance over the past decade for in vitro and/or in vivo gene delivery (2–5). However, there is still a need for the development of gene transfer systems with improved and original properties.

Our approach with the development of "fluorinated" lipoplexes based either on highly fluorinated lipospermines (6, 7) or on a fluorinated glycerophosphoethanolamine helper lipid (e.g., [F8E11][C16]OPE in Scheme 1 which is an analogue of dioleoylphosphatidylethanolamine, DOPE) (8) proved to some extent successful as these systems showed a higher in vitro and in vivo transfection potential than conventional lipoplexes (6–8) or PEI polyplexes (8). More particularly, the use of [F8E11][C16]OPE (which on its own is inactive in promoting transfection) as colipid of the cationic lipopolyamine pcTG90 (see structure in Scheme 1) increased the in vitro and in vivo gene transfer capability of pcTG90 to a larger extent than DOPE (8). Although the exact mechanism which governs lipoplex-mediated gene delivery and ex-

Scheme 1

pression is unclear, several reasons may account for the gene expression improvement resulting from the use of [F8E11][C16]OPE in place of DOPE. This improvement could be due to the larger ability of the fluorinated colipid to preserve the integrity of complexed DNA in a biological environment. Indeed, owing to its increased hydrophobic and lipophobic character, this colipid is expected to prevent the fluorinated lipoplexes it forms with cationic lipids from interactions with lipophilic and hydrophilic biocompounds, and from degradation to a larger extent than conventional helper lipids, as shown for fluorinated lipoplexes formed from fluorinated lipospermines as compared with conventional ones (7). This improvement could also be related to the larger propensity of the fluorinated colipid to promote fusion with and destabilization of the endosome membrane allowing more efficient DNA release in the cytosol, thus preventing internalized DNA from endosome and lysosome degradation to a larger extent than when DOPE is used as helper lipid (9–12). This fluorinated PE displays also a more pronounced cone-shape geometry than DOPE as a consequence of the larger size of its fluorinated chain when compared with hydrocarbon ones (13). One therefore expects a greater tendency for [F8E11][C16]OPE to promote a lamellar to inverted hexagonal HII phase transition (13) and, thus, a greater effectiveness in disrupting membranes than DOPE (the role in membrane fusion of DOPE was indeed attributed to its capability to initiate such a phase transition (11, 12)).

The goals of the present study was aimed at extending the library of fluorinated glycerophosphoethanolamines (*F*-PEs), and at examining (i) their lipid helper effect on lipofection and (ii) the cationic lipid specificity of their transfection enhancement potential, as compared with that of DOPE. The molecular structure of this second generation of *F*-PEs (listed in Scheme 1) follows a modular design (one or two fluorinated chains, saturated or unsaturated chains, ester or ether bond) aimed at the establishment of structure/properties (transfection helper

potential) relationships. We report here on their synthesis and on their helper lipid properties as in vitro gene transfer components of pcTG90, DOGS (Transfectam), and DOTAP-based lipoplexes (see structures in Scheme 1), as compared with DOPE. These (poly)cationic lipids were selected for their well-documented high transfection efficiency which is significantly improved with DOPE (for pcTG90, see (8, 14, 15), for DOGS, see (16) and for DOTAP, see (17, 18)). They were also chosen for their specific structural and geometrical features (linear or branched polyamino or single quaternary ammonium polar head) which might have quite different effects on the phases these cationic lipids associated to the *F*-PEs are susceptible to form. The thermotropic phase behavior of the *F*-PEs in water was also investigated by differential scanning calorimetry (DSC) in order to highlight its role on lipoplex formulation and lipofection (10, 12). In our initial study (8), the optimized conditions for the in vitro and in vivo transfection tests, which led us to show a significantly higher transfection helper potential of [F8E11][C16]OPE as compared with that of DOPE, were corresponding to pcTG90-based lipoplexes formulated in HEPES and in 5% glucose, respectively. However, in vitro, when the lipoplexes were formulated in 5% glucose, both colipids displayed a comparable transfection helper potential. In anticipation of in vivo testing, lipofection with the *F*-PEs as colipids was investigated here only for lipoplexes formulated in 5% glucose.

EXPERIMENTAL PROCEDURES

General Experimental and Analytical Conditions. Most of the reactions were performed in anhydrous solvents under dry and oxygen-free nitrogen. Anhydrous solvents were prepared by standard methods. The purifications by column chromatography were carried out using silica gel 60 (Merck, 70–230 mesh) and chloroform (CHCl_3), dichloromethane (CH_2Cl_2), methanol (MeOH), or mixtures thereof as indicated. Unless noted otherwise, the ratios describing the composition of solvent mixtures represent relative volume. Advancing of the reaction was followed by thin-layer chromatography (TLC) on silica plates F_{254} (Merck). The following developing systems were used: UV light, KMnO_4 , $\text{H}_2\text{SO}_4/\text{EtOH}$, Dragendorff reagent (Sigma), ninhydrin reagent (Sigma).

The perfluoroalkyl iodides were purified over neutral alumina before use. DF4C11OPE, DOGS (or Transfectam), and DOTAP were prepared as described in refs 19, 6, and 17, respectively. The lipopolyamine pcTG90 was from Transgène (Strasbourg, France) (20). DOPE was purchased from Sigma. All other organic chemicals were from Aldrich, Fluka, or Novabiochem.

^1H , ^{13}C , $^{31}\text{P}\{^1\text{H}\}$, and ^{19}F NMR spectra were recorded on a Bruker AC-200 at 200, 50.3, 81, and 188.3 MHz, respectively. Chemical shifts were measured relative to CHCl_3 (δ 7.27 ppm) or CH_3OD (δ 3.35 ppm) for ^1H , to CDCl_3 (δ 76.9 ppm) for ^{13}C and expressed indirectly in relation to TMS, to external ref 75% H_3PO_4 for ^{31}P , and to CCl_3F as internal reference for ^{19}F . The following abbreviations are used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). Chemical shifts are expressed in ppm and listed as follow: shift in ppm (multiplicity, coupling, integration and attribution). Elemental analyses were carried out by the Service Central de Microanalyses du CNRS.

Synthesis of the Glycerol Derivatives 2a–c. *rac*-2,3-Di-[11-(*F*-butyl)undecanoyl]glycerol, 2a. The synthesis of 2a from *rac*-1-*O*-benzylglycerol was performed according to published procedures (21).

rac-3-[11-(F-Octyl)undec-10-enyloxy]-2-(hexadecyloxy)propan-1-ol, 2b. The syntheses of derivatives **4** to **6** from 1,3-*O*-benzylideneglycerol, **3**, were performed according to published procedures (19).

rac-3-(Benzyloxy)-2-(hexadecyloxy)propan-1-ol, 4. The alkylation of **3** with 1-bromohexadecane under phase-transfer catalysis conditions gave 5-hexadecyloxy-2-phenyl-1,3-dioxane [white powder, 73%; TLC (hexane/ethyl acetate 8:2, UV and H₂SO₄): *R*_f = 0.72. ¹H NMR (CDCl₃): δ 0.84 (t, ³*J* = 6.1 Hz, 3H, CH₃); 1.20–1.50 (broad s, 26H, CH₃(CH₂)₁₃); 1.51–1.80 (m, 2H, CH₂CH₂O); 3.10–3.20 (m, part X of a ABX system, 1H, CH₂CHCH₂); 3.68 (t, ³*J* = 6.6 Hz, 2H, CH₂CH₂OCH); 4.05, 4.38 (part AB of a ABX system, ²*J*_{AB} = 12.4 Hz, ³*J*_{AX} = 1.6 Hz, ³*J*_{BX} = 1.3 Hz, 4H, CH₂CHO); 5.60 (s, 1H, CHPh); 7.31–7.49, 7.50–7.65 (m, m, 3H, 2H, Ph). ¹³C NMR (CDCl₃): δ 14.3 (CH₃); 22.8 (CH₃CH₂); 26.3 (CH₂CH₂CH₂O); 29.5, 29.6, 29.7, 29.8, 29.9 (CH₃(CH₂)₂(CH₂)₉, CH₂CH₂O); 32.1 (CH₃CH₂CH₂); 69.2, 69.3 (CH₂O); 70.7 (CH₂OCH); 101.4 (CHPh); 126.2, 128.2, 128.8, 138.3 (Ph)]. The reductive cleavage of the 1,3-*O*-benzylidene group in 5-hexadecyloxy-2-phenyl-1,3-dioxane with BH₃·THF gave **4** (colorless oil, 85%). TLC (CHCl₃; UV and H₂SO₄): *R*_f = 0.25. ¹H NMR (CDCl₃): δ 0.90 (t, ³*J* = 6.1 Hz, 3H, CH₃); 1.10–1.40 (broad s, 26H, CH₃(CH₂)₁₃); 1.50–1.70 (m, 2H, CH₂CH₂O); 2.22 (broad s, 1H, OH); 3.35–3.78 (m, 7H, CH₂O, CHO); 4.56 (s, 2H, CH₂Ph); 7.20–7.35 (m, 5H, Ph). ¹³C NMR (CDCl₃): δ 14.3 (CH₃); 22.8 (CH₃CH₂); 26.3 (CH₂CH₂CH₂O); 29.5, 29.6, 29.7, 29.8, 29.9 (CH₃(CH₂)₂(CH₂)₉, CH₂CH₂O); 32.1 (CH₃CH₂CH₂); 63.0 (CH₂OH); 70.2, 70.6 (CH₂O); 73.7 (CH₂Ph); 78.7 (OCH); 127.6, 127.7, 128.4, 138.1 (Ph).

rac-1-[3-(Undec-10-enyloxy)-2-(hexadecyloxy)propyloxy]benzene, 5. The alkylation of **4** via its anion with 11-bromoundecene gave **5** (colorless oil, 84%). TLC (CHCl₃; UV and H₂SO₄): *R*_f = 0.47. ¹H NMR (CDCl₃): δ 0.90 (t, ³*J* = 6.1 Hz, 3H, CH₃); 1.10–1.40 (broad s, 38H, CH₃(CH₂)₁₃, (CH₂)₆(CH₂)₂O); 1.41–1.70 (m, 4H, CH₂CH₂O); 2.00–2.20 (m, 2H, CH₂=CHCH₂); 3.35–3.78 (m, 9H, CH₂O, CHO); 4.56 (s, 2H, CH₂Ph); 4.80–5.10 (m, 2H, CH₂=CH); 5.65–5.95 (m, 1H, CH₂=CH); 7.20–7.35 (m, 5H, Ph).

rac-1-[3-(11-(F-Octyl)undec-10-enyloxy)-2-(hexadecyloxy)propyloxy]benzene, 6. The addition of CF₃(CF₂)₇I on the terminal CH₂=CH bond of **5** gave **6** (colorless oil, 73%). TLC (CH₂Cl₂; UV and H₂SO₄): *R*_f = 0.40. ¹H NMR (CDCl₃): δ 0.92 (t, ³*J* = 6.1 Hz, 3H, CH₃); 1.10–1.40 (broad s, 38H, CH₃(CH₂)₁₃, (CH₂)₆(CH₂)₂O); 1.41–1.70 (m, 4H, CH₂CH₂O); 2.10–2.30 (m, 2H, CH=CHCH₂); 3.35–3.78 (m, 9H, CH₂O, CHO); 4.56 (s, 2H, CH₂Ph); 5.30–5.80 (m, 1H, CF₂CH=CH); 6.30–6.55 (m, 1H, CF₂CH=CH); 7.20–7.35 (m, 5H, Ph). ¹³C NMR (CDCl₃): δ 14.2 (CH₃); 22.8 (CH₃CH₂); 26.2, 26.3 (CH₂CH₂CH₂O); 28.1, 29.1, 29.2, 29.4, 29.5, 29.6, 29.7, 29.8, 29.9, 30.3 (CH₂CH₂O, CH₃(CH₂)₂(CH₂)₁₀, CH=CHCH₂(CH₂)₅); 32.1 (CH₃CH₂CH₂, =CHCH₂); 70.5, 70.8, 70.9 (CH₂O); 73.5 (CH₂Ph); 78.6 (CHO); 116.9 (t, ²*J*_{CF} = 23 Hz, CF₂CH=CH); 126.2, 128.2, 128.8, 138.3 (Ph); 143.4 (t, ³*J*_{CF} = 9 Hz, CF₂CH=CH trans); 144.0 (t, ³*J*_{CF} = 5 Hz, CF₂CH=CH, cis). ¹⁹F NMR (CDCl₃): δ -81.3 (3F, CF₃); -107.2 (0.2F, CF₂CH cis); -112.7 (1.8F, CF₂CH trans); -122.0, -122.5, -123.2, -124.0 (2F, 4F, 2F, 2F, CF₃CF₂(CF₂)₅); -126.6 (2F, CF₃CF₂).

rac-3-[11-(F-Octyl)undec-10-enyloxy]-2-(hexadecyloxy)propan-1-ol, 2b. A suspension of FeCl₃ and 4.4 g of **6** in 15 mL CH₂Cl₂ was stirred for 90 min at room temperature. The organic phase was then washed, dried over Na₂SO₄ and evaporated, and the residue was purified by silica gel chromatography (CH₂Cl₂:MeOH 100:0

to 99:1) to afford 2.9 g of **2b** (white powder, 73%). TLC (CHCl₃; H₂SO₄): *R*_f = 0.20. ¹H NMR (CDCl₃): δ 0.85 (t, 3H, ³*J* = 6.5 Hz, CH₃); 1.05–1.45 (broad s, 38H, (CH₂)₆-CH₂CH₂O, CH₃(CH₂)₁₃); 1.45–1.70 (m, 4H, CH₂CH₂O); 2.07–2.28 (m, 2H, CH=CHCH₂); 2.48 (broad s, 2H, CH₂OH); 3.30–3.80 (m, 9H, CH₂O, CHO); 5.40–5.74 (m, 1H, CF₂CH=CH); 6.35–6.50 (m, 1H, CF₂CH=CH). ¹³C NMR (CDCl₃): δ 13.8 (CH₃); 22.6 (CH₃CH₂); 26.0 (CH₂CH₂CH₂O); 27.9, 28.9, 29.2, 29.3, 29.6, 30.0 (CH₂CH₂O, CH₃(CH₂)₂(CH₂)₉, =CHCH₂(CH₂)₅); 31.8 (CH₃CH₂CH₂, =CHCH₂); 62.8 (CH₂OH); 70.3, 70.7, 71.6 (CH₂O); 78.3 (CHO); 116.7 (t, ²*J*_{CF} = 23 Hz, CF₂CH=CH); 143.0 (t, ³*J*_{CF} = 9 Hz, CF₂CH=CH trans); 145.0 (CF₂CH=CH cis). ¹⁹F NMR (CDCl₃) identical to that of **6**.

rac-3-[11-(F-Octyl)undecyloxy]-2-(hexadecyloxy)propan-1-ol, 2c. The simultaneous benzyl deprotection and C=C hydrogenation of **4** (1.8 g; 1.8 mmol) in 15 mL of EtOH and 0.2 mL of AcOH was performed at room temperature under 40 atm H₂ pressure with Pd/C (10%) as catalyst. Usual workup and silica gel chromatography (CH₂Cl₂) afforded 1.0 g (60%) of **2c** as a white powder (60%). TLC (CH₂Cl₂; H₂SO₄): *R*_f = 0.55. ¹H NMR (CDCl₃): δ 0.88 (t, 3H, ³*J* = 6.5 Hz, CH₃); 1.15–1.48 (broad s, 40H, (CH₂)₇CH₂CH₂O, CH₃(CH₂)₁₃); 1.48–1.72 (m, 4H, CH₂CH₂O, CF₂CH₂CH₂); 2.06 (t, ³*J* = 7.5 Hz, ³*J*_{HF} = 19.0 Hz, 2H, CF₂CH₂); 2.22–2.34 (broad s, 1H, CH₂OH); 3.38–3.83 (m, 9H, CH₂O, CHO). ¹³C NMR (CDCl₃): δ 14.0 (CH₃); 20.6 (t, ³*J*_{CF} = 4 Hz, CF₂CH₂CH₂); 22.6 (CH₃CH₂); 26.1 (CH₂CH₂CH₂O); 29.2, 29.3, 29.6, 30.0 (CH₂CH₂O, CH₃(CH₂)₂(CH₂)₁₀, CF₂(CH₂)₂(CH₂)₆); 30.9 (t, ²*J*_{CF} = 22 Hz, CF₂CH₂); 31.8 (CH₃CH₂CH₂); 63.1 (CH₂OH); 70.4, 70.9, 71.8 (CH₂O); 78.3 (CHO). ¹⁹F NMR (CDCl₃): δ -79.6 (3F, CF₃); -113.3 (2F, CF₂CH₂); -120.7 (6F, (CF₂)₃CF₂-CH₂); -121.6 (2F, CF₃(CF₂)₂CF₂); -122.4 (2F, CF₃-CF₂CF₂); -125.0 (2F, CF₃CF₂).

Synthesis of the F-PE Derivatives. The phosphorylation of the glycerol derivatives **2a–c** and the deprotection step of the BOC-protected intermediates **7a–c** with TFA were performed according to the procedures described for the synthesis of DF4C11OPE (19). The F-PE derivatives were isolated as TFA salts.

rac-2,3-Di[11-(F-butyl)undecanoyl]glycero-1-phosphoethanolamine, DF4C11PE. **rac-1,2-Di[10-(F-butyl)undecanoyl]glycero-3-phospho(tert-butoxy-carbonyl)ethanolamine, 7a** (30% yield): ¹H NMR (CDCl₃:CD₃OD): δ 1.02–1.37 (m, 37H, (CH₂)₇(CH₂)₂C(O), CH₃ (BOC); 1.37–1.57 (m, 4H, CH₂CH₂C(O)); 1.92 (tt, ³*J* = 7.5 Hz, ³*J*_{HF} = 19.0 Hz, 4H, CF₂CH₂); 2.09–2.26 (m, 4H, CH₂C(O)); 3.07–3.26 (m, 2H, CH₂N); 3.66–3.90 (m, 4H, CH₂OPOCH₂); 3.95–4.32 (m, 2H, C(O)OCH₂); 5.03–5.16 (m, 1H, CH). ¹³C NMR (CDCl₃/CD₃OD): δ 20.3 (t, ³*J*_{CF} = 4 Hz, CF₂CH₂CH₂); 25.0, 25.1 (CH₂CH₂C(O)); 28.4 (C(CH₃)₃); 29.5, 29.6 ((CH₂)₆(CH₂)₂C(O)); 30.9 (t, ²*J*_{CF} = 22 Hz, CF₂CH₂); 34.2, 34.4 (CH₂C(O)); 41.1 (d, ³*J*_{CP} = 6 Hz, CH₂N); 62.9 (OCH₂); 64.1 (d, ²*J*_{CP} = 5 Hz, POCH₂-CH₂N); 65.1 (d, ²*J*_{CP} = 5 Hz, CHCH₂OP); 71.1 (d, ³*J*_{CP} = 8 Hz, CH); 80.1 (C(CH₃)₃); 157.1 (NC(O)); 173.6, 174.6 (CH₂C(O)). ¹⁹F NMR (CDCl₃/CD₃OD): δ -80.0 (3F, CF₃); -113.5 (2F, CF₂CH₂); -123.3, -124.9 (2F, 2F, CF₃(CF₂)₂). ³¹P{¹H} NMR (CDCl₃/CD₃OD): δ -8.1 (s).

DF4C11PE (15% yield from **7a**): TLC (CH₂Cl₂:MeOH 7:3; ninhydrine): *R*_f = 0.70. ¹H NMR (CDCl₃/CD₃OD): δ 0.80–1.18 (m, 28H, (CH₂)₇(CH₂)₂C(O)); 1.18–1.50 (m, 4H, CH₂CH₂C(O)); 1.75 (tt, ³*J* = 7.5 Hz, ³*J*_{HF} = 19.0 Hz, 4H, CF₂CH₂); 1.90–2.12 (m, 4H, CH₂C(O)); 2.75–2.96 (m, 2H, CH₂N); 3.48–4.18 (m, 6H, CH₂OPOCH₂, C(O)OCH₂); 5.06–5.21 (m, 1H, CH). ¹³C NMR (CDCl₃/CD₃OD): δ 19.6 (t, ³*J*_{CF} = 4 Hz, CF₂CH₂CH₂); 24.5 (CH₂CH₂CO); 28.7, 28.8, 30.0 ((CH₂)₆(CH₂)₂CO); 30.4 (t, ²*J*_{CF} = 22 Hz,

CF₂CH₂); 33.6, 33.7 (CH₂C(O)); 40.1 (d, ³J_{CP} = 6 Hz, CH₂N); 61.3 (d, ²J_{CP} = 5 Hz, POCH₂CH₂N); 62.2 (C(O)-OCH₂); 63.5 (d, ²J_{CP} = 5 Hz, CHCH₂OP); 70.1 (d, ³J_{CP} = 8 Hz, CH); 173.5, 173.8 (CO). ¹⁹F NMR (CDCl₃/CD₃OD): δ -82.5 (3F, CF₃); -115.9 (2F, CF₂CH₂); -125.7, -127.4 (4F, CF₃(CF₂)₂). ³¹P NMR {¹H} (CDCl₃/CD₃OD): δ -0.2 (s). Anal. (C₃₅H₅₂F₁₈NO₈P + 1H₂O) Calcd: C, 41.80; H, 5.21; N, 1.39. Found: C, 41.78; H, 5.17; N, 1.38.

rac-3-[11-(F-Octyl)undec-10-enyl]-2-(hexadecyl)-glycero-1-phosphoethanolamine, [F8E11][C16]OPE. rac-1-[11-(F-Octyl)undec-10-enyl]-2-(hexadecyl)-glycero-3-phospho(tert-butoxycarbonyl)ethanolamine, 7b (70% yield): TLC (CHCl₃/MeOH: 7:3, v/v; molybdenum blue): R_f = 0.60. ¹H NMR (CDCl₃/CD₃OD): δ 0.85 (t, ³J = 6.1 Hz, 3H, CH₃); 1.05–1.35 (s large, 38H, CH₃(CH₂)₁₃, (CH₂)₆(CH₂)₂O); 1.35–1.63 (m, 13H, CH₂-CH₂O, CH₃(BOC)); 2.10–2.28 (m, 2H, CH=CHCH₂); 3.17–3.32 (m, 2H, CH₂N); 3.32–3.65 (m, 7H, CH₂OCH₂, CH₂OCH); 3.73–3.95 (m, 4H, CHCH₂OP, POCH₂CH₂N); 5.42–5.72 (m, 1H, CF₂CH=CH); 6.38–6.50 (m, 1H, CF₂CH=CH). ¹³C NMR (CDCl₃/CD₃OD): δ 13.6 (CH₃); 22.4 (CH₃CH₂); 25.9 (CH₂CH₂CH₂O); 28.0 (CH₃(BOC)); 27.8, 28.8, 29.2, 29.4, 29.6, 30.0 (CH₂CH₂O, CH₃(CH₂)₂-(CH₂)₁₀, CH=CHCH₂(CH₂)₅); 31.8, 31.9 (CH₃CH₂CH₂, =CHCH₂); 40.8 (d, ³J_{CP} = 6 Hz, CH₂N); 64.3 (d, ²J_{CP} = 5 Hz, POCH₂CH₂N); 65.2 (d, ²J_{CP} = 5 Hz, CHCH₂OP); 70.1, 70.5, 71.6 (CH₂OCH₂, CH₂OCH); 77.7 (CH); 79.2 (C(CH₃)₃); 116.7 (t, ²J_{CF} = 23 Hz, CF₂CH=CH); 143.0 (t, ³J_{CF} = 9 Hz, CF₂CH=CH trans); 145.0 (CF₂CH=CH cis); 157.2 (C(O)). ¹⁹F NMR (CDCl₃/CD₃OD): identical to that of **6**. ³¹P {¹H} NMR (CDCl₃/CD₃OD): δ 2.1 (s).

Differential Scanning Calorimetry (DSC). For DSC measurements in the +4 to 95 °C temperature range, the samples were prepared by weighing the powdered phospholipid (~10 mg) into pierced aluminum pans and adding a weighed amount of deionized water to obtain a water concentration of 60% (w/w). DSC measurements were carried out at a rate of 10 °C/min with a Mettler-Toledo DSC 821e apparatus which was previously calibrated using indium, zinc, and lead standards. The samples were sealed and heated in a static atmosphere. Transition enthalpies and temperatures were determined after several heating/cooling cycles. The reported values of the T_c represent the temperature at maximum excess heat capacity.

Preparation of Complexes Composed of the Cationic Lipids, the Helper Lipids and Plasmid pTG11033. The plasmid pTG11033 was produced by Transgène. The endotoxin content of the plasmid preparation was checked using a Limulus Amebocyte Lysate kit (Biogenic, Maurin, France). This value was below 1 endotoxin unit/mg of plasmid, hence below the 5 e.u./mg of DNA recommended for in vivo protocols. The quantities of compounds used were calculated according to the desired DNA concentration of 0.1 mg/mL, the N/P ratio, the molar weight, and the number of positive charges in the selected cationic lipid (CL). The N/P ratio of 10, for example, corresponds to the molar amount of CL necessary to have a ratio of 10 amino group nitrogens (for 1 mol of CL) per one phosphate in the DNA (330 Da mean Mw), as described elsewhere (1, 22, 27). The DNA/CL: colipid(s) complex is formulated by adding a desired volume of the liposomal CL:colipid(s) preparation at a CL concentration of 10 mg/mL in 5% glucose to the desired volume of DNA solution to reach a DNA concentration of 0.1 mg/mL. Thus for the preparation of the DNA/DOGS:DOPE (1:1 mol) complex at N/P ratio 5 and 0.1 mg/mL DNA, the desired volume of DOPE (10 mg/mL chloroform solution) to get mol:mol DOGS:DOPE was

added to 50 μL of DOGS solution (10 mg/mL in EtOH), and then the mixture was transferred to a borosilicate glass tube (16 $\times$ 100 mm). The solvent was evaporated in Rotavap evaporation system (45 $^{\circ}\text{C}$, 30 pm, 0.2 bar, 40 min). 50 μL of 5% glucose were added to the film obtained. The preparation was vortexed for 2 h and then sonicated for 5–10 min to yield a liposomal preparation of 50–100 nm mean size as measured by photon correlation spectroscopy (see below). Then, 47.9 μL of this preparation was added to 952.1 μL of DNA solution [(100 μL DNA (1 mg/mL) diluted with 852.1 μL of 5% glucose)]. This preparation was vortexed for 10 s and was used within 1 h for the particle size measurements and the in vitro transfection experiments.

Measurement of the Size of the Lipoplexes. The sample was diluted with 5% glucose in the measurement tube and homogenized, and the average sizes were measured by photon correlation spectroscopy using a Coulter N4Plus particle size analyzer, as described in ref 5. The formulations and analyses were reproduced twice.

Agarose Gel Electrophoresis. Each sample was analyzed and plasmid integrity in each sample was confirmed by electrophoresis after decomplexing the lipoplex with sodium dodecyl sulfate, following the procedures described in ref 5.

In Vitro Transfection of A549 Cells. Twenty-four hours before transfection, A549 cells (epithelial cells derived from human pulmonary carcinoma) were grown in Dulbecco-modified Eagle culture medium (DMEM) (GIBCO-BRL, Life Technologies, Cergy Pontoise, France), containing 10% fetal calf serum, FCS (SIGMA, Saint Quentin Fallavier, France), in 96-well plates (2 $\times$ 10⁴ cells per well), in a wet (37 $^{\circ}\text{C}$) and 5% CO₂/95% air atmosphere. Volume of DNA/CL:colipid(s) (1:1 mol) or (1:2 mol) lipoplex (5 and/or 1 μL) was diluted to 100 μL in DMEM supplemented with 10% FCS in order to obtain various amounts of DNA (0.5 and/or 0.1 μg , respectively) in the preparation. The culture medium was removed and replaced by 100 μL of DMEM supplemented with 10% FCS and containing the desired amount of DNA. After 4 and 24 h, 50 μL and 100 μL of DMEM supplemented with 30 and 10% FCS, respectively, were added. Forty-eight hours after transfection, the culture medium was discarded, and the cells were washed twice with 100 μL of PBS and then lysed with 50 μL of lysis buffer (Promega, Charbonnières, France). The lysates were frozen at -40°C awaiting analysis of luciferase activity. These measurements were done for 10 s on 10 μL of the lysis mixture in a Berthold LB96P luminometer in dynamic mode, using the "Luciferase" determination system (Promega) in 96-well plates. The total protein concentration per well was determined using conventional techniques (BCA test, Pierce, Montluçon, France). For cells grown in the absence of lipoplexes, a well contains around 30 to 50 μg of proteins. The percentage of cell viability of the lipoplexes was calculated as the ratio of the total protein amount per well of the transfected cells relative to that measured for untreated cells $\times$ 100%. The given means $\pm$ SEM were calculated from four independent experiments.

Statistical Analyses. Statistical analyses were performed using a Student *t* test. The difference between two means was considered as statistically significant when *p* is $\leq$ 0.05.

RESULTS AND DISCUSSION

Synthesis. The synthesis of the fluorocarbon DF4C11PE, [F8E11][C16]OPE, and [F8C11][C16]OPE

phosphoethanolamines from their respective glycerol precursors **2a–c** was performed according to well documented procedures that have been published for the preparation of DF4C11OPE (19). These procedures, illustrated in Scheme 2 part C, involved phosphorylation of these **2a–c** synthons with POCl₃, condensation with *N*-BOC-ethanolamine, hydrolysis, and then BOC-deprotection using trifluoroacetic acid (TFA), affording the expected *F*-PEs as TFA salts (15–50% yields from **2a–c**).

The ester-linked glycerol derivative **2a** was obtained in two steps from benzylglycerol which included conventional acylation and benzyl deprotection by hydrogenolysis (Scheme 2, part A). The more demanding preparation of the mixed fluorocarbon/hydrocarbon 1,2-di-ether linked glycerol derivatives **1b,c** (Scheme 2, part B) was best performed from 1,3-*O*-benzylideneglycerol **3** using a strategy developed for close analogues (19). In this cyclic-strained protected glycerol, the secondary hydroxyl function has been shown to be more accessible and easier to alkylate than in acyclic protected analogues (23). Alkylation of **3** performed under phase catalysis conditions using hexadecyl bromide, followed by the reductive cleavage of the 1,3-benzylidene-protecting group with BH₃/THF (23) afforded derivative **4** (70% yield). Subsequent alkylation of the hydroxyl thus liberated in **4** using 11-undecenyl bromide yielded the benzyl-protected derivative **5** (70% yield). The addition of the linear perfluorooctyl iodide (C₈F₁₇I) on the terminal CH₂=CH—double bond of **5** was performed using the modified method of Burton and Kehoe (24): this two-step one-pot reaction led to the perfluorooctyl unsaturated derivative **6**, in 75% yield. According to ¹⁹F NMR which showed more particularly the presence of two resonances for the CF₂ in α to the double bond, the isolated compound consisted in a mixture of *E*- and *Z*-isomers. The most abundant one was the *E*-isomer (at least 85%). These products were also contaminated by a compound (less than 5%) which possesses a CF₂—CH₂—CH=CH— sequence, as a result of a β,γ -HI elimination during the perfluoroalkylation step (19, 24). This was evident from the presence of, respectively, a doublet of triplets (³*J*_{HH} = 7 Hz, ³*J*_{HF} = 18 Hz) at 2.7 ppm, a triplet (²*J*_{CF} = 23 Hz) at 34.7 ppm for the CH₂ group and a CF₂ resonance at -115.8 ppm, in the ¹H, ¹³C, and ¹⁹F NMR spectra of **6**.

Selective benzyl-deprotection was performed by action of excess FeCl₃ in anhydrous CH₂Cl₂ followed by hydrolysis (25). This procedure afforded the mixed fluorocarbon/hydrocarbon unsaturated 1,2-glycerol derivative **2b** in 75% yield. The saturated and benzyl-deprotected analogue **2c** was obtained in nearly 60% yield by simultaneous benzyl-deprotection and double-bond hydrogenation using high-pressure hydrogenolysis conditions (40 atm H₂ in the presence of 10% Pd/C). Under milder hydrogenolysis conditions (1 atm H₂), double-bond hydrogenation but only partial debenzylation was observed.

Thermotropic Phase Behavior. The thermotropic phase behavior of samples consisting of hydrated powders of the *F*-PEs was investigated by DSC. Table 1 collects the thermodynamic parameters (*T*_c, gel (crystalline) to liquid-crystalline main phase transition and/or lamellar to inverted hexagonal phase transition, see hereafter, and their associated ΔH and ΔS) determined on these dispersions by DSC. The phase behavior of hydrated DF4C11OPE has been investigated in detail by X-ray diffraction, DSC, and optical microscopy with polarized light (26). This latter study, performed as a function of

temperature, showed that DF4C11OPE, in excess water, forms a hexagonal phase above 28 °C, (i.e., below but close to the phase transition temperature measured by DSC). It showed also that the unique and broad phase transition detected by DSC consisted in a superposition of transitions, which included the lamellar gel to liquid-crystalline phase transition followed, almost simultaneously, by a transition to a hexagonal phase. Owing to their very close molecular structures, one can therefore assume that the unique and broad phase transition detected by DSC for the other fluorinated PEs is also most likely a transition to a hexagonal phase. The presence of a HII phase at a temperature above the phase transition temperature detected by DSC was further attested by optical microscopy with polarized light.

Lipoplex Formation and Characterization. The capability of the various F-PEs as colipid of cationic lipids, CL (= DOGS, pcTG90 or DOTAP) to form lipoplexes was analyzed for various CL:DOPE:F-PE molar ratios $[1:(1-x):x]$ with $x = 0.5, 0.75$, or 1, and $[1:(2-y):y]$ with $y = 1, 1.5$, or 2, and for various N/P ratios (10, 5, 2.5, 1.25, and 0.8), as compared to CL:DOPE (1:1) or (1:2

mol) control lipoplexes. These studies were performed with pTG11033 plasmid, also used for the in vitro transfection assays (see next section). The procedure applied for the lipoplex preparation relies on the dilution of a liposomal solution obtained from CL and the colipid(s) in 5% glucose with the DNA solution in 5% glucose, using N/P ratios of 10, 5, 2.5, 1.25, and 0.8 (N = number of lipid cations; P = number of DNA phosphates (22, 27)). These formulations were analyzed by agarose gel electrophoresis which showed the absence of « free » plasmid for N/P ratios from 10 to 1.25, DNA being totally protected from ethidium bromide interaction. By contrast, the plasmid was accessible to ethidium bromide in the case of N/P 0.8 formulations. These formulations were also analyzed by light scattering spectroscopy (LSS) for size determination (which is an important parameter to control when in vivo uses are contemplated or when their in vitro transfection efficiency is evaluated (16, 22)). For the CL:colipid(s) (1:1 mol) formulations, and irrespective of the nature of CL and colipid(s) and of colipid composition, one observed most often lipoplexes of mean size in the 50–180 nm range for an excess of cationic charges ($N/P \geq 2.5$) and in the 150–400 nm range for $N/P = 0.8$ while precipitates were systematically detected for $N/P = 1.25$ (data not shown). Concerning the pcTG90:colipid(s) (1:2 mol) formulations, a very similar behavior was observed, i.e., lipoplexes of mean size in the 50–150 nm range for $N/P \geq 2.5$, in the 150–300 nm range for $N/P = 0.8$, and precipitates for $N/P = 1.25$ except when co-formulated with DF4C11OPE or DF4C11PE (data not shown). This latter result is noteworthy as most often precipitates for a N/P ratio of 1.25 (which corresponds to almost neutrally charged lipoplexes) were reported in the literature (4, 5, 28). Concerning the N/P 0.8, 2.5, 5, and 10 formulations, our results are also close to those

Figure 1. A: Luciferase expression (bars) and cell viability (points) in A549 cells of the lipoplexes prepared in 5% glucose and made of CL(= pcTG90, DOGS, or DOTAP):DOPE:[F8E11][C16]OPE (1:1 - $x:x$ with $x = 0.5, 0.75$, or 1) and plasmid pTG11033 (DNA) for various N/P ratios, as compared to control DOPE lipoplexes ($x = 0$). The given means $\pm$ SEM were calculated from four independent experiments. B: Transfection efficiency of the [F8E11][C16]OPE-based lipoplexes vs that of their corresponding DOPE control lipoplexes. The luciferase level LLR is the ratio of luciferase amount measured for the fluorinated formulation vs that measured for its corresponding DOPE control. The efficiency is significantly higher if LLR is ≥ 5 , significantly lower if LLR ≤ 0.2 , or comparable if $0.2 < \text{LLR} < 5$. When outside this range, $p < 0.01$ were carried out in a pairwise comparison. The values given as statistics correspond to the number of formulations that satisfy the given LLR condition vs the total number of formulations investigated, and to the respective percentages. *The luciferase expression levels (in the 2×10^3 to 7×10^3 fg luciferase per mg protein range) corresponding to the F-PE and control N/P 0.8 pcTG90-based formulations are not shown.

reported for other lipoplexes, i.e., stable dispersions for "negatively" ($N/P = 0.8$) and positively charged lipoplexes ($N/P \geq 2.5$) (4, 5, 28).

As compared with DOPE alone, no impact of the F-PE's nature or of their molecular structure on lipoplex size could be evidenced. Our results indicate that the fluorinated PEs are as effective colipids as DOPE in terms of compacting DNA with DOGS, pcTG90 or DOTAP into small-sized particles. These data suggest further that the lamellar to hexagonal phase transition temperature of the F-PEs, and the expected lower miscibility between the fluorinated colipids and the cationic lipids as compared with DOPE (fluorinated amphiphiles are usually not miscible with hydrocarbon ones (29)) are not determinant for the DNA compaction process when using cationic lipids in combination with such colipids.

In Vitro Transfection. To evaluate the contribution of the various F-PEs to in vitro lipoplex-mediated gene transfer, we examined the transfection potential of the above-described lipoplexes formulated with these F-PEs (alone or in combination with DOPE) as colipids of pcTG90, DOGS, or DOTAP. Both CL:colipid(s) (1:1 mol) and (1:2 mol) formulations were investigated as the pcTG90:colipid(s) (1:1 mol) and (1:2 mol) lipoplexes proved to be more efficient in vitro and in vivo transfection assays, respectively (8, 14, 15). Lipofection was assayed in vitro on lung epithelial A549 cells, from human pulmonary carcinoma. These assays were performed using the luciferase reporter plasmid pTG11033 (pCMV-intronHMG-luciferase-SV40pA, 9572 bps) in the presence of 10% fetal calf serum for 48 h. All the lipoplex formulations described in the precedent section were

Figure 2. A: Luciferase expression (bars) and cell viability (points) in A549 cells of the lipoplexes prepared in 5% glucose and made of CL(= pcTG90, DOGS, or DOTAP):DOPE:[F8C11][C16]OPE (1:1 - x : x with $x = 0.5, 0.75$, or 1) and plasmid pTG11033 (DNA) for various N/P ratios, as compared to control DOPE lipoplexes ($x = 0$). The given means $\pm$ SEM were calculated from four independent experiments. B: Transfection efficiency of the [F8E11][C16]OPE-based lipoplexes vs that of their corresponding DOPE control lipoplexes. *The luciferase expression levels (in the 2×10^3 to 7×10^3 fg luciferase per mg protein range) corresponding to the F-PE and control N/P 0.8 pcTG90-based formulations are not shown. For more details concerning LLR, and the statistics, see caption of Figure 1. When LLR is outside the 0.2–5 range, $p < 0.01$ in a pairwise comparison.

tested, except those that precipitated. The transfection efficiency of the lipoplexes, expressed in femtograms (fg) of luciferase/mg of protein, was evaluated for a DNA amount of 0.5 μ g/well: in our transfection protocol, a plateau of luciferase expression was generally obtained for such a DNA amount. For comparison, naked DNA and the control lipoplexes based on DOPE as sole colipid were also tested. Cells treated with naked DNA under equivalent conditions showed expression levels of about 10^{2-3} fg of luciferase/mg of protein. The cell viability of the lipoplexes was also checked by determining the total protein amount per well of the transfected cells relative to that measured for untreated cells (for which the total protein amount per well is in a 30–50 μ g/well range).

The transfection and cell viability results for the lipoplexes based on [F8E11][C16]OPE, [F8C11][C16]OPE, DF4C11OPE or DF4C11PE are illustrated in Figures 1A

to 4A for the CL:colipid(s) (1:1 mol) formulations and in Figure 5A for the pcTG90:colipid(s) (1:2 mol) ones. These results indicate that the “fluorinated” lipoplexes formed from any of these F-PEs (used as sole colipid or in combination with DOPE) and any of the cationic lipids (pcTG90, DOGS, or DOTAP) do transfect cells to a larger extent than naked DNA.

Concerning the CL:colipid(s) (1:1 mol) formulations (Figures 1A to 4A), the highest luciferase expression levels (LEL) were most frequently observed for N/P ratios of 2.5, 5, and 10 in the case of pcTG90, of 2.5 and 5 in the case of DOGS (LEL $\geq 10^6$ fg per mg protein), and of 0.8, 2.5, and 5 in the case of DOTAP (LEL $\geq 10^5$ fg per mg protein). A much lower plasmid expression was evidenced for the N/P 0.8 lipoplexes formulated with pcTG90 ($2 \times 10^3 < \text{LEL} < 7 \times 10^3$ fg per mg protein, data not shown) or DOGS ($10^4 < \text{LEL} \leq 10^6$ fg per mg

Figure 3. A: Luciferase expression (bars) and cell viability (points) in A549 cells of the lipoplexes prepared in 5% glucose and made of CL(= pcTG90, DOGS, or DOTAP):DOPE:DF4C11OPE (1:1 - $x:x$ with $x = 0.5, 0.75$, or 1) and plasmid pTG11033 (DNA) for various N/P ratios, as compared to control DOPE lipoplexes ($x = 0$). The given means $\pm$ SEM were calculated from four independent experiments. B: Transfection efficiency of the DF4C11OPE-based lipoplexes vs that of their corresponding DOPE control lipoplexes. *The luciferase expression levels (in the 2×10^3 to 7×10^3 fg luciferase per mg protein range) corresponding to the F-PE and control N/P 0.8 pcTG90-based formulations are not shown. For more details concerning LLR, and the statistics, see caption of Figure 1. When LLR is outside the 0.2–5 range, $p < 0.01$ in a pairwise comparison.

protein). Concerning the pcTG90:colipid(s) (1:2 mol formulations (Figure 5A), the highest LEL ($\geq 10^5$ fg per mg protein) were observed for N/P 5 and 2.5 while for N/P 1.25 and 0.8, LELs remained below 10^4 fg per mg protein (results not shown).

The lower transfection efficiency of the N/P 0.8 and 1.25 lipoplexes is most probably related to a lower cellular uptake of these “anionic” and “neutral” formulations as compared with that of the more cationic lipoplexes owing to expected lower lipoplex-cell electrostatic interactions. The mechanism of cellular endocytic uptake of the lipoplexes is indeed mainly governed by electrostatic interactions between the DNA complexes and the anionic proteoglycans expressed at the surface of these adherent cells (30, 31), this uptake increasing further with raising the N/P ratio of the lipoplexes (32). However, lower luciferase expression was evidenced for some of the N/P

10 lipoplexes as compared with that of their corresponding N/P 5 and 2.5 ones (and even of the N/P 0.8 ones in the case of DOTAP). Concomitantly, cell viability of the N/P 10 lipoplexes (and more particularly for pcTG90 or DOGS) was improved, indicating that cytotoxicity induced by these lipoplexes was not responsible for the lower gene expression. That the transfection efficiency of the lipoplexes does not necessarily increase with a N/P ratio increase was recently shown to be related to significant differences in intracellular distribution and trafficking (probably release from the endosomes or lysosomes) of the lipoplexes between these N/P ratios (32).

As illustrated in Figure 6, it appears, for $N/P \geq 2.5$ and irrespective of the fluorinated colipid and of the F-PE:DOPE molar ratio, that most of the “fluorinated” pcTG90- and DOGS-based formulations (90 and 79% of

Figure 4. A: Luciferase expression (bars) and cell viability (points) in A549 cells of the lipoplexes prepared in 5% glucose and made of CL (= pcTG90, DOGS, or DOTAP):DOPE:DF4C11PE(1:1 - $x:x$ with $x = 0.5, 0.75$, or 1) and plasmid pTG11033 (DNA) for various N/P ratios, as compared to control DOPE lipoplexes ($x = 0$). The given means $\pm$ SEM were calculated from four independent experiments. B: Transfection efficiency of the DF4C11PE-based lipoplexes vs that of their corresponding DOPE control lipoplexes. *The luciferase expression levels (in the 2.10^3 to 7.10^3 fg luciferase per mg protein range) corresponding to the F-PE and control N/P 0.8 pcTG90-based formulations are not shown. For more details concerning LLR, and the statistics, see caption of Figure 1. When LLR is outside the 0.2–5 range, $p < 0.01$ in a pair-wise comparison.

48 formulations, respectively) were at least 10-fold more efficient ($p < 0.01$) for transfecting A549 cells than their corresponding DOTAP lipoplexes. In a pairwise comparison, two formulations were considered to have comparable transfection efficiency when the LLR ratio of their respective LEL was within the 0.2–5 range, and of significantly different efficiency if this ratio is outside this range, providing its associated p value is ≤ 0.05 . One should further underscore the higher transfection potential of the pcTG90-based lipoplexes when compared with the DOGS ones: if 60% of the 48 pcTG90 formulations investigated were found to lead to comparable LELs to those of their corresponding DOGS complexes, 35% of the 48 pcTG90 formulations led however to LELs that were at least 5-fold higher ($p < 0.05$). The transfection efficacy sequence evidenced for the F-PE-based lipoplexes (i.e., pcTG90 $\geq$ DOGS $>$ DOTAP) for $N/P \geq 2.5$ is further

identical to that observed for the lipoplexes based on DOPE as sole colipid. The higher in vitro transfection efficiency of the pcTG90 and DOGS lipopolyamines as compared with that of DOTAP can be attributed to their endosomolytic activity related to the presence of protonable amine functions of low pK_a ("proton sponge" effect) (2, 14, 15). However, for the "negatively charged" lipoplexes (N/P 0.8), the opposite tendency was found for both the F-PEs and DOPE, as shown in Figure 6. Their transfection efficiency was indeed seen to decrease along the sequence DOTAP $>$ DOGS $>$ pcTG90. Concerning the fluorinated lipoplexes, 63 and 100% of the 16 DOTAP-based formulations were significantly more efficient than their corresponding DOGS- (at least 10-fold, $p < 0.01$) or pcTG90-based lipoplexes (at least 10- to 100-fold, $p < 0.01$), respectively, and 69% of the 16 DOGS-based lipoplexes were significantly more efficient (at least 10-

Figure 5. A: Luciferase expression (bars) and cell viability (points) in A549 cells of the lipoplexes prepared in 5% glucose and made of pcTG90:DOPE:F-PE (1:2 - y:y with $y = 1, 1.5$, or 2) and plasmid pTG11033 (DNA) for N/P 2.5 and 5, as compared to control DOPE lipoplexes ($y = 0$). The given means $\pm$ SEM were calculated from four independent experiments. B: Transfection efficiency of the F-PE-based lipoplexes vs that of their corresponding DOPE control lipoplexes. For more details concerning LLR, and the statistics, see caption of Figure 1. When LLR is outside the 0.2–5 range, $p < 0.01$ in a pair-wise comparison.

fold, $p < 0.01$) than the pcTG90-based ones. As for the cationic lipids, the different tendency observed for their N/P 0.8 lipoplexes as compared with that found for their more cationic ($N/P \geq 2.5$) ones is most likely attributable to significant differences in the mechanism of cellular uptake and of intracellular traffic of the lipoplexes between these cationic lipids and N/P values.

Irrespective of the nature of the F-PE and of the DOPE: F-PE molar ratio, increasing the colipid content from 50 to 66.7% mol (1:1 to 1:2 formulations) led, as shown in Figure 7, most often for the N/P 5 lipoplexes to a significant decrease in transfection (67% of the 12 F-PE formulations) while comparable and higher LELs were observed for 67 and 33% of the 12 N/P 2.5 F-PE formulations, respectively. These differences can tentatively be attributed to differences in intracellular distribution and

trafficking of the lipoplexes between these N/P and pcTG90:colipid molar ratios (32). One can further observe that, whatever the N/P ratio, [F8C11][C16]OPE constituted the sole colipid (among the F-PEs and DOPE) for which transfection was not affected by or increased with this CL:colipid molar ratio increase.

The main objectives of this study were aimed at examining the lipid helper effect on lipofection of the F-PEs as compared with that of DOPE and at determining whether their lipid helper potential was cationic lipid specific or not. Our results indicate that the F-PEs display such a lipid helper effect that is most often comparable with that of DOPE. However, their helper effect shows some dependency on the cationic lipid. This is strongly supported by the statistics deduced from panels B of Figures 1 to 4 and of Figure 5 for the (1:1)

Figure 6. Dependence of the *F*-PE lipid helper effect with the cationic lipid. The luciferase level ratios, LLR, correspond to the ratios of luciferase amount measured for the formulations based on [F8E11][C16]OPE (A), [F8C11][C16]OPE (B), DF4C11OPE (C), or DF4C11PE (D) and (i) on pcTG90 vs that measured for their corresponding DOGS (upper section) or DOTAP (middle section) lipoplexes, or (ii) on DOGS vs that measured for their corresponding DOTAP (lower section) lipoplexes. For more details concerning LLR, and the statistics, see caption of Figure 1. When LLR is outside the 0.2–5 range, $p < 0.01$ in a pair-wise comparison.

and (1:2 mol) formulations, respectively. These panels display the luciferase level ratios (LLR) measured for the formulations based on-[F8E11][C16]OPE, [F8C11][C16]OPE, DF4C11OPE, or DF4C11PE, respectively, vs that measured for their corresponding control lipoplexes (which contain DOPE as sole colipid). The “helper” effect related to the presence of *F*-PE (in place of part of or of all DOPE) is significantly higher or lower to that of DOPE if this ratio is higher or lower than 5 or 0.2, respectively, providing its associated p value is ≤ 0.05 , and this effect is comparable with that of DOPE if this ratio is within the 0.2–5 range. Irrespective of the *F*-PE chemical structure, of the colipid mixture composition, and of the *N/P* ratio, we found indeed that, when using one of the *F*-PEs as colipid in place of part of or of all DOPE, comparable transfection levels were most frequently measured for the fluorinated lipoplexes and their respective control DOPE lipoplexes. This is the case for 75–100% of the 12 pcTG90-based (1:1 mol) formulations investigated for each *F*-PE, for 83% of the 24 pcTG90-based (1:2 mol) formulations, and for 75–50% of the 12 DOGS-based formulations investigated for each *F*-PE. However, a significant proportion of fluorinated DOGS-based lipoplexes (8–33% of the 12 formulations investigated for each *F*-PE) were found to display a higher transfection efficiency than their DOPE control. By contrast for the DOTAP-based lipoplexes, the opposite tendency was evidenced: if statistically comparable

transfection levels were obtained for 75–25% of the 12 formulations investigated for each *F*-PE, the complementary 25–75% ones displayed significantly lower transfection levels than their respective DOPE control lipoplexes.

The dependence of the lipid helper potential of the *F*-PEs on the cationic lipid can be tentatively explained by considering the geometrical complementarity between the cationic lipids and the colipids, which might have an effect on the packing within the lamellar phases formed between each of the CLs and each of the *F*-PEs or DOPE, and, consequently, on the physicochemical and biological properties of the DNA lipoplexes they form, and on transfection. Of the three cationic lipids investigated, it is DOGS with its branched polar head which displays the most-pronounced “direct” cone-shaped geometry (pure DOGS was shown to form mainly direct micelles when dispersed in water (33)). The *F*-PEs displaying a more-pronounced “inverted” cone-shaped geometry than DOPE, one therefore expects a higher degree of geometrical complementarity between the *F*-PEs and DOGS, which should result in more tightly packed (or more stable) lamellar phases than between DOPE and DOGS or than between any of the *F*-PEs and any of the two other cationic lipids. Consequently, one expects that, among the different combinations, more stable lipoplexes are formed from the *F*-PEs and DOGS, and thus a more pronounced helper effect for the *F*-PEs when used with

Figure 7. Effect of increasing the colipid content on luciferase expression in A549 cells of the pcTG90:colipid(s) lipoplexes (from 1:1 to 1:2). The luciferase level ratio LLR is the ratio of luciferase amount measured for the 1:2 mol formulation vs that measured for its corresponding 1:1 mol formulation. For more details concerning LLR, and the statistics, see caption for Figure 1. When LLR is outside the 0.2–5 range, $p < 0.01$ in a pair-wise comparison.

DOGS. Conversely, DOTAP which, of the three cationic lipids, displays a geometry that is the closest to a cylinder, forms lamellar phases which when combined with the *F*-PEs are expected to be substantially less tightly packed (or more destabilized) than those formed between DOTAP and DOPE. Owing to the lower degree of geometrical complementarity between DOTAP and the *F*-PEs, one expects a helper effect of the *F*-PEs that is below that of DOPE, as observed.

Where the helper effect on transfection resulting from the composition of the colipid mixture (DOPE:*F*-PE molar ratio) is concerned, it seems most preferable to use a DOPE:*F*-PE (1:3 mol) colipid combination than *F*-PE alone or than a *F*-PE:DOPE (1:1 mol) mixture, whatever the cationic lipid and the *F*-PE. If a preference for a specific DOPE:*F*-PE combination could not be evidenced among the few (eleven) CL:colipid(s) (1:1 mol) formulations that led to significantly higher transfection levels than their respective DOPE controls (see Figure 1B to 4B), this is however not the case for the 36 formulations that displayed a significantly lower transfection level than the DOPE controls. Indeed, of these 36 less efficient formulations, only 7 (19%) concerned the DOPE:*F*-PE (1:3 mol) colipid combination while 12 (33%) and 17 (48%) concerned lipoplexes based on the (1:1 mol) colipid mixture and on *F*-PE as sole colipid, respectively, indicating

Figure 8. Panel A: Effect of the presence of a fluorinated tail on one or on both hydrophobic chains on lipofection. LLR represents the ratio of luciferase amount measured for the [F8E11][C16]OPE-based formulation vs that measured for its corresponding DF4C11OPE-based one. Panel B: Effect of the presence of a double bond in the hydrophobic chain on lipofection. LLR represents the ratio of luciferase amount measured for the unsaturated [F8E11][C16]OPE-based formulation vs that measured for its corresponding saturated [F8C11][C16]OPE-based one. Panel C: Impact of the chemical connexion (ester vs ether) on lipofection. LLR represents the ratio of luciferase amount measured for the ester DF4C11PE-based formulation vs that measured for its corresponding ether DF4C11OPE-based one. For more details concerning LLR, and the statistics, see caption of Figure 1. When LLR is outside the 0.2–5 range, $p < 0.01$ in a pair-wise comparison.

that transfection was likely optimal for a DOPE:*F*-PE (1:3 mol) colipid combination.

The aim of this study was also to highlight the impact of the *F*-PE structural elements (one fluorinated tail on one or on both hydrophobic chains, saturated or unsaturated hydrophobic chains, ester or ether-linkage) on their helper potential. Concerning the effect of the presence of a fluorinated tail on one or on both hydrophobic chains (as in [F8E11][C16]OPE or DF4C11OPE, respectively), a statistical analysis performed on the 33 [F8E11][C16]OPE-based formulations as compared with their respective DF4C11OPE ones did not allow to distinguish between these two *F*-PEs (Figure 8, panel A). This analysis demonstrated comparable, higher and lower transfection levels for 65, 15, and 20% of the formulations, respectively. Although of very different structures, these two *F*-PEs contain almost the same number of fluorine atoms (17 vs 18). Both compounds display furthermore a phase transition temperature which is below or close to the incubation temperature. One expects therefore a similar hydrophobic and lipophobic character,

and comparable interactions with the cationic lipids, serum proteins, and cellular constituents that have no consequences on transfection.

The presence of a double bond in the hydrophobic chain, although not determinant, was found to favor transfection, as supported by the statistical analysis performed on the 33 formulations containing [F8E11]-[C16]OPE as compared with their respective [F8C11]-[C16]OPE ones. This analysis (panel B of Figure 8) showed that, irrespective of the cationic lipid, the composition of the colipid mixture, the CL:colipid(s) molar ratio, and the *N/P* ratio, higher and comparable transfection levels were measured for 21 and 70% of these formulations, respectively. This result is in line with literature which showed that optimal transfection activity was preferably achieved when using cationic lipids and/or colipids containing hydrophobic chains that organize as "fluid" lamellar phases (e.g., lipids with olefinic chains such as [F8E11][C16]OPE which displays a phase transition temperature of 38 °C) rather than "gel" lamellar ones (e.g. lipids with long saturated chains such as [F8C11]-[C16]OPE which displays a phase transition temperature of 45 °C) (3, 10, 11, 34–37).

Finally, a comparable helper potential was evidenced for the ester DF4C11PE and ether DF4C11OPE: indeed 85% of the 33 formulations containing DF4C11PE displayed similar transfection levels than their corresponding ones based on DF4C11OPE (panel C of Figure 8). This result is not surprising as both colipids possess a very close thermotropic phase behavior and is in line with data from literature concerning DOTAP and its ether analogue DOTMA (17). One should underscore that, under the conditions of transfection used, the chemical nature of the linkage had no impact on lipoplex cell viability.

CONCLUSION

The present work indicates that "fluorinated" lipoplexes formulated with fluorinated helper lipids and conventional cationic lipids are definitely very attractive candidates for gene delivery, highlighting the diversity of lipids leading to efficient transfection. The remarkable in vitro and in vivo transfection potency found for such fluorinated lipoplexes (8) and that reported for fluorinated lipoplexes formulated with fluorinated lipospermines (6, 7) confirms further that lipophobicity and restricted miscibility of the lipoplex lipids with the endogenous lipids does not preclude efficient gene transfer and expression. Their transfection potency is rather attributable to their unique lipophobic and hydrophobic character (resulting from the formulation of DNA with fluorinated lipids), thus preventing DNA to some extent from interactions with lipophilic and hydrophilic biocompounds, and from degradation (7). Further experiments aimed at evaluating the in vivo helper transfection potential of the fluorinated PEs are currently underway.

ACKNOWLEDGMENT

We wish to thank Drs. H.V.J. Kolbe and O. Meyer (Transgène) for their interest in this project. Many thanks to Dr. B. Cavallini (Transgène) for supplying the plasmid.

Synthesis and Characterization of ^{111}In -DTPA-N-TIMP-2: A Radiopharmaceutical for Imaging Matrix Metalloproteinase Expression

Birgitte K. Giersing, Michael T. Rae, Montserrat CarballidoBrea, Richard A. Williamson,* and Philip J. Blower*

Biosciences Department, University of Kent, Canterbury CT2 7NJ, UK. Received March 28, 2001; Revised Manuscript Received June 15, 2001

The matrix metalloproteinases (MMPs) are enzymes involved in the turnover of the extracellular matrix. Their overexpression in tumors is implicated in the metastatic process and may provide a target for diagnostic tumor imaging by using a radiolabeled inhibitor. MMPs are inhibited by endogenous tissue inhibitors of metalloproteinases (TIMPs). Thus, TIMPs are potential targeting molecules which could be used as vehicles for selective radionuclide delivery by virtue of their binding to MMPs. The aim of this work was to produce a radiopharmaceutical with which to evaluate this potential. The 127 amino acid N-terminal domain of recombinant human TIMP-2 (N-TIMP-2) was conjugated with the bifunctional chelator diethylenetriamine pentaacetic acid (DTPA). Singly modified DTPA-N-TIMP-2 conjugate (identified by electrospray ionization mass spectrometry) was isolated by anion-exchange chromatography. The primary site of DTPA modification on N-TIMP-2 was mapped to lysine-116, which is distant from the site of MMP interaction. The conjugate was radiolabeled with indium-111 to give ^{111}In -DTPA-N-TIMP-2 with a specific activity of at least 4 MBq/ μg and a radiochemical yield and purity of >95%, by incubation with $^{111}\text{InCl}_3$, without need for postlabeling purification. The product was sterile, pyrogen-free, and stable in serum over 48 h and retained full inhibitory activity in a fluorimetric binding assay. With these attributes, ^{111}In -DTPA-N-TIMP-2 is a suitable radiopharmaceutical for in vivo biological and clinical investigation of the potential benefits of imaging MMP expression.

INTRODUCTION

MMPs are a family of matrix-degrading enzymes, consisting of 18 currently known members, which are involved in the turnover of the extracellular matrix (ECM). They have a broad substrate specificity, and their synergetic action enables them to degrade all components of the ECM and basement membrane. To control tissue remodeling, MMP activity is tightly regulated at several levels, including enzyme expression, enzyme activation, enzyme autodegradation, and enzyme inhibition. Malfunction of these regulatory mechanisms results in uncontrolled MMP activity and the potential development of pathological conditions including rheumatoid arthritis, arteriosclerosis, and tumor invasion and metastasis (White et al., 1997).

Initial evidence for the involvement of MMPs in tumor progression arose from several in vivo studies correlating the level of MMPs with tumor appearance and progression (Stetler-Stevenson et al., 1996). The level of MMP expression appears to correlate with tumor stage, with metastatic tumors having the highest levels. Consequently, MMPs are increasingly considered as biochemical markers of metastatic potential and prognosis in cancer (Duffy and McCarthy, 1998). We propose that, in addition to serving as a useful biochemical marker, MMP expression may also provide a target for the diagnostic

in vivo imaging of tumors using a radiolabeled inhibitor. Imaging MMP expression in this way might be a useful noninvasive method of localizing tumors and evaluating MMP activity within them.

MMPs are inhibited in vivo by endogenous tissue inhibitors of matrix metalloproteinases (TIMPs). TIMPs are proteins that bind to MMPs noncovalently with high affinity (10^{-10} to 10^{-16} M, Murphy and Willenbrock, 1995; Hutton et al., 1998). To date four TIMPs have been identified: TIMP-1 (Sellers et al., 1979), TIMP-2 (Stetler-Stevenson et al., 1989), TIMP-3 (Uria et al., 1994), and TIMP-4 (Greene et al., 1996). All consist of two domains (the N- and C-terminal), each of which is defined by three disulfide bonds (Williamson et al., 1990). The N-terminal of TIMP-2 (N-TIMP-2) has been shown to fold independently of the C-terminal (Murphy et al., 1991; Williamson et al., 1994), forming an autonomous protein domain that retains inhibitory activity (Murphy et al., 1991). N-TIMP-2 has been structurally characterized (Williamson et al., 1994; Muskett et al., 1998; Williamson et al., 1999), and its interaction with MMPs has been elucidated (Williamson et al., 1997; Fernandez-Catalan et al., 1998).

N-TIMP-2 has several attributes that render it attractive as a carrier molecule for radionuclides to investigate the feasibility of in vivo MMP imaging. It has a higher MMP binding affinity (K_d range 10^{-12} to 10^{-9} M) than any of the synthetic peptide-based inhibitors (typically 10^{-9} M) that have been devised as drugs to reduce the rate of tumor proliferation (for a review of these see, Brown, 1999). It should be rapidly cleared from circulation due to its modest molecular weight (14084 Da), and it has several exposed lysine residues that could be

conjugated with a bifunctional chelator. It is a human protein and thus should not elicit an immune response. Finally, recombinant N-TIMP-2 can be expressed and purified from *E. coli* in a pure, pyrogen-free form (Williamson et al., 1996).

Indium-111 rather than technetium-99m was chosen as the gamma-emitting radionuclide with which to radiolabel N-TIMP-2. Technetium-labeling entails the use of reducing agents that might cleave the intramolecular disulfide bonds, which are critical for the inhibitory activity of N-TIMP-2.

This paper describes the synthesis and full in vitro characterization of an indium-111 labeled conjugate of N-TIMP-2 designed to assess the clinical value of MMP imaging in vivo. Although the labeling of biomolecules with indium-111 using the diethylenetriamine pentaacetic acid (DTPA) bifunctional chelator is well-established, the analytical methods used in this work provide a more detailed characterization of the In-DTPA-conjugated protein than has been reported hitherto for any other protein of comparable size.

MATERIALS AND METHODS

Preparation and Purification of DTPA-N-TIMP-2 and DTPA-Myoglobin. Human N-TIMP-2 was expressed in *E. coli* BL21 (DE3) and purified from inclusion bodies as described by Williamson et al. (1996). To produce a pyrogen-free product, all buffers were prepared using pyrogen-free water, and the chromatography columns were sanitized before use by washing with several column volumes of 0.5 M NaOH followed by thorough rinsing with pyrogen-free water. Similarly, all glassware, nonsterile plastic ware, and the chromatography system were sanitized with 0.5 M NaOH and rinsed with pyrogen-free water. Sterile plastic ware was used wherever possible for the collection and handling of the protein. All batches of DTPA-N-TIMP-2 produced using these measures were certified as pyrogen-free by in vivo testing in rabbits by a commercial laboratory.

N-TIMP-2 (5 mg, 1.0 mg/mL) was conjugated with DTPA in 50 mM sodium bicarbonate, pH 8.2. A 3-fold molar excess of DTPA cyclic anhydride (dissolved in anhydrous DMSO at a concentration of 7.5 μ M under N₂ gas) was added to the protein solution and the mixture incubated for 30 min at room temperature (final DMSO concentration of 1% v/v). To determine the degree of DTPA conjugation, the reaction mixture was analyzed by SDS-PAGE (Novex NuPage), isoelectric focusing (IEF; Novex pH 3–10 precast gels), and electrospray mass spectrometry (ES-MS). ES-MS was carried out on a Finnigan Mat LCQ ion trap mass spectrometer with in-line desalting by reverse-phase HPLC. Spectra were acquired in the high mass mode and deconvoluted using Bioexplore software.

DTPA-N-TIMP-2 was purified from the conjugation mixture by anion-exchange chromatography. The reaction mixture (2 mL) was loaded onto a 1 mL Resource-Q column (Pharmacia) equilibrated in buffer A (25 mM Tris-HCl, pH 8.0). The column was eluted with a linear gradient of 0–0.25 M NaCl in buffer A over 25 min at a flow rate of 1 mL/min. Those fractions (1 mL each) containing protein (detected by absorbance at 280 nm) were analyzed by IEF and ES-MS as described above.

Myoglobin was conjugated with DTPA as described for N-TIMP-2. Excess DTPA was removed from the crude conjugation mixture by gel filtration on Sephacryl S-100 (2.6 (diam) $\times$ 38 cm column, Pharmacia). The column was run in 50 mM citrate buffer, pH 5.5, at a flow rate of 1.4

mL/min and 2 mL fractions were collected. Absorbance was measured at 280 nm (to detect elution of protein) and 230 nm (to detect elution of excess unconjugated DTPA). Fractions containing DTPA-myoglobin were pooled and concentrated to 1 mg/mL by ultrafiltration in a 50 mL Amicon stirred cell with a YM10 membrane.

Peptide Mapping of DTPA-N-TIMP-2. N-TIMP-2 and the purified singly modified conjugate DTPA-N-TIMP-2 (200 μ g, 1 mg/mL), were incubated with dithiothreitol (DTT; 0.3 mM) in 50 mM MOPS buffer, pH 7, for 10 min at 30 °C. Trypsin was added to a final concentration of 0.05 mg/mL, and the samples were incubated for 4 h at 30 °C. Digestion was terminated by freezing at –20 °C. Additional DTT (to a final concentration of 2.2 mM) was added to each sample to ensure complete disulfide bond reduction before analysis by reverse-phase HPLC (Vydac 218TP54 C₁₈ column) at room temperature. The column was equilibrated with solvent A (0.1% v/v TFA in water) prior to loading the sample (100 μ g) and eluted with a linear gradient of 5–70% solvent B (0.1% v/v TFA, 70% v/v acetonitrile in water) over 120 min at a flow rate of 1 mL/min. Fractions were collected manually by following their absorbance at 215 nm. MALDI-TOF (matrix assisted laser desorption ionization time-of-flight) mass spectra were recorded for each fraction on a VG ToF spectrometer with an α -cyano-4-hydroxycinnamic acid (97%) matrix. The mass spectrometer was calibrated with bradykinin (572 Da) and insulin (5733.5 Da). For all samples, the detector was set in linear mode with a laser voltage of 1750 V, and spectra were measured using the lowest possible laser energy necessary for ionization of the sample. N-Terminal amino acid sequencing of selected peptides was carried out at the Wellcome Trust Protein Science Facility, University of Kent, on an Applied Biosystems 492 Protein Sequencer.

Radiolabeling of DTPA-N-TIMP-2 and Evaluation of the Radiolabeling Reaction. Samples of DTPA-N-TIMP-2 (1 mg/mL) were dialyzed against 2 L of 100 mM sodium citrate buffer, pH 5.5, overnight at room temperature in order to remove adventitious metal ions bound to the conjugate prior to radiolabeling. ¹¹¹InCl₃ (Mallinckrodt Medical b.v., Petten, Netherlands) was diluted 8-fold to a volume of 1.5–2.5 mL with 100 mM citrate buffer, pH 5.5, prior to use in the radiolabeling procedure to increase the pH of the acidic ¹¹¹InCl₃ solution to pH 5.5. ¹¹¹InCl₃ and ¹¹¹In-citrate were manipulated using Hamilton glass syringes and stainless steel needles, and radiolabeling reactions were carried out in 3 mL glass vials. The desired amount of conjugate (30 μ L of 1 mg/mL solution) was added to the ¹¹¹In-citrate solution (4 MBq/ μ g protein) and incubated at 37 °C for 1 h. To check for ¹¹¹In complexed to any contaminating unconjugated DTPA, a TLC system was used comprising Merck 60F₂₄₅ silica gel plates with a mobile phase of 40% aqueous ammonium formate (1.56 M)/40% methanol/20% citric acid (0.5 M). Nonspecific binding of ¹¹¹In to protein was checked by ITLC (Gelman ITLC-SG) using 100 mM citrate buffer, pH 5.5, as the mobile phase. The percentage of radioactivity remaining at the origin (¹¹¹In-DTPA-N-TIMP-2) was taken as the radiochemical yield. Samples were spotted using glass capillaries, and the TLC plates were scanned on a Bioscan TLC plate scanner at 2.5 cm/min.

Serum Stability of ¹¹¹In-DTPA-N-TIMP-2. Fresh human serum was obtained by the centrifugation (5000 g for 10 min) of clotted blood (20 mL). ¹¹¹In-DTPA-N-TIMP-2, ¹¹¹In-DTPA and ¹¹¹InCl₃ (1 MBq of each) were incubated in 6 mL of serum under 5% CO₂, and samples

(50 kBq) were taken at 4, 24, and 48 h. Each sample (diluted to 1 mL in running buffer) was loaded directly on to the Sephacryl S-100 gel filtration column (2.6 cm (diameter) $\times$ 38 cm, Pharmacia) run in 100 mM sodium citrate buffer, pH 5.5, at 1.4 mL/min. Fractions (2 mL) were collected and counted for 60 s. The activity of each fraction was recorded as a percentage of the total eluted activity. A standard chromatogram for each protein was also determined using unlabeled material by measuring the absorbance of each fraction at 280 nm (transferrin and N-TIMP-2) and 230 nm (In-DTPA). In a separate stability study, purified ^{111}In -DTPA-N-TIMP-2, ^{111}In -DTPA, and $^{111}\text{InCl}_3$ (10 MBq of each) were diluted to 20 μL with 100 mM sodium citrate buffer, pH 5.5, and incubated with serum (200 μL) at 37 $^\circ\text{C}$ as described above. Samples (10 μL) were taken at several time intervals between 5 min and 48 h and analyzed by nonreducing SDS-PAGE. Nonreducing conditions were used to avoid boiling with dithiothreitol, which causes indium to be transchelated from the DTPA conjugate to form a low molecular weight indium thiolate complex. The gels were developed by Coomassie-blue staining and autoradiography.

MMP Activity Assay. The inhibitory activity of In-DTPA-N-TIMP-2, (In-DTPA) $_2$ -TIMP-2, and In-DTPA-myoglobin was compared to that of N-TIMP-2 using the fluorimetric peptide assay described by Murphy et al. (1995). A 10-fold molar excess of nonradioactive InCl_3 (1 mg/mL) was added to 5 nmol of N-TIMP-2, DTPA-N-TIMP-2, (DTPA) $_2$ -N-TIMP-2, and DTPA-myoglobin at a protein concentration of 1 mg/mL. Chelation of indium was confirmed by ES-MS. The solutions were diluted to 200 μL with incubation buffer (50 mM Tris-HCl, 0.1 M NaCl, 10 mM CaCl_2 , 0.05% Brij 35, pH 7.5) and excess InCl_3 removed by ultrafiltration (microconcentrator devices, Amicon). All four proteins were diluted to a stock solution of 1 μM in incubation buffer using the A_{280} extinction coefficient of $12450 \text{ M}^{-1}\text{cm}^{-1}$ for N-TIMP-2, DTPA-N-TIMP-2, and (DTPA) $_2$ -N-TIMP-2, and the A_{556} extinction coefficient of $12900 \text{ M}^{-1}\text{cm}^{-1}$ for DTPA-myoglobin. A 1 μM stock solution of the catalytic N-terminal domain of stromelysin (N-MMP-3) was also prepared (Marcy et al., 1991), and 50 μL of this was added to each of a series of tubes containing 0–100 μL of the inhibitor stock solution diluted with incubation buffer to bring the total incubation volume to 150 μL . Thus each incubation mixture contained enzyme at a concentration of 0.33 μM and a putative inhibitor at 0–0.67 μM . These inhibitor/enzyme mixtures were incubated for 30 min before adding 50 μL of each to 445 μL assay buffer and 5 μL substrate peptide solution, as described by Knight et al. (1992). The fluorescence (excitation 328 nm, emission 393 nm) was monitored over 4 min at 25 $^\circ\text{C}$, corrected for background (nonenzymatic) peptide cleavage, and plotted against inhibitor concentration.

RESULTS

Preparation and Characterization of DTPA-N-TIMP-2. Production, refolding, and purification of N-TIMP-2 was performed according to the methods of Williamson et al. (1996). The final protein product was analyzed by electrospray mass spectrometry (ES-MS) and was of the correct molecular weight (found: 14085 Da; expected: 14084) for the N-TIMP-2 sequence containing three disulfide bonds (Figure 1, top panel, peak a). A trace amount of the N-terminally acetylated form seen on recombinant expression in *E. coli* was also detected (peak b). N-TIMP-2 incubated with a 3-fold molar excess of DTPA produced the highest yield of singly modified

Figure 1. Deconvoluted electrospray mass spectra of N-TIMP-2 conjugates with DTPA. Top: crude reaction mixture; bottom: fraction 25 isolated from the crude reaction mixture by ion-exchange chromatography. Assignments: (a) 14085 (calcd for unmodified N-TIMP-2: 14084); (b) 14127 (calcd for acetylated N-TIMP-2: 14126); (c) 14441 (calcd for internally cross-linked DTPA-N-TIMP-2: 14441); (d) 14459 (calcd for DTPA-N-TIMP-2: 14459); (e) 14501 (calcd for peak (c) + Cu^{2+} - 2H^+ : 14502); (f) 14517 (calcd for DTPA-N-TIMP-2 + Cu^{2+} - 2H^+ : 14520); (g) 14799 (calcd for (DTPA) $_2$ -N-TIMP-2 with two internal cross-links: 14798); (h) 14816 (calcd for (DTPA) $_2$ -N-TIMP-2 with one internal cross-link: 14816); (i) 14837 (calcd for (DTPA) $_2$ -N-TIMP-2: 14834).

DTPA-N-TIMP-2 conjugate (peak d, estimated at 25% of total protein from relative abundance by ES-MS), while minimizing the amount of doubly modified conjugate (peak i). A secondary peak (peak c, 14% of total protein) of 18 mass units below the singly modified conjugate was consistently observed. As detailed below, this was assigned as an internally cross-linked species in which the DTPA bridges between two lysine residues. The doubly conjugated protein peak i was associated with two such peaks (g and h, respectively) of 18 and 36 Da less than the mass of the conjugate. Peaks e and f correspond to the addition of a metal ion (adventitious copper originating both from buffer salts and as an artifact from within the ES-MS instrument) to peaks c and d. Much of the metal was found to be readily removable by dialysis against citrate buffer. SDS-PAGE showed the presence of an additional minor species with twice the molecular weight of N-TIMP-2. This was assigned to protein dimers cross-linked by DTPA.

IEF resolved the proteins into three distinct groups of bands with pI 6.4–6.5, 5.1–6.2, and 4.5–4.9 (Figure 2). The results suggested that these protein species could

Figure 2. Isoelectric focusing of N-TIMP-2 conjugates with DTPA. Lane 1: pI markers; lane 2: N-TIMP-2 standard. The band with pI slightly lower than that of N-TIMP-2 is assigned to the N-terminally acetylated form. Lane 3: Crude conjugation mixture after incubation of N-TIMP-2 with DTPAA. Band group a is unmodified N-TIMP-2 and its N-terminally acetylated form; group b includes forms of DTPA–N-TIMP-2; group c includes forms of (DTPA)₂–N-TIMP-2.

Figure 3. Ion-exchange chromatography of the crude conjugation mixture produced by incubation of N-TIMP-2 with DTPAA. ES-MS and IEF analysis of the fractions show that unmodified N-TIMP-2 elutes at 17.71 min, DTPA–N-TIMP-2 at 23.48 min (referred to in the text as fraction 25), and (DTPA)₂–N-TIMP-2 at 30.58 min.

be separated by elution with increasing salt concentration at basic pH on an anion-exchange column. Indeed, three groups of peaks were well-resolved by anion exchange chromatography at pH 8 (Figure 3), with elution times of 18–20 min, 23–27 min, and 31–33 min. IEF of these fractions showed that they corresponded to the groups with pI 6.4–6.5, 5.1–6.0, and 4.5–4.9, respectively. ES-MS of the fractions (data not shown) showed that the pI 6.4–6.5 group consisted of unmodified N-TIMP-2 and its N-terminally acetylated form, the pI 5.1–6.2 group consisted of various forms of DTPA–N-TIMP-2, and the pI 4.5–4.9 groups consisted of forms of (DTPA)₂–N-TIMP-2. ES-MS also showed that the multiplicity of bands within each group was due to combinations of both internal cross-linking and metal ion scavenging. Fraction 25 from the ion-exchange column, containing the major peak in the DTPA–N-TIMP-2 group (elution time 23.48 min) and having a major IEF band at a pI of approximately 5.4, was selected for further development as a radiopharmaceutical and subjected to tryptic peptide

Figure 4. Reverse-phase HPLC of tryptic digests of (a) N-TIMP-2 and (b) ion-exchange purified DTPA–N-TIMP-2 (fraction 25 in Figure 3). Peak 32 contains a DTPA conjugated to lysine-116, while peak 64 contains two peptide sequences cross-linked by DTPA between lysine-116 and lysine-51.

mapping to determine the site of DTPA modification (see below). ES-MS of this fraction showed that it contained DTPA–N-TIMP-2 together with up to 20% of its internally cross-linked form, but no unmodified N-TIMP-2 and no (DTPA)₂–N-TIMP-2 (see Figure 1, bottom panel).

Peptide Mapping of DTPA–N-TIMP-2. The primary site of DTPA modification on N-TIMP-2 was determined by tryptic peptide mapping of fraction 25 isolated by ion-exchange chromatography (see Figure 3). Reverse-phase HPLC chromatograms of tryptic digests of unmodified N-TIMP-2 and DTPA–N-TIMP-2 are shown in Figure 4. Two new peaks numbered 32 (major) and 64 (minor), appear following conjugation, with a concomitant decrease in the heights of peaks 20 and 85 compared to unmodified N-TIMP-2. Peaks 32 and 64 from the DTPA–N-TIMP-2 digest were collected and analyzed by MALDI-TOF-MS. The masses obtained for the peptides in these peaks were compared to the theoretical masses of the peptides predicted from complete and incomplete (i.e., with cleavage blocked at modified lysine residues) N-TIMP-2 tryptic digestion (Table 1).

The mass of peptide 32 corresponded to residues 116–121, which has the sequence KSLNHR. This peptide contains only one lysine residue, lysine-116 (at which trypsin cleavage did not occur); therefore, the position of the DTPA-modification in this sequence was unambiguous and sequencing was considered unnecessary. The mass of the peptide contained in peak 64, however, did not correspond to the theoretical mass of any simple linear sequence from N-TIMP-2 or DTPA-conjugate thereof. MALDI-TOF analysis after the addition of indium chloride to peaks 32 and 64 confirmed that each peptide contained a single DTPA moiety, as the mass of both peptides increased by approximately 110 corresponding to replacement of four protons by a single indium ion (results not shown).

The first 12 amino acids of peptide 64 were sequenced in order to identify the modified lysine residue. Three

Table 1. Mass Spectrometry (MALDI-TOF MS) and Amino Acid Sequence Analysis for Peptides 32 and 64

	Peptide 32	Peptide 64 (crosslinked)
Experimentally observed mass (Da)	1132	1906
Sequence of "best match" peptide	K ¹¹⁶ SLNHR DTPA	QIK ⁵¹ MFK DTPA K ¹¹⁶ SLNHR
Calculated mass of "best match" peptide	1129	1905
Residue numbers of sequence	116-121	49-54 & 116-121
Number of missed cleavages due to DTPA modification	1 (K ¹¹⁶)	2 (K ⁵¹ & K ¹¹⁶)

sequences were detected, one of which was a minor impurity present at very low concentration and corresponded to the first 12 residues of the N-TIMP-2 sequence (C¹–R²⁰). The remaining two peptides produced amino acid residues expected for sequences Q⁴⁹–K⁵⁴ and K¹¹⁶–R¹²¹ except that one lysine residue was missing from each sequence (lysine-51 and lysine-116, respectively). The observation that this peptide binds only one indium ion, despite the presence of two modified lysine residues, suggests that the same DTPA moiety was bound simultaneously to both lysine-51 and lysine-116, i.e., the sequences were cross-linked to give a single peptide species Q⁴⁹–K⁵⁴ and K¹¹⁶–R¹²¹ with a DTPA linker between K⁵¹ and K¹¹⁶. This is supported by the ES-MS of the intact conjugate in which a cross-linked species was identified as a peak with a mass 18 units less than expected (Figure 1), and the fact that the calculated mass of the suggested cross-linked species (1905 Da) is close to the experimental mass of peptide 64 determined by MALDI-TOF MS (1906 Da, Table 1).

Radiolabeling of DTPA–N-TIMP-2 with Indium-111. Two chromatographic assays were used to evaluate the purity and yield of the radiolabeled product. ¹¹¹In–DTPA has an *R_f* of 0.6 in the silica gel thin-layer chromatography (TLC) assay, while uncomplexed ¹¹¹InCl₃ and ¹¹¹In–protein have an *R_f* of zero, permitting this system to be used as a check for unconjugated DTPA in the sample. Instant thin-layer chromatography (ITLC) in 100 mM citrate buffer, pH 5.5, was used to determine incorporation of ¹¹¹In into DTPA–N-TIMP-2. In this system radiolabeled protein has an *R_f* of zero while uncomplexed ¹¹¹InCl₃ and ¹¹¹In–DTPA have an *R_f* close to 1. A control ITLC after incubation of unconjugated N-TIMP-2 with ¹¹¹InCl₃ showed no radioactivity at an *R_f* of zero (all radioactivity being close to an *R_f* value of 1) showing that ¹¹¹InCl₃ does not bind nonspecifically to the protein under the conditions of the chromatography. Purified DTPA–N-TIMP-2 that had been freed from adventitious metal ions by dialysis against citrate buffer was consistently radiolabeled with ¹¹¹In to a specific activity of 4.5 MBq/μg and a radiochemical yield and purity of >95% after 1 h of incubation (Figure 5). Undialyzed samples of DTPA–N-TIMP-2 containing significant amounts of adventitious metal ion chelated by the DTPA conjugate, as detected by ES-MS, consistently failed to radiolabel satisfactorily.

Serum Stability of ¹¹¹In–DTPA–N-TIMP-2. The stability of ¹¹¹In–DTPA–N-TIMP-2 in serum was determined by size exclusion chromatography and SDS–PAGE electrophoresis. Nonradioactive standards transferrin, N-TIMP-2, and In–DTPA were analyzed beforehand in order to determine their elution profiles by UV absorbance measurement (results not shown). Transferrin eluted in fractions 1–10, N-TIMP-2 in fractions 18–28, and In–DTPA in fractions 43–50. The elution profiles of ¹¹¹In–DTPA–N-TIMP-2 and the controls ¹¹¹InCl₃ (which in serum rapidly incorporates ¹¹¹In into transferrin) and ¹¹¹In–DTPA after incubation in serum for up to 48 h were also determined (Figure 6). No radioactive peaks corresponding to ¹¹¹In–DTPA or low molecular weight protein fragments appeared, showing that ¹¹¹In–DTPA–N-TIMP-2 is stable to degradation by serum proteases. However, approximately 5% of the radioactivity is lost from the conjugate to a species coeluting with transferrin over 48 h. Approximately 10% of the radioactivity in the incubation mixture eluted close to ¹¹¹In–DTPA. This is also present in the ¹¹¹In–serum control and is due to a contaminant introduced during labeling of the conjugate prior to addition to serum. It arises from plasticware used to handle the ¹¹¹InCl₃ and is not a DTPA complex. [We found that undiluted ¹¹¹InCl₃ reacted with certain types of plasticware, including pipet tips and microcentrifuge tubes, to form an unidentified complex that was stable to competition by excess DTPA and had an *R_f* value of 0.7 on the silica gel TLC assay. Excessive manipulation of ¹¹¹InCl₃ caused this contamination, and consequently ¹¹¹InCl₃ was handled exclusively with glassware, i.e., glass vials, glass syringes, and capillaries. With

**Figure 5.** Time-dependent incorporation of ¹¹¹In into purified DTPA–N-TIMP-2 at 37 °C. From these results, an incubation time of 60 min was adopted as standard for preparation of ¹¹¹In–DTPA–N-TIMP-2.

Figure 6. Serum stability, determined by size exclusion chromatography after 2, 24, and 48 h of incubation, of ^{111}In -DTPA-N-TIMP-2 and control species $^{111}\text{InCl}_3$ and ^{111}In -DTPA. ^{111}In -DTPA-N-TIMP-2 elutes in fraction 20, and this peak is only slightly depleted by 48 h while a small new peak corresponding to ^{111}In -transferrin (fraction 5) appears. Free ^{111}In in the control experiment binds to transferrin and elutes at fraction 5 (labeled " InCl_3 "), and ^{111}In -DTPA elutes at fraction 40 (labeled " In -DTPA"). The constant peak at fraction 42 is an ^{111}In -labeled impurity arising prior to incubation in serum (see text) and is not attributed to instability of the labeled conjugate in serum.

these precautions the contaminant did not appear. The contaminant was responsible for the appearance of the peak seen in fractions 43–50 of the ^{111}In -DTPA-N-TIMP-2 samples in the serum stability determination. It was therefore considered to be an artifact of the radiolabeling procedure rather than an indication of instability of ^{111}In -DTPA-N-TIMP-2. It does not increase during incubation in serum and its presence does not indicate any instability of the labeled conjugate.

The stability of ^{111}In -DTPA-N-TIMP-2 in serum was further supported by nonreducing SDS-PAGE of the radiolabeled conjugate following incubation in serum. After a 48 h incubation, no changes in the intensity of the radioactive ^{111}In -DTPA-N-TIMP-2 band were seen, and no new radioactive bands were evident, indicating that In -DTPA-N-TIMP-2 was not degraded over this period of time (data not shown).

MMP-Binding Activity of In -DTPA-N-TIMP-2. Nonradioactive In -DTPA-N-TIMP-2 and $(\text{In-DTPA})_2$ -N-TIMP-2 (separated from one another by ion exchange chromatography), and a control protein DTPA-myoglobin, were subjected to the fluorimetric binding assay described by Murphy et al. (1995). In this experiment, increasing amounts of inhibitor are incubated with the catalytic domain of MMP-3 (N-MMP-3) and the resulting proteinase activity measured subsequently by the addition of an internally quenched substrate. The rate of fluorescence increase is proportional to the rate of substrate cleavage and hence MMP activity. Figure 7 shows that In -DTPA-N-TIMP-2 inhibited N-MMP-3 to the same extent as unmodified N-TIMP-2. Hence incorporation of a single DTPA into N-TIMP-2, and subsequent reaction with InCl_3 did not affect inhibitory activity under the conditions used. In contrast, $(\text{In-DTPA})_2$ -N-TIMP-2 had no inhibitory activity under these conditions, and its binding to N-MMP-3 was comparable to DTPA-myoglobin, the negative control. Thus the incorporation of a second DTPA severely compromised the inhibitory activity.

DISCUSSION

Conjugation of N-TIMP-2 with DTPA resulted in a yield of approximately 25% of singly modified protein and

Figure 7. N-MMP-3 inhibition assay comparing the activity of In -DTPA-N-TIMP-2 and $(\text{In-DTPA})_2$ -N-TIMP-2, with positive (unmodified N-TIMP-2) and negative (In -DTPA-myoglobin) controls. N-MMP-3 was present at 33 nM in all incubations with substrate peptide. N-TIMP-2 ($\blacklozenge$) gave almost full inhibition at a concentration of 33 nM, as expected for the formation of a 1:1 complex. In -DTPA-N-TIMP-2 ($\square$) retained full inhibitory activity identical to unmodified N-TIMP-2. $(\text{In-DTPA})_2$ -N-TIMP-2 ($\square$) and In -DTPA-myoglobin ($\times$) showed no N-MMP-3 inhibitory activity.

an additional 14% of internally cross-linked singly modified protein. The latter was identified on the ES-MS spectrum as a peak of 18 mass units less than the conjugate peak. Also present, identified by SDS-PAGE, ES-MS, and IEF, were unmodified N-TIMP-2 and small amounts of intermolecularly cross-linked dimers, multiply conjugated N-TIMP-2 species and their intramolecularly cross-linked derivatives, and complexes of the conjugates with metal ions.

Product heterogeneity resulting from DTPA conjugation is well documented (Maisano et al., 1992; Ogan et al., 1987). Heterogeneity can result from conjugation at more than one lysine residue, conjugation at tyrosine residues, DTPA cross-linking, and metal ion contamination of the conjugate (Hnatowich, 1985). Most imaging studies with ^{111}In -DTPA conjugates utilize the crude conjugate, which may have a comparatively low specific radioactivity and may contain some inactivated material as a result of multiple conjugation. Separation of these various conjugation products is desirable as it allows thorough characterization of the various species leading to the development of a homogeneous product with optimal biological activity and specific radioactivity. Isolation of the desired species DTPA-N-TIMP-2 was shown to be straightforward using ion-exchange chromatography, as a result of the significant change in isoelectric point caused by the DTPA conjugation. This method also removes excess DTPA, offering a convenient single-step procedure for purification of the required conjugate.

Tryptic peptide mapping of the purified DTPA-N-TIMP-2 isolated two HPLC fractions containing DTPA-modified peptides. The major peak, peak 32, contained a peptide whose mass corresponded to that expected for the cleaved sequence $\text{K}^{116}\text{SLNHR}^{121}$. The primary site of DTPA modification in singly conjugated N-TIMP-2 is thus lysine-116. This is located on helix 2 of N-TIMP-2 and is spatially distant from the site of MMP interaction (Fernandez-Catalan et al., 1998; Muskett et al., 1998). Lysine-116 was also identified as the primary conjugation site following the reaction of N-TIMP-2 with Bolton-Hunter reagent (Giersing et al., 2000). The principal peptide of peak 64 consisted of two sequences present in equal concentrations corresponding to the cleavage sequences $\text{Q}^{49}\text{-K}^{54}$ and $\text{K}^{116}\text{-R}^{121}$. The combination of amino acid sequencing and MALDI-TOF MS suggests that peptide 64 consists of two sequences bridged by a DTPA linker between lysine-116 and lysine-51.

Examination of the three-dimensional structure of N-TIMP-2 (Muskett et al., 1998) and the dimensions of DTPA suggests that lysine-116 and lysine-51 are close enough together on the surface of N-TIMP-2 for a molecule of DTPA to link simultaneously with both ϵ -amino groups. Thus, a plausible model for the conjugation reaction is that the primary site of modification is lysine-116, and a fraction of the DTPA linked at this site then reacts with nearby lysine-51. In contrast, analysis of myoglobin by ES-MS shows no signs of formation of intramolecular cross-linked species on reaction with DTPAA. Intramolecular cross-linking does not prevent the chelator from binding In^{3+} , as shown by ES-MS. However, we have not determined whether the cross-linked species becomes labeled with ^{111}In under the labeling conditions used, in which DTPA–N-TIMP-2 is present in a large molar excess over indium. The fluorescence binding assay showed that no inhibitory activity was lost on conjugation with a single DTPA, even in the cross-linked form (which constituted approximately 20% of the conjugate used in this assay). On the other hand, the fact that the inhibitory activity of $(\text{DTPA})_2$ –N-TIMP-2 is abolished upon conjugation and subsequent reaction with indium suggests that the second site of DTPA modification is important for the correct functioning of the MMP interaction site. The second site of modification has yet to be identified, but it is unlikely to be lysine-51 since this is spatially distant from the MMP-binding site, and modification at lysine-51 (as seen in the internally cross-linked form of the conjugate) retains MMP-binding activity. A likely candidate for the second modification is the amino-terminus. Higashi and Miyazaki (1999) showed that this was the primary site of modification of full-length TIMP-2 with cyanate, and that this modification abolished MMP-inhibitory activity. This would be consistent with our observation that the second modification inactivates N-TIMP-2. It is possible, in light of the proven accessibility of the N-terminus, that one of the discarded singly modified fractions immediately following fraction 25 in the ion-exchange purification is conjugated at the N-terminus.

The ^{111}In –DTPA–N-TIMP-2 used here is sufficiently stable in serum to undergo evaluation as a diagnostic imaging agent. Approximately 5% of indium-111 is lost to transferrin over a 48 h period. This is consistent with the findings of Gobuty et al. (1985).

In summary, DTPA–N-TIMP-2 can be synthesized in high yield and isolated free from unmodified N-TIMP-2 (so that it can be labeled to high specific activity), free from $(\text{DTPA})_2$ –N-TIMP-2 (so that it retains full activity), and free from pyrogens. It can be radiolabeled in >95% radiochemical yield to a specific activity of at least 4 MBq/ μg (58 MBq/nmol). The conjugate has been produced in a kit formulation which can be stored at -20°C until needed for radiolabeling. The radiolabeling reaction and the appropriate TLC and ITLC quality controls can be completed within 2 h. These attributes render DTPA–N-TIMP-2 suitable for in vivo evaluation.

ACKNOWLEDGMENT

The authors are grateful to the UK Biotechnology and Biological Sciences Research Council, East Kent Hospitals NHS Trust, Association of International Cancer Research, and Arthritis Research Campaign for support of this work. The ES-MS and amino acid sequencing data were collected using the Wellcome Trust-funded facilities at the University of Kent, and the authors would like to thank Mr. K. Howland for his expert advice and assistance.

Revised Manuscript Received July 25, 2001

To investigate the mechanism leading to an oriented immobilization of recombinant proteins onto synthetic copolymers, five genetically modified HIV-1 p24 capsid proteins (RH24, RH24A₄K₂, RH24R₆, RH24R₄K₂, and RH24K₆) were tested for their efficiency to covalently bind to maleic anhydride-*alt*-methyl vinyl ether (MAMVE) and *N*-vinyl pyrrolidone-*alt*-maleic anhydride (NVPMA) copolymers. These proteins contain, at their C-termini, tags differing in cationic and/or reactive amino acids density. We demonstrated that an increase of the charge and amine density in the tag enhances the coupling yield, the most efficient tag being a six lysine one. The reactivity of the proteins depends directly on the reactivity of the tag, and this led us to conclude that the tag was the site where the covalent grafting with the polymer occurred. Thus, design of such tags provides a new efficient and versatile method allowing oriented immobilization of recombinant proteins onto copolymers.

INTRODUCTION

Immobilization of proteins has been widely studied and has found numerous applications in purification processes (affinity chromatography), diagnostic field (immunoassays, biosensors), and large-scale industrial production (bioreactors). According to the expected application, many immobilization processes of proteins are commonly used ranging from ionic interactions, adsorption, complexation, or covalent binding, but covalent immobilization is often required to obtain very stable preparations with extended active life (1). However, binding often occurs via a random attachment of the proteins to the support through several amino acid residues, leading to a partial loss of biological properties, i.e., loss of enzymatic activity for an enzyme or loss of biological recognition for immobilized antibodies or antigens (2). The advantage of oriented grafting of biologically active proteins is mainly good steric accessibility of the active binding site. Regarding protein covalent immobilization as a chemical alteration of the biomolecule, it is of great interest to make this reaction occur at a specific site of the protein that is not involved in the biorecognition process, which is called oriented binding (3). This can be achieved using specific chemistry, for instance, the chemistry of thio groups of antibody Fab fragments or aldehyde chemistry after mild oxidation of carbohydrate moieties (3). With recombinant proteins, site-directed mutagenesis allows introduction of reactive groups, such as cystein residues, at virtually any position of a protein to achieve site-specific conjugation with functional polymers (4, 5).

The use of amine groups for the conjugation of a protein is a more generic method than using specific chemistry since every protein has primary amines avail-

able for conjugation. Furthermore, it is easier to use than thiol chemistry, as this chemistry does not suffer from the unwanted oxidation of the free cysteine groups, leading to unreactive protein dimers. Finally, it is a very flexible approach, as many different reaction conditions in terms of pH, ionic strength, and temperature can lead to the formation of a stable amide bond, linking the protein to the polymer. Hershfield et al. used site-directed mutagenesis to enhance protein modification with poly(ethylene glycol) by mutating arginine to lysine (6). Controlling the site of conjugation using amine chemistry is not a trivial issue, as lysine residues are randomly distributed along the protein. Our idea was to use electrostatic interactions with a polyanionic polymer to favor and direct the chemical immobilization of lysine-tagged protein onto poly(maleic anhydride-*alt*-methyl vinyl ether), the hexalysine tag being both positively charged and reactive toward the anhydride moieties of the copolymer. Preliminary investigations demonstrated the feasibility of this approach, as the coupling yields of the tagged protein were higher than its nontagged counterpart. Furthermore, we showed that the reaction was enhanced by electrostatic interactions between the polymer and the biomolecule (7).

This paper reports on a more thorough investigation on this approach, willing to address the effects of the reactivities and of the natures of both the polymer and the tag introduced on a HIV-1 modified p24 capsid protein. To assess the impact on the efficiency of the coupling reaction of (i) the primary amines density and (ii) the charge density composing the tag, competitive experiments using peptides have been performed. Investigation of the coupling isotherms and the corresponding Scatchard plots demonstrated a positive cooperative effect of the presence of the tag, provided it bore positively charged amino acids.

Figure 1. Sequence alignment of recombinant RH24, RH24A₄K₂, RH24R₆, RH24R₄K₂, and RH24K₆ proteins (derived from HIV-1 p24 strain HXB2). The polyhistidine tag (H₆) used for metal chelate affinity chromatography is indicated in italic, arginine (R) and lysine (K) residues are indicated in bold letters.

from Cheynet et al. (8). They all present a six-histidine tag (H) at their N-terminal end, allowing a one-step purification by ion metal affinity chromatography (IMAC). They were termed RH24, RH24A₄K₂, RH24R₆, RH24R₄K₂, and RH24K₆ for recombinant protein with respectively no tag at their C-terminal end, a tag containing four alanines and two lysines (A₄K₂), six arginines (R₆), four arginines and two lysines (R₄K₂), and six lysines (K₆) for the last one. *E. coli* strain XL1 was transformed with the expression plasmids. The extracts of soluble proteins were purified on an FPLC Äkta system using a Zn-NTA activated gel. Purified proteins were analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and by size exclusion chromatography on a Shodex Protein Pack column on a Kontron HPLC (detection 280 nm).

Theoretical molar masses and isoelectric points were determined with the Mac Vector software (version 6.5.3) and compared with the experimental values obtained by mass spectrometry and isoelectric focusing. The amino acid sequence for each protein is reported in Figure 1. Ten lysines and 11 arginines groups are randomly dispersed along the nontagged RH24 protein macromolecule and conserved within all five recombinant proteins. NMR (9) and crystal structure data (10, 11, 12) demonstrated that, in the 3D structure, the 10 lysine groups were accessible for grafting though displaying different reactivities (13).

Protein Characterization. Mass Spectrometry (LC-ESI-MS). Analyses were performed with a single quadrupole API 100 mass spectrometer, 140B pumps, and a

785A detector (Perkin-Elmer). Reversed-phase liquid chromatography was performed on a C4 column (Vydac ref 214PT5115, 5 µm particle size). Solvent A was 0.1% (v/v) formic acid in water and solvent B was 0.1% (v/v) formic acid in water/acetonitrile mixture (5:95 v/v). A gradient of 40 to 60% of B was used.

Isoelectric Focusing (IEF). IEF were performed with a PhastSystem and PhastGel IEF 5-8 from Pharmacia. The separation method used for that IEF required three steps: a prefocusing step (2000 V, 2 mA, 3.5 W, 15 °C, 75 Vh), the sample application (200 V, 2 mA, 3.5 W, 15 °C, 15 Vh) and the focusing step (2000 V, 5 mA, 3.5 W, 15 °C, 510 Vh). After separation, PhastGel was colored using PhastGel Blue R, a coomassie R350 dye on the Phast-System from Pharmacia. The different steps of the fast coomassie staining were (i) fix: 20% trichloroacetic acid, (ii) wash/destain: 30% methanol and 10% acetic acid in distilled water (3:1:6), and (iii) stain: 0.02% PhastGel Blue R solution in approximately 30% methanol and 10% acetic acid in distilled water and 0.1% (w/v) CuSO₄. After development, gels were dried.

Copolymers. Four polymers were used, differing in molar masses and in nature of the comonomer used with maleic anhydride (MA). Alternate copolymers were obtained with either methyl vinyl ether (MVE) [sample MAMVE67 = 67000 g/mol and sample MAMVE20 = 20000 g/mol] or *N*-vinylpyrrolidone (NVP) [sample NVP-MA58 = 58400 g/mol and sample NVPMA29 = 29100 g/mol]. MAMVE copolymers were obtained from Poly-science Inc. (Warrington, PA). NVPMA were synthesized in the laboratory according to Veron et al (14).

Coupling of Proteins to Copolymers. The appropriate amount of copolymers was dissolved in anhydrous dimethyl sulfoxide (DMSO from Aldrich) at 37 °C. To a protein buffer solution at the appropriate concentration was added the required volume of polymer solution in DMSO. A standard reaction consisted of 100 µg of protein and 5 µg of polymer in 100 µL of buffer. The final concentration of DMSO in the mixture was 5%. The reaction mixture was stirred for 3 h at 37 °C. Bioconjugates were stored at 4 °C. For the bioconjugates obtained with partially hydrolyzed polymers, the polymers were dissolved in DMSO containing 10% (volume percent) H₂O and incubated 48 h at 37 °C before conjugation with proteins.

Bioconjugate Characterization. Bioconjugates were analyzed by size exclusion chromatography using a Shodex Protein KW-803, a Kontron HPLC 422 pump, a Kontron HPLC autosampler 465, and a Kontron UV diode array detector. Purification was run in a 0.1 M phosphate buffer pH 6.8 0.5% (w/v) of sodium dodecyl sulfate (SDS) with a flow rate of 0.5 mL/min. Detection was achieved by measuring the protein absorbance at 280 nm (the polymer did not generate any signal under our experimental conditions). The ratio of the peak area corresponding to the polymer bound protein versus the sum of the two peaks corresponding to the unbound and bound protein (i.e., the total amount of protein involved in the reaction) gave the coupling yield (Y). To assess the average amount of protein molecules per polymer chain: $N = nY/n'$ where n and n' , respectively, correspond to the number of protein molecules and the number of polymer chains in the reaction mixture.

RESULTS

Protein Characterization. The five recombinant proteins described above differ at their C-terminal end by the introduction of a tag containing variable density of primary amines and/or cationic charges (Table 1). The nontagged recombinant RH24 protein contains 11 arginines and 10 lysines representing respectively 4.5 and 4.1% of the total amount of amino acids. After purification by IMAC on a Zn-NTA activated gel, the purity of the proteins was greater than 95% as determined on a Coomassie Blue stained SDS polyacrylamide gel.

Every protein displayed the same behavior by size exclusion chromatography (HPLC) as well as in SDS polyacrylamide gel electrophoresis. Experimental determination of the molar masses by electrospray mass spectrometry was in accordance with the expected theoretical value for all recombinant proteins (Table 2). RH24R₆ protein exhibited an additional peak correspond-

ing to the expected value minus 722 mass unit. Such a deletion may occur at the N-terminal of the protein and correspond to the MRGSHH sequence, representing a 723 Da sequence. Moreover, MRGSHH-deleted RH24R₆ protein would exhibit a theoretical isoelectric point of 6.5 which is compatible with the experimental IEF gel pattern obtained (see below). Although such a deletion has never been observed for any six-histidine-tagged proteins manufactured in our laboratory (8, 15,16), the four remaining histidines are enough for an efficient purification (17). As the six-arginine tag remains nonaltered in the cleaved RH24R₆ protein, even if a C-terminal deletion might occur (SVDES- COOH and RSVDES- COOH deletion would represent 649 and 805 Da, respectively), this protein preparation was used in further experiments.

Theoretical isoelectric points were determined using Mac Vector software (version 6.5.3) and were compared to the experimental values. After isoelectric focusing, it appears on a Coomassie Blue stained gel that all the five proteins displayed a band corresponding to the expected isoelectric point (Table 2). Nevertheless, RH24A₄K₂, RH24R₄K₂, and RH24R₆ proteins displayed one or more unexpected bands which may be due to impurities, oxidized forms of p24 (data not shown) as previously described (18), or cleaved recombinant proteins as observed for RH24R₆ by MS analysis.

Protein Immobilization Conditions. In our previous paper (7), we demonstrated that the six-lysine-tagged protein reacted under a broader range of experimental conditions than the nontagged RH24 protein. Furthermore, it came out from this previous investigation that ionic strength was the physicochemical factor that had the most important impact on the course of the reaction, a reduction of the ionic strength of the coupling medium leading to an increase in coupling efficiency. Interestingly, the improvement was more important with the lysine-tagged protein. The present work aims at getting a better insight of the mechanisms involved in the formation of covalent conjugates between tagged proteins and reactive copolymers. Therefore, we investigated the effects of the natures and reactivities of both the polymer and the tag on the course of the immobilization reaction. Two different polymers were investigated whose reactivities were modified by controlling the level of hydrolysis of the functional groups prior to running the reaction. Tags of various compositions were genetically introduced in the proteins, and different reaction buffers were investigated. The results will be discussed first in term of immobilization efficiencies and, then, more in a fundamental viewpoint on the role of the tag in the covalent process.

Figure 2. Coupling yield of recombinant proteins RH24, RH24A₄K₂, RH24R₆, RH24R₄K₂, and RH24K₆ to MAMVE67 copolymer, 3 h at 37 °C, in 20 mM carbonate buffer pH 8.2 (empty bar), 50 mM tris pH 7.0 (grey bar), and 50 mM phosphate pH 7.8 (black bar). [protein] = 0.95 g/L (3.56×10^{-9} mol) and [MAMVE67] = 0.048 g/L (7.46×10^{-11} mol). Experiments were performed in triplicate. The indicated data is the mean value $\pm$ two standard deviations.

Figure 3. Coupling yield of recombinant proteins RH24, RH24A₄K₂, RH24R₆, RH24R₄K₂, and RH24K₆ to MAMVE67 (empty bar), MAMVE20 (clear grey bar), NVPMA58 (dark grey bar), and NVPMA29 (black bar) copolymers at 37 °C during 3 h in 50 mM phosphate buffer pH 7.8. [protein] = 0.95 g/L (3.56×10^{-9} mol), [MAMVE67] = 0.048 g/L (7.46×10^{-11} mol), [MAMVE20] = 0.048 g/L (2.5×10^{-10} mol), [NVPMA58] = 0.048 g/L (8.56×10^{-11} mol), and [NVPMA29] = 0.048 g/L (1.71×10^{-10} mol). Experiments were performed in triplicate. The indicated data is the mean value $\pm$ two standard deviations.

The effect of the buffer on the course of the reaction is reported in Figure 2 for each of the proteins. Carbonate and phosphate buffers presented similar patterns for the five proteins, excepted for RH24 whose coupling yield was quite poor in carbonate buffer as previously obtained (7). Conversely, the Tris buffer exhibited a quite different behavior. The coupling yields obtained with the less-reactive RH24 and RH24A₄K₂ proteins were higher in Tris buffer than in phosphate or in carbonate buffers.

Unexpectedly, in the Tris buffer, the two proteins containing arginine in the tags (RH24R₆ and RH24R₄K₂) precipitated on addition of the polymer solution in DMSO, leading to coupling yields close to 0%. Finally, the most reactive RH24K₆ protein exhibited the best coupling yields close to 100% whatever the buffer. This result led us to conclude that the more reactive the tag on the protein, the less important the influence of the coupling medium on the coupling yield. The phosphate buffer was retained for extensive investigations of the parameters involved in protein–copolymer coupling reaction. This is, in addition, convenient as it is the protein storage buffer.

Using the phosphate buffer, the effect of the nature and the molar mass of the polymer were investigated in terms of coupling yield for each of the five recombinant proteins used. In most cases, the lower molar mass polymers allowed slightly more efficient grafting reactions than the higher molar mass ones (Figure 3). As a general trend, the *N*-vinylpyrrolidone copolymers were slightly less reactive than the methyl vinyl ether based ones, reflecting their higher susceptibility to hydrolysis as reported by Véron et al (14). Nevertheless, as already noticed for the buffer, no significant difference was obtained when coupling the most reactive protein RH24K₆ to the four copolymers.

The level to which their functional groups were hydrolyzed by water (Figure 4) altered the reactivities of the polymers. Preliminary experiments showed that after storing the MAMVE polymer in a 10% (v/v) water DMSO mixture for 24 h, no alteration was observed in coupling efficiency. After 96 h of storage, the coupling yields were lower than 70% for RH24K₆, illustrating the loss of reactivity of the polymer due to hydrolysis of the functional groups. In Table 3, the effect of prehydrolysis of the polymers for 48 h prior to running the coupling reaction is shown. For RH24K₆, prehydrolysis of the MAMVE copolymer resulted in a slight decrease in the immobilization efficiency. The observed decrease was more important for the NVPMA copolymer, as its hydrolysis rate is higher than MAMVE (14). For RH24 and RH24R₆, which are less reactive than RH24K₆, the effect of prehydrolysis on the course of the reaction is more strongly marked. In addition, the reproducibility of the reaction under these conditions seems poor; the more sensitive to hydrolysis the polymer, the more variations in the results were observed. For ease of comparison, these results can be reported in percent of decrease of the coupling yield using the nonhydrolyzed polymer as a reference (Table 3). For the nontagged RH24 protein, the drop in binding efficiency is quite dramatic ranging from 80 to 98%. Conversely, the binding efficiency is moderately affected for the lysine-tagged RH24K₆ pro-

tein, ranging from 17 to 37%. An intermediate situation is obtained for the six-arginine-tagged RH24R₆ protein, which exhibits decrease binding efficiency ranging from 68 to 84%. As already noticed for the previous parameters, the overall reaction efficiency is moderately affected by the amount of copolymer reactive functions when the protein counterpart is highly reactive, such as RH24K₆.

Finally, the nature of the tag was investigated as shown in Table 1. In the six-lysine tag, the amino groups were both positively charged and potentially reactive with the anhydride groups of the polymer. Therefore, in the following experiments, the chemical reactivity and the presence of positive charges in the tag ('physicochemical reactivity') were investigated. Recombinant RH24A₄K₂ protein bears a tag in which four out of six lysines were substituted by alanine, a neutral amino acid, reducing therefore the amount of charged/reactive amino acids in the tag. In recombinant protein RH24R₆, the tag is only composed of six arginine residues, still positively charged but barely capable of reacting with anhydride groups. The tag in protein RH24R₆K₂ is fully positively charged and bears two lysines that are the reactive amino acids of the tag. From Figures 2 and 3, it appears that the reactivity of the proteins depends on the presence in the tag of both positive charges and reactive amino groups. The least reactive tagged protein is RH24A₄K₂ featuring only two charged lysines in the tag whereas the most reactive one is the six-lysine-tagged RH24K₆ (higher coupling yields). Between these two extreme examples, RH24R₆ binds more efficiently to the polymer than RH24A₄K₂. Substituting two unreactive arginines of the R₆ tag by lysines (RH24R₄K₂) allowed an increase in the reactivity of the protein toward coupling onto the polymer. These results clearly demonstrate that the reactivities of the proteins are directly related to the reactivities of the tag.

Role of the Tag in the Immobilization Process.

The reactive amino acids of the tag which so drastically affect the course of the reaction as demonstrated above, correspond to ca. 2% of modification in the amino acid composition of the proteins. So, to better understand how such low amino acid variations in protein composition can impact so drastically on the reactivity of the protein, we investigated both the intrinsic reactivity of the tag toward the polymer and their behaviors in competition experiments with the proteins. In Table 4 is reported the composition of the peptides used in further experiments. The peptides contain 18 amino acid residues. The 12 carboxyl-terminal amino acids perfectly mimic the C-terminal end of a protein. The amino-terminal sequence consists of a stretch of six amino acids different from the flanking sequences of the recombinant proteins. The two N-terminal acetylated (Ac-K₆ and Ac-R₆) peptides mimic a situation where a protein does not contain, in a close vicinity of the tag, any primary amino group available for grafting. Conversely, NH₂-K₆ and NH₂-R₆ peptides

Table 4. Amino Acid Sequences of the Peptides Used to Mimic the Tags and Their Coupling Yield to MAMVE67 Copolymer

exhibit a free terminal amine accessible for grafting. A non K non R containing peptide was used as control (NH₂-Ct).

The intrinsic reactivities of the tags were assessed in conjugation reactions of the peptides with copolymer MAMVE67 under identical experimental conditions used for the proteins (50 mM phosphate buffer, pH 7.8). The following gradation in coupling efficiency was observed, NH₂-R₆ > NH₂-K₆ > Ac-K₆ >> Ac-R₆, from the most to the least reactive peptide (Table 4). Comparison from acetylated versus nonacetylated peptides showed that, at least in such short peptides, the amino terminal group is a major site involved in grafting. In an NH₂-terminal free reactive group context, the R₆-containing peptide proves more valuable in grafting than the K₆ one. Taken together, these two last results confirm our preliminary study on a model peptide reported earlier (19). From these data, it can be stated that arginine groups are as efficient as lysine groups at generating attractive electrostatic interactions with the copolymer. The lower grafting yield of the NH₂-K₆ peptide may be due to multiple reaction sites on the polymer because of the presence of seven potentially reactive primary amine. Conversely, NH₂-R₆ can only react via the terminal amino group and is so bound to the polymer via a single attachment point. Quite logically, Ac-K₆ peptide was much more reactive than the Ac-R₆ one, whose residual reactivity may be explained by the presence of the weak nucleophilic hydroxyl of serine, or/and by a disfavored, but still existing, reaction of arginine groups onto reactive anhydrides.

The properties of these peptides were further evaluated in competition assays with the most reactive RH24K₆ protein in grafting reactions with MAMVE67 copolymer. The deduced percentages of inhibition, resulting from the addition of increasing amounts of peptides to the coupling mixture, are reported in Figure 5. All curves displayed a characteristic shape with a more or less steep slope and a variable plateau value. At a peptide/protein molar ratio lower than 25, the percentage of inhibition increased with increasing amount of peptides in the coupling mixture, except for the control peptide NH₂-Ct, which being uncharged, had no interference with the immobilization of RH24K₆. The following gradation in competition efficiency was observed NH₂-K₆ > NH₂-R₆ > Ac-K₆ >> Ac-

Figure 5. Percent inhibition of the formation of bioconjugates RH24K₆ to MAMVE67 as a function of the nature of the peptide during a competitive coupling reaction. [protein] = 0.34 g/L (1.28×10^{-9} mol), [MAMVE67] = 0.048 g/L (7.46×10^{-11} mol). Peptides: NH₂-K₆ (□), Ac-K₆ (■), NH₂-R₆ (○), Ac-R₆ (●), NH₂-Ct (×). Coupling reaction in 50 mM phosphate buffer pH 7.8, 3 h at 37 °C. Because samples precipitated when the peptide/protein molar ratio was greater than 25/1, a plateau value was not obtained for curve NH₂-R₆ (○).

R₆ in descending order. The same gradation is observed at molar ratio higher than 25. All curves tend toward a plateau, which was reached as early as a ratio of 50 by NH₂-K₆ peptide. No plateau could be obtained for the NH₂-R₆ peptide due to a precipitation of the conjugates when peptide/protein molar ratio was greater than 25.

These data clearly show that in this reaction, the reactivity of the peptide is related to both its amine and charge density.

Finally, the most reactive NH₂-K₆ peptide and its acetylated counterpart were used in competition assays, in the grafting reaction, with the five recombinant proteins bearing tags of variable reactivities. The deduced percentage of inhibition are reported in Figure 6. The curves displayed patterns similar to those described above. It appears that the inhibition potential of the peptide strongly depended on the nature of the tag on the protein (Figure 6). Ac-K₆ peptide competed more efficiently with the least reactive proteins (RH24 and RH24A₄K₂) than with the most reactive ones (RH24R₆, RH24R₄K₂, or RH24K₆), as shown by the steepest slope and highest plateau value of the inhibition curves. The same inhibition pattern was obtained with NH₂-K₆ peptide, although with a more pronounced effect than its acetylated counterpart, due to greater reactivity of NH₂-K₆ peptide as discussed above. These results show evidence that recombinant protein reactivity in the grafting reaction is directly correlated with the density of charges (R and K) and primary amines (K) within the C-terminal-fused tag.

DISCUSSION

The molar masses and compositions of the polymers, as well as their reactivities, have moderate effects on the course of the reaction compared to the drastic ones observed with tags of differing compositions. The reactivities of the proteins were increased if the tag bore six positively charged amino acids, and to a better extent if it comprised functional groups susceptible to react with the anhydride moieties of the polymer (Figure 2, Figure 3, and Table 3). These results prompted us to investigate the effects of the reactivities of the tag on the mechanism of binding of the proteins. By definition, a reactive tag is

positively charged and its overall reactivity increased by increasing the amount of lysine residues in its composition. Immobilization isotherms presented in Figure 7 show that both the maximal amount of covalently bound protein (plateau value) and the affinity (slope) of the protein for the polymer are directly related to the amino acid composition of the tags (Table 5). The more reactive the tag, the steeper the slope of the isotherms and the more proteins were bound per polymer chain. The Scatchard plots presented in Figure 8, corresponding to the

isotherms, can be divided into two groups. The first group corresponds to the exponential decrease observed for proteins RH24 and RH24A₄K₂, respectively bearing no tag or a poorly reactive one. For these two proteins, the curve is concave up, corresponding to a binding process taking place with negative cooperativity (20), i.e. the already bound proteins preventing the binding of others via steric hindrance and/or electrostatic repulsive forces. Conversely, for proteins with a reactive tag, the Scatchard plots displayed a bell-shaped curve, revealing that the binding process occurred with positive cooperativity (21). The maxima of the bell-shaped curves were directly dependent on the reactivities of the tags; the more reactive, the higher the ratio and, thus, the more efficient the binding reaction. Similarly, the positions of the maxima along the X-axis respected the order of reactivities of the tags: situated at five proteins per chain for the least charged tag, the maximum is found at 30 for the most reactive one.

The strong dependency of the performance of the reaction with the reactivities of the tags suggests the reaction to be mainly mediated by the tag, in a regioselective manner. In other words, the binding reaction preferentially takes place at the site of the tag, or in its close vicinity. Supposing saturation of the polymer is

obtained for 60 protein molecules bound per polymer chain ($N_{\max} = 60$) as observed with the most reactive RH24K₆, then the fractional saturation can be determined as $\theta = N/N_{\max}$. Hill's plots ($\log(\theta/(1 - \theta))$ vs C_{eq}) of grafting data for RH24 and RH24A₄K₂ featured the same linearity, and the slope (Hill coefficient) was 0.49. This low value confirms the negative cooperativity observed in the Scatchard plots. Conversely, for the data obtained with the positively charged tags, no existing model could fit our experimental data despite that Langmuir, multi-equilibrium, or Freundlich models were taken into account. Even 'the multibinding sites ligand' model, developed by Mc Ghee and von Hippel (22), was not successfully fitted with our experimental data though it actually predicts bell-shaped Scatchard plots for positive cooperativity. In fact, our data feature a deformed-bell shape with a linear increase of the ratio values up to the maximum. This linear increase can be explained by a high affinity of the protein for the polymer due to the existence of electrostatic interactions that exhausts the protein content of the medium, up to a level of pseudo-saturation (the decreasing and plateau sections). After this saturation level, the binding process gets less efficient and becomes dependent on the protein concentration. In addition, the chemical reactivity is an important factor as, when the amino acids are susceptible to react with the polymer, the protein/polymer affinity is higher and more protein can be accommodated onto the macromolecular chain, because the grafting reaction takes place at the site of the tag. Interestingly, the shapes of the Scatchard plots obtained for the proteins proved similar to those reported earlier for peptides, the chemical reactivities of which were directly related to the amino acid composition of the tags.

CONCLUSION

This paper points out the importance of the reactivity of the tag introduced in the protein on the efficiency of the covalent grafting. We demonstrated that the more reactive the tag, the less important the other parameters (i.e., the nature of the buffer, the nature and size of the polymer, and then the reactivity of the polymer) on the control of the covalent immobilization. This allows the use of a great variety of many experimental conditions to perform the covalent grafting, provided the tag be reactive enough.

In a previous work, we had demonstrated that 50 molecules of a lysine-tagged protein could be immobilized per polymer chain. The accommodation of so many molecules on the polymer required an end-on conformation from the protein, taking into account its dimensions, the link between the polymer and the protein was supposed to take place via the tag. In the present work, we demonstrated that the reactivity of a protein depended directly on the reactivity of its tag, which confirmed our previous hypothesis that the tag was the

site where the interactions with the polymer occurred. The coupling isotherms and the Scatchard plots of the immobilization process of each of the tagged proteins pointed out that the binding of proteins bearing highly reactive tags took place with a positive cooperativity. Conversely, in absence of tag or with a poorly reactive one, the binding occurred with a negative cooperativity.

Our investigations demonstrated that the immobilization of tagged recombinant proteins can occur in a regioselective manner, by taking profit of attractive electrostatic forces between the polymer and the natural macromolecule. This concept will be used in further developments for various applications such as diagnostics or for the realization of macromolecular assemblies for the delivery of bioactive substances.

Synthesis and Biological Studies of 5-Aminolevulinic Acid-Containing Dendrimers for Photodynamic Therapy

Sinan H. Battah,[†] Cheng-Ean Chee,[‡] Hiroaki Nakanishi,[‡] Sandra Gerscher,[‡] Alexander J. MacRobert,[‡] and Christine Edwards^{*,†}

Department of Biological Sciences, University of Essex, Wivenhoe Park, Colchester, Essex, CO4 3SQ, UK, and National Medical Laser Centre, Royal Free and University College Medical School, University College London, UK. Received March 29, 2001; Revised Manuscript Received September 25, 2001

Using a convergent growth approach, a series of novel 5-aminolevulinic acid (ALA)-containing dendrimers have been synthesized. In these molecules, ALA residues are attached to the periphery by ester linkages, with amide bonds connecting the dendrons. Three first-generation dendrimers, bearing either 6 or 9 ALA residues, were synthesized by attachment of a tris(Boc-protected ALA)-containing wedge (**1**) to a di- or tripodent aromatic, or tripodent aliphatic core. Two second generation 18-ALA-containing dendrimers were also synthesized using a 3,3'-iminodipropionic acid spacer unit between wedge **1** and the aromatic core. These compounds differed only in the distance between the core and the linker unit. The Boc-protected dendrimers were deprotected using trifluoroacetic acid and isolated as their TFA salts. The potential of these ALA ester dendrimers as macromolecular prodrugs for photodynamic therapy has been demonstrated in the tumorigenic keratinocyte PAM 212 cell line.

INTRODUCTION

Photodynamic therapy (PDT) is a nonthermal technique for inducing tissue damage with light following administration of a light-activated photosensitizing drug which can be selectively retained in malignant or diseased lesions relative to normal adjacent tissue (1). Activation of the photosensitizer results in the generation of reactive oxygen species (ROS), mainly singlet oxygen via interaction of the sensitizer triplet state with molecular oxygen. The ROS oxidize intracellular substrates such as lipids and amino acid residues leading to cell death.

The most widely studied application of PDT to date is in cancer therapy. However, using conventional exogenous sensitizers, skin photosensitivity can be prolonged, and damage to normal tissue is rarely avoidable due to poor tumor selectivity. The use of 5-aminolevulinic acid (ALA) is a relatively new approach in PDT. ALA is a natural precursor of protoporphyrin IX (PpIX), an effective photosensitizer, and cellular concentrations of PpIX can be increased by the administration of 5-aminolevulinic acid (ALA) (2). A certain amount of tumor selectivity can be achieved since porphobilinogen deaminase (a rate-limiting enzyme in heme biosynthesis) activity is increased (3) and ferrochelatase (the enzyme which catalyzes the conversion of photoactive PpIX into inactive heme) levels are decreased in tumor cells (4). For therapeutic applications, PpIX is activated using red light (typically at 635 nm), with mitochondria (5) believed to be key targets of singlet oxygen oxidative damage resulting in cell death mainly via apoptosis (6). PpIX levels return to normal after 24 h, following administra-

tion so skin photosensitization is relatively short-lived compared to many exogenous sensitizers (7).

A major limitation of ALA-PDT is the low intracellular availability of ALA. Cellular uptake of ALA occurs via a relatively slow active transport mechanism (8, 9). Recently it has been shown that ALA esters, being more lipophilic than ALA (e.g., ALA hexyl ester), can quickly cross the cell membrane by diffusion and (10, 11), once inside the cell, are cleaved by nonspecific esterases (11–18). Since higher intracellular ALA levels lead to higher PpIX concentrations, lipophilic ALA prodrug derivatives are more efficient at inducing PpIX photosensitization. A further improvement based on this strategy would be to design a prodrug that can deliver several ALA molecules into the cell, and selectivity of the prodrug for target cells would be an obvious advantage.

Polymeric drug delivery systems present an attractive method for drug targeting, particularly in cancer chemotherapy (19). In the past, most of the polymers investigated as drug carriers have been polydisperse and either linear or highly branched. Recent advances in polymer chemistry now allow the synthesis of structurally defined, hyperbranched polymers (or dendrimers) which can be conjugated with drug molecules (20). The drug can either be reacted with a preformed dendrimer (21–23), in which case the exact loading of the drug cannot easily be controlled, or can be incorporated into the structure of the dendrimer during synthesis. The latter offers the opportunity for a polymeric prodrug which is structurally defined with a known size and drug loading. Here we describe the synthesis of a novel series of dendritic ALA ester prodrugs for use in PDT applications.

MATERIALS AND METHODS

General Methods. ¹H and ¹³C NMR spectra were recorded on a JEOL EX270 MHz spectrometer. Chemical shifts are quoted in ppm measured downfield relative to

TMS. Ultraviolet–visible spectra were recorded on a Unicam UV2 spectrophotometer in dichloromethane solution. Infrared spectra were recorded on a Nicolet FTIR spectrophotometer as thin films in dichloromethane. Mass spectra were obtained using either an EI, CI, FAB or electrospray technique with a NOBA matrix. Melting points were measured using a Kofler hot-plate microscope. Analytical thin-layer chromatography was carried out using Merck silica gel 60, aluminum-backed silica-coated plates which were visualized using ultraviolet light (254 nm). Column chromatography was carried out using Prolabo silica gel (220–400 mesh flash grade). All compounds were purified to one spot by TLC and R_f values are quoted using the same solvent system as used for column chromatography unless otherwise stated. All reagents were purchased from Aldrich, Avocado, or Acros chemical companies and used without further purification.

Dendrimer Synthesis. ALA was prepared by the method of Hart et al. (24). Compounds **2**, **3**, **4**, **7**, and **11** were prepared according to Ashton et al. (25).

N-tert-Butyloxycarbonyl-5-aminolevulinic Acid (8, Boc-ALA). A solution of 5-aminolevulinic acid (0.42 g, 2.50 mmol) in water (5 mL) was adjusted to pH 8–10 with aqueous sodium hydroxide (0.1 N). Di-tert-butyl dicarbonate (1.16 g, 5.33 mmol) was dissolved in 1,4-dioxane (5 mL) and added to the mixture which was stirred at room temperature for 18 h. The excess of di-tert-butyl dicarbonate was removed by washing the mixture with diethyl ether (2 × 50 mL). Ethyl acetate (50 mL) was added, and the aqueous layer was acidified with dilute hydrochloric acid (1 N). Separation of the organic layer, followed by removal of the solvent, gave 0.35 g (60%) of Boc-ALA as a colorless oil; IR (film) 3445, 2765, 2242, 1721, 1389, 1364 cm^{-1} ; ^1H NMR (270 MHz, CDCl_3) δ 10.42 (br s, 1H), 5.25 (br s, 1H), 4.00 (s, 2H), 3.26 (m, 4H), 1.42 (s, 9H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 204.47, 176.75, 155.89, 128.58; 80.10, 49.61, 33.88, 27.34; CI-MS m/z 232 (M^+ + H).

N-(Benzyloxycarbonyl)[tris(N-tert-butyloxycarbonyl-5-aminolevulinylloxymethyl)methyl]methylamine (9). Compound **7** (0.31 g, 1.22 mmol) in DMF (10 mL) was added dropwise, over 50 min, to a mixture of Boc-ALA (**8**, 1.0 g, 4.30 mmol), DCC (0.82 g, 4.10 mmol), and DMAP (0.05 g, 0.42 mmol) in dichloromethane and DMF (15 mL, 2:1 v/v). The mixture was stirred at room temperature for 48 h, after which time the heavy precipitate was filtered off, and the solvents were evaporated in vacuo. The residue was purified by column chromatography on silica gel (EtOAc/hexane 7:3, R_f = 0.46) to obtain 0.52 g (75%) of compound **9** as a colorless oil; IR (film) 3372, 2680, 2352, 1755, 1718, 1513, 1457, 1370 cm^{-1} ; ^1H NMR (270 MHz, CDCl_3) δ 7.41 (m, 5H), 5.86 (br s, 1H), 5.58 (br s, 3H), 5.13 (s, 2H), 4.47 (s, 6H), 4.05 (d, J = 5.2 Hz, 6H), 2.76 (m, 6H), 2.09 (m, 6H), 1.37 (s, 27H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 127.68, 127.86, 153.23, 155.17, 171.17, 172.33, 203.44; 127.54, 79.11, 61.85, 56.50, 48.92, 33.48, 27.64, 27.35, 26.90; FAB-MS m/z 917 (M^+ + Na); FAB-HRMS calcd for $\text{C}_{42}\text{H}_{62}\text{N}_4\text{O}_{17}\text{Na}$ (M^+) 917.4008, found 917.3998.

Tris(tert-butyloxycarbonyl-5-aminolevulinylloxymethyl)methylamine (1). The Z-protected amine **9** (0.53 g, 0.59 mmol) was dissolved in ethyl acetate and methanol (15 mL, 2:1 v/v). Palladium on carbon (0.17 g, 10%) was added, and the mixture was stirred under an atmosphere of hydrogen for 8 h at room temperature. The reaction mixture was filtered through Celite which was washed with a further amount of ethyl acetate. The solvents were evaporated in vacuo, and the residue was

dried to obtain 0.44 g (97%) of compound **1** as a colorless oil; IR (film) 3375, 2654, 1760, 1718, 1370 cm^{-1} ; ^1H NMR (270 MHz, CDCl_3) δ 8.95 (br s, 2H), 5.54 (br s, 3H), 4.32 (s, 6H), 3.98 (d, J = 4.3 Hz, 6H), 2.75 (s, 6H), 2.69 (m, 6H), 1.38 (s, 27H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 205.56, 171.90, 155.62, 79.64, 65.36, 54.05, 49.99, 34.07, 28.15, 27.45; ES-MS m/z 761 (M^+ + H); ES-HRMS calcd for $\text{C}_{34}\text{H}_{57}\text{N}_4\text{O}_{15}$ (M^+ + H) 761.3820, found 761.3821.

1,3,5-Benzenetricarbamido-N,N',N''-tris(ethylpropionate) (10). A solution of 1,3,5-benzenetricarbonyl trichloride (3.10 g, 11.34 mmol) in dichloromethane and DMF (15 mL, 2:1 v/v) was slowly added, over a period of 2 h, to a stirred mixture of β -alanine ethyl ester hydrochloride (6.90 g, 45.0 mmol) and triethylamine (4.20 mL, 30.0 mmol) in dichloromethane and DMF (15 mL, 2:1 v/v) at 0 °C. Stirring was continued at the same temperature for 4 h and at room temperature for 16 h. The reaction mixture was then filtered, and the solvents were evaporated in vacuo. The resulting residue was dissolved in dichloromethane (50 mL) and washed successively with aqueous hydrochloric acid (50 mL, 2 N), saturated aqueous sodium hydrogen carbonate (50 mL), and water (20 mL), dried (MgSO_4), and evaporated to obtain 6.20 g (61%) of the title compound as a white powder, mp 181–183 °C; IR (film) 3419, 2276, 2340, 1710, 1650 cm^{-1} ; ^1H NMR (270 MHz, CDCl_3) δ 8.10 (s, 3H), 7.49 (s, 3H), 4.18 (q, J = 4.0 Hz, 6H), 3.71 (m, 6H), 2.69 (m, 6H), 1.27 (t, J = 4.0 Hz, 9H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 173.00, 166.42, 135.36, 128.56, 61.30, 36.28, 34.26, 14.55; CI-MS m/z 508 (M^+ + H); EI-HRMS calcd for $\text{C}_{24}\text{H}_{33}\text{N}_3\text{O}_9$ (M^+) 507.2217, found 507.2228.

1,3,5-Benzenetricarbamido-N,N',N''-tripropionic Acid (5). Compound **10** (4.00 g, 7.92 mmol) was dissolved in methanol (15 mL), and the solution was cooled to 0 °C. Aqueous sodium hydroxide (70 mL, 2 N) was added, and the solution was left to stir for 3 h. The resultant precipitate was dissolved by the addition of water (7 mL), and the solution was neutralized with Amberlite IR-120 (H^+ form) ion-exchange resin, filtered, evaporated, and dried thoroughly to afford 0.61 g (93%) of **5** as a white powder, mp 251–252 °C; IR (Nujol) 3455, 2237, 1689, 1631 cm^{-1} ; ^1H NMR (270 MHz, d_6 -DMSO) δ 12.42 (br s, 3H), 8.91 (t, J = 5 Hz, 3H), 8.51 (s, 3H), 3.68 (m, 6H), 2.63 (m, 6H); ^{13}C NMR (67.5 MHz, d_6 -DMSO) δ 172.88, 165.49, 134.80, 128.51, 35.72, 33.61; CI-MS m/z 424 (M^+ + H); CI-HRMS calcd for $\text{C}_{18}\text{H}_{22}\text{N}_3\text{O}_9$ (M^+ + H) 424.1356, found 424.1368.

N,N'-[N-[Tris(N-tert-butyloxycarbonyl-5-aminolevulinylloxymethyl)methyl]acetamido]terephthalamide (11). A solution of **1** (0.42 g, 0.58 mmol) in dichloromethane (10 mL) was added dropwise to a mixture of **3** (70 mg, 0.22 mmol), EDC (0.12 g, 0.50 mmol), and HOBt (74 mg, 0.50 mmol) in dichloromethane and DMF (15 mL, 2:1 v/v) at 0 °C under argon. The reaction mixture was allowed to stir for 48 h at room temperature. The solvents were then evaporated, and the residue was dissolved in ethyl acetate (30 mL) and washed with hydrochloric acid (2 × 20 mL, 2 N), saturated aqueous sodium hydrogen carbonate (2 × 20 mL), and water (2 × 20 mL). The solvent was evaporated to give a crude oily product which was subjected to column chromatography on silica gel (EtOAc/MeOH 9:1, R_f = 0.55) to give 0.19 g (46%) of compound **11** as a white solid, mp 106 °C; IR (film) 3397, 2359, 2229, 2130, 1695, 1598, 1394 cm^{-1} ; UV (MeOH) 202, 241 nm; ^1H NMR (270 MHz, CDCl_3) δ 7.95 (s, 4H), 7.82 (br s, 2H), 6.93 (br s, 2H), 5.49 (br s, 6H), 4.44 (s, 12H), 4.07 (d, J = 6.1 Hz, 4H), 4.01 (d, J = 7.5 Hz, 12H), 2.88 (m, 12H), 2.61 (m, 12H), 1.43 (s, 54H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 206.17,

171.51, 166.60, 155.22, 135.86, 127.08, 79.45, 62.33, 59.88, 49.64, 43.45, 33.70, 28.84, 27.81, 27.53; FAB-MS m/z 1787 ($M^+ + Na$). Anal. Calcd for $C_{80}H_{120}N_{10}O_{34}$: C, 54.4; H, 6.9; N, 7.9. Found: C, 53.9; H, 6.9; N, 7.7.

***N,N'*-[*N*-[Tris(5-aminolevulinylloxymethyl)methyl]acetamido]terephthalamide-6Trifluoroacetic Acid (12).** Compound **11** (30 mg, 20 μ mol) was dissolved in dichloromethane (10 mL), trifluoroacetic acid TFA (2 mL) was added, and the mixture was stirred at room temperature for 2 h. The solvents were evaporated under reduced pressure to yield an oily product which was crystallized from a mixture of methanol, ethyl acetate, and diethyl ether. 20 mg (63%) of compound **12** was obtained as a pale yellow solid; ^1H NMR (270 MHz, CD_3OD) δ 7.98 (s, 4H), 4.43 (s, 12H), 4.40 (s, 4H), 4.01 (s, 12H), 2.82 (m, 12H), 2.68 (m, 12H); ^{13}C NMR (67.5 MHz, CD_3OD) δ 200.89, 171.57, 169.66, 160.62, 135.76, 126.63, 76.51, 61.27, 58.81, 45.99, 42.25, 33.12, 29.17, 26.31.

1,3,5-Tris(*N*-[*N*-[tris(*N*-*tert*-butyloxycarbonyl-5-aminolevulinylloxymethyl)methyl]acetamido]carbamido)benzene (13). A solution of **1** (0.50 g, 2.16 mmol) in dry dichloromethane (10 mL) was added dropwise to a stirred solution of **4** (0.23 g, 0.60 mmol), DCC (0.43 g, 2.14 mmol), and HOBt (0.28 g, 2.14 mmol) in dichloromethane and DMF (15 mL, 2:1 v/v) at 0 °C under argon. The reaction mixture was left to stir at room temperature for 4 days and then filtered, and the solvents were evaporated. The resulting residue was dissolved in ethyl acetate and washed with 5% hydrochloric acid (2 $\times$ 30 mL), saturated sodium hydrogen carbonate (30 mL), and water (2 $\times$ 30 mL). The organic layer was evaporated and the residue purified by column chromatography (EtOAc/MeOH 8:2, R_f = 0.45) to obtain 0.61 g (40%) of **13** as a foamy solid, mp 115–116 °C; IR (film) 3366, 2955, 2365, 2137, 1693, 1678, 1519, 1364 cm^{-1} ; UV (MeOH) 209, 240 nm; ^1H NMR (270 MHz, $CDCl_3$) δ 8.81 (s, 3H), 8.22 (br s, 3H), 6.17 (br s, 3H), 6.12 (br s, 9H), 4.36 (s, 6H), 3.97 (s, 18H), 3.94 (d, J = 6.5 Hz, 18H), 2.65 (m, 18H), 2.45 (m, 18H), 1.31 (s, 81H); ^{13}C NMR (67.5 MHz, d_6 -acetone) δ 206.22, 172.74, 170.32, 156.88, 135.63, 129.98, 79.36, 63.16, 62.97, 59.10, 50.57, 44.39, 34.67, 28.96, 28.56; FAB-MS m/z 2632 ($M^+ + Na$). Anal. Calcd for $C_{117}H_{177}N_{15}O_{51}$: C, 53.8; H, 6.8; N, 8.1. Found: C, 54.6; H, 7.4; N, 7.7.

1,3,5-Tris[*N*-[*N*-[tris(5-aminolevulinylloxymethyl)methyl]acetamido]carbamido]benzene-9Trifluoroacetic Acid (14). Compound **13** (30 mg, 10 μ mol) was dissolved in dichloromethane (10 mL). TFA (2 mL) was added to the solution, and the mixture was stirred at room temperature for 2 h. The solvents were evaporated under reduced pressure to yield an oily product which was crystallized from a mixture of methanol, ethyl acetate, and diethyl ether to obtain 2 mg (66%) of the TFA salt as a pale yellow solid; ^1H NMR (270 MHz, CD_3OD) δ 8.58 (s, 3H), 4.45 (s, 18H), 4.35 (s, 6H), 4.04 (d, J = 4.5 Hz, 18H), 2.87 (m, 18H), 2.70 (m, 18H); ^{13}C NMR (67.5 MHz, CD_3OD) δ 206.22, 205.92, 172.74, 170.32, 156.88, 135.63, 129.98, 79.36, 63.16, 62.97, 59.10, 50.57, 44.39, 34.67.

Tris[*N*-[tris(*N*-*tert*-butyloxycarbonyl-5-aminolevulinylloxymethyl)methyl]acetamido]amine (15). Nitrotri-acetic acid (**6**, 60 mg, 0.32 mmol) was dissolved in dichloromethane and DMF (20 mL, 2:1 v/v), and DCC (0.23 g, 1.10 mmol) and HOBt (0.15 g, 1.10 mmol) were added. The mixture was stirred under argon for 30 min at 0 °C, and then compound **1** (0.85 g, 1.14 mmol) was added dropwise over 50 min. The mixture was allowed to stir at room temperature for 3 days, the precipitate was filtered off, and the solvents were evaporated. The

residue was dissolved in ethyl acetate (30 mL) and washed with hydrochloric acid (2 $\times$ 30 mL, 2 N), saturated sodium hydrogen carbonate (30 mL), and water (2 $\times$ 30 mL). The organic layer was evaporated to give an oily product which was subjected to flash chromatography (EtOAc/MeOH 49:1, R_f 0.6). The product was crystallized from a mixture of methanol, diethyl ether, and ethyl acetate giving 0.45 g (60%) of compound **15** as a foamy solid, mp 102–104 °C; IR (film) 3372, 2980, 2365, 1699, 1640, 1364 cm^{-1} ; UV (MeOH) 214 nm; ^1H NMR (270 MHz, $CDCl_3$) δ 6.39 (br s, 3H), 5.41 (br s, 9H), 4.37 (s, 18H), 4.04 (s, 18H), 2.75 (m, 18H), 2.65 (m, 18H), 2.51 (s, 6H), 1.44 (s, 81H); ^{13}C NMR (67.5 MHz, $CDCl_3$) δ 204.28, 171.51, 171.38, 155.37, 61.78, 57.64, 49.64, 33.91, 33.72, 29.41, 27.01, 27.16; FAB-MS m/z 2419 (M^+). Anal. Calcd for $C_{108}H_{171}N_{13}O_{48}$: C, 53.6; H, 7.1; N, 7.5. Found: C, 53.9; H, 7.0; N, 7.6.

Tris[*N*-[tris(5-aminolevulinylloxymethyl)methyl]acetamido]amine-9Trifluoroacetic Acid (16). Compound **15** (0.34 g, 0.22 mmol) was dissolved in dichloromethane (15 mL), TFA (3 mL) was added, and the solution was stirred at room temperature for 2 h. The solvents were evaporated under reduced pressure to yield an oily product which was crystallized from a mixture of methanol, ethyl acetate, and diethyl ether to obtain 0.24 g (69%) of the TFA salt as a pale yellow solid; ^1H NMR (270 MHz, CD_3OD) δ 4.31 (s, 18H), 3.97 (s, 18H), 2.80 (m, 18H), 2.63 (m, 18H), 2.54 (s, 6H); ^{13}C NMR (67.5 MHz, CD_3OD) δ 203.78, 203.32, 174.72, 173.66, 163.07, 162.54, 63.31, 59.05, 35.32, 30.37, 28.31.

***N*-(Benzyloxycarbonyl)imino-3,3'-bis[*N*-[tris(*N*-*tert*-butyloxycarbonyl-5-aminolevulinylloxymethyl)methyl]propionamide] (18).** Compound **2** (0.12 g, 0.43 mmol) was dissolved in dichloromethane and DMF (20 mL, 2:1 v/v). DCC (0.21 g, 0.96 mmol) and HOBt (0.14 g, 0.96 mmol) were added, and the mixture was allowed to stir for 30 min at 0 °C under argon. Compound **1** (0.80 g, 1.11 mmol) was added dropwise over 50 min. The reaction mixture was stirred at room temperature for 3 days, and then the solvents were evaporated. The residue was dissolved in ethyl acetate (20 mL) and washed with hydrochloric acid (2 $\times$ 25 mL, 2 N), saturated aqueous sodium hydrogen carbonate (25 mL), and water (2 $\times$ 25 mL). The organic layer was evaporated to give an oily product, which was subjected to flash chromatography on silica gel (EtOAc/MeOH 19:1, R_f 0.6) to yield 0.51 g (66%) of compound **18** as a colorless oil; IR (film) 3347, 2974, 2924, 1712, 1709, 1513, 1370 cm^{-1} ; UV (MeOH) 209, 240 nm; ^1H NMR (270 MHz, $CDCl_3$) δ 7.48 (m, 5H), 7.45 (br s, 2H), 6.34 (br s, 6H), 5.21 (s, 2H), 4.48 (s, 12H), 4.05 (s, 12H), 2.88 (m, 12H), 2.79 (m, 12H), 2.69 (m, 12H), 2.59 (m, 12H), 1.49 (s, 54H); ^{13}C NMR (67.5 MHz, $CDCl_3$) δ 203.740, 173.97, 170.79, 157.96, 134.44, 130.45, 129.89, 80.50, 74.58, 73.63, 67.76, 52.14, 51.82, 36.82, 35.87, 31.15, 30.86, 29.29, 23.69; ES-MS m/z 1803 ($M^+ + Na$).

Imino-3,3'-bis[*N*-[tris(*N*-*tert*-butyloxycarbonyl-5-aminolevulinylloxymethyl)methyl]propionamide] (19). Compound **18** (0.50 g, 0.32 mmol) was dissolved in ethyl acetate and methanol (30 mL, 2:1 v/v). Palladium on carbon (0.17 g, 10%) was added, and the mixture was stirred under an atmosphere of hydrogen gas for 8 h at room temperature. The reaction mixture was filtered through Celite and washed with ethyl acetate. The solvents were evaporated, and the residue was dried to obtain 0.38 g (82%) of **19** as a colorless oil; IR (film) 3353, 2980, 2930, 2365, 1712, 1513, 1364, 1258, 1159, 1046, 860 cm^{-1} ; UV (MeOH) 208 nm; ^1H NMR (270 MHz, $CDCl_3$) δ 7.43 (br s, 2H), 6.30 (m, 7H), 4.09 (s, 12H), 4.05 (s, 12H), 2.89 (m, 12H), 2.72 (m, 12H), 2.70 (m, 12H), 2.67

(m, 12H), 1.49 (s, 45H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 202.32, 176.84, 155.91, 80.06, 77.50, 60.42, 50.06, 34.03, 28.19, 27.58, 20.95, 14.07, 9.16; FAB-MS m/z 1647 (M^+).

1,3,5-Tris[*N*-(*N*-bis[*N*-[tris(*N*-*tert*-butyloxycarbonyl-5-aminolevulinylloxymethyl)methyl]propionamido}acetamido)carbamido]benzene (20). Compound **19** (0.05 g, 0.11 mmol) was dissolved in dichloromethane and DMF (20 mL, 2:1 v/v), EDC (90 mg, 0.48 mmol) and HOBt (0.06 g, 0.48 mmol) were added, and the mixture was stirred for 30 min under argon at 0 °C. Compound **4** (0.77 g, 0.55 mmol) was dissolved in dichloromethane (5 mL) and added dropwise over 50 min. The mixture was stirred at room temperature for 3 days, and then the solvents were evaporated. The residue was dissolved in ethyl acetate and washed with hydrochloric acid (2 $\times$ 25 mL, 2 N), saturated aqueous sodium hydrogen carbonate (25 mL), and water (2 $\times$ 20 mL). The organic layer was evaporated to give an oily product which was purified by flash chromatography on silica gel (EtOAc/MeOH 3:1, R_f 0.35) yielding 0.37 g (54%) of compound **20** as a foamy white solid, mp 126–128 °C; IR (film) 3384, 2974, 2918, 2359, 1711, 1699, 1513, 1364 cm^{-1} ; ^1H NMR (270 MHz, CDCl_3) δ 7.28 (s, 3H), 6.39 (br s, 3H), 5.34 (br s, 6H), 5.06 (br s, 18H), 4.31 (m, 6H), 4.23 (s, 36H), 3.97 (s, 36H), 3.68 (m, 12H), 2.70 (m, 36H), 2.57 (m, 36H), 2.45 (m, 12H), 1.37 (s, 162H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 203.56, 172.49, 171.61, 155.39, 134.31, 128.01, 79.46, 65.32, 62.30, 61.74, 59.66, 57.52, 49.61, 33.78, 33.72, 29.50, 27.80, 14.74. Anal. Calcd for $\text{C}_{237}\text{H}_{366}\text{N}_{30}\text{O}_{102}$: C, 54.0; H, 7.0; N, 8.0. Found: C, 54.1; H, 7.4; N, 8.1.

1,3,5-Tris[*N*-(*N*-bis[*N*-[tris(5-aminolevulinylloxymethyl)methyl]propionamido}acetamido)carbamido]benzene-18Trifluoroacetic Acid (21). Compound **20** (0.28 g, 50 μmol) was dissolved in dichloromethane (20 mL), TFA (4 mL) was added, and the solution was stirred at room temperature for 2 h. The solvents were evaporated under reduced pressure to yield an oily product which was crystallized from a mixture of methanol, ethyl acetate, and diethyl ether to obtain 0.18 g (62%) of the TFA salt as a pale yellow solid; ^1H NMR (270 MHz, CD_3OD) δ 7.36 (s, 3 H), 4.40 (s, 36 H), 4.35 (m, 6 H), 4.03 (s, 36 H), 3.76 (m, 12 H), 2.89 (m, 36 H), 2.85 (m, 36 H), 2.69 (m, 12 H); ^{13}C NMR (67.5 MHz, CD_3OD) δ 204.22, 172.00, 155.70, 130.60, 128.00, 79.87, 65.51, 62.84, 58.05, 54.22, 50.17, 41.78, 34.59, 34.24, 28.30, 27.73, 27.60.

1,3,5-Tris[*N*-(*N*-bis[*N*-[tris(*N*-*tert*-butyloxycarbonyl-5-aminolevulinylloxymethyl)methyl]propionamido}propionamido)carbamido]benzene (22). Compound **5** (30 mg, 60 μmol) was dissolved in dichloromethane and DMF (15 mL, 2:1 v/v), EDC (40 mg, 0.20 mmol) and HOBt (30 mg, 0.20 mmol) were added, and the mixture was stirred under argon for 30 min at 0 °C. Compound **19** was dissolved in dichloromethane (0.39 g, 0.21 mmol) and added dropwise to the mixture over 50 min. The mixture was stirred at room temperature for 3 days, the heavy precipitate was filtered off, and the solvents were evaporated. The residue was dissolved in ethyl acetate (25 mL) and washed with hydrochloric acid (2 $\times$ 25 mL, 2 N), saturated aqueous hydrogen carbonate (25 mL), and water (2 $\times$ 25 mL). The organic layer was evaporated to give an oily product which was subjected to flash chromatography on silica gel (EtOAc/MeOH 3:1, R_f 0.35). Crystallization of the product using a mixture of dichloromethane, diethyl ether, and ethyl acetate gave 0.22 g (63%) of compound **22** as a foamy solid, mp 129–128 °C; IR (film) 3384, 2980, 2930, 2359, 2253, 1706, 1699, 1507, 1370 cm^{-1} ; ^1H NMR (270 MHz, d_6 -acetone) δ 8.46 (br s, 3H), 8.30 (s, 3H), 6.17 (br s, 6H), 5.62 (br s, 18H), 4.41 (s, 36H), 4.11 (m, 6H),

4.03 (s, 36H), 3.73 (m, 12H), 2.73 (m, 36H), 2.70 (m, 6H), 2.66 (m, 36H), 2.63 (m, 12H), 1.44 (s, 162H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 204.48, 172.06, 171.98, 168.92, 155.69, 128.46, 72.26, 65.79, 61.97, 60.06, 54.16, 50.12, 48.98, 34.18, 33.84, 28.24, 27.54, 25.54, 24.86. Anal. Calcd for $\text{C}_{240}\text{H}_{372}\text{N}_{30}\text{O}_{102}$: C, 54.3; H, 7.1; N, 7.9. Found: C, 54.2; H, 7.2; N, 7.6.

1,3,5-Tris[*N*-(*N*-bis[*N*-[tris(5-aminolevulinylloxymethyl)methyl]propionamido}propionamido)carbamido]benzene-18Trifluoroacetic Acid (23). Compound **22** (0.31 g, 60 μmol) was dissolved in dichloromethane (20 mL), TFA (4 mL) was added, and the solution was stirred at room temperature for 2 h. The solvents were evaporated under reduced pressure to yield an oily product that was crystallized from a mixture of methanol, diethyl ether, and ethyl acetate to obtain 0.12 g (41%) of the TFA salt as a pale yellow solid; ^1H NMR (270 MHz, CD_3OD) δ 8.40 (s, 3H), 4.40 (s, 36H), 4.17 (m, 6H), 4.14 (s, 36H), 4.01 (m, 12H), 2.95 (m, 36H), 2.93 (m, 6H), 2.84 (m, 36H), 2.82 (m, 12H); ^{13}C NMR (67.5 MHz, CDCl_3) δ 203.71, 203.03, 173.76, 173.14, 163.02, 162.38, 132.67, 127.23, 63.12, 58.36, 51.80, 36.14, 35.27, 35.14, 34.67, 29.02, 28.34, 28.01.

Cell Culture. PAM 212 cells (naturally transformed murine keratinocytes)(26) were grown monolayered in sterile, vented-capped, angled-necked cell culture flasks. The culture medium was RPMI 1640 medium containing L-glutamine (0.02 mM) and phenol red, supplemented with 10% foetal calf serum (FCS) (First Link), penicillin (500 units/mL), streptomycin (0.5 mg/mL), and HEPES buffer (0.01 M). Cells were maintained at 37 °C in a humidified 5% CO_2 incubator until confluent. Approximately twice weekly, the cells were passaged. The cells were detached from the flasks with a solution of 0.05% trypsin and 0.02% ethylenediaminetetraacetic acid (EDTA) in phosphate-buffered saline (PBS), spun down in a centrifuge at 1500 rpm for 5 min, resuspended in fresh medium, and subcultured in new flasks.

Chemicals and Solutions. ALA was purchased from Photocure (Norway) as the hydrochloride salt. ALA and dendrimers **16** and **21** were dissolved in FCS- and phenol red-free RPMI medium immediately prior to incubation (serum is known to cause release of PpIX from the cells, thus resulting in loss of the fluorescence signal(27) and phenol red would optically interfere with the detection of PpIX). Solutions were sterile filtered using a 0.2 μm syringe-tip filter before incubation. Incubation in the presence of ALA or an ALA-containing dendrimer was performed under subdued lighting.

Fluorescence Spectroscopy. Fluorescence spectroscopy allows quantification of porphyrin yields over a period of time. Cells were seeded in gamma-sterilized 96-well plates at a density of 5×10^4 cells per well, 48 h prior to constant drug exposure, and solutions of ALA and ALA-containing dendrimers were freshly prepared and sterile-filtered. PpIX fluorescence was recorded at 2, 4, and 6 h after drug exposure. PpIX fluorescence was measured with a well plate fluorescence reader (Perkin-Elmer, UK) connected to a Perkin-Elmer LS 50B fluorescence spectrophotometer (Perkin-Elmer, UK) using 410 nm excitation and 635 nm emission with slit widths set to 10 nm both on the excitation and emission monochromators, and an internal 530 nm highpass filter used on the emission side; spectral scans were made between 550 and 750 nm to check for the presence of other porphyrins. Intensity calibrations were performed using rhodamine B embedded in a Perspex disk as a standard. Control wells containing RPMI alone were included. The experiments were performed in quadruplicate, and stan-

**Figure 1.** Dendrimer building blocks.**Figure 2.** Synthesis of ALA-containing dendrimer, 1.

dard deviations expressed as error bars. The respective controls were used for background subtraction of the spectrum, and equalization of the number of cells in the solution to reduce the error caused by scattering effects.

Photocytotoxicity. Forty-eight hours prior to the experiment, 5×10^4 cells were seeded in 16 wells located in the middle of each 96-well plate—the irradiation zone produced by the laser is up to 6 cm in diameter and covers 16 wells (4 wells $\times$ 4 wells) on the well plate. Three different controls were prepared. Two controls consisted of cells incubated with RPMI, and only one of them was irradiated with light. In the third control, cells were incubated with the maximum concentration of each compound (2 mM) with no light irradiation to determine dark cell toxicity.

The cells were incubated with ALA or an ALA-containing dendrimer for 4 h at 37 °C in a humidified 5% CO₂ atmosphere. After 4 h, the compounds were removed and replaced with 0.1 mL of RPMI containing 10% FCS (warmed at 37 °C). For illumination a diode laser was used (Diomed) emitting at a wavelength of 630 nm, for which the power output at the fiber tip was set at 1.13 W using a power meter (Gentech). The cells were irradiated in a 6 cm diameter area within a single field, providing simultaneous illumination of all wells. Exposure time was 125 s, providing an energy density of 5 J/cm² (fluence rate: 40 mW/cm²). Cells were not rinsed before irradiation; loss of PpIX in the medium has been neglected since it does not affect cell survival (28). Once irradiated, the cells were placed into the incubator (37 °C in a humidified 5% CO₂ atmosphere) and cell cytotoxicity was determined 18 h later using the MTT assay.

MTT Assay. Cell viability was tested by means of an MTT assay. This technique allows quantification of cell survival after cytotoxic insult by testing the enzymatic activity of the mitochondria. It is based on the reduction of a water-soluble tetrazolium salt to a purple, insoluble formazan derivative by mitochondrial enzyme dehydrogenases. This enzymatic function is only present in living, metabolically active cells. The optical density of the product was quantified by its absorption at 570 nm using a 96-well microplate reader (MR 700 Dynatech). A 0.1 mL volume of a solution of 3-[4,5-dimethylthiazolyl]-2,5-diphenyltetrazolium bromide (MTT) in PBS (1 mg/mL) was added to each well, and the cells were incubated for 3 h at 37 °C in a humidified 5% CO₂ atmosphere (29). Control studies showed no cytotoxicity induced by the dendrimers in the absence of light. Phototoxicity results are expressed as percentage of cell viability against control cells under the same conditions but in the absence of test compound.

RESULTS AND DISCUSSION

Dendrimers are constructed by stepwise methods yielding structurally and topologically defined, monodisperse, unimolecular entities. There are two approaches to the synthesis of dendritic polymers based on either convergent or divergent synthesis. In the divergent approach, growth of the polymer begins at the center and proceeds radially outward in a series of coupling reactions, whereas in the convergent approach, growth begins at the chain ends. A disadvantage of using the divergent method is that, because the number of polymer chain ends increases geometrically at each coupling or activation process, it eventually becomes difficult to ensure that all chain ends have reacted at each stage of growth. A convergent growth strategy, similar to that of Ashton et al. (25), has therefore been adopted for the synthesis of the ALA-containing dendrimers. The dendrimers were assembled in segments: first the individual building blocks were synthesized, and then these dendrons were attached to a multipodent core unit in the final steps of dendrimer construction. Classical coupling chemistry using either DCC or EDC with HOBt was used to join the individual dendrons by amide bonds.

The synthetic strategy adopted makes use of easily accessible building blocks (Figure 1). Dendron **1**, which bears three Boc-protected ALA molecules, is the terminal dendron in all five dendrimers. Four different core molecules were used: the diglycyl amide of 1,4-benzenedicarboxylic acid (**3**), the triglycyl amide of 1,3,5-benzenetricarboxylic acid (**4**), the tri- β -alanyl amide of 1,3,5-benzenetricarboxylic acid (**5**), and nitrilotriacetic acid (**6**). In the larger dendrimers, Z-protected 3,3'-iminodipropionic acid (**2**) was used as a branching unit. These building blocks, when combined in a suitable synthetic

sequence, gave rise to a series of dendrimers varying in size and ALA loading.

The three primary hydroxyl groups of tris(hydroxymethyl)aminomethane (TRIS) allowed attachment of three ALA molecules through ester linkages, and the free amino group enabled further elaboration through the formation of an amide bond with either a branching unit or a core molecule. Therefore, Z-protection of TRIS using benzyl chloroformate gave **7** (25), which was then coupled with *N*-*tert*-butoxycarbonyl-5-aminolevulinic acid (Boc-ALA, **8**), giving rise to compound **9**. Removal of the Z-protecting group by hydrogenation gave the terminal dendron **1** (Figure 2).

The core molecules **3** and **4** were prepared by reacting the corresponding di- and tribenzoic acid chlorides and glycine methyl ester, followed by basic hydrolysis of the di- and triester products (25). Core molecule **5** was synthesized in an analogous fashion: 1,3,5-benzenetricarbonyl trichloride reacted with β -alanine ethyl ester to give the triester **10** and base-induced hydrolysis gave **5**. Compound **6** is commercially available (Figure 3).

Attempts to directly couple dendron **1** with 1,3,5-benzenetricarboxylic acid failed due to steric congestion around the core. However, when **1** was reacted with the extended core **4**, using DCC as the coupling reagent, the reaction proceeded smoothly to give dendrimer **13**. Dendron **1** also reacted with core **3** to give dendrimer **11** which contains six ALA residues. The 9-ALA dendrimer **15**, which has an aliphatic core, was synthesized by the reaction between dendron **1** and nitrilotriacetic acid in the presence of DCC and HOBt (Figure 4).

Branching unit **2** was prepared by hydrolysis of the nitrile groups in 3,3'-iminodipropionitrile using barium hydroxide to give the corresponding dicarboxylic acid as

Figure 5. Synthesis of the second-generation dendrimer, **21**.

its hydrogen sulfate salt (**17**) (25). Z-Protection using benzyl chloroformate gave compound **2** (25). DCC coupling between dendron **1** and branching unit **2** gave dendron **18**. Hydrogenation gave amine **19**, however, using DCC as the coupling reagent, the reaction between this new 6-ALA dendron and core molecule **4** did not give the desired second generation dendrimer **20**. When EDC was used for the amide coupling, **20** was obtained in good yield (Figure 5). The homologous dendrimer **22** was prepared by coupling dendron **20** with core molecule **5** (Figure 6).

The Boc protecting groups were removed from dendrimers **11**, **13**, **15**, **20**, and **22** by treatment with trifluoroacetic acid, and the cationic dendrimers **12**, **14**, **16**, **21**, and **23**, respectively, were isolated as their trifluoroacetate salts (Figures 5 and 6).

The simplicity and reliability of this approach should permit an extension of this synthetic methodology to the synthesis of higher-generation dendrimers by the incorporation of additional branching units. Although higher molecular weight dendrimers would be required for enhanced permeability and retention in tumor tissue, we have evaluated the concept of using dendrimers as macromolecular carriers for the delivery of ALA to the tumorigenic cell line, PAM 212, in vitro. Figure 7(a) shows the PpIX fluorescence induced by ALA, the 9-ALA dendrimer **16**, and the 18-ALA dendrimer **21** at 0.1 mM concentration in PAM 212 cells. The ALA-containing dendrimers are clearly able to pass through the cell membrane and release ALA intracellularly; however,

there is no direct correlation between the number of ALA molecules attached to the dendrimer and PpIX accumulation. The more than 2-fold greater efficacy of **21**

Figure 6. The second-generation dendrimer, **23**.

Figure 7. (a) Mean PpIX fluorescence induced by 0.1 mM ALA, dendrimer **16** or dendrimer **21**. (b) Cell survival using 4 h incubation with 0.1 mM and 0.5 mM ALA, dendrimer **16** or dendrimer **21**, after illumination with 5 J cm⁻².

over **16** may be due to increased uptake of the larger dendrimer by endocytosis. Figure 7b shows the results of a PDT experiment in which the cells were illuminated 4 h after incubation with either ALA, dendrimer **16**, or dendrimer **21**. At the concentrations used, neither of the dendrimers induced cytotoxicity in the absence of light, and dendrimer **21** again shows greatest potency. These results demonstrate the potential of this type of multi-valent ALA carrier for the delivery of ALA in PDT applications.

ACKNOWLEDGMENT

We thank the University of Essex for a research studentship, the Wellcome Trust for the award of a vacation research studentship, and the EPSRC Mass Spectrometry Service, Swansea. The authors would also like to thank Dr. Ross Boyle and Dr. Keith Matthews for useful discussion before embarking on this project.

Polyethylenimine (PEI) is a polycation with potential application as a nonviral vector for gene delivery. Here we show that after conjugation with homobifunctional amine reactive reducible cross-linking reagents, low molecular weight polyethylenimine efficiently mediates *in vitro* gene delivery to Chinese hamster ovary (CHO) cells. Two cross-linking reagents, dithiobis(succinimidylpropionate) (DSP) and dimethyl-3,3'-dithiobispropionimidate·2HCl (DTBP), were utilized based on their reactivity and chemical properties. Both reagents react with primary amines to form reducible cross-links; however, unlike DSP, the DTBP cross-linker maintains net polymer charge through amidine bond formation. PEI with a reported weight-average molecular weight (M_w) of 800 Da was reacted with either DSP or DTBP at PEI primary amine:cross-link reactive group ratios of 1:1 and 2:1. The transfection efficiencies of the resulting cross-linked products were evaluated in CHO cells using a luciferase reporter gene under a cytomegalovirus (CMV) promoter. Our results show that cross-linked polymers mediate variable levels of transfection depending on the cross-linking reagent, the extent of conjugation, and the N/P ratio. In general, we found conjugate size to be proportional to gene transfer efficiency. Using gel retardation analysis, we also evaluate the capacity of the cross-linked polymers to condense plasmid DNA before and after reduction with 45 mM dithiothreitol (DTT). DTT mediated reduction of intra-cross-link disulfide bonds and inhibited condensation of DNA by conjugates cross-linked with DSP at a ratio of 1:1, but had little effect on the remaining polymers. Analogous intracellular reduction of transfection complexes by reduced glutathione could facilitate uncoupling of PEI from DNA to enhance gene expression.

INTRODUCTION

The primary obstacle toward implementing an effective gene therapy using nonviral vectors remains their relatively inefficient gene delivery *in vivo*. Although viral vectors are able to overcome this problem, and generally yield higher gene expression, there are concerns over the immunogenic, cytotoxic, and recombinogenic potential of viral gene transfer. Due to the improved safety profile and ease of preparation and manipulation, nonviral techniques for gene delivery continue to be explored and optimized.

Polyethylenimine (PEI) is a cationic polymer which has proven to be an effective transfection agent both *in vitro* (1–3) and *in vivo* (4–8). Due to the chemical properties of PEI, primarily the high cationic charge density, it is able to effectively condense DNA and form nanometric particles capable of being endocytosed (9). In addition, since every third atom in the polymer is an amino nitrogen capable of being protonated, PEI effectively buffers the endosomal environment, thus protecting DNA from lysosomal nuclease degradation and facilitating endosomal escape to the cytoplasm. Cellular uptake of PEI–DNA complexes likely results from nonspecific electrostatic interactions between positively charged polymer–DNA complexes and negatively charged residues on the cell surface (10). Several groups have

demonstrated improved transfection efficiencies with PEI by incorporating targeting ligands such as galactose (11), mannose (12), transferrin (13), or antibodies (14, 15).

Dithiobis(succinimidylpropionate) (DSP) is a homobifunctional NHS (*N*-hydroxysuccinimide) ester-based electrophilic cross-linking reagent containing an 8 atom spacer 12 Å in length (16). Dimethyl-3,3'-dithiobispropionimidate·2HCl (DTBP) is a similar molecule containing an 8 atom spacer 11.9 Å in length, but utilizes an imidoester reactive group to form amidine bonds, resulting in the retention of net positive charge (16). Both cross-linking reagents react with primary amines to form stable covalent linkages, and are constructed around a centrally located disulfide bond, which is cleavable with common reducing agents after conjugation (Figure 1).

It is well established that branched high molecular weight polyethylenimines (>25 kDa) are effective transfection agents, and recent reports indicate that relatively low molecular weight PEI (~10 kDa) can also be used to deliver DNA efficiently with lower toxicity (17, 18). With this in mind, we hypothesized that high molecular weight conjugates composed of cross-linked 800 Da PEI would yield transfection efficiencies comparable to those obtained with high molecular weight PEI. Furthermore, we expected that when the transfection complexes were exposed to the reducing environment of the cytoplasm that the disulfide bonds introduced by the cross-linking reagents would be cleaved. This reduction would promote reversion of the high molecular weight complexes back to their low molecular weight counterparts, presumably leading to lower toxicity and potentially easier access by the transcription machinery (Figure 2).

Figure 1. Proposed reaction scheme for conjugating polyethylenimine with cross-linking reagents DSP and DTBP. Also shown is the effect of disulfide bond reduction by DTT.

In this report, we examine the transfection properties of low molecular weight PEI cross-linked with either DSP or DTBP in CHO cells. We also evaluate the DNA condensing properties of the cross-linked conjugates before and after reduction with 45 mM DTT.

MATERIALS AND METHODS

Polymers, Plasmid, and Cross-Linking Reagents.

PEI with M_w of 800 Da and 25 kDa were purchased from Aldrich, and used as 0.16 mM aqueous solutions (3 nmol of N/ μ L) in all transfection experiments. Plasmid DNA containing the luciferase reporter gene, pcDNA3-CMV-Luc (7.1 kb), was kindly provided by Dr. Leaf Huang (University of Pittsburgh Medical Center). Cloning and preparation of plasmid DNA were performed by propagating transformed *E. coli* in LB medium containing ampicillin (50 μ g/mL), followed by isolation and purification with a commercially available plasmid purification kit (Qiagen). Concentration and purity of DNA were assessed spectrophotometrically by measuring absorbance at wavelengths of 260 and 280 nm ($OD_{260}/OD_{280} \sim 1.7$). Plasmid size and integrity were confirmed using agarose gel electrophoresis (0.9% agarose gel containing

Figure 2. Proposed transfection scheme using reversibly cross-linked low molecular weight polyethylenimine. Following endocytosis and subsequent endosome release, intracellular reduction of polymer disulfide bonds leads to the release of DNA for nuclear uptake and transcription.

0.5 μ g/mL ethidium bromide) and cleavage with the restriction endonuclease *Hind*III (Gibco BRL). Cross-linking reagents, dithiobis(succinimidylpropionate) (DSP) (MW 404.42) and dimethyl-3,3'-dithiobispropionimidate·2HCl (DTBP) (MW 309.28), were purchased from Pierce.

PEI Cross-Linking with DSP and DTBP. Prior to cross-linking, PEI (800 Da) was labeled with fluorescein isothiocyanate (FITC) (Sigma) at a molar ratio of 100:1 (PEI:FITC) to aid in concentration determination of the cross-linked polymers. Briefly, 800 mg of PEI was dissolved in 4 mL of DMSO for a final concentration of 200 mg/mL. Next, 389.4 μ L of FITC dissolved in DMSO (10 mg/mL) was added dropwise to the PEI solution while vortexing. The reaction was allowed to proceed in the dark at room temperature (RT) for 30 min, and was then stored at 4 $^{\circ}$ C protected from light. Precipitation of the labeled polymer confirmed that the reaction between PEI and FITC proceeds to completion, shown by the absence of free FITC in the supernatant. PEI-FITC was then cross-linked with either DSP or DTBP at PEI primary amine:cross-link reactive group ratios of 1:1 and 2:1. Based on reports in the literature (17,19), we estimated the primary amine content of PEI (800 Da) to be 25% of the total amines. To achieve PEI primary amine:cross-link reactive group molar ratios of 1:1 or 2:1, 117 or 58.5 mg of the appropriate cross-linking reagent was dissolved in 1 or 0.5 mL of DMSO, respectively. The DSP or DTBP solutions were then added dropwise to PEI-FITC solutions containing 100 mg of PEI-FITC in approximately 550 μ L of DMSO. The reactions were then allowed to proceed for 1 h at RT. Prior to use, aliquots of cross-linked polymer samples were diluted 1:4 with ddH₂O to a volume of 0.5 mL. The diluted samples were then purified on a 1.5 $\times$ 8 cm Sephadex G-25 fine column using ddH₂O as the eluent under atmospheric pressure. One milliliter fractions were collected, and the concentration of each fraction was determined spectrophotometrically by measuring the absorbance at 495 nm and extrapolating concentration from a standard curve obtained with uncross-linked PEI-FITC of known concentrations. Finally,

each sample was diluted to 0.16 mM (3 nmol of N/ μ L) for use in transfection experiments.

Transfection of CHO Cells. CHO cells were cultured in RPMI 1640 medium (Gibco BRL) supplemented with 10% fetal bovine serum (Gibco BRL), 100 units/mL penicillin, 100 μ g/mL streptomycin, 300 μ g/mL L-glutamine, and 100 μ M sodium citrate (Gibco BRL). For transfection experiments, 1.5×10^5 cells/well were seeded on 24-well plates (Falcon) and allowed to incubate for approximately 20 h in normal growth media at 37 °C in a humidified atmosphere containing 5% CO₂ (~70% confluent). Prior to transfection, the medium was replaced with 0.75 mL of serum-free growth medium. Polymer–DNA complexes were prepared in 37.5 mM NaCl solutions by addition of 150 μ L of PEI or cross-linked PEI-FITC to 7.5 μ g of pcDNA3-CMV-Luc plasmid DNA to achieve the desired N/P ratios in a final volume of 300 μ L (experiments performed in triplicate for 100 μ L/well or 2.5 μ g of DNA/well). Following a 20 min incubation at RT, the transfection complexes were applied to CHO cells and allowed to incubate for 4 h. The medium was then replaced with normal growth medium supplemented with 10% FBS, and luciferase gene expression was measured 24 h later using a commercially available kit (Promega). Protein concentrations were determined using the bicinchoninic acid (BCA) protein determination assay (Pierce), using bovine serum albumin (BSA) standards (Sigma).

Gel Retardation Assays. One microgram of pcDNA3-CMV-Luc plasmid DNA was condensed with PEI or cross-linked PEI at selected N/P ratios by addition of polymer to DNA in 37.5 mM NaCl solution. Prior to electrophoresis (0.9% agarose gel containing 0.5 μ g/mL ethidium bromide), the complexes were allowed to incubate at RT for 20 min. To evaluate the effect of a reducing agent on DNA condensation, some complexes were incubated further for 30 min in the presence of 45 mM DTT (Sigma); 0.5 μ g of DNA was loaded in each well.

Viscosity Measurements. One milliliter of PEI or cross-linked PEI was prepared at a concentration (*c*) of 50 mg/mL in ddH₂O. The time required for each sample to flow through a 1 mm (outside diameter) capillary tube under atmospheric pressure was recorded, and these values were used to calculate the inherent viscosity (η_{inh}) of the polymer solutions. The $\eta_{inh} = \ln \eta_{rel}/c$, where η_{rel} is the relative viscosity which equals $t_{solution}/t_{solvent}$, or the time required for the polymer–solvent solution to flow through the capillary tube divided by the time required for the solvent alone. The molecular weight of cross-linked polymers was estimated by comparison with unconjugated polyethylenimine standards.

RESULTS

CHO cells were transfected in vitro with 2.5 μ g of pcDNA3-CMV-Luc plasmid DNA condensed with various polyethylenimines. Luciferase gene expression is quantified as relative light units (RLU) and femtomoles of luciferase standardized for protein concentration and corrected for background (Figure 3). The data show that among the different PEI polymers tested, 800 Da PEI was the least effective transfection agent. In fact, gene expression using this vector was immeasurable below a N/P ratio of 18. This finding is consistent with previous reports, which show negligible gene expression for PEI with nominal molecular weights below 1800 Da (1). In contrast, cells transfected with 25 kDa PEI produced high levels of luciferase activity, yielding optimal gene expression of 2×10^9 RLU/mg of protein at a N/P ratio of 9.

Figure 3. Transfection efficiency of various polyethylenimines in CHO cells at selected N/P ratios. Results are shown as relative light units (RLU)/mg of protein on the left ordinate, and as fmol of luciferase/mg of protein on the right ordinate. Transfection agents are identified in the figure legend.

Transfection with cross-linked 800 Da PEI-FITC yielded variable results depending on the cross-linking reagent, the extent of conjugation, and the N/P ratio. The DTBP conjugate prepared at a PEI primary amine:imidoester reactive group ratio of 2:1 (DTBP 2:1) was relatively ineffective, yielding gene expression on the order of 10^4 – 10^6 RLU/mg of protein. Changing the cross-linking ratio to 1:1 (DTBP 1:1) increased gene expression by several orders of magnitude at N/P ratios ≥ 9 . Interestingly, no luciferase activity was detected using this conjugate at a N/P ratio of 5. This result is surprising given the fact that the DTBP 2:1 conjugate was able to mediate gene transfer at this ratio, albeit at relatively low levels. The DSP conjugate prepared at a PEI primary amine:NHS reactive group ratio of 2:1 (DSP 2:1) yielded gene expression over a wide range, 10^3 – 10^8 RLU/mg of protein, facilitating higher gene expression at larger N/P ratios. Analogous to the DTBP conjugates, we found that increasing the cross-linking ratio to 1:1 (DSP 1:1) led to increased luciferase activity. In fact, the DSP 1:1 conjugate was able to mediate the highest levels of transgene expression among the cross-linked polymers tested, 4×10^8 RLU/mg of protein at N/P ratios of 9 and 13.

By measuring protein concentrations of cellular lysates from adherent cells in each well after transfection, we were able to infer the relative toxicities of cross-linked polymers in relation to unmodified PEI (Figure 4). We assumed an inverse relationship between the protein concentration and cytotoxicity, concluding that lower protein concentrations were indicative of fewer adherent cells and therefore greater toxicity. Wells transfected with 25 kDa PEI consistently produced the lowest protein concentrations, yielding less protein as the charge ratio increased. This finding corroborates earlier reports of toxicity observed after transfection with high molecular weight PEI at large N/P ratios (3). Conversely, protein concentrations measured from cells transfected with 800 Da PEI remained steady at approximately 175 μ g/mL at all charge ratios, and yielded the highest protein concentrations among the transfection agents studied.

Similar to the gene expression data, conjugated PEI-FITC yielded intermediate protein concentrations depending on the cross-linking reagent, the degree of conjugation, and the N/P ratio. PEI-FITC conjugated with DSP at a ratio of 1:1 produced the lowest protein concentrations among cross-linked polymers. Analogous to the trend observed with 25 kDa PEI, concentrations decreased with increasing charge ratio. The DTBP 1:1 conjugate yielded a similar profile, but protein values

Figure 5. Gel retardation analysis of PEI-FITC cross-linked with DSP at a primary amine:NHS ester reactive group ratio of 1:1. Lane 1 is phage λ DNA digested with *Hind*III used as a size marker; lane 2 is pcDNA3-CMV-Luc plasmid DNA only; lanes 3–5 are plasmid DNA condensed with the DSP 1:1 conjugate at N/P ratios of 5, 9, and 13, respectively; lanes 6–8 are identical to lanes 3–5 except the polymer–DNA complexes were treated with 45 mM DTT.

were higher than those found with DSP 1:1 and 25 kDa PEI. Conjugates prepared at a ratio of 2:1 yielded concentrations $\geq 125 \mu\text{g/mL}$, and did not display the characteristic decrease at higher charge ratios observed with the 1:1 conjugates.

Using gel retardation analysis, we evaluated the DNA condensing properties of the various polyethylenimines used for transfection before and after reduction with 45 mM DTT. We hypothesized that reduction of intramolecular disulfide bonds present in the cross-linked PEI would inhibit DNA condensation by disrupting the structure of the high molecular weight conjugates. However, we found this to be true only in the case of DSP conjugates formed at a ratio of 1:1 (Figure 5). Our results show that at a N/P ratio of 5, the DSP 1:1 conjugate is unable to completely condense DNA as shown by the lack of ethidium bromide exclusion. However, after DTT reduction, this effect is even more pronounced and very little DNA condensation is observed. In contrast, at a N/P ratio of 9, DNA can be visualized only after cleavage with

DTT. At higher charge ratios, condensation is complete regardless of disulfide bond integrity. Unmodified PEI, both the 800 Da and 25 kDa forms, was able to effectively condense DNA at all charge ratios examined (data not shown). This result is in agreement with previous work, which shows complete DNA condensation with PEI above N/P ratios of 2 (11).

Finally, using inherent viscosity calculations we were able to approximate the weight-average molecular weights of the cross-linked PEI conjugates. We found that 800 Da PEI cross-linked with DTBP at a PEI primary amine:imidoester reactive group ratio of 2:1 yielded conjugates with an average molecular weight of nearly 8 kDa. Increasing the cross-linking ratio to 1:1 led to an increase in the molecular weight, yielding conjugates around 23 kDa. Similarly, PEI cross-linked with DSP at a PEI primary amine:NHS ester reactive group ratio of 2:1 also produced conjugates with an average molecular weight of about 23 kDa. The DSP 1:1 conjugate yielded the largest molecular weight, with a value of approximately 75 kDa. These results show that DSP mediated more extensive cross-linking at equal cross-linking ratios.

DISCUSSION

In order for nonviral vectors to be clinically useful, it will be necessary to develop formulations that mediate high levels of cell-specific gene expression with favorable toxicity profiles. Here we build on the foundation of successful gene delivery using polyethylenimine by evaluating a new strategy to enhance gene expression. Previous research has shown that several parameters affect the performance of polyethylenimine vectors for gene delivery (3, 20–23). Our findings verify the importance of polymer molecular weight on transfection efficiency. We show that cross-linking low molecular weight PEI with homobifunctional amine reactive cross-linking reagents to form high molecular weight conjugates leads to efficient transfection of CHO cells *in vitro*. In general, transfection results show that DSP conjugates outperformed DTBP conjugates at similar cross-linking ratios. Furthermore, although 25 kDa PEI proved to be the most effective transfection agent, cross-linked PEI-FITC was able to achieve gene expression of similar magnitude at higher N/P ratios.

Based on relative viscosity measurements, we obtained approximate weight-average molecular weights for PEI-FITC conjugated with DSP and DTBP. Cross-linking 800 Da PEI-FITC with DTBP at a ratio of 2:1 produced conjugates with an average molecular weight of nearly 8 kDa. Therefore, it is not surprising to find that this conjugate consistently yielded relatively low gene expression. The DTBP 1:1 and DSP 2:1 conjugates had similar molecular weights around 23 kDa. However, transfection experiments show that these polymers mediated variable degrees of gene expression despite their similar size. Specifically, the DSP 2:1 conjugate proved less effective at lower N/P ratios. Finally, cross-linking PEI with DSP at a ratio of 1:1 led to the formation of conjugates having an approximate molecular weight of 75 kDa. As expected, this conjugate yielded the highest luciferase activity among the cross-linked polymers tested.

The success of the cross-linking reactions, characteristics of the resulting conjugates and subsequent transfection performance, can be explained, in part, by the chemical nature of the cross-linking reagents utilized for conjugation. At identical cross-linking ratios, we found DTBP conjugates to have lower molecular weights than DSP conjugates. We suspect that this difference is due

to electrostatic repulsion between the positive charge carried on the imidoester reactive group of DTBP and the highly cationic polyethylenimine polymer. This repulsion likely led to less extensive cross-linking, and ultimately smaller conjugates. Differences in the inherent reactivities of the cross-linking reagents toward primary amines could also play a role. Although DSP was able to mediate more extensive cross-linking, reaction of the DSP NHS esters with PEI primary amines led to the elimination of positive charges carried by the polymer, whereas amidine bonds introduced by DTBP compensated for this loss. In effect, DTBP conjugates were able to achieve higher gene expression than DSP conjugates of similar molecular weight at equal N/P ratios because even though the N/P ratios were the same, the charge ratios were different. The increase in net charge for DTBP conjugates would promote greater interaction between positively charged transfection complexes and negatively charged cell membranes, potentially leading to increased gene transfer.

Measurements of protein concentration allowed us to infer the relative toxicities of the various transfection complexes. In general, wells transfected with DSP conjugates yielded lower protein concentrations (higher toxicity) than DTBP conjugates formed at analogous cross-linking ratios, although this effect was more pronounced with conjugates prepared at a ratio of 1:1. Furthermore, protein levels decreased to a greater extent at high N/P ratios with conjugates cross-linked at a ratio of 1:1. The lack of increased toxicity at higher charge ratios is particularly encouraging for the DSP 2:1 conjugate, which showed relatively high gene expression at a N/P ratio of 18. Furthermore, although 25 kDa PEI yielded higher transfection, it also produced the greatest toxicity among the polymers tested.

To our knowledge, this is the first report describing the transfection properties of cross-linked low molecular weight polyethylenimine. However, cross-linking strategies have been used previously to increase the transfection performance and stability of nonviral vectors. Trubetskoy et al. utilized DTBP to cross-link the amine groups of polylysine and polyallylamine after condensation of DNA to form a caged DNA complex that increased their stability in salt solution (24). McKenzie et al. hypothesized that incorporating cysteine residues into low molecular weight peptides would result in the formation of reducible disulfide bridges between the cysteine residues after DNA condensation. They found they were able to create small, stable complexes with enhanced transfection properties in several cell lines (25). Our work shows that 800 Da PEI-FITC cross-linked with DSP or DTBP can be used to efficiently transfect CHO cells in vitro with lower overall toxicity. Furthermore, in the case of conjugates cross-linked with DSP at a ratio of 1:1, reduction of disulfide bonds leads to a decrease in the DNA condensing properties of this polymer. Since the cytoplasmic environment is markedly reducing, it is reasonable to expect that disulfide bonds introduced via cross-linking reagents will be reduced intracellularly by reduced glutathione, leading to the breakdown of PEI conjugates. In fact, glutathione reductase acts essentially in one direction so that the ratio of reduced glutathione to oxidized glutathione is approximately 500:1 in most cells (26). Although the transfection efficiency using conjugated polymers does not appear to be superior to 25 kDa PEI, there is the apparent advantage of reduced toxicity. Transfection with polyethylenimine could lead to an accumulation of PEI localized in the nucleus. This PEI would be able to interact with endogenous DNA,

potentially leading to undesirable side effects. Using cross-linked polymers at the appropriate conjugation ratio would alleviate these concerns due to a decrease in the affinity for DNA observed after reduction of intracellular disulfide bonds.

In closing, cross-linking low molecular weight PEI with DSP or DTBP may confer a pharmacokinetic advantage to polyethylenimine vectors in vivo. PEI is an organic polymer that cannot be metabolized or broken down by cellular enzymes. As a result, total body clearance of high molecular weight PEI will likely be a slow process potentially leading to an accumulation of the polymer in vivo. The introduction of disulfide bonds through DSP and DTBP should promote reversion of the high molecular weight transfection complexes back to their low molecular weight counterparts. These low molecular weight fragments should be cleared more easily from the body due to enhanced diffusion and potentially easier filtration through glomerular capillaries.

ACKNOWLEDGMENT

In addition to a grant (RPG-99-097-01-MGO) from the American Cancer Society National Division, this work was partly supported by a development grant from the Parenteral Drug Association (PDA).

Pharmacokinetics and Delivery of Tat and Tat-Protein Conjugates to Tissues in Vivo

Hwa Jeong Lee and William M. Pardridge*

Department of Medicine, UCLA School of Medicine, Los Angeles, California 90095-1682. Received April 11, 2001; Revised Manuscript Received August 10, 2001

The membrane permeation in vivo of therapeutic proteins may be enhanced by conjugation of the protein to cationic import peptides, such as the tat protein of the human immune deficiency virus. The organ uptake, expressed as a percent of injected dose (ID) per gram of tissue, is a function of both membrane permeability and the area under the plasma concentration curve (AUC), which is a function of the plasma pharmacokinetics. The purpose of the present studies was to examine the effect of the tat peptide on the plasma AUC of a model exogenous protein, streptavidin, and to examine the extent to which changes in the plasma AUC influence organ uptake (%ID/g) of the protein. The cationic portion of the tat protein is comprised of a lysine/arginine-rich sequence, designated tat^{48–58}. A biotin analogue of this cationic peptide, tat-biotin, was radioiodinated and injected intravenously into rats with or without conjugation to streptavidin. The unconjugated tat-biotin peptide was nearly instantaneously cleared from plasma by all tissues with a very high systemic clearance of 29 ± 4 mL/min/kg and a high systemic volume of distribution of 4160 ± 450 mL/kg. The plasma clearance of the tat-biotin/streptavidin conjugate, 1.37 ± 0.01 mL/min/kg, was reduced relative to the clearance of unconjugated tat peptide, but was higher than the plasma clearance of the unconjugated streptavidin, 0.058 ± 0.005 mL/min/kg. Conjugation of cationic import peptides such as tat^{48–58} to higher molecular weight proteins results in a marked increase in the rate of removal of the protein from the circulation, which is reflected in the reduced plasma AUC. In summary, tat conjugation of a protein has opposing effects on membrane permeation and the plasma AUC. Therefore, the organ %ID/g is not increased in proportion to the increase in membrane permeation caused by tat conjugation of proteins.

INTRODUCTION

The application of genomics and gene microarray is predicted to lead to the discovery of many new therapeutic proteins (1). However, the delivery of large-molecule pharmaceuticals into tissues in vivo is restricted by transport across the capillary microvascular endothelial barrier. Transport of therapeutic proteins to the brain is particularly restricted because of the presence of the blood–brain barrier (BBB).¹ One strategy for mediating the uptake of proteins by cells in culture and by tissues in vivo is cationization of the protein (2). The cationic charge forms electrostatic interactions with anionic charges on the cellular surface, and this triggers absorptive-mediated endocytosis and absorptive-mediated transcytosis across endothelial barriers (3, 4). Proteins may be cationized directly by conversion of surface carboxyl moieties into extended primary amino groups, and this raises the isoelectric point (pI) of the protein from the neutral/acidic range to the cationic range (5). Alternatively, a cationic peptide or protein, such as

polylysine, may be conjugated to the therapeutic protein (6). Polycations that have been used in the past include polylysine, protamine, histone, or import peptides. Import peptides are oligopeptide-containing sequences derived from larger proteins and are arginine (R)- or lysine (K)-rich peptides of strong cationic charge. Import peptides include the R-rich sequence from the third helix of the Antennapedia (Antp) protein (7, 8), which is a *Drosophila* transcription factor, the K-rich transportan peptide (9), the R/K-rich D-penetrin or the R-rich SynB1 (10), and the R-rich sequence from the tat protein of the human immune deficiency virus (HIV)-1 (11, 12). When arginine and/or lysine residues are clustered in a particular conformation, there is high-affinity binding to anionic proteoglycans such as heparin on cellular surfaces (13).

The R-rich sequence of the tat peptide encompasses the amino acids from positions 48–58 of the tat protein, which has a sequence of GRKKRRQRRP (14), and the cationic region of the tat peptide was observed to mediate uptake by cells in tissue culture (15). The conjugation of synthetic peptides containing the R/K-rich tat sequence to proteins, such as β -galactosidase, results in enhanced tissue uptake in vivo based on histochemical assays (11, 12). Histochemistry is a qualitative assay of protein uptake, and does not evaluate the plasma pharmacokinetics of the conjugate. The extent to which tissue uptake of an exogenous protein, which is expressed as percent injected dose (%ID) per gram of tissue, is increased by conjugation of cationic peptides to the protein is a dual function of (a) the increased membrane permeability of the conjugate and (b) the area under the plasma concentration curve (AUC), which is determined by the plasma

Figure 1. (A) Structure of [^{125}I]tat-biotin/streptavidin conjugate. (B) Elution of [^{125}I]tat $^{48-59}$ -biotin with high salt from a cationic exchange column results in a single homogeneous peak. There is no elution of noncationic components from the column prior to the high-salt wash, indicating the absence of radiochemical impurities from the iodinated tat $^{48-58}$ peptide.

pharmacokinetics of the tat-protein conjugate. Conjugation of cationic peptides to protein therapeutics would be expected both to increase membrane permeability and to decrease the plasma AUC, and these could have offsetting effects on the organ %ID/g. The organ %ID/g, the plasma AUC, and membrane permeation were examined in the present study. A biotinylated tat $^{48-58}$ synthetic peptide was prepared and conjugated to streptavidin (SA). The tat peptide contained a tyrosine residue, which allowed for radiolabeling with ^{125}I . The conjugate of the [^{125}I]tat-biotin and SA is designated [^{125}I]tat-biotin/SA, and is shown in Figure 1A. The organ uptake in vivo of [^{125}I]tat-biotin/SA was compared to the organ uptake of native SA, which was labeled with [^3H]biotin, and designated [^3H]biotin/SA.

EXPERIMENTAL PROCEDURES

Materials. Na ^{125}I was purchased from Amersham-Pharmacia Biotech (Arlington Heights, IL), and [^3H]biotin was obtained from NEN Life Sciences (Boston, MA). Sep-Pak C $_{18}$ cartridge and CM Bio-Gel were obtained from Waters (Milford, MA) and Bio-Rad (Hercules, CA), respectively. Acetonitrile was purchased from Fisher Scientific (Pasadena, CA), and trifluoroacetic acid was supplied by Pierce (Rockford, IL). Recombinant streptavidin (SA) and all other chemicals were obtained from Sigma-Aldrich, Inc. (St. Louis, MO). Male Sprague Dawley rats were obtained from Harlan Sprague Dawley (San Diego, CA). The tat-biotin peptide with the sequence biotin-Ahx-GGGGYGRKKRRQRRP-NH $_2$, where Ahx = 6-aminoheptanoic acid, was synthesized and purified to >95% homogeneity on HPLC by Multiple Peptide Systems (San Diego, CA). The molecular mass, 2224 daltons, determined by mass spectrometry, equaled the expected molecular mass. This peptide contains an amino-terminal biotin, an Ahx-(G) $_4$ linker, and the Y ^{47} -P ^{58} sequence of the tat protein of HIV-1 (14). The tyrosine (Y) at position 47 enables radio-iodination (Figure 1A).

Iodination of Tat-Biotin Peptide. The tat-biotin peptide (29 μg , 13 nmol) was iodinated with [^{125}I]iodine (2 mCi, 1 nmol) and chloramine T (10 nmol), and the reaction was quenched by the addition of sodium metabisulfite (62 nmol). The mixture was then applied to an

activated C $_{18}$ Sep-Pak cartridge, followed by elution in 40% acetonitrile/0.1% trifluoroacetic acid. The radiochemical purity of this preparation was assayed by measurement of the fractional precipitation of the peptide by cold 10% trichloroacetic acid (TCA) in the presence of 5% carrier albumin, and the TCA precipitation of the peptide was only 65%. A TCA precipitation of <95% is indicative of either radiochemical impurities or an incomplete acid precipitation of the peptide owing to the small size of the peptide. Therefore, the radiochemical purity was assayed further with cation exchange chromatography. The fraction of [^{125}I]tat-biotin eluted from the C $_{18}$ Sep-Pak cartridge was evaporated to 0.5 mL and then applied to a 0.7 $\times$ 6 cm Biogel CM column. The column was eluted with 10 mL of 0.01 M Na $_2\text{HPO}_4$, pH 7.4, followed by 10 mL of 0.01 M Na $_2\text{HPO}_4$, pH 7.4, containing 0.5 M NaCl. No radiolabeled impurities eluted in the low-salt fraction, and the [^{125}I]tat-biotin peptide eluted as a single peak with the high-salt fraction, indicating a high degree of radiochemical purity of the iodinated tat-biotin peptide (Figure 1B). The [^{125}I]tat-biotin was added to a molar excess of recombinant SA 30 min prior to injection in rats. Owing to the very high affinity of SA binding of biotin ($K_D = 10^{-15}$ M, dissociation $t_{1/2} = 89$ days) (16), there is nearly instantaneous formation of the [^{125}I]tat-biotin/SA complex.

Pharmacokinetics and in Vivo Biodistribution.

Rats (320–350 g) were anesthetized with a mixture of ketamine (100 mg/kg) and xylazine (2 mg/kg) intraperitoneally, and a femoral vein and artery were cannulated with PE50 tubing. A 0.25 mL aliquot of 0.005 M Na $_2\text{HPO}_4$ /0.25 M NaCl, pH 7.4, containing either 4 μCi of unconjugated [^{125}I]tat-biotin peptide or 4 μCi of [^{125}I]tat-biotin peptide conjugated to 20 μg of SA was injected into the femoral vein. In addition, SA bound to [^3H]biotin was injected in a separate group of rats. Blood was removed from the femoral artery at 0.25, 1, 2, 5, 15, 30, and 60 min after injection of the compound. The volume of blood removed was replaced by an equal volume of 0.9% saline via the femoral artery catheter. The blood samples were centrifuged, serum was counted for total radioactivity, and samples containing ^{125}I were precipitated by 10% TCA. The animals were decapitated at 60 min after the isotope administration, and radioactivity (cpm/g) was measured in brain, liver, kidney, heart, lung, and spleen.

Pharmacokinetic parameters were calculated by fitting serum radioactivity data to either a mono- or a biexponential equation using a derivative-free nonlinear regression analysis (PARBMDP, Biomedical computer P-Series, developed at UCLA Health Science Computing Facilities). For the studies with the tat-peptide, the TCA-precipitable serum radioactivity was used. The data were either unweighted or weighted with weight = $1/(\text{concentration})^2$, where concentration = %ID/mL of serum and ID = injected dose, so as to obtain the lowest residual sum of squares. The systemic clearance (Cl), the systemic volume of distribution (V_{ss}), and the area under the plasma concentration curve (AUC) were determined as described previously (17). The organ clearance was determined as follows:

$$\text{clearance} = (V_d - V_o) \cdot C_p(60 \text{ min}) / \text{AUC}_{0-60 \text{ min}}$$

where V_d is the organ volume of distribution ($\mu\text{L/g}$), $C_p(60 \text{ min})$ is the terminal serum concentration, and V_o are the plasma volumes for the respective organs, which have been reported previously (17). The organ uptake, %ID/g, was computed from the product of organ clearance and $\text{AUC}_{0-60 \text{ min}}$. The organ V_d was determined from the

Table 1. Pharmacokinetic Parameters

ratio of total dpm/g in the tissue divided by the dpm/μL of TCA-precipitable serum radioactivity. The plasma TCA precipitation data were normalized by dividing by the control TCA precipitation of the uninjected peptide, which was 63% and 85% for the unconjugated tat-biotin peptide and for the tat-biotin/SA conjugate, respectively. This approximation was necessary owing to the incomplete precipitation of the tat^{48–58} peptide by TCA (Figure 1). However, the differences in TCA precipitation of [¹²⁵I]tat-biotin and the [¹²⁵I]tat-biotin/SA complex are small compared to the large differences in systemic clearance of these conjugates.

The organ clearance, also called a membrane permeability–surface area (PS) product, is a measure of membrane permeation of the tat-SA conjugate or the unconjugated SA protein. Since organ radioactivity was measured at 60 min after injection, the organ clearance may underestimate the actual PS product if there is significant efflux of radioactivity from the organ after initial uptake.

RESULTS

The serum concentration following intravenous injection of [³H]biotin/SA, of unconjugated [¹²⁵I]tat-biotin, and of [¹²⁵I]tat-biotin/SA is shown in Figure 2 (left panel). These data demonstrate marked differences in the rate of removal of the proteins from blood in the rat in vivo. The serum radioactivity data were subjected to pharmacokinetic analysis (Experimental Procedures), and the pharmacokinetic parameters are listed in Table 1. The unconjugated [¹²⁵I]tat-biotin peptide is rapidly removed from blood following intravenous injection as demonstrated by the extremely high rate of plasma clearance, 29 ± 4 mL/min/kg, and the high systemic volume of distribution, 4160 ± 450 mL/kg (Table 1). The plasma clearance of the [¹²⁵I]tat-biotin peptide was reduced 21-fold following conjugation to SA (Table 1). The plasma clearance of the tat-biotin/SA conjugate was 24-fold greater than the plasma clearance of biotin/SA (Table 1). In parallel with the rapid rate of removal of the tat peptide from plasma, there was rapid degradation of the unconjugated tat peptide in vivo as demonstrated by the rapid decline in the serum radioactivity that was precipitable by TCA (Figure 2, right panel).

The individual organ clearance for the unconjugated tat peptide was high in all tissues (Figure 3). There was a reduction in the organ clearance of the tat peptide following conjugation to SA (Figure 3). However, the organ clearance of the tat-SA conjugate was still greater than the organ clearance of the unconjugated SA, as shown in Figure 4 (top panel). These data demonstrate that conjugation of the tat peptide to SA increases protein uptake in all tissues, particularly kidney. However, when organ uptake was measured as percent injected dose (%ID) per gram of tissue, the increased uptake of SA

Figure 2. (Left panel) The percent injected dose (%ID) per milliliter of serum is plotted versus time for [³H]biotin/SA, [¹²⁵I]tat-biotin/SA, and unconjugated [¹²⁵I]tat-biotin. Data are mean ± SE (*n* = 3 rats per point). (Right panel) Percent of serum radioactivity that is precipitable by trichloroacetic acid (TCA) is plotted versus time after intravenous injection.

Figure 3. Organ clearance values for [¹²⁵I]tat-biotin without (–) or with (+) conjugation to streptavidin. These organ clearances are related to membrane permeation of the conjugates. Values were determined at 60 min after a single intravenous injection. Data are mean ± SE (*n* = 3 rats).

following conjugation of the tat peptide was more modest, as demonstrated in Figure 4 (bottom panel). The differences between the organ clearance and the organ %ID/g values in Figure 4 are due to the difference in the plasma AUC values. The plasma AUC at 60 min for [³H]biotin/SA is decreased 4-fold compared to the plasma AUC of [¹²⁵I]tat-biotin/SA, and the steady-state plasma AUC of SA is decreased 8-fold following conjugation with the tat peptide (Table 1).

Figure 4. (Top panel) Organ clearance of $[^3\text{H}]$ biotin/SA (white columns) or $[^{125}\text{I}]$ tat-biotin/SA (black columns) at 60 min after intravenous injection. Data are mean $\pm$ SE ($n = 3$ rats). (Bottom panel) Organ uptake is expressed as percent injected dose (%ID) per gram of tissue. %ID/g = (clearance) $\times$ (60 min plasma AUC). The 60 min AUC values are shown in Table 1. The heart and lung values for $[^3\text{H}]$ biotin/SA are not visible as these are zero.

DISCUSSION

The results of these studies are consistent with the following conclusions. First, cationic oligopeptides such as tat^{48–58} are removed from blood nearly instantaneously owing to rapid uptake by virtually all tissues. Second, the organ uptake of a model protein, SA, is increased following conjugation with a cationic oligopeptide such as tat^{48–58}. Third, conjugation of proteins with cationic peptides such as tat^{48–58} has opposite effects on (i) the membrane permeation, as reflected in the estimate of organ clearance, and (ii) the plasma AUC. These opposing effects on membrane permeation and plasma AUC result in a more modest change in the organ uptake of the tat-protein conjugate, as reflected in the %ID/g (Figure 4). The %ID/g is directly proportional to both membrane permeation and the plasma AUC (Experimental Procedures).

Conjugation of cationic import peptides such as polylysine or tat oligopeptides triggers electrostatic interactions with anionic sites on cellular membranes, and this causes absorptive-mediated endocytosis (2). The mechanism of cellular uptake of cationic peptides is said not to involve endocytosis, because the uptake is not suppressed by incubations at 4 °C in tissue culture (18). However, confocal microscopy investigations of the uptake of tat or Antp import peptides uniformly show sequestration of the peptide in intracellular endosomes (8, 18, 19), which suggests the cationic peptides enter cells via absorptive-mediated endocytosis (2).

Cationic import peptides such as tat^{48–58} are rapidly cleared from blood following intravenous injection, and more than 90% of the injected dose is removed from blood within the first 60 s after intravenous administration (Figure 2, left panel). The V_{ss} of the $[^{125}\text{I}]$ tat-biotin peptide, 4160 ± 450 mL/kg (Table 1), is 50-fold higher than the blood volume, which is indicative of rapid sequestration of the peptide in peripheral tissues follow-

ing the initial extravascular distribution of the $[^{125}\text{I}]$ tat-biotin peptide. In the present studies, a radio-iodinated form of the tat peptide was used. It is possible that the organ transport of the tat peptide is altered by the addition of the ^{125}I -labeled nuclide. However, the ^{125}I moiety comprises only 5% of the mass of the iodinated tat peptide. In addition, prior work has shown that the pharmacokinetics of peptide clearance from blood are identical whether the peptide is labeled with ^{125}I versus another radionuclide, such as ^{111}In (20). The identical clearance of a peptide labeled with either ^{125}I or ^{111}In indicates that surface deiodination of the peptide in vivo is not significant. In the case of the tat peptide, surface deiodination of the peptide in vivo would have to be nearly instantaneous to explain the rapid removal of the radioactive peptide from blood (Figure 2), and this has not been described for iodinated peptides in vivo.

The tat^{48–58} is an oligopeptide with a molecular mass of 2200 daltons, and this oligopeptide rapidly traverses the microvascular endothelial barrier in tissues in vivo. The rapid extravascular distribution of the unconjugated tat peptide is exemplified by the very high systemic volume of distribution, 4160 ± 450 mL/kg (Table 1). There is a marked reduction in the systemic volume of distribution of the tat peptide following conjugation to SA, but the V_{ss} of the tat-biotin/SA conjugate is still nearly 3-fold greater than the V_{ss} of the unconjugated SA (Table 1). The increased V_{ss} of the tat-biotin/SA conjugate relative to biotin/SA is paralleled by the organ clearance data shown in Figure 4 (top panel). These data indicate that conjugation of the tat^{48–58} import peptide enhances the organ clearance of streptavidin, a 50 000 dalton protein.

The dose of the streptavidin delivered to the tissue, as reflected in the %ID/g parameter, is not increased in proportion to changes in the organ clearance parameter (Figure 4). This is because the %ID/g is an equal function of the organ clearance and the 60 min plasma AUC. Owing to the rapid uptake of the tat-biotin/SA conjugate in all tissues, there is a substantial decrease in the 60 min plasma AUC of the SA protein following tat conjugation (Table 1). Therefore, conjugation of SA with the tat peptide increases the organ permeability (clearance) for the exogenous protein, but the conjugation of the tat peptide causes a parallel decrease in the plasma AUC, owing to enhanced uptake in nearly all tissues.

The rapid rate of systemic clearance of conjugates of proteins and cationic peptides such as tat may require the systemic administration of relatively large amounts of the conjugate in order to exert pharmacologic effects in vivo. For example, to detect β -galactosidase enzyme activity in tissues in vivo in mice, it was necessary to inject 7–25 mg/kg doses of the conjugate of β -galactosidase and either tat^{37–72} or tat^{48–58} (11, 12). The injection of mg/kg doses of cationic peptide, which are required because of the low plasma AUC of the cationic peptide conjugate, may have toxic effects in vivo. Comparable doses of cationic peptides increase membrane permeability in vivo (21, 22).

In summary, cationization of a protein therapeutic has effects on the plasma pharmacokinetics and tissue uptake that are similar to the effects of lipidization of small-molecule drugs. Assuming no significant plasma protein binding, increasing the lipid solubility of a small molecule, or increasing the cationic charge of a large molecule, has two parallel effects: (i) the membrane permeation (organ clearance) parameter is increased, and (ii) the plasma AUC is decreased. The increase in the membrane permeation and the decrease in the plasma

AUC have opposing effects on the tissue %ID/g. Therefore, the organ %ID/g is not increased in proportion to changes in membrane permeation following drug lipidization (23). Similarly, attachment of a cationic import peptide, such as tat^{48–58}, results in an increase in membrane permeation, but also causes a parallel decrease in the plasma AUC, and these have offsetting effects on the organ %ID/g. Pharmacological effects in vivo are determined not by the organ clearance parameter, but by the %ID/g.

A Streptavidin Mutant Useful for Directed Immobilization on Solid Surfaces

Gabriel O. Reznik, Sandor Vajda, Charles R. Cantor, and Takeshi Sano[†]

Center for Advanced Biotechnology and Departments of Biomedical Engineering and Pharmacology and Experimental Therapeutics, Boston University, Boston, Massachusetts 02215, and Center for Molecular Imaging Diagnosis and Therapy and Basic Science Laboratory, Department of Radiology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts 02215. Received April 24, 2001; Revised Manuscript Received July 5, 2001

A streptavidin mutant has been designed and produced that allows the specific, covalent immobilization of streptavidin on solid surfaces. This streptavidin mutant was constructed by fusing a six-residue sequence, containing a single cysteine, to the carboxyl terminus of streptavidin. Because this mutant has no other cysteine residues, the reactive sulfhydryl group of the cysteine residue serves as a unique immobilization site for conjugation using sulfhydryl chemistry. This streptavidin mutant was efficiently immobilized on maleimide-coated solid surfaces via its unique immobilization site. Characterization of the immobilized streptavidin mutant for the ability to bind to biotinylated macromolecules and the dissociation rates of bound biotin showed that the biotin-binding properties of this mutant were minimally affected by immobilization on solid surfaces. This streptavidin could be readily incorporated into a wide variety of solid-phase diagnostic tests and biomedical assays. This could enhance the performance of streptavidin-based solid-phase assay systems.

INTRODUCTION

Streptavidin is a tetrameric protein produced by *Streptomyces avidinii*. This protein binds the vitamin D-biotin with an affinity higher than any other known biological binding site ($K_d \sim 10^{-15}$ M) (1–4). Streptavidin is a highly stable protein that can maintain its functional structure even under a variety of harsh conditions, such as high temperatures and the presence of high concentrations of denaturants and organic solvents. These unique properties, along with the ability of biotin to be incorporated easily into various biological materials without disturbing their properties and structures, allow streptavidin to serve as a powerful, versatile tool in biomedical science and clinical diagnostics.

One group of applications of streptavidin involves solid-phase assays, in which streptavidin is immobilized covalently on a solid surface. The extremely high biotin-binding affinity of streptavidin allows tight, efficient immobilization or capture of biotinylated materials on streptavidin-coated solid surfaces. The properties of such immobilized streptavidin were recently analyzed (5). The streptavidin-coated solid surface was produced by using natural core streptavidin, lacking both the N- and C-terminal sequences present in the parental full-length streptavidin, which was immobilized covalently through its amino groups on a polystyrene surface. This study indicated that the properties of the immobilized streptavidin are heavily altered as compared to those in solution. In particular, its binding affinity for biotin is much lower than that in solution, and its accessibility to biotinylated materials is significantly reduced. These and other alterations severely reduce the efficacy of immobilized streptavidin as a solid support for biomedical assays. This suggests that, if streptavidin could be

immobilized specifically on solid surfaces without affecting its properties, various solid-phase assay systems with immobilized streptavidin could be considerably enhanced. In this work, we designed and produced a streptavidin mutant that can be immobilized efficiently on a solid surface with minimal effects on the fundamental properties of streptavidin.

MATERIALS AND METHODS

Construction of an Expression Vector. An expression vector was constructed by using pTSA-13 carrying a cloned streptavidin gene (6) as a starting material. A PCR (polymerase chain reaction)-based site-directed mutagenesis method was used to modify the coding sequence for a C-terminal region of streptavidin. A DNA sequence encoding six amino acid residues with a translation termination codon, GGT GGT TCT GGT TGC CCG TAG (Gly-Gly-Ser-Gly-Cys-Pro-Stop), was fused to the codon for Val-133 (GTG) (7). The entire coding sequence was cloned between the *Nde* I and *Bam* H I sites of the plasmid pET-3a under the control of the $\phi 10$ promoter of bacteriophage T7 (8). The resulting expression vector pTSA-C encodes a streptavidin mutant, Stv-C, which consists of the core region of streptavidin encoded in pTSA-13 (6), with the six-residue sequence Gly-Gly-Ser-Gly-Cys-Pro at the C-terminus.

Expression and Purification of a Streptavidin Mutant. Expression and purification of Stv-C was carried out as previously described (6, 9, 10) by using the *Escherichia coli* strain BL21(DE3)(pLysE) (8) carrying pTSA-C. During renaturation of Stv-C, 2-mercaptoethanol was included in all solutions at a concentration of 10 mM to prevent the formation of disulfide bonds (9, 10).

Immobilization of Stv-C on a Maleimide-Coated Solid Surface. Stv-C was immobilized on microtiter wells coated with maleimide groups (Reacti-Bind Male-

[†] Harvard Medical School.

imide Activated Plates; Pierce Chemical). Stv-C was added to maleimide-coated microtiter wells at various concentrations (0.4–4 μ M subunits) in phosphate-buffered saline (PBS; 0.137 M sodium chloride, 2.7 mM potassium chloride, 10 mM phosphate buffer, pH 7.4). TCEP-HCl [tris(2-carboxyethyl)phosphine hydrochloride] was included in the reaction mixture at a 10-fold molar excess over sulfhydryl groups present to avoid the formation of disulfide bonds. The immobilization reaction was carried out with shaking at room temperature ($\sim 22^\circ\text{C}$) overnight. Unbound Stv-C was removed by washing microtiter wells three times with PBS containing 1 mM TCEP-HCl. To each microtiter well, 200 μ L of 5 mM iodoacetamide in 0.2 M Tris-HCl pH 8.5 was added and incubated for 2 h in the dark to block unreacted sulfhydryl groups of Stv-C, followed by washing the microtiter wells with PBS.

The biotin-binding capacity of immobilized Stv-C was estimated by using D-[carbonyl- ^{14}C]biotin (54 mCi/mmol; Amersham Pharmacia). A known amount of D-[carbonyl- ^{14}C]biotin in PBS was added to each microtiter well and incubated for 30 min. Then, unbound D-[carbonyl- ^{14}C]biotin was collected, and its radioactivity was determined by liquid scintillation counting. The amount of bound D-[carbonyl- ^{14}C]biotin was estimated from the difference in the amount between the total D-[carbonyl- ^{14}C]biotin added and unbound D-[carbonyl- ^{14}C]biotin.

Preparation of a Biotinylated, Radiolabeled DNA.

A biotinylated 500-bp double-stranded DNA was generated by PCR using the plasmid pUC19 as a template with the oligonucleotide primers 5'-GGCGTATCACGAGG-3' and 5'-biotin-AACAGCTATGACCATG-3'. The 5'-terminus of the nonbiotinylated oligonucleotide primer had been labeled with ^{32}P by phosphorylation using T4 polynucleotide kinase (New England Biolabs) and [γ - ^{32}P]-adenosine 5'-triphosphate (3000 Ci/mmol; Amersham Pharmacia). The resulting biotinylated, ^{32}P -labeled 500-bp PCR product (4.88 Ci/mmol), which contained one biotin moiety per molecule, was purified by using a PCR purification kit (Qiagen) and stored at -20°C until used.

Preparation of Biotinylated, Radiolabeled IgG and F(ab')₂ Fragment. Approximately 350 μ g of goat immunoglobulin G (IgG) against rabbit IgG (150 kDa; Roche Molecular Biochemicals) or 350 μ g of a goat F(ab')₂ fragment against rabbit IgG (110 kDa; Sigma) was incubated on ice for 90 min with 3.2 pmol of a [^{35}S]sulfur labeling reagent (>800 Ci/mmol; Amersham Pharmacia) in 100 mM boric acid pH 8.0 (reaction volume, 175 μ L). Then, 1 mg (1.8 μ mol) of sulfo-NHS-LC-biotin (Pierce Chemical) in 25 μ L of 100 mM boric acid pH 8.0 was added to each mixture, which was incubated for an additional 90 min. Each reaction mixture was subjected to gel filtration chromatography on a Superdex 75 HR column (1 cm $\times$ 30 cm; Amersham Pharmacia) using 150 mM NaCl, 20 mM Tris-HCl pH 7.4 as the eluent to remove unreacted ^{35}S -sulfur labeling reagents and sulfo-NHS-LC-biotin. The eluted protein samples [biotinylated ^{35}S -labeled IgG (3.25 Ci/mmol) and a biotinylated ^{35}S -labeled F(ab')₂ fragment (2.08 Ci/mmol)] were stored at 4°C until used. By a modified 2-[4'-hydroxyazobenzene]-benzoic acid (HABA) displacement assay (11) using the protocol provided with ImmunoPure HABA (Pierce Chemical), the number of biotin moieties per molecule was estimated to be 18 and 10 for the biotinylated ^{35}S -labeled IgG and the biotinylated ^{35}S -labeled F(ab')₂ fragment, respectively.

Binding Capacities of Immobilized Stv-C for Biotinylated Macromolecules. The binding capacity of immobilized Stv-C for biotinylated DNA was analyzed

by adding 10 pmol of the biotinylated, ^{32}P -labeled 500-bp double-stranded DNA, prepared above, to each Stv-C-coated microtiter well (biotin-binding capacity, 10.1 pmol/well) in 1 M NaCl, 10 mM Tris-HCl pH 7.4 containing 0.02% Nonident P-40. The mixtures were incubated for 1 h, after which time unbound DNA was collected and quantitated by liquid scintillation counting. The difference between the total DNA added and unbound DNA was used to estimate the amount of bound DNA. Non-specific binding of DNA to Stv-C-coated microtiter wells was determined in the same manner, except that target ^{32}P -labeled DNA contained no biotin.

The binding capacities of immobilized Stv-C for the biotinylated ^{35}S -labeled IgG and the biotinylated ^{35}S -labeled F(ab')₂ fragment, prepared above, were analyzed by adding 25 pmol of each protein target to each Stv-C-coated microtiter well (biotin-binding capacity, 25 pmol/well) in PBS containing 0.02% Nonident P-40. The mixtures were incubated for 1 h, after which time unbound materials were collected and quantitated by liquid scintillation counting. The difference between the total protein added and unbound protein was used to estimate the amount of bound protein. Nonspecific binding of these protein targets to Stv-C-coated microtiter wells was measured by using the same procedure, except that ^{35}S -labeled protein targets contained no biotin.

Determination of Dissociation Rate Constants of Bound Biotin from Immobilized Stv-C.

Rate constants of dissociation of bound biotin from immobilized Stv-C were determined by using the following procedure. Each Stv-C-coated microtiter well (biotin-binding capacity, 64 pmol/well) was incubated with approximately 64 pmol of D-[8,9- ^3H]biotin (0.875 Ci/mmol; Amersham Pharmacia) for 30 min in 300 μ L of 20 mM Tris-HCl pH 8.0. Stv-C-coated microtiter wells were washed three times with 20 mM Tris-HCl pH 8.0 to remove unbound D-[8,9- ^3H]biotin. Then, 64 nmol of biotin in 300 μ L of 20 mM Tris-HCl pH 8.0 was added to each microtiter well, which was incubated with shaking at room temperature. At various incubation times over a period of 5 days, 100- μ L aliquots were collected from three wells at a time. The radioactivity of the collected aliquots, derived from D-[8,9- ^3H]biotin released from immobilized Stv-C, was measured by liquid scintillation counting and used to calculate the dissociation rate constant of bound biotin from immobilized Stv-C.

RESULTS AND DISCUSSION

Streptavidin-coated solid surfaces, on which streptavidin is covalently immobilized, have proven very useful for a variety of biomedical assays, including clinical diagnostics (12–14). The properties of one such streptavidin-coated solid surface (5) were recently investigated. This study showed that the properties of natural core streptavidin are heavily altered by immobilization on a solid surface. In particular, several different classes of biotin-binding sites are present, each of which has a weaker biotin-binding affinity by, at least, a few orders of magnitude than in solution. Molecular simulation analysis using the known three-dimensional structure of streptavidin (15, 16) suggested that two of the four biotin-binding sites of each immobilized natural core streptavidin molecule are very unlikely to be available for binding to biotin due to their close proximity to the solid surface. These alterations are likely to result from the direct interaction of streptavidin molecules with the solid surface, which may cause a structural distortion of streptavidin. This suggests that, if an appropriate dis-

Figure 1. Schematic illustration of a streptavidin mutant with a six-residue immobilization sequence, Stv-C, immobilized on a solid surface. The immobilization sequence (Gly-Gly-Ser-Gly-Cys-Pro) is shown in a fully extended conformation.

tance could be introduced between an immobilized streptavidin molecule and a solid surface, the properties of streptavidin could be maximally maintained upon immobilization. To test this, we attempted to design a specific immobilization sequence, which can be fused to a terminus of streptavidin recombinantly. The immobilization sequence has a unique immobilization site, which serves as the point of attachment to a solid surface. The sequence between the immobilization site and the core region of streptavidin should serve as a linker that can be used to adjust the distance between the streptavidin molecule and the solid surface.

Cysteine was chosen as an immobilization site because of the high reactivity of its sulfhydryl group. Due to the absence of cysteines in natural streptavidin (9, 10), a cysteine residue in a recombinant streptavidin should be useful for specific, directed immobilization of streptavidin on a solid surface using sulfhydryl chemistry. The appropriate length of the immobilization sequence was estimated by using the known three-dimensional structure of streptavidin (15, 16) with the protein-modeling program QUANTA (Pharmacopeia, Princeton, NJ). This analysis suggested that four amino acid residues between the immobilization site (cysteine residue) and the C-terminus of the core region of streptavidin should be optimal to maintain the properties of streptavidin upon immobilization. Shorter sequences between the immobilization site and streptavidin may reduce the capacity of immobilized streptavidin for biotinylated macromolecules due to the close proximity of biotin-binding sites to the solid surface. Longer immobilization sequences seem to be unnecessary and even disadvantageous since they might sterically prevent biotinylated macromolecules from docking into the biotin-binding sites of streptavidin. With a distance of four residues between the immobilization site and streptavidin, only two covalent linkages should be formed between each streptavidin molecule and the solid surface, thereby fully exposing two of the biotin-binding sites (Figure 1). On the basis of these analyses, the immobilization sequence designed is Gly-Gly-Ser-Gly-Cys-Pro. This six-residue sequence is flexible and has four residues between the C-terminus of the core region of

Figure 2. SDS-PAGE analysis of purified Stv-C. Stv-C (approximately 2.5 μ g) in the presence of 1.5% SDS and 10 mM TCEP, with and without heat treatment in boiling water for 3 min, was analyzed by SDS-PAGE (18) using a 15% polyacrylamide gel. Streptavidin is known to retain its tetrameric structure in the presence of SDS without heat treatment (19). Proteins were stained with Coomassie brilliant blue R. Lane 1, Stv-C without heat treatment; lane 2, molecular mass standard proteins; and lane 3, Stv-C with heat treatment. The positions of subunit tetramers (top) and monomers (bottom) are shown by arrows.

streptavidin and the immobilization site (cysteine). A proline residue was placed at the C-terminus to enhance the stability of the C-terminal sequence against exopeptidases. The design of the linker sequence took into account the absence of highly charged or hydrophobic residues to avoid electrostatic or hydrophobic interactions, respectively, with the core region of streptavidin or other molecules present in the sample.

We constructed an expression vector for a streptavidin mutant, Stv-C, which consists of the core region (from Gly-16 to Val-133) of streptavidin (7) with a methionine at the N-terminus and the six-residue immobilization sequence, described above, at the C-terminus. The encoded Stv-C was expressed efficiently in *E. coli* by using the bacteriophage T7 expression system (8). Expressed Stv-C was purified to homogeneity (Figure 2) by a procedure that includes 2-iminobiotin affinity chromatography (9, 10). The average yield was 1.2 mg of purified Stv-C from 100 mL of culture. Purified Stv-C formed a tetrameric molecule and had full biotin-binding ability, indicating that the fusion of the six-residue immobilization sequence to the C-terminus has little, if any, effect on the fundamental properties of streptavidin.

Purified Stv-C was used to test if it can be immobilized efficiently on a solid surface. A maleimide-coated microtiter plate (Pierce Chemical) was used as the solid surface because of the specific reactivity of maleimide for sulfhydryl groups. Biotin-binding capacities of the resulting Stv-C-coated microtiter wells, determined by using D-[carboxyl- ^{14} C]biotin, showed that approximately 30 pmol of Stv-C subunits were immobilized per well, when Stv-C was used at a subunit concentration of 4 μ M during immobilization. This corresponds to a Stv-C density of 420 fmol subunits/mm².

The binding capacities of immobilized Stv-C, prepared as above, for biotinylated macromolecules were determined by using a biotinylated 500-bp double-stranded DNA (one biotin moiety per molecule), a biotinylated F(ab')₂ fragment (10 biotin moieties per molecule), and a biotinylated IgG (18 biotin moieties per molecule) as targets (see Materials and Methods). Stv-C-coated mi-

Figure 3. Dissociation of bound biotin from Stv-C immobilized on maleimide-coated microtiter wells. The logarithm of the ratio of the initial concentration of Stv-C-biotin complexes (time 0) ($[BS]_0$) to that at time t ($[BS]_t$) is plotted as a function of time. Each data point represents the mean $\pm$ standard deviation ($n = 3$). Best-fit lines are shown, which indicate the biphasic nature of the dissociation of bound biotin from immobilized Stv-C.

cro-titer wells with a biotin-binding capacity of 10.1 pmol/well bound 1.21 pmol of the biotinylated 500-bp DNA. Stv-C-coated microtiter wells with a biotin-binding capacity of 20.8 pmol per well bound 2.73 pmol of the biotinylated F(ab')₂ fragment or 1.77 pmol of the biotinylated IgG. The reduced binding capacities of immobilized Stv-C for these biotinylated macromolecules, as compared to that for biotin, are very likely caused by steric hindrance, generated by the binding of the biotinylated macromolecules to Stv-C that was immobilized in a high density on a solid surface. The Stv-C-coated microtiter wells used showed no detectable nonspecific binding by the equivalent target molecules lacking a biotin moiety. In a previous study (5), a streptavidin-coated solid surface, which was produced by the immobilization of natural core streptavidin on a polystyrene surface through its amino groups, bound approximately 22 pmol of a biotinylated 526-bp double-stranded DNA per 300 pmol of biotin-binding sites. Thus, approximately 7.3% of the biotin-binding sites can be bound by the biotinylated DNA (17). In contrast, approximately 12% of the biotin-binding sites of the Stv-C-coated microtiter wells can be bound by the equivalent biotinylated DNA. This implies that the accessibility of the biotin-binding sites of immobilized Stv-C by biotinylated macromolecules is higher than that of immobilized streptavidins prepared by using the natural protein.

The rate constant of dissociation of bound biotin from immobilized Stv-C was determined to estimate the homogeneity of the biotin-binding sites. The dissociation of streptavidin-biotin complexes should be a first-order process. Thus, the logarithm of the ratio of the initial concentration of Stv-C-biotin complexes (time 0) to that at time t is plotted as a function of time (Figure 3). This plot shows a biphasic curve, suggesting that there are, at least, two types of biotin-binding sites. Their dissociation rate constants are estimated at $5.0 \times 10^{-6} \text{ sec}^{-1}$ and $3.3 \times 10^{-6} \text{ s}^{-1}$ at pH 7.4. These dissociation rate constants appear to be slightly faster than that of streptavidin in solution ($2.8 \times 10^{-6} \text{ sec}^{-1}$ at pH 7.0) (3). In contrast, natural streptavidin, immobilized on a polystyrene surface through its amino groups, showed three types of

biotin-binding sites with dissociation rates of $4.9 \times 10^{-5} \text{ s}^{-1}$, $8.3 \times 10^{-6} \text{ s}^{-1}$, and $2.5 \times 10^{-6} \text{ s}^{-1}$ (5).

In conclusion, the fusion of the six-residue immobilization sequence containing a unique cysteine as the immobilization site to the carboxyl terminus of streptavidin has made the resulting streptavidin (Stv-C) immobilizable on a solid surface with minimal effect on the biotin-binding characteristics upon immobilization. In particular, immobilized Stv-C appears to have a higher binding capacity for biotinylated macromolecules than streptavidin-coated solid surfaces produced by using the natural protein. In addition, the biotin-binding characteristics of immobilized Stv-C are only slightly different from those of streptavidin in solution, suggesting that the six-residue immobilization sequence allows the maintenance of the biotin-binding properties of streptavidin upon immobilization. This streptavidin construct should be readily adapted to solid surfaces currently used for a variety of solid-phase assays. This could enhance the performance of current streptavidin-based solid-phase assay systems.

Stearyl-Arginine-Rich Peptides: A New Class of Transfection Systems

Shiroh Futaki,^{*,†} Wakana Ohashi,[†] Tomoki Suzuki,[†] Miki Niwa,[†] Seigo Tanaka,[†] Kunihiro Ueda,[†] Hideyoshi Harashima,[‡] and Yukio Sugiura^{*,†}

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611-0011, Japan, and Graduate School of Pharmaceutical Sciences, Hokkaido University, Sapporo, Hokkaido 060-0812, Japan. Received April 26, 2001; Revised Manuscript Received July 25, 2001

Membrane-permeable arginine-rich peptides, such as HIV-1 Tat-(48–60), HIV-1 Rev-(34–50), and flock house virus (FHV) coat-(35–49), have been shown to possess the ability to transfect COS-7 cells with luciferase-coding plasmid as efficiently as polyarginine (MW 5000–15 000) and polylysine (MW 9800). Not only these virus-derived cationic peptides but also oligoarginines of 4–16 residues were found to be able to transfect cells. In the case of the Tat, FHV, and octaarginine peptides, N-terminal stearylation of the peptides increases the transfection efficiency by approximately 100 times to reach the same order of magnitude as that of LipofectAMINE, one of the most efficient commercially available transfection agents. Also, a certain correlation was observed between the transfection efficiency of stearyl-(Arg)_n peptides (stearyl-R_n: *n* = 4, 8, 12, 16) and the membrane permeability of the corresponding (Arg)_n peptides (R_n).

INTRODUCTION

Arginine-rich peptides derived from human immunodeficiency virus (HIV)-1 Tat and Antennapedia homeo-domain have been reported to translocate through cell membranes quite easily and to be utilized as carriers of macromolecules such as proteins and oligoDNAs by conjugating these basic peptides with the cargo macromolecules (1–10). Intracellular delivery of β -galactosidase (120 kDa) was achieved by the covalent conjugation with these carrier peptides (4). OligoDNAs up to ~30 bases were also introduced to cells with the help of these carrier peptides aiming at antisense or triple-helix therapy (9, 10). Recently, we reported that not only the Tat-derived peptide but also various arginine-rich basic peptides derived from RNA-binding proteins, such as HIV-1 Rev and flock house virus (FHV) coat proteins, can penetrate through the cell membranes and bring exogenous proteins into the cells (11). The peptides composed of only arginine residues were also found to have the above-mentioned property (11, 12). The fluorescence microscopic observation indicated that the peptide comprising eight residues of arginine translocated through cell membranes quite easily and accumulated in the nucleus. There was a certain dependence on the chain length for the cellular localization as well as the membrane permeability among these oligoarginine peptides. Quite interestingly, not only the smaller but also the larger the number of arginine residues became, the lower the membrane permeability and the less evident nuclear accumulation of the peptides became. In the case of the peptide comprising 16 arginine residues, the peptide was prominently observed on the membrane, and the accumulation in the nucleus was not significant (11). The results contradicted our expectation that, if only the

positive charge was the driving force for the translocation, the efficiency should become higher as the peptide charge increased.

On the other hand, polyarginine and polylysine have been employed for the delivery of plasmid DNAs and antisense oligonucleotides into mammalian cells (13). In the delivery using the above membrane-permeable arginine-rich peptides, the cargo proteins or oligoDNAs were covalently attached to the arginine-rich carrier peptides and applied to the cells. In contrast, transfection of the plasmid DNA and the antisense nucleic acid using these polypeptides was usually conducted simply by mixing them and forming a peptide/nucleic acid complex. In such a case, peptides of high molecular weight (5000 or the higher) have often been employed with the hope of forming a tight and compact complex with plasmid DNAs (14). The transfection efficiency of small peptides of a distinctive structure, such as octaarginine, has been studied less extensively compared with other cationic polymers. In relationship to the potential of the arginine-rich peptides as a protein carrier, we were interested in the applicability of these “short” arginine-rich peptides to the transfection for plasmid DNA of a few kilobase pairs. In this report, the transfection efficiency of arginine-rich membrane-permeable peptides (Figure 1) was assessed for the first time on the basis of the luciferase assay, using a strategy of simply mixing the peptides with the plasmid DNA. The effect of peptide modification by hydrophobic moieties was also examined.

EXPERIMENTAL PROCEDURES

Materials. Fmoc-amino acid derivatives were purchased from Calbiochem-Novabiochem (Läufelfingen, Switzerland). Rink amide resin (TGS-RAM) was purchased from Shimadzu (Kyoto, Japan). Poly-L-lysine (MW 9800) and poly-L-arginine (MW 5000–15 000) were from Sigma (St. Louis, MO). LipofectAMINE and fetal bovine serum (FBS) were obtained from Life Technologies (Rockville, MD). Dulbecco's modified Eagle's medium (DMEM) was from Nissui Pharmaceutical (Tokyo, Ja-

pan). Plasmid DNA containing a firefly luciferase gene together with a simian virus 40 (SV40) promoter (PicaGene control vector2, PGV-C2) was from Toyo Ink (Tokyo, Japan). Other reagents were purchased from Aldrich (Milwaukee, MI) and Wako Chemical (Osaka, Japan).

Peptide Synthesis. All the peptides used in this report were synthesized by Fmoc-solid-phase peptide synthesis on Rink amide resin using a Shimadzu PSSM-8 synthesizer as reported (15). Stearyl-peptides were prepared by treatment of the corresponding peptide resins with stearic acid and diisopropylcarbodiimide in the presence of *N*-hydroxybenzotriazole followed by deprotection using trifluoroacetic acid (TFA)/ethanedithiol (EDT) (95:5). Lauryl- R_8 and cholyl- R_8 were similarly prepared using lauric acid and cholic acid in place of stearic acid, respectively. Cholesteryl- R_8 was prepared by treatment of the peptide resin with cholesteryl chloroformate in the presence of diisopropylethylamine followed by deprotection using TFA/EDT (95:5). All of the peptides were purified by reverse-phase HPLC. Fidelity of the products was ascertained by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOFMS): HIV-1 Tat-(48–60), 1719.0/1719.1; HIV-1 Rev-(34–50), 2437.5/2437.8; FHV coat-(35–49), 2665.0/2664.5; R_4 , 642.7/642.8; R_8 , 1267.5/1267.5; R_{12} , 1891.5/1892.3; R_{16} , 2517.6/2517.0; stearyl-Tat, 1984.8/1985.2; stearyl-Rev, 2702.1/2702.8; stearyl-FHV, 2430.4/2430.6; stearyl- R_4 , 909.2/909.2; stearyl- R_8 , 1534.0/1533.9; stearyl- R_{12} , 2158.0/2158.7; stearyl- R_{16} , 2783.4/2783.5; stearyl-D- R_8 , 1533.7/1533.9; lauryl- R_8 , 1449.2/1449.9; cholesteryl- R_8 , 1737.5/1737.3; cholyl- R_8 , 1714.8/1715.2 [found/expected for $(\text{M}+\text{H})^+$].

In Vitro Gene Transfection and Luciferase Assay. COS-7 cells, a simian kidney cell line transformed with SV40 (5×10^5 cells/well), were grown to just before confluence in a 24-well plate in DMEM containing 10% FBS under 5% CO_2 at 37 °C. Plasmid DNA coding a luciferase (PGV-C2, 5.2 kbp) (2.5 μg) in serum-free DMEM (25 μL) was added to the solution of a peptide or an N-terminal modified peptide in serum-free DMEM (25 μL), allowed to stand for 30 min, and diluted with serum-free DMEM (200 μL). The cells were washed 3 times with 500 μL of serum-free DMEM. The above peptide/DNA mixture was then gently added to the cells. After incuba-

tion for 12 h at 37 °C, DMEM (250 μL) containing 20% FBS was added. After 12 h, the medium was replaced with fresh DMEM (500 μL) containing 10% FBS. The cells were further incubated for 36 h. Harvest of cells and luciferase assay were performed following the protocol of a Pica Gene luminescence kit (Toyo Ink, Tokyo, Japan) as reported by Niidome et al. (16). The light units were analyzed by a BLR-201 luminescence reader (Aloka, Japan). The light unit values shown in the figures represent the specific luciferase activity (RLU/mg of protein) which is standardized for the total protein content of the cell lysate [10^6 RLU corresponds to 0.37 ng (6 fmol) of luciferase]. The measurement of gene transfer efficiency was performed in triplicate.

Transfection using LipofectAMINE was similarly conducted as stated above. Following the supplier's protocol, LipofectAMINE (2.5 μL) was employed for 2.5 μg of the plasmid DNA in place of oligoarginine in serum-free DMEM (25 μL).

Particle Size Determination. Particle size determination was carried out using a DLS-700 dynamic light scattering spectrophotometer equipped with a vertically polarized 5-mW He–Ne laser (633 nm) (Otsuka Electronics, Hirakata, Japan). Plasmid DNA (PGV-C2) (25 μg) in HEPES-buffered saline (HBS) (21 mM HEPES containing 135 mM NaCl, 5.0 mM KCl, and 0.76 mM Na_2HPO_4 , pH 7.4) (250 μL) was mixed with the appropriate amount of a peptide or liposomes in HBS (250 μL) to give a cation:anion charge ratio of 2:1 and subjected to size determination.

Ethidium Bromide Displacement Assay (17). To a solution of plasmid DNA (PGV-C2) (3.5 μg) in HBS (600 μL) was added ethidium bromide (EtBr) (21 ng) in HBS (0.4 μL) and vortexed. An appropriate amount of stearyl- R_8 in HBS (2 μL) was added to the solution to give the desired cation:anion charge ratio. The fluorescence from the intercalated EtBr was monitored using a Hitachi fluorescence spectrophotometer F-3010 by the excitation and emission wavelengths at 510 and 595 nm, respectively.

MTT Assay (18). Cytotoxicity on transfection using stearyl- R_8 and LipofectAMINE was evaluated by MTT assay. COS-7 cells were placed in a 96-well plate (1×10^4 cells/well) in serum-free DMEM (50 μL) in the presence of the plasmid DNA (PGV-C2) (0.5 μg) and

Figure 2. In vitro luciferase activity for PGV-C2 plasmid DNA after transfection of COS-7 cells using membrane-permeable arginine-rich peptides. Peptides were mixed with plasmid DNA at a cation:anion charge ratio of 2:1, where 15 nmol (as cation charge) of each peptide was used for 2.5 μ g of plasmid DNA, respectively. Each bar represents the mean and standard deviation of three determinations.

stearyl- R_8 (0.6 μ g) [or LipofectAMINE (0.5 μ L)] and incubated at 37 $^{\circ}$ C under 5% CO_2 for 12 h. DMEM containing 20% FBS (50 μ L) was then added, and incubation was continued for another 12 h. The medium was removed, and the cells were treated with 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (50 μ g) in DMEM containing 10% FBS (100 μ L) for 4 h. Cell viability was expressed as the ratio of the A_{570} of cells treated with a transfection agent together with plasmid to that of the control samples.

RESULTS

Transfection Efficiency of Membrane-Permeable Arginine-Rich Peptides. The efficiency of HIV-1 Tat-(48–60), HIV-1 Rev-(34–50), FHV coat-(35–49), and octaarginine (R_8) in the transfection of COS-7 cells was examined using a plasmid DNA containing a firefly luciferase reporter gene (Figure 2). All of the peptides have already been proved to be highly membrane-permeable. As references, the transfection efficiency of conventional transfection agents, polylysine (molecular weight ~9800) and polyarginine (molecular weight 5000–15 000), was examined. In these experiments, a peptide and the plasmid were mixed in a cation:anion charge ratio of 2:1. Comparison of the transfection efficiency with that of LipofectAMINE, which is often employed as one of the most efficient cationic liposomes for transfection, was also conducted. The dose of LipofectAMINE for the plasmid DNA was selected following the manufacturer's protocol. The cation:anion charge ratio in this case was calculated to be 1.6:1. After mixing the plasmid with a peptide or LipofectAMINE, the mixture was applied to COS-7 cells, a simian kidney cell line transformed with SV40. Transfection was conducted for 12 h in the absence of serum, and the cells were incubated for 48 h in the presence of serum. Luciferase activity from the cells transfected with the peptides corresponding to HIV-1 Tat-(48–60), HIV-1 Rev-(34–50), and FHV coat-(35–49) was found to be comparable with that from the cells transfected with polyarginine. Transfection efficiency of the

Figure 3. Effect of N-terminal modification of R_8 peptide on transfection efficiency. Peptides were mixed with plasmid DNA at a cation:anion charge ratio of 2:1, where 15 nmol (as cation charge) of each peptide was used for 2.5 μ g of plasmid DNA, respectively. Each bar represents the mean and standard deviation of three determinations.

R_8 peptide was also determined to be comparable to those for the above peptides. Therefore, the arginine-rich peptides as short as ~10 residues have the ability to transfect the cells in almost the same efficiency as those for polylysine and polyarginine. In another words, a long peptide chain length is not necessarily needed for cationic peptide-mediated transfection. However, the transfection efficiency of these peptides was almost 2 orders of magnitude lower than that of LipofectAMINE.

Effect of N-Terminal Modification of R_8 . To improve the transfection efficiency, efforts have been focused on the compaction of DNA-carrier complexes, with the hope of facilitating the cellular uptake of DNA through endocytosis or pinocytosis. For example, the application of polylysine bearing cysteine cross-linking (19, 20), branched cationic peptides (17), cationic polymers (21), and cationic dendrimers (22) has been reported. On the other hand, Nishikawa et al. successfully introduced hydrophobic cores such as aliphatic and cholesteryl moieties in the hydrophilic polysaccharides to obtain a complex of well-defined particle size (23). It has also been reported that the use of partially stearylated polylysine in the presence of low-density lipoprotein increased the transfection efficiency compared with the usage of polylysine (24). If arginine residues attach to the DNA phosphates, partial introduction of a hydrophobic moiety might result in the aggregation of these hydrophobic moieties to produce a compact plasmid/ R_8 complex. Utilization of amino acid-based cationic lipid for the compaction of DNA has also been reported (25, 26). We thus prepared stearyl-octaarginine (stearyl- R_8) as a model of the 'short' membrane-permeable arginyl peptides and examined the transfection efficiency of R_8 in the presence of stearyl- R_8 (Figure 3). The results were, however, not as intended. We did transfection using mixtures comprising stearyl- R_8 : R_8 molar ratios of 0:100, 1:99, 50:50, and 100:0 (Figure 3). The transfection efficiency of these mixtures increased as the ratios of stearyl- R_8 increased. Maximum efficiency was obtained when 100% of stearyl- R_8 was employed for transfection.

Figure 4. (A) Effect of cation:anion charge ratios on the luciferase activity from COS-7 cells transfected with plasmid DNA (PGV-C2, 2.5 μ g) using stearyl- R_8 . Each bar represents the mean of three determinations. The standard deviation in these cases was so small that the error bars do not appear on the figure. (B) Ethidium bromide (EtBr) displacement assay (17) for stearyl- R_8 . Aliquots of stearyl- R_8 in HEPES-buffered saline (HBS) were added to a complex of plasmid DNA (PGV-C2) and EtBr in HBS. Decreases in fluorescence intensity, representing binding of the peptide to DNA and subsequent dissociation of EtBr, were recorded using excitation and emission at 510 and 595 nm, respectively.

In this case, transfection efficiency was improved by almost 2 orders of magnitude over the unmodified R_8 ; the efficiency became comparable to that of LipofectAMINE. The N-terminal stearylation of the R_8 peptide thus turned out to produce considerable improvement in the transfection efficiency.

The contribution of hydrophobic moieties to transfection efficiency has also been reported in other peptide carriers (27). Therefore, we prepared three more R_8 peptides bearing a hydrophobic moiety. These included lauryl- R_8 , cholesteryl- R_8 , and cholyl- R_8 peptides (Figure 1). Again, stearyl- R_8 gave the best transfection efficiency (Figure 3), followed by lauryl- R_8 and cholesteryl- R_8 . A significant effect on modification was not recognized for cholyl- R_8 .

Effect of Charge Ratio. The above results suggested that stearyl- R_8 is promising as a new type of transfection agent. To establish the peptide/DNA stoichiometry to achieve maximum transfection efficiency, the effect of the charge ratio of stearyl- R_8 and plasmid DNA was next examined. Transfection was carried out using different charge ratios of stearyl- R_8 /DNA mixtures from 1:1 to 8:1. The highest luciferase activity was obtained from the cells treated with a cation:anion charge ratio of 2:1 (Figure 4A). The ethidium bromide displacement assay (17) showed a plateau in the fluorescence intensity at a charge ratio of 2:1 or greater, suggesting that stearyl- R_8 effectively complexed with DNA at a charge ratio of 2:1 and higher (Figure 4B).

Sequence Effect of the Arginyl Peptides. In our preceding paper on the membrane permeability of the arginine-rich peptides, we observed that a subtle difference in the number of arginine residues dramatically influenced the mode of membrane permeability and cellular localization of the peptides (11). A peptide comprising four arginine residues rarely crossed the membrane. In contrast, a highly efficient translocation and accumulation in the nucleus was observed for a peptide comprising six or eight arginine residues. However, as the number of arginine residues in the peptide further increased, membrane permeability again decreased. Internalization and nuclear localization of the peptide bearing 16 arginine residues were not significant; the peptide was observed mostly to stay on the membrane. A similar tendency was observed in the intracellular protein delivery using arginine-rich peptides as

Figure 5. Comparison of transfection efficiency of stearyl-oligoarginine (stearyl- R_n) and oligoarginine (R_n) having a different number of arginine residues ($n = 4, 8, 12, 16$). Peptides (15 nmol as cation charge) were respectively mixed with plasmid DNA (PGV-C2, 2.5 μ g) at a cation:anion charge ratio of 2:1 and used for transfection of COS-7 cells. Open bars indicate the transfection efficiency for R_n peptides. Closed bars indicate that for stearyl- R_n peptides.

a carrier molecule (11). Carbonic anhydrase (MW 29 000) covalently conjugated with a peptide comprising eight arginine residues was quite efficiently delivered into the cells. On the other hand, the protein conjugated with a peptide comprising 16 arginine residues was not able to translocate through the cell membrane as efficiently. Therefore, we examined whether a similar tendency was recognized in the transfection using stearyl-oligoarginine. In this experiment, DNA was simply mixed with stearyl-arginine peptides but not covalently cross-linked. We thus synthesized stearyl-oligoarginine of different chain lengths [stearyl- R_n ($n = 4, 8, 12, 16$)] (Figure 1). For comparison, oligoarginine peptides which lack the stearyl moiety [R_n ($n = 4, 8, 12, 16$)] were also prepared.

Without the stearyl moiety, slight differences were observed in transfection efficiency (Figure 5). However, the efficiency of these peptides was almost of the same order as that for polyarginine. On the other hand, considerable improvement in the transfection efficiency was observed by the N-terminal stearylation, especially in the case of stearyl- R_8 and stearyl- R_{12} . Almost 2 orders of magnitude increase in the transfection efficiency were obtained by stearylation of these peptides. Significant influence of the chain length on translocation efficiency was also observed. Stearyl- R_8 gave the best result in transfection efficiency. The smaller or the larger the number of arginine residues became, the less efficient was the transfection using the peptide. In the case of stearyl- R_{16} , improvement in translocation efficiency was not as obvious as in the case of other stearyl- R_n peptides. These tendencies were quite parallel to those observed in the above-mentioned internalization of the arginine peptides themselves and the peptide-mediated intracellular protein delivery (11). Transfection efficiency of the D-amino acid derivative of stearyl- R_8 (stearyl-D- R_8), where all the arginine residues were D-form, was 2.3×10^8 RLU/mg of protein, almost 3 times that of the L-form, stearyl- R_8 . This result is also parallel to that observed in the quantification of internalized peptides where the (D-Arg) $_8$ peptide internalized more efficiently than the (Arg) $_8$ peptide (12).

Figure 6. Transfection efficiency of stearylated arginine-rich membrane-permeable peptides and the effect of chloroquine. Peptides were mixed with plasmid DNA at a cation:anion charge ratio of 2:1, where 15 nmol (as cation charge) of each peptide was used for 2.5 μ g of plasmid DNA, respectively. Cells were treated with 50 μ M chloroquine during the transfection. Each bar represents the mean and standard deviation of three determinations. Closed bars indicate the efficiency in the absence of chloroquine. Hatched bars indicate that with chloroquine treatment.

The effect of stearylation on the transfection efficiency was also examined for the HIV-1 Tat-(48–60), HIV-1 Rev-(34–50), and FHV coat-(35–49) peptides (Figure 6). Two orders of magnitude of improvement were also observed by stearylation of the HIV-1 Tat-(48–60) and FHV coat-(35–49) peptides, and a transfection efficiency close to that of LipofectAMINE was achieved. Of interest is the result for the stearyl-Rev peptide. The ability for translocation as well as protein delivery was similarly observed for all three of these peptides. However, little improvement in transfection efficiency by stearylation was observed only for the Rev peptide.

Addition of chloroquine has often been reported to be effective in improving the transfection efficiency using polyarginine and other cationic peptides (13, 27). A considerable increase was actually observed for the transfection efficiency using polylysine and polyarginine in the presence of chloroquine. For transfection using the stearyl-Tat and stearyl-FHV peptides, little improvement with the addition of chloroquine was observed (Figure 6). In the case of stearyl- R_n peptides ($n = 4, 8, 12, 16$), a significant effect of chloroquine on the transfection efficiency was not recognized (Figure 7).

Particle sizes of peptide/DNA complex were estimated using direct light scattering in HBS 3 min after mixing the peptides with DNA and then 30 min later. The latter incubation period is identical with that of the peptide/DNA mixture before the addition to cells (Table 1). Compared to polyarginine and LipofectAMINE, stearyl- R_8 formed a larger complex with DNA. The average particle size of the complex was almost 3 times larger than the lipofectAMINE/DNA complex 3 min after mixing, and 8 times larger after 30 min. The large standard deviation in the particle size also suggested that stearyl- R_8 formed complexes with DNA that easily aggregated into particles with a wide size distribution. While stearyl-Rev also formed large complexes with DNA, the average particle size and the standard deviation after 30 min

Figure 7. Effect of chloroquine on the transfection efficiency of stearyl- R_n peptides ($n = 4, 8, 12, 16$). Conditions are the same as mentioned in Figure 6. Closed bars indicate the efficiency in the absence of chloroquine (same as in Figure 5). Hatched bars indicate that with chloroquine treatment.

Table 1. Particle Size Determination of Peptide–Plasmid Complexes Using Dynamic Light Scattering^a

	particle size (nm)	
	3 min	30 min
stearyl- R_8	1437 $\pm$ 1273	5148 $\pm$ 3377
stearyl-Rev	2198 $\pm$ 769	3692 $\pm$ 1120
R_8	1667 $\pm$ 537	2917 $\pm$ 738
poly-arginine	317 $\pm$ 43	663 $\pm$ 341
LipofectAMINE	462 $\pm$ 92	752 $\pm$ 398

^a Each peptide was mixed with plasmid DNA (PGV-C2) to give a cation:anion charge ratio of 2:1. The amount of LipofectAMINE mixed with the plasmid was adjusted following the manufacturer's protocol. The particle size of each complex was determined 3 min after mixing and again 30 min later. The mean and standard deviation of three determinants are shown.

were smaller than those for stearyl- R_8 . The effect of R_8 on the compaction of DNA was not so large as that of polyarginine.

Cytotoxicity of the administration was assessed by the MTT assay (18) after incubation of cells with transfection reagents in serum-free medium for 12 h followed by incubation in serum for another 12 h. These incubation periods correspond to that where the peptide/DNA mixture was actually exposed to the cells. The cells were then harvested and subjected to the assay (Figure 8). The cytotoxicity of stearyl- R_8 , polyarginine, and LipofectAMINE in the presence of plasmid DNA was judged to be comparable.

DISCUSSION

In this paper, we have exemplified that membrane-permeable arginine-rich peptides, such as HIV-1 Tat-(48–60), HIV-1 Rev-(34–50), and FHV coat-(35–49), have the ability to transfect COS-7 cells with luciferase-coding plasmid as efficiently as polyarginine (MW 5000–15 000) and polylysine (MW 9800). Not only these virus-derived cationic peptides, but also R_n peptides ($n = 4, 8, 12, 16$) were found to be able to transfect cells. In the case of the Tat, FHV, and R_8 peptides, stearylation on the N-terminus of the peptides dramatically increased the efficiency of transfection to reach the order of

Figure 8. Cytotoxicity of the peptides and those complexed with the plasmid DNA. Cytotoxicity on transfection was evaluated by MTT assay (18). COS-7 cells were placed in a 96-well plate (1×10^4 cells/well) in serum-free DMEM and treated with a peptide or LipofectAMINE in the presence and absence of plasmid DNA (PGV-C2) for 12 h. An equal amount of DMEM containing 20% FBS was then added, and incubation was continued for another 12 h. The medium was removed, and the cells were subjected to MTT assay. Open bars, cell viability in the absence of plasmid DNA; closed bars, cell viability in the presence of plasmid DNA.

magnitude of that of LipofectAMINE, one of the most efficient commercially available transfection agents.

Polyarginine and polylysine of molecular weights more than 5000 have often been used for transfection. Presumably because of the availability of peptides, the transfection efficiency of 'short' arginine-rich peptides of distinctive molecular structure as used in this study has not been as extensively studied as those using cationic polypeptides and polymers. In relationship with the membrane permeability of these 'short' arginine-rich peptides, it is quite interesting that these peptides have the ability to deliver plasmid DNA into cells even without covalent conjugation with the plasmid.

N-terminal stearylation of the R₈ peptide showed a dramatic effect. Improvement of the transfection efficiency by almost 2 orders of magnitude was achieved. The effect of N-terminal modification by lauryl, cholesteryl, and cholyl moieties was studied. Modification by a straight chain lauryl moiety also gave about a 30-times increase in transfection efficiency. The cholyl moiety, which has an amphiphilic structure, contributed little to the improvement of transfection efficiency.

The average particle size of the stearyl-R₈/DNA complex 3 min after their mixing (1437 nm) was significantly larger than for the polyarginine/DNA complex (317 nm) and LipofectAMINE/DNA complex (462 nm). The average particle size of the stearyl-R₈/DNA complex increased faster than the other particles to exceed 5000 nm after 30 min. Because the 30-min incubation period was identical with that before transfection, it could be deduced that stearyl-R₈ forms a considerably larger complex than polyarginine and LipofectAMINE when added to the cells. Considering that stearyl-R₈ was added to plasmid DNA at a charge ratio of 2:1, it is expected that many stearyl moieties are exposed to the surface of the complex. One possible explanation for the high transfection efficiency of the stearyl-R₈/DNA complex could, therefore, be that the hydrophobic moiety contributes to absorbing of the complex on the membranes. A detergent-like effect

could also be expected for stearyl-R₈ to destabilize the membranes to facilitate cellular uptake of the peptide/DNA complex.

One of the mechanisms for chloroquine to improve transfection efficiency has been attributed to destabilization of endosomal particles (13). Though a significant improvement was observed in the transfection efficiency for polyarginine and a slight decrease for LipofectAMINE with the addition of chloroquine, it did not produce a certain effect on the cellular uptake of the stearyl-R_n/DNA complex. The ineffectiveness of chloroquine on the transfection using the stearyl-R₈/DNA complex suggests that stearyl-R₈ would disrupt endosomes by itself. Also, the uptake mechanism of the stearyl-R₈/DNA complex by the cells may not be exactly the same as that of polyarginine and LipofectAMINE.

Dependence on the number of arginine residues for the transfection efficiency of stearyl-R_n peptides ($n = 4, 8, 12, 16$) correlated well with that observed for the internalization of the R_n peptides. Superiority of stearyl-D-R₈ over the L-peptide (stearyl-R₈) in transfection efficiency also coincided with that of the (D-Arg)₈ peptide over the (Arg)₈ peptide in membrane permeability reported by Wender et al. (12). The R₈ peptides showed the highest degree of nuclear localization among the R_n peptides in our previous observations (11). It would be quite interesting if the tendency in nuclear localization of R_n peptides could have something to do with that in transfection efficiency of the corresponding stearyl peptides. The Tat and FHV peptides also accumulate in the nucleus (2, 11), and the corresponding stearyl peptides gave high efficiency of transfection. Inefficiency of stearyl-Rev for transfection may have some relation to the peptide conformation. Among the arginine-rich peptides examined in this study, only Rev peptide takes on a helical structure (11). As a result, stearyl-Rev may form a complex with DNA in a different manner from those in the case of other stearyl peptides.

Taken together, the combination of the stearyl moiety and membrane-permeable basic peptides would provide a novel framework for the development of an efficient transfection system. Among other advantages expected for the stearyl-arginine peptides, low immunogenicity can be pointed out. Arginyl peptides delivered into the cells are expected to be easily degraded by cellular trypsin-like proteases as we observed in the translocation of arginine-rich peptides (11). Also, in accordance with degradation or dissociation of stearyl-arginine peptides in the cell, free plasmid DNA would be released to the cytosol followed by reaching the nucleus. It has been suggested that cationic polymers forming a very tight complex with DNA sometimes face difficulty in unwinding the complex in the cell, causing a reduction of transfection efficiency (17). COS-7 cells express the SV40 large T-antigen. This protein binds the SV40 promoter of the plasmid and may influence intracellular trafficking. However, the effect of the T-antigen on the delivery of the plasmid in the presence of stearyl-peptides is unclear at this stage.

Further study is necessary to understand the precise mechanism of transfection using stearyl-arginine-rich peptides. However, the above data as well as our previous report on peptide translocation (11) indicated that 'short' arginyl peptides are an abundant source of peptides having therapeutic potential. Further refinement of the peptide structure will result in more sophisticated molecules for intracellular gene delivery.

ACKNOWLEDGMENT

This work was supported by Grants-in-Aid for Scientific Research on the Priority Area of Molecular Synchronization for Design of New Materials from the Ministry of Education, Culture, Sports, Science and Technology of Japan. This work was also supported in part by the Suzuken Memorial Foundation. We are grateful to Dr. T. Niidome (Nagasaki University) for helpful discussions. We are also grateful to Dr. K. Akiyoshi (Kyoto University) for advice on measurement of dynamic light scattering.

Synthesis of LJP 993, a Multivalent Conjugate of the N-Terminal Domain of β_2 GPI and Suppression of an Anti- β_2 GPI Immune Response

David S. Jones,* Keith A. Cockerill, Christina A. Gamino, Jeffrey R. Hammaker, Merle S. Hayag, G. Michael Iverson, Matthew D. Linnik, Patricia A. McNeeley, Martina E. Tedder, Huong-Thu Ton-Nu, and Edward J. Victoria

La Jolla Pharmaceutical Company, 6455 Nancy Ridge Drive, San Diego, California 92121. Received May 8, 2001; Revised Manuscript Received August 22, 2001

LJP 993, a tetravalent conjugate of the amino-terminal domain (domain 1) of β_2 GPI, was synthesized, and studies were carried out to explore the ability of LJP 993 to bind anti- β_2 GPI antibodies and to function as a B cell toleragen. Domain 1 was expressed in *Pichia pastoris*, and the N-terminus was site-specifically modified by a transamination reaction converting the N-terminal glycine to a glyoxyl group. A tetravalent platform was synthesized with linkers that terminate in aminoxy groups. This was accomplished by preparing an ethylene glycol-based heterobifunctional linker that contains both a Boc-protected aminoxy group and a free primary amine. The linker was used to modify a tetravalent platform molecule by reacting the amino groups on the linker with 4-nitrophenyl carbonate esters on the platform to provide a linker-modified platform, and the Boc protecting groups were removed to provide a tetravalent aminoxy platform. Glyoxylated domain 1 was attached to the platform to provide LJP 993 by formation of oxime bonds. The protein domains of LJP 993 retain activity as evidenced by the ability of LJP 993 to bind to anti- β_2 GPI antibodies. Dissociation constants (K_d) for domain 1 and LJP 993 bound to immobilized affinity-purified anti- β_2 GPI antibodies from autoimmune thrombosis patients were determined using surface plasmon resonance. An immunized mouse model was developed to test the ability of LJP 993 to act as a toleragen. A thiol containing domain 1 analogue was expressed in insect cells using the baculovirus expression system, and it was used to prepare an immunogenic conjugate of domain 1 and maleimide-derivatized keyhole limpet hemocyanin (KLH). Mice were immunized with the KLH conjugate, and spleen cells were harvested from the immunized mice. The cells were incubated with various concentrations of LJP 993 and transferred to mice whose immune systems had been compromised by irradiation. The hosts were then boosted with the KLH-domain 1 conjugate, and after 7 days their antibody levels were measured. Host mice receiving cells that were treated with LJP 993 produced significantly lower amounts of anti-domain 1 antibodies than controls which received untreated cells, indicative of B cell tolerance.

INTRODUCTION

Multivalent presentation of a B cell epitope, in the absence of T cell epitopes, can specifically tolerize B cells (1). The B cells become nonresponsive to immunogenic forms of the epitope resulting in an antigen-specific decrease in antibody production (2, 3). Molecules that present B cell epitopes in a multivalent fashion, and that immunospecifically suppress antibody production, are called B cell toleragens; likewise, antigen-specific suppression of antibody production in response to treatment with a toleragen is termed B cell tolerance. An early example of B cell tolerance was the demonstration that 2,4-dinitrophenyl (DNP) groups attached to the D-lysines in polymers consisting of D-amino acids could suppress IgG production in animals that had been immunized with DNP-derivatized proteins (2).

The ability to specifically suppress antibody production provides a basis for a therapeutic approach to the treatment of autoimmune disorders by specifically tolerizing the B cells responsible for producing pathogenic

autoantibodies. B cell tolerance was demonstrated in mice that were immunized with synthetic double-stranded oligonucleotides. Treatment with a tetravalent oligonucleotide conjugate on a poly(ethylene glycol) based platform suppressed anti-oligonucleotide antibody formation (4). Further refinement of that molecule led to LJP 394, which consists of four double-stranded oligonucleotides connected to a defined, nonpolymeric platform. LJP 394 was designed to treat lupus nephritis and has been shown to reduce anti-dsDNA antibodies in human clinical trials (5, 6).

The prospect of using this approach to develop treatments for other autoimmune diseases led us to search for peptide mimotopes of naturally occurring proteinaceous antigens. β_2 -Glycoprotein I (β_2 GPI) has been implicated as the natural antigen of what have been historically referred to as anticardiolipin antibodies (ACA) which are associated with arterial and venous thrombosis, recurrent fetal loss, and thrombocytopenia (7). Anti- β_2 GPI binding peptides were discovered by screening random-peptide phage libraries, and multivalent conjugates of the peptides were prepared. The peptide conjugates could tolerize mice that had been immunized with the peptides resulting in down-regulation of anti-peptide antibodies (8). Although toleragenic,

peptide conjugates lacked cross-reactivity between patient antibodies. The effectiveness of a peptide was restricted to the specificity of the antibody used to screen the phage libraries. (9).

The discovery that the first domain of β_2 GPI (domain 1) was broadly cross-reactive with patient anti- β_2 GPI antibodies has led to efforts aimed at developing a multivalent construct of this native polypeptide sequence as a toleragen for autoimmune thrombosis (10). We describe a prototypical synthesis of a tetravalent conjugate of domain 1 and experiments that illustrate the potential of using such a conjugate as a therapeutic toleragen for anti- β_2 GPI mediated pathologies. Studies are presented to show that the conjugate binds anti- β_2 -GPI antibodies and acts as a toleragen by suppressing antibody formation in the spleen cells of mice that had been immunized and boosted with a conjugate of domain 1 on KLH.

EXPERIMENTAL PROCEDURES

General. All chemicals were used as purchased unless otherwise specified. *N*-(*tert*-Butyloxycarbonyl)hydroxylamine, 1,2-bis(2-chloroethoxy)ethane, and glyoxylic acid were purchased from Aldrich. Carboxypeptidase A-agarose was purchased from Sigma. Reductacryl beads were purchased from Calbiochem. Nestle Carnation nonfat dry milk was purchased at a supermarket. Optical densities of microtiter plate wells were read using an EL310 Microplate autoreader (Bio-Tek Industries, Inc.). Maleimidyl-activated KLH was purchased from Pierce Chemical Company (cat. no. 77105). *Bordetella pertussis* organisms were obtained from the Massachusetts Department of Public Health.

Silica gel chromatography was performed on silica gel (230–400 mesh ASTM) purchased from Baxter. TLC was performed on silica gel TLC plates (5554) manufactured by EM Separations. Phosphate buffered saline (PBS) was prepared by dissolving 175 g of NaCl, 6.5 g of $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$, and 40.9 g of $\text{Na}_2\text{HPO}_4 \cdot \text{H}_2\text{O}$ in H_2O and diluting to a final volume of 20 L. Tris-buffered saline (TBS) was prepared by dissolving 219.9 g of NaCl and 151.4 g of tris(hydroxymethyl)aminomethane in H_2O , adjusting the pH to 8.0, at a final volume of 25 L, with HCl. Melting points are reported uncorrected. NMR spectra were recorded on a Bruker AC-300 spectrometer with broad band probe. Elemental analyses were performed by Desert Analytics of Tucson, Arizona. Mass spectra were recorded on a Finnigan LCQ electrospray mass spectrometer or obtained from the Mass Spectrometry Lab at the Scripps Research Institute, San Diego, CA. High-resolution MALDI mass spectra and high-resolution FAB mass spectra were obtained from the Mass Spectrometry Lab at the Scripps Research Institute, San Diego, CA.

Protein concentrations were determined by UV absorbance at 280 nm using a molar extinction coefficient of $9531 \text{ L mol}^{-1} \text{ cm}^{-1}$ ($1.35 \text{ mL mg}^{-1} \text{ cm}^{-1}$) for the domain 1 polypeptide.

Surface plasmon resonance experiments were performed on a Biacore 2000 using a CM5 chip, *N*-hydroxysuccinimide (NHS), 1-(3-dimethylaminopropyl)-3-ethyl carbodiimide hydrochloride (EDC), and HBS-EP buffer [0.01 M HEPES, pH 7.4, 0.15 M NaCl, 3 mM EDTA and 0.005% (v/v) surfactant P20], all obtained from Biacore (Piscataway, NJ). Pooled normal human IgG was obtained from Zymed (South San Francisco, CA).

1,2-Bis(2-iodoethoxy)ethane, 1. This compound was prepared in a manner similar to that previously described (11). A solution of 10.0 g (5.3 mmol) of 1,2-bis(2-chloro-

ethoxy)ethane and 16.0 g (107 mmol) of sodium iodide in 110 mL of acetone was heated at reflux for 18 h. The mixture was concentrated, and the residue was triturated with CHCl_3 , which dissolved the product. The undissolved salts were removed by filtration, and the filtrate was concentrated to give an orange oil. Purification by silica gel chromatography (step gradient, 10/90 EtOAc/hexanes to 15/85 EtOAc/hexanes) provided 17.8 g (90%) of compound **1** as an orange oil: ^1H NMR (CDCl_3) δ 3.28 (t, 4H), 3.67 (s, 4H), 3.78 (t, 4H); ^{13}C NMR (CDCl_3) δ 3.6, 70.5, 72.2.

2-[2-(2-*N*-(*tert*-Butyloxycarbonyl)aminoxyethoxy)-ethoxy]ethyl iodide, 2. DBU (284 μL , 290 mg, 1.90 mmol) was added to a suspension of 266 mg (2.0 mmol) of *N*-(*tert*-butyloxycarbonyl)hydroxylamine in 2.96 g (8.0 mmol) of compound **1**, and the mixture was stirred to obtain a viscous homogeneous solution, which solidified within 15 min. The mixture was allowed to stand for an additional 45 min, and it was dissolved in 5 mL of CH_2Cl_2 . The resulting solution was added to 50 mL of EtOAc resulting in a white precipitate that was removed by filtration. The filtrate was concentrated to a viscous oil that was partitioned between 100 mL of EtOAc and $3 \times 50 \text{ mL}$ of 1 N HCl solution. The EtOAc layer was washed with 5% sodium bisulfite solution and concentrated to provide 2.6 g of yellow oil. Purification by silica gel chromatography (step gradient, 20/80 to 45/55 EtOAc/hexanes) gave 515 mg (69%) of compound **2** as a yellow oil: ^1H NMR (CDCl_3) δ 1.50 (s, 9H), 3.28 (t, 2H), 3.68 (s, 4H), 3.72 (m, 4H), 4.02 (t, 2H), 7.72 (s, 1H); ^{13}C NMR (CDCl_3) δ 2.9, 28.3, 68.9, 69.4, 70.2, 70.6, 72.0, 75.4, 81.6, 156.9; HRMS (MALDI) calculated for $\text{C}_{11}\text{H}_{22}\text{INaO}_5$ ($\text{M}+\text{Na}$): 398.0435. Found: 398.0435.

2-[2-(2-*N*-(*tert*-Butyloxycarbonyl)aminoxyethoxy)-ethoxy]ethyl azide, 3. To a solution of 258 mg (0.69 mmol) of compound **2** in 5 mL of DMF under nitrogen atmosphere was added 358 mg (5.50 mmol) of sodium azide. The mixture was stirred for 18 h at room temperature, 100 mL of water was added, and the mixture was extracted with $3 \times 50 \text{ mL}$ of EtOAc. The EtOAc layers were combined and washed with 50 mL of water, dried (Na_2SO_4), filtered, and concentrated to provide 294 mg of a colorless oil. Purification by silica gel chromatography (30/70 acetone/hexanes) provided 187 mg (93%) of compound **3** as a colorless oil: ^1H NMR (CDCl_3) δ 1.47 (s, 9H), 3.41 (t, 2H), 3.69 (brd s, 4H), 3.73 (m, 4H), 4.03 (t, 2H), 7.50 (s, 1H); ^{13}C NMR (CDCl_3) δ 28.1, 50.5, 69.1, 70.1, 70.4 (two signals), 75.2, 81.3, 156.7; HRMS (MALDI) calculated for $\text{C}_{11}\text{H}_{22}\text{NaN}_4\text{O}_5$ ($\text{M}+\text{Na}$): 313.1482. Found: 313.1496.

2-[2-(2-*N*-(*tert*-Butyloxycarbonyl)aminoxyethoxy)-ethoxy]ethylamine, 4. Compound **3** (1.36 g, 4.70 mmol) and triphenylphosphine (1.48 g, 5.64 mmol) were dissolved in 24 mL of THF and 8 mL of H_2O , and the resulting solution was stirred at room temperature for 2 h. Approximately 160 μL (eight drops) of 1 N NaOH was added, and the mixture was stirred for 18 h. The mixture was concentrated under vacuum, and the concentrate was purified by silica gel chromatography (80/8/2 $\text{CH}_3\text{CN}/\text{H}_2\text{O}/\text{con NH}_4\text{OH}$) to give 1.16 g (94%) of **4** as a yellow oil: ^1H NMR (CDCl_3) δ 1.50 (s, 9H), 1.90 (brd, 2H), 2.88 (t, 2H), 3.56 (t, 2H), 3.65 (m, 4H), 3.71 (m, 2H), 4.01 (m, 2H); HRMS (MALDI) calculated for $\text{C}_{11}\text{H}_{25}\text{N}_2\text{O}_5$ ($\text{M}+\text{H}$): 265.1758. Found: 265.1758.

Boc-protected aminoxy platform, 6. Triethylamine (157 μL , 114 mg, 1.13 mmol) was added to a stirred solution of 193 mg (0.188 mmol) of compound **5** (obtained as described in ref 12) in 1 mL of CH_2Cl_2 . The mixture was stirred at 0°C , and a solution of 298 mg (1.13

mmol) of compound **4** in 2 mL of CH_2Cl_2 was added. The mixture was allowed to come to room temperature and was stirred overnight. The mixture was cooled to 0°C , acidified with 1 N HCl, and partitioned between 20 mL of 1 N HCl and 4×20 mL of CH_2Cl_2 . The combined organic layers were washed with saturated NaHCO_3 solution, dried (MgSO_4), filtered, and concentrated to give 279 mg of yellow oil. Purification by silica gel chromatography (97/3 $\text{CH}_2\text{Cl}_2/\text{MeOH}$) provided 210 mg (73%) of **6** as an oil: ^1H NMR (CDCl_3) δ 1.49 (s, 36H), 3.35 (m, 8H), 3.46–3.78 (m, 44H), 4.04 (t, 8H), 4.21 (m, 12H), 5.80 (m, 4H), 7.91 (s, 4H); ^{13}C NMR (CDCl_3) δ 28.4, 41.0, 47.7, 48.2, 63.0, 64.8, 69.3, 69.5, 70.2, 70.3, 70.6, 75.4, 81.7, 156.0, 156.6, 157.1; mass spectrum (ESI) m/z calculated for $\text{C}_{62}\text{H}_{117}\text{N}_{10}\text{O}_{33}(\text{M}+\text{H})^+$: 1528.8. Found: 1528.5; HRMS (FAB) calculated for $\text{C}_{62}\text{C}_s\text{H}_{116}\text{N}_{10}\text{O}_{33}(\text{M}+\text{Cs})^+$: 1661.6761. Found: 1661.6672.

Aminoxy Dissolved in 10 mL of 1/9 trifluoroacetic acid/ CH_2Cl_2 , and the mixture was kept at room temperature for 3 h. A gentle stream of nitrogen was used to evaporate the solvent, and the residue was dissolved in a minimal amount of chromatography solvent (5/7.5/87.5 concentrated $\text{NH}_4\text{OH}/\text{H}_2\text{O}/\text{CH}_3\text{CN}$), which was used to load the mixture onto a silica gel column. Purification by silica gel chromatography (step gradient, 5/7.5/87.5 to 5/10/85 conc $\text{NH}_4\text{OH}/\text{H}_2\text{O}/\text{CH}_3\text{CN}$) provided 36 mg (82%) of **7 as a colorless oil: ^1H NMR (CDCl_3) δ 3.37 (m, 8H), 3.58 (m, 16H), 3.67 (s, 16H), 3.71 (m, 12H), 3.86 (m, 8H), 4.17–4.29 (m, 12H), 4.93 (brd, 8H), 5.91 (m, 4H); ^{13}C NMR (CDCl_3) δ 40.9, 47.7, 48.2, 62.9, 64.7, 69.4, 69.6, 70.2, 70.3, 70.5, 74.8, 156.1, 156.6; mass spectrum (ESI) m/z calculated for $\text{C}_{42}\text{H}_{85}\text{N}_{10}\text{O}_{25}(\text{M}+\text{H})^+$: 1129. Found: 1129; HRMS (MALDI) calculated for $\text{C}_{42}\text{H}_{85}\text{N}_{10}\text{O}_{25}(\text{M}+\text{H})^+$: 1129.5682. Found: 1129.5669.**

For the purpose of checking the purity of compound **7** by analytical HPLC, the tetraacetone oxime derivative was prepared as follows. Compound **7** (0.38 mg, 0.34 μmol) was dissolved in 240 μL of 0.1 M NaOAc pH 4.6 buffer in an HPLC sample vial. To the solution was added 10 μL of a solution of 49 μL of acetone in 2.0 mL of 0.1 M NaOAc buffer. The mixture was allowed to stand for 1 h, and an aliquot was analyzed by HPLC (4.6 mm $\times$ 250 mm C_{18} column, 1 mL/min, 210 nm detection, gradient, 10–60% B over 20 min, A = 0.1% TFA/ H_2O , B = 0.1% TFA/ CH_3CN , t_R = 19 min); mass spectrum of collected eluent (ESI) m/z calculated for $\text{C}_{54}\text{H}_{101}\text{N}_{10}\text{O}_{25}(\text{M}+\text{H})^+$: 1289. Found: 1289.

Recombinant Synthesis of the First Domain of $\beta_2\text{GPI}$, **9. Expression of Domain 1 Polypeptide with Histidine Expression Tag, **8**, in Insect Cells.** Compound **8** was prepared using the baculovirus expression vector system and isolated using nickel affinity chromatography as previously described (10).

Preparation of Compound **9 by Digestive Removal of Expression Tag.** Compound **8** was dialyzed against 1/9 glycerol/TBS to provide a solution of the polypeptide at a concentration of 2 mg/mL. A 16 mL aliquot of the solution (32 mg, 4.5 μmol) of compound **8** was added to 15 mL of carboxypeptidase A derivatized agarose beads (Sigma) that had been washed with six 30 mL portions of TBS. The mixture was incubated at 37°C for 2 days at which time the digestion was complete as evidenced by analytical mass spectrometry (ESI, conversion of m/z 8043 to 7060). The supernatant was recovered using TBS to wash the beads. The washes were combined to provide a solution of approximately 28 mg of **9** in 73 mL of TBS. Purification was accomplished by preparative HPLC (10 mm diphenyl column (Vydac); gradient 25% B to 40% B

over 40 min, 3 mL/min, A = 0.1% TFA/ H_2O , B = 0.1% TFA/ CH_3CN) to provide 23 mg (72%) of **9**.

Expression of Compound **9 in Yeast.** Compound **9** was expressed as a secreted product in *Pichia pastoris*. (13) Standard molecular biological techniques were used to create a fusion of domain 1 with the yeast alpha factor signal peptide in the vector pPICZalpha (Invitrogen Corporation, Carlsbad, CA). *Pichia* transformants were screened for secreted product using dot blots with an antibody to domain 1. Fermentation of selected clones yielded recombinant domain 1 that was correctly cleaved from the signal peptide as confirmed by mass spectrometry. The protein was isolated from the supernatant using a strong cation-exchange resin. Approximately 6 L of supernatant at pH 3 was loaded onto a 2-in column packed with strong cation-exchange resin (Toso Haas, Toyopearl SP-650M) using 0.2 M NaCl adjusted to pH 3 prepared by addition of HCl. The column was eluted with a step gradient (0.2 M NaCl, pH 3 to 0.4 M NaCl, pH 3) to provide approximately 400 mg of protein. Fractions containing the domain 1 polypeptide were pooled and purified by reversed phase HPLC (2-in C_4 column (Vydac); gradient 25% B to 40% B over 1 h, 50 mL/min, A = 0.1% TFA/ H_2O , B = 0.1% TFA/ CH_3CN) to provide 262 mg of compound **9**. An additional 109 mg of protein was isolated in which the methionine was oxidized to a sulfoxide. An additional 99 mg of partially purified compound **9** was isolated. Compound **9** was characterized using mass spectroscopy: mass spectrum (ESI, average m/z) calculated for $\text{C}_{320}\text{H}_{496}\text{N}_{82}\text{O}_{88}\text{S}_5$ 7060. Found: 7060.

Transamination of Domain 1; Synthesis of Compound **10.** Water and sodium acetate buffer were sparged with helium before use. Compound **9** (10.55 mg, 1.49 μmol) was dissolved in 0.5 mL of H_2O in a polypropylene tube, and 4.0 mL of 2 M pH 5.5 NaOAc buffer was added. A solution of 3.73 mg (14.9 μmol) of CuSO_4 in 0.5 mL of H_2O was added to the mixture, followed by a solution of 2.75 mg (29.9 μmol) of glyoxylic acid in 0.5 mL of 2 M pH 5.5 NaOAc buffer. The mixture was kept under nitrogen atmosphere and agitated gently for 18 h at which time the reaction appeared complete by analytical HPLC using a 4.6 $\times$ 250 mm, 300 $\text{\AA}$, 5 μm , diphenyl column (Vydac) with detection at 280 nm (1 mL/min; gradient 25–45% B, 0–20 min, A = 0.1% TFA/ H_2O , B = 0.1% TFA/ CH_3CN). Approximate retention times are as follows: domain 1, 13.2 min; transaminated domain 1, 13.7 min; oxidized transaminated domain 1, 13.4 min). The mixture was diluted to a volume of 20 mL with H_2O , filtered, and purified by HPLC (22.4 $\times$ 250 mm, 300 $\text{\AA}$, 10 μm , diphenyl column (Vydac) (12 mL/min; gradient 25%–40% B, 0–40 min, A = 0.1% TFA/ H_2O , B = 0.1% TFA/ CH_3CN). Fractions containing pure transaminated domain 1 (compound **10**), as evidenced by analytical HPLC, were pooled and lyophilized to provide 5.0 mg (48%) of compound **10**: mass spectrum (ESI, average m/z) calculated for $\text{C}_{320}\text{H}_{493}\text{N}_{81}\text{O}_{89}\text{S}_5$: 7059. Found: 7041 (loss of H_2O).

Synthesis of Tetravalent Domain 1 Conjugate, LJP 993. Compound **10** (5.20 mg, 7.37×10^{-7} mol) was dissolved in 2.0 mL of He sparged 0.1 M sodium acetate pH 4.60 buffer in a polypropylene tube. To the mixture was added 15.07 μL (139 μg , 1.23×10^{-7} mol) of a 8.147 $\mu\text{mol}/\text{mL}$ solution of compound **7** in 0.1 M sodium acetate pH 4.60 buffer. The mixture was agitated gently under nitrogen for 23 h at which time the reaction appeared to be complete by analytical HPLC using a 4.6 mm $\times$ 250 mm, 300 $\text{\AA}$, 5 μm , diphenyl column (Vydac) with detection at 280 nm (1 mL/min; gradient 25–45% B, 0–20 min, A = 0.1% TFA/ H_2O , B = 0.1% TFA/ CH_3CN). Approximate

retention times are as follows: compound **10**, 13.7 min; LJP 993, 17.2 min). The mixture was diluted with water to a volume of 5 mL and purified by HPLC (10 $\times$ 250 mm, 300 Å, 5 μ m, diphenyl column (Vydac) (3 mL/min; gradient 25–45% B, 0–40 min, A = 0.1% TFA/H₂O, B = 0.1% TFA/CH₃CN). Fractions containing pure LJP 993, as evidenced by analytical HPLC, were pooled and lyophilized to provide 1.73 mg (48%) of LJP 993: mass spectrum (ESI, average *m/z*) calculated for C₁₃₂₂H₂₀₄₈N₃₃₄O₃₇₇S₂₀: 29 294. Found: 29 294.

Domain 1 Polypeptide Analogue with C-Terminal Cysteine-Glutathione Disulfide, Compound 11. Compound **11** was prepared recombinantly using the baculovirus expression vector system and isolated using nickel affinity chromatography in a manner essentially similar to that previously described for domain 1 with a histidine expression tag (10). The purified fractions were pooled and dialyzed against pH 6.8 phosphate buffered saline containing 2 mM EDTA (PBS/EDTA/6.8) to provide approximately 100 mL of a solution of compound **11** at a concentration of 1 mg/mL: mass spectrum (ESI, average *m/z*) calculated for C₃₇₉H₅₇₈N₁₀₄O₁₀₃S₇: 8463. Found: 8463.

Reduction of Compound 11 to Provide Compound 12. The solution of compound **11** from the previous step was sparged with helium, and 1.2 g of Reductacryl beads were washed with helium-sparged PBS/EDTA/6.8 until the wash solutions tested negative for sulphydryl groups using Ellman's reagent (14). The freshly washed Reductacryl beads were added to the solution, and the mixture was gently mixed for 1 h and centrifuged at 150 g. The supernatant was collected and dialyzed against PBS/EDTA/6.8 at 4°C for 18 h using a 1000 MW cutoff membrane to provide a solution of compound **12**: mass spectrum (ESI, average *m/z*) calculated for C₃₆₉H₅₆₃N₁₀₁O₉₇S₆: 8158. Found: 8158.

Preparation of Domain 1 Immunogen, Compound 14. To the solution of compound **12** was added 12.9 mL of a 10 mg/mL solution of maleimidyl-activated KLH, compound **13**, and the mixture was mixed by rotation for 2 h at room temperature. The mixture was dialyzed against cold PBS at 4°C using a 25 000 MW cutoff membrane to remove unconjugated polypeptide. The resulting solution contained approximately 130 mg of protein at a concentration of approximately 0.8 mg/mL. An aliquot of the dialyzed sample was removed and shown to contain immunoreactive domain 1 as evidenced by binding antiphospholipid antibodies in an ELISA using patient-derived affinity purified antiphospholipid antibodies. A solution of unreacted maleimidyl-activated KLH, used as a negative control, did not bind antiphospholipid antibodies.

Determination *K_d* for Compounds 9 and LJP 993. Anti- β_2 GPI antibodies 6501 and 6626 were obtained from autoimmune thrombosis patients and affinity-purified using cardiolipin-containing multilamellar dispersions with bound β_2 GPI (15). Dissociation constants (*K_d*) were measured using surface plasmon resonance at 25°C with a flow rate of 10 μ L/min. Chip equilibration and binding studies were done with degassed HBS-EP buffer. Covalent coupling of antibodies to the CM5 chip was accomplished as follows. The carboxyl groups on the chip were activated by flowing 40 μ L of a solution of 0.05 M NHS and 0.2 M EDC in water over the chip. Affinity purified antibodies and normal IgG, used as a negative control, were immobilized by flowing 100 μ L of a 100 μ g/mL solution of the antibody in 10 mM acetate, pH 4.8, over the activated chip. Excess reactive groups on the

Table 1. *K_d* Values for Compound 9 and LJP 993 Binding to Surface Plasmon Resonance Sensor Chips Coated with Antibodies from Three Patients^a

	patient 6501	patient 6626	patient 6701
9	533 nM	456 nM, 363 nM	571 nM, 534 nM

^a Concentrations determined by absorbance at 280 nm using a molar extinction coefficient of 9531 L mol⁻¹ cm⁻¹ (1.35 mL mg⁻¹ cm⁻¹) for the domain 1 polypeptide (20).

chip surface were quenched with 40 μ L of 1 M ethanolamine, pH 8.5.

Solutions of **9** and LJP 993 at concentrations of 3.73, 1.24, 0.42, 0.14, 0.05, and 0.00 μ M in HBS-EP buffer were flowed over the chip, and response values were collected for 780 s. The chips were regenerated between sample exposures with 80 μ L of 0.1 M glycine-HCl (pH 2.1), 0.1 M NaCl. Since the approach to binding equilibrium was incomplete during the measurement period, the equilibrium binding value (*R_{eq}*) was determined by fitting the association curves to the equation [*R_t* = *R_{eq}*(1 - e^{-*k_s*(*t* - *t*₀)}) + *R*₀] using the manufacturer software (BiaEvaluation version 2.2, Uppsala, Sweden) where *R_t* is the measured response at time *t*, *R_{eq}* is the equilibrium plateau response, *t* is time, *t*₀ is initial time, *k_s* is an apparent association constant (*k_s* = *k_a**C* + *k_{dis}*, where *k_a* is the association constant, *C* is the analyte concentration, and *k_{dis}* is the dissociation constant), and *R*₀ is a response offset (Marquart-Levenberg algorithm).

Each titration association curve was corrected by subtracting the signal from a negative control (normal IgG) flow cell. The calculated *R_{eq}* were plotted versus concentration, and molar *K_d* values were calculated by fitting the data to a one site binding equation using GraphPad Prism software version 2.01. The values are reported in Table 1.

Ex Vivo Tolerance in Mice Immunized with Compound 14. Female C57Bl/6 mice 6–8 weeks of age (Jackson Laboratories, Bar Harbor, ME) were immunized with compound **14**, a conjugate of domain 1 polypeptide covalently attached to KLH. Five mice were used for each dosing group. The immunizations were accomplished by intraperitoneal (IP) injection of 0.5 mL of a solution containing 10 μ g of compound **14** precipitated on 2 mg of alum and 2 $\times$ 10⁹ *B. pertussis* organisms as an adjuvant (16). Three weeks after immunization, spleens were harvested and made into a single cell suspension. The cells were incubated in complete RPMI-1640 medium (Gibco/BRL) at 37°C for 1 h with the indicated concentrations of LJP 993. The cells were washed three times and suspended at a concentration of approximately 1 spleen per 1.5 mL with Hanks' balanced salt solution (Gibco). The washed cells from one-third of a spleen (0.5 mL) were transferred IP into irradiated (650R, ⁶⁰Co) syngeneic recipient mice (C57Bl/6). One day later the recipient mice were boosted with an IP injection of a solution of 10 μ g of conjugate **14** in 0.5 mL of PBS. Seven days after boosting, the mice were bled, and their sera were analyzed for anti-KLH antibodies and anti- β_2 GPI antibodies.

ELISA Assay for Measurement of Anti-KLH Antibodies. The amount of anti-KLH antibodies was determined relative to a standard pool of plasma. Each test sample was run in duplicate at three dilutions. The standard pool was obtained from mice that had been primed and boosted with compound **14**, as described for the ex vivo tolerance experiments. Standard curves were generated by testing eight dilutions of the standard pool in duplicate. Wells of 96-well Falcon plates (Becton

Dickinson and Co., NJ) were coated with KLH (Pacific Biomarine) by adding 100 μL of a 4 $\mu\text{g}/\text{mL}$ solution of KLH in 0.1 M sodium carbonate buffer pH 9.5. The plates were incubated at 4 $^\circ\text{C}$, overnight, and washed three times with PBS. The wells were then treated with 0.5% bovine serum albumin (BSA) in PBS for 1 h at room temperature. The plates were again washed three times with PBS and treated with 100 μL of serum sample in 0.5% BSA-PBS for 1 h at 37 $^\circ\text{C}$. The plates were again washed three times with PBS, and all wells were treated with 100 μL of alkaline phosphatase conjugated rabbit-anti-mouse IgG (gamma chain specific) (AP-anti-MIgG, # 61-022, Zymed) which had been diluted 1/1000, for 1 h at 37 $^\circ\text{C}$. The plates were washed three times with PBS, treated with chromogenic substrate, and incubated for 30 min at room temperature.

ELISA Assay for Measurement of anti- $\beta_2\text{GPI}$ Antibodies. The amount of anti- $\beta_2\text{GPI}$ antibodies was determined relative to the same standard pool of plasma used to determine the amount of anti-KLH antibodies. Each test sample was run in duplicate at three dilutions. Standard curves were generated by testing eight dilutions of the standard pool in duplicate. Wells of 96-well Maxisorp plates (Nunc-Nalgene) were coated by treating overnight with 50 μL of a 5 $\mu\text{g}/\text{mL}$ solution of $\beta_2\text{GPI}(\text{His})_6$ (10) in pH 9.5 0.1 M sodium carbonate. The wells were washed with PBS and then blocked for 1 h with reconstituted 2% nonfat dry milk (NFDm). The wells were washed with PBS and treated with 50 μL of serial dilutions of individual mouse serum, in 2% NFDm, for 1 h at room temperature. The wells were washed with PBS

and treated for 1 h at room temperature with 50 μL of alkaline phosphatase conjugated rabbit-anti-mouse IgG (gamma chain specific) (AP-anti-MIgG, # 61-022, Zymed) which had been diluted 1/1000, for 1 h at 37 $^\circ\text{C}$. The plates were washed three times with PBS, treated with chromogenic substrate, and incubated for 30 min at room temperature.

RESULTS

A tetravalent aminoxy platform was developed to which glyoxylated domain 1 could be attached. The approach taken is described as follows. Heterobifunctional linker 4 was prepared as described in Scheme 1. Thus 1,2-bis(2-iodoethoxy)ethane, compound 1 (obtained as described in ref11), was treated with 0.25 equiv of *N*-(*tert*-butoxycarbonyl)hydroxylamine and DBU to provide compound 2 (17). Compound 2 was converted to azide 3 by treatment with sodium azide in DMF. The azide of compound 3 was subsequently reduced with triphenylphosphine in THF/water to provide the amine-containing linker, compound 4.

The linkers were attached to a tetrameric platform intermediate to provide the tetrameric platform, compound 7, as described in Scheme 2. Compound 5 was obtained using a one-pot two-step procedure that is a convenient approach to multivalent platforms comprised of branched carbamates (12). Compound 5 has four 4-nitrophenyl carbonate esters that react with compound 4 in the presence of triethylamine to provide the tetra-carbamate ester, 6. Removal of the Boc protective groups from compound 6 was accomplished using 10% trifluoroacetic acid in CH_2Cl_2 to yield the tetra-aminoxy platform 7. Purification of 7 was accomplished using silica gel chromatography under basic conditions. Under acidic conditions, compound 7 is particularly reactive with trace aldehydes and ketones; however, at alkaline pH compound 7 is reasonably stable and can be stored in solution (1/1 100 mM pH 8.0 tris acetate/acetonitrile) for extended periods of time. For analytical purposes, it was convenient to derivatize compound 7 as an acetone oxime which was amenable to HPLC analysis.

(a) carboxypeptidase A; (b) pH 5.5, 2 M NaOAc, CuSO₄, glyoxylic acid; (c) compound 7, pH 4.6, 100mM NaOAc.

A tetravalent conjugate of domain 1, LJP 993, was prepared in a two-step process involving site-specific introduction of an aldehyde functionality at the N-terminus of compound 9 followed by oxime formation with the tetravalent aminooxy platform, compound 7, as described in Scheme 3. Recombinant human domain 1, compound 9, was produced in two different expression systems. Initially, it was produced in insect cells using the baculovirus expression system using a histidine affinity tag at the carboxy-terminus which is comprised of the additional amino acid sequence VGHHHHHHH at the carboxy terminus (10). The protein was isolated by affinity chromatography on a nickel column providing compound 8. The expression tag was removed by digestion with an immobilized form of carboxypeptidase A, which cannot digest the arginine, providing the domain 1 polypeptide 9. Compound 9 could also be expressed as a secreted product in *P. pastoris* using standard techniques (13, 18). Purification of compound 9 produced from *Pichia* was accomplished using cation exchange chromatography. Compound 9 produced by either method could be further purified using reversed phase preparative HPLC.

The N-terminal glycine of domain 1 was converted to a glyoxyl group by treatment of the polypeptide with 10 equiv of CuSO₄ and 20 equiv of glyoxylic acid in 2.0 M sodium acetate buffer at pH 5.5. Domain 1 contains one methionine which was prone to oxidation. It was important to exclude oxygen in the reaction to avoid converting the methionine thioether to a sulfoxide. Methionine oxidation could be minimized by using He-sparged buffer and performing additions of reagents under a nitrogen atmosphere, however, even with those precautions some oxidation always took place. Purification of the transaminated polypeptide, compound 10, was accomplished by reverse phase preparative HPLC.

LJP 993 was prepared by treating compound 7 with an excess of compound 10 in 0.1 M sodium acetate buffer at pH 4.6. The reaction appeared to be complete after approximately 1 day as evidenced by analytical HPLC.

Figure 1. Surface plasmon resonance response plots for LJP 993 and 9 flowing over patient 6501 antibody covalently bound to sensor chip.

Purification was accomplished by preparative reverse phase HPLC.

The ability of LJP 993 and domain 1 to bind to affinity purified antibody from three patients with elevated anticardiolipin antibodies (anti- β_2 GPI) was measured using surface plasmon resonance (Biacore). Affinity purified anti- β_2 GPI antibodies from three autoimmune thrombosis patients were immobilized on sensor chips following the manufacturer's protocol. Solutions of compound 9 or LJP 993 were passed over the sensor surface, and responses were measured. No loss of antibody binding activity was observed in the sensorgram for compound LJP 993 as compared with compound 9; rather, an apparent increase in affinity was observed which roughly corresponds to the 4-fold increase in valence. Table 1 presents dissociation constants (K_d) which were calculated from the equilibrium response plateaus (Req) (15, 19). Typical response plots are described in Figure 1 for the binding of 9 and LJP 993 to the patient antibody 6501 bound to a sensor chip.

The ability of LJP 993 to tolerize B cells was tested in mice immunized with a conjugate of domain 1 and keyhole limpet hemocyanin (KLH). Spleen cells were treated in vitro to avoid having to deal with drug clearance and distribution. Recombinant human domain 1 with an additional cysteine and a histidine expression tag was expressed in insect cells using the baculovirus expression vector system (10). Compound 11 was isolated as a glutathione mixed disulfide using nickel affinity

Scheme 4. Preparation of the Domain 1 Polypeptide with an N-Terminal Cysteine**Scheme 5. Preparation of Immunogen**

chromatography. The glutathione disulfide was removed by selective reduction using immobilized dithiothreitol to provide compound **12**, a form of domain 1 with a free thiol (Scheme 4).

Compound **12** was reacted with maleimidyl-KLH, compound **13** (Pierce), to provide compound **14**, a conjugate of domain 1 on KLH as shown in Scheme 5. Small molecules including unreacted **12** were removed by dialysis. KLH is an approximately 4 MDa multidomain protein complex (21), so chemical characterization of compound **14** was not practical. When coated on plastic microtiter plates, however, compound **14** was able to bind anti- β_2 GPI antibodies as demonstrated in a direct binding ELISA. Most importantly, conjugate **14** elicited an immune response against domain 1 when used to immunize mice (data not shown).

Spleen cells of immunized mice were treated with LJP 993 and transferred to naive syngeneic mice whose immune systems had been compromised by irradiation. One day later, the mice were boosted with compound **14**. Seven days after boosting the mice were bled, and their sera were analyzed for anti-KLH antibodies and anti-domain 1 antibodies using ELISA assays with either KLH or β_2 GPI coated on plastic microtiter plates. Mice treated with compound LJP 993 showed a dose-dependent reduction of anti-domain 1 antibodies, whereas the anti-KLH response was the same in all groups, demonstrating that the effect was antigen specific. These results, presented in Table 2 and graphically in Figure 2, show that treatment of primed cells with LJP 993 suppresses antibody formation.

DISCUSSION

The objective was to prepare a tetravalent domain 1 conjugate with the following properties. Each domain 1 polypeptide should retain the ability to bind anti- β_2 GPI antibodies, and the conjugate should be biologically stable, nontoxic, and nonimmunogenic. At the outset, it was recognized that it would be preferable that the conjugate comprises a site-specific attachment of the polypeptide to a tetravalent platform and that the polypeptide retain both affinity and specificity of antibody binding.

Table 2. Relative Amounts of Anti-Domain 1 Antibody Measured in an ELISA Assay

conc of LJP 993 (μ M)	anti-domain 1 antibodies		anti-KLH antibodies	
	amounts ^a	% reduct	amounts ^a	% reduction
0	83.3 $\pm$ 26.2		103.0 $\pm$ 27.2

**Figure 2.** Graphical presentation of the data in Table 2.

For a multivalent B cell epitope to function as a toleragen, it is necessary that it does not contain T cell epitopes which would make it immunogenic. The domain 1 polypeptide did not stimulate T cells harvested from mice immunized with **14**, as evidenced by lack of thymidine uptake by those cells after treatment with compound **9** (data not shown).

The chemical modification of proteins has been an area of intense interest over the past decades, and a number of excellent reviews have been published (22–25). Site-specific modifications of proteins can provide well-defined derivatives that retain native biological activity; whereas, other less specific modifications tend to provide heterogeneous derivatives with possible loss of activity. Oxime bond formation has been used extensively to form bioconjugates by the reaction of one molecular partner, containing an aminoxy group, with another partner containing an aldehyde or ketone. Oxime bond formation involving polypeptides is generally a very selective and predictable reaction. The reaction yields are good because the functional groups present in native polypeptides are not reactive with aldehyde or aminoxy groups, neither of which is present in native polypeptides.

Formation of oximes from aminoxy compounds is chemically analogous to hydrazone formation using hydrazides (26); however, the oxime bond is reported to be hydrolytically more stable than the hydrazone bond (27). Oxime bond formation has been used to chemically ligate aminoxy-containing synthetic polypeptide segments with ketone-containing polypeptide segments (28). Recently, aminoxy containing saccharides have been chemically attached to ketones generated on the surfaces of cells (29). Aminoxy-derivatized PEG has been attached site-specifically to the N-terminus of polypeptides which have an N-terminal glyoxyl group (27). The strategy described in this report, for attaching the domain 1 polypeptide to

a multivalent platform, was to generate a glyoxyl group at the N-terminus of the polypeptide. The glyoxyl group would provide an effective handle for a selective reaction with aminoxy groups on a multivalent platform and provide a well-defined multivalent domain 1 conjugate.

There are two ways to generate a glyoxyl group at the N-terminus of a polypeptide. A process, called transamination, converts the N-terminus to an aldehyde or ketone (30). Transamination of a polypeptide with a glycine at the N-terminus converts the glycine to a glyoxyl group. N-terminal glyoxyl groups can also be generated from N-terminal serine or threonine containing polypeptides by periodate oxidation (27, 31). There are a number of precedent bioconjugates of transaminated polypeptides. For instance, transaminated staphylococcal nuclease has been conjugated to dinitrophenylhydrazine, via hydrazone formation (32). Transaminated IL-1 receptor antagonist has been conjugated to aminoxy modified poly(ethylene glycol) by forming an oxime bond (27). Since recombinantly produced domain 1 polypeptide has an N-terminal glycine, a logical approach toward creating a glyoxylated derivative was to convert the glycine to a glyoxyl group through a transamination reaction.

Transamination of the domain 1 polypeptide provided a site for attachment to a multivalent aminoxy platform. The resulting oxime conjugate, LJP 993, retained biological activity as determined using surface plasmon resonance to measure affinity for anti- β_2 GPI antibody from autoimmune thrombosis patients, and it suppressed anti-domain 1 antibody production in animals immunized with domain 1. These results indicate that multivalent domain 1 conjugates can act as B cell toleragens in vitro in a dose-dependent manner when the cells are exposed to drug for 1 h. In addition to dose, the efficacy of a toleragen may be related to the time of exposure of drug to the B cell, the affinity of the epitopes for the B cell receptors, and the physical properties of the toleragenic molecule which affect its ability to aggregate B cell receptors.

Future studies are aimed at developing a therapeutic for autoimmune thrombosis based on the multivalent presentation of domain 1 with pharmacokinetics, affinity, and dimensions and flexibility of platform all expected to influence the potency of the drug.

Synthesis of a Hoechst 33258 Analogue Amino Acid Building Block for Direct Incorporation of a Fluorescent, High-Affinity DNA Binding Motif into Peptides

Carsten Behrens,^{†,‡} Niels Harrit,[†] and Peter E. Nielsen^{*,§}

Department of Chemistry, University of Copenhagen, Universitetsparken 5, DK-2100, Copenhagen, Denmark, and Center for Biomolecular Recognition, Department of Biochemistry B, The Panum Institute, Blegdamsvej 3c, DK-2200, Copenhagen, Denmark. Received May 9, 2001; Revised Manuscript Received July 15, 2001

The synthesis of a new versatile “Hoechst 33258-like” Boc-protected amino acid building block for peptide synthesis is described. It is demonstrated that this new ligand is an effective mimic of Hoechst 33258 in terms of DNA affinity and sequence specificity. Furthermore, this minor groove binder was conjugated to a DNA condensing peptide (KSPKKAKK) by continuous solid-phase peptide synthesis, and the conjugate exhibited increased DNA affinity (ca. 10-fold), but similar sequence preference compared to Hoechst 33258 as analyzed by DNase I footprinting. Finally, the fluorescence quantum yield of the new chromophore is found to increase 30% upon binding to double stranded DNA.

INTRODUCTION

Sequence-specific recognition of DNA by proteins such as transcription factors and repressors play a central role in cellular gene regulation at the transcriptional level and is also crucial in DNA replication and recombination. One long-term objective of structural and biophysical studies of protein DNA interactions is to understand the molecular basis for these processes (1, 2). Such understanding can provide valuable input to the development of new principles for design of DNA recognizing drugs for direct modulation of gene expression, e.g., for use as gene therapeutic drugs (3).

Protein DNA recognition relies on hydrogen bonds, electrostatic interactions, and van der Waals contacts between individual amino acid residues of the protein and nucleotides in the cognate DNA target. However, no simple “amino acid–nucleotide” recognition code has been identified, and the sequence specificity of protein binding to DNA is therefore not a “digital readout” but rather an “analogue readout” of the DNA base sequence in which the entire binding region of the protein exhibit “molecular complementarity” to the major (or more rarely the minor) groove of the DNA target (1, 2, 4).

Most success so far in developing small synthetic ligands for sequence specific recognition of double stranded DNA has come from using major groove binding, triple helix forming oligonucleotides (5), helix-invading peptide nucleic acids (PNA) (6), and minor groove binding, hairpin polyamides (7). Furthermore, it has been possible to use “zink-finger” peptide modules (each recognizing three base pairs) to construct sequence-targeted proteins (8). Finally, several attempts without major breakthroughs have been described to select small peptides from chemical libraries that sequence selectively bind

double-stranded DNA, to discover novel recognition motifs and/or principles (9–10).

We recently described such a combinatorial method for probing small peptides for DNA minor groove recognition potential (9). Bead-supported tripeptides, each placed between *N*-methylpyrrole amino acid containing polyamides operating as DNA minor groove binding anchoring points, were synthesized in a library format and subsequently screened against double-stranded DNA probes (9). Although reliable procedures are available for synthesizing polyamides of *N*-methylpyrrole amino acids by peptide coupling of protected *N*-methyl-4-aminopyrrole-2-carboxylate units (11), their synthesis is resourceful as three or more interlinked units are required for obtaining strong DNA minor groove binding. To improve our methodology, we aimed to minimize the number of synthetic operations needed for library production and therefore required a monomer building block that in a single synthesis step introduces a DNA minor groove binding anchoring point into peptides.

The fluorescent chromosomal stain Hoechst 33258 is a well-known DNA binding agent made of two linked benzimidazoles, with a phenol and a *N*-methylpiperazine substituent in either end. The interaction between Hoechst 33258 and double-stranded DNA has been extensively studied using DNase I footprinting (12), electric linear dichroism, and solution-phase NMR techniques (13) as well as X-ray crystallography (14–16). Studies have shown that Hoechst 33258 binds with high affinity to the minor groove of double stranded B-DNA with a strong preference for AT-rich regions.

As a part of our continuous studies on peptide DNA interactions, we now report the synthesis of a novel protected amino acid based on Hoechst 33258. The building block is suitable for use in solid-phase peptide synthesis following Boc strategy and designed to allow for direct incorporation of one or multiple DNA minor groove-binding motifs into any arbitrary position of a peptide sequence. We illustrate the potential of this novel Hoechst 33258 amino acid analogue by preparing a small series of peptides and 9-amino acridine conjugates and

analyzing their DNA binding properties by DNaseI footprinting.

EXPERIMENTAL SECTION

General Comments. All reagents (Aldrich, Fluka, or NovaBiochem) and solvents (LabScan) were of standard quality and used without further purification unless indicated. NMR spectra were recorded on either a Bruker 250 MHz or a Varian 400 MHz spectrometer with tetramethylsilane (^1H and ^{13}C) as internal standard. Melting points were recorded on a Büchi melting point apparatus and are uncorrected. Microanalyses were performed at The Microanalytical Laboratory, Department of Chemistry, University of Copenhagen.

2-(4-Cyanophenyl)benzimidazole-5-carboxylic Acid (3). 3,4-Diaminobenzoic acid (4.00 g, 26 mmol) and *p*-cyanobenzaldehyde (3.45 g, 26 mmol) were dissolved in nitrobenzene (120 mL) and heated to 150 °C. After 1 h, a turbid solution was obtained. DMF (20 mL) was added to dissolve the precipitate, and heating was resumed for an additional 5 h (TLC¹ monitoring in $\text{CHCl}_3/\text{NEt}_3/\text{MeOH}$ (7:1:2 v/v/v)). The mixture was cooled on an ice bath, and the crystals that separated out were collected by filtration and washed several times with cold petroleum ether to remove traces of nitrobenzene. Recrystallization from ethanol/water afforded 5.02 g (73%) of the title material. $R_f = 0.45$ in $\text{CHCl}_3/\text{NEt}_3/\text{MeOH}$ (7:1:2 v/v/v). Mp > 300 °C. ^1H NMR (DMSO- d_6) δ : 7.70 (d, 1H); 7.86 (dd, 1H); 8.04 (d, 2H); 8.22 (d, 1H); 8.37 (d, 2H), 12.75 (bs, 1H). ^{13}C NMR (DMSO- d_6) δ : 112.78; 115.17; 117.06; 117.82; 124.33; 125.94; 127.49; 133.19; 133.90; 139.59; 142.23; 151.82; 168.13. MS-FAB+: 264.09 [M + H]⁺. Anal. Calcd for $\text{C}_{15}\text{H}_9\text{N}_3\text{O}_2 \cdot \text{H}_2\text{O}$: C, 64.05; H, 3.94; N, 14.93. Found: C, 64.11; H, 3.96; N, 14.78.

Ethyl *N*³-(2-(4-Cyanophenyl)benzimidazole-5-carboxyl)-3,4-diaminobenzoate (4). 2-(4-Cyanophenyl)benzimidazole-5-carboxylic acid (**3**, 5.02 g, 19 mmol) was suspended in DMF (120 mL). HBTU (7.22 g, 19.0 mmol) was added followed by DIEA (5.0 mL). The mixture was stirred at room temperature for 10 min before the addition of ethyl 3,4-diaminobenzoate (3.43 g, 19 mmol). After the mixture was stirred for 24 h at room temperature, water (400 mL) was added. The precipitated product was collected by filtration, washed with water three times, and dried in a vacuum oven overnight. Yield: 5.75 g (71%). $R_f = 0.4$ in $\text{MeOH}/\text{CH}_2\text{Cl}_2$ (1:9, v/v). MS-FAB+: 426.16 [M + H]⁺. Mp = 222–225 °C. ^1H NMR (DMSO- d_6) δ : 1.28 (t, 3H); 4.22 (q, 2H); 5.83 (bs, 2H); 6.81 (d, 1H); 7.58 (d, 1H); 7.70 (m, 1H); 7.83 (d, 1H); 7.96 (d, 1H); 8.06 (d, 2H); 8.36 (m, 1H); 8.40 (d, 2H); 9.73 (bs, 1H); 13.46 (bs, 1H). ^{13}C NMR (DMSO- d_6) δ : 14.45; 59.82; 111.84; 112.38; 114.72; 116.62; 118.63; 119.21; 119.46; 122.21; 123.57; 127.33; 128.38; 129.00; 133.12; 133.96; 144.98; 146.29; 148.47; 151.78; 165.76; 166.12. Anal. Calcd for $\text{C}_{24}\text{H}_{19}\text{N}_5\text{O}_3$: C, 67.76; H, 4.50; N, 16.46. Found: C, 66.57; H, 4.31; N, 16.56.

Ethyl 2-(2-[4-Cyanophenyl]benzimidazol-5-yl)benzimidazole-5-carboxylate (5). Ethyl *N*³-(2-(4-cyanophenyl)benzimidazole-5-carboxyl)-3,4-diaminobenzoate (**4**, 5.75 g, 13.5 mmol) was suspended in nitrobenzene (120 mL), and concentrated H_2SO_4 (0.5 mL) was added. The mixture was heated to 190 °C for 12 h during which time complete ring closure took place according to TLC

($\text{MeOH}/\text{CH}_2\text{Cl}_2$ (1:9, v/v)). After being cooled to room temperature, the product was precipitated as an oil by addition of petroleum ether. The adhesive oil turned into a fine powder after repeated addition and decanting of petroleum ether. The powder, which contained traces of hydro sulfate salts, was dissolved in a mixture of DMF (120 mL), saturated Na_2CO_3 (50 mL), and water (150 mL) by heating. The clear dark solution thus obtained was allowed to cool slowly, and the precipitating product was collected by filtration. $R_f = 0.45$ in $\text{MeOH}/\text{CH}_2\text{Cl}_2$ (1:9, v/v). The yield after oven-drying overnight was 4.15 g (75%). Mp = 257–259 °C. ^1H NMR (DMSO- d_6) δ : 1.35 ppm (t, 3H); 4.33 (q, 2H); 7.67 (d, 1H); 7.80 (d, 1H); 7.83 (d, 1H); 8.04 (d, 2H); 8.14 (d, 1H); 8.19 (s, 1H); 8.37 (d, 2H); 8.45 (s, 1H). ^{13}C NMR (DMSO- d_6) δ : 14.28 ppm.; 60.92; 112.52; 114.24; 115.45; 118.52; 119.84; 122.33; 123.39; 124.86; 125.41; 127.34; 129.95; 132.89; 135.08; 135.39; 138.40; 139.72; 141.21; 151.75; 152.83; 165.55. MS-FAB+: 408.09 [M + H]⁺. Anal. Calcd for $\text{C}_{24}\text{H}_{17}\text{N}_5\text{O}_2 \cdot \text{H}_2\text{O}$: C, 67.75; H, 4.50; N, 16.46. Found: C, 67.49; H, 4.32; N, 16.40.

Ethyl 2-[2-[4-(*tert*-Boc-aminomethyl)phenyl]benzimidazol-5-yl]benzimidazole-5-carboxylate (6). Ethyl 2-(2-[4-cyanophenyl]benzimidazol-5-yl)benzimidazole-5-carboxylate (**5**, 4.00 g, 9.8 mmol) was dissolved in DMF (120 mL) by heating. After the solution was cooled to room temperature, di-*tert*-butyl pyrocarbonate (2.50 mL, 10.8 mmol) and DIEA (6.0 mL, mmol) were added, followed by palladium catalyst (10% on charcoal, 520 mg). The solution was then hydrogenated at room temperature for 48 h (1 atm hydrogen pressure). The catalyst was removed by filtration and the solvent removed by rotary evaporation, in vacuo, to leave a dark tar. This was redissolved in ethanol (100 mL), and the product was precipitated as a solid by addition of water (200 mL). Pure title material was obtained after recrystallization from ethanol/water. Yield: 4.20 g (83%). $R_f = 0.4$ in $\text{MeOH}/\text{CH}_2\text{Cl}_2$ (1:9, v/v). Mp: 195–200 °C dec. ^1H NMR (DMSO- d_6) δ : 1.36 ppm (t, 3H); 1.41 (s, 9H); 4.22 (d, 2H); 4.34 (q, 2H); 7.44 (d, 2H); 7.51 (t, 1H); 7.68 (d, 1H); 7.75 (d, 1H); 7.85 (d, 1H); 8.10 (d, 1H); 8.17 (d, 2H); 8.20 (s, 1H); 8.42 (s, 1H). ^{13}C NMR (DMSO- d_6) δ : 14.36; 28.34; 43.34; 60.58; 78.06; 121.62; 123.31; 123.54; 123.65; 126.82; 127.60; 128.11; 142.78; 153.15; 154.83; 155.96; 166.35; 197.16 (only the strong signals are reported). MS-FAB+: 512.26 [M + H]⁺. Anal. Calcd for $\text{C}_{29}\text{H}_{29}\text{N}_5\text{O}_4 \cdot 3 \text{H}_2\text{O}$: C, 61.58; H, 6.23; N, 12.38; found: C, 61.49; H, 6.01; N, 12.52.

2-[2-[4-(*tert*-Butoxycarbonylaminomethyl)phenyl]benzimidazol-5-yl]benzimidazole-5-carboxylic Acid (7). Ethyl 2-[2-[4-(*tert*-Boc-aminomethyl)phenyl]benzimidazol-5-yl]benzimidazole-5-carboxylate (**6**, 2.98 g, 5.83 mmol) was dissolved in ethanol (80 mL), and aqueous sodium hydroxide solution (1 N, 50 mL) was added. The clear solution was heated to reflux for 2 h. The solution was cooled to room temperature and the reaction volume reduced to one-third by rotary evaporation, in vacuo. Water was added to a total volume of 150 mL and the clear solution extracted with diethyl ether (2 $\times$ 100 mL). The solution was acidified to pH 3.5 with 4 N HCl and extracted twice with *n*-butanol. The organic phase was dried with Na_2SO_4 , filtered, and taken to dryness. The oil thus obtained was dissolved in a 5% ethanolic water solution by gentle heating, and after lyophilization of this solution, a fine white powder was obtained. Yield: 1.98 g (70%). $R_f = 0.3$ in $\text{CHCl}_3/\text{NEt}_3/\text{MeOH}$ (7:1:2, v/v/v). Mp > 300 °C. ^1H NMR (DMSO- d_6) δ : 1.28 (t, 3H); 4.07 (d, 2H); 7.41 (d, 2H); 7.48 (d, 1H); 7.70 (d, 1H); 7.84 (d, 1H); 8.08 (d, 1H); 8.15 (s, 1H); 8.23 (d, 2H); 8.42 (s, 1H). ^{13}C

¹ Abbreviations: CT-DNA (calf thymus DNA), DIEA (diisopropylethylamine), DMF (dimethylformamide), DMSO (dimethyl sulfoxide), HBTU (benzotriazol-1-yl 1,1,3,3-tetramethyluronium hexafluorophosphate), TFMSA (trifluoromethanesulfonic acid), TLC (thin-layer chromatography).

3-Dimethylaminopropyl 2-[2-[4-(Aminomethyl)-phenyl]benzimidazol-5-yl]benzimidazole-5-carboxamide (8). 2-[2-[4-(*tert*-Butoxycarbonylaminoethyl)-phenyl]benzimidazol-5-yl]benzimidazole-5-carboxylic acid (**7**, 250 mg; 0.51 mmol) was dissolved in dimethylformamide (8 mL), and 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU, 195 mg; 0.51 mmol) and diisopropylethylamine (DIEA, 500 μ L; 2.87 mmol) were added. The mixture was stirred at room temperature for 15 min, and then 3-(dimethylamino)propylamine (500 μ L; 3.97 mmol) was added. After being stirred for a further 2 h at room temperature, the solvent was removed by rotary evaporation to leave an oil. The oil was dissolved in saturated aqueous sodium hydrogen carbonate (20 mL). Aqueous sodium hydroxide (1 M, 4 mL) was added, and the solution was extracted twice with *n*-butanol (20 mL). The combined organic phases were dried with anhydrous sodium sulfate and taken to dryness to leave a colorless foam. The foam was suspended in 2 N aqueous hydrochloric acid (40 mL), and the suspension was refluxed until a clear solution was obtained. Solvent was removed, in vacuo, and the crystalline residue recrystallized from ethanol to leave the title material as a crystalline slightly hygroscopic powder. Yield: 130 mg (68%). Mp = 283–286 °C dec. ¹H NMR (D₂O, 250 MHz) δ : 1.97 ppm (d, 2H); 2.88 (s, 6H); 3.14 (d, 2H); 3.26 (t, 2H); 3.95 (s, 2H); 7.36–7.40 (m, 4H); 7.52 (s, 2H); 7.59 (s, 2H); 7.61 (s, 1H); 7.67 (s, 1H). Anal. Found: C, 51.26; H, 6.62; N, 15.48 (agree with the dihydrochloride pentahydrate). MS found 468.29; calcd for [C₂₇H₂₉N₇O + H]⁺ 468.58.

Spectroscopic Methods. Absorption spectra were recorded on a Perkin-Elmer UV-vis Lambda 16 spectrophotometer in 1 cm cells. Fluorescence spectra were recorded on an LS 50B Perkin-Elmer luminescence spectrometer in perpendicular geometry. In all excitation and fluorescence spectra shown, excitation and emission band-pass were 1 nm. All excitation spectra are corrected. However, no correction was performed for the wavelength-

dependent response function of the detection system. Concentration of CT-DNA was calculated using $\epsilon_{258} = 16\,800\text{ M}^{-1}\text{ cm}^{-1}$ pr. base-pair from the absorption at 256 nm (Figure 3, trace b) corrected for absorption of **8** (using the unbound absorption coefficient).

Oligomer Synthesis. Peptides and peptide conjugates were synthesized by standard Boc protocol on an MBHA resin at a loading of 0.1 mmol/g. Oligomers were cleaved off the resin using the low/high TFMSA procedure, purified by reversed-phase HPLC, and were characterized by MALDI-TOF mass spectrometry recorded on a Kratos Compact MALDI II instrument operating in the positive-ion mode, using 3,5-dimethoxy-4-hydroxycinnamic acid as the matrix (17).

DNA Footprinting. Footprinting with DNaseI was performed in 100 μ L of buffer (50 mM Tris-HCl, pH 7.4, 1 mM MgCl₂) using a 3'-³²P-end labeled *Eco*RI-*Pvu*II fragment of plasmid pUC19. The DNaseI was titrated to yield ca. 20% cleavage after 30 min incubation at room temperature (20 °C). The DNA was precipitated with 66% ethanol, 0.1 M K-acetate, washed, dried, and analyzed by electrophoresis in 10% polyacrylamide sequencing gels run in standard Tris-Borate-EDTA buffer, pH 8.3. Radioactive DNA bands were visualized by autoradiography (18).

RESULTS AND DISCUSSION

Chemistry. The construction of the 2-(2-arylbenzimidazol-5-yl)benzimidazole framework is outlined in Scheme 1 and essentially followed previously described strategies (19). Initially, 4-cyanobenzaldehyde (**1**) was condensed with 3,4-diaminobenzoic acid (**2**) under oxidative conditions, leaving 2-(4-cyanophenyl)benzimidazol-5-carboxylic acid (**3**) in 73% yield. Installation of the second benzimidazole moiety was accomplished in three steps: (1) conversion of **3** to its 1,2,3-hydroxybenzotriazole ester (HOBt ester) by reaction with HBTU, (2) condensation with ethyl 3,4-diaminobenzoate to form amide **4**, and finally, (3) acid-catalyzed ring closure using sulfuric acid in nitrobenzene (53% overall for the three steps). Reduction of the cyano group in **5**, in the presence of di-*tert*-butyl pyrocarbonate and DIEA, directly afforded the Boc-protected benzylic amine (**6**), which after saponification provided the target building block **7** in 70% yield.

Scheme 2^a

^a Key: (a) HBTU, DIEA in DMF, 10 min, rt, then 3-dimethylaminopropylamine in DMF, 2 h, rt; (b) 2 N HCl, reflux 10 min (68% overall).

Scheme 3

DNA Recognition of Conjugates. To evaluate the potential of this new amino acid, we used it to prepare a simple Hoechst 33258 analogue (**8**, Scheme 2), a conjugate to a DNA binding (condensing) peptide motif, that is found in histone H1 (20) (**9**), and a further conjugation of **9** to the DNA intercalator 9-amino acridine (**10**) (Scheme 3). All conjugates were synthesized on solid support starting with the peptide, and were characterized by MALDI-TOF mass spectrometry.

The DNA recognition properties of these compounds were evaluated by DNaseI footprinting (Figure 1) using a ³²P-end labeled plasmid DNA restriction fragment (Figure 2). Comparing the footprint produced by **8** with that of Hoechst 33258 shows close to identical (AT target) sequence preference of the two compounds. Concordant with this conclusion, an NMR study of a DNA–**8** complex shows AT-minor groove binding (21) fully analogous to that typically observed for Hoechst 33258. The present results (Figure 1a, e.g., compare lanes 4 and 10–11) also indicate a 4–8-fold higher affinity of **8** as compared to Hoechst 33258.

In terms of sequence specificity, the binding of the conjugates **9** and **10** is almost identical to that of Hoechst 33258 (and thus also identical to that of **8**). All major binding sites contain (A/T)₄ motifs (cf. Figure 2), exhibiting the following order of potency (5′-3′-orientation) as

judged from the concentration resulting in ca. 50% protection from DNaseI cleavage: AATTAAT ~ AATTT > AATT > ATTA > TTTAT > ATAA > TTAA. Furthermore, as estimated from the binding to the most 3′ ATTA target (and also the TTAA target), similar protection by **9** is achieved at 60-fold lower concentration than that required for Hoechst 33258 (compare, e.g., lanes 3 and 7 of Figure 1). Therefore, **9** binds to the DNA targets with ~60-fold higher affinity than Hoechst 33258, and thus with ca. 10-fold higher affinity than the nonconjugated **8**. Finally, no sequence-specific binding of the peptide alone (**11**, H-KSPKKAKK-NH₂) was detected by DNaseI footprinting. Therefore, conjugation of the cationic peptide, KSPKKAKK increases the DNA affinity of the minor groove binder by approximately 10-fold without affecting the sequence preference. Attachment of a DNA intercalating acridine to **9** yielding **10**, surprisingly only seem to contribute little additional affinity. As would be expected from the very limited sequence preference found for DNA binding of 9-aminoacridines (22), the sequence preference of **10** was not changed either as compared to **9**.

Fluorescence Properties. Hoechst 33258 is widely used as a DNA stain in molecular biology and in cytology based on the great increase in quantum yield from 0.01 to 0.6 of its bright blue fluorescence upon binding to DNA

Figure 1. Autoradiograms of DNaseI footprinting experiments. The compound used is indicated above the lanes, while the concentrations are indicated below the lanes. The putative binding sites are indicated by bars between the autoradiograms. S is an A/G sequence reaction, while C is a control without reagent.

(23). The dye shows pronounced preference for A/T-rich regions, but also exhibits multiple binding modes and distinct fluorescence emission spectra depending on dye/base pair ratios (24). As the benzimidazole derivative **8** is closely related to the Hoechst chromophore, we decided to investigate the fluorescence properties of the compound.

The electronic spectra of **8** and its complex with CT-DNA are displayed in Figure 3. The absorption spectrum (trace a) displays two absorption maxima in the range 250–400 nm. The long-wavelength absorption undergoes

a blue shift from 332 to 340 nm upon complexation with DNA (traces a and b). Upon excitation into the long wavelength band, unbound **8** fluoresces with a maximum at 390 nm (trace e). The spectral profile features an unresolved vibronic structure. However, the fluorescence from the **8**-DNA complex (trace f) is more intense (integrated intensity is up by 31% relative to unbound) and appears with three clearly resolved vibronic bands at 372, 392 (max), and 412 nm, corresponding to an average progression of 1300 cm^{-1} .

The excitation spectra derived from the fluorescence of compound **8** are seen to comply completely with the long wavelength absorption bands, whether in the free (traces a and c) or in the DNA-bound state (traces b and d). Furthermore, excitation spectra recorded with emission wavelengths set at the three vibronic bands at 372, 392 and 412 nm of trace f were found to be completely identical (spectra not shown), which implies that only one fluorescing species is present when **8** binds to DNA. The maximum observed at 280 nm in the excitation spectrum of DNA-bound **8** (trace d) indicates a small contribution of resonance energy transfer from DNA, the DNA absorption itself is seen going off-scale in trace b.

Figure 3. Electronic spectra of compound **8** and its complex with CT-DNA in water containing NaCl (0.1 M), KH_2PO_4 (10 mM), and EDTA (0.1 mM). In all spectra $[\mathbf{8}] = 2.2 \mu\text{M}$. In traces b, d, and f [basepair CT-DNA] = $22 \mu\text{M}$ (see the Experimental Section): (a) absorption, compound **8** ($\epsilon_{256} = 2.8 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$, $\epsilon_{332} = 3.3 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$); (b) absorption, compound **8** ($\lambda_{\text{max}} = 340 \text{ nm}$) bound to CT-DNA; (c) excitation ($\lambda_{\text{em}} = 400 \text{ nm}$) of compound **8** ($\lambda_{\text{max}} = 331 \text{ nm}$); (d) excitation ($\lambda_{\text{em}} = 400 \text{ nm}$) of compound **8** ($\lambda_{\text{max}} = 339 \text{ nm}$) bound to CT-DNA; (e) fluorescence ($\lambda_{\text{ex}} = 338 \text{ nm}$, same intensity scale as spectrum f) of compound **8** ($\lambda_{\text{max}} = 390 \text{ nm}$); (f) fluorescence ($\lambda_{\text{ex}} = 338 \text{ nm}$, same intensity scale as spectrum e) of compound **8** bound to CT-DNA.

In general, when comparing corresponding absorption and fluorescence bands, it is fairly common to see a vibrational fine structure in the absorption spectrum being lost in fluorescence (25). Far more unusual is the observation of fine structure in a fluorescence band that corresponds to a structureless absorption, as it can be seen for the **8**-DNA complex by comparing traces b and f of Figure 3, respectively. To a lesser extent the same feature is found in the spectra of unbound **8** (traces a and e).

The default example of this phenomenon is biphenyl for which a range of torsional conformers is present among ground-state molecules while the distribution narrows in on a more planar conformation in the excited singlet state (26). The same process seems to occur in case of **8** and is especially pronounced when it is bound to DNA. This conclusion is supported by the full-width-at-half-maximum (fwhm) values of the fluorescence spectra, being 4660 cm^{-1} for unbound **8** (trace e) and 3600 cm^{-1} for the **8**-DNA complex (trace f). The conformational distribution is narrower among the molecules of **8** when it is bound to DNA. Furthermore, the fluorescence appear at virtually the same wavelength whether **8** is free (trace e) or DNA bound (trace f). Most likely, DNA-bound **8** is already forced into planar configuration in the ground state. Thus, the Stoke shift is smaller (3900 cm^{-1} , traces b and f) when **8** is bound than in the unbound form (4490 cm^{-1} , traces a and e) indicating that less reorientation occurs in the excited state of **8** in the complex relative to the unbound molecule. This conclusion is also consistent with minor groove binding of **8**, which indeed requires (enforces) coplanarity of the two aromatic systems, as is also consistent with the NMR structure determination of the complex (21).

CONCLUSION

The presently described Hoechst analogue represents a versatile and convenient building block for introducing a high affinity minor groove binder into peptides or other

oligoamides via Boc solid-phase chemistry. Thus the monomer should also be useful in combinatorial library approaches. Furthermore, the fluorescence properties of the ligand may be exploited to study DNA binding.

^{99m}Tc-Labeled Neuropeptide Y Analogues as Potential Tumor Imaging Agents

Michael Langer,^{†,‡} Roberto La Bella,[§] Elisa Garcia-Garayoa,[§] and Annette G. Beck-Sickinger^{*,†}

Institute of Biochemistry, University of Leipzig, 04103 Leipzig, Germany, Department of Applied Biosciences, Federal Institute of Technology, 8057 Zürich, Switzerland, and Center for Radiopharmaceutical Science, Paul Scherrer Institute, 5232 Villigen, Switzerland. Received May 16, 2001; Revised Manuscript Received September 11, 2001

The possible use of neuropeptide Y (NPY) as a novel radiopeptide has been investigated. NPY is a 36-amino acid peptide of the pancreatic polypeptide family, which is expressed in the peripheral and central nervous system, and is one of the most abundant neuropeptides in the brain. Its receptors are produced in a number of neuroblastoma and the thereof derived cell lines. As structure–activity relationships of NPY are well-known, we could assume where a radionuclide might be introduced without affecting receptor affinity. We applied the novel [^{99m}Tc(OH₂)₃(CO)₃]⁺ aqua complex and PADA (2-picolylamine-*N,N*-diacetic acid) as bifunctional chelating agent. The peptides were synthesized by solid-phase peptide synthesis, and PADA was coupled to the side chain of Lys⁴ of the resin-bound peptide. Upon postlabeling of [K⁴(PADA)]-NPY, ^{99m}Tc(CO)₃ did not only bind to the desired PADA, but presumably as well to the His in position 26. Since the replacement of His²⁶ by Ala only slightly decreased binding affinity, [K⁴(PADA),A²⁶]-NPY was specifically postlabeled, and the ¹⁸⁵Re surrogate maintained high binding affinity. Furthermore, the prelabeling approach has been applied for the centrally truncated analogue [Ahx^{5–24}]-NPY, which is highly selective for the Y₂ receptor. The resulting Ac-[Ahx^{5–24},K⁴(^{99m}Tc(CO)₃-PADA)]-NPY was produced with a yield of only 16%. Therefore, postlabeling was applied for the short analogue as well, again substituting His²⁶ by Ala. Competitive binding assays using ¹⁸⁵Re as a surrogate for ^{99m}Tc showed high binding affinity of Ac-[Ahx^{5–24},K⁴(¹⁸⁵Re(CO)₃-PADA),A²⁶]-NPY. Internalization studies with the corresponding ^{99m}Tc-labeled analogue revealed receptor-mediated internalization. Furthermore, biodistribution studies were performed in mice, and stability was tested in human plasma. Our centrally truncated analogue revealed a 6-fold increased stability compared to the natural peptide NPY. We conclude that Ac-[Ahx^{5–24},K⁴(^{99m}Tc(CO)₃-PADA),A²⁶]-NPY has promising characteristics for future applications in nuclear medicine.

INTRODUCTION

Peptides can be considered as ideal agents for diagnostic and therapeutic applications, adopting Paul Ehrlich's concept of the "magic bullet" (1). Tumor tissues expressing receptors for a peptide can be addressed specifically by the peptide or differently labeled analogues (2). To date, radiolabeled receptor-binding peptides have emerged as a new class of radiopharmaceuticals (3, 4).

However, there are several prerequisites for peptides used for scintigraphy. The corresponding receptors have to be expressed on the target in suitable amounts, and it is crucial that the radiolabeled analogue retains a high affinity. Specificity is to be considered as well. Whereas the natural ligand usually binds with similar affinities to several receptor subtypes, chemically modified synthetic analogues often display pronounced subtype selectivity for only one or few receptor subtypes (3). Peptides that are taken up by receptor-mediated internalization may be preferred, as this results in accumulation of the radioligand in the target, providing an

increased signal for scintigraphy (5). A main concern of radiolabeled peptides is their stability under physiological conditions, i.e., peptide fragmentation by peptidases and the stability of the radiometal–chelator complex (6). As the natural peptides usually exhibit a short half-life in plasma, metabolically more stable analogues had to be developed. Somatostatin (SST) receptor scintigraphy using different radiolabeled SST analogues has been extensively clinically applied for tumor diagnosis (7, 8). Furthermore, bombesin and VIP have been evaluated as radiopharmaceuticals (9–11), and many further peptides are promising candidates, for instance neurotensin, α-MSH, substance P, and CCK (12).

Here, we investigate the possibility to use neuropeptide Y (NPY) as a novel radiopeptide, while taking into account the above-mentioned prerequisites. NPY is a 36-amino acid peptide of the pancreatic polypeptide family. It is expressed in the peripheral and central nervous system and is one of the most abundant neuropeptides in the brain (13). Several physiological activities such as induction of food intake, inhibition of anxiety, increase in memory retention, presynaptic retention of neurotransmitter release, and vasoconstriction have been attributed to NPY (14). Its receptors are produced in a number of neuroblastoma and the thereof derived cell lines, making them optimal targets for tumor scintigraphy. Five distinct NPY receptors have been cloned, which have been named Y₁, Y₂, Y₄, Y₅, and y₆ receptor subtype

Figure 1. Structures of ^{99m}Tc -labeled NPY analogues. (A) Full length NPY analogue $[\text{K}^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA}),\text{A}^{26}\text{]-NPY}$ and (B) Centrally truncated analogue $\text{Ac-}[\text{Ahx}^{5-24},\text{K}^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA}),\text{A}^{26}\text{]-NPY}$. Ahx stands for 6-aminohexanoic acid, and PADA for 2-picolylamine-*N,N*-diacetic acid.

(15). Because structure–activity relationships of NPY are well-known (16, 17), we could assume where the radionuclide ^{99m}Tc might be introduced without affecting receptor affinity. The nuclear properties of ^{99m}Tc (monoenergetic γ -radiation of 140 keV, $t_{1/2}$ of 6 h) are virtually ideal for diagnostic imaging (18). We applied the method of Alberto (19) by using the $[\text{K}^4(^{99m}\text{Tc}(\text{OH})_2)_3(\text{CO})_3]^+$ aqua complex and PADA (2-picolylamine-*N,N*-diacetic acid) as bifunctional chelating agent (BFCA). Pre- and postlabeling approaches with attachment of PADA on the Lys⁴ side chain of NPY were investigated, and the full length analogue $[\text{K}^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA}),\text{A}^{26}\text{]-NPY}$ as well as centrally truncated ones such as $\text{Ac-}[\text{Ahx}^{5-24},\text{K}^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA}),\text{A}^{26}\text{]-NPY}$ (Ahx = 6-aminohexanoic acid) were produced (Figure 1). Synthesis, labeling, stability, binding affinities, internalization, and biodistribution studies are presented.

MATERIALS AND METHODS

Materials. Fmoc-protected amino acids, 4-(2',4'-dimethoxyphenyl)-Fmoc-aminomethyl)phenoxy resin, and 1*H*-benzotriazolium,1-[bis(dimethylamino)methylene]-, tetrafluoroborate(1-),3-oxide (TBTU) were obtained from NovaBiochem (Läufelfingen, Switzerland), diisopropylcarbodiimide (DIC) and thioresol from Aldrich, 1-hydroxybenzotriazole (HOBt), *N*-ethyl-diisopropylamine (DIPEA), trifluoroacetic acid, thioanisole, acetic anhydride, hydrazine, and piperidine from Fluka, and *tert*-butyl alcohol from Merck. Dimethylformamide and diethyl ether were purchased from Scharlau (La Jota, Barcelona, Spain). Acetonitrile was obtained from Romil (Cambridge, England). Bovine serum albumin and bacitracin were purchased from Sigma, Minimum Essential Medium with Earle's salts (MEM), Dulbecco's MEM/Nut-Mix F12 medium, fetal calf serum, trypsin-EDTA, Dulbecco's phosphate-buffered saline (PBS) without calcium and magnesium, glutamine, sodium pyruvate, and nonessential amino acids from Gibco. EDTA, Pefabloc SC, and all other chemicals were from Fluka. ^3H -propionyl-NPY (specific activity of 3.63 TBq/mmol) was purchased from Amersham. $\text{Na}[^{99m}\text{TcO}_4]$ was eluted from a Mallinckrodt $^{99}\text{Mo}/^{99m}\text{Tc}$ generator (Petten, The Netherlands) using 0.9% saline.

Peptide Synthesis. The peptides were synthesized by automated multiple solid-phase peptide synthesis using a robot system (Syro, MultiSynTech, Bochum, Germany). To obtain the peptide amide, 4-(2',4'-dimethoxyphenyl)-

Fmoc-aminomethyl)phenoxy resin was used. The polymer matrix was polystyrene–1%-divinylbenzene (30 mg; 15 μmol). The side-chain protection was chosen as follows: Tyr(*tert*-butyl), Glu(*tert*-butyl), Arg(2,2,3,5,5-pentamethylchromansulfonyl), His(trityl), Gln(trityl), Asn(trityl), Thr(*tert*-butyl), Lys(*tert*-butoxy-carbonyl), or Lys(4,4-dimethyl-2,6-dioxocyclohex-1-ylideneethyl) (Lys(Dde)). Double coupling procedures were performed with diisopropylcarbodiimide/1-hydroxybenzotriazole (DIC/HOBt) activation, 10-fold excess and a coupling time of 40 min (20). Upon completion of the peptide sequence, the coupling of $\text{Re}(\text{CO})_3\text{-PADA}$ was performed on the resin (after hydrazine-based deprotection of Lys⁴(Dde)) (21) by DIC/HOBt activation, 10-fold excess, and a coupling time of 24 h. For the PADA-peptides, PADA was activated by diisopropylcarbodiimide for 45 min and subsequently coupled with a 10-fold excess to the selectively deprotected Lys⁴ side chain. The N-termini were either Boc-protected or had been acetylated.

The peptide amides were cleaved with 1 mL of trifluoroacetic acid/thioanisole/thiocresol (90:5:5) within 3 h. The peptide was precipitated from cold diethyl ether, collected by centrifugation, and lyophilized from water/*tert*-butyl alcohol (1:1). Analysis of the product was performed by analytical reversed-phase HPLC at 220 nm on nucleosil C-18 columns from Merck-Hitachi (5 μm , 3×125 mm). Acetonitrile (25% to 75%) with 0.1% trifluoroacetic acid within 30 min was used as an eluent for the full length analogues, whereas for the centrally truncated ones 5% to 60% within 30 min was applied. Correct mass was identified by ion-spray mass spectrometry (SSQ 710, Finnigan MAT, Bremen, Germany).

Radiolabeling. The preparation of $[\text{K}^4(^{99m}\text{Tc}(\text{OH})_2)_3(\text{CO})_3]^+$ was done according to earlier description (19). A mixture of 4 mg disodium carbonate (0.04 mmol), 5.5 mg sodium borohydride (0.15 mmol), and 20 mg potassium sodium tartrate tetrahydrate (0.07 mmol), inclosed in a Wheaton sample vial, were flushed with 1 atm CO for 15 min. One milliliter of a $[\text{K}^4(^{99m}\text{TcO}_4)]^-$ generator eluate in saline (about 1 GBq) was added, and the solution was heated for 30 min at 75°C. The solution was adjusted with approximately 100 μL of a mixture of 1 M phosphate buffer pH 7.4 and 1 N HCl (1:2) to pH 7. For postlabeling, 10 μL of 0.001 M solutions of the different PADA-NPY analogues were added to 90 μL of the neutralized ^{99m}Tc -(I)-tricarbonyl solution and heated for other 60 min at 75°C. Prelabeling was done as described in (10). The labeling procedures and conjugates have been analyzed by RP-HPLC on a Macherey-Nagel CC Nucleosil 100–5 C18 reversed-phase column (10 mm, 250×4.6 mm). A gradient system from 5% to 60% acetonitrile with 0.1% trifluoroacetic acid in 30 min and a flow rate of 1.5 mL/min were applied.

Stability. To analyze the chemical stability of the radiolabeled NPY conjugates, challenging assays were done according to the method of Stalteri et al. (22) with some modifications. A 10 μL amount of the ^{99m}Tc labeled peptide was added to 90 μL of 0.1 M solution of histidine or cysteine (1000-fold molar excess of challenging agents). The resulting solutions were incubated at 37 °C, and progress of the reaction was followed by RP-HPLC with radiometric detection. The proteolytic degradation in plasma of the NPY analogues was determined in vitro in freshly prepared human plasma. Plasma from healthy donors was incubated with the ^{99m}Tc -labeled NPY analogues at a concentration of 0.2 pmol/mL for different time periods at 37 °C. After incubation, samples were precipitated with acetonitrile/ethanol and centrifuged at

4 °C. The supernatant was analyzed by reverse-phase HPLC using a Superdex peptide HR 10/30 (300 mm, 13–15 μ m).

Cell Culture. SK-N-MC cells were grown in Minimum Essential Medium (MEM) with Earl's salts containing 10% fetal calf serum, 4 mM glutamine, 1 mM sodium pyruvate, and 1% nonessential amino acids. SMS-KAN cells were grown under the same conditions using Dulbecco's MEM/Nutrient mix F12 1:1 with 15% fetal calf serum. Cells were grown to confluency at 37°C and 5% CO₂. The growth medium was removed, and the cells were washed with Dulbecco's PBS. After incubation at room temperature for 3 min with PBS containing 0.02% EDTA, the cells were detached by mechanical agitation and suspended in new medium or incubation buffer.

Receptor Binding Studies. Binding assays on SK-N-MC and SMS-KAN cells were performed as previously described (23). In brief, cells were washed with PBS and resuspended in incubation buffer (minimum essential medium with Earl's salts containing 0.1% bacitracin, 50 μ M Pefabloc SC, and 1% bovine serum albumin). A 200 μ L volume of the suspension containing 400000 cells was incubated with 25 μ L of 10 nM ³H-propionyl-NPY and 25 μ L 10 pM to 10 μ M of NPY-analogues. Nonspecific binding was defined in the presence of 1 μ M cold NPY. After 1.5 h at room temperature, the incubation was terminated by centrifugation at 2000g and 4 °C for 5 min. The pellets were then washed once with PBS by centrifugation, resuspended in PBS, transferred to scintillation vials, and mixed with scintillation cocktail. Radioactivity was determined using a β -counter.

Internalization Studies. Studies of internalization of receptor-bound ^{99m}Tc labeled NPY analogues were performed as previously described (24, 25) with some modifications. Briefly, SK-N-MC or SMS-KAN cells were incubated at 37 °C in 6-well plates with about 300000 cpm [$K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY or Ac-[Ahx⁵⁻²⁴, $K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY, respectively. To determine nonspecific binding and internalization, the incubation was also performed in the presence of 1 mM NPY or [Ahx⁵⁻²⁴]-NPY. Incubation was terminated after different time periods (5, 30, 60, 120, and 180 min), and the cells were washed with ice-cold medium containing 1% bovine serum albumin. Cell-surface bound radioligand was removed by two steps of acid wash (50 mM glycine·HCl/100 mM NaCl, pH 2.8) at room temperature for 5 min. The pH were neutralized with PBS, and subsequently the cells were solubilized by incubation with 1 N NaOH at 37°C to determine internalized radioligand.

Biodistribution. Biodistribution of the radioconjugate Ac-[Ahx⁵⁻²⁴, $K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY was estimated in BALB/c mice. The analogue was injected intravenously into the tail vein (3.7 MBq/mouse). For blocking studies, coinjections with [Ahx⁵⁻²⁴]-NPY (0.3 mg/mouse) and NPY (0.25 mg/mouse) were performed. Organs and tissues (blood, heart, lung, spleen, kidneys, stomach, pancreas, duodenum, ileum, colon, liver, muscle, bone, brain) were excised from the sacrificed animals 1.5 and 24 h postinjection. The tissues were weighed, and the radioactivity was determined by γ -counting. Results were expressed as percentage of injected dose per gram of tissue (% ID/g).

RESULTS

Peptide Synthesis. Upon completion of the peptide sequence on the robot, the coupling of PADA or Re(CO)₃-PADA was performed manually to the resin-bound peptide. For the conjugation of Re(CO)₃-PADA, activation by

TBTU/HOBT/DIPEA was tested, but resulted in an incomplete coupling, even after several repetitive coupling steps. Therefore, the activation with DIC/HOBT was used, where a 10-fold excess of DIC/HOBT and Re(CO)₃-PADA and a coupling time of 24 h was applied. For the PADA-peptides, a preactivation of PADA with DIC for 45 min and subsequently coupling with a 10-fold excess to the peptide was suitable. As the BFCA PADA was coupled to the selectively deprotected Lys⁴ side chain, the N-termini had to be protected, which was achieved by either Boc-protection or acetylation. The PADA-peptides and Re(CO)₃-PADA conjugates yielded in high purity (>95%), as determined by analytical HPLC. A synthesis scheme is shown in Figure 2, and the analytical data are summarized in Table 1.

Radiolabeling. Upon postlabeling of [$K^4(\text{PADA})$]-NPY, the aquaion ^{99m}Tc(CO)₃ did not only bind to the desired PADA, but as well to a secondary labeling site, as indicated by two peaks in the HPLC chromatogram. As His is known to be a strong binding chelator for the aquaion as well (26), we assumed that the His in position 26 of NPY is the second labeling site. Therefore, His²⁶ was substituted by Ala, and this [$K^4(\text{PADA})$,A²⁶]-NPY was selected for postlabeling. Specific labeling could be achieved, as shown by a single peak in the HPLC chromatogram. By the comigration of the resulting [$K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY with its cold ¹⁸⁵Re surrogate on HPLC (retention times 23.5 min and 23.7, respectively), identity was confirmed.

The prelabeling approach has been applied for labeling of the centrally truncated analogue [Ahx⁵⁻²⁴]-NPY. The resulting Ac-[Ahx⁵⁻²⁴, $K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$]-NPY was produced with a yield of about 16%. As subsequent purification steps make the prelabeling approach very time-consuming, we applied postlabeling for the short analogue as well, again substituting His²⁶ by Ala. The resulting Ac-[Ahx⁵⁻²⁴, $K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY nicely comigrated with its cold analogue on RP-HPLC (retention times 20.5 min and 20.8, respectively).

Stability. Neither histidine nor cysteine led to significant ligand exchange and/or decomposition after 24 h incubation at 37 °C. The results of these challenge experiments are shown in Table 2. In addition, the degradation of [$K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY and Ac-[Ahx⁵⁻²⁴, $K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY was determined in human plasma. The former full length NPY analogue showed almost no degradation after 1 h. In contrast, the centrally truncated analogue Ac-[Ahx⁵⁻²⁴, $K^4(^{99m}\text{Tc}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY was metabolized as shown in Figure 3, and a half-life time of 24.7 $\pm$ 2.0 min was calculated.

Receptor Binding Studies. To determine the affinity of the NPY analogues, competition binding assays at two neuroblastoma cell lines were performed ($n = 3$). The SK-N-MC cell line has been shown to express the NPY Y₁ receptor, whereas the SMS-KAN line is known to express the Y₂ receptor (27, 28). ¹⁸⁵Re was used as a cold surrogate for ^{99m}Tc. As shown in Table 3, the peptides were still able to bind to the corresponding receptors. The natural ligand pNPY has a high affinity to the Y₁ and Y₂ receptor subtype (IC₅₀ 1 and 0.5 nM, respectively). By replacing His²⁶ by Ala, this affinity decreased to 8.5 and 5.3 nM, respectively. The introduction of the BFCA PADA on the Lys⁴ side chain resulted only in a slight affinity reduction, and finally the cold radiopeptide analogue [$K^4(^{185}\text{Re}(\text{CO})_3\text{-PADA})$,A²⁶]-NPY exhibited an IC₅₀ value of 16.0 nM for the Y₁ and 8.5 nM for the Y₂ receptor. A similar stepwise reduction of receptor binding upon acetylation, attachment of PADA and Re(CO)₃-PADA was also seen for the short NPY analogue on the Y₂ receptor.

	histidine	cysteine
[K ⁴ (^{99m}Tc (CO) ₃ -PADA),A ²⁶]-NPY		
1 h	98	99
4 h	98	98
24 h	96	97
Ac-[Ahx ⁵⁻²⁴ ,K ⁴ (^{99m}Tc (CO) ₃ -PADA),A ²⁶]-NPY		
1 h	98	99
4 h	97	98
24 h	95	96

[Ahx⁵⁻²⁴]-NPY has an IC₅₀ value of 0.2 nM, whereas the cold surrogate Ac-[Ahx⁵⁻²⁴,K⁴(¹⁸⁵Re(CO)₃-PADA),A²⁶]-NPY binds with 2.5 nM affinity. As the replacement of the amino acid sequence 5–24 of NPY by the spacer Ahx leads to subtype-specific high affinity analogue for the Y₂ receptor and a complete loss of affinity at all other receptors (29), these short analogues were not tested at the Y₁ receptor.

Internalization Studies. Internalization of the ^{99m}Tc -labeled peptides was investigated in vitro by incubating

Figure 3. Proteolytic degradation of Ac-[Ahx⁵⁻²⁴,K⁴(^{99m}Tc (CO)₃-PADA),A²⁶]-NPY after incubation in human plasma at 37 °C.

[K⁴(^{99m}Tc (CO)₃-PADA),A²⁶]-NPY on SK-N-MC and Ac-[Ahx⁵⁻²⁴,K⁴(^{99m}Tc (CO)₃-PADA),A²⁶]-NPY on SMS-KAN cells at 37 °C. Almost no specific binding and internalization was observed for [K⁴(^{99m}Tc (CO)₃-PADA),A²⁶]-NPY. In contrast, Ac-[Ahx⁵⁻²⁴,K⁴(^{99m}Tc (CO)₃-PADA),A²⁶]-NPY was specifically internalized in SMS-KAN cells. The uptake was time-dependent, as shown in Figure 4. After 120 min, 25%, and after 180 min, 33% of the radiolabeled ligand

were internalized, whereas the surface-bound fraction accordingly decreased.

Biodistribution. Table 4 shows the tissue distribution of Ac-[Ahx⁵⁻²⁴,K⁴(^{99m}Tc(CO)₃-PADA),A²⁶]-NPY in BALB/c mice after intravenous injection. Time points at 1.5 (row A) and 24 h p.i. (row D) were chosen in order to follow the time course of disappearance from the blood, kidney, and liver. The peptide exhibited a rapid clearance from the blood pool. The levels after 24 h in both kidneys and liver might indicate urinary and hepatobiliary excretion. Blocking has been performed with cold [Ahx⁵⁻²⁴]-NPY and full length NPY. Blood, heart, spleen, brain, muscle, and bone had small activities and no difference

in the uptake with or without coinjection. Differences were observed after coinjection with cold NPY, especially at the gastrointestinal tract, where the highest uptake was found in the duodenum. However, specific blocking by a cold analogue could usually not be observed, and the interindividual variations in the mice were considerably high.

DISCUSSION

In the postlabeling approach, a BFCA is first attached to the peptide, and the radionuclide is subsequently coupled to the free chelating group of the BFCA (30). This method can be combined with the advantages of solid-phase peptide synthesis (SPPS). Applying a molar excess of BFCA, complete coupling to the resin-bound peptide can be achieved, and unreacted BFCA is easily washed away. Subsequent cleavage from the resin yields the highly pure BFCA-peptide conjugate. Using the organometallic aquaion [^{99m}Tc(OH)₂(CO)₃]⁺ has been shown to be very suitable for labeling (31). Efficient postlabeling of histidine derivatives of neurotensin has been performed (32, 33), and a bombesin analogue was successfully prelabeled applying PADA as BFCA (10).

Accordingly, we synthesized NPY derivatives on a rinkamide resin, selectively deprotected Lys⁴ by hydrazine and coupled the BFCA PADA to this side chain. Upon postlabeling of [K⁴(PADA)]-NPY, the ^{99m}Tc did not only bind to the desired PADA, but presumably as well to the His in position 26, as His is a preferred binding chelator (26). Therefore, we tried to replace the disturbing amino acid, which is not an essential position for binding (16, 34). The replacement of His²⁶ by Ala resulted in a specific ^{99m}Tc-labeling of PADA. As assumed, high binding affinity at the Y₁ and Y₂ receptor was maintained, as tested by the cold ¹⁸⁵Re surrogate.

Another way how to circumvent the attachment of ^{99m}Tc to His²⁶ is the prelabeling approach, where the radionuclide-BFCA complex is formed prior to its attachment to the peptide (30). To avoid polymerization due to the activation in solution, we applied the shortened analogue [Ahx⁵⁻²⁴]-NPY, in which all the reactive aspartate amino acids are omitted. By replacing the sequence 5–24 in NPY by Ahx, receptor subtype selectivity for the Y₂ receptor is achieved (29). The resulting Ac-[Ahx⁵⁻²⁴,K⁴(^{99m}Tc(CO)₃-PADA)]-NPY was produced with a yield of only 16%. Therefore, we again substituted His²⁶ by Ala and attached PADA on the Lys⁴ side chain. Competitive binding assays showed surprisingly high affinity of the so produced Ac-[Ahx⁵⁻²⁴,K⁴(¹⁸⁵Re(CO)₃-PADA),A²⁶]-NPY, considering the bulky chelator on the short peptide sequence. Thus, although substitution of a single amino acid, introduction of spacer, N-terminal protection and introduction of an organometallic moiety was performed, the NPY analogues maintained high binding to their corresponding receptor.

Internalization studies with the two ^{99m}Tc labeled analogues revealed receptor-mediated internalization only for the short analogue Ac-[Ahx⁵⁻²⁴,K⁴($^{99m}\text{Tc}(\text{CO})_3\text{-PADA,A}^{26}$)]-NPY. We have previously shown that fluorescent and ^3H -marked NPY internalizes in a time- and temperature-dependent manner (25), determined to be 20–30%, which corresponds to our current measurements. As internalization may lead to higher uptake and retention in the target tissue, the short analogue seems to be more appropriate for future application as a tumor imaging agent. Moreover, it revealed to be stable to enzymatic degradation. Most peptides undergo rapid proteolysis in plasma by endogenous peptidases (35) and have to be molecularly engineered to prevent their enzymatic destruction (12). The N-terminal acetylation and introduction of an unnatural spacer Ahx within the sequence made our analogue a stable candidate, as the natural ligand NPY exhibits a half-life time of only 4 min in humans (36), whereas we were able to increase the stability to a half-life time of about 24 min. This is a crucial step in the development of a novel peptide radiopharmaceutical, since the normally rapid enzymatic degradation is one of the major disadvantages of peptides. As an example, only the discovery of the stable somatostatin analogue octreotide ($t_{1/2}$ 90 min vs the $t_{1/2}$ 3 min of somatostatin) enabled the use and success of OctreoScan, the most commonly used radiopharmaceutical to date.

The full length NPY analogue [K⁴($^{99m}\text{Tc}(\text{CO})_3\text{-PADA,A}^{26}$)]-NPY seems to have lost its biological activity upon postlabeling, as no specific binding to the Y₁ receptor or receptor-mediated internalization could be detected. This might explain as well its too-good stability in plasma: the enzymes involved in the metabolism of NPY might be not capable of degrading this biologically inactive form.

In the biodistribution studies, the short peptide exhibited a rapid clearance from the blood pool. As seen by the low activity in the brain, the peptide is not crossing the intact blood–brain barrier. Blocking studies have been performed with cold [Ahx⁵⁻²⁴]-NPY (Y₂ selective) and full length NPY (binds to all NPY subtype receptors). Blood, heart, spleen, muscle, and bone had small activities and no difference in the uptake with or without coinjection, indicating either no receptors or at least no Y₂ receptors in these tissues. Differences were observed after coinjection with cold NPY, especially at the gastrointestinal tract, an area which expresses NPY receptors. An explanation for this fact could be the inhibitory effect of the cold NPY on contractility and secretion in the intestine (37). Upon injection of the labeled short analogue alone, the highest activity was found at the ileal level, whereas upon coinjection with cold NPY, the highest activity corresponded to the duodenal level. This might be provoked by the high NPY dosage inducing slower transit and inhibition of intestinal fluid secretion. However, this high accumulation at intestinal level could hide a possible specific binding or blocking of the labeled analogue to its receptor. Generally, there is little known about the Y₂ receptor distribution in mice, and distribution varies from one species to another, as shown in autoradiographic studies performed in rabbit and rat (38, 39).

In conclusion, we here demonstrate for the first time the novel application of modified NPY analogues as radiopharmaceuticals. Using our knowledge of structure–activity relationships of NPY, and combining the advantages of SPPS and a stable, well-defined BFCA such as PADA for complexing [$^{99m}\text{Tc}(\text{OH}_2)_3(\text{CO})_3$]⁺, we could produce a chemically and metabolically stable candidate,

which maintains high binding affinity to its receptor and even exhibits receptor-mediated internalization. Therefore, Ac-[Ahx⁵⁻²⁴,K⁴($^{99m}\text{Tc}(\text{CO})_3\text{-PADA,A}^{26}$)]-NPY has promising characteristics for future applications in tumor diagnosis or even therapy, when using a suitable radionuclide such as ^{188}Re .

A Novel Approach to the High-Specific-Activity Labeling of Small Peptides with the Technetium-99m Fragment [$^{99m}\text{Tc}(\text{N})(\text{PXP})$] $^{2+}$ (PXP = Diphosphine Ligand)

Alessandra Boschi,[†] Cristina Bolzati,[†] Elisa Benini,[†] Erica Malagò,[†] Licia Uccelli,[†] Adriano Duatti,^{*,†} Adriano Piffanelli,[†] Fiorenzo Refosco,[§] and Francesco Tisato[§]

Laboratory of Nuclear Medicine, Department of Clinical & Experimental Medicine, University of Ferrara, Via L. Borsari, 46, 44100 Ferrara, Italy, and ICTIMA, CNR, Corso Stati Uniti, 4, 35020 Padova, Italy. Received May 24, 2001; Revised Manuscript Received September 28, 2001

A new labeling approach for incorporating bioactive peptides into a technetium-99m coordination complex is described. This method exploits the chemical properties of the novel metal-nitrido fragment [$^{99m}\text{Tc}(\text{N})(\text{PXP})$] $^{2+}$, composed of a terminal $\text{Tc}\equiv\text{N}$ multiple bond bound to an ancillary diphosphine ligand (PXP). It will be shown that this basic, molecular building block easily forms in solution as the dichloride derivative [$^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2$], and that this latter complex selectively reacts with monoanionic and dianionic, bidentate ligands (YZ) having soft, π -donor coordinating atoms to afford asymmetrical nitrido heterocomplexes of the type [$^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})$] $^{0/+}$ without removal of the basic motif [$^{99m}\text{Tc}(\text{N})(\text{PXP})$] $^{2+}$. The reactions of the amino acid cysteine was studied in detail. It was found that cysteine readily coordinates to the metal fragment [$^{99m}\text{Tc}(\text{N})(\text{PXP})$] $^{2+}$ either through the [NH_2 , S^-] pair of donor atoms or, alternatively, through the [O^- , S^-] pair, to yield the corresponding asymmetrical complexes in very high specific activity. Thus, these results were conveniently employed to devise a new, efficient procedure for labeling short peptide sequences having a terminal cysteine group available for coordination to the [$^{99m}\text{Tc}(\text{N})(\text{PXP})$] $^{2+}$ fragment. Examples of the application of this novel approach to the labeling of the short peptide ligand H-Arg-Gly-Asp-Cys-OH ($\text{H}_2\text{1}$) and of the peptidomimetic derivative H-Cys-Val-2-Nal-Met-OH (H_2) will be discussed.

INTRODUCTION

The labeling of biologically relevant molecules with γ - and positron-emitting radionuclides is currently an active field of research in diagnostic nuclear medicine, as it is mostly focused on the production and development of new categories of imaging agents for in vivo monitoring of metabolic processes and receptor distributions (1–12). A central issue of this effort comes from the requirement that the labeling procedure should not dramatically change the biological properties of the selected active molecule. Generally, the introduction of a positron-emitting radionuclide such as ^{11}C , ^{18}F , and ^{13}N requires only a slight modification of the chemical structure of the starting biological substrate due to the natural occurrence of these elements in biological compounds. However, these positron-emitting nuclides can be obtained only through the use of a cyclotron, and their radioactive decays are, usually, characterized by short half-lives. This fact strongly limits the application of positron-emitting tracers for routine clinical studies. In contrast, the γ -emitting radionuclide technetium-99m exhibits almost ideal nuclear properties for nuclear imaging ($E_\gamma = 140.5$ keV, $t_{1/2} = 6.01$ h) and is easily available through a $^{99}\text{Mo}/^{99m}\text{Tc}$ generator (13). Nonetheless, technetium is a transition metal having almost no natural occurrence, and its chemical behavior is far from being similar to that of any biologically relevant element. Thus, it has to be expected that, in some situations, the labeling of a

biomolecule with ^{99m}Tc might give rise to a strong perturbation of its chemical structure and, consequently, to the loss of its biological properties. To avoid this problem, a number of chemical strategies have been proposed. At present, the most successful procedure, known as 'bifunctional approach', consists of tethering a strong chelating group for the metal to a point of a biomolecule that is irrelevant for preserving its biological properties (1, 8, 12). The resulting bifunctional ligand would act as a bridging backbone between the metal center and the bioactive group. This method has been successfully applied to the production of a number of new Tc-99m radiopharmaceuticals with different bioactive compounds and was mostly exploited using the chemistry of oxo complexes containing the [$\text{Tc}=\text{O}$] $^{3+}$ basic motif (1, 3, 8–11). However, it suffers from many drawbacks, as it usually requires a large excess of ligand to achieve a satisfactory labeling yield (>90%) and, in addition, the resulting complexes are not always sufficiently stable.

It is apparent that the bifunctional approach puts its main concern on the design of the bifunctional ligand itself. Recently, an alternative strategy for the labeling of biomolecules has emerged. The central idea behind this new radiopharmaceutical design is to set up a specific arrangement of ligands bound to a technetium center, which should exhibit a remarkable inertness toward oxidation–reduction reactions. An additional characteristic of this hypothetical precursor metal complex should be also in possessing a few substitution-labile coordination positions where some transient ligand could be easily replaced by a stronger coordinating group without affecting that part of the complex corresponding to the 'robust' metal-containing fragment. In this new context,

Figure 1. The diphosphine ligands (PXP) utilized in this study.

therefore, the main focus becomes shifted from the ligand to the metal-containing block. When the incoming ligand has been made to carry on a bioactive side-chain, its selective interaction with the metal fragment would result in the prompt formation of a final complex incorporating the biological substrate. The first, definite example of this novel approach has been reported by Alberto and co-workers (14–17). These authors were able to devise an efficient preparation, at tracer level, of the precursor aquo-carbonyl Tc-99m complex $[^{99m}\text{Tc}(\text{CO})_3(\text{H}_2\text{O})_3]^+$. In this species, the technetium ion has a +1 oxidation state and appears highly stable toward changes of its oxidation number due to the inertness of the d^6 electronic configuration. In addition, the three water molecules are only weakly bound to the metal center and can be easily displaced by some incoming bidentate or tridentate ligand to form new complexes. In contrast, the carbonyl fragment $[^{99m}\text{Tc}(\text{CO})_3]^+$ remains untouched in the course of the substitution reaction. Thus, the metal fragment $[^{99m}\text{Tc}(\text{CO})_3]^+$ could be viewed as an efficient synthon for the preparation of a wide class of carbonyl Tc(I) complexes.

A further example of this type of radiopharmaceutical design is described here. It is based on the chemical properties of the new metal nitrido fragment $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$, where PXP represents an ancillary diphosphine ligand having some heteroatom ($X = \text{N}, \text{O}$) within the backbone connecting the two P atoms (Figure 1). The fragment $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ is easily produced in aqueous physiological solution as the dichloride derivative $[^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2]$. It will be shown that this precursor complex selectively reacts with ligands having soft π -donor coordinating atoms such as S, O, and N without removal of both the $\text{Tc}\equiv\text{N}$ multiple bond and the ancillary PXP ligand. In particular, it was found that, at tracer level, cysteine readily reacts with $[^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2]$ as a bidentate ligand through the $[\text{NH}_2, \text{S}^-]$ or $[\text{O}^-, \text{S}^-]$ pair of chelating atoms in nearly stoichiometric ratio with the radiometal. In principle, therefore, biologically active molecules having a terminal cysteine group could be efficiently labeled with Tc-99m using this alternative

Figure 2. Ligands and peptide-derived ligands utilized in this study.

route. The application of these findings to the labeling of short peptide sequences will be discussed.

EXPERIMENTAL PROCEDURES

General. Reagents employed in the preparations were purchased from Aldrich Chimica (Milan, Italy) or Fluka (Milan, Italy) and used without further purification. Succinic dihydrazide [SDH = $\text{H}_2\text{N}-\text{NH}-(\text{O}=\text{C})-(\text{CH}_2)_2-\text{C}(=\text{O})-\text{NH}-\text{NH}_2$], L-cysteine ethyl ester hydrochloride (HcysOEt·HCl), N-acetyl-L-cysteine (H₂cysNAC), glutathione (GSH), and the bidentate ligands 2-aminoethanethiol hydrochloride (HNS·HCl), mercaptoacetic acid (H₂OS), and thiosalicylic acid (H₂TSA) (Figure 2) were obtained from Aldrich Chimica. The peptide ligand H₂1 and the peptidomimetic derivative H₂2 (Figure 2) were obtained from Bachem AG (Bubendorf, Switzerland). The diphosphine ligands bis(diphenylphosphino)ether [POP = $(\text{C}_6\text{H}_5)_2\text{P}(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{P}(\text{C}_6\text{H}_5)_2$], bis(diphenylphosphino)ethyl n-butylamine [PNP1 = $(\text{C}_6\text{H}_5)_2\text{P}(\text{CH}_2)_2-\text{N}(\text{C}_4\text{H}_9)-(\text{CH}_2)_2\text{P}(\text{C}_6\text{H}_5)_2$], bis(diphenylphosphino)ethyl methoxyethylamine [PNP2 = $(\text{C}_6\text{H}_5)_2\text{P}(\text{CH}_2)_2-\text{N}(\text{C}_2\text{H}_4\text{OCH}_3)-(\text{CH}_2)_2\text{P}(\text{C}_6\text{H}_5)_2$], bis(dimethoxypropylphosphino)ethyl methoxyethylamine [PNP3 = $(\text{CH}_3\text{OC}_3\text{H}_6)_2\text{P}(\text{CH}_2)_2-\text{N}(\text{C}_2\text{H}_4\text{OCH}_3)-(\text{CH}_2)_2\text{P}(\text{C}_3\text{H}_6\text{OCH}_3)_2$], and bis(dimethylphosphino)ethyl methylamine [PNP4 = $(\text{CH}_3)_2\text{P}-\text{N}(\text{CH}_3)-\text{P}(\text{CH}_3)_2$] (Figure 1) were prepared using literature procedures (18–20) or purchased from Argus Chemical (Florence, Italy). High performance liquid chromatography (HPLC) was performed on a System Gold Instrument equipped with a programmable solvent Module 126, a scanning detector Module 166, and a radioisotope detector Module 170 (Beckman Instruments, Fullerton, CA). Chromatographic analyses were carried out using a reversed-phase C₁₈ Beckman ODS precolumn (25 × 4.6 mm) and a reversed-phase C₁₈ Beckman ODS column (250 × 4.6 mm, $\phi = 10 \mu\text{m}$). Thin-layer chromatography (TLC) was carried out on silica gel plates and reversed-phase C18 plates (Merck). TLC chromatograms were analyzed with a Cyclone instrument equipped with a phosphor imaging screen and an OptiQuant image analysis software (Packard, Meriden, CT). The radiochemical purity (RCP) of Tc-99m complexes was expressed as the ratio between the activity associated with a single radiocompound, revealed as a single spot on a TLC strip, and the total activity on the strip or, alternatively, as the percent of the area under the corresponding HPLC peak.

The chemical nature of all Tc-99m compounds described in this study was investigated by chromatographic analysis. For selected complexes, a further comparison was performed between their chromatographic behavior and that of the corresponding complexes prepared at the macroscopic level with the long-lived isotope Tc-99 g as described elsewhere (21–24). Chromatographic data for the resulting products are showed in Table 1.

Preparation of the Complexes $^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2$ (PXP = POP, PNP1, PNP2, PNP3, PNP4). A 5.0 mg amount of SDH, 0.05 mg of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ (suspended in 0.1 mL of saline), and 1.0 mL of ethanol were placed in a vial purged with argon, followed by addition of 0.250 mL of generator-eluted $\text{Na}^{99m}\text{TcO}_4$ (activity range 50 MBq–2 GBq). The mixture was kept at room temperature for 30 min. Then, 3.0 mg of the appropriate diphosphine ligand PXP (dissolved in 0.25 mL of ethanol) were added, and the reaction solution was further kept at room temperature for 30 min (yield > 98%).

Preparation of the Complexes $^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})^{0/+}$ (PXP = PNP2, PNP3, PNP4; YZ = H_2TSA , NSH , H_2OS). *Method a.* After completing the procedure described above for the preparation of the precursor complex $^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2$, 5.0 mg of the appropriate YZ ligand was added, and the reaction mixture was heated at 100 °C for 30 min (yield > 95%).

Method b. A 5.0 mg amount of SDH, 0.05 mg of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ (suspended in 0.1 mL of saline) and 1.0 mL of ethanol were placed in a vial purged with argon, followed by 0.250 mL of generator-eluted $\text{Na}^{99m}\text{TcO}_4$ (activity range 50 MBq–2 GBq). The solution was kept at room temperature for 30 min. Then, 5.0 mg of the appropriate YZ ligand was added to the reaction mixture that was further kept at room temperature for 30 min or, alternatively, heated at 100 °C for 15–20 min. Finally, after addition of 3.0 mg of the appropriate diphosphine ligand PXP (dissolved in 0.20 mL of ethanol), the reaction solution was heated at 100 °C for 30 min (yield > 90%).

Method c. A 5.0 mg amount of SDH, 0.05 mg of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ (suspended in 0.1 mL of saline) and 1.0 mL of ethanol were placed in a vial purged with argon. Then, 0.250 mL of generator-eluted $\text{Na}^{99m}\text{TcO}_4$ (activity range 50 MBq–2 GBq) were added, and the mixture was kept at room temperature for 30 min. Finally, 1.0 mg of PXP (dissolved in 0.20 mL of ethanol) and 3.0 mg of the appropriate YZ ligand were added to the resulting solution, and the reaction was heated at 100 °C for 30 min (yield > 95%).

Preparation of the Complexes $^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{cysOEt})^+$ and $^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{cysNac})$ (PXP = PNP3, PNP4). These complexes were prepared following both methods a and c as described before. Briefly, using method a, 5.0 mg of cysOEt (or cysNac) was added to the vial containing the intermediate complex $^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2$. Alternatively, using method c, 3.0 mg of the appropriate PXP ligand and 5.0 mg of cysOEt (or cysNac) were mixed in the same vial containing the mixture of Tc-99m precursor nitrido complexes first produced by reaction of $\text{Na}^{99m}\text{TcO}_4$ with SDH and Sn^{2+} ions. In both preparations, the resulting solutions were heated at 100 °C for 30 min (yield > 95% for both preparations).

High-Specific-Activity Labeling of Cysteine-Derived Ligands. In all preparations described below, freshly generator-eluted $\text{Na}^{99m}\text{TcO}_4$ (4.0 GBq), contained in a volume of saline ≤ 0.25 mL, was used. The final volume of the reaction solution was always kept within the range 1.5–2.0 mL by addition of saline. Solutions of the cysteine-derived ligands were always stored under an argon atmosphere and checked before use with Ellman's test (25) to ensure the absence of disulfide bridges.

In a vial purged with argon, $\text{Na}^{99m}\text{TcO}_4$ was mixed with 5.0 mg of SDH, 0.05 mg of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ (suspended in 0.1 mL of saline), and 1.0 mL of ethanol. The resulting solution was kept at room temperature for 30 min. Then, the ligands PNP3 (dissolved in 0.2 mL of ethanol) and cysOEt (or cysNac) (dissolved in 0.2 mL of water) were added together to the same vial, and the reaction solution was heated at 100 °C for 1 h. More precisely, in a series of preparations, the amount of the diphosphine ligand was fixed and that of the cysteine-derived ligand was progressively decreased. The final labeling yield was determined by HPLC analysis. Results were analyzed by plotting the percent radiochemical yield as a function of the amount of the cysteine-derived ligand used in each preparations (see Results).

Stability. The in vitro stability of the heterocomplexes described here was evaluated by monitoring RCP at different time points (15, 30, 60, 120, 360 min) using the following procedure. After preparation, the selected complex was purified by HPLC. Then, 100 μL of the resulting eluate were incubated at 37 °C with 900 μL of (a) saline, (b) PBS, (c) rat serum, and (d) human serum. RCP was measured by TLC analysis.

Figure 3. Schematic drawing of the structure of the metal-containing fragment $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$.

Cysteine and Glutathione (GSH) Challenge. A 250 μL volume of PBS (0.2 M, pH = 7.4), 150 μL of water, 50 μL of a freshly prepared aqueous solution of L-cysteine or, alternatively, of GSH (10.0 mM), and 50 μL of the appropriate HPLC-purified complex were placed in a test tube and incubated in a water bath at 37 $^{\circ}\text{C}$. A blank experiment was carried out using an equal volume of H_2O in place of the cysteine (GSH) solution. Aliquots of the resulting solutions were withdrawn at 1, 15, 30, 60, and 120 min, and analyzed by TLC.

RESULTS

Preparation of the Complexes $[^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2]$ (PXP = POP, PNP1, PNP2, PNP3, PNP4). The precursor metal fragment $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ ($\text{X} = \text{O}, \text{N}$) easily forms, at tracer level (μM concentration), by simple mixing of the ligand PXP with a solution containing a starting nitrido Tc(V) complex. Essentially, this two-step preparation requires the preliminary action on Tc-99m pertechnetate of different reagents such as a donor of nitrido nitrogen atoms (N^{3-}) (SDH) and a reducing agent (SnCl_2) to obtain a mixture of intermediate complexes all containing the $\text{Tc}\equiv\text{N}$ group. The detailed description of this latter procedure for preparing the $\text{Tc}\equiv\text{N}$ bond at tracer level has been reported previously (26–28). In turn, the resulting mixture of nitrido intermediates is quantitatively converted into the precursor metal fragment by reaction with PXP. The structure of the fragment $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ is schematically drawn in Figure 3. It is formed by a terminal $\text{Tc}\equiv\text{N}$ multiple bond coordinated to a diphosphine ligand PXP through the two neutral phosphorus atoms. It is easy to note that the molecular arrangement $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ is coordinatively unsaturated and thus it cannot exist in solution as an independent species. In fact, two residual positions of the coordination geometry are available for the bonding of two monodentate ligands or of one bidentate ligand (arrows in Figure 3). This suggests that, in aqueous physiological solution, this fragment should appear under different chemical forms depending on the pH. In particular, the formation of the aqua complex $[^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{H}_2\text{O})_2]^{2+}$, and of the hydroxo complexes $[^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{H}_2\text{O})(\text{OH})]^+$ and $[^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{OH})_2]$, could be envisaged as well as that of a series of chloro complexes of the type $[^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2]$, $[^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{H}_2\text{O})\text{Cl}]$, and $[^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{OH})\text{Cl}]$. This prediction was nicely confirmed by HPLC analysis of aqueous solutions of this fragment. Actually, though it was commonly observed that the dichloro complex was always the predominant species in solution (Figure 4), a mixture of different compounds was produced after addition of a buffer. In particular, when the preparation was conducted at pH = 7.4 by addition of a phosphate buffer, only 60% of the activity in solution was associated with the mixed halogeno-diphosphine complex $[^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2]$. Furthermore, a mixture of different compounds, always including the dichloro-diphosphine complex, was obtained both at lower pH (acetate buffer, pH = 4.5) and at higher pH (carbonate buffer, pH = 8.5). The distribution of the activity between the various species was also found to

Figure 4. HPLC chromatogram of the complex $[^{99m}\text{Tc}(\text{N})(\text{PNP3})\text{Cl}_2]$. It elutes at a retention time of 20.30 min.

be dependent on temperature. Though it was difficult to determine exactly the chemical nature of all complexes in the mixture, the finding that these compounds were easily and quantitatively converted into a single product of the type $[^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})]^{0/+}$ by reaction with a bidentate chelating ligand (YZ) (see below) strongly indicates that they should possess the same basic structural framework corresponding to the motif $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$.

Despite this, an accurate characterization of one of the compounds in the mixture, namely the dichloro complex $[^{99m}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2]$ (PXP = POP, PNP1, PNP2, PNP3, PNP4), has been possible by comparison of its HPLC profile with that recorded for the analogous complex prepared at macroscopic level (mM concentration range) with the long-lived isotope Tc-99g or, alternatively, with the seventh-group transition-metal congener rhenium, an element exhibiting a chemical behavior closely similar to that of technetium. Specifically, the complexes $[^{99g}\text{Tc}(\text{N})(\text{PXP})\text{Cl}_2]$ (PXP = PNP3, PNP4) have been prepared by reacting the precursor complex $[^{99g}\text{Tc}(\text{N})(\text{PPh}_3)_2\text{Cl}_2]$ with PXP in dichloromethane, and characterized by elemental analysis and spectroscopic methods (29). In addition, the synthesis of similar complexes with the diphosphine ligands POP, PNP1, and PNP2 have been reported previously (20–24). Results showed that the compound $[^{99g}\text{Tc}(\text{N})(\text{POP})\text{Cl}_2]$ can exist in two different isomeric forms depending on the relative cis or trans position of the two chloride atoms or, equivalently, of the cis or trans position of the two phosphorus atoms showing an identical geometrical behavior. In solution, the cis isomer was irreversibly converted into the trans isomer. This fact suggests that this latter arrangement should be the most stable form of this complex. The crystal structures of the trans isomer of the complex $[^{99g}\text{Tc}(\text{N})(\text{POP})\text{Cl}_2]$ (21) and that of the cis isomer of the rhenium analogue $[\text{Re}(\text{N})(\text{PNP2})\text{Cl}_2]$ (24, 29) have been determined. No evidence of the existence in solution of a cis–trans isomerism was found for all complexes with PNP-type ligands, a fact that was attributed to the steric hindrance determined by the alkyl substituent on the nitrogen atom of PNP. HPLC characterization of Tc-99g complexes clearly showed that they have the same retention time of the corresponding Tc-99m counterparts, thus suggesting that these complexes possess an identical chemical structure.

Preparation of the Complexes $[^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})]^{0/+}$ (PXP = PNP2, PNP3, PNP4; YZ = H_2TSA , NSH , H_2OS). It was further observed that $[\text{Tc}(\text{N})(\text{PXP})]^{2+}$ selectively reacted with bidentate chelating ligands (YZ) possessing a pair of soft π -donor coordinating atoms.

These reactions afforded the asymmetrical heterocomplexes $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})]^{0/+}$ composed by two different bidentate chelating ligands bound to the same $\text{Tc}\equiv\text{N}$ group. Figure 2 illustrates the bidentate ligands employed here to afford various examples of asymmetrical heterocomplexes. Using dianionic bidentate ligands, having $[\text{S}^-, \text{O}^-]$ as a pair of coordinating atoms, the neutral heterocomplexes $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})]$ were obtained. In contrast, with monoanionic bidentate ligands having $[\text{S}^-, \text{NH}_2]$ as coordinating pair, monocationic species of the type $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})]^+$ were isolated. It is interesting to note that ligands having $[\text{N}, \text{O}^-]$, $[\text{N}, \text{N}]$, or $[\text{O}, \text{O}^-]$ as chelating system exhibited a low reactivity toward the fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$. In these preparations, negligible yields ($<10\%$) of formation of the corresponding asymmetrical complexes were obtained. Table 1 reports TLC and HPLC characterization of the various Tc-99m heterocomplexes described here. As before, the chemical nature of selected, asymmetrical complexes was investigated by comparison of their HPLC behavior with that of the corresponding Tc-99g complexes, synthesized previously and fully characterized by elemental analysis, mass spectroscopy, and ^{31}P and proton NMR spectra (21–24, 29).

The reactions of the fragments comprising PNP-type diphosphine ligands were investigated in much detail. Basically, these preparations have been conducted in two different ways. A three-step procedure involved the preliminary production of the starting mixture of intermediate nitrido complexes, generated by reacting $[\text{}^{99m}\text{TcO}_4]^-$ with SDH and SnCl_2 . This was followed by the formation of the metal fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP})]^{2+}$ (PNP = PNP2, PNP3, PNP4) obtained through the reaction with PNP. The preparation was, then, completed by the addition of the appropriate bidentate chelating ligand YZ to yield the final asymmetrical heterocomplex. Alternatively, a two-step preparation could be also used. This procedure was carried out through the simultaneous addition of both ligands PNP and YZ to the same reaction vial containing the intermediate nitrido complexes. Interestingly, both procedures gave almost the same final radiochemical yields of formation of the asymmetrical products, and conversion to the corresponding symmetrical complexes comprising two identical bidentate ligands was never detected.

Preparation of the Complexes $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{cysOEt})]^+$ and $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{cysNAc})]$ (PXP = PNP3, PNP4). Due to its potential relevance in setting up a convenient new route for labeling peptides as schematically represented in Figure 5 (see Discussion), the reactions of some cysteine derivatives with the metal fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP3})]^{2+}$ were studied extensively. Figure 2 shows the drawings of the two ligands *cysNAc* and *cysOEt* utilized here. They differ mainly in the set of two-donor atoms used for coordination to the $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP3})]^{2+}$ fragment. Specifically, the ligand *cysOEt*, bearing an ethoxy protecting group on the carboxylic function of cysteine, was designed to bind the metal ion through the $[\text{S}^-, \text{NH}_2]$ pair, thus affording the monocationic complex $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP3})(\text{cysOEt})]^+$. The HPLC profile of this complex is reported in Figure 6. On the contrary, the ligand *cysNAc*, having an acetyl protecting group on the cysteine amine nitrogen, bound through the $[\text{S}^-, \text{O}^-]$ pair to give rise to the neutral complex $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP3})(\text{cysNAc})]$. Both complexes were formed as a mixture of two isomers arising from the relative syn or anti position of the lateral (ethoxy or acetyl) substituents with respect to the $\text{Tc}\equiv\text{N}$ multiple bond. This mixture was clearly detected by HPLC, which always showed the

Figure 5. Schematic representation of the new labeling approach described in this study.

Figure 6. HPLC chromatogram of the complex $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP3})(\text{cysOEt})]^+$. Retention times are 24.783 and 26.567 min.

Figure 7. Variation of the labeling yield (%) of the complex $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP3})(\text{cysOEt})]^+$ as a function of the amount (mg) of the ligand *cysOEt* utilized in the preparation (see Experimental Section). In each curve, the amount of PNP3 is kept constant. A similar behavior was found for the complex $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP3})(\text{cysNAc})]$ (not shown here).

presence of two peaks of different intensity associated with this syn and anti isomeric pair. Though the overall yield of formation was higher than 95%, the relative labeling yields of the two isomers were not equal and one isomer was always formed in a greater amount (relative yield of the main isomer, approximately 60–70%). It should be noted that the existence of this isomeric pair was not always detected by TLC chromatography.

High-Specific-Activity Labeling of Cysteine-Derived Ligands. In studying the preparation of the complexes with cysteine-derived ligands, the influence of the molar stoichiometric ratio between PNP3 and each of these two ligands on the radiochemical yield of the resulting heterocomplexes was also investigated. Figure 7 illustrates the dependence of the radiochemical yield

of formation of the complex $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\text{cysOEt})]^+$ as a function of the concentration of cysOEt. The diagram was drawn by plotting the labeling yield of the radioactive complex (measured as percent of the total starting activity) as a function of the weighted amount of cysOEt added to the various preparations. A fixed amount of the initial activity (approximately 4.0 GBq) of freshly eluted $[^{99m}\text{TcO}_4]^-$ was used in each preparation, and the final volume of the reaction mixture was always kept in the interval 1.5–2.0 mL. The amount of cysOEt was decreased from 5.0 mg to 1.0 μg . A series of sigmoid curves were obtained showing the variation of the yield of formation upon decreasing the concentration of cysOEt. Inspection of this diagram revealed that, for a given amount of PNP3, the highest labeling yield was always achieved when the molar ratio PNP3/cysOEt did not exceed a specific value. An almost identical behavior was observed with the ligand cysNAC (data not showed). In particular, for all curves, the maximum radiochemical yield (>95%) obtained using the lowest amount of L (L = cysOEt, cysNAC) matched approximately the molar ratio $\text{PNP3/L} = 3.5$. A final specific activity of approximately 70 $\text{GBq}/\mu\text{mol}$ (2 $\text{Ci}/\mu\text{mol}$) was attained for both ligands cysOEt and cysNAC.

The results reported above with the two cysteine-derived ligands demonstrated that a terminal cysteine group was an efficient chelating system for the fragment $[^{99m}\text{Tc}(\text{N})(\text{PNP3})]^{2+}$. Thus, the labeling of the short peptide ligand **H₂1** and of the peptidomimetic derivative **H2** (Figure 2) was investigated in detail. These peptidic ligands were selected because they possess a cysteine residue at one terminus of the amino acidic chain. In **H2**, cysteine is joined to the remaining sequence through its carboxylic group, thus yielding a $[\text{NH}_2, \text{S}^-]$ pair of coordinating atoms. On the contrary, in **H₂1** the linkage of cysteine is through its amino nitrogen atom, and the resulting chelating system is composed by a $[\text{O}^-, \text{S}^-]$ pair of atoms. The most suitable reaction conditions were determined through a careful balance of the relative amounts of PNP3 and **H₂1**, and of PNP3 and **H2**, used in the two preparations, respectively. The optimal molar ratio $\text{PNP3/H}_2\mathbf{1}$ was found to be 3.5, and the resulting asymmetrical complex $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{1})]$ was obtained with a radiochemical yield > 90%. The final specific activity for the labeling of **H₂1** was 180 $\text{GBq}/\mu\text{mol}$ (5 $\text{Ci}/\mu\text{mol}$). Similarly, the optimal molar ratio PNP3/H2 was 3.3, and the complex $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{2})]^+$ was obtained with a radiochemical yield > 90% and a specific activity equal to 220 $\text{GBq}/\mu\text{mol}$ (6 $\text{Ci}/\mu\text{mol}$). The two complexes $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{1})]$ and $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{2})]^+$ were characterized by chromatographic methods (Table 1). In $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{1})]$, the ligand **1** is coordinated to the metal through the $[\text{O}^-, \text{S}^-]$ pair of donor atoms of the terminal cysteine group, and the resulting complex is neutral. In $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{2})]^+$, the terminal cysteine group is bound to the central ion through the $[\text{NH}_2, \text{S}^-]$ pair of atoms, thus giving rise to a monocationic compound. As observed with the ligands cysOEt and cysNAC, HPLC analysis showed that the complex $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{1})]$ can exist in two distinct isomeric forms corresponding to the syn or anti orientations of the peptide side chains with respect to the apical $\text{Tc}\equiv\text{N}$ bond. However, in this situation, the final yield of one isomer (84%) was significantly higher than that of the other (12%). Apparently, this effect was even more pronounced with the complex $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{2})]^+$ where only one peak was detected also under different chromatographic condi-

Figure 8. HPLC chromatogram of the complex $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{2})]^+$. It elutes at a retention time of 22.583 min.

tions (Table 1). A representative HPLC chromatogram for the complex $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{2})]^+$ is reported in Figure 8.

Stability. It was observed that all the heterocomplexes with two different bidentate ligands described in this study were highly stable both in solution and in blood. A remarkable result was obtained by studying the in vitro stability of the complexes $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\text{cysOEt})]^+$, $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\text{cysNAC})]$, $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{1})]$, and $[^{99m}\text{Tc}(\text{N})(\text{PNP3})(\mathbf{2})]^+$. Data showed that these compounds were completely stable in solution and in blood, and highly inert toward transchelation by free cysteine and glutathione, a fact which is of fundamental importance in view of the potential, in vivo application of this novel class of radiopharmaceuticals.

DISCUSSION

In this study, a novel route to the labeling of short peptide sequences with Tc-99m was investigated. This new procedure is driven by the chemical properties exhibited by the nitrido metal fragment $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ (Figure 3). A salient property of this arrangement of atoms around the Tc(V) center is that the overall structure can switch between square pyramidal (sp) and trigonal bipyramidal (tbp) geometries depending on the relative cis or trans position of the two π -acceptor phosphorus substituents. A tbp arrangement is much more favored as a result of the strong tendency of the two P atoms to span a reciprocal trans position (24). This apparently less remarkable feature is the key factor controlling the selective reactivity of this fragment toward nucleophilic ligands. In fact, the transition from sp to tbp structure brings also a complete rearrangement of the electronic density, which appears to concentrate on the two π -acceptor atoms. This leaves the other two coordination positions depleted of electrons and, thus, activated toward reaction with electron-rich, incoming ligands surrounded by a set of filled atomic orbitals having the appropriate symmetry to overlap with the empty antibonding π -orbitals of the metal fragment (29). Experimental findings completely agreed with this prediction. Indeed, the fragment $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ was found to react only with ligands carrying soft π -donors as coordinating atoms. Such a behavior is highly specific and is particularly interesting in reactions where bidentate chelating ligands (YZ) are employed. When mono- or dianionic bidentate ligands, YZ, react with the fragment $[^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$, only the asymmetrical mixed heterocomplexes, $[^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})]^{0/+}$, are formed, and no concomitant production of the symmetrical species

$[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})_2]^{2+}$ or $[\text{}^{99m}\text{Tc}(\text{N})(\text{YZ})_2]^{0/2-}$ does occur. Furthermore, the fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ appears to be almost inert toward coordination by electrophilic or hard π - and σ -donor ligands. The reason of the high stability of the coordination arrangement composed by two P atoms and two Y, Z atoms bound to a $\text{Tc}\equiv\text{N}$ group originates from the perfect balance between the π -acceptor properties of the diphosphine ligand and the π -donor properties of the YZ ligand.

The peculiar chemical behavior of the fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ was experimentally evidenced here by using, in particular, PNP-type diphosphine ligands (Figure 1) and the bidentate YZ ligands illustrated in Figure 2. A key advantage of these reactions was that all the asymmetrical complexes $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{YZ})]^{0/+}$ could be also efficiently prepared by simply mixing in the same vial both the ligands PXP and YZ with the starting mixture of nitrido precursors. This procedure, therefore, did not require separate formation of the fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ and then letting it react with the bidentate ligand YZ. As predicted, during these preparations, no detectable formation of the symmetrical nitrido complexes, comprising two identical bidentate ligands, was observed.

The finding that the amino acid cysteine exhibited excellent coordinating properties toward the fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ prompted us to make use of this chelating system for incorporating short peptide chains into a Tc-99m asymmetrical complex. Cysteine was able to coordinate the fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$ both through the $[\text{NH}_2, \text{S}^-]$ pair of coordinating atoms or, alternatively, through the $[\text{O}^-, \text{S}^-]$ pair. This reaction was highly specific and quantitative, due to the peculiar properties of the fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})_2]^{2+}$. Thus, it was almost straightforward to exploit these coordination properties for labeling short peptide sequences having a cysteine group sufficiently accessible to bind the technetium center of the basic motif $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})]^{2+}$. A schematic drawing of the novel labeling method proposed here is shown in Figure 5. The main approach can be outlined as follows. A selected peptide is combined with a bidentate cysteine chelating group either through the N-terminus or through the COO-terminus. Then, the resulting bifunctional ligand, $\text{cys}\sim$, is reacted with the metal fragment $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})_2]^{2+}$ to afford the mixed, asymmetrical complex $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})(\text{cys}\sim)]^{0/+}$. As a result, the peptide sequence remains stably incorporated into the structure of the final complex. The overall charge of the resulting asymmetrical complex is dependent on the nature of the π -donating atoms of cysteine. In fact, when the metal chelating system is composed by the $[\text{NH}_2, \text{S}^-]$ pair, the resulting complex will be monocationic. On the other hand, neutral complexes will arise when cysteine coordinates through the $[\text{O}^-, \text{S}^-]$ pair. It should be noted that cysteine has been already used as a coordinating moiety for technetium (30, 31), in particular in conjunction with other amino acids to form tetradentate chelating systems in oxo-Tc(V) complexes (1, 3). Generally, however, a large excess of the tetradentate ligand has to be employed to achieve satisfactory radiochemical yields owing to the lack of bonding specificity of these chelating groups toward the $[\text{Tc}=\text{O}]^{3+}$ core.

A successful application of the novel labeling approach was carried out using the two simple peptidic ligands showed in Figure 2. These two ligands efficiently coordinated to the $[\text{}^{99m}\text{Tc}(\text{N})(\text{PNP3})]^{2+}$ fragment through their terminal cysteine residues, which were oriented in an opposite manner in the two sequences. It was found that these reactions were highly selective, and only the

formation of the asymmetrical complexes were detected. Moreover, a quite surprising result was obtained by studying the stability of these two complexes in solution. Actually, results demonstrated that they were completely stable in solutions containing excess of free cysteine or glutathione, which are known to behave as excellent competing ligands toward metal transchelation in physiological conditions. This fact appears to further support the view that the arrangement composed by two π -acceptor and two π -donor coordinating atoms around a $[\text{Tc}\equiv\text{N}]^{2+}$ core should possess a rather considerable thermodynamic and kinetic stability.

CONCLUSIONS

A new approach to the labeling of peptides with Tc-99m was proposed here. This procedure makes use of the selective reactivity of cysteine toward the $[\text{}^{99m}\text{Tc}(\text{N})(\text{PXP})_2]^{2+}$ metal fragment, which exclusively coordinates to this amino acid residue through both the $[\text{NH}_2, \text{S}^-]$ and $[\text{O}^-, \text{S}^-]$ chelating systems. Other amino acids possessing different chelating systems were found to be less reactive. These properties could be conveniently exploited to set up a general procedure for the labeling of short peptides simply by selecting those sequences having a terminal cysteine group or, alternatively, by placing a cysteine residue at either the N- or COO-terminus of a specific peptide chain. It is expected that this almost 'natural' way of introducing a strong chelating group for the metal into a peptide would not dramatically alter its biological properties as it occurred with other labeling methods. Obviously, to fully evaluate the usefulness of the proposed approach, future work should be devoted to investigate both the influence of the peptide length and conformation on the efficiency of the labeling procedure and, ultimately, the possibility to preserve the biological properties of the native peptide sequence.

Quadruplex and Pentaplex Self-Assemblies of Oligonucleotides Containing Short Runs of 8-Aza-7-deaza-2'-deoxyisoguanosine or 2'-Deoxyisoguanosine

Frank Seela* and Rita Kröschel

Laboratorium für Organische und Bioorganische Chemie, Institut für Chemie, Universität Osnabrück, Barbarastrasse 7, D-49069 Osnabrück, Germany. Received June 1, 2001; Revised Manuscript Received July 30, 2001

Oligonucleotides containing 8-aza-7-deaza-2'-deoxyisoguanosine (**4**) were investigated regarding their self-assembly in aqueous solution. The aggregation of **4** was compared with that of oligonucleotides containing 2'-deoxyisoguanosine (**2b**) and 2'-deoxyguanosine (**1b**). For this purpose the phosphoramidite of **4** was synthesized which was protected by a dibutylaminomethylidene residue at the amino group and a diphenylcarbamoyle residue at the 2-oxo function. Solid-phase synthesis furnished oligonucleotide containing short runs of the nucleoside **4**. The self-assembly of the oligonucleotide 5'-d(T₄**4**T₂) was studied by ion-exchange chromatography. The formation of a pentaplex was observed in the presence of Cs⁺, while a tetraplex is formed when the counter ion is Na⁺ or Rb⁺. The cation selectivity of the oligonucleotide 5'-d(T₄**4**T₂) was found to be different from the parent 5'-d(T₄isoG₄T₂) which was forming the tetraplex as well as a pentaplex in aq RbCl solution.

INTRODUCTION

Guanosine (**1a**) as well as guanosine derivatives such as 2'-deoxyguanosine (**1b**) and their oligonucleotides form self-assemblies in the presence of metal ions (1–3). These aggregates can be considered as nucleoside conjugates held together by hydrogen bonds and coordination forces (metal ions) and not by covalent linkages. Oligonucleotides with short runs of guanine, such as d(T₄G₄), d(T₄G₄T), or d(T₄G₄T₄), were shown to form tetrameric complexes, and the G-quartet binds cations with a selectivity of K⁺ (1.33 Å) > Rb⁺ (1.49 Å) > Na⁺ (0.98 Å) >> Cs⁺ (1.65 Å), Li⁺ (0.78 Å) (4–7) following the Hoogsteen base-pair motif. The ions are surrounded by the 6-oxo groups of the hydrogen-bonded guanine quartet. Investigations on the structure of self-assembled nucleosides as well as oligonucleotides have been performed using various techniques such as NMR spectroscopy (8–11), X-ray analyses (12, 13), electrospray ionization mass spectroscopy (14), electrophoresis (5), and energy perturbation studies (15). The X-ray analyses gave a detailed picture of the G-quartet structure showing that the central cation of the complexes is located between two layers of the guanine tetrads.

The guanosine-related nucleoside isoguanosine (**2a**) was found to form also aggregates in aqueous solution. The phenomenon was already observed in 1976 by Golas et al. on poly(isoguanic acid) (16). Several structures of the aggregated homopolymer have been suggested. The first defined complex formed by an 2'-deoxyisoguanosine (**2b**) containing oligonucleotide has been reported by our laboratory. The dodecamer d(T₄isoG₄T₄) was found to form a tetrameric assembly in the presence of sodium ions which is structurally different from that formed by 2'-deoxyguanosine (17, 18). Nitrogen-7 is not participat-

ing in the hydrogen bonding pattern. Thus, 7-deaza-2'-deoxyisoguanosine (**3**) forms an aggregate structure (19) while 7-deaza-2'-deoxyguanosine prevents guanine-rich oligonucleotides from aggregation (20). Recently pentameric complexes have been reported for an isoguanosine derivative (21) as well as for 2'-deoxyisoguanosine containing oligonucleotides both, in the presence of cesium ions (22).

This manuscript reports on the self-assembly of oligonucleotides containing 8-aza-7-deaza-2'-deoxyisoguanosine (**4**). Corresponding oligonucleotides are prepared by solid-phase synthesis using the protocol of phosphoramidite chemistry. The self-assembly of those oligonucleotides is investigated for the dependence on the size of the alkali cation, and the aggregate formation of 8-aza-

7-deaza-2'-deoxyisoguanosine oligonucleotides is compared to those containing 2'-deoxyisoguanosine (**2b**) and 2'-deoxyguanosine (**1b**).

EXPERIMENTAL PROCEDURES

General Remarks. Thin-layer chromatography (TLC) was performed on TLC aluminum sheets silica gel 60 F₂₅₄ (0.2 mm, Merck, Germany). Solvent systems for FC and TLC: CH₂Cl₂/MeOH 9:1 (A), CH₂Cl₂/MeOH 95:5 (B), CH₂Cl₂/MeOH 98:2 (C), CH₂Cl₂/acetone 9:1 (D), CH₂Cl₂/acetone 98:2 (E), CH₂Cl₂/EtOAc 85:15 (F). Reverse phase HPLC was carried out on a 4 × 250 mm RP-18 (10 μm) LiChrosorb column (Merck) with a Merck-Hitachi HPLC pump (model 655 A-12) connected with a variable wavelength monitor (model 655-A), a controller (model L-5000), and an integrator (model D-2000). UV-spectra were recorded on a U-3200 spectrophotometer (Hitachi, Japan), λ_{max} in nm, ε in dm³ mol⁻¹ cm⁻¹. Half-life values (τ) were measured on a U-3200 spectrophotometer (Hitachi, Japan) connected with a temperature controller (Lauda, Germany). NMR spectra were measured on an Avance DPX 250 and an AMX 500 spectrometer (Bruker, Germany); chemical shifts (δ) are in ppm downfield from internal TMS (¹H, ¹³C) or external 85% H₃PO₄ (³¹P). The *J*-values are given in Hz. The solvents were purified and dried according to standard procedures.

Ion-Exchange HPLC. The ion-exchange chromatography was performed on a 4.6 × 100 mm Gen-Pak Fax Column (Waters, WAT015490) using a Merck-Hitachi HPLC apparatus with a pump (model L-7100), and a UV-detector (model L-4250) connected with an integrator (model D-2000). A column oven (model L-7350, Merck, Germany) was used to control the temperature of the ion-exchange column. The oligonucleotides were prepared as follows. A sample of 0.1 A₂₆₀-units was dissolved in 20 μL of 1.0 M MCl-buffer (M: Na, K, Rb, Cs). The solution was heated to 60 °C for 5 min, brought to room temperature and kept in a refrigerator (−23 °C) for 15 min up to 16 h (depending on the oligonucleotide). Then, the sample was brought to room temperature, diluted with 100 μL of buffer A, and injected into the system, which had been preheated to 30 °C. The column was eluted using the following systems: 0–40 min with 0–80% B in A with a flow rate of 0.5 mL min⁻¹ (A: 25 mM Tris-HCl, 1.0 mM EDTA, pH 8.0; B: 1.0 M MCl (M: Na, K, Rb, Cs) 25 mM Tris-HCl, 1.0 mM EDTA, pH 8.0).

Oligonucleotides. The oligonucleotide syntheses were carried out on an ABI 392-08 DNA synthesizer (Applied Biosystems, Weiterstadt, Germany) in a 1 μmol scale using the phosphoramidite **10**, those of the regular 2'-deoxynucleosides (Applied Biosystems, Weiterstadt, Germany) together with the DPC- and acetamidide-protected phosphoramidite of 2'-deoxyisoguanosine following the synthesis protocol for 3'-β-cyanoethylphosphoramidites. After cleavage from the solid support, the oligonucleotides were deprotected in 25% aqueous ammonia solution for 12–16 h at 60 °C. Purification of the 5'-dimethoxytrityl-oligomers was performed by reversed-phase HPLC (RP-18) with the following solvent gradient system (A: 0.1M (Et₃NH)OAc (pH 7.0)/MeCN 95:5; B: MeCN): 3 min 20% B in A with a flow rate of 1.0 mL min⁻¹, 12 min 20–40% B in A with a flow rate of 1 mL min⁻¹. Treatment with 2.5% CHCl₂COOH/CH₂Cl₂ for 5 min at room temperature to remove the 4,4'-dimethoxytrityl residues. The detritylated oligomers were purified by reversed-phase HPLC with the gradient: 20 min 0–20% B in A with a flow rate of 1 mL min⁻¹. The oligomers were desalted and lyophilized on a Speed-Vac evaporator to yield colorless solids.

4-Amino-1-(2-deoxy-β-D-erythro-pentofuranosyl)-1H-pyrazolo[3,4-d]pyrimidin-6-one (4). To a solution of 4,6-diamino-1-(2-deoxy-β-D-erythro-pentofuranosyl)-1H-pyrazolo[3,4-d]pyrimidine (**5**) (200 mg, 0.75 mmol) and sodium nitrite (200 mg, 2.9 mmol) in water (6 mL) was added acetic acid (300 μL) dropwise at 60 °C under stirring. Stirring was continued for 8 min, and the pH of the yellowish solution was adjusted to 8.0 with 25% aqueous NH₃ solution. The precipitated crude material was filtered, and the residue dissolved in water and applied to a Serdolit AD-4 column (4 × 20 cm, resin 0.1–0.2 mm, Serva, Germany). The column was washed with water (500 mL), and the product was eluted with H₂O–PrⁱOH (1:1). Compound **4** was obtained as a yellowish powder (98 mg, 49%). UV, ¹H and ¹³C NMR spectra are identical with the published data (23).

1-(2-Deoxy-β-D-erythro-pentofuranosyl)-4-(N,N-dibutylaminomethylidene)-1H-pyrazolo[3,4-d]pyrimidin-6-one (6). To a stirred suspension of **4** (440 mg, 1.65 mmol) in MeOH (15 mL) was added *N,N*-dibutylformamide dimethylacetal (800 μL) (24). The mixture was stirred at 40 °C for 2 h and evaporated to dryness. The residue was applied to flash chromatography (FC; silica gel, column 2 × 10 cm, CH₂Cl₂–MeOH 98:2 to 95:5) and eluted stepwise. Colorless foam of **6** (450 mg, 67%). TLC (A): *R*_f 0.32; UV (MeOH): 233 (24300); 278 (13000); 338 (15500). ¹H NMR (*d*₆-DMSO): 2.20 (1H, m, 2'-H_α); 2.65 (1H, m, 2'-H_β); 3.36 (2H, m, 5'-H₂); 3.80 (1H, m, 4'-H); 4.37 (1H, s, 3'-H); 5.21 (2H, m, 3'-OH, 5'-OH); 6.30 (1H, "t", *J* = 6.5, 1'-H); 7.93 (1H, s, 3-H); 8.56 (1H, s, H–C=N). Anal. Calcd for C₁₉H₃₀N₆O₄ (406.5): C, 56.14; H, 7.44; N, 20.68. Found: C, 56.08; H, 7.50; N, 20.59.

4-Amino-1-(2-deoxy-β-D-erythro-pentofuranosyl)-6-[(diphenylcarbamoyl)oxyl]-1H-pyrazolo[3,4-d]pyrimidine (7). Compound **4** (100 mg, 0.37 mmol) was dried by repeated coevaporation with anhydrous pyridine and then suspended in anhydrous pyridine (2 mL). Diphenylcarbamoyl chloride (DPC-Cl) (150 mg, 0.65 mmol) and *N,N*-diisopropylethylamine (100 μL, 0.57 mmol) were added, and the reaction mixture was stirred for 2 h at room temperature. The excess of DPC-Cl was hydrolyzed with crushed ice. Then, the mixture was poured into a 5% aqueous NaHCO₃ (4 mL) and extracted with CH₂Cl₂ (3 × 5 mL). The combined CH₂Cl₂ layers were dried (Na₂SO₄) and filtered. After evaporation of the solvent, the residue was applied to FC (silica gel, column 2 × 15 cm). Elution with CH₂Cl₂–MeOH (98:2) followed by CH₂Cl₂–MeOH (9:1) furnished as a colorless foam (105 mg, 61%). TLC (A): *R*_f 0.41. ¹H NMR (*d*₆-DMSO): 2.27 (1H, m, 2'-H_α); 2.80 (1H, m, 2'-H_β); 3.35–3.57 (2H, m, 5'-H₂); 3.81 (1H, m, 4'-H); 4.42 (1H, m, 3'-H); 4.71 (1H, "t", *J* = 5.9, 5'-OH); 5.23 (1H, d, *J* = 4.6, 3'-OH); 6.43 (1H, "t", *J* = 6.3, 1'-H); 7.26–7.50 (10H, m, arom. H), 7.80–8.24 (3H, m, NH₂, 3-H). Anal. Calcd. for C₂₃H₂₂N₆O₅ (462.5): C, 59.73; H, 4.79; N, 18.17. Found: C, 59.65; H, 4.79; N, 18.11.

1-(2-Deoxy-β-D-erythro-pentofuranosyl)-4-(N,N-dibutylaminomethylidene)-6-[(diphenylcarbamoyl)oxyl]-1H-pyrazolo[3,4-d]pyrimidine (8). To a suspension of compound **6** (290 mg, 0.71 mmol) in dry pyridine (5 mL) were added diphenylcarbamoyl chloride (300 mg, 1.29 mmol) and *N,N*-diisopropylethylamine (220 μL, 1.26 mmol), and the reaction mixture was stirred for 1 h at room temperature. The mixture was poured into 5% aqueous NaHCO₃ (7 mL) and extracted with CH₂Cl₂ (3 × 5 mL). The combined CH₂Cl₂ layers were dried (Na₂SO₄) and filtered. After evaporation of the solvent, the

Compound **8** (200 mg, 0.33 mmol) was dried by repeated coevaporation with anhydrous pyridine and dissolved in anhydrous pyridine (1 mL). The solution was treated with dimethoxytrityl chloride (163 mg, 0.48 mmol) at 30 °C under stirring (45 min). MeOH (1 mL) was added, and the stirring was continued for 5 min. The mixture was poured into 5% aqueous NaHCO_3 solution (5 mL) and extracted with CH_2Cl_2 (3×5 mL). The combined organic layers were dried (Na_2SO_4). After evaporation of the solvent, the residue was applied to FC (silica gel, column 2×15 cm), which was prewashed with CH_2Cl_2 and eluted with CH_2Cl_2 -acetone (stepwise elution from 98:2 to 9:1) to give a colorless foam (195 mg, 65%). TLC (D): R_f 0.60. UV (MeOH): 236 (31200), 319 (44800). ^1H NMR (d_6 -DMSO): 0.94 (6H, m, CH_3); 1.28, 1.99 (8H, m, 4 CH_2); 2.31 (1H, m, $2'\text{-H}_\alpha$); 2.77 (1H, m, $2'\text{-H}_\beta$); 3.01, 3.53 (4H, m, NCH_2); 3.65–3.67 (8H, m, $5'\text{-H}_2$, OCH_3); 3.94 (1H, m, $3'\text{-H}$); 5.32 (1H, d, $J = 5.1$, $3'\text{-OH}$); 6.56 (1H, m, $1'\text{-H}$); 6.68–7.44 (23H, m, arom. 1-[2-Deoxy-5-O-(4,4'-dimethoxytriphenylmethyl)- β -D-erythro-pentofuranosyl]-4-(N,N-dibutylaminomethylidene)-6-[(diphenylcarbamoyl)oxyl]-1H-pyrazolo[3,4-d]pyrimidine 3'-(2-cyanoethyl-N,N-diisopropyl)phosphoramidite (10). A solution of compound **9** (200 mg, 0.22 mmol) in CH_2Cl_2 (2 mL) was preflushed with argon and kept under argon atmosphere. Then, 2-cyanoethyldiisopropylphosphoramidochloridite (233 μL , 1.04 mmol) and N,N -diisopropylethylamine (88 μL , 0.51 mmol) were added at room temperature. Stirring was continued for 45 min. An aqueous solution of 5% NaHCO_3 (10 mL) was added. The mixture was shaken, the layers were separated, and the aqueous layer was extracted with CH_2Cl_2 (3×15 mL). The combined organic extracts were dried (Na_2SO_4), filtered, evaporated, and applied to FC (silica gel, column 2×10 cm, CH_2Cl_2 -EtOAc (85:15) containing a few drops of Et_3N) yielding a colorless foam (196 mg, 80%). TLC (F): R_f 0.95. ^{31}P NMR (CDCl_3): 149.6, 149.9.

RESULTS AND DISCUSSION

Synthesis of Monomers. Earlier, 8-aza-7-deaza-2'-deoxyisoguanosine (**4**) has been synthesized from 8-aza-

Scheme 1

2-chloro-7-deaza-2'-deoxyadenosine (**11**) by photochemical substitution of the 2-chloro substituent (23). As this synthetic route is limited to small scale preparation, the nucleoside **4** was now prepared by deamination of the 4,6-diamino-1-(2-deoxy- β -D-erythro-pentofuranosyl)-1H-pyrazolo[3,4-d]pyrimidine **5** (25) as it was reported for the ribonucleoside **2a** (26). Selective deamination of compound **5** at position-2 with sodium nitrite and glacial acetic acid furnished the nucleoside **4** (Scheme 1).

To investigate the stability of the glycosylic bond of compound **4**, it was hydrolyzed in 0.5 M HCl at room temperature, and the kinetic of hydrolysis was followed UV-spectrophotometrically at 268 nm leading to a half-life (τ) of 12.5 min. Compared to the acid-labile purine nucleoside **2b** ($\tau = 14$ min, 0.1 M HCl, 25 °C) (27) it possesses a significantly more stable glycosylic bond. This favorable property makes this compound to a useful substitute for 2'-deoxyisoguanosine as depurination can be avoided during oligonucleotide synthesis or longer storage of oligonucleotides.

Next, the conformational analysis of the 2'-deoxyribose moiety of **4** was performed using the program PSEUROT 6.2 (28, 29) which calculates the conformational parameters from ^1H , ^1H coupling constants and relates them to the corresponding mole fractions of the conformers. The populations of the staggered rotamers across the $\text{C}(4')\text{—C}(5')$ bond were calculated according to Westhof et al. (30). Table 1 summarizes the coupling constants and the conformational data. For comparison, the data of 2'-deoxyisoguanosine (**2b**) and 2'-deoxyguanosine (**1b**) as well as of 7-deaza-2'-deoxyisoguanosine (**3**) are listed in Table 1. While the population of N vs S conformers is similar in all cases, the nucleosides **1b**, **2b**, and **3** prefer the $\gamma^{\text{g}+}$ (+sc) conformation around the $\text{C}(4')\text{—C}(5')$ bond and for the base-modified compound **4** the +sc-population is reduced to 39%.

Earlier, the amino group of 2'-deoxyisoguanosine (**2b**) was protected with an amidine function, and the 2-oxo group with a diphenylcarbamoyl residue (27). The same protocol was now applied to compound **4**. Three different amidine residues were employed which lead on one hand to an increase of the stability of the glycosylic bond and on the other hand to a greater lipophilicity, thus facilitating chromatographic separation (24). Treatment of compound **4** with N,N -dimethylformamide dimethylacetal furnished **12**; the isomeric dibutylformamide dimethylacetates gave compounds **6** and **13** while the reaction

with diphenylcarbamoyl chloride in pyridine furnished compound 7.

To test the applicability of the protecting groups for oligonucleotide synthesis, their stability was studied under alkaline conditions. The kinetics of deprotection were followed UV-spectrophotometrically in 25% aqueous ammonia (Table 2). As the formamidine 12 was found to be rather labile and the isobutylamidine 13 was too stable to be used, thus the butylamidine 6 was chosen for further reactions.

**Figure 1.** Structures of (a) G₄-quartet, and (b) isoG₄-pentaplex

The resulting amidine 6 was then blocked at the 2-oxo group with the diphenylcarbamoyl residue (33). This protecting group has already been used for the 2-oxo-protection of related purine nucleosides (27, 34–36). From the NMR spectra it was concluded that the DPC-group is protecting the 2-oxo function as the chemical shift (δ) of C(3a) is remarkably shifted (downfield) about 7 ppm by introduction of a DPC group. An additional change of the C(4)-signal can also be observed. Nevertheless, this is not an unambiguous proof since protection at one of the pyrimidine nitrogens formed by tautomerization cannot be completely ruled out as such reactions have been observed in the case of 2-aza-2'-deoxyinosine by Fernandez-Forner et al. (37). Compound 8 was then converted into the 5'-O-(dimethoxytriphenylmethyl)-protected ((MeO)₂Tr) derivative 9 under standard conditions (38) (Scheme 2). Finally, the phosphoramidite 10 was prepared from 9 by treatment with 2-cyanoethyl-diisopropylphosphoramidochloridite in the presence of *N,N*-diisopropylethylamine under argon atmosphere. All compounds were characterized by ¹H and ¹³C NMR spectroscopy (see Table 3 and Experimental Procedures) as well as by elemental analysis.

The Self-Assembly of Oligonucleotides Containing Short Runs of 8-Aza-7-deaza-2'-deoxyisoguanosine (4). The formation of oligonucleotide aggregates containing 2'-deoxyisoguanosine is well established

Figure 2. Ion-exchange HPLC elution profile of 5'-d(T₄(c'z⁸iG)₄T₂) (**14**) at 30 °C in the presence of Na⁺ (a), Rb⁺ (b), and Cs⁺ (c); conditions: see Experimental Procedures.

Figure 3. Ion-exchange HPLC elution profiles of 5'-d(T₄G₄T₂) (**16**) at 30 °C in the presence of Na⁺ (a), Rb⁺ (b), and Cs⁺ (c); conditions: see Experimental Procedures.

(16, 17, 22). The 12-mer d(T₄isoG₄T₄) forms two well-separated peaks when applied to an ion-exchange resin (Dionex NucleoPac PA-100) in the presence of sodium ions (18). The fast migrating peak refers to the single strand, while the slow-migrating one represents the aggregate. When the oligomer d(T₄G₄T₄) is analyzed under identical conditions, two peaks are also detected showing similar retention times (7). Again, the first one is the monomer while the second one was assigned to be the tetramer. So far oligonucleotides containing 2'-deoxyisoguanosine show a similar tendency to form aggregates as those containing 2'-deoxyguanosine. An equivalent study as performed by our laboratory applying ion-exchange chromatography and using the mobility differences of the monomeric and tetrameric assemblies (17) was performed later by gel electrophoresis (39). The complex formation of d(T₄isoG₄T₄) was also studied in the presence of other monovalent cations indicating that rather stable isoguanine conjugates are formed in the presence of cesium ions, while in the case of the guanine-containing oligomer d(T₄G₄T₄) fairly unstable complexes did occur. The stabilizing ability of dG-tetrads by Cs⁺ is ranking in the range of Li⁺ (40), and in this case K⁺ has the optimum ionic radius for the formation of the tetraplex (41). The aggregate stability of oligonucleotides

containing 2'-deoxyisoguanosine (**2b**) was also investigated in dependence of the ion radii of the alkali cations. However, little attention was given by our laboratory to a discontinuity of the complex stabilities between the potassium-, rubidium-, and cesium-ions (7). Chaput and Switzer found that oligonucleotides containing short runs of 2'-deoxyisoguanosine residues such as d(T₄iG₄T) or d(T₈iG₄T) form pentameric assemblies in the presence of cesium ions while in the presence of potassium ions tetrameric complexes or mixtures of tetrameric and pentameric structures are observed (22) (Figure 1).

As nitrogen-7 is not participating in the hydrogen-bonding pattern of the 2'-deoxyisoguanosine assembly (19) the 8-aza-7-deaza-2'-deoxyisoguanosine, which usually forms stronger hydrogen bonds upon base pairing than 2'-deoxyisoguanosine (**2b**) does, was incorporated in an oligonucleotide containing a short run of compound **4** residues. A decanucleotide 5'-d(T₄(c'z⁸iG)₄T₂) (**14**), containing four consecutive nucleoside **4** residues as well as tails of 4 dT's at the 5'-terminus and two dT's at the 3'-end, was synthesized. The oligonucleotides 5'-d(T₄isoG₄T₂) (**15**) and 5'-d(T₄G₄T₂) (**16**) having a similar structure, but containing either four 2'-deoxyisoguanosine or four 2'-deoxyguanosine residues, were synthesized for comparison.

Figure 4. Structures of (a) $c^7z^8iG_d$ -tetraplex, and (b) $c^7z^8iG_d$ -pentaplex.

At first, the self-assembly of $5'-d(T_4(c^7z^8iG)_4T_2)$ (**14**) was studied. The oligonucleotide was stored in 1.0 M MCl solution (M: Na^+ , Rb^+ , Cs^+) at $-23^\circ C$ for 16 h. Subsequently, the solution was injected onto an ion-exchange Gen-Pak Fax column thermostated at $30^\circ C$. The ion-exchange chromatography of the sodium complex performed in the presence of NaCl is shown in Figure 2a. The peak with the short retention time contains the single-stranded oligomer while the slower migrating peak represents the conjugate. The same experiment (storage and ion exchange chromatography) was then performed with the 2'-deoxyguanosine-containing oligonucleotide $5'-d(T_4G_4T_2)$ (**16**) showing the same sequence, but $c^7z^8iG_d$ was replaced by dG. This HPLC profile (Figure 3a) shows also two peaks when Na^+ is the counterion. Earlier

studies have shown that the faster migrating peak results from the single-stranded oligonucleotide while the slower one represents the tetramer. As the peak of the aggregate formed by oligomer **14** shows a similar retention time as that of **16** (33 min vs 30 min), the complex of the aggregate was also assigned to be a tetraplex. The same protocol was performed with Rb^+ as counterion (see Figure 2b); according to this figure a tetraplex is also formed in this case. The chromatographic mobility changed when Cs^+ was used. Incubation of **14** in 1.0 M CsCl and chromatography in a running buffer containing CsCl leads to a chromatographic profile shown in Figure 2c. The mobility of the second peak of oligonucleotide **14** shows a significantly increased retention time over that of the sodium complex (37 min vs 33 min) while that of **16** remains unaffected. From this observation it is concluded that the aggregate containing 8-aza-7-deaza-2'-deoxyisoguanosine is a tetraplex in the presence of Na^+ , K^+ , and Rb^+ while a pentaplex is formed in Cs^+ . This observation is in line with findings on oligonucleotide assemblies containing 2'-deoxyisoguanosine (22). From the series of experiments shown in Figure 2a–c and 3a–c, it is apparent that the Cs^+ complex of **14** has a similar stability as the sodium complex while the complex of the oligomer **16** containing 2'-deoxyguanosine becomes less stable in an aqueous CsCl solution.

As there was no unambiguous proof whether the lower mobility of this complex formed in the presence of Cs^+ results from the formation of a pentameric structure or other phenomena induced by the pyrazolo[3,4-*d*]pyrimidine system we searched for experimental conditions which allow the detection of both types of complexes in the same solution. The experiments were performed in the presence of a counterion which is smaller than Cs^+ (1.65 Å) but significantly larger than sodium (0.98 Å) (Figure 4). For this purpose Rb^+ was chosen exhibiting an ion radius of 1.49 Å. However, as shown in Figure 2b, both complexes are not formed in the case of the oligonucleotide **14**. Therefore, we went back to the oligonucleotide $5'-d(T_4isoG_4T_2)$ (**15**) containing the purine nucleoside 2'-deoxyisoguanosine. This oligomer forms a tetraplex in the presence of Na^+ and a pentaplex in the presence of Cs^+ (Figure 5a,b). Then, the experiments were performed in the presence of RbCl which was used for incubation and in the chromatographical runs (Figure 5c). In this case two well-separated slow-migrating peaks

Figure 5. Ion-exchange HPLC elution profiles of $5'-d(T_4isoG_4T_2)$ (**15**) at $30^\circ C$ in the presence of Na^+ (a), Cs^+ (b), and Rb^+ (c); conditions: see Experimental Procedures.

Figure 6. Structure of (a) isoG₄-tetraplex, and (b) pentaplex.

Figure 7. Ion-exchange HPLC elution profiles of 5'-d(T₄-isoG₄T₂) (**15**) and 5'-d(T₄G₄T₂) (**16**) in the presence of Cs⁺; conditions: see Experimental Procedures.

appeared. The faster migrating one was considered to be the tetraplex while the slower one represents the pentameric structure. The mobility change of the conjugates arises from the increased number of negative charges of the pentameric complex resulting in a stronger binding to the ion-exchange resin than the less charged tetrameric complex.

To show that the tetrameric complex can be distinguished from the pentamer another experiment was performed. It is now well established that 2'-deoxyisoguanosine-containing oligomers form pentameric assemblies in the presence of Cs⁺ ions while 2'-deoxyguanosine forms exclusively tetraplexes even in aqueous CsCl solution. Thus, a chromatographical run of a mixture of the oligonucleotides 5'-d(T₄G₄T₂) (**16**) and 5'-d(T₄-isoG₄T₂) (**15**) in the presence of CsCl should lead to two

aggregate peaks—the tetramer of **16** and the pentamer of **15**. This is actually the case. Apart from the rather high amount of the monomeric oligonucleotide of 5'-d(T₄G₄T₂) (**16**) and its tetrameric assembly which is present in aqueous CsCl solution the pentameric assembly of **15** is observed. As the mobilities of the self-assembled aggregates of **15** and **16** (Figure 7) look similar to those of Figure 5c it is obvious that the peaks of the tetraplexes migrate significantly faster than those of the pentaplexes, no matter whether the tetraplex is formed by dG or an isoG₄ quartet. It also confirms the presence of two complexes, the tetraplex and the pentaplex of **15**, in the presence of Rb⁺.

The difference of the complex stability observed for the various cations in the case of the oligonucleotide **14** containing 8-aza-7-deaza-2'-deoxyisoguanosine and **15** containing 2'-deoxyisoguanosine was unexpected. It might be traced back to conformational differences of the monomeric pyrazolo[3,4-*d*]pyrimidine vs the purine nucleoside residues (high-anti vs anti conformation) (42). This can affect the thermodynamic stability of the aggregates and/or the kinetics of complex formation and decay. In this regard it is worth mentioning that the self-aggregation of 2'-deoxyisoguanosine containing oligonucleotides occurs much faster than that of containing 2'-deoxyguanosine or 8-aza-7-deaza-2'-deoxyisoguanosine.

CONCLUSION

Oligonucleotides containing short runs of 8-aza-7-deaza-2'-deoxyisoguanosine (**4**) form tetrameric as well as pentameric self-assemblies, which can be considered as oligonucleotide conjugates held together by hydrogen bonds and coordination forces (metal ions) and not by covalent linkages. Those conjugates require the presence of a central cation, as it has been observed for oligomers containing 2'-deoxyisoguanosine (**2b**) and 2'-deoxyguanosine (**1b**). In the latter cases it was shown that the metal ion is surrounded by the tetrameric or pentameric assembly of the nucleobases in a sandwich type structure (X-ray) (43). Such a structure is also expected for the self-assemblies of 8-aza-7-deaza-2'-deoxyisoguanosine and its oligonucleotides. The formation of the various complexes (tetraplexes or pentaplexes) depends on the size of the cation. Cs⁺ generates a pentaplex while the smaller cations (Na⁺: 0.98 Å, Rb⁺: 1.49 Å, Cs⁺: 1.65 Å) can induce a tetraplex structure. In the case of the 2'-deoxyisoguanosine containing oligonucleotide **15** a tetraplex as well as a pentaplex can be observed in the same solution when Rb⁺ is the counterion, while the self-assembly formed by the 8-aza-7-deaza-2'-deoxyisoguanosine containing oligonucleotide 5'-d(T₄G₄T₂) yields only one species which is expected to be the tetraplex.

ACKNOWLEDGMENT

We thank Mr. Yang He and Dr. Helmut Rosemeyer for the NMR spectra, Mr. Harald Debelak for the PSEUROT calculation, and Mrs. Elisabeth Feiling for the oligonucleotide synthesis. Financial support by the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

Systematic Modulation of Michael-Type Reactivity of Thiols through the Use of Charged Amino Acids

M. P. Lutolf,[†] N. Tirelli,^{†,*} S. Cerritelli,[‡] L. Cavalli,[†] and J. A. Hubbell[†]

Received June 22, 2001; Revised Manuscript Received August 7, 2001

A quantitative structure–reactivity relationship for the Michael-type addition of thiols onto acrylates was determined. Several thiol-containing peptides were investigated by examining the correlation between the second-order rate constant of their addition onto PEG-diacrylate and the pK_a of the thiols within a peptide. By introducing charged amino acids in close proximity to a cysteine, the pK_a of the thiol was systematically modulated by electrostatic interactions. Positive charges from the amino acid arginine decreased the pK_a of the thiol and accelerated the reaction with acrylates while negative charges from aspartic acids showed the opposite effect. A linear correlation between thiolate concentrations and kinetic constants was found, confirming the role of thiolates as the reactive species in this Michael-type reaction. The relevant factors influencing the reactivity were the sign and the number of the neighboring charges, while the position of these charges had little effect on reactivity. These results provide a basis for the rational design of peptides, where the kinetics and thus selectivity of protein/peptide conjugation with polymeric structures via Michael-type addition reactions can be controlled.

INTRODUCTION

Conjugation with poly(ethylene glycol) (PEG), also termed PEGylation, is a common method for the modification of proteins and peptides, as well as other drugs, with synthetic polymers. As a result of the favorable properties of PEG, such as protein repellence, high hydrophilicity, and low degradability by mammalian enzymes, PEGylation can dramatically extend the stability and improve the pharmacology of a biomolecule in vivo (1, 2). One common coupling strategy involves the modification of terminal hydroxyl groups with electrophilic functionalities, such as the *N*-hydroxysuccinimide esters of PEG carboxylic acids (PEG-NHS) (3–5), PEG-oxycarbonylimidazole (CDI-PEG) (6), or PEG nitrophenyl carbonate (7, 8). However, since these functionalized PEGs react unselectively with both thiols and amines, a distribution of products can be obtained, resulting in grafting at multiple sites of the biomacromolecule, additionally with an uncontrolled PEGylation degree (due to the limited stability of thioester linkages). To achieve a better coupling selectivity, two classes of functional groups have been utilized. The first one is based on substitution onto groups such as iodo-, bromo-, and chloroacetamides and -acetates (9, 10); the second class on the conjugate addition (Michael-type) onto unsaturated groups such as maleimides (10), vinyl sulfones (11, 12), acrylamides (13), and acrylates (14).

Our recent interests have focused on the development of PEG-based synthetic hydrogels in contact with pro-

teins (15), isolated cells, and tissues via the use of in situ cross-linking reactions, e.g., by reacting a multifunctional PEG with a correspondingly reactive multifunctional PEG or peptide. A satisfactory exploitation of this scheme depends on the possibility of obtaining quantitative conversions in biologically or surgically relevant time scales and with adequate selectivity. Furthermore, the same scheme could be applied to PEGylate biologically active molecules, so as to graft them into the above matrixes. Among the other reactions, the Michael-type addition of thiols onto unsaturated esters is an ideal candidate for such processes, due to its high speed, the ease of preparation of the unsaturated compound, the negligible influence of competing reactions with other nucleophiles (at physiological pH, amines react generally at least 1 order of magnitude slower than thiols (16)), and the absence of any byproducts. Preliminary experiments (17) have shown acrylates to react considerably faster than other unsaturated esters (methacrylates, crotonates, 2,2-dimethylacrylates, cinnamates, cyclopropanecarbonylates) and were therefore chosen as standard conjugated unsaturated partner.

To better meet the requirements for bioconjugation and gel formation and to optimally exploit the selectivity of the Michael-type addition reaction, knowledge of the thiol structure–reactivity relationship is crucial. Thiols are key players in determining the structure and function of many proteins, for example, as active sites of enzymes. The protonation state of the active site of many enzymes is determined by its pK_a which in turn strongly influences protein catalytic activity (18, 19). For example, thioredoxin (20) and thioltransferase (21) have highly reactive thiols with very low pK_a 's, which increases their activity toward reducing disulfide bonds. Many examples in the literature reveal that pK_a shifts of thiols can be induced by electrostatic interactions with neighboring ionizable amino acids (22) and/or polar residues (e.g. amides

dipoles (23)) or surfactants (19). For instance, changes in enzymatic activity have been observed for thioredoxin (22) and 4-oxalocrotonate tautomerase (24) as a result of pK_a shifts in the active site due to mutations on charged residues close to the active thiol. It was stated that charge not only influences pK_a shifts, but can also change the transition state energy (19) influencing the reaction kinetics. Since thiolates rather than thiols are reported to be the reactive species also in Michael-type reactions (9,16,25), the pK_a value of the sulfhydryl-group is the design parameter of choice for this study.

The present work outlines a quantitative relationship between the chemical structure and the Michael-type reactivity for a model system constituted of PEG-diacrylate and peptide thiols (see Figure 1). A homologous series of peptides with charged and/or neutral amino acids in close proximity to a cysteine residue was designed in order to confirm the role of thiolates in the Michael addition and quantitatively show how the charge of the neighboring groups of a thiol can influence its pK_a . In this system, pK_a -shifts— independent of any other structural factors—linearly correlate with a change in reaction kinetics. This knowledge will aid in the rational design of peptides and proteins conjugated to polymeric structures with controlled kinetics and selectivity.

EXPERIMENTAL SECTION

Materials. Poly(ethylene glycol) mol wt 3400 (PEG3400) and triethylamine were purchased from Aldrich (Buchs, Switzerland) and were used without purification. Acryloyl chloride was purchased from Aldrich (Buchs, Switzerland) and was used freshly after distillation over quinoline.

All standard chemicals used in peptide synthesis were analytical grade or better and were purchased from Novabiochem (Läufelfingen, Switzerland).

^1H NMR spectra were recorded on a 300 MHz Bruker spectrometer. FT-IR spectra were recorded in ATR mode on a Spectrum One Perkin-Elmer spectrometer. UV-Vis spectra were recorded on Perkin-Elmer Lambda 20 spectrometer

Synthesis of PEG Diacrylate. PEG diol with 3400 MW (10 g, 2.94 mmol) was dissolved under argon in 300 mL of toluene and dried azeotropically. After cooling to

5 °C, 50 mL of dichloromethane was added. After the addition of triethylamine (1.64 mL, 2.0 equiv), acryloyl chloride (0.72 mL, 1.5 equiv) was added dropwise, and the reaction proceeded overnight, in the dark, at room temperature. The resulting solution was filtered through a neutral alumina bed. Sodium carbonate was added to the toluene solution and removed by filtration, and the volume of the solution was reduced by rotary evaporation. The polymeric material was precipitated twice in with diethyl ether and dried in vacuo to yield a white powder. Yield: 88%; conversion of OH to acrylate: 100% (from ^1H NMR analysis). ^1H NMR (CDCl_3): 3.6 (156H, PEG chain protons), 4.3 (t, 2H, $\text{CH}_2\text{CH}_2\text{OCOCH}=\text{CH}_2$), 5.8 (dd, 1H, $\text{CH}_2=\text{CHCOO}$), 6.1 and 6.4 (dd, 1H, $\text{CH}_2=\text{CHCOO}$) ppm. FT-IR (film on KBr plate): 2990–2790 (ν C–H), 1724 (ν C=O), 1460 (δ_s CH_2), 1344, 1281, 1242, 1097 (ν_{as} C–O–C), 952, 842 (ν_s C–O–C) cm^{-1} .

Peptide Synthesis and Purification. A series of cysteine-containing peptides was synthesized, derived from four amino acid building blocks: a positively charged (at neutral pH) (arginine, R), a negatively charged (aspartic acid, D), a neutral (glycine, G), and a thiol-bearing amino acid (cysteine, C). The peptide sequences and their abbreviations used throughout the paper are listed in Table 1.

Synthesis was performed by solid-state chemistry on resin using an automated peptide synthesizer (Perceptive Biosystems, Farmington, MA), with standard 9-fluorenylmethyloxycarbonyl chemistry (26). Peptides were purified by C18 chromatography (Perceptive Biosystems Biocad 700E) and analyzed by MALDI-TOF mass spectrometry. All peptides were synthesized bearing a *N*-acetylglycine at the amino terminus, to suppress reaction of acrylate-groups with the α -amine.

Validation of an Analytical Method To Determine Reaction Kinetics. The Michael-type reactions on two model compounds, namely cysteine and PEGDA, was followed monitoring the absorbance at 233 nm, where a pH-dependent absorption peak is shown by thiols (associated to the thiolate form) (22,27) and where unsaturated esters absorb too. The method was validated using reaction mixtures prepared by keeping the overall number of reacting groups (the sum of acrylates and thiols) constant, but varying their relative quantities. In this

way, the absorption could be divided by the number of reacting groups, yielding an averaged extinction coefficient, ϵ , which is a linear combination of the extinction coefficients of the absorbing species.

Determination of Michael Addition Kinetics for Thiol-Containing Model Peptides on PEGDA. Peptides (Table 1) were dissolved in 100 mM HEPES [4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid] buffered saline and reacted with PEGDA (pH 7.4 and 37 °C) at different molar ratios. The overall concentration of both reacting groups was kept constant at 2.5 mM. The absorption data at 233 nm were fitted with single exponential decays of the form $y(t) = y_0 + A_1(\exp - t/\tau)$. For a second-order reaction, the equation

$$\ln([PEGDA]/[peptide]) = \ln([PEGDA]_0/[peptide]_0) + k_{\text{eff}}t \quad (1)$$

with $k_{\text{eff}} = k([PEGDA]_0 - [peptide]_0)$, implies a linear time dependence for $\ln([PEGDA]/[peptide])$.

pK_a Determination. The pK_a of all thiols was determined spectrophotometrically using a method related to the one described above for measurement of reaction kinetics. The absorption at 233 nm was measured for each peptide at various pH for solutions having identical concentrations. Solutions of peptides (0.1 mM) were prepared in a buffer system (depending on the pH regime), composed of two components: a 0.01 M acetate-, phosphate-, tris- or borate-buffer (depending on the pH), and 0.1 M NaCl (stable ionic strength). Freshly prepared solutions were immediately measured in the UV region with a scan from 190 to 300 nm.

Statistics. Kinetic studies were conducted in triplicate for every peptide. Mean values and standard error of the mean are shown.

RESULTS AND DISCUSSION

Validation of an Analytical Method To Determine Reaction Kinetics. In a buffered environment, the intensity of the 233 nm peak is proportional to the concentration of unreacted acrylates and thiolates; compared to the Michael-type addition, the proton transfer is instantaneous, and from the equilibrium $[S^-] = [SH]/K_a/[H^+]$ one can assume $[S^-]$ to be constantly proportional to the overall thiol concentration $C_{\text{thiol}} = [S^-] + [SH] = [S^-](1 + [H^+]/K_a)$. Thus, whether the active group is the thiol, the thiolate, or both of them, the time evolution of this peak allows one to monitor on-line the extent of every thiol-consuming reaction. Saturated esters and thioethers (in the reaction product) have a negligible absorption at that wavelength.

If the change of the 233 nm absorption depends only on the reaction extent, this is indicative of a 1:1 reaction, and if disulfide formation plays a negligible role during the reaction (at least for cysteine), then a graph of ϵ vs the equivalent fraction of PEGDA (number of acrylates divided by the number of reacting groups; the same applies to cysteine) at time ∞ (complete reaction) should show a minimum at 0.5, corresponding to ϵ of the pure product. Moreover, the time dependence of ϵ should follow a single-exponential decay, because thiols and acrylates would be consumed at the same rate. These assumptions were all indeed confirmed, as shown by the reaction diagram in Figure 2A and by the time dependence of the absorption in Figure 2B. Thus, this method was used for all further kinetic experiments.

Influence of the Primary Structure of the Peptide on the Michael Addition Reactivity. According

Figure 2. (A) Reaction diagram for PEGDA and cysteine as model compounds obtained by measuring absorbance at 233 nm for various PEGDA/Cys molar ratios. The overall concentration c of both reacting groups was kept constant at 2.5 mM. The absorbance divided by c is depicted on the ordinate as ϵ . The ratio between the concentrations of reacting groups was drawn on the abscissa as fraction of acrylic groups. (B) Absorbance of a PEGDA-cysteine solution over time ($c = 2.5$ mM). The reaction is complete after approximately 30 min under these conditions (pH 7.4, 37 °C), yielding a minimum of ϵ corresponding to the pure product.

to eq 1, true second order kinetics would imply a linear time dependence for $\ln([PEGDA]/[peptide])$. This was indeed shown by all peptides investigated. In Figure 3, the kinetic data for some peptides upon reaction with PEGDA at 80:20 acrylate over thiol ratio are shown.

Positive charges close to the SH-groups were observed to speed the reaction considerably, while the opposite effect was shown by nearby groups of negative charge. The effect did not depend on the precise location of the charges: the rate constant for **crr** and **rcr** or **rcd**, **crd**, and **cdr** were not significantly different from each other. The sequence **cdd** possessed a considerably higher k -value than **dcd**, but this may be due to the low precision in the **dcd** measurement.

Michael-type addition was generally faster in the presence of excess of acrylic groups, particularly when positive charges were close to the thiol, as depicted in Figure 4 for some peptides and cysteine. In our interpretation, however, this difference derives from an incorrect estimation of the concentration of initial thiols in

Table 2. k and pK_a Values of the Cysteine-Containing Peptides. Both pK_a and k Respond to Changes in the Primary Peptide Structure

peptide	crr	rcr	cr	cys	rcd	crd	cdr	cd	dcd	cdd

**Figure 3.** $\ln([PEGDA]/[peptide])$ over time for several peptides (as examples) reacted with PEGDA (here at 80:20 acrylate over thiol ratio). The linearity indicates true second-order kinetics according to eq 1.**Figure 4.** τ values from single-exponential fit from second-order reaction for various PEGDA/peptide ratios. Error bars are standard error of the mean, $n = 3$.

reduced form. We assume the disulfide concentration to be roughly quadratically dependent on the peptide concentration. Thus, in high excess of peptide, disulfide formation could reduce the effective thiol concentration and hence also the calculated reaction rate: e.g., changing a theoretical 80:20 to an actual 75:25 molar ratio. This assumption can be confirmed by the asymmetry in the τ plot of Figure 4. The slowest reacting mixture should be the one having acrylic and thiol groups in stoichiometric amounts. However, an interpolation of the graphic revealed that this was exhibited with samples having a peptide excess of ca. 5–10%. Furthermore,

cysteine, generally assumed to dimerize at a rate 2–4 times lower than other peptides (10), did not show this asymmetry.

Relationship between Primary Structure of the Thiol and Its pK_a . A typical titration curve followed spectrophotometrically at 233 nm is shown in Figure 5A for the peptide GCDDG (**cdd**). Since at high pH, thiols are completely deprotonated, the absorbance $A_{\max}$ was assumed equal to $\epsilon_{S^-}C_{\text{thiol}}$, where ϵ_{S^-} is the absorption coefficient of the thiolate, and C_{thiol} is the peptide concentration.

The pK_a was determined by observing, that for a measurement i , the following holds:

$$-\log([SH]_i/[S^-]_i) = pH_i - pK_a \quad (2)$$

and

$$[SH]_i/[S^-]_i = (C_{\text{thiol}} - [S^-]_i)/[S^-]_i = (A_{\max} - A_i)/A_i \quad (3)$$

As required by eq 3, the intercept with the abscissa in a graphical representation of $-\ln[(A_{\max} - A_i)/A_i]$ vs pH yielded the pK_a value (Figure 5B).

The pK_a of cysteine agrees with the commonly accepted value of 8.4–8.5. The presence of charges close to the thiols strongly influenced the pK_a (Table 2), hindering the deprotonation in case of negative charges and facilitating it for positive ones. In contrast to the results obtained for the second-order rate constants, pK_a values generally responded to the charge location. The pK_a of **crr** and **cdd** could be distinguished from **rcr** and **dcd**, respectively. A stronger charge effect was found for peptides bearing vicinal charges (**crr**, **cdd**). For the zwitterionic peptides **rcd**, **crd**, and **cdr**, as well as for cysteine (which is zwitterionic itself), similar values were measured.

Quantitative Relationship between Thiol pK_a and Michael Addition Reactivity. Positive charges were shown to decrease the pK_a of thiols, that is, at constant pH, to increase the concentration of thiolates. Along with the protonation state, an increase in Michael-type reactivity was observed (as described above). The parallel change of both parameters would confirm the observation of other groups (25), that thiolates are the reactive moiety in this reaction. Under this assumption, the second-order kinetic equation $v = kC_{\text{thiol}}C_{\text{acrylate}}$ can be expressed as

$$v = k_{\text{real}}[S^-]C_{\text{acrylate}} \quad (4)$$

$$\text{thus, } k = k_{\text{real}}[1/(1 + [H^+]/K_a)] = k_{\text{real}}K_a/(K_a + [H^+]) \quad (5)$$

According to eq 5, a linear relationship should be seen between $K_a/(K_a + [H^+])$ and k . Whereas cysteine did not precisely follow this correlation, a good agreement was shown for all peptides (Figure 6). The behavior of cysteine is likely due to the shorter distance of the ionic groups from the thiol and to the different structure of the molecule (no peptide bond).

Figure 5. (A) Absorbance at 233 nm as a function of pH for the peptide GCDDG. (B) $\log[(A_{\max} - A_i)/A_i]$ vs pH. The pK_a value corresponds to the intercept with the abscissa. The linear approximation was only used in the buffer region (in this case, the five central points).

Figure 6. Correlation of $K_a/(K_a + [H^+])$ and k . Peptides (○), cysteine (■). Error bars indicate standard error of the mean, $n = 3$.

A linear fit of the k values for the all investigated peptides gave a k_{real} value of $1040 \pm 40 L/(mol \times e1 \cdot min)$.

CONCLUSION

Due to its selectivity and favorable kinetics in physiological conditions, the Michael-type addition of sulfhydryl-containing biomolecules onto unsaturated groups is an ideal method for many bioconjugation purposes, both in the formation of cross-linked gels and in the PEGylation of therapeutic proteins. Obtaining high self-selectivity in the coupling and tailoring the reaction kinetics to the needs of an application can be crucial in many applications, e.g., in the preparation of polymer-peptide conjugates for in vivo cross-linking materials. In the present work, this issue was approached by designing a homologous series of peptides with charged amino acids flanking a cysteine, to elaborate the relationship between structure of the reaction partners and Michael-type reactivity. The influence of the peptide primary structure on thiol reactivity was significant: charged amino acids close to the SH groups considerably altered the second-order reaction kinetics, positive charges increasing and negative charges decreasing the reaction rate. In terms of changes in pK_a , a decrease of approximately 0.2 or an increase of approximately 0.2 units per positive or negative charge, respectively, was observed. The good correlation between the variations in pK_a and reaction rate confirmed the thiolates to be the only active group

and that the effect of thiolate concentration on reaction kinetics most likely overwhelms any other structural factor.

These results provide the basis for the rational design of peptides or proteins for optimal use in conjugation schemes with polymeric structures, where selectivity and controlled reaction kinetics are desired.

ACKNOWLEDGMENT

We would like to thank Dr. Roberta Marcone for preliminary work on difunctional PEGs (other than acrylates). We also would like to thank Dr. Jason C. Schense for helpful discussions and review of the manuscript.

Evaluation of Radiolabeled Type IV Collagen Fragments as Potential Tumor Imaging Agents

W. Barry Edwards, Carolyn J. Anderson,* Gregg B. Fields,[†] and Michael J. Welch

Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, Missouri 63110 and Department of Chemistry and Biochemistry, Florida Atlantic University, Boca Raton, Florida 33431. Received June 26, 2001; Revised Manuscript Received September 18, 2001

The objective of this study was to examine radiopharmaceuticals that target the $\alpha\beta 1$ integrin to determine if these agents target tumors for diagnostic imaging and/or targeted radiotherapy of cancer. Prior studies had shown that residues 531–542 from the $\alpha 1$ chain of type IV collagen bind a variety of tumor cell $\alpha\beta 1$ integrins. A peptide mimic of this sequence containing all D-amino acids (designated D-Hep-III) was synthesized by solid-phase methods. The tetraazamacrocyclic chelator, TETA, was conjugated to the peptide while it was resin-bound. TETA-D-Hep-III and D-Hep-III were radiolabeled with ^{64}Cu and ^{125}I , respectively, in high specific activity and radiochemical purity. Heterologous competitive binding assays between D-Hep-III and either ^{125}I -D-Hep-III or ^{64}Cu -TETA-D-Hep-III indicated low micromolar affinity of D-Hep-III. The biodistribution of each radiolabeled analogue of D-Hep-III was carried out in rats and tumor-bearing mice. Both analogues were rapidly cleared from the blood in normal rats, with the kidneys receiving the highest accumulation of each. SKOV3 human ovarian tumor cells, known to strongly express $\alpha\beta 1$, were xenografted in SCID mice. Localization of ^{125}I -D-Hep III and ^{64}Cu -TETA-D-Hep III in the xenografts were low ($<2\%$ ID/g), and in the case of ^{125}I -D-Hep III, not inhibited by a competitive dose of D-Hep III. The low tumor accumulation is likely not due to receptor down-regulation, but rather due to the weak affinity of the radioligands for the $\alpha\beta 1$ integrin.

INTRODUCTION

Radiolabeled analogues of peptide hormones are under current investigation as diagnostic imaging agents and radiotherapeutics for the diagnosis or treatment of cancer (for reviews see refs 1–3)). These radiolabeled peptide receptor ligands are targeted to tumors that have up-regulated receptors on the tumor cell surface. For example, ^{111}In -DTPA–octreotide is currently in routine clinical use for imaging neuroendocrine tumors overexpressing the somatostatin receptor (4).

Integrins are a family of receptors that bind various components of the ECM¹. They are heterodimeric glycoproteins comprised of two subunits, α and β , that each span the cell membrane once. A β -subunit can pair with a number of different α -subunits, and this combination confers the unique binding properties of that integrin. Also, cell type-specific factors appear to play a role in determining specificities of integrins. For example, $\alpha 2 \beta 1$ is a receptor for collagen but not laminin on platelets (5); however, $\alpha 2 \beta 1$ is a receptor for both ligands on other cell types (6). In addition to promoting adhesion, integrins

provide a linkage between the ligand and intracellular proteins and can promote signal transduction (7). The cells of most normal human tissues express a variety of integrins including $\alpha 1 \beta 1$, $\alpha 2 \beta 1$, $\alpha 3 \beta 1$, and $\alpha 6 \beta 1$, which are primarily required for adhesion to collagen and laminin (for reviews, see refs 8, 9, 10). Radiolabeled ECM fragments have been investigated as imaging agents (11–14) since their integrins are up-regulated in certain types of tumors and can therefore be a target for diagnosis or therapy.

Immunohistochemical analysis of human tissue showed expression of $\alpha 3 \beta 1$ in dermal and lung epithelium, in large vessel and capillary endothelium (15), and in certain cell types within rat and human kidney (16, 17). Immunohistochemical methods on surgically excised specimens from human tumors showed strong expression of $\alpha 3 \beta 1$ on primary tumors from the ovary, colon–rectum, stomach, and skin as well as on tumors from their metastatic sites (18). Moreover, $\alpha 3 \beta 1$ is frequently expressed on cultured human tumor cell lines such as ovarian carcinoma (19), breast carcinoma (20), and melanoma (21, 22). A noninvasive means of assessing $\alpha 3 \beta 1$ expression could provide useful information about the extent of metastasis prior to therapy or surgery by possibly revealing metastatic sites too small for conventional imaging techniques.

Since the natural ligands for several integrins are collagens, radiolabeled fragments of collagen have the potential to serve as imaging agents. Recently, peptides incorporating segments of type IV collagen have demonstrated specific binding to the $\alpha 3 \beta 1$ integrin. One of these peptides, Hep-III (GEFYFDLRLKGDK), consisting of residues 531–543 from the $\alpha 1$ chain of type IV collagen, promoted 40–50% adhesion of human ovarian, breast

¹ ECM, extracellular matrix; PET, positron emission tomography; TETA, 1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid; DBU, 1,8-diazabicyclo[5.4.0]undec-7-ene; HBTU, O-(1H-benzotriazol-1-yl)-N,N,N',N'-tetramethyluronium hexafluorophosphate; BSA, bovine serum albumin; DIEA, diisopropylethylamine; TFA, trifluoroacetic acid; Mab, monoclonal antibody; ATCC, American Type Culture Collection).

carcinoma, and melanoma cell lines at concentrations of 7–11 μM (23). An all D-isomer of Hep-III (D-Hep-III) was as effective as the L-isomer in promoting cell adhesion of these cell lines, indicating that the receptor does not discriminate between the two enantiomers (23, 24). Furthermore, D-Hep-III was found to bind $\alpha 3\beta 1$ integrins on cultured human tumor cells in a fashion similar to Hep-III (19, 24). Radiopharmaceuticals derived from all D-peptides are particularly attractive due to their anticipated resistance to proteolysis (24, 25).

Copper-64 ($t_{1/2} = 12.7$ h, $\beta^+ = 0.655$ MeV [19.3%], $\beta^- = 0.573$ MeV [39.6%]) has emissions suitable for PET imaging (β^+) as well as radiotherapy (β^-) (3, 26). A commercially available chelator, TETA, has been conjugated to both peptides and monoclonal antibodies (Mabs) for subsequent labeling with radiometals such as ^{64}Cu . The resulting complex has demonstrated relatively high *in vivo* stability (27–29). The N-terminal amine of D-Hep III was chosen as the site for conjugation of one of the carboxylic arms of TETA because the N-terminus did not appear important in binding (23). Iodine radionuclides are also of interest due to the availability of cyclotron-produced ^{124}I ($t_{1/2} = 4.2$ d, $\beta^+ = 2.14$ MeV [25%]) for PET imaging (30–32) and ^{131}I for therapy. Because $\alpha 3\beta 1$ is highly expressed in several types of human neoplasms, it was hypothesized that ^{64}Cu - or ^{125}I -labeled D-Hep III would localize to tumors in a receptor specific manner. The aim of this investigation was to demonstrate that ^{64}Cu - and ^{125}I -labeled D-Hep III peptides were specifically bound to receptor positive cells or tissues, estimate receptor affinities *in vitro*, and determine whether they would localize within tumor xenografts in a receptor specific manner *in vivo*.

EXPERIMENTAL SECTION

Reagents. All standard peptide synthesis chemicals were analytical reagent grade or better and obtained from Applied Biosystems (Foster City, CA) or Fisher Scientific (St. Louis, MO). DBU and TETA·4HCl were obtained from Aldrich (Milwaukee, WI). Fmoc-Tyr(t-Bu)-HMP resin (substitution level = 0.31 mmol/g) was from Millipore Corporation (Bedford, MA). HBTU was from Richlieu Biotechnologies (St. Hyacinthe, Quebec). Glass test tubes precoated with Iodogen were obtained from Pierce (Rockford, IL). The mouse anti-human integrin, $\alpha 3$ monoclonal antibody (Mab anti- $\alpha 3$) was obtained from Chemicon International (Temecula, CA). BSA and 0.5 M EDTA were from Sigma (St. Louis, MO), and ammonium acetate was from Fluka (Ronkonkoma, NY). C-18 Sep-pak Light cartridges were from Waters (Milford, MA). Sprague–Dawley rats were obtained from either Charles River (Wilmington, MA) or Harlan Bioproducts (Indianapolis, IN), and SCID mice were from Taconic (Germantown, NY). Copper-64 was produced as previously described (33). ^{125}I was obtained from Amersham (Piscataway, NJ). Radio-TLC detection was accomplished using a BIOSCAN System 200 Imaging Scanner (Washington, DC). Radioactive samples were counted using a Beckman 8000 automated well-type counter (Fullerton, CA).

High Performance Liquid Chromatography. HPLC analysis and purification was performed on one of two systems: Spectra Physics 8700 ternary pump and controller with a Waters 486 UV detector, or a Waters 600E quaternary pump and controller with a Waters 991 photodiode array UV–Vis detector and Waters 771 autosampler. Both systems were fitted with Rheodyne 7125 injectors and radioactivity was detected by NaI scintillation.

Scheme 1. Solid-Phase Synthesis of TETA-D-Hep-III. All Residues Are in the D-Configuration Except for Glycine

Peptide Synthesis, Purification, and Analysis.

The peptides were assembled on the Fmoc-Tyr(t-Bu)-HMP resin by Fmoc chemistry as previously described (34) on an Applied Biosystems 431A Peptide Synthesizer. Purity was assessed on an analytical Vydac C-18 RP-HPLC column (300 Å, 5 μm , 4.6 $\times$ 250 mm) using a solvent system of A, consisting of H₂O (0.1%TFA) and B, consisting of acetonitrile (0.1%TFA):H₂O (0.1%TFA), 9:1, v:v. The peptides were purified on a Vydac C-18 semipreparative column (300 Å, 15–20 μm , 22 $\times$ 250 mm) unless noted. The flow rates were 1.0 and 12.0 mL/min for the analytical and semipreparative column, respectively. Edman degradation analysis was performed on an Applied Biosystems 477A Protein Sequencer/120A Analyzer. Peptide molecular weights were determined on a Finnigan (San Jose, CA) LCQ ion-trap electrospray mass spectrometer by the Protein and Nucleic Acid Chemistry Laboratories in the Departments of Medicine and Molecular Biology and Pharmacology at the Washington University School of Medicine. Data were collected and analyzed using the Finnigan LCQ Bioworks software (version 1.1). Size-exclusion chromatography was performed on a Superdex HR 10/30, 10 $\times$ 100 mm, using a solvent system consisting of 20 mM NH₄OAc pH 7.5 at a flow rate of 0.8 mL/min. The column was calibrated against insulin, D-Hep-III and 3-iodotyrosine, which eluted at 13.6, 18.5, and 38.2 min, respectively (BSA eluted at 10.4 min in the void volume). A plot of the elution volume vs log molecular weight was linear ($r = 0.98$). Peptide concentrations were determined by UV absorbance at 280 nm utilizing the extinction coefficient for tyrosine in water ($\epsilon = 1200$ L M⁻¹ cm⁻¹) (35). Because D-Hep-III contains two tyrosine residues, the molar extinction coefficient (ϵ) was for D-Hep-III was assumed to be 2400 L M⁻¹ cm⁻¹.

Solid-Phase Synthesis of TETA-D-Hep III. TETA-D-Hep III was synthesized by coupling TETA to the N-terminal amine of the resin-bound peptide (Scheme 1). LiOH·H₂O (34.6 mg, 0.82 mmol) was added to TETA·4HCl (106 mg, 0.18 mmol) and dissolved in 1.5 mL of DMSO. HBTU (63 mg, 0.16 mmol) was added to 208 mg (0.046 mmol) of resin containing the D-Hep-III sequence. The TETA solution was added, immediately followed by 64 μL (0.37 mmol) of DIEA. After 4 h, the mixture was filtered over a fine, fritted, glass funnel, and the resin was rinsed with 3 $\times$ 5 mL DMSO, 3 $\times$ 5 mL DMF, 2 $\times$ 5 mL methanol:H₂O, 1:1, 2 $\times$ 5 mL H₂O, and 3 $\times$ 5 mL methanol and was then dried *in vacuo*. The peptide was released from the resin and side-chain protecting groups

were simultaneously removed in 3.5 h with 3.5 mL of TFA: H₂O, 19:1. The resin was filtered through a fine, fritted glass funnel and rinsed with 2 mL of TFA. Greater than 90% of the peptide was cleaved from the resin. The filtrate was concentrated to 1.5 mL in vacuo and added to 35 mL of *tert*-butyl-methyl ether (4 °C). The white precipitate was collected by centrifugation at 3000 rpm for 10 min at 4 °C. The pellet was rinsed twice with 35 mL of *tert*-butyl-methyl ether (4 °C). RP-HPLC analysis showed about 40% coupling of TETA to the *N*-terminal amine. The crude mixture was dissolved in TFA (30 mg/mL) and 4.9 mg was loaded onto a semipreparative Vydac C-18 RP-HPLC column and purified with a gradient of 24 to 34% B in 45 min. TETA-D-Hep III (1.0 mg) was recovered in 20% yield and D-Hep III (0.8 mg) in 16% yield. Both were greater than 98% pure as determined by RP-HPLC. The peptides were identified by ES-MS (D-Hep III: calcd 1751, obsvd 1751; TETA-D-Hep-III: calcd 2165, obsvd 2165).

Radiolabeling of TETA-D-Hep III with ⁶⁴Cu. TETA-D-Hep III (1.5 μg) was labeled in ammonium acetate (100 mM, pH 5.5, 0.1% BSA) with 200–1000 μCi of ⁶⁴Cu-acetate at room temperature. After 15–30 min, 0.5 M EDTA was added to the reaction mixture (for a final concentration of 1 mM EDTA). By HPLC, ⁶⁴Cu-TETA-D-Hep III eluted at 20.26 min (22 to 32% B in 20 min, analytical) while unbound ⁶⁴Cu or ⁶⁴Cu-EDTA both eluted in the void volume. By radio-TLC (C-18, Whatman, 3:2 methanol: 10% ammonium acetate), ⁶⁴Cu-TETA-D-Hep III had a *R_f* of 0.6, compared to ⁶⁴Cu-acetate, which remained at the origin, and ⁶⁴Cu-EDTA, which migrated to the solvent front. The mixture was purified on a C-18 Sep-Pak preconditioned with ethanol and water and eluted with labeling buffer to remove ⁶⁴Cu-EDTA. Elution with ethanol produced ⁶⁴Cu-TETA-D-Hep III in ≥ 95% purity as demonstrated by HPLC and TLC.

Radiolabeling of D-Hep III with ¹²⁵I. D-Hep-III (10 μg, 1.0 mg/mL, 1:9 DMSO:H₂O) was added to 20 μL of sodium phosphate (200 mM, pH 7.5) in a 1.5 mL polypropylene vial. Sodium (¹²⁵I)-iodide (1.3 mCi) was added to the vial followed by 100 μg of chloramine-T (10 mg/mL in sodium phosphate, 200 mM, pH 7.5). After 2 min, the iodination was quenched with 500 μg of Na₂S₂O₅ (10 mg/mL in sodium phosphate, 200 mM, pH 7.5). The mixture was diluted with 200 μL of TFA and purified on an analytical Vydac C-18 column eluted with 25 to 35% B in 45 min. D-Hep-III eluted at 15.0 min, and the major radioactive product, ¹²⁵I-D-Hep-III, eluted at 21.0 min. Radiochemical yield was 24% and purity was ≥95%. Purity was assessed on an analytical Vydac C-18 RP-HPLC column. As a control to test for degradation of D-Hep-III by chloramine-T, 40 μg of D-Hep-III in 1:9 DMSO:H₂O was added to 40 μL of chloramine-T (10 μg/μL in sodium phosphate, 200 mM, pH 7.5). After 2 min, the mixture was added to 500 μg of Na₂S₂O₅ (10 mg/mL in sodium phosphate, 200 mM, pH 7.5) to quench the chloramine-T.

Iodination of Mab anti-α3. A precoated Iodogen tube was rinsed with 1 mL of Tris-HCl (200 mM, pH = 7.5). Tris-HCl (40 μL, 200 mM, pH = 7.5) was added to the glass tube followed by Na(¹²⁵I)I (181 μCi) and then Mab anti α3 (5 μg). The mixture was allowed to react for 20 min. The iodination mixture was transferred to a 1.5 mL polypropylene tube and allowed to stand for 5 min before addition of Tris-HCl (200 mM, 1 mg/mL BSA, pH = 7.5) to a final volume of 200 μL. Incorporation of ¹²⁵I into the Mab was determined by precipitation of total protein with 10% trichloroacetic acid. Incorporation was 92% and the

¹²⁵I-Mab-anti-α3 was not further purified. Specific activity of ¹²⁵I-Mab-anti-α3 was determined to be 33 μCi/μg.

Serum Stability of Radiolabeled D-Hep III Analogues. ¹²⁵I-D-Hep-III (50 μL) in ethanol was added to 500 μL of rat serum and incubated at 37 °C for 3 h. The incubation mixture was monitored on an analytical Vydac C-18 RP-HPLC column eluted with a gradient of 20 to 90% B in 30 min (1 mL/min, A = H₂O, 0.1% TFA; B = acetonitrile, 0.1% TFA). Stability was monitored for 3 h by RP-HPLC. To estimate serum protein binding of ¹²⁵I-D-Hep-III, it was concentrated from RP-HPLC eluant in vacuo with 20 μL of PBS containing 1 mg/mL BSA and incubated for 40 min at 37 °C and then analyzed by SEC. To investigate whether higher concentrations of D-Hep-III caused aggregation of ¹²⁵I-D-Hep-III, 280 μM D-Hep III was incubated with ¹²⁵I-D-Hep-III prepared as described above (serum protein binding experiment) in both rat serum (75 μL) and PBS (75 μL) at 37 °C for 30 min followed by analysis by SEC.

Copper-64-TETA-D-Hep-III in ethanol was concentrated in vacuo with 10 μL of NH₄OAc (100 mM, pH 5.5, 10 mg/mL BSA). Rat serum (75 μL) was added, and the mixture was incubated at 37 °C for 1 h. Stability was monitored for 1 h by RP-HPLC.

Cell Maintenance. The SKOV3 human ovarian tumor cell line was obtained from ATCC (Rockville, MD) and maintained in McCoy's 5A media (Iwakata and Grace modification with glutamine) from Mediatech (Herndon, VA) with 10% fetal bovine serum supplemented with 50 units/mL penicillin and 0.05 mg/mL streptomycin. Cells were passaged for 4–5 weeks and then replaced from frozen stocks of earlier passages to minimize phenotypic drift. SKOV3 cells were detached with either 0.05% trypsin with 0.53 mM EDTA in HBSS or 5 mM EDTA in PBS each without calcium or magnesium salts.

Preparation of Membranes from Harvested Xenografts and SKOV3 Cultured Cells. SKOV3 cells were split 1:2 24 h prior to harvesting to ensure they were in the growth phase. Cells were detached at about 80% confluency with 5 mM EDTA in PBS and concentrated by centrifugation at 200g for 10 min at 4 °C. The supernatant was discarded, and the cells were suspended in a homogenizing buffer consisting of 50 mM Tris·HCl, 5 mM MgCl₂, pH 7.5, containing aprotinin (0.5 μg/mL), leupeptin (10 μg/mL), pepstatin A (10 μg/mL), phenylmethylsulfonyl fluoride (2 μg/mL), and *N*-ethylmaleimide (2 μg/mL). The cells were lysed by sonication and centrifuged at 34000g for 30 min at 4 °C. After Dounce homogenization of the pellet in the homogenizing buffer, the membranes were quantified with the BCA assay (Pierce, Rockford, IL) relative to BSA. The membranes were centrifuged at 34000g for 30 min at 4 °C and then suspended at a concentration of 1.5 mg/mL in PBS, 1 mM MgCl₂, 1 mg/mL BSA, and stored in aliquots at –80 °C.

Membranes from xenografted tumor were prepared by homogenization of 0.5 g tumor/10 mL homogenizing buffer at 4 °C. After centrifugation at 2000g, the supernatant was stored on ice while the pellet was rehomogenized and recentrifuged twice. The combined supernatants were then recentrifuged at 34000g for 30 min at 4 °C. The pellet was resuspended in 15 mL of homogenizing buffer, and protein content quantified by the BCA method relative to BSA. The membranes were centrifuged at 34000g for 30 min at 4 °C and then suspended at a concentration of 1.5 mg/mL in PBS, 1 mM MgCl₂, and 1 mg/mL BSA, and stored in aliquots at –80 °C.

Binding of ¹²⁵I-Mab-anti-α3 to Membranes Prepared from Xenografted SKOV3 tumor. The specific binding of ¹²⁵I-Mab-anti-α3 was measured at infinite

Figure 1. Binding of ^{125}I -Mab-anti- $\alpha 3$ to membranes from SKOV3 cells (▲) and SKOV3 xenografts (■). K represents the amount of membrane protein required to bind one-half of the bindable fraction of ^{125}I -Mab-anti- $\alpha 3$. K for xenografted SKOV3 membranes = $12.3 \pm 4.7 \mu\text{g}$ and K for SKOV 3 membranes from cell culture = $11.7 \pm 3.0 \mu\text{g}$.

antigen excess (36) with membranes from SKOV3 cells and SKOV3 xenografted tumor (passage 10). Seven 1:2 serial dilutions of $833 \mu\text{g/mL}$ membrane protein were made in PBS containing MgCl_2 (1 mM) and BSA (1 mg/mL). Iodine-125-labeled Mab-anti- $\alpha 3$ was added to the membranes for a final concentration of 466000 to 497000 cpm/mL. To assess nonspecific binding, Mab-anti- $\alpha 3$ was added to membranes containing the radioiodinated Mab for a final concentration of $33 \mu\text{g/mL}$. Nonspecific binding of ^{125}I -Mab-anti- $\alpha 3$ to the glass fiber filters was assessed by adding the tracer to the binding buffer alone. The samples were allowed to bind at 24°C for 2 h, and then five 125 mL aliquots were filtered in a 96-well plate with $1.0 \mu\text{m}$ glass fiber filters. The filters were rinsed with $3 \times 50 \mu\text{L}$ of cold (4°C) binding buffer, dried at $\sim 40^\circ\text{C}$, and removed to 1.5 mL polypropylene centrifuge tubes by the Millipore Multiscreen system (Bedford, MA) and counted in a gamma counter. The data (Figure 1) were fit by nonlinear regression according to a one-site binding hyperbola model with the following equation: $Y = (R_f^{\text{max}}) \cdot (X) / (K + X)$ with Graphpad Prism, where $X = \mu\text{g}$ membrane protein; $Y = \text{reactive fraction}$; R_f^{max} = maximum reactive fraction; K = amount of membranes (μg) required to bind one-half of the ^{125}I -Mab-anti- $\alpha 3$.

To establish $\alpha 3\beta 1$ density, a homologous competitive binding assay was carried out between the ^{125}I -Mab-anti- $\alpha 3$ and Mab-anti- $\alpha 3$. Briefly, membranes from SKOV3 xenografted tumor ($200 \mu\text{g}$, passage 10) were suspended in binding buffer (PBS, 1 mg/mL BSA, 1 mM MgCl_2) along with ^{125}I -Mab-anti- $\alpha 3$ (0.0144 nM , $\sim 80000 \text{ cpm}$) and either 0.02, 0.1, 0.6, 2.9, 14, 72, or 177 nM Mab-anti- $\alpha 3$. One preparation contained only ^{125}I -Mab-anti- $\alpha 3$. The total volume was $370 \mu\text{L}$. The samples were allowed to bind at 24°C for 2 h, and then four $40 \mu\text{L}$ aliquots were filtered in a 96-well plate with $1.0 \mu\text{m}$ glass fiber filters. The filters were rinsed with $3 \times 50 \mu\text{L}$ cold (4°C) binding buffer, dried at $\sim 40^\circ\text{C}$, removed to 1.5 mL polypropylene centrifuge tubes by the Millipore Multiscreen system (Bedford, MA), and counted in a gamma counter. Specifically bound cpm were plotted against $\log [\text{Mab-anti-}\alpha 3]$ concentration, and the data was fit by nonlinear regression to a one-site competition curve in Prism (Graphpad, San Diego, CA) (Figure 2).

Heterologous Competitive Binding Assays. Membranes from SKOV3 xenografts (passage 10) were thawed, Dounce homogenized, and diluted in PBS containing MgCl_2 (1 mM), BSA (1 mg/mL) (binding buffer) to prepare a stock solution of membranes. Either ^{125}I -D-Hep-III or ^{64}Cu -TETA-D-Hep-III was diluted to prepare a stock

Figure 2. Homologous competitive binding between ^{125}I -Mab-anti- $\alpha 3$ and Mab anti $\alpha 3$ to membranes from SKOV3 xenografts, passage 10 ($\text{IC}_{50} = 5.3 \text{ nM}$).

solution of tracer in the binding buffer. D-Hep-III (1 mg/mL in 1:9 DMSO:water) was serially diluted in the same vehicle at a volume of $25 \mu\text{L}$ in 1.5 mL polypropylene centrifuge tubes. Membranes ($500 \mu\text{L}$) and tracer ($250 \mu\text{L}$) were added to the D-Hep-III for a final concentration of 400 to $600 \mu\text{g/mL}$ membrane protein and 200 to 300 kcpm/mL tracer, respectively. The mixtures were allowed to mix at room temperature for 2 h, and then four to five aliquots of $100\text{--}125 \mu\text{L}$ were layered over $250 \mu\text{L}$ of dioctylphthalate:dibutylphthalate (55:45) in 1.5 mL polypropylene centrifuge tubes. To separate tracer bound to membrane protein from unbound, the aliquots were centrifuged at 14000 rpm in an Eppendorf 5415 benchtop centrifuge. After removing the supernatant, the pellets were counted in a gamma counter. Specifically bound cpm were plotted against $\log [\text{D-Hep-III}]$ concentration, and the data was fit by nonlinear regression to a one-site competition curve using Prism.

Biodistribution Studies: General. The laboratory rats and mice were maintained in the animal facilities operated by the Division of Comparative Medicine at Washington University School of Medicine in accordance with the American Association for Accreditation of Laboratory Animal Care (AAALAC) requirements. The radiolabeled D-Hep-III analogues and blocking doses were injected into the tail vein of anesthetized rats and mice. The vehicle was either 0.9% NaCl or 10 mM NH_4OAc , pH 6, each containing 0.1% BSA. Animals were sacrificed by cervical dislocation while under Metofane anesthesia at specific time points postinjection. Organs of interest were excised, counted in a gamma counter, and then weighed to generate the percent injected dose/organ (% ID/organ) and percent injected dose/gram tissue (% ID/g).

Biodistribution of ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III in Male Sprague–Dawley Rats. Copper-64-TETA-D-Hep-III ($5.0 \mu\text{Ci}/100 \mu\text{L}/\text{rat}$ 0.1 M ammonium acetate, 1 mg/mL BSA $\geq 95\%$ radiochemical purity, specific activity $798 \text{ Ci}/\text{mmol}$) and ^{125}I -D-Hep-III ($5.0 \mu\text{Ci}/100 \mu\text{L}/\text{rat}$; water, 1 mg/mL BSA, $\geq 98\%$ radiochemical purity, specific activity $2000 \text{ Ci}/\text{mmol}$) were coinjected into male-Sprague–Dawley rats ($\sim 500 \text{ g}$). The gamma counter windows were adjusted so that none of the cpm from the ^{125}I contributed to the cpm of ^{64}Cu . After 6 days (> 10 half-lives, ^{64}Cu) the tissues were recounted for ^{125}I .

SKOV3 Xenografts in SCID Mice. One hundred microliter aliquots (7.5×10^6 cells) were implanted sc in the right and left flank of ≥ 5 week old female SCID mice. Tumor growth was measured every 3–5 days with calipers. The tumors grew to 500 to 1500 mm^3 within 3–4 weeks. This tumor model was maintained by serial passages of solid tumor out to passage 12 by implantation of two tumor pieces ($\sim 3 \text{ mm}^3$) in the right and left flank of female SCID mice.

Biodistribution of ^{64}Cu -TETA-D-Hep-III in SCID Mice Bearing SKOV3 Tumors. Nine mice bearing xenografted SKOV3 tumors (passage 3) implanted bilaterally on the flank were used at 21 days post-implantation. Five mice received ^{64}Cu -TETA-D-Hep-III ($5.8 \mu\text{Ci}/100 \mu\text{L}/\text{mouse}$, 0.1 M ammonium acetate, 1 mg/mL BSA, 540 Ci/mmol). The animals were sacrificed at 1 h post-injection, and tissues were removed and counted in a gamma counter for biodistribution as described above.

Biodistribution of ^{125}I -D-Hep-III in SCID Mice Bearing SKOV3 Tumors. Four SCID mice bearing bilateral SKOV3 xenografts (passage 5) received ^{125}I -D-Hep-III ($1 \mu\text{Ci}/100 \mu\text{L}/\text{mouse}$, 0.9% NaCl, 1 mg/mL BSA, $\geq 2000 \text{ Ci/mmol}$). Four tumor-bearing mice were coinjected with $1 \mu\text{Ci}$ ^{125}I -D-Hep-III ($1 \mu\text{Ci}/100 \mu\text{L}/\text{mouse}$, 0.9% NaCl, 1 mg/mL BSA, $\geq 2000 \text{ Ci/mmol}$) and $9 \mu\text{g}$ D-Hep-III. Three mice were coinjected with $1 \mu\text{Ci}$ ^{125}I -D-Hep-III ($1 \mu\text{Ci}/100 \mu\text{L}/\text{mouse}$, 0.9% NaCl, 1 mg/mL BSA, $\geq 2000 \text{ Ci/mmol}$) and $1.7 \mu\text{g}$ D-Hep-III. The animals were sacrificed at 1 h postinjection and biodistribution was determined as described above.

RESULTS

Peptide Synthesis. Following Fmoc solid-phase synthesis of D-Hep-III, the peptide was found to be compositionally correct by Edman degradation sequence analysis. D-Hep-III was isolated by RP-HPLC and further characterized by mass spectrometry. Purities were determined by analytical RP-HPLC, with monitoring both at $\lambda = 222$ and 280 nm , and were greater than 98% .

TETA was coupled to D-Hep-III while it was resin-bound. TETA-4HCl had low solubility in DMF or DMSO; however, neutralization with lithium hydroxide improved its solubility in DMSO. Coupling yields were in the range of 40 to 50% and could not be improved by further coupling reactions. RP-HPLC analysis of the unpurified cleavage mixtures showed that D-Hep-III and TETA-D-Hep-III eluted closely, even with a relatively shallow gradient, which resulted in numerous fractions from the semipreparative purification to be mixtures of both peptides in varying amounts. TETA-D-Hep III was recovered in 20% yield and D-Hep III in 16% yield.

Radiochemistry. Radiochemical yields of ^{64}Cu -TETA-D-Hep-III ranged from 40 to 90% and radiochemical purity $\geq 95\%$ and specific activities ranged from 500 to 2000 Ci/mmol . D-Hep-III contains two tyrosine residues, each of which has the potential for radioiodination. RP-HPLC of the purified ^{125}I -D-Hep-III utilizing a shallow gradient showed a small shoulder in the trace for the major component, suggesting a mixture of two mono-radioiodinated species. Therefore, the ^{125}I -D-Hep-III used in vitro assays and in vivo studies was a probable mixture of two mono-radioiodinated peptides. Whether or not this affected the binding affinity of the peptide is unknown. RP-HPLC investigation of a mixture of D-Hep-III and chloramine-T showed no degradation of the peptide. Separation of the ^{125}I -D-Hep-III from D-Hep-III yielded specific activities of $\geq 2000 \text{ Ci/mmol}$.

Serum Stability. The stability of ^{125}I -D-Hep-III and ^{64}Cu -TETA-D-Hep-III were monitored by RP-HPLC and no changes in retention time or the appearance of new radiolabeled components were observed within 3 h which is indicative of the stability of the radiolabeled D-Hep III analogues. Although RP-HPLC is sensitive to changes in structure, such as cleavage of the peptide bonds, it may not have revealed whether either of the radiolabeled D-Hep-III analogues bound serum proteins. Furthermore, in cases where there were mixtures of the radiolabeled

D-Hep-III analogues and D-Hep-III at a concentration equal to or in excess of $10 \mu\text{M}$, a SEC HPLC column especially designed for low molecular weight peptides showed there was no aggregation of D-Hep-III and its radiolabeled analogues. This is an important control for biodistributions where ^{125}I -D-Hep-III was coinjected with D-Hep-III ($25 \mu\text{M}$) as well as for the competitive binding assays where ^{125}I -D-Hep-III analogues were combined with D-Hep-III ($10 \mu\text{M}$). D-Hep-III at $280 \mu\text{M}$ did not cause the aggregation of ^{125}I -D-Hep-III either in aqueous buffer or rat serum.

Heterologous Competitive Binding Assays between Radiolabeled D-Hep III Analogues and D-Hep III. The heterologous competitive binding assay between ^{125}I -D-Hep-III or ^{64}Cu -TETA-D-Hep-III and D-Hep-III on membranes from SKOV3 cultured cells and xenografts (Figures 3 and 4, Table 3) show that both the D-Hep-III and the radiotracers are specifically bound to cell surface receptors. The 95% confidence intervals ($95\% \text{ CI}$) for the IC_{50} values are large in cases where the concentration of D-Hep-III was not great enough to completely block tracer

Table 3. IC₅₀ Values for D-Hep-III in Heterologous Binding Assays

radioligand	membrane source	IC ₅₀ , nM	95% CI, nM
^{125}I -D-Hep-III	SKOV3 cultured cells	360	210–614
^{125}I -D-Hep-III	SKOV3 xenograft passage 10	3700	1682–8061
^{64}Cu -TETA-D-Hep-III	SKOV3 cultured cells	4700	1402–15620

binding. The concentrations of the radioligands in the binding assays did not exceed 100 pM.

Biodistributions of ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep III in Normal Rats. A biodistribution of ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III in male Sprague–Dawley rats showed that both radiolabeled analogues cleared from the circulation by 4 h ($\leq 0.06 \pm 0.01\%$ ID/g) with the highest accumulation for each in the kidney (Table 1). ^{125}I -D-Hep-III ($27.3 \pm 2.61\%$ ID/g) accumulated 9-fold more ($P < 0.01$) in a single kidney than did ^{64}Cu -TETA-D-Hep-III ($2.98 \pm 0.48\%$ ID/g). Accumulation in the other organs was low except for the thyroid accumulation in the case of ^{125}I -D-Hep-III ($3.67 \pm 1.33\%$ ID/g).

Biodistribution of ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III in Tumor Bearing SCID Mice. ^{64}Cu -TETA-D-Hep-III was evaluated in SCID mice bearing bilateral SKOV3 human ovarian tumors (Table 2). ^{64}Cu -TETA-D-Hep-III cleared rapidly from the blood ($0.53 \pm 0.14\%$ ID/g) but demonstrated low tumor accumulation ($0.55\% \pm 0.055\%$ ID/g) at 1 h. High accumulation of ^{64}Cu -TETA-D-Hep III in the kidney was observed ($29.7 \pm 2.82\%$ ID/g).

^{125}I -D-Hep-III was evaluated in SCID mice bearing bilateral sc SKOV3 xenografts with and without competitive doses of 1.7 and 9 μg of D-Hep III. Tumor accumulation was low ($1.25 \pm 0.12\%$) and no dose dependent blocking of tumor accumulation was observed ($\geq 1.72 \pm 0.20\%$ ID/g) at the doses administered ($P > 0.05$). Kidney accumulation after 1 h was very high ($244 \pm 17\%$ ID/g) but dose-dependent blocking was also not observed ($\geq 237 \pm 45\%$ ID/g, $P > 0.05$). However, increases in liver (3.4-fold, $P < 0.05$) and spleen (3.1-fold, $P < 0.01$) accumulation of the radioiodinated peptide were observed with coinjection of D-Hep-III (9 μg), but concomitant decreases in accumulation in other tissues were not apparent.

Binding of ^{125}I -Mab-anti- $\alpha 3$ to Membranes from SKOV3 Cells and Xenografted Tumor. One possible explanation for the low accumulation of either of the radiolabeled D-Hep-III analogues in tumors may be down-regulation of $\alpha 3\beta 1$ expression. Therefore, binding assays were carried out with a radioiodinated monoclonal antibody specific for the $\alpha 3$ subunit of the targeted integrin. Equal amounts of ^{125}I -Mab-anti- $\alpha 3$ at the same specific activity were added to varying amounts of membrane protein. The reactive fraction of ^{125}I -Mab-anti- $\alpha 3$ was

relatively low, $9.4 \pm 1.3\%$, for xenografted membranes and $8.2 \pm 0.7\%$ for SKOV3 cells grown in culture. Moreover, the amount of membrane protein required to bind one-half the tracer was $12.3 \pm 4.7 \mu\text{g}$ for xenografted membranes and $11.7 \pm 3.0 \mu\text{g}$ for SKOV3 membranes (Figure 1). This indicates that $\alpha 3\beta 1$ is present in membranes from SKOV3 xenografts, as well as from SKOV3 membranes of cells grown in culture. Furthermore, since $\alpha 3\beta 1$ is proportional to the amount of membrane protein, and since the same amount of membrane protein from each receptor source will bind one-half the ^{125}I -Mab-anti- $\alpha 3$, it is concluded that the density of $\alpha 3\beta 1$ is equivalent between the two preparations.

In the homologous competitive binding assay between the ^{125}I -Mab-anti- $\alpha 3$ and Mab anti- $\alpha 3$, all of the radioligand bound at concentrations of competitive Mab of 0.01, 0.02, 0.1, and 0.6 nM because of the low immunoreactivity of the ^{125}I -Mab (Figure 2). Insufficient data points remained for Scatchard analysis. Therefore, the minimum density of $\alpha 3\beta 1$ integrin can be estimated from the amount of ^{125}I -Mab specifically bound in the preparations containing 14 and 72 nM Mab, where 1400 and 970 cpm bound, respectively. Using the following conversion factors, values of 2700 and 9800 pM total bound were obtained: 33 $\mu\text{Ci}/\mu\text{g}$ Mab, 150 KDa, 0.6 dpm/cpm, $2.22 \times 10(6)$ dpm/ μCi , $1 \times 10(6)$ pmol/ μmol . With 75 μL aliquot containing 40 μg of protein, a log-dose dependent displacement of ^{125}I -Mab-anti- $\alpha 3$ by Mab anti $\alpha 3$ was observed (Figure 2; $\text{IC}_{50} = 5.3$ nM, 95% confidence interval 3.2 to 8.7 nM).

DISCUSSION

Radiolabeled derivatives of peptide hormones targeted to cell surface receptors, such as vasoactive intestinal peptide (VIP) (38), somatostatin (39), and melanotropin stimulating hormone (αMSH) (40), have demonstrated receptor mediated accumulation of the radiotracer at tumor sites in animal models or humans and therefore have potential as tumor imaging agents. Besides peptide hormones, another class of peptides derived from ECM proteins has been investigated as tumor imaging agents (11–14). D-Hep-III, derived from the ECM protein, type IV collagen, was investigated as an imaging agent for the $\alpha 3\beta 1$ integrin.

The tetraazamacrocyclic TETA was coupled to the N-terminal amine of D-Hep-III while it was resin bound,

as structure–activity studies indicated that the *N*-terminal region of D-Hep-III does not significantly impact receptor binding (23). TETA-D-Hep-III and D-Hep-III were radiolabeled with ^{64}Cu and ^{125}I , respectively, for evaluation as a receptor specific imaging agents.

To establish that both ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III bound specifically to $\alpha 3\beta 1$ positive tissues, heterologous competitive binding assays between D-Hep-III and ^{125}I -D-Hep-III or ^{64}Cu -TETA-D-Hep-III were carried out on membranes isolated from SKOV3 cultured cells and SKOV3 xenografts. Both ^{125}I -D-Hep-III and ^{64}Cu -TETA-D-Hep-III were specifically bound to cell surface receptors on membranes originating from the SKOV3 ovarian tumor cell line. However, the IC_{50} value for D-Hep-III was 10-fold higher on membranes isolated from SKOV3 xenografts ($\text{IC}_{50} = 3700 \text{ nM}$) than from those isolated from cultured cells ($\text{IC}_{50} = 360 \text{ nM}$). The concentration of ^{125}I -D-Hep-III was 50 and 26 pM in the experiments with SKOV3 membranes and xenografts, respectively. According to the Cheng-Prusoff equation [$K_D = \text{IC}_{50} / (1 + [\text{radioligand}] / K_D)$], where K_D = affinity of the competitor for the receptor; K_D = affinity of the radioligand for the receptor; IC_{50} = concentration of competitive ligand required to displace one-half the radioligand], a 2-fold decrease in tracer concentration cannot account for a 10-fold increase in IC_{50} unless either the K_D of D-Hep-III or ^{125}I -D-Hep-III or both were different on membranes isolated from SKOV3 cells or xenografts. This indicates that either or both of the ligands were interacting with different receptors between the two preparations. The higher affinity interaction observed on membranes from SKOV3 cells may have been with an integrin other than $\alpha 3\beta 1$ since the Hep III sequence is contained within a region of type IV collagen that is known to bind both the $\alpha 2\beta 1$ and $\alpha 3\beta 1$ integrins (ref 7 and references therein). Furthermore, L-Hep-III (i.e., all residues except glycine are in the *L*-configuration) binds both the $\alpha 2\beta 1$ and $\alpha 3\beta 1$ integrins from human mesangial (kidney) cells (41).

The radioligands were also evaluated in normal and tumor-bearing animal models. The biodistribution of ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III in normal rats resulted in rapid blood clearance and low accumulation in most of the tissues examined. The highest accumulation was in the kidney, which is known to highly express $\alpha 3\beta 1$ (16, 17, 37). While kidney uptake could have been receptor-mediated, it is important to note that renal clearance is also the major excretory pathway of the radiotracers. However, coadministration of up to 9 μg doses of D-Hep-III in SCID mice resulted in no observed decreases in kidney accumulation. The observed accumulation of the tracers in the kidneys could simply be a result of clearance although other radiolabeled peptides, such as ^{64}Cu - and ^{125}I -labeled somatostatin analogues, do not accumulate in the kidneys to such a great extent (42, 43). Alternatively, the 9 μg blocking dose may not have been sufficient to block the potentially large number of integrin receptors present in the kidneys.

To determine if ^{64}Cu -TETA-D-Hep-III would accumulate preferentially in $\alpha 3\beta 1$ rich tumor tissues, a biodistribution of ^{64}Cu -TETA-D-Hep-III was obtained in SCID mice bearing bilateral SKOV3 xenografts. SKOV3 cells strongly express $\alpha 3\beta 1$ in culture (44) but $\alpha 3\beta 1$ density of SKOV3 or any other xenografts of cultured cells known to express $\alpha 3\beta 1$ has not been reported. To determine if SKOV3 xenograft accumulation was receptor mediated for ^{125}I -D-Hep-III, a blocking dose of D-Hep-III (1.7 and 9 μg) was coinjected with ^{125}I -D-Hep-III. Accumulation of the radioactivity in the liver and spleen increased with

increasing doses of D-Hep-III. However, the accumulation of the radioactivity in the tumor was low and not significantly different than that of the blood or tumors from animals that received the blocking doses. The accumulation of radiolabeled D-Hep-III analogues in the tumor may not be receptor-mediated; however, if the $\alpha 3\beta 1$ expression is dense, higher blocking doses may be needed to displace the tracers.

Low tumor accumulation of ECM-derived peptides had been previously observed with peptides derived from other ECM proteins. Peptides incorporating the sequence YIGSR, a fragment proposed to bind to laminin receptors, were radiolabeled with ^{131}I and investigated in a tumor bearing animal model (12). In mice bearing Lewis lung carcinoma tumors, ^{131}I -YIGSR uptake in the tumor, while low ($1.15 \pm 0.28\% \text{ ID/gram}$, 24 h), was much higher than blood ($0.014 \pm 0.007\% \text{ ID/gram}$, 24 h). However, this ratio was achieved at 24 h postinjection. In contrast, previous work in mice bearing xenografted melanoma showed that cyclic peptides incorporating the RGD sequence [cyclo-(RGD-D-YV)] and radioiodinated with ^{125}I displayed low tumor accumulation ($1.30 \pm 0.13\% \text{ ID/gram}$, 1 h) (11). In these studies, clearance from the blood was rapid ($0.17 \pm 0.02\% \text{ ID/gram}$, 1 h), and a tumor-to-blood ratio of ~ 8 was achieved. In our study, the evaluation of the radiolabeled D-Hep-III analogues in tumor-bearing animals extended to only 1 h, and this time interval may not have been long enough to reach optimal tumor-to-blood ratios indicative of receptor-mediated accumulation.

The primary goal of this study was to determine whether ^{125}I -D-Hep-III or ^{64}Cu -TETA-D-Hep-III would localize in a receptor specific manner in $\alpha 3\beta 1$ rich tissues, and the results suggest that the observed accumulation was not receptor-mediated. Receptor down-regulation or degradation of the radiotracers are two factors that could have adversely affected receptor-mediated tumor accumulation. However, the results from the binding assay at infinite $\alpha 3\beta 1$ excess to ^{125}I -Mab-anti- $\alpha 3$ indicate that $\alpha 3\beta 1$ density is equivalent between SKOV3 cultured cells and SKOV3 xenografts. Furthermore, the minimum density of $\alpha 3\beta 1$ of 5 to 18 pmol/mg protein is a relatively high value since xenografted somatostatin-positive tumors routinely express 300 fmol/mg protein (26). Therefore, $\alpha 3\beta 1$ down-regulation or sparse density cannot explain the lack of receptor mediated accumulation. Moreover, both ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III are stable in serum long enough to reach their targets.

It was previously shown that a monoclonal antibody, GA17 ($K_D = \sim 2 \text{ nM}$), directed toward $\alpha 3\beta 1$ and radiolabeled with either ^{125}I or ^{111}In , selectively localized to human tumor xenografts which expressed $\alpha 3\beta 1$ in vitro, thus demonstrating $\alpha 3\beta 1$ as a viable target for high affinity radiolabeled ligands (45). Although the epitope of GA17 is unknown, Mab binding is not necessarily dependent on $\alpha 3\beta 1$ conformation or competition from endogenous ligand, two possibilities that would explain the low tumor accumulation of either ^{125}I -D-Hep-III or ^{64}Cu -TETA-D-Hep-III in the xenograft.

Another possible explanation for the low accumulation of the ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III is low affinity for the receptor. The K_D of radiolabeled D-Hep-III analogues would have to approach the concentration of the tracer in the competitive binding experiments, which ranged from 26 to 100 pM, for IC_{50} values of D-Hep-III to differ greatly from the K_D of D-Hep-III. The $\text{IC}_{50} = 3700 \text{ nM}$ for D-Hep-III on membranes from SKOV3 xenografts suggests a weak affinity for D-Hep-III. Furthermore, $\alpha 3\beta 1$ is known to be recruited to focal contacts of cells adhering to type IV collagen after the collagen is

bound by integrins ($\alpha 2\beta 1$ and $\alpha 1\beta 1$) with demonstrated high affinity for type IV collagen, suggesting that $\alpha 3\beta 1$ has a weak affinity for type IV collagen (7). Successful radiotracers that have accumulated in their target tissue by a receptor-mediated process have demonstrated affinity in the low nanomolar region. Micromolar affinity is likely to be insufficient for receptor-mediated uptake in target tissue (46) and would explain the low accumulation of ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III.

CONCLUSIONS

Radiolabeled TETA-D-Hep-III and D-Hep-III were evaluated as imaging agents for human neoplasms where the $\alpha 3\beta 1$ integrin is strongly expressed. On tissues known to express $\alpha 3\beta 1$ integrin, binding of both of ^{64}Cu -TETA-D-Hep-III and ^{125}I -D-Hep-III was inhibited in a log-dose dependent manner on membranes from cultured SKOV3 cells and SKOV3 xenografts, demonstrating that these ligands are bound to cell surface receptors. IC_{50} values of D-Hep-III in the low micromolar region suggest a weak affinity of D-Hep-III and radiolabeled analogues of D-Hep-III for $\alpha 3\beta 1$. In the in vivo tumor model used in this study low accumulation of both radiotracers was observed within the xenograft at the time points investigated despite the relatively dense expression of $\alpha 3\beta 1$. The combination of the results obtained from the in vitro and in vivo data strongly suggest that peptides of this class targeted to the $\alpha 3\beta 1$ would not be suitable as in vivo imaging agents in humans.

Targeting Endothelial Cells Overexpressing VEGFR-2: Selective Toxicity of Shiga-like Toxin–VEGF Fusion Proteins

Marina V. Backer* and Joseph M. Backer

SibTech, Inc., Newington, Connecticut 06111. Received July 24, 2001

Growing endothelial cells at the sites of angiogenesis express high numbers of VEGF receptors and therefore may be particularly sensitive to VEGF-mediated drug delivery. To test this hypothesis we have constructed a protein containing the catalytic A-subunit of Shiga-like toxin I fused to VEGF₁₂₁ (SLT-VEGF/L). Wild-type A-subunit is a site-specific N-glycosidase of 28S rRNA that inhibits protein synthesis after being delivered into cells by separate cell-binding B-subunits. SLT-VEGF/L retains functional activities of both SLT and VEGF₁₂₁ moieties, since it inhibits protein synthesis in a cell-free translation system and induces VEGFR-2 tyrosine autophosphorylation. SLT-VEGF/L selectively inhibits growth of porcine endothelial cells expressing 2.5×10^5 VEGFR-2/cell with an IC₅₀ of 0.2 nM and rapidly induces apoptosis at concentrations >1 nM. We found that sensitivity of VEGFR-2 transfected PAE cells to SLT-VEGF/L declined as the cellular VEGFR-2 density decreased; PAE cells expressing 25000 VEGFR-2/cell were as sensitive as parental cells lacking the receptor. Growth inhibition and induction of apoptosis by SLT-VEGF/L require intrinsic N-glycosidase activity of the SLT moiety, but take place without significant inhibition of protein synthesis. Selective cytotoxicity of SLT-VEGF/L against growing endothelial cells overexpressing VEGFR-2 suggests that it may be useful in targeting similar cells at the sites of angiogenesis.

INTRODUCTION

Angiogenesis is a tightly controlled process of growing new blood vessels that in the adult organism under normal circumstances takes place only during muscle or wound healing (reviewed in refs 1, 2). However, angiogenesis occurs in a large number of pathologies, such as solid tumor growth, various eye diseases, chronic inflammatory states, and ischemic injuries (reviewed in ref 3). Growing endothelial cells at the sites of angiogenesis are unique targets for treatment of several major pathologies, and a number of compounds targeting angiogenesis are currently at various stages of development (reviewed in ref 4). Several positive and negative regulators control angiogenesis, and the shift in equilibrium between these regulators is presumably responsible for angiogenesis in pathological situations (reviewed in refs 5, 6). The crucial positive regulator of angiogenesis is vascular endothelial growth factor (VEGF) also known as vascular permeability factor (reviewed in ref 7). VEGF is a secreted homodimeric glycoprotein that, as a result of alternative mRNA splicing, may consist of polypeptides with 121, 145, 165, 189, or 206 amino acid residues. VEGF is expressed by normal and tumor cells in response to hypoxia and nutritional deprivation, and its expression appears to be regulated on several levels (reviewed in refs 8, 9). The action of VEGF on endothelial cells is mediated by tyrosine kinase Flt-1 and KDR/Flk-1 receptors, also known as VEGFR-1 and VEGFR-2, with the latter playing the dominant role in angiogenesis (reviewed in refs 9, 10). These receptors are preferentially expressed on endothelial cells, and there is evidence that

endothelial cells at the sites of angiogenesis express significantly higher numbers of VEGFR-2 than quiescent endothelial cells (11–15). VEGF binding to VEGFR-2 induces receptor dimerization followed by tyrosine phosphorylation of the SH2 and SH3 domains and internalization of the complexes (reviewed in refs 9, 10). Since VEGF binds specifically to endothelial cells, this growth factor provides a unique opportunity for targeted drug delivery to the sites of angiogenesis. Indeed, it has been shown that conjugation or fusion of the catalytically active fragments of diphtheria toxin (DT) to VEGF yielded proteins that inhibited growth of endothelial cells and displayed anti-angiogenic activity in in vivo models of angiogenesis (16–18).

To inhibit angiogenesis without damaging quiescent endothelium, the toxin–VEGF fusion proteins should selectively target endothelial cells at the sites of angiogenesis that overexpress VEGFR-2. We hypothesized that overexpression of VEGFR-2 receptor in the growing endothelial cells may endowed them with enhanced sensitivity to some toxin–VEGF fusion proteins. To test this hypothesis we have constructed a protein containing the catalytic A-subunit of Shiga-like toxin I fused to VEGF₁₂₁ (SLT-VEGF/L). SLT-1 produced by *E. coli* O157:H7 is a “natural killer” for endothelial cells. Damage to endothelial cells caused by SLT-1 plays a causative role in the pathogenesis of hemorrhagic colitis and hemolytic uremic syndrome induced by *E. coli* O157:H7 (19–22). SLT-1 is composed of a single copy of a 32 kDa A-subunit associated with a ring shaped pentamer of 7 kDa B-subunits that bind to the cellular receptor globotriaosylceramide known as Gb₃/CD77. SLT-1 enters cells via CD77-mediated endocytosis, whereby the A-subunit is cleaved into disulfide bond linked 27.5 kDa A₁ and 4.5 kDa A₂ fragments (22, 23). The processed A-subunit is a site-specific N-glycosidase that cleaves off A₄₃₂₄ in the 5' terminus of 28S rRNA (24). Depurination of A₄₃₂₄ inhibits

binding of the elongation factor EF-1/aminocyl-tRNA complex to ribosomes, resulting in the inhibition of the protein synthesis and initiation of apoptosis. Proteolytic processing of the A-subunit is not required for its enzymatic activity, since the full length A-subunit, and truncated A-subunits missing most of the A₂ region, retain significant N-glycosidase activity in vitro (25–27). Furthermore, fusion proteins containing the full length A-subunit as well as various truncated A-subunits fused to the N-terminus of CD4 retain N-glycosidase activity and are cytotoxic for cells expressing the HIV-1 gp120/gp41 complex (26, 27).

Our preliminary data indicated that SLT-VEGF/L inhibits growing cells overexpressing VEGFR-2 (28). We report here that the number of VEGFR-2 receptors on endothelial cells determines their sensitivity to SLT-VEGF/L. Furthermore, contrary to a commonly held view that plant and bacterial toxin act via inhibition of protein synthesis we found that SLT-VEGF/L induces apoptosis without significant inhibition of protein synthesis.

MATERIALS AND METHODS

Plasmids. The pJB144 plasmid encoding VT1/SLT-1 holotoxin was kindly provided by Dr. A. Solyk (Samuel Lunfield Research Institute, Toronto, Canada). The pBalPst/KDR mammalian expression plasmid containing the full-length human VEGFR-2 was kindly provided by Dr. B. Terman (Albert Einstein School of Medicine, NY).

Construction of Expression Plasmids. Primers for cloning and mutagenesis of SLT-1 fragments (GenBank accession: AB015056) were synthesized by CeneLink (Thornwood, NY). The full-length (1–293 aa) and truncated (62–264 aa) fragments of the SLT-1 A-subunit were amplified by PCR using the pJB144 plasmid as a template. The “sense” primers for the full-length (5′-CCG-AGATCTGAAGGAATTTACCTTAGAC) and for the truncated (5′-CCCAGATCTGCTACGGCTTATTGTTGAACG) SLT-1 fragments included *Bgl*II sites (underlined). The “antisense” primers for the full-length (5′-ATAGGTACCACTGCTAATAGTTCTGCG) and for the truncated (5′-ATAGGTACCATCTGCCGACACATAGAAG) SLT-1 fragments introduced *Kpn*I sites (underlined). PCR-amplified full-length (L) and truncated (S) SLT-1 fragments were cloned separately into VEGF₁₂₁ encoding pET32-VEGF₁₂₁ plasmid (constructed as described in 29) in-frame with VEGF₁₂₁. The resulting plasmids, pET32/SLT-VEGF/L and pET32/SLT-VEGF/S, were confirmed by sequencing (CSU-Macromolecular Resources, Ft. Collins, CO). Site-specific mutagenesis of SLT-1 A-subunit encoded by pET32/SLT-VEGF/L was done using GeneEditor in vitro Site-Directed Mutagenesis System (Promega). Two mutagenic primers were designed to introduce three point mutations (underlined): Y114S (5′-ACGTGGTAGAGCTACTGTCACC), and E167Q and R170L (5′-TTGCCGAAAAAGTAAAGCTTGAGCTGTACAG). The Y114S and R170L mutations were confirmed by sequencing of mutated DNA isolated from two clones. The E167Q mutation was not detected in either clone.

Expression of Fusion Proteins. VEGF₁₂₁ and SLT-VEGF fusion proteins were expressed in *E. coli* strain Origami(DE3)pLysS (Novagen). After induction with 1 mM isopropyl-1-thio-β-D-galactopyranoside (Life Technologies), bacteria were grown for 4 h at 30 °C, harvested, and lysed by freezing-thawing in 50 mM Tris-HCl pH 7.5, 0.1 mM MgCl₂, 1% NP-40, and all protease inhibitors. After DNase treatment inclusion bodies were pelleted at 5000g for 30 min, washed twice with 20 mM Tris-HCl pH 8.0, 0.5 M NaCl, 5 mM imidazole, and solubilized in

8 M urea by sonication. The proteins were refolded by dialysis against 10 mM Tris-HCl pH 8.0, 150 mM NaCl. For dialysis of truncated form of SLT-VEGF, the buffer was supplemented with 0.01% Brij-35. All fusion proteins contained S-tags on the N-termini, making it possible to determine their molar concentrations by S-Tag Assay (Novagen).

Cell Cultures. Porcine aortic endothelial (PAE) cells and 293 human primary embryonic kidney cells were obtained from American Type Culture Collection (Rockville, MD). PAE cells expressing 2×10^5 VEGFR-2 per cell (PAE/KDR) and PAE cells transfected with the empty vector (PAE/V) were kindly provided by Dr. B. Terman (Albert Einstein School of Medicine, NY). 293 cells expressing 2.5×10^6 VEGFR-2 per cell (293/KDR) were described elsewhere (29). PAE cells expressing different numbers of VEGFR-2 (PAE/0.25-KDR and PAE/0.10-KDR clones) were constructed by transfection of PAE cells with the pBalPst/KDR plasmid using TransIT-LT1 reagent (PanVera Corporation), followed by selection in the presence of 0.375 μg/mL puromycin. All cells and their derivatives were maintained in DMEM supplemented with 10% fetal bovine serum (FBS, Life Technologies), 2 mM L-glutamine, and antibiotics at 37 °C, 5% CO₂.

VEGFR-2 Autophosphorylation. VEGFR-2 autophosphorylation was assayed as described (28). Briefly, subconfluent cells were incubated in serum-free DMEM at 37 °C for 4 h and then shifted to serum-free DMEM containing 0.1 mM orthovanadate, 100 ng/mL bovine serum albumin, 25 mM HEPES pH 7.2, for 20 min at 37 °C, followed by a 20-min incubation at 4 °C. After addition of SLT-VEGF cells were incubated for 1 h at 4 °C and then for 10 min at 37 °C, lysed, and analyzed by SDS-PAGE.

Western Blot Analysis. Cell lysates were separated by SDS-PAGE on 7.5% gels and transferred to nitrocellulose membranes (Life Technologies). After incubation with primary antibodies, phosphotyrosine RC20H (PharMingen), α-fodrin (Chemicon), or rabbit polyclonal anti-VEGFR-2 serum (kindly provided by Dr. B. Terman, Albert Einstein School of Medicine, NY), immune complexes were visualized by the *femto*Lucent Chemiluminescence System (Genotechnology).

Protein Synthesis Inhibition in Vitro. The protein inhibition activities of SLT-VEGF fusion proteins were measured in an in vitro translation system containing a rabbit reticulocyte lysate programmed with luciferase mRNA (Promega) according to the manufacturer's instructions. Protein synthesis in the presence of 1 μM recombinant VEGF₁₂₁ was taken as 100%.

³⁵S-Incorporation. PAE/KDR were plated onto 24-well plates, $(6-8) \times 10^3$ cells/well. Twenty hours later cells were shifted to fresh culture medium containing 2.5 nM SLT-VEGF/L, 1 mL/well. After 1–52 h of incubation at 37 °C cells from duplicate wells were counted in a Coulter Counter. Protein synthesis was measured at each time point by replacing media with methionine-free DMEM containing 0.45 μCi/mL [³⁵S]-Methionine (1000 Ci/mmol, Amersham Pharmacia Biotech). After a 30-min incubation at 37 °C cells were washed twice with ice-cold 10% TCA, lysed in 0.1 M KOH, and counted in a beta-counter. ³⁵S-incorporation assays were performed in triplicate.

DNA Laddering. PAE/KDR cells were plated onto six-well plates, 2×10^5 cells/well. Twenty-four hours later cells were shifted to fresh culture medium containing 2.5 nM SLT-VEGF/L, 1.5 mL/well. After 3–72 h of incubation at 37 °C, DNA was extracted and purified with Suicide-

Figure 1. SLT-VEGF fusion proteins. All proteins were expressed in *E. coli* strain Origami(DE3)pLysS, solubilized from inclusion bodies, and refolded as described in Materials and Methods. A, Schematic representation of the proteins. B, SDS-PAGE analysis of the purified proteins (15% PAAG gel, Coomassie Blue staining). Lane V, VEGF₁₂₁.

Track DNA Ladder Isolation kit (Oncogene) and fractionated on 1.5% agarose gels.

Cytotoxicity Assay. Cells were plated in 24-well plates, $5-10 \times 10^3$ cells/well. Twenty hours later 2.5 nM SLT-VEGF/L (unless otherwise indicated) in fresh culture medium was added to duplicate wells, 1 mL/well. After 72-h, treatments cells were detached with trypsin-EDTA and counted in a Coulter Counter. Cytotoxicity assays were performed in triplicate.

RESULTS

Expression of SLT-VEGF Proteins. SLT-VEGF fusion proteins (Figure 1A) were constructed, expressed, and purified as described in Materials and Methods. The VEGF₁₂₁ isoform was chosen for construction of these proteins because, unlike other VEGF isoforms, (1) it does not contain heparin-binding domain(s) that are involved in nonspecific electrostatic interactions with the cell surface and extracellular matrix components, and (2) it has a selective affinity to VEGFR-2 (30). Full-length and truncated SLT-1 A-subunits were fused to VEGF₁₂₁ with the expectation that the resulting SLT-VEGF/L and SLT-VEGF/S fusion proteins would display different N-glycosidase activities (25–27). To separate the effects of ribosome inactivation from other effects that might be induced by recombinant SLT-VEGF proteins we have constructed SLT-VEGF/Lci protein containing a double mutant A-subunit with the Y114S and R170L amino acid substitutions. Each substitution significantly decreases the enzymatic activity of SLT-1 A-subunit, while not affecting its antigenic properties (31, 32). We therefore reasoned that simultaneous mutation of these residues might yield an SLT-1 moiety that lacks N-glycosidase activity. VEGF₁₂₁ and SLT-VEGF proteins were expressed in Origami(DE3)pLysS *E. coli*, recovered from inclusion bodies as 90–95% pure proteins (Figure 1B), and used in the following experiments without additional purification.

Figure 2. Functional activities of SLT-VEGF fusion proteins. A, Effects of SLT-VEGF/L (○), SLT-VEGF/S (●), or SLT-VEGF/Lci (X) on luciferase production in an in vitro translation system containing a rabbit reticulocyte lysate programmed with luciferase mRNA. Activity of luciferase translated in the presence of 1 μ M recombinant VEGF₁₂₁ was taken as 100%. B, Dose-dependence of VEGFR-2 tyrosine autophosphorylation in 293/KDR cells induced by SLT-VEGF fusion proteins and VEGF₁₂₁. Arrows indicate positions of 205 kDa markers.

SLT and VEGF Moieties Are Active in SLT-VEGF.

The fully activated A-subunit isolated from the AB₅ holotoxin inhibits protein synthesis in cell-free system with the IC₅₀ value of 0.1 nM (33). We therefore tested catalytic activity of SLT-VEGF in a cell-free translation system programmed with luciferase mRNA. We found that SLT-VEGF/L and SLT-VEGF/S inhibited protein synthesis by 90% at concentrations 0.04 nM and 2 nM, respectively (Figure 2A). Thus, SLT-VEGF/L may be even more effective inhibitor of protein synthesis than the wild type A-subunit. A 50-fold difference in activities of SLT-VEGF/L and SLT-VEGF/S suggested that truncation affected either the intrinsic catalytic activity of SLT-1 moiety, or its ability to fold properly within the fusion protein (Figure 2A). SLT-VEGF/Lci did not inhibit protein synthesis (Figure 2A).

The ability of SLT-VEGF fusion proteins to interact with VEGFR-2 was tested in a VEGFR-2 tyrosine autophosphorylation assay with 293/KDR cells. All SLT-VEGF fusion proteins induced VEGFR-2 tyrosine autophosphorylation in a dose-dependent manner in the same concentration range as parental VEGF₁₂₁ (Figure 2B). Different plateau levels observed in this assay suggested that complexes of VEGF fusion proteins with VEGFR-2 possess different intrinsic efficacies in tyrosine autophosphorylation. SLT-VEGF/L and SLT-VEGF/Lci were similarly efficacious (Figure 2B), indicating that mutations in the A-subunit, which eliminated N-glycosidase activity, did not affect interactions with the VEGFR-2. SLT-VEGF/S was more efficacious than SLT-VEGF/L and SLT-VEGF/Lci (Figure 2B), suggesting that SLT-VEGF/S may be better suited for induction of VEGFR-2 mediated processes. The ability of SLT-VEGF/L and SLT-VEGF/S to induce VEGFR-2 tyrosine autophosphorylation in PAE/KDR cells was reported previously (28).

Figure 3. SLT-VEGF/L is selectively cytotoxic against growing endothelial cells overexpressing VEGFR-2. PAE/KDR cells were plated onto 24-well plates at densities of $5\text{--}10 \times 10^3$ cells/well and exposed to SLT-VEGF/L 20 h later. After a 72-h exposure cells were counted in a Coulter Counter. A, PAE/KDR cells treated with 2.5 nM SLT-VEGF/L (○) and untreated cells (●). B, PAE/KDR cells (○) and PAE cells lacking VEGFR-2 (●) exposed to varying concentrations of SLT-VEGF/L. C, Confluent PAE/KDR were maintained at 100% confluence for 3 days; then treated with 20 nM SLT-VEGF/L for 72 h. Growing PAE/KDR were exposed to 20 nM SLT-VEGF/L for 5 min and then shifted to fresh culture medium and counted after 72 h. D, effect of depletion of SLT-VEGF preparation. SLT-VEGF/L (0.5 mL of 25 nM solution in DMEM serum-free) was combined with 0.1 mL S-protein agarose (Novagen). After a 30-min incubation at 4 °C, the solution was cleared at 500g for 5 min, diluted 10-fold with complete culture medium, and added to cells (open bars). Control cells were treated with 2.5 nM SLT-VEGF/L (filled bars).

SLT-VEGF/L Is Selectively Cytotoxic for Growing Cells Overexpressing VEGFR-2.

To test VEGFR-2-mediated effects of SLT-VEGF fusion proteins on endothelial cells we have used PAE/KDR cells engineered to express 2.5×10^5 VEGFR-2/cell (29). PAE/V or wild type PAE cells were used as controls. After an exposure to 2.5 nM SLT-VEGF/L, PAE/KDR, but not control cells, ceased to grow, and their number progressively decreased below the number of plated cells because of widespread death (Figure 3A). SLT-VEGF/L inhibited growth of PAE/KDR cells in a dose-dependent manner with an IC_{50} of 0.19 ± 0.13 nM (average $\pm$ STD for five independent preparations of SLT-VEGF/L) and was highly cytotoxic to PAE/KDR cells at concentrations ≥ 1 nM (Figure 3B for a typical SLT-VEGF/L preparation). These effects were mediated by VEGFR-2, since parental PAE cells lacking VEGFR-2 were inhibited by SLT-VEGF/L with an IC_{50} of 3.95 ± 0.95 (Figure 3B). This sensitivity of nontransfected PAE cells might be mediated by VEGFR-1 present on parental PAE cells (34), since several other cell lines without known VEGF receptors were not affected by SLT-VEGF/L at concentrations as high as 20 nM (28). Presence of VEGFR-2 appears to be necessary, but not sufficient for induction of endothelial cell death by SLT-VEGF/L. We found that quiescent PAE/KDR cells were not affected by a 72-h exposure to SLT-VEGF/L even at concentrations as high as 20 nM (Figure 3C). In contrast, growing PAE/KDR cells exposed to 20 nM SLT-VEGF/L for 5 min, and then shifted to fresh culture medium and counted after 72 h, were dramatically affected (Figure 3C). To confirm a causative role of SLT-VEGF/L in the

observed effects, a preparation of SLT-VEGF/L was depleted of recombinant proteins by capturing them with S-protein agarose. The depleted preparation was ineffective against PAE/KDR and PAE/V cells (Figure 3D).

Effect of SLT-VEGF/L on Endothelial Cells Depends on the VEGFR-2 Density. To test effects of VEGFR-2 density on cytotoxicity of SLT-VEGF/L, we have constructed two clones of PAE cells expressing different numbers of VEGFR-2. The levels of VEGFR-2 expression were estimated by Western blot analysis with PAE/KDR cells (2.5×10^5 VEGFR-2/cell) used as a standard. Two clones of VEGFR-2 transfected PAE cells, PAE/0.25-KDR and PAE/0.10-KDR, expressed, respectively, four and ten times less VEGFR-2/cell than PAE/KDR (Figure 4). We found that sensitivity of VEGFR-2 transfected PAE cells to SLT-VEGF/L declined as the VEGFR-2 density decreased (IC_{50} on Figure 4). PAE/0.10-KDR cells expressing ~ 25000 VEGFR-2/cell were approximately as sensitive as PAE/V cells, indicating that only a high level of VEGFR-2 expression conferred sensitivity of growing endothelial cells to SLT-VEGF/L.

Requirement for Catalytic Activity of SLT Moiety in SLT-VEGF Fusion Proteins. To establish the role of N-glycosidase activity of SLT moiety in the observed effects, we tested SLT-VEGF/Lci containing a catalytically inactive A-subunit. As was described before, SLT-VEGF/Lci did not inhibit protein synthesis but retained the ability to bind and activate VEGFR-2 (Figure 2). We found that 2.5 nM SLT-VEGF/Lci did not affect growth of PAE/KDR or PAE/V cells (Figure 5A), establishing that the ability to damage ribosomes was the basis of the SLT-

Figure 4. High level of VEGFR-2 is necessary to confer sensitivity of cells to SLT-VEGF/L. Three clones of VEGFR-2 transfected and control PAE/V cells were grown in six-well plates. Subconfluent cells were washed with PBS, detached with PBS containing 1 mM EDTA, counted in a Coulter Counter, and lysed in SDS-PAGE loading buffer. Cell lysates containing equal numbers of cells were analyzed by SDS-PAGE on 7.5% gels followed by Western blotting. IC₅₀ for each clone was determined as described in the legend for Figure 3B. Each experiment was done in triplicate.

Figure 5. Cytotoxicity of SLT-VEGF proteins requires catalytic activity of SLT moieties. PAE/KDR and PAE/V cells were plated onto 24-well plates at densities of $(6-8) \times 10^3$ cells/well. Twenty hours later cells were exposed to (A) 2.5 nM SLT-VEGF/Lci containing a catalytically inactive SLT A-subunit, or (B) varying concentrations of SLT-VEGF/S containing a truncated SLT A-subunit. (○), PAE/KDR; (●), PAE/V. After a 72-h exposure to the fusion proteins, cells were counted in a Coulter Counter.

VEGF/L cytotoxicity. The role of N-glycosidase activity of SLT moiety of SLT-VEGF proteins was further explored using SLT-VEGF/S that, in comparison with SLT-VEGF/L, was less active in inhibition of cell-free translation, but more active in induction of VEGFR-2 tyrosine phosphorylation (see, Figure 2A and 2B). SLT-VEGF/S inhibited growth of PAE/KDR cell, while PAE/V cells were marginally affected (Figure 5B), indicating the VEGFR-2-mediated mechanism of action. Surprisingly, despite ~50-fold lower activity in a cell-free translation assay (Figure 2A), SLT-VEGF/S inhibited PAE/KDR growth in the same concentration range as SLT-VEGF/L (compare Figure 3A and 5B). Perhaps, lower catalytic

Figure 6. SLT-VEGF/L induces apoptosis in PAE/KDR cells. A, Apoptotic DNA fragmentation. Cells were plated onto six-well plates at a density of 2×10^5 cells/well and exposed to 2.5 nM SLT-VEGF 24 h later. After indicated periods of time DNA was isolated from cell lysates and fractionated on 1.5% agarose gel. B, Western blot analysis of α-fodrin. Cells were plated onto 24-well plates at a density of 4×10^4 cells/well and exposed to 2.5 nM SLT-VEGF 20 h later for indicated periods of time.

activity of SLT-VEGF/S was compensated by its ability to induce higher levels of VEGFR-2 tyrosine phosphorylation (Figure 2B) that might lead to a better uptake and/or processing of SLT-VEGF/S(VEGFR-2)₂ complexes. Unfortunately, a very low yield of SLT-VEGF/S prevented further experiments.

SLT-VEGF/L Induces Apoptosis in PAE/KDR Cells.

We found that SLT-VEGF induces rapid apoptotic changes in PAE/KDR cells. After 5–10 h of exposure to 2.5 nM SLT-VEGF, PAE/KDR cells progressively underwent morphological alterations resembling apoptosis (data not shown). An apoptotic DNA laddering was observed after a 9-h exposure, and little or no high molecular weight DNA was detectable after 24 or 48-h exposures (Figure 6A). Another hallmark of apoptosis, cleavage of 240 kDa α-fodrin into 150 kDa and 120 kDa fragments (35) was readily detectable after a 24-h exposure (Figure 6B).

Effects of SLT-VEGF/L on Protein Synthesis.

Native SLT-1, and presumably SLT-VEGF/L, inhibits protein synthesis by damaging ribosomes via depurination of A₄₃₂₄ in 28S rRNA. The resulting apoptosis may be initiated by collapse of protein synthesis. Alternatively, apoptosis may be initiated by ribosome damage through the recently discovered ribotoxic response mechanism that is mediated by activation of stress-response kinases and does not require significant inhibition of protein synthesis (36). To choose between these alternatives, we tested the effects of SLT-VEGF/L on protein synthesis in PAE/KDR cells. We found that ³⁵S-methionine incorporation per well with SLT-VEGF/L treated cells was progressively lower than that for untreated cells, with approximately 50% inhibition observed after a 20-h treatment (Figure 7A). Similar results have been reported recently for protein synthesis inhibition in SLT treated Caco-2 cells (37). However, this effect reflected mostly the difference in the cell numbers, since ³⁵S-methionine incorporation per cell varied only by 30–50% for both treated and control cells (Figure 7B). In contrast, cycloheximide treatment (0.1 mg/mL) rapidly inhibited protein synthesis on a per cell basis (Figure 7B). It was possible that even small alterations in protein synthesis might inhibit cell growth and be cytotoxic to PAE/KDR cells. However, this explanation appears unlikely since even an 80% inhibition of protein synthesis by cyclohex-

Figure 7. Protein synthesis inhibition in PAE/KDR. PAE/KDR cells were plated onto 24-well plates at densities of $6\text{--}10 \times 10^3$ cells/well and 20 h later exposed either to 2.5 nM SLT-VEGF/L or to varying amounts of cycloheximide. A, effects of SLT-VEGF/L on PAE/KDR growth (○) and ^{35}S -incorporation (●), B, effects of SLT-VEGF/L on ^{35}S -incorporation per cell for SLT-VEGF/L treated (○) and untreated cells (●). Effect of 0.1 mg/mL cycloheximide (X) is shown for comparison. C, Effects of cycloheximide on PAE/KDR growth (○) and ^{35}S -incorporation (●).

himide caused only a 40% inhibition of PAE/KDR cell growth (Figure 7C).

DISCUSSION

Growing endothelial cells at the sites of angiogenesis express high numbers of VEGF receptors (11–15) and therefore may be more sensitive to toxin-VEGF fusion proteins than quiescent endothelial cells. To test this hypothesis, we have constructed a protein containing the 293 amino acid catalytic A-subunit of Shiga-like toxin I fused to VEGF₁₂₁ (SLT-VEGF/L). Judging by its ability to inhibit protein synthesis in a cell-free system and to induce VEGFR-2 tyrosine autophosphorylation (Figure 2),

both SLT and VEGF moieties in the fusion proteins are folded into functionally active conformations. It is somewhat surprising that VEGF isoform containing 121 amino acid residues can accommodate a 293 amino acid N-terminal extension and retain 3-D structure suitable for interactions with VEGFR-2 (38).

SLT-VEGF/L was tested on growing and quiescent endothelial cells and on endothelial cells expressing different levels of VEGFR-2. We report here that SLT-VEGF/L inhibits growth of PAE/KDR cells expressing 2.5×10^5 VEGFR-2 receptors/cell with an IC_{50} of ~ 0.2 nM and induces massive apoptosis at concentrations ≥ 1 nM (Figure 3A). These effects are mediated by VEGFR-2, since parental cells lacking VEGFR-2 are only marginally affected by SLT-VEGF/L (Figure 3A).

However, the presence of VEGFR-2 appears to be necessary but not sufficient for the sensitivity of endothelial cells to SLT-VEGF/L. We found that quiescent PAE/KDR cells are not affected by a 72-h exposure to 20 nM SLT-VEGF/L, while growing PAE/KDR cells are killed by a 5-min exposure (Figure 3A and Figure 3C). Resistance of quiescent PAE/KDR to SLT-VEGF/L may be due to the lower metabolic rates in quiescent cells. Indeed, a lower sensitivity of quiescent endothelial cells to DT-VEGF conjugate was reported previously (17). Sensitivity to SLT-VEGF/L for growing endothelial cells expressing lower numbers of VEGFR-2 ($\sim 6 \times 10^4$ and 2.5×10^4 receptors per cell) progressively declines to the level of PAE/V cells lacking VEGFR-2 (Figure 4). These results are in agreement with our previous finding that human umbilical vein endothelial cells (HUVEC) and mouse MS1 endothelial cells expressing $(3\text{--}5) \times 10^4$ VEGFR-2/cell are not sensitive to SLT-VEGF/L at concentrations as high as 20 nM (28). Taken together the requirements for growth and for high number of VEGFR-2 suggest that growing endothelial cells at the sites of angiogenesis cells would be more sensitive to SLT-VEGF/L than quiescent endothelium.

It should be noted that the lack of sensitivity of HUVEC to SLT-VEGF/L is in contrast to the reported high sensitivity of these cells to DT-VEGF proteins (IC_{50} of 36 pM) (18). The differential sensitivity of HUVEC may reflect differences in internalization, and/or intracellular processing of DT-VEGF and SLT-VEGF/L proteins (39–41). Furthermore, DT and SLT target different steps in protein biosynthesis, whereby DT catalyzes ADP-ribosylation of EF-2, while SLT damages ribosomes. However, the high activity of DT-VEGF against HUVEC raises a question whether this protein would discriminate between endothelial cells with low and high numbers of VEGFR-2 in a manner similar to SLT-VEGF/L.

Our finding that catalytically inactive SLT-VEGF/Lci does not affect PAE/KDR cells indicates that enzymatic inactivation of ribosomes is crucial for the cytotoxic activity of SLT-VEGF/L. However, we found that a collapse of protein synthesis is not required for SLT-VEGF/L induced onset of growth inhibition and apoptosis. Indeed, in the presence of 2.5 nM SLT-VEGF/L protein synthesis per PAE/KDR cell is inhibited marginally after 12 h, and only by 30% after 50 h (Figure 7B). Nevertheless, under the same conditions, apoptotic DNA laddering is readily detectable in treated cells after 9 h, and a 50-h treatment kills $\sim 30\%$ of plated cells (Figure 3A).

There is evidence that bacterial toxins and immunotoxins may induce apoptosis not only through shortage of de novo synthesized proteins, but also through other mechanism(s) (37, 42–44). Moreover, the inhibitory effect of toxins on protein synthesis may be overestimated

because many studies rely on comparison of ^{35}S -incorporation per well of treated vs control cells (see, for example 18, 43). In such comparison a decrease in ^{35}S -incorporation per well reflect both a decrease in a number of treated cell and a possible decrease in protein synthesis in each cells. Recently, Iordanov et al., discovered a ribotoxic stress response that can be initiated by site-specific damage of 28S rRNA by ricin and α -sarcin and by several other agents (36, 45, 46). This response includes activation of stress-activated protein kinases that initiate signal transduction cascades leading to apoptotic death (reviewed in 47). Indeed, it was shown recently, that treatment of Caco-2 cells with SLT holotoxin induces expression of MAPK phosphatase (MKP-1) and activation of JNK (37). Alternatively, a surveillance mechanism may connect damage of ribosomes to transcription machinery that activate expression of proapoptotic cytokines. Indeed, it has been shown recently that treatment of monocytes, macrophages, and tumor cells with native SLT-1 induces cytokine production (48). Finally, existence of fine-tuned mechanisms for monitoring the integrity of ribosomes is suggested by the recent finding that ribosomal S6 protein is dispensable for growth but not proliferation (49). Regardless of molecular mechanism(s) of action, SLT-VEGF/L displays remarkably selective cytotoxicity against growing endothelial cells overexpressing VEGFR-2. Experiments are now in progress to determine efficacy of SLT-VEGF/L in animal angiogenesis models.

ACKNOWLEDGMENT

This work was supported in part by National Institutes of Health Grant # 1 R43 CA81832-01. We thank Dr. C. Hamby for numerous discussions and help in preparation of the manuscript.

Identification and Activities of Human Carboxylesterases for the Activation of CPT-11, a Clinically Approved Anticancer Drug

Peter D. Senter,* Kevin S. Beam, Bruce Mixan, and Alan F. Wahl

Seattle Genetics, Inc. 21823 30th Drive SE, Bothell, Washington 98021. Received August 1, 2001;
Revised Manuscript Received September 26, 2001

CPT-11 is a clinically approved anticancer drug used for the treatment of advanced colorectal cancer. Upon administration, the carbamate side chain of the drug is hydrolyzed, resulting in the release of SN-38, an agent that has approximately 1000-fold increased cytotoxic activity. Since only a very small percentage of the injected dose of CPT-11 is converted to SN-38, there is a significant opportunity to improve its therapeutic efficacy and to diminish its systemic toxicity by selectively activating the drug within tumor sites. We envisioned that a mAb-human enzyme conjugate for CPT-11 activation would be of interest, particularly since the conjugate would likely be minimally immunogenic, and the prodrug is clinically approved. Toward this end, it was necessary to identify the most active human enzyme that could convert CPT-11 to SN-38. We isolated enzymes from human liver microsomes based on their abilities to effect the conversion and identified human carboxylesterase 2 (hCE-2) as having the greatest specific activity. hCE-2 was 26-fold more active than human carboxylesterase 1 and was 65% as active as rabbit liver carboxylesterase, the most active CPT-11 hydrolyzing enzyme known. The anti-p97 mAb 96.5 was linked to hCE-2, forming a conjugate that could bind to antigen-positive cancer cells and convert CPT-11 to SN-38. Cytotoxicity assays established that the conjugate led to the generation of active drug, but the kinetics of prodrug activation ($48 \text{ pmol min}^{-1} \text{ mg}^{-1}$) was insufficient for immunologically specific prodrug activation. These results confirm the importance of hCE-2 for CPT-11 activation and underscore the importance of enzyme kinetics for selective prodrug activation.

INTRODUCTION

The anticancer drug CPT-11 (irinotecan) is a water-soluble derivative of camptothecin and is clinically approved for the treatment of colorectal carcinoma (reviewed in refs 1–5). As with other camptothecin family members, CPT-11 inhibits DNA topoisomerase 1, an enzyme involved in relaxation of supercoiled DNA. This leads to the generation of DNA single strand breaks and eventual cytotoxic activity. Although CPT-11 has demonstrated significant antitumor activities in the clinic, the drug has several serious side effects including gastrointestinal toxicity and neutropenia (1–5). There is a great deal of interest in understanding the biochemical basis for the dose-limiting toxicities of CPT-11 and to find improved forms and delivery mechanisms for the drug.

One of the distinguishing features of CPT-11 is that it is metabolized to SN-38 (Figure 1), an agent that is more potent in assays for topoisomerase 1 inhibition and in cytotoxicity activity on transformed cell lines (6, 7). Early on, it was found that carboxylesterases effected the conversion of CPT-11 to SN-38 and that enzymes from several species carried out the reaction (8, 9). In these studies, the most active enzyme was from guinea pig livers and had very low specific activity ($4.5 \text{ nmol min}^{-1} \text{ mg}^{-1}$). The human enzyme used for comparison had only 3% of this activity. It is noteworthy that carbamates in general and CPT-11 in particular can act as serine carboxylesterase inhibitors, due to the stability of the active site serine-carbamate intermediates formed (10).

Consequently, even though carboxylesterases are widespread throughout the body (11–14), only 2–5% of the injected dose of CPT-11 in people is converted to SN-38. Most of the drug is excreted through the liver and kidneys without modification of the carbamate bond (1–5). If SN-38 could be intratumorally generated from CPT-11 in an efficient manner, it might be possible to improve CPT-11 therapeutic efficacy and at the same time minimize the severe toxicities associated with this drug.

Several methods can be envisioned to enhance intratumoral CPT-11 activation. One approach that has recently been explored involves gene therapy (15) in which the gene encoding an enzyme that can activate CPT-11 is transfected into the target cancer cell population. Candidate genes include those corresponding to rabbit liver carboxylesterase (16, 17), human and horse butyrylcarboxylesterase (18), and two forms of human carboxylesterase known as hCE-1 (16, 19, 20) and hCE-2 (21), all of which convert CPT-11 to SN-38. Of these enzymes, rabbit liver carboxylesterase (rCE) was regarded as being the most effective, since it catalyzed CPT-11 carbamate hydrolysis 100–1000-fold more efficiently than hCE-1 (16, 17). Human rhabdomyosarcoma cells transfected with the gene for rCE were sensitized to CPT-11 to a greater extent than were nontransfected cells or cells transfected with the gene encoding hCE-1. These results were confirmed in vivo in mice with subcutaneous tumor implants (16). Other studies have shown that some cell lines transfected with hCE-1 were modestly more sensitive to CPT-11 than control cells (19, 20).

Another method to enhance the activation of CPT-11 within tumors would be to utilize a prodrug activation strategy known commonly as ADEPT, antibody directed

Figure 1. Structure of the prodrug CPT-11 and its conversion to the active metabolite SN-38.

enzyme prodrug therapy (reviewed in refs 22–23). This is a two-step targeting strategy, involving the administration of a monoclonal antibody (mAb)–enzyme conjugate that binds to tumor associated antigens, followed at an appropriate time by a prodrug that is activated by the targeted enzyme. For the purposes of CPT-11, the enzyme would be selected for its ability to efficiently hydrolyze the carbamate bond present within the drug and to generate cytotoxic levels of SN-38 intratumorally. Such an enzyme/prodrug combination would be distinguished from others that have been reported, since the human enzyme would likely be minimally immunogenic, and the prodrug for activation is already clinically approved. Toward developing such a system, we noted that a detailed search for suitable human enzymes has not been published. Here, we report the purification and characterization of CPT-11 activating enzymes from human liver along with their applications for specific prodrug activation.

EXPERIMENTAL METHODS

Materials and General Methods. Pharmaceutical grade CPT-11 was obtained as a pure preparation (by HPLC as indicated below) at 20 mg/mL. SN-38 was a gift from Dr. Ruiwen Zhang at the University of Alabama in Birmingham. The mAb 96.5 is of the IgG2a isotype and binds to the p97 antigen, which is expressed on most melanoma cells (24). The 3677 human melanoma (24) and L2987 human lung adenocarcinoma (25) cell lines were established from surgically resected tumors. A pathogen-free frozen human liver was obtained from the Northwest Tissue Center, Seattle, WA, and was stored at -80°C . Protein assays were conducted using the Pierce Micro BCA assay. The purification of guinea pig liver microsomal esterase has been previously described (26). Rabbit liver carboxylesterase was purchased from Sigma and purified by size exclusion chromatography to a high degree of homogeneity as evidenced by both SDS–PAGE and isoelectric focusing.

Enzyme Assays. With *p*-Nitrophenylacetate as Substrate. Protein samples were added to 1 mL of a 0.1 mM solution of *p*-nitrophenylacetate in phosphate buffered saline pH 7.2 (PBS), and the change in absorbance at 405 nm was recorded for 1 min. The protein samples were diluted to ensure that the measurements were linear during this time period. A change in absorbance of 1 OD represents the generation of 90 nmol of *p*-nitrophenol.

With CPT-11 as Substrate. Protein samples were added to a solution of CPT-11 in water so that the final CPT-11 concentration was 8 μM . Incubation was carried out at 37°C for 15–48 h, at which point HCl (final concentration 60 mM) was added to reform the lactone ring. Analysis by HPLC was performed as follows: injected 0.1 mL onto a C-18 column (4.6×75 mm) using a mobile phase of 60 mM ammonium carbonate, 4 mM tetrabutylammonium phosphate, 24% acetonitrile (pH 5.0) at 1 mL/min, and a detector set at 365 nm. The amount of

CPT-11 consumed and SN-38 generated was quantified using standard solutions of these agents that were treated identically to the test samples. The conversion of CPT-11 to SN-38 was linear over this time period.

Enzyme Purification. *Step 1. Microsome Purification.* A 300 g portion of a human liver was thawed and blended in a homogenizer with 500 mL of 1.5% KCl. The mixture was centrifuged at 8700g for 4 h at 4°C , and the clear supernatant was further centrifuged at 105000g for 1 h at 4°C .

Step 2. Ammonium Sulfate Precipitation. The microsome pellet was suspended in 100 mL of tris[hydroxymethyl]aminomethane (Tris) at pH 8.0, 1.5 g of saponin was added, and the mixture was gently rotated for 1 h at 4°C . Saturated aqueous ammonium sulfate was slowly added to a final concentration of 30%, and the precipitated material was removed by centrifugation at 11300g for 30 min at 4°C . To the supernatant was slowly added solid ammonium sulfate to a final concentration of 70%, and the precipitated material was removed by centrifugation at 11300g for 30 min at 4°C . The pellet was resuspended in and dialyzed against 10 mM Tris pH 8.0 overnight.

Step 3. Anion Exchange Chromatography. The dialysate from step 2 was applied to a 46 mL Q Sepharose Fast Flow column (Amersham Pharmacia), and the column was washed with 10 mM Tris pH 8.0 buffer until there was no absorbance at 280 nm. Bound proteins were eluted with a gradient of 10 mM Tris pH 8.0 to 10 mM Tris, 500 mM NaCl, pH 8.0, over 3 h at a flow rate of 5 mL/min. The fractions (10 mL each) were monitored for both *p*-nitrophenylacetate and CPT-11 hydrolysis activities. Significant activity was obtained in the unbound material, and in fractions 52–62.

Step 4. Hydrophobic Interaction Chromatography. The unbound material and fractions 52–62 from step 3 were separately diluted with 1.5 vol of 2 M ammonium sulfate in PBS, applied to a 1.5×12 cm phenylsepharose column (Amersham Pharmacia), and the column was washed until there was no absorbance at 280 nm in the eluant. The bound material was eluted with a 400 mL linear gradient from 0.8–0 M ammonium sulfate in PBS. Fractions that contained enzymatic activity were pooled and concentrated to 2 mL by ultrafiltration.

Step 5. Size Exclusion Chromatography. The material from step 4 was applied to a 2×65 cm Superdex 200 PS column (Amersham Pharmacia) and eluted with PBS. Fractions (3 mL each) were monitored for enzyme activity and purity by SDS–PAGE.

Sequence Analysis. The purified proteins (0.15–0.3 mg) were dialyzed against 10 mM Tris pH 8.0, concentrated to dryness on a vacuum centrifuge, and were dissolved in 0.03–0.1 mL of cyanogen bromide (Aldrich) in 70% aqueous formic acid (Fisher, sequencing grade). After 24 h at room temperature, 1.5 mL of water was added, and volatile material was evaporated in a vacuum centrifuge. This was repeated twice with 0.3 mL of water

to remove traces of acid. The residual material was dissolved in PBS (0.1 mL), applied to a 10% NuPage gel (Novex), and the gel was run using Novex MES running buffer. The gels were blotted onto PVDF filters, which were then stained with Coomassie Blue. The bands were cut out and sequenced by Sandy Kielland at the Protein Microsequencing Laboratory, University of Victoria, Victoria, BC, Canada.

Preparation of 96.5-hCE-2. A solution of the 96.5 mAb (0.29 mL at 7.0 mg/mL in PBS) was diluted with 0.05 mL of 0.5 M borate containing 0.5 M NaCl at pH 8.0, and 9 μL of *N*-(γ -maleimidobutyryloxy)succinimide ester (GMBS, Pierce) at 10 mM in DMSO was added. After 30 min at 37 °C, the solution was applied to a Sephadex G-25 PD 10 column (Amersham Pharmacia), and the modified protein was eluted in a 1.8 mL volume with 100 mM sodium phosphate containing 0.5 M NaCl at pH 7.2. A total of 1.77 mg of protein was obtained, based on the absorbance at 280 nm ($E_{0.1\%} = 1.4$). The maleimide content was determined by diluting 0.3 mL of the protein with 0.6 mL of PBS. To this was added 10 μL of a 1 mM aqueous solution of 2-mercaptoethanol, followed 1 min later by 25 μL of 50 mM 5,5'-dithio-bis-(2-nitrobenzoic acid) (DTNB). The difference in absorbance at 412 nm ($\epsilon = 14\,150$) as compared to a control containing no protein indicated that there were a total of 0.7 maleimides/mAb. The modified mAb was kept at 4 °C prior to being added to the enzyme.

hCE-2 (0.8 mL at 0.83 mg/mL in PBS; 33 $\mu\text{mol min}^{-1} \text{mg}^{-1}$ specific activity using *p*-nitrophenylacetate as substrate) was diluted with 0.2 mL of 0.5 M sodium borate containing 0.5 M NaCl at pH 8.0. The protein was cooled on ice and treated with 53 μL of 20 mM 2-iminothiolane in water. After 180 min at 4 °C, low molecular weight agents were separated on a Sephadex G-25 PD 10 column, and the protein was collected in 2 mL of 100 mM sodium phosphate containing 0.5 M NaCl at pH 7.2. The protein concentration was 0.49 mg/mL, based on absorbance at 280 nm ($E_{0.1\%} = 1.01$). Sulfhydryl group analysis, determined by the addition of 25 μL of DTNB using the difference in absorbance at 412 nm ($\epsilon = 14\,150$), indicated that there were 2.5 SH groups/protein molecule.

The proteins were combined and concentrated to 1 mL by ultrafiltration. After 15 min at room temperature, 10 μL of 10 mM *N*-ethylmaleimide in DMSO was added, followed 5 min later by 20 μL of 10 mM 2-mercaptoethanol in water. The solution was further concentrated to 0.2 mL and then applied to a 7.8 $\times$ 300 mm Bio-Sil size-exclusion chromatography column (Biorad), which was eluted with PBS. Fractions that contained mainly monomeric conjugate mixed with unconjugated 96.5 mAb were gel filtered into 25 mM Tris buffer containing 125 mM NaCl at pH 7, and then applied to a 1 mL Q Sepharose column equilibrated with the same Tris buffer. Under these conditions, unconjugated mAb bound very poorly to the resin. The column was washed until there was no absorbance at 280 nm, and bound material was

eluted with 25 mM Tris buffer containing 1 M NaCl at pH 7. The resulting conjugate was almost entirely monomeric, with very small amounts of unconjugated 96.5 and aggregated protein. The specific activity with *p*-nitrophenylacetate was 5.2 $\mu\text{mol min}^{-1} \text{mg}^{-1}$ of total protein, or 17.1 $\mu\text{mol min}^{-1} \text{mg}^{-1}$ hCE-2 component.

Binding Studies. 3677 cells were suspended in polypropylene tubes (10^5 cells/tube in 0.6 mL of RPMI culture medium containing 10% fetal bovine serum), and 96.5-FITC (1 $\mu\text{g/mL}$ final concentration) was added with or without 96.5-hCE-2 at 0, 10, 25, and 50 $\mu\text{g/mL}$ final 96.5 concentration. After 1 h at 4 °C, the cells were washed, and fluorescence was determined on a fluorescence activated cell sorter. The competition of binding was compared to cells that were treated with 96.5-FITC (1 $\mu\text{g/mL}$ final concentration) together with unconjugated 96.5 at 0, 10, 25, and 50 $\mu\text{g/mL}$. 96.5-hCE-2 and unconjugated 96.5 were indistinguishable in this competition binding assay.

Cytotoxicity Assays. CPT-11 and SN-38 were made as 10 mM stocks in DMSO and diluted in media just prior to use. Cells (5×10^3 cells/well) were plated into 96-well tissue culture plates in 0.1 mL of RPMI medium containing 10% fetal bovine serum. To the wells were added 0.05 mL of the drugs at various concentrations, followed by 0.05 mL of the enzyme, 96.5-hCE-2, or PBS in media for the times indicated in the figure legends. The plates were centrifuged at 200g for 5 min, media was aspirated off, and the cells were washed three additional times by centrifugation and aspiration. Additional media (0.15 mL) was added, and incubation was continued for a total of 72 h, at which time the cells were treated with XTT (2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-[(phenylamino)carbonyl]-2H-tetrazolium hydroxide, Sigma) and evaluated for toxicity according to previously described methods (27, 28).

RESULTS

The purification protocol of human liver microsomal proteins that effected the conversion of CPT-11 to SN-38 (Figure 1) is shown in Table 1. Throughout protein purification, an HPLC-based assay was used to monitor this hydrolysis reaction, and the data were supplemented with total esterase activity using *p*-nitrophenylacetate as a substrate along with SDS-PAGE analysis. In establishing the HPLC assay, it was found as reported earlier (10), that the conversion of CPT-11 to SN-38 was more facile at CPT-11 concentrations that minimally inhibited the enzymatic hydrolysis of *p*-nitrophenylacetate. This is most likely due to the stability of the active site serine carbamate formed during the course of CPT-11 hydrolysis (10). Anion-exchange chromatography of the ammonium sulfate precipitated proteins led to two separate populations of protein that hydrolyzed CPT-11, one that bound to the resin and was eluted with a salt gradient, and one that did not bind to Q Sepharose. The subsequent purification steps, illustrated in Table 1 for the material that bound to the anion-exchange resin, were used for

Figure 2. Analysis of purified proteins by gel electrophoresis. (A) The purification of carboxylesterases from human liver microsomes was monitored by SDS-PAGE (10% polyacrylamide). Lanes 1–4 illustrate the purification of hCE-2. Lane 1, ammonium sulfate precipitated protein; lane 2, after anion-exchange chromatography; lane 3, after hydrophobic interaction chromatography; lane 4, after size exclusion chromatography. Lane 5, hCE-1 using the same purification steps. Molecular weight standards gave bands as indicated. (B) Isoelectric focusing gel (pH 3–7) of purified proteins. Lane 1, hCE-1; lane 2, hCE-2. The IEF protein standards were obtained from Amersham Pharmacia. Both gels were stained with Coomassie Blue.

both populations. After hydrophobic interaction chromatography on phenyl Sepharose, followed by size exclusion chromatography, the resulting protein was homogeneous by SDS-PAGE (Figure 2A) and had a diffuse pI, most likely due to post-transcriptional protein modification, centered at pH 4.4 (Figure 2B). The active protein that did not bind to the Q Sepharose resin was similarly purified and had a pI value of approximately 6.0. The two purified proteins had apparent molecular masses of 65 kDa.

Attempts to identify the proteins by N-terminal sequencing failed since both proteins apparently had blocked amino termini. For that reason, the proteins were fragmented with cyanogen bromide, and some of the fragments that were separated by SDS-PAGE were subjected to N-terminal sequence analysis using Edman degradation chemistry. The results (Figure 3) indicate that the primary amino acid sequence of the lower activity enzyme corresponds to human carboxylesterase 1 (hCE-1, Figure 3A), and the higher activity protein corresponds to human carboxylesterase 2 (hCE-2, Figure 3B). In both cases, there was 100% homology between the sequenced peptides and the published sequences for hCE-1 and hCE-2 (16, 29).

The specific activities of the purified human carboxylesterases were compared to highly purified samples of rabbit liver carboxylesterase (rCE) and guinea pig liver carboxylesterase (gpCE). The latter two enzymes were chosen based on reports describing them as being proficient at catalyzing the hydrolysis of CPT-11 (9, 16). Unexpectedly, hCE-2 had 66% of the activity of rCE and gpCE on CPT-11. Consistent with previous reports, hCE-1 was significantly less active than hCE-2 and the other enzymes tested (9, 16, 17).

In vitro studies were carried out to compare the enzymes for their abilities to enhance the cytotoxicity of CPT-11. Tumor cell lines were exposed to varying concentrations of SN-38, CPT-11, or CPT-11 in the presence of purified carboxylesterases for a total of 24 h. Cell viability was measured 2 days later using XTT, a tetrazolium dye that measures mitochondrial membrane potential (27, 28). As expected (6, 30), SN-38 was approximately 1000-fold more potent than CPT-11 (Figure

Figure 3. Sequence data from purified proteins. The peptide sequences determined from cyanogen bromide fragments of the purified proteins are underlined and bold. The sequences were 100% homologous to the sequences within (A) hCE-1 (16) and (B) hCE-2 (29).

4). The degree to which CPT-11 was activated on both L2987 human lung adenocarcinoma (Figure 4A,B) and on 3677 human melanoma (Figure 4C) cells was greater for hCE-2, rCE, and gpCE than for hCE-1. In addition, it was found that the extent of prodrug activation for hCE-2, rCE, and gpCE was equivalent and dose-dependent on the L2987 human lung adenocarcinoma cell line. The cytotoxic activity was greater at 5 μ g/mL carboxylesterase (Figure 4B) than at 1 μ g/mL (Figure 4A). On 3677 cells, hCE-2 was slightly less effective than rCE and gpCE (Figure 4C). These data show that hCE-2 activates CPT-11 under the conditions of the cytotoxicity assays.

Conjugates of hCE-2 were prepared by linking the enzyme to the 96.5 mAb, a murine IgG2a that binds to the p97 antigen on most melanomas and on several carcinomas (24). The initial approach used was to react hCE-2 with *N*-(γ -maleimidobutyryloxy)succinimide ester (GMBS), which reacts with reactive amines such as those present on lysine side chains. However, the conjugates formed by combining hCE-2–GMBS adducts with antibody sulphydryl groups suffered from approximately 90% reductions in enzyme activity. An alternative approach was more successful, in which sulphydryl groups were appended to hCE-2 using 2-iminothiolane, and then the modified protein was reacted with maleimide-substituted 96.5. The 96.5-hCE-2 conjugate was then subjected to a two-step purification procedure that involved gel filtration to remove aggregates and free enzyme, followed by anion-exchange chromatography to separate most of the unconjugated mAb. Analysis by SDS-PAGE indicated that the conjugate was >75% monomeric. As has been previously shown with 96.5 enzyme conjugates (24, 25), binding studies using flow cytometric analysis indicated that 96.5-hCE-2 bound selectively to antigen positive 3677 melanoma cells and had unimpaired binding activity as compared to unmodified 96.5 (see Experimental Methods). 96.5-hCE-2 retained 52 and 69% of the specific activity with *p*-nitrophenylacetate and CPT-11 as substrates, respectively, as compared to the hCE-2 that was used for the conjugation (Table 2).

In vitro cytotoxicity experiments were conducted on 3677 melanoma cells (p97 antigen positive) that were

Figure 4. In vitro cytotoxicity assays. (A) and (B) L2987 human lung adenocarcinoma and (C) and (D) 3677 human melanoma cells were exposed to drugs with or without purified carboxylesterases for 24 h, washed, and the cytotoxic effects were determined 48 h later using XTT as an indicator of cell viability. For (D), 96.5-hCE-2 was used at 5 $\mu\text{g/mL}$ total protein, representing 1.5 $\mu\text{g/mL}$ hCE-2. Conjugate treated cells were either exposed to conjugate throughout the period of CPT-11 treatment (bound + unbound), or were washed to removed unbound conjugate prior to CPT-11 treatment (bound).

Table 2. Activities of Purified Carboxylesterases

protein ^a	specific activity	
	<i>p</i> -nitrophenylacetate ($\mu\text{mol min}^{-1} \text{mg}^{-1}$)	CPT-11 ($\text{pmol min}^{-1} \text{mg}^{-1}$)
hCE-1	10	3.5
hCE-2	60	92
rCE	28	142
gpCE	46	140
96.5-hCE-2 ^b	17	48

^a The abbreviations used for the proteins are hCE-1, human carboxylesterase 1; hCE-2, human carboxylesterase 2; rCE, rabbit liver carboxylesterase; gpCE, guinea pig liver carboxylesterase; 96.5-hCE-2, the conjugate formed between the 96.5 IgG and hCE-2. ^b The specific activity is based on the hCE-2 component of the conjugate, which had 33 $\mu\text{mol min}^{-1} \text{mg}^{-1}$ and 70 $\text{pmol min}^{-1} \text{mg}^{-1}$ activity on *p*-nitrophenylacetate and CPT-11, respectively.

exposed to 96.5-hCE-2 prior to treatment with CPT-11. If the cells were extensively washed prior to prodrug treatment, there was no enhancement in the cytotoxic effects of CPT-11 (Figure 4D). In contrast, cells that were treated with the combination of 5 μg of 96.5-hCE-2/mL (contains 1.5 $\mu\text{g/mL}$ hCE component) and CPT-11 for 24 h were sensitized to CPT-11, albeit to a slightly lesser extent than corresponding cells treated with free hCE at 5 $\mu\text{g/mL}$. These results indicate that the enzyme within the conjugate is active and capable of activating CPT-11 under the conditions used in the cytotoxicity experiments, but that the amount of antigen-bound activity is too low to achieve detectable levels of prodrug activation. Several experiments were conducted using increased conjugate concentrations, exposing cells at high density with saturating concentrations of conjugate (31), using other mAb targeting vehicles for hCE-2, and using assays involving the binding of biotinylated hCE-2 to mAb-streptavidin conjugates. The results were invariable in that bound enzyme conjugates did not release cytotoxic concentrations of active drug. We conclude that the activity of hCE-2 is insufficient for targeting strategies utilizing

mAb-hCE-2 conjugates for antigen-specific CPT-11 activation.

DISCUSSION

The use of mAb-enzyme conjugates for prodrug activation at tumor sites has received considerable attention, and several targeted enzyme/prodrug combinations have demonstrated significant levels of antitumor activity in preclinical cancer models (reviewed in refs 22–23). The most advanced systems include bacterial enzymes, such as carboxypeptidase G2 and β -lactamase for the activation of nonclinically approved anticancer prodrugs (reviewed in refs 22, 23). One of the shortcomings of using such proteins is their expected immunogenicity in people, as evidenced by the anti-CEA mAb conjugate A5B7-mAb-carboxypeptidase G2 where all patients treated mounted significant immune reactions against the foreign protein (32). An additional complication in such systems is that the prodrugs are not clinically approved, and have unknown toxicities, pharmacokinetics, and biological effects. A preferable combination would be to utilize mAb-human enzyme conjugates for the activation of clinically approved anticancer prodrugs. No such examples exist, although there have been reports of activating clinically approved anticancer prodrugs with foreign proteins (33) and activating nonapproved anticancer prodrugs with human proteins (34, 35, reviewed in ref 26).

In using a human enzyme for the activation of the clinically approved anticancer drug CPT-11, we were aware that the known enzymes that converted CPT-11 to SN-38 had very poor activities. With the intent of exploring which enzyme might be the most efficient, we began by purifying enzymes from human liver microsomes on the basis of their abilities to effect the hydrolysis reaction. This search led us to hCE-1, one of the most abundant of the microsomal carboxylesterases (16, 17), and to hCE-2, which was reported during the course of our work as being more active than hCE-1 with CPT-11 as a substrate (21). In our hands,

hCE-2 was 26-fold more active than hCE-1 with CPT-11 and was almost as active as rCE, the highest activity enzyme known for the hydrolysis of CPT-11 (16, 19). Previous studies have shown that cancer cell lines transfected with the genes for either rCE (16, 17) or with hCE-1 (19, 20) were rendered significantly more sensitive to CPT-11 treatment as compared to the parental cells. Our results would suggest that the gene for hCE-2 might have considerably greater potential for gene therapy for CPT-11 activation, since it is more active than hCE-1 and would not be expected to induce an immune reaction like rCE.

It is significant that in vitro potentiation of CPT-11 activity could be obtained by gene therapy with hCE-1 and with rCE2 (16, 17, 19, 20) but that we were unable to demonstrate any such activity on cells that were exposed to 96.5-hCE-2. Another conjugate, 96.5- β -lactamase, has been used successfully for specific activation of many anticancer prodrugs under conditions involving subsaturating concentrations and prodrug exposure for very short periods of time (24, 25). Here, we were unable to effect prodrug activation even at saturating 96.5-hCE-2 concentrations and with prodrug exposures for as long as 24 h. We believe the reason for the discrepancy between these two systems lies in the kinetics of the enzymes used. While β -lactamase has specific activities in the range of $315 \mu\text{mol min}^{-1} \text{mg}^{-1}$ with a doxorubicin prodrug (25) to $1470 \mu\text{mol min}^{-1} \text{mg}^{-1}$ for a melphalan prodrug (36), hCE-2 has activity 10^6 – 10^7 -fold lower than that. The fact that hCE-1 and rCE have proven useful in gene therapy studies might be attributed to very high level expression of the protein inside the target cells as compared to the amount that can be delivered through a mAb-enzyme conjugate, and to possible differences between intracellular and extracellular generation of SN-38.

We conclude that the activity of hCE-2 must be significantly increased to be effective for ADEPT. One of the lowest activity enzymes successfully used to activate an anticancer prodrug in an immunologically specific manner was penicillin G-amidase for the activation of a prodrug of doxorubicin (31). The specific activity of the enzyme was $12.7 \text{ nmol min}^{-1} \text{mg}^{-1}$, which is only 140-fold greater than hCE-2. It is reasonable to expect that directed evolution of hCE-2 toward CPT-11 hydrolysis should achieve catalytic efficiencies in this range or higher. Such studies are warranted, given the clinical need to improve the therapeutic window for CPT-11 and the advantages in using a potentially nonimmunogenic conjugate for doing so.

TECHNICAL NOTES

DOTA Tris(phenylmethyl) Ester: A New Useful Synthon for the Synthesis of DOTA Monoamides Containing Acid-Labile Bonds

Pier Lucio Anelli, Luciano Lattuada,* Milena Gabellini, and Paola Recanati

Bracco Imaging spa, Milano Research Centre, via E. Folli, 50; 20134 Milano, Italy. Received April 8, 2001

The synthesis of DOTA tris(phenylmethyl) ester **2**, a new monoreactive derivative of DOTA, is described. This versatile synthon can be easily coupled to compounds bearing an amino group and then deprotected to DOTA monoamide under mild and neutral conditions by catalytic hydrogenolysis. Accordingly, compound **2** has been used in the synthesis of a DOTA monoamide gadolinium complex containing two palmitic esters, which is a component of mixed micelles as MRI contrast agents.

INTRODUCTION

The 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) is a well-studied ligand which forms extremely stable complexes with a variety of metals (1–5). Such metal complexes have found a widespread use in therapy and diagnostic imaging (6–9). For example, the gadolinium complex of DOTA is currently used as extravascular contrast agent for magnetic resonance imaging (MRI) (10, 11).

The search for more and more specific therapeutic and diagnostic entities incorporating a metal complex has led to the conjugation of the DOTA moiety to a variety of biomolecules [e.g., peptides (12, 13), bile acids (14, 15), proteins (16)] which should act as carriers, delivering the product to a selected district of the body.

Since the conversion of a carboxyl moiety of DOTA into a carboxamide does not dramatically affect the stability of the final metal complex (13, 17), the easiest way to conjugate DOTA to a carrier is by formation of an amide bond. In this respect the activation with isobutyl chloroformate (13, 18) or by formation of a sulfo-NHS active ester (16) have been reported. The statistical polyactivation of the four carboxylic groups of DOTA is the main drawback of this strategy, and to overcome this problem a triprotected derivative should be employed. Indeed, the synthesis of DOTA tris(*tert*-butyl) ester **1** has been recently reported (12, 19), and conjugation of **1** to a somatostatin derivative gives rise, after acid deprotection of the *tert*-butyl esters, to a DOTA monoamide analogue of OctreoScan (12).

In the past we took advantage of **1** for the coupling of DOTA to bile acid derivatives (14, 15) in order to obtain gadolinium complexes for the magnetic resonance imaging (MRI) of the liver (Figure 1).

Recently, we focused our attention on the synthesis of lipophilic gadolinium complexes which were found to be very useful agents for magnetic resonance angiography (MRA) when formulated as mixed micelles (20, 21). Mixed micelles are multicomponent micelles containing a phos-

Figure 1. Structures of DOTA tris(*tert*-butyl) ester **1** and DOTA tris(phenylmethyl) ester **2**.

pholipid, a biocompatible nonionic surfactant (e.g., Synperonic F-108), and a lipophilic gadolinium complex, such as **8** or **9** (Figure 2). In particular, compound **8** was found very interesting. The mixed micelles containing **8** show high relaxivities and long blood permanence in rats, two essential features for a MRA agent. The only drawback of **8** is its elimination. In fact, 7 days after injection in rats of the formulation only 50% of injected dose is eliminated by the liver while the remaining is still present into the animal body. To increase the elimination, the synthesis of **9** was taken into account. Compound **9** contains two palmitic esters which should be hydrolyzed in vivo, giving rise to a small, hydrophilic gadolinium complex more easily eliminable.

We now report here the synthesis of DOTA tris(phenylmethyl) ester **2**, which is a valid alternative to compound **1** especially in all those cases in which the conjugated counterpart cannot survive acid deprotection conditions, as assessed for example in the synthesis of **9**.

EXPERIMENTAL PROCEDURES

General. Organic and inorganic reagents were purchased from Merck KGaA (Darmstadt, Germany) and Fluka A.G. (Buchs, Switzerland) except for 1-propane-phosphonic acid cyclic anhydride **12** (Lancaster, Mülheim am Main, Germany). 1,4,7,10-Tetraazacyclododecane **3** was synthesized following our patented procedure (22). Resin Amberlite XAD 16.00 was purchased from Rohm and Haas Italia Srl (Gessate, Italy). Thin-layer chromatography (TLC) was carried out on silica gel plates (Merck KGaA, Silica 60 F254, 0.2 mm), and spots were visualized with 1% KMnO₄ in 1 N NaOH. Flash chromatography was performed on Merck KGaA silica

gel 60 (230–400 mesh). IR spectra were recorded on KBr cells on a Perkin-Elmer Infrared 882 spectrometer. ^1H and ^{13}C NMR spectra (in CDCl_3 , if not differently specified) were recorded on a Bruker AC 200 spectrometer. Electrospray ionization was performed on a Finnigan TSQ 700 triple quadrupole mass spectrometer fitted with a Finnigan ESI interface. Melting points were determined in open capillaries with a Büchi B-540 apparatus and are uncorrected. Elemental analysis were performed by Redox Laboratories (Monza, Italy).

1,4,7,10-Tetraazacyclododecane-1-acetic acid 1,1-Dimethylethyl Ester (4). A solution of *tert*-butyl bromoacetate (25.3 g, 130 mmol) in CHCl_3 (500 mL) was added dropwise in 7 h to a solution of 1,4,7,10-tetraazacyclododecane **3** (112.3 g, 650 mmol) in CHCl_3 (2 L) maintained under nitrogen at room temperature. After 14 h, the solution was concentrated to 800 mL, washed with H_2O (9×200 mL) to eliminate the excess of **3**, dried over Na_2SO_4 , and evaporated to give **4** (39 g, 99%) as a pale yellow oil: IR 1728 cm^{-1} ; ^1H NMR δ 1.12 (s, 9H, *t*Bu), 2.26 (m, 8H, CH_2N), 2.43 (m, 8H, CH_2N), 2.93 (s, 2H, CH_2COO); ^{13}C NMR δ 27.77 (CH_3), 44.9, 45.7, 46.6, 51.4 (CH_2N), 56.7 (CH_2COO), 80.4 (C), 170.4 (CO); MS m/z 287 [$\text{M} + \text{H}$] $^+$. Anal. Calcd for $\text{C}_{14}\text{H}_{30}\text{N}_4\text{O}_2$: C, 56.20; H, 10.06; N, 18.56. Found: C, 56.36; H, 10.34; N, 17.84.

1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid 1,1-dimethylethyl tris(phenylmethyl) ester adduct with NaCl (5). A solution of **4** (36 g, 126 mmol) in DMF (200 mL) was added dropwise in 7 h to a stirred suspension of benzyl bromoacetate (94.96 g, 414 mmol) and K_2CO_3 (86.8 g, 628 mmol) in DMF (250 mL) maintained under nitrogen at room temperature. After 14 h the suspension was filtered and the orange solution evaporated to dryness. The residue was dissolved in EtOAc (500 mL), washed with H_2O (3×400 mL) then with brine (2×300 mL). The organic phase was separated, dried over Na_2SO_4 and evaporated. The resi-

due was purified by flash chromatography ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 15:1) to give **5** (51 g, 51%) as a sticky pale orange solid: IR 1730 cm^{-1} ; ^1H NMR δ 1.29 (s, 9H, *t*Bu), 2.19–3.26 (m, 24H, CH_2N), 4.94–4.98 (m, 6H, CH_2Ph), 7.13–7.16 (m, 15H, Ph); ^{13}C NMR δ 27.8 (CH_3), 48–53 (broad signal, CH_2N), 55.0, 55.6 (CH_2COO), 66.8 (CH_2Ph), 82.1 (C), 128.2, 128.4, 128.4, 134.9, 135.0 (Ph), 172.9, 173.4 (CO); MS m/z 754 [$\text{M} + \text{Na}$] $^+$. Anal. Calcd for $\text{C}_{41}\text{H}_{54}\text{ClN}_4\text{NaO}_8$: C, 62.38; H, 6.91; N, 7.10; Na, 2.91; Cl, 4.49. Found: C, 61.77; H, 6.74; N, 6.90; Na, 2.90; Cl, 4.95.

1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic Acid Tris(phenylmethyl) Ester (2). Compound **5** (47.11 g, 60 mmol) was dissolved in dioxane (500 mL), and then 12 N HCl (500 mL) was added under nitrogen at room temperature, obtaining a white precipitate. After stirring for 16 h, the pale yellow suspension was evaporated and the residue dissolved in H_2O (700 mL) by ultrasound sonication. The solution (pH 2) was loaded onto an Amberlite XAD-16.00 resin column (900 mL) and eluted with a $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ gradient. The product elutes with 40% $\text{CH}_3\text{CN}/\text{H}_2\text{O}$. The fractions containing the product were concentrated to remove CH_3CN and then extracted with EtOAc. The organic phase was dried over Na_2SO_4 and evaporated. The pale yellow residue was triturated with EtOAc (150 mL) to give **2** (21 g, 52%) as a white solid: mp $108\text{--}110\text{ }^\circ\text{C}$; IR 1735 cm^{-1} ; ^1H NMR δ 2.64 (m, 8H, CH_2N), 2.90 (m, 4H, CH_2N), 3.34–3.58 (m, 12H, CH_2N), 5.01 (m, 6H, CH_2Ph), 7.24 (m, 15H, Ph); ^{13}C NMR δ 48.1, 50.2, 53.1, 53.2, 55.4, 55.6, 56.1 (CH_2N), 66.1, 66.3 (CH_2Ph), 128.1, 128.2, 128.3, 128.4, 128.5, 135.2 (Ph), 166.5, 170.4, 171.1 (CO); MS m/z 697 [$\text{M} + \text{Na}$] $^+$. Anal. Calcd for $\text{C}_{37}\text{H}_{46}\text{N}_4\text{O}_8$: C, 65.86; H, 6.87; N, 8.30. Found: C, 66.00; H, 7.03; N, 8.33.

1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic Acid Phenylmethyl Ester (6). This product elutes with 10% $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ from the column used for purification of **2**. Evaporation of the eluate gave **6** (3 g, 10%) as a pale yellow solid: mp $87\text{--}92\text{ }^\circ\text{C}$ (dec); IR 1737 cm^{-1} ; ^1H NMR δ (CD_3OD) 3.14–3.85 (m, 24 H, CH_2N), 5.13 (s, 2H, CH_2Ph), 7.36 (m, 5H, Ph); ^{13}C NMR δ (CD_3OD) 49.6, 50.1, 52.6, 53.0, 54.3, 54.9, 58.2 (CH_2N), 67.8 (CH_2Ph), 129.7, 129.9, 137.4 (Ph), 170.4, 172.4, 175.0 (CO); MS m/z 517 [$\text{M} + \text{Na}$] $^+$. Anal. Calcd for $\text{C}_{23}\text{H}_{34}\text{N}_4\text{O}_8$: C, 55.85; H, 6.93; N, 11.33. Found: C, 55.84; H, 7.09; N, 11.08.

1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic Acid 1,4-bis(Phenylmethyl) Ester (7). This product elutes with 20% $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ from the column used for purification of **2**. Evaporation of the eluate gave **7** (3 g, 8.5%) as a pale yellow solid: mp $78\text{--}82\text{ }^\circ\text{C}$ (dec); IR 1736 cm^{-1} ; ^1H NMR δ ($\text{DMSO}-d_6$) 2.71–3.63 (m, 24H, CH_2N), 5.10 (s, 4H, CH_2Ph), 7.35 (m, 10H, Ph); ^{13}C NMR δ ($\text{DMSO}-d_6$) 49.3, 49.9, 50.8, 51.1, 54.2, 55.6 (CH_2N), 65.3 (CH_2Ph), 127.9, 128.4, 136.0 (Ph), 169.2, 170.9 (CO); MS m/z 607 [$\text{M} + \text{Na}$] $^+$. Anal. Calcd for $\text{C}_{30}\text{H}_{44}\text{N}_4\text{O}_8$: C, 61.20; H, 7.54; N, 9.52. Found: C, 61.52; H, 6.97; N, 9.43.

10-[2-[Bis(2-[(1-oxohexadecyl)oxy]ethyl)amino]-2-oxoethyl]-1,4,7,10-tetraazacyclododecane-1,4,7-triacetic Acid Tris(Phenylmethyl) Ester Adduct with NaCl (13). A 50% EtOAc solution of 1-propanephosphonic acid cyclic anhydride **12** (23) (16.9 g, 26.6 mmol) was added to a solution of **2** (13 g, 19.3 mmol), hexadecanoic acid iminodi-2,1-ethanediyl ester hydrochloride **11** (24) (12 g, 19.4 mmol) and Et_3N (12.6 mL, 90.5 mmol) in CH_2Cl_2 (600 mL). The reaction mixture was stirred under nitrogen at room temperature for 24 h, and then more 50% EtOAc solution of **12** (6.1 g, 9.6 mmol) was added. After another 24 h, the mixture was washed with brine (2×300 mL), dried over Na_2SO_4 , and evaporated.

The residue was purified by flash chromatography ($\text{CH}_2\text{Cl}_2/\text{MeOH}$ 9:1) to give **13** (12 g, 48%) as a yellow oil: IR 1735 cm^{-1} ; ^1H NMR δ 0.81 (t, 6H, $J = 6.7\text{ Hz}$, CH_3), 1.19 (m, 48H, aliphatic chain), 1.49 (m, 4H, $\text{CH}_2\text{-CH}_2\text{COO}$), 2.20 (m, 4H, CH_2COO), 2.26–3.56 (m, 28H, CH_2N), 4.14 (m, 4H, CH_2OOC), 5.07 (m, 6H, CH_2Ph), 7.27 (m, 15H, Ph); ^{13}C NMR δ 13.9 (CH_3), 22.5, 24.3, 24.6, 29.0, 29.1, 29.2, 29.3, 29.5, 31.7, 33.9 (aliphatic chain CH_2), 46.4, 46.8 (CONCH_2), 48–53 (broad signals, tetraazacyclo CH_2), 55.0 (NCH_2CO), 61.8 (CH_2OOC), 66.7, 66.8 (CH_2Ph), 126.9, 128.0, 128.3, 128.4, 135.1, 135.2 (Ph), 172.0, 173.2, 173.4 (CO); MS m/z 1261 [$\text{M} + \text{Na}$] $^+$. Anal. Calcd for $\text{C}_{73}\text{H}_{115}\text{ClN}_5\text{NaO}_{11}$: C, 67.59; H, 8.94; N, 5.40; Cl, 2.73; Na, 1.77. Found: C, 66.91; H, 9.09; N, 5.34; Cl, 3.10; Na, 1.92.

10-[2-Bis[2-[(1-oxohexadecyl)oxy]ethyl]amino]-2-oxoethyl]-1,4,7,10-tetraazacyclododecane-1,4,7-triacetic Acid (14**)**. Pd (10% on carbon (1.43 g) was added to a solution of **13** (10 g, 7.7 mmol) in EtOH (150 mL), and the suspension was stirred over 12 h under a hydrogen atmosphere at room temperature. The mixture was filtered over Millipore FT 0.45 μm and the solution evaporated under reduced pressure. The residue was suspended in H_2O (200 mL), stirred for 1 h, and then centrifuged (10 $^\circ\text{C}$, 8000 rpm, 30 min). The solution was decanted away to eliminate the dissolved NaCl, and the remaining solid was dried (1.3 kPa, P_2O_5) to give **14** (7.4 g, 98%) as a white solid: mp $82\text{ }^\circ\text{C}$ (dec); IR 1736 cm^{-1} ; ^1H NMR δ 0.84 (t, 6H, $J = 7\text{ Hz}$, CH_3), 1.22 (m, 48H, aliphatic chain), 1.55 (m, 4H, $\text{CH}_2\text{CH}_2\text{COO}$), 2.25 (m, 4H, CH_2COO), 2.5–3.9 (broad m, 28H, CH_2N), 4.15 (m, 4H, CH_2OOC); ^{13}C NMR δ 13.9 (CH_3), 22.5, 24.4, 24.7, 29.1, 29.2, 29.6, 31.8, 34.0, 34.8 (aliphatic chain CH_2), 46.9–58.0 (broad signals, CH_2N), 61.7 (CH_2OOC), 173.3, 173.4 (CO); MS m/z 991 [$\text{M} + \text{Na}$] $^+$. Anal. Calcd for $\text{C}_{52}\text{H}_{97}\text{N}_5\text{O}_{11}$: C, 64.50; H, 10.10; N, 7.23. Found: C, 64.07; H, 9.78; N, 7.22.

RESULTS AND DISCUSSION

The use of compound **1** for the synthesis of **9** is hampered by the fact that the acid deprotection of *tert*-butyl esters leads to a significant hydrolysis of the palmitic esters too. For this reason we planned the synthesis of synthon **2** (Scheme 1), since the benzyl esters

Scheme 1. Synthesis of DOTA Tris(phenylmethyl) Ester **2**

can be deprotected by catalytic hydrogenolysis without affecting the esters with the palmitic residues.

Reaction of an excess of 1,4,7,10-tetraazacyclododecane **3** (5 mol equiv) with *tert*-butyl bromoacetate gave the monoalkylated derivative **4** in nearly quantitative yield.

Figure 3. Structures of the byproducts recovered during the purification of **2**.

Peralkylation of **4** with benzyl bromoacetate in DMF and K_2CO_3 gave tetraester **5** as NaCl adduct, after workup with brine. The ability of DOTA tetraesters to coordinate sodium ions has been already assessed (25, 26). The presence of NaCl made the purification of **5** easier by flash chromatography on silica gel, avoiding the use of large amounts of ammonia in the eluent.

Deprotection of the *tert*-butyl ester of **5** with 12 N HCl in dioxane gave compound **2**, which was purified and desalted by elution through an Amberlite XAD 16.00 resin column with $\text{CH}_3\text{CN}/\text{H}_2\text{O}$.

Minor amounts of DOTA benzyl ester **6** and 1,4-dibenzyl ester **7** were also recovered during the purification of **2**. The structure of **7** was assigned on the basis of symmetry and the ^{13}C NMR spectrum (Figure 3). In fact, the ^{13}C NMR spectrum of **7** shows six different methylene groups on nitrogen, while the corresponding 1,7-dibenzyl ester should have only four.

The usefulness of intermediate **2** was proved in the synthesis of ligand **14** (Scheme 2). DOTA tribenzyl ester

Scheme 2. Synthesis of Ligand **14**

2 was coupled to amine hydrochloride **11** (24) using 1-propanephosphonic acid cyclic anhydride **12** as condensing agent (23) to obtain **13** as NaCl adduct. Cleavage of the benzyl ester protections of **13** by hydrogenolysis yielded the triacid **14**. Complexation of **14** with $(\text{CH}_3\text{-COO})_3\text{Gd}$ in $\text{CHCl}_3/\text{MeOH}/\text{H}_2\text{O}$ at $50\text{ }^\circ\text{C}$ gave the complex **9** in quantitative yield.

Mixed micelles containing complex **9** show a better elimination profile than those containing complex **8**. In fact, 7 days after injection in rats, 67% of the injected dose is eliminated (for complex **8** was only 50%). Moreover, 27% of injected dose is found in urine, and this is an indirect evidence of a partial hydrolysis in vivo of complex **9** (21).

In conclusion, compound **2** can be easily coupled to a variety of carriers bearing an amino group and then deprotected to DOTA monoamide under mild and neutral conditions by catalytic hydrogenolysis. This is a considerable advantage over compound **1** which requires acidic conditions for the deprotection. Indeed, this was proved with the synthesis of gadolinium complex **9**, which is a promising component of mixed micelles for MRI coronary angiography.

Hyaluronic Acid-*N*-hydroxysuccinimide: A Useful Intermediate for Bioconjugation

Yi Luo and Glenn D. Prestwich*

Department of Medicinal Chemistry, The University of Utah, Salt Lake City, Utah 84112-5820.

Received May 9, 2001; Revised Manuscript Received September 20, 2001

Hyaluronic acid (HA) is an abundant nonsulfated glycosaminoglycan component of synovial fluid and the extracellular matrix. HA is an important building block for biocompatible and biointeractive materials with applications in drug delivery, tissue engineering, wound repair, and viscosupplementation. Herein we describe the synthesis and characterization of HA-*N*-succinimide, an activated ester of the glucuronic acid moiety. This HA-active ester intermediate is a precursor for fluorescent probes, drug-polymer conjugates, and cross-linked hydrogels. As a demonstration, we used HA-NHS to prepare HA-BODIPY by coupling with the hydrazide derivative of the fluor. Intracellular uptake of HA-BODIPY into human ovarian cancer cells, which overexpress cell-surface HA receptors, was visualized using confocal microscopy.

Hyaluronic acid (hyaluronan, HA), a (β -1,4)-linked D-glucuronic acid and (β -1,3) *N*-acetyl-D-glucosamine polysaccharide (Figure 1), is a nonsulfated glycosaminoglycan (GAG) found in the extracellular matrix (ECM). HA plays an important role in the structure and organization of ECM, including the maintenance of extracellular space, the transport of ion solutes and nutrients, and the preservation of tissue hydration. HA concentrations increase whenever rapid tissue proliferation, regeneration, and repair occur. HA also binds specifically to proteins in ECM, on cell-surface receptors, and within the cell cytosol. These protein-ligand interactions are important in stabilizing the cartilage ECM (1, 2), regulating cell adhesion and motility (3, 4), mediating proliferation and differentiation (5), and the action of growth factors (6). HA has also been implicated in morphogenesis and embryonic development (7), in cancer (8–14), in modulating inflammation (12), in stimulating angiogenesis and healing (15), and as a protective coating (16). HA and its chemically modified derivatives (17) have emerged as versatile building blocks for novel biomaterials (18).

Chemical modification of HA has employed the carboxyl group, the hydroxyl groups, the reducing end, and in some cases partially *N*-deacetylated materials. The attempted carbodiimide-mediated coupling of primary amines to HA resulted in negligible coupling due to the protonation of the required nucleophilic nitrogen at the reaction pH. The major product was the *N*-acylurea adduct. Recently, a modified method for carbodiimide/active ester-mediated coupling of polyfunctional amines to HA was developed in which HA was reacted with 30-fold excess of the amine component at pH 6.8 in the presence of EDCI and 1-hydroxybenzotriazole (HOBt) with DMSO/H₂O (1:1) as solvent (19). Antitumor agents have been coupled to HA to provide polymeric conjugates that deliver chemotherapeutics to target tissues. For

example, adriamycin (20), mitomycin C, and epirubicin (21) were coupled to HA using carbodiimide chemistry, and butyric acid-HA was synthesized by reaction of butyric anhydride with HA (22).

In this technical note, we describe a convenient route to the HA-*N*-succinimide active ester (Figure 1). Ion-exchange (23) and lyophilization afforded the HA tetrabutylammonium salt (HA-TBA). Next, 2 mol equiv (based on the calculated number of glucuronic acid residues present) of purified *N*-hydroxysuccinimido diphenyl phosphate (SDPP), mp 89–90 °C (24), were added to a solution of 2 wt % HA-TBA in DMSO. The reaction was stirred for either 2 h or overnight at room temperature, and the product was precipitated by addition of 3 volumes of hexane followed by excess acetone. The residue was dissolved in 2 mL of H₂O and purified on a Sephadex G-25 (20–80 μ m) (Sigma, St. Louis, MO) gel filtration column. In our experience, SDPP activation gave superior yields of HA-*N*-succinimide active ester (HA-NHS) in less time and under milder conditions than those reported previously (19, 23, 25–28).

The degree of substitution was calculated by integration of the succinimide ester methylenes (¹H NMR, broad singlet at δ = 2.62 ppm, 4H) relative to the methyl of the acetamido moiety of the GlcNAc residues resonance (δ = 1.95 ppm, 3H) (25). The degrees of substitution were 50 mol % and 80 mol % with the reaction time of 2 and 12 h, respectively. In some cases, triethylamine facilitated the carboxyl group activation reaction by SDPP (24). In the present example, however, use of triethylamine as a cosolvent led to ion exchange and isolation of the HA-triethylamine salt instead of HA-NHS.

The HA-NHS active ester is a versatile precursor for bioconjugation with reporter and effector molecules. BODIPY-FL hydrazide (Molecular Probes, Inc., Portland, OR) was used to demonstrate this versatility. Thus, 20 mg of HA-NHS (50 mol %) was dissolved in 2 mL of H₂O while stirring at room temperature; 1 mg of BODIPY-FL hydrazide in 0.5 mL of DMSO was then added with 3 drops of 0.1 N Na₂CO₃ buffer (pH 8.0). The reaction was stirred at room temperature for 3 days in the dark. Next, 2-aminoethanol (100 μ L) was added to

Figure 1. Synthesis of HA-NHS active ester and HA-BODIPY probe: (i) SDPP, DMSO, rt; (ii) DMSO/H₂O, rt.

consume any unreacted active ester. Solvents were removed by lyophilization, and the residue was dissolved in 1 mL of H₂O and purified by gel filtration. The purity of HA-BODIPY was measured at 210 nm (HA absorption) and 502 nm (BODIPY absorption) using analytical gel permeation chromatography (GPC) (Figure 2a). The low molecular weight HA-NHS has high efficiency of BODIPY coupling than the high molecular weight chains. The degree of substitution of BODIPY determined spectrophotometrically was 4.5 wt %. Interestingly, the HA-BODIPY conjugate had a 5-nm blue shifted absorbance with excitation at 488 nm as compared to the BODIPY hydrazide reagent (Figure 2b). In addition, a broadening of the fluorescence emission was observed (Figure 2c). It is possible that π -stacked or hydrophobically interacting aggregates could be formed in aqueous solution when a hydrophobic fluorophore is conjugated to a water-soluble polymer, thus altering the absorbance and emission of the fluorophore. (29). At the low modifications employed, this does not appear to be a problem, as a soluble, homogeneous derivative was obtained. This is consistent with previous work with HA-taxol (30) and HA-FITC-taxol derivatives (31).

HA-BODIPY was readily internalized by human ovarian cancer cells (SK OV-3), which overexpresses the HA receptor CD44 on the cell surface. Thus, SK OV-3 cells were incubated in a cell culture flask, harvested by trypsinization, and transferred into an 8-well cell culture slide. Cells (20,000) were seeded in each well of the slide and cultured for 48 h. The culture medium was replaced with medium containing HA-BODIPY probe (100 μ g/mL HA). Cells were cultured with the conjugates for various lengths of time. Unbound probe was removed by washing the cell layer three times with Dulbecco's phosphate-buffered saline (DPBS) (Sigma, St. Louis, MO). Cells were fixed with 3% paraformaldehyde for 10 min at room temperature and washed again with DPBS. Internalization of BODIPY-HA was visualized by fluorescence confocal microscopy (Figure 3). Initially, BODIPY-HA can be seen on the cell membranes, and with time it is gradually endocytosed and accumulates in the cytoplasm. Thus, HA and probe-modified HA bind to the cell surface via interactions with CD44 or RHAMM, and a portion subsequently undergoes endocytosis (4, 30, 31). Internalization of [³H]-labeled HA previously revealed that intracellular degradation of HA occurs within a low pH environment (32), such as that of the lysosome. In the

Figure 2. (a) GPC profile of HA-BODIPY detected at 210 and 502 nm. GPC was carried out on the following system: Waters 515 HPLC pump, Waters 410 differential refractometer, Waters 486 tunable absorbance detector, Waters Ultrahydrogel 250 and 2000 columns (7.8 mm ID $\times$ 30 cm) (Milford, MA). The GPC eluent was 150 mM phosphate buffer/MeOH = 80:20 (v/v), pH 6.5, and the flow rate was 0.5 mL/min. (b) UV/vis spectra of BODIPY and HA-BODIPY. (c) Fluorescence spectra of BODIPY and HA-BODIPY.

Figure 3. Time course internalization of HA-BODIPY by SK OV-3 cells. Cells were examined using an inverted microscope (Nikon) and a Bio-Rad (Hercules, CA) MRC 1024 laser scanning confocal microscope. A coverslip was mounted on a microscope slide containing fixed cells with ProLong Antifade Kit (Molecular Probes, Eugene, OR) as the mounting medium. Cell images were collected by using a 60 × oil immersion objective, and no postacquisition enhancement of images were performed. Image acquisition used the BHS block of filters (excitation 488 nm and emission through a 522 nm 32 band-pass filter). Fluorescence images were scaled to 256 Gy levels.

present study, the uptake and degradation of HA in cellular compartments resulted in the release of fluorescent molecules into the cytoplasm.

In conclusion, a new method was developed to prepare an HA-active ester derivative. This HA-active ester intermediate will find numerous applications in biomedical research, including the preparation of fluorescent probes, drug-polymer conjugates, and cross-linked hydrogels.

ACKNOWLEDGMENT

Financial support for this work was provided by Department of Army (DAMD 17-9A-1-8254) and by the Huntsman Cancer Foundation at The University of Utah (UUtah). We are grateful to Joseph C. Shope and Dr. Daryll B. DeWald of Department of Biology of Utah State University for assistance with confocal microscopy. We thank Dr. L. Y.-W. Bourguignon of University of Miami Medical School for providing SK-OV-3 cells. We thank Clear Solutions Biotech, Inc. (Stony Brook, NY) for providing HA and the Center for Cell Signaling (UUtah), supported by the Utah Centers of Excellence Program, for cell culture facilities.
